1998 Hoffmann La Roche Award Lecture Understanding and exploiting glycosidases[1]

Stephen G. Withers

Abstract: Glycosidases fall into two major mechanistic classes; those that hydrolyse the glycosidic bond with retention of anomeric configuration and those that do so with inversion. Retaining glycosidases employ a mechanism involving a covalent glycosyl–enzyme intermediate formed and hydrolysed with acid–base catalytic assistance via oxocarbenium ion-like transition states. This intermediate has been trapped in two distinct ways, either by modification of the substrate through fluorination, or of the enzyme through mutation of key residues. This allows the amino acid residue to which this sugar is attached to be identified through LC/MS–MS analysis of peptic digests. Three-dimensional structures of several of these glycosyl–enzyme complexes, along with those of Michaelis complexes, have been determined through X-ray crystallographic analysis, revealing the identities of important amino acid residues involved in catalysis, particularly the involvement of the catalytic nucleophile in strong hydrogen bonding to the sugar 2-hydroxyl. They have also revealed evidence of substantial substrate distortion upon binding. Insight into the function of the acid–base catalyst Glu172 in *Bacillus circulans* xylanase has been obtained through NMR titration of side chain ^{13}C-labelled glutamic acid enzyme both free and in the 2-fluoroxylobiosyl–enzyme complex. The pK_a of Glu172 is relatively high in the free enzyme, consistent with its role as an acid catalyst, but drops 2.5 units upon formation of the intermediate, consistent with its new role as a base catalyst. This "cycling" of the pK_a is shown to be a direct consequence of the change in charge of the nucleophile, Glu78. Finally, an efficient catalyst for synthesis, but not hydrolysis, of glycosidic bonds has been generated by mutation of the glutamic acid catalytic nucleophile of a β-glucosidase to an alanine. When used with α-glucosyl fluoride as a glycosyl donor, along with a suitable acceptor, oligosaccharides up to five sugars in length have been made with yields of up to 90% on individual steps. These new enzymes have been named glycosynthases.

Key words: enzymatic mechanism, glycoside hydrolysis, inhibitors.

Résumé : Les glycosidases appartiennent à deux grandes classes de mécanismes : celles qui hydrolysent la liaison glycosidique avec rétention de la configuration anomérique et celles qui le font avec inversion. Les glycosidases qui conduisent à une rétention font appel à un mécanisme avec formation d'un intermédiaire covalent glycosyl–enzyme et une hydrolyse assistée par une catalyse acide–base comportant un état de transition qui ressemble à un ion oxocarbénium. On a piégé cet intermédiaire de deux façons distinctes en procédant à une modification du substrat par fluoration ou de l'enzyme par mutation de résidus clés. Une analyse par chromatographie liquide/spectrométrie de masse – spectrométrie de masse (CL/SM–SM) sur les produits de digestion peptique permet alors d'identifier l'acide aminé auquel le sucre est attaché. Faisant appel aux méthodes d'analyse cristallographiques par diffraction des rayons X, on a déterminé les structures tridimensionnelles de plusieurs de ces complexes glycosyl–enzymes avec ceux de complexes de Michaelis; elles permettent d'identifier les résidus d'acides aminés importants dans la catalyse et, en particulier, elles permettent de démontrer l'implication du nucléophile catalytique dans la forte liaison hydrogène avec l'hydroxyle en position 2 du sucre. Elles ont aussi permis de mettre en évidence la présence d'une distorsion importante du substrat lors de sa fixation. On a effectué des titrages RMN sur des enzymes, autant libre que formant un complexe 2-fluorooxylobiosyl–enzyme, comportant de l'acide glutamique marqué au ^{13}C dans la chaîne latérale; ces données ont permis d'obtenir des informations sur la fonction de l'acide du Glu172 de la xylanase du *Bacillus circulans* comme catalyseur acide–base. Le pK_a du Glu172 est relativement élevé dans l'enzyme libre et cette valeur est en accord avec son rôle comme catalyseur acide; il diminue toutefois de 2,5 unités lors de la formation de l'intermédiaire et ceci est en accord avec son nouveau rôle comme catalyseur basique. On a montré que cette « variation » du pK_a est une conséquence directe du changement de charge du nucléophile, le Glu78. Enfin, on a effectué le remplacement de l'acide glutamique, qui agit comme nucléophile d'une β-glucosidase, par une alanine; cette opération a permis de générer un catalyseur efficace pour la synthèse, mais pas pour l'hydrolyse, des liaisons glycosidiques. Lorsqu'on l'a utilisé avec un fluorure d'α-glucosyle, agissant comme donneur, avec un accepteur

[Traduit par la Rédaction]

Introduction

Glycosidic bonds occur in a wide range of contexts. These include polysaccharides, which function as storage, structural, or recognition components; oligosaccharides, which function in energy storage or also as recognition elements; and a wide variety of other glycoconjugates such as glycolipids, glycoproteins, or saponins. In large part reflecting this wide variety in substrate structure, there also exists a wide range of different enzymes, glycosidases, whose function is the cleavage of these bonds. Amino acid sequences of well over 1000 different glycoside hydrolases are now available, primarily deduced from their gene sequences, and these have been arranged into over 60 different families on the basis of sequence similarities (1). At the time this article is being written an excellent web site is available that gives updated listings of these family members, plus some other information on the identities of important amino acid residues (http://afmb.cnrs-mrs.fr/~pedro/CAZY/db.html). This categorization has proved to be extremely useful in understanding structural and mechanistic relationships, and has been reviewed recently (2, 3). Three-dimensional structures are now available as representatives of at least 27 of these families, revealing their incredible diversity. Monomer sizes range from approximately 14 000 to 170 000 Da, and compositions range from essentially completely α-helical to almost exclusively β-sheet. The reasons for this diversity are likely twofold: the diverse nature of the substrates themselves, and different evolutionary pathways.

Enzymatic hydrolysis of glycosidic bonds is carried out with one of two stereochemical outcomes, net retention or net inversion of anomeric configuration; thus glycosidases are classified as either retaining or inverting. Elementary mechanisms for these two classes of glycosidase were proposed by Koshland some 45 years ago (4), and these mechanisms (Fig. 1) have largely passed the test of time, having been supported by structural, mechanistic, and kinetic analyses since that time. The inverting glycosidases use a direct displacement mechanism in which two carboxylic acids at the active site are suitably positioned such that one provides base catalytic assistance to the attack of water while the other provides acid catalytic assistance to cleavage of the glycosidic bond. Reaction proceeds through an oxocarbenium ion-like transition state.

Catalysis by retaining glycosidases proceeds via a double-displacement mechanism in which a covalent glycosyl–enzyme intermediate is formed and hydrolysed via oxocarbenium ion-like transition states. Again the reaction is acid–base catalysed, though in this case all such catalysis is provided by a single group at the active site that acts as an acid catalyst for the first (glycosylation) step and as a base catalyst for the second (deglycosylation) step. The active sites of the two classes of enzymes are similar in that they provide an array of amino acid side chains suitable for stabilizing an oxocarbenium ion-like transition state. One significant difference, however, is that the two carboxylic acid side chains are much closer together (5.5 Å apart) in the retaining enzymes than in the inverters (11 Å apart) (5–7). This greater separation in the inverters allows the inclusion of a water molecule in the active site at the same time as the leaving group. Background information on these mechanisms, and references to the original publications, can be found in the following reviews: refs. 2, and 7–9.

Trapping the intermediate

Research within our group, in close collaboration with that of Dr. Tony Warren (Department of Microbiology, University of British Columbia), has focussed on mechanistic studies of retaining glycosidases, and in particular on developing methods to trap the covalent intermediate formed during catalysis. Attempts initially focussed upon methods involving modification of the substrate. The basic strategy involved slowing *both* the glycosylation and deglycosylation steps by destabilization of the oxocarbenium ion-like transition states. This was achieved by replacement of the 2-hydroxyl of the substrate with a fluorine, thereby inductively destabilizing the positively charged transition states. In addition, this substitution removed a key hydrogen-bonding substituent, interactions with the 2-position hydroxyl having been shown to contribute up to 10 kcal/mol to transition state stabilization (10–12). Having slowed both steps it was then necessary to reaccelerate the glycosylation step in order to render the intermediate kinetically accessible. This was achieved by incorporation of a reactive leaving group such as dinitrophenolate or fluoride into the substrate. Such a group would accelerate the glycosylation step, but could have no effect upon deglycosylation.

Compounds such as 2,4-dinitrophenyl 2-deoxy-2-fluoro-β-D-glucopyranoside were therefore synthesized and shown to be effective mechanism-based inactivators, functioning via the accumulation of a covalent 2-deoxy-2-fluoroglycosyl–enzyme intermediate, as shown in Fig. 2. Evidence for the accumulation of this intermediate was obtained from the inactivation itself, from ^{19}F NMR studies of the inactivated enzyme, from the stoichiometric burst of dinitrophenolate released upon inactivation of the enzyme, and from the mass increase of the enzyme. The intermediate so formed was surprisingly stable, with half-lives for turnover in the order of hundreds of hours. However, turnover could be considerably accelerated by inclusion of a sugar in the reactivation mixture, the reactivation in this case occurring by a more efficient transglycosylation reaction (Fig. 2). For leading references see the following publications and reviews: refs. 13–17.

An interesting feature of these 2-fluoro inactivators is that, while they are successful with all β-glycosidases thus far studied, they are relatively ineffective as inactivators of α-glycosidases, serving rather as slow substrates. Alternative approaches have therefore been evolved for α-glycosidases.

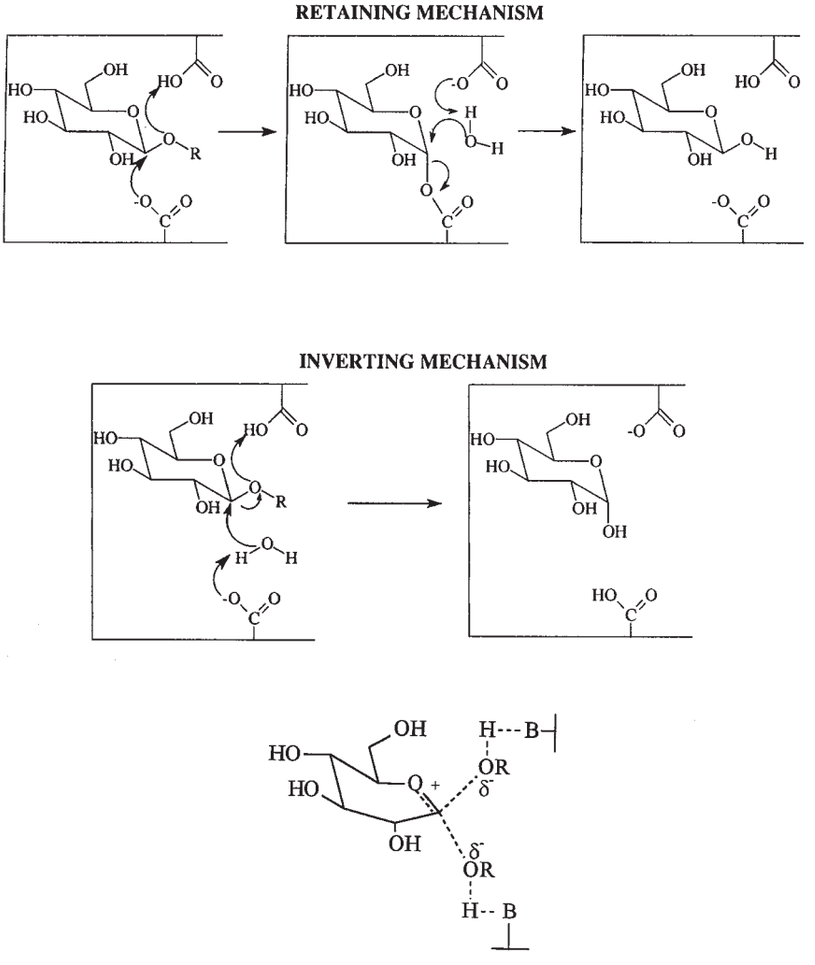

Fig. 2. Inactivation and reactivation with 2-fluoroglycosides.

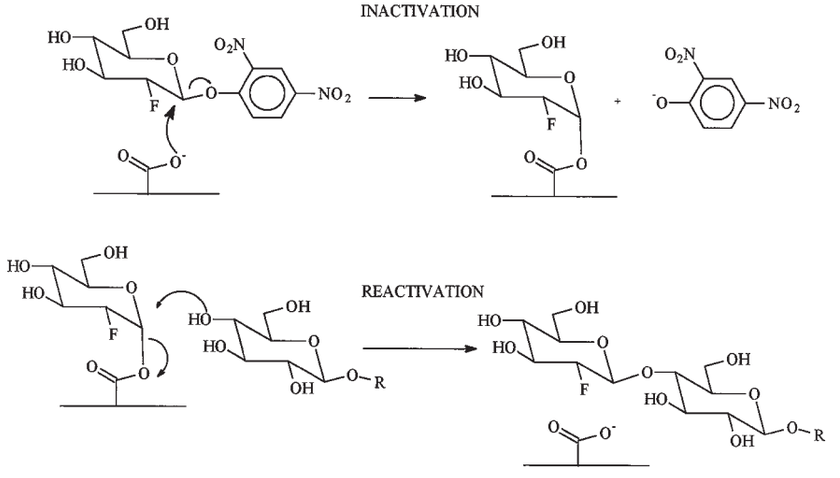

One has involved the use of a 2-deoxy-2,2-difluoro glycoside, the idea being that the presence of a second fluorine would ensure that turnover would occur only *much* more slowly. Such compounds require even more reactive leaving

groups to allow accumulation of the intermediate; thus trinitrophenyl derivatives such as that shown in Fig. 3 were synthesized and shown to be effective in trapping intermediates on an α-glucosidase as well as on human pancreatic α-amylase (18). A more subtle approach was taken in moving the fluorine from the 2-position to the 5-position, the idea being that this substituent is close to the endocyclic oxygen, where most of the charge accumulation at the transition state is taking place. This resulted in compounds such as 5-fluoro-α-D-glucosyl fluoride and 5-fluoro-β-L-idosyl fluoride, both of which can be used to trap an intermediate on yeast α-glucosidase (Fig. 3). The compounds of opposite anomeric stereochemistry were shown to be equally effective at trapping intermediates on β-glycosidases (19, 20).

Both the 2-fluoro and 5-fluoro glycosyl fluorides have been used to derivatize and thereby ultimately identify the catalytic nucleophiles of a large number of glycosidases. This work was originally devised in collaboration with Dr. Ruedi Aebersold, now in the Department of Molecular Biotechnology, University of Washington. The identification was achieved by labelling the enzyme, cutting it into a peptide mixture using pepsin, then separating the peptides by HPLC. Use of on-line MS–MS analysis has allowed localization of the glycosylated peptide within such mixtures by means of a neutral loss experiment in which a specific fragmentation event of the glycosylated peptide within the collision cell of the mass spectrometer is identified. Having localized the peptide, its sequence is determined by subsequent tandem mass spectrometric analysis in the daughter ion mode. In this way the identities of the catalytic nucleophiles in a large number of the families of retaining glycosidases have now been determined (13, 15, 17, 21).

Structural studies on the intermediate

Further insight into catalysis has come from the determination of the three-dimensional structures of several covalent glycosyl–enzyme intermediates. The first of these to be resolved was that of the 2-deoxy-2-fluorocellobiosyl–enzyme intermediate formed on the *exo*-xylanase/cellulase Cex from *Cellulomonas fimi* in collaboration with Dr. David Rose (Ontario Cancer Institute, Toronto) (22). This structure revealed that no significant structural change occurs within the protein upon formation of the glycosyl–enzyme. It also revealed the identities of the amino acid side chains involved in binding and catalysis, including those interacting with the 6-hydroxyl and therefore likely responsible for determining the cellulose/xylan specificity (Fig. 4). This was supported by the subsequent determination of the structure of the 2-deoxy-2-fluoroxylobiosyl–enzyme in which two of the residues that had moved position slightly in the fluorocellobiosyl–enzyme complex no longer moved, consistent with the higher specificity for xylan (23). Surprisingly, when mutations at one of these positions were made there was no significant effect upon the cellulose/xylan specificity.

The structures also provided clues concerning the nature of the very strong interactions (>10 kcal/mol) formed with the 2-position of the natural substrate at the transition state. Residues close to the fluorine of the substrate moiety were the highly conserved Asn126 and the carbonyl oxygen of the nucleophile itself. While the interaction with the amide moiety of Asn126 is undoubtedly important (and mutants are currently under construction to test this hypothesis), the transition state interaction with the charged nucleophile itself seems the most likely source of the majority of this stabilization at the transition state. However, the fact that the actual substituent present at the 2-position in this structure is a fluorine, which of course does not interact positively, detracts from the value of this structure. A structure with a hydroxyl at this position would be preferred. To achieve the trapping of a 2-hydroxy-intermediate without significant turnover of substrate, the glycosyl–enzyme was trapped by mutating the enzyme instead of modifying the substrate.

The first attempt to do this involved mutation of the acid–base catalyst Glu127 to Ala. This mutant was active, but with a k_{cat} value some 300-fold lower than the wild-type enzyme (24). By use of a substrate with an excellent leaving group, such as 2,4-dinitrophenolate, it was possible to accumulate the intermediate. However, turnover was still too fast for crystallographic analysis. A second mutant was therefore constructed in which the histidine residue (His 205) that

© 1999 NRC Canada

hydrogen bonds to the catalytic nucleophile, Glu233, was mutated to Asn and Ala. Again these mutants were found to have substantially decreased activities (8500-fold and 4800-fold, respectively), and they also accumulated intermediates when activated substrates were employed. However, again the turnover of this intermediate was too fast for crystallographic analysis. The final solution to this problem involved creation of a double mutant in which both mutations were present. When His205Asn/Glu233Ala Cex was reacted with 2,4-dinitrophenyl cellobioside it relatively rapidly formed a cellobiosyl–enzyme complex that turned over only on a time scale of weeks. The catalytic domain of Cex so trapped was then crystallized and its three-dimensional structure solved to 1.8 Å (25). Apart from some small changes in the positioning of the nucleophile itself and rearrangement of hydrogen-bonding patterns as a consequence of the mutations, the overall structure was very similar to that of the wild-type enzyme in its 2-deoxy-2-fluorocellobiosyl–enzyme form. Most importantly, however, the carbonyl oxygen of the nucleophile was now found to be hydrogen bonded to the sugar 2-hydroxyl with an O—O distance of 2.35 Å. This is a rather short interaction, reminiscent of those proposed to be low-barrier hydrogen bonds (26, 27). This short distance, and the fact that very strong interactions (>10 kcal/mol) are known to be formed with the 2-hydroxyl at the transition state, suggests that the hydrogen bond formed at this position is a major contributor to transition state stabilization. The interaction seen in this structure is, of course, that present in an intermediate complex, not that at the transition state. The suggestion is that this interaction is optimized at the transition state both geometrically, as the ring flattens, and electronically, as the positive charge develops at the anomeric centre, acidifying the 2-hydroxyl and thereby increasing its hydrogen bond donor capability.

Other insights have been obtained through structural studies, in collaboration with Dr. Gideon Davies (Department of Chemistry, University of York, U.K.), on the endoglucanase Cel5A from *Humicola insolens*. These studies have provided "snapshots" of the enzyme at every stable state along the reaction coordinate diagram: free enzyme, Michaelis complex, covalent intermediate, and product complex (Fig. 5) (28). These structures were achieved as follows. Excellent crystals of the native enzyme, whose pH optimum is around 7.0, were obtained at a pH of 4.5, and the structure was solved to 0.95 Å resolution. Even though the enzyme has only very low activity at this pH, substrates diffused into crystals, with their extremely high enzyme concentration, were nonetheless cleaved before data could be collected. However, by use of 2,4-dinitrophenyl 2-deoxy-2-fluoro-β-cellobioside as substrate, the structure of the Michaelis complex could be solved. The interesting feature of this structure was the substantial distortion of the substrate sugar bound in the –1 site to a $^{1}S_{3}$ skew boat, thereby placing the leaving group dinitrophenyl moiety in a pseudo-axial orientation. Such distortion should serve to facilitate the formation of the planar transition state structure. It also removes the barrier to attack of the nucleophile at the anomeric centre arising from 1,3-diaxial interactions present in the $^{4}C_{1}$ conformation.

The structure of the covalent intermediate was solved by reacting the enzyme with 2,4-dinitrophenyl 2-deoxy-2-fluoro β-cellobioside (and also the cellotrioside) at pH 7, then lowering the pH to 4.5 and crystallizing the enzyme in that form. As with *C. fimi* Cex, the intermediate was clearly seen in an undistorted $^{4}C_{1}$ conformation. Finally, simply soaking the enzyme with cellotriose and collecting data solved the structure of the product complex. This structure was unremarkable in that no significant distortion was observed, although the reducing end of the oligosaccharide was somewhat disordered, suggesting the presence of some destabilizing interactions. These structures have therefore provided useful insights into catalysis and the roles of specific residues, and of distortion, therein.

Acid–base catalysis

While the structural picture for these enzymes at least would seem now to be fairly clear, a remaining mechanistic concern was how the acid–base catalyst could efficiently function both as a good acid catalyst in the glycosylation step and then as a good base catalyst in the deglycosylation step. To probe this, ^{13}C NMR measurements of the pK_a values of the two key active site carboxylic acids of the *Bacillus circulans* xylanase (Bcx) were undertaken in collaboration with Dr. Lawrence McIntosh (Departments of Biochemistry and Chemistry, University of British Columbia) (29). Bcx was chosen for this study because it is small (20 kDa), its X-ray structure has been determined (30), and it has the enviable property of containing only two glutamic acid residues, these being the nucleophile, Glu78, and the acid–base catalyst, Glu172. The gene encoding Bcx was therefore moved into a strain of *Escherichia coli* that is auxotrophic for glutamic acid, the organism grown in the presence of side chain ^{13}C-labelled glutamic acid, and the labelled protein isolated. Because this strain will still interconvert glutamic acid and glutamine, all five glutamines were also labelled, giving a total of seven resonances in the ^{13}C NMR spectrum.

The two resonances arising from Glu78 and Glu172 were initially assigned on the basis of parallel studies with mutants in which Glu78 and Glu172 had been individually replaced; these assignments were later confirmed from the complete assignment of the ^{13}C and ^{15}N NMR spectra of this protein (31). In this way the five glutamine resonances were also assigned. ^{13}C NMR spectra were measured at a series of pH values, as shown in Fig. 6, and, from the changes in chemical shift with pH, pK_a values for the two glutamic acid residues were determined. Interestingly, several of the glutamine resonances shifted with pH also, their chemical shifts changing in response to the lower pK_a ionization. Particularly surprising in this regard was the fact that the largest such shift was observed for Gln7, a residue some 10 Å away from either active site carboxylic acid. Since Gln7 sits in close proximity to Tyr166, which hydrogen bonds through Tyr69 to Glu78, it seems likely that the large shift observed is a consequence of changing aromatic ring current effects on the chemical shift of Gln7 arising from small changes in conformation. In any case, pK_a values for Glu78 and Glu 172 of 4.2 and 6.7, respectively, were determined (Fig. 7). These values are completely consistent with the optimal pH of this enzyme (5.5) since at this pH the nucleophile will be largely deprotonated and the acid catalyst protonated,

as required for the first step. Indeed, the two pK_a values measured agree exactly with those determined from the dependence of k_{cat}/K_m upon pH, as would be expected.

The pK_a of Glu172 for the second step was measured by trapping the ^{13}C-labelled Bcx as its 2-deoxy-2-fluoroxylobiosyl–enzyme intermediate and then once again titrating the sample and measuring ^{13}C NMR spectra. To our delight the pK_a was found to have dropped to 4.2 in this intermediate, a decrease of 2.5 pH units. This lower pK_a therefore sets Glu172 up to function as the base catalyst for the second

step, exactly as needed. It is of interest to consider the reasons for this abrupt change in pK_a. In the free enzyme the pK_a of Glu172 is raised above its normal value by the presence of the negative charge on Glu78, just as in any dicarboxylic acid. Good evidence for this is the fact that the pK_a of Glu172 in the Glu172Gln mutant, where the charge at that position has been removed, is 4.2 (Fig. 7). The shift in pK_a value upon formation of the intermediate therefore appears to be caused primarily by the removal of the charge on the catalytic nucleophile upon formation of the ester. In this way the enzyme automatically "cycles" the pK_a of the acid–base catalyst to suit its role at each step by an intrinsic mechanism involving the charge on the other key active-site residue. It is likely that this mechanism is quite general for retaining glycosidases, and possibly for other enzyme classes in which charge is masked in a covalent intermediate.

Glycosynthases: mutant glycosidases for oligosaccharide synthesis

The knowledge of the mechanism and the tools developed in the process were then put to use in the generation of a new class of mutant enzyme for the synthesis of oligosaccharides. There is a rapidly increasing interest in the use of oligosaccharides as possible therapeutics (32–34). However, the difficulties attendant in the large-scale synthesis of such molecules are slowing progress in this field. While classical organic synthetic approaches are able to yield almost any oligosaccharide needed, the quantities of compound available through such routes are typically very limited. Enzymatic synthesis provides an alternative approach, and indeed glycosyl transferases, Nature's own biosynthetic catalysts, are finding increasing application as they become available in greater numbers (35–38). However, the cost of the nucleotide diphosphosugars is still prohibitive. Glycosidases run "in reverse" are another alternative, indeed, one that has been pursued for over 85 years (38–40). There are two basic approaches that can be followed, one being an equilibrium approach in which very high concentrations of the sugars of interest are mixed and reaction allowed to approach equilibrium. This typically nets very low yields and complex product mixtures. The other is the kinetic approach in which the glycosyl–enzyme intermediate is formed using a reactive glycosyl donor and then intercepted with a second sugar acceptor molecule rather than water. This is the more useful approach as it can give very specific products. However, again yields are typically rather low unless some device is used to limit product hydrolysis. *Based on our observations*,

we sought a mutant that would catalyse the formation of oligosaccharides while minimizing product hydrolysis.

The best method for completely eliminating activity in a retaining glycosidase through a single mutation, while keeping the structure intact, is to mutate the catalytic nucleophile to a non-nucleophilic residue such as alanine. If this mutation and purification are carried out with considerable care to minimize the amount of translational misincorporation and of contamination from wild-type enzyme or other active mutants during purification, then such Ala mutants of retaining glycosidases are essentially devoid of activity, having maximal rates at least 10^5 times lower than the wild-type enzyme (5). The protein active site so generated might therefore provide a useful environment in which to carry out the synthetic reaction, the mutant being folded correctly, as evidenced by CD measurements, and even X-ray crystallographic analyses in several cases (G. Brayer, D. Rose, and S.G. Withers. Unpublished results). Such a protein has an active site, capable of binding both the glycone and aglycone moieties, that is optimized for stabilization of the oxocarbenium ion-like transition state (although lacking the negative charge from the carboxylate). It also contains an acid–base residue that, due to the absence of a charged nucleophile, is likely in the deprotonated form, therefore is optimally set up as a base catalyst. In full, therefore, the enzyme is set up to carry out the transglycosylation step, but cannot do so because it has not formed a reactive α-glycosyl–enzyme intermediate. The answer to the problem was to provide the mutant with a glycosyl donor that was a chemical mimic of this reactive α-glycosyl–enzyme intermediate, incorporating a leaving group that is sufficiently small to fit into the space in the active site generated by removal of the catalytic nucleophile. The reagent of choice was an α-glycosyl fluoride since such compounds are reactive

glycosyl donors with a very small substituent/leaving group, fluoride, and are very readily synthesized. Incubation of the mutant with this donor in the presence of a suitable glycosyl acceptor should lead to product formation as shown in Fig. 8.

© 1999 NRC Canada

This approach was first established (41) with the β-glucosidase from *Agrobacterium sp.* (Abg), a Family 1 β-glycosidase with broad specificity that has been studied extensively in our group (11, 14, 42–45). The buffer chosen was either 150 mM sodium phosphate, or 150 mM ammonium bicarbonate, the latter being preferred due to its volatility. High buffer concentrations are required in order to neutralize the HF released stoicheometrically. As an illustration of this approach on the 2 mL scale, the Glu358Ala mutant of Abg was incubated with α-galactosyl fluoride (40 mM) as donor and *p*-nitrophenyl β-cellobioside (30 mM) as acceptor in the presence of AbgGlu358Ala (0.01 mg) in 150 mM ammonium bicarbonate buffer. After 8 h, TLC analysis indicated that reaction was complete and the reaction was worked up by ultrafiltration to remove the enzyme (which can be reused). Lyophilization, then HPLC purification, yielded 34 mg (92% isolated yield) of Gal-β-1,4-Glu-β-1,4-Glu-β-*p*-nitrophenyl.

The enzyme was shown to be capable of transferring galactose residues to a range of different acceptors, as shown in Table 1. The products formed were poor acceptors for the enzyme (as also is galactose), thus reaction terminated after a single transfer. α-Glucosyl fluoride also acts as an excellent donor. However, in this case the products, being glucosides, are also excellent acceptors, resulting in longer oligomers. The size of the oligosaccharide product can be controlled to a reasonable extent through the number of equivalents of donor employed, though such control is not perfect. Examples are shown in Table 2. A final interesting example, which illustrates the power of this approach, is that of the synthesis of some 2-fluorocello-oligosaccharide based cellulase inactivators. Incubation of AbgGlu358Ala with 2,4-dinitrophenyl 2-deoxy-2-fluoro β-glucoside plus 1.5 equiv. of α-glucosyl fluoride yielded an intentional mixture of 2,4-dinitrophenyl 2-deoxy-2-fluoro β-cellobioside and trioside (84% total yield) that was readily separated by HPLC. It is interesting to note that this reaction could not be carried out by standard glycosidase transglycosylation since the 2-fluorosugar would have inactivated the enzyme, a process that is not possible with the mutant.

As is clear from the above data, this approach provides very good yields of product in a very simple reaction starting with easily accessible reagents. It therefore has good potential as a method for synthesis of oligosaccharides, particularly on the large scale. The approach has therefore been patented (U. S. Patent no. 5,716,812 (1998)) and work is currently ongoing to extend this approach to the synthesis of a range of different oligosaccharides.

Acknowledgments

This work was carried out in collaboration with a number of colleagues who have been named in the article. I owe my thanks to them and to all our graduate students, postdoctoral fellows, and technicians. Their names are apparent in the references quoted, or the references therein. The work was supported by research funds from the Natural Sciences and Engineering Research Council of Canada and the British Columbia Science Council. It was also supported by the Government of Canada's Network of Centres of Excellence programme supported by the Medical Research Council and the Natural Sciences and Engineering Research Council of Canada through PENCE Inc. (the Protein Engineering Network of Centres of Excellence of Canada).

Ryanoids and related compounds. Isolation and characterization of four minor ryanoids from the plant *Ryania speciosa* Vahl: 8,9-didehydroryanodine, 10-*O*-acetylryanodol, 3-*O*-benzoylryanodol, and a first natural 4-deoxyryanoid: 4-deoxy-8_{ax}-hydroxy-10-*O*-methyl-10-epiryanodine (4-deoxyester A)[1]

Luc Ruest, Carl Berthelette, Marco Dodier, Laurence Dubé, and David St-Martin

Abstract: In a search for minor ryanoids from the plant *Ryania Speciosa* Vahl, we characterized four new members of that family of natural compounds: 8,9-didehydroryanodine (**5**), 10-*O*-acetylryanodol (**6**), 3-*O*-benzoylryanodol (**9**), and the first member of the natural 4-deoxyryanoid series: 4-deoxy-8_{ax}-hydroxy-10-*O*-methyl-10-epiryanodine (**10**) (4-deoxyester A).

Key words: natural ryanoids, ryanodine, deoxyryanoids, ryanodol derivatives.

Résumé : En cherchant à identifier les ryanoïdes mineurs de la plante *Ryania Speciosa* Vahl, nous avons caractérisé quatre nouveaux membres de cette famille de produits naturels : la 8,9-didéhydroryanodine (**5**), le 10-*O*-acétylryanodol (**6**), le 3-*O*-benzoylryanodol (**9**) et un tout premier membre de la série 4-déoxyryanoïde : la 4-déoxy-8_{ax}-hydroxy-10-*O*-méthyl-10-épiryanodine (**10**) (4-déoxyester A).

Mots clés : ryanoïdes naturels, ryanodine, déoxyryanoïdes, dérivés du ryanodol.

Introduction

Ryanodine (**1**) (Fig. 1) is known to be a potent modulator of the sarcoplasmic reticulum calcium release channel (1). After ryanodine structure elucidation by Wiesner (2), a few groups (3–12) reported that this complex polycyclic, polyhydroxylic compound was not the sole insecticidal principle in the plant *Ryania speciosa* Vahl. In a recent review on the pharmacology of ryanodine and related compounds (1), 18 structurally related compounds, the ryanoids, were reported. These structures have been elucidated by extensive NMR analysis and also by X-ray diffraction (12, 13). These natural compounds represent very interesting molecules in which the ryanodine molecule is slightly modified by different orientations of the functional groups and the nature of the functional groups (e.g., **1–4**, **7**, **8**). Most of the natural ryanoids would be very difficult to obtain by multistep transformations of ryanodine (**1**) or of 9,21-didehydroryanodine (**2**), the two most abundant ryanoids in that plant. The total syntheses of ryanodol (**3**) (14) and 3-epiryanodine (not shown)(15) from ryanodol (**3**) have been reported.

The biological activities of these metabolites and of several of their derivatives have been studied (ref. 1, and references therein). A number of hypotheses have been formulated regarding the effects of specific structural moieties on the binding affinity of these compounds at the ryanodine binding site (1, 15–27).

In a search for other members of this family, we have very recently identified new ryanoids **5**, **6**, **9**, and **10** (Fig. 1) in the extracts of the plant. Compound **10** represents the first known member of a novel series: the 4-deoxyryanoids. These four metabolites are very minor components, each one representing ~1–5 ppm quantities (w/w) of the dried powdered wood, compared to approximately 500–800 ppm for **1** and **2**.

Results and discussion

The observation of the presence of the new ryanoids came after usual separation of the known major ones. In the mother liquors of crystallization of 9,21-didehydroryanodine (**2**), the already known natural 9α,21-epoxyryanodine (**4**, ref. 12) and the new 8,9-didehydroryanodine (**5**) were observed.

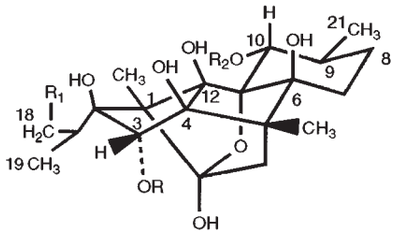
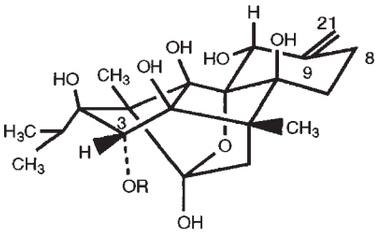
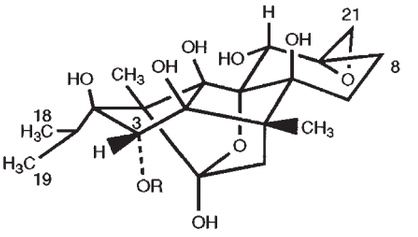
Fig. 1. Structures of the new metabolites **5**, **6**, **9**, and **10**, together with some relevant known structures.



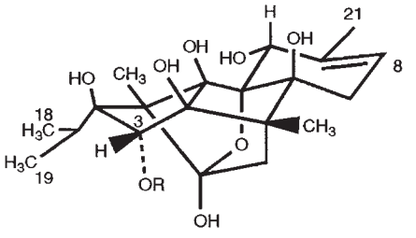
1: $R_1 = R_2 = H$; R = Pyr: Ryanodine
3: $R_1 = R_2 = R = H$: Ryanodol
6: $R = R_1 = H$; $R_2 = -CO-CH_3$
7: $R_1 = OH$; $R_2 = H$; R = Bz
9: $R_1 = R_2 = H$; R = Bz



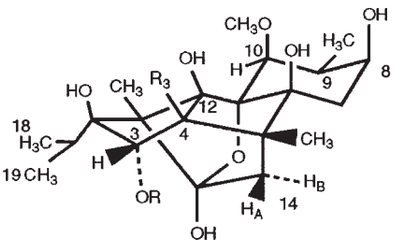
2: R = Pyr: 9,21-Didehydroryanodine



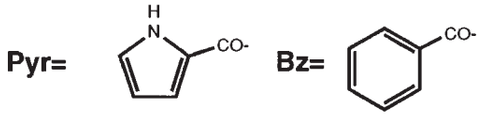
4: R = Pyr: 9α,21-Epoxyryanodine



5: R = Pyr: 8,9-Didehydroryanodine



8: R = Pyr; R_3 = OH: Ester A
10: R = Pyr; R_3 = H: 4-Deoxy-Ester A



This latter compound had been obtained previously by palladium-catalyzed isomerization of the 9,21 double bond of compound **2**. (4, 25). Its identification was thus highly facilitated.

The new 10-*O*-acetylryanodol (**6**) was first detected by NMR and TLC analysis of the mother liquors of crystallization of ryanodine, together with the previously described 18-hydroxy-3-*O*-benzoylryanodol (**7**, ref. 12). It is very slightly less polar than ryanodine and undetectable by usual UV light detection. Combining HPLC and multiple preparative TLC, we finally obtained this new natural compound in a pure form. Compound **6** and ryanodol (**3**) show very similar NMR spectra, the sole major differences being the position of the HC10 doublet (at δ 5.23 for **6**) and the presence of a new singlet (3H) of an acetyl group at δ 2.04. The structure of compound **6** was confirmed by chemical correlation with ryanodol (**3**) from which 10-*O*-acetyl-4-*O*,15-*O*-dibenzylryanodol (**11**) was obtained following a reported method (14*b*) (Scheme 1). Derivative **11** gave compound **6** under hydrogenolysis of the benzyl ether moieties. It had been shown previously that direct acetylation of ryanodol leads to a complex mixture of di-, tri-, and tetraacetate derivatives (14*b*). The present strategy makes it possible to obtain a good yield of single specific derivatives of ryanodol at position 10.

During the purification of 8_{ax}-hydroxy-10-*O*-methyl-10-epiryanodine (**8**), the so-called ester A (4, 10), by HPLC techniques combined with plate chromatography, we observed the presence of two new ryanoids: 3-*O*-benzoylryanodol (**9**), a compound slightly more polar than ester A, and 4-deoxyester A (**10**), slightly less polar than ester A. Compound **9** and ryanodine show very similar NMR spectra, differing mainly in the typical aromatic hydrogens of a benzoic ester moiety and in the downfield chemical shift of HC3 (δ 5.76 compared to δ 5.62 for ryanodine). Compound **10** shows an NMR spectrum very close to that of ester A (**8**), but an unusual doublet at δ 5.68 (8.4 Hz) for HC3 revealed the presence of a vicinal hydrogen atom (at C2 or C4) appearing as a doublet of doublets at δ 3.24 (8.4 and 1.6 Hz). By means of COSY experiments, it was shown that the small coupling constant is due to a long-range interaction (W-coupling) with one of the protons at position 14 (H_BC14).

The biological activities and affinities to ryanodine binding sites of the new ryanoids **5**, **6**, **9,** and **10** are currently under analysis in the laboratories of Professor William Welch, Department of Biochemistry, University of Nevada, Reno, Nevada.

Experimental section

Melting points were recorded on a Reichert hot-stage apparatus and are uncorrected. Mass spectra (MS) and peak matching (HRMS) data were determined at 70 eV on a VG Micromass ZAB-1F spectrometer. The ^1H (300 MHz) NMR

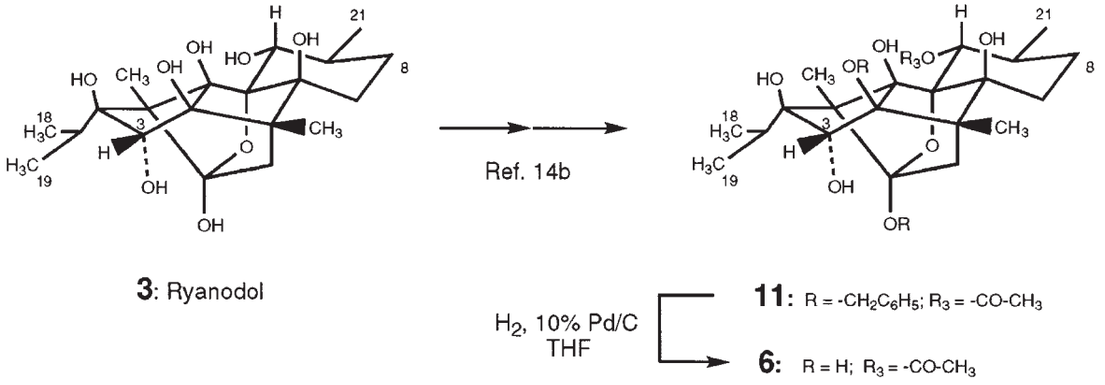
Scheme 1. Synthesis of the new ryanoid **6** from ryanodol (**3**).



spectra were recorded on a Bruker AC-300 instrument (with CHD_2OD as internal standard centered at δ 3.30). The usual standard abbreviations have been used to indicate the multiplicity of the proton signals. Analytical and preparative thin-layer chromatography were done on 0.25 or 0.5 mm glass plates precoated with silica gel 60F-250 (Merck). A typical solvent was a mixture of 5–15% of methanol in chloroform to which may be added 0.5–2.0% of commercial 40% aqueous methylamine. Column chromatography (flash) was performed with Merck silica gel (200–400 mesh). High-performance liquid chromatography (HPLC) utilized a Waters model 510 instrument equipped with a Vydac C18 reverse-phase preparative column (15 μm, 2.5 × 25 cm) and a Waters 484 tunable UV detector set at 254 nm. A typical solvent for HPLC preparative separation was a mixture of 40% methanol in water. All reactions were performed under argon atmosphere and in solvents purified by standard methods. Reaction mixtures were extracted with at least five portions of distilled ethyl acetate. Solutions in organic solvents were washed with brine, dried over anhydrous magnesium sulfate or anhydrous sodium sulfate, filtered, and then stripped of solvents with a rotatory evaporator connected to a water aspirator.

Isolation of the new ryanoids

Extraction of powdered Ryania wood was carried out as previously described in ref. 11. The isolation of each of the new ryanoids was done as described above.

*8,9-Didehydroryanodine (**5**)*

By TLC analysis, compound **5** is very slightly more polar than 9,21-didehydroryanodine (**2**). The spectroscopic and physical properties of synthetic **5** have been reported previously (4).

*10-*O*-Acetylryanodol (**6**)*

This compound was obtained from the extracts by HPLC techniques combined with careful multi-elution preparative thin-layer chromatography using a mixture of chloroform–methanol (9:1) as a solvent: mp 220–224°C (MeOH); ^{1}H NMR (CD_3OD, δ ppm): 5.23 (d, 11.6 Hz, 1H, HC10), 4.06 (s, 1H, HC3), 2.52 (d, 13.4 Hz, 1H, H_AC14), 2.13 (m, 1H, HC13), 2.13–1.95 (m, 2H, $H_{ax}C7$, HC9), 2.04 (s, 3H, -CO-CH_3), 1.74 (d, 13.4 Hz, 1H, H_BC14), 1.55 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.33 (s, 3H, CH_3C1), 1.29 (m, 1H, $H_{eq}C8$), 1.11 (s, 3H, CH_3C5), 1.07 (d, 6.8 Hz, 3H, CH_3C9), 0.98 (d, 6.5 Hz, 3H, CH_3C13), 0.83 (d, 6.6 Hz, 3H, CH_3C13); MS *m/e*: 406 ($M^+ - 2H_2O$); HRMS calcd. for $C_{22}H_{30}O_7$ ($M^+ - 2H_2O$): 406.1991; found: 406.1994.

Synthesis of **6** from compound **11**, obtained from ryanodol as described in ref. 14*b*, was as follows:

At ambient temperature, a solution of ryanodol derivative **11** (20 mg, 0.032 mmol) in tetrahydrofuran (THF) was transferred (canula) to a stirred suspension of prehydrogenated (15 min) catalyst (10% Pd/C, 20 mg) in THF (5 mL). The mixture was stirred under hydrogen atmosphere for 24 h, then filtered, and the solvent was evaporated. The crude product was purified by preparative thin-layer chromatography (10% methanol in chloroform, two elutions) to give compound **6** (13.5 mg, 95%).

*3-*O*-Benzoylryanodol (**9**)*

Amorphous solid; ^{1}H NMR (CD_3OD, δ ppm): 8.05 (app d, 7.3 Hz, 2H, *o*-ArH), 7.65 (app t, 7.4 Hz, 1H, *p*-ArH), 7.53 (app t, 7.8 Hz, 2H, *m*-ArH), 5.76 (s, 1H, HC3), 3.79 (d, 10.2 Hz, 1H, HC10), 2.56 (d, 14.0 Hz, 1H, H_AC14), 2.29 (m, 1H, HC13), 2.09 (m, 1H, $H_{ax}C7$), 1.94 (d, 14.0 Hz, 1H, H_BC14), 1.84 (m, 1H, HC9), 1.6–1.4 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.40 (s, 3H, CH_3C1), 1.35–1.20 (m, 1H, $H_{eq}C8$), 1.13 (d, 6.7 Hz, 3H, H_3C18), 1.00 (d, 6.5 Hz, 3H, CH_3C9), 0.81 (s, 3H, CH_3C5), 0.72 (d, 6.4 Hz, 3H, H_3C19); MS *m/e*: 504 (M^+); HRMS calcd. for $C_{27}H_{36}O_9$: 504.2359; found: 504.2345.

*4-Deoxy-8$_{ax}$-hydroxy-10-*O*-methyl-10-epiryanodine (4-deoxyester A) (**10**)*

Amorphous solid; ^{1}H NMR (CD_3OD, δ ppm): 7.00, 6.84, and 6.22 (3 dd for pyrrole ring hydrogens), 5.68 (d, 8.4 Hz, 1H, HC3), 3.89 (m, 1H, HC8), 3.49 (s, 3H, CH_3-O-C10), 3.42 (d, 3.2 Hz, 1H, HC10), 3.24 (dd, 8.4 and 1.6 Hz, 1H, HC4), 2.36 (m, 1H, HC13), 2.34 (d, 13.7 Hz, 1H, H_AC14), 2.20 (dd, 13.7 and 3.7 Hz, 1H, $H_{ax}C7$), 2.12 (m, 1H, HC9), 1.68 (br d, 13.7 Hz, 2H, H_BC14 and $H_{ax}C7$), 1.34 (s, 3H, CH_3C1), 1.19 (d, 7.3 Hz, 3H, H_3CC9), 1.13 (d, 6.7 Hz, 3H, H_3C18), 0.83 (d, 6.4 Hz, 3H, H_3C19), 0.79 (s, 3H, CH_3C5); MS *m/e*: 507 (M^+); HRMS calcd. for $C_{26}H_{37}O_9N$: 507.2468; found: 507.2471.

Distortions in square-planar palladium(II) halides: a nonempirical molecular orbital model study

Pierre D. Harvey and Christian Reber

Abstract: Density functional theory is used to characterize the lowest energy excited spin triplet orbital configurations of square-planar halide complexes of palladium(II). Calculations for the $e_g \rightarrow b_{1g}$ orbital excitation (D_{4h} labels) predict a non-totally symmetric distortion along the b_{1g} normal coordinate, leading to unequal bond lengths for perpendicular metal–ligand bonds (D_{2h} symmetry). Calculated bond length changes are 0.15 Å (0.11 Å) and 0.05 Å (0.00 Å) for $PdCl_4^{2-}$ ($PdBr_4^{2-}$). These values compare favorably to the emitting-state distortions of 0.12 Å and 0.09 Å for K_2PdCl_4 (0.12 Å, and 0.07 Å for K_2PdBr_4) determined from resolved single-crystal luminescence spectra. The calculations indicate that the non-totally symmetric distortion is an intrinsic molecular property of these complexes.

Key words: palladium(II) complexes, excited state distortions, density functional theory.

Résumé : La théorie de fonctionnelle de la densité est appliquée à la caractérisation des premières configurations triplet excitées de deux complexes plan-carrés du palladium(II). Les calculs pour l'excitation $e_g \rightarrow b_{1g}$ (groupe ponctuel D_{4h}) prédisent une distorsion le long de la coordonnée normale b_{1g}. Cette distorsion mène à des longueurs de liaison inégales pour liaisons métal–ligand perpendiculaires (groupe ponctuel D_{2h}). Les changements calculés sont de 0,15 Å (0,11 Å) et 0,05 Å (0,00 Å) pour $PdCl_4^{2-}$ ($PdBr_4^{2-}$). Ces valeurs sont proches aux distorsions de l'état émissif de 0,12 Å et 0,09 Å pour K_2PdCl_4 (0,12 Å et 0,07 Å pour K_2PdBr_4), déterminées à partir des spectres de luminescence de monocristaux. Les calculs indiquent que la distorsion de symétrie non-totale est une propriété intrinsèque de ces complexes.

Mots clés : complexes du palladium(II), distorsions des états excités, théorie de fonctionnelle de la densité.

Introduction

Modern theoretical methods such as density functional theory have become powerful tools to characterize challenging molecules, including transition metal complexes and organometallic compounds (1). Their large number of electrons and energetically close excited states have until recently limited theoretical studies to semiempirical methods such as the Extended Hückel approach, which can not be used to reliably calculate structures of the ground and excited electronic states (2). Over the past few years, density functional theory has provided reliable excited-state structures for a number of octahedral and tetrahedral coordination compounds (3–6), for organometallic molecules such as ruthenocene (7, 8), and for polynuclear palladium complexes with metal–metal bonds (9).

Square-planar palladium(II) and platinum(II) complexes with four identical monodentate ligands are attractive molecules for a density functional study of the ground and excited orbital configurations. Resolved absorption and luminescence spectra of crystalline solids at low temperature are reported for a series of complexes, leading to quantitative excited-state energies and distortions, an important prerequisite for a detailed comparison of calculated and experimental quantities (10–21). In several square-planar complexes, most notably K_2PtCl_4, K_2PdCl_4, and K_2PdBr_4, unusual non-totally symmetric distortions along the b_{1g} mode were analyzed in the resolved luminescence spectra (18, 20, 21). In addition, a distortion along the totally symmetric a_{1g} normal coordinate is expected if antibonding orbitals such as the b_{1g} ($d_{x^2-y^2}$) LUMO orbital of the title compounds are occupied.

In this study, we use a simplified approach to the calculation of structural changes as a consequence of electronic excitations in $PdBr_4^{2-}$ and $PdCl_4^{2-}$, isolated square-planar complexes with the [Kr]4d^8 electron configuration. In D_{4h} symmetry, the d orbitals split into the occupied a_{1g} (d_{z^2}), b_{2g} (d_{xy}), and e_g (d_{xz},d_{yz}) orbitals at lower energy than the empty b_{1g} ($d_{x^2-y^2}$) orbital. This splitting pattern has been discussed extensively in the literature and orbital energies have been calculated with a variety of computational methods, as sum-

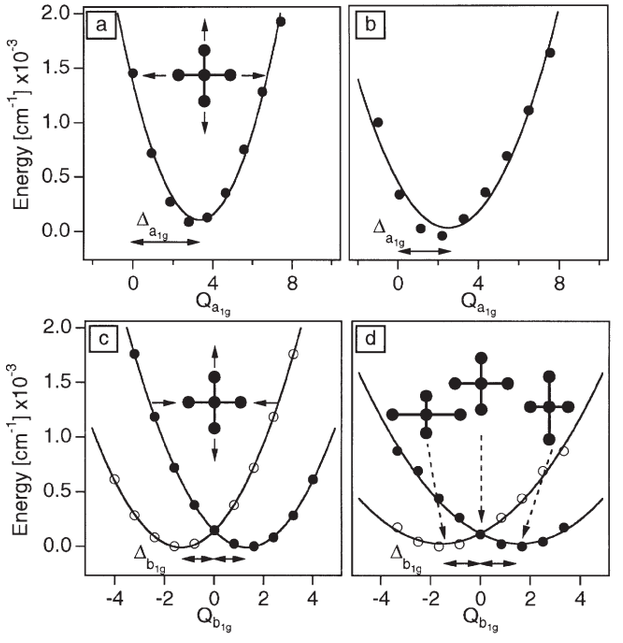
Fig. 1. One-dimensional potential energy surfaces for $PdCl_4^{2-}$ (*a*), (*c*) and $PdBr_4^{2-}$ (*b*), (*d*). The dots indicate calculated energies for the $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ triplet excited configuration along the totally symmetric $Q_{a_{1g}}$ (*a*), (*b*) and the non-totally symmetric $Q_{b_{1g}}$ (*c*), (*d*) normal coordinates, which are given in dimensionless units. The ground state molecular structure defines the origin of the abscissa in panels (*a*)–(*d*). The totally symmetric a_{1g} and non-totally symmetric b_{1g} vibrational modes are illustrated schematically in panels (*a*) and (*c*), respectively. Panel (*d*) shows the molecular structures corresponding to the two potential minima and the structure at the crossing point of the potential energy curves.



marized in ref. 22. Three one-electron excitations are possible within these orbital energy levels. We limit our study to these changes in the orbital populations and focus on the energetically most favorable structure of the spin triplet configuration arising from the $e_g \rightarrow b_{1g}$ excitation, leading to the lowest energy ^3E_g excited state. This is the only configuration in which non-totally symmetric distortions can occur. The limitation to orbital configurations is a dramatic simplification of the physical situation and prevents us from calculating accurate energies of electronic transitions, but it has an intuitive appeal with respect to the characterization of metal–ligand bonds. It is particularly appropriate for the title compounds with only one set of doubly degenerate orbitals, in contrast to octahedral and tetrahedral complexes where both HOMO and LUMO orbitals are degenerate. Models based on empirical *orbital* parameters such as 10*Dq* have been successfully used to rationalize overall bond length changes in excited states of these high-symmetry molecules, further supporting the approach chosen for this study (23).

Computational methodology

All molecular orbital calculations were carried out using the HFS-LCAO program system A-MOL (Amsterdam density functional: ADF program), developed by Baerends et al. (24, 25) and vectorized by Ravenek (26). The numerical integration procedure applied for the calculations was developed by te Velde and co-workers (27). The electronic configurations of the molecular systems were described by an uncontracted double-ζ STO basis set (28, 29) for 4*s*, 4*p*, 5*s*, and triple-ζ for 5*d*. The double-ζ STO basis sets (30–32) for chloride (3*s*, 3*p*) and bromide (4*s*, 4*p*) were augmented with single 4*d* and 5*d* polarization functions for Cl and Br, respectively. No polarization function was used for palladium. The $1s^22s^22p^63s^23d^{10}$ configuration of the palladium center, the $1s^22s^2$ configuration of chloride, and the $1s^22s^22p^63s^2$ configuration of bromide were treated by the frozen-core approximation. A set of auxiliary (33) s, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used to fit the molecular density and represent Coulomb and exchange potentials accurately in each self-consistent field (SCF) cycle. Energy differences were calculated by including the local exchange-correlation potential by Vosko et al. (34) with Becke's (35) nonlocal exchange corrections and Perdew's (36) nonlocal correlation correction. The three lowest energy spin triplet configurations used for our calculations are of different symmetries and can therefore easily be obtained from DFT calculations.

The potential energy surfaces for the $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ spin triplet excited configuration for both PdX_4^{2-} complexes (X = Cl, Br) have been calculated using the complex total energies as a function of the Pd—X distances ranging from 2.30 to 2.66 Å for $PdCl_4^{2-}$ and from 2.42 to 2.72 Å for $PdBr_4^{2-}$. Bond length increments of 0.03 Å were used for both compounds. The results are reported as one-dimensional potential energy curves in Fig. 1 and as contour maps of the full grid of molecular geometries using 200 cm^{-1} energy intervals between contour lines in Fig. 2. The origin of the coordinate system in Fig. 2 indicates the calculated ground state minimum energy position. The molecular structures of $PdCl_4^{2-}$ and $PdBr_4^{2-}$ at the calculated potential energy minima are summarized in Fig. 3, with a definition of the molecular axes used in the following.

The most important simplification made for this study is the limitation to one-electron excitations. To justify this approach, we present full crystal field calculations using the angular overlap formalism (37). We reproduce the energies given for selected states of square-planar palladium(II) and platinum(II) complexes in the literature (16) to within 10 cm^{-1}. In the following, we use the parameters derived from our low-temperature absorption and luminescence spectra (21). The Racah parameters *B* and *C* are identical to those determined earlier from absorption spectra (16). Our e_σ and e_π angular overlap parameters vary by less than 5% from those in ref. 16. These small variations were made to better account for the weak low-energy absorption bands and for the lower limit to excited state energies imposed by the luminescence spectra. The complete results of these calculations are presented in Tables 1 and 2 and are intended to link this work to the extensive literature on crystal field states of square-planar complexes with the d^8 electron configuration. Only partial listings of the energies of crystal field states have been published before, often omitting the orbital parentage of the calculated excited states.

Fig. 2. Two-dimensional potential energy surfaces for the component of the $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ triplet excited configuration given by black dots in Fig. 1. Surfaces are given for both $PdCl_4{}^{2-}$ (*a*) and $PdBr_4{}^{2-}$ (*b*). The position of the ground-state potential energy minima is at the origin of the Δr_i coordinate system. The minimum of the potential surfaces in the figure is set to an energy of 0 cm^{-1} and contours are shown at an interval of 200 cm^{-1}. Calculations were made in steps of 0.03 Å along the horizontal and vertical axes, as indicated by the tick marks. The directions of the normal coordinates $Q_{a_{1g}}$ and $Q_{b_{1g}}$ in Fig. 1 are indicated for comparison.

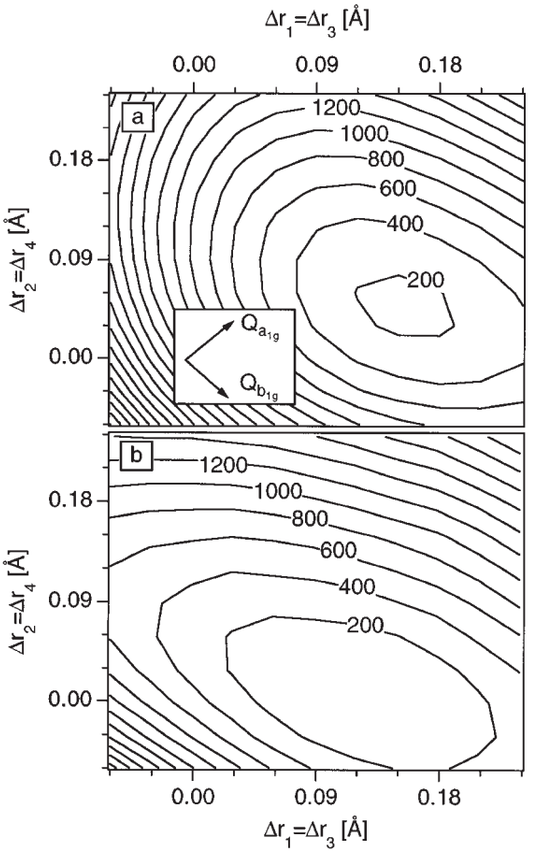

Fig. 3. Calculated molecular distortions for the excited $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ orbital configuration of $PdCl_4{}^{2-}$ and $PdBr_4{}^{2-}$. The coordinate system schematically defines the axes used in Fig. 2.

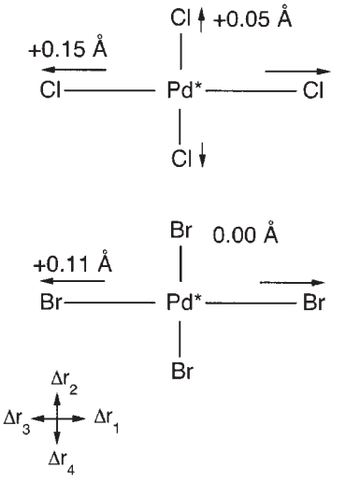

Results and discussion

(a) Crystal field calculations and orbital excitations

Square-planar complexes such as the title compounds present a very particular energy order of their excited states. Tables 1 and 2 summarize all crystal field excited states with their strong field electron configurations. An inspection of the states calculated without spin-orbit coupling shows that all three low-energy spin triplet excited states correspond to almost pure one-electron excitations. They are separated by more than 20 000 cm^{-1} from higher energy triplet states of the same symmetry, formally arising from two-electron excitations. This large energy difference justifies the limitation to orbital excitations, which can be expected to reveal the most important structural characteristics of the low-energy spin triplet excited states.

Of particular interest to us is the structure of the lowest energy ^3E_g excited state arising from the $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ configuration, because this state is susceptible to a Jahn–Teller effect that can involve both the b_{1g} and b_{2g} modes in addition to the elongation of all palladium–halide bonds along the a_{1g} normal coordinate. The Jahn–Teller effect lifts the degeneracy of the e_g orbitals, leading to a net stabilization because of the asymmetric occupation of these orbitals. Orbitally nondegenerate electronic states can only undergo distortions along the totally symmetric a_{1g} normal coordinate. The distortions of the $a_{1g}{}^2b_{2g}{}^2e_g{}^3b_{1g}{}^1$ configuration along the different normal coordinates are therefore intrinsic and not resulting from interactions with other states of the same symmetry. We have recently shown for a series of octahedral nickel(II) complexes with the same d^8 electron configuration as the title compounds that distortions can be induced by spin-orbit coupling between excited states of the same symmetry separated by less than 2000 cm^{-1} (38). The vibronic progression observed in an electronic spectrum for the state with only a small or no distortion is determined by another state of identical symmetry with a large offset along one or more normal coordinates. This situation does not apply here because the nearest ^3E_g state arises from a double excitation, corresponding to the $a_{1g}{}^2b_{2g}{}^1e_g{}^3b_{1g}{}^2$ electron configuration, and it is calculated at energies higher by 22 783 cm^{-1} and 22 159 cm^{-1} than the first ^3E_g state for $PdCl_4{}^{2-}$ and $PdBr_4{}^{2-}$, respectively. The energy difference between the two ^3E_g states is larger by more than an order of magnitude than for states where the distortions are significantly influenced by spin-orbit coupling, leading to weak or negligible effects. Every triplet state has a corresponding singlet excited state approximately 5000 to 7000 cm^{-1} higher in energy. A comparison of the electron configurations of these states in Tables 1 and 2 shows that their configurations are almost identical to those of the corresponding triplet states. Singlet and triplet states have therefore very similar potential energy surfaces and their interactions do not significantly influence

the positions of the potential minima along the normal coordinates.

Spin-orbit coupling has an important influence on the energetic order of the states arising from the low-energy spin triplet configurations. It is important to realize that a distortion of the ^3E_g state (other than a bond elongation along the totally symmetric normal coordinate) can not be induced by spin-orbit coupling with a nearby orbitally nondegenerate state. The crystal field calculations show that the orbital occupations of the antibonding b_{1g} orbital for the low-energy

triplet states change by less than 0.007 as a consequence of spin-orbit coupling, indicating that all these excited states involve almost exclusively one-electron excitations. We describe here one of very few situations where it is possible to gain insight on excited state distortions from a study limited to orbital excitations. We note that crystal field calculations involving only the electron configurations corresponding to one-electron excitations (21, 39) lead to energies of the first excited states that are higher by approximately 500 cm^{-1} than those of the full calculations in Tables 1 and 2. This is

© 1999 NRC Canada

the likely origin of a recent controversy over crystal field calculations on square-planar complexes (40–42). The small differences of less than 3% of the excited state energies calculated from different crystal field models are further evidence confirming that the following analysis of orbital configurations is physically reasonable for the title compounds.

(b) Density functional calculations of excited spin triplet configurations

In a first series of molecular orbital calculations, we use the density functional approach to calculate palladium–halide distances for the electronic ground state of the two target molecules. We obtain values of 2.360 and 2.482 Å for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively. These values compare favorably with the crystallographic bond lengths of 2.313 and 2.444 Å for K_2PdCl_4 and K_2PdBr_4 (43, 44). The small differences of approximately 0.05 Å qualitatively indicate that the molecular and overall electronic structures for the complexes in condensed phases and for the isolated molecules used for our model systems are comparable, an important foundation for the following analysis. This similarity is experimentally confirmed by the resemblance of absorption spectra measured in solution and in the solid state (11–14). A sophisticated density functional study (5) of octahedral complexes of chromium(III), including the electrostatic effects of the crystal lattice, has led to differences between calculated and crystallographic bond lengths of less than 0.01 Å, again underlining the approximate nature of our model study.

The calculated energy differences between the occupied e_g orbital and the lowest unoccupied b_{1g} orbital are 15 240 and 14 430 cm^{-1} for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively. Without taking into account the singlet–triplet state interactions and the total energies of the complexes in their ground and excited electronic configurations, these values compare favorably to the energy range of the first absorption bands (21). Detailed discussions of calculated orbital energies for the title compounds are given in the literature (11, 22) but the comparison between the energies of experimental transition energies and the calculated differences between occupied and empty orbitals is not the focus of the present work. The density functional calculations predict an energy difference between the e_g and b_{1g} orbitals that is higher by 810 cm^{-1} for $PdCl_4^{2-}$ than for $PdBr_4^{2-}$. In the angular overlap approach, this difference is equal to $3e_\sigma - 2e_\pi$ (16). The energy difference from density functional calculations compares favorably with the difference of 960 cm^{-1} calculated from the crystal field parameters in Table 1 and is also in good agreement with the value of 1133 cm^{-1} determined from an alternative angular-overlap analysis (22) of the absorption spectra. It is within an order of magnitude of the difference of 210 cm^{-1} between the electronic origins of the luminescence spectra of K_2PdCl_4 and K_2PdBr_4 (21). The electronic origins are experimentally well defined and are therefore much better suited to a semiquantitative comparison with calculated energies than the maxima of broad bands, which are notoriously hard to determine accurately. Preliminary calculations for the platinum(II) analogs of the title compounds have led to energy differences higher by approximately 2500 cm^{-1} than for the palladium halides, again comparable to the experimental emission energies that are higher by 1500 cm^{-1} for the platinum(II) complexes (15, 18). These trends confirm that density functional theory and our orbital model provide a good representation of the low-energy electronic excitations.

(c) Potential energy surfaces from density functional calculations

We have made density functional calculations for a series of geometries and for all three low-energy spin triplet configurations of $PdCl_4^{2-}$ and $PdBr_4^{2-}$ in D_{4h} symmetry. Average bond length increases of 0.12 and 0.10 Å are calculated for the chloride and bromide complexes, respectively, with variations of less than 0.01 Å between the different orbital configurations. Three low-energy absorption bands to the first three triplet excited states are resolved in the low-temperature spectrum of K_2PdBr_4 (21). Their widths and vibronic patterns are similar, a qualitative experimental confirmation of the very small variation of calculated bond length changes for the three spin triplet configurations. The calculated values are within the range determined from broad *d–d* bands in a variety of transition metal complexes, further underlining that our simplified model produces physically reasonable structural characterizations of the excited complexes. Identical changes of all four palladium–halide bonds are the only structural variations possible for the $a_{1g} \rightarrow b_{1g}$ and $b_{2g} \rightarrow b_{1g}$ orbital excitations, leading to the parent configurations of nondegenerate electronic states.

The most interesting orbital excitation is $e_g \rightarrow b_{1g}$, because the resulting $a_{1g}^2 b_{2g}^2 e_g^3 b_{1g}^1$ configuration gives rise to orbitally degenerate excited states. We first examine its energy in wavenumber units as a function of the dimensionless normal coordinates Q_i (i: a_{1g} or b_{1g}) in Fig. 1. This choice of units allows for easy comparisons to similar diagrams derived from electronic spectra in the literature (18, 20, 21) and to the energies summarized in Tables 1 and 2. The potential minima Δ_i and vibrational frequencies $\hbar\omega_i$ associated with the potentials in Fig. 1 are obtained from the equation:

$$[1] \qquad E_i = 0.5\ \hbar\omega_i\ (Q_i - \Delta_i)^2$$

where E_i is the energy calculated along Q_i with the adjustable parameters Δ_i and $\hbar\omega_i$. All calculated energies shown as solid dots in Fig. 1 were used for the least-squares refinement of the parameters and the resulting harmonic potentials reproduce the calculated energies well.

The curves in Fig. 1 can be regarded as cross sections through the full configurational space defined by the plane of the complexes and shown in detail in Fig. 2. Figure 1 shows the schematic definition of both relevant normal coordinates and the calculated energies as the title complexes are deformed along both coordinates. The fits using eq. [1] lead to vibrational frequencies of 227 and 133 cm^{-1} for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively. These values are lower by approximately 30% than the experimental Raman frequencies of 303.6 and 187.4 cm^{-1} (45) or 307 and 190 cm^{-1} (46). Lower vibrational frequencies are expected for the title compounds because of the increased population of the antibonding b_{1g} orbital. The calculations probably overestimate the decrease: a density functional study on octahedral complexes of chro-

© 1999 NRC Canada

mium(III) reports ground state vibrational frequencies that are lower by 20% than the experimental values (6). The ratio of the Raman frequencies of the a_{1g} modes of $PdCl_4^{2-}$ and $PdBr_4^{2-}$ is 0.62, very similar to the ratio of 0.59 obtained for the calculated frequencies. The minima $\Delta_{a_{1g}}$ of the potentials along $Q_{a_{1g}}$ are at 3.33 and 2.50 for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively, again in reasonable agreement with the spectroscopic values of 3.68 and 3.90, especially in view of the limitation to orbital configurations. The two potentials along the b_{1g} coordinate represent a simple Jahn–Teller situation. The molecule has D_{4h} symmetry at the crossing point and distorts to D_{2h} symmetry at the two potential minima, as indicated in Fig. 1*d*. The two minima are offset by the same amount from the crossing point, denoted by the horizontal arrows. Minima along the $Q_{b_{1g}}$ coordinate are calculated at ±1.35 and ±1.61 for $PdCl_4^{2-}$ and $PdBr_4^{2-}$. Both the magnitude of $\Delta_{b_{1g}}$ for each complex and the trend between the two title compounds are in good agreement with the spectroscopic values of ±1.18 and ±1.73 for $\Delta_{b_{1g}}$ in $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively (21). Figure 1 illustrates that the calculated vibrational frequency of the b_{1g} mode is lower than that of the totally symmetric a_{1g} mode. Calculated vibrational frequencies for the b_{1g} mode are 170 and 133 cm^{-1} for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively. Raman spectroscopy gives frequencies of 269.9 cm^{-1} (45) or 274 cm^{-1} (46) for $PdCl_4^{2-}$ and 166.6 cm^{-1} (45) or 171 cm^{-1} (46) for $PdBr_4^{2-}$. The calculated potential curves in Fig. 1 are in qualitative agreement with the spectroscopic results obtained for a series of square-planar halide complexes and confirm the observation of distortions along both the a_{1g} and b_{1g} coordinates (18, 20, 21).

The main results of our study are represented as a full two-dimensional potential energy surface in Fig. 2, showing the energy of this configuration for both target complexes as a function of the length change of all four palladium–halide bonds. Only one of the two surfaces illustrated by the one-dimensional cross sections in Figs. 1*c* and 1*d* is included in Fig. 2. It is obvious from the symmetry of the surfaces in Figs. 1*c* and 1*d* that this is sufficient to determine structural distortions of this excited configuration. The origin of the coordinate system is at the calculated bond lengths for the ground state orbital configuration and calculations were made every 0.03 Å. The energy minima correspond to rhombus structures with pairs of opposite palladium–halide bonds of equal length (18). This structure involves distortions of similar magnitude along both the totally symmetric $Q_{a_{1g}}$ and the non-totally symmetric $Q_{b_{1g}}$ normal coordinates. The directions of both normal coordinates are given in Fig. 2. Bond length changes Δr_i and changes along normal coordinates ΔQ_i of the excited orbital configuration are related by:

$$[2] \qquad \Delta Q_{a_{1g}} = 1/2(\Delta r_1 + \Delta r_2 + \Delta r_3 + \Delta r_4)$$

$$[3] \qquad \Delta Q_{b_{1g}} = 1/2(\Delta r_1 - \Delta r_2 + \Delta r_3 - \Delta r_4)$$

$\Delta Q_{a_{1g}}$ is determined by moving across the potential energy surfaces in Fig. 2 along the $Q_{a_{1g}}$ axis from the origin to the energy minimum. The values for Δr_i can then be read directly from the horizontal and vertical axes. Moving along the $Q_{b_{1g}}$ direction from the minimum along $Q_{a_{1g}}$ leads to the global minimum of the potential energy surface, and the corresponding values of Δr_i can again be directly determined from the figure. The structures corresponding to the energy minimum for this excited orbital configuration are summarized in Fig. 3. The calculated bond length changes of 0.15 and 0.05 Å for perpendicular bonds in $PdCl_4^{2-}$ are remarkably close to the experimental emitting state distortions of 0.12 and 0.09 Å in K_2PdCl_4 (21). The calculated bond length changes for $PdBr_4^{2-}$ are 0.11 and 0.00 Å, in fair agreement with the emitting state bond length changes of 0.12 and 0.07 Å in K_2PdBr_4 (21). We note that the potential energy minimum for $PdBr_4^{2-}$ in Fig. 2*b* is shallow because of the lower vibrational frequencies of this complex, a situation that could lead to larger uncertainties in the Δr_i values than for $PdCl_4^{2-}$.

The "valley" in Fig. 2 is oriented along the b_{1g} coordinate, and its minimum corresponds to the total excited state distortions, as described before. The b_{1g} mode is therefore in fact the most important non-totally symmetric distortion, in agreement with the spectroscopic results (21). The density functional approach consistently determines the dominant Jahn–Teller active mode as the in-plane b_{1g} stretching vibration and not the b_{2g} bending mode. A significant distortion along this additional normal coordinate would lead to an orientation of the "valley" that deviates from $Q_{b_{1g}}$. A small distortion along $Q_{b_{2g}}$ cannot be excluded from the calculations; especially in $PdBr_4^{2-}$ the orientation of the calculated "valley" appears to deviate somewhat from the $Q_{b_{1g}}$ direction. Indirect spectroscopic evidence for a small distortion involving the b_{2g} mode is discussed in ref. 21. Our simplified model cannot be used to prove the presence of such a minor distortion, especially in view of a recent detailed density functional study on ruthenocene illustrating that non-totally symmetric excited state distortions can be induced by the environment of the molecule in a crystal, an effect neglected here for the title compounds (8).

Potential energy barriers along $Q_{b_{1g}}$ can be estimated as the difference between the global energy minimum and the energy minimum along the $Q_{a_{1g}}$ axis on the surfaces in Fig. 2, leading to values of 150 and 110 cm^{-1} for $PdCl_4^{2-}$ and $PdBr_4^{2-}$, respectively. These values compare very favorably to the crossing point of the diabatic surfaces of the emitting states of K_2PdCl_4 and K_2PdBr_4 (21), determined from the spectra as 190 and 280 cm^{-1}. Preliminary calculations for $PtCl_4^{2-}$ have led to a barrier of approximately 140 cm^{-1}, lower by an order of magnitude than the experimentally determined barrier of 2600 cm^{-1} (20). This discrepancy could be due to the lack of precise relativistic corrections for the 5*d* metal center, but it is important to note that the non-totally symmetric distortion is again predicted from the calculations to occur along $Q_{b_{1g}}$ in the platinum(II) complex, in agreement with the distortions derived from spectroscopic data (18).

Density functional calculations on the title compounds show that the non-totally symmetric distortion along the $Q_{b_{1g}}$ normal coordinate is a direct consequence of the molecular electronic structure. This dominant Jahn–Teller active mode is determined from the potential energy surfaces, illustrating that density functional calculations correctly predict Jahn–Teller distortions for square-planar compounds with D_{4h} point group symmetry, in agreement with density functional

Accurate density-functional calculation of core-electron binding energies with a scaled polarized triple-zeta basis set. VI: Extension to boron-containing molecules

Germán Cavigliasso and Delano P. Chong

Abstract: Our procedure for calculating core-electron binding energies (CEBEs), based on the unrestricted generalized transition state model using B88/P86 functional, was extended to boron-containing molecules. Both unscaled (cc-pVTZ, cc-pVQZ, cc-pV5Z) and scaled (scaled-pVTZ and scaled-pVQZ) basis sets were used. The average absolute deviation from experiment for boron CEBEs with the scaled-pVTZ basis set was found to be 0.24 eV, compared to 0.23 eV for the much larger cc-pV5Z basis set.

Key words: DFT, boron, core-electron binding energies.

Résumé : Notre méthode de calcul des énergies de liaison des électrons de coeur (ELEC), basée sur le modèle de l'état de transition généralisé sans restriction en utilisant une fonctionnelle B88/P86, a été étendue aux molécules contenant du bore. On a utilisé aussi bien des ensembles de base non gradués (cc-pVTZ, cc-pVQZ, cc-pV5Z) et gradués (p-VTZ et p-VQZ gradués). La déviation absolue moyenne par rapport aux expériences pour les ELEC avec l'ensemble de base p-VTZ gradué est de 0,24 eV; elle se compare avantageusement à la valeur de 0,23 eV obtenue avec l'ensemble de base cc-pV5Z beaucoup plus gros.

Mots clés : théorie de la densité fonctionnelle (TDF); énergies de liaison des électrons de coeur.

[Traduit par la rédaction]

1. Introduction

Accurate calculations of core-electron binding energies (CEBEs) have been recently shown to be a valuable tool for analytical purposes. Investigations of the CEBEs of isomers of C_2H_4O, C_3H_3NO, C_3H_6O, and C_6H_6 (1, 2) have provided results that support the possible use of electron spectroscopy for chemical analysis (ESCA). Surface science is also an important area for ESCA applications. Studies by Bureau and coworkers (3, 4) have shown that the use of CEBEs determined by an accurate computational approach for the interpretation of XPS spectra on a molecular scale provides a useful method for tracing the interactions of molecules with a surface. Also, this approach has been shown to assist the interpretation of XPS spectra of compounds for which there is no gas-phase reference spectrum (4).

The present work is an extension of the recent studies by Chong et al. (1, 2, 5–11) on the use of density functional theory (DFT) and the unrestricted generalized transition state (uGTS) (12) model for the accurate calculation of core-electron binding energies. Our experiences have shown that the best procedure for calculating CEBEs involves the uGTS model combined with Becke's 1988 exchange functional and Perdew's 1986 correlation functional. Calculations were initially performed for C, N, O, and F employing large basis sets and the average absolute deviation (AAD) from experiment for over 50 computed CEBEs was found to be 0.2 eV (6). More recently, a more efficient basis set was proposed and tested. It consists of Dunning's correlation-consistent polarized valence triple-zeta (cc-pVTZ) basis for the neutral parent molecule and the same basis scaled for the atom with the partial core-hole according to the screening constants derived by Clementi and Raimondi (13). Our initial investigation (1, 9) of over 60 cases showed that the AAD from experiment remains at 0.2 eV for CEBEs calculated with this scaled basis set.

The purpose of this work is to extend our uGTS-based density functional method of calculating core-electron binding energies to boron-containing molecules.

2. Computational approach

In the unrestricted generalized transition-state model, Williams et al. (12) extended Slater's transition-state method to approximate the endothermiticity of vertical ionization by

$$[1] \qquad E_{\lambda=1} - E_{\lambda=0} = \frac{1}{4}\left(\frac{\partial E}{\partial \lambda}\right)_{\lambda=0} + \frac{3}{4}\left(\frac{\partial E}{\partial \lambda}\right)_{\lambda=2/3}$$

where λ is assumed to be a continuous variable, with $E_{\lambda=0}$ and $E_{\lambda=1}$ denoting the total energies of the neutral molecule

and cation, respectively. For the ionization of an electron from the *k*th molecular orbital (MO) ψ_k, λ represents the fraction of electron removed from this MO. $\partial E/\partial\lambda$ is the negative of the orbital energy $\epsilon_k(\lambda)$ according to Janak's theorem (14).

The uGTS approach involves a partial core-ionized cation. We used scaled basis functions to account for the different screening that electrons experience in these cations. For Gaussian-type orbital (GTO) basis functions, the scaling factor for the exponent is the square of the ratio of the effective nuclear charge

$$[2] \qquad scaling = \left(\frac{Z-\sigma'}{Z-\sigma}\right)^2$$

where Z is the nuclear charge of the atom considered, σ and σ' are the screening constants of the neutral molecule and the partial core-ionized cation, respectively. The screening constants for the partial core-ionized atoms were determined using the formulas provided by Clementi and Raimondi (13) with a reduced screening by the 1*s* electron (1).

3. Calculations

In the present study, experimental geometries (15) of the neutral parent molecules were used in the calculations. The deMon density functional program (16) was used, with extrafine nonrandom grid and the auxiliary fitting functions denoted by (3,1;3,1) for H, (4,4;4,4) for B, C, N, O, and F, (5,4;5,4) for P and Cl, and (5,5;5,5) for Br and I. The basis sets used were the *s*, *p*, *d* parts of the correlation-consistent (cc) polarized valence (pV) basis set given by Dunning and co-workers (17–19). The *d*-type basis funtions consisted of six Cartesian components. Calculations were carried out for cc-pVTZ, cc-pVQZ, and cc-pV5Z, and for scaled pVTZ and scaled pVQZ basis sets. For Br and I, the polarized valence double-zeta basis sets in the deMon program were used. All calculations were performed with the DFT functional labeled as B88/P86, which consists of Becke's 1988 exchange functional (20) and Perdew's 1986 correlation functional (21).

[a] Relativistic effects removed (see text).

For the calculation of partial core-hole states, difficulties for converging the density functional SCF procedure were sometimes encountered in molecules with two or more identical atoms, both in cases where these atoms were chemically equivalent and distinct. Our general solution to this problem was to restart the computation with the density of a partial core-hole state artificially created with fictitious nuclear charge. To obtain this density we replaced the atom with its isoelectronic cationic or anionic counterpart (e.g., N^+ or B^- for C) and computed the starting uGTS density with two-thirds of an electron removed from the corresponding fictitious core orbital.

4. Results and discussion

The results of CEBEs of boron are summarized in Tables 1 and 2. The range of experimental CEBEs is almost 10 eV, from 192.9 eV for $BH_3P(CH_3)_3$ to 202.8 eV for BF_3. The CEBEs of C, N, O, and F were also calculated and are shown

[a] Relativistic effects removed (see text).

in Tables 3 and 4. The experimental CEBEs were taken from the compilation by Jolly et al. (22) and from the article by Beach and Jolly on borane adducts (23).

The results of our calculations are compared with experimental CEBEs modified by the exclusion of approximate relativistic corrections. These corrections are based on the studies by Pekeris (24) for two-electron ions and were estimated with the following empirically derived equation (6)

$$[3] \quad C_{\text{rel}} = K\, I_{\text{nrel}}^{N}$$

where C_{rel} is the relativistic correction, I_{nrel} is the nonrelativistic CEBE in eV, $K = 2.198 \times 10^{-7}$, and $N = 2.178$. K and N are two fitting parameters of the relation between the relativistic correction and the nonrelativistic CEBEs for Pekeris' two-electron ions. The "experimental" CEBEs listed in Tables 1–4 were obtained by subtracting the relativistic corrections from the original data.

For the phosphine–trifluoroborane adduct and for borazine, experimental CEBEs have not been reported. Therefore, these results represent our predictions for the CEBEs of boron-containing molecules.

Average absolute deviations (AAD) and maximum deviations (MD) of the calculated CEBEs from the experimental values and from the estimated complete basis set (CBS) limits are given in Table 5. The estimated CBS limits for 19 of the test cases were determined from the results of the corresponding cc-pVTZ, cc-pVQZ, and cc-pV5Z calculations, according to the empirically derived equation (25)

$$[4] \quad A(x) = A(\infty) + B\, \mathrm{e}^{-Cx}$$

where x is the cardinal number of the basis set (3, 4, 5 for TZ, QZ, 5Z, respectively) and $A(\infty)$ is the estimated CBS limit for the property.

For the 9 cases studied with the cc-pVQZ and cc-pV5Z basis sets and the 17 cases investigated with the cc-pVTZ basis set, the AAD from experiment for the boron CEBEs is smallest for cc-pV5Z, and the cc-pVQZ performance is almost as good as that of cc-pV5Z. It is also observed that with exponent scaling the results from the triple-zeta basis set (scaled-pVTZ) significantly improve upon those from the corresponding unscaled basis set (cc-pVTZ), and they are very close to the results obtained from cc-pV5Z calculations. Exponent scaling does not have an appreciable effect on the performance of the pVQZ basis set as far as agreement with experimental results is concerned. However, comparisons with the estimated CBS limits are more meaningful if the aim is to design an efficient basis set applicable to large molecules. Also, experimental observations are affected by experimental error whereas the CBS limit gives a fixed value. The cc-pV5Z basis set approximates the CBS limit very well and the scaled-pVTZ basis set also performs well. The scaled-pVQZ results do show some improvement upon those from cc-pVQZ calculations when compared with the CBS limit.

The effect of relativistic corrections is either very small or negligible for boron CEBEs. This was expected from the fact that the relativistic correction calculated via eq. [3] was found to be only 0.02 eV for the boron 1s energies.

Table 5. Average absolute deviation (in eV) and maximum deviation (in eV) of calculated core-electron binding energies from experiment and from CBS.

Basis set	Deviations from experiment		Deviations from CBS	
	AAD	MD	AAD	MD
Boron test cases [a]				
cc-pVTZ	0.36 (17)	+ 0.73	0.34 (10)	0.46
cc-pVQZ	0.24 (9)	− 0.59	0.05 (10)	0.07
cc-pV5Z	0.23 (9)	− 0.63	0.01 (10)	0.01
Scaled-pVTZ	0.24 (17)	− 0.57	0.07 (10)	0.10
Scaled-pVQZ	0.24 (9)	− 0.64	0.03 (10)	0.06
CBS	0.23 (9)	− 0.64		
All test cases [a]				
cc-pVTZ	0.41 (32)	+ 1.11	0.38 (19)	0.60
cc-pVQZ	0.25 (17)	± 0.59	0.06 (19)	0.08
cc-pV5Z	0.26 (17)	− 0.63	0.01 (19)	0.01
Scaled-pVTZ	0.26 (32)	+ 0.58	0.07 (19)	0.10
Scaled-pVQZ	0.24 (17)	− 0.61	0.04 (19)	0.06
CBS	0.26 (17)	− 0.64		

[a] Number of cases given in parentheses.

The results for the CEBEs of all five second-period elements investigated — 32 cases with pVTZ and 17 cases with pVQZ and pV5Z — gave an AAD from experiment of 0.26 eV for both the cc-pV5Z and scaled-pVTZ basis sets. This compares very well with our previous study (9) of 66 CEBEs of small closed-shell molecules, in which the AAD was found to be 0.22 eV.

5. Conclusions

The results presented here confirm that the excellent approach of density functional theory combined with the unrestricted generalized transition-state model can be extended to the calculation of the CEBEs of boron-containing molecules.

The scaled-pVTZ calculations for boron 1*s* energies gave an average absolute deviation of 0.07 eV from the estimated complete basis set limit, confirming that this is a highly accurate procedure for describing the core-hole state. Very good agreement with experiment — comparable to that obtained for cc-pV5Z calculations — is also observed for the scaled basis sets.

Quantum molecular similarity. Part 2: The relation between properties in BCP space and bond length

Sean E. O'Brien and Paul L.A. Popelier

Abstract: In previous work we introduced an abstract space of bond critical point properties, called BCP space, to measure the similarity between molecules. In this contribution we critically examine the dependence of properties in BCP space on equilibrium bond length, a topic which has been extensively investigated in the literature. For that purpose we have designed a data set of 57 molecules yielding 731 bond critical points. We confirm the existence of *local* linear relationships provided the bonds vary little in their chemical surroundings. Such relationships break down completely for larger subsets of bond critical points encompassing a wider variety of bonds. The patterns observed in the global picture show so little correlation that one may safely conclude that BCP properties cannot be trivially recovered or even predicted by knowledge of bond length alone.

Key words: atoms in molecules, molecular similarity, bond critical points.

Résumé : Dans un travail antérieur, on a introduit un espace abstrait des propriétés de points critiques des liaisons dans le but de mesurer la similarité entre les molécules; on l'a appelé espace « BCP ». Dans ce travail, on examine d'une façon critique la dépendance des propriétés dans l'espace BCP sur la longueur de la liaison à l'équilibre, un sujet qui a été examiné d'une façon extensive dans la littérature. À cette fin, on a mis au point un ensemble de données relatives à 57 molécules qui nous ont permis d'extraire 731 points critiques de liaison. Nous pouvons confirmer l'existence de relations linéaires *locales*, à la condition que l'environnement chimique des liaisons varie peu. Ce type de relation n'existe plus avec des sous ensembles plus larges de points critiques de liaison comprenant une variété plus grande de liaisons. Les patrons observés pour l'ensemble montre qu'il y a peu de corrélation et on peut conclure qu'il n'est pas possible de récupérer facilement les propriétés BCP ou même de les prédire par la connaissance uniquement de la longueur de liaison.

Mots clés : atomes dans les molécules, similarité moléculaire, points critiques de liaison.

[Traduit par la Rédaction]

1. Introduction

This contribution is the second in a series of papers proposing a useful and feasible method to measure molecular similarity employing ab initio calculations. In the previous paper (P.L.A. Popelier. J. Phys. Chem. In press.) we explained the main idea behind our approach and systematically delineated some practical questions that will arise during the full implementation of the intended program. This paper addresses a technical, but fundamental, issue arising within the context of the method that we are currently developing. In essence we employ the theory of "Atoms in Molecules" (AIM) (1) to represent the electronic structure of molecules in a reliable and compact way. We then define a molecular similarity measure that operates directly on this AIM representation.

On several occasions it has been suggested in the literature that many simple (e.g., linear) relationships exist between the magnitudes constituting the AIM representation and the equilibrium bond length. Although we confirm the existence of these relationships, we have proven that they occur only *locally*, in other words within a restricted subset of bonds sharing roughly the same chemical environment. When a much wider class of bonds is included a different *global* picture emerges. Much more complex relationships — if any — are seen between the AIM-based values and the bond length. Consequently we invalidate the possible objection that our AIM representation can be trivially recovered from known (linear) relationships acting on tabulated bond lengths. All this will become much clearer below where we briefly review our approach and expound the broader picture into which the present contribution fits.

Bioisosterism (2) is the concept that similar molecules can exhibit comparable biological activities. This traditional idea has often been used in pharmaceutical, agrochemical, and other industries to improve drug design. A description of relative activity, or a similarity index, can be attained by examining several different and varied physical and chemical properties. It is in the search for a fundamental, underlying quantity to describe molecules that Carbó et al. (3) examined the electron density and proposed a similarity index between

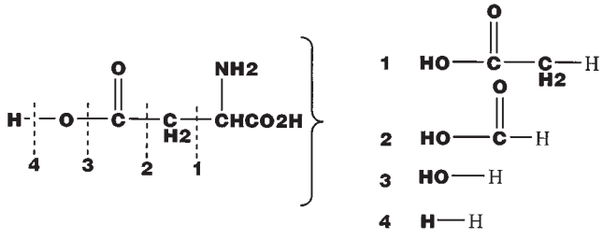
Z	HF/6–31G(d,p)	//HF/6–31G

Note: Basis sets **A–E** were selected after consulting ref. 13. **Z** was used by Bader in studies on substituted benzenes (16).

Fig. 1. Data set generation. The amino acid aspartate is cleaved in positions **1**–**4** and the resulting fragments capped with a hydrogen atom to produce the following molecules: **1**, ethanoic acid; **2**, methanoic acid; **3**, water; **4**, hydrogen.



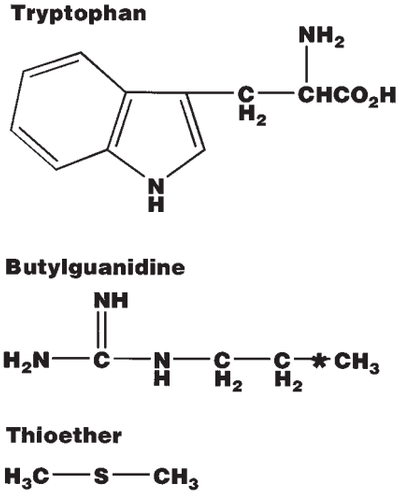
two molecules in terms of electron density overlap integrals. Although the main idea behind this similarity measure has shown its merit (4), the method has proved to be time consuming and suffers from certain technical difficulties.

Major problems arise from the superimposition of two electron densities that are overlaid so as to maximize the similarity index. This procedure is extremely expensive and can also produce multiple (undesirable) maxima. In addition, it is unclear whether the comparisons should be limited to small regions or performed over the whole molecule. Finally, the measure is severely biased by core densities (near nuclei). Although several methods (5–9) have sought to solve these problems, difficulties still remain. Therefore we propose to utilize the tools provided by the theory of Atoms in Molecules (AIM)(1) to extract information about similarities concealed within the electron density.

One of the innovations of AIM is the rigorous division of a molecule into its constituent atomic fragments. These atomic basins are linked by a number of bond paths from which one can construct a molecular graph. This describes the network of bonds that link the atoms in a molecule at its equilibrium geometry and recovers our experimentally obtained view of atoms linked by chemical bonds. Each bond path contains a point of special interest — a bond critical point (BCP) — at which the bond can be characterized. These BCPs occur at the point of minimal electron density, along the bond path, but at a point of maximal density perpendicular to the bond path.

It is possible to evaluate certain properties at these BCPs such as ρ, the electron density; $\nabla^2\rho$, the Laplacian of ρ; ε, the ellipticity (10) of the bond; and K and G, the kinetic energy densities. These local properties constitute an accurate and unique quantum chemical fingerprint of any particular BCP and hence any bond can be represented in terms of the properties at its BCP. Some of these properties were reported to depend linearly on the bond length but, as mentioned above,

Fig. 2. Molecules used for basis set testing.



we will demonstrate in this paper that this no longer holds provided we look at a large set of bonds in very different chemical surroundings. The properties at bond critical points span a hyperspace in which any molecule or molecular fragment can be represented discretely. It is by representing molecules as they appear in "BCP space" that we aim to develop a similarity index.

First we introduce the collection of molecules from which a vast set of BCPs was drawn, followed by an investigation justifying the level of calculation to be used throughout our BCP-space research program. We refer to this collection of molecules as the *data set* in this and future work. Subsequently each of the five properties listed above is systematically investigated for all C—C and C=O bonds in turn. By focusing on certain subsets of the data set, we reveal typical, local relationships occurring between these BCP properties and equilibrium bond length.

2. Data set

To properly explore BCP space a large, consistent group of molecules that gradually varied was required. To this end a set of molecules was generated from the 20 natural amino acids. How this is done becomes clear with Fig. 1. The bond between the C_α and the side chain of each amino acid was cleaved (bond **1**) and the chain fragment was capped with a hydrogen atom. Cutting and capping was continued in this manner, along the side chain, away from the C_α (following the sequence of bonds **2, 3,** and **4** on Fig. 1), until the small-

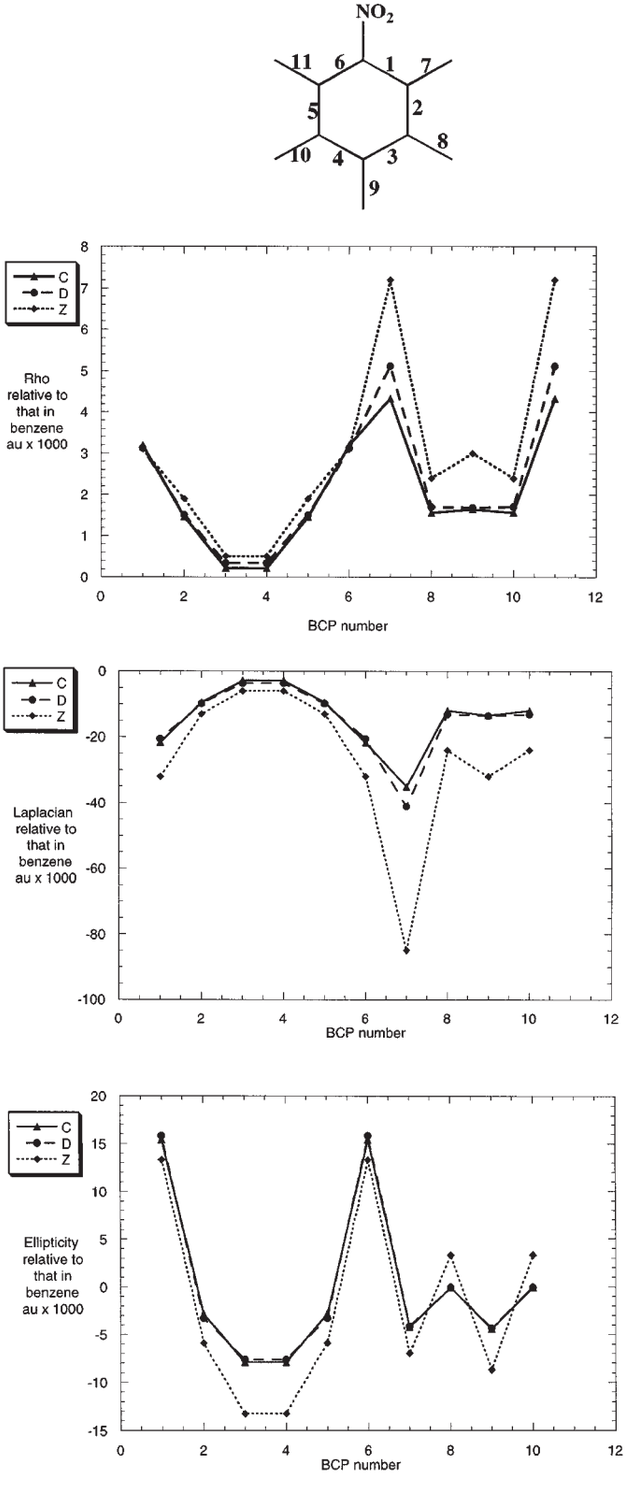
Fig. 3. The quantities ρ, Laplacian, and ellipticity are shown for nitrobenzene, relative to the values calculated for benzene in the appropriate basis set **C**, **D**, and **Z**. Each BCP number is marked on the molecule shown in the figure above. The trends in BCP properties are shown as they vary around the ring structure. It is clear that qualitatively each basis set reveals the same picture. In fact, sets **C** and **D** often produce indistinguishable points.



est possible molecule was produced. During this process only single bonds were sliced, i.e., all double bonds and ring structures were left intact, and any molecule duplicated was included only once. Together with the 20 original amino acids, this process left us with a data set of 57 unique molecules. Once evaluated, this set contained 731 BCPs.

3. Level of calculation

To include the effects of electron correlation it was decided to use Density Functional Theory (DFT). It is computationally less demanding than MP2 and QCISD, especially for large systems, and has been found to yield comparable results for BCP properties (11, 12). Of the available functionals, B3LYP has been found to have the best overall coherence with MP2 for properties at the BCPs (12),and a better overall performance than other functionals in general (13). All wave functions were generated via the program GAUSSIAN94 (14) and the BCPs were obtained using MORPHY98 (15).

Employing the above level of theory, the wave functions, and then the properties at the BCPs, of three molecules were calculated at five different basis set levels. This was to discover if (and, if so, how) altering the basis set changed the values of the said properties. The molecules tested were representative of the data set (Fig. 2). They included all types of atoms present, both rings and chains, and were of varying sizes. The basis set levels (Table 1) were selected after consulting ref. 13. Basis set **A** was the largest available and was used as a benchmark from which to calculate the deviations of the other basis sets. The selections decrease steadily in size from **B** to **E,** varying both the level of optimization and the level of single point calculation.

From running the above calculations it can be observed that the properties at the BCPs vary significantly from basis set to basis set. Table 2 shows the values obtained at the five levels **A–E** for a C—C bond (marked with * in Fig. 2) of butylguanidine. This is an example of a common bond showing typical basis set error. The bond is not particularly exotic and yet produces some strikingly large deviations between the basis sets. Taking into account all the bonds studied, there is no regular shift from the benchmark value within a particular set, i.e., **C** does not always calculate ρ_b to deviate from **A** by 2.2%. Several conclusions can be drawn from these results. The first is that the absolute values of BCP properties are highly basis set dependent. It must, however, be stated that the "Pople" basis sets used in this study, and frequently elsewhere, are not large enough to achieve the HF limit. If basis sets of sufficiently large size are employed, BCP properties will eventually converge to physically limiting values. This fact does not negate the above conclusion, as the values of most BCP properties calculated today will be largely affected by choice of basis set. Secondly, the relative stabilities of these properties to the choice of basis set are also revealed; $\rho_b > G_b$, $\nabla^2\rho_b$, $K_b > \varepsilon_b$, with ρ_b being the most steady. The ellipticity is seen to be most unstable although the extent of this instability can be misleading if only the percentage deviation is studied. Small and physically insignificant ellipticities, i.e., ~ <0.1 au, tend to show much larger percentage deviations. Finally, in general, the larger the basis set, the smaller the difference from **A**.

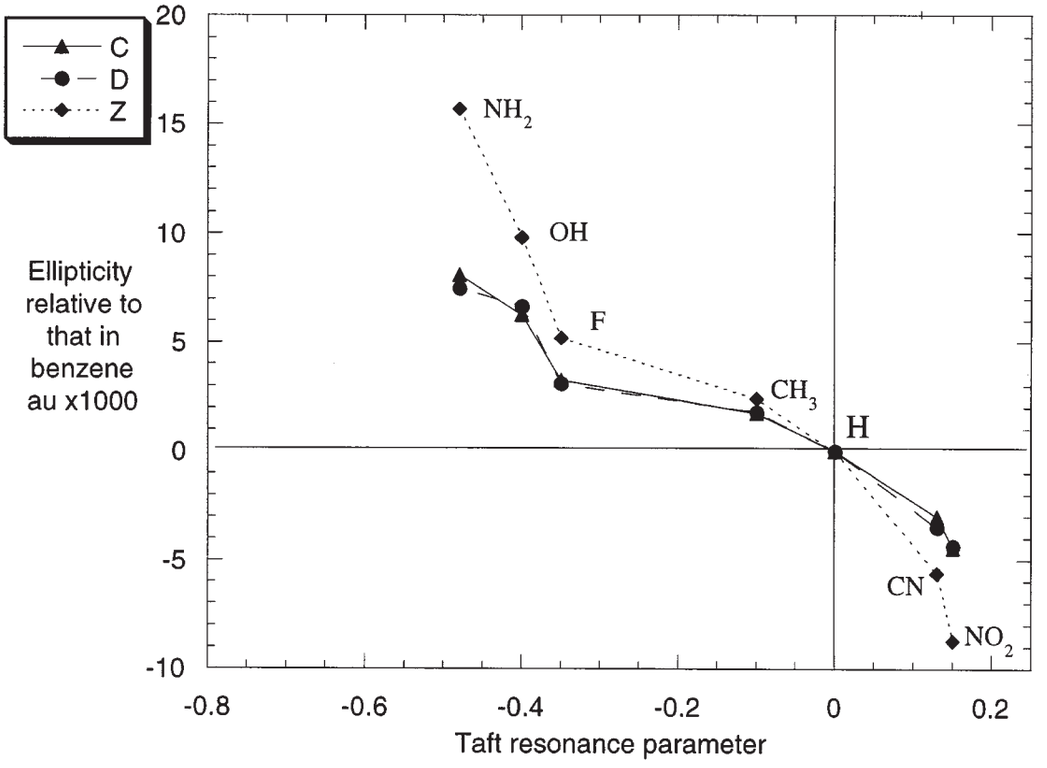
C – A	0.005 43	0.060 51	0.001 37	0.019 67	0.004 62
%	**2.22**	**10.67**	**20.30**	**9.82**	**7.88**
D	0.249 65	0.626 15	0.008 25	0.219 61	0.06306
D – A	0.005 22	0.059 14	0.001 5	0.019 24	0.004 45
%	**2.14**	**10.43**	**22.22**	**9.60**	**7.59**
E	0.255 33	0.656 14	0.009 22	0.228 84	0.064 79
E – A	0.010 9	0.089 13	0.002 47	0.028 47	0.006 18
%	**4.46**	**15.72**	**36.59**	**14.21**	**10.54**

Note: This demonstrates the effect of changing basis set on the values of BCP properties. For each basis set the calculated value is subtracted from that found using set **A**. The percentage differences are marked in bold. These particular figures come from looking at the C—C bond in butylguanidine marked by an asterisk in Fig. 2. All values are in au.

Fig. 4. *para* C—H bond ellipticities for Ph-X substituted benzenes calculated at basis sets **C**, **D**, and **Z** are plotted versus the Taft resonance parameter σ_R^0. The trends shown by all three basis sets are the same. Note that sets **C** and **D** hardly deviate from each other The values for **D** correlate fairly well with σ_R^0 (r = 0.972).



One feature of B3LYP that became apparent (and has been noted before for more general molecular properties (13)) is its relative insensitivity to the level of optimization, i.e., for a more accurate result it is more important to increase the level of the single point calculation than that of the optimization. As a consequence, sets **D** and **E** show fairly similar results. However, the maximum error for **E** is larger (cf. ref. 13). Due to the unfeasibility of **A** owing to its large size, SCF convergence problems when using **B** and **C,** and the larger maximum error found when using **E,** it was decided to use level **D** — B3LYP/6-311+G(2d,p)//HF/6-31G(d) for the data set calculations.

Although this study provided a probable choice of basis set, it also revealed the need for further investigation. If the choice of basis set could alter the values of BCP properties, sometimes drastically, could observations made while using one basis set still be valid when using another? In comparing BCP properties between benzene and substituted

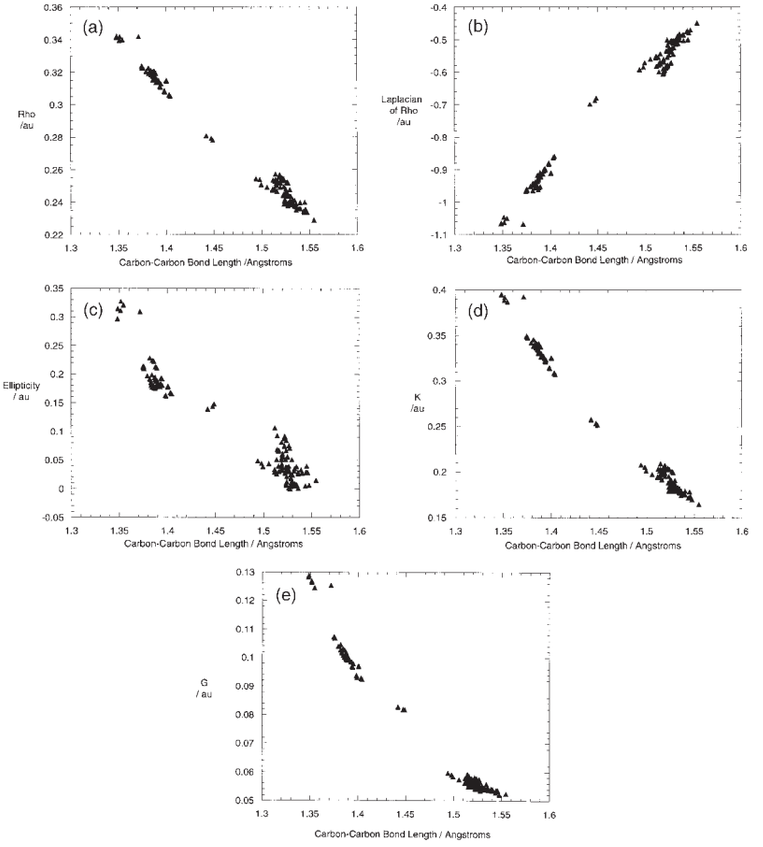
Fig. 5. Plots of BCP properties against equilibrium bond length. Amongst this set of 160 C—C bonds strong correlation can be seen between ρ_b, $\nabla^2\rho_b$, ε_b, K_b, and G_b and *R*e. Although some graphs (especially 5*e*) might appear to obey a power law relationship better than a linear one, this does not prove to be the case with this data set. A gradual change in the magnitude of each property can be seen as the longer single-bond lengths shorten to become aromatic.



benzenes (16), Bader found that ρ_b and $\nabla^2\rho_b$ paralleled small changes in bond length and that C—H bond ellipticities recovered the relative directing abilities of the ipso substituents. Could Bader's following of substituent effects by analysis of the properties at BCPs be reproduced using other basis sets? To answer this question a set of substituted benzenes Ph-X (where X = NH_2, OH, F, CH_3, H, CN, and NO_2) were examined. Bader and Chang used the following level of theory, HF/6-31G(d,p)//HF/6-31G, which we denote by **Z.** Their results were compared to those obtained using sets **C** and **D**. As before, the absolute values of the relevant properties tended to differ. However, when plotted against each other (Fig. 3), it is clear that the way in which ρ_b, $\nabla^2\rho_b$, and ε_b vary around the benzene ring is similar in all three basis sets. The trends shown are the same. The basis set HF/6-31G(d,p)//HF/6-31G, which is the smallest, has a tendency to exaggerate the peaks and troughs when compared to the set of points produced by **C** and **D.** Although the graph appears slightly stretched for the latter levels, the patterns seen are the same. In spite of Edgecombe's demonstration of the need for "large basis sets to avoid significant basis set errors"(17) it is worth knowing that Stutchbury and Cooper (18) noted how even a set as small as 4-31(G) is sufficient to preserve trends seen in electron density properties. Hence we can conclude that observations made about relative BCP properties are consistently reproduced whichever basis set is being used.

Table 3. Pearson correlation coefficients for BCP properties vs. bond length along the C—C, C—O, C—OH bond paths and for all the bonds in the data set.

Bond	ρ_b	$\nabla^2\rho_b$	ε_b	K_b	G_b
C—C	–0.994	0.993	–0.958	–0.994	–0.989
C—O	–1.000	–0.983	–0.990	–1.000	–0.999
C—OH	–0.984	–0.188	–0.140	–0.980	–0.950
All	–0.647	0.687	0.505	–0.463	0.050

As noted by Bader and Chang (16), the C—H bond path acts as a "probe of the interatomic surface" of the attached carbon atom. The ellipticity at the C—H BCP distinguishes between the directing abilities of the π-donating (OH, CH_3, F, NH_2) and π-abstracting (CN, NO_2) substituents. In fact, they mirror the experimentally obtained Taft resonance parameter (σ_R^0) (19).This is a measure of the F NMR shift in *meta*- and *para*-substituted fluorobenzenes. As this is zero for X = H, all values are relative to nonsubstituted benzene. As σ_R^0 parallels the directing abilities of the various substituents, so does the C—H bond ellipticity for the *para* carbon (this BCP is in the same position as the one numbered 9

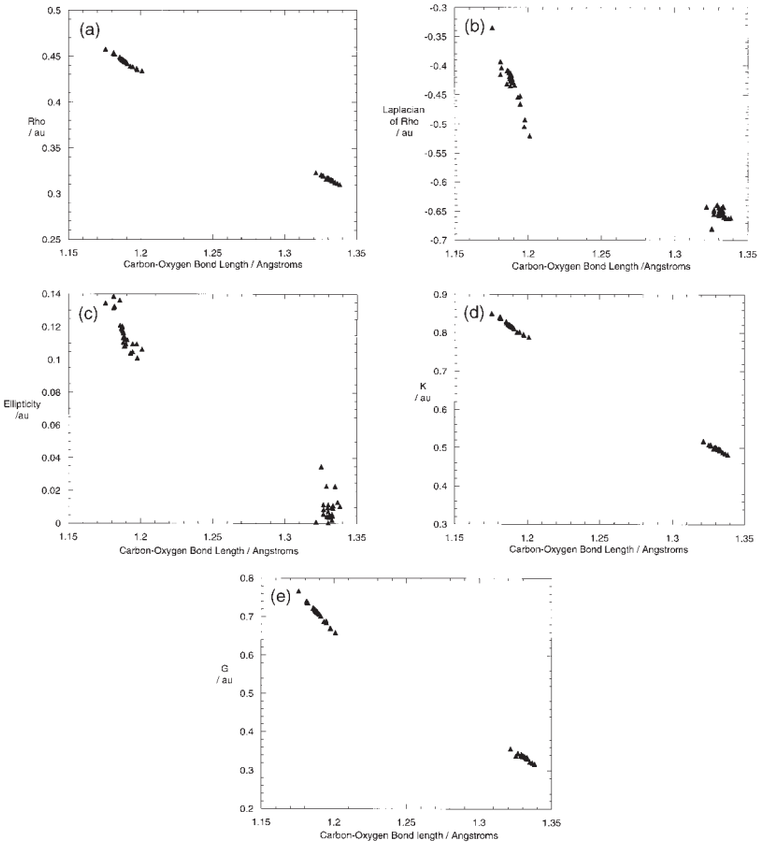
Fig. 6. Plots of BCP properties versus equilibrium bond lengths for 51 C—O bonds. It is clear that there are two groups of bonds present. Obvious linear relationships appear in 6*a*, 6*d*, and 6*e*. The patterns (if any) present in 6*b* and 6*c* are not so apparent.



in Fig. 3). Figure 4 shows how these values compare at all three basis sets used (**C, D, Z**). Rather than producing perfectly linear relationships, this graph clearly shows the trends in site activation of the ipso substituents. As seen in Figs. 3 and 4, the patterns produced by each basis set are similar. However, these trends appear more pronounced when calculated using **Z**. Basis sets **C** and **D** regularly produce overlapping points and hence virtually identical patterns. Although equivalent pictures are given by all basis sets, the comparatively large fluctuations produced by smaller sets probably serve to exaggerate and distort these trends. Set **C**, as well as being unfeasible due to SCF convergence problems, gives no clearer picture than **D**. There is no discernible advantage to be gained in using the larger basis set. Hence in all further data set calculations B3LYP/6-311+G(2d,p)//HF/6-31G(d) was used.

4. BCP space

To fully understand BCP space it is necessary to explore its dimensions. We need to see how each property relates to each of the others and how they might be related to any external observables. If any of these are correlated in a simple manner it will affect the final dimensionality of BCP space. It is unnecessary and in fact can be highly misleading to have linked parameters. Examining how variables are interrelated enables us to construct a multidimensional property space that has orthogonal axes and contains no redundant information. Simultaneously it would be pointless calculating the values of a BCP property if these could easily be obtained from an already known quantity. It was for these reasons that the relationships between BCP properties and equilibrium bond length (R_e) were examined.

Bader et al. (20) first mention a highly linear correlation between R_e and ρ_b for C—C bonds in ethane, benzene, and ethylene. As conjectured, ρ_b increases as the bond length decreases — the electron density between the nuclei balances the forces of repulsion, which augment as the atoms move closer. It is important to note that when strained hydrocarbons such as cyclopropane are fitted into this scheme the relationship no longer holds. However, when geometrical bond length is replaced with bond path length (R_b) a linear relationship is once more observed (10). In the majority of cases $R_e = R_b$ and this problem does not arise. Knop and Boyd (21) suggest a power law relationship of the form $\rho_b = AR_e^{-B}$. This was originally observed as being a better fit than a linear one for several S—S bond lengths. They propose that this "relationship may hold for any class of (binary) bond." This phenomenon has now been recorded for several different classes of bonds and has been observed with both experimental (22, 23) and calculated (24–28) densities. In his examination of condensed aromatic systems (28) Wiberg

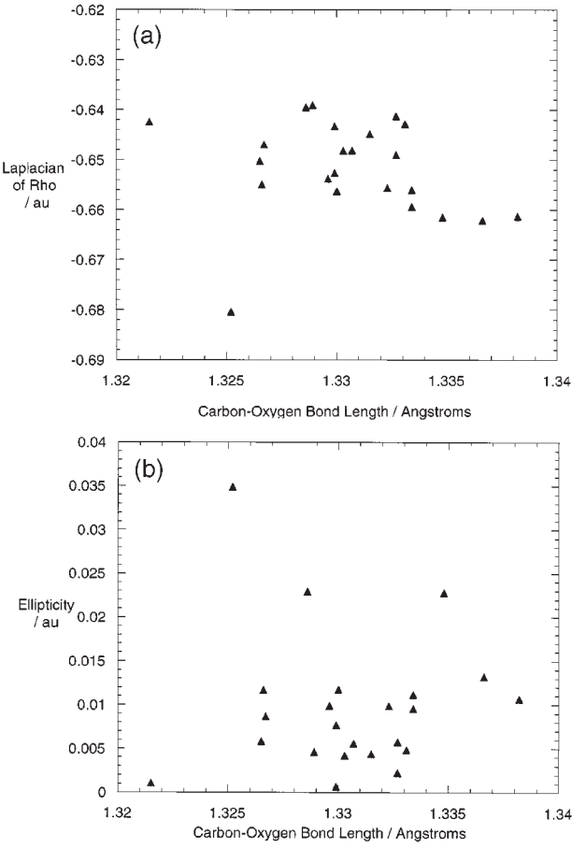
Fig. 7. The graphs are shown for the reduced C—O group. This now contains only C—OH bonds. In focusing on this subset, no apparent relationship can be seen between $\nabla^2\rho_b$ or ε_b and R_e. This demonstrates that any line fits (linear or power law) are only valid within the appropriate data set. Any resizing of the group, or altering of its boundaries, can lead to considerable changes in observed relationships. Compare 7*a* and 7*b* to 6*b* and 6*c*.



shows a linear graph of ρ_b vs. R_e and also includes a plot of ellipticity vs. bond length that shows a clear relationship between the two quantities. Howard's study of benzenoid hydrocarbons (26) also produces excellent linear correlations between the bond length, ρ_b (r = –0.998), ε_b (r = –0.978), and even $\nabla^2\rho_b$ (r = 0.997).

Within our amino acid based data set we also recover such relationships. However, these are found not only for the properties mentioned immediately above but also for K_b and G_b. This is demonstrated graphically for carbon–carbon bonds in Fig. 5 and also for carbon–oxygen bonds in Fig. 6. The linear relationships can immediately be seen from these plots and from the table of correlation coefficients (Table 3). The C—C set consists of 160 C—C bond critical points that encompass "pure" single bonds (longer bond length, lower ρ_b) through to aromatic BCPs (shorter bond length, higher ρ_b). In a similar fashion the C—O set comprises 51 BCPs. This includes C=O bonds present as aldehydes, ketones, and carboxylic acids (shorter bond length, higher ρ_b) and C—OH bonds both in amino acids and alcohols (longer bond length, lower ρ_b).

In general, the correlations between the BCP properties and R_e indicate excellent linear relationships. These can be verified by comparison with Figs. 5 and 6. If there always were a good correlation between a particular BCP property and bond length then one would expect the coefficients for the C—C set to be very similar to those in the C—O set. For the most part this is the case. The one striking exception is found to be $\nabla^2\rho_b$. The correlation completely switches sign when calculated for the two classes of bonds. Although $\nabla^2\rho_b$ and R_e still show a relatively linear relationship for C—O bonds it is now *opposite* to that observed for the C—C bonds. It is known that $\nabla^2\rho_b$ indicates the degree of covalency of a bond (1).The lower, or more negative, the value of $\nabla^2\rho_b$, the more covalent the bond. For C—C bonds, the shorter the bond, the higher the degree of covalency and thus the positive correlation seen. However, for C—O bonds, the shorter bond is C=O. This is known to exhibit some degree of ionic character (hence its frequent representation as $C^{\delta+}=O^{\delta-}$), and therefore has a higher, or less negative, value of $\nabla^2\rho_b$ than the C—OH bond.

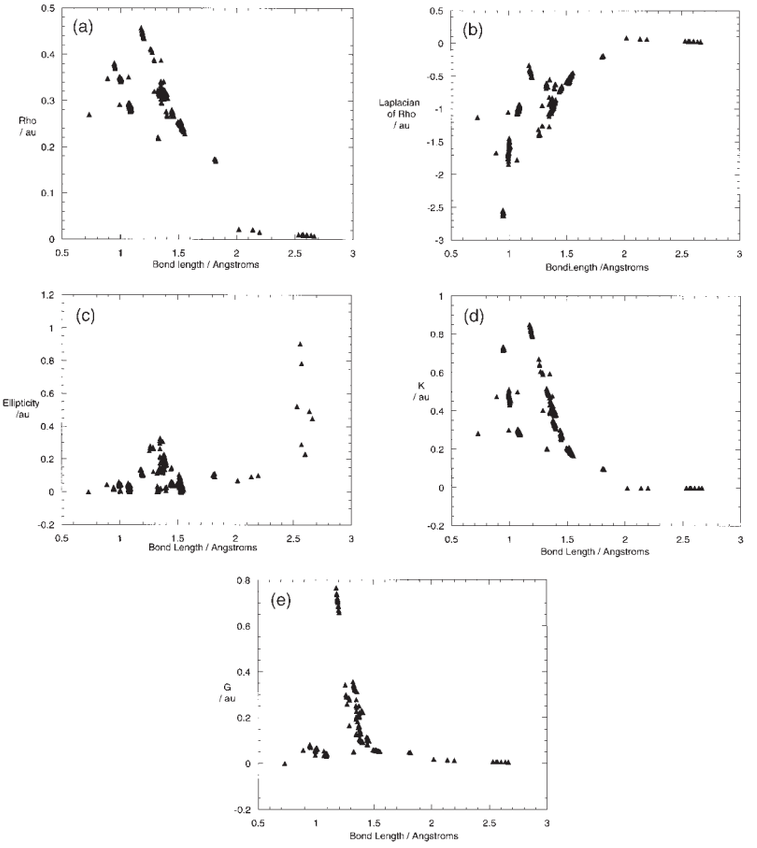
Upon inspection of Figs. 5*c*, 6*b*, and 6*c* the validity of the correlation coefficients can be called into question. It is well known (29) that this regression statistic can be misleading and the use of graphical methods for reviewing data is recommended. When used with caution, however, the statistic can equally be very revealing. It is the ellipticities for both bonds and the previously mentioned values of $\nabla^2\rho$ at the C—O BCPs that need more examination. For these bonds, shorter bond lengths are characterized by increased π-character. The subsequent shift of the bond shape (perpendicular to the bond path) from circular to ovoid is reflected in higher values of ε_b. This is true for both sets of bonds. A lower correlation between ε_b and R_e than between ρ_b and R_e or $\nabla^2\rho_b$ and R_e is seen here and was also observed by Howard (26) for a set of C—C bonds. The linear relationships appearing in both sets of data are very similar, Howard's values showing slightly higher correlation than ours. This may be due to the more varied nature of the bonds featured in our set.

To obtain a clearer picture of the anomalies revealed in the C—O set the C=O bonds were removed. If the 27 C—OH are examined separately, a completely different picture emerges for $\nabla^2\rho_b$ and ε_b. Figure 7 shows how there is a complete lack of structure in the set of values now present. This is reflected in the C—OH correlation coefficients (Table 3). Note especially the values for $\nabla^2\rho_b$ and ε_b, which are completely different from before and are now negligible. Those for the other quantities, while still indicating strong correlation, have also changed. These last results indicate that one must be very careful in assigning any significance to such relationships. What may appear a strong correlation when observed from one perspective can in fact be much altered when viewed from another. Similarly, what is a perfectly valid conclusion at a small scale can appear hopelessly inadequate in the larger picture.

When all 731 BCPs are included, the bigger picture becomes apparent (Fig. 8). There is quite obviously no simple relationship (linear, power law, or otherwise) between BCP properties and bond length. Table 3 confirms this impression, showing no correlations of any significance. If any small cluster visible on these graphs were examined more

© 1999 NRC Canada

Fig. 8. The graphs shown are for the complete data set of amino acid derived molecules. Each BCP property is plotted versus equilibrium bond length. They each contain data from 731 BCPs. None suggest any simple relationships between the plotted quantities. The bond lengths around 2–2.5 Å belong to hydrogen bonds that appear in the calculated amino acid structures. They show low values of all quantities except ε_b in 8*c*. Higher values of ellipticity have been associated with relative instability (1).



closely one might find some form of relationship between a BCP property and bond length. However, when viewed outside the boundaries of the chosen cluster, do the observations still hold?

It seems likely that ρ_b is always related to R_e for any "class of (binary) bond." Whether this can be expressed as a power law or in a linear way may be dependent on the range of bond lengths covered in the data set. Once this particular relationship is known for any class of bond, then bond lengths may indeed be "estimated from a single parameter"(ρ_b)(21) — though it seems more likely one would wish to use the relationship to discover ρ_b rather than R_e. On the other hand, $\nabla^2\rho_b$ has been shown to be unpredictable even within the confines of a particular class of bond. The ellipticity correlations appear to deviate wildly when altering the boundaries of a (small) group. It seems improbable that a reliable $\nabla^2\rho_b$ vs. R_e or ε_b vs. R_e relationship can be established. At first glance it might seem likely that the kinetic energy density K_b is related to R_e in the same way as ρ_b. Both have graphs that are remarkably similar in form for all sets shown. For the C—C and C—O sets, they correlate identically with R_e (Table 3) and on such a basis it would not be unreasonable to assume that they were closely linked. However, their correlation values with R_e are not the same when viewed in the context of the whole data set (Table 3). Thus they cannot be linked as closely as one might have previously thought. Similarly R_e and G_b show very strong correlation within given boundaries but exhibit absolutely none in the larger picture.

5. Conclusion

As part of our molecular similarity program we attempt to understand BCP space better. One particular question that arises is how properties in BCP space are correlated with bond length. Based on a set of bonds larger than any previously published we are able to say that one cannot predict any BCP property on the basis of bond length alone. A set of bonds has to be defined and coefficients fitted (linear, power law, or other) before this is feasible. The definition of any set has also to include the basis set, as we have seen that choice of basis set can greatly distort BCP properties. The relationships between ρ_b and bond length for given systems seem to be pretty robust, as they have often been quoted in the literature although they only hold within a given basis set. It has been shown that, even within a given subset of bonds, $\nabla^2\rho_b$ and ε_b cannot be reliably linked to bond length. Within the limits provided by the C—O and C—C data sets the kinetic energy densities K_b and G_b do appear to obey highly linear relationships with R_e.

Synthesis, structure, and reactivity of macrocyclic heterobimetallic complexes of (Co, Cu), (Co, Ni), (Co, Zn), (Zn, Cu), (Zn, Ni) combinations

H. Golchoubian, W.L. Waltz, and J.W. Quail

Abstract: A series of macrocyclic heterobimetallic complexes of type $[M_c(tntnam)M_o](PF_6)_n$ and $[M_c'(tntnim)Ni](PF_6)_n$ where M_c = Co(III) and Zn(II), M_c' = Co(II), Co(III), and Zn(II), and M_o = Ni(II), Cu(II), and Zn(II) have been synthesized and characterized. The macrocyclic ligands tntnim **2** and tntnam **3** contain two geometrically distinct compartments, 6-coordinate (closed site) and 4-coordinate (open site), which are bridged by phenolic oxygens. The heterobimetallic complexes with Zn(II) or Ni(II) in the open site are primarily formed as 5-coordinate with a chloride ion as a fifth ligand; the latter can be removed by Ag^+ ion. The crystal structures of $[Zn(tntnim)NiCl]PF_6\cdot C_2H_5OH$, **5**, $[Zn(tntnam)Ni](PF_6)_2$, **11**, $[Zn(tntnam)Cu](PF_6)_2$, **12**, and $[Co(tntnam)Ni(H_2O)](PF_6)_3\cdot 4H_2O$, **14** were determined. Crystal data for **5**: monoclinic, T = 123 K, a = 15.822(2), b = 15.6230(10), c = 16.432(2) Å, β = 104.570(10)°, Z = 4, space group Pc, R = 0.0371 ($wR2$ = 0.0843) for 5826 reflections with $I \geq 2\sigma(I)$. Crystal data for **11**: tetragonal, T = 123 K, $a = b$ = 24.122(2), c = 14.397(7) Å, Z = 8, space group $P4_12_12$, R = 0.0625 ($wR2$ = 0.1549) for 3250 reflections with $I \geq 2\sigma(I)$. Crystal data for **12**: tetragonal, T = 123 K, $a = b$ = 24.180(2), c = 14.281(4) Å, Z = 8, space group $P4_12_12$, R = 0.0588 ($wR2$ = 0.1219) for 3452 reflections with $I \geq 2\sigma(I)$. Crystal data for **14**: triclinic, T = 287 K, a = 12.664(2), b = 12.983(2), c = 16.216(3) Å, α = 80.317(14)°, β = 69.585(12)°, γ = 74.791(12)°, Z = 2, space group $P\bar{1}$, R = 0.0573 ($wR2$ = 0.1332) for 3443 reflections with $I \geq 2\sigma(I)$. The structures were solved by direct methods and refined by full-matrix least-squares procedures. The crystal structures demonstrate that the expected *trans* pyridine structures are formed. The magnetic moments, electrospray mass spectra, electronic absorption and emission spectra, and redox couples are reported.

Key words: cobalt, copper, nickel, zinc, heterobimetallic, macrocycle.

Résumé : On a synthétisé et caractérisé une série de complexes macrocycliques hétérobimétalliques du type $[M_c(tntnam)M_o](PF_6)_n$ et $[M_c'(tntnim)Ni](PF_6)_n$ dans lesquels M_c = Co(III) et Zn(II), M_c' = Co(II), Co(III) et Zn(II) et M_o = Ni(II), Cu(II) et Zn(II). Les ligands macrocycliques tntnim, **2**, et tntnam, **3**, contiennent deux compartiments géométriquement distincts à coordination de 6 (site fermé) et à coordination de 4 (site ouvert) qui sont reliés par les oxygènes phénoliques. Les complexes hétérobimétalliques avec le Zn(II) ou le Ni(II) dans le site ouvert existent principalement sous une forme pentacoordinée dans laquelle l'ion chlorure agit comme cinquième ligand; on peut récupérer ce dernier à l'aide de l'ion Ag^+. On a déterminé les structures cristallines des complexes $[Zn(tntnim)NiCl]PF_6\cdot C_2H_5OH$, **5**, $[Zn(tntnam)Ni](PF_6)_2$, **11**, $[Zn(tntnam)Cu](PF_6)_2$, **12**, et $[Co(tntnam)Ni(H_2O)](PF_6)_3\cdot 4H_2O$, **14**. Les données cristallographiques pour **5** : monoclinique, T = 123 K, a = 15,822(2), b = 15,6230(10) et c = 16,432(2) Å, β = 104,570(10)°, Z = 4, groupe d'espace Pc, R = 0,0371 ($wR2$ = 0,0843) pour 5826 réflexions avec $I \geq 2\sigma(I)$. Les données cristallographiques pour **11** : tétraédrique; T = 123 K, $a = b$ = 24,122(2) et c = 14,397(7) Å, Z = 4, groupe d'espace $P4_12_12$, R = 0,0625 ($wR2$ = 0,1549) pour 3250 réflexions avec $I \geq 2\sigma(I)$. Les données cristallographiques pour **12** : tétraédrique; T = 123 K, $a = b$ = 24,180(2) et c = 14,281(4) Å, Z = 8, groupe d'espace $P4_12_12$, R = 0,0588 ($wR2$ = 0,1219) pour 3452 réflexions avec $I \geq 2\sigma(I)$. Les données cristallographiques pour **14** : triclinique, T = 287 K, a = 12,664(2), b = 12,983(2) et c = 16,216(3) Å, α = 80,317(14)°, β = 69,585(12)° et γ = 74,791(12)°, Z = 2, groupe d'espace $P\bar{1}$, R = 0,0573 ($wR2$ = 0,1332) pour 3443 réflexions avec $I \geq 2\sigma(I)$. On a résolu les structures par des méthodes directes et on les a affinées par les méthodes des moindres carrés (matrice complète). Les structures cristallines démontrent qu'il y a formation des structures attendues à pyridine *trans*. On a aussi déterminé les moments magnétiques, les spectres de masse, les spectres d'absorption électronique et les spectres d'émission ainsi que les couples redox.

Mots clés : cobalt, cuivre, nickel, zinc, hétérobimétallique, macrocycle.

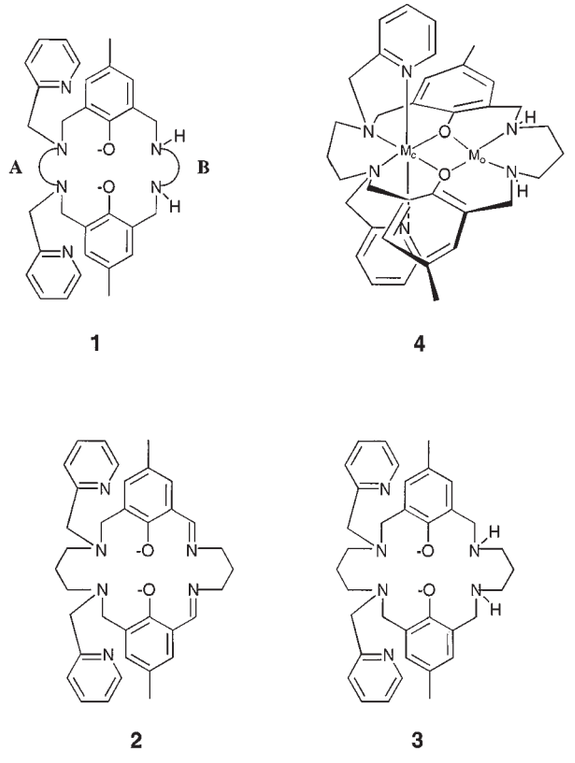
Scheme 1.



Introduction

Heterobimetallic complexes are of interest because of the unique physicochemical properties that arise from metal–metal interaction (1–6) and their potential as sources for multielectron transfers (7–9). In particular, the recent recognition of heterobimetallic cores at the active sites of purple acid phosphatase (FeZn) (10), human calcineurin (FeZn) (11), and human protein phosphatase 1 (MnFe) (12) has stimulated study in the functions of heterobimetallic core complexes. Macrocycles with dissimilar coordination sites are a great advantage for the studies of heterobimetallic complexes because such macrocyclic complexes are thermodynamically stabilized and kinetically retarded toward metal dissociation or substitution relative to complexes of the corresponding noncyclic ligands (macrocyclic effects) (13). Phenol-base bimetallic macrocycles have often been used for the study of bimetallic complexes (14–33). Macrocycles of the type **1** (Scheme 1), whose two metal-binding sites are dissimilar with respect to their coordination environments around each metal, have been studied by Bosnich and co-workers (34, 35) and Busch and co-workers (14). This macrocyclic ligand contains two compartments, a sexadentate closed site and a contiguous quadridentate open site. The nomenclature introduced by McCollum et al. (36) to describe the heterobimetallic complexes is designed, first, to designate the closed-site metal, M_c, followed by the closed-site link, A, the open-site link, B, and then followed by im or am to designate the diimine or diamine, the open-site metal, M_o, and followed by ligand L (where it exists), i.e., [M_c(closed-site link) (open-site link) (im or am) M_oL].

One of the objectives of this work has been to synthesize heterobimetallic complexes of the Bosnich's ligands tntnim[2] **2** and tntnam[3] **3**. These ligands, both having trimethylenediamine (tn) links, have been found in other systems to provide one topological isomer among three possible isomers with *trans*-disposed pyridine and *cis*-phenolate groups as shown in **4** (36). For purposes of characterization and comparison, investigations both of liquid solutions and of the solid state have been made. The relatively close juxtaposition of the two metal centers is favorable towards the coordination of small molecules, and we have investigated this facet in regard to the photoactivation of dioxygen.

Experimental

Apparatus and procedures

Conductance measurements were made at 25°C with a Wayne Kerr 6425 conductance meter on 1.00×10^{-3} M samples in CH_3CN. Infrared spectra were recorded in KBr mixtures by the diffuse reflectance technique on a single-beam Bio-Rad FTS-40 FTIR. The UV–VIS–NIR solution spectra were obtained on a Varian (Cary) 2315 spectrophotometer using spectral grade CH_3CN. Electrospray mass spectral studies were conducted on a VG Quattro II (Fision) triple–quadruple electrospray mass spectrometer with 100% methanol as the mobile phase. The compounds were dissolved in a mixture of acetonitrile and methanol (1:1) and in some cases acetonitrile:methanol:formic acid (1:1:1). The dissolved compounds were injected directly into the spectrometer via a Rheodyne injector using a Fision LC syringe pump to deliver the solution at a flow rate of 20 μL s^{-1}. Nitrogen was used for nebulization and as a drying gas with flow rates of approximately 20 and 250 L h^{-1}, respectively. Elemental analyses were performed on a Perkin–Elmer 2400 CHN elemental analyzer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker 300 Fourier transform spectrometer. All samples were dried to constant weight under vacuum prior to analysis. Magnetic susceptibilities of the samples in solution were measured by the modified Evans method (37) using the above-mentioned constant field, 300 Fourier transform instrument. Coaxial NMR tubes were used with tetramethylsilane (TMS) as an internal reference. The inner tube contained acetone-d_6 (CD_3COCD_3) and TMS (1% v/v) while the outer tube contained the same matrix plus sample. Magnetic susceptibilities of powder samples were measured at 20°C using a Johnson Matthey magnetic susceptibility balance.[4] Diamagnetic corrections were made using Pascal's constant (38). All electrochemical experiments were done using a setup consisting of a PC 486, 66 MHz, microcomputer equipped with a data acquisition board (POL-818PG,

[2] μ-[11,23-Dimethyl-15,19-bis(2-pyridinylmethyl)-3,7,15,19-tetraazatricyclo[19.3.1.^{9,13}]hexacosa-1(25),2,7,9,11,13(26),21,23-octaene-25,26-diolato(2–)-N^3,N^7,O^{25},O^{26}:N^{15},$N^{15'}$,N^{19},$N^{19'}$,O^{25},O^{26} or tntnim.

PC-Labcard Co.) and a custom-made potentiostat (39). The data acquisition and data processing program used in the electrochemical measurements was developed by A. Baranski.[5] Cyclic voltammograms that were 0.1 M in *n*-Bu_4NPF_6 supporting electrolyte and 1×10^{-3} M in sample were recorded in the range of +2 to –2 V in deaerated CH_3CN solution. Redox potentials were measured using a Pt disk electrode (0.25 mm in diameter), a tungsten wire as a pseudo-reference electrode, and another tungsten wire as an auxiliary electrode. They were standardized with a ferrocene internal and in some cases external standard (40). Acetonitrile used in the electrochemistry experiments was distilled twice over CaH_2.

Emission spectra were obtained on a Spex Flurolog Fl 221 with a cooled photomultiplier R928 using software DM 3000, version 3.3, SPEX Inc. Time-resolved experiments were carried out using a DL2160B Phase-R coaxial flash-lamp dye laser. The absorbances of the irradiated solutions were set at $A = 0.4$ for a wavelength of 490 nm (the wavelength of the irradiation laser light). After oxygenation for 1 h, the solution was irradiated by laser pulses (2.3 J $pulse^{-1}$). The same experiments were performed on deaerated solutions. In the deaeration process, a stream of argon presaturated with acetonitrile was passed through the solution during the course of the experiment. A C30642 planar PIN InGaAs photodiode detector, which was constructed by Dr. E. Janata,[6] was used to monitor the phosphorescence of singlet molecular oxygen, O_2 ($^1\Delta_g$), at a wavelength of 1270 nm. The electronic spectra of the solutions were studied, by UV–VIS spectrophotometry, before and after the laser pulses.

In the steady-state photolysis experiments, a 10 cm Pyrex-jacketed cell was filled with the solution. The concentration of the solution was adjusted so that the absorbance of the solution was 2.0 at 25°C. A 1000 W Hg–Xe lamp (Oriel 6293) was used for quantum yield measurements. To filter out infrared and UV light, a water cell and another cell containing an aqueous solution of 0.1 M $CuSO_4$ were placed in front of the beam. Subsequently an interference filter (Edmund Scientific Co., CWL 415, λ_{max} = 415 nm, fwhm 12 nm) was placed immediately prior to the photocell. Oxygenation was achieved by passing a stream of O_2 presaturated with water through the solution during the course of the experiment. A sample of solution was maintained in the dark at the same temperature in order to provide a control for any thermal component of the reaction and to serve as a reference for the spectrophotometric measurement. During the photolysis, the solution was stirred with a small magnetic bar. After a suitable irradiation period, the irradiated solution was analyzed for the concentration of peroxide species as follows: to the irradiated and control solutions were added solutions of KI (5.00 mL, 0.200 mol L^{-1}) and acetic acid (1.0 mL, 1.00 mol L^{-1}). The solutions were allowed to stand for 30 min for the colour development of I_3^- (41). The resulting solutions were extracted with CCl_4 (4 × 5 mL) and the combined organic fractions were made up to 25 mL. The absorbance of the organic solutions was measured at a wavelength of 517 nm against the control sample. This method provides a limit of detection of 5×10^{-6} mol L^{-1} for the peroxide. Quantum yields of reaction ($\Phi_{peroxide}$) were determined using ferrioxalate actinometry (42).

Materials

All solvents used in reactivity studies were distilled twice. Ethanol used in this work refers to absolute ethanol. Acetone was dried over 4 Å molecular sieves. Other solvents were of BDH (Omnisolv) grade. Water purified by a Millipore Super-Q system was used to prepare the aqueous solutions. All preparations of Co(II) complexes were conducted under argon using deaerated solvents and standard Schlenk techniques (43). Yields of compounds were calculated after purification. The physical data (elemental analyses, molar conductance, and ^1H NMR data) are detailed below for each complex. The identity of each compound was confirmed by electrospray mass spectrometry, and these data are given in the results and discussion section. The compounds $[Co(tntnim)(H^+)_2](PF_6)_2$ (36), $[Co(tntnam)(H^+)_2](PF_6)_3$ (35), $[Zn(tntnim)(H^+)_2](PF_6)_2$ (36), and $[Zn(tntnam)(H^+)_2](PF_6)_2$ (35) were prepared by standard methods found in the literature.

Preparation of imine complexes, $[M_c(diimine)M_o]^{q+}$ complexes

The complexes are air stable as solids. Unless indicated otherwise, each of the heterobimetallic complexes was purified by recrystallization from CH_3CN–ethanol using one of two general procedures.

Method 1: The crude salt was dissolved in a minimal volume of CH_3CN (ca. 2 mL for each 0.15 g of complex) at room temperature and the solution was filtered. To the CH_3CN solution was added absolute ethanol (ca. 5 mL). A steady stream of argon was passed over the solution in order to reduce the CH_3CN content, and additional aliquots of ethanol (3 × 3 mL) were added over time. The solution was typically allowed to stand overnight. The crystalline complex was then collected and washed with ethanol (3 × 3 mL), ether (2 × 3 mL), and pentane (2 × 3 mL) and was dried under vacuum for 5–6 h.

Method 2: The crude compound was dissolved in CH_3CN (ca. 2 mL for each 0.200 g of complex) at room temperature and the solution was filtered. To the CH_3CN solution was added absolute ethanol (ca. 4 mL) and the resulting solution was placed in a small flask, which was then put in a jar containing ethanol (ca. 25 mL). This jar was capped to allow for slow diffusion of ethanol into the solution. After several days, the crystalline complex was collected and washed with ethanol (3 × 3 mL), Et_2O (2 × 3 mL), and pentane (2 × 3 mL) and dried under vacuum for 5–6 h.

$[Zn(tntnim)NiCl]PF_6 \cdot C_2H_5OH$, ***5***

To a solution of the $[Zn(tntnim)(H^+)_2](PF_6)_2$ (189 mg, 0.20 mmol) in CH_3CN (5 mL) was added a solution of $NiCl_2 \cdot 6H_2O$ (52.3 mg, 0.22 mmol) in ethanol (10 mL) and Et_3N (55.7 mL, 0.40 mmol). The yellow-green mixture was stirred for 12 h. During the course of the reaction, small

© 1999 NRC Canada

amounts of a gelatinous green compound precipitated that was discarded after filtration. NH_4PF_6 (140 mg, 0.86 mmol) in ethanol (5 mL) was added to the resultant solution. The solution was partially concentrated at room temperature to reduce the CH_3CN content; ethanol was then added in portions (2 × 10 mL), and the solution allowed to stand overnight. The solid was collected and washed with water (2 × 5 mL), ethanol (2 × 10 mL), ether (2 × 10 mL), and pentane (2 × 10 mL). The crude compound was recrystallized by method 1 to give green polyhedra (76%). Crystals suitable for X-ray crystal structure determination were grown by vapour diffusion of ethanol into a CH_3CN:ethanol solution of the complex. Λ_m = 170 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{40}N_6O_2PF_6ClZnNi\cdot C_2H_5OH$: C 48.59, H 4.94, N 8.95; found: C 48.59, H 4.78, N 8.99.

[Zn(tntnim)Ni](PF$_6$)$_2$, ***6***

The [Zn(tntnim)NiCl]PF_6 (90 mg, 0.10 mmol) was dissolved in acetone (5 mL) and an acetonitrile solution of $AgPF_6$ (25 mg, 0.10 mmol) was added to precipitate chloride ion. The resultant cloudy brown solution was stirred for 30 min, then filtered through Celite, and concentrated by passing a stream of argon over the surface of the solution at room temperature. The green residue was dissolved in acetone (ca. 2 mL) and filtered through Celite again, and was then reconcentrated. The green residue was recrystallized by method 2, which yielded [Zn(tntnim)Ni]$(PF_6)_2$ as brown needles (77%). Λ_m = 272 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{40}N_6O_2P_2F_{12}ZnNi$: C 43.12, H 4.02, N 8.38; found: C 43.23, H 4.10, N 8.34.

[Co(tntnim)NiCl]PF$_6$, ***7***

[Co(tntnim)NiCl]PF_6 was prepared by the general procedure described for **5** except that the reaction mixture was stirred for 30 min. The crude compound was purified by method 2 and yielded an orange solid (70%). Λ_m = 163 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{40}N_6O_2PF_6CoClNi$: C 48.76, H 4.55, N 9.48; found: C 48.68, H 4.55, N 9.43.

[Co(tntnim)Ni](PF$_6$)$_2$, ***8***

The [Co(tntnim)NiCl]PF_6 was dechlorinated by the procedure described for **6** to yield [Co(tntnim)Ni]$(PF_6)_2$, **8**, as a dark-red solid (51%). This cobalt(II) compound is sensitive to air in the solid state and in solution and turns to a black compound over a period of time. Anal. calcd. for $C_{36}H_{40}N_6O_2P_2F_{12}CoNi$: C 43.40, H 4.05, N 8.44; found: C 42.74, H 3.80, N 8.31.

[Co(tntnim)Ni](PF$_6$)$_3$, ***9***

To an acetone solution (5 mL) of **8** (199 mg, 0.20 mmol) under argon was added ferrocenium hexafluorophosphate, $[Cp_2Fe]PF_6$ (66.4 mg, 0.20 mmol), in deaerated acetonitrile (ca. 2 mL). The dark-green solution was stirred under argon for 15 min, then opened to air, and concentrated in vacuo. The black residue was triturated with ether until washes were colourless. The crude compound was recrystallized by method 2. [Co(tntnim)Ni]$(PF_6)_3$, **9**, was obtained as a black needle-like solid (96%). Λ_m = 372 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{40}N_6O_2P_3F_{18}CoNi$: C 37.89, H 3.53, N 7.36; found: C 38.03, H 3.80, N 7.50.

Preparation of amine complexes, [M$_c$(diamine)M$_o$]$^{q+}$

All of the diamine complexes showed a characteristic intense absorption band in the electronic spectrum at λ_{max} 293–307 nm (ε ca. 6 × 10 ^{3} L mol^{-1} cm^{-1}) in CH_3CN solution, whereas for diimine the most intense bands and those assigned to the azomethine $\pi \rightarrow \pi^*$ transition (44) occur at longer wavelengths in the range 330–352 nm (ε ca. 1 × 10^4 L mol^{-1} cm^{-1}).

The crude materials were purified by one of two procedures.

Method 1: The crude compound was dissolved in CH_3CN (ca. 2 mL for ca. 0.200 g of complex) at room temperature and the solution was filtered. To the CH_3CN solution was added absolute ethanol–Et_2O (50:50) (ca. 4 mL), and the resulting solution was placed in a small flask, which was then put in a jar containing ethanol–Et_2O (50:50), (ca. 25 mL). After several days the crystalline complex was collected and washed with ethanol–Et_2O (50:50) (3 × 3 mL), Et_2O (2 × 3 mL), and pentane (2 × 3 mL) and dried under vacuum for 5–6 h.

Method 2: The crude compound was dissolved in acetone (ca. 5 mL for each 0.100 g of complex) at room temperature and the solution was filtered. To the acetone solution was added about 5 mL of absolute ethanol. This solution was placed in a small flask, inside a jar containing diethyl ether (ca. 25 mL). After 3 days the crystalline material was collected and washed with ethanol (3 × 3 mL), Et_2O (2 × 3 mL), and pentane (2 × 3 mL) and dried under vacuum for 5–6 h.

The [M(tntnam)MCl]$^{q+}$ complexes were generally prepared by the procedure described below for [Zn(tntnam)NiCl]PF_6, **10,** with minor variations being noted for some complexes. Dechlorination of [M(tntnam)MCl]$^{q+}$ complexes followed the procedure described above for the imine complex [Zn(tntnim)Ni]$(PF_6)_2$, **8**.

[Zn(tntnam)NiCl]PF$_6$, ***10***

[Zn(tntnam)$(H^+)_2$]$(PF_6)_2$ (100 mg, 0.10 mmol) was dissolved in CH_3CN (5 mL), followed by addition of $NiCl_2\cdot 6H_2O$ (24.3 mg, 0.10 mmol) in methanol (5 mL). To the stirred reaction mixture was added $LiOH\cdot H_2O$ (8.6 mg, 0.20 mmol) in methanol (1.5 mL), dropwise over 5 min. The resulting yellow-green solution was stirred for 30 min and then NH_4PF_6 (81.5 mg, 0.50 mmol) in methanol (2 mL) was added. After 10 min, the green solution was taken to dryness in vacuum. The resultant pale green residue was washed with EtOH (2 × 2 mL), Et_2O (2 × 2 mL), and pentane (2 × 2 mL) and dried under vacuum. The compound was recrystallized by method 2. [Zn(tntnam)NiCl]PF_6, **10**, was obtained as pale pink solid (55%). Λ_m = 157 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{44}N_6O_2PF_6NiZnCl$: C 48.19, H 4.94, N 9.37; found: C 47.94, H 4.95, N 9.26.

[Zn(tntnam)Ni](PF$_6$)$_2$, ***11***

[Zn(tntnam)Ni]$(PF_6)_2$, **11** (44%), was obtained as dark pink polyhedral crystals from dechlorination of compound **10** followed by recrystallization using method 2. This compound is very sensitive to solvent: it is purple in CH_3CN, pink-violet in acetone, and yellow in ethanol. Crystals suitable for X-ray structure determination were obtained upon a

© 1999 NRC Canada

second recrystallization. Λ_m = 276 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{44}N_6O_2P_2F_{12}NiZn$: C 42.95, H 4.41, N 8.35; found: C 42.71, H 4.27, N 8.15.

*[Zn(tntnam)Cu](PF$_6$)$_2$, **12***

$Cu(OAc)_2 \cdot H_2O$ was used instead of $CuCl_2$ as starting material because of the greater solubility of the former compound. The [Zn(tntnam)Cu](PF$_6$)$_2$, **12** (71%), was obtained, after recrystallization by method 1, as a gray-red crystalline solid that was suitable for X-ray structure determination. Λ_m = 248 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{44}N_6O_2P_2F_{12}CuZn$: C 42.76, H 4.38, N 8.31; found: C 42.74, H 4.32, N 8.28.

*[Co(tntnam)NiCl](PF$_6$)$_2$·H$_2$O, **13***

[Co(tntnam)NiCl](PF$_6$)$_2$·H$_2$O**, 13** (55%), was obtained as a dark-green solid after recrystallization. For recrystallization, method 2 was used and recrystallization typically took several days. Λ_m = 281 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{46}N_6O_3ClP_2F_{12}CoNi$: C 41.03, H 4.40, N 7.97, Co 5.59, Ni 5.57; found: C 41.08, H 3.82, N 7.59, Co 5.52, Ni 5.26.

*[Co(tntnam)Ni(H$_2$O)](PF$_6$)$_3$·4H$_2$O, **14***

[Co(tntnam)Ni(H$_2$O)](PF$_6$)$_3$·2H$_2$O (30%) was obtained as a green powder after recrystallization by method 2. Elemental analyses indicated that there are two molecules of water along with the complex. Green polyhedron crystals with four water molecules suitable for X-ray structure determination were obtained by recrystallization of the product three more times. Λ_m = 387 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{50}N_6O_5P_3F_{18}CoNi$: C 36.05, H 4.20, N 7.01, Co 4.91, Ni 4.86; found: C 36.17, H 4.15, N 7.02, Co 4.96, Ni 4.91.

*[Co(tntnam)Cu](PF$_6$)$_3$, **15***

[Co(tntnam)Cu](PF$_6$)$_3$, **15** (17%), was obtained as a dark-green solid after recrystallization twice by method 1. Λ_m = 378 Ω^{-1} mol^{-1} cm^2. Anal. calcd. for $C_{36}H_{44}N_6O_2P_3F_{18}CoCu$: C 37.59, H 3.86, N 7.31; found: C 37.80, H 4.08, N 7.09.

*[Co(tntnam)ZnCl](PF$_6$)$_2$, **16***

The diamagnetic [Co(tntnam)ZnCl](PF$_6$)$_2$, **16** (52%), was obtained as dark-green needles after recrystallization by method 1. Λ_m = 281 Ω^{-1} mol^{-1} cm^2. ^{1}H NMR (300 MHz, CD_3COCD_3), δ 1.87 (m, H), 1.98 (m, H), 2.08 (s, 3H), 2.28 (s, 3H), 2.44 (m, 4H), 2.59 (m, H), 2.75 (d, *J* = 13.4 Hz, H), 2.85 (m, 2H), 3.44 (m, 5H), 3.78 (t, d, *J* = 12.1, 1.7 Hz, H), 4.19 (m, 6 H), 4.43 (t, d, *J* = 12.1, 1.7 Hz, H), 4.71 (t, *J* = 11.9 Hz, H), 4.92 (d, *J* = 17.7 Hz, H), 5.32 (d, *J* = 18.9 Hz, H), 6.74 (s, H), 6.91 (s, H), 6.99 (s, H), 7.12 (s, H), 7.28 (d, *J* = 7.9 Hz, H), 7.42(t, *J* = 6.4 Hz, H), 7.82 (d, *J* = 7.4 Hz, 2H), 7.91 (t, *J* = 7.6 Hz, H), 8.31 (t, *J* = 7.6, H), 8.44 (d, *J* = 5.8, H), 9.42 (d, *J* = 5.2 Hz, H). Anal. calcd. for $C_{36}H_{44}N_6O_2ClP_2F_{12}CoZn$: C 41.48, H 4.25, N 8.06; found: C 41.38, H 4.15, N 7.91.

*[Co(tntnam)Zn](PF$_6$)$_3$·CH$_3$CN, **17***

The diamagnetic cobalt(III) complex [Co(tntnam)Zn](PF$_6$)$_3$·CH$_3$CN, **17** (67%), was obtained as a black needle-like solid after recrystallization by method 1. Λ_m = 368 Ω^{-1} mol^{-1} cm^2. ^{1}H NMR (300 MHz, CD_3CN), δ 1.19 (m, 2H), 2.16 (s, 6H), 2.24 (m, 2H), 2.62 (m, 4H), 2.94 (m, 2H), 3.23 (d, *J* = 15.0 Hz, 4H), 3.41 (d, *J* = 13.1 Hz, 2H), 3.87 (m, 2H), 3.94 (d, *J* = 4.2 Hz, 2H), 3.98 (s, 2H), 4.31, 4.48 (syst AB, J_{AB} = 18.3 Hz, 4H), 6.84 (s, 2H), 6.94 (s, 2H), 7.41 (d, *J* = 7.8 Hz, 2H), 7.62 (t, *J* = 6.3 Hz, 2H), 8.03 (t, *J* = 7.8 Hz, 2H), 8.53 (d, *J* = 5.6 Hz, 2H). Anal. calcd. for $C_{36}H_{44}N_6O_2P_3F_{18}CoZn \cdot CH_3CN$: C 38.26, H 3.97, N 8.22; found: C 38.21, H 3.74, N 8.22.

Crystallography

The single-crystal X-ray diffraction structures of complexes **5**, **11,** and **12** were determined at 123(2) K and corrected for absorption using the ψ-scan method (45). Data for complex **14** was collected at 287(2) K and no absorption correction applied because the crystal was lost before a ψ-scan could be collected. The crystallographic data are summarized in Table 1. For compound **14**, most reflections beyond θ = 23.8° were insufficiently intense to give meaningful observations.

Data were collected on an Enraf–Nonius CAD-4 diffractometer, using the CAD-4 Express operating system (46). Three standard reflections were checked every 200 reflections. Data were processed using XTAL3.5 (47) and the structure solved using NRCVAX (48). The structures were refined by full-matrix least squares on F^2 using SHELXL-97 (49). The methyl H atoms were positioned geometrically in a staggered conformation using a riding model and all other H atoms were placed in calculated positions using a riding model with U(H) = 1.2 U_{eq}(attached atom). The bond lengths assumed were sp^3(methyl), C—H = 0.98 Å at 123 K and 0.96 Å at 287 K; sp^3(methylene), C—H = 0.99 Å at 123 K and 0.97 Å at 287 K; sp^2, C—H = 0.95 Å at 123 K and 0.93 Å at 287 K; sp^3, N—H = 0.93 Å at 123 K and 0.91 Å at 287 K;

Three of the compounds ([Zn(tntnam)Cu](PF$_6$)$_2$, [Zn(tntnam)Ni](PF$_6$)$_2$, and [Zn(tntnim)NiCl](PF$_6$)·C$_2$H$_5$OH) crystallize in acentric space groups ($P4_12_12$, $P4_12_12$, and *Pc*, respectively), even though the compounds are prepared as racemic mixtures. These acentric structures were refined for racemic twinning. The PF_6^- units were all disordered to various extents. For example, in [Zn(tntnam)Cu](PF$_6$)$_2$ and [Zn(tntnam)Ni](PF$_6$)$_2$ (isomorphous and almost isostructural), the P of one PF_6^- ion (P(2)) is very close to a special position (~0.25 Å from $\bar{x}$+1/2, *x*+1/2, 1/4), resulting in an occupancy of 0.5 and disorder. Another PF_6^- in this structure (P3) is lying on a special position (*x*+1/2, $\bar{x}$+1/2, 3/4) with large resultant disorder. Many attempts were made to model the disorder of the PF_6^- units with partially occupied isotropic atom sites, but none of these models improved the agreement factors without introducing many more variables into the refinement. It was concluded that the anisotropic temperature factors for the fluorine atoms best described the PF_6^- units with the fewest variable parameters. Some of the fluorine thermal ellipsoids are very large and elongated (e.g., F(31) and F(34) of **11**), but it was believed that this refinement allowed the best determination of the structure of the bimetallic cation. In addition, in [Zn(tntnim)NiCl](PF$_6$)·C$_2$H$_5$OH, half of the ethanol solvate molecules were disordered and in [Co(tntnam)Ni](PF$_6$)$_3$·4 H$_2$O the water solvate molecules were disordered. The bimetallic complex ions are generally well behaved and there is only one example of refineable disorder (C(26) in [Zn(tntnam)Cu](PF$_6$)$_2$ has two positions of nearly equal occupancy). Many alternative models of the

disorders were tried. The models reported in this paper gave the most reasonable results with the simplest models.[7]

Results and discussion

An extensive study on the effect of the closed-site link on the topology of mono- and bimetallic complexes by McCollum et al. has shown that the presence of a 6-membered ring such as trimethylenediamine, tn, at the closed-site link results in mono- and bimetallic complexes that adapt a C_2 symmetrical structure with *trans*-disposed pyridine groups (35, 36) as shown in **4** (Scheme 1). This topological isomer results regardless of the nature of the metal used at the closed site. It has been shown that no scrambling occurs in the preparation of heterobimetallic complexes bearing labile metals (50). Our solid- and liquid-phase results support the absence of scrambling. The diimine groups located at the open site were reduced to amine groups to provide the flexibility required for the bond-length contraction associated with change in oxidation state of metals at the closed and open sites.

Synthesis

Diimine heterobimetallic complexes were prepared by a general method as exemplified in eq. [1]

$$[1] \quad [\text{M(diimine ligand)}(H^+)_2]^{2+} + NiCl_2 \rightleftharpoons [\text{M(diimine ligand)NiCl}]^+ + HCl$$

where M is Co(II) or Zn(II). To drive the reaction to completion, two equivalents of trimethylamine were added. The heterobimetallic complexes prepared in this way contain chloride ion that is bound to the open-site metal at a fifth coordination position. In acetonitrile, all of the chloro complexes were found to be 1:1 electrolytes, indicating that the chloride ligand is bound to the metal in this solvent. The chloride ligand was removed by Ag^+ as a white precipitate in the acetonitrile–acetone solution and gave heterobimetallic complexes of the type $[M^{II}(\text{diimine})Ni]^{2+}$ with molar conductances expected of 2:1 electrolytes in acetonitrile solution (51). The cobalt(II)–nickel(II) complex **7** appears to be reasonably air-stable both in the solid state and in acetonitrile and acetone solutions; however, upon removal of coordinated Cl^- ligand from this complex using Ag^+ salt and exposure to air, a darkening of the solution occurs, suggesting oxidation of the closed-site Co(II). Consistent with this is that compound **8** can be oxidized to the Co(III) complex by ferrocinium ion.

The general method for preparation of diamine heterobimetallic complexes is analogous to the method used for diimine heterobimetallic complexes except that a stronger base, such as LiOH, is required to drive the reaction to completion. Generally the diamine heterobimetallic complexes proved to be more soluble but also more difficult to crystallize than their diimine analogues. All Co(III) heterobimetallic complexes are slightly soluble in water. Aqueous solutions of **13** and **16** undergo loss of chloride ligand over a period of the time as evidenced by increases in molar conductance of the solution and by comparing the UV–VIS spectra of the products with those of **14** and **17**, respectively.

Crystal structures

The fractional atomic coordinates of complexes **5**, **11**, **12,** and **14** are given in Table 2. A number of features of the crystal structures bear noting. First, the structures consist of two metal centres bridged by two phenoxide oxygen atoms. Secondly, the two pyridine groups are bound to the closed-site metals in a *trans* fashion, but there is considerable deviation from ideal octahedral geometry as shown by comparison of the apical angles. Thirdly, the 1,3-diaminopropane in the closed-site link has a skew conformation rather than chair as required for *trans* disposition of the pyridine groups. The bond lengths for M—N, M—O, and M—Cl are generally in the range expected.

*Structure of [Co(tntnam)Ni(H_2O)](PF_6)$_3$·4H_2O, **14***

Two views of the cation of **14** along with the numbering scheme are given in Fig. 1 and selected bond lengths and bond angles are listed in Table 3. The results demonstrate that a molecule of water is bound to the Ni(II) atom at the open site and it is H-bonded to other molecules of water in the lattice. The least-squares plane determined by N(2), N(3), Co, and Ni has all atoms within 0.112(8) Å of the plane. Relative to this plane the distances to O(1), O(2), O(3), N(5) and N(6) are –0.160(6), –0.073(6), 1.502(8), –1.462(8), and 0.248(10) Å, respectively. As a result the Ni(II) at the open site is a five-coordinate ion with a distorted trigonal bipyramidal environment. The Co(III) ion is located in the plane defined by O(1), O(2), N(2), N(3), and the Ni(II) ion is 0.252(6) Å above this plane. The two metal centres are separated by 3.0904(15) Å with Co-O-Ni bridge angles of 102.4 (2)° and 105.1 (2)°. The O(1)-Ni-O(2) angle is compressed to 73.77(18)° whereas the N(5)-Ni-N(6) angle is broadened to 96.7 (3)°. The amine groups at the closed site and open site are in *S*,*S* and *R*,*S* configurations, respectively, for the isomer whose topological chirality about the Co(III) ion is Λ, and vice versa for the Δ isomer.

*Structure of [Zn(tntnim)NiCl]PF_6·C_2H_5OH, **5***

Two views of the cation of **5** along with the numbering scheme are given in Fig. 2. Selected bond lengths and bond angles are listed in Tables 4 and 5. There are two crystallographically different cations in the asymmetric unit (molecule A and molecule B) whose geometric parameters are slightly different (see Tables 4 and 5). In the isomer in which the Zn(II) ion has a Δ configuration, the configuration about the nitrogen atoms of the amine group in the closed-site link are *S*,*S*, and vice versa for the Λ isomer. In mole-

[7] Supplementary material available: tables of anisotropic displacement parameters, hydrogen coordinates and isotropic displacement parameters, torsion angles and planes involving metal atoms for compounds **5**, **11**, **12**, and **14** have been deposited, and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of crystal data and refinement, atomic coordinates, bond lengths and angles, and hydrogen atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

cule A, the least-squares plane determined by N(2), N(3), Zn, and Ni has all atoms within 0.003(6) Å of the plane. Relative to this plane, the distances to O(1), O(2), N(5), N(6), and Cl are +0.433(6), –0.116(6), +0.954(8), +0.564(8), and –2.165(2) Å, respectively. In molecule B, the least-squares plane determined by N(2), N(3), Zn, and Ni has all atoms within 0.060(8) Å of the plane. Relative to this plane, the distances to O(1), O(2), N(5), N(6), and Cl are +0.434(6), –0.095(6), +1.440(7), +0.367(9), and –1.990(3) Å, respectively. As a result, the open-site metal has a distorted trigonal bipyramidal environment. The imine bond lengths, C(28A)—N(6A), C(24A)—N(5A), C(28B)—N(6B), and C(24B)—N(5B) are 1.294(9), 1.274(9), 1.287(10), and 1.287(9) Å, respectively, and are shorter with respect to the amine bond lengths C(36A)—N(3A), C(16A)—N(2A), C(36B)—N(3B), and C(16B)—N(2B) with 1.503(9), 1.504(8), 1.493(8), 1.501(8) Å, respectively. The intermetallic separations between Zn(II) and Ni(II) ions in molecules A and B are 3.1811(11) and 3.1526(11) Å, respectively.

Fig. 1. Two views of the molecular structure of the bimetallic cation of $[Co(tntnam)Ni(H_2O)](PF_6)_3 \cdot 4H_2O$, **14**, drawn with 30% probability ellipsoids. The hydrogen atoms have been deleted for clarity.

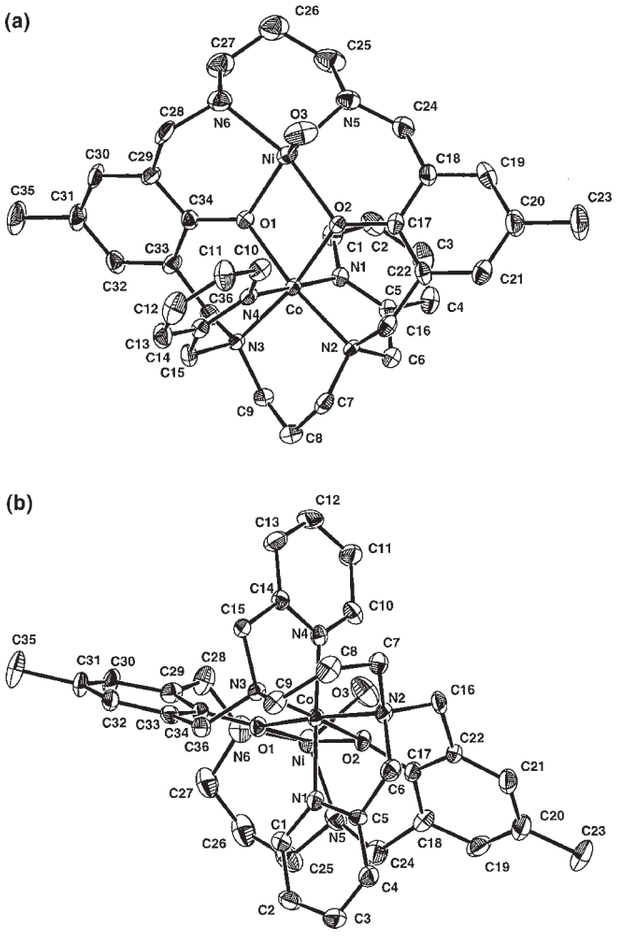

Fig. 2. Two views of the molecular structure of the bimetallic cation of $[Zn(tntnim)NiCl](PF_6) \cdot C_2H_5OH$, **5,** drawn with 50% probability ellipsoids. The hydrogen atoms have been deleted for clarity.

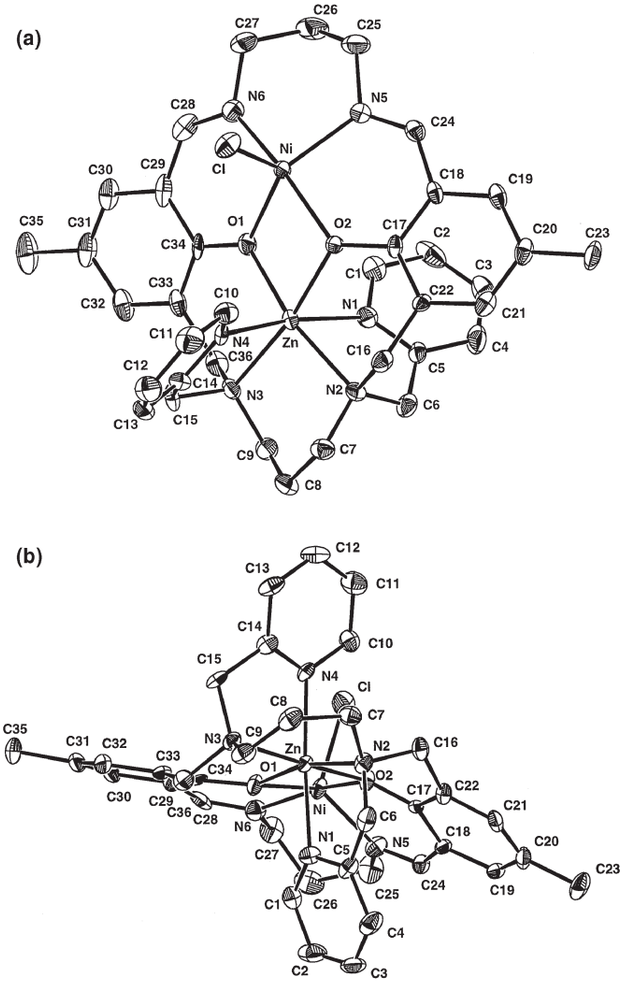

*Structure of [Zn(tntnam)Ni]$(PF_6)_2$, **11***

Two views of the cation of **11** along with the numbering scheme are given in Fig. 3 and selected bond lengths and bond angles are listed in Table 6. The isomer whose topological chirality about the Zn(II) ion is Λ has the *R,R* configuration for both nitrogen atoms of the amine groups at the closed site and the open site, and vice versa for the Δ isomer. The Zn(II) and Ni(II) ions are in the macrocyclic plane defined by N(2), N(3), O(1), O(2), N(5), and N(6) atoms. The O(2)-Ni-N(6) and O(1)-Ni-N(5) bond angles are 172.6 (3)° and 166.3 (4)°, respectively. The two metal centres are separated by 3.0711(18) Å with Zn-O-Ni bridge angles of 102.1 (3)° and 100.5 (3)°. The O(1)-Ni-O(2) angle is compressed to 82.6(3)° whereas the N(5)-Ni-N(6) angle is broadened to 98.6(4)°.

*Structure of [Zn(tntnam)Cu]$(PF_6)_2$, **12***

Two views of the cation of **12** along with the numbering scheme are given in Fig. 4. Selected bond lengths and bond angles are listed in Table 7. The isomer whose topological chirality about the Zn(II) ion is Λ has the *R,R* configuration for both nitrogen atoms of the amine groups at the closed site and the open site, and vice versa for the Δ isomer. Both Zn(II) and Cu(II) ions are in the same plane defined by N(2), N(3), O(1), O(2), N(5), and N(6) atoms. The O(2)-Cu-N(6) bond angle is 168.5 (3)° and the opposing angle O(1)-Cu-N(5) is 165.5 (3)°. The Cu atom and four of the atoms of the open-site link (N(5), N(6) C(25), and C(27)) are located in the same plane, but the disordered atom C(26) is out of the plane. The crystal structure data indicate that there are two different conformers of the open-site link. The only difference between these two conformers is the position of the C(26) atom. With respect to the plane defined by the open-site link, C(26) is above the plane in one conformer but below in the other. The intermetallic distance between the two metal centres is close to that found in compound **11** at 3.0983(15) Å.

cated. Significant differences between the imines and amines in the spectra are the emergence of a sharp, but weak, band at 3268 cm^{-1}, which is attributed to the N–H stretch of the quaternized amine, and the disappearance of the strong band at 1643 cm^{-1}, corresponding to the C=N stretch of the imine groups (52). Appearance of a band near 1550 cm^{-1} for all of the complexes is assigned to the skeletal vibration of the aromatic rings (53). A broad signal centred at around 3500 cm^{-1} for **14** is likely the stretching modes for the mixed form of coordinated and uncoordinated water. The presence of a sharp band at 2316 cm^{-1} for **17** is due to the presence of lattice CH_3CN.

Electrospray mass spectra

Electrospray mass spectrometry is proving to be a very powerful analytical tool for characterization of macrocyclic complexes in the liquid phase because it allows for transfer of preexisting ions from solution to the gas phase with minimal fragmentation. All major signals for the complexes, including the assignments, are listed in Table 8. Particularly noteworthy is that the presence of a given metal centre is accompanied by a set of signals for each *m*/*z* due to relative isotope abundance. The number and relative intensities of these peaks are unique for each bimetallic complex and thus indicative of the formation of the expected heterobimetallic complexes. Multiply charged ions are usually harder to observe and they give signals of low intensities in ESMS because of the formation of ion-pair adducts with counterions in the solution (54). Proton loss, as observed here in some cases, is also a common mechanism in the ESMS as it reduces the charge on the multicharged compounds (55).

Magnetic moments

The magnetic susceptibilities of all of the paramagnetic complexes were determined in acetone solution at 25°C by the Evans ^1H NMR method (56). These are tabulated in Table 9, together with the magnetic susceptibilities of selected complexes in the solid state and the calculated spin-only values for these complexes. All of the Co(III) complexes are found to be spin paired. For the bimetallic complexes containing Co(III) or Zn(II) at the closed site, the calculated magnetic moments fall within the ranges expected for magnetically dilute complexes containing a single paramagnetic ion (38). A magnetic moment of 1.6 BM for **12** and **15** indicates the presence of one unpaired electron per molecule. The solution magnetic moments of heterobimetallic complexes with Ni(II) at the open site are normal for two unpaired electrons per molecule. However, **6** exhibits a diamagnetic property in the solid state. The different magnetic behaviour of **6** in the solid state and in solution may be due to a change in coordination geometry of the Ni(II) ion in solution as a result of coordination of solvent molecule(s). The cobalt(II)–nickel(II) complex **7**, which contains two paramagnetic ions, exhibits a magnetic moment of 5.3 BM, which is slightly less than the spin-only value. This suggests that a weak antiferromagnetic exchange coupling exists between neighbouring paramagnetic ions, presumably through the phenoxide bridging ligands (57–60).

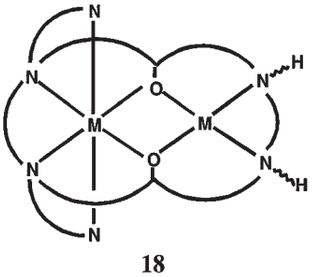
NMR spectra

The bimetallic complexes of macrocyclic amine ligands are potentially more complicated than their imine analogues. This complexity arises from the chirality of the nitrogen atoms of the amine groups at the open site coupled with the topology of the closed site. McCollum et al. (35) have shown that with a single chiral isomer for the closed-site bimetallic complexes type **18**, the open-site nitrogen groups can be (*S*,*S*), (*R*,*R*), or (*R*,*S*). The first two are C_2 symmetric and the third is C_1. The aforementioned isomers can be identified by the chemical shifts of the α-pyridyl and *p*-tolylmethyl proton signals. The ^{1}H NMR and ^{13}C NMR spectra of the diamagnetic **16**, obtained in acetone-d_6 solution at 25°C, indicate a structure of C_1 symmetry, but upon addition of 1 equiv. of $AgPF_6$ to remove the coordinated chloride, the ^{1}H NMR and ^{13}C NMR spectra become consistent with a C_2 symmetric complex. Also, equilibrium among isomers has been reported for di-zinc complexes (35). However, the presence of other isomers was not detected in **16** and **17**. Since ^{1}H NMR spectroscopy does not distinguish between the (*S*,*S*) and (*R*,*R*) diastereomers, the assignment of the isomer remains open, but these results do indicate that the structures of cobalt(III)–zinc(II) complexes in solution contain *trans*-disposed pyridine ligands above and below the mean macrocyclic plane as in **4**, Scheme 1.

Electronic absorption spectroscopy

The purpose of this study was to correlate the *d*–*d* transi-



18

tions with the geometries of the metal ions and to determine whether any intravalence transitions occurred in the bimetallic complexes (61). However, the latter do not appear to be present. The electronic absorption spectra of **5–17** were recorded in room-temperature acetonitrile solution over the range 300–2000 nm. These regions encompass the *d*–*d* transitions at the lower energies and some of the metal–ligand charge-transfer bands and the $\pi \rightarrow \pi^*$ azomethine transitions at higher energies (62). Table 10 lists the positions and intensities of azomethine, phenolate charge-transfer, and the *d*–*d* bands observed in the spectra of bimetallic complexes. The azomethine chromophores in all of the diimine com-

plexes appear as intense bands in the 330–355 nm region as the dominating UV feature for all spectra of the complexes. All mono- and bimetallic complexes with Co(III) at the closed site have similar visible spectra. Their characteristic features consist of intense absorption bands at 420–435 nm (ε ca. 2000–4000 M^{-1} cm^{-1}) due to phenolate–cobalt(III) charge transfer and another band at 565–600 nm (ε ca. 800–1800 M^{-1} cm^{-1}) attributed to the *d–d* transition of Co(III) (35). The high molar absorptivity of this latter band might be due to structural deviation as shown in Table 3. All heterobimetallic complexes of Zn(II)–Ni(II) display bands that are characteristic of a 5-coordinated spin-free Ni(II) structure in the acetonitrile solvent although it is difficult to distinguish clearly between trigonal bipyramidal and square pyramidal structures for Ni(II) (63, 64). In the near-infrared region, the heterobimetallic complexes of Co(III)–Ni(II) have similar band positions and shapes as those for the analogous Zn(II)–Ni(II) complexes, but the higher energy bands of Ni(II) at the open site are obscured by the intense bands of Co(III) at the closed site. The cobalt(II)–nickel(II) compound **7** displays five bands in the absorption spectrum. A

characteristic transition for cobalt(II) at the closed site is a band in the 960–1000 nm region (35); however, because open-site Ni(II) has an absorption band in the same region, the assignment of the near IR is problematical. Upon removal of chloride ion and oxidation of the cobalt(II) centre with ferrocinium ion, the absorption in the visible region changes to that characteristic of Co(III) at the closed site.

The zinc–copper complex **12** displays three bands at 350, 410, and 614 nm. The weak band at 614 nm occurs in the expected *d–d* transition region and is assigned accordingly (65, 66). The two other bands are assigned as metal to phenolate charge transfer (67–70). Both of these charge-transfer bands are relatively weak, which is not unusual for these types of ligands because the major source of intensity of these transitions is the promotion of an electron from d_{xz}, d_{yz} orbitals of the copper ion (68, 71). The position of the *d–d* band suggests that the Cu(II) ions may have a square-planar environment at the open site (65, 66). Three bands are resolved for **15** at 357, 414, and 576 nm. The moderately strong band at 414 nm is probably associated with phenolate–cobalt(III) charge transfer and the broad band at 576 nm is attributed to the *d–d* transition of Co(III), which tails into the near-IR region and tends to obscure the weaker *d–d* transition of Cu(II). The band at higher energy seems to be due to Cu(II) because neither compound **17** nor $[Co^{III}(tntnam)(H^+)_2]^{3+}$ shows such a band in this region, and it is probably associated with metal to phenolate charge transfer.

Redox properties

One of our objectives has been to develop a heterobimetallic system in which both metals contribute to the oxidative addition of reactants such as dioxygen. For such a process to occur, both of the metals at their respective open

[b]Magnetic susceptibilities were determined at 25°C by the Evans ^1H NMR method on samples dissolved in CD_3COCD_3.

[c]Magnetic susceptibilities were determined at 20°C by Evans balance method.

[d]Spin-only values are determined for the bimetallic ensemble, where $\mu_{s.o} = (n(n+2)+2))^{1/2}$ and n = total number of unpaired spins (e.g., for Co(II)–Ni(II) complex, $n = 5$).

[e]Total number of unpaired spins.

[f]No paramagnetism.

and closed coordination sites must be capable of transferring electrons to the dioxygen molecule. To investigate cooperative interaction of metals for the electron transfer process, we studied the change in redox properties of an invariant metal by variations of the neighbouring metal in bimetallic complexes. Cyclic voltammetry was used to measure the formal potentials, E_f, of the metal ions. The open-site Ni(II)/Ni(I) and Cu(II)/Cu(I) couples were monitored for three series, $[M(ligand)Ni]^{q+}$, $[M(ligand)NiCl]^{q+}$, and $[M(ligand)Cu]^{q+}$, where M = Co(III) and Zn(II) and ligand = tntnim or tntnam. The cyclic voltammograms were measured at 25°C in acetonitrile solution containing 0.1 M n-Bu_4NPF_6 as the supporting electrolyte. Cyclic voltammograms were recorded using a tungsten reference electrode. All potentials E_f reported or discussed are adjusted relative to the ferrocenium/ferrocene (Fc^+/Fc) couple that was used as an

[a]1.0 mM sample, 0.1 M *n*-Bu_4NPF_6 in CH_3CN. Scan rate: 100 mV/s. Solutions were deaerated with Ar for 10 min prior to each run.

[b]Reduction potentials are reported relative to the ferrocenium/ferrocene (Fc^+/Fc) couple, assigned a value of 0.00 V.

[c]Scan rate: 200 mV/s.

internal reference (40) except for those of the macrocyclic Co(II) complexes. In the case of Co(II) complexes, the redox waves corresponding to the ferrocene internal reference coincide with Co(III)/Co(II) waves for the complexes, and thus here the Fc^+/Fc couple was used as an external reference (40). Table 11 lists the redox couples E_f found in acetonitrile solutions. Most of the compounds gave quasi-reversible waves, with clear anodic and cathodic peak separations, $E_{pa} - E_{pc}$. The Co(III)/Co(II) couple of $[Co(tntnam)(H^+)_2]^{3+}$ appears as a broad quasi-reversible wave. The waves at –0.65 to –0.15 V are ascribed to the Co(III)/Co(II) couples (35). It appears that the Co(III) ions in the bimetallic complexes are more difficult to reduce than that in the monometallic Co(III) complex. This may be due to more flexibility in the monometallic complex. Bimetallic complexes are constrained by the presence of a second metal ion at the open site. The cyclic voltammograms of selected Cu(II) complexes are shown in Fig. 5. The complex **15** shows two redox couples. We ascribe the quasi-reversible wave at –0.20 V to the Co(III)/Co(II) couple and that at –1.23 V to the Cu(II)/Cu(I)couple. The voltammogram of **12** also contains a quasi-reversible wave at –1.04 V and is assigned to the copper ion at the open site. There are no significant differences in Co(III)/Co(II) and Cu(II)/Cu(I) couples for **15** compared to **12** (Zn–Cu) and **17** (Co–Zn). These results point to a lack of substantial cooperative interaction between the two metal centres.

Complexes of **10**, **11**, **13**, **14**, **16,** and **17** were prepared in order to assess the Co(III)–Ni(II) interaction with reference to redox properties in amine complexes. The crystal structures of the **5**, **11**, and **14** complexes show *trans*-disposed pyridines and it is likely that other complexes have a *trans* configuration. This was also observed in other bimetallic complexes with trimethylenediamine at the open- and closed-

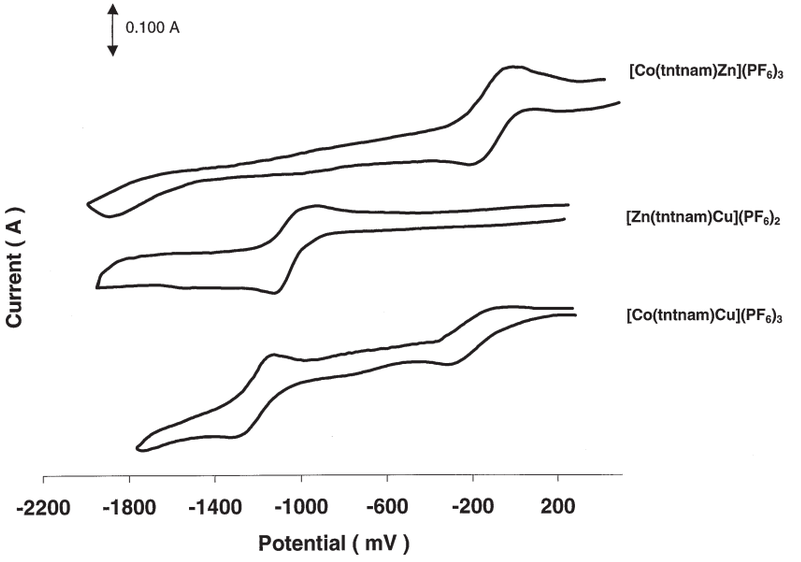

Fig. 6. The cyclic voltammograms of selected Co(III)– and Ni(II)–tntnam complexes in acetonitrile solutions referenced to Fc^+/Fc.

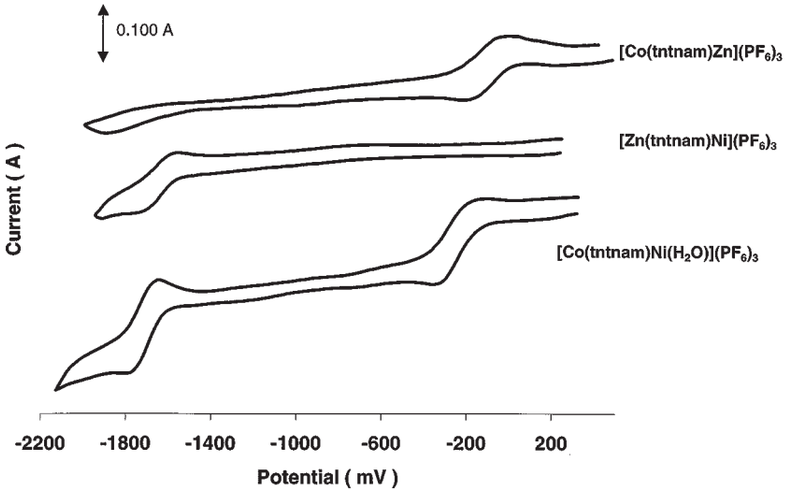

site links (36). As a result, there may be some slight structural differences in the closed-site Co(III) ion as the open-site metal is varied. Representative collections of cyclic voltammograms are given in Fig. 6. In addition to the waves ascribed to the Co(III)/Co(II) couple at –0.24 V, redox couples were also observed at –1.72 and –1.74 V arising from the open-site Ni(II) complexes in **13** and **14,** respectively. Redox couples were observed at similar potentials for analogous closed-site Zn(II) complexes **10** and **11**.

The analogous amine complexes of Ni(II) show more negative potentials than their imine counterparts. Presumably the more negative Ni(II)/Ni(I) potentials observed for amine complexes are related, at least in part, to the increased flexibility provided in the open-site link for diamine as compared to diimine. As a result, the diamine linkage at the open site is expected to be better able to adjust to the bond length changes accompanying the Ni(II) $\rightarrow$ Ni(I) transformation. Another observation that is apparent from the data in Table 11 is the variation of the closed-site Co(III)/Co(II) potential between diamine and diimine complexes of $[Co(ligand)NiCl]^{q+}$. Compound **13** has a redox couple that is significantly more negative than the ferrocenium/ferrocene couple and is consistent with ready oxidation of the Co(II) analogue with the ferrocenium ion. In the diimine analogue **7**, however, the Co(III)/Co(II) couple occurs at a much more positive potential, 0.09 V. It is not surprising, therefore, that we were unable to oxidize **7** with the ferrocenium ion. Upon removal of the coordinated Cl^- ligand, the resulting **8** is very sensitive to air and is readily oxidized to **9** by ferrocenium ion as evidenced by the redox potential of **9** in Table 11. Complex **9** shows two waves in the voltammogram, including one at –1.45 V attributable to the Ni(II)/Ni(I) couple of the open site, and the second one at –0.18 V that is ascribed to the closed-site Co(III)/Co(II) couple. The waves corre-

sponding to Ni(III)/Ni(II) and Cu(III)/Cu(II) in heterobimetallic complexes containing Ni(II) and Cu(II) were not observed in the potential range studied. It appears that oxidation of a metal at the given site deactivates the oxidation of metal at the other site (35).

Although the Co(II) oxidation state is expected to be more stereochemically labile than that of Co(III), it seems unlikely that the ligand coordination rearranges from the original C_2-symmetric structure of $[Co^{III}(ligand)M^{II}]^{3+}$ and $[Co^{III}(ligand)M^{II}Cl]^{2+}$ to the unsymmetrical structure, with *cis*-disposed pyridyl ligands, on the time scale of the electrochemical experiment (38, 56). Such extensive rearrangement, were it to occur, would likely give almost irreversible waves, which were not observed.

Reactivities towards molecular oxygen

The emission spectra of room temperature aerated and deaerated solutions of heterobimetallic complexes **9**, **11**, **13**, **14**, and **15** and free ligand tntnamH_2 were recorded in aqueous and acetonitrile solutions. An emission band occurred in all of the bimetallic complexes and for the free ligand at 416–526 nm upon excitation of the charge transfer bands of the compounds. The emission intensities significantly depend on molecular oxygen and decrease when the solutions are saturated with oxygen. No emission was observed from excitation of the *d–d* bands of the metal complexes. The origin of the emission band seems to be the intraligand charge transfer of the ligand system.

Time-resolved studies were carried out on the heterobimetallic complexes in oxygenated acetonitrile solutions to investigate the possible formation of singlet molecular oxygen, O_2 ($^1\Delta_g$), as a result of oxygen quenching. However, we were unable to detect the presence of singlet molecular oxygen.

To investigate the possibility of the formation of peroxide species as a result of oxidative quenching of the emission of the heterobimetallic complex in the aerated media, aqueous solutions of complexes **9**, **13**, and **14** were irradiated by visible light (415 nm) and the formation of the peroxide species was monitored by a standard method (41). The results show that the quantum yields for the production of hydrogen peroxide are less than 10^{-5}. This is in keeping with the absence of oxidation waves for Ni(II)/Ni(III) couples in the cyclic voltammetry experiments. The general observation that the absorption spectra remain unchanged upon extensive irradiation also shows the robust character of these complexes.

Acknowledgement

We express appreciation to the Natural Sciences and Engineering Research Council of Canada and the Ministry of Culture and Higher Education of the Islamic Republic of Iran for financial support. We also thank Professor A.S. Baranski for useful suggestions and discussions in the electrochemistry work. The authors gratefully acknowledge the assistance of Dr. Peter Wassell in measuring the magnetic susceptibility of the powdered samples. We wish also to thank Professor G. McKay and Dr. K. Lee for performing the electrospray mass analysis of the samples.

Kinetics and mechanism of the reduction of Cr^{VI} to Cr^{III} by D-ribose and 2-deoxy-D-ribose

Verónica Daier, Sandra Signorella, Marcela Rizzotto, María Inés Frascaroli, Claudia Palopoli, Carlos Brondino, Juan Manuel Salas-Peregrin, and Luis F. Sala

Abstract: The oxidation of D-ribose and 2-deoxy-D-ribose by Cr^{VI} yields the aldonic acid and Cr^{3+} as final products when an excess of sugar over Cr^{VI} is used. The redox reaction occurs through $Cr^{VI}\rightarrow Cr^{III}$ and $Cr^{VI}\rightarrow Cr^{V}\rightarrow Cr^{III}$ paths. The complete rate laws for the Cr^{VI} oxidation reactions are expressed by $-d[Cr^{VI}]/dt = k_H[H^+]^2$ [ribose][Cr^{VI}], where $k_H = (5.9 \pm 0.1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1}, and $-d[Cr^{VI}]/dt = (k_0 + k_H'[H^+]^2)$ [2-deoxyribose][Cr^{VI}], where $k_0 = (1.3 \pm 0.5) \times 10^{-3}$ mol^{-1} dm^3 s^{-1} and $k_H' = (4.2 \pm 0.1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1}, at 33°C. An intermediate sugar alkoxide radical could be trapped with DMPO and observed by EPR as a multiline signal at $g = 2.003$. Cr^V is formed in a rapid step by reaction of the sugar radical with Cr^{VI}. Cr^V reacts with the substrate faster than Cr^{VI} does. The EPR spectra show that five- and six-coordinate oxochromate(V) intermediates are formed, and the distribution of these Cr^V species in the reaction mixture essentially depends on the solution acidity.

Key words: ribose, 2-deoxyribose, chromium, redox, mechanism, kinetics.

Résumé : L'oxydation du D-ribose et du 2-désoxy-D-ribose par le Cr^{VI} conduit aux acides aldoniques et au Cr^{3+} lorsque le sucre est en excès par rapport au Cr^{VI}. La réaction redox se produit par les voies $Cr^{VI}\rightarrow Cr^{III}$ et $Cr^{VI}\rightarrow Cr^{V}\rightarrow Cr^{III}$. Les lois de vitesse complètes pour les réactions d'oxydation par le Cr^{VI} s'expriment par les équations $-d[Cr^{VI}]/dt = k_H[H^+]^2$[ribose][$Cr^{VI}$] dans laquelle $k_H = (5{,}9 \pm 0{,}1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1} et $-d[Cr^{VI}]/dt = (k_0 + k_H'[H^+]^2)$ [2-désoxyribose][Cr^{VI}] dans laquelle $k_0 = (1{,}3 \pm 0{,}5) \times 10^{-3}$ mol^{-1} dm^2 s^{-1} et $k_H' = (4{,}2 \pm 0{,}1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1}, à 33°C. Faisant appel au DMPO, il est possible de piéger un radical alcoolate intermédiaire du sucre et de l'observer par RPE sous la forme d'un signal multiligne à $g = 2{,}003$. Le Cr^V se forme dans une étape rapide par réaction du radical avec du Cr^{VI}. La vitesse de réaction du Cr^V réagit avec le substrat est plus grande que celle du Cr^{VI}. Le spectre RPE montre qu'il y a formation d'intermédiaires oxochromates(V) penta- et hexacoordinés et que la distribution de ces espèces Cr^V dans le milieu réactionnel dépend essentiellement de l'acidité de la solution.

Mots clés : ribose, 2-désoxyribose, chrome, redox, mécanisme, cinétiques.

[Traduit par la Rédaction]

Introduction

Hexavalent chromium, in many different compounds, is a well-established carcinogen and mutagen (1–5). The observation of Cr^V and Cr^{IV} intermediates in the selective oxidation of organic substrates by Cr^{VI} and their implication in the mechanism of Cr-induced cancers (6–8) has generated a considerable amount of interest in their chemistry and biochemistry (9–12).

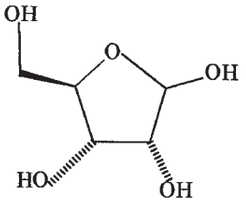
The biological reduction of Cr^{VI} to lower states has been observed with a wide variety of naturally occurring cellular reductants (13–15). Ligands that possess two oxygen atoms able to form five-membered rings about the metal ion, such as 1,2-diols and α-hydroxyacids, are effective as nonenzymatic reductants and complexation agents towards hypervalent chromium and can stabilize the labile oxidation states of chromium (12, 16–19). For this reason sugars, or their derivatives, may play an important role in the chemistry of Cr^{VI}.

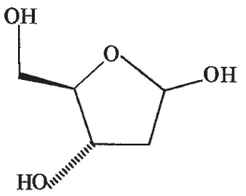
We are studying the possible fate of Cr^{VI} and Cr^V in biological systems by examining reactions of Cr^{VI} with low-molecular-weight biological and model reductants, as a means of more fully understanding the processes involved in the genotoxicity of chromium. In previous work we have found that the stereochemistry of the sugars or their derivatives affects the Cr^{VI} reduction rate (20–27). In any case, the first reaction step involves the formation of a Cr^{VI} ester, which is followed by the slow redox steps. For aldohexoses, this precursor is formed in rapid pre-equilibrium, and C(1)O, C(2)O, and in a little extent, C(6)O have been found to be the preferred coordination sites either in the Cr^{VI} or Cr^V electron-transfer precursors (20, 24). On the other hand, 2-deoxyaldohexoses form with Cr^{VI} a precursor ester, which

 © 1999 NRC Canada

behaves as a steady state, and they yield several Cr^{V} intermediate complexes which are in rapid pre-equilibria before the slow redox steps take place, with C(1)O and C(6)O being the preferred coordination sites (21, 22). In this paper, we compare the Cr^{VI} reduction by D-ribose and 2-deoxy-D-ribose, and provide with new information on the influence of the furanose hydroxyl groups on the reaction kinetics and mechanism as well as on the nature and reactivity of the intermediate Cr^{V} species.



D-Ribose



2-deoxy-D-Ribose

Experimental

Materials

D-Ribose (Rib) (Sigma grade), 2-deoxy-D-Ribose (2dRib) (Sigma grade), potassium dichromate (BDH), sodium perchlorate (Fluka grade), acrylonitrile (Aldrich grade), and perchloric acid (P.A. Merck) were used without further purification.

For experiments performed in the 2–7 pH range, the pH of the solutions was adjusted by addition of 0.5 mol dm^{-3} NaOH and 0.5 mol dm^{-3} $HClO_4$.

The spin trap 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) (Aldrich grade) was purified by charcoal decolorization. The method consists of successively treating the DMPO with activated charcoal until all free-radical impurities disappeared by EPR spectroscopy (28).

Warning: chromic acids and acrylonitrile are toxic and carcinogens.

Spectrophotometric measurements

Kinetics measurements were made at 350 nm, by monitoring the absorbance changes on a Guilford Response II spectrophotometer with fully thermostated cell compartments. The reactions were followed under pseudo-first-order conditions, using at least a 25-fold excess of sugar over Cr^{VI}. Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength (*I*) of 1.0 mol dm^{-3}. Reactant solutions were previously thermostated and transferred into a cell of 1 cm path length immediately after mixing. Experiments were performed at 33°C unless otherwise mentioned.

Disappearance of Cr^{VI} was followed at 350 nm until at least 80% conversion. In most experiments the concentration of Cr^{VI} was kept constant at 8×10^{-4} mol dm^{-3} while the sugar concentration was varied from 0.02 to 0.16 mol dm^{-3}. The observed pseudo-first-order rate constants (k_{obs}), determined from the linear part of plots of ln (A_{350}) vs. time, were deduced from multiple determinations and were within ±5% of each other. The first-order dependence of the rate upon $[Cr^{VI}]$ was verified. The k_{obs} were calculated at various $[Cr^{VI}]_0$, but at constant temperature, $[sugar]_0$, $[H^+]$, and *I*. As expected on the basis of a $-d(\ln [Cr^{VI}])/dt = k_{obs}$ rate law, where $k_{obs} = f([sugar][H^+])$, k_{obs} was found to be essentially constant with increasing $[Cr^{VI}]_0$. The formation of Cr^{III} was monitored at 570 nm. At the end of the reaction the two d–d bands ascribed to Cr^{III} were observed at λ_{max} = 410 nm (ε = 18 dm^3 mol^{-1} cm^{-1}) and 576 nm (ε = 15.5 dm^3 mol^{-1} cm^{-1}) ($[HClO_4]$ = 0.5 mol dm^{-3}). Both, visible and UV spectral maxima and intensities, are in close agreement (vide infra) with those observed for the $[Cr(H_2O)_6]^{3+}$ ion. The assignment was verified by comparing the spectral features with those of the acid solutions of independently synthesized $[Cr(RibaH_{-3})(H_2O)_2]$ (λ_{max} = 421 nm (ε = 27.4 dm^3 mol^{-1} cm^{-1}) and 573 nm (ε = 25.8 dm^3 mol^{-1} cm^{-1})), $K[Cr_2(OH)(Riba)_2(Rib)_2]$ (λ_{max} = 408 nm (ε = 452 dm^3 mol^{-1} cm^{-1}) and 571 nm (ε = 146 dm^3 mol^{-1} cm^{-1})) (29), and $Na_3[Cr(RibH_{-2})_2(OH)_2]$ (λ_{max} = 298 nm (ε = 137 dm^3 mol^{-1} cm^{-1}) and 576 nm (ε = 15.5 dm^3 mol^{-1} cm^{-1})) complexes.

Products analysis

Under the conditions used in the kinetic measurements (ratios of Rib (2dRib) to Cr^{VI} from 25:1 to 200:1), qualitative identification of D-ribonic acid (Riba) (or 2-deoxy-D-ribonic acid (2dRiba)) as the reaction product was carried out by paper chromatography. Riba (2dRiba) was identified against an authentic sample using *n*-butanol/acetic acid/water (4:1:5) as eluent. Paper chromatograms were visualized by two kinds of development reagents: a three-stage dip of silver nitrate, sodium hydroxide, and sodium thiosulphate and *p*-anisidine reagent (30, 31). Riba (2dRiba) identification as the only reaction product was also made by ^{13}C NMR. A mixture of Rib (2dRib) (13.2×10^{-3} mol) and potassium dichromate (6.6×10^{-3} mol) in 1 mol dm^{-3} $HClO_4$ (10 cm^3) was allowed to react at 33°C. After the reaction had proceeded to completion the mixture was stirred with a Dowex 50W-X8 cation exchange resin until all the Cr^{III} was removed from the solution and a concentrated sample was analysed by ^{13}C NMR. Riba (2dRiba) and unreacted Rib (2dRib) were identified by comparing against authentic samples.

The presence of free radicals was tested for in the reaction of Rib (2dRib) with Cr^{VI}. To a solution of potassium dichromate (0.005 mmol) and Rib (2dRib) (0.1 mmol) in 4 cm^3 of 0.25 mol dm^{-3} $HClO_4$ was added acrylonitrile (0.5 cm^3) at 33°C. After a few minutes a white precipitate appeared. Control experiments (without potassium dichromate or reductant present) did not show the formation of a precipitate.

EPR spectroscopy

The EPR spectra were obtained on a Bruker ESP 300 E spectrometer. The microwave frequency was generated with a Bruker 04 ER (9–10 GHz) and measured with a Racal–Dana frequency meter. The magnetic field was measured with a Bruker NMR-probe Gauss meter. All of the EPR experiments were carried out at room temperature.

Results and discussion

Cr^{VI} reduction by Rib and 2dRib

Over the whole range of $HClO_4$ concentrations used in the kinetic measurements, spectrophotometric studies showed

[a]Rate constants obtained from multiple determinations.

Fig. 1. Time evolution of the UV-vis spectrum of a mixture of Rib (0.2 mol dm^{-3}) and Cr^{VI} (8×10^{-3} mol dm^{-3}). $[HClO_4]$ = 0.25 mol dm^{-3}; T = 25°C, over a period of ca. 113 min, showing the Cr^{III} growth and Cr^{VI} decay with one isosbestic point.

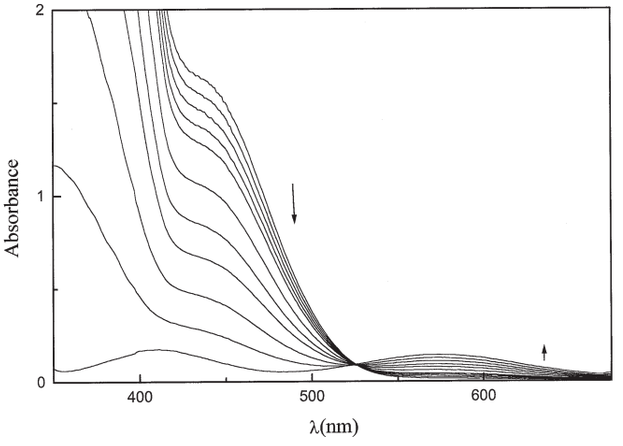

Fig. 2. Effect of [Rib] on k_{obs} at 33°C, I = 1.00 mol dm^{-3}, and $[H^+]$ (mol dm^{-3}): (*a*) 0.10; (*b*) 0.25; (*c*) 0.50; (*d*) 0.60; (*e*) 0.75; (*f*) 0.90; (*g*) 1.00.

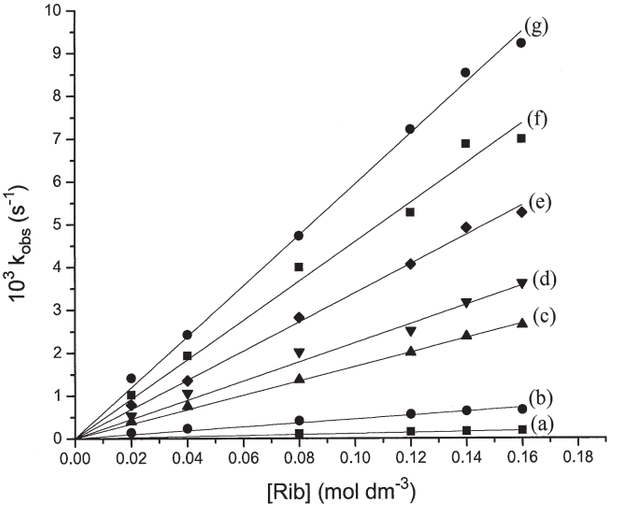


that the reaction of the sugar and Cr^{VI} resulted in an absorbance band at 350 nm and a shoulder at 420–500 nm. The absorbance vs. time curves at 350 nm exhibit a monotonic decrease. At this wavelength, kinetic traces show an initial deviation from first-order decay over short time periods. It is known that Cr^V species absorb strongly at 350 nm and may superimpose Cr^{VI} absorbance yielding the wrong interpretation of spectrophotometric absorbance decay values (32). However, if Cr^V reacts faster than Cr^{VI} and exists in solution in a sufficiently small concentration, changes in absorbance at 350 nm essentially reflect changes in Cr^{VI} concentration. We calculated pseudo-first-order rate constants from the slope of the linear part of the ln (Abs) vs. time curves; a good criterion only if Cr^V decays faster than Cr^{VI}. The relative values of the Cr^{VI} vs. Cr^V reduction rate constants obtained from the Cr^V EPR signal intensity variation during the reaction course (discussed below) demonstrate this is the case for the present reaction. Besides, we have followed the formation of Cr^{III} at 570 nm, and we have found that the rate of Cr^{III} formation equals the rate of Cr^{VI} decay. This is consistent with the observation of an isosbestic point at 525 nm (Fig. 1) and implies a low $[Cr^V]$ throughout the reaction in the $[H^+]$ range used in the kinetic measurements.

Table 1 summarizes values of k_{obs} for various concentrations of Rib at fixed concentrations of $HClO_4$. Plots of k_{obs} vs. [Rib] (Fig. 2) gave good straight lines from which values of k were determined (Table 2). Figure 3 shows the dependence of k with $[HClO_4]$, which may be expressed as in eq. [1].

$$[1] \qquad k = k_H[H^+]^2$$

where $k_H = (5.9 \pm 0.1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1}.

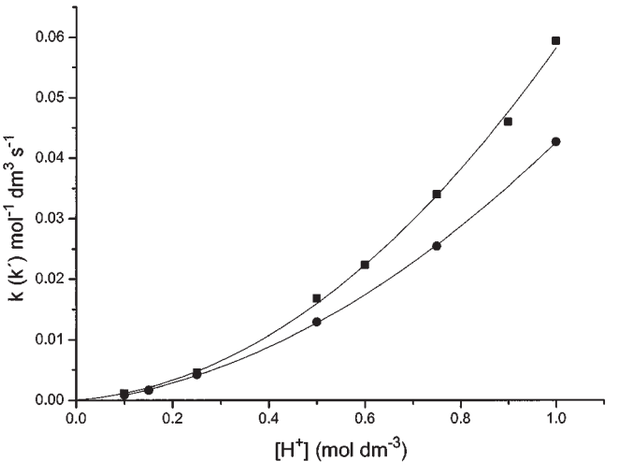
The complete rate law is then given by

© 1999 NRC Canada

Table 2. Values of k and k' for different $[HClO_4]$. T = 33°C; $[Cr^{VI}]_0 = 3.6 \times 10^{-4}$ mol dm^{-3}; I = 1.00 mol dm^{-3}.

$[HClO_4]$/ mol dm^{-3}	0.10	0.15	0.25	0.50	0.60	0.75	0.90	1.00
10^3 k/mol^{-1} dm^3 s^{-1}	1.13(3)	—	4.5(2)	16.8(2)	22.3(5)	34.0(5)	45.9(1)	59.4(6)
10^3 k'/mol^{-1} dm^3 s^{-1}	0.86(4)	1.66(4)	4.20(6)	12.9(3)	—	25.5(1)	—	42.7(4)

Fig. 3. Effect of acidity on k (■) and k' (●).



[2] $$-d[Cr^{VI}]/dt = k_{obs}[Cr^{VI}]_T = k_H[H^+]^2[Rib][Cr^{VI}]_T$$

where $[Cr^{VI}]_T$ represents the total Cr^{VI} concentration.

For the oxidation of 2dRib, plots of k_{obs}' (Table 1) vs. [2dRib] (Fig. 4) gave straight lines with zero intercept from which values of k' were determined (Table 2). A plot of k' vs. $[H^+]^2$ gave a straight line with a positive intercept, showing that the second-order rate constant may be expressed as consisting of an acidity independent and an acidity dependent term:

[3] $$k' = k_0 + k_H'[H^+]^2$$

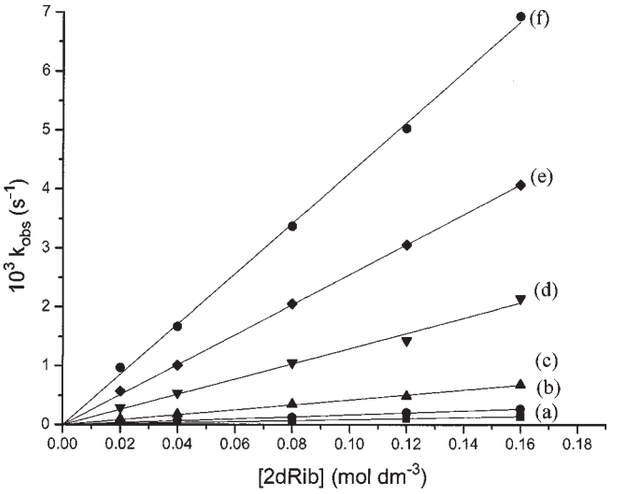
where $k_0 = (1.3 \pm 0.5) \times 10^{-3}$ mol^{-1} dm^3 s^{-1} and $k_H' = (4.2 \pm 0.1) \times 10^{-2}$ mol^{-3} dm^9 s^{-1}.

The complete rate law is then given by

[4] $$-d[Cr^{VI}]/dt = k_{obs}'[Cr^{VI}]_T = (k_0 + k_H'[H^+]^2)[2dRib][Cr^{VI}]_T$$

The rate laws for the oxidation of Rib and 2dRib by Cr^{VI} differ in that, for the second, a term independent of $[H^+]$ is observed. These two terms in the rate law (eq. [4]) for 2dRib result from the fact that there are at least two transition states, differing in composition but similar in energy, through which the reduction of Cr^{VI} can proceed. Thus, the oxidation of 2dRib by Cr^{VI} should occur through two parallel slow steps leading to the redox products. In the case of Rib, the redox reaction proceeds through one path of consecutive reactions leading to the products only after protonation of the 1:1 Rib–Cr^{VI} intermediate species. This fact explains why at high pH the oxidation of 2dRib occurs faster than that of Rib. For both sugars, in the range of substrate concentrations employed, only substrate first-order dependence was observed and Riba (or 2dRiba) was the only detected reaction product. A mechanism taking account of these facts is proposed for Rib and 2dRib in Scheme 1.

Fig. 4. Effect of [2dRib] on k_{obs}' at 33°C, I = 1.00 mol dm^{-3}, and $[H^+]$ (mol dm^{-3}): (*a*) 0.10; (*b*) 0.15; (*c*) 0.25; (*d*) 0.50; (*e*) 0.75; (*f*) 1.00.



In the $[H^+]$ range studied, Cr^{VI} exists mainly as $HCrO_4^-$ (33). Thus, the first step of the mechanism proposed in Scheme 1(*a*) may be interpreted as the formation of a monochelate with Rib acting as a bidentate ligand bound to Cr^{VI} at C1-O and C2-O to yield the anionic species A^-. Even when several linkage isomers might be formed by coordination of the sugar with Cr^{VI} via any properly disposed hydroxyl groups, we think that the complex with the anomeric hydroxyl group bound to Cr^{VI} should be the precursor of the slow redox steps. Then, the monoprotonated form of this intermediate (AH) yields the redox product through an acid catalyzed step.

The rate law corresponding to this mechanism may be expressed as in eq. [5]:

[5] $$-d[Cr^{VI}]/dt = k_2K_1K_2[H^+]^2[Rib][Cr^{VI}]$$

where $k_2K_1K_2 = k_H$ of the experimental rate law.

An alternative mechanism might involve the formation of an intermediate bis-chelate Cr^{VI}-Rib_2, where only one of the two Rib molecules involved in the Cr^{VI} complex formation is oxidized to Riba through the two-electron intramolecular redox path.

The first step of the mechanism proposed for the oxidation of 2dRib in Scheme 1(*b*) corresponds to the formation of a 1:1 2dRib–Cr^{VI} binary complex, with 2dRib acting as a monodentate ligand bound to Cr^{VI} at the anomeric hydroxyl group to yield the anionic species B^-. This intermediate may decompose directly to the products or give BH. This monoprotonated intermediate yields the redox products

© 1999 NRC Canada

Scheme 1. $A^- = [(RibH_{-2})CrO_2(H_2O)OH]^-$, $B^- = [(2dRibH_{-1})\ CrO_2(H_2O)(OH)_2]^-$.

(a) $Rib + Cr^{VI} \overset{K_1}{\rightleftharpoons} A^- \overset{K_2, H^+}{\rightleftharpoons} AH \overset{k_2, H^+}{\longrightarrow} Cr^{IV} + Riba$

(b)
$$2dRib + Cr^{VI} \overset{K_a}{\rightleftharpoons} B^- \overset{k_a}{\longrightarrow} Cr^{IV} + 2dRiba$$
$$K_b \Big\downarrow H^+$$
$$BH \overset{k_b, H^+}{\longrightarrow} Cr^{IV} + 2dRiba$$

through an acid-catalyzed step. The rate law corresponding to this mechanism may be expressed as in eq. [6]:

[6] $$-d[Cr^{VI}]/dt = (k_aK_a + k_bK_aK_b[H^+]^2)[2dRib][Cr^{VI}]$$

where $k_aK_a = k_0$ and $k_bK_aK_b = k_H'$ of the experimental rate law.

For either Rib or 2dRib, after the slow steps, reactions [7]–[9] may take place.

[7] $$Sugar + Cr^{IV} \rightarrow sugar^{\cdot} + Cr^{III}$$

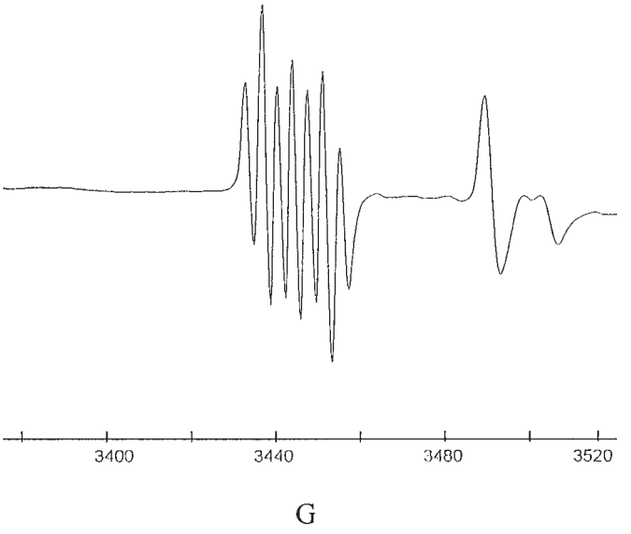
[8] $$Sugar^{\cdot} + Cr^{VI} \rightarrow sugar\ acid + Cr^{V}$$

[9] $$Sugar + Cr^{V} \rightarrow sugar\ acid + Cr^{III}$$

Cr^{IV} formed in the slow steps yields the final Cr^{III} and the $sugar^{\cdot}$ radical in a subsequent fast step. The formation of these sugar radicals is supported by the observed polymerization after addition of acrylonitrile. Besides, DMPO was used to detect any sugar radical intermediate formed during the reduction of Cr^{VI} by Rib. The addition of DMPO to the reaction mixture resulted in the appearance of a spin adduct signal at $g = 2.003$ (Fig. 5) with splitting constants of $a_N = 7.48 \times 10^{-4}$ cm^{-1}, $a_H = 3.65 \times 10^{-4}$ cm^{-1} (× 2). This is the first time that a signal corresponding to a DMPO/sugar radical adduct is reported, and confirms our proposal. Cr^V formed by rapid reaction of the radical and Cr^{VI} can further oxidize the sugar to yield the final redox products.

Unlike Rib, aldohexoses kinetic profiles yield saturation curves (20, 24). This means that aldohexoses form more "stable" intermediate Cr^{VI} complexes (with higher K). But, also, under the same reaction conditions, the kinetic parameter (kK) for the $[H^+]^2$ dependent term is, at least, six times lower for aldohexoses than for Rib. Thus, the $k_{ox}/K_{complexation}$ ratio is higher for the Rib/Cr^{VI} system, meaning that intramolecular electron transfer paths are faster within the less stable Cr^{VI} intermediate complexes. The same difference was observed when 2-deoxy-glucose/Cr^{VI} and glucose/Cr^{VI} systems were compared (21, 22). The more stable the intermediate Cr^{VI} complex, precursor of the redox steps, the higher the energy barrier to overcome in the slow electron transfer steps. Comparing the kinetic parameters of the acidity dependent term for Rib and 2dRib it can be observed that they are of the same order of magnitude, meaning that, in this case, k and K compensate each other, yielding a similar value for the kK product.

Fig. 5. EPR spectrum recorded from a 0.1 mol dm^{-3} $HClO_4$ solution containing 25 mmol dm^{-3} Cr^{VI}, 250 mmol dm^{-3} Rib, and 73 mmol dm^{-3} DMPO. The spectrum was recorded 3 min after mixing. Modulation amplitude: 0.514 G, centre field: 3450 G, frequency = 9.66 GHz.



It must be noted that the slow redox steps, involving either A^- or B^- (BH) intermediate complexes, are two electron steps, and the final chromium species, Cr^{III}, is formed through either a $Cr^{VI} \rightarrow Cr^{IV} \rightarrow Cr^{III}$ or a $Cr^{VI} \rightarrow Cr^{V} \rightarrow Cr^{III}$ path.

Intermediacy of Cr^V

The reaction of Cr^{VI} with an excess of 5–100 times of Rib, in the 4–7 pH range, at 25°C, generates an EPR spectrum dominated by a single detectable signal at $g_{iso} = 1.9787$ (Fig. 6) with the four weak ^{53}Cr (9.55% abundance, $I = 3/2$) hyperfine peaks at 15.7×10^{-4} cm^{-1} spacing, typical of five-coordinate oxochromate(V) complexes (34–36). In this pH range, Cr^V remains in solution several days. We found that varying the modulation amplitude, the superhyperfine (shf) pattern partially resolved, and the Cr^V EPR spectrum

Fig. 6. X-band EPR signal of a mixture of Rib (3.75×10^{-1} mol dm^{-3}) and Cr^{VI} (3.75×10^{-2} mol dm^{-3}) at different [H^+]. T = 25°C, modulation amplitude = 4 G, centre field = 3550 G; frequency = 9.85 GHz.

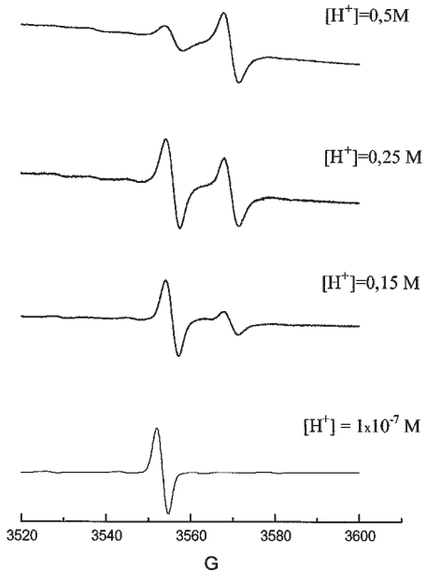

Fig. 7. X-band EPR signal of a mixture of 2dRib (3.75×10^{-1} mol dm^{-3}) and Cr^{VI} (3.75×10^{-2} mol dm^{-3}) at different pH. T = 25°C, modulation amplitude = 8 G, centre field = 3550 G; frequency = 9.84 GHz.

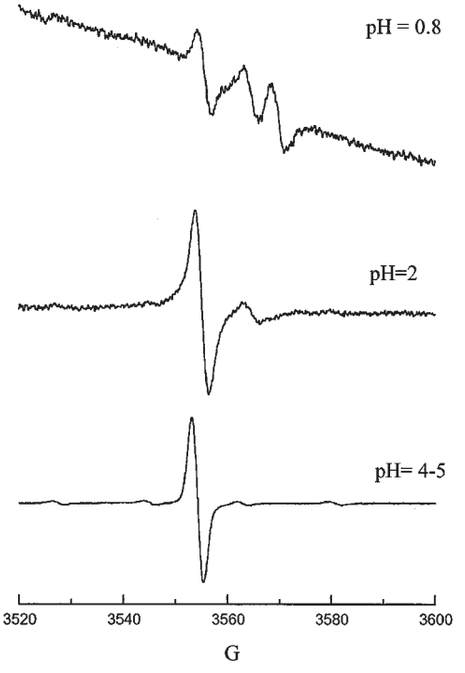

resulted to be a composite of several Cr^V species. Even when the complex chemistry of the Cr^V-Rib species present in solution makes accurate determinations of g_{iso} values difficult, specially due to the overlap of the shf coupling, the g_{iso} values for all of these signals are in the range of those expected for five-coordinate oxochromate(V) complexes (34).

At [$HClO_4$] ≥ 0.1 M, the reaction of Cr^{VI} with excess Rib resulted in the formation of two types of relatively long-lived Cr^V species. The relative intensity of the two Cr^V EPR signals, at g_1 = 1.9787 and g_2 = 1.9711, depends on the [H^+] (Fig. 6), but is independent of the rib:Cr^{VI} ratio employed (from 5:1 to 100:1). The g_2 value is significantly lower than the values observed for the five-coordinate oxochromate(V) complexes, and since the g values of the Cr^V species are very sensitive to coordination (37), it may be assigned to a six-coordinate oxochromate(V) complex (35). However, the lack of a resolved shf pattern from the protons prevented a more detailed analysis of this signal. For [H^+] = 0.1–0.15 M, the five-coordinate species (g_1) is the major one; it forms rapidly (the maximum concentration is reached at t < 3 min) and decays slowly. Under these conditions, the minor species always decays with time. At [H^+] = 0.25 M, the total amount of Cr^V reached a maximum concentration at t < 1 min, and both signals always decay with time. In the [H^+] range 0.25–1.0 M the six-coordinate species (g_2) is the major one, i.e., at [H^+] = 1 M, after 6 min of reaction, the g_1/g_2 signal ratio was 0.07. Thus, the five-coordinate oxochromate(V) complexes are formed at any [H^+], whereas the formation of the six-coordinate species requires acid conditions. At each pH, the two Cr^V signals decay at different rates, and these rates increase with decreasing pH, indicating that proton catalysis is present in the oxidation of the sugar by Cr^V. The observed behavior seems to indicate that both types of complexes, five- and six-coordinate, are formed independently and they yield the final Cr^{III} by two parallel paths.

In the 4–7 pH range, the sugar should essentially form binary Rib:di-oxochromate(V) complexes, with the sugar binding Cr^V as a bidentate ligand at a 1,2-diolate moiety, or bound to Cr^V at a 1,2,3-triolate moiety (34). The appearance of the six-coordinate Cr^V species at high [H^+] might be interpreted as the consequence of the protonation of the anionic dioxochromate(V) species, yielding the monooxochromate(V) complexes with the sixth coordination position occupied by an additional solvent molecule.

The reaction of Cr^{VI} with an excess of 2dRib, in the 4–7 pH range, at 25°C, results in only one Cr^V intermediate species, with g_{iso} = 1.9791 and A_{iso} = 16.6×10^{-4} cm^{-1} (Fig. 7), typical of a five-coordinate oxochromate(V) complex (34). In this case, the signal did not split when the modulation amplitude was lowered. So, probably, only one species is responsible for this EPR signal. At pH = 2, a minor signal at g_2 = 1.9735 appears, and when the [H^+] > 0.1 M a third signal at g_3 = 1.9707 is observed. The g_{iso} values of the two signals at higher field may be assigned to six-coordinate oxochromate(V) complexes (34). The relative proportions of the three species depend essentially on the acidity. The time course of the peak-to-peak height of the first derivative of the signals as a function of time for an initial ratio 2dRib:Cr^{VI} = 10:1, at different pH, revealed that the two (or three) signals decay at comparable rates; therefore, these Cr^V intermediates are in rapid equilibrium compared to the time scale of their subsequent reduction to Cr^{III}. Again, these rates increased with decreasing pH, indicating that proton catalysis is also present in this case. A similar behavior had

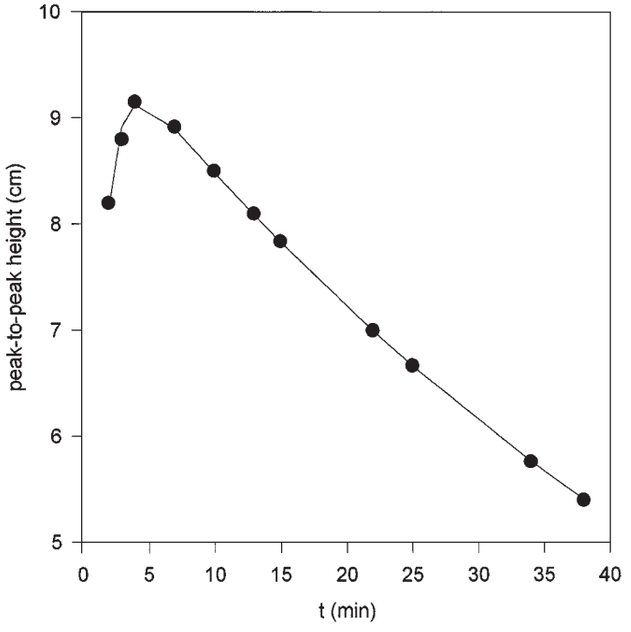
Fig. 8. Peak-to-peak heights of Cr^{V} EPR signals vs. time. [Rib] = 3.75×10^{-1} mol dm^{-3}; [Cr^{VI}] = 3.75×10^{-2} mol dm^{-3}; [H^{+}] = 0.15 mol dm^{-3}; I = 1 mol dm^{-3}; T = 25°C. T_{max} = 4.4 min.



been previously observed for the reaction of 2dGlc and Cr^{VI} (21).

For the reduction of Cr^{VI} by either Rib or 2dRib, the time of maximum Cr^{V} concentration is very short compared to the time required for the reaction completion. At [H^{+}] = 0.15 mol dm^{-3}, [Rib] = 0.375 mol dm^{-3} and $[Cr^{VI}]_0$ = 0.0375 mol dm^{-3}, at room temperature, Cr^{VI} requires 12 h to be completely reduced to Cr^{III}. Figure 8 shows a curve for peak-to-peak height of Cr^{V} EPR signal vs. time obtained on a reacting solution. Values of the rate constant for the disappearance of Cr^{VI} (k_6) and Cr^{V} (k_5), respectively, may be calculated by eq. [10] (26, 38), which fits well the experimentally observed Cr^{V} intermediate growth and decay curve in Fig. 8.

$$[10] \quad h = Ak_6(\exp(-k_5t) - \exp(-2k_6t))/(2k_6 - k_5)$$

In eq. [10], h is the peak-to-peak height, and A depends on the spectrometer settings and is adjusted by the fitting program.

For conditions stated in the figure, $k_6 = 1.35 \times 10^{-4}$ s^{-1} and $k_5 = 1.57 \times 10^{-2}$ s^{-1}, and the time of maximum Cr^{V} concentration, T_{max}, is 14.4 min. To verify if this assignment of the rate constant values — and not the reverse one — was correct, we have evaluated k_{obs} ($2k_6$) spectrophotometrically at 25°C under conditions used in the EPR experiments, and we have reproduced the k_{obs} ($2k_6$) value. Thus, the fact that k_5 is 116 times higher than k_6 justifies our initial assumption that changes in absorbance at 350 nm essentially reflect changes in Cr^{VI} concentration.

The ultimate fate of the chromium in these reactions is a Cr^{III} species and a typical broad Cr^{III} EPR signal centered at g ~1.98 is always observed at later time points.

Conclusions

These results show that Cr^{V}, generated by reaction of the sugar radical with Cr^{VI}, oxidizes Rib (or 2dRib) to the sugar acid faster than Cr^{VI} does. The reduction of both Cr^{VI} and Cr^{V} by the furanose is acid catalysed and yields the same oxidized product. Comparing the Cr^{VI} redox rates with those of allose (Allo) — the aldohexose with the same configuration of C2 and C3 — the second-order rate constant (k, M^{-1} s^{-1}) is six-fold higher for Rib than for Allo, a fate probably resulting from the furanose vs. pyranose forms of these two sugars. That the furanose ring favors oxidation vs. complexation processes might be interpreted as the consequence of the influence of the strain-induced instability of the chromate ester on the redox rate. This effect is enhanced in the Cr^{V}–furanose species, as evidenced when k_5 and k_6 for pyranose vs. furanose forms are compared. In the chromic oxidation of aldohexoses (pyranose form), k_5 values are no more than 10 times higher than k_6; whereas in the present case, $k_5 > 100k_6$.

The energy barrier for CO migration in $Mn_2(CO)_6(H_2PCH_2PH_2)_2$: a PM3(tm) study

Stephen A. Decker and Mariusz Klobukowski

Abstract: Carbonyl fluxionality in $Mn_2(CO)_6(dhpm)_2$ (dhpm = bis(dihydrophosphino)-methane), serving as a model of $Mn_2(CO)_6(dppm)_2$ (dppm = bis(diphenylphosphino)-methane), was studied using both the PM3(tm) semiempirical method and the DFT//PM3(tm) approach. When the PM3(tm) method is used for both geometry optimization and energy determination, the most stable conformer of $Mn_2(CO)_6(dppm)_2$ is predicted to possess six planar carbonyls, two of which are symmetrically bridging the Mn atoms, in contrast to the usually assumed planar all-terminal structure of $Mn_2(CO)_6(dppm)_2$. Carbonyl scrambling via the pairwise exchange mechanism in $Mn_2(CO)_6(dppm)_2$ is predicted to occur as follows at the PM3(tm)//PM3(tm) level: lowest energy, planar symmetrically di-bridged conformer → planar, all-terminal conformer → lowest energy, planar symmetrically di-bridged conformer. The corresponding barrier to the exchange process is 32 kcal/mol, much higher than the experimental value of 10 kcal/mol in the related $Mn_2(CO)_6(dppm)_2$ complex. Calculation of the total energies using density functional theory at the PM3-optimized geometries improves results in two ways. Firstly, the energy barrier to scrambling is reduced to only 15–19 kcal/mol depending on the functional employed. Secondly, the energy ordering of the conformers is reversed, with the planar, all-terminal structure of $Mn_2(CO)_6(dppm)_2$ being more stable than the bridging structure. The resulting mechanism is identical to that found in our earlier work on $Mn_2(CO)_{10}$. When DFT is used to optimize the conformer geometries, the energy barrier is further reduced to 13 kcal/mol.

Key words: PM3(tm) semiempirical method, density functional theory, carbonyl scrambling.

Résumé : Faisant appel à la méthode semiempirique PM3(tm) et à l'approche DFT//PM3(tm), on a étudié la fluxionalité du carbonyl dans le $Mn_2(CO)_6(dhpm)_2$ (dhpm = bis(dihydrophosphino)-méthane) qui sert de modèle pour le $Mn_2(CO)_6(dppm)_2$ (dppm = bis(diphénylphosphino)-méthane). Quand on utilise la méthode PM3(tm) tant pour l'optimisation de la géométrie que pour la détermination de l'énergie, on prévoit que le conformère le plus stable du $Mn_2(CO)_6(dhpm)_2$ comportera six carbonyls planaires, deux formant un pont symétrique entre les atomes de Mn; ceci est en opposition avec l'hypothèse habituelle selon laquelle le $Mn_2(CO)_6(dppm)_2$ assumerait une structure planaire dans laquelle tous les substituants seraient terminaux. Les calculs au niveau PM3(tm)//PM3(tm) permettent de prédique que, dans le $Mn_2(CO)_6(dhpm)_2$, un mécanisme d'échange par paire conduira à un mélange des groupes carbonyls : conformère biponté planaire et symétrique de plus faible énergie → conformère planaire avec tous les substituants terminaux → conformère biponté planaire et symétrique de plus basse énergie. La barrière correspondant au processus d'échange est de 32 kcal/mol, beaucoup plus élevée que la valeur expérimentale de 10 kcal/mol observée dans le complexe apparenté $Mn_2(CO)_6(dppm)_2$. Le calcul des énergies globales en utilisant la théorie de la densité fonctionnelle avec des géométries optimisées au niveau PM3 permet d'améliorer les calculs de deux façons : premièrement, la barrière d'énergie du brouillage est réduite à 15 à 19 kcal/mol suivant la fonctionnelle utilisée; deuxièmement, l'énergie de mise en ordre des conformères est renversée alors que la structure planaire avec tous les groupements en positions terminales du $Mn_2(CO)_6(dhpm)_2$ est plus stable que la structure pontée. Le mécanisme qui en résulte est identique à celui trouvé dans nos travaux antérieurs sur le $Mn_2(CO)_{10}$. Lorsqu'on utilise l'approche DFT pour optimiser les géométries des conformères, la barrière d'énergie est encore réduite à 13 kcal/mol.

Mots clés : méthode semiempirique PM3(tm), théorie de la densité fonctionnelle, brouillage des carbonyls.

1. Introduction

The last decade has seen a dramatic increase in the application of computational chemistry to the study of the properties and reactions of transition metal complexes (see, for instance, the review by Veillard (1)). This may be attributed to advances in theory, in particular density functional theory (DFT) methodologies (illustrated in the review of Ziegler (2)) and pseudopotential techniques (see the recent reviews by Frenking et al. (3) and Cundari et al. (4)), coupled with

technological advances in computer hardware and computational chemistry software. Currently nonlocal, gradient-corrected DFT is the method of choice for studies on transition metal compounds. However, using the workstation hardware typically available in research groups, the computational cost of DFT often makes it prohibitively expensive for modelling the large systems encountered in transition metal chemistry. The need for more cost-efficient techniques for studies of transition metal complexes has prompted the development of semiempirical methods, of which the PM3(tm) method available in the Spartan program[3] is frequently used. The semiempirical PM3(tm) method requires much less computing time; however, its reliability in applications to molecules containing transition metals has not yet been fully evaluated. A search of the literature shows only two papers that probe the utility of the PM3(tm) method in calculations involving transition metal complexes. Adam et al. (5) studied the ability of PM3(tm) to predict molecular structures of high- and low-spin nickel(II) teraaza macrocycle complexes. Looking only at geometry structures, they found PM3(tm) to be inferior to an extended MM2 molecular mechanics force field, derived for macrocycles of low-spin nickel(II). Børve et al. (6) performed a comparative study of PM3(tm) vs. DFT in calculations of Ti, Cr, and Zr complexes. They found the PM3(tm) method to be quite successful in predicting geometries of stable, closed-shell complexes, in close agreement with both experiment and DFT calculations. However, they also found that PM3(tm) gave poor relative energies and activation barriers for ethylene insertion reactions. Single-point energy calculations, using nonlocal density functional theory at the PM3(tm) optimized geometries, yielded more reliable and accurate activation barriers, reasonably close to those obtained if the DFT method were used throughout. Their approach may be denoted as the DFT//PM3(tm) method. In the current paper we use the DFT//PM3(tm) method in modelling carbonyl scrambling in transition metal dimer complexes.

Carbonyl scrambling has been found in all types of transition metal complexes of varying nuclearity, from simple mononuclear complexes to clusters containing many metal atoms (7, 8). There are two accepted mechanistic schemes for carbonyl scrambling: pairwise exchange and one-for-one exchange. In the pairwise exchange mechanism, proposed by Adams and Cotton (9) in the early 1970s, two of the migrating ligands are mutually exchanged between the two metal atoms. Symmetrical ligand bridges are opened and closed pairwise in a *trans*, coplanar, concerted fashion. This is the most common mechanism proposed for carbonyl migration, and may proceed from either an all-terminal or symmetrically bridging conformation. In the one-for-one mechanism, first proposed by Evans et al. (10) for carbonyl exchange in *trans*-$(\eta^5\text{-}C_5H_5)_2Rh_2(CO)_3$ and $(\eta^5\text{-}C_5H_5)_2Rh_2\text{-}(CO)_2P(OC_6H_5)_3$, the migrating ligands are not coplanar and are exchanged unsymmetrically in a stepwise fashion. The conventional experimental means of studying the dynamic fluxionality of ligands is NMR spectroscopy. To be detected by NMR, the exchange process must have a rate in the range 10^{-1}–10^6 s^{-1} (7). Furthermore, the solvents employed in NMR restrict the range of temperatures at which the process can be followed, thereby imposing limitations on the activation energy. The activation energy ($\Delta G^{\ddagger}$) for these fluxional processes must fall within the range 3–25 kcal/mol in order for the process to be studied by NMR (7).

The two Mn complexes, $Mn_2(CO)_{10}$ and $Mn_2(CO)_6(dppm)_2$, where dppm denotes bis(diphenylphosphino)-methane, show very different fluxional behaviour in solution. The carbonyl ligands in $Mn_2(CO)_{10}$ remain fixed up to a temperature of 130°C, as shown by ^{13}C and ^{17}O NMR studies (11). However, when four of the carbonyl ligands are replaced with two bidentate dppm ligands, then carbonyl fluxionality is observed, both by ^{13}C and ^{31}P NMR, down to a temperature as low as –75°C (12). Marsella and Caulton(12) proposed that carbonyl scrambling in $Mn_2(CO)_6(dppm)_2$ proceeds via the pairwise exchange (merry-go-round) mechanism from the most stable all-terminal conformer through a symmetrically di-bridged transition state or intermediate with an energy barrier of 10.2 kcal/mol. Conformational differences between $Mn_2(CO)_6(dppm)_2$ and the parent species $Mn_2(CO)_{10}$ were thought to be the driving force behind the observed difference in fluxional behaviour. In the lowest-energy conformer of $Mn_2(CO)_{10}$ the equatorial carbonyls are staggered and must undergo an initial rotation about the Mn—Mn bond to give the eclipsed conformation required for the merry-go-round scrambling of the carbonyls; this rotation would then contribute to the overall activation energy for the exchange process. On the other hand, in $Mn_2(CO)_6(dppm)_2$ the six carbonyls are believed to be already coplanar in the most stable conformer, and may proceed directly to scrambling without any prerequisite rotation about the Mn—Mn bond.

Our previous calculations (13), employing nonlocal density functionals for both geometry optimization and total energy evaluation, predicted that carbonyl migration in $Mn_2(CO)_{10}$ proceeds from the most stable staggered (D_{4d}) conformation, Fig. 1(*a*), to the eclipsed (D_{4h}) conformation, Fig. 1(*b*), via rotation about the Mn—Mn bond, with a barrier of only 5–6 kcal/mol, and then on to the planar, di-bridged (D_{2h}) conformer, Fig. 1(*c*), with an additional barrier of 14–15 kcal/mol. The overall activation barrier for carbonyl scrambling in $Mn_2(CO)_{10}$ via the pairwise exchange mechanism was therefore calculated from the total energies to be about 19–21 kcal/mol, close to the upper limit of 25 kcal/mol (7) for the process to be detected experimentally by NMR. The PM3(tm) method gave structural parameters that were close to both experimental data and the results from the DFT calculations; however, the PM3(tm) energy barrier for the rotation about Mn—Mn bond (converting the staggered and eclipsed conformers) was found to be 11 kcal/mol, about twice the DFT values. Using the DFT//PM3(tm) approach, we obtained an energy barrier of 3.8 kcal/mol, much closer to the value computed using the DFT//DFT approach.

In the present paper we use the PM3(tm)//PM3(tm), DFT//PM3(tm), and DFT//DFT energies to compute the energy barrier to CO migration in the $Mn_2(CO)_6(dppm)_2$ model system, in order to gauge the predictability of each method. The paper is divided into two sections, the first dealing with

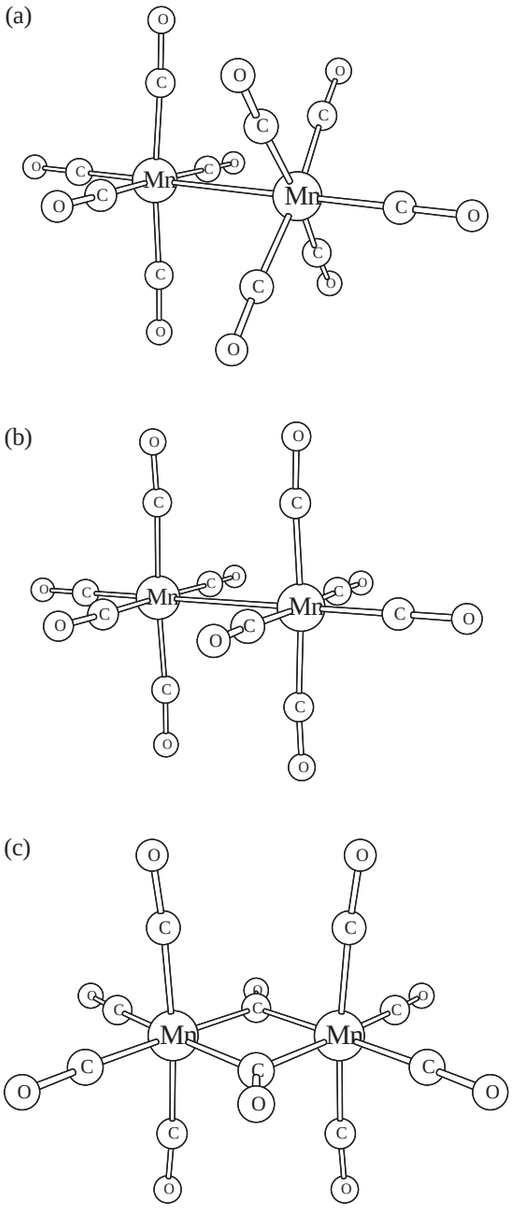
Fig. 1. The conformers of $Mn_2(CO)_{10}$ involved in CO migration: (*a*) staggered (D_{4d}), (*b*) eclipsed (D_{4h}), and (*c*) symmetrically bridged (D_{2h}).



geometric structures and the second discussing the relative energies of the conformers involved in the scrambling process and the resulting activation barrier for the process.

2. Computational methods

To simplify the problem and reduce the computational cost, the phenyl rings of the bidentate dppm ligand were replaced with hydrogen atoms, giving the bis(dihydrophosphino)-methane (dhpm) ligand. Assuming that carbonyl scrambling in both the experimental $Mn_2(CO)_6(dppm)_2$ and model $Mn_2(CO)_6(dppm)_2$ systems proceeds via the pairwise exchange (merry-go-round) mechanism, the PM3(tm) semiempirical method was employed to optimize the geometries and determine the energies of the conformers that play an integral role in the scheme. In addition, structural parameters were optimized for $Mn_2(CO)_5(dhpm)_2$ and the parent $Mn_2(CO)_6(dppm)_2$ system. All geometries, with the exception of one of the $Mn_2(CO)_6(dppm)_2$ conformers with constrained angles (see below), were fully optimized using analytical gradient techniques, and the nature of the resulting stationary point was characterized by harmonic vibrational analysis at the PM3(tm) level. The Hessian was not obtained for the $Mn_2(CO)_6(dppm)_2$ conformers due to their significant size and the computational cost involved, even at the semiempirical level of theory. The choice of semiempirical method was based solely on the availability of parameters for Mn, and the unpublished PM3(tm) parameters in the Spartan program[3] were used.

To obtain a more reliable estimate of the activation barrier, the total energies of the $Mn_2(CO)_6(dppm)_2$ conformers involved in the carbonyl migration were computed via single-point energy calculations at their respective PM3-optimized geometries using density functional theory. Several density functionals were employed: BLYP (Becke's nonlocal exchange functional (14) in conjunction with the nonlocal correlation functional of Lee, Yang, and Parr (15)), BP86 (Becke's nonlocal exchange functional (14) coupled with Perdew's nonlocal correlation functional (16)), B3LYP (comprised of Becke's three-parameter hybrid gradient-corrected exchange functional (17) coupled with the gradient-corrected correlation functional of Lee, Yang, and Parr (15)), and B3PW91 (Becke's three-parameter hybrid gradient-corrected exchange functional (17) in conjunction with the gradient-corrected correlation functional of Perdew and Wang (18)). The effective core potentials (ECPs) of Stevens et al. (19) were used for all heavy atoms. In DFT calculations, ECPs have been shown to yield results close to experiment and of equivalent accuracy to that of all-electron calculations for a variety of transition metal complexes at a much reduced computational cost (3, 4). The valence space contractions used were as follows: P, C, and O (31/31/1*) and Mn (4211/4211/3111). The *d* polarization functions for the main-group elements were taken from the compilation of Huzinaga (20). The 3-21G basis set was used for the H atoms (21). The same basis set was used in DFT calculations with the BLYP functional to optimize the geometries of the conformers involved in the scrambling process, yielding a DFT//DFT value for the energy barrier. All of the DFT calculations were carried out using the Gaussian94 program (22).

3. Results of calculations and discussion

A. PM3(tm) Predicted structures

1. $Mn_2(CO)_6(dppm)_2$

The geometrical parameters of five different conformers of $Mn_2(CO)_6(dppm)_2$ and the lowest energy conformer of $Mn_2(CO)_5(dhpm)_2$, as calculated with the PM3(tm) method, are listed in Table 1 along with the experimental crystal structure values from the related complex $Mn_2(CO)_5(dppm)_2$ (23). Conformers A and B (Figs. 2(*a*) and 2(*b*)), differing only in the orientation of the methylene unit, have a planar

arrangement of the CO ligands with two of them symmetrically bridging the Mn atoms. In conformers C and D (Figs. 2(*c*) and 2(*d*)), all of the CO ligands are in the terminal positions but they adopt a pseudo-staggered arrangement, similar to the staggered conformer of $Mn_2(CO)_{10}$ in Fig. 1(*a*). In conformer E (Fig. 2(*e*)), all of the CO ligands occupy terminal positions in a planar arrangement. The following naming convention for the carbonyl ligands is used: In the all-terminal conformers (C and D, Figs. 2(*c*), 2(*d*); E, Fig. 2(*e*)) the *axial* carbonyls are defined to be colinear to the Mn—Mn bond, while the remaining carbonyls are labelled as *equatorial*. In the planar, di-bridged conformers (A and B, Figs. 2(*a*), 2(*b*)) *bridged* is used to label the two μ_2-carbonyls, while *terminal* labels the remaining four carbonyls. For the $Mn_2(CO)_5(dhpm)_2$ complex (conformer F, Fig. 3) *bridged* labels the lone μ_2-CO, *axial* labels the two CO ligands colinear to the Mn—Mn bond, while the two remaining carbonyls are labelled *equatorial*.

Interestingly, whenever the geometry optimization was commenced from a structure in which the six carbonyls were coplanar, the carbonyls in the final optimized structure remained coplanar and two of them became symmetrically bridged (conformers A and B, Figs. 2(*a*), 2(*b*)). This planarity was maintained even though no symmetry constraints were placed on the system (i.e., C_1 point group was used). When the optimization was initiated from a structure with the six carbonyls in a pseudo-staggered arrangement, then the final optimized structure was also pseudo-staggered with all carbonyls in the terminal positions (conformers C and D, Figs. 2(*c*), 2(*d*)). The coplanar, all-terminal species (conformer E, Fig. 2(*e*)) could only be obtained by constraining certain angles. Such behaviour could indicate that the molecule has a very complicated potential energy hypersurface with a large number of local minima.

As illustrated in Table 1, the PM3(tm) method predicts structural parameters that agree reasonably well with the corresponding parameters of $Mn_2(CO)_5(dppm)_2$ (23) given the steric differences between the two phosphine ligands and the presence of a semibridging CO ligand in the experimental complex. This semibridging carbonyl would make the experimental structure resemble a conformation intermediate between the computed symmetrically di-bridging (A, B) and planar, all-terminal (E) conformers. PM3(tm) overestimates the experimental Mn—Mn bond distance by 0.14 Å in the planar, all-terminal conformer (E), not surprisingly, as the semibridging CO ligand should act to bring the Mn atoms closer. The deviation between the experimental Mn—Mn distance and that predicted by PM3(tm) is smaller for the symmetrically di-bridged conformers, around 0.05 Å. The difference could be ascribed to either the shortcomings of PM3(tm), or to crystal packing effects, or both. There also appears to be a significant difference between the computed and experimental Mn—C distance for the equatorial or terminal CO ligands. The experimental distance is much

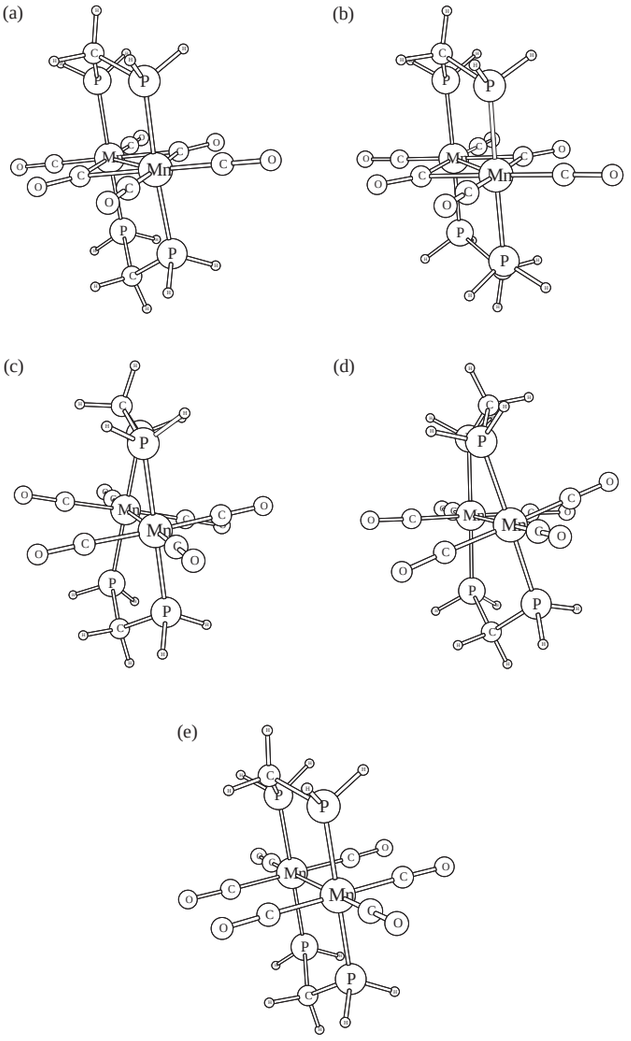
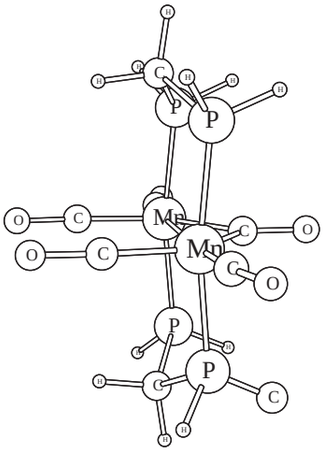
Fig. 2. The conformers of $Mn_2(CO)_6(dppm)_2$: (*a*) *cis*-$Mn_2(CO)_4(\mu_2\text{-}CO)_2(dhpm)_2$ (Conformer A), (*b*) *trans*-$Mn_2(CO)_4(\mu_2\text{-}CO)_2(dhpm)_2$ (Conformer B),(*c*) *cis*-$Mn_2(CO)_6(dhpm)_2$ (Conformer C), (*d*) *trans*-$Mn_2(CO)_6(dhpm)_2$ (Conformer D), (*e*) planar, all-terminal $Mn_2(CO)_6(dppm)_2$ (Conformer E).



shorter (0.07–0.15 Å) than the computed values, and may be due to the different coordination at the Mn atoms in the experimental structure. The Mn atoms have different coordination numbers in the experimental $Mn_2(CO)_5(dppm)_2$ structure and the computed $Mn_2(CO)_6(dppm)_2$ structure. The loss of an equatorial CO ligand in the experimental species should make the Mn atoms more electron rich and thus more capable of back-donation to the remaining equatorial carbonyls, resulting in a shorter Mn—C_{eq} distance. However, as with the Mn—Mn distance, both crystal packing effects and PM3(tm) deficiencies could be contributing to this disagreement. There is good agreement between the PM3(tm)-computed values and experimental values for those parameters least sensitive to the semibridging CO ligand and the differing steric demands of the phosphines, e.g., the Mn—C_{ax}, Mn—P, P—CH_2, and C—O distances.

Fig. 3. The lowest energy conformer of $Mn_2(CO)_5(dhpm)_2$ (Conformer F).



As a further test of the ability of the PM3(tm) method to predict geometric structures of transition metal complexes, we removed one of the bridging CO ligands from conformer A and optimized the resultant $Mn_2(CO)_5(dhpm)_2$ complex (shown in Fig. 3 and labeled as conformer F in Table 1) for comparison with the respective experimental crystal structure. As seen in Fig. 3, the bridging CO ligand is oriented symmetrically between the two Mn atoms, normal to the Mn—Mn bond. As discussed above, the experimental structure, on the other hand, shows the semibridging nature of the CO ligand (being bound to one of the Mn atoms through the C atom and to the other through the C—O triple bond). Apart from the Mn—Mn and Mn—C_{br} distances, predicted to be too long by 0.39 Å and 0.11 Å, respectively, there is quite good agreement between the computed and experimental values for the remaining geometric parameters, with deviations of 0.06 Å or less. Of course the deviation between the computed and experimental Mn-C_{br}-O_{br} bond angle is largest, 125° vs. 173°, reflecting the different bonding nature of the bridging carbonyl ligands. There is reasonable aggreement between computation and experiment for the remaining bond angles, typically less than 5°.

It must be added that conformer F is a minimum on the potential energy surface, reached from several different initial geometries with no symmetry constraints imposed on the system (i.e., C_1 symmetry), as indicated by the results of the harmonic vibrational analysis. One of the lowest frequency modes (42 cm^{-1}) corresponds to the Mn–Mn stretch. This indicates that the potential energy hypersurface is very flat and that the molecule may be easily compressed by the crystal-

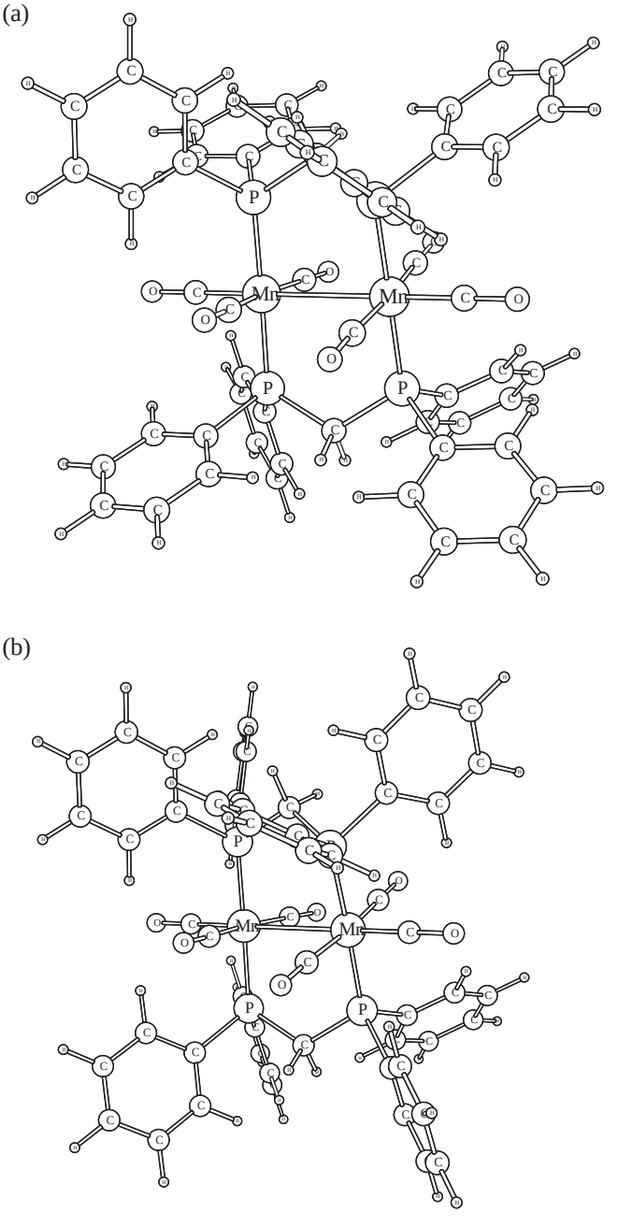
Fig. 4. The two conformers of $Mn_2(CO)_6(dppm)_2$.



line environment, perhaps explaining why in the gas phase our PM3(tm) calculations exaggerate the Mn—Mn distance. As seen in Table 1, this compression may be simulated in the gas phase by the addition of a second bridging carbonyl. Furthermore, several other higher energy conformers, differing in the orientation of the lone bridging CO ligand with respect to the CH_2 groups of the dhpm ligands, were also located.

A comparison of the Mn—Mn distance in the bridged (A and B) and nonbridged, all-terminal (C, D, and E) conformers shows that the formation of the μ_2-carbonyls results in a shortening of the Mn—Mn distance by over 0.1 Å. Contrary to what one would expect from steric and electrostatic considerations, the conversion from a staggered conformation (C and D) to an eclipsed conformation (E) shortens the

[c]Values taken from the crystal structure of the related complex $Mn_2(CO)_5(dppm)_2$ (23).

Mn—Mn bond by 0.02 Å. From the calculated Mn—C distances one can conclude that the terminal carbonyls in the di-bridged conformers (A and B) are bound more strongly to Mn than the equatorial carbonyls, but more weakly than the axial carbonyls of the pseudo-staggered conformers (C and D). In accord with experimental data for symmetrically bridged species (24), the PM3(tm) calculations predict the bridging carbonyls to have the longest Mn—C and C—O distances.

Interestingly, the arrangement of the phosphine moiety is slightly different in the five conformers: the Mn—P distance is shorter, by over 0.02 Å, in the pseudo-staggered conformers (Fig. 3) than in the planar, dibridged species (Fig. 2). Furthermore, the P-CH_2-P angle appears to be more affected by the planarity of the six carbonyls (conformers A, B, and E versus C and D), than the *cis* or *trans* arrangement of the methylene unit in the bidentate phosphine ligand (conformers A, C, and E versus B and D).

At the PM3(tm) level the stationary points corresponding to the optimized geometries of conformers A, B, C, and D were all found by harmonic vibrational analysis to be local minima. The planar all-terminal conformer E was found to be a second-order saddle point (with very small imaginary frequencies of 25*i* and 13*i* cm^{-1}). The vibrational mode for the frequency of 25*i* corresponds to the scrambling motion of the carbonyls towards the planar, di-bridged conformer A, while the other one corresponds to rotation about the Mn—Mn bond to form the pseudo-staggered conformer C. Furthermore, in each conformer about one third of the computed vibrational frequencies are smaller than 500 cm^{-1}, in-

dicating a very flat potential energy hypersurface near the local minima.

The DFT-optimized Mn—Mn bond length in conformer A was shorter than the value obtained using the PM3(tm) method, while in conformer E DFT predicts a longer Mn—Mn bond than PM3(tm). As discussed above for the $Mn_2(CO)_5(dhpm)_2$ system (conformer F), the absence of bridging carbonyls in conformer E brings about a longer Mn—Mn bond. Compared with PM3(tm), DFT also predicts longer Mn—C distances for the axial and equatorial/terminal carbonyls for both conformers, and a shorter Mn—C_{br} distance in conformer A. Interestingly, in both conformers the geometry of the dhpm ligand computed at the DFT level is different from its PM3(tm) geometry, as indicated by the significant changes in the Mn—P and P—CH_2 distances and the P-CH_2-P angle. As illustrated in Table 1, all of the remaining DFT-optimized bond lengths and angles agree reasonably well with their PM3(tm) counterparts.

2. $Mn_2(CO)_6(dppm)_2$

Geometry optimizations at the PM3 level of theory were performed for the two different conformers of $Mn_2(CO)_6(dppm)_2$ shown in Fig. 4, differing only in the tilt angle of the plane of the phenyl rings. For both conformers, the PM3 calculations (Table 2) predict a pseudo-staggered arrangement of carbonyls, similar to that observed in the $Mn_2(CO)_6(dppm)_2$ system (Figs. 2(*c*) and 2(*d*)), with dihedral angles deviating from planarity by 14°–17°. (The pseudo-staggered conformation was obtained even when the optimization was initiated from a structure with a coplanar arrangement of carbonyls.) The differences in bond lengths between the axial and equatorial carbonyls and the Mn atom suggest stronger binding of the axial carbonyls to the metal atom, as observed in the dhpm conformers. As stated before, there is no experimental structure known for $Mn_2(CO)_6(dppm)_2$, and although the X-ray crystal structure is known for $Mn_2(CO)_5(dppm)_2$ (23), the presence of the semibridging CO ligand is expected to induce a number of structural changes, as discussed above for the dhpm complex. As seen in comparison with the computed dhpm structures, the experimental Mn—Mn distance is shorter than that predicted by the PM3(tm) calculations. Again, the agreement is quite satisfactory for those parameters least likely to be affected by the semibridging carbonyl (M—C_{ax}, P—C, and C—O distances). The agreement becomes worst for the M—P distance and M—CO_{eq} distance, perhaps reflecting the sensitivity of these parameters to the presence of the semibridging CO ligand, the tilt of the phenyl rings of the dppm ligands, and, possibly, crystal packing effects or shortcomings of the PM3(tm) methodology.

The differences in the geometric structures of the two conformers are negligible, with conformer A more stable by 5 kcal/mol. It is interesting to note that a slight change in the tilt of the phenyl rings was a sufficient structural perturbation to locate a completely different stationary point on the potential energy hypersurface. This, along with the fact that we failed to locate a structure with a planar conformation of CO ligands, again suggests a very complicated potential energy hypersurface with a large number of shallow local minima, leading to significantly different structures with similar total energies. The size of these systems prevented the characterization of the stationary points corresponding to the optimized geometries by harmonic vibrational analysis, even at the PM3(tm) level.

B. Relative energies and the barrier to CO migration

The relative energies of the different conformers of $Mn_2(CO)_6(dhpm)_2$ are shown in Table 3. The PM3(tm)//PM3(tm) calculations predict conformers A and B with a coplanar arrangement of CO ligands, two of which are symmetrically bridging the two Mn atoms, to be the lowest in energy. The total energy of the planar, all-terminal conformer E is 32 kcal/mol above the energy of conformer A. The pseudo-staggered conformers C and D have energies about 29 kcal/mol higher than that of A. The PM3(tm)//PM3(tm) approach finds a slight preference for a *cis* arrangement of the methylene units in the two bidentate dhpm ligands, in agreement with the arrangement found in the crystal structure of $Mn_2(CO)_5(dppm)_2$.

The results obtained at the PM3(tm)//PM3(tm) level imply that carbonyl scrambling in the model $Mn_2(CO)_6(dppm)_2$ system proceeds from the coplanar, symmetrically bridged conformation (A and B) to the coplanar, all-terminal conformer E, and then back to A/B, with an activation barrier of about 32 kcal/mol. This energy barrier is higher than the upper limit for an NMR-detectable process (ca. 25 kcal/mol (7)) and much higher than the barrier of 10 kcal/mol reported by Marsella and Caulton (12). This finding is consistent with the overestimated PM3(tm)//PM3(tm) energy barrier for rotation about the Mn—Mn bond in $Mn_2(CO)_{10}$ (13).

We employed the DFT//PM3(tm) scheme, with several density functionals, to calculate the total energies and the energy barrier to carbonyl scrambling in the model

© 1999 NRC Canada

$Mn_2(CO)_6(dppm)_2$ system. The results, collected in Table 3, show that all of the density functionals predict a stability trend opposite to that found at the PM3(tm)//PM3(tm) level. The planar, all-terminal conformer E is found to have the lowest energy, smaller by 15–19 kcal/mol than the energy of the planar, symmetrically bridged conformer A. The DFT//PM3(tm) calculations predict the pseudo-staggered conformer C to lie 0.3–0.7 kcal/mol above the lowest-energy conformer E. Hence, based solely on the computed energy differences, the DFT//PM3(tm) approach models the carbonyl scrambling in $Mn_2(CO)_6(dppm)_2$ as proceeding from the planar, all-terminal conformer E to the planar, di-bridged conformer A, and back to conformer E. This mechanism is similar to that predicted for carbonyl scrambling in $Mn_2(CO)_{10}$ in our previous DFT//DFT study (13). Depending on the functional used, the DFT//PM3(tm) approach yields an energy barrier of 15–19 kcal/mol for carbonyl migration in the $Mn_2(CO)_6(dppm)_2$ system, nearly halved with respect to the PM3(tm)//PM3(tm) barrier. These values are smaller than the upper limit for NMR detectable processes (25 kcal/mol (7)) and closer to the value of 10 kcal/mol estimated from NMR experiments by Marsella and Caulton (12). Using the total energies of conformers A and E at their respective DFT-optimized geometries (DFT//DFT), the energy barrier for scrambling is reduced to only 13 kcal/mol. We expected a further lowering of the DFT//PM3(tm) energy barrier upon reoptimization of the geometries using the DFT approach since the PM3(tm) parameters were not trained on any bridging systems similar to the one studied here.[4]

4. Conclusions

The PM3(tm) semiempirical method successfully locates the local minima involved in CO migration, and gives an indication of the flatness of the surface, as illustrated by the large number of low vibrational frequencies. Although the experimental structure data were obtained from a crystal structure of $Mn_2(CO)_5(dppm)_2$ (23) in which one of the carbonyls was semibridging in nature, the agreement between the experimental and the PM3(tm)-optimized $Mn_2(CO)_6(dppm)_2$ and $Mn_2(CO)_5(dhpm)_2$ geometries was very good for those structural parameters least likely to be affected by the presence of the semibridging carbonyl and the different steric demands of the dppm ligand. The deviations are largest for the Mn—Mn, Mn—CO_{br}, and Mn—CO_{eq} distances, and may be attributed to the chemical differences between the experimental and calculated complexes, and to shortcomings of the PM3(tm) method. In addition, crystal packing effects may be quite large for the flat $Mn_2(CO)_n(dhpm)_2$ potential energy hypersurfaces.

The PM3(tm)//PM3(tm) energy barrier of 32 kcal/mol for CO scrambling in $Mn_2(CO)_6(dppm)_2$ is vastly overestimated compared to the experimental value of 10 kcal/mol. The barrier was reduced by a factor of two using energies from DFT calculations at the PM3(tm)-optimized geometries. In addition, the relative energy ordering of conformers was changed. Using the DFT//PM3(tm) scheme, carbonyl scrambling was found to proceed in a manner similar to that predicted for $Mn_2(CO)_{10}$ using the DFT//DFT approach: from the planar, all-terminal conformation to a planar, di-bridged conformation and then back to the original conformation with an energy barrier of 15–19 kcal/mol, depending on the functional employed. The DFT//PM3(tm) method successfully improves the energy barrier obtained when the PM3(tm) is used throughout; however, the barrier is still overestimated by 5–10 kcal/mol. This value was reduced even further to 13 kcal/mol upon optimization of the structures using DFT, overestimating experiment by only 3 kcal/mol. This improvement was expected, since the training set used to develop the PM3(tm) parameters contained more complexes with terminal carbonyls than bridging carbonyls; as a result the lowest energy all-terminal conformer E should be better represented at the PM3(tm) level than the symmetrically bridged conformer A.

Since semiempirical methods rely on experimental data for the training of parameters, the results of these semiempirical calculations will be close to experiment as long as the calculated molecules resemble those in the training set. It has been established that the modern DFT approach brings about results close to experiment for a variety of transition metal complexes (2). Given the sparsity of reliable structural data, especially for molecules containing transition metal atoms, an alternative approach to the parametrization of semiempirical methods could utilize these reliable DFT results. In this approach, the semiempirical parameters would be derived not from experimental data, but rather from quantities calculated using accurate DFT methods in conjunction with very large extended basis sets, leading to a *semitheoretical method*.

Acknowledgments

This study was inspired by a lecture given by Professor J. Takats at the University of Alberta. Subsequent discussions with Professor Takats are gratefully acknowledged. M.K. is grateful to Professor W.A.G. Graham for enlightening comments on the nature of bridging carbonyls. The calculations were done on the IBM RS/6000 workstations and on the IBM SP2 installation at the University of Alberta. This work was financed partly by a research grant from the Natural Sciences and Engineering Research Council of Canada (NSERC), and partly by the University of Alberta. S.A.D. would also like to thank the Faculty of Graduate Studies at the University of Alberta for a scholarship and the Department of Chemistry for the Harry Emmett Gunning Graduate Fellowship.

Dioxirane oxidation of nitrosoamines. An ab initio study

Gennady V. Shustov and Arvi Rauk

Abstract: Pathways for oxidation of the parent nitrosoamine **2**, nitrosodimethylamine **3**, and *anti*-nitrosoethylmethylamine **4** by the parent dioxirane **1** have been explored computationally using the B3LYP hybrid density functional theoretical method in conjunction with the 6-31G* and 6-311+G** basis sets. Oxygen transfer from **1** to the nitrogen of the NO group (NO oxidation), yielding nitroamines **5**, **7**, and **10**, has the lowest activation barrier (15, 12.8, and 12 kcal mol^{-1} for **2**, **3**, and *anti*-**4**, respectively). Oxidation of the amine nitrogen (N oxidation) in **2**, **3** leads to nitric oxide and nitroxyl radicals **6**, **8** and is characterized by the highest activation energy: 28.5 kcal mol^{-1} for **2**, 22.3 kcal mol^{-1} for **3**. The potential barrier to hydroxylation of the methyl groups in **3** (CH oxidation) is intermediate — ca. 19 kcal mol^{-1}. Introduction of a methyl group to the carbon reaction centre decreases the activation barrier of the *anti*-CH oxidation by 2–3 kcal mol^{-1}. In **3**, a gas-phase small preference for *anti*-CH oxidation over *syn*-CH oxidation, 0.1 kcal mol^{-1}, is predicted to increase dramatically to 4.7 kcal mol^{-1} when the reaction is carried out in a dielectric medium (acetone, IPCM model). In general, polar solvents (CH_2Cl_2, acetone) lower the activation barriers for the NO, N, and CH oxidations, more so for the species of higher polarity than those of lower polarity (reactive complexes (**1+3**), (**1**+*anti*-**4**), transition state *anti*,*syn*-$\mathbf{TS_{CH}}$ **(1+4)**]. However, the chemoselectivity ($E_a^{NO} < E_a^{anti\text{-}CH} < E_a^{syn\text{-}CH} < E_a^{N}$) in the polar solvents is predicted to be the same as in the gas phase.

Key words: dioxirane, nitrosoamines, oxidation, ab initio, computation.

Résumé : En se basant sur des calculs faisant appel à la méthode théorique de la densité fonctionnelle hybride B3LYP en conjonction avec des ensembles de base 6-31G* et 6-311+G**, on a examiné les diverses voies réactionnelles pour l'oxydation de la nitrosamine (**2**), de la nitrosodiméthylamine (**3**) et de l'*anti*-nitrosoéthylméthylamine (**4**) par le dioxirane (**1**). Le transfert d'oxygène de **1** vers l'azote du groupe NO (oxydation de NO), conduisant aux nitramines **5**, **7** et **10** donne lieu à la barrière d'oxydation la plus faible (respectivement 15, 12,8 et 12 kcal mol^{-1} pour **2**, **3** et *anti*-**4** respectivement). L'oxydation de l'azote de l'amine (oxydation de l'azote) des composés **2** et **3** conduit à l'oxyde nitrique et aux radicaux nitroxyles **6** et **8** et elle est caractérisée par une énergie d'activation plus élevée 28,5 kcal mol^{-1} pour **2** et 22,3 kcal mol^{-1} pour **3**. La barrière de potentiel pour l'hydroxylation des groupes méthyles de **3** (oxydation d'un CH) est intermédiaire, soit environ 19 kcal mol^{-1}. L'introduction d'un groupe méthyle au centre réactionnel carboné diminue la barrière d'activation de l'oxydation du *anti*-CH par 2 à 3 kcal mol^{-1}. Lors de l'oxydation du composé **3** en phase gazeuse, on prévoit une légère préférence (0,1 kcal mol^{-1}) pour l'oxydation du CH *anti* par rapport au CH *syn*; cette différence croît d'une façon dramatique (à 4,7 kcal mol^{-1}) lorsque la réaction serait effectuée dans un milieu diélectrique (acétone, modèle IPCM). En général, les solvants polaires (CH_2Cl_2, acétone) conduisent à des barrières d'activation plus faibles pour les oxydations de NO, de N ou de CH; ceci est plus vrai pour les espèces de polarité élevée que pour celles de faible polarité (complexes réactifs (**1+3**), (**1**+*anti*-**4**) état de transition *anti*,*syn*-$\mathbf{ET_{CH}}$ **(1+4)**). Toutefois, on prévoit que la chimiosélectivité sera la même dans des solvants polaires qu'en phase gazeuse ($E_a^{NO} < E_a^{anti\text{-}CH} < E_a^{syn\text{-}CH} < E_a^{N}$).

Mots clés : dioxirane, nitrosamines, oxydation, ab initio, calcul théorique.

[Traduit par la Rédaction]

Introduction

Oxidation of nitrosodialkylamines continues to be a matter of intense, current interest, mainly because it is the main path of metabolism and metabolic activation (1–5). In addition, oxidation is offered (6–8) as one of the most effective methods for removing these highly carcinogenic, mutagenic, and toxic substances from wastewater of rocket fuel, metallurgical and food industries. Finally, oxidation of nitrosodialkylamines can be used for the preparation of *N*-nitroamines — highly energetic materials (9–12).

In general, two kinds of oxidative processes have been studied. The first one is the reactions of nitrosodialkylamines with various oxidants (O_2, H_2O_2, PhIO, hydroperoxides, peracids) in the presence of catalysts — salts (13, 14) and complexes of metals (Fe, Mn) (15). In the catalytic processes, oxidation of an alkyl group of a nitrosodialkylamine occurs usually at the α-carbon atom, forming α-hydroxy-*N*-nitro-

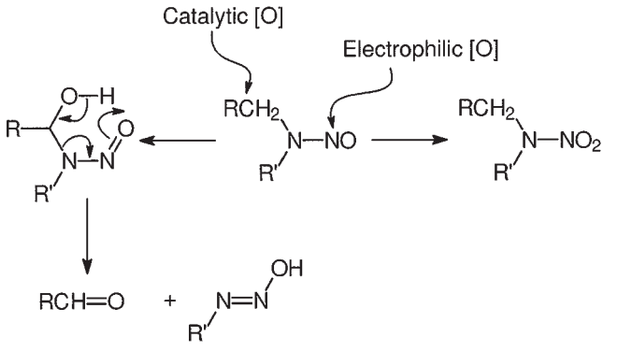
Scheme 1.

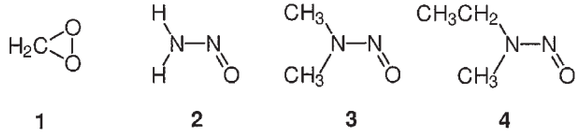


soamines which undergo further fragmentation (Scheme 1) (16–18). This kind of oxidation includes also metabolic degradation mediated by cytochromes P-450 (1–5).

The second kind is electrophilic oxidation by peracids (9–11) or concentrated HNO_3 in the presence of trifluoroacetic anhydride (12). The electrophilic oxidants attack the nitrogen of the nitroso group, yielding the corresponding *N*-nitroamines (Scheme 1).

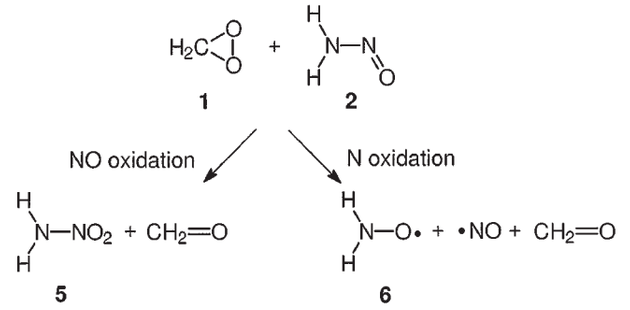
Dioxiranes, which have proved to be powerful and selective oxidants (18–23), nevertheless, have not yet been employed for oxidation of nitrosodialkylamines. It was reported that the efficacy of the dioxirane oxidation of aliphatic CH bonds in organic substrates approaches the efficacy of enzyme oxidation (18–25). The presence of an electron-donating group in the α-position to the CH bond accelerates the dioxirane oxidation (24). At the same time, in reactions with alkylamines, dioxiranes behave as electrophilic oxidants and attack the nitrogen atom of the amino group (26–28). Electrophilicity of dioxiranes reveals itself also in reactions with sulfides and sulfoxides (29, 30). Hence, in nitrosodialkylamines, the probable points for the dioxirane attack can be both nitrogen atoms as well as an α-CH bond. It is not obvious which of these sites is the most vulnerable because, unlike the nitrogen in alkylamines, the nitrogens in nitrosodialkylamines are substantially less nucleophilic. In addition, the reactivity of the CH bonds in *syn*- and *anti*-alkyl groups should be different. Therefore, it is of interest to study, firstly, the mechanism of the dioxirane oxidation of nitrosoamines and, secondly, the chemo- and regioselectivity of this oxidation. Knowledge of the selectivity is important for the practical use of dioxiranes for oxidation of nitrosodialkylamines.

Here we describe a theoretical study of the dioxirane oxidation of nitrosoamines. Reactions of the parent dioxirane **1** with the parent nitrosoamine **2**, nitrosodimethylamine **3**, and *anti*-nitrosoethylmethylamine **4** were chosen as theoretical models.



1 **2** **3** **4**

Scheme 2.



5 **6**

Earlier, theoretical studies of the dioxirane oxidations of heteroatoms in organic substrates were performed using the B3LYP hybrid density functional theory (28) and MP2 methods (28, 30). Recently, we showed (24) that the MP2 method is not appropriate for the description of the dioxirane oxidation of aliphatic CH bonds, whereas the B3LYP method gives results agreeing with experiment. Therefore, the latter method was employed in the present work.

Computational methods

All calculations presented here were performed with the Gaussian 94 system of programs (31). The geometry optimizations and frequency calculations were carried out at the B3LYP hybrid density functional theory level with the internal 6-31G* and 6-311+G** basis sets using procedures implemented in the Gaussian molecular orbital package. Harmonic frequency analysis verified the nature of the stationary points as minima (all real frequencies) or as transition structures (one imaginary frequency) and was used to provide an estimate of the zero-point vibrational energies (ZPVE). Zero-point corrections (ΔZPVE) were scaled by a 0.98 factor. Total energies and ZPVEs of all species are given in Tables S-1, S-2, and S-3, which are included as supplementary material.[2]

The intrinsic reaction coordinate (IRC) (32, 33) path was traced in order to check the B3LYP/6-31G* energy profiles for the reactions of the parent dioxirane **1** with nitrosoamine **2**.

The effects of dielectric medium were simulated at the B3LYP/6-311+G** level by single-point SCRF calculations with the IPCM model (34) as implemented in Gaussian 94.

Results and discussion

Parent nitrosoamine – parent dioxirane

For the parent system, dioxirane **1** – nitrosoamine **2**, the possibility of the dioxirane attack on the two sites of nitrosoamine **2** — on the nitrogen of the nitroso group (NO oxidation) and on the amine nitrogen (N oxidation) — has been explored (Scheme 2).

NO oxidation

Dioxirane **1** attacks the nitrogen of the nitroso group along the axis of the nitrogen lone pair, revealing itself as an electrophilic oxidant. A substantial elongation of the O—O

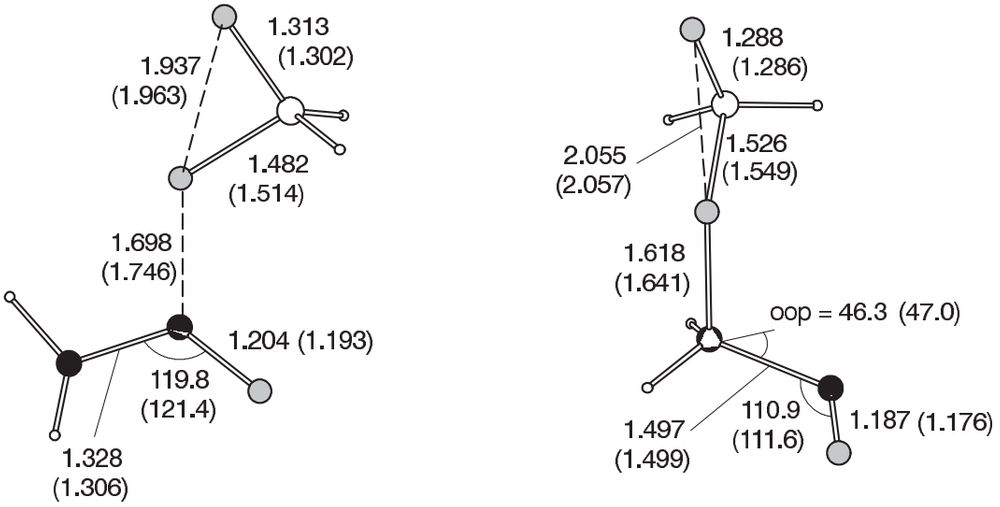
reactive complex (1+2)



TS_{NO}(1+2) **TS_{N}(1+2)**

bond in the transition state of the NO oxidation, **TS_{NO}(1+2)** (Fig. 1), indicates a dominant role of the antibonding σ^*_{OO} orbital, which determines the electrophilic properties of the dioxirane. The dioxirane ring takes up a position in the average plane of the nitrosoamine group.

The path of the reaction of dioxirane **1** with nitrosoamine **2** to nitroamine **4** via transition state **TS_{NO}(1+2)** was confirmed by the IRC-B3LYP/6-31G* calculation. It was found that the reactants form a reactive complex **(1+2)** (Fig. 1*a*), which lies somewhat lower in energy (–2.9 kcal mol^{-1}) than its predecessors. It is interesting that in this complex, the dioxirane ring settles in a plane, which is almost perpendicular to the average plane of the nitrosoamine. Full geometry optimization of complex **(1+2)** led to formation of the hydrogen bond between an oxygen of the dioxirane ring and the *anti*-hydrogen of the nitrosoamine (Fig. 1*b*). The relative energy of the complex was decreased to –5.5 kcal mol^{-1}, apparently owing to this hydrogen bond.

In **TS_{NO}(1+2)**, the σ^*_{OO} orbital of dioxirane **1** interacts with the nonbonding orbital of the nitrogen of the nitroso

anti,syn-**TS_{CH}(1+4)**

group, which is a principal component of the HOMO of nitrosoamine **2**. Hence, the NO oxidation is characterized by a rather low potential barrier (15.0 kcal mol^{-1}). This barrier is close to the barrier (12.2 kcal mol^{-1}) of the N oxidation of methylamine with dimethyldioxirane, calculated at the same theoretical level (28). However, the reaction with nitrosoamine is substantially more exothermic (–48.5 kcal mol^{-1}) than the reaction with methylamine (–18.9 kcal mol^{-1}) (28).

N oxidation

Upon formation of the transition state for the oxidation of the amino N (N oxidation), **TS_N(1+2)**, dioxirane **1** approaches also along the axis of the nitrogen lone pair (Fig. 1). The *gauche*-orientation of the dioxirane ring with respect to the N—N bond is apparently caused by a secondary interaction of the nonbonded orbital (*n*) of the dioxirane oxygen atom with the antibonding σ* orbital of this bond (Chart 1).

Investigation of the reaction path of the N oxidation by means of an IRC-B3LYP/6-31G* calculation revealed that the products of the reaction, besides formaldehyde, are nitroxyl **5** and nitric oxide (Fig. 2). This implies that the expected nitrosoamine N-oxide is not a minimum on the $CH_2N_2O_3$ potential-energy surface.

The nonbonding orbital of the amine nitrogen of nitrosoamine **2** is in conjugation with the π^*_{NO} orbital making this nitrogen a poor electron donor. As a result, the activation barrier for the N oxidation is almost twice as high as the barrier for the NO oxidation (Table 1). As in the case of methylamine oxidation, the exothermicity of the reaction is lower than the exothermicity of the NO oxidation.

Nitrosodimethylamine 3 – parent dioxirane

Besides the NO and N oxidations, the CH oxidation of the *syn*- and *anti*-methyl groups has been studied in nitrosodimethylamine **3** (Scheme 3).

NO and N oxidations

Introduction of the methyl groups to the amine nitrogen leads to a decrease of the potential barriers of the NO and N oxidations by ca. 2 and 5.5 kcal mol^{-1}, respectively. Naturally, the barrier of the amino N oxidation is more sensitive because the introduction is carried out directly at the reaction centre. In spite of this, the energy of activation for the NO oxidation remains substantially lower than the energy of activation for the N oxidation (Table 2).

Qualitatively the geometries of transition states **TS_{NO}(1+3)** and **TS_N(1+3)** (Fig. 3) are similar to those for the parent system, whereas the geometry of the reactive complex of the NO oxidation is quite different. For the dimethyl system, this complex has a "proper" geometry, i.e., the dioxirane ring settles in the average plane of the nitrosoamino group as it does in **TS_{NO}(1+3)**. Complex **(1+3)** is relatively less stable with respect to its precursors (Table 2) than complex **(1+2)** because of the lack of the hydrogen bond, which stabilizes the latter.

CH oxidation

It was recently shown (24, 25) that the transition state of the dioxirane oxidation of aliphatic CH bonds corresponds

to electrophilic oxygen insertion with a pronounced hydride transfer character and some diradical character. Electron-donating substituents at the reaction carbon atom of the substrate decrease the activation barrier for this reaction.

A similar nature is apparently inherent in the transition state of the oxidation of the CH bonds in nitrosoamine **3**. In both isomers, *syn*- and *anti*-$\mathbf{TS_{CH}(1+3)}$, the breaking CH bond settles almost perpendicularly to the average plane of the nitrosoamine group (Fig. 4). In such geometry, the orbital interactions between the reaction centre and the amine nitrogen is maximum, although the *n* orbital of this nitrogen is involved in the competitive conjugation with π^* orbital of the N=O bond. As a result of this conjugation, the ability of the amine nitrogen to stabilize the hydride transfer is weakened. In fact, the activation barrier for the dioxirane oxidation of the CH bonds in nitrosodimethylamine **3** (ca. 19 kcal mol^{-1})

anti,syn–TS_{CH}**(1+4)**

is closer to the barrier for methanol (19.9 kcal mol^{-1}) than for methylamine (10.4 kcal mol^{-1}), calculated at the same theoretical level (24).

The *gauche* orientation of the dioxirane ring with respect to the C—N bond in *syn*- and *anti*- TS_{CH}**(1+3)** (Chart 1, Fig. 4) is determined by the secondary n-σ^* orbital interaction, as in the case of the CH oxidation of methanol (24).

The mechanism of the dioxirane oxidation of the aliphatic CH bonds and, correspondingly, the intrinsic nature of its transition state continues to be a matter of lively discussion (24, 25, 35). Experimental data may be interpreted (19–23, 35) so as to support both electrophilic oxygen insertion and a free-radical mechanism via a molecule-induced homolysis of the O—O bond of the dioxirane (35). The discovery (24)

Scheme 4.

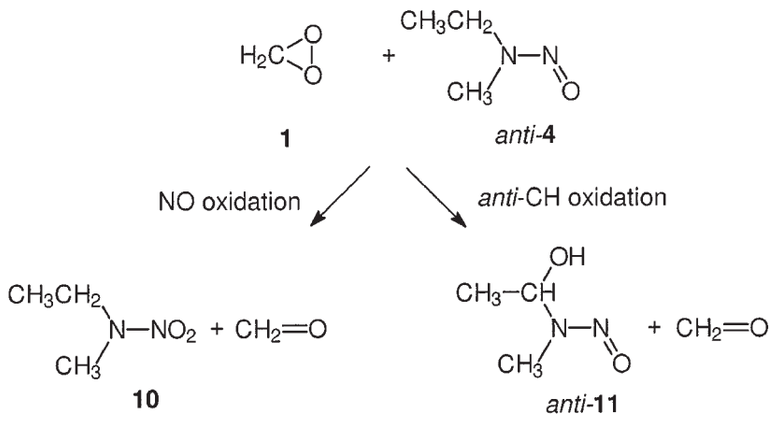

Chart 2.

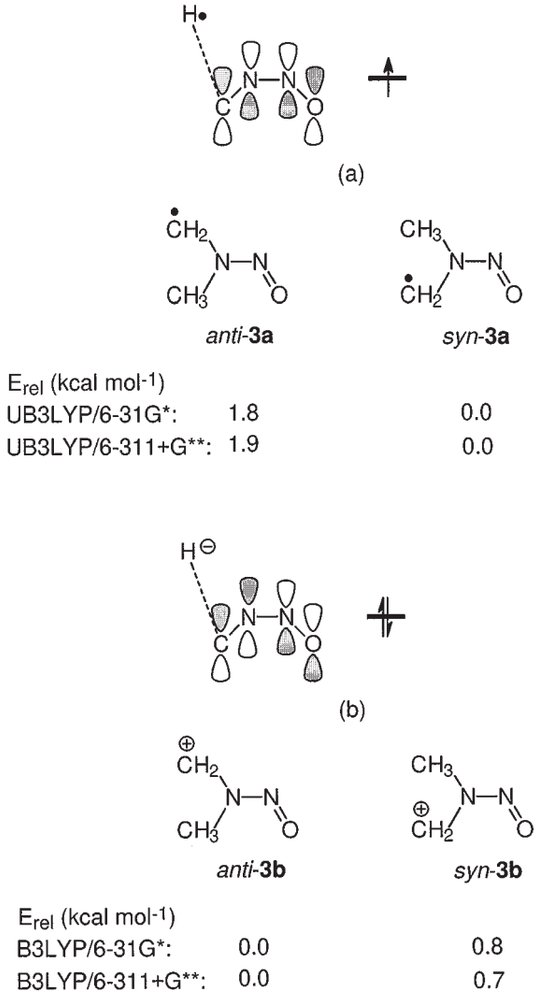

of a bifurcation in the reaction path subsequent to the transition state for CH oxidation of methane suggests a mechanistic compromise. At the bifurcation point, the system can convert into a radical pair or relax straightforwardly into the products of electrophilic oxygen insertion, i.e., the corresponding alcohol and carbonyl compound. Obviously, a greater diradical character of the transition state increases the probability of the conversion into the radical pair at the bifurcation point and vice versa.

The dominant character of the transition state for the CH oxidation of nitrosoamine **3** can be revealed from the *syn*- versus *anti*-regioselectivity of the reaction. Let us examine nodal characteristics of the highest occupied π-like orbitals of the nitrosoamine fragment of $\mathbf{TS_{CH}(1+3)}$. These will be different depending on whether the transition state involves primarily hydrogen atom transfer (i.e., has free-radical character) (Chart 2*a*) or hydride transfer (i.e., has electrophilic character) (Chart 2*b*). In the first case, the singly occupied fragment orbital is in phase at the two ends, and one can expect an extra stabilization of the *syn*-transition state.[3] In the second case, the frontier orbital is doubly occupied, out of phase at the two ends, and the *syn*-transition state would be destabilized by the out-of-phase interaction of the terminal p AOs. This qualitative picture is confirmed by calculations of the relative stability of the *syn*,*anti*-isomers of model compounds — C-radical **3a** and C-cation **3b**. It was found that the *syn*-isomer is more stable for C-radical **3a**, whereas C-cation **3b** prefers the *anti*-configuration (Chart 2). Thus, dominant radical character in $\mathbf{TS_{CH}(1+3)}$ should lead to *syn*-regioselectivity and dominant hydride transfer character to the *anti*-regioselectivity.

The calculations at the B3LYP/6-311+G** level give a small preference (0.1 kcal mol^{-1}) to *anti*-$\mathbf{TS_{CH}(1+3)}$ over its *syn*-isomer in the gas phase. However, as it will be shown below, the *anti*-regioselectivity becomes considerable when the influence of a dielectric medium is taken into account. All these data confirm the supposition that the transition state of the dioxirane oxidation of the aliphatic CH bonds has mainly the hydride transfer character.

anti-Nitrosoethylmethylamine – parent dioxirane

As it follows from above, the oxidations of the nitroso group and the C—H bond of the *anti*-methyl group are the

[3] Such stabilization was considered earlier for *syn*-α-C anions of nitrosodialkylamines (36).

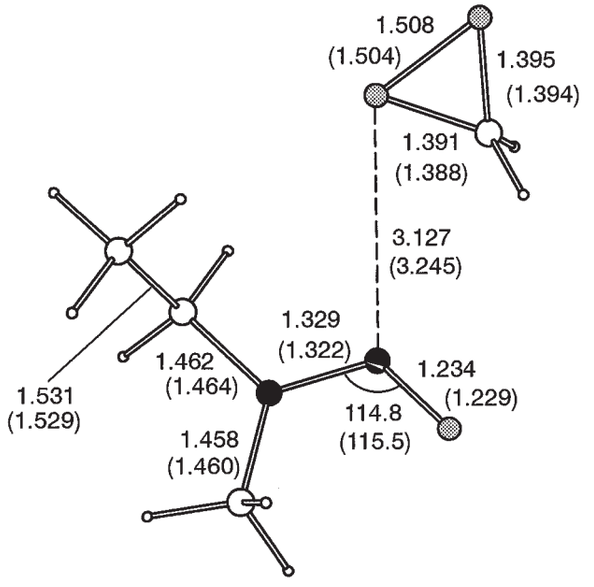
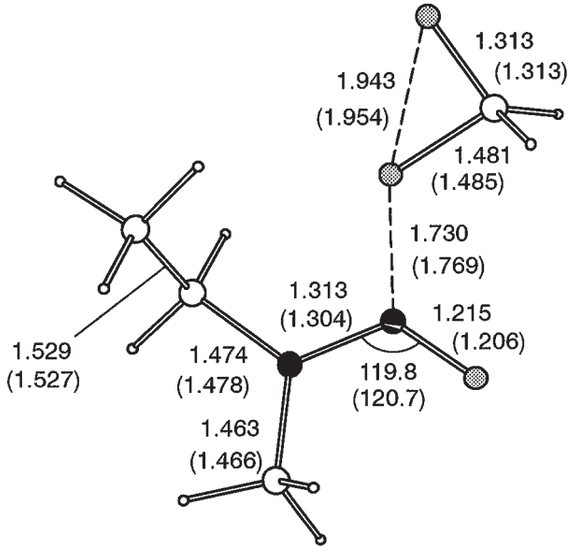
Fig. 5. B3LYP structures of the reactive complex and concerted transition state for the NO oxidation of nitrosoethylmethylamine **4** with the parent dioxirane **1** calculated with the 6-31G* and 6-311+G** (in parentheses) basis sets. Bond lengths are given in angstroms and angles in degrees.



reactive complex (1+*anti*–4)



***anti*–TS$_{NO}$(1+4)**

main competing processes in the interaction of dioxirane **1** with nitrosodimethylamine **3**. A difference in activation energies of these processes is 5.8 kcal mol^{-1} in favor of the NO oxidation. It was earlier (24) found for the CH oxidations of methanol and ethanol by dioxirane **1** that the introduction of the methyl group to the reaction centre of the substrate decreases the potential barrier for the reaction by 5.5 kcal mol^{-1} (B3LYP/6-311+G**, gas phase) owing to the electron donor ability of the methyl group. Hence, one can suppose equalization of the rates of the NO and *anti*-C oxidations or inversion of their ratio in higher nitrosodialkylamines. To check this supposition, we have studied the NO and *anti*-C oxidations in *anti*-nitrosoethylmethylamine **4** (Scheme 4).

NO oxidation

The optimized geometries of reactive complex **(1**+*anti*-**4)** and transition state *anti*-$\mathbf{TS_{NO}(1+4)}$ (Fig. 5) are practically the same as in the case of nitrosodimethylamine **3** (Fig. 3). The C-methyl group takes a position almost perpendicularly to the average plane of the nitrosoamine group and does not impede the dioxirane attack on the nitroso group that proceeds in this plane. As a result, the relative energies of complex **(1**+*anti*-**4)** and *anti*-$\mathbf{TS_{NO}(1+4)}$ are very close to the relative energies of the corresponding species for nitrosoamine **3** (Tables 2, 3).

CH oxidation

For the CH oxidation of the methylene group in *anti*-**4**, two transition states, *anti,anti*-$\mathbf{TS_{CH}(1+4)}$ and *anti,syn*-$\mathbf{TS_{CH}(1+4)}$ (Fig. 4), were found. These differ by the mutual orientation of the C-methyl and nitroso groups, *anti* in the first and *syn* in the second. In both transition states, the dioxirane ring is in the *gauche*-position with respect to the C—N bond due to the *n*-σ* orbital interaction (Chart 1).

Selectivity for CH oxidation in nitrosoamines **3**, **4** is not as great as was observed in alcohols. The greatest difference (2.6 kcal mol^{-1}) in energies of the transition states (of the *anti*-CH oxidations) of nitrosodimethylamine **3** and nitrosoethylmethylamine **4**, is notably smaller than the difference (5.5 kcal mol^{-1}) for the CH oxidation of methanol versus ethanol (24). We assume that in the case of nitrosoamines **3**, **4**, the electronic stabilizing effect from the introduction of the methyl group is compensated to a substantial extent by steric repulsion with the N substituents. Indeed, flattening of the carbon reaction centre upon formation of the transition state of the *anti*-CH oxidation of nitrosoamine **4** must lead to an increase of the steric interactions of the C-methyl group with the N-methyl group in *anti,anti*-$\mathbf{TS_{CH}(1+4)}$ and with the nitroso group in *anti,syn*-$\mathbf{TS_{CH}(1+4)}$. Such steric strains cannot arise in the transition state of the CH oxidation of ethanol, which has only the hydrogen of the OH group instead of the bulky N-methyl and nitroso groups in **4**. To judge from the relative energies of *anti,anti*- and *anti,syn*-$\mathbf{TS_{CH}(1+4)}$, the MeC---NO steric repulsion is rather greater than the MeC---MeN one.

Chemo- and regioselectivity of the oxidation of 3 and *anti*-4 in a dipolar medium

Solvent polarity has been shown experimentally (19–23, 37, 38) and theoretically (24, 28, 30) to have a substantial influence on the rate and selectivity of dioxirane oxidations. In all these works, a decrease of the activation barrier for the reaction in polar solvents has been noted, presumably due to a higher polarity of the transition state.

The transition states of the NO, N, and CH oxidations of nitrosoamine **3** are also characterized by a high polarity, and the SCRF calculations, using the IPCM model of a dielectric medium, predict a considerable decrease of the potential barriers for these reactions upon transition from the gas phase into such solvents as methylene chloride and acetone (Table 3). The greatest decrease of the barrier is observed for *anti*-CH oxidation of nitrosoamine **3** — by 9.3 kcal mol^{-1} (gas phase → acetone). By contrast, the barrier for the *syn*-CH oxidation of **3** is decreased to the least extent — by

© 1999 NRC Canada

4.7 kcal mol^{-1}. Thus, the *anti*-regioselectivity of the CH oxidation is predicted to increase dramatically in polar solvents. Equally affected by solvent polarity are the activation energies for the NO and N oxidations of nitrosoamine **3**, which are each decreased by ca. 6–7 kcal mol^{-1}, i.e., to a more moderate extent than the activation energy for the *anti*-CH oxidation in the polar solvents. However, in spite of the differential solvation effects, the chemoselectivity order remains the same as in the gas phase, i.e., the nitrogen of the nitroso group should be oxidized most readily, followed by the CH bond of the *anti*-methyl group.

The introduction of the methyl group to the *anti*-(to NO)-carbon atom decreases the polarity of the transition states of both NO and CH oxidations. As a result, a relatively smaller influence of the polar solvents on the potential barriers of the oxidations of nitrosoethylmethylamine **4** is observed (Table 4). For the least polar transition state *anti*,*syn*-$\mathbf{TS_{CH}(1+4)}$, as well as for the relatively low polar reactive complexes **(1+3)** and **(1+*anti*-4)**, the SCRF calculations even predict an increase of the relative energies in the polar solvents.

Conclusions

According to the present B3LYP study, in the reactions with nitrosodialkylamines, dioxiranes behave as electrophilic oxidants. The nitrogen of the nitroso group is the most readily attacked. The α-CH bond of the *anti*-alkyl group is the second probable site for the oxidation, and the amine nitrogen is the least reactive. In accord with the electrophilic character of the dioxirane, the transition state of the CH oxidation of nitrosodialkylamines **3**, **4** has mainly hydride transfer character with a concomitant electron deficiency on the reaction carbon atom of the substrate. The introduction of an additional methyl group to the *anti*-α-carbon atom leads to a narrowing of the difference between the potential barriers of the NO and *anti*-C oxidations but not a reversal. The electronic stabilizing effect of the methyl group is compensated to a substantial extent by steric repulsions.

The decrease of the difference in the activation barriers for the NO and *anti*-CH oxidations of nitrosodimethylamine **3** from 5.8 kcal mol^{-1} in the gas phase to 3.3 kcal mol^{-1} in acetone (IPCM model) presupposes the possibility of actually reversing the chemoselectivity in experimental conditions, depending on the solvent. However, on the basis of our results on the ethylmethyl system, **4**, this seems improbable for higher nitrosodialkylamines, which form less polar transition states of the dioxirane CH oxidations. For example, the difference in the barriers for the NO and *anti*-CH oxidations is predicted to increase when the reaction is transferred from the gas phase (4.0 kcal mol^{-1}) into CH_2Cl_2 (5.3 kcal mol^{-1}) or acetone (5.4 kcal mol^{-1}).

On the basis of the calculated activation energies for the NO oxidation in solution (6–7 kcal mol^{-1}), one can predict that dialkyldioxiranes would be effective reagents for the conversion of nitrosodialkylamines into nitrodialkylamines. This reaction can be used also for removing highly hazardous nitrosodialkylamines from wastewater taking into account the possibility of the generation of dialkyldioxiranes in situ in aqueous solutions, and a low commercial cost of the reagents (22).

Can there be more than a single definition of an atom in a molecule?

R.F.W. Bader

Abstract: Arguments are presented that the theoretical definition of an atom in a molecule or of a functional grouping of atoms that derive from experimental chemistry must be unique. Definitions based on the orbital model or, as recently proposed, in terms of domains defined by isovalued density envelopes fail for a number of reasons, among them being their failure to enable a quantum mechanical description of the atomic or group properties. Chemistry is concerned with the observation and measurement of properties. Definitions that do not predict the measurable, additive properties found for atoms in molecules fail to recover the essence of the atomic concept and can play no operational or predictive role in chemistry. Atoms exist in real space and their form determines their properties. There is but a single definition for an atom, free or bound, that meets this essential requirement.

Key words: atoms in molecules, proper open systems.

Résumé : On présente des arguments pour que la définition théorique d'un atome dans une molécule ou dans un groupe fonctionnel d'atomes qui dérive de la chimie expérimentale soit unique. Les définitions basées sur le modèle des orbitales ou, comme il l'a été récemment proposé, en fonctions de domaines définis par des enveloppes de densité de valeurs égales ne sont pas appropriées pour un certain nombre de raisons; une d'elles est leur inhabilité à fournir une description de mécanique quantique des propriétés atomiques ou du groupe. La chimie s'intéresse à l'observation et à la mesure de propriétés. Les définitions qui ne permettent pas de prédire des propriétés additives, mesurables observées pour des atomes dans des molécules faillissent à la tâche de récupérer l'essence du concept atomique et elles ne peuvent jouer aucun rôle prédictif ou opérationnel en chimie. Les atomes existent dans des espaces réels et leurs formes déterminent leurs propriétés. Il n'y a qu'une seule définition pour un atome, libre ou non libre, qui rencontre cette exigence essentielle.

Mots clés : atomes dans les molécules, systèmes ouverts appropriés.

[Traduit par la Rédaction]

The definition of a functional group

The concept of a functional group — that an atom or linked grouping of atoms can exhibit a set of characteristic properties — is central to our understanding and prediction of chemical behaviour. Since this behaviour is observed experimentally, it must be definable in terms of quantum mechanics. Indeed, the definition of a functional group must meet well-defined theoretical as well as experimental constraints if it is to recover the chemical characteristics associated with such groups and, in particular, recover their measured values in systems where additivity of properties is experimentally observed (1, 2). If theory is to apply, then the definition of a functional group must be such that the expectation values and the associated equations of motion be uniquely defined for all observables. Experiment requires: (*a*) that the properties so defined be characteristic and additive, the group properties summing to yield the corresponding value for the total system, (*b*) that the group properties be as transferable from one system to another as is the form of the group in real space, that is, as is the group's charge distribution in real space, and (*c*) that its definition maximize its extent of transferability from one system to another. Thus the definition of a functional group is not arbitrary, at least not if one wishes to recover the functional groups of chemistry.

It has been shown that groups composed of atoms defined as proper open systems meet the above constraints (1–3). A proper open system (4) is a region of real space Ω bounded by a surface $S(\Omega,\boldsymbol{r})$ exhibiting a local zero flux in the gradient vector field of the electron density, as stated in eq. [1]:

$$[1] \qquad \nabla\rho(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) = 0 \;\forall\; \boldsymbol{r} \quad S(\Omega,\boldsymbol{r})$$

Equation [1] is a statement of the boundary condition for obtaining Schwinger's principle of stationary action for an open system from the quantum action principle (5). While no one has disputed the finding that proper open systems faithfully recover the characteristics of the functional groups of chemistry, other definitions have been put forth. Indeed, Liu and Parr (6) overlook the derivation of a proper open system obtained from the action principle, in expressing the opinion "The atom (or functional group) in a molecule is not easily defined. There are always subjective factors for any definition, or strict partition of the molecule. What model one chooses is subject to one's particular needs." This state-

ment is scientifically acceptable only to the extent that "one's needs" are satisfied by a definition of a functional group that recovers its chemical characteristics and by the requirement that the group and its properties be defined by quantum mechanics. Schwinger's principle of stationary action (5), along with Feynman's equivalent path integral approach (7), are considered by some (8) to provide the true foundation of quantum mechanics. The use of Schwinger's principle to define both the atom and its properties through its identification with a proper open system removes any and all "subjectivity" in the definition of an atom in a molecule (3, 4).

The definition of a functional group obtained from the quantum action principle is the only physically acceptable one. The description of a system provided by physics is unique. When alternative formulations are provided, such as the Heisenberg and Schrödinger representations of quantum mechanics or Schwinger's and Feynman's reformulation of quantum mechanics using the action principle, they are found to be equivalent. Thus there are no other definitions of a group that will yield its energy, magnetic susceptibility, polarizability, and all other properties as they are defined by quantum mechanics for a proper open system. It is the values of the properties defined in this manner that are found to be in agreement with the experimentally measured group properties, measurements that are possible in those cases where the properties of a group are found to be transferable, as well as additive (1, 3). The definition of a functional group as a quantum mechanical proper open system is thus unique and no other definition can recover its properties. To demonstrate this uniqueness we show the inadequacy of alternative definitions and provide a further example of how the properties of a proper open system are determined by its form, a consequence of the truism that two identical pieces of matter exhibit identical properties.

Orbital and overlapping models of atoms in a molecule

The quotation by Liu and Parr is from a paper in which they report calculations of atomic and orbital electronegativities and hardnesses for an atom in a molecule (6). Ideally, they wish to consider the ground state of an atom with N electrons (not necessarily integer) in an external potential that in principle is chosen to be "appropriate for the molecular environment." The authors do not explicitly take account of the potential exerted by the environment. Instead, their model of an atom in a molecule consists of an isolated atom with continuously variable orbital occupation numbers. It is their contention that the effect of the environment is reflected in the variation of the orbital occupation numbers. While the population of an open system is variable, it changes only in response to changes in its surroundings. Their model, however, takes no account of the contribution to the potential of the open system from its environment, the single most important feature of an open, as opposed to an isolated, system. Indeed, it is a property of a quantum open system that it changes only in response to changes in the forces exerted on its surface by its surroundings, a property of an open system in classical mechanics, as well (3). The transferable behaviour exhibited by atoms is a consequence of the energy and form of the atoms responding only to the change in the net virial of the forces exerted by its surroundings, the external virial, but not to the individual contributions to that change (3, 4). The atom of Liu and Parr (6) is in reality not an open system, but simply an isolated atom with a population that is arbitrarily varied at will.

Parr et al. (9, 10) equate the electronegativity to the negative of the Lagrange multiplier μ introduced into density functional theory as a constraint that the density integrate to N, the total number of electrons in a system. They argue that μ is the derivative $\partial E/\partial N$, where E is the total energy, and should be identified with the chemical potential. In thermodynamics, the chemical potential is defined as the rate of change of the total energy with respect to a change in the average number of particles of a particular component of the total system or of a bounded open system contained within the total system, the other thermodynamic variables being fixed in value. In the model of the atom used by Liu and Parr (6), the orbital electronegativity is equated to the negative of the corresponding chemical potential in a process that involves taking the derivative of the energy of the atom with respect to the orbital occupation number with the orbitals held fixed, an expression due to Janak (11). Thus the thermodynamic analogy in this case would lead one to identify the atom with the total system and the orbitals with the open components, since it is the energy of the atom that is differentiated with respect to the orbital occupation numbers.

The interpretation given to μ by Parr and co-workers has been questioned for two reasons (12). (*a*) The identification assumes that N in a closed quantum mechanical system is a continuously variable property. (*b*) It was shown that the value of μ is, at the point of variation, independent of the value of the normalization constraint placed on the density, that is, independent of N, the number of electrons in the system. In fact, the normalization constraint may be assigned any arbitrary value λ without affecting the value of μ, as λ is a purely mathematical parameter without physical significance. The same paper shows how the theory of atoms in molecules enables one, in principle, to determine the necessary derivative of a molecule's total energy with respect to the average population of any of its constituent atoms, each of which is a bounded proper open system. This would yield a quantity in formal accord with the thermodynamic definition of the chemical potential, although whether it would satisfy the property of equalization of atomic chemical potentials as suggested by Parr et al. (9, 10) remains to be determined.

Parr et al. (9, 10) previously considered the problem of defining an atom in a molecule as an open system, based on the premise that "at equilibrium" one will have an equality in the chemical potentials of all the atoms in the molecule corresponding to the equalization of their electronegativities. Their model requires an undefined partitioning of the total density into a sum of atomic contributions that are not assumed to be disjoint, and perhaps involving some "bond charge" as well. They conclude (10) that "partitionings with overlapping atoms also have advantages," as opposed to the disjoint partitioning of space achieved through eq. [1].

Both of the models by Parr et al. are readily demonstrated to be incompatible with the physics of an open system, one because of its orbital basis, the other because of the related

© 1999 NRC Canada

problem of overlapping atomic domains. Starting with Schrödinger's equation one derives, in a few steps, the result that a quantum mechanical expectation value and its time rate of change are determined only for open systems that are bounded in real space. In addition to excluding the models proposed by Parr et al. (6, 9, 10), the result has broader implications, namely, that one must forego all definitions of an atom in a molecule based on the orbital model or on partitionings of the basis sets used in their expansion, as these definitions assume the atom to be without boundaries and to extend over all space.

Schrödinger's equation yields the result given in eq. [2] that describes the time rate of change of the value of some property G in an infinitesimal volume element, $d\tau$ (3):

$$[2] \qquad d\rho_G(\boldsymbol{r})/dt = (1/2)\{(i/\hbar)N\int d\tau' \Psi^* [\hat{H}, \hat{G}(\boldsymbol{r})]\Psi - \nabla \cdot \boldsymbol{j}_G(\boldsymbol{r}) + cc\}$$

In this equation $\rho_G(\boldsymbol{r})$ is the density of property G represented by the quantum observable $\hat{G}(\boldsymbol{r})$ and $\boldsymbol{j}_G(\boldsymbol{r})$ is the current density of G, where the densities are defined in eqs. [3] and [4]:

$$[3] \qquad \rho_G(\boldsymbol{r}) = (N/2)\int d\tau' \{\Psi^* \hat{G}(\boldsymbol{r})\Psi + (\hat{G}(\boldsymbol{r})\Psi)^* \Psi\}$$

$$[4] \qquad \boldsymbol{j}_G(\boldsymbol{r}) = (\hbar/2mi)N\int d\tau' \{\Psi^* \nabla(\hat{G}(\boldsymbol{r})\Psi) - (\nabla\Psi^*)\hat{G}(\boldsymbol{r})\Psi\}$$

The mode of integration denoted by $N\int d\tau'$ implies a summation over all spins and an integration over all coordinates save those denoted by the vector $\boldsymbol{r}$ (the coordinate of the electron whose ultimate integration is restricted to the open system) followed by multiplication by N, the number of electrons. This mode of integration is not arbitrary but follows directly from the field theoretic derivation of the principle of stationary action wherein every operator $\hat{G}(\boldsymbol{r})$ is identified with a generator that acts on a single field point (4). It is this feature of the theory that yields a spatial density $\rho_G(\boldsymbol{r})$ and a current $\boldsymbol{j}_G(\boldsymbol{r})$ describing its flow for every property G (2). Equation [2] equates the local change in the density of property G to a contribution arising from within the volume element $d\tau$, as determined by the commutator, and to a contribution from the net flux in the current of G through the surface bounding $d\tau$, as determined by the divergence of the current density. If $\hat{H}$ and $\hat{G}(\boldsymbol{r})$ commute, then eq. [2] reduces to the corresponding equation of continuity for property G, relating its time rate of change to the divergence of its current. For example, if $\hat{G}(\boldsymbol{r})$ equals the unit operator then $\rho_G(\boldsymbol{r})$ and $\boldsymbol{j}_G(\boldsymbol{r})$ reduce to the electron density and its current to yield the equation of continuity for $\rho(\boldsymbol{r})$.

Integration of the densities in eq. [2] over a region Ω yields eq. [5], the Heisenberg equation of motion for $\hat{G}(\boldsymbol{r})$ for an open system. The equation is expressed in the Schrödinger representation in terms of average values.

$$[5] \qquad \int_\Omega d\boldsymbol{r}\partial\rho_G(\boldsymbol{r})/\partial t = (1/2)\{(i/\hbar)\langle\Psi, [\hat{H}, \hat{G}(\boldsymbol{r})]\Psi\rangle_\Omega - \oint dS(\Omega, \boldsymbol{r})\, \boldsymbol{j}_G \cdot \boldsymbol{n}(\boldsymbol{r}) + cc\}$$

The derivation of eq. [5] from Schwinger's principle of stationary action (5) is, however, restricted to a proper open system, one bounded by a zero-flux surface, as stated in eq. [1] (2–4). The surface bounding the total system at infinity also satisfies eq. [1] and thus a single principle determines the properties of the total system and its constituent proper open systems. The surface term vanishes for the total system and eq. [5] then corresponds to the usual statement of the Heisenberg equation of motion for an observable.

The terms in eq. [5] have the same meaning as in eq. [2], with Gauss' theorem being used to replace the volume integral of the divergence of the current with a corresponding surface term relating the change in G to the flux in its current density through the surface of the open system. Equations [2] and [5] demonstrate that, in addition to the total system that is bounded at infinity, the quantum mechanical description of a property and its time rate of change are determined only for bounded regions of real space, be they of infinitesimal or finite extent, and that an essential part of this description is provided by the flux in the associated current density through the surface of an open system. Thus if one's ultimate goal is to use quantum mechanics to define the properties of an atom in a molecule, then one must forego the use of orbitals or of the basis functions used in their expansion in the definition, as these functions extend over all space. A partitioning based on overlapping atomic domains is similarly excluded.

Prefacing their modelling of an atom as an open system, Parr and Yang (10) pose the question "…what is an atom in a molecule? How can one find it in the Schrödinger equation? The problem is a profound one." However, this problem has already been solved by the definition of a proper open system using Schwinger's principle of stationary action. This was first demonstrated for a system in a stationary state (13) in which case the derivation of Schwinger's principle in fact reduces to a corresponding generalization of Schrödinger's derivation of his "wave equation." This work is described in ref. 3 and was recently reviewed in ref. 2. In 1926 Schrödinger showed that making an energy functional, which he termed the Hamilton integral, stationary with respect to first-order variations in the wave function and subject to the constraint that ψ remain normalized, yielded $\hat{H}\psi = E\psi$ as the Euler equation. Repeating Schrödinger's variation of the same functional used in this original paper, but expressed for an open system satisfying the zero-flux boundary condition, eq. [1], yields not only Schrödinger's equation but, in addition, the stationary state expression of Schwinger's principle (2, 3, 13). This principle may be stated as in eq. [6], the stationary state form of eq. [5],

$$[6] \qquad (1/2)\{(i/\hbar)\langle\Psi, [\hat{H}, \hat{G}(\boldsymbol{r})]\Psi\rangle_\Omega + cc\} = (1/2)\{\oint dS(\Omega, \boldsymbol{r})\, \boldsymbol{j}_G \cdot \boldsymbol{n}(\boldsymbol{r}) + cc\}$$

Equation [6], together with the wave equation, completely determines the physics of a proper open system in a stationary state, that is, the physics of an atom in a molecule. When Ω refers to all space the surface integral in eq. [6] vanishes and one recognizes the hypervirial theorem for the observable $\hat{G}(\boldsymbol{r})$. Thus the principle of stationary action generalizes the variation of the energy functional for a stationary state or

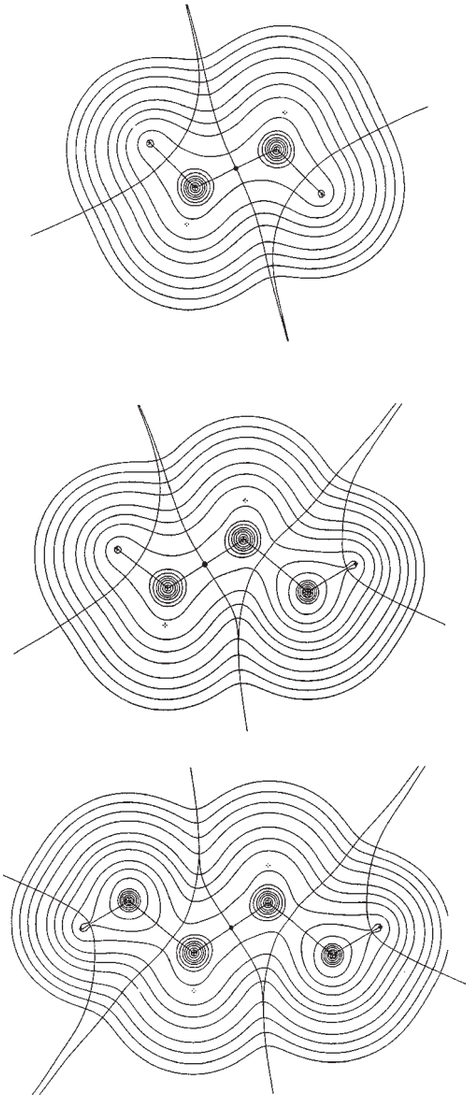

Fig. 1. Contour maps of the electron density for ethane in the H-C-C-H plane, ethanol in the H-C-C-O-H plane, and ethylene glycol in the H-O-C-C-O-H plane, showing the bond paths and the intersections of the interatomic surfaces with the plane of the diagram. The bcp of each C|C surface is denoted by a dot. The density contours of the methyl and the methylenehydroxy groups up to the C|C interatomic surface in the hybrid molecule ethanol are close to being superimposable on the corresponding contours of the related group in ethane and ethylene glycol, significant differences being found only in a small region of the C|C surface beginning with the 0.02 au contour outwards to lower values in the lower portion of the ethanol diagram. The C|H, C|O, and O|H surfaces in the hybrid molecule are separately superimposable with those in the parent molecules. Geometry changes in forming the hybrid, while present, are so small as to be nearly undetectable in these diagrams. The reader may check the transferability of the density distributions by making a copy of the diagram and superimposing it on the original. The final contour to encompass the H-C-C-O-H nuclei in the diagram for ethanol has the value 0.200 au. All the density beyond this contour and some of the density lying within it, up to that at the C—O bcp, would be excluded from the CH_3CH_2 and OH groups defined as density domains using a value for the density somewhat greater than that for the C—O bcp.

of the action integral for a time-dependent system, so that one obtains the equation of motion not only for the state function, but also for each of the observables, eqs. [5] and [6]. This result is obtained only for a proper open system. Thus the principle of stationary action defines both the atom and its properties and this is how one finds an atom in a molecule "in the Schrödinger equation" — by retracing Schrödinger's path. Indeed, it is the extension of Schrödinger's variation to an open system that leads one to Schwinger's principle (13). The extension to an open system necessarily includes a variation of its surface and retention of the variation of the state function on this surface, followed by the identification of these surface variations with the action of infinitesimal generators, the very steps that Schwinger purposefully takes in his generalization of the action principle. One may use the stationary state form of Schwinger's variational principle to obtain Schrödinger's equation together with all properties for the total system by restricting the variations to the basin of a proper open system interior to the total system.

Definition of a functional group as a density domain

We consider next a definition of a functional group proposed by Mezey (14). While he defines a group to be a bounded region of real space, the definition is arbitrary and consequently the groups so defined do not recover nor reflect the observed chemistry. His definition equates a functional group to a "density domain," a region of space enveloped by a closed isovalued surface of the electron density. As one progressively decreases the value of the density $\rho(\boldsymbol{r})$ that is used to define the surfaces within a molecule, starting from a value that typically yields surfaces that separately envelope the individual nuclei, the enveloped regions expand. When $\rho(\boldsymbol{r})$ attains its minimum value along a line of maximum density linking two nuclei, that is, when it attains the value of the density at a bond critical point (bcp) (3) denoted by ρ_b, the envelope will expand to encompass both nuclei or however many equivalent pairs of nuclei as are linked by the same value of the density at their bcps. Thus pairs of nuclei are linked in order of the decreasing value of the density at the associated bcp to yield linked groupings of nuclei of increasing size, a process that terminates when a single envelope encompasses all of the nuclei in the molecule. Reference to the electron density of ethane in Fig. 1, for example, shows that in this case the first polynuclear groups defined in this manner would be two groups of CH_3 nuclei; all C—H bond paths have the same ρ_b value, one that is greater than that for the C—C interaction, Table 1. The program EXTREME (15) of the theory of atoms in molecules locates and characterizes all cps in a density distribution, enabling one to determine all bcps and arrange them in order of decreasing value, and thereby determining the order of the creation and merging of density domains. While

Table 1. Values of electron density at bond critical points in atomic units.[a]

	CH_3CH_2OH	CH_3CH_2OH	CH_3CH_3	$HOCH_2CH_2OH$
Link[b]	Basis a	Basis b	Basis b	Basis b
C—H	0.2785	0.2898	0.2913	
C—H	0.2806	0.2920	0.2913	
C—H	0.2876	0.2993		0.3008
C—C	0.2669	0.2692	0.2569	0.2775
C—O	0.2608	0.2650		0.2662
O—H	0.3780	0.4046		0.4036

[a]Basis set a is 6-31G*; basis set b is 6-311++G(3df,2p).

[b]The first two C—H values are for CH_3: in ethanol, the first is *trans* to the O—H, the second is for the two equivalent C—H bond paths. The third C—H listing is for the CH_2OH group.

Mezey does not associate the merging of domains with the density attaining the value at a bcp, it is the analytical way of determining this information.

Mezey applies his criterion for a group to the electron density in the ethanol molecule and comes to the somewhat surprising conclusion (14) that "the methyl group does not appear as a formal functional group of separate entity within the ethanol molecule." This statement is followed by "This result is in good agreement with chemical practice: few organic chemists would attempt to use ethanol as a methylating agent for incorporation of methyl group into another molecule." This latter statement confuses the concept of a functional group — a linked set of atoms exhibiting a characteristic set of properties in different molecules — with the use of a group in a form that enables one to transfer it in a particular chemical reaction. The methyl and methylene groups in saturated hydrocarbons, while generally unreactive, provided the first quantitative experimental examples of the transferability and additivity of group properties and played an essential role in the development of the concept of a functional group. The presence of a carbonyl group, an example of a chemically more reactive group, is readily recognized by its characteristic infrared and NMR spectroscopic properties and by its chemical susceptibility to protonation at oxygen and nucleophilic attack at carbon, regardless of whether or not the group is chemically transferable in a particular chemical reaction.

In actual fact the methyl group in ethanol, when defined as a proper open system, exhibits characteristic properties as anticipated for a functional group. This has been exemplified by showing that not only is the methyl group defined in the series of molecules CH_3CH_2X where X = H, CH_3, NH_2, OH, and F, but that it contributes nearly identical amounts to their heats of formation, magnetic susceptibilities, and volumes, as well as exhibiting characteristic external contributions to the ^{13}C chemical shift, in spite of the very different nature of X (16, 17).

Mezey's analysis of the density domains in the ethanol molecule (14) is discussed using the electron density for this molecule displayed in Fig. 1. In ethanol, the first binuclear density domain obtained links O to H, as this bond path has the greatest ρ_b value (Table 1). This is followed by the progressive separate linking of each C to its neighbouring protons to yield the nuclear sets CH_3, CH_2, and OH at an intermediate stage, followed next by the linking of the two carbons and finally of C to O, the order determined by the decrease in the ρ_b values, Table 1. Unfortunately, Mezey apparently did not consider the equilibrium geometry or made an error in interpreting his visual displays of the envelopes, as he links the carbons before linking the carbon of methyl to its unique H. This is an incorrect result and, as pointed out above, one that is easily avoided through the use of the program EXTREME. The ρ_b values for C—H bonds in saturated hydrocarbons exceed those for C—C single bonds for equilibrium geometries at any basis set and this result remains true for ethanol. The ρ_b values for ethanol using the 6-31G* set employed by Mezey are also listed in Table 1. The values for the C—H bond paths range from 0.279 to 0.281 au, compared to 0.267 au for C—C. Thus the finding by Mezey that the methyl group is not defined by a density domain in ethanol is incorrect. Ignoring the error in Mezey's conclusion resulting from the incorrect assignment of the value of ρ_b for the C—C link, there are a number of general criticisms that can be made of his procedure, in addition to the obvious one that it misses the known chemistry of the methyl group as determined by its characteristic properties, properties that are necessarily recovered in the transferable forms exhibited by these groups when defined as proper open systems.

(*a*) One cannot assign meaningful values to the properties of groups defined as density domains, however the properties themselves are defined, since the group properties can never sum to yield the corresponding values for the total system. This is a result of electron density being excluded from groups that are separately defined by any isodensity envelope with a value greater than zero. Only the envelope at infinity or, operationally, one that encompasses all of the nuclei, can effectively contain all of the density in the entire system. In the case of ethanol, for example, the OH and CH_3CH_2 groupings of nuclei are separately defined by the surface with a density value lying between 0.269 and 0.265 au, the values of the density at the C—C and C—O bcps, respectively. Thus all density with a value less than ~0.267 au is necessarily excluded if the two groupings of nuclei are to be separately defined, a sizeable fraction of the valence density as is obvious by reference to the contour map in Fig. 1.

(*b*) There is no physical basis for separating groups of atoms on the basis of ρ_b, the value of the density at the bcp. The value of ρ_b provides a qualitative relative measure of bond strength (3, 18) and the use of an isovalued density surface for the definition of a group would forbid the existence of any group that contained, interior to it, a bond with a ρ_b value less than (that is, a bond weaker than) those linking it to the rest of the molecule. The value of ρ_b for the C—C link in ethanol exceeds that for the C—O link by only 0.004 au using the larger basis set, a difference that hardly seems to justify, on any physical grounds, denying the existence of the latter link in preference to the former.

(*c*) The dependence of ρ_b on internuclear separation represents another shortcoming of the use of isodensity envelopes to define a group, in that existing groups would disappear and new groups would appear as the molecule underwent vibrational motions, the resulting changes in molecular geometry changing the order of the *relative* values of ρ_b. The definition of a group and the associated definition of molecular structure provided by the theory of atoms in molecules,

© 1999 NRC Canada

on the other hand, frees these concepts from the classical notion of a molecular geometry by associating a group and a molecular structure with an open region of nuclear configuration space, removing thereby even the need of invoking the Born–Oppenheimer approximation (3). Molecular and group structure is generic and persists over nuclear vibrations, until progress along a given reaction coordinate leads to a catastrophic change in the topology of the system's electron density distribution that leads to the creation of a new structure (3).

Utilizing the transferability of the methyl group in a theoretical synthesis

A simple theoretical synthesis is used to illustrate that the methyl group is not only definable in ethanol but that it emulates the essential feature required of a functional group by chemistry, namely, that its properties mirror its form in real space. Figure 1 shows the electron density distributions for ethane ($CH_3|CH_3$) and ethylene glycol ($HOCH_2|CH_2OH$), considered as parent molecules, together with the density for the hybrid molecule, ethanol ($CH_3|CH_2OH$). The vertical bar in each formula denotes the C|C zero-flux interatomic surface. It is clear from the three diagrams that the density distributions of the $HOCH_2|$ and $|CH_3$ groups are little changed upon transfer from their defining molecules to the hybrid. Consequently one could imagine performing a theoretical synthesis of ethanol by combining the methyl and the methylene hydroxyl groups defined as proper open systems by the C|C interatomic surface in each of the two original molecules. For this to be a useful procedure would require the properties of ethanol to be the arithmetic mean of the properties of the two parent molecules, a situation that is very closely obeyed (16). Thus one finds the error incurred in the estimate of the energy of ethanol by this procedure is –0.33 kcal/mol, compared to –0.32 kcal/mol obtained using experimental values of heats of formation (19). The error incurred in the magnetic susceptibility is 0.1 u out of a total value of 37.8 u (u = -1×10^{-6} emu) and the error in the van der Waals volume is 0.36 au out of a value of 81.69 au. The calculations use a 6-311++G(3df,2p) basis and incorporate self-consistent virial scaling to ensure satisfaction of the virial theorem.[2]

This synthesis provides an example of compensatory transferability wherein each group changes in response to its new neighbor in such a way as to minimize the overall change, the more prevalent response of a group to a change in environment (16). The electron population is necessarily conserved in forming the heteromolecule, with –0.047 e being transferred from $CH_3|$ to $HOCH_2|$, but what is perhaps surprising is the extent to which other properties are nearly similarly conserved. The apparent additivity of their properties is a result of the small changes in the properties of one group being nearly nullified by compensatory changes in its new neighbor. Thus the energies of $CH_3|$ and $|CH_2OH$ change by –2.6 and +1.9 kcal/mol, their magnetic susceptibilities by +0.28 and –0.18 u, and the van der Waals volumes by –3.14 and +3.50 au, respectively. (The difference in the sum of the changes in the group energies, obtained by numerical integration over the separate atomic basins, differs from that calculated by subtracting the total energies by 0.4 kcal/mol, a measure of the accuracy of the atomic integrations.)

While a simple empirical averaging of the properties of the two parent molecules would yield the results described above, such a procedure would have no physical basis. The procedure would correspond to the use of fragments obtained by a partitioning in the plane perpendicular to the bond midpoint in each of the parent molecules, as opposed to use of the interatomic surfaces that reflect the alternating symmetry axes present in the parent molecules. As a result, the density contours would not match across the interfragment surface in the hybrid and the partitioning would result in a portion of the oxygen basin becoming part of the "methyl" fragment and a portion of the carbon basin becoming part of the "methylene hydroxyl" fragment. In addition, of course, the properties of such improper fragments are not defined by theory. Thus the properties assigned to the fragments in this empirical procedure would not reflect their charge distributions, and form would not determine property as found in nature.

The second-order properties induced by an applied magnetic field are determined by the induced magnetization density $\boldsymbol{r} \times \boldsymbol{j}^{[1]}(\boldsymbol{r})$, where $\boldsymbol{j}^{[1]}(\boldsymbol{r})$ is the first-order induced current (17). The magnetic shielding σ_A of nucleus A is determined by the integration of the shielding density $\boldsymbol{r}_A \times \boldsymbol{j}^{[1]}(\boldsymbol{r})/r^3_A$, with origin at nucleus A, over the basin of each atom, enabling one to determine the atomic contributions to σ_A (20). A carbon nucleus in ethane, with a shielding constant σ_C = 181 ppm, is more shielded than the methyl carbon in ethanol by 12 ppm (20). It is a property of a given nucleus in a functional group that all of the shift in its shielding occurs as a consequence of small perturbations to the shielding density within the atomic basin containing the nucleus in question, the contributions from the remaining atoms in the system, regardless of their number and kind, contributing a nearly constant amount to the shielding and exhibiting variations of less than 1 ppm (20). Thus the external contribution to the shielding of a carbon nucleus of a terminal methyl group in saturated hydrocarbons or their corresponding normal alcohols varies from 17.0 to 17.8 ppm, equaling 17.4 in ethane and 17.0 in ethanol, with the three methyl hydrogens contributing 4.2 ppm in both cases. The internal contributions to σ_C predict C in ethanol to be less shielded than C in ethane, by 8 ppm compared to the experimental 12 ppm (20).

The transferable nature of the groups illustrated here and elsewhere is a consequence of their being bounded by a zero-flux surface. Any other choice of surface would result in a loss of transferability, as would any attempt to define the atoms as unbounded overlapping systems using, for example, a Mulliken partitioning of a set of basis functions into gross atomic sets by the equal division of the overlap terms between two participating nuclear centres. This latter approach is still frequently employed and is the method used by Walker and Mezey in their MEDLA approach to obtaining molecular density fragments for use in the construction

[2] T.A. Keith. Private communication.

of large molecules (21). Such a partitioning eschews the very property of the density that forms the core of the concept of an atom in a molecule — namely, that it can exhibit characteristic properties in spite of changes in its neighbouring atoms. To take a simple example, one that contributed to the observational basis underlying the theory (22), consider the Li atom in LiH and LiF. The distribution of the electron density over the basin of the Li atom up to its interatomic surface is so similar in the two molecules, when the Li atom is defined as a proper open system, that it must be considered truly remarkable, considering the very different natures of its bonded neighbours (2, 3, 22). Contrawise, the density distributions in the basins of the neighbouring hydrogen and fluorine atoms are completely different. However, since properties follow form in real space, the expectation values of all observables are very similar for the Li atom in the two molecules, in spite of the very different distributions of density in the neighbouring atomic basins (22). Thus the integration of the density over the Li basin in LiF yields 2.06 electronic charges and a net charge on Li of +0.94e, compared to a net charge of +0.91e in LiH. The electronic kinetic energies of the Li atoms differ by 9 kcal/mol, a value that, by the atomic virial theorem, equals the magnitude of the difference in their total energies (3).

If, however, the atomic density distributions are defined in terms of nuclear centred basis functions, then the physical similarity observed in real space is lost: in one case the Li density includes contributions from the density in the hydrogen basin while in the other it includes density lying within the basin of the F atom. The distribution of the density in the H basin is very different from that in the F basin and hence the density ascribed to the Li atom by this procedure is different for the two molecules. In addition, of course, differing amounts of density within the Li basin are assigned to the H and F atoms, with the net result that the densities assigned to the Li atoms do not appear similar. In fact, the net charges for Li determined by the Mulliken partitioning are +0.59e in LiF and +0.37 in LiH, compared to charges that differ by only 0.03e when the Li atom is defined as a proper open system. In addition to judging the atom to be different in the two molecules, neither charge gives any indication of the close approach of the density of the Li atom to that of the core density associated with a Li^+ ion that is evident in the contour maps for the two molecules (2, 3, 22).

The one-electron density matrix, whose diagonal elements determine the electron density, determines the quantum stress tensor. The stress tensor, through the local expressions of the equations of motion for the force and virial operators, determines the kinetic and potential energy densities and thus the mechanics of a molecule. It has been demonstrated that the one-electron density matrix is short-sighted (23) and thus the transferable nature of an atom or a functional group is a consequence of the parallel short-range behaviour of the density and its local energy contributions that is observed for proper open systems (2, 4, 23, 24). The effective potential field experienced by a single electron in a many-electron system is determined by the virial field. The virial field is a dressed real-space density (2, 3) that determines all of the complex interactions between the electrons and nuclei that are determined by the many-electron wave function. It provides the most short-range description possible of the interactions experienced by an element of the density, because it integrates to the total potential energy, including the nuclear repulsion energy. Not only does the virial field, like the kinetic energy density, mimic the transferable nature of the electron density, the negative of the virial field has been shown to be structurally homeomorphic with $\rho(\boldsymbol{r})$ (24). Thus a density that has the appearance of a scaled version of $\rho(\boldsymbol{r})$ has the property of integrating to twice the total energy of the molecule.

Conclusions

The philosophy of Parr and others such as March (25), concerning the definition of an atom in a molecule, is summarized (26) in the statement "what an atom in a molecule is must be defined and there is no unique definition." The argument presented here is that if one wishes to define the atoms of chemistry, those that meet the necessary experimental and theoretical constraints outlined in the introduction, then one has no freedom of choice. Instead, like all true physical concepts, that is, those determined by observation, the choice is dictated by physics and the definition of an atom in a molecule is unique. Specifically, it has been shown that Parr's proposal (6, 10, 26) that a molecular density be partitioned into overlapping atoms, however this might be done, precludes the use of quantum mechanics in the definition of the contributions the atoms make to the measurable properties of a system. Parr has used the model of overlapping atoms to define the energy required to promote an atom in a molecule into a non-quantum mechanical "valence state" (26, 27), and the same model, supplemented with an intervening bond density, has been employed in a discussion of force constants (28). One should not attempt to justify one's desire to formulate a subjective model of an atom for use in a particular problem by the premise that a unique definition of the atoms of experimental chemistry is impossible.

Conceptually, models that partition a molecular density into distinct contributions from overlapping atoms and from bonds derive from the orbital model of electronic structure. The atoms and the bonds correspond to the atomic and overlap contributions to the density that are obtained from the expansion of the orbitals using atomic centred basis functions. Historically, the notion of a "bond" as being separate from the atoms it links traces back to the ball and stick model of molecular structure. The adoption of the theory of atoms in molecules requires the replacement of any model of structure that imparts an existence to a *bond* as being separate from the atoms it links with the concept of *bonding*; two atoms are bonded if they share an interatomic surface and hence are linked by a bond path, as illustrated in Fig. 1. The presence of a bond path — a line of maximum density linking neighbouring nuclei in an equilibrium geometry — provides a universal indicator of bonding between atoms (29), but does not itself represent a bond or any finite amount of electronic charge. The interatomic surfaces separating neighbouring basins appear to some to cut the bond paths, causing Parr and Yang (10), in a critique of the theory of atoms in molecules, to state "···and the chemical bond itself seems to

© 1999 NRC Canada

have disappeared into thin air." This is a valid comment but they fail to add that the resulting theory of molecular structure and structural stability obtained by replacing the notion of "a bond" with that of "bonding" yields the first and so far the only theory of structure and structural stability that recovers and quantifies all of the structural concepts of chemistry, one that defines all possible structures and all possible mechanisms of structural change (3, 30) for a given system.

While Mezey defines an atom or a functional group to be a bounded region of space, the resulting density domains do not recover the properties associated with the functional groups of chemistry, one reason being that they exhaust neither the total system nor its properties. Also, according to Mezey's stated findings (14), the methyl group is not definable as a density domain in ethanol. Yet physically, the space occupied by the electron density of the atoms associated with the CH_3 grouping exhibits nearly identical properties in ethanol as in ethane, where the group is represented by a density domain. In fact, when defined as a proper open system the methyl group of ethanol is found to exhibit properties characteristic of the methyl group in hydrocarbons and substituted hydrocarbons. Density domains may be of use in the topological characterization of molecular shape and similarity (14), but the concept cannot be used to define a functional group of chemistry. Thus Mezey's concluding remark "by this criterion, the electron density distribution does not justify regarding the terminal CH_3 moiety as a formal functional group" is at variance with the demonstration that it is possible to define a methyl group in ethanol whose form and properties are characteristic of those exhibited by the methyl group in other molecules, that is, it behaves as a functional group of chemistry.

Mezey's statements (14) that the electron density is "fuzzy" and that the Heisenberg uncertainty principle somehow limits one's ability to employ the density to obtain physical definitions that are not in conflict with quantum mechanics are misleading. The electron density is the measurable expectation value of the density operator (31), an operator that is both linear and Hermitian, the requirements placed by Dirac on the definition of an observable (32). Our ability to measure or calculate this expectation value is not limited by any inherent quantum uncertainty but rather, as for other properties, only by our experimental abilities (33). Even the position of a single electron can be measured (a process that has nothing to do with the measurement of the many-electron density). What one cannot do is simultaneously measure its momentum with unlimited accuracy. The overuse of the "fuzzy" aspect of quantum mechanics is discussed by Feshbach and Weisskopf (34) in an article entitled "Ask a foolish question." In particular, the representation of a molecular structure in terms of an equivalence class of molecular graphs defined by the topology of the density (3, 30) is in complete accord with quantum mechanics, even though an individual molecular graph, as defined by the network of bond paths, is a portrayal of the "skeletal" image of structure that Mezey (14) claims to be incompatible with physics and an impediment to our thinking.

Preparation of *N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acetamides from trilithiated acetoacetanilides and lithiated methyl thiosalicylate

April J. Angel, Anne E. Finefrock, Kristen L. French, Douglas R. Hurst, Angela R. Williams, Mary E. Rampey, Shannon L. Studer-Martinez, and Charles F. Beam

Abstract: Acetoacetanilide and substituted acetoacetanilides were trilithiated in excess lithium diisopropylamide, and the polylithiated intermediates were regioselectively condensed with lithiated methyl thiosalicylate, followed by acid cyclization to afford substituted *N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acetamides (thiochromone-2-acetamides).

Key words: thiochromones, strong-base multiple anion synthesis, Claisen-type condensation.

Résumé : On a effectué une trilithiation de l'acétoacétanilide et d'acétoacétanilides substitués en procédant dans un excès de diisopropylamidure de lithium, et les intermédiaires polylithiés ont subi une condensation régiosélective par réaction avec du thiosalicylate de méthyle lithié, suivie d'une cyclisation acide conduisant à des *N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acétamides (thiochromon-2-acétamides).

Mots clés : thiochromones; synthèse, base forte anion multiple; condensation du type de Claisen.

[Traduit par la Rédaction]

Introduction

Chromones (4*H*-1-benzopyran-4-ones) have been extensively investigated regarding their synthesis, their isolation as secondary metabolites, and their potential for broad spectrum biological activity (1, 2). In comparison, thiochromones (4*H*-1-benzothiopyran-4-ones) have received considerably less investigative attention (3, 4). These compounds have been prepared and studied for their biological potential, especially as bacteriocides and anticancer agents (5–8). Very few thiochromone-2-acetic acid derivatives (e.g., thiochromone-2-acetic acid, ethyl ester and related esters) have been reported (9–11). These compounds have been prepared by the condensation–cyclization of phenyl mercaptan with β-oxocarboxylic acid esters (9). Also, 3-carboethoxy- (10) or 3-carbomethoxy- (11) thiochrome-2-acetic acid, ethyl or methyl esters, have been prepared by the condensation–cyclization of methyl thiosalicylate with either 1,3-dicarbethoxyallene or 1,3-dicarbmethoxyallene, respectively.

Thiochromone-2-acetic acid has not been reported, but related thiochromone acetic acids or their derivatives have been made for which the acetic acid or acetamido moiety was in the 3-, 5-, 6-, or 8-position (12–15). These materials were also studied for their antitumor, schistosomicidic, or hypolipemic activity. Generally, biological and other studies involving thiochromones have lagged behind chromones, due in part to the lack of synthetic routes or the availability of starting materials to these compounds (3).

In our initial study (16), we trilithiated acetoacetanilide and treated this intermediate with select electrophilic reagents in order to prepare new products such as chromone-2-acetamides (*N*-aryl-4-oxo-4*H*-1-benzopyran-2-acetamides). A part of the initial study dealt with the condensation–cyclization of trilithiated acetoacetanilide with lithiated salicylate esters.

These electrophilic reagents presented a challenge because of the potential for diminished electrophilicity and reactivity of the carboxyl carbon, which is in a resonance position relative to the phenoxide ion portion of the electrophilic substrate (17–19). The condensation–cyclization of these trianion-type intermediates with lithiated methyl thiosalicylate (20) was not attempted at that time, and such an investigation offered the potential for the preparation of thiochromone-2-acetamides (*N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acetamides) that may be difficult to prepare by traditional procedures.

Results and discussion

During the current investigation, 11 acetoacetanilides were trilithiated with excess LDA and condensed with lithiated methyl thiosalicylate (Fig. 1). This was followed by neutral-

ization of *C*-acylated intermediates and cyclization with aqueous hydrochloric acid to afford products **1**–**11**.

All of the thiochromone-2-acetamides **1**–**11** prepared by this strong-base procedure are new, and they were characterized by absorption spectra with support from combustion analyses for C, H, and N. The infrared spectra displayed a number of absorptions between 1600 and 1700 cm^{-1} that were attributed to the thiopyranone carbonyl, the amide carbonyl group, or aromatic absorptions. Proton magnetic resonance absorptions displayed sharp singlets for the methylene hydrogens (CH_2CO) ranging from δ 3.81 to δ 4.01 ppm, and the thiopyranone ring C_3-H singlets, δ 7.01–7.05 ppm, were usually upfield and distinguishable from aromatic absorptions. Pendant group hydrogen absorptions were noted as singlets for $ArCH_3$ and $ArOCH_3$ ranging from δ 2.17 to 2.24 and δ 3.67 to 3.86 ppm, respectively. In each instance the NH was displayed as a sharp singlet distinctly downfield from aromatic absorptions ranging from δ 9.53 to 10.73 ppm. Representative ^{13}C NMR absorptions were noted for methylene carbons ranging from δ 40.4 to 44.5 ppm, ring carbonyl carbons from δ 165.1 to 166.2 ppm, and amide carbonyl carbon primarily at δ 179.0 ppm.

Conclusions

The yields of thiochromone-2-acetamides **1**–**11** ranged from 38 to 92%, which indicates that the general experimental procedure is satisfactory for the expedient preparation of gram quantities of the desired products. This is especially attractive for characterization, biological testing, and other uses; however, it may not necessarily represent the optimum conditions for the preparation of each individual compound. Most reagents used in the preparation are commercially available, and the substituted acetoacetanilides for **9** and **11** were prepared by one-step documented procedures (21–23). The strong-base procedure is general enough so that it is readily reproducible by someone not necessarily familiar with these techniques, and it does not require an elaborate experimental setup.

Experimental

Melting points were obtained with a Mel-Temp II melting point apparatus in open capillary tubes and are uncorrected. Fourier Transform infrared spectra were obtained on a Nicolet Impact 410 FT-IR spectrometer (paraffin oil mull for each compound). Proton and ^{13}C nuclear magnetic resonance spectra were obtained with a Varian Associates Mercury Oxford 300 MHz nuclear magnetic resonance spectrometer, and chemical shifts are recorded in δ ppm downfield from an internal tetramethylsilane (TMS) standard (dimethyl sulfoxide-d_6, solvent for each compound).

Combustion analyses were performed by Quantitative Technologies, Inc., P.O. Box 470, Salem Industrial Park, Bldg. 5, Whitehouse, NJ 08888, U. S. A. The tetrahydrofuran (THF) was distilled from sodium (benzophenone ketyl) prior to use, and chemicals were obtained from Aldrich Chemical Co. and Pfaltz and Bauer, Inc. The acetoacetanilides, *N*-(4-bromophenyl)-3-oxo-butanamide and *N*-(4-methylphenyl)-3-oxo-butanamide, for the preparation of thiochromone-2-acetamides **9** and **11**, were made by the condensation of *p*-bromoaniline or *p*-toluidine with ethyl acetoacetate (21–23).

General experimental procedure for preparing *N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acetamides 1–11

In a typical experiment, the acetoacetanilide was added to excess lithium diisopropylamide (LDA), followed by the thiosalicylate ester (entry compound:LDA:ester, 1:5:1), and then acid-cyclized to the product. The LDA was prepared by adding 5.37 g (0.0525 mol) of diisopropylamine, dissolved in 45–55 mL of dry THF, to 33 mL (0.0525 mol) of *n*-butyllithium (1.6 M, N_2, 0°C). After 20 min, 0.0100 mol of the acetoacetanilide, dissolved in 35–45 mL of THF, was added at a fast dropwise rate (5 min). After stirring at 0° C for 3 h, 1.82 g (0.0105 mol) of methyl thiosalicylate, dissolved in 25–35 mL of THF, was added at a fast dropwise rate (5 min), and the resulting mixture was stirred at 0°C for an additional 2 h. The mixture was quenched by addition of 100 mL of 3 N hydrochloric acid, and the resulting two-phase mixture was stirred and heated under reflux for 1 h. The mixture was then poured into a large flask containing ice (ca. 100 g) and, after adding solvent-grade ether (ca. 100 mL), it was neutralized with solid sodium bicarbonate. The layers were separated, the aqueous layer was extracted with ether (2 × 75 mL), and the ether extracts were combined and evaporated. The resulting solid or oil was crystallized from routine solvents.

*Preparation of 4-oxo-*N*-phenyl-4*H*-1-benzothiopyran-2-acetamide (1)*

Compound **1** was prepared by the general procedure from the condensation–cyclization of 0.0100 mol of trilithiated acetoacetanilide (3-oxo-*N*-phenyl-butanamide) and 0.0105 mol of lithiated methyl thiosalicylate. Yield: 2.21 g (75%); mp 214–216°C (95% ethanol). IR (cm^{-1}): 3311, 1691, 1606, and 1585; ^1H NMR δ (ppm): 3.90 (s, 2H, CH_2), 7.03 (s, 1H, C_3-H), 7.07–7.90, 8.34-8.37 (m, 9H, ArH), and 10.41 (s, 1H, NH); ^{13}C NMR δ (ppm): 44.5, 119.1, 123.6, 125.7, 126.8, 127.5, 127.9, 129.9, 131.9, 137.0, 138.6, 149.4, 165.6, and 179.0. Anal. calcd. for $C_{17}H_{13}NO_2S$: C 69.13, H 4.44, N 4.74; found: C 69.03, H 4.34, N 4.69.

Réactions d'addition conjuguée d'organolithiens aux acides carboxyliques α, β-insaturés

Jacques Mortier, Michel Vaultier, Barbara Plunian et Sourisak Sinbandhit

Résumé : Les organolithiens et les acides carboxyliques α,β-insaturés non protégés donnent des réactions d'addition conjuguée dans le tétrahydrofurane à –78°C. Les réactions des acides 1- et 2-naphtoïques avec divers organolithiens et réactifs électrophiles sont présentées. Deux études de diffraction des rayons X montrent que la réaction s'effectue avec une excellente diastéréosélectivité : l'énolate de dilithium intermédiairement formé additionne exclusivement le réactif électrophile par la face opposée à celle d'entrée de l'organolithien. L'étude des spectres de résonance magnétique nucléaire du proton des produits obtenus permet de mettre en évidence l'existence d'une conformation privilégiée de ces composés en solution. La protonolyse de l'énolate intermédiaire par l'acide trifluoroacétique en mode inverse donne accès à des dihydronaphtalènes disubstitués en 1 et 2. Avec les acides carboxyliques α,β-insaturés acycliques, la réaction présente une diastéréosélectivité faible. Avec le butyllithium secondaire, la protonolyse des énolates intermédiaires donne les produits d'addition 1,4 avec une diastéréosélectivité moyenne. La réaction de l'acide phénylpropiolique avec le butyllithium conduit à la formation d'un produit résultant de la *trans* addition de l'organolithien à la triple liaison, l'organolithien additionnant en α de la fonction acide carboxylique.

Mots clés: réactions d'addition 1,4; acides carboxyliques; organolithiens.

Abstract: In THF at –78°C, organolithium derivatives and unprotected α,β-unsaturated carboxylic acids give a conjugated addition reaction. Reactions of 1- and 2-naphthoic acids with various organolithium derivatives and electrophiles are reported. Two X-ray studies show that the reaction occurs with a good diastereoselectivity: the dilithiated enolate formed as an intermediate adds the electrophile exclusively via the face opposite to that of the organolithium. A study of the ^{1}H NMR spectra of the products obtained shows that these compounds adopt a preferred conformation in solution. The protonolysis of the intermediate enolate by trifluoroacetic acid in an inverted mode gives rise to the formation of 1,2-disubstituted dihydronaphthalenes. With acyclic α,β-unsaturated carboxylic acids, the diastereoselectivity of the reaction is marginal. With secondary butyllithium, the protonolysis of the intermediate enolates gives a 1,4-addition and an average diastereoselectivity. Reaction of phenylpropiolic acid with butyllithium gives rise to the formation of a product resulting from a *trans* addition to the triple bond; the organolithium derivative adds in α to the carboxylic group.

Key words: 1,4-addition reactions, carboxylic acids, organolithium derivatives.

[Journal translation]

1. Introduction

La réaction d'addition de Michael constitue une méthode chimique générale de formation de la liaison carbone–carbone (1). Les réactifs organométalliques les plus couramment mis à contribution dans ce type de transformation sont ceux contenant du lithium, du magnésium et du cuivre. En regard de la terminologie HSAB de Pearson (2), la molesse des composés organométalliques croît dans l'ordre lithium → magnésium → cuivre (3). Il en résulte que les réactivités chimiques de ces réactifs sont différentes et donc souvent complémentaires les unes des autres. Les dérivés carbonylés α,β-insaturés constituent probablement la classe d'accepteurs de Michael la mieux étudiée. Avec ces composés, les réactifs organométalliques moux donnent d'une manière générale des réactions d'addition 1,4 alors que les dérivés organométalliques durs produisent préférentiellement les composés résultant d'une addition 1,2 (revues concernant les réactions d'addition conjuguée des organolithiens : voir réf. 4).

Ainsi, la réaction des organocuprates de lithium avec les esters éthyléniques chiraux et achiraux conduit aux produits d'addition 1,4 avec une stéréosélectivité généralement excellente (réf. 1, chap. 4, pp. 218–225). Les énolates lithiés de cétones stabilisés par conjugaison π réagissent préférentiellement en 1,4 avec les esters éthyliques et méthyliques (5, 6), les nitriles (réf. 6, p. 687, et réf. 7) et les amides tertiaires (8) α,β-insaturés. Le crotonamide de diméthyle conduit ainsi à des adduits *syn* avec de bons rendements après réaction avec les électrophiles (8). Les énolates lithiés d'esters et d'amides tertiaires réagissent de façon similaire avec les es-

ters α,β-insaturés (9). Les carbanions lithiés d'α-cyanoamines réagissent également en 1,4 avec les esters éthyliques α,β-insaturés donnant accès à des γ-oxoalcénoates après hydrolyse acide (10). Les nitroalcanes présentent une réactivité analogue avec les esters α,β-insaturés en présence d'une quantité catalytique de bases telles que HCO_2Na (11), TBAB (12), TBAF (13), NEt_3 (14) et AcOK (15). De même, les carbanions α-thiosulfonylés stabilisés par conjugaison π additionnent les esters α,β-insaturés (16). Corey et Hegedus ont montré que les anions acyles masqués par un atome de nickel ($RCO\text{-}Ni(CO)_3$) additionnent en β le crotonate de méthyle (17). Enfin, les allylsilanes donnent des réactions d'addition 1,4 avec les dérivés d'acrylate et d'acrylonitrile en présence d'une quantité catalytique d'ion fluorure (18). D'excellentes revues concernant l'addition conjuguée stéréosélective des énolates et des organocuprates achiraux aux esters éthyléniques chiraux ou de carbanions chiraux à des esters α,β-insaturés achiraux sont parues (1).

Les composés organométalliques durs donnent préférentiellement des réactions d'addition 1,2 avec les composés α,β-insaturés du type C=C-COR, C=C-CHO et $C{=}C\text{-}CO_2Et$. Un groupement protecteur encombrant permet de diminuer la nucléophilie de la fonction CO facilitant l'addition du réactif organométallique en β (4). Les amides et les thioamides secondaires et tertiaires α,β-insaturés constituent de bons accepteurs de Michael avec les nucléophiles durs tels que les alkylithiens non stabilisés (4, 19). La formation de produits d'addition conjuguée peut également être favorisée en utilisant des groupements protecteurs de carbonyle du type $C{=}C\text{-}COCPh_3$ (20) et $C{=}C\text{-}CO_2Ar$ (Ar = 2,6-di-*tertio*-butyl-4-méthoxyphényle) (21). Les (*E*)-alcényloxazolines chirales et les organolithiens non stabilisés donnent des réactions d'addition 1,4 avec de très bonnes stéréosélectivités (22, 23).

Les acides carboxyliques α,β-insaturés *non protégés* ($C{=}C\text{-}CO_2H$) réagissent avec les organolithiens selon quatre grandes voies (schéma 1). À une température comprise entre –40 et 0°C dans l'éther ou le THF, l'addition 1,2 de l'organolithien est essentiellement observée et la méthode donne accès à des cétones α,β-insaturées (voie A) (24, 25). À température plus élevée (i.e., T = +20°C) dans le THF, le butyllithium additionne de façon compétitive la fonction acide carboxylique *préalablement* à l'étape de déprotonation, conduisant à l'espèce PhC(OLi)(OH)Bu (26). Les acides carboxyliques comportant un hydrogène acide en position γ sont déprotonés par le LDA dans le THF à –78°C (voie B) (mise au point : réf. 27). L'énolate formé réagit avec les composés carbonylés par le carbone α ou par le carbone γ en fonction des conditions réactionnelles utilisées (28). Nous avons montré récemment que les acides benzoïques *ortho*-fonctionnalisés peuvent être obtenus par lithiation d'acides benzoïques non protégés, via un intermédiaire dianionique *ortho*-lithio benzoate de lithium, sans protection préalable de la fonction acide carboxylique (voie C) (29, 30). Le traitement à –90°C d'un acide benzoïque par 2,2 équivalents du complexe 1 : 1 butyllithium secondaire (*s*-BuLi)/TMEDA dans le THF conduit, après réaction avec des électrophiles variés à –78°C, à des acides benzoïques *ortho*-substitués (applications à la synthèse de pesticides : réf. 31).

Quelques rares exemples de la littérature montrent que les composés organiques possédant une fonction acide carboxylique α,β-insaturée sont susceptibles de donner des réactions d'addition conjuguée avec les composés organométalliques *sans protection préalable de la fonction acide*. Les chlorures de phényle et de *tertio*-butyle magnésium donnent des produits d'addition 1,4 avec des rendements faibles par réaction avec les acides carboxyliques α,β-insaturés (32). Des réactions d'addition conjuguée ont également été observées entre les acides carboxyliques α,β-insaturés et $RCu{\cdot}BF_3$ (33). La réaction de MeCu avec l'acide phénylpropiolique conduit à un énolate de configuration stable à température ambiante (32*c*). Cet énolate donne l'acide *Z*-β-méthylcinnamique après hydrolyse.

L'addition conjuguée des organolithiens aux acides carboxyliques α,β-insaturés a été décrite dans quelques rares cas (voie D). Snieckus et Majewski ont montré que le traitement de l'acide (*E*)-3-méthylbut-2-énoïque avec le 2-lithiodithiane dans le THF à 0°C conduit au produit d'addition 1,4 avec un rendement de 65 % (34). La réaction de l'acide (*E*)-3-triméthylsilylpropénoïque avec le butyllithium dans le THF–hexane à –70°C donne un mélange en produits d'addition 1,2 (55 %) et 1,4 (45 %) (35). L'addition 1,4 des organolithiens aux acides carboxyliques α,β-insaturés α-silyciés s'effectue avec des rendements médiocres. Dans ce cas, l'addition 1,2 est rendue plus difficile par la présence de l'atome de silicium qui augmente la densité de charge en α de la fonction carbonyle (36).

Dans cet article, nos travaux concernant l'étude de la réactivité des acides 1- et 2-naphtoïques et des acides carboxyliques α,β-insaturés acycliques avec divers organolithiens et réactifs électrophiles dans le THF à basse température (–78°C) sont présentés. La stéréosélectivité de la réaction est excellente avec les acides 1- et 2-naphtoïques.

2. Synthèse d'acides dihydronaphtoïques 1,1,2- et 1,2,2-trisubstitués

L'addition nucléophile de complexes organométalliques au système π de naphtalènes permet l'introduction régio et stéréosélective de substituants alicycliques dans le squelette naphtalène (schéma 2). Les études effectuées dans ce domaine concernent en particulier l'addition d'alkyllithiens au naphtalène non substitué (37), l'addition de réactifs de Gri-

gnard aux acylnaphtalènes (38), aux nitronaphtalènes (39) et aux 1(2)-naphtyloxazolidines (40), et les réactions de complexes « ate » de boranes avec le fluorosulfonate de méthyle (41).

Kündig a montré que les organolithiens donnent des réactions d'addition conjuguées avec les complexes benzène–$Cr(CO)_3$ et naphtalène–$Cr(CO)_3$ (42). Alors que les phényloxazolines peuvent être *ortho*-métallées puis alkylées par les réactifs électrophiles (43), les 1-naphtyloxazolines présentent une réactivité différente : les organolithiens additionnent stéréosélectivement ces composés et conduisent à des 1,2-dihydronaphtalènes trisubstitués après piégeage de l'intermédiaire azaénolate par un réactif électrophile (44). Lorsque l'oxazoline est chirale, la méthode permet de préparer des composés optiquement actifs avec d'excellents excès énantiomériques (schéma 3) (44). Dans ces réactions, le réactif électrophile réagit avec l'énolate en *anti* par rapport à l'organolithien. Les organolithiens et les 2-naphtyloxazolines possèdent une réactivité similaire (45). Meyers a utilisé cette réaction comme étape clé dans la synthèse totale de composés d'intérêt biologique accessibles à partir de précurseurs possédant le squelette 1,2-dihydronaphtalène (44).

Les benzamides tertiaires peuvent être facilement *ortho*-métallés (46). Les 1-naphtylamides tertiaires présentent une réactivité analogue (47). Des travaux de Tomioka et coll. (48) et de Denmark et al. (49) montrent qu'en présence d'une quantité stœchiométrique ou catalytique de ligands chiraux tels que ceux représentés au schéma 4, les organolithiens réagissent avec l'ester 2,6-di-*tertio*-butyl-4-méthoxyphénylnaphtalène pour donner les adduits correspondants avec des excès énantiomériques compris entre 60 et 95 %.

Nous montrons dans ce travail que l'addition des organolithiens aux acides 1- et 2-naphtoïques (**1** et **2**, schéma 5) et le piégeage des énolates de dilithium **3** et **5** (communication préliminaire : réf. 50) par un réactif électrophile conduisent à des dihydronaphtalènes trisubstitués (**4** et **6**). Dans la littérature, ce type d'énolates est également obtenu par déprotonation d'acides alcanoïques par le LDA (51).

Avec le butyllithium secondaire à –78°C dans le THF, l'acide 1-naphtoïque **1** conduit à la formation d'un couple de diastéréoisomères **4a** et **4a′** dans le rapport 9 : 1 via l'énolate **7** (schéma 6 et entrée 1 du tableau 1).[2] La stéréochimie de l'isomère majoritaire **4a** isolé pur par recristallisation fractionnée a été déterminée par analyse cristallographique aux rayons X dont l'ORTEP est représenté à la fig. 1. Cette analyse montre que les groupes butyle secondaire en C2 et méthyle en C1 ont une géométrie *trans*. Cette étude permet également de préciser la configuration relative du carbone C2′. La stéréochimie au niveau des carbones C1 et C2 est confirmée par RMN ^{1}H (effet Overhauser entre l'hydrogène en C2 et le groupe méthyle en C1 de 13 %). Dans les mêmes conditions réactionnelles, le butyllithium conduit à un isomère unique **4e** (entrée 5). Comme l'étude RMN ^{1}H montre que dans ce cas également l'hydrogène en C2 et le groupe méthyle en C1 ont une géométrie *cis* (éclipsée) (effet Overhauser de 10 %), l'isomère minoritaire **4a′** obtenu avec le butyllithium secondaire diffère vraisemblablement de l'isomère majoritaire **4a** par la configuration relative du carbone latéral C2′. Avec l'iodoéthane et le disulfure de diméthyle (entrées 2 et 3), l'introduction du carbone latéral dissymétrique de l'organolithien s'effectue avec une moins bonne stéréosélectivité (75 : 25 et 65 : 35, respectivement). Compte tenu des résultats obtenus avec l'iodométhane, il est raisonnable de proposer une géométrie *cis* aux groupes butyle se-

[2] De façon standard, l'acide naphtoïque en solution dans le THF est ajoute au goutte-a-goutte à une solution de l'organolithien dans le THF prealablement refroidie à –78°C (voir partie experimentale). Le réactif électrophile est ajouté à la solution résultante à la même température. Un changement de température lors de la derrière addition affecte peu le rendement de la transformation et pratiquement pas la diastéréosélectivité. L'addition de HMPT ou de TMEDA est également sans effet sur le cours de la réaction.

[a]BuLi dans l'hexane; *s*-BuLi dans un mélange cyclohexane–hexane; 2,2 équiv. de RLi sont utilisés.
[b]Rendements en produits purifiés.
[c]Les rapports diastéréoisomériques sont déterminés par RMN ^{1}H du mélange réactionnel brut.
[d]Les produits d'addition 1,**4 4d,d′** et **6b,b′**n'ont pas été isolés mais sont détectables par analyse RMN ^{1}H du mélange brut réactionnel.

condaire en C2 et CO_2H en C1. La réaction du dianion dérivé de l'acide 1-naphtoïque avec l'hexachloroéthane ne conduit pas aux produits d'addition 1,4 attendus **4d,d′** mais à l'acide 2-(2-méthylpropyl)naphtoïque **9** (schéma 7 et entrée 4, tableau 1). Ce dernier composé résulte vraisemblablement de la déshydrohalogénation de **4d,d′** dans les conditions réactionnelles basiques.

Avec l'acide 2-naphtoïque **2**, des résultats analogues sont observés. L'énolate **8** résultant de l'addition du butyllithium secondaire conduit, après piégeage par l'iodométhane, aux diastéréoisomères **6a** et **6a′** dans le rapport 7 : 3 (schéma 8). L'analyse cristallographique aux rayons X de l'isomère majoritaire **6a** isolé pur par recristallisation fractionnée permet de montrer que dans ce cas également les groupements butyle secondaire en C1 et méthyle en C2 ont une géométrie *trans* (fig. 2). L'électrophile réagit par la face opposée à la face d'entrée de l'organolithien. Comme le composé **6c** est uniquement obtenu lorsque le butyllithium est utilisé comme nucléophile, l'isomère minoritaire **6a′** formé avec le butyllithium secondaire diffère vraisemblablement de l'isomère

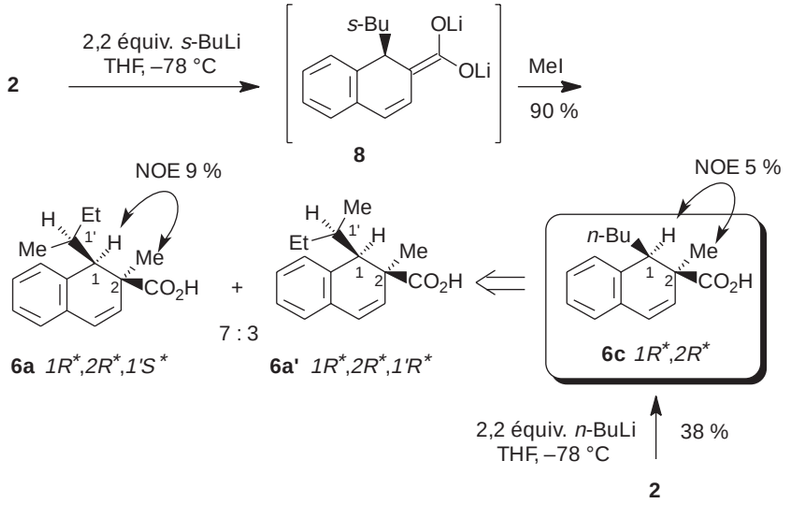
Schéma 8.

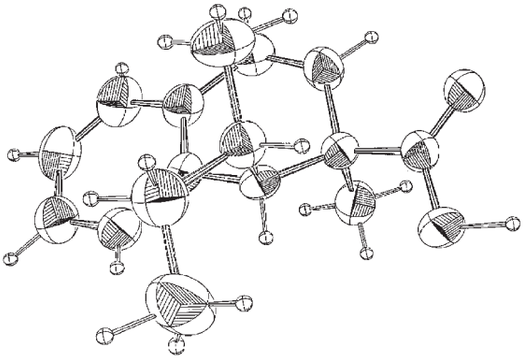


majoritaire **6a** par sa configuration au niveau du carbone latéral C1′. L'hexachloroéthane conduit au produit d'aromatisation **10** dans les conditions réactionnelles basiques (schéma 7 et entrée 7, tableau 1). Dans chacun des exemples étudiés, les produits d'addition 1,**2 11**–**14** sont obtenus avec des rendements inférieurs à 10 %.

3. Synthèse d'acides dihydronaphtoïques 1,2-disubstitués

La protonolyse des énolates résultant de l'addition du butyllithium secondaire à l'acide 1-naphtoïque **1** à –78°C dans le THF conduit à un mélange de dihydronaphtalènes 1,2-disubstitués diastéréoisomères **15a,a′,b,b′** (78 %) dans les proportions 56 : 14 : 24 : 16 (schéma 9). Comme ces produits sont susceptibles d'épimérisation ou (et) d'aromatisation dans les conditions réactionnelles basiques ou au cours de la protonolyse, l'acide trifluoroacétique dont la base conjuguée est faible a été utilisé. Lorsque l'acide trifluoroacétique en solution dans le THF est ajouté au goutte-à-goutte à l'énolate, le dihydronaphtalène formé peut être épimérisé également par l'énolate présent en excès dans le milieu. Cette éventualité n'est pas envisagée par Meyers et al. dans leurs travaux concernant la préparation de naphtyloxazolines 1,2-disubstituées chirales (44*a*).

Fig. 2. ORTEP de **6a**.



L'énolate de dilithium est préparé en additionnant le butyllithium secondaire à une solution préalablement refroidie à –78°C d'acide 1-naphtoïque dans le THF (mode inverse).[3] Cette solution est ultérieurement ajoutée au goutte-à-goutte à une solution d'acide trifluoroacétique (4 équivalents molaires) en solution dans le THF préalablement refroidi à –78°C.

[3] L'appareillage utilisé permet le transfert aisé en mode inverse de substances peu ou pas solubles et (ou) thermiquement instables. Voir la réf. 52.

Une chromatographie sur colonne de silice du mélange brut réactionnel permet d'isoler chacun des deux couples qui diffèrent par leurs configurations au niveau des carbones C1 et C2. Leurs configurations respectives ont été établies à partir des spectres RMN ^{1}H et ^{13}C (vide infra). Nous avons pu vérifier que les isomères **15a,a′,b,b′** sont obtenus dans les mêmes proportions mais avec un rendement moins bon (59 %) lorsque l'acide trifluoroacétique en solution dans le THF est ajouté à l'énolate à –78°C (mode d'addition normal). Aucune équilibration n'est observée lorsque chaque couple de diastéréoisomères est placé dans les conditions réactionnelles basiques.

La réaction de l'acide 2-naphtoïque avec le butyllithium secondaire conduit, en mode d'addition inverse, à un couple de diastéréoisomères **17a,a′** qui diffèrent par leurs configurations au niveau des carbones C1 et C1′ (66 %, 70 : 30) (schéma 10). Ces deux composés résultent de la protonation en position γ de l'anion allylique **16**. Une réactivité analogue a été observée par Meyers et al. avec les 2-naphtyloxazolines (53). La présence de deux doublets dédoublés à 6,47 (*J* = 9,4 et *J* = 3,1 Hz) et 6,23 ppm (*J* = 9,4 et *J* = 1,8 Hz) dans le spectre de RMN ^{1}H du mélange brut réactionnel montre que le produit d'addition conjugué **18** résultant de la protonation en position α de l'anion allylique **16** a également été formé (15 %). La stéréochimie de ce composé (mélange de diastéréoisomères) n'a pas été déterminée.

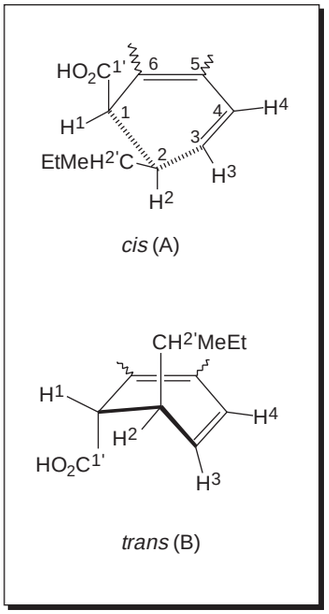
4. Analyse conformationnelle des composés 15a,a′,b,b′ et 4a,a′ dans le chloroforme deutérié par la spectroscopie RMN ^{1}H et ^{13}C

4-1. Étude des composés 15a,a′ et 15b,b′

L'analyse des constantes de couplage des spectres RMN ^{1}H effectués dans le chloroforme deutérié permet d'obtenir des informations intéressantes concernant la stéréochimie des composés synthétisés. Dans certains cas, il est même possible de mettre en évidence l'existence de conformations privilégiées.

© 1999 CNRC Canada

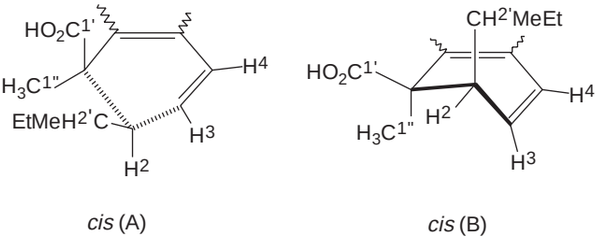
Fig. 3.



Les déplacements chimiques et les constantes de couplage des composés **15a,a′** et **15b,b′** sont indiqués dans le tableau 2. Pour **15a**, l'irradiation du multiplet à 2,59 ppm correspondant au proton H2 entraîne un effet Overhauser de 9 % au niveau du doublet de H1 à 3,86 ppm. Ce composé possède donc les deux protons H1 et H2 en *cis* et peut présenter deux conformations privilégiées A ou B éventuellement en équilibre (fig. 3). Pour chacune des deux conformations, les carbones C1 et C3–C6 sont quasi coplanaires, le carbone C2 étant situé au dessous (conformère A) ou au dessus du plan (conformère B). Dans le cas du conformère A, la valeur de l'angle dièdre formé par les plans H1-C1-C2 et C1-C2-H2 de 47° déterminée à partir du modèle moléculaire (Dreiding) et la valeur de la constante de couplage mesurée $J(1,2)$ = 6,5 Hz, sont en accord avec la relation de Karplus (54) adaptée empiriquement par Bothner-By (54*b*). La constante de couplage entre les protons H2 et H3, $J(2,3)$ = 3 Hz, est également compatible avec un angle dièdre formé par les plans H3–C3–C2 et C3–C2-H2 mesuré de 110° (55). En RMN ^{13}C, la constante de couplage entre le carbone du carbonyle C1′ et le proton H2, J(C1′,H2) = 11 Hz, est en accord avec l'angle déterminé à l'aide du modèle moléculaire (environ 180°). Par contre, cette constante de couplage de 11 Hz est incompatible avec l'angle mesuré pour une conformation B de la molécule (C1′ équatorial-H2 équatorial). De plus, dans l'hypothèse d'une conformation B, l'angle dièdre formé par les plans H3-C3-C2 et C3-C2-H2 mesuré de 25° n'est pas non plus compatible avec la valeur de la constante de couplage $J(2,3)$ de 3 Hz. En conséquence, le diastéréoisomère majoritaire **15a** possède en solution dans le chloroforme une géométrie *cis* au niveau des carbones C1 et C2 pour une conformation bloquée A.

Dans le cas de l'isomère minoritaire **15a′**, l'irradiation du signal à 2,51 ppm attribuable au proton H2 entraîne une augmentation de 10 % de l'intensité du signal de H1 à 3,79 ppm

Fig. 4.



par effet Overhauser. Les constantes de couplage $J(1,2)$ = 6,2 Hz et $J(2,3)$ = 2,6 Hz sont compatibles avec la conformation A. Ce diastéréoisomère possède donc la même géométrie *cis* au niveau des carbones C1 et C2 et se présente sous une conformation privilégiée identique à celle de l'isomère majoritaire **15a**. Les deux diastéréoisomères **15a** et **15a′** ne diffèrent que par la configuration du carbone C2′.

Le couple d'isomères **15b,b′** correspond alors, soit à une structure de géométrie *cis* (au niveau des carbones C1 et C2) de conformation B (fig. 3), soit à une structure de géométrie *trans* de conformation A ou B. Un effet Overhauser de 5 % est observé entre les protons H1 (3,76 ppm) et H2′ (1,44 ppm) de l'isomère majoritaire **15b**. Les protons H1 et H2′ doivent être proches dans l'espace, ce qui implique une géométrie *trans* au niveau des carbones C1 et C2. Le composé **15b** possède l'une des deux conformations privilégiées A ou B. La valeur de la constante de couplage $J(1,2)$ de 4,1 Hz n'est pas compatible avec une géométrie axiale–axiale des protons H1 et H2 (conformation A). L'angle dièdre mesuré entre les plans H1-C1-C2 et C1-C2-H2 de 60° (H1 et H2 en positions équatoriales) dans le cas de la conformation B est par contre cohérent avec cette valeur. De plus, la valeur de la constante de couplage $J(2,3)$ de 5,1 Hz est en accord avec l'angle dièdre formé par les plans H3-C3-C2 et C3-C2-H2 (25°). La proximité de H2 et H3 est confirmée par un effet NOE de 5 % entre ces deux protons. En RMN ^{13}C, le couplage J(C1′,H2) égal à 5 Hz est également compatible avec les positions C1′ axiale et H2 équatoriale. La même étude effectuée avec l'isomère minoritaire **15b′** conduit à des résultats similaires. Le couple de composés **15b,b′** possède une géométrie *trans* au niveau des carbones C1 et C2 et la conformation privilégiée des deux diastéréoisomères est B.

4-2. Étude des composés 4a,a′

Dans le cas de l'isomère majoritaire **4a** résultant de la réaction de l'énolate **7** avec l'iodométhane, les conformères *cis* (A) et *cis* (B) sont compatibles avec un effet Overhauser de 13 % observé au niveau du proton H2 lorsque le groupe méthyle en C1 à 1,57 ppm est irradié (fig. 4). En RMN ^{13}C, dans le cas du conformère A, la constante de couplage entre le carbone du carbonyle C1′ et le proton H2, J(C1′,H2) de 1 Hz ne correspond pas à l'angle déterminé à l'aide du modèle moléculaire (environ 180°). La constante de couplage entre les protons H2 et H3, $J(2,3)$ = 5,7 Hz, n'est pas non plus en accord, d'après la relation de Karplus adaptée empiriquement par Garbisch, avec l'angle dièdre formé par les plans H2-C2-C3 et C2-C3-H3 (110°). Pour la conformation B, le même angle qui a pour valeur 30° est compatible avec la constante de couplage $J(2,3)$ = 5,7 Hz. Par contre, l'angle

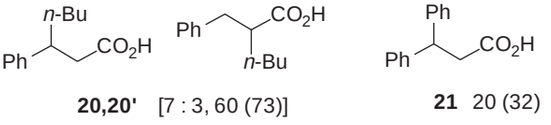
dièdre formé par les plans C1′′-C1-C2 et C1-C2-H2 de 62° n'est pas cohérent avec le fort effet Overhauser observé (13 %). Le cyclohexadiène est vraisemblablement légèrement déformé par des effets stériques tendant à diminuer l'angle entre les plans C1′′-C1-C2 et C1-C2-H2. Ce résultat est confirmé par les valeurs mesurées par analyse cristallographique aux rayons X : les angles 41,9° pour les plans C1′′-C1-C2 et C1-C2-H2, 75,1° pour les plans C1′-C1-C2 et C1-C2-H2 et 35,3° pour les plans H2-C2-C3 et C2-C3-H3 sont compatibles avec les constantes de couplage observées J(2,3) = 5,7 Hz, J(C1′,H2) = 1 Hz et avec l'effet Overhauser de 13 %. Le composé **4a** possède vraisemblablement la conformation privilégiée B.

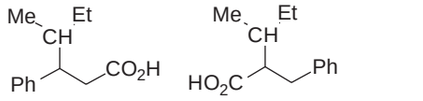
5. Addition stéréosélective d'organolithiens aux acides carboxyliques α,β-insaturés acycliques

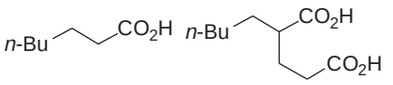
Les acides carboxyliques α,β-insaturés acycliques et les organolithiens donnent préférentiellement des réactions d'addition conjuguée dans le THF à –78°C (56) (schéma 11). Avec l'acide crotonique, le butyllithium, le phenyllithium et le butyllithium secondaire, les produits **19a,d,e,e′** sont obtenus avec de bons rendements, après piégeage de l'énolate de dilithium intermédiaire par l'acide trifluoroacétique (schéma 12). Le méthyllithium ne réagit pas dans les mêmes conditions et conduit au produit d'addition sur la fonction carbonyle par réaction à température plus élevée (24). L'énolate de dilithium formé intermédiairement peut être protoné par l'acide trifluoroacétique, méthylé par l'iodométhane ou méthylsulfénylé par le disulfure de diméthyle. La réaction du butyllithium et de l'iodométhane conduit avec un bon rendement purifié (76 %) à un mélange de composés diastéréoisomères **19b** et **19b′** dans le rapport 1 : 1 qui diffèrent au niveau de leurs carbones C2 et C3. Le disulfure de diméthyle conduit dans les mêmes conditions aux deux diastéréoisomères **19c** et **19c′** avec un rendement brut moyen 3 : 2 (50 %). La réaction du butyllithium secondaire suivie d'une protonolyse conduit aux diastéréoisomères **19e** et **19e′** qui diffèrent au niveau de leurs carbones C3 et C4 (7 : 3, 46 %).

Schéma 13.



[ratio, rendement purifié (rendement brut[a]) %]
[a] déterminé par RMN-^{1}H





La réaction du butyllithium et du butyllithium secondaire avec l'acide (*E*)-3-phénylpropénoïque conduit dans chaque cas à la formation de deux isomères de position, l'addition en β de la fonction acide carboxylique étant majoritaire (schéma 13). Quelques rares exemples de la littérature décrivent l'addition conjuguée d'organolithiens en position β d'un groupe phényle (35, 57). Les structures **20** et **20'** peuvent être facilement différenciées en RMN ^{13}C par la multiplicité et par le déplacement chimique du signal du carbone de la fonction acide carboxylique. L'acide acrylique réagit avec le butyllithium dans le THF à –78°C et les acides **24** et **25** sont obtenus avec des rendements de 50 % et 30 % respectivement. Le composé **25** résulte de la double addition de l'énolate intermédiaire à l'acrylate de lithium (autres méthodes de préparation du composé **25** : réf. 58).

La réaction de l'acide phénylpropiolique **26** avec le butyllithium dans le THF à –78°C et la protonolyse par l'acide trifluoroacétique à la même température conduisent à la formation exclusive du composé **27** facilement purifiable par recristallisation (heptane – acétate d'éthyle) (70 %, schéma 14).[4,5] Le dianion **28** résultant de la *trans* addition du butyllithium au phénylpropiolate de lithium est formé préférentiellement. Il est intéressant de noter l'analogie structurale existant entre **28** et le dianion *ortho*-lithio benzoate de lithium **29** obtenu par traitement de l'acide benzoïque avec le complexe 1 : 1 *s*-BuLi/TMEDA (29, 30). L'interaction forte — responsable

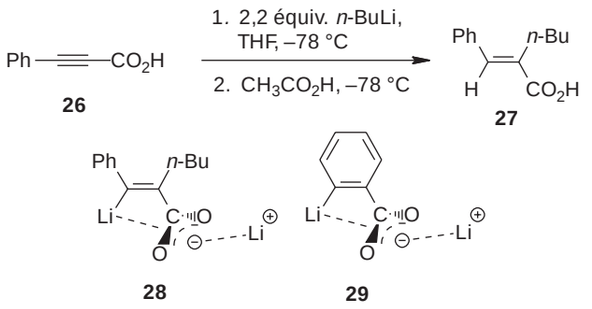
Schéma 14.



de l'effet CIPE observé (60) — existant à –78°C entre le carboxylate et le cation lithium contribue probablement à augmenter la stabilité des dianions **28** et **29**.

6. Partie expérimentale

Le butyllithium secondaire (1,3 M en solution dans un mélange cyclohexane–hexanes), le butyllithium (1,6 M en solution dans l'hexane) et le méthyllithium (1 M en solution dans l'éther) commercialisés par Acros Chemicals et Aldrich Chemical Company, sont titrés périodiquement par l'alcool 2,5-diméthoxybenzylique. Le THF est distillé sur sodium–benzophénone. Les spectres de RMN ont été enregistrés sur un spectromètre Bruker ARX 200 ou Bruker AM 300 opérant à 200 et 300 MHz pour le proton et à 50,3 et 75,5 MHz pour le carbone-13. Les déplacements chimiques δ sont exprimés en ppm par rapport au tétraméthylsilane (TMS) utilisé comme référence interne lorsque $CDCl_3$ est le solvant. Les constantes de couplage sont exprimés en Hz. Les abréviations suivantes sont utilisées : s (singulet), sl (singulet large), d (doublet), dl (doublet large), dd (doublet dédoublé), t (triplet), q (quadruplet), m (multiplet). Les spectres SM-EI ont été réalisés sur un spectromètre Varian MAT 311.

Les (flash) chromatographies sur colonne ont été effectuées sur gel de silice 60 Merck (70–230 mesh et 230–400 mesh). Les plaques Merck en aluminium recouvertes de gel de silice 60 F 254 (0,2 torr (1 torr = 133,3 Pa)) sont utilisées pour les chromatographies analytiques sur couche mince. Les éluants et solvants de recristallisation (éther, heptane, acétate d'éthyle) sont utilisés sans purification préalable. Les points de fusion ont été déterminés à l'aide d'un appareil Büchi 510. Les distillations sont effectuées au four tubulaire Büchi GRK 50. Les points d'ébullition sont déterminés à ±10 degrés. Les analyses centésimales ont été réalisées par le Service central d'analyse du CNRS de Gif-sur-Yvette.

Synthèse d'acides dihydronaphtoïques — Mode opératoire général

Dans un ballon de 250 mL à tubulure latérale muni d'une ampoule à addition isobare sous argon, sont introduits successivement le THF et l'organolithien à –30 à 40°C. Le mélange est refroidi à –78°C et l'acide 1- ou 2-naphtoïque en solution dans le THF (20 mL) est ajouté au goutte-à-goutte. Le mélange est agité pendant une heure à –78°C puis le réactif électrophile en solution dans le THF (20 mL) est additionné lentement. Le milieu réactionnel est amené à température ambiante sous agitation puis traité par de l'eau (30 mL). La phase aqueuse est lavée deux fois avec de l'éther (40 mL). Le séchage et l'évaporation du solvant permettent d'isoler le produit d'addition 1,2 avec un rendement généralement compris entre 3 et 10 % après chromatographie sur colonne de silice (heptane – acétate d'éthyle). La phase aqueuse est acidifiée par HCl 2 M (40 mL) puis additionnée d'éther (40 mL). La phase organique est séparée, lavée par une solution saturée de bicarbonate de sodium (40 mL) et par de l'eau (40 mL) puis séchée sur $MgSO_4$. La filtration du sel et l'évaporation du solvant conduisent à un mélange brut constitué des adduits 1,4 qui peuvent être isolés et purifiés par recristallisation ou chromatographie.

trans-*1-Carboxy-1-méthyl-2-(2-méthylpropyl)-1,2-dihydronaphtalènes (**4a,a′**)*

Selon le mode opératoire général, la réaction de l'acide 1-naphtoïque (2,58 g, 15 mmol) et du butyllithium secondaire (25,4 mL d'une solution 1,3 M dans un mélange cyclohexane–hexanes, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'iodométhane (8,52 g, 60 mmol) dans le THF (20 mL) conduisent au composé **4a** obtenu pur (2,64 g, 72 %) après recristallisation fractionnée (heptane – acétate d'éthyle) (**4a**,**4a′** 9 : 1). Les caractéristiques spectroscopiques de l'isomère minoritaire **4a′** (8 %) sont obtenues par différence à partir des spectres du mélange.

1-Carboxy-2-(2-méthylpropyl)-1,2-dihydronaphtalènes (15a,a′ et 15b,b′) — addition de l'énolate au réactif électrophile en mode inverse

L'appareillage pour addition inverse utilisé est décrit à la réf. 52. Dans un ballon B de 250 mL à trois tubulures muni d'une ampoule à addition isobare sous argon, sont introduits successivement le THF (60 mL) et le butyllithium secondaire (22,7 mL d'une solution 1,4 M dans un mélange cyclohexane–hexanes, 33 mmol) à –30 à 40°C. Le mélange est refroidi à –78°C et l'acide 1-naphtoïque (2,58 g, 15 mmol) en solution dans le THF (20 mL) est ajouté au goutte-à-goutte. Le milieu réactionnel est agité pendant 1 h à –78°C. Dans un ballon A de 250 mL à deux tubulures et purgé sous argon est placé l'acide trifluoroacétique (4,6 mL, 60 mmol) en solution dans le THF (20 mL). La solution résultante est refroidie à –78°C. À cette solution est ajoutée au goutte-à-goutte l'énolate précédemment préparé. Le milieu réactionnel est amené lentement à température ambiante puis traité par une solution de HCl 2 M (40 mL). La phase aqueuse est lavée avec de l'éther (40 mL). Les phases organiques sont rassemblées et lavées par une solution saturée de bicarbonate de sodium (20 mL) et par de l'eau (40 mL) puis séchée sur $MgSO_4$. La filtration du sel et l'évaporation du solvant conduisent à un mélange brut constitué des adduits **15a,a′** et **15b,b′** (78 %, 56 : 14 : 24 : 16) purifiés par chromatographie sur colonne de silice (gradient d'élution 9 : 1 → 7 : 3, heptane – acétate d'éthyle). Les couples de diastéréoisomères **15a,a′** et **15b,b′** sont isolés avec des rendements respectifs de 30 et 16 %. Huiles rouge-ocre.

Synthèse d'acides alkanoïques acycliques — mode opératoire général

Dans un ballon de 250 mL à tubulure latérale muni d'une ampoule à addition isobare sous argon, sont introduits successivement le THF (50 mL) puis l'organolithien à –30 à 40°C. Le milieu réactionnel est refroidi à –78°C et l'acide carboxylique α,β-insaturé en solution dans le THF (20 mL) est ajouté au goutte-à-goutte. Le mélange est agité pendant 1 h à –78°C puis le réactif électrophile en solution dans le THF (20 mL) est additionné lentement. Le milieu réactionnel est amené à température ambiante sous agitation puis traité par une solution de HCl 2 M (40 mL). La phase aqueuse est lavée avec de l'éther (40 mL). Les phases organiques sont rassemblées, lavées trois fois par une solution saturée de bicarbonate de sodium (20 mL). La phase aqueuse est séparée, acidifiée par une solution de HCl 2 M (60 mL) puis additionnée d'éther (60 mL). La phase organique est séparée puis séchée sur $MgSO_4$. La filtration du sel et l'évaporation du solvant permettent de récupérer après recristallisation ou distillation les produits de réaction purs.

*Acide 3-méthylheptanoïque (**19a**)*

Selon le mode opératoire général, la réaction de l'acide crotonique (1,29 g, 15 mmol) et du butyllithium (20 mL d'une solution 1,6 M dans l'hexane, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (2,31 mL, 33 mmol) dans le THF (20 mL) conduisent au composé **19a** obtenu pur (1,72 g, 80 %) après distillation (Eb = 75–80°C/1 torr). Huile incolore. RMN ^1H (200 MHz) δ ppm : 11,80 (sl, 1H), 2,36 (dd, 1H, J = 6 et 15 Hz), 2,14 (dd, 1H, J = 8 et 15 Hz), 1,96 (m, 1H), 1,36–1,21 (m, 6H), 0,96 (d, 3H, J = 6,5 Hz), 0,89 (t, 3H, J = 6 Hz). RMN ^{13}C (50,3 MHz) δ ppm : 180,3; 41,7; 36,4; 30,2; 29,1; 22,8; 19,7; 14,1. SM-HR calc. pour $C_4H_7O_2$ [M – $C_4H_9]^+$: 87,0446; tr. : 87,0445.

*Acides 2,3-diméthylheptanoïques (**19b,b′**)*

Selon le mode opératoire général, la réaction de l'acide crotonique (1,29 g, 15 mmol) et du butyllithium (16,5 mL d'une solution 2 M dans l'hexane, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'iodométhane (3,73 mL, 60 mmol) dans le THF (20 mL) conduisent au mélange des diastéréoisomères **19b** et **19b′** purifiés par distillation (1,28 g, 54 %) (Eb = 70°C/0,01 torr). Huile incolore. RMN ^1H (200 MHz, mélange) δ ppm : 11,36 (br, 2H), 2,40 (m, 2H), 2,00–1,67 (m, 2H), 1,46-1,17 (m, 12H), 1,13 (d, 3H, J = 7 Hz), 1,08 (d, 3H, J = 7 Hz), 0,98–0,86 (m, 12H). RMN ^{13}C (50,3 MHz, mélange) δ ppm : 183,5; 183,2; 44,7; 44,0; 35,8; 35,1; 34,5; 32,9; 29,5; 29,2; 22,9; 22,8; 17,2; 15,6; 14,1; 13,6; 11,7. SM-HR calc. pour $C_5H_9O_2$ [M – $C_4H_9]^+$: 101,0602; tr. : 101,0592.

*Acide 2-méthylthio-3-méthylheptanoïque (**19c,c′**)*

Selon le mode opératoire général, la réaction de l'acide crotonique (1,29 g, 15 mmol) et du butyllithium (17,8 mL d'une solution 1,85 M dans l'hexane, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par le disulfure de diméthyle (5,32 mL, 60 mmol) dans le THF (20 mL) conduisent au mélange des composés **19c,c′** (1,42 g, 40 : 60 (rapport diastéréoisomérique déterminé sur le mélange distillé), 50 %) purifiés par distillation (Eb = 55–65°C/0,1 torr). Huile jaune. RMN ^1H (200 MHz, mélange) δ ppm : 11,00 (sl, 1H), 3,00 (d, 1H, J = 8,3 Hz), 2,16 (s, 3H), 1,43–0,89 (m, 13H). RMN ^{13}C (50,3 MHz) δ ppm : 178,8; 178,6; 54,5; 54,2. SM-HR calc. pour $C_9H_{18}O_2S$: 190,1027; tr : 190,1030.

*Acide 3-phénylbutyrique (**19d**)*

Selon le mode opératoire général, la réaction de l'acide crotonique (1,29 g, 15 mmol) et du phényllithium (33 mL d'une solution 1 M dans l'éther, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (4,62 mL, 60 mmol) dans le THF (20 mL) conduisent au composé **19d** obtenu pur (0,95 g, 40 %) après distillation (Eb = 90°C/0,1 torr). Huile incolore. RMN ^1H (200 MHz) δ ppm : 10,00 (sl, 1H), 7,35–7,16 (m, 5H), 3,26 (m, 1H), 2,68 (dd, 1H, J = 15,7 et 7 Hz), 2,56 (dd, 1H, J = 15,7 et 8,5 Hz), 1,31 (d, 3H, J = 7 Hz). RMN ^{13}C (50,3 MHz) δ ppm : 178,7; 145,4; 128,6; 126,7; 126,5; 42,6;

*Acides 3-phényl-heptanoïque (**20**) et 2-benzyl-hexanoïque (**20′**)*

Selon le mode opératoire général, la réaction de l'acide (*E*)-3-phénylpropénoïque (2,22 g, 15 mmol) et du butyllithium (20 mL d'une solution 1,6 M dans l'hexane, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (4,62 mL, 60 mmol) dans le THF (20 mL) conduisent au mélange d'isomères **20** et **20′**. Le composé **20** peut être obtenu pur après distillation : Eb = 90°C/0,1 torr (litt. (62) Eb = 118°C/0,3 torr) et chromatographie sur colonne de silice (95 : 5 heptane – acétate d'éthyle) (1,64 g, 48 %). Huile incolore. RMN ^{1}H (300 MHz) δ ppm : 9,90 (sl, 1H), 7,28–7,15 (m, 5H), 3,10–3,01 (m, 1H, *J* = 7 et 8 Hz), 2,66 (dd, 1H, *J* = 7 et 15,5 Hz), 2,59 (dd, 1H, *J* = 8 et 15,5 Hz), 1,73-1,52 (m, 2H), 1,35–1,04 (m, 4H), 0,82 (t, 3H, *J* = 7 Hz). RMN ^{13}C (75,5 MHz) δ ppm : 178,4; 143,9; 128,5; 127,4; 126,5; 41,8; 41,5; 35,9; 29,5; 22,5; 13,9. SM-HR calc. pour $C_{13}H_{18}O_2$: 226,1307; tr. : 226,1313.

20′ : RMN ^{1}H (200 MHz) δ ppm : 11,60 (sl, 1H), 7,83–7,14 (m, 5H), 2,94 (m, 1H), 2,77–2,62 (m, 2H), 1,69–1,58 (m, 2H), 1,31–1,08 (m, 4H), 0,86 (t, 3H, *J* = 6,5 Hz). RMN ^{13}C (50,3 MHz) δ ppm : 182,4; 139,1; 128,9; 128,4; 126,4; 47,4; 38,1; 31,4; 29,3; 22,5; 13,8. SM-HR calc. pour $C_{13}H_{18}O_2$: 226,1307; tr. : 226,1313.

*Acide 3,3-diphényl-propionique (**21**)*

Selon le mode opératoire général, la réaction de l'acide (*E*)-3-phénylpropénoïque (2,22 g, 15 mmol) et du phényllithium (33 mL d'une solution 1 M dans l'éther, 33 mmol) dans le THF (40 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (4,62 mL, 60 mmol) dans le THF (20 mL) conduisent au composé **21** obtenu pur (0,68 g, 20 %) après recristallisation dans un mélange toluène–hexane. Poudre blanche. *F* = 154–156°C (litt. (63) *F* = 155°C). RMN ^{1}H (200 MHz) δ ppm : 10,90 (br, 1H), 7,32–7,14 (m, 10 H), 4,52 (t, 1H, *J* = 8 Hz), 3,08 (d, 2H, *J* = 8 Hz). RMN ^{13}C (50,3 MHz) δ ppm : 177,0; 143,2; 128,6; 127,6; 126,6; 46,6; 40,3.

*Acides 3-phényl-4-méthylhexanoïques (**22′,22″,23′,23″**)*

Selon le mode opératoire général, la réaction de l'acide (*E*)-3-phénylpropénoïque (2,22 g, 15 mmol) et du butyllithium secondaire (25,4 mL d'une solution 1,3 M dans un mélange cyclohexane–hexanes, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (4,62 mL, 60 mmol) dans le THF (20 mL) conduisent au mélange des diastéréosomères **22′,22″,23′,23″** (42 : 22 : 23 : 13, détermination RMN ^{13}C) purifiés par distillation (2,37 g, 70 %, Eb = 110°C/0,3 torr). Huile incolore. SM-HR calc. pour $C_{13}H_{18}O_2$: 226,1307; tr. : 226,1310.

*Acides hexanoïque (**24**) et 2-pentyl-glutarique (**25**)*

Selon le mode opératoire général, la réaction de l'acide acrylique (1,03 mL, 15 mmol) et du butyllithium (16,5 mL d'une solution 2 M dans l'hexane, 33 mmol) dans le THF (40 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (4,62 mL, 60 mmol) dans le THF (20 mL) conduisent à un mélange des composés **24** et **25** (5 : 3, proportions déterminées par RMN ^{1}H) non séparable par distillation (Eb = 90–92°C/0,1 torr) (80 %) (58). Huile jaune.

24 : RMN ^{1}H (300 MHz) δ ppm : 10,54 (sl, 1H), 2,35 (t, 2H, *J* = 7,6 Hz), 1,63 (q, 2H), 1,38–1,25 (m, 6H), 0,85 (t, 3H, *J* = 6,8 Hz).

25 : RMN ^{1}H (300 MHz) δ ppm : 10,54 (sl, 2H), 2,44 (t, 2H, *J* = 7,3 Hz), 2,42 (m, 1H), 2,02–1,81 (m, 2H), 1,68 (m, 1H), 1,48 (m, 1H), 1,25–1,38 (m, 6H), 0,88 (t, 3H, *J* = 6,8 Hz).

24, ***25*** : RMN ^{13}C (50,3 MHz) δ ppm : 182,3; 180,6; 179,6; 44,7 (**25**); 34,1 (**24**); 32,0; 31,9 (**25**); 31,7; 31,4; 28,7; 26,8; 26,6 (**25**); 22,5 (**24**); 14,0 (**24**, **25**).

SM-HR calc. pour $C_{10}H_{17}O_3$ $[M - OH]^+$: 185,1178; tr : 185,1194.

*Acide 2-butyl-3(*E*)-phényl-but-3-en-2-one (**27**)*

Selon le mode opératoire général, la réaction de l'acide phénylpropiolique (2,19 g, 15 mmol) et du butyllithium (20,6 mL d'une solution 1,6 M dans l'hexane, 33 mmol) dans le THF (60 mL) et le traitement de l'énolate résultant par l'acide trifluoroacétique (2,31 mL, 30 mmol) dans le THF (20 mL) conduisent au composé **27** purifié par recristallisation (heptane – acétate d'éthyle) (1,6 g, 52 %). *F* = 82–84°C (litt. (64) *F* = 83–84°C). Solide blanc. RMN ^{1}H (300 MHz) δ ppm : 11,3 (sl, 1H), 7,81 (s, 1H), 7,41–7,30 (m, 5 H), 2,57–2,52 (m, 2H), 1,64–1,53 (m, 2H), 1,46–1,34 (m, 2H), 0,93 (t, 3H, *J* = 7 Hz). RMN ^{13}C (50,3 MHz) δ ppm : 174,3; 140,9; 135,6; 132,9; 129,4; 128,7; 128,5; 31,3; 27,0; 22,9; 13,8. SM-HR calc. pour $C_{13}H_{16}O_2$: 204,1150; tr. : 204,1139.

A versatile synthetic route to 1,5-dithiocins from *o*-mercapto aromatic aldehydes[1]

Ian W.J. Still, Rosanne Natividad-Preyra, and F. Dean Toste

Abstract: An earlier procedure for the facile preparation of benzo-fused 1,5-dithiocins **2a–2c** from *o*-mercapto-benzaldehydes has been improved and shown to be capable of extension to the preparation of several naphthalene-derived analogues. The general method also afforded several N-alkylated 1,5-dithiocins **4, 5** by replacing NH_3 with the appropriate primary amine. It was found that N-acylation of the 1,5-dithiocins was successful only with methyl chloroformate. Attempted N-phenylation met with limited success but was shown to be unnecessary since even the less reactive aniline readily undergoes the general reaction of primary amines. When simple α-amino acids, or their methyl esters, were employed as the primary amine in the reaction with *o*-mercaptobenzaldehyde, the formation of the N-alkylated 1,5-dithiocins **4a**, **17a**, **17b** with accompanying loss of -COOH or -COOMe was observed, in preparatively useful yields. A mechanism is proposed for this interesting transformation.

Key words: 1,5-dithiocins, α-amino acids, N-acylation, decarboxylation.

Résumé : On a amélioré une méthode proposée antérieurement pour préparer facilement des benzo-1,5-dithiocines, **2a–2c**, à partir des *o*-mercaptobenzaldéhydes et on a démontré qu'on peut l'étendre à la préparation de plusieurs dérivés du naphtalène. La méthode générale permet aussi d'obtenir plusieurs 1,5-dithiocines *N*-alkylées (**4, 5**) en remplaçant le NH_3 par l'amine primaire appropriée. On a observé que la *N*-acylation des 1,5-dithiocines ne se fait correctement qu'avec du chloroformiate de méthyle. Des essais en vue d'effectuer une *N*-phénylation ont conduit à des résultats mitigés; toutefois, cette limitation ne présente pas de problèmes puisque l'on peut obtenir le même produit en procédant à la réaction générale en présence d'aniline, même si celle-ci est moins réactive. Lorsqu'on utilise des acides α-aminés simples ou leurs esters méthyliques comme amine primaire dans la réaction avec l'*o*-mercaptobenzaldéhyde, on observe la formation des 1,5-dithiocines *N*-alkylées, **4a, 17a**, **17b**, avec des rendements préparativement utiles. On propose un mécanisme pour cette transformation intéressante.

Mots clés : 1,5-dithiocines, acides α-aminés, *N*-acylation, décarboxylation.

[Traduit par la Rédaction]

Introduction

Molecules possessing a structurally well-defined, V-shaped molecular cleft have recently attracted considerable attention due to their application toward problems in the areas of molecular recognition, self-assembly, and supramolecular chemistry (1, 2). Molecules possessing molecular chirality in addition are of interest as potential chiral ligands and solvating agents. Chiral molecules that lock two aromatic rings in almost perpendicular planes, such as Tröger's base **1** (3) are of special interest as DNA probes owing to their different possible modes of interaction with DNA and to their chiral properties (4, 5). We felt that it would be advantageous to prepare this type of compound containing a readily functionalized group (such as a secondary amine) for which a variety of derivatives could easily be produced. The preparation of the racemic 6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocins **2a–2c**, representing easily obtained examples of such compounds, was reported earlier by us (6).

The preparation of the imino-bridged, 1,5-dithiocin ring system was reported as early as 1958 (7) and that of the dibenzo[*b*,*f*] analog **2b** by Gol'dfarb et al. (8) in 1966. These synthetic procedures, and the later serendipitous preparations of dibenzo[*b*,*f*]-1,5-dithiocins by Corrigan and West (9) and, more recently, Brieaddy and Donaldson (10), were of limited utility. Moreover, structural proof, notably the absence of NMR spectra in the earlier papers cited, was inadequate. Our previous work (6) was therefore important not only in establishing the structure of **2b** and its analogues by X-ray analysis but also in making available a general synthetic approach to such molecules.

We describe herein an improved experimental procedure for the preparation of **2a–2c** that also allows the facile preparation of N-alkyl and N-aryl analogues of these molecules. We also describe our attempts to prepare N-acyl analogues and the ready extension of our methodology to several

naphtho-fused analogues of **2a**. Finally, the results of our attempts to prepare chiral N-alkylated analogues of **2a** *directly* by utilizing natural α-amino acids or their methyl esters in our general approach will be discussed.

Results and discussion

The benzo-fused 1,5-dithiocins **2a–2c** were prepared, as reported previously (6), starting from the appropriate thiol and carrying out a selective *ortho* formylation via a doubly lithiated (S,C-) intermediate. We have found that yields in the formylation could be almost doubled (to 63–81%) if *N*-formylpiperidine was used as the formylating agent, in place of DMF. We have also discovered that the subsequent cyclization step converting **3a–3c** into **2a–2c** is more conveniently achieved with NH_4OAc in refluxing ethanol rather than in nitromethane, presumably by the mechanism we had previously outlined (6). The reaction was also attempted using other amonium salts (e.g., NH_4Cl, NH_4SCN) but, with the exception of NH_4HCO_3, only the acetate seems to offer the right balance between acid and base catalysis, which seems to be crucial.

By modifying the reaction of **3a** or **3b** and replacing the ammonium acetate with a mixture of primary amine and acetic acid (1:4) we have been able to prepare the N-alkyl analogues **4a–4c** and **5a**, **5b** in excellent yields (83–91%). Interestingly, **4a** could also be obtained in the absence of acetic acid but in a very much lower yield (27%).

It was felt that the creation of the naphtho-fused analogues of these 1,5-dithiocins would provide molecules with more pronounced clefts and potentially more interesting solvating effects. We accordingly undertook the synthesis of the three isomeric *ortho*-mercaptonaphthaldehydes **6–8**. Compound **6** was readily obtained from 1-naphthalenethiol,[3] by our general procedure using *N*-formylpiperidine, in 43% yield. It was found in the naphthalene series that a slightly higher molar ratio of both the *n*-butyllithium and the TMEDA complexing agent gave the best results (2.5 equiv. of each, vs. 2.2 equiv. for the benzene analogues).

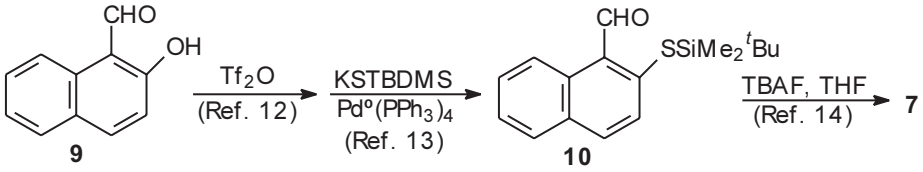
Scheme 1.



Application of our general formylation procedure to the isomeric 2-naphthalenethiol afforded the two isomeric aldehydes **7** and **8**, in isolated yields of 45% and 30%, respectively. That the major isomer was the (expected) result of 1-formylation of the naphthalene nucleus was confirmed by an unambiguous synthesis of **7** from 2-hydroxy-1-naphthaldehyde **9** in 42% overall yield, by the three-step sequence shown in Scheme 1 (11), slightly modified in Step 2 (see Experimental).

With the necessary three naphthaldehydes in hand, we were able to complete our synthesis of the three isomeric naphtho-fused 1,5-dithiocins **11**–**13**, from **6**, **7**, and **8**, respectively. The same experimental procedure was used as for the benzo-fused analogues **2a**–**2c** and excellent yields (>90%) of these crystalline solids were obtained for all three cases. Recently, Biehl et al. (15) reported the synthesis of the 1,5-dioxocin **14a** (analogous to **12**) by the reaction of **9** with ammonium acetate, accompanied by a small amount of the O-bridged derivative **14b**. The mechanism proposed by these authors for the formation of **14a** is essentially identical to that which we had earlier proposed (6), differing only in the order of the steps involved.

Attempts have been made to introduce an N-acyl group into these imino-bridge molecules. Using **4b** as a representative example, we sought to introduce N-benzoyl and N-propanoyl groups by reaction of **4b** with benzoyl chloride and propanoic acid–DCC, respectively, but failed to obtain the amides in preparatively useful yields. When methyl chloroformate was used, however, in refluxing acetone with K_2CO_3 (or, better still, Cs_2CO_3 (16)) as the base, we ob-

tained the expected carbamate **15** in over 60% yield. Unlike the starting imino analogue and its congeners, **15** shows the two methine protons, in addition to the expected downfield shift, as nonequivalent (δ_H = 6.74, 6.57), presumably due to restricted bond rotation in the N—CO_2Me bond.

We have also attempted to introduce an N-phenyl substituent in the 1,5-dithiocins. Using a procedure described by Barton et al. (17) we first attempted this with **2a**, using Ph_3Bi as phenylating agent, with $Cu(OAc)_2$ as the catalyst. The reaction mixtures obtained in various trials were complex and in no case was more than 25% of the desired **4d** present. Accordingly, we reverted to our standard methodology, using **3a**, aniline, and a somewhat longer reflux period, and were rewarded by obtaining the crystalline **4d** in 75% yield.

One potential application of our 1,5-dithiocins was in the area of asymmetric base-catalyzed reactions. The early work of Noyori and coworkers (18) established (–)-sparteine, a readily available alkaloid, as a potential agent for enantioinduction at carbanion centres and several recent reports have made good use of this type of methodology (refs. 19 (for recent reviews) and 20). For our compounds to be useful in this type of application, it will be necessary to prepare enantiomerically pure 1,5-dithiocins. As one approach to this problem we decided to investigate the use of enantiomerically pure amines in our general method since, in principle, the diastereomeric dithiocins so obtained should be readily separable.

Our first attempt along these lines employed *R*-1-phenylethylamine as the derivatizing amine, in a reaction with **3b**. Disappointingly, however, we were unable to achieve a complete separation of the diastereomeric pair of dithiocins **16** so formed, under a variety of conditions. We next decided to use one of the readily available, inexpensive, α-amino acids to achieve our purpose. Reaction of **3a** with L-leucine under the usual conditions led, much to our surprise, to a benzo-fused dithiocin which showed no evidence for -COOH either in the IR or the proton NMR. The structure of the product has been established as **17a**, the *N*-(3′-methylbutyl) analogue of the N-alkylated series, formed here in 68% yield. When the reaction was repeated using L-leucine methyl ester the same product was obtained. Thus, formation of the N-alkylated 1,5-dithiocins in these reactions from α-amino acids *or* their methyl esters is accompanied by loss of the carboxylate moiety.

Confirmation that the structural assignment to the products of this new reaction was correct came from the reaction of **3a** with L-phenylalanine methyl ester. The product, obtained in 63% yield, was identical in all respects with **4a**, obtained independently as described above. A further example of this interesting reaction was shown by the formation of the 2′-hydroxyethyl analogue **17b** in 75% yield when **3a** was allowed to react with L-serine methyl ester under the usual conditions.

We propose that this novel reaction may proceed by a mechanism akin to the known enzymatic decarboxylation of

α-amino acids, catalyzed by pyridoxal phosphatase (21). The key intermediate in our proposed mechanism for the reaction with L-leucine (Scheme 2) is the initial iminium ion **18**, which, under the approximately neutral pH conditions employed, leads to decarboxylation and a second iminium species **19**, which undergoes a protropic rearrangement to the more stable iminium ion **20** and is trapped by thiol (thiolate), leading to the 1,5-dithiocin in the usual way. Since thiolate ions are known to be excellent nucleophiles it is quite conceivable that intramolecular demethylation could first occur in the analogous reaction with the methyl ester, leading to the same carboxylate species **18**. Indirect support for this hypothesis came from a preliminary reaction using L-leucine *tert*-butyl ester, which should be stable to thiolate ion attack. Gratifyingly, the N-alkylated dithiocin **17c**, obtained in 71% yield, showed no loss of the -COO^{t}Bu group. As expected, signals for the diastereomeric methine protons in **17c** were observable (δ_H = 5.78, 5.70) in the ^{1}H NMR spectrum, indicating a 70:30 ratio of the diastereomers. Further work is under way to optimize this finding using the *tert*-butyl esters of other natural amino acids. Effective separation of the presumably scalemic diastereomers is also a prerequisite for the successful application of this approach.

Work is continuing in our attempts to prepare enantiomerically pure examples of the 1,5-dithiocins from readily accessible starting materials. We also plan to investigate the solvating and metal-complexing properties of these interesting molecules.

Experimental

General information

For all anhydrous reactions, glassware was dried in the oven overnight at 120°C prior to its use. All anhydrous reactions were run under an argon atmosphere. DMF and nitromethane were distilled from P_2O_5 and stored over 3Å sieves. Methanol was distilled from magnesium turnings and stored over activated 3Å sieves. Hexanes, THF, toluene, and diethyl ether were distilled from sodium – benzophenone ketyl. Triethylamine and TMEDA were distilled from calcium hydride prior to use. Alkyllithium solutions were obtained from Fluka and were titrated regularly (22). Work-up procedures involving the drying of organic extracts utilized Na_2SO_4. Purification was initially carried out by (flash) column chromatography, using Merck 40–60 μm silica gel or aluminum oxide and the appropriate solvent system (q.v.)

IR spectra were obtained as neat films or as KBr pellets, as indicated, and data were recorded in cm^{-1}. ^{1}H NMR spectra were recorded at 200 MHz in $CDCl_3$, unless otherwise stated. ^{13}C NMR and DEPT spectra were run at 100.6 MHz. High- and low-resolution mass spectra were obtained at 70 eV. Elemental analyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario. Compounds for which high-resolution mass measurements are given were homogeneous by TLC analysis and gave satisfactory ^{1}H and (or) ^{13}C NMR spectra indicative of their purity. ^{1}H NMR data for compounds **2a–2c**, **4a–4d**, **5a**, **5b**, **11**, **12**, **13**, and **15** have been collected in Table 1.

2-Mercaptobenzaldehyde 3a

To a solution of thiophenol (2.00 mL, 19.47 mmol) in 45 mL of dry hexanes under argon, TMEDA (6.43 mL, 42.83 mmol) was added via addition funnel. The clear solution was stirred for 5 min and cooled to 0°C. The 2.2 M *n*-BuLi (19.47 mL, 42.83 mmol) was added with a syringe over a period of 20 min, giving the solution a yellow colour. The mixture was stirred for an additional 0.5 h at 0°C, warmed to room temperature, and stirred for 17 h. The resulting solution turned white and became very thick in appearance. On cooling to 0°C, *N*-formylpiperidine (4.34 mL, 38.94 mmol) was slowly added, forming a red solution and an orange pastelike precipitate. The reaction mixture was stirred at 25°C for 18 h, then acidified with 1 M HCL (2 × 25 mL), extracted with CH_2Cl_2 (4 × 25 mL), and washed with saturated NaCl (25 mL). The solution was dried and concentrated to afford a dark orange-brown oil (2.77 g,

© 1999 NRC Canada

93%). Flash chromatography, eluting with CH_2Cl_2 (R_f = 0.35) afforded an oil (2.42 g, 81%). IR (film), ν: 3085, 2839, 2750, 1680, 1590, 1560, 850, 750; ^{1}H NMR, δ: 10.25 (s, 1H), 7.89 (dd, 1H, *J* = 7.5, 1.6 Hz), 7.80 (dd, 1H, *J* = 7.8, 1.6 Hz), 7.50 (td, 1H, *J* = 7.8, 1.6 Hz), 7.39 (td, 1H, *J* = 7.5, 1.6 Hz), 5.49 (s, 1H).

2-Mercapto-5-methylbenzaldehyde 3b

This aldehyde was prepared according to the same procedure. A crude orange-brown oil (1.19 g, 88%) was obtained from the solution. Flash chromatography, eluting with CH_2Cl_2 (R_f = 0.39), afforded a yellow oil (1.01 g, 75%). IR (film), ν: 3018, 2925, 2875, 2545, 1665, 815, 780; ^{1}H NMR, δ: 9.99 (s, 1H), 7.52 (d, 1H, *J* = 2.6 Hz), 7.19 (m, 2H), 5.31 (s, 1H), 2.37 (s, 3H).

3-(*tert*-Butylthio)-2-mercapto-5-methylbenzaldehyde 3c

To a solution of *p*-thiocresol (0.30 g, 2.40 mmol) in 30 mL of dry hexanes under argon, TMEDA (0.80 mL, 5.32 mmol) was added via addition funnel. The clear solution was stirred for 5 min and was cooled to 0°C. The 1.6 M *n*-BuLi (3.32 mL, 5.32 mmol) was added with a syringe, over a period of 20 min, giving the solution a yellow colour. The mixture was stirred for an additional 0.5 h at 0°C, warmed to room temperature, and stirred for 17 h. The resulting solution turned white and, was cooled to –10°C. Slow addition of freshly distilled *tert*-butyl disulfide (0.74 mL, 3.84 mmol) turned the mixture red in colour and stirring was continued for 16 h. The solution was washed with 1 M HCl (2 × 20 mL), saturated NaCl (20 mL), dried, and evaporated to afford a brown oil (0.38 g, 81%). Kugelrohr distillation afforded 2-(*tert*-butylthio)-4-methylbenzenethiol (0.33 g, 70%), bp 130–134°C/7 Torr (1 Torr = 133.3 Pa). IR (film), ν: 2961, 2934, 2518, 818; ^{1}H NMR, δ: 7.41 (d, 1H, *J* = 1.5 Hz), 7.29 (d, 1H, *J* = 7.8 Hz), 7.04 (dd, 1H, *J* = 7.8, 1.5 Hz), 4.77 (s, 1H), 2.33 (s, 3H), 1.39 (s, 9H).

The thiol so obtained (0.20 g, 0.94 mmol) was lithiated in dry hexanes (20 mL) and TMEDA (0.33 mL, 2.17 mmol), using 2.2 M *n*-BuLi (0.98 mL, 2.17 mmol) as in the general procedure. The resulting orange mixture was treated with *N*-formylpiperidine (0.21 mL, 1.88 mmol) at 25°C. The mixture turned yellow and was stirred for 18 h. The solution was washed with 1 M HCl (2 × 15 mL), saturated NaCl (15 mL), dried, and concentrated to afford a brown oil (0.16 g, 74%). Flash chromatography, eluting with CH_2Cl_2 (R_f = 0.45), yielded a yellow oil (0.13 g, 63%). IR (film), ν: 2960, 2925, 2893, 2480, 1684, 1672, 769; ^{1}H NMR, δ: 10.05 (s, 1H), 7.63 (d, 1H, *J* = 1.6 Hz), 7.56 (d, 1H, *J* = 1.6 Hz), 6.98 (s, 1H), 2.15 (s, 3H), 1.33 (s, 9H).

6,12-Imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 2a

The thiosalicylaldehyde **3a** (0.90 g, 6.52 mmol) dissolved in absolute ethanol (30 mL) was treated with ammonium acetate (0.55 g, 7.17 mmol), the solution turning a yellow colour. The solution was refluxed for 3.5 h and cooled to room temperature, resulting in the formation of a white precipitate. Filtration and drying afforded a yield of (0.75 g, 89%), mp 131–133°C (lit. (6) mp 130–132°C). IR (KBr), ν: 3334, 3115, 3005, 1595, 1499, 763.

2,8-Dimethyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 2b

The same procedure as that used for the preparation of **2a** was employed. A white solid was obtained directly from the reaction mixture (0.85 g, 91%), mp 205–206°C (lit. (6) mp 206–206.5°C). IR (KBr), ν: 3358, 3056, 2965, 1482, 796.

4,10-Bis(*tert*-butylthio)-2,8-dimethyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 2c

The same procedure as that used for the preparation of **2a** was employed. A yellow solid was obtained from the reaction mixture (0.05 g, 90%), mp 45–47°C (lit. (6) mp 44–46°C). IR (KBr), ν: 3054, 2920, 2874, 1493, 804, 737.

***N*-(2′-Phenylethyl)-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 4a**

Method A

To a solution of thiosalicylaldehyde **3a** (0.04 g, 0.28 mmol) in absolute ethanol (10 mL), 0.5 mL of HOAc was added. Addition of the phenethylamine (0.02 mL, 0.15 mmol) to the above reaction vessel immediately turned the yellow solution orange in colour. The mixture was refluxed for 3.5 h, quenched with H_2O (5 mL), and extracted with CH_2Cl_2 (2 × 10 mL). The organic layer was dried and concentrated to afford a brown oil. Flash chromatography, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.52), yielded a light yellow solid, (0.04 g, 84%), mp 147–150°C. IR (KBr), ν: 3116, 3032, 2996, 1625, 1487, 815. Exact Mass calcd. for $C_{22}H_{19}NS_2$: 361.0959; found: 361.0954. Anal. calcd. for $C_{22}H_{19}NS_2$: S 17.74; found: S 18.14.

Method B

A mixture of **3a** (0.14 g, 1.03 mmol), L-phenylalanine methyl ester hydrochloride (0.09 g, 0.57 mmol), and absolute ethanol (15 mL) was refluxed for 2.5 h. The clear yellow solution was cooled to room temperature and the solvent was evaporated to yield a yellow-brown oil. The oil was dissolved in CH_2Cl_2 (15 mL) and the organic layer washed with saturated $NaHCO_3$ (15 mL). Drying and concentration afforded a white powdery solid (0.12 g, 63%). Flash chromatography, eluting with CH_2Cl_2–hexanes (85:15) (R_f = 0.57) gave white crystals (0.10 g, 51%), mp 149–151°C, identical in all respects with **4a** prepared above.

***N*-(Isobutyl)-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 4b**

To a solution of **3a** (0.05 g, 0.35 mmol) in absolute ethanol (8 mL), 0.5 mL of HOAc was added. Addition of isobutylamine (0.02 mL, 0.19 mmol) to the above reaction vessel immediately turned the yellow solution orange in colour. Reaction was carried out as in Method A above and, after flash chromatography, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.52), gave **4b** as a yellow solid (0.04 g, 83%), mp 129–131°C. IR (film), ν: 3053, 2456, 1515, 1489, 792, 743. Exact Mass calcd. for $C_{18}H_{19}NS_2$: 313.0958; found: 313.0956.

***N*-(*tert*-Butyl)-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 4c**

To a solution of **3a** (0.06 g, 0.40 mmol) in absolute ethanol (10 mL), 0.5 mL of HOAc and *tert*-butylamine

© 1999 NRC Canada

(0.02 mL, 0.22 mmol) were added. Reaction and work-up procedure identical with those for **4a**, **4b** afforded, on flash chromatography, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.56), **4c** as a yellow solid (0.04 g, 87%), mp 136–138°C. IR (film), ν: 3322, 3057, 2970, 2924, 1695, 1589, 1463, 819. Exact Mass calcd. for $C_{18}H_{19}NS_2$: 313.0958; found: 313.0968.

N-Phenyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 4d

A mixture of **3a** (0.23 g, 1.64 mmol), aniline (0.08 g, 0.90 mmol), acetic acid (0.5 mL), and absolute ethanol (15 mL) was refluxed for 6.5 h. The clear yellow solution was cooled to room temperature and the solvent was evaporated to yield a brown oil (0.24 g, 87%). Flash chromatography, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.58), resulted in a white solid (0.20 g, 75%), mp 70–72°C. IR (KBr), ν: 3075, 2961, 835; ^{13}C NMR, δ: 147.1s, 133.3s, 130.3s, 129.5d, 128.6d, 128.0d, 127.9d, 125.0d, 123.0d, 119.5d, 61.1d. Exact Mass calcd. for $C_{20}H_{15}NS_2$: 333.0645; found: 333.0651. Anal. calcd. for $C_{20}H_{15}NS_2$: C 72.12, H 4.54, N 4.20, S 19.25; found: C 71.63, H 4.51, N 3.93, S 19.78.

N-(2′-Phenylethyl)-2,8-dimethyl-6,12-imino-6*H*,12*H*-dibe nzo[*b*,*f*]-1,5-dithiocin 5a

The same procedure was used as in the formation of **4a**. A crude yellow oil was obtained (0.06 g, 96%). Flash chromatography, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.58), yielded a beige solid (0.05 g, 83%), mp 132–134°C. Exact Mass calcd. for $C_{24}H_{23}NS_2$: 389.1272; found: 389.1263.

N-Isobutyl-2,8-dimethyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 5b

The same procedure as for the formation of **4b** was used. Flash chromatography of the crude product, eluting with CH_2Cl_2–hexanes (4:1) (R_f = 0.60), yielded a yellow oil (0.06 g, 86%) bp 150–153°C/5 Torr. Exact Mass calcd. for $C_{20}H_{23}NS_2$: 341.1272; found: 341.1270.

1-Naphthalenethiol

Concentrated hydrochloric acid (11.40 mL) was added to crushed ice (30 g) in a round-bottom flask, with stirring. 1-Naphthalenesulfonyl chloride (1.00 g, 4.41 mmol) was added portionwise via spatula, making sure that the solution was kept below 0°C. Tin (6.30 g, 53.04 mmol) was added to the vessel, turning the solution yellow. The mixture was refluxed for 6 h and the solution became clear. The solution was then extracted with CH_2Cl_2 (2 × 20 mL), washed with saturated NaCl solution, dried, and concentrated to yield a yellow oil (0.63 g, 89%), bp 138–140°C/7 Torr (lit. (23) bp 138–140°C/2 Torr).

1-Mercapto-2-naphthaldehyde 6

1-Naphthalenethiol (0.94 g, 5.87 mmol) was dissolved in dry hexanes (50 mL) under argon, and TMEDA (2.20 mL, 14.67 mmol) was added to the mixture. The reaction was cooled to 0°C and 1.6 M *n*-BuLi (9.17 mL, 14.67 mmol) was added dropwise. The solution initially turned cloudy white and eventually became yellow and clear. The mixture was then stirred for 0.5 h at 0°C, then warmed to room temperature before stirring for an additional 16 h. *N*-Formylpiperidine (1.11 mL, 9.98 mmol) was added via syringe and a dark red paste resulted. Vigorous stirring for 10 h formed a yellow mixture, which was then washed with 1 M HCl (2 × 25 mL) and extracted with CH_2Cl_2 (4 × 25 mL). Additional washing with saturated NaCl (25 mL), drying, and concentration yielded a brown oil (0.62 g, 56%). Chromatography on aluminum oxide, eluting with CH_2Cl_2–MeOH (95:5) (R_f = 0.45), gave a yellow oil (0.47 g, 43%), bp 139–142°C/7 Torr. IR (film), ν: 3050, 2924, 2864, 1682, 1495, 825, 753; ^{1}H NMR, δ: 9.82 (s, 1H), 8.33 (m, 2H), 7.95 (m, 2H), 7.66 (m, 1H), 7.31 (m, 1H), 5.31 (s, 1H). Exact Mass calcd. for $C_{11}H_8OS$: 188.0288; found: 188.0283.

2-Mercapto-1-naphthaldehyde 7 and 3-mercapto-2-naphthaldehyde 8

2-Naphthalenethiol (2.00 g, 12.48 mmol) was ground and dissolved in dry hexanes (80 mL), under argon, and TMEDA (4.69 mL, 31.20 mmol) was added to the mixture. The mixture was cooled to 0°C and 1.6 M *n*-BuLi (19.50 mL, 31.20 mmol) was added dropwise. The solution initially turned a cloudy white colour and eventully became yellow and clear. The mixture was then stirred for 0.5 h at 0°C and warmed to room temperature before stirring for an additional 16 h. *N*-Formylpiperidine (2.78 mL, 24.96 mmol) was added via syringe and a dark red paste resulted. Vigorous stirring for 10 h formed a yellow mixture, which was washed with 1 M HCl (2 × 30 mL) and extracted with CH_2Cl_2 (4 × 30 mL). Washing with saturated NaCl (30 mL), drying, and concentration afforded a brown oil (1.76 g, 75%). Chromatography on aluminum oxide, eluting with CH_2Cl_2–MeOH (95:5) (R_f = 0.64), resulted in compound **7** (0.70 g, 45%), mp 122–124°C. IR (film), ν: 2957, 2924, 2851, 2725, 2555, 1722,774; ^{1}H NMR, δ: 11.03 (s, 1H), 8.66 (d, 1H, *J* = 7.5 Hz), 7.84 (d, 1H, *J* = 7.6 Hz), 7.63 (m, 1H), 7.48 (m, 1H), 7.34 (d, 1H, *J* = 7.5 Hz), 7.31 (d, 1H, *J* = 7.7 Hz), 4.85 (s, 1H). Exact Mass calcd. for $C_{11}H_8OS$: 188.0288; found: 188.0285.

An earlier fraction obtained on eluting with CH_2Cl_2 –MeOH (95:5) (R_f = 0.33) resulted in **8** (0.47 g, 30%), mp 134–136°C. IR (film), ν: 2970, 2930, 2850, 2578, 1708, 1525, 734; ^{1}H NMR, δ: 10.15 (s, 1H), 8.26 (s, 1H), 7.89 (d, 1H, *J* = 3.9 Hz), 7.73 (m, 1H), 7.68 (m, 1H), 7.52 (d, 1H, *J* = 7.6 Hz), 7.45 (dd, 1H, *J* = 7.6, 3.8 Hz), 5.48 (s, 1H). Exact Mass calcd. for $C_{11}H_8OS$: 188.0288; found: 188.0281.

Synthesis of 7 by an alternative route, from 2-hydroxy-1-naphthaldehyde 9

*A. 2-(*tert*-Butyldimethylsilylthio)-1-naphthaldehyde **10***

To a solution of 2-hydroxy-1-naphthaldehyde (1.00 g, 5.81 mmol), in 16 mL of pyridine at 0°C, triflic anhydride (1.09 mL, 6.45 mmol) was slowly added. Evolution of a white gas occurred and the resulting mixture was stirred at 0°C for an additional 5 min. The mixture was then warmed to room temperature and stirred for 24 h. Water (15 mL) was added to the solution, which was extracted with diethyl ether (2 × 15 mL), washed with H_2O (15 mL), 10% aqueous HCl, and then with saturated NaCl (15 mL). The organic layer was dried and concentrated to obtain a brown, foamy solid (1.32 g, 75%). Recrystallization from CH_2Cl_2–hexanes af-

© 1999 NRC Canada

forded a beige solid (1.15 g, 65%). IR (KBr), ν: 3160, 2834, 2755, 1702, 1587, 856, 784; ^{1}H NMR, δ: 10.81 (s, 1H), 8.45 (d, 1H, *J* = 6.3 Hz), 8.25–7.17 (m, 5H).

Dry THF (25 mL) was saturated with H_2S gas, and the reaction vessel was then cooled to –78°C. The 1.6 M *n*-BuLi (8.00 mL, 13.00 mmol) was added dropwise to the above solution, which was allowed to warm to 0°C, with stirring for 0.5 h. The mixture was then recooled to –78°C and TBDMS-Cl (1.68 g, 11.11 mmol) was added portionwise with a spatula. The yellow mixture was warmed to room temperature and was partitioned between pentane (50 mL) and H_2O (25 mL). The organic layer was extracted and washed with H_2O (20 mL), dried, and concentrated to afford TBDMS-SH as a clear oil (83%). IR (film), ν: 2737, 2560; ^{1}H NMR, δ: 0.97 (s, 9H),0.29 (s, 6H), 0.11 (s, 1H).

Potassium hydride (0.31 g, 7.69 mmol), was initially washed with dry pentane (3 × 20 mL) and was placed in a flask with 10 mL of pentane. The silanethiol above (1.13 g, 7.63 mmol) was added slowly to the reaction mixture at 0°C and stirring was continued for 2 h. Solvent was removed and a white solid was obtained (0.98 g, 69%). The salt was recrystallized from toluene to yield white crystals of TBDMS-SK (0.87 g, 61%).

A solution of this salt (0.12 g, 0.66 mmol) in dry THF (15 mL) was added to tetrakis(triphenylphosphine)palladium (0) (0.06 g, 0.05 mmol) and the triflate obtained above (0.20 g, 0.66 mmol) in toluene (20 mL). The brown solution was refluxed for 5 h, after which it was partitioned between H_2O (25 mL) and ethyl acetate (25 mL). The organic layer was washed with H_2O (2 × 15 mL), dried, and concentrated to afford a brown oil (0.14 g, 73%). Flash chromatography, eluting with CH_2Cl_2 (R_f = 0.44), afforded **10** as a yellow oil (0.10 g, 52%). IR (film), ν: 2990, 2946, 2856, 2725, 1722, 1597, 1517; ^{1}H NMR, δ: 10.85 (s, 1H), 8.35 (d, 1H, *J* = 8.2 Hz), 7.98 (d, 1H, *J* = 7.1 Hz), 7.78 (dd, 1H, *J* = 8.1, 4.0 Hz), 7.60 (m, 1H), 7.41 (m, 1H), 7.17 (dd, 1H, *J* = 7.0, 3.9 Hz), 1.05 (s, 9H), 0.48 (s, 6H).

*B. Deprotection of **10** to give **7***

To a solution of the protected thiol **10** (0.53 g, 0.18 mmol) in THF (10 mL) at 0°C, tetrabutylammonium fluoride (0.20 mL, 0.19 mmol) was added dropwise. The mixture was stirred for 3 h, eventually turning a deep yellow colour. The reaction mixture was washed with saturated NH_4Cl (10 mL) and extracted with CH_2Cl_2 (3 × 10 mL), dried, and concentrated to afford a brown oil (0.30 g, 90%). Flash chromatography, eluting with CH_2Cl_2 (R_f = 0.48), resulted in a yellow solid (76% yield), mp 124–126°C. This product was identical (mixture mp, IR, ^{1}H NMR) with the *2-mercapto-1-naphthaldehyde* **7** prepared as described above.

8,16-Imino-8*H*,16*H*-dinaphtho [2,1-*b*,*f*]-1,5-dithiocin 12

A mixture of the naphthaldehyde **7** (0.04 g, 0.20 mmol) and ammonium acetate (0.02 g, 0.20 mmol) in absolute ethanol (15 mL) was refluxed for 3.5 h. The solution was cooled and the ethanol was removed. The yellow solid was recrystallized from methanol to give **12** (0.03 g, 94%), mp 160–163°C. IR (KBr), ν: 3356, 2952, 1583, 835, 806. Exact Mass calcd. for $C_{22}H_{15}NS_2$: 357.0646; found: 357.0647.

8,16-Imino-8*H*,16*H*-dinaphtho [1,2-*b*,*f*]-1,5-dithiocin 11

The same procedure outlined for compound **12** was used for the formation of **11**. Yellow crystals were obtained (0.03 g, 92%) mp 168–170°C. IR (KBr), ν: 3033, 2953, 2846, 1529, 818. Exact Mass calcd. for $C_{22}H_{15}NS_2$: 357.0646; found 357.0643.

8,16-Imino-8*H*,16*H*-dinaphtho [2,3-*b*,*f*]-1,5-dithiocin 13

The same procedure was used for the formation of **13**. Yellow crystals were obtained, recrystallized from methanol (0.04 g, 96%), mp 170–172°C. IR (KBr), ν: 3197, 2953, 1590, 1495, 1492, 805. Exact Mass calcd. for $C_{22}H_{15}NS_2$: 357.0646; found: 357.0640.

8,16-Imino-8*H*,16*H*-dinaphtho[2,1-*b*,*f*]-1,5-dioxocin 14a

A mixture of 2-hydroxy-1-naphthaldehyde (1.72 g, 10.00 mmol) and ammonium acetate in 15 mL of ethanol was refluxed for 4.5 h, then cooled to room temperature. The ethanol was partially evaporated and the yellow solid was recrystallized to yield **14a** (1.55 g, 95%), mp 241–243°C (lit. (15) mp 240–242°C). IR (KBr), ν: 3332, 1616, 955; ^{1}H NMR, δ: 8.18 (d, 2H, *J* = 6.0 Hz), 7.72 (t, 4H, *J* = 5.8 Hz), 7.59 (d, 2H, *J* = 6.0 Hz), 7.36 (d, 2H, *J* = 5.8 Hz), 7.05 (d, 2H, *J* = 5.8 Hz), 6.63 (d, 2H, *J* = 2.5 Hz), 3.00 (br s, 1H); ^{13}C NMR, δ: 150.3s, 131.5s, 131.0d, 128.9s, 128.4d, 127.2d, 123.7d, 121.9d, 118.3d, 112.4s, 75.6d. Exact Mass calcd. for $C_{22}H_{15}NO_2$: 325.1101; found: 325.1093.

***N*-(Methoxycarbonyl)-2,8-dimethyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 15**

The amine **2b** (0.20 g, 0.70 mmol) was dissolved in acetone (15 mL), then cesium carbonate (1.37 g, 4.20 mmol) was added to the solution, which was stirred for 5 min. Slow addition of methyl chloroformate (0.22 mL, 2.80 mmol) with a syringe resulted in a red-coloured solution. The mixture was refluxed for 16 h under argon. Removal of the Cs_2CO_3 by gravity filtration and evaporation of the acetone solution yielded an orange oil. A solution of 4% NaOMe in methanol was added to the oil and stirring was continued for 2 h. A white precipitate was obtained (0.16 g, 67%), which was filtered off and recrystallized from CH_2Cl_2–hexanes, mp 143–146°C. IR (KBr), ν: 3347, 2975, 2846, 1698, 1503, 731. Exact Mass calcd. for $C_{18}H_{17}NO_2S_2$: 343.0700; found: 343.0702.

***N*-(1′-Phenylethyl)-2,8-dimethyl-6,12-imino-6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin 16**

To thiosalicylaldehyde **3b** (0.11 g, 0.69 mmol) dissolved in 20 mL of absolute ethanol and 1 mL of acetic acid, the *R*-(+)-1-phenylethylamine (0.05 mL, 0.38 mmol) was added dropwise. The solution turned an orange colour and was then refluxed for 4.5 h. The mixture was washed with H_2O (10 mL), extracted with CH_2Cl_2 (3 × 15 mL), dried, and concentrated to yield a brown oil (0.12 g, 86%). Flash chromatography, eluting with ethyl acetate – hexanes (1:1) (R_f = 0.57), gave a foamy beige solid (0.10 g, 77%), mp 81–83°C. IR (KBr), ν: 3367, 2949, 1485; ^{1}H NMR, δ: 7.39 (m, 4H), 6.92 (m, 7H), 5.53, 5.48 (2s, 2H), 4.17, 3.90 (2q, 1H, *J* = 7.8 Hz), 2.25 (s, 6H), 1.61, 1.55 (2d, 3H, *J* = 7.8 Hz); ^{13}C NMR, δ: 143.2s, 134.3s, 133.1s, 129.8d, 129.2d, 127.6d, 127.5d, 127.4s, 127.2d, 126.5d, 60.0d, 59.3d, 22.5q, 20.9q.

© 1999 NRC Canada

Exact Mass calcd. for $C_{24}H_{23}NS_2$: 389.1272; found: 389.1264.

_N_-(3′-Methylbutyl)-6,12-imino-6_H_,12_H_-dibenzo[_b_,_f_]-1,5-dithiocin 17a

A mixture of thiosalicylaldehyde **3a** (0.12 g, 0.85 mmol), L-leucine (0.06 g, 0.47 mmol), and absolute ethanol (30 mL) was refluxed for 4.5 h. The clear yellow solution was cooled to room temperature and the solvent was evaporated to yield a yellow oil (0.09 g, 68%). Flash chromatography, eluting with CH_2Cl_2 – hexanes (85:15) (R_f = 0.52), gave a yellow oil (0.08 g, 60%). IR (film), ν: 3057, 2945, 2853, 830, 742; ^{1}H NMR, δ: 7.28 (m, 2H), 7.0 (m, 6H), 5.41 (s, 2H), 2.98 (m, 1H), 1.62 (m, 4H), 0.91 (d, 6H, J = 7.5 Hz). Exact Mass calcd. for $C_{19}H_{21}NS_2$: 327.1115; found: 327.1112.

_N_-(2′-Hydroxyethyl)-6,12-imino-6_H_,12_H_-dibenzo[_b_,_f_]-1,5-dithiocin 17b

A mixture of **3a** (0.14 g, 1.03 mmol), L-serine methyl ester hydrochloride (0.09 g, 0.57 mmol), and absolute ethanol (15 mL) was refluxed for 4.5 h. The clear yellow solution was cooled to room temperature and the solvent was evaporated to yield a yellow-brown oil. This was dissolved in CH_2Cl_2 (15 mL) and the organic layer was washed with saturated $NaHCO_3$ (15 mL), dried, and concentrated to afford a yellow oil (0.14 g, 88%). Flash chromatography, eluting with CH_2Cl_2–hexanes (85:15) (R_f = 0.57), gave white needle crystals (0.11 g, 75%), mp 165–167°C. IR (film), ν: 3395, 2993, 1626, 1505, 806; ^{1}H NMR, δ: 7.82 (dd, 4H, J = 7.8, 7.6 Hz), 7.32 (dt, 4H, J = 7.8, 7.7 Hz), 6.21 (s, 2H), 4.35 (m, 2H), 3.50 (m, 3H).

_N_-(1′-_tert_-Butyloxycarbonyl-3′-methylbutyl)-6,12-imino-6_H_,12_H_-dibenzo[_b_,_f_]-1,5-dithiocin 17c

A mixture of **3a** (0.22 g, 1.60 mmol), L-leucine *tert*-butyl ester (0.19 g, 0.88 mmol), and absolute ethanol (15 mL) was refluxed for 4.5 h. Work-up as for **17b**, followed by flash chromatography, eluting with CH_2Cl_2–hexanes (85:15) (R_f = 0.67), gave a yellow solid (0.24 g, 71%), mp 154–156°C. ^{1}H NMR, δ: 7.33 (m, 4H), 7.01 (m, 4H), 5.78, 5.70 (2s, 2H), 3.65 (t, 1H, J = 9.1 Hz), 1.82 (m, 1H), 1.64 (m, 2H), 1.20 (s, 9H), 0.90 (d, 6H, J = 9.4 Hz). Exact Mass calcd. for $C_{24}H_{29}NO_2S_2$: 427.1639; found: 427.1644.

The molecular complexes of deoxycholic acid and cholesterol with CH_3COOD studied by infrared spectroscopy

Alpha O. Diallo, Claude Meyer, and Nguyen Van-Thanh

Abstract: The frequencies of the O-D stretching vibrations of CH_3COOD have been measured in the liquid and vapour phases and in the form of molecular associations with deoxycholic acid and cholesterol. The spectra confirm that the vapour phase is a mixture of monomeric and dimeric forms at room temperature. The vibrational assignment made for the gaseous phase is used in conjunction with prior data available on the monomeric O-D stretching frequencies in solutions to explain the spectroscopic behaviour of the molecular complexes. The pattern of frequency shifts suggests that deuterium bonding links the cholesterol and CH_3COOD in the hydrophilic regions and that the self association of the heavy acid is limited to the dimeric species in the complex with deoxycholic acid. Extra absorption bands observed in the spectral region characteristic of the deuterium bond vibrations are tentatively considered to arise from O-D groups in different local environments with different vibrational energies compared with the D-bonded species. Further evidence for steroid–CH_3COOD interactions is obtained from a study of the O-H and C=O stretching vibrations of the compounds.

Key words: acetic acid-*d*, complexation with deoxycholic acid and cholesterol, infrared spectroscopy.

Résumé : Les fréquences des vibrations d'élongation O-D de CH_3COOD ont été étudiées dans les états gazeux et liquide et sous la forme de complexes avec l'acide deoxycholique et le cholestérol. Les spectres confirment que la phase gazeuse est un mélange de formes monomères et dimères à la température ambiante. L'interprétation des vibrations O-D à l'état gazeux est utilisée de concert avec les fréquences des monomères étudiées antérieurement en solutions pour expliquer les propriétés spectroscopiques des composés moléculaires. Les modèles des déplacement des fréquences suggèrent que le cholestérol et CH_3COOD sont associés par liaison deutérium dans les régions hydrophiles et que l'autoassociation de l'acide lourd est limitée à la dimérisation dans le complexe formé avec l'acide deoxycholique. Des bandes d'absorption en surnombre observées dans le domaine spectral caractéristique des vibrations de la liaison deutérium sont considées comme provenant des groupements O-D dans des environnements différents avec des énergies vibrationnelles différentes comparées avec les espèces associées. En outre, l'étude des vibrations de valence des liaisons O-H et C=O des composés a permis de mettre en évidence quelques interactions entre CH_3COOD et les stéroides dans les complexes.

Mots clés : acide-*d* acétique, complexation avec l'acide déoxycholique et le cholestérol, spectroscopie infrarouge.

1. Introduction

The vibrational spectra of aliphatic carboxylic acids, RCOOH, have been extensively studied with special emphasis on the location of the monomeric O-H and O-D stretching bands and the frequency shifts of these bands by change of the external conditions (1–4). It is well known that the molecules in the solid and liquid states are different from the molecules in the gas phase due to their association through hydrogen bonding. These differences are reflected in the relatively different vibrational spectra. For both the O-H and O-D groups, the vibrational frequencies referred to above, are lowered with increasing strength of the O-H(D)···O bonding on going from the gaseous to the condensed phase spectra. For the O-H group, the most thoroughly investigated, the condensed phase spectra generally appear as broad absorptions consisting in some cases of many sub-bands. The interpretation of these complex spectra has been attempted but cannot be said to have been satisfactorily resolved (3, 4).

We have measured the infrared spectra of acetic acid-*d*, CH_3COOD, in the liquid and vapour phases and in the form

of complexes with deoxycholic acid, DCA, and cholesterol, to obtain additional information on the spectroscopic behaviour of deuterium bond forming molecules. The results of the investigation are presented below.

2. Experimental

All the reagents were Aldrich commercial compounds. The molecular complexes were obtained from recrystallization of the steroids in the acid (5, 6). All the manipulations necessary in the preparation of the solutions were carried out in a dry nitrogen atmosphere using glove boxes. The steroids are not very soluble in the medium. The powdered solid (~0.5–1.0 g) was suspended in 5–10 mL of the acid, and the flasks were stopped in the glove boxes. The suspensions were warmed on a steam bath (~50°C) until complete dissolution. The resulting clear solutions were allowed to cool to room temperature, protected against light and set aside for crystallization. The solid crystals were collected by suction filtration, dried under a well ventilated hood, and stored in a closed container. These crystals can be handled at room temperature, but they decompose on heating. Since the composition may vary in a way mentioned later, it is difficult to determine the true dissociation temperature accurately. The addition compound from cholesterol and CH_3COOD separates into the component molecules by the action of high vacuum and by strongly pressing the crystals. That formed from deoxycholic acid and CH_3COOD is quite stable under the same conditions. The spectra of the complexes were obtained as solids ground in nujol and in KBr pressed disks. The liquid and vapour phases were examined in conventional cells.

The set IR measurements at ambient temperature has been carried out on a Bruker IFS66V Fourier transform spectrometer. It was equipped with a vacuum bench which was pumped to better than 1 Torr. The standard mid-IR source was a current stabilized water-cooled SiC glowbar. For the 1500–4000 cm^{-1} spectral range, the detector was a room-temperature DTGS equipped with a KBr window. The beamsplitter material was KBr. All the spectra measured in the present work were apodized and obtained at a resolution (full width at half maximum) of 0.5 cm^{-1} in the considered spectral window. Thirty-two scans were superimposed to yield each interferogram, and a four-point apodization function was used. The ratio of the spectral slit width to the band system width is less than 1×10^{-2}. This is sufficiently small to avoid line-shape corrections due to the finite slit width. The absolute calibration of the wave numbers was accomplished using the well-known positions of lines to the 1←0 band of $^{12}C^{16}O$.

The absorption coefficient $k(\nu)$ at the frequency $\nu(cm^{-1})$ was obtained from the measurement of incident and transmitted, I_0 and I_t, respectively, corresponding to:

$$k(\nu)(cm^{-1}) = l^{-1} \ln (I_0/I_t)$$

where l is the optical path length.

Each absorption spectrum $I_t(\nu)$ of the gas, liquid, or solid sample was digitally divided by a background $I_o(\nu)$ of the same sample cell that was emptied. This resulted in a transmittance:

$$T(\nu) = I_t(\nu)/I_o(\nu)$$

The experimental results are given in Table 1 and illustrated in Figs. 1–5 which include the O-D, O-H, and C=O absorption bands.

3. Discussion

a. General considerations

The behaviour of CH_3COOH (guest) with regard to the formation of addition compounds with deoxycholic acid and cholesterol (hosts) have been previously described (5, 6). The complex of deoxycholic acid and CH_3COOH appears to be of an inclusion type, according to X-ray crystallographic study (7). The CH_3COOH molecules linked together into long chains by hydrogen bonding, as in the crystal structure of the acid itself, are held in channels between stacked sheets of the deoxycholic acid bound head-to-tail by hydrogen bonds. Likewise, by means of thermal gravimetric analysis of the adduct of cholesterol and CH_3COOH, the host–guest stoichiometry of the complex was established as 2:1 (6). The crystal structure is not known but it is probable that hydrogen bonds link the constituent species in the hydrophilic regions, perhaps with alternating arrangements of the molecules (6).

From the above information it is a great tentation to assume that similar structures are also obtained for the D-analogue. However, it is not clear how far the analogy can be taken with safety, as the arrangement of the molecules is not determined by van der Waals forces between them, but by hydrogen bondings between electronegative groups. For example, microwave studies of hydrogen-bonded simple car-

boxylic acids have shown that the O-H(D)···O distances are longer for D-bonding than for H-bonding (8).

Therefore it is impossible to be sure whether the D-bonds might be strong enough to maintain long and flexible chain molecules in their ordered crystalline-like state, as in the case of CH_3COOH referred to above. On the other hand, the possibility of isotopic exchange reaction such as

$$\text{-COOD} + \text{HO-host} \rightarrow \text{-COOH} + \text{DO-host}$$

between the carboxyl deuterium of the guest and the hydroxyl group of the host cannot be surely excluded. Such isotopic exchange, if it occurs, is likely to affect in an impredictable fashion the intermolecular host–guest organization. As will be shown later, it is hazardous to predict the way in which the molecules are arranged in the complexes under investigation. Because of this, an empirical approach to an understanding of the observed spectra seems more profitable at present. Of particular interest in our IR spectra

are the frequencies of the O-D, O-H, and C=O stretching vibrations usually considered as characteristic frequencies.

b. Interpretation of the spectroscopic results

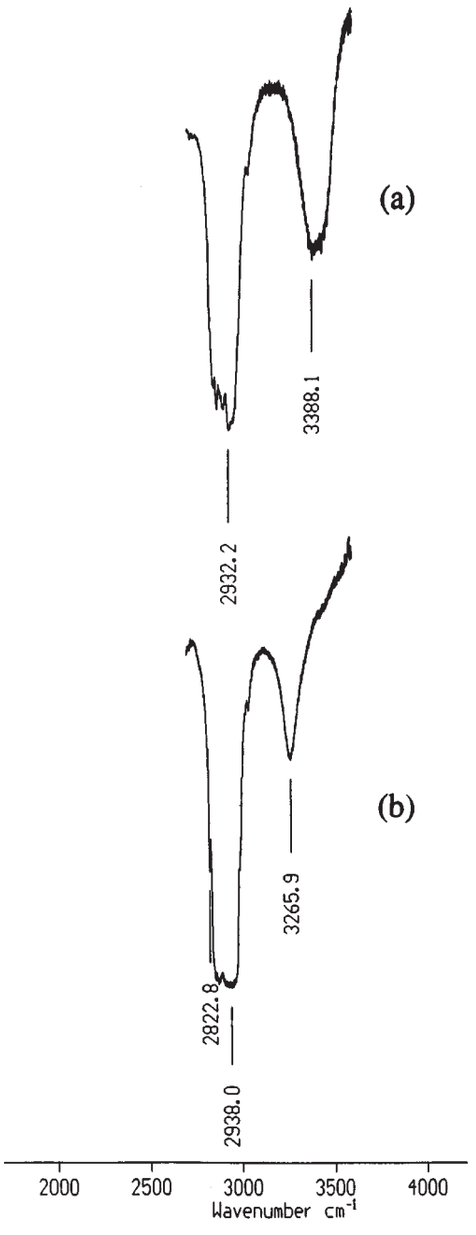
Region associated with the O-D stretching vibrations

The monomeric O-D stretching frequencies of aliphatic carboxylic acids are most easily identified in the gaseous phase at high temperature. Experiments of this type have been made in earlier IR studies of the CH_3COOD molecules. The O-D fundamental vibration was assigned to a band observed at ≈2642 cm^{-1} (9, 10). In the present investigation of the vapour-phase spectrum of the molecules at ambient temperature, a weak absorption is clearly observable at the expected position (see Figs. 1*a* and 2*a*). The band appears to have a PQR contour, with the Q-branch located at 2641 cm^{-1}. We therefore accept this band as due to the monomeric stretching vibration.

The effect of D-bond formation on the position of the O-D absorption is to shift this band to lower frequencies (see Introduction). For example, the dimeric CH_3COOD and the polymeric HCOOD have been reported to show the

© 1999 NRC Canada

Fig. 5. IR absorption bands in the expected positions of the (O-H) stretching frequencies of cholesterol: (*a*) uncomplexed species; (*b*) complexed with CH_3COOD.



bonded O-D absorptions at 2268 and 2160 cm^{-1}, respectively (10, 11).

Actually, as can be seen in Figs. 1–3, there is a series of bands extending from 2060 to 2490 cm^{-1} in our spectra. The bands on the low-frequency side (viz. 2063–2142 cm^{-1}) are observed in all the curves with variable distribution of intensity from one spectrum to another. The intensity changes shift the relative position of the ν_{max} within the band system. However, the effects are small and the absorptions can be considered together. The intensities seem somewhat low for fundamental vibrations. We tentatively consider this group of bands as due to summation and (or) overtones of fundamentals, although the combinations responsible for them are difficult to ascertain.

In contrast to the above, on the high-frequency side from 2500 to 2200 cm^{-1} the spectra are extremely sensitive to the experimental conditions (compare Figs. 1–3).These observations agree qualitatively with the expected spectral behaviour of the O-D stretching modes of D-bonded species (see Introduction). Thus, these bands may be considered as the shifted O-D fundamentals involved in some type of intermolecular interactions, the nature of which remains to be determined.

In a number of previous works (3, 4), the band-width phenomena of the liquid phase and the multiplicity of peaks which occur in the vibrational studies of hydrogen-bonded systems, as observed here, have been interpreted in terms of anharmonic coupling between the O-H fundamentals and low-frequency motions of the molecules together with Fermi resonance involving levels of the same species.

Unfortunately, the pattern of frequency shifts of the O-D stretching modes presented in Fig. 3 is not easily accounted for in terms of such processes. Consequently, a different interpretation of the spectroscopic effects reported here, susceptible of experimental examination, is proposed below.

We deal with the vapour- and liquid-phase frequencies of CH_3COOD first. In the spectral region under consideration, the vapour-phase spectrum shows an incompletely resolved doublet with the two peaks located at 2306 and 2274 cm^{-1} (see Figs. 1*a* and 2*a*). As mentioned earlier, the lower of these frequencies falls close to the frequency assigned by previous authors (10) to the O-D stretching vibration of the dimeric species at 2268 cm^{-1}. The occurrence of a pair of bands, only 30 cm^{-1} apart, could indicate that more than one structure is represented. We therefore believe that a mixture of two kinds of dimers — for example, a cyclic and an open structure — is most likely, since higher polymers can be expected to have stronger D-bonds and hence to absorb at lower frequencies (12). Similarly the O-D bandwidth in liquid CH_3COOD (see Figs. 1*b* and 2*b*) may be explained by supposing, as above, that the acids are associated through deuterium bonds to a different extent into various polymeric species distributed at random. On this assumption the broad region of absorption represents the envelope of many unresolved sub-bands. The same type of explanation has been used before by Bellamy (3) to account for the broad character of the ν_{OH} bands in the spectra of aliphatic alcohols in the liquid state.

The spectra of the complexes are more difficult to explain because of the relatively wide separation of the bands and the multiplicity of peaks (see Fig. 3). Factor group splitting of the O-D stretching vibrations seems improbable, since similar frequencies are seen in the vapour and dilute solution spectra (see below). The only source of information available that might be used as guide in interpreting the observations are the vapour-phase spectrum referred to above and a study of solvent effects on the spectra of CH_3COOD reported by Bellamy et al.(13). These authors have carried out measurements of the O-D sretching frequencies attributable to the monomeric structure in solvents with different polar

© 1999 NRC Canada

properties. Some of their results are reproduced in Table 1 for comparison.

Comparison of the spectra of the gas and the complexes

Once more, reference to the frequencies assigned to the O-D stretching vibrations of the dimeric CH_3COOD shows that the band at 2274 cm^{-1} has a close counterpart at 2271 cm^{-1} in the spectrum of the molecular association with deoxycholic acid (compare Figs. 1*a* and *c*), but it is absent from the spectrum of the addition product with cholesterol. Instead a new band is observed at 2222 cm^{-1} (Fig. 2*c*). The fact that the band positions are relatively independent of whether the acid is in the vapour or the complexes would seem to imply that they have similar origin. Thus the presence of the dimeric CH_3COOD in the inclusion complex with deoxycholic acid is suggested by the experimental results. With regard to the combination with cholesterol, the postulation of intermolecular deuterium bonding between the carboxyl deuterium of CH_3COOD and the hydroxyl oxygen atom in the 3-position of the steroid would account for the observed frequency.

The remaining IR absorption bands of the complexed CH_3COOD molecules appear at higher frequencies than those of the vapour phase and cannot be ascribed to dimerization (see Figs. 1, 2 and Table 1). Of course, the frequency shifts of the dimer would be expected to differ from those of higher polymers presumed to have linear D-bonds. However, as already noted above, the O-D stretching absorptions should occur at lower frequencies as the extent of polymerization increases (12).

The frequency rise, as compared with the dimeric CH_3COOD, is probably a result of an increase of the force constant for the vibration and hence a weakening of the intermolecular D-bonding. In this respect, CH_3COOD differs strikingly from CH_3COOH. The light acetic acid molecules hydrogen bond with each other to form polymeric chains held in tunnels between hydrogen-bonded sheets of deoxycholic acid (7).

Comparison of the spectra of the complexes and the solutions

The possibility that the frequencies higher than those of the dimeric CH_3COOD are influenced by some new factors is strongly suggested by the data available on the monomeric stretching frequencies measured in a range of solvents already referred to in the foregoing. An examination of Table 1 reveals, indeed, that some of the solution frequencies are of the same order of magnitude as those found here. Thus, the comparison shows that the O-D stretching frequency at 2437 cm^{-1} in CH_3CN is nearly the same as the frequency at 2432 cm^{-1} in the spectrum of the addition compound with cholesterol. Similarly the monomeric stretching frequencies at 2472 and 2370 cm^{-1} in *o*-$C_6H_4(COOCH_3)_2$ and $(CH_3)_2CO$, respectively, have parallels at 2490 and 2397 cm^{-1} in the spectrum of the complex formed between CH_3COOD and deoxycholic acid.

The above qualitative similarities between low solute concentration spectra and those of the complexed species are consistent with the view that D-bonding intermolecular interactions between adjacent CH_3COOD molecules do not play a significant part in determining the band positions under discussion. Of course, the two effects may be caused by different mechanisms. The solvent effects observed have been ascribed to local interactions with the solutes (13). In the case of the complexed CH_3COOD, it is also quite possible that the regions of the hosts surrounding the O-D groups play some role in the spectra. Accordingly, the spectroscopic results can be understood by assuming that the variations in frequencies reflect the extent to which the local environment of the individual O-D groups affects the vibrations independently of D-bonding. Such specific effects, if any, would then result in a loss of the ability of the acids to associate further and a corresponding increase of the O-D stretching frequencies over those of the dimeric CH_3COOD.

Unfortunately, the intermolecular effects in inclusion complexes have not been made the subject of a systematic study (14). For this reason the specific intermolecular forces between structural units, considered above, cannot be discussed usefully at present. Further experimental work is necessary before the factors responsible for the observed frequency shifts can be correlated with the structure around the O-D groupings.

However, in order to see whether the IR absorption characteristics of the steroids are also affected by the effects of complexation, we have examined other regions of the spectra from which additional informations may be obtained.

Regions asociated with the O-H stretching vibrations of the steroids

The O-H bands of deoxycholic acid: According to X-ray diffraction study of several deoxycholic acid complexes, previously reported (7, 14), the steroid molecules hydrogen bond only with each other. The O-H···O bonding structure includes the -COOH group of the side chain and the hydroxyl -OH groups in the 3- and 12-positions of the A and C rings, respectively. Such information is of particular interest in the present case, since the above-mentioned individual OH groups may be expected to have different vibrational frequencies in the 3 μm region (3).

Actually, in the spectrum of deoxycholic acid a strong and unsymmetrical band with a broad shoulder on the low-frequency side occurs at 3340 cm^{-1} (Fig. 4*a*). Considering this unresolved band as being due to the overlapping of at least two components, the observed frequencies are consistent with the expectation for hydrogen-bonded O-H vibrations of the steroid molecules (3).

In the spectrum of its molecular association with CH_3COOD, the absorptions appear as a doublet with the maxima at 3346 and 3206 cm^{-1} (Fig. 4*b*). It seems likely that these bands arise from two kinds of O-H···O bonds different in strength. Since the OH vibration frequencies are not appreciably altered on going from one spectrum to the other, we must assume that the hydrogen-bonding arrangement of the deoxycholic acid molecules persists after complexation. As will be seen from Figs. 4*a* and *b* the essential difference between the spectra of the complexed and uncomplexed species lies in the fact that the former shows much better defined vibrational bands than the latter. This change in the band contours suggests that the molecular association is accompanied by the formation of a more organized crystal structure of these compounds.

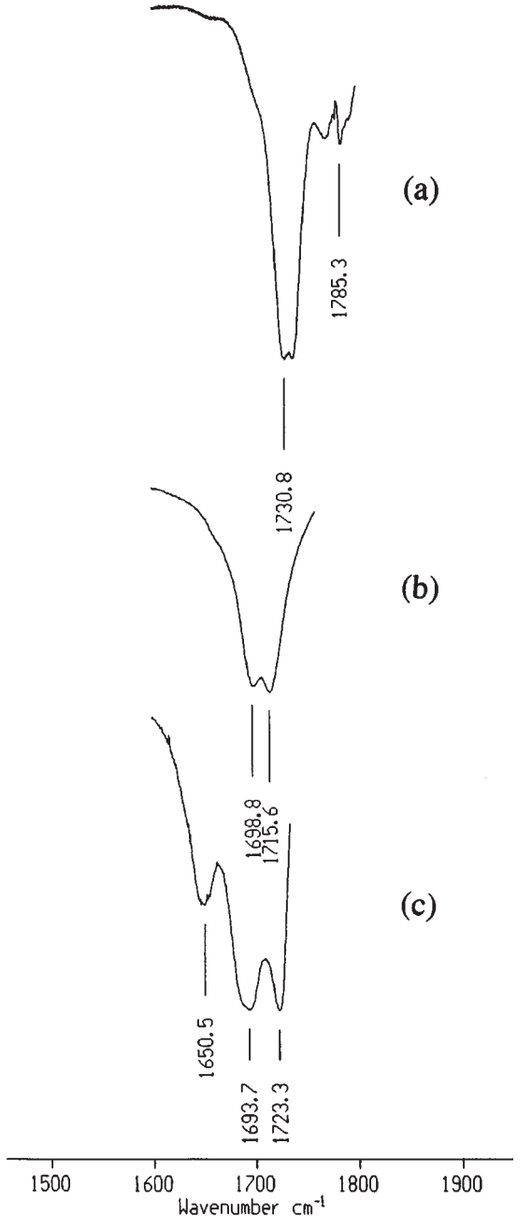
Fig. 6. IR absorption bands in the expected positions of the (C=O) stretching frequencies of deoxycholic acid and CH_3COOD: (*a*) CH_3COOD gas; (*b*) uncomplexed deoxycholic acid; (*c*) complexed species.



The OH bands of cholesterol: The crystal structure of anhydrous cholesterol has been determined by X-ray diffraction analysis (15). Hydrogen bondings of the same kind and strength link the molecules into separate chains forming a bilayer arrangement. In accord with this only a single absorption band attributable to the O-H···O stretching vibrations occurs at 3388 cm^{-1} in the IR spectrum of the steroid (Fig. 5*a*). In the complexed state the band is found to be shifted at 3265 cm^{-1} (Fig. 5*b*). This displacement of the OH absorption band is presumably due to the formation of an additional D bonding to the same hydroxyl oxygen atom already mentioned in the comparison of the spectra of the gas and the complexes (16).

Region associated with the C=O stretching vibrations: The IR absorption bands observed in the region of the C=O stretching frequencies are shown in Fig. 6. Acetic acid-*d*, as a gas, absorbs at 1785 cm^{-1} (Q-branch) and at 1730 cm^{-1} (doublet contour Fig. 6*a*). The former frequency can be assigned to the vibration of the free carbonyl of the monomeric species. The latter frequency could be caused by the similar vibration of the dimeric forms shifted by D bonding effect.

In the spectrum of deoxycholic acid there are two strong bands at 1715 and 1698 cm^{-1} (Fig. 6*b*).When the steroid forms complex with CH_3COOD it absorbs strongly at 1723 and 1693 cm^{-1} (Fig. 6*c*). A weaker additional band, separated enough from those mentioned above to make it distinguishable, appears at 1650 cm^{-1}. This latter band is believed to arise from the carboxyl carbonyl vibration of the CH_3COOD molecules. It is not known whether the large displacement of the frequency from its positions in the gaseous phase (Fig. 6*a*) is an indication of intermolecular interactions or whether it reflects the influence of structural change around the carboxyl group on the carbonyl frequency. The comparison of the spectra of the steroid and its complex shows some resemblance though there is a significant difference. The C=O stretching frequencies of the two main bands are not appreciably altered on going from one spectrum to another (compare Figs. 6*b* and *c*). However, their relative intensities are markedly different. The most remarkable difference is an increase of the bandwidth of the lower frequency absorption at 1693 cm^{-1} (Fig. 6*c*).

From these last results it may be concluded once again that the assumption of some type of steroid–CH_3COOD interactions accounts for the apparent spectroscopic behaviour of these molecular compounds. Since the nature of the intermolecular forces involved cannot be determined from vibrational spectroscopy alone, it is highly desirable that the crystal structures should be investigated.

Acknowledgments

The sample of cholesterol used in the present work was kindly supplied to us by Professor Lutton, Laboratoire de Physiologie de la Nutrition, Campus d'Orsay, Bât. 447, 91405 Orsay.

^{13}C NMR and crystallographic evidence of push–pull effects in furoindolic β-enamino esters

Martha S. Morales-Ríos, Oscar R. Suárez-Castillo, Celina Alvarez-Cisneros, and Pedro Joseph-Nathan

Abstract: A series of cyclic enamine derivatives, stabilized through conjugation with an electron-attracting CO_2Me group at the β-carbon of the enamine system, has been prepared. The influence of substituents at the vinylogous donor NH_2 group on ^{13}C chemical shifts has been investigated, and the results analyzed on the basis of resonance and steric effects on the dipolar charge distribution in the molecule. Intramolecular H-bonding was established for the *N*-methylated enamines **4a** and **4b** based on the high-frequency shift of the NH proton and its solvent immutability. Several deuterium-induced isotope effects on ^{13}C chemical shift [$^n\Delta$C(ND)] due to deuteration at the enamine nitrogen have been measured. The crystal structures of the enamine **1b** and the *N*,*N*-diacetylated enamine **3a**, determined by X-ray analyses, show that these compounds, in the solid state, adopt an *s-trans* disposition around the C—C=O bond, with the carbonyl ester group and the C=C double bond in an almost coplanar conformation. Comparison of bond lengths of **1b** and **3a** in the crystalline state provides information on changes in the extent of *n*–π delocalization arising from the nature of the *N*-substituent.

Key words: β-enamino esters, furo[2,3-*b*]indoles, push–pull effects, ^{13}C NMR, X-ray.

Résumé : On a préparé une série d'énamines cycliques, stabilisées par conjugaison avec un groupe CO_2Me, attracteur d'électron, situé en position β du système énamine. On a étudié l'influence des substituants attachés au groupe NH_2 vinylogue donneur sur les déplacements chimiques en RMN du ^{13}C et on a analysé les résultats en fonction de la résonance et des effets stériques sur la distribution de la charge dipolaire dans la molécule. En se basant sur le déplacement du proton NH vers une haute fréquence et sur son immutabilité dans les solvants, on a pu mettre en évidence la présence d'une liaison hydrogène intramoléculaire dans les énamines *N*-méthylées **4a** et **4b**. Lors de la deutération de l'azote de l'énamine, on a pu mesurer plusieurs effets isotopiques induits par le deutérium sur le déplacement chimique du ^{13}C [$^n\Delta$C(ND)]. Faisant appel à la diffraction des rayons X, on a déterminé les structures cristallines de l'énamine **1b** et de l'énamine *N*,*N*-diacétylée, **3a**; elles montrent que, à l'état solide, ces composés adoptent une disposition *s-trans* autour de la liaison C—C=O alors que le groupe carbonyle de l'ester et la double liaison C=C se trouvent pratiquement dans une conformation coplanaire. Une comparaison des longueurs des liaisons dans les composés **1b** et **3a** à l'état solide fournit de l'information sur les changements dans l'amplitude de la délocalisation *n*–π découlant de la nature du substituant fixé sur l'azote.

Mots clés : β-énaminoesters, furo[2,3-*b*]indoles, effet «push–pull», RMN du ^{13}C, rayons X.

[Traduit par la Rédaction]

Introduction

The structures of β-enamino esters (see reviews, ref. 1) have been extensively studied, considering a variety of factors such as hydrogen-bond pattern (2), tautomerism involving the imine–enamine forms (3), *cis*/*trans* isomerism about the olefinic C=C double bond (4), and barriers to rotation around the N—C(sp^2) and C(sp^2)—CO_2R single bonds (5) in combination with the electron distribution inside these mesomeric systems. As in similar push–pull olefins, NMR spectroscopy combined with X-ray studies can provide information on these matters. In continuation of our studies on furoindolic β-enamino esters (6), we present herein detailed assignment of the ^{13}C NMR spectra of dihydro-2-amino-3-carbomethoxyfuro[2,3-*b*]indoles **1a**–**1d**. We also discuss the ^{13}C chemical shift variations in the so-called push–pull system caused by changing one or both protons attached to the vinylogous donor NH_2 group for electron-releasing and electron-withdrawing substituents in the series **1a**–**1d** (Scheme 1). The corresponding mono and doubly acetylated β-enamino esters were prepared by treatment with acetic anhydride (7). In this work, we emphasize the importance of bond lengths, obtained by X-ray analyses, in revealing the extent of *n*–π delocalization of the enaminocarbonyl framework (N—C=C—C=O). Thus, an increase in *n*–π overlap is expected to be accompanied by a shortening of the N—C and C—C single bond distances, and by a lengthening of the C=C double bond distance (8).

The intramolecular H-bonding in aminocarbonyl systems has been recently approached by the study of secondary deuterium isotope effects on the ^{13}C, ^{15}N, and ^{17}O nuclear shielding [$^n\Delta X(ND)$] (9, 10). In the case of the ^{13}C nuclear shielding, it has been shown that the deuteration of the amino nitrogen, involved in an intramolecular H-bond, produces a relatively large low-frequency shift on the resonance of the nitrogen-bearing carbon atom, the magnitude of which correlates with the H-bond energy (11). To evaluate the substituent effects on H-bonding, the ^{13}C NMR spectra of the β-enamino esters **1b**, **2b**, and **4b**, partially deuterated at the enamine nitrogen, have been investigated.

Results and discussion

Preparation of *N*-substituted enamines 2–4

Furoindolic β-enamino esters **1a**–**1d** (R = Me, Et, i-Pr, *t*-Bu) were synthesized by rearrangement of the corresponding α-cyano-γ-butyrolactones (6). Critical reaction conditions were required for the preparation of *N*-acetyl and *N*,*N*-diacetyl substituted enamines **2** and **3.** The significant stability of the amino group and, therefore, the rather weak nucleophilicity of the nitrogen atom arise from an expected extended conjugation of the enamine moiety with the carbonyl ester group, which increases the *n*–π overlap in the system. Treatment of β-enamino esters **1a**,**1b** (R = Me, Et) with acetic anhydride and sodium acetate afforded a mixture of monoacetylated compounds **2a**,**2b** and the corresponding diacetylated compounds **3a**,**3b** in an overall yield of ca. 80%, and in a nearly 1:1 ratio, as determined by ^1H NMR analysis of the crude reaction outcome. These reactions were conducted in the presence of 0.1 equiv. of NaOAc at 90°C and were completed within 1 h, as revealed by TLC. The reactions can easily be monitored by TLC, since enamines are more polar than their corresponding diacetylated derivatives, but less polar than the monoacetylated compounds. An increase either in the reaction time, sodium acetate amount, or in the reaction temperature results in significant decomposition. The conversion of enamines **1a–1d** to the corresponding diacetyl derivatives **3a**–**3d** was improved using pyridine instead of sodium acetate. In this way yields increased from 40% to 75–85% at the expense of the monoacetyl derivatives **2**, which were formed in yields ranging from 2 to 11%. It should be noted that the pyridine-catalyzed reaction occurs at 110°C. Pure samples of each of these compounds were obtained after chromatographic separation.

N-Alkylation of enamines with a tetrasubstituted double bond, **1a**,**1b,** was carried out by treatment with excess dimethyl sulfate, at reflux in dry acetone for 8 days. In this way, only the corresponding monosubstituted compounds **4a**,**4b** were obtained in a nearly quantitative yield.

^{13}C NMR and push–pull effect

The pertinent ^{13}C chemical shifts for compounds in series **1–4** are summarized in Table 1. Straightforward evidence for the assignment of the ^{13}C resonances was obtained from selective double resonance ^1H,^{13}C experiments, C–H coupling constants, deuterium isotope effects, and the usual expectation of self-consistent substituent chemical shift effects. From the ^1H and ^{13}C NMR spectra it follows that the *Z*-fixed cyclic β-enamino esters **1–4** appear to exist in $(CD_3)_2SO$ solution exclusively as the enamino tautomer, and rotamers around the C2—N and C3—CO_2Me bonds were not found. The protonated carbons were assigned from HETCOR experiments and the unprotonated carbons were assigned with the aid of multiple-bond ^1H,^{13}C FLOCK correlation experiments. These experiments, for **1a–4a**, showed relevant cross peaks corresponding to $^3J_{CH}$ couplings between the protons of the methyl group attached to C3a and the carbons C3 and C3b. Informative cross peaks, which allow differentiation between C3b and C7a, were also visible between H5/C3b and H5/C7. The signal due to the carbonyl ester group, which appears to be very close or coincident with that owing to C2 in compounds **1a**–**1d** and **4a**, was identified by its long-range coupling $^3J_{CH}$ to the CO_2Me protons. In addition, H8a showed a cross peak to the C2 and C3 carbons in compound **3a**. The ^{13}C NMR spectra display the carbamate carbonyl signal in the expected chemical shift region

Table 2. Mulliken atomic charges of enamines **1a–4a**.

	C2	C3		C2	C3
1a	0.125	–0.362	**3a**	0.190	–0.266
2a	0.158	–0.372	**4a**	0.148	–0.373

of δ 153–155 ppm (12). Assignment of the two coincident acetyl carbonyl peaks in **3a–3d** was assisted by considering their relative intensities and the two-bond coupling constants. The values of these coupling constants further allowed assignment of the acetyl carbonyl in **2a**,**2b**. The olefinic carbons in compounds **1b**, **2b**, and **4b** were further evidenced, in some cases, by the resolved deuterium isotope shift effects, which caused additional splitting of both C2 and C3 resonances.

Comparison of the data in Table 1 reveals the β- and γ-effects exerted by the alkyl group on the chemical shifts in series **1a**–**1d** and **3a**–**3d**. These effects are the result of adding methyl groups on going through the series Me, Et, i-Pr, *t*-Bu. Thus, C3a moves to lower frequency as the alkyl group increases, while for C3 and C3b the reverse situation is true. Although the chemical shift variations of C8a are less systematic than those observed for C3 and C3b, the tendency to higher frequency is also seen. The chemical shifts for the remaining carbons are almost unchanged.

Series **1–4** provide a useful set for investigating the push–pull effect. It is apparent from analysis of the ^{13}C chemical shifts for the donor- and acceptor-substituted carbons C2 and C3 that the C2 signal (165.9 ± 0.2 ppm) in **1a–1d** is significantly less shielded than the corresponding C2 signal in dihydrofuran (145.6 ppm). At the same time, the signal due to the acceptor-substituted carbon C3 (78.2 ± 1.3 ppm) for the same compounds is significantly more shielded than the corresponding C3 signal in dihydrofuran (98.4 ppm) (13). These differences demonstrate, as in other push–pull olefins (14), a strong *n*–π delocalization with appreciable charge polarization of the enaminocarbonyl framework. The electron delocalization in these compounds is reflected in a large chemical shift difference (Δδ) (15) of ca. 88 ppm between the olefinic C2 and C3 carbons ($\Delta\delta = \delta_{C2} - \delta_{C3}$). This Δδ is in the range of other push–pull alkenes in which the acceptor ester group at C3 promotes more extensive charge delocalization (14*a*). These findings are, further, in accord with the observed reactivity described above for the β-enamino esters **1a–1d**.

Inspection of Table 1 shows that for R = Me in **1–3**, the *N*-acetyl substitution causes a dramatic effect on the C3 chemical shifts. The C3 carbon signal moves gradually to a higher frequency in the order NH_2 < NHAc < NAc_2, whereas that of the C2 carbon is shifted to a lower frequency. This difference is attributed to the electron-withdrawing and steric effects of the *N*-acetyl group that reduce or prevent the conjugation of the nitrogen electron lone pair with the enamine double bond, thus resulting in a large redistribution of π-electron charge density within this residue. The pronounced twisting of the NAc_2 group out of the plane of the C=C-CO_2Me system in **3a**, with the consequent nil *n*–π overlap, was confirmed by X-ray analysis and geometry optimization using MO calculation, vide infra. The ^{13}C chemical shift difference Δδ in compounds **1a–3a** varies from 86 to 48 ppm. This variation is associated with the decreasing polarization of the enamine double bond in the order NH_2 > NHAc > NAc_2. Similar results were observed for R = Et in **1–3**. Methyl substitution at the vinylogous donor NH_2 group has only a small effect on the chemical shifts. When comparing **4a**, **4b** with **1a**, **1b** in Table 1, we note a very small lower frequency shift of C3, leading to an increase in Δδ of about 1 ppm.

The results (Table 2) of PM3 semiempirical calculation of the atomic charges in compounds **1a–4a** are in line with the expected electronic behavior of the β-enamino esters studied, where C2 is positive while C3 is negative. The largest positive charge at C2 (0.190) as well as the smallest negative charge at C3 (0.266) were obtained for the diacetylated enamine **3a**. The Mulliken atomic charge difference between C2 and C3 decreases in the order **1a** > **4a** > **2a** > **3a**, in ac-

Isotope effects and hydrogen bonding

A summary of deuterium isotope effects on ^{13}C chemical shifts due to partial deuteration at the enamine nitrogen atom [$^{n}\Delta$C(ND)] for compounds **1b**, **2b**, and **4b**, measured in either DMSO-d_6 or $CDCl_3$, as well as the corresponding NH proton chemical shifts, measured in both DMSO-d_6 and $CDCl_3$, is given in Table 3. Only low-frequency deuterium-induced chemical shifts were observed (negative sign). For **1b**, both amino protons may be partially deuterium exchanged, and therefore the signals due to C2 and C3 in the ^{1}H decoupled ^{13}C NMR spectra show three resonances per nucleus, owing to the isotopomeric ternary mixture constituted by the NH_2, NHD, and ND_2 species. In these multiplets the signal at lower frequency arises from the ND_2 species. The two-bond isotope effect on C2 ($^{2}\Delta$C2 = –75 ppb) was small, as judged from the effects normally found for hydrogen-bonded enamino esters (–156 to –214 ppb) (9*a*, 9*c*, 16). The small isotope effect at C2, as well as the observed low-frequency shift of the NH_2 protons in $CDCl_3$ (δ = 5.80 ppm) must be average values resulting from an exchange between the free hydrogen and its hydrogen-bonded partner. A small three-bond isotope effect on C3 ($^{3}\Delta$C3 = –11 ppb) was also observed.

Measurement of the ^{13}C NMR spectrum of partially deuterated **2b** in DMSO-d_6 shows the ^{13}C lines substantially broadened, and therefore the $^{n}\Delta$C(ND) values were determined in $CDCl_3$. The relatively large $^{2}\Delta$C2 effect caused by deuterium substitution of the amide NH proton can be associated with the corresponding high-frequency shift of this NH proton (δ = 9.94 ppm in $CDCl_3$). We have already demonstrated that $^{2}\Delta$C(ND) are valuable in describing cross-conjugated systems of the type C(sp^2)-NH(D)-C(sp^2), such as indoles, acetanilides, and benzanilides (17*a*–*d*). In this work, we further described the application of $^{2}\Delta$ isotope effects to account for the competitive interplay of electronic delocalization. Thus, an interesting feature is that the $^{2}\Delta$ isotope effect at C2 in **2b** (–135 ppb) is significantly larger than that observed at the amide carbonyl carbon ($^{2}\Delta$C=O = –64 ppb), the origin of this large difference (71 ppb) can be attributed to a strong conjugative interaction between the nitrogen lone pair and the C2=C3-CO_2Me fragment (17*b*, *c*), and consequently an increase in the N—C2 bond order. The three-bond isotope effect $^{3}\Delta$C3 was not resolved in **2b**.

Compounds **4a** and **4b** exist in the *Z-s-cis* conformation as a result of stabilization through the intramolecular H-bond between the C=O oxygen and the NH hydrogen. The H-bond formation in the *N*-methylated enamines **4a** and **4b** has been established, based on the observed high-frequency shift of the N-H proton chemical shift (δ = 7.15 ppm in $CDCl_3$) when compared with those of related compounds (18). The same conclusion is reached from the observed immutability of the corresponding ^{1}H NMR spectra (in $CDCl_3$) upon dilution. The H-bonding formation in compounds **4a**, **4b** is further related to the donor nature and steric requirements of the methyl group, which contribute to the approach of the groups involved in the H-bonding. It is worth noting that the corresponding $^{2}\Delta$ isotope effects in **4a** and **4b** cannot be seen as the N*H* resonance is somewhat broad and the signals owing to the olefinic C2 carbon and the carbonyl ester group overlapped. Isotope effects at the olefinic C3 carbon and at the *N*-Me group were measured in compound **4b** ($^{3}\Delta$ = –29 and $^{2}\Delta$ = –66 ppb, respectively).

X-ray structure determination

The higher degree of n–π overlap of enamines **1** as compared to the corresponding mono- or diacetylated enamines **2** or **3**, initially inferred from ^{13}C NMR evidence, was fully corroborated by single-crystal X-ray analysis of **1b** and **3a**. The molecular structures are shown in Figs. 1 and 2, respectively. Details of the structure determination are found in Table 4.[2] Selected bond lengths and angles are compared in Table 5. The molecular structures exhibit a *syn*-periplanar orientation of the C13 carbon atom of the alkyl group and the H8a proton along the C3a—C8a bond (dihedral angle C13-C3a-C8a-H8a of 9.9° for **1b** and of 3.2° for **3a**). The two virtually planar pyrrole and furane rings are *cis* ring-fused. The overall shape of the molecules is therefore bent. The carbonate N8 atom has, in both cases, a trigonal planar geometry, with an average of bond angles around N8 close to 120°. The short N8—C11 bond lengths (1.362(6), 1.361(6) Å), as compared with a carbon–nitrogen single bond (1.477–1.467 Å) (19), are indicative of the participation of the nitrogen lone pair in the respective N8—C11

[2] Tables of atomic coordinates, complete bond lengths and angles, and other refinement data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. This supplementary material has also been deposited with the Cambridge Crystallographic Data Center, and can be obtained on request from The Director, Cambridge Crystallographic Data Center, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U. K.

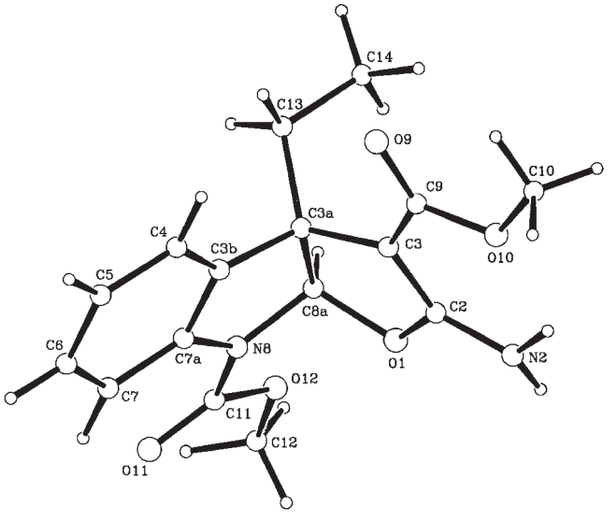

Fig. 2. Perspective view of **3a**.

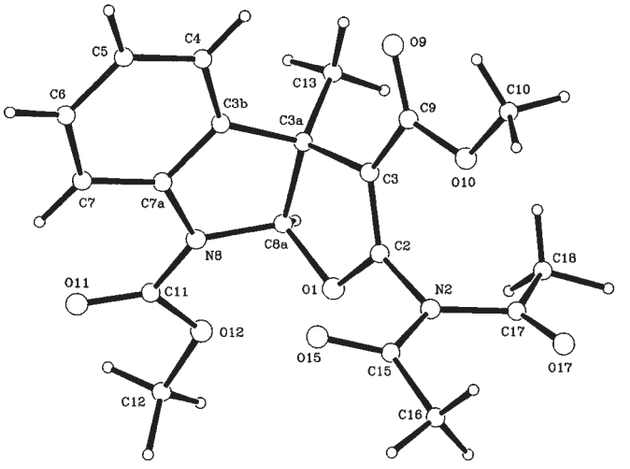

bonds. The carbonyl carbamate group is in an *E* configuration with C8a along the N8—C11 bond (dihedral angle, O11-C11-N8-C8a of –179.3° for **1b** and of –176.2° for **3a**).

A feature that is apparent from Fig. 1 is that one of the N—H bonds in **1b** almost eclipses the C2=C3 bond (dihedral angle C3-C2-N2-H2a is –13.8°), whereas molecule **3a** (Fig. 2) adopts a conformation in which the double bond C2=C3 bisects the C15-N2-C17 angle (dihedral angles C3-C2-N2-C15 and C3-C2-N2-C17 of 96.7° and –75.5°, respectively) in order to minimize the steric strain introduced by the relatively bulky acetyl groups at N2 (20). These results are in agreement with the PM3 geometry optimization (dihedral angles C3-C2-N2-C15 and C3-C2-N2-C17 of 97.2° and –75.2°, respectively). It is also clear from the molecular diagram of **3a** (Fig. 2) that the O15 atom of an acetyl group is oriented to the concave side of the molecule, and exhibits a *syn*-periplanar conformation with the C2—N2 bond (dihedral angle C2-N2-C15-O15 of –0.7°), whereas in the other acetyl group the O17 atom is oriented away from the C2—N2 bond (dihedral angle C2-N2-C17-O17 of 163.2°). A comparison of the bond lengths in **1b** and **3a** provides information on changes in the extent of n–π overlap in these enamine systems (8, 21). An increase in n–π overlap in **1b** with respect to **3a** is accompanied by a shortening of both the N(2)—C(2) and C(3)—C(9) distances by 0.08 and 0.04 Å, respectively, while the C(2)—C(3) bond is lengthened by about 0.03 Å. The geometry around the enamine N2 atom in **3a** is similar to N8, trigonal planar (sum of the angles 359.3°). As far as the carbonyl ester group is concerned, in both compounds **1b** and **3a**, it is found in an almost *anti*-periplanar conformation with the C=C double bond (dihedral angle C2-C3-C9-O9 of 176.3 for **1b** and of –175.5° for **3a**).

Experimental

Analytical TLC was carried out on precoated plates (Aldrich silica gel 60 F 254) and the products were visualized with UV light (254 nm). Silica gel used for column chromatography was Merck 60. Melting points were measured on a microscopic Fisher–Johns apparatus and are uncorrected. IR spectra were obtained using a Perkin Elmer 727B spectrophotometer; only diagnostic peaks are reported. ^{1}H and ^{13}C NMR spectra were recorded on a Varian XL300GS spectrometer working at 300 and 75.4 MHz, respectively, in DMSO-d_6 solutions with $SiMe_4$ as internal standard. Multiplicities are indicated by one or more of the following: s (singlet), d (doublet), t (triplet), h (heptet), m (multiplet), br (broad); the list of coupling constants (J in Hz) corresponds to the order of the multiplicity assignment. Elemental analysis was performed by the MHW Laboratories, Phoenix, Ariz., U.S.A. Electron impact mass spectra (EIMS) were recorded on a Hewlett Packard 5989A spectrometer. High-resolution mass spectra (HRMS) were measured on a Jeol JMS-SX 102A spectrometer. Semiempirical MO calculations were performed by using the PM3 program (22). The dihydro-2-amino-3-carbomethoxyfuro[2,3-*b*]indoles **1a–1d** were prepared as previously described (6).

General procedure for the acetylation of *cis*-(±)-dimethyl 3a,8a-dihydro-3a-alkyl-2-amino-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylates 1a–1d

Method A

The appropriate furoindolic β-enamino ester (**1a** or **1b**) (0.30 mmol) was stirred with sodium acetate (0.1 equiv.) in acetic anhydride (5 mL) at 90°C for 4 h until TLC analysis indicated complete loss of starting material. The solvent was evaporated under reduced pressure and the residue was dissolved in ethyl acetate, washed with saturated NH_4Cl solution (2 × 10 mL), dried (Na_2SO_4), and evaporated. The oily residue was chromatographed on silica gel eluting with hexane – diethyl ether (2:3) to afford successively the corresponding diacetylated (**3a** or **3b**) and monoacetylated (**2a** or **2b**) compounds in a ratio of ca. 1:1.

Method B

The appropriate furoindolic β-enamino ester (**1a–1d**) (0.30 mmol) was dissolved in a mixture of acetic anhydride (5 mL) and pyridine (1 mL). The solution was stirred at

a colourless oil. IR ν_{max} /cm^{-1}: 1729, 1665, 1624; ^{1}H NMR δ: 9.88 (1 H, s, NHAc), 7.67 (1 H, br s, H7), 7.52 (1 H, dd, *J* 7.6, 1.2, H4), 7.24 (1 H, td, *J* 7.6, 1.2, H6), 7.04 (1 H, td, *J* 7.6, 1.0, H5), 6.44 (1 H, s, H8a), 3.83 (3 H, s, OMe carbamate), 3.71 (3 H, s, OMe ester), 2.06 (3 H, s, COMe), 1.64 (3 H, s, Me); MS *m*/*z*: 346.3 (M$^+$, 28%) and 255.3 (100); HRMS calcd. for $C_{17}H_{18}O_6N_2$, *M*: 346.1165; found: 346.1170.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-acetylamino-3a-ethyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (2b)**

The title compound was prepared by methods A and B in 38 and 5% yield, respectively. The product was crystallized from diethyl ether – hexane as colourless crystals, mp 135–137°C; IR ν_{max} /cm^{-1}: 1728, 1670, 1624; ^{1}H NMR δ: 9.95 (1 H, s, NHAc), 7.71 (1 H, br s, H7), 7.51 (1 H, dd, *J* 7.6, 1.0, H4), 7.26 (1 H, td, *J* 7.8, 1.3, H6), 7.06 (1 H, td, *J* 7.5, 1.0, H5), 6.51 (1 H, s, H8a), 3.86 (3 H, s, OMe carbamate), 3.72 (3 H, s, OMe ester), 2.23 and 1.92 (2 H, 2 m, *C*H$_2$CH$_3$), 2.09 (3 H, s, COMe), 0.78 (3 H, t, CH$_2$*C*H$_3$); MS *m*/*z*: 360.3 (M$^+$, 24%) and 269.3 (100); HRMS calcd. for $C_{18}H_{20}O_6N_2$, *M*: 360.1321; found: 360.1321.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-diacetylamino-3a-methyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (3)**

The title compound was prepared by methods A and B in 40 and 82% yield, respectively, and crystallized from diethyl ether – hexane as colourless crystals, mp 152–155°C; IR ν_{max}/cm^{-1}: 1728, 1656; ^{1}H NMR δ: 7.73 (1 H, br d, *J* 6.0, H7), 7.54 (1 H, dd, *J* 7.5, 1.2, H4), 7.28 (1 H, td, *J* 7.5, 1.2, H6), 7.07 (1 H, td, *J* 7.5, 1.1, H5), 6.57 (1 H, s, H8a), 3.82 (3 H, s, OMe carbamate), 3.69 (3 H, s, OMe ester), 2.20 (6 H, br s, 2 COMe), 1.72 (3 H, s, Me); MS *m*/*z*: 388 (M$^+$, 4%), 287 (100), and 255 (93); HRMS calcd. for $C_{19}H_{20}O_7N_2$, *M*: 388.1271; found: 388.1268. Anal. calcd. for $C_{19}H_{20}O_7N_2$: C 58.76, H 5.19, N 7.21; found: C 58.80, H 5.30, N 7.21.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-diacetylamino-3a-ethyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (3b)**

The title compound was prepared by methods A and B in 41 and 75% yield, respectively, and crystallized from diethyl ether – hexane as colourless crystals, mp 118–120°C; IR ν_{max} /cm^{-1}: 1728, 1654; ^{1}H NMR δ: 7.73 (1 H, br d, *J* 6.8, H7), 7.50 (1 H, dd, *J* 7.2, 1.0, H4), 7.28 (1 H, td, *J* 7.5, 1.3, H6), 7.06 (1 H, td, *J* 7.5, 1.0, H5), 6.62 (1 H, s, H8a), 3.82 (3 H, s, OMe carbamate), 3.68 (3 H, s, OMe ester), 2.34 and 1.92 (2 H, 2 m, *C*H$_2$CH$_3$), 2.19 (6 H, br s, 2 COMe), 0.86 (3 H, t, CH$_2$*C*H$_3$); MS *m*/*z*: 402.3 (M$^+$, 35%) and 269.3 (100); HRMS calcd. for $C_{20}H_{22}O_7N_2$, *M*: 402.1427; found: 402.1415.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-diacetylamino-3a-isopropyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (3c)**

The title compound was prepared by method B in 75% yield as an oil; IR ν_{max}/cm^{-1}: 1728, 1656; ^{1}H NMR δ: 7.79 (1 H, br d, *J* 8.0, H7), 7.56 (1 H, d, *J* 8.0, H4), 7.34 (1 H, td, *J* 8.0, 1.3, H6), 7.14 (1 H, td, *J* 8.0, 1.0, H5), 6.65 (1 H, s, H8a), 3.86 (3 H, s, OMe carbamate), 3.70 (3 H, s, OMe ester), 2.93 (1 H, h, CH), 2.19 (6 H, br s, 2 COMe), 1.05 and 0.57 (6 H, 2 d, *J* 7.0, 2 Me); MS *m*/*z*: 416.3 (M$^+$, 9.5%) and 283.3(100); HRMS calcd. for $C_{21}H_{24}O_7N_2$, *M*: 416.1584; found: 416.1587.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-diacetylamino-3a-*tert*-butyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (3d)**

The title compound was prepared by method B in 85% yield and crystallized from diethyl ether – hexane as colourless crystals, mp 104–106°C; IR ν_{max}/cm^{-1}: 1728, 1642; ^{1}H NMR δ: 7.85 (1 H, d, *J* 8.0, H4), 7.77 (1 H, br d, *J* 8.0, H7), 7.31 (1 H, td, *J* 8.0, 1.3, H6), 7.09 (1 H, td, *J* 8.0, 1.1, H5), 6.62 (1 H, s, H8a), 3.86 (3 H, s, OMe carbamate), 3.65 (3 H, s, OMe ester), 2.20 (6 H, br s, 2 COMe), 1.02 (9 H, s, CMe$_3$); MS *m*/*z*: 430.3 (M$^+$, 6.3%) and 273.3 (100); HRMS calcd. for $C_{22}H_{26}O_7N_2$, *M*: 430.1740; found: 430.1746.

***cis*-(±)-Dimethyl 3a,8a-dihydro-2-methylamino-3a-methyl-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (4a)**

A solution of **1a** (90 mg, 0.3 mmol) in 40 mL of acetone was treated with K_2CO_3 (165 mg, 1.2 mmol) and dimethyl sulfate (0.1 mL, 1.1 mmol). The mixture was stirred at reflux and the reaction followed by TLC. After the starting material disappeared (8 days), the solvent was evaporated under reduced pressure and the residue was dissolved in ethyl acetate (60 mL), washed twice with brine (15 mL), dried (Na_2SO_4), and concentrated. The residue was crystallized in diethyl ether – hexane to give **4a** as colourless crystals. Yield 98%; mp 175–177°C; IR ν_{max} /cm^{-1}: 3682, 3336, 1722, 1674, 1632; ^{1}H NMR δ: 7.64 (1 H, br s, H7), 7.54 (1 H, br d, *J* 7.3, H4), 7.21 (1 H, td, *J* 8.0, 1.4, H6), 7.20 (1 H, br s, N*H*Me),7.02 (1 H, td, *J* 8.0, 1.0, H5), 6.29 (1 H, s, H8a), 3.85 (3 H, s, OMe carbamate), 3.63 (3 H, s, OMe ester), 2.77 (3 H, d, J 5.0, NH*Me*), 1.61 (3 H, s, Me); MS *m*/*z*: 318.3 (M$^+$, 28.5%) and 255.3 (100); HRMS calcd. for $C_{16}H_{18}O_5N_2$, *M*: 318.1216; found: 318.1219.

***cis*-(±)-Dimethyl 3a,8a-dihydro-3a-ethyl-2-methylamino-8*H*-furo[2,3-*b*]indole-3,8-dicarboxylate (4b)**

The title compound was prepared following the above procedure starting from **1b**. After work-up, the oily residue was chromatographed on silica gel eluting with hexane – diethyl ether (2:3) to afford **4b** as a colourless oil, in 92% yield; IR ν_{max} /cm^{-1}: 3480, 3336, 1720, 1667; ^{1}H NMR δ: 7.66 (1 H, br s, H7), 7.52 (1 H, br d, *J* 7.1, H4), 7.21 (1 H, td, *J* 7.8, 1.3, H6), 7.21 (1 H, br s, N*H*Me),7.03 (1 H, td, *J* 7.5, 1.0, H5), 6.34 (1 H, s, H8a), 3.87 (3 H, s, OMe carbamate), 3.64 (3 H, s, OMe ester), 2.79 (3 H, d, J 5.1, NH*Me*), 2.16 and 1.90 (2 H, 2 m, *C*H$_2$CH$_3$), 0.73 (3 H, t, CH$_2$*C*H$_3$); MS *m*/*z*: 332.3 (M$^+$, 100%), 301.3 (27), and 269.3 (62).

X-ray crystallographic analyses

Crystallographic data appear in Table 3. The X-ray structures were determined using a Nicolet R3m diffractometer with the θ–2θ scan technique, Cu-Kα radiation (λ = 1.54178 Å), graphite monochromator. The final unit-cell parameters

© 1999 NRC Canada

were obtained by least squares on the setting angles for 9 reflections for **1b** and for 16 reflections for **3a**. The intensities of two standard reflections, measured every 98 reflections throughout the data collections, showed no significant variation. The data were corrected for Lorentz and polarization effects and for absorption (based on azimuthal scans).

The structures were solved by direct methods using SHELX86. The hydrogen atoms were refined isotropically. The hydrogen atoms for the NH_2 group in **1b** and one hydrogen atom for all the methyl groups in **1b** and **3a** were located on a difference map, and all remaining hydrogen atoms of both compounds were fixed in calculated positions with C—H = 1.00 Å. Non-hydrogen atoms were refined anisotropically. Values given for $R(F)$, $R(W)$, and goodness of fit are based on those reflections with $I \geq 3\sigma(I)$. After removal of the redundant reflections, a few additional reflections were also removed by hand to improve the final fit.

Acknowledgments

This work was supported in part by CONACYT México. We thank I.Q. Luis Velasco Ibarra (Instituto de Química, UNAM) for recording the HRMS.

Heterocyclic aromatic amide protecting groups for aryl and phthalocyaninesulfonic acids

Zhaopeng Li, Johan van Lier, and Clifford C. Leznoff

Abstract: Pyrroles, indole, imidazole, and a pyrazole were treated with 3,4-dibromobenzenesulfonyl chloride to form 3,4-dibromobenzenesulfonamides. The 1-(3,4-dibromophenylsulfonyl)pyrrole and 1-(3,4-dibromophenylsulfonyl)indole were stable to CuCN in DMF to produce 1-(3,4-dicyanophenylsulfonyl)pyrrole and 1-(3,4-dicyanophenylsulfonyl)indole, which upon treatment with ammonia in 2-*N*,*N*-dimethylaminoethanol gave the protected phthalocyanine-2,9,16,23-tetrasulfonamides. Base cleavage of these sulfonamides yielded the free acids. A mixed condensation of 4,5-diheptylphthalonitrile and 1-(3,4-dicyanophenylsulfonyl)pyrrole gave 9,10,16,17,23,24-hexakis(1-heptyl)-2-(1-pyrrolylsulfonyl)phthalocyanine. Cleavage of the latter yielded the lithium salt of the monosulfonic acid.

Key words: sulfonic acid blocking groups, phthalocyanine sulfonic acids, 1-(3,4-dicyanophenylsulfonyl)pyrrole, 1-(3,4-dicyanophenylsulfonyl)indole.

Résumé : La réaction du chlorure de 3,4-dibromobenzènesulfonyle avec des pyrroles, l'indole, l'imidazole et un pyrazole conduit à la formation de 3,4-dibromobenzènesulfonamides. Le 1-(3,4-dibromophénylsulfonyl)pyrrole et du 1-(3,4-dibromophénylsulfonyl)indole ont été soumis à l'action du CuCN dans le DMF pour produire du 1-(3,4-dicyanophénylsulfonyl)pyrrole et du 1-(3,4-dicyanophénylsulfonyl)indole qui, par traitement avec de l'ammoniac dans le 2-*N*,*N*-diméthylaminoéthanol conduit aux phtalocyanine-2,9,16,23-tétrasulfonamides protégés. Le clivage basique de ces sulfonamides conduit aux acides libres. Une condensation mixte du 4,5-diheptylphtalonitrile et du 1-(3,4-dicyanophénylsulfonyl)pyrrole conduit à la 9,10,16,17,23,24-hexakis(1-heptyl)-2-(1-pyrrolylsulfonyl)phtalocyanine. Le clivage de cette dernière fournit le sel de lithium de l'acide monosulfonique.

Mots clés : acide sulfonique comme agents bloqueurs, acides phtalocyanine sulfoniques, 1-(3,4-dicyanophénylsulfonyl)pyrrole, 1-(3,4-dicyanophénylsulfonyl)indole.

[Traduit par la Rédaction]

Introduction

Phthalocyanine (Pc) sulfonic acids have potential as photodynamic therapy (PDT) agents of cancer tumours (1, 2). Although phthalocyanine -2,9,16,23-tetrasulfonic acid is commercially available as a mixture of isomers, it has been shown that phthalocyanine-2-sulfonic acid and phthalocyanine-2,9-disulfonic acid are more effective for direct cell kill (3–9). Unfortunately, only small samples obtained by high-performance liquid chromatography (HPLC) of these unsymmetrical phthalocyanine sulfonic acids (6–8) were available for PDT studies (9, 10). Some recent attempts at preparing mono sulfonated Pcs by the oxidation of sulfides (11) or trisulfonated Pcs (12, 13) via subphthalocyanines (14, 15) gave Pcs in low yield.

One roadblock in the development of a rich variety of readily available sulfonated Pcs is the paucity of suitable blocking groups or precursors of sulfonic acids. Sulfonamides are common compounds made from sulfonyl chlorides and amines, and sulfonamides are widely used as blocking groups of amines. Cleavage (16) of sulfonamides to recover the free amines is not a trivial operation, but a large number of sophisticated procedures (17) have been used to accomplish this task, often requiring harsh conditions such as the use of concentrated acid and high temperatures (18), or reducing agents (19). In most of these procedures little attention is paid to the sulfonic acid residue remaining after the cleavage, and indeed, the sulfonic acid group is often transformed in the process (17–19). The recent description of a neopentyl ester group as a blocking group (20) of sulfonic acid seemed interesting to us but early experiments indicated it to be unsuitable for phthalocyanine synthesis.

Aryl sulfonyl chlorides have been used as blocking groups of five-membered ring aromatic amines such as imidazole, (21, 22), pyrrole (23), and indole (24), and these were cleaved under a variety of conditions, liberating both the amine and recovered sulfonic acids, and hence we directed our attention to the use of these five-membered heterocyclic amines as blocking groups of aryl sulfonic acids. It proved to be essential to develop an aryl sulfonic acid blocking group that was stable to both phthalonitrile and phthalo-

cyanine formation and yet could be cleaved under conditions in which the sulfonic acid groups remained intact.

Results and discussion

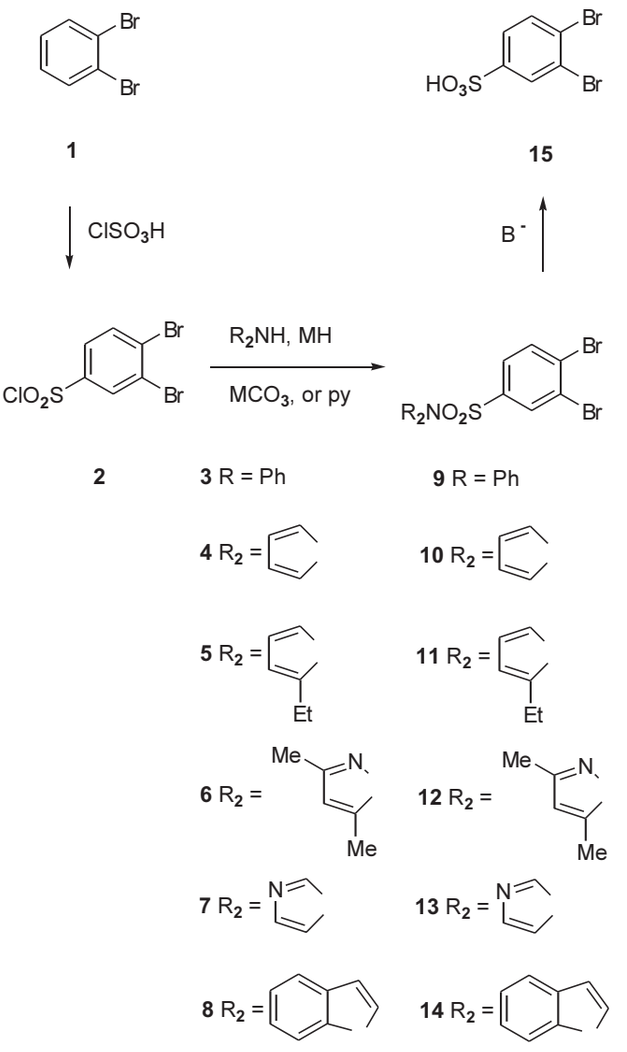
Chlorosulfonation of 1,2-dibromobenzene (**1**) readily gave 3,4-dibromobenzenesulfonyl chloride (**2**) (25). Solov'eva et al. (25) described the synthesis of a wide variety of *N*,*N*-dialkyl-3,4-dibromobenzenesulfonamides for use in phthalonitrile and phthalocyanine synthesis, but these sulfonamides are *not* readily cleaved to the free acids. We first decided to try to see if aryl groups such as diphenylamine (**3**) used in making *N*,*N*-diphenylbenzenesulfonamide would be useful in phthalocyanine synthesis and at the same time compare that analog with a series of heteroarylbenzenesulfonamides derived from pyrrole (**4**), 2-ethylpyrrole (**5**), 3,5-dimethylpyrazole (**6**), imidazole (**7**), and indole (**8**).

Treatment of sulfonyl chloride **2** with **3** in refluxing $CHCl_3$ and pyridine (py) afforded 3,4-dibromo-*N*,*N*-diphenylbenzenesulfonamide (**9**) in high yield. On the other hand, pyrroles **4** and **5** were first treated with NaH in tetrahydrofuran (THF) to form the sodium derivatives, which then reacted with **2** at room temperature to give 1-(3,4-dibromophenylsulfonyl)pyrrole (**10**), 1-(3,4-dibromophenylsulfonyl)-2-ethylpyrrole (**11**), and 1-(3,4-dibromophenylsulphonyl)-3,5-dimethylpyrazole (**12**) in 50, 3, and 84% yields, respectively. The reaction of imidazole (**7**) and indole (**8**) with base in $CHCl_3$ likewise gave 1-(3,4-dibromophenylsulfonyl)imidazole (**13**) and 1-(3,4- dibromophenylsulfonyl)indole (**14**) in 34 and 50% yields, respectively (Scheme 1). The low yield of **11** precluded further work on this compound, although we had envisioned that the ethyl group of **5** would afford enhanced solubility to the subsequent phthalonitrile and phthalocyanine.

At this point it was important to test the stability of sulfonamides **9**, **10,** and **12**–**14** to the conditions of (*i*) the Rosenmund – von Braun reaction (CuCN, 200°C, DMF) (26), (*ii*) phthalocyanine formation (MOR or NH_3), and (*iii*) sulfonamide cleavage. Sulfonamides **9**, **10**, **13**, and **14** were stable to the Rosemund – von Braun reaction, but **12** was not and was abandoned for further consideration. Sulfonamides **9**, **10,** and **14** were stable to $NaOCH_3$ at room temperature and NH_3 in 2-*N*,*N*-dimethylaminoethanol (DMAE), possible methods for use in phthalocyanine formation but **13** did not survive these conditions (Table 1) and was dropped as a potential candidate for Pc formation. Sulfonamides **10** and **14** were solvolyzed by $NaOCH_3$ in refluxing methanol to give 3,4-dibromophenylsulfonic acid (**15**) (27), but again **12** and **13** gave **15** simply upon stirring at room temperature as above (Table 1). All sulfonamides were stable to concentrated HCl at room temperature. Thus, only sulfonamides **9**, **10**, and **14** were suitable substrates for development for phthalocyanine synthesis.

The dibromosulfonamides **9**, **10**, and **14** were readily converted via CuCN in DMF to 3,4-dicyano-*N*,*N*-diphenylbenzenesulfonamide (**16**), 1-(3,4-dicyanophenylsulfonyl)pyrrole (**17**), and 1-(3,4-dicyanophenylsulfonyl)indole (**18**) in 29, 43, and 45% yields, respectively (Scheme 2). The *N*,*N*-diphenylsulfonamide **16** readily formed *N*,*N*,*N*′,*N*′,*N*″,*N*″,*N*‴,*N*‴-octaphenylphthalocyanine-2,9,16,23-tetrasulfonamide (**19**) in 50% yield when treated with lithium in DMAE at 70°C (28).

Scheme 1.



Since we had already shown that **10** and **14** are cleaved by metal alkoxides at refluxing methanol conditions, we treated **17** and **18** with NH_3 in DMAE to form *N*,*N*′,*N*″,*N*‴-tetrakis-(1-pyrrolyl)phthalocyanine-2,9,16,23-tetrasulfonamide (**20**) and *N*,*N*′,*N*″,*N*‴-tetrakis-(1-indolyl) phthalocyanine-2,9, 16,23-tetrasulfonamide (**21**) in 33 and 42% yields, respectively. Under similar conditions to the formation of **21** and **22**, but with the addition of $Zn(OAc)_2$, **17** and **18** were converted directly to *N*,*N*′,*N*″,*N*‴-tetrakis- (1-pyrrolyl)phthalocyanine-2,9,16, 23-tetrasulfonamide zinc(II) (**22**) and *N*,*N*′,*N*″,*N*‴-tetrakis-(1-indolyl)phthalocyanine-2, 9,16, 23-tetrasulfonamide zinc(II) (**23**) in 32 and 68% yields, respectively (Scheme 2).

As expected Pc **19** proved to be resistant to solvolysis, but Pc sulfonamides **20** and **21** were readily converted to phthalocyanine-2,9,16,23-tetrasulfonic acid (**24**) by treatment with lithium 2-*N*,*N*-dimethylaminoethoxide in DMAE (for **20**) or lithium methoxide in THF–MeOH for **21** (Scheme 2).

Early experiments towards the synthesis of a phthalocyanine monosulfonic acid via a mixed condensation of **17** and phthalonitrile gave insoluble residues difficult to separate by chromatography. To increase the solubility of the

phthalocyanine product, **17** was condensed with 4,5-diheptylphthalonitrile (**25**) (29), as for the formation of **22**, to give 9,10,16,17,23,24-hexakis(1-heptyl)phthalocyanine-2-(*N*-pyrrolyl)sulfonamide (**26**) in 14.7% yield. Treatment of **26** with $Zn(OAc)_2$ in DMF readily afforded 9,10,16,17, 23, 24-hexakis(1-heptyl)phthalocyanine-2-(*N*-pyrrolyl)sulfonamide zinc(II) (**27**) in 86% yield. Hydrolysis of **27** with lithium methoxide in methanol afforded lithium 9,10,16,17,23,24-hexakis(1-heptyl)phthalocyanine-2-sulfonate zinc(II) (**28**) in 85% yield (Scheme 3).

Spectral data of all new compounds were consistent with their structures (see Experimental). Pcs **19**–**23** exhibited multiplets in their NMR spectra, consistent with the fact that they exist as mixtures of isomers. Mass spectra of all sulfonamides exhibited ions showing loss of SO_2 and peaks representing both fragments (30).

We have demonstrated that indole and pyrrole moieties can be successfully used to form sulfonamides as blocking groups in the synthesis of phthalocyanine sulfonic acids.

Experimental

All organic solvents were dried by appropriate methods and distilled before use. All reagents were freshly distilled, or were recrystallized and then dried under reduced pressure, before use. Unless otherwise noted, magnetic stirring methods under an inert atmosphere (Matheson High Purity argon) were utilized during distillation or reaction processes, and round-bottom glass vessels chosen such that the quantity of reagents and solvent did not exceed half of the available volume. Water-cooled condensers were used if reaction processes were held near, or at, reflux conditions. Melting points were determined using a Kofler hot-stage melting point apparatus and are reported uncorrected. Infrared spectroscopy was performed on either a Pye Unicam SP3-2000 or a Perkin Elmer 1310 infrared spectrophotometer and FTIR spectroscopy was performed on a Unicam Matheson 3000 FTIR spectrometer, using samples prepared as KBr discs unless otherwise noted. Mass spectral analyses were performed by Dr. B. Khouw (York University, Toronto, Ontario), Dr. R. Smith (McMaster University, Hamilton, Ontario), and Dr. R.N. Cerny (Midwest Center for Mass Spectrometry, University of Nebraska–Lincoln, Lincoln, Nebraska). HRMS were preformed by Dr. R. Smith (McMaster University, Hamilton, Ontario). Nuclear magnetic resonance (NMR) spectroscopy was performed at 295–300 K unless otherwise noted, using a Bruker ARX 400 high-field Fourier transform instrument. Chemical shifts are reported in parts per million relative to a tetramethylsilane (TMS) internal standard.

3,4-Dibromobenzenesulfonyl chloride (2)

To a flask containing 1,2-dibromobenzene **(1)** (20 g, 88.47 mmol) and dry $CHCl_3$ (120 mL), which was cooled to ca. –10°C by an ice–NaCl bath, was added chlorosulfonic acid (30 g) over 20 min. The light brown solution was stirred at room temperature for 20 h. The reaction mixture turned red during this period. The solution was refluxed for 1 h. After cooling to room temperature, the vigorously stirred reaction mixture was poured onto crushed ice (200 g). The aqueous and organic layers were separated. The former was washed with CH_2Cl_2 (100 × 2 mL). The combined organic layer was washed with aqueous $NaHCO_3$ (10%, 150 mL) followed by water until pH neutral. After drying over $MgSO_4$, and evaporating the solvent, vacuum distillation afforded a colourless solid product (120–125°C/5 mmHg (1 mmHg = 133.3 Pa), 22.7 g, 85%), mp 31–33°C (lit. (27) mp 34°C); ^{1}H NMR ($CDCl_3$) δ 8.28 (d, J = 1.8, 1H, H_4), 7.91 (d, J = 8.4, 1H, H_6), 7.85 (dd, J_1 = 1.8, J_2 = 8.4, 1H, H_5).

3,4-Dibromo-*N*,*N*-diphenylbenzenesulfonamide (9)

To a solution of 3,4-dibromobenzenesulfonyl chloride (**2**) (1.0 g, 3.2 mmol) in dry $CHCl_3$ (10 mL) were added diphenylamine (**3**) (0.7 g, 3.0 mmol) and pyridine (0.5 mL). The solution was refluxed for 14 h, and cooled at room temperature, washed with aqueous HCl (5%, 10 mL) and water until neutral. After drying over $MgSO_4$ and evaporating the solvent, the crude product was recrystallized from ethanol to give colourless crystalline needles (0.9 g, 65%), mp 160–161°C; IR (KBr cm^{-1}): 1957, 1886, 1589, 1449, 1446, 1351; ^{1}H NMR ($CDCl_3$) δ 7.93 (d, J = 2.0, 1H), 7.74 (d, J = 8.0, 1H), 7.45 (dd, J_1 = 8.0, J_2 = 2.0, 1H), 7.31 (m, 10H); MS (*m*/*z*, relative intensity): 469 (M^+, 15), 467 (M^+, 30), 465 (M^+, 14), 167 (100). Anal. calcd. for $C_{18}H_{13}NBr_2NO_2S$: C 46.25, H 2.78, N 3.00; found: C 46.41, H 2.66, N 2.96.

1-(3,4-Dibromophenylsulfonyl)pyrrole) (10)

To freshly distilled pyrrole (**4**) (220 mg, 30 mmol) in dry THF (5 mL), cooled to 0°C, was added NaH (300 mg, 60%

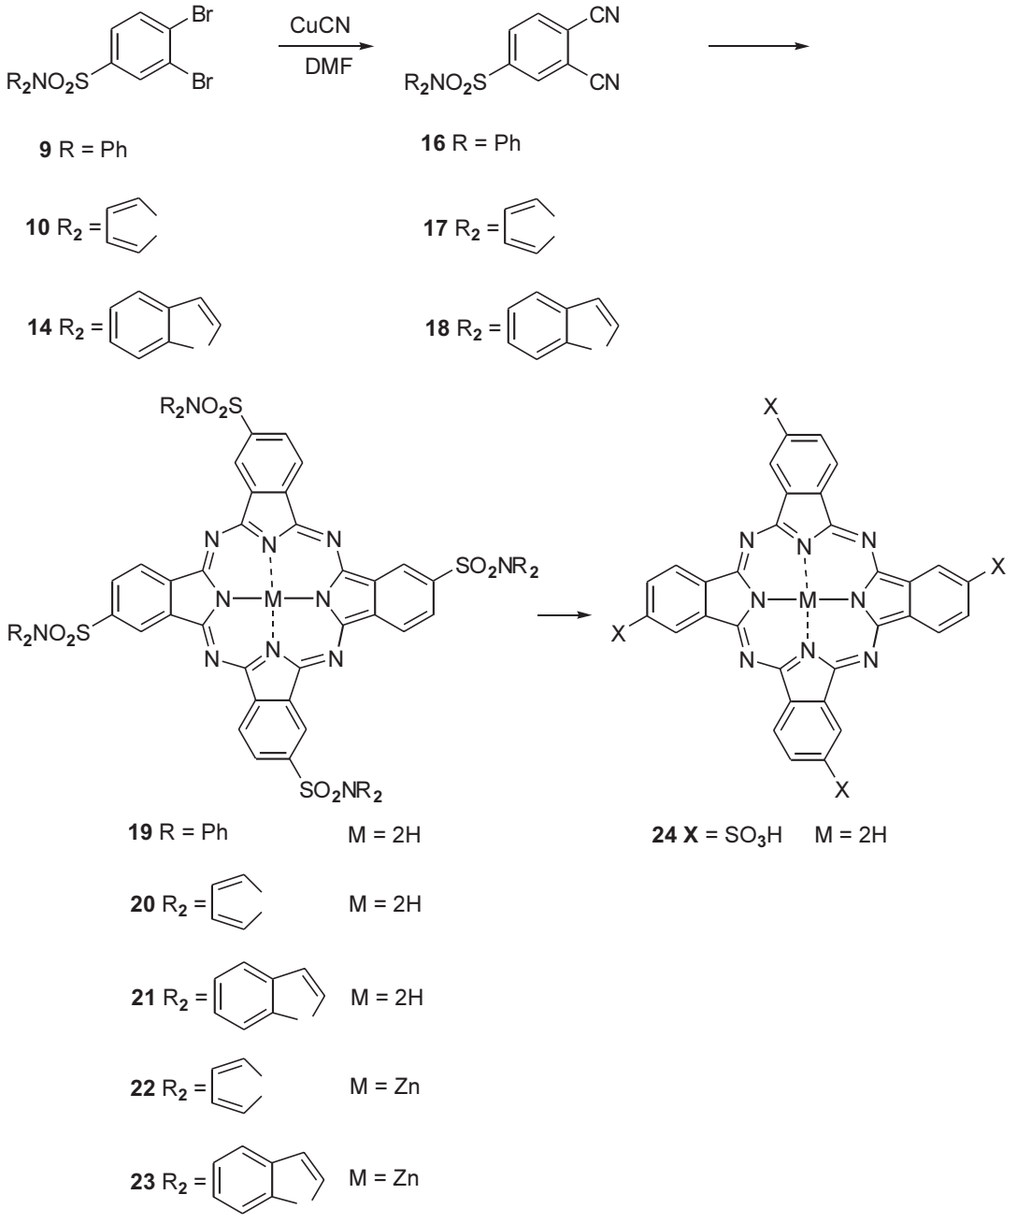
Scheme 2.



oil dispersion). 3,4-Dibromobenzenesulfonyl chloride (**2**) (1.0 g, 3.2 mmol) was added over 30 min. under Ar. After stirring at room temperature for 6 h, the brown reaction mixture was carefully poured into a saturated NH_4Cl solution (30 mL) placed in an ice bath. Ether (30 mL) was added and the aqueous layer was washed with ether (20 mL). The combined organic layer was washed with saturated NH_4Cl until neutral. After drying over $MgSO_4$ and evaporating the solvent, the crude product was recrystallized from ethanol to give colourless crystalline needles (545 mg, 50%), mp 141–142°C; IR (KBr cm^{-1}): 3075 (s, ArH), 1375 (s, SO_2N), 1186 (s, SO_2N); ^1H NMR ($CDCl_3$) δ 8.10 (d, J = 2.0, 1H), 7.77 (d, J = 8.4, 1H), 7.63 (dd, J_1 = 8.4, J_2 = 2.0, 1H), 7.16 (m, 2H), 6.36 (m, 2H); MS (*m*/*z*, relative intensity): 367 (M^+, 50), 365 (M^+, 95), 363 (M^+, 50), 299 (90), 235 (100). relative intensity): 393 (M^+, 75), 379 (70), 315 (67), 299 (70), 80 (100). Anal. calcd. for $C_{12}H_{11}Br_2NO_2S$: C 36.64, H 2.80, N 3.56; found: C 37.27, H 2.74, N 3.52.

1-(3,4-Dibromophenylsulphonyl)-3,5-dimethylpyrazole (12)

The crude product, obtained as described for **10** but using 3,5-dimethylpyrazole (**6**), was recrystallized from ethanol twice to give 0.98 g of **12** in 84% yield, mp 145–147°C; IR (KBr cm^{-1}): 3082 (s, ArH), 1374 (s, SO_2N), 1188 (s, SO_2N); ^1H NMR ($CDCl_3$) δ 8.19 (d, J = 1.5, 1H), 7.75 (m, 2H), 5.94 (s, ^1H), 2.51 (s, 3H), 2.22 (s, 31H); MS (*m*/*z*, relative intensity): 394 (M^+, 10), 328 (100), 299 (30), 250 (40), 236 (50). Anal. calcd. for $C_{11}H_{10}Br_2N_2O_2S$: C 33.50, H 2.54, N 7.11; found: C 33.72, H 2.30, N 7.14.

1-(3,4-Dibromophenylsulfonyl)imidazole (13)

To a solution of (**3**) (1.0 g, 3.2 mmol) in a mixture of chloroform (5 mL) and methanol (1 mL) was added imidazole (**7**) in chloroform (2 mL) and Na_2CO_3 (1.0 g). The mixture was stirred at room temperature for 22 h, filtered, and the filtrate was washed with HCl (10%, 20 mL) and water until neutral. After drying over $MgSO_4$ and evaporating the solvent, the crude product was chromatographed with 40% ethyl acetate – hexane to give pure **13** as fine, colourless crystals (320 mg, 34%), mp 119–120°C; IR (KBr cm^{-1}): 1938 (m), 1768 (m), 1564 (s), 1464 (s), 1381 (s, SO_2N); ^1H NMR ($CDCl_3$) δ 8.19 (d, J = 2.0, 1H), 8.04 (s, 1H), 7.85 (d, J = 8.0, 1H), 7.73 (dd, J_1 = 8.0, J_2 = 2.0, 1H), 7.32 (brs, 1H); 7.16 (brs, 1H); MS (*m*/*z*, relative intensity): 366 (M^+, 95) 299 (100), 235 (100). Anal. calcd. for $C_9H_6Br_2N_2O_2S$: C 29.51, H 1.64, N 7.65; found: C 29.61, H 1.46, N 7.61.

1-(3,4-Dibromophenylsulfonyl)indole (14)

Ground NaOH (2.0 g) was mixed with tetrabutylammonium hydrogen sulfate (140 mg) in CH_2Cl_2 (30 mL). The reaction flask was cooled by a salt–ice bath to 0–4°C after which indole (**8**) (1.85 g, 15.8 mmol) was added. Sulfonyl chloride (**7**) (5.0 g, 15.0 mmol) was added over 30 min. and stirred for an additional 30 min. in the ice bath. The solution was stirred at room temperature for 20 h, washed with HCl (10%, 20 mL) and with water until neutral. After drying over $MgSO_4$ and evaporating the solvent, the crude product was chromographed with 20% ethyl acetate – hexane to give **14** as a fine, colourless crystals (3.1 g, 50% mp) 125–126°C; IR (KBr cm^{-1}): 3140, 3081 (s, ArH), 1376 (s, SO_2N); ^1H NMR ($CDCl_3$) δ 8.13 (d, J = 2.0, 1H), 7.99 (d, J = 8.0, 1H), 7.66 (m, 2H), 7.56 (m, 2H), 7.37 (m, 1H); 7.29 (m, 1H), 6.74 (d, J = 4.0, 1H); MS (*m*/*z*, relative intensity): 417 (M^+, 45), 415 (M^+, 88) 413 (M^+, 43) 116 (100). Anal. calcd. for $C_{14}H_9Br_2NO_2S$: C 40.68, H 2.18, N 3.39; found: C 40.79, H 1.95, N 3.37.

3,4-Dibromobenzenesulfonic acid (15)

Compound **13** (50 mg, 0.14 mmol) was dissolved in methanol (5 mL) and NaOMe (40 mg, 0.74 mmol) was added.

© 1999 NRC Canada

The reaction solution was stirred at room temperature for 20 h. The solvent was evaporated. The residue was dissolved in water (50 mL) and washed with ether (10 mL) followed by neutralization with aqueous HCl (36%). The solvent was evaporated, the residue recrystallized from water, and the product was further purified by ion-exchange resin (Dowex 50X8-400). Recrystallization from EtOH (80%) afforded pale, yellow needles of **15** (26 mg, 60%), mp 64–66°C (lit. (27) mp 66.5–67.5°C); ^{1}H NMR (D_2O) δ 7.99 (s, 1H), 7.74 (d, 1H), 7.52 (dd, 1H). In a similar manner **12** gave **15** in 69% yield, while **10** and **14** were cleaved in methanol at reflux to give **15** in 72 and 57% yield, respectively.

3,4-Dicyano-*N*,*N*-diphenylbenzenesulfonamide (16)

To a solution of **9** (1.80 g, 3.87 mmol) in dry DMF (20 mL) was added CuCN (1.80 g, 20 mmol). The reaction solution was gently refluxed for 6 h, cooled to room temperature, and CH_2Cl_2 (200 mL) was added. A fine insoluble powder precipitated overnight. The crude product was purified by chromatography with 30% ethyl acetate – hexane as eluent to give colourless, scaly crystals (395 mg, 29%), mp 185–187°C; IR (KBr cm^{-1}): 3091 (s, ArH), 2235, (s, CN), 1360 (s, SO_2N), 1186 (s, SO_2N); ^{1}H NMR ($CDCl_3$) δ 7.90 (s, 1H), 7.82 (d, J = 8.0, 1H), 7.76 (d, J = 8.0), 7.19 (m, 5H), 7.07 (m, 5H); MS (*m*/*z*, relative intensity): 359 (M^+, 60), 168 (100). Anal. calcd. for $C_{20}H_{13}N_3O_2S$: C 66.85, H 3.62, N 11.70; found: C 66.36 H 3.33, N 11.56.

1-(3,4-Dicyanophenylsulfonyl)pyrrole (17)

In a manner identical to that of **16**, **10** gave a crude product **17**, which on flash chromatography with 30% ethyl acetate – hexanes as eluents yielded fine, colourless crystals (43%), mp 155–157°C; IR (KBr cm^{-1}): 2235 (s, CN), 1388, 1287 (s, SO_2N); ^{1}H NMR ($CDCl_3$) δ 8.22 (d, J = 1.2, 1H), 8.17 (dd, J_1 = 1.2, J_2 = 8.2, 1H), 7.97 (d, J = 8.2, 1H), 7.16 (d, J = 1.8, 2H), 6.41 (d, J = 1.8, 2H); MS (*m*/*z*, relative intensity): 257 (M^+, 100), 193 (70). Anal. calcd. for $C_{12}H_7N_3O_2S$: C 56.03, H 2.72, N 16.34; found: C 56.17 H 2.62, N 16.34.

1-(3,4-Dicyanophenylsulfonyl)indole (18)

As for **16** above, **14** gave a crude product, which on purification by flash chromatography with 30% ethyl acetate – hexane as eluents, yielded pale yellow, fine crystals (45%), mp 171–173°C; IR (KBr cm^{-1}): 3110 (s, ArH), 2242 (s, CN), 1391 (s, SO_2N); ^{1}H NMR ($CDCl_3$) δ 8.25 (s, 1H, H_1), 8.17 (dd, J_1 = 1.6, J_2 = 8.5, 1H, H_3), 7.96 (d, J = 8.5, 1H, H_2), 7.88 (d, J = 8.0, 1H, H_4), 7.58 (d, J = 7.7, 1H, H_7), 7.51 (d, J = 3.5, 1H, H_9), 7.40 (t, J_1 = 8.0, J_2 = 7.3, 1H, H_5), 7.32 (t, J_1 = 7.3, J_2 = 8.0, 1H, H_6), 6.79 (d, J = 3.5, 1H, H_8); MS (*m*/*z*, relative intensity): 3.07 (M^+, 53), 116 (52), 105 (100). Anal. calcd. for $C_{16}H_9N_3O_2S$: C 62.54, H 2.93, N 1368; found: C 62.95, H 2.81, N 13.62.

***N*,*N*,*N*′,*N*′,*N*″,*N*″,*N*‴,*N*‴-Octaphenylphthalocyanine-2,9,16,23-tetrasulfonamide (19)**

Small pieces of metal lithium (30 mg, 4.3 mmol) were dissolved in DMAE (2 mL) to which **16** (100 mg, 0.28 mmol) was added. The reaction solution was stirred at 60–70°C (oil bath) for 20 h, cooled to room temperature, and the sticky blue solution was poured into a mixture of ice (5 g) and aqueous HCl (10 mL, 4 M). The precipitate was collected by filtration, and the crude product was purified using flash chromatography with 5% THF–CH_2Cl_2 as eluent to give a dark blue, fine powder of **19** (11 mg, 11%), mp >310°C. IR (KBr cm^{-1}): 1394, 1164 (s, SO_2N); UV-vis (THF) (λ_{max}): 698, 664, 636, 604, 344, 238; ^{1}H NMR (pyridine-d_5): 8.91 (s) 8.46 (s), 7.85 (m), 7.37 (m), 6.96 (s); MS (FAB$^+$, *m*/*z* relative intensity): 1438 (M^+). Anal. calcd. for $C_{80}H_{54}N_{12}O_8S_4$: C 66.76, H 3.75, N 11.68; found: C 66.95, H 3.66, N 10.82.

2,9,16,23-Tetrakis(1-pyrrolysulfonyl)phthalocyanine (20)

Compound **17** (200 mg, 0.78 mmol) was dissolved in *N*,*N*-dimethylaminoethanol (DMAE) (2 mL). As ammonia gas was bubbled through, the reaction mixture was heated to 100–110°C (sand bath) for 1 h and then refluxed for 4 h. The reaction mixture was cooled to room temperature, the solvent evaporated, and water (10 mL) was added to the resulting sticky solution. The blue precipitate was collected by filtration or centrifugation and purified by flash chromatography using 5% THF–CH_2Cl_2 as eluent to give in the first fraction phthalocyanine **20** as dark blue crystals (66 mg, 33%), mp >310°C; IR (KBr cm^{-1}): 3141 (m, ArH), 1374 (s, SO_2N), 1191 (s, SO_2N); UV-vis (THF), (λ_{max}): 696, 662, 634, 608, 394, 348; ^{1}H NMR (THF-d_8) δ 9.40, 9.38, 8.45 (m, 4H, H_3), 7.79 (m, 4H, H_4), 6.95, 5.87 (m, 8H, H_1), 6.93 (m, 8H, H_2), 664 (m, 4H, H_5); MS (FAB$^+$, *m*/*z*, relative intensity): 1030 (M^+). Anal. calcd. for $C_{48}H_{130}N_{12}O_8S_4$: C 55.92, H 2.91, N 16.31; found: C 55.80, H 2.90, N 15.78.

2,9,16,23-Tetrakis(1-indolylsulfonyl)phthalocyanine (21)

As for **20**, but from **18**, phthalocyanine **21** was obtained as dark, blue crystals in 42% yield, mp >310°C; IR (KBr cm^{-1}): 1387 (s, SO_2N) 1173 (s, SO_2N); UV-vis (THF) (λ_{max}): 698, 666, 634, 612, 346, 248; ^{1}H NMR ($CDCl_3$) δ: 9.56 (m, br), 8.88 (m, br), 8.70 (m, br), 8.54 (m), 8.14 (m), 8.03 (m), 7.67(m), 7.55 (m), 7.01 (m), 6.92 (m); MS (FAB$^+$, *m*/*z*, relative intensity): 1230 (M^+, 40), 671 (70), 539 (100). Anal. calcd. for $C_{64}H_{38}N_{12}O_8S_4$: C 62.44, H, 3.09, N 13.66; found: C 62.85, H 3.32, N 13.27.

2,9,16,23-Tetrakis(1-pyrrolylsulfonyl)phthalocyanine zinc(II) (22)

Compound **17** (200 mg, 0.78 mmol) was dissolved in 2-*N*,*N*-dimethylaminoethanol (DMAE) (2 mL) containing anhydrous $Zn(OAc)_2$ (200 mg). The reaction mixture was heated to 100–110°C (sand bath) and kept at that temperature for 1 h while ammonia gas was bubbled through it. The solution was refluxed for 4 h and cooled to room temperature. The solvent was evaporated and water (10 mL) was added to the resulting sticky solution. The blue precipitate was collected by filtration or centrifugation and purified by flash column chromatography using 50% THF–CH_2Cl_2 as eluent to give in the first fraction **22** as dark crystals (68 mg, 32%), mp >310°C; IR (KBr cm^{-1}): 1371 (m, SO_2N) 1167 (s, SO_2N); UV-vis (THF) (λ_{max}): 672, 610, 350, 242; ^{1}H NMR (THF-d_8) δ 9.73 (br), 7.36–8.66 (m, br), 6.59–6.90 (m, br). MS (FAB$^+$, *m*/*z*, relative intensity): 1093 (M^+ + 1250), 964 (20), 625 (52) 558 (100). Anal. calcd. for $C_{48}H_{128}N_{12}O_8S_4Zn$: C 52.70, H 2.56, N 15.37; found: C 52.29, H 2.80, N 14.46.

© 1999 NRC Canada

2,9,16,23-Tetrakis(1-indolylsulfonyl)phthalocyanine zinc(II) (23)

As for **22**, **18** yielded a crude product which was purified by flash chromatography by using 40% THF–benzene as eluent to give **23** as dark blue crystals (68%), mp >310°C; IR (KBr cm^{-1}): 1376 (m, SO_2N), 1173 (s, SO_2N); UV-vis (THF) (λ_{max}): 676, 610, 360, 244; ^1H NMR ($CDCl_3$) δ 9.79 (m), 9.12 (m), 8.68 (m), 8.31 (m), 8.04 (m), 7.60 (m), 7.17 (m), 6.86 (m), 6.62 (m); MS (FAB+, *m*/*z*, relative intensity): 1293 (M^+, 60), 1113 (50), 919 (100). Anal. calcd. for $C_{64}H_{36}N_{12}O_8S_4Zn$: C 59.40, H 2.78, N 12.99; found: C 59.19; H 3.09, N 12.65.

Phthalocyanine-2,9,16,23-tetrasulfonic acid (24)

Method A

Small pieces of metal lithium (400 mg, 58 mmol) were dissolved in DMAE (20 mL) and **20** (100 mg, 0.097 mmol) was added. The solution was stirred at 60–70°C for 30 h. An aliquot was taken and added to a mixture of water and CH_2Cl_2. The organic solution appeared colourless. The reaction mixture was cooled to room temperature, water was added, and the solvent was reduced to half volume under vacuum. After acetone (15 mL) was added, the precipitates were separated by centrifugation and washed with aqueous HCl (36%, 5 × 3 mL). Drying under high vacuum gave a dark blue powder of **24** (25, 31) (70 mg, 86%), mp >310°C; IR (KBr cm^{-1}): 3400 (s, SO_3H), 1472 (s, SO_3H); UV-vis (MeOH) (λ_{max}): 692, 656; ^1H NMR (DMSO-d_6) δ 10.19 (br, 4H), 9.71 (br, 4H), 9.53 (m, 4H), 8.60 (m, 4H); MS (electrospray, *m*/*z*): 834.13 $(M + 1 - H)^-$, 753.50 $(M + 1 - H\text{-}SO_3H)^-$, 416.11 $(M - 2H)^{2-}$, 277.07 $(M - 3H)^{3-}$, 250.19 $(M + 1 - SO_3H\text{-}3H)^{3-}$, 207.49 $(M - 4H)^{4-}$.

Method B

Small pieces of metal lithium (40 mg, 5.8 mmol) were dissolved in a mixture of methanol (2 mL) and THF (2 mL) to which **21** (20 mg) was added. The solution was refluxed for 20 h. TLC with 5% THF–CH_2Cl_2 as eluent showed that the starting material had disappeared. The solvent was evaporated and the residue was washed with aqueous HCl (36%, 5 × 3 mL) to give a product identical with that from method A (23 mg, 84%).

9,10,16,17,23,24-Hexakis-(1-heptyl)-2-(1-pyrrolylsulfonyl)phthalocyanine (26)

Excess 4,5-diheptylphthalonitrile (**25**) (29), prepared by our previously described method (32), (200 mg, 0.69 mmol) and **17** (20 mg, 0.078 mmol) were dissolved in DMAE (3 mL). As ammonia gas was bubbled through, the reaction mixture was heated to 100–110°C (sand bath). After 1 h, the solution was raised to reflux temperatures and refluxed for 20 h. The reaction mixture was cooled to room temperature, ice (5 g) was added to the resulting sticky solution, and the precipitates were separated by centrifugation followed by sequential washing with water (10 × 2 mL) and methanol (10 × 2 mL). The blue precipitate was collected by filtration or centrifugation and purified by flash column chromatography using CH_2Cl_2 as eluent. After evaporation of the solvent, the residue was rechromatographed with 10% EtOAc–hexanes and then 5% THF–CH_2Cl_2 as eluents. The first fraction contained two spots, which was rechromatrographed later. The second fraction was a mixture of multisulfonate Pcs (8.7 mg). The first fraction was separated by column chromatography using 50% CH_2Cl_2–hexanes to give **26** (4.5 mg, 4.7%), mp >310°C; IR (KBr cm^{-1}): 1337 (m, SO_2N), 1167 (s, SO_2N); UV-vis (THF) (λ_{max}): 714, 692, 686, 656; ^1H NMR ($CDCl_3$) δ 9.54 (s, 1H), 9.03 (s, 1H), 8.71 (m 3H), 8.50 (m, 2H), 8.25 (d, *J* = 7.6, 1H), 7.69 (s, 1H), 7.57 (s, Py-H, 2H), 6.42 (s, Py-H, 2H), 3.15 (m, 12H), 1.49 (m, 78H); MS (FAB+ *m*/*z*): 1232 ($M^+ + 1$). Anal. calcd. for $C_{78}H_{105}N_9O_2S$: C 76.04, H 8.53, N 10.24; found: C 76.62, H 8.85, N 9.52.

9,10,16,17,23,24-Hexakis-(1-heptyl)-2-(1-pyrrolylsulfonyl)-phthalocyanine zinc(II) (27)

Metal-free Pc **26** (10 mg, 0.008 mmol) was dissolved in a mixture of toluene (3 mL) and DMF (3 mL) to which anhydrous $Zn(OAc)_2$ was added. The reaction solution was refluxed for 24 h, the solvent evaporated, and the residue washed with water (10 mL × 2) and methanol (10 mL × 2). After drying under vacuum, the crude product was purified by column chromatography using 5% THF–CH_2Cl_2 as eluent to give **27** as a dark blue powder (9 mg, 86%), mp >310°C; IR (KBr cm^{-1}): 1339, 1166 (s, SO_2N); UV-vis (THF) (λ_{max}): 692, 666, 634, 604, 354; ^1H NMR (C_6D_6) δ 9.96 (br, 1H), 9.10–8.12 (m, 8H), 7.45 (py-H, 2H), 6.13 (py-H, 2H), 3.15 (m, 12H), 1.70 (m, 60H), 1.01(m, 18H); MS (FAB+, *m*/*z*, relative intensity): 1295 ($M^+ + 1$, 100), 736 (60). Anal. calcd. for $C_{78}H_{103}N_9O_2SZn$: C 72.33, H 7.96, N 9.74; found: C 72.12, H 8.21, N 9.14.

Lithium 9,10,16,17,23,24-hexakis-(1-heptyl)phthalocyanine-2-sulfonate zinc(II) (28)

To a solution of lithium (40 mg) in MeOH (2 mL) was added **27** (17 mg). The solution was refluxed for 24 h, the solvent evaporated, and the crude product purified by column chromatography (Si-gel, 70–230 mesh) using 40% EtOAc–hexanes and methanol as eluents to give **28** as a dark blue fine powder (14 mg, 85%), mp >310°C; IR (KBr cm^{-1}): 1110 (s, SO_3Li). UV-vis (THF) (λ_{max}): 676, 616, 346, 240 (0.47); ^1H NMR (DMSO-d_6) δ 9.60 (br, 1H), 9.31 (d, *J* = 8.0, 1H), 9.15 (m, 6H), 8.42 (d, *J* = 8.0, 1H), 1.94 (m, 6H), 1.38 (m, 60H), 0.92 (m, br, 18H); MS (FAB+, *m*/*z*, relative intensity): 1251 (M^+, 100).

The total synthesis of a technetium chelate – tamoxifen complex

Russell A. Bell, Kieran C. Dickson, and John F. Valliant

Abstract: A potential agent for imaging breast cancer has been synthesized by derivatization of the anti-estrogen tamoxifen. A multistep synthesis was required to conjugate a technetium chelate to tamoxifen in such a fashion that the biodistribution of the complex should mimic that of the parent compound.

Key words: tamoxifen, radioimaging, technetium, synthesis.

Résumé : En procédant à la préparation d'un dérivé du tamoxifène, un anti-estrogène, on a synthétisé un agent pouvant éventuellement être utilisé dans l'imagerie du cancer du sein. Il a fallu recourir à une synthèse en plusieurs étapes pour conjuguer un chélate du technétium au tamoxifène d'une façon telle que la biodistribution du complexe puisse ressembler à celle du composé parent.

Mots clés : tamoxifène, radioimagerie, technétium, synthèse.

[Traduit par la Rédaction]

Introduction

One method of developing a site-specific radioimaging agent is to derivatize a drug or bioactive molecule with a chelate – radio nuclide complex (1). To maintain receptor selectivity the chelate must be attached to the biomolecule at a point distant from the part of the molecule which binds to the receptor. One bioactive compound of particular interest is tamoxifen (Fig. 1), a drug used for the treatment of hormone dependent breast cancer (2). An imaging agent based on tamoxifen could potentially detect tumours in their infancy, which is crucial if chemotherapy is to be effective (3).

Tamoxifen, (*Z*-1(*p*-(2-dimethylaminoethoxy)phenyl)-1,2-diphenylbut-1-ene) exerts its biological effect by binding to estrogen receptors which, for certain types of cancers, are more numerous in cancer cells than normal cells (4). ^{131}I derivatives of *E* and *Z* tamoxifen were used successfully to image tumours in mice (5); however, there was insufficient uptake in human cancer patients to develop a commercial imaging agent. The location of the iodine label and the loss of iodine due to the relatively weak carbon–iodine bond could explain the insufficient tumour uptake in human breast cancer tumours. One method of overcoming these problems is to covalently attach a chelate, the technetium complex of which is known to be stable in vivo, to a site in which substituents do not tend to affect the biodistribution of the parent molecule.

Substitution on ring B of tamoxifen is not feasible because data from binding assays of tamoxifen derivatives suggests that ring B derivatives alter the pharmacological activity of tamoxifen (6). From the aforementioned binding studies of tamoxifen derivatives, ring A appears to be a more attractive location for conjugation to a chelate. *E*-2-methyl-tamoxifen, where the methyl substituent was in the *ortho* position of ring A, had an estrogen receptor binding affinity identical to that of tamoxifen (7). From this, we concluded that the *ortho* position of ring A would be a logical site, through a spacer chain, to attach a chelate.

Results and discussion

The diamido dithiol (DADT) chelate (**4**, Scheme 1) (8), which is known to bind ^{99m}Tc ($t_{1/2}$ = 6.0, γ = 140 KeV), the most commonly used radionuclide in diagnostic imaging, was synthesized by modifying the approach used by Bell et al. (9). 2,3-Diaminopropionic acid (**1**) was converted to the methyl ester **2** via a Fisher esterification with *p*-toluenesulfonic acid prior to reaction with the *N*-hydroxysuccinimido ester of *S*-triphenylmethylmercaptoacetic acid (1). In preparation for conjugation to the tamoxifen derivative (vide infra) the methyl ester **3** was hydrolysed by reaction with aqueous sodium hydroxide in THF to produce the desired chelate **4**.

Two approaches to the synthesis of DADT-tamoxifen conjugate were used; approach A involved the total synthesis of the tamoxifen derivative before coupling to the chelate, while strategy B entailed coupling of a chloro-tamoxifen species to the chelate prior to the addition of the dimethylamine moiety.

The synthesis, based on the approach of McCague and co-worker (10) (Scheme 2) began by following the literature procedure for the mono substitution of 1,2-dichloroethane by phenolate under phase transfer conditions (11). The chloroether was subsequently subjected to Friedel–Crafts acylation (12) by use of either (±)-2-phenylbutyric acid and trifluoroacetic anhydride (TFAA) or the acid chloride of

(±)-2-phenylbutyric acid and aluminum trichloride in carbon disulfide (12) to give **6** in 79 and 57% yields, respectively. Evidence from ^{1}H and ^{13}C NMR confirmed that the acylation product was entirely *para* substituted. The linker arm for the chelate was now added in the form of the *tert*-butyldimethylsilyl ether of 2-bromophenethyl alcohol (13), the nucleophile being generated by metal halogen exchange. The anion reacted with the ketone **6** to generate two diasteriomeric alcohols **9**, which were not normally isolated but converted directly to the alkenes **10** by reaction with thionyl chloride and pyridine at –10°C. These milder elimination conditions were used because the literature procedure employing concentrated HCl in ethanol caused the loss of the silyl protecting group and subsequent elimination of the resultant alcohol. The silyl group of **10** was removed in good yield (96%) by the use of tetrabutylammonium fluoride in THF (13).

The chemical shift of the proton and carbon atoms of each diasteriomer of **10**, at 200 MHz and 50 MHz, respectively, were significantly different and each isomer could be distinguished readily. To assign the signals of each isomer required the use of a two-dimensional nuclear Overhauser effect (2-D NOE) experiment (NOESY). From the ^{1}H spectrum the pair of doublets at 6.812 and 6.50 ppm were assigned to the AB spin system of ring B. The doublet at 6.812 ppm exhibited a NOE correlation to signals in the aromatic region but showed no correlation to the methylene of the ethyl group of tamoxifen; this confirmed that these signals belonged to the *E*-isomer. The COSY spectrum was then used to assign the remaining signals belonging to that isomer, and it was concluded that the major isomer, as Cram's rules (14) predicted, was the *E*-isomer in a ratio of approximately 5:1.

Fatty acid derivatives were selected as the spacer chain because the length of the spacer can be altered easily as there are numerous fatty acid derivatives which are commercially available. Once the general synthetic route was developed, varying lengths of spacers can be tested until the optimum length associated with high binding efficiency is found. In the present synthesis (Scheme 3), bromododecanoic acid was converted to the azide prior to reaction with thionyl chloride. The acid chloride was then converted to an ester by reaction with alcohol **11**. An unexpected advantage of using the long-chain fatty acid was that small quantities of each isomer of **12** could be separated by radial chromatography. During the development of the synthetic methodology towards **15**, a relatively large quantity of **12** was required, and for practical purposes, the nonenriched 5:1 *E*:*Z* ratio, material was used. Should the results of the biodistribution studies show promise, the isomers of **12** can be separated and pure *E*-**15** and *Z*-**15** synthesized. Because of the ratio of 5:1 for *E*:*Z* isomers, it was possible to assign many of the NMR signals for each isomer in mixtures of compounds **13**–**17**.

In approach A, the azido-chloride species **12** was converted to the dimethylamino species **13** by reaction with dimethylamine in ethanol at an elevated temperature. If extensive reaction times were used (greater than 4 days) a minor byproduct occurred as a result of cleavage of the ester bond by either a dimethylamine or ethoxide nucleophile with the resulting species being the phenethyl alcohol **11**. The azide **13** was reduced by the use of triphenylphosphine (15) because other methods (lithium aluminum hydride and catalytic hydrogenation) would cause reduction of the alkene and (or) ester groups. Reduction appeared to occur quantitatively as indicated by TLC, however, isolation of the resulting amine was difficult, and only a low yield of product was isolated (25%). The amine **14** was immediately coupled to the chelate (**4**) by the use of EDC (16) in good yield, as judged by thin-layer chromatography. Again, however, puri-

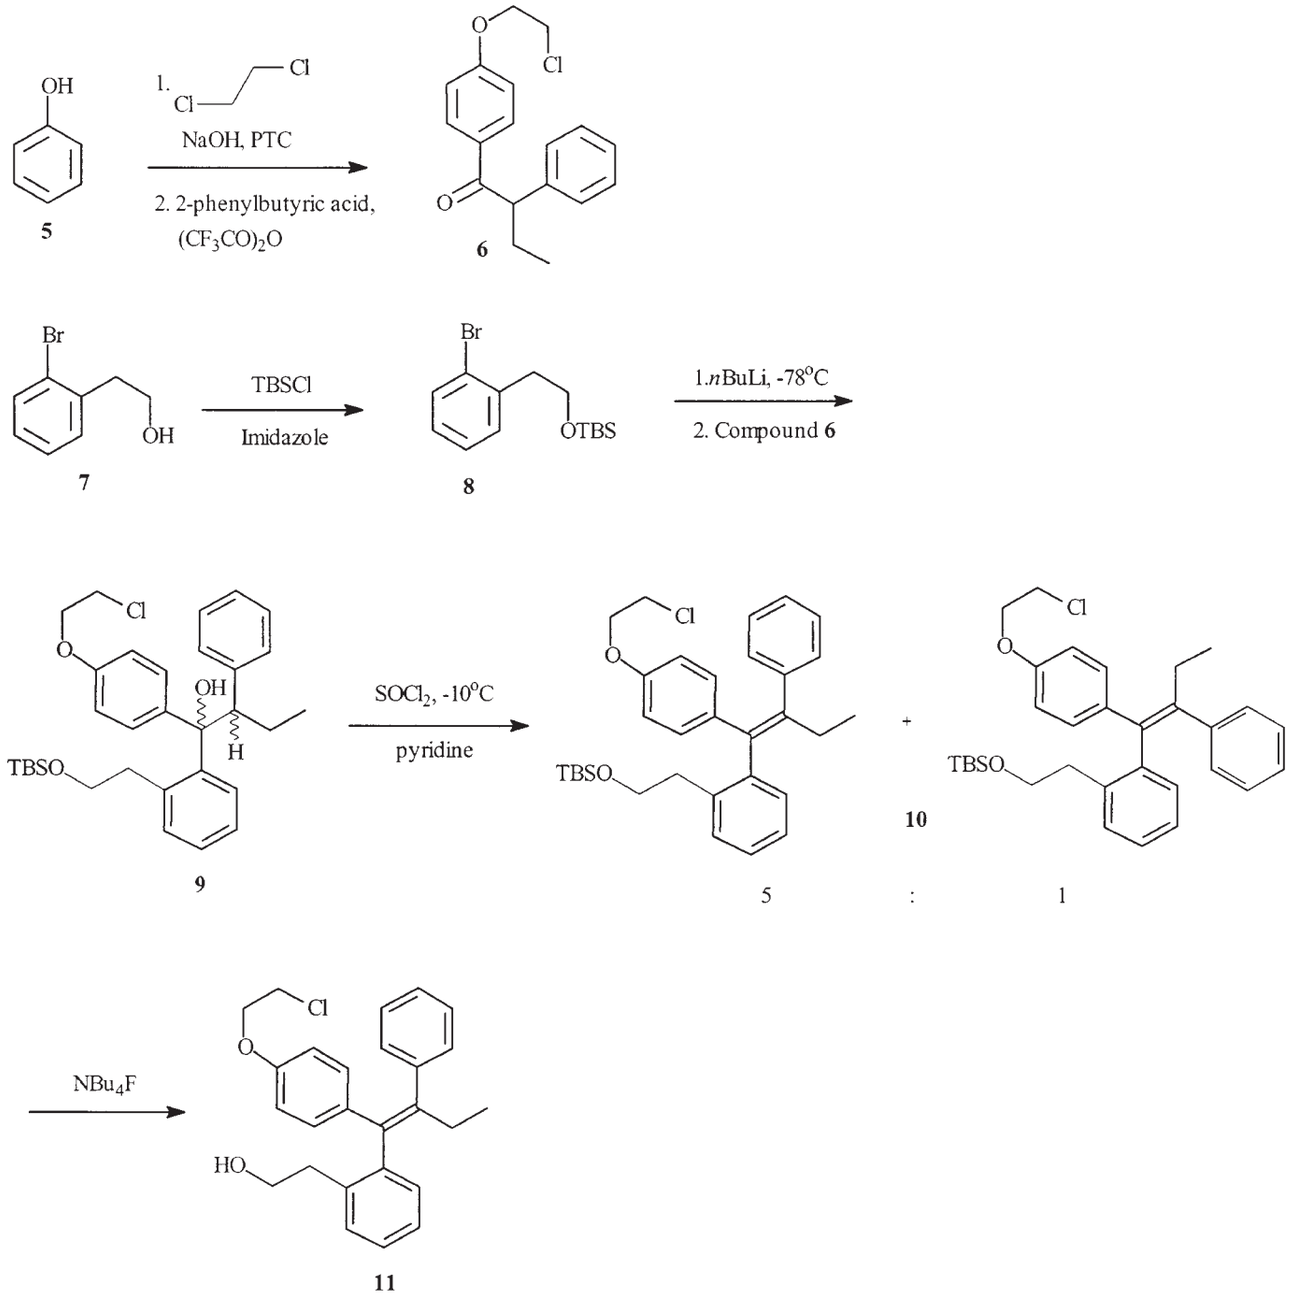
Scheme 2. Synthesis of **11**.



fication of the product proved difficult and resulted in a low yield of the desired product (26%).

In an attempt to improve the yields of synthesis A, strategy B was developed. The azide **12** was reduced by the use of the aforementioned triphenylphosphine approach (Scheme 4). Formation of the phosphonium salt from the alkyl chloride fragment was not a concern because the reduction was carried out at room temperature. The resulting amine **16** was coupled to the chelate in good yield (76%), and replacement of the chloro substituent with dimethylamine also occurred in good yield (60%). There was no evidence for decomposition of the ester or amide bonds so long as the reaction time was kept to a reasonable length (20–24 h).

The addition of dimethylamine to **17** could be observed in the ^{1}H NMR as the two singlets at 2.325 and 2.267 ppm, corresponding to the two isomers, were assigned to the *N*-methyl protons. There was also a significant shift of the methylene protons adjacent to the dimethylamine moiety, upon substitution, the protons shifted upfield by approximately 1 ppm. The ^{13}C NMR contained no ambiguities, the resonances associated with the *N*-methyl protons were ob-

served at 45.80 ppm. The methylene protons adjacent to the *N*-methyl moiety shifted downfield upon substitution of the chloro group from 41.99 ppm to 58.18 ppm.

Experimental section

Analytical TLC was performed on silica gel 60-F_{254} (Merck) with detection by long wavelength ultraviolet light. Chromatography was performed with a chromatotron (Harrison Research Model 7924T) that used a 4 mm plate (EM Science silica gel 60 PF_{254} that contained gypsum). All commercial reagents were used as supplied. Solvents were distilled, under nitrogen, from calcium hydride. Nitrogen was dried by passing it through calcium sulphate. All reactions were protected from light and carried out under a slow flow of nitrogen. Solvents were evaporated with a rotary evaporator (20 mmHg (1 mmHg = 133.3 Pa)) at moderate temperatures (30–50°C).

Selected NMR spectra were recorded on a Bruker Avance DRX-500 spectrometer. Proton spectra were acquired at 500.130 MHz with a 5 mm broadband inverse probe with triple-axis gradient capability. Spectra were obtained in 8 scans in 32K data points over a 4.006 kHz spectral width (4.096 s acquisition time). The compounds used in this study were dissolved in $CDCl_3$ (Isotec, Inc.) to a concentration of approximately 15.0 mg mL^{-1}. Chemical shifts are reported in ppm relative to TMS. The residual solvent signals at 7.24 and 77.0 ppm were used as internal references for the ^1H and ^{13}C spectra, respectively. Coupling constants are given in Hertz (Hz). All other NMR spectra were recorded on a Bruker AC-200 spectrometer. Proton spectra were acquired at 200.133 MHz with a 5 mm dual frequency probe. Spectra were obtained in 8 scans in 16K data points over a 2.403 KHz spectral width (3.408 s acquisition time). Spectra were acquired at ambient probe temperature. The free induction decay (FID) was processed with exponential multiplication (line broadening: 0.1 Hz) and was zero-filled to 32K before Fourier transformation. Carbon-13 NMR spectra were recorded at 50.323 MHz with the 5 mm QNP probe. The spectra were acquired over a 12.195 kHz spectral width in 16K data points (0.672 s acquisition time).

Synthetic procedures

Methyl 2,3-diaminopropanoate p-*toluenesulfonate salt (**2**)*

To 2.0 g (14.28 mmol) of (±) 2,3-diaminopropionic acid monhydrochloride suspended in methanol (60 mL), *p*-toluenesulfonic acid was added (10.82 g, 56.9 mmol). After the solution was heated at reflux for 24 h it was evaporated to dryness at reduced pressure, and the remaining solid was washed with diethyl ether (200 mL), rendering the methyl ester as colourless crystals. Yield: 6.5 g, 99%; mp 200°C (decomp.); ^1H NMR (CD_3OD) (200 MHz) δ 7.719 (d, J = 8.3, 2H, H-*ortho*), 7.251 (d, 2H, H-*meta*), 5.003 (brd, NH), 4.494 (m, 1H, C*H*), 3.853 (s, 3H, OCH_3), 3.529 (m, 2H, CH_2), 2.354 (s, 3H, PhCH_3); ^{13}C NMR (CD_3OD)

(50 MHz) δ: 167.99 (*C*OOMe), 143.00 (C-*para*), 141.99 (C-*ipso*), 129.91 (C-*meta*), 126.90 (C-*ortho*), 54.55 (*C*H), 51.14 (O*C*H$_3$), 39.51 (*C*H$_2$), 21.32 (Ph-*C*H$_3$).

Methyl 2,3-bis(triphenylmethylthioacetylamino)propanoate (3)

To 3.62 g (8.40 mmol) of 2-(triphenylmethylthio)ethanoic acid-*N*-hydroxysuccinimido ester (1) dissolved in dichloromethane (50 mL), 1.92 g (4.16 mmol) of **2** was added. To the rapidly stirred mixture, diisopropylethylamine (DIPEA) (1.34 mL, 7.69 mmol) was added and the solution heated to reflux for 8 h. The solution was cooled and extracted with 1 M HCl (2 × 10 mL), 1 M NaHCO$_3$ (2 × 10 mL), and distilled water (distilled water) (3 × 15 mL). The solution was evaporated to dryness at reduced pressure, and the solid was washed with distilled water (200 mL), methanol (5 mL), and ether (5 mL). The colourless solid was recrystallized from acetone and subsequently dried in vacuo to give 2.2 g (78%) of **3**. The compound showed mp 68–70°C; TLC: R_f = 0.44 (2% CH$_3$OH–CH$_2$Cl$_2$); ^{1}H NMR (CDCl$_3$) (200 MHz) δ: 7.324–7.075 (m, 17H, H-*aryl*), 6.708 (d, *J* = 6.7, 1H, CHN*H*), 6.094 (m, 1H, CH$_2$N*H*), 4.064 (m, 1H, C*H*), 3.087 (m, 2H, CHC*H*$_2$), 2.934 (s, 2H, C*H*$_2$); ^{13}C NMR (CDCl$_3$) (50 Mhz) δ: 170.06 (*C*OOMe), 168.55, 168.89 (*C*(O)NH), 143.87 (C-*ipso*), 129.50 (C-*ortho*), 128.09 (C-*meta*), 126.98 (C-*para*), 67.71 (Ph$_3$*C*), 52.72 (*C*H and O*C*H$_3$), 41.24 (CH*C*H$_2$), 35.93 (*C*H$_2$), 35.72 (S*C*H$_2$).

2,3-Bis(triphenylmethylthioacetylamino)propanoic acid (4)

To 1.0 g (1.33 mmol) of **3** in a 1:1 mixture of THF and water (80 mL), 100 mg (2.5 mmol) of NaOH was added. After the mixture was heated to reflux for 3 h under an atmosphere of nitrogen, the solution was cooled, acidified to pH 3.9 using 6 M HCl, and concentrated to 30 mL under reduced pressure. The precipitate that formed was collected by filtration, and the colourless solid washed with distilled water (100 mL) and sparingly with ether (5 mL). The filtrate was concentrated and diluted with methanol (15 mL) and refrigerated overnight. The resulting solid was collected by filtration and washed again with distilled water and ether as above, yielding an additional crop of the title compound. Yield 900 mg, (97%); mp 214–215°C; TLC: R_f = 0.22 (10% CH$_3$OH–CH$_2$Cl$_2$); ^{1}H NMR (CD$_3$OD) (200 MHz) δ 7.643 (m, 15H, H-*aryl*), 4.590 (m, 1H, C*H*), 4.063 (m, 2H, C*H*$_2$CH), 3.269 (m, 2H, TrSC*H*$_2$); ^{13}C NMR (CD$_3$OD) (50 MHz) δ 171.21 (C-*C*OOH), 168.90, 168.55 (*C*(O)NH), 143.87 (C-*ipso*), 129.50 (C-*ortho*), 128.09 (C-*meta*), 126.98 (C-*para*), 65.88 (Ph$_3$*C*), 52.05 (*C*H), 43.96 (*C*H$_2$CH), 35.85, 32.33 (TrS*C*H$_2$).

(2-Chloroethoxy)benzene

The procedure described by McCague (10) was used. Phenol (28.2 g, 300 mmol), dimethyldioctadecylammonium bromide (1.8 g, 3.0 mmol), sodium hydroxide (24.0 g, 600 mmol) in distilled water (225 mL), and 1,2-dichloroethane (225 mL) were heated to reflux for 48 h. The organic phase was separated, dried with magnesium sulfate, and concentrated under reduced pressure to produce a translucent yellow oil. This crude product was subsequently purified by vacuum distillation to give the title compound as a colourless oil (35.6 g, 76%). The compound showed bp 100–102°C @ 12 mmHg; ^{1}H NMR (CDCl$_3$) (200 MHz) δ: 7.30 (m, 5H, H-*aryl*), 4.23 (t, 2H, OC*H*$_2$), 3.81 (t, 2H, *J* = 5.9, C*H*$_2$Cl); ^{13}C NMR (CDCl$_3$) (50 MHz) δ 159.8 (C- *ipso*), 131.0 (C-*meta*), 122.5 (C-*para*), 118.3 (C-*ortho*), 67.86 (O*C*H$_2$), 41.86 (*C*H$_2$Cl).

*1-[4-(2-Chloroethoxy)phenyl]-2-phenyl-1-butanone (**6**)*

The procedure developed by McCague was used (10). 1-Chloro-2-phenoxyethane (21.8 g, 140 mmol), (±)-2-phenylbutyric acid (20.2 g, 120 mmol), and trifluoroacetic anhydride (27.3 g, 130 mmol) were mixed and stirred magnetically at 20°C for 70 h. The reaction mixture was then poured slowly into distilled water (150 mL) to give a pink solid which was collected and recrystallized from ethanol to give colourless crystals (28.8 g, 79%). The compound showed mp 65–70°C; TLC: R_f = 0.79 (100% CH_2Cl_2); ^{1}H NMR ($CDCl_3$) (200 MHz) δ: 7.98–6.85 (m, 9H, H-*aryl*), 4.39 (t, 1H, *J* = 7.3, PhC*H*), 4.24 (t, 2H, OCH_2), 3.80 (t, 2H, *J* = 5.8, CH_2Cl), 2.02 (m, 2H, CH_2CH$_3$), 0.89 (t, 3H, *J* = 7.4, CH_3); ^{13}C NMR ($CDCl_3$) (50 MHz) δ: 198.07 (*C*(O)), 162.11–107.38 (*C*-aryl), 67.53 (*C*HPhCH$_2$CH$_3$), 55.17 (OCH_2), 41.39 (*C*H$_2$Cl), 26.48 (*C*H$_2$), 12.15 (*C*H$_3$).

*2-(2-Bromophenyl)-*O*-(*tert*-butyldimethylsilyl)ethan-2-ol (**8**)*

The procedure developed by Corey and Venkateswarlu (13) was used. 2-Bromophenethyl alcohol (2.0 g, 9.95 mmol) and imidazole (1.02 g, 14.9 mmol) were dissolved in dichloromethane (30 mL) under nitrogen and cooled over ice before *tert*-butyldimethylsilyl chloride (2.25 g, 14.9 mmol) was added. After 8 h the reaction mixture was filtered and the residue washed with dichloromethane (25 mL). The filtrate was extracted with distilled water (3 × 30 mL), concentrated to 1 mL, and passed down a silica column (petroleum ether – dichloromethane). The first band to elute from the column was collected, evaporated to dryness, and dried under high vacuum until the odour of the silicon starting material could no longer be detected (2–3 h). The product, a colourless oil (2.6 g, 83%), showed TLC: R_f = 0.66 (50:50 v/v CH_2Cl_2/hexanes); ^{1}H NMR ($CDCl_3$) (200 MHz) δ: 7.58–6.99 (m, 4H, H-*aryl*), 3.85 (t, 2H, *J* = 8.8, CH_2O), 2.99 (t, 2H, PhCH_2), 0.90 (s, 9H, SiC(CH_3)$_3$), 0.03 (s, 6H, Si(CH_3)$_2$); ^{13}C NMR ($CDCl_3$) (50 MHz) δ 138.29 (C-2), 131.7, 132.6 (C-3, C-6), 127.8, 127.1, (C-4, C-5), 124.56 (C-*ipso* i.e., C-1), 62.40 (*C*H$_2$O), 53.27 (Si*C*(CH$_3$)$_3$), 39.59 (PhCH$_2$), 25.89 (SiC(*C*H$_3$)$_3$), 18.22 (Si(*C*H$_3$)$_2$); MS (NH$_3$ DCI) *m*/*z* (RI%): 334 (100) (M + 2H$^+$ + NH$_3$), 332 (89) (M + NH$_3$), 331 (20) (M + NH$_3$ – H$^+$), 317 (100) (M + 2H$^+$), 315 (90) (M).

*1-[4-(2-Chloroethoxy)phenyl]-1-[2-(*O*-(*tert*-butyldimethylsilyl)ethyl)phenyl]-2-phenyl butan-1-ol (**9**)*

Compound **8** (2.02 g, 6.41 mmol) was dissolved in 5 mL of dry THF in a flame-dried flask under an argon atmosphere and cooled to –78°C. When *n*-butyllithium (4.0 mL, 1.6 M solution in hexanes) was added via syringe the solution became heterogeneous; it was left to stir for an additional 20 min. After the addition of compound **6** (1.09 g, 3.6 mmol in 5 mL dry THF) the solution cleared. The solution was allowed to gradually warm to room temperature and after 12 h the reaction was complete. Distilled water (50 mL) was added slowly and the solution extracted with ether (3 × 50 mL). The organic layers were combined, dried over sodium sulfate, filtered, and evaporated to dryness. The resulting oil was used without further purification or characterization.

*1-[4-(2-Chloroethoxy)phenyl]-1-[2-(*O*-(*tert*-butyldimethylsilyl)ethyl)phenyl]-2-phenyl but-1-ene (**10**)*

Compound **9** was dissolved in freshly distilled pyridine (10 mL) and cooled to –10°C; thionyl chloride (788 µL, 10.8 mmol) was added and the mixture stirred under argon for 3 h. The yellow–orange coloured solution was diluted cautiously with distilled water (20 mL) and extracted with diethyl ether (4 × 40 mL). The organic layers were combined and evaporated to dryness. The product was isolated by radial chromatography (10:1 low boiling petroleum ether/ether). The compound, a yellow oil (1.18 g, 64%), showed TLC: R_f = 0.72 (10:90 v/v ether/petroleum ether); ^{1}H NMR ($CDCl_3$) (200 MHz) δ:7.102 (m, H-aryl), 6.500 (d, 2H, H-*ortho* ring B), 4.189 (t, *J* = 3.9, 2H, *Z*-isomer OCH_2CH$_2$Cl), 4.042 (t, *J* = 3.8, 2H, *E*-isomer OCH_2CH$_2$Cl), 3.910 (m, 1H, SiOCH_2), 3.769 (t, *J* = 3.9, 2H, *Z*-isomer CH_2Cl), 3.672 (t, *J* = 4.0, 2H, *E*-isomer CH_2Cl), 3.449 (m, TBSOCH_2), 2.867 (t, *J* = 3.6, 2H, *E*-isomer CH_2Ph), 2.787 (m, 1H, *E*-isomer CH_2CH$_3$), 2.686 (t, *J* = 4.9, 2H, *E*-isomer CH_2Ph), 2.560 (m, 1H, *Z*-isomer CH_2CH$_3$), 2.276 (m, 2H, *Z*-isomer CH_2CH$_3$), 1.007 (t, *J* = 4.9, CH_3), 0.814 (m, SiC(CH_3)$_3$), 0.02 (s, Si-CH_3); ^{13}C NMR ($CDCl_3$) (50 MHz) δ 156.77, 156.06, 142.77, 142.53, 142.16, 141.89, 141.74, 137.55, 136.95, 135.97, 134.77, 131.71, 131.55, 130.65, 130.42, 130.01, 129.73, 129.46, 128.96, 128.26, 127.97, 127.47, 126.95, 126.20, 126.0, 125.36, 120.05, 117.0, 114.18, 113.505 (C-*aryl*), 67.93 (*Z*-isomer OCH$_2$CH$_2$Cl), 67.70 (*E*-isomer OCH$_2$CH$_2$Cl), 63.43 (*E*-isomer SiOCH$_2$), 63.20 (*Z*-isomer SiOCH$_2$), 41.76 (*C*H$_2$Cl), 36.72 (*E*-isomer *C*H$_2$Ph), 36.43 (*Z*-isomer *C*H$_2$Ph), 29.51 (*C*H$_2$CH$_3$), 25.93 (SiC(*C*H$_3$)$_3$), 18.31 (Si*C*H$_3$), 13.80 (*Z*-isomer CH$_2$*C*H$_3$), 12.93 (*E*-isomer CH$_2$*C*H$_3$); MS (NH$_3$ DCI) *m*/*z* (RI%): 538 (100) (M + NH$_3$), 520 (80) (M), 406 (85) (M – TBS + H).

*1-[4-(2-Chloroethoxy)phenyl]-1-[2-(hydroxyethyl)phenyl]-2-phenyl but-1-ene (**11**)*

The procedure developed by Corey and Venkateswarlu (13) was used. To compound **10** (800 mg, 1.54 mmol) in 10 mL of THF, tetrabutylammonium fluoride (5.07 mL, 1.0 M solution in THF) was added. The reaction was allowed to stir for 24 h before dilution with distilled water (20 mL) and extraction with diethyl ether (4 × 25 mL). The organic layer was concentrated to a volume of 2 mL and the product isolated by radial chromatography (hexanes–dichloromethane). The title compound (600 mg, 96%), an oil, showed TLC: R_f = 0.15 (100% CH_2Cl_2); ^{1}H NMR ($CDCl_3$) (200 MHz) δ: 7.20 (m, H-*aryl*), 6.520 (d, 2H, H-*ortho* ring B), 4.143 (t, *J* = 5.9, *Z*-isomer, OCH_2CH$_2$Cl), 3.996 (t, *J* = 5.9, 2H, *E*-isomer OCH_2CH$_2$Cl), 3.725 (t, *J* = 5.8, 2H, *Z*-isomer CH_2Cl), 3.629 (t, *J* = 5.9, 2H, *E*-isomer CH_2Cl), 3.425 (m, *E*/*Z*, CH_2OH), 2.711, 2.200 (m, overlap, CH_2Ph, CH_2CH$_3$), 0.954 (t, *J* = 7.5, 3H, *Z*-isomer CH_3), 0.769 (t, *J* = 7.4, 3H, *E*-isomer CH_3); ^{13}C NMR ($CDCl_3$) (50 MHz) δ: 156.10, 156.06, 142.98, 142.69, 142.05, 141.70, 136.65, 136.37, 136.15, 135.86, 134.60, 132.01, 131.50, 130.35, 130.24, 129.65, 128.87, 127.98, 127.52, 127.22, 126.50, 126.26, 126.06, 125.64, 114.24, 113.52 (C-*aryl*), 67.93 (*Z*-isomer OCH_2CH$_2$Cl), 67.67 (*E*-isomer OCH_2CH$_2$Cl), 62.63 (*E*-isomer *C*H$_2$OH), 62.41 (*Z*-isomer *C*H$_2$OH), 41.79 (*C*H$_2$Cl), 36.47 (*E*-isomer PhCH$_2$), 36.14 (*Z*-isomer PhCH$_2$),

29.49 (*E*-isomer CH_2CH_3), 28.04 (*Z*-isomer CH_2CH_3), 13.77 (*Z*-isomer CH_3), 12.92 (*E*-isomer CH_3).

12-Azido-dodecanoic acid

Sodium azide (4.7 g, 72.3 mmol) was added to a solution of 12-bromododecanoic acid (2.0 g, 7.16 mmol) in DMF (45 mL). After heating at 80°C for 12 h, the reaction mixture was cooled to room temperature and poured into distilled water (100 mL). The solution was extracted with ether (2 × 70 mL) and the organic fractions pooled and evaporated in vacuo. The resulting yellow oil was diluted with a 3:1 mixture of water/brine (10 mL) and refrigerated overnight. The resulting colourless precipitate was collected by filtration, washed with cold water (30 mL), and dried in air. The compound (1.56 g, 90%) showed ^{1}H NMR ($CDCl_3$) (200 MHz) δ: 3.320 (t, *J* = 6.8, 2H, CH_2-N_3), 2.313 (t, *J* = 7.4, 2H, CH_2COOH), 1.570 (m, 4H, CH_2), 1.257 (m, 18H, CH_2); ^{13}C NMR ($CDCl_3$) (50 MHz) δ: 180.04 (*C*OOH), 51.45 (CH_2-N_3), 34.15 (CH_2COOH), 29.40, 29.18, 29.09, 29.02, 28.8, 26.67, 24.68 (CH_2); MS(ES) *m*/*z* (RI%): 241.4 (18) (M), 240.4 (100) (M – H).

*1-[4-(2-Chloroethoxy)phenyl]-1-[2-[(12-azidododecanoyl)oxyethyl)phenyl]-2-phenyl but-1-ene (**12**)*

12-Azido-dodecanoic acid (500 mg, 2.07 mmol) was dissolved in thionyl chloride (8 mL) and heated to reflux under nitrogen for 1 h. Residual thionyl chloride was evaporated in vacuo and the residue dissolved in dry dichloromethane (25 mL), which was subsequently evaporated. The oily residue was redissolved in dry dichloromethane (20 mL) and compound **11** (766 mg, 1.89 mmol) in dry dichloromethane (5 mL) was added. The solution was heated to reflux for 12 h before the slow addition of 10% Na_2CO_3 (20 mL). The solution was extracted with chloroform (2 × 50 mL), and the organic layers were pooled, concentrated to 2 mL, and the product, a yellow oil (766 mg, 64%), isolated by radial chromatography (petroleum ether – ether). Samples of pure *E*-12 and pure *Z*-12 can be isolated by using a new chromatatron plate (activated with petroleum ether), a very gradual gradient of 100% petroleum ether up to 10% ether and collecting small aliquots as the major product band elutes from the chromatatron. The compound showed MS (HRDEI): obs: 629.33695, calcd.: 629.3384. *E*-Isomer: ^{1}H NMR ($CDCl_3$) (500 MHz) δ: 7.280 (m, H-*aryl*), 6.764 (d, *J* = 9.3, 2H, H-*meta*- ring B), 6.512 (d, 2H, H-*ortho*- ring B), 4.117 (m, 1H, OCH_2CH_2Ph), 4.063 (m, 2H, OCH_2CH_2Cl), 3.914 (m, 1H, OCH_2CH_2Ph), 3.694 (t, 2H, *J* = 6.0, CH_2Cl), 3.233 (t, 2H, CH_2N_3), 2.734 (m, 2H, OCH_2CH_2Ph), 2.325 (m, 1H, CH_2CH_3), 2.224 (t, *J* = 6.2, 2H, $CH_2C(O)$), 2.211 (m, 1H, CH_2CH_3), 1.564, 1.344, 1.245 (m, CH_2), 0.810 (t, *J* = 7.4, 3H, CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ 173.61 (*C*OOR), 156.13, 142.68, 142.28, 141.76, 136.50, 135.82, 134.48, 131.53, 130.28, 130.20, 129.70, 128.00, 127.20, 126.44, 126.28, 113.60 (C-*aryl*), 67.78 (OCH_2CH_2Cl), 63.71 (OCH_2CH_2Ph), 51.48 (CH_2N_3), 41.78 (CH_2Cl), 34.32 ($CH_2OC(O)$), 32.48 OCH_2CH_2Ph), 29.42, 29.38, 29.23, 29.10 (CH_2), 28.82 (CH_2CH_3), 26.69, 24.94 (CH_2), 12.90 (CH_3). *Z*-Isomer: ^{1}H NMR ($CDCl_3$) (500 MHz) δ: 7.00 (m, H-*aryl*), 4.166 (t, *J* = 6.0, 2H, OCH_2CH_2Cl), 3.816 (m, OCH_2CH_2Ph), 3.746 (t, *J* = 6.0, 2H, OCH_2CH_2Cl), 3.652 (m, OCH_2CH_2Ph), 3.191 (t, *J* = 7.0, 2H, CH_2N_3), 2.801, 2.620, 2.553 (m, overlap, OCH_2CH_2Ph and CH_2CH_3), 2.192 (t, *J* = 7.6, 2H, $CH_2C(O)$), 1.511, 1.288 (m, CH_2), 0.960 (t, *J* = 7.4, 3H, CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ: 173.60 (*C*OOR), 142.92, 142.01, 137.18, 135.65, 131.95, 130.39, 129.71, 128.95, 127.54, 126.52, 126.12, 125.80, 114.35 (C-*aryl*), 68.05 (OCH_2CH_2Cl), 63.72 (OCH_2CH_2Ph), 51.48 (CH_2N_3), 41.83 (CH_2Cl), 34.33 ($CH_2OC(O)$), 32.05 (OCH_2CH_2Ph), 29.45, 29.25, 29.13, 28.82 (CH_2), 26.70 (CH_2CH_3), 24.95 (CH_2), 13.79 (CH_3).

*1-[4-(2-Dimethylaminoethoxy)phenyl]-1-{2-[(12-azidododecanoyl)oxyethyl]phenyl}-2-phenyl but-1-ene (**13**)*

The procedure developed by McCague (10) was used. In a round-bottom flask fitted with a dry ice condenser, compound **12** (150 mg, 0.235 mmol) was dissolved in dimethylamine (20 mL, 5.6 M solution in ethanol) and the mixture was heated to reflux for 2 days. The solution was evaporated to dryness, the residue dissolved in DCM (2 mL), and the title compound isolated by centrifugal chromatography ($CHCl_3$–MeOH). The title compound, a yellow oil (76 mg, 50%), showed ^{1}H NMR ($CDCl_3$) (500 MHz) δ: 7.298 (m, H-*aryl*), 6.934 (d, *J* = 8.9, 2H, *H-meta* ring A), 6.512 (d, 2H, H-*ortho*, ring A), 4.110 (m, OCH_2CH_2Ph), 3.916 (overlap, t, *J* = 6.0, $OCH_2CH_2NMe_2$, and m, OCH_2CH_2Ph), 3.242 (t, *J* = 6.8, 2H, CH_2N_3), 2.713 (m, OCH_2CH_2Ph), 2.644 (t, *J* = 5.7, 2H, CH_2NMe_2), 2.210 (m, overlap, CH_2CH_3, CH_2COOR, NCH_3), 1.331 (m, $(CH_2)_n$), 0.813 (t, *J* = 7.2, 3H, CH_2CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ: 173.59 (*C*OOR), 156.69, 142.72, 141.88, 141.74, 136.57, 135.76, 133.68, 131.33, 130.21, 130.11, 129.65, 128.89, 127.90, 127.46, 127.07, 126.34, 126.14, 114.05 (C-*aryl*), 65.52 ($OCH_2CH_2NMe_2$), 63.67 (OCH_2CH_2Ph), 58.13 (CH_2N), 51.38 (CH_2N_3), 45.73 (NCH_3), 34.25 (CH_2COOR), 32.42 (OCH_2CH_2Ph), 29.37, 29.18, 29.05 ($(CH_2)_n$), 28.75 (CH_2CH_3), 26.63, 24.88 ($(CH_2)_n$), 12.90 (CH_2CH_3); MS (HRDEI): obs: 638.4190, calcd.: 638.4196.

*1-[4-(2-Dimethylaminoethoxy)phenyl]-1-{2-[(12-aminododecanoyl)oxyethyl]phenyl]-2-phenyl but-1-ene (**14**)*

To compound **13** (69 mg, 0.108 mmol) in THF (1 mL), triphenylphosphine (29 mg, 0.110 mmol) followed by distilled water (3.0 μL) were added. The reaction was allowed to stir for 24 h whereupon an additional aliquot of triphenylphosphine (29 mg, 0.110 mmol) and water (3.0 μL) were added. After an additional 24 h the solution was evaporated to dryness, diluted with chloroform (1 mL), and the title compound isolated by centrifugal chromatography (16 mg, 25%). The compound showed ^{1}H NMR ($CDCl_3$) (500 MHz) δ 7.230 (m, H-*aryl*), 6.691 (d, *J* = 8.8, 2H, *H-meta* ring A), 6.488 (d, 2H, H-*ortho*, ring A), 4.036 (m, OCH_2CH_2Ph), 3.832 (overlap, t, *J* = 5.8, $OCH_2CH_2NMe_2$, and m, OCH_2CH_2Ph), 2.637 (m, overlap, CH_2NH_2, OCH_2CH_2Ph, CH_2NMe_2), 2.197 (m, CH_2CH_3, CH_2COOR, NCH_3), 1.492, 1.353, 1.182 (m, $(CH_2)_n$), 0.743 (t, *J* = 7.2, 3H, CH_2CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ: 173.64 (*C*OOR), 156.73, 142.72, 141.87, 141.76, 136.58 135.77, 133.66, 131.33, 130.22, 130.22, 130.11, 129.66, 128.25, 127.91, 127.07, 126.34, 126.14, 113.34 (C-*aryl*), 65.60 ($OCH_2CH_2NMe_2$), 63.68 (OCH_2CH_2Ph), 58.18 (CH_2N), 45.78 (NCH_3), 42.08 (H_2NCH_2), 34.27 (CH_2COOR), 33.69 ($(CH_2)_n$), 32.42

© 1999 NRC Canada

(OCH_2CH_2Ph) 29.44, 29.21(($CH_2)_n$), 29.06 (CH_2CH_3), 26.82, 24.89 (($CH_2)_n$), 12.91 (CH_2CH_3); MS (NH_3 DCI) *m*/*z* (RI%): 613 (100) (M + 1), 541 (14) (M – $CH_2CH_2NMe_2$).

*1-[4-(2-Dimethylaminoethoxy)phenyl]-1-{2-[(12-((2,3-bistriphenylmethylthioacetylamino)propanamido)dodecanoyloxy)ethyl]phenyl}-2-phenyl but-1-ene (**15**)*

Compound **14** (16 mg, 0.026 mmol) was dissolved in DCM (10 mL) and triethylamine was added (1 mL), followed by compound **4** (20 mg, 0.027 mmol). To this well stirred solution, EDC (19 mg, 0.099 mmol) was added slowly. The reaction mixture was stirred for 48 h before dilution with DCM (10 mL) and extraction with brine (3 × 10 mL). The organic phase was concentrated to 1 mL and an impure fraction of the title compound isolated by radial chromatography ($CHCl_3$–MeOH). This fraction was concentrated to 0.5 mL, and a pure sample of the title compound isolated by preparative TLC (silica). The title compound was a yellow oil (9 mg, 26%).

*1-[4-(2-Chloroethoxy)phenyl]-1-{2-[(12-aminododecanoyl)oxyethyl]phenyl}-2-phenyl but-1-ene (**16**)*

Triphenylphosphine (326 mg, 1.24 mmol) was added to a solution of compound **12** (710 mg, 1.13 mmol) in THF (2 mL) and water (50 μL). The solution was stirred (protected from light) for 12 h before concentration of the solvent under reduced pressure. The oily residue was dissolved in chloroform (2 mL), and the product, a yellowish oil (450 mg, 66%), was isolated by radial chromatography ($CHCl_3$–MeOH) and used immediately after isolation.

*1-[4-(2-Chloroethoxy)phenyl]-1-[2-((12-((2,3-bistriphenylmethylthioacetylamino)propanamide)dodecanoyl)oxyethyl)phenyl]-2-phenyl but-1-ene (**17**)*

To a dichloromethane solution (10 mL) of compound **16** (180 mg, 0.298 mmol) and compound **4** (264 mg, 0.36 mmol), EDC (70 mg, 0.36 mmol) and triethylamine (1 mL) were added. The mixture was allowed to stir for 48 h whereupon the solvent was evaporated at reduced pressure, the oily residue dissolved in chloroform (2 mL), and the product isolated by radial chromatography (hexanes–chloroform). The compound, a yellow oil (300 mg, 76%), showed ^{1}H NMR ($CDCl_3$) (500 MHz) δ: 7.250 (m, H-*aryl*), 6.755 (d, *J* = 8.9, 2H, H-*meta* ring A), 6.491 (d, 2H, H-*ortho*, ring A), 4.150 (t, *J* = 5.8, 2H, *Z*- OCH_2CH_2Cl), 4.118 (m, overlap, OCH_2CH_2Ph), 4.028 (t, *J* = 3.9, 2H, *E*-OCH_2CH_2Cl), 3.771 (m, overlap, $CHCH_2$ and OCH_2CH_2Ph), 3.761 (t, *J* = 4.2, *Z*-OCH_2CH_2Cl), 3.665 (t, *J* = 5.8, 2H, *E*- OCH_2CH_2Cl), 3.181 (m, 2H, $CHCH_2$), 2.971 (s, 4H, CH_2S), 2.718 (m, overlap, *E*/*Z* OCH_2CH_2Ph), 2.246 (m, overlap, *E*/*Z* CH_2CH_3), 2.179 (t, *J* = 5.6, 2H, CH_2COOR), 1.534, 1.385, 1.200 (m, $(CH_2)_n$), 0.988 (t, *J* = 7.5, 3H, *Z*-CH_2CH_3), 0.793 (t, *J* = 7.3, 3H, CH_2CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ 173.54 (ester *C*(O)), 169.71, 169.08, 168.88 (amide C(O)), 156.00, 143.81, 142.78, 142.56, 142.15, 141.63, 136.39, 135.69, 134.32, 131.43, 130.21, 130.08, 129.60, 129.42, 129.35, 128.85, 128.02, 127.45, 127.12, 126.90, 126.36, 126.19, 125.71, 114.22, 113.46 (C-*aryl*), 83.14 (CPh_3), 67.65 (*Z*-OCH_2CH_2Cl), 67.62 (*E*-OCH_2CH_2Cl), 63.61 (OCH_2CH_2Ph), 51.11 ($CHCH_2$), 41.99 (*Z*-CH_2Cl), 41.76 (*E*-CH_2Cl), 39.55 ($CHCH_2$), 36.04, 35.74 (SCH_2), 34.22 (CH_2COOR), 32.38 (OCH_2CH_2Ph), 30.81, 29.42, 29.18, 26.79 (($CH_2)_n$), 29.03 (CH_2CH_3), 26.79, 24.86 (($CH_2)_n$), 13.05 (*Z*-CH_2CH_3); 12.85 (*E*-CH_2CH_3).

*1-[4-(2-Dimethylaminoethoxy)phenyl]-1-{2-[(12-((2,3-bistriphenylmethylthioacetylamino)propanamide)dodecanoyl)oxyethyl]phenyl}-2-phenyl but-1-ene (**15**)*

A sample of 300 mg (0.227 mmol) of **17** was dissolved in a 5.6 M solution of dimethylamine in ethanol (5 mL) in a round-bottom flask that was fitted with a dry-ice condenser. The solution was heated to reflux for 24 h when, after cooling, the solvent was evaporated in vacuo. The product, a dark oily semi-solid (181 mg, 60%), was isolated by radial chromatography (chloroform–methanol). The compound showed TLC: R_f = 0.36 (10% CH_3OH–CH_2Cl_2); ^{1}H NMR ($CDCl_3$) (500 MHz) δ: 7.250 (m, H-*aryl*), 6.735 (d, *J* = 8.9, H, *H-meta* ring A), 6.505 (d, 2H, H-*ortho*, ring A), 4.122 (m, overlap, OCH_2CH_2Ph,$CHCH_2$), 4.055 (m, *Z*-OCH_2CH_2N), 3.926 (m, overlap, OCH_2CH_2Ph), 3.896 (t, *J* = 5.9, *E*-OCH_2CH_2N), 3.194 (m, $CHCH_2$), 2.985 (s, 4H, CH_2S), 2.718 (m, overlap, *Z*-OCH_2CH_2N and OCH_2CH_2Ph), 2.625 (t, *J* = 5.8, 2H, *E*-OCH_2CH_2N), 2.325 (s, *Z*-NCH_3), 2.267 (*E*-NCH_3), 2.211 (m, overlap, *E*/*Z* CH_2CH_3, CH_2COOR), 1.540, 1.407, 1.213 (m, $(CH_2)_n$), 0.994 (t, *J* = 7.4, 3H, *Z* = CH_2CH_3), 0.797 (t, *J* = 7.5, 3H, CH_2CH_3); ^{13}C NMR ($CDCl_3$) (125 MHz) δ 173.63 (ester *C*(O)), 169.86, 169.21, 168.96 (amide *C*(O)), 156.73, 143.87, 142.75, 141.92, 136.60, 135.82, 133.72, 131.37, 130.26, 129.69, 129.50, 129.42, 128.94, 128.11, 126.98, 126.38, 126.19, 114.10, 113.39, (C-*aryl*), 67.73 (CPh_3), 65.57 (OCH_2CH_2N), 63.70 (OCH_2CH_2Ph), 58.18 (CH_2N), 54.55 ($NHCH_2$), 45.80 (NCH_3), 42.07 ($CHCH_2$), 39.64 ($CHCH_2$), 36.10, 35.79 (SCH_2), 34.31 (CH_2COOR), 32.45 (OCH_2CH_2Ph), 29.48, 29.26 (($CH_2)_n$), 29.03 (CH_2CH_3), 26.86, 24.94 (($CH_2)_n$), 13.05 (*Z*-CH_2CH_3); 12.95 (*E*-CH_2CH_3). C, H analysis: calcd. for $C_{85}H_{94}N_4S_2O_6 \cdot 2.5H_2O$: C 74.06, H 7.42%; obs.: C 74.18, H 7.20%.

Conclusions

Using approach B, a 5:1 *E*:*Z* sample of compound 15 was synthesized in 18 steps in reasonable yield. It is was also discovered that the *E* and *Z* isomers of compound 12 could be separated by radial chromatography. This work is an example of a total synthesis of a biomolecule–chelate complex for the purpose of developing a site-specific radioimaging agent. Testing of compound 15 in tumour models remains work in progress.

COMMUNICATION

Self-assembly of one-dimensional polymers by coordination and hydrogen bonding in palladium(II) complexes

Zengquan Qin, Hilary A. Jenkins, Simon J. Coles, Kenneth W. Muir, and Richard J. Puddephatt

Abstract: The ligands L = pyridine- or quinoline-carboxylic acid easily give complexes *trans*-[$PdCl_2L_2$], which self-assemble through hydrogen bonding between carboxylic acid groups to give one-dimensional polymers, as proved by structure determinations when L = NC_5H_4COOH-4, NC_5H_4COOH-3, and 2-Ph-NC_9H_5COOH-4.

Key words: polymer, hydrogen-bonding, palladium, coordination.

Résumé : Les ligands L = acide pyridine-3-carboxylique, acide pyridine-4-carboxylique ou acide quinoléine-4-carboxylique donnent facilement des complexes *trans*-[$PdCl_2L_2$], qui s'auto-assemblent, au moyen de liaisons hydrogènes entre les groupes carboxyliques, pour donner des polymères unidimensionnels comme le démontrent les déterminations de structure lorsque L = NC_5H_4-4-COOH, NC_5H_4-3-COOH et 2-Ph-NC_9H_5-4-COOH.

Mots clés : polymère, liaison hydrogène, palladium, coordination.

[Traduit par la Rédaction]

The design of supramolecular architectures that self-assemble in a predictable way presents a challenge in modern chemistry (1). Hydrogen bonding is known to control organic structures in both natural (2) and synthetic (3) systems, resulting in the formation of one-, two-, and three-dimensional architectures of many kinds. The use of coordination chemistry in self-assembly is also developing rapidly (4), based on the easy templating effect of the metal centres, the opportunity that metal centers in neighbouring molecules can be linked through interactions that have strengths similar to those of hydrogen bonds, and the potential importance of new metal-containing materials in electronic, optical, or sensing devices. The combination of both coordination chemistry and hydrogen-bonding approaches is particularly powerful (5, 6) but relatively little work has yet been reported on the use of hydrogen bonding between simple carboxylic acid groups as substituents in coordination compounds to give supramolecular arrays (6). This communication reports the synthesis and characterization of one-dimensional polymers based on *trans*-[$PdCl_2L_2$] complexes, where L is a ligand containing both a pyridine donor and a free carboxylic acid group.

Several new *trans*-[$PdCl_2L_2$] complexes, including **1**, L = NC_5H_4COOH-4; **2**, L = NC_5H_4COOH-3, and **3**, L = 2-Ph-NC_9H_5COOH-4, were prepared by displacement of the weakly bound benzonitrile ligands in *trans*-[$PdCl_2(NCPh)_2$] by the corresponding ligand L. All the new complexes are yellow, air-stable solids. These complexes are expected to self-assemble in the solid state but it proved difficult to grow crystals suitable for structure determination since the complexes were essentially insoluble in most organic solvents. They do dissolve in dimethyl sulfoxide (DMSO) or *N*,*N*-dimethylformamide (DMF), but these solvents may displace the pyridine ligands and certainly break up the presumed polymeric structures by acting as hydrogen-bond acceptors. Thus, crystals of **2**·2DMSO and **3**·4DMF were

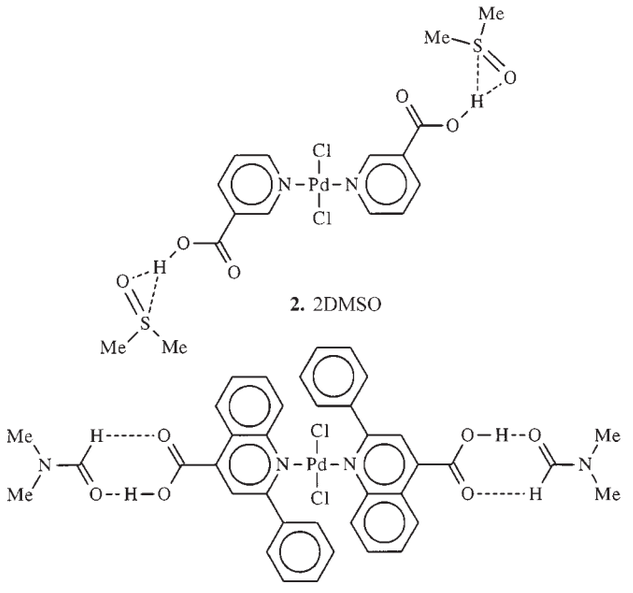
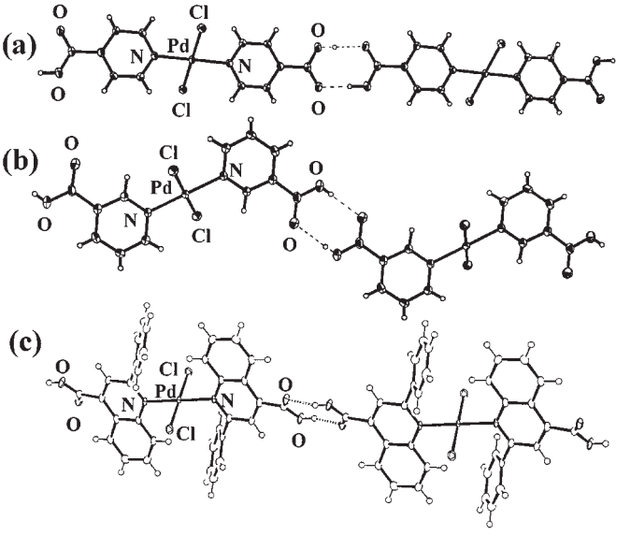
Chart 1. Structures showing H bonding in the DMSO and DMF solvates.



shown to contain molecular units only, as depicted in Chart 1;[2] the ligand displacement was also a significant problem with DMSO solvent but it was possible to characterize the complexes in DMF-d_7 solution by ^{1}H NMR.[3]

Finally, a method for obtaining single crystals of complexes **1**, **2**, and **3** was discovered, in which separate solutions of *trans*-[$PdCl_2(NCPh)_2$] in acetone and the ligand L in water were allowed to diffuse together slowly in a narrow-bore glass tube; crystals formed over a period of several weeks close to the interface where the ligand substitution occurred, and proved suitable for structure determinations.[2] All three complexes self-assemble into infinite one dimensional polymeric arrays through intermolecular hydrogen-bonding as shown in Fig. 1. In each case, the palladium atom lies on a cystallographic inversion centre so the angles N-Pd-N and Cl-Pd-Cl are 180°. Crystals of **1** contain strictly

Fig. 1. Views of the 1-D chain structures of the H-bonded polymers showing 30% probability ellipsoids for all non-H atoms. Selected bond distances (Å) and angles (°):
(*a*) *trans*-[$PdCl_2(NC_5H_4COOH\text{-}4)_2$], **1**: Pd—N = 2.021(2) Å, Pd—Cl = 2.3051(7) Å, N-Pd-Cl = 90.5(1)°.
(*b*) *trans*-[$PdCl_2(NC_5H_4COOH\text{-}3)_2$], **2**: Pd—N = 2.022(2) Å, Pd—Cl = 2.305(1) Å, N-Pd-Cl = 90.1(1)°.
(*c*) *trans*-[$PdCl_2$(2-Ph-$NC_9H_5COOH\text{-}4)_2$], **3**: Pd—N = 2.035(2) Å, Pd—Cl = 2.308(1) Å, N-Pd-Cl = 91.8(1)°



linear chains of molecules (Fig. 1*a*) and the O···O distances in hydrogen-bonded OH···O groups are 2.637(4) Å, typical of such distances in carboxylic acids (1–3). Complex **2**, with L = $NC_5H_4CO_2H$-3, naturally gives zigzag chains; the hydrogen bonding is similar to that in **1**, with intermolecular distances O···O = 2.634(3) Å (Fig. 1*b*). Complex **3**, with L = 2-Ph-NC_9H_5COOH-4, again gives a structure that is remarkably similar to that of **1**, with strictly linear chains assembled through hydrogen bonding and with O···O distances of 2.655(3) Å (Fig. 1*c*). In the solid state structures of both **1** and **2**, there are other short non-bonded contacts involving C-H groups and Pd-Cl groups of neighbouring chains and

Note that in this structure **2** DMF are H-bonded and **2** are not (Chart 1). Complete X-ray data are available as supplementary material, which may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. These data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[3] Selected ^{1}H NMR data in DMF-d_7: **1**, δ(^{1}H): 9.10 (d, ^3J(HH) = 7 Hz, 4H, H^{2,6}), 8.07 (d, ^3J(HH) = 7 Hz, 4H, H^{3,5}); **2**, δ(^{1}H): 9.41 (d, ^4J(HH) = 2 Hz, 2H, H^2), 9.13 (dd, ^3J(HH) = 6 Hz, ^4J(HH) = 1 Hz, 2H, H^6), 8.58 (ddd, ^3J(HH) = 8 Hz, ^4J(HH) = 2 Hz, ^4J(HH) = 1 Hz, 2H, H^4), 7.83 (dd, ^3J(HH) = 8 Hz, ^3J(HH) = 6 Hz, 2H, H^5); **3**, δ(^{1}H): 9.11 (d, ^3J(HH) = 8 Hz, 2H, H^8), 8.71 (dd, ^3J(HH) = 8 Hz, ^4J(HH) = 1 Hz, 2H, H^5), 8.21–8.30 (br, m, 4H, H^{6,7}), 7.78–8.14 (br, m, 12H, H^3 and C_6H_5). Satisfactory C, H, and N analyses were obtained for all new complexes.

© 1999 NRC Canada

these, though clearly weak, may be attractive, thereby contributing to the insolubility of the complexes. Hence the complex **3** was prepared in the hope that the bulky substituents might prevent these secondary intermolecular interactions and so lead to enhanced solubility. It is clear from Fig. 1*c* that the bulky substituents do indeed protect the palladium centres and so prevent intermolecular association through these atoms, but the complex is still insoluble in organic solvents that are not capable of breaking down the intermolecular hydrogen bonding. We conclude therefore that the polymerization through hydrogen bonding alone is sufficient to lead to the observed insolubility of these and similar complexes.

In conclusion, this work shows that both linear and zigzag one-dimensional hydrogen-bonded polymers can be prepared by self-assembly from very simple ligands by using palladium(II) centres as templates. The hydrogen bonding in these polymers is strong and leads to insolubility of the complexes. The inability to recrystallize these compounds presented a problem in the development of this chemistry, but it is now shown that single crystals can be grown in situ by slow diffusion of the reagents together. Clearly, the method can be extended to create many more complex supramolecular arrays by using different metal centres as templates.

1998 Alfred Bader Award Lecture
Tangents and targets: The synthetic highway from natural products to medicine[1]

Alex G. Fallis

Abstract: Synthetic studies directed toward various classes of compounds including taxoids and enediyne systems are described. These investigations include tether-controlled imtramolecular Diels–Alder reactions, carbometallation routes to dienes and furans, the use of carbohydrate building blocks, pentadienyl indium reagents for tandem cycloadditions to steroid and triterpenoid skeletons, and the synthesis of taxamycins and revolveneynes and related cyclophanes.

Key words: cycloaddition, taxoids, enediyne, cyclophanes, carbometallation.

Résumé : On décrit des études orientées vers la synthèse de diverses classes de composés, y compris des systèmes taxoïdes et ènediynes. Ces recherches comprennent des réactions de Diels–Alder intramoléculaires sous contrôle d'attaches, des voies de carbométallation conduisant à des dienes et à des furanes, l'utilisation de synthons dérivés des sucres, de réactifs pentadiényl-indium pour les cycloadditions en tandem conduisant aux squelettes des stéroïdes et aux triterpénoïdes ainsi que la synthèse de taxamycines, de révolvèneynes et de cyclophanes apparentés.

Mots clés : cycloaddition, taxoïdes, ènediyne, cyclophanes, carbométallation.

[Traduit par la Rédaction]

Introduction

Synthetic organic chemistry occupies a significant position in many diverse scientific disciplines and related areas of modern society in addition to its importance in its own right. This central role involves key interactions and overlap with pharmaceutical discovery and development, medical research, molecular biology, and material science. Nature has often provided the impetus for synthesis due to the complex, biologically active molecules that are produced and the significant preparative challenge these structures present.

A frequent advantage of synthetic investigations is the unexpected discoveries and developments that result from adversity. Woodward pointed out that "*the specific objective which the synthetic chemist uses as the excuse for his (her) activity is often not of special importance in the general sense; rather the important things are those that he finds out in the course of attempting to reach his (her) objective*." In this respect targets become vehicles for discovery and the tangents and cul de sacs encountered stimulate new chemistry. In addition, "systematic serendipity" provides new insights and opportunities for further investigation. In this regard, our studies directed toward the total synthesis of taxoids have been particularly rewarding.

In the course of these investigations, the following topics have been developed: (*a*) studies of cyclic α-diazoketones and reactions with enol ethers to afford unstable donor–acceptor cyclopropanes as precursors to dihydrofurans; (*b*) oxetane synthesis by epoxide rearrangement; (*c*) diene preparation by palladium coupling; (*d*) routes to taxane Ring A building blocks; (*e*) carbometallation of alkynes with organomagnesium reagents for the synthesis of dienes, enediynes, and furans; (*f*) development of tether-control groups for a variety of stereocontrolled cycloadditions; (*g*) indium-mediated additions to aldehydes for dienes and trienes; (*h*) increased knowledge of Diels–Alder reactions in diverse ring systems; (*i*) development of tandem cycloadditions for steroid and triterpenoid skeletons; (*j*) synthesis of novel enediyne systems such as taxamycins and revolveneynes.

The yew tree has played an important role in human history and since antiquity has been honoured for its longevity (Druids) and practical applications due to the density of its wood (1). The European yew (*Taxus baccata*) has been detected in Triassic fossils from 200 million years ago and, in an early example of superior armaments, the English employed long bows from yew trees to defeate the French at the battle of Crécy in 1346. In Britain, ancient yew trees predate the birth of Julius Caesar. An aqueous extract from the needles of *Taxus canadensis* was used by Canadian Indians for the treatment of rheumatism and as a tea after childbirth. Taxol® (paclitaxel) was first detected in the Pacific yew (*Taxus brevifolia*) in 1964, its structure published in 1971 (2), its novel mode of action determined in 1979 (3), and its approval as a drug attained in 1993. Initially public controversy surrounded the interactions between competing groups, including loggers, environmentalists (the yew forest

is home of the endangered spotted owl), and drug firms. This was a consequence of the large numbers of yew trees that had to be sacrificed to obtain material for the initial clinical trials (4).

The development of screening methods for taxoid activity have revealed new structures such as the epothilones (5), discodermolide (6), and eleutherobin (7) with similar biological profiles (Fig. 1).

Taxoid synthesis

We, in common with several other research groups, have been interested in the synthetic challenge presented by the taxoids. The proven clinical utility of the potent anti-tumor agents paclitaxel (Taxol®) and docetaxel (Taxotere®) for the treatment of ovarian and breast cancer has established these compounds as an important new class of chemotherapeutic agents. These antimitotic drugs alter the equilibrium between soluble tubulin dimers and polymerized microtubule structures. The microtubules are stabilized, depolymerization suppressed, and cell division inhibited (3, 8). This novel mode of action, plus the significant synthetic challenge presented by the sterically congested multicyclic structure, has stimulated worldwide interest in these molecules (9). Our initial approach to the tricyclo[9.3.1.0^{3,8}]pentadecene nucleus was based on a left-to-right sequence (ring A to BC) intramolecular Diels–Alder strategy in which ring A cyclohexene building blocks were selected as anchors to facilitate the construction of the B and C rings simultaneously (Scheme 1, eq. [1]) (10). A very large number of [4 + 2]

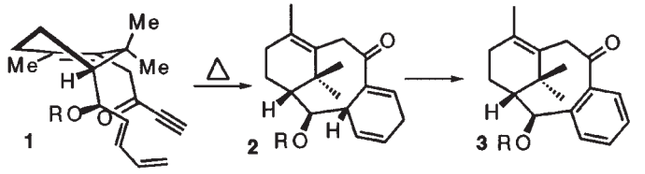
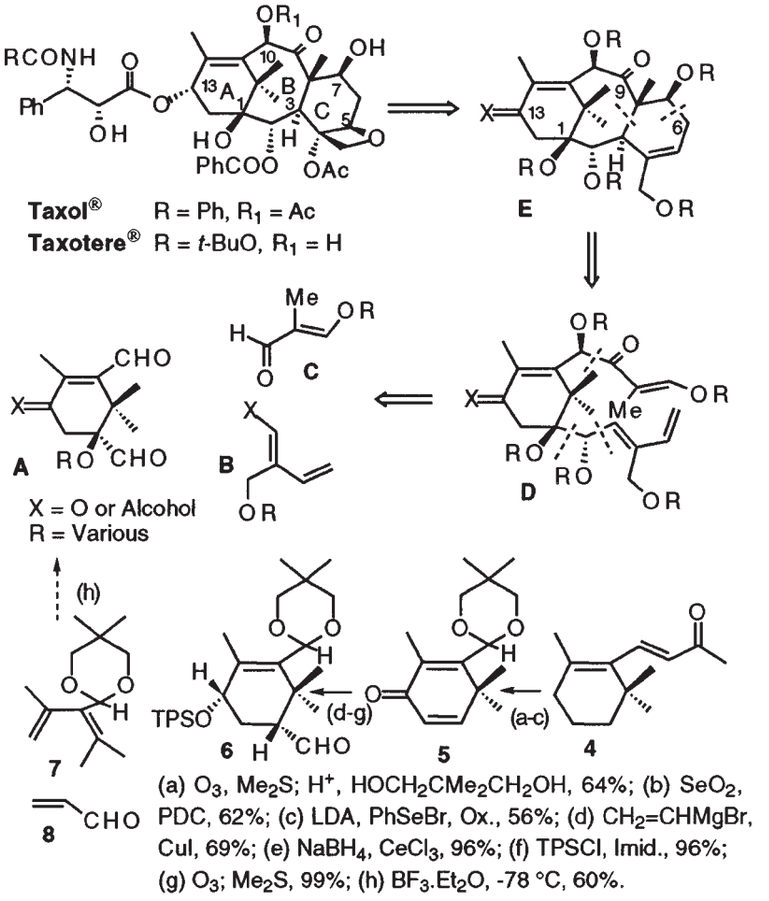


Scheme 3. Convergent A to BC intramolecular Diels–Alder approach.



combinations may be envisioned for the tricyclic skeleton. Our investigations have evolved to encompass aspects of several diverse cycloaddition strategies (eqs. [1]–[3]), but many other variations, such as those in the boxes, have not been examined.

In previous studies, the C ring has been constructed using a bicyclo[2.2.2]octene precursor as an scaffold (11). It was assumed that the rigid geometry imparted by this bicyclic framework was required to hold the diene in an axial orientation. This maintains the close proximity of the reactive components in order to achieve the proper alignment for the cyclization transition state and overcome the entropic difficulties that were believed to be associated with a conformationally mobile ring system such as a cyclohexene. Conformational analysis of substituted cyclohexenes suggested that additional ring constructions should not be required to access the transition state geometry for ring C directly, when the diene and dienophile are attached to a cyclohexene. To further encourage the cycloaddition, the rotational parameters normally encountered with olefinic partners were minimized by selecting an acetylenic dienophile. Model studies using this convergent approach led to the successful preparation of the functionalized tricyclo-[9.3.1.$0^{3,8}$]pentadecatriene adduct **2** from **1,** and the structure was confirmed by conversion to the aromatic system **3** (Scheme 2) (10). The C_2 stereocentre controls the adduct stereochemistry from an *endo* transition state in accord with other studies concerning the π-facial selectivity of related cycloadditions (12).

A more detailed retrosynthetic analysis requires replacement of the ester side chain by a carbonyl or alcohol and removal of the ring D oxetane to afford the tricyclic skeleton **E** (Scheme 3). Subsequent double disconnection between C_6–C_7 and C_3–C_8 in ring C (retro-Diels–Alder) in this

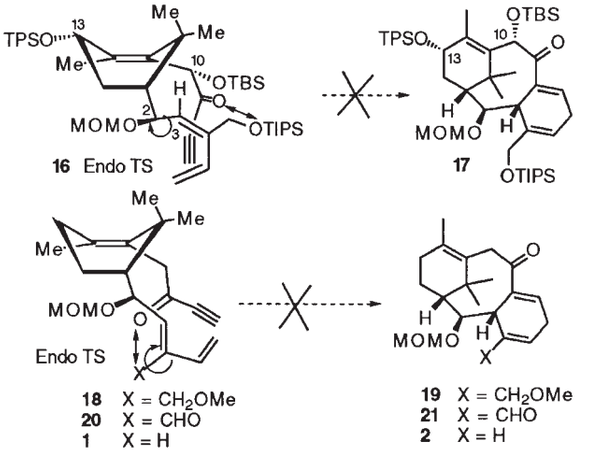
intermediate suggests a precursor related to the tetraene **D** (Scheme 3). In principle this intermediate could contain the majority of the paclitaxel (Taxol®) oxygen substituents, although in practice the use of less substituted systems appeared more prudent. Construction of **D** may be envisaged in a direct manner from further disconnections between C_1–C_2 or C_2–C_3 and C_9–C_{10}. In total, this leads to a highly convergent approach to the taxane nucleus from a suitably functionalized ring A building block in the form of a masked dialdehyde synthon related to **A** followed by attachment of the lower diene and upper dienophile units **B** and **C**, respectively.

The extension of this chemistry required the introduction of more oxygen functionality and a hydroxymethyl diene substituent (such as **B**) for the eventual introduction of the oxetane. As our research has progressed, the field has advanced rapidly and a better understanding of the factors that must be considered in any synthetic approach to the taxoids has emerged. In particular, it has proven difficult to manipulate many of the required oxygen-containing centres in the intact nucleus. Consequently, it appeared preferable to carry several of these functional groups from an early stage.

The required ring A building blocks were constructed using β-ionone (**4**) to give **6**, or, more directly, by the Diels–Alder reaction between an appropriate trimethyl-substituted diene-acetal **7** and acrolein (**8**) under Lewis acid catalyzed conditions (Scheme 3) (13).

Scheme 5. Representative attempted cycloadditions.



The required dienes **B** were initially synthesized by palladium-mediated addition and coupling of the appropriate alkene unit followed by halodesilylation (14). However, a more versatile route employed the addition of vinylmagnesium chloride to trimethylsilylpropargyl alcohol (**9**) via the putative magnesium chelate **10** to afford the (*E*) and (*Z*) dienes **13** or **14** as required (Scheme 4) (15). Condensation of the derived vinyl anion with the appropriate ring A aldehyde proceeded in yields of 80–95% with a diastereoselectivity of ~5:1 (Table 1), and attachment of the upper acetylenic dienophile afforded the cycloaddition precursors in Scheme 5 (16).

It was anticipated that cyclization of these compounds would provide the desired tricyclic nucleus. Molecular models and computer modeling suggested the cycloaddition transition states illustrated (Scheme 5) should be preferred. These reactions failed. Initially it appeared the potential 1,3 interaction between the C_{13} ether and the axial bond connecting the diene side chain was the culprit. However, this is not the case, since after completion of these investigations, Winkler et al. (17) reported the successful cyclization of a closely related example **22** to **23** (Scheme 6) with an *endo* C_{13} ether substituent. Danishefsky and co-workers (18) dis-

© 1999 NRC Canada

covered that an epimeric ether (compared to Taxol®) at C_{10} (as contained in **16**) inhibited the Diels–Alder cyclization of ring A in a steroid-based model. This was not the problem in this case, as compound **18** differs from the successful model system **1** only by the inclusion of the methoxymethyl ether diene substituent in place of hydrogen (X = CH_2OMe vs. X = H). The preferred transition state in which the cyclohexene is distorted into a boatlike conformation allows reasonable alignment between the acetylenic ketone and the diene unit. However, the substituent (X = CH_2OMe), due to its rapid free rotation, inhibits the close approach of the dienophile. Even the sterically less demanding aldehyde **20** (X = CHO) did not cyclize to **21**, in spite of the fact that carbonyl groups in the 2-position of dienes usually render them particularly reactive (19). The Winkler results (17) confirm that the diene substituent is the problem, as the diene in **22** (Scheme 6) is both more reactive and lacks this substituent. A revision of our approach to the challenging tricyclo-[9.3.1.$0^{3,8}$]pentadecene nucleus was required.

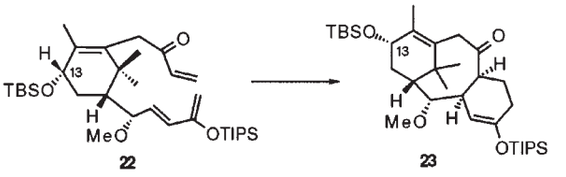
Tether control groups

In related research we are developing various "tether-control groups" (Table 2) for intramolecular reactions (pericyclic, free radical, dipolar, enolate, metal mediated, etc.) (20). These constructs are useful, as intramolecularity by itself is often insufficient to ensure the best levels of stereoselectivity in complex reactions. Functional groups that limit the flexibility of the side chain and impose a restricted geometry on the reactive components will facilitate the achievement of the requisite transition state and lower the activation barrier. When a chiral group is employed it will induce the desired enantioselectivity to afford chiral nonracemic products. In addition, the group should be selected so the product will contain useful functionality for subsequent synthetic manipulation.

The effect on intramolecular [4 + 2] cycloadditions will be significant, provided the group selected promotes the achievement of a dominant transition state. For example, Diels–Alder cycloaddition of simple trienes to generate decalins often requires long reaction times, high temperatures, and the selectivity is often disappointing (21). However, limiting the flexibility in the side chain, through the incorporation of a planar moiety (such as an olefin or aromatic or heterocyclic ring), should enhance the transition state interaction between the reactive components (A, B) and facilitate a variety of intramolecular reactions. Various examples of this beneficial template effect have appeared in the literature, but a systematic study does not appear to have been reported. Representative reactions include intramolecular alkylations for 10-membered rings (22), radical cyclizations (23), olefin metathesis (24), and cycloadditions of metal carbenes (25). Chiral, nonracemic tartrate- and carbohydrate-derived isopropylidene acetals also fulfill the criteria above and can be synthesized easily. In addition, they are usually available in both optical series and these groups supply useful functionality.

Previous strategies to increase the level of regio- and stereochemical control in intramolecular cycloadditions have included the use of cleavable control groups such as silyl acetal tethers (26) that may contain stereocenters (27*a*), conformationally restricted diester spacers (27*b*), as well as chiral Lewis acids (28), chiral auxiliaries (29), magnesium chelation (30), and chiral copper complexes (31). The ring cleavage products, from removal of the control group of appropriate adducts, constitute an intermolecular cyclohexene synthesis, while the bicyclo[4.4.0] nucleus can be used independently or expanded.

Scheme 6. Diels–Alder cycloaddition (17).



The following examples illustrate the utility of planar control groups. Thus with a benzene group in the tether the cycloaddition illustrated (**24** to **26**, Scheme 7) occurred readily during oxidation with Dess–Martin periodinane (2 h, 48°C, 95% yield) to give a single diastereomer (X-ray) (20). This result illustrated the dramatic improvement that arose from the restricted rotational freedom in the side chain due to the presence of the aromatic ring. Thus, the required diene–dienophile interaction was readily achieved. This adduct arose from preferential addition *anti* to the methoxymethyl ether substituent via an *endo* transition state as illustrated. This orientation places the OR_1 group in an axial position. Thus the 1,3-allylic interaction with the bulky group on the diene (arrow) that occurs in the *endo* approach from the opposite face (hydrogen and ether are interchanged) is avoided. Varying the ether substituents (PMB, Bn, Bz) in **24** did not alter the π-facial selectivity observed, but the yields were reduced (52–83%). This stereochemical preference is consistent with related diene – allylic ether cycloadditions (12).

A *cis*-olefin produced a similar beneficial effect in refluxing dichloromethane and provided the adduct **27** in 73% yield but with lower selectivity (2:1). Cyclopentadiene reacted readily with the enone **27** at 0°C in the presence of diethylaluminum chloride to generate the expected tetracyclic ketone in 87% yield (*syn/anti*, 9:1) as a consequence of *endo* addition of the cyclopentadiene *syn* to the methoxymethyl ether substituent.

New taxoid approach

Encouraged by these results, a new convergent, double, intramolecular Diels–Alder strategy for taxoids has been devised that proceeds in a right-to-left (C to BA) direction (Scheme 1, eq. [2]) (32). A key feature of this route is the use of a chiral isopropylidene acetal tether control group in **30** (Scheme 8) to impart asymmetry, facilitate the attainment of the requisite transition state for the intramolecular cycloaddition to form the C ring, and introduce latent functionality for subsequent ring cleavage to a substituted cyclohexene. Thus functional group modification of **31** leads to a second Diels–Alder precursor **29**. An ester group was selected as a surrogate for the C_{19} methyl group in order to facilitate the chelated transition state illustrated in Scheme 9 (**32**). Lewis acid coordination should occur between this ester and the dienophilic carbonyl to give the desired adduct

33. However, careful choice of the reactive components is required, as certain substitution patterns have been found to afford the unnatural (C-1 epimeric) stereochemistry from an *exo–anti* cyclization (Scheme 10) (33*a*).

Isopropylidene acetals hold promise for the control of many intramolecular reactions although only a few cases of this beneficial effect have appeared in the literature and a systematic study does not appear to have been reported. Representative examples include radical cyclizations (34) and 2-azaallyl cycloadditions (35). In addition, the behavior of 1,7,9-decatriene-3-ones bearing isopropylidene acetals adjacent to the diene have been examined by Roush and coworkers (36) in their synthesis of nargenicin A_1. However, as discussed below, placement of the acetonide β to both the diene and dienophile improved the stereoselectivity for the synthesis of substituted decalins.

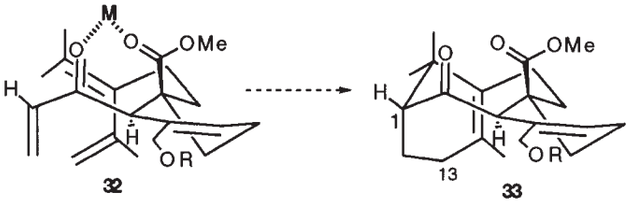
The required trienol precursors related to **30** were prepared from the known *tert*-butyldimethylsilyl ether-aldehyde **36** (Scheme 11) (37). Condensation of this aldehyde with the organolithium reagent derived from the halogen–metal exchange with butadiene **14** (15) afforded the secondary alcohol as a 2:1 epimeric mixture. The major diastereomer was separated and protected as its methoxymethyl ether to give **37**. Desilylation was effected with *n*-tetrabutylammonium fluoride to give **38** (94%). Subsequent Swern oxidation and vinyl magnesium bromide addition yielded the trienol **39** (38). To ascertain the potential influence of the methoxymethyl ether substituent upon the stereoselectivity of the cycloaddition in this *trans* series, the trienol **43** was synthesized from (L)-ascorbic acid via the epoxide intermediate **40** (39), followed by epoxide ring opening by butadienyllithium addition (40) to give **41**. Subsequent isomerization afforded **42**, while oxidation to the aldehyde and condensation with vinyl magnesium chloride gave **43**.

Swern oxidation of **39** afforded ketone **44**, which cyclized readily to afford **45** (X-ray) as a single enantiomer (Scheme 12). Acid hydrolysis of the acetal and lead tetraacetate cleavage of the resulting diol in methanol gave the ester-aldehyde **46.** Wittig condensation with **46** afforded the alkene **47**. Unfortunately, base-catalyzed methods to introduce the diene side chain were unsatisfactory and it was necessary to add this component as a vinyl anion. The methyl-substituted diene-vinyl iodide appendage **52** required for the taxane nucleus was synthesized by a copper-mediated addition followed by coupling of **50** and **51** as illustrated (Scheme 13) and demonstrates the power of modern organometallic chemistry for the facile preparation of these triene systems. Thus the parallel sequence to Scheme 12 provided the pentadiene ketone **55**. The results from several *trans* isopropylidene acetal mediated cycloadditions are listed in Table 3 (38). In favourable cases the intermediate ketones were not isolated, but were cyclized directly to avoid a mixture of adduct and enone. The efficient cyclization of **55** to the adduct **56** (97%) under mild conditions and without recourse to Lewis acid was particularly gratifying. Thus the stage appeared to be set for conversion of this material to the taxane nucleus.

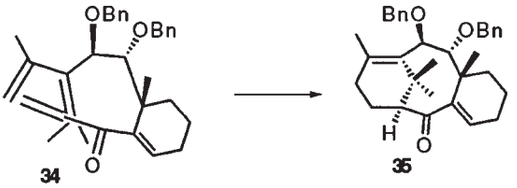
These decalin adducts **45**, **54**, and **56** arose from preferential addition via an *endo* transition state in which the side chain adopted a chairlike conformation, as illustrated in **59**. The number of possible transition states was reduced due to the presence of the *trans* isopropylidene unit in which the

© 1999 NRC Canada

Scheme 9. Proposed ring A cycloaddition.



Scheme 10. *exo* Ring A cycloaddition.



oxygen substituents were constrained to a diequatorial orientation. The altertative *endo* transition state **60** prefers a boatlike conformation with a 1,3-allylic interaction between the ether substituents. In the case of **57**, which lacks both the secondary ether and the vinyl substituent, the stereoselectivity of the cycloaddition might be expected to be reduced. However, the interactions between these groups were less important due to the overriding influence of the cyclic acetal, which afforded the same predominant stereochemistry in the adduct **58**.

Treatment of **56** (Scheme 14) with aqueous acid generated the diol **61**. Unfortunately, in contrast to the model studies with **45**, the oxidative cleavage of this diol with lead tetraacetate was very troublesome and did not afford the desired ester-aldehyde **62**, but instead gave only a low yield (~20%) of the acetal-lactone **63** from capture of the methoxyhemiacetal by the carboxylic acid. The diol was inert to treatment with sodium metaperiodate and related reagents even at elevated temperatures. This lack of reactivity is a consequence of the preferred conformation of **61** in which the methoxymethyl ether and the diene substituent adopt equatorial positions to minimize their steric interactions. This places the adjacent hydroxyl functions in a diaxial orientation. Thus reagents that require a cyclic intermediate prior to bond cleavage will not be effective. Oxidation of **61** to the triketone was not a clean reaction, and reduction with sodium borohydride to the triol followed by cleavage experiments was also unsatisfactory. Consequently, the best alternative, to capitalize on the chemistry we have developed, is the use of a "*cis*-tartrate" precursor for the cycloaddition.

The required *cis* substrates for the model studies were synthesized as summarized in Scheme 15 following a sequence that was developed from (L)-arabinose (41), or alternatively from (L)-gulonolactone via the bis acetal **69** (42), followed by reduction and protection to give **70** and selective periodic acid oxidation to generate the aldehyde **71**. Unfortunately the Horner–Emmons reaction with **64** could not be scaled up efficiently nor was it possible to selectively protect the primary alcohol due to the preference of **64** to exist in the closed hemiacetal form. In addition, our desire to have a hydroxymethyl substituent was thwarted by the instability of the required reagents. Thus a novel pentadienyl indium synthon has been developed to introduce the triene unit via the intermediacy of the homo-allylic alcohol **66**, followed by elimination of water to afford **67** (Y = $CH{=}CH_2$). These versatile building blocks hold promise for diverse transformations, particularly tandem cycloadditions of the triene unit. In contrast to pentadienyllithium reagents, these indium species add selectively at the γ position (43). To complete the synthesis of these tetraenols, the upper dienophyllic units were added as described above.

As listed in Table 4, the *cis* isopropylidene acetal systems cyclized readily at mild temperatures to afford the single adducts **73**, **75**, **78**, and **79** in good yield. The cycloadditions of **76** and **77** were particularly expedient and the enone was not detected. Thus epimerization of an acetal centre improved the efficiency of the reaction and led to the same stereochemical result as above from the preferred transition state **80**, via a boatlike conformer that placed the diene and dienophile in close proximity for facile cyclization. Other transition states such as **81** are disfavoured due to the significant nonbonded interactions illustrated. Scheme 16 outlines the anticipated route for the preparation of the desired taxoid skeleton **84**.

The versatility of **68** derived from the pentadienyl indium reagent is illustrated (Scheme 17) by the rapid assembly of highly oxygenated, nor-methyltriterpenoid and steroid type skeletons from a double cycloaddition sequence. Thus the synthesis of **85** and **86** from **68** arises directly from a tandem cycloaddition to afford tetracyclic systems enantioselectively. The fourth ring added from the most accessible convex face of **78** in an *endo* fashion. In addition, the diketone ring in **85** may be viewed as either the A or the D ring component depending upon the synthetic objective. Furthermore, the ring fusion may be adjusted due to the presence of the adjacent ketone functionality. Less complex triene units allow the rapid construction of multicyclic skeletons by tandem cycloadditions with the same dienophile.

Enediynes

The enediyne family of anticancer antibiotics continues to be a topic of considerable current interest. This is a consequence of their novel mechanism of DNA cleavage involving cycloaromatization to benzyne diradicals and the synthetic challenge presented by the natural products themselves. This has also stimulated the design and synthesis of simpler less toxic analogs (44). Esperamicin (45) and calicheamicin (46) in particular have received widespread attention. In addition, preliminary studies on a number of hybrid structures that mimic established biologically active agents have been reported. These include incorporation of part of

the steroid nucleus (estramycins) (47), β-lactams (lactendiynes) (48), and enediynes linked to diethylstilbestrol (49).

We have designed a new family of potential anti-tumor agents (taxamycins (**88**), Scheme 18) (50) that combine aspects of the important pharmacophores in both the taxoid and enediyne families in which suitable functionality should facilitate tubulin binding and cycloaromatization would induce cell damage. In addition, it was hoped that the 12-membered ring system might suffice for the synthesis of aromatic taxanes (Scheme 18).

To investigate this potential, the 12-, 11-, and 10-membered ring species have been prepared. Condensation of our triisopropylsilyl-enediyne building block **87** with suitable ring A precursors allowed conversion to suitable iodoacetylene aldehydes. The best cyclization conditions involved the use of the $[CrCl_2(THF)_2]$ complex to afford the bridged bicyclic systems (Scheme 19) (51). Thermolysis of **93** gave only small amounts (5%) of aromatic material. As Table 5 indicates, the c–d separation exceeds the 3.1 Å distance required for spontaneous cyclization, and thus removal of the bridgehead double bond will be required for facile cycloaromatization.

It was anticipated, by analogy with taxoid systems, that allylic oxidation of **96** and **101** would introduce the desired oxygen at C_{13} (taxane numbering) for attachment of the appropriate side chain. However, oxidation by reagents such as CrO_3 or PCC resulted only in recovery of starting material. Treatment of the acetate **96** with selenium dioxide in dioxane at 60–70°C afforded exclusively the C_2 ketone **97** in 89% yield. The strain and lack of orbital overlap in this ring system is reflected in the carbonyl IR band at 1740 cm^{-1}. Initially it appeared that the acidity of the reaction medium had resulted in hydrolysis of the MOM ether followed by oxidation of the resulting alcohol. However, this was not the case, as a parallel oxidation of the methyl ether **101** with excess SeO_2, in dioxane at reflux for 2 h, also gave the corresponding ketone **102** in a yield of 77% (Scheme 20). Consistent with the accepted mechanism of selenium dioxide oxidations (52) these reactions likely proceeded via an ene reaction to form the allene intermediate **99**, followed by

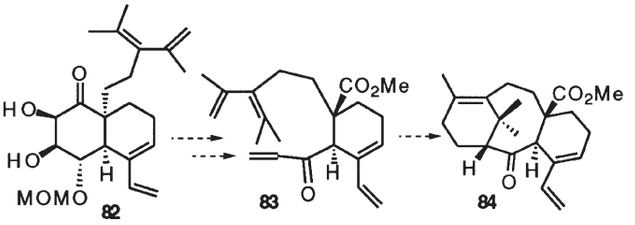
Scheme 16. Proposed ring cleavage and ring A cycloaddition.



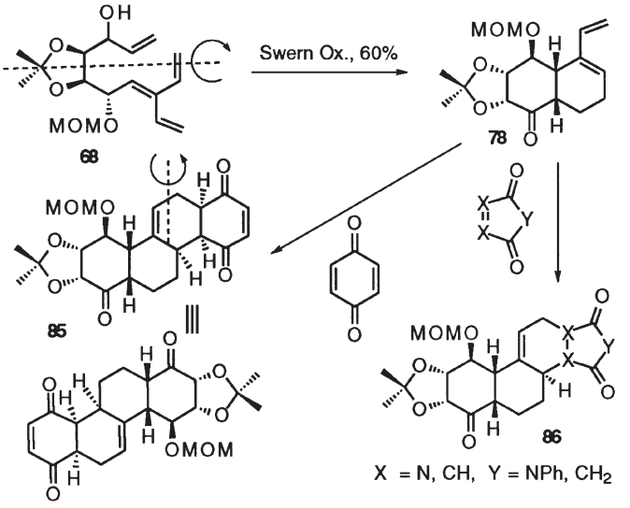
rearrangement to the acetal species **100** and hydrolysis to the ketones upon aqueous work-up. The double bond in the A ring is hindered by both the enediyne bridge on one face and by the sterically demanding *gem* dimethyl group on the other. These features apparently inhibit the approach of the SeO_2 and thus the rearrangement pathway is observed. In principle, the generation of the allene should facilitate the cycloaromatization (Myers cyclization), but this was not observed due to the presence of the bridgehead olefin. However, this oxidation sequence may have potential as a trigger mechanism in other cases.

For proper evaluation, the synthesis of these taxoid mimics (taxamycins) requires the incorporation of a paclitaxel or docetaxel side chain at C_{13} of the bicyclic enediyne framework. In view of the failure to introduce oxygen as described above, the bis-nor methyl system **104** was synthesized (53). The intramolecular coupling of the iodoacetylene **103** proceeded readily, based on our previous research (50, 51) with freshly prepared $[CrCl_2(THF)_2]$ complex (51) in THF to afford the bicyclic system **104** as a single diastereomer in 76% yield. Reasonable yields (60–70%) were also obtained with commercial anhydrous (toluene azeotrope) $CrCl_2$. In contrast to the more sterically demanding cyclizations examined earlier (51), catalytic $NiCl_2$ was not required in these decaenediyne systems. This is consistent with related 10-membered ring enediyne cyclizations (54), although the mechanistic role of Ni(II) in these reactions remains obscure, as many cases require a catalytic amount of $NiCl_2$ (55). A 60% yield of **104** was also achieved from treatment of the aldehyde **103** (R = H) with KHMDS at –78°C, although the anhydrous fluoride-mediated cyclization procedure on the corresponding silylacetylene-aldehyde failed.

Conversion of **104** to its acetate **105** set the stage for oxygen introduction. Oxidation with SeO_2 provided the allylic alcohol **106** (Scheme 21) as a single diastereomer in a yield of 66%. Consistent with a related example (56), this oxidation occurred from the top face as a consequence of the steric hindrance of the enediyne bridge. The diastereomeric alcohol **108** was prepared by oxidation of **106** with Dess–Martin periodinane to afford the crystalline cyclohexenone **107**. X-ray analysis of **107** confirmed the structures in this series. Reduction of the ketone **107** with sodium borohydride in the presence of $CeCl_3$ resulted in the preferential formation of alcohol **108** accompanied by its diastereoisomer (60:40 ratio).

Independently, the two alcohols **106** and **108** were coupled with the oxazolidine **109** (57) (a protected form of the Taxotere® side chain) to provide two separate diastereomeric mixtures (1:1) in quantitative yield represented by the hetero-

Scheme 17. Tandem cycloadditions to nor-triterpenoids and steroids.



cyclic ester **110.** Acid-catalyzed ring opening afforded the four distinct esters that were resolved by chromatography (SiO_2). The individual silyl ether isomers were converted to their C_1 alcohols upon exposure to *n*-tetrabutylammonium fluoride in THF. For clarity, only the taxamycin-10 **111**, possessing the Taxotere® side chain, is illustrated. The stereochemical and electronic features of this compound most closely mimic those of the natural products.

Compared to Taxol®, compound **111** displayed negligible effects on tubulin polymerization and in protecting against Ca^{2+} induced depolymerization. This established that even a functionalized A ring (side chain, double bond, C_1-OH, C_{10}-OAc) is insufficient for tubulin binding. This information will help delineate the structural and functional features required for future investigation. Cytotoxic activity with the HT-29 human cancer cell line was too weak to be useful. This cytotoxic activity should increase in the presence of a cycloaromatization initiator that removes the bridgehead double bond. This double bond was inert to hydrogenation, a feature consistent with hyperstable alkenes (58), and activation by oxidation of the vinyl methyl group failed (SeO_2, CrO_3, PCC).

It was anticipated that formation of a five-membered ring, such as **112**, by conjugate addition, would induce cyclization due to the induced proximity of the terminal acetylenes (Scheme 22). However, generation of the anionic intermediate from the alcohol derived by hydrolysis of acetate **107** after treatment with carbon disulfide resulted in cyclization onto the acetylenic bond to generate **113** instead. Additional efforts to induce cycloaromatization included both intramolecular [4 + 2] and [2 + 2] cycloadditions as well as radical cyclizations. These were not successful and nature, as usual, knows best, since the sulfur anion in the natural products is oriented so that it approaches the double bond in a perfectly perpendicular direction as required for reaction.

Our next goal is to synthesize and examine compounds that possess both antiestrogenic and cytotoxic activity as illustrated in the general concept outlined in Scheme 23. Thus a simpler enediyne **117** has been synthesized as outlined. It

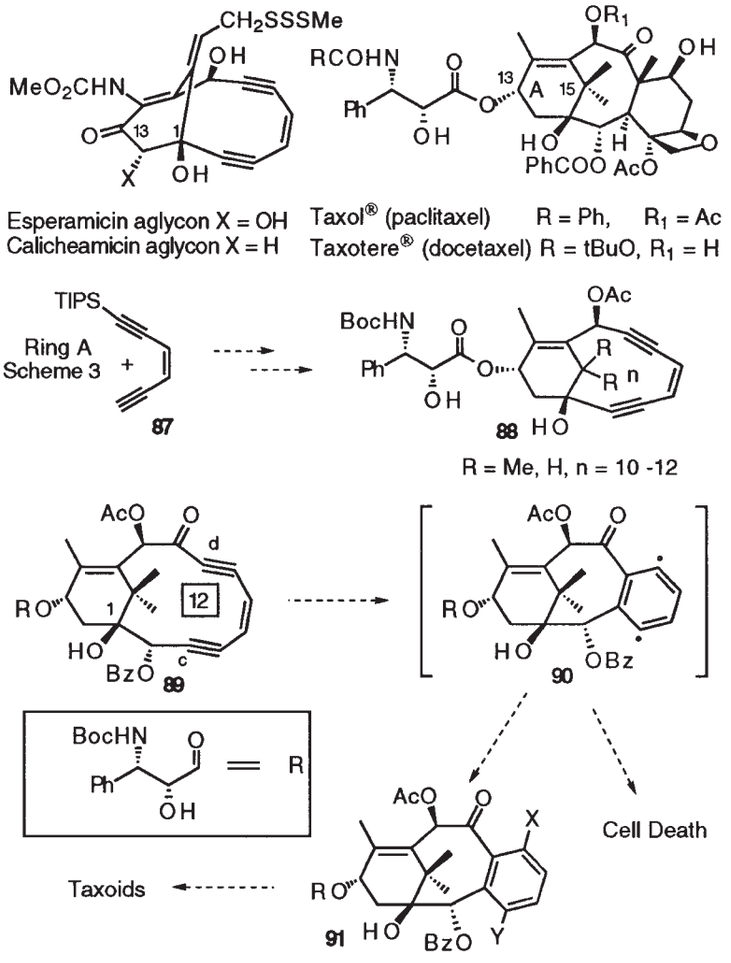
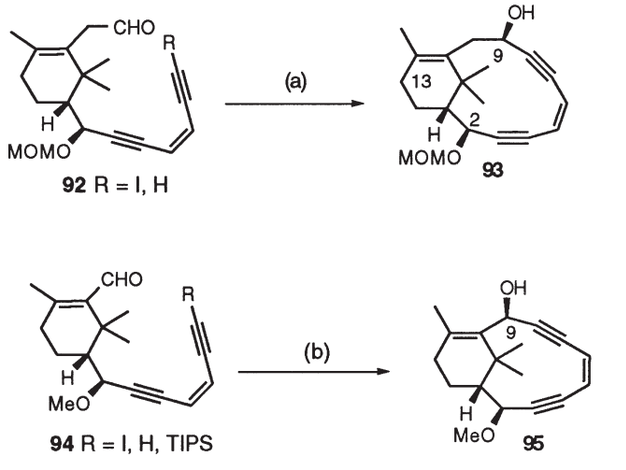


Scheme 19. Synthesis of taxamycin-12 and -11 ring cores.



should undergo cycloaromatization below 50°C. The acetal in **115** acted as both a chiral auxiliary and a control group to facilitate the cyclization. In addition, the strain inherent in the *trans* isopropylidene moiety should inhibit Bergman cyclization initially but allow the close acetylene contact required upon hydrolysis. The enediyne will be linked to a steroidal mimic such as Toremifene®, which is known to interact with the breast cancer receptor. A more interesting and potent combination is to combine a modified form of the new Canadian drug **EM-652** with **117** to generate a viable mimic with therapeutic potential for the treatment of breast cancer.

Enediyne cyclophanes

Diverse families of cyclophanes and assorted cage compounds with novel structures and properties continue to be topics of widespread current interest. (59). We have synthesized the first members of a novel class of enediyne cyclophanes (60) by sequential palladium- or copper-mediated coupling. In contrast to normal [*n.m*]paracyclophanes, the rotation of the ring is not restricted by the bridge. In these compounds the benzene rings rotate freely, and as a consequence of this "skipping rope" property (61), in which the bridging units and one ring may swing around the other, we call these structures revolveneynes. These compounds are

helical and thus chiral. These arrays have considerable potential as liquid crystals, as hosts when heteroatoms are present, possibly as chiral sources of Rh and Pd for catalytic transformations, and for carbon networks including fullerenes.

A double Wittig reaction on 1,4-benzenedicarboxaldehyde afforded the *Z*-dibromodiene **118** in 42% isolated yield. Palladium(0)-based coupling of **118** with trimethylsilylacetylene generated the TMS-protected diacetylene **119,** and the silyl groups were removed with K_2CO_3 in methanol at 21°C to give **119** (R = H) (Scheme 24). The synthesis of **120** was effected by palladium-mediated coupling of the dibromide **118** and the diacetylene in 9% yield. The dimer **121** was synthesized directly (50%) by oxidative coupling. A parallel sequence commencing with 1,2-dibromocyclopentene pro-

vided the diene-tetrayne system **124** (12%) accompanied by the dimer **121** (15%).

Rigid "Dreiding type" molecular models revealed that the unsaturated linkage imparted a helical twist to these structures similar to related D_2 symmetric olefinic paracyclophanes (62). Thus, the strain is relieved by rotation of one benzene ring with respect to the other about an axis that

passes through the centre of both rings. This gyrochiral property implies that at suitable temperatures the enantiomers with substituents or additional bridges may also be resolvable (**122**). As illustrated, the two rings are offset slightly with respect to one another. These structures possess accordionlike flexibility and yet the rigid nature of the bridge presents a large cavity for complexation (inclusion) (63). For example, structures derived from the bipyridine **123** would possess different reactive sites for subsequent functionalization.

In an extension of these studies the diacetylene **127** was prepared and the oxidative coupling examined with the expectation that the dimer **128** would be produced (Scheme 25). Instead, the strained monomer **129** was formed in 91% yield when the reaction was conducted at 80°C. Using similar chemistry, the trienetriyne compound **132** was synthesized from the appropriate Wittig combination (Scheme 26). The reactions in the boxes lacked stereocontrol. Under carefully controlled conditions **132** gave rise to the triply bridged dimer **133.** The hexasubstituted systems have the potential for more complex structures. Thus, by modification of literature protocol (64), the building block **137** was constructed from simpler units (Scheme 27) in the hope that under appropriate conditions it could be trimerized to a hexasubstituted benzene ring. Unfortunately, it was unstable above 40°C and despite a huge effort and a wide range of catalysts (Co, Pd, Pt, Ni, Ti, Ag) the silyl-protected version of **139** was not detected. The synthesis of **139** is being purused by other routes since, as illustrated in Scheme 28, oxidative dimerization of **139** should give **140** by analogy with our previous studies. Bromination–dehydrobromination of the styrenyl bonds should introduce the triple bonds to give the C_{60} allotrope **141** (30 acetylenic bonds, strain energy ~500 kcal/mol greater than C_{60}, (Buckminsterfullerene)) (65). C_{60} sits in a potential well, and by analogy with earlier studies with adamantane (66), thermal rearrangement of **141** should give the spherical C_{60} system. This route has a high probability of providing interesting inclusion compounds (endohedral fullerenes) if complexation precedes rearrangement, as well as more complex fullerenes of higher molecular weight.

Carbometallation studies

We continue to search for short direct routes to the taxane nucleus that may be adapted to prepare analogs, as well as improved methods to prepare Diels–Alder components. In this context, we have further expanded our study of the magnesium chelates used earlier for the synthesis of our dienes

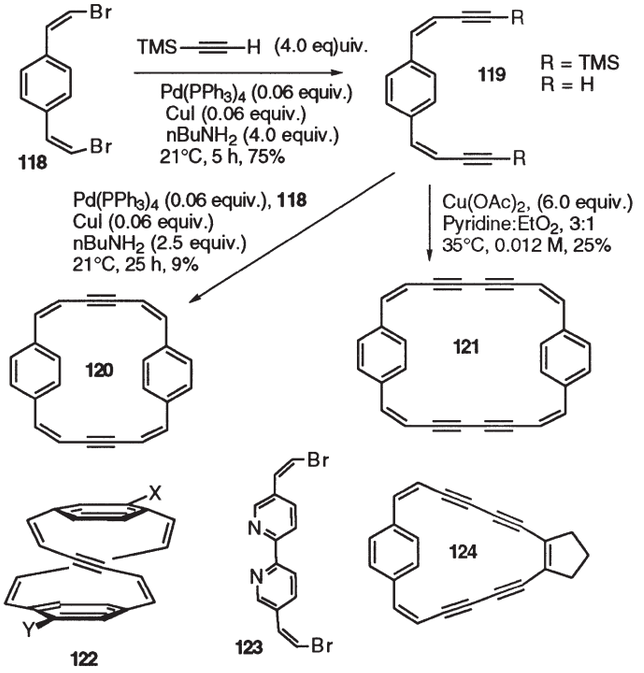
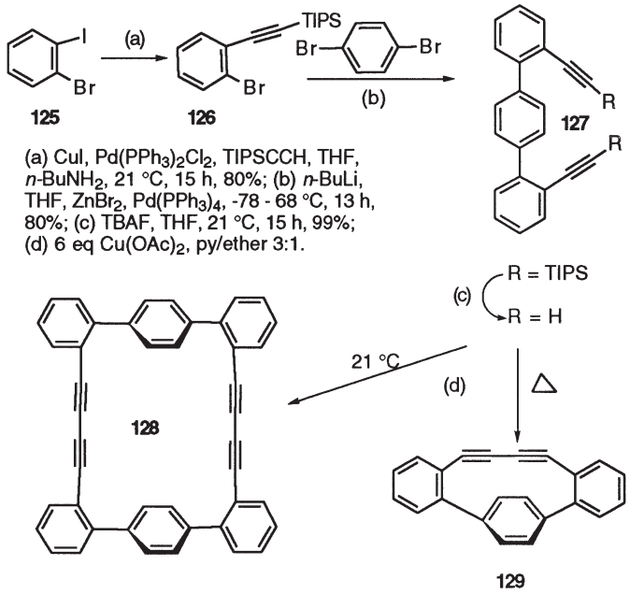


Scheme 25. Synthesis of novel cyclophanes.



(Scheme 4, **10**). Procedures have been developed for the direct condensation of this putative intermediate with aldehydes by conducting the reaction in cyclohexane. Thus direct condensation of **10** (Scheme 29) with the hemiacetal **143** afforded a 40% yield (3:1) of the diene triol **146**. If **10** is reacted directly with DMF, the resultant hemiacetal **142** is converted to the furan **144** (90%) upon acidic work-up. Alternatively, condensation with a nitrile leads to substituted furans of type **145**. These furans may serve as precursors for double cycloaddition reactions (vinyl group, then furan, after isomerization of the exocyclic double bond) and (or) natural products by modification of the substitution pattern. It should be possible to modify these methods for the synthesis of thiophenes and pyrroles.

A further refinement is to generate the key intermediate **10** (Scheme 30) in a different manner by commencing with a lithium acetylide **147**. Condensation with the aldehyde **148** afforded the lithium alkoxide **149**. Subsequent addition of vinylmagnesium chloride and condensation of **10** with nitriles has allowed the synthesis of tetra-substituted furans (**145**) in one reaction pot, a significant improvement over current routes to furans. If **150** is added to trimethylsilylpenta-2,4-diynyl alcohol (**151**), the interesting enediyne alcohol **152** (66) can be prepared in a single step. This type of synthon has many potential applications.

Finally, a potentially short, versatile, strategy for synthesis of taxane systems is being developed based on the following combination. Sequential reaction of the components in Box A (Scheme 31) afforded the diol-pentaene **153** in which R is phenyl. With a methyl group, the corresponding compound **154** (R = Me) has been prepared in a stepwise fashion. After conversion to **154** it is anticipated that the planar tether will facilitate the cycloaddition to **155,** and a final ring C cyclization in either an inter- or, preferably, intramolecular manner may provide **156**. Alternatively, these cyclization steps could be reversed; however, this remains to be tested experimentally.

Concluding comment

In summary, modern life has been greatly enriched by the achievements and discoveries derived from synthetic organic chemistry. It is an important area of investigation in its own right and occupies a key role in a myriad of other disciplines that range from medicine to molecular biology to materials

C(2)-H isotopic exchange in coordinated imidazoles revisited. The case of the $[Co(NH_3)_5ImH]^{3+}$ ion

Charles R. Clark, Allan G. Blackman, M. Ross Grimmett, and Akbar Mobinikhaledi

Abstract: The temperature dependence of the acid ionization constants of $[Co(NH_3)_5ImH]^{3+}$ in H_2O (I = 1.0 M ($NaClO_4$)): pK_a (°C) = 10.10 ± 0.04 (25.0), 9.92 ± 0.03 (30.0), 9.82 ± 0.02 (35.0), 9.62 ± 0.03 (40.0), and $[Co(ND_3)_5ImD]^{3+}$ in D_2O (I = 0.35 M ($NaClO_4$)): pK_a (°C) = 10.58 ± 0.06 (25.0), 9.46 ± 0.08 (60.0) is reported. Observed first-order rate constants for H/D exchange at C-2 in $[Co(ND_3)_5ImD]^{3+}$ over the pD range 8.08–11.20 (60.0°C, I = 0.35 M ($NaClO_4$)) follow an equation of the form: $k_{obs} = k_{OD}K_w/(a_{D+} + K_a)\gamma_{\pm}$, with k_{OD} (0.27 ± 0.06 M^{-1} s^{-1}) corresponding to the rate constant for OD^--catalyzed abstraction of H-2 in $[Co(ND_3)_5ImD]^{3+}$, and K_a ((2.8 ± 0.7) × 10^{-10} M, pK_a = 9.55 ± 0.13) to the acid ionization constant of this species. No evidence was found for a pathway to H/D exchange in the imidazolate moiety of $[Co(ND_3)_5Im]^{2+}$.

Key words: kinetics, H/D-exchange, imidazole, metal complex.

Résumé : On a la relation entre la température et les constantes d'ionisation acide du $[Co(NH_3)_5ImH]^{3+}$ dans l'eau (I = 1,0 M ($NaClO_4$)): pK_a (°C) = 10,10 ± 0,04 (25,0), 9,92 ± 0,03 (30,0), 9,82 ± 0,02 (35,0), 9,62 ± 0,03 (40,0) et du $[Co(ND_3)_5ImD]^{3+}$ dans le D_2O (I = 0,35 M ($NaClO_4$)): pK_a (°C) = 10,58 ± 0,06 (25,0), 9,46 ± 0,08 (60,0). Les constantes de vitesses du premier ordre observées pour l'échange H/D en C-2 du $[Co(ND_3)_5ImD]^{3+}$, à des pD allant de 8,08 à 11,20 (60,0°C, I = 0,35 M ($NaClO_4$)), obéissent à une équation de la forme: $k_{obs} = k_{OD}K_w/(a_{D+} + K_a)\gamma_{\pm}$ dans laquelle k_{OD} (0,27 ± 0,06 M^{-1} s^{-1}) correspond à la constante de vitesse de la réaction d'ablation du H-2 du $[Co(ND_3)_5ImD]^{3+}$ par OH^- et K_a ((2,8 ± 0,7) × 10^{-10} M, pK_a = 9,55 ± 0,13) à la constante d'ionisation acide de cette espèce. On n'a observé aucune voie permettant l'échange H/D de la portion imidazolate du $[Co(ND_3)_5ImD]^{3+}$.

Mots clés : cinétiques, échange H/D, imidazole, complexe métallique.

[Traduit par la Rédaction]

Introduction

There have been a number of studies focusing on isotopic hydrogen exchange in coordinated imidazoles (1–7). Such exchange is base-catalyzed, is favored for C-2 rather than C-4, C-5 (5), and appears to involve rate-determining formation of ylide intermediates (5–7). One such investigation, which has laid the foundation for knowledge in this area, is that by Buncel et al. (7), who described the pathways leading to detritiation of the substitution inert complex $[Co(NH_3)_5[2\text{-}^3H]ImH]^{3+}$ (cf. Fig. 1). Two routes to exchange were reported to be involved: for weakly alkaline solutions reactivity was said to be dominated by an OH^--catalyzed reaction on the $[Co(NH_3)_5[2\text{-}^3H]ImH]^{3+}$ ion, whereas for pH > 10 it was stated that a similar process on the conjugate base, $[Co(NH_3)_5[2\text{-}^3H]Im]^{2+}$, became increasingly important. The latter result was most surprising since OH^--catalyzed H-atom abstraction from the anionic imidazolate center would be expected to be very unfavorable from the energetic point of view. We have had occasion to re-examine C(2)-H exchange in $[Co(NH_3)_5ImH]^{3+}$, and our findings are at odds with those originally reported. Our results derive from a kinetic study of H/D exchange in $[Co(NH_3)_5ImH]^{3+}$ and are given below.

Experimental

Caution: Although no problems were encountered in the synthesis and handling of the materials described below, those containing perchlorate are potentially explosive and should be handled with great care.

$[Co(NH_3)_5ImH](ClO_4)_3$ (8) and $[Co(NH_3)_5ImCo(NH_3)_5](ClO_4)_5$ (9) were prepared using standard procedures. Both were purified by recrystallization from water. D_2O (99.9 atom% D) and NaOD solution (30 wt.%, 99+ atom% D) were obtained from Aldrich. ^1H NMR spectra were recorded using a Varian VXR 300 spectrometer.

Rates of H/D exchange at C-2 for $[Co(NH_3)_5ImH]^{3+}$ in D_2O were obtained by following the decay of the H-2 signal by ^1H NMR spectroscopy. For kinetic runs at pD < 9.3 solutions of the complex (0.05 M, 350 μL) and $NaClO_4$ (0.40 M, 350 μL) in D_2O were mixed, and the pD adjusted to the required value with NaOD (1.0 M). The resultant solution

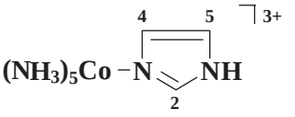
Fig. 1. Atom numbering scheme for imidazole coordinated to the $Co(NH_3)_5$ center.



was placed in a sealed NMR tube and maintained at 60.0 ± 0.1°C (water bath). At known time intervals the room temperature ^{1}H NMR spectrum of the sample was recorded. For reactions carried out at pD > 9.3 direct integration failed to give reliable peak areas, owing to increasing broadness of the signals. In these cases a quench method was employed. A reaction mixture consisting of 3.0 mL of complex (0.05 M), and 3.0 mL of $NaClO_4$ (0.40 M) in D_2O was maintained at 60.0 ± 0.1°C. At various times aliquots (700 μL) were placed in an NMR tube, and DCl (30–40 μL, 0.9 M) was added. The ^{1}H NMR spectrum of the acidic solution was then recorded and peak areas obtained by integration as before. H-2 signal areas were measured relative to nonexchanging H-4 and H-5. Plots of ln (normalized peak area) versus time were linear over $3t_{1/2}$, and rate constants were obtained from their slopes.

pD measurements were made using a Radiometer PHM 82 pH meter fitted with G2040B glass and K4040 calomel electrodes. Measurements were carried out using a salt bridge (NH_4NO_3 = 1.6 M, $NaNO_3$ = 0.2 M) to separate the test solution from the calomel electrode. The system was standardized using 0.025 M Na_2HPO_4 – 0.025 M KH_2PO_4 (pH 6.865 (25°C), 6.836 (60°C)) and 0.0100 M Borax buffers (pH 9.185 (25°C), 8.962 (60°C)). pD was obtained using the empirical relationship $pD = pH_{meter\ reading} + 0.40$ (10). Rate constants were calculated using $pK_w(D_2O) = 13.918$ at 60.0 °C (11) and a value for $\gamma_\pm$ of 0.67 at I = 0.35 M $NaClO_4$ (interpolated from data given by ref. 12).

pK_a values are given as mixed constants, i.e., $K_a(D_2O) = a_{D+}[A^-]/[DA]$, $K_a(H_2O) = a_{H+}[A^-]/[HA]$. For $[Co(NH_3)_5\ ImH](ClO_4)_3$ in D_2O the pK_a was determined at 25.0 and 60.0°C (I = 0.35 M, $NaClO_4$) by potentiometric titration of 0.0183 M solutions (10 mL) with standardized NaOD (0.283 M). Data were treated by the method of Albert and Serjeant (13). The pK_a of $[Co(NH_3)_5ImH](ClO_4)_3$ in H_2O was similarly determined at 25.0 (10.10 ± 0.04), 30.0 (9.92 ± 0.03), 35.0 (9.82 ± 0.02), and 40.0°C (9.62 ± 0.03) for I = 1.0 M ($NaClO_4$).

Results and discussion

In neutral to alkaline D_2O solution all ammine–amine hydrogens in $[Co(NH_3)_5ImH]^{3+}$ exchange rapidly with solvent. Thus, for this condition the species finally present is the $[Co(ND_3)_5ImD]^{3+}$ ion.[2] Potentiometric titration of ca. 0.02 M solutions of the complex in D_2O (I = 0.35 M ($NaClO_4$)) established pK_a = 10.58 ± 0.06 at 25.0°C and pK_a = 9.46 ± 0.08 at 60.0°C, cf. eq. [1]. These data indicate a temperature dependence for the pK_a of –0.032 units/°C, which compares

Table 1. Observed and calculated rate constants for H/D exchange at C-2 in $[Co(ND_3)_5ImD]^{3+}$ at 60.0°C, D_2O solution, I = 0.35 M ($NaClO_4$).

pD[a]	$10^9 a_{D^+}$/M	$10^6 k_{obs}/s^{-1}$	$10^6 k_{calc}/s^{-1}$[b]
8.08	8.32	1.25	0.986
8.32	4.79	2.36	1.67
8.64	2.29	2.78	3.29
8.79	1.62	4.17	4.45

9.90	0.126	21.4	20.6
10.09	0.0813	26.9	23.1
10.57	0.0269	27.8	27.2
10.99	0.0102	27.5	28.7
11.20	0.00631	27.8	29.1

[a]Obtained from pD measurements at 25.0°C using a correction factor for the $[Co(ND_3)_5ImD]^{3+}$–$[Co(ND_3)_5Im]^{2+}$ buffer system of –0.032 pD units/°C.

[b]Calculated using eq. [2] and the values of the constants given in the text.

$$[1] \quad [Co(ND_3)_5Imd]^{3+} + D_2O \overset{K_a}{\rightleftharpoons} [Co(ND_3)_5Im]^{2+} + D_3O^+$$

with –0.032 units/°C for ionization of $[Co(NH_3)_5ImH]^{3+}$ in H_2O, see above. Thus, the deutero substrate in D_2O (pK_a = 10.58, 25.0°C) is a somewhat weaker acid than its protio counterpart in H_2O (pK_a = 10.10, 25.0°C, I = 1.0 M $NaClO_4$), as is usually observed (14). Also, the acidity difference ($\Delta pK_a \approx 0.5$) is of the expected magnitude; e.g., $[Co(ND_3)_5OD_2]^{3+}$ in D_2O, pK_a = 6.70; $[Co(NH_3)_5OH_2]^{3+}$ in H_2O, pK_a = 6.22 (25.0°C, I = 0.30 M $NaClO_4$) (15).

Rate data for H/D exchange at C-2 were obtained using ^{1}H NMR spectroscopy over the pD range 8.08–11.20 at 60.0°C for self-buffered solutions of $[Co(ND_3)_5ImD]^{3+}$–$[Co(ND_3)_5Im]^{2+}$. Under these conditions H-4 and H-5 do not exchange to any measurable extent. For pD > 9.3 the ^{1}H NMR signals of the heterocyclic ligand were increasingly broadened, presumably from quadrupolar coupling by imidazolate nitrogen; however, acid quenching of the kinetic solutions resulted in sharpened signals with a concomitant improvement in integration quality. No evidence was found for complex decomposition at high alkalinity, as has been reported for the protic system (7). Observed first-order rate constants, Table 1, vary according to eq. [2] and are plotted as log k_{obs} versus pD in Fig. 2. Least-squares fitting of the data to eq. [2] using the known

$$[2] \quad k_{obs} = \frac{k_{OD}K_w}{(a_{D^+} + K_a)\gamma_\pm}$$

value for $K_w(D_2O)$ of 2.08×10^{-14} M^2 (i.e., pK_w = 13.918, 60°C, (11)) gave k_{OD} = 0.27 ± 0.06 M^{-1} s^{-1} and K_a = (2.8 ± 0.7) × 10^{-10} M (i.e., pK_a = 9.55 ± 0.13). We interpret these results in terms of the mechanism given in Scheme 1, with exchange at C-2 occurring exclusively via an OD^--catalyzed

[2] Such exchange necessarily results in isotopic dilution of solvent D_2O. For the 0.02–0.05 M $[Co]_T$ solutions used in the present study deuteration at the ammine–amine centers introduces 0.29–0.72 atom% H into the solvent.

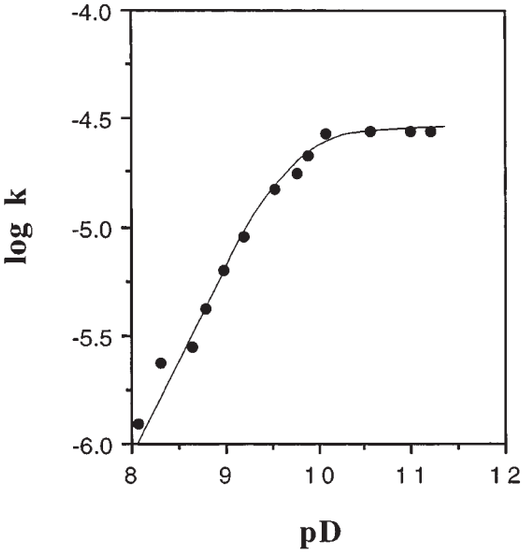
Fig. 2. Plot of log k_{obs} versus pD for exchange of H-2 in $[Co(ND_3)_5ImD]^{3+}$ (D_2O, 60.0°, I = 0.35 M ($NaClO_4$)). The points are experimental, and the curve is drawn using eq. [2] and the values of the constants given in the text.



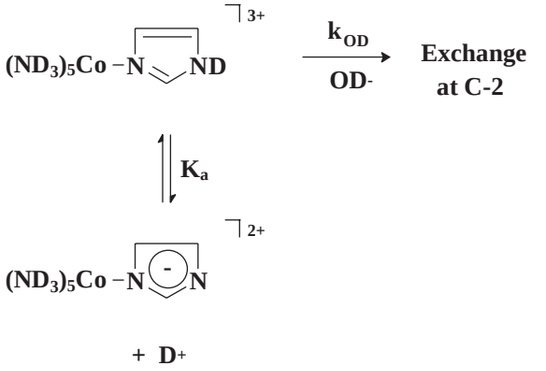
reaction (k_{OD}) on $[Co(ND_3)_5ImD]^{3+}$. The value of the kinetically defined acidity constant is in excellent agreement with that obtained by independent potentiometric measurements for the same conditions (i.e., pK_a = 9.46, 60.0°C, I = 0.35 M). Also, and most importantly, the data appear to exclude a pathway involving OD^--catalyzed exchange in the $[Co(ND_3)_5Im]^{2+}$ ion.

In the earlier study (7) it was claimed that observed rate constants for detritiation of $[Co(NH_3)_5[2\text{-}^3H]ImH]^{3+}$ in H_2O at 60.0°C followed the rate law given by eq. [3], with k_{OH} (= 1.24 M^{-1} s^{-1}) and

$$[3] \qquad k_{obs} = \frac{k_{OH}K_w + k'_{OH}K_a[OH^-]}{[H^+] + K_a}$$

k'_{OH} (= 1.21 × 10^{-3} M^{-1} s^{-1}), respectively, representing the rate constants for OH^--catalyzed detritiation of $[Co(NH_3)_5[2\text{-}^3H]ImH]^{3+}$ and its conjugate base, $[Co(NH_3)_5[2\text{-}^3H]Im]^{2+}$. However, for this interpretation to be valid the pH-rate profile is required to be sigmoidal (cf. eq. [3]), and the certain reactivity of the $[Co(NH_3)_5[2\text{-}^3H]Im]^{2+}$ ion is demonstrated only if a first-order in $[OH^-]$ dependence is observed at high pH. The *experimental data* of the earlier study did not support the proposal, since k_{obs} tended toward a limiting value at pH ≈ 9.5 but never exhibited the necessary first order in $[OH^-]$ behavior at higher pH.[3] This, taken with the present results, argues against an exchange pathway involving Co(III)-coordinated imidazolate. On the assumption that reaction by this route could make a 5% contribution to the observed rate at pD 11.2 and remain undetected we calculate a maximum value for k'_{OD} (cf. k'_{OH} of eq. [3] but for H/D exchange) of ≤5 × 10^{-4} M^{-1} s^{-1}. This finding is in agreement with expectations for this system.

Scheme 1.



H/D exchange rates in imidazoles are reasonably well correlated with ^1H NMR signal positions.[4] The latter provide a measure of electron density at C-2, with any increase in electron withdrawal from the heterocyclic ring manifesting itself in a down-field shift in H-2 and favoring OD^- attack. This is readily seen when data for the dimethylimidazolium and methylimidazolium ions (k_{OD} = 10^3–10^4 M^{-1} s^{-1}, 60°C; H-2, δ (D_2O) = 8.65–8.68 ppm), for various substitution-inert Pt(II)- and Co(III)-imidazole and -*N*-methylimidazole complexes (k_{OD} = 1–10^{-2} M^{-1} s^{-1}, 60°C; H-2, δ (D_2O) = 8.06–7.73 ppm), and for *N*-methylimidazole (k_{OD} = 5 × 10^{-5} M^{-1} s^{-1}, 60°C; H-2, δ (D_2O) = 7.59 ppm) are compared (these data are given in ref. 5, but see also ref. 16). The absence of a detectable pathway for H/D exchange in the $[Co(ND_3)_5Im]^{2+}$ ion (H-2, δ (D_2O) = 7.44 ppm, (2)) is not unexpected when the above trends are considered. Finally, it is of interest to note that we were unable to find evidence for H-2 exchange (<10%) in $[Co(ND_3)_5ImCo(ND_3)_5]^{5+}$ (H-2, δ (D_2O) = 7.77 ppm) after 170 h in 0.10 M NaOD solution at 60°C. This result implies that k_{OD} must take a value of less than 2 × 10^{-5} M^{-1} s^{-1}, and indicates that the total charge carried by a metal–imidazole complex is not a factor in determining exchange rate, nor H-2 signal position an unequivocal guide. Indeed, for $[Co(ND_3)_5ImCo(ND_3)_5]^{5+}$, hydrogen bonding of the incoming base to amine centres of the flanking $Co(ND_3)_5$ substituents might well provide an effective barrier to H-atom abstraction. Work in this area is continuing.

[3] A limiting rate is certainly indicated when errors in the observed rate constants given in ref. 7 are taken into account. The reported reactivity of $[Co(NH_3)_5[2\text{-}^3H]Im]^{2+}$ derives solely from a possible superiority in the least-squares fit of the data (six points) to eq. [3] compared to an equation of the form given by eq. [2]. It is also noted that in this case the kinetically determined pK_a (8.0, 60°C) appears to be too low when compared with that calculated (9.0 ± 0.1) from the temperature dependence of $[Co(NH_3)_5ImH]^{3+}$ acidity, see above.

[4] Available data do not always allow quantitative comparisons. Reported k_{OD} values (= $k_{obs}/[OD^-]$) for H/D exchange at elevated temperatures often appear to have been erroneously calculated by using solution OD^- concentrations applicable to the 25°C situation. The use of such uncorrected data can lead to order of magnitude errors in k_{OD}.

Porphyrins incorporating heterocyclic *N*-oxides: (oxidopyridyl)porphyrins, porphyrin-*N*-oxides, and a tirapazamine–porphyrin conjugate

Jeffrey J. Posakony, Russell C. Pratt, Steven J. Rettig, Brian R. James, and Kirsten A. Skov

Abstract: Porphyrins containing one to four 4-pyridyl groups as *meso*-substituents were synthesized via a mixed aldehyde condensation, and then "*N*-oxidized" with *m*-chloroperbenzoic acid to produce five novel (oxidopyridyl) porphyrins and seven porphyrin-*N*-oxides, which were characterized by analysis and spectroscopic methods, especially NMR; an X-ray crystal structure of 5-(1-oxido-4-pyridyl)-10,15,20-triphenylporphyrin was also obtained. Crystals of (oxidopyridyl)triphenylporphyrin are tetragonal, $a = b = 15.174(1)$, $c = 13.709(1)$ Å, $Z = 4$, space group *I*2*d*. The structure was solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.031$ ($R_w = 0.026$) for 685 reflections with $I \geq 3\sigma(I)$. Sulfonation of two of the (oxidopyridyl)porphyrins was achieved readily with no loss of oxygen from the oxidopyridyl groups. Tirapazamine (3-amino-1,2,4-benzotriazine-1,4-di-*N*-oxide) was treated with triphosgene to yield the previously reported 2*H*-[1,2,4]oxadiazolo[3,2-*c*][1,2,4]benzotriazin-2-one-5-oxide (**1**); this reacts like an isocyanate and with 5-(4-aminophenyl)-10,15,20-triphenylporphyrin yields a tirapazamine-porphyrin conjugate (**2**).

Key words: porphyrin-*N*-oxides, (oxidopyridyl)porphyrins, tirapazamine.

Résumé : Faisant appel à une condensation mixte d'aldéhyde, on a synthétisé des porphyrines contenant d'un à quatre groupes 4-pyridyles comme substituants *méso* et on les a ensuite oxydées à l'aide d'acide *m*-chloroperbenzoïque pour produire cinq nouvelles (oxydopyridyl)porphyrines et sept *N*-oxydes de porphyrine que l'on a caractérisés par analyse et par spectroscopie, principalement la RMN; on a aussi déterminé la structure cristalline de la 5-(1-oxydo-4-pyridyl)-10,15,20-triphénylporphyrine par diffraction des rayons X. Les cristaux de la (oxydopyridyl)triphénylporphyrine sont tétragonaux, groupe d'espace *I*2*d*, avec $a = b = 15{,}174(1)$ et $c = 13{,}709(1)$ Å et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}031$ et $R_w = 0{,}026$ pour 685 réflexions avec $I \geq 3\sigma(I)$. On a effectué la sulfonation de deux des oxydopyridylporphyrines facilement, sans perte d'oxygène à partir des groupes oxydopyridyles. On a traité la tirapazamine (le 1,4-dioxyde de la 3-amino-1,2,4-benzotriazine) avec du triphosgène pour obtenir la 5-oxyde de la 2*H*-[1,2,4]oxadiazolo[3,2-*c*][1,2,4]benzotriazine-2-one (**1**) rapportée antérieurement; celle-ci réagit comme un isocyanate et, avec la 5-(4-aminophényl)-10,15,20-triphénylporphyrine, elle fournit une tirapazamine–porphyrine conjuguée.

Mots clés : *N*-oxyde de porphyrine, (oxydopyridyl)porphyrine, tirapazamine.

[Traduit par la Rédaction]

Introduction

One advantage of porphyrin-based, cancer therapies is that neoplastic tissue has been reported to accumulate many porphyrins to a greater degree than many normal tissues; this phenomenon also occurs with other aromatic macrocycles (e.g., naphthalocyanines, phthalocyanines, and chlorins) (1, 2). The mechanisms of tumor localization of such aromatic macrocycles have been discussed and are complex (2–5).

Heterocyclic *N*-oxides, most notably aromatic tirapazamine (6) and RB90740 (6, 7) have been investigated as radiosensitizers and hypoxia-selective agents. Thus, because of our ongoing interest in the development of porphyrin-based anticancer agents (8–10), we have pursued porphyrins incorporating heterocyclic *N*-oxides, as this might improve the delivery of heterocyclic *N*-oxides to neoplastic tissue. Herein, we describe the *N*-oxidation of several *meso*-pyridyl porphyrins to yield their corresponding (oxidopyridyl)porphyrins and their corresponding porphyrin-*N*-oxides, and the conjugation of tirapazamine to a porphyrin.

Experimental

All solvents were reagent grade or better. Unless otherwise indicated, all commercial chemicals were used as purchased from Aldrich Chemical Co., Strem, or Sigma Chemical Co. Pyrrole was dried over and distilled from CaH_2 or vacuum-transferred before use. Benzaldehyde, 4-pyridine-

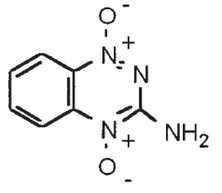
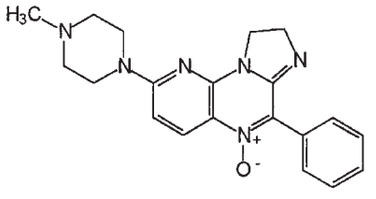
Table 1. Abbreviations used for the *meso*-pyridyl porphyrins, and corresponding (oxidopyridyl)porphyrins and porphyrin-*N*-oxides.

Porphryin precursor	Abbrev.	Oxidopyridyl abbrev.	Corresponding porphyrin-*N*-oxide abbrev.
5,10,15-Triphenyl-20-(4-pyridyl)porphyrin	TrPhPyP	OPyTrPhP	OPyTrPhP-21O, OPyTrPhP-23O
5,15-Diphenyl-10,20-bis(4-pyridyl)porphyrin	*t*-DPhBPyP[a]	*t*-BOPyDPhP	Not isolated
5,10-Diphenyl-15,20-bis(4-pyridyl)porphyrin	*c*-DPhBPyP	*c*-BOPyDPhP	*c*-BOPyDPhP-21O, *c*-BOPyDPhP-22O, *c*-BOPyDPhP-24O
5-Phenyl-10,15,20-tris(4-pyridyl)porphyrin	PhTrPyP	TrOPyPhP	TrOPyPhP-21O, TrOPyPhP-23O
5,10,15,20-Tetrakis(4-pyridyl)porphyrin	TPyP	TOPyP	Not isolated

[a]Present in small amounts as an impurity in TrPhPyP.



Tirapazamine



RB90740

carboxaldehyde, and trifluoroacetic acid (TFA) were freshly distilled before use. Tirapazamine (3-amino-1,2,4-benzotriazine-1,4,-di-*N*-oxide) was a gift from Dr. M. Tracy (SRI International, Menlo Park, Calif.). Reaction products were dried in vacuo at 78°C overnight, unless otherwise noted.

The alumina used for chromatography was Fisher, activity I, and was deactivated by adding water to give a standard range of activities (11). Unless otherwise noted, the silica gel used in the chromatographies was Merck Silica Gel 60, 230–400 mesh, whilst R_f values were measured on Merck silica TLC Al sheets (silica gel 60 F_{254}). Preparative TLCs of porphyrin free bases were performed with Merck silica gel 60, 0.5 mm plates (without indicator, to avoid metallation of the products). In general, the visualization of non-porphyrinic compounds was achieved with the aid of a UV lamp. Dialysis tubing (SpectraPor) used in the purification of the sulfonated porphyrins had a molecular weight cutoff of 1000.

^{1}H and ^{13}C NMR spectra were recorded on a BRUKER AC-200, a Varian XL-300, or a BRUKER WH-400 instrument, and UV-vis spectra on an HP8452A photo-diode array spectrophotometer (± 2 nm) with molar absorptivity (ϵ) values recorded for analytically pure porphyrins. IR spectra were recorded as KBr pellets or as a thin film on a KBr disk (from slow evaporation of a solution of the compound on the surface of a KBr disk) on an AIT Mattson Genesis Series FTIR instrument. Elemental analyses were performed by Mr. P. Borda of the Department of Chemistry (UBC). High- (HR-MS) and low-resolution (LR-MS) mass spectra were obtained on a KRATOS MS50 (EI), a KRATOS MS80 (CI), a KRATOS Concept IIHQ (LSIMS), or a BRUKER Biflex MALDI-TOF mass spectrometer. When analyzed with EI techniques, the mass spectra of free-base porphyrins often showed a peak at 61 *m*/*z* higher ($M^+ - 2H + Cu$) than the parent mass due to a gas phase metallation reaction with Cu from the ionization source.

Porphyrin precursors

The *meso*-pyridyl porphyrins were synthesized according to literature methods (8, 12); the abbreviations used for these porphyrins and the corresponding (oxidopyridyl)porphyrin and porphyrin-*N*-oxide derivatives are given in Table 1.

***N*-Oxidations**

Based on published procedures for the preparation of pyridine-*N*-oxide (13), excess *meta*-chloroperoxybenzoic acid (*m*-CPBA, 60–85%, the rest being benzoic acid and H_2O) was added to a stirred solution of the starting porphyrin in CH_2Cl_2 or CH_2Cl_2–MeOH at room temperature (r.t.). Addition of 1–2 equiv. aliquots of *m*-CPBA gave the (oxidopyridyl)porphyrins, while a single addition of several equivalents gave the corresponding porphyrin-*N*-oxides in low and variable yield. The reactions were monitored by TLC on silica (CH_2Cl_2:MeOH 100:1 to 10:1); Et_3N was added to the final reaction mixture, and the product was purified by chromatography after preadsorbing the product mixture on silica. With very polar eluent mixtures, metallation (with Zn from the fluorescent indicator in the silica) occurred on the TLC plate. In such cases, analytical TLC plates without indicator were used. Tables 2–6 summarize, respectively, ^{1}H NMR data for the (1-oxido-4-pyridyl)porphyrins, ^{1}H NMR data for some porphyrin-*N*-oxides, UV-vis data, elemental analyses, and mass spectrometry data; the ^{1}H NMR assignments are considered in Results and Discussion. IR data for the (oxidopyridyl)porphyrins and the two sulfonated derivatives (Table S1) and the porphyrin-*N*-oxides (Table S2) are available as supplementary material.[2]

If the porphyrin-*N*-oxides were not produced or their isolation was not pursued, the product was purified by first removing the solvent under reduced pressure, and the residue

[a]Measured at r.t. in $CDCl_3$ (400 MHz); δ in ppm, signal pattern (number of protons). An H_2O signal was observed in all spectra.
[b]*J* values typically ~5 Hz.
[c]*J* values typically ~7 Hz.
[d]*J* values typically ~6 Hz; addition of D_2O changed these signals to broad multiplets.
[e]Integration includes H_2O peak; the peak disappeared when D_2O was added.
[f]Integrations did not match.

then being washed with acetone. The resulting solid contained mostly the (oxidopyridyl)porphyrin, while the filtrate contained the corresponding porphyrin-*N*-oxides and other reaction byproducts (e.g., large amounts of *m*-chlorobenzoic acid (*m*-CBA)). Excess *m*-CBA complicated the chromatography, and also could be removed by washing the reaction mixture with dilute aq. NaOH. In some cases, mixtures of porphyrins (e.g., *c*-DPhBPyP and PhTrPyP) were treated with *m*-CPBA to give mixtures of (oxidopyridyl)porphyrins and the corresponding porphyrin-*N*-oxides. The mixtures were separated by chromatography, but no yield was determined for the minor components, as the molar ratio of the compounds was not determined prior to the reaction.

Because of the polar solvent mixtures used in chromatography, the porphyrin samples were often contaminated with silica. To obtain analytically pure material, the porphyrin was allowed to crystallize slowly (days to weeks) from a CH_2Cl_2:MeOH (~10:1) solution in a vial placed in a chamber containing EtOH.

The (oxidopyridyl)porphyrins were deoxygenated under the conditions of EI or LSIMS mass spectrometry and had to be analyzed by MALDI-TOF mass spectrometry. The corresponding porphyrin-*N*-oxides were deoxygenated to a lesser degree, and in some cases the parent peaks were intense enough to be analyzed by HR-MS (EI).

5-(1-Oxido-4-pyridyl)-10,15,20-triphenylporphyrin (OPyTrPhP)

TrPhPyP (0.223 g, 0.36 mmol) was dissolved in CH_2Cl_2 (150 mL), and treated with excess *m*-CPBA (3 × 0.1 g aliquots)

[a]Calculated (found); not obtained for OPyTrPhP-23O, TrOPyPhP-21O, and TrOPyPhP-22O.

over 1–2 h while the solution was stirred. Et_3N (20 mL) was then added, and the product was preadsorbed on silica and chromatographed on silica ($CHCl_3$: pyridine 10:1). The solvent was removed from the main product band to yield 0.128 g (56% yield) of OPyTrPhP. The reaction was scaled up to ~0.5 g of TrPhPyP with similar results. Slow solvent evaporation from a CH_2Cl_2–MeOH solution of the porphyrin yielded analytically pure crystals which were studied by X-ray crystallography.

5-(1-Oxido-4-pyridyl)-10,15,20-triphenylporphyrin-21-oxide (OPyTrPhP-21O), and -23-oxide (OPyTrPhP-23O)

From reactions in which several equivalents of *m*-CPBA were added all at once to a solution of TrPhPyP in CH_2Cl_2:MeOH, two additional products were isolated (~5% yield each) after OPyTrPhP was first isolated chromatographically. The two bands following that of OPyTrPhP were collected; the solvent was removed, and a second chromatography column silica (CH_2Cl_2:THF:MeOH 100:5:2.5) was used to separate two isomers. The less polar band was OPyTrPhP-23O, and the more polar band was OPyTrPhP-21O.

The porphyrin-*N*-oxides metallated rapidly when mixed with $Zn(OAc)_2$ in CH_2Cl_2–MeOH to give OPyTrPhPZn-21O and OPyTrPhPZn-23O (see Table 4 for UV-vis data). Attempts to grow crystals of the free-base porphyrin-*N*-oxides or Zn-porphyrin-*N*-oxides were unsuccessful.

5,15-Bis(1-oxido-4-pyridyl)-10,20-diphenylporphyrin (*t*-BOPyDPhP)

t-BOPyDPhP was prepared in the same manner as OPyTrPhP. The *m*-CPBA was added in 1–2 equiv. aliquots to a solution of an impure sample of TrPhPyP containing a small amount of *t*-DPhBPyP. The products were purified by column chromatography on silica; OPyTrPhP was eluted from the column with $CHCl_3$:pyridine (10:1), and *t*-BOPyDPhP was eluted with $CHCl_3$:pyridine (10:3). The yield was not determined. Because only small amounts of *t*-DPhBPyP were obtained from the mixed-aldehyde synthesis (8, 12), the synthesis of the corresponding porphyrin-*N*-oxide was not pursued.

5,10-Bis(1-oxido-4-pyridyl)-15,20-diphenylporphyrin (*c*-BOPyDPhP)

c-BOPyDPhP was synthesized in the same manner as OPyTrPhP. To a solution of *c*-DPhBPyP (0.5 g, 0.8 mmol,

but containing a small percentage of PhTrPyP) in CH_2Cl_2:MeOH (125:25 mL) was added excess *m*-CPBA (4 × ~1.25 g aliquots), and the reaction monitored by TLC. Et_3N (~10 mL) was added; the product was preadsorbed on silica and intially chromatographed on silica (CH_2Cl_2:pyridine:MeOH 20:1:2 to 20:1:3). The product bands were poorly resolved, possibly because of large amounts of residual *m*-CPBA and *m*-CBA; the porphyrin-containing fractions were washed with dilute aq. NaOH. The product mixture was rechromatographed on silica (CH_2Cl_2:pyridine:MeOH 10:1:2.5); *c*-BOPyDPhP eluted first (~0.27 g, ~50% yield), followed by a mixture of porphyrin-*N*-oxides, and then a small amount (~20 mg) of TrOPyPhP. A *c*-BOPyDPhP sample of analytical purity was obtained by slow crystallization from a solution of the compound in CH_2Cl_2:MeOH.

5,10-Bis(1-oxido-4-pyridyl)-15,20-diphenylporphyrin-21-oxide (*c*-BOPyDPhP-21O), -22-oxide (*c*-BOPyDPhP-22O), and -24-oxide (*c*-BOPyDPhP-24O)

A mixture of porphyrin-*N*-oxides was isolated (~30 mg, ~5%) from the reaction of *c*-DPhBPyP with a large excess of *m*-CPBA (see above). Attempts to separate the mixture on

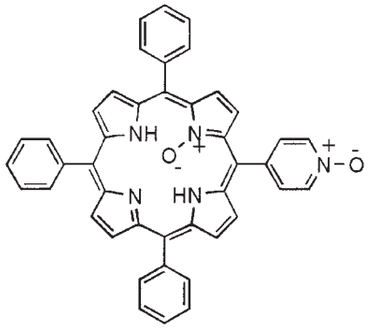
OPyTrPhP-23O



OPyTrPhP-21O

silica (CH_2Cl_2:pyridine:MeOH 20:1:2.5) were unsuccessful. There are three possible porphyrin-*N*-oxides isomers: *c*-BOPyDPhP-21O, *c*-BOPyDPhP-22O, and *c*-BOPyDPhP-24O.

The ^{1}H NMR data given below support the presence of at least two of these. The two doublets for the β-pyrrole-NO protons (δ 7.57 and 7.51) indicate the presence of *c*-BOPyDPhP-21O, while the corresponding singlet at δ 7.60 indicates the presence of either *c*-BOPyDPhP-22O or *c*-BOPyDPhP-24O, or both. ^{1}H NMR (400 MHz, $CDCl_3$) δ 9.05 (d, J = 5 Hz), 8.99 (overlapping ds, J = 5 Hz), 8.93 (d, J = 5 Hz), 8.91 (d, J = 5 Hz), 8.85 (d, J = 5 Hz), 8.74 (d, J = 5 Hz), 8.65 (m), 8.22 (dd, J_1 = 6 Hz, J_2 = 1.5 Hz), 8.15 (m), 8.08 (d), 7.8 (m), 7.60 (s), 7.57 (d, J = 6 Hz), 7.51 (d, J = 6 Hz). Because the ratio of products is unknown, the ^{1}H NMR signals are not assigned; general δ_H values for the (oxidopyridyl)porphyrins and porphyrin-*N*-oxides can be found in Tables 2 and 3.

5,10,15-Tris(1-oxido-4-pyridyl)-20-phenylporphyrin (TrOPyPhP)

TrOPyPhP was produced in the same manner as OPyTrPhP. PhTrPyP was present in small amounts in the sample of *c*-DPhBPyP used above, and TrOPyPhP was isolated from the reaction mixture. The yield was not determined. A sample of analytical purity was obtained by slow crystallization from CH_2Cl_2–MeOH.

5,10,15-Tris(1-oxido-4-pyridyl)-20-phenylporphyrin-21-oxide (TrOPyPhP-21O), and -22-oxide (TrOPyPhP-22O)

TrOPyPhP-21O and TrOPyPhP-22O were prepared in the same manner as the porphyrin-*N*-oxides of OPyTrPhP. The product was purified by preparative TLC on silica (CH_2Cl_2:MeOH 10:1 to 5:1). Only ~1 mg of each porphyrin-*N*-oxide was obtained (<5% yield).

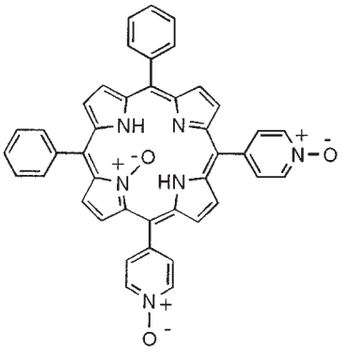
5,10,15,20-Tetrakis(1-oxido-4-pyridyl)porphyrin (TOPyP)

Oxidation of TPyP

TOPyP was prepared in the same manner as OPyTrPhP. TPyP (0.35 g, 0.57 mmol) was dissolved in CH_2Cl_2:MeOH (150:25 mL) and excess *m*-CPBA (6 × 0.5 g) was added in aliquots over 3 h to the stirred mixture. TLC showed at least four intermediates as the reaction progressed. Et_3N (~20 mL) was added to the reaction mixture and the solvent was removed. The residual solid was rinsed with MeOH, acetone, and H_2O, and air-dried. Further purification was achieved by dissolving the product in H_2O:TFA (20:1), neutralizing the solution (NaOH), and subsequently filtering off the crude TOPyP precipitate; total yield 0.275 g (0.40 mmol, ~70%). Analytically pure TOPyP was obtained by slow crystallization from CH_2Cl_2:MeOH. Alternatively, small amounts of the product could be chromatographed on Al_2O_3(III) (CH_2Cl_2:MeOH 20:1). TOPyP was insoluble in $CDCl_3$, and thus its ^{1}H NMR spectrum was measured in $CDCl_3$–CD_3OD.

*Acid-catalyzed condensation of pyrrole and 4-pyridinecarboxaldehyde-*N*-oxide*

Attempts were also made to prepare TOPyP via acid-catalyzed condensation of pyrrole and 4-pyridinecarboxaldehyde-*N*-oxide. Pyrrole (0.3 mL, 0.4 mmol) and 4-pyridinecarboxal-



c-BOPyDPhP-21O

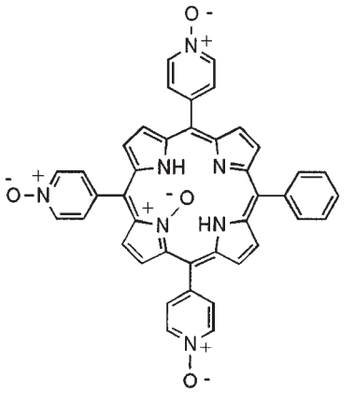
TrOPyPhP-21O



TrOPyPhP-22O

dehyde-*N*-oxide (0.05 g, 0.4 mmol) were dissolved in propionic acid (2 mL), and the solution was refluxed for ~50 min. UV-vis spectroscopy indicated that a porphyrin had formed (Soret 418 nm), but TLC analysis of the mixture on silica (CH_2Cl_2–MeOH) indicated numerous side products and so further isolation was not attempted. Attempts to synthesize TOPyP with Lindsey-type conditions in CH_2Cl_2 with pyrrole and 4-pyridinecarboxaldehyde (4 or 8 mM), using TFA or BF_3·MeOH and subsequent oxidation with 2,3,5,6-tetrachloro-1,4-benzoquinone (TCQ), yielded only traces of porphyrin by UV-vis spectroscopy.

TPyP synthesis via Lindsey conditions

When Lindsey conditions (14) were applied to the synthesis of TPyP using trichloroacetic acid, TFA, or BF_3·MeOH catalysis, TPyP was produced when aliquots of the reaction mixture were treated with TCQ, which showed that the precursor porphyrinogen was forming. However, the porphyrinogen was eventually consumed by a side reaction that gave a very polar, unidentified, blue compound. The rate of the side reaction increased with increasing acid strength and concentration.

Sulfonations

Sodium 5-(1-oxido-4-pyridyl)-10,15,20-tris(4-sulfonatophenyl)porphyrin (OPyTrSPhP)

Based on the literature procedure for the sulfonation of 5,10,15,20-tetraphenylporphyrin (TPhP) (8), OPyTrPhP (0.535 g, 0.85 mmol) was dissolved in conc. H_2SO_4 (10 mL), and the solution was heated at 110°C for 4 h. The reaction was monitored by first neutralizing an aliquot of the mixture (using aq. Na_2CO_3), then analyzing by TLC on silica (CH_2Cl_2:MeOH 100:1 to 5:1). The reaction mixture was cooled with an ice-bath, and cold, distilled H_2O (50 mL) was added, with the pH of the solution being adjusted to 7–8 with aq. NaOH and aq. Na_2CO_3. The solvent was removed and the porphyrin washed from the residue with MeOH. Then the MeOH was removed and the porphyrin subsequently dialyzed in dialysis tubing in a beaker of distilled H_2O to yield 0.51 g (~53% yield) of OPyTrSPhP·$11H_2O$. The ^{1}H NMR signals were assigned with the help of a ^{1}H-2D-COSY spectrum.

*Sodium 5,10-bis(1-oxido-4-pyridyl)-15,20-bis(4-sulfonatophenyl)porphyrin (*c*-BOPyBSPhP)*

c-BOPyDPhP (0.10 g, 0.15 mmol) was sulfonated in the same manner used for OPyTrSPhP. The reaction was monitored by TLC; an intermediate band appeared between that of the starting material and the baseline, and heating was continued ~0.5 h after the intermediate had disappeared (6 h total). After dialysis of the worked up product, its ^{1}H NMR spectrum revealed the presence of an impurity. Redissolving the product in conc. H_2SO_4 and heating at 100°C for another 2 h with the same work-up procedure did not remove the impurity (i.e., it is not a monosulfonatophenyl product). Attempts to purify by chromatography on silica MeOH or by recrystallization from MeOH–acetone were unsuccessful. The results of the elemental analysis (Table 5) suggest that the composition of the impurity does not differ significantly from that of *c*-BOPyBSPhP. Careful TLC analysis of the sample of *c*-BOPyDPhP used here showed the presence of another compound with an R_f nearly identical to that of *c*-BOPyDPhP; the presence of the impurity was not evident in the ^{1}H NMR spectrum ($CDCl_3$).

2*H*-[1,2,4]Oxadiazolo[3,2-*c*][1,2,4]benzotriazin-2-one-5-oxide (1)

Based on a literature reaction between phosgene and tirapazamine (15), a suspension of tirapazamine (0.3 g, 1.7 mmol) in dry toluene (5 mL) was heated to 90°C, and triphosgene (0.173 g, 0.58 mmol) was added. Within 5 min, the suspension turned from orange to yellow and TLC indicated near quantitative conversion to **1** (R_f = 0.75 silica (CH_2Cl_2:MeOH ~50:1)). (When the solution was heated for ~2 h, TLC indicated that some **1** had been reconverted to tirapazamine (R_f = 0.18).) The reaction mixture was cooled, and the precipitate was filtered off and washed with hexanes to yield 0.324 g (1.59 mmol, 94% yield) of **1** as a yellow–brown solid, which contained a small amount of tirapazamine (by TLC). The product was used without further purification in subsequent reactions. Compound **1** was reconverted to tirapazamine when exposed to H_2O vapor or when co-spotted with H_2O on a TLC plate, and tirapazamine was isolated in variable amounts from subsequent reactions involving **1**. 1

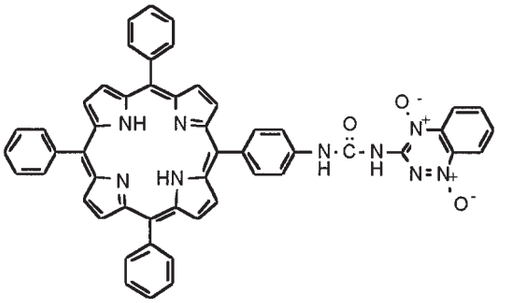
5-(4-*N*-(*N*′-(1,4-dioxido-1,2,4-benzotriazin-3-yl)aminocarbonyl)aminophenyl)-10,15,20-triphenylporphyrin (2)

To a solution of 5-(4-aminophenyl)-10,15,20-triphenylporphyrin (APhTrPhP) (8) (31 mg, 0.05 mmol) in dry DMF (3 mL) was added **1** (11 mg, 0.055 mmol), and the mixture was stirred at r.t. in the dark for 26 h. TLC (silica (CH_2Cl_2:MeOH 100:2–3)) showed a new product (R_f = 0.4), some APhTrPhP (R_f = 0.65), but little **1**; so another 1.0 equiv. of **1** was added, and the mixture was stirred another 24 h. The solvent was removed, and the desired product was isolated from several minor products by preparative TLC on silica (CH_2Cl_2:MeOH 100:2–3). The isolated product was washed with hexanes, dissolved in CH_2Cl_2:MeOH (20:1), and the solution was washed with H_2O. The solvent was removed to yield 20 mg of a purple powder (~50%). IR (KBr pellet, cm^{-1}): 3312 w, 1709 m, 1597 m, 1526 vs, 1405 m, 1332 m, 1311 m, 1225 m, 1181 w, 964 m, 799 m, 727 m, 701 m; UV-vis (2.4×10^{-6} M, CH_2Cl_2:MeOH (100:1)) corresponding to the tirapazamine moiety: 280 (log ε: 4.65), 478 (4.26) nm, corresponding to the porphyrin core: 418 (5.81), 514 (4.54), 550 (4.28), 586 (4.16), 646 (4.03). LR-MS (+LSIMS): 834 (0.25, M^{+1}), 818 (1, M^{+1} – O), 802 (0.25 M^{+1} – 2O), 656 (12, M^{+1} – tirapazamine). HR-MS (+LSIMS) calcd. for $C_{52}H_{36}N_9O_3$: 834.29411, found: 834.29456; calcd. for $C_{52}H_{36}N_9O_2$: 818.29919, found 818.29953. Anal. calcd. for $C_{52}H_{35}N_9O_3 \cdot 0.5H_2O$: C 74.10, H 4.30, N 14.96; found: C 73.96, H 4.18, N 14.41%. The ^{1}H NMR data for **2** appear in Table 7.



2

X-ray crystallographic analysis of OPyTrPhP

Crystallographic data appear in Table 8. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with $2\theta = 45.4 – 80.4°$. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, showed only small random fluctuations. The data were processed[3] corrected for Lorentz and polarization effects and absorption (based on azimuthal scans).

The space group ambiguity (space groups $I4_1md$ and $I2d$ are possible) was resolved by trial and error. The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The molecule is centred at a point of crystallographic S_4 symmetry, thus the pyridine-*N*-oxide ligand and the N-H protons are statistically disordered. Position C(9)/N(2) was refined as 0.75C and 0.25N; the N and C atoms are too close to resolve. The oxygen position is 1/4 occupied and the N-H proton position is half occupied. All non-hydrogen atoms were refined with anisotropic thermal parameters. The full-occupancy hydrogen atoms were refined isotropically and the N-H and C(9)-H hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å, N—H = 0.91 Å and $B_H = 1.2B_{\text{bonded atom}}$. A correction for secondary extinction was applied (Zachariasen type, isotropic, Gaussian), the final value of the extinction

coefficient being 1.54(5) × 10^{-6}. A parallel refinement of the mirror image gave marginally larger residuals (by a factor of 1.001). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 16. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths and bond angles appear in Tables 9–11, respectively. Infrared spectroscopy data, hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least squares planes are included as supplementary material.[2]

Results and discussion

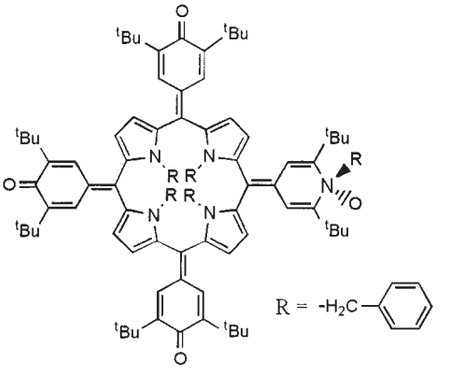
Porphyrin-*N*-oxides and (1-oxido-4-pyridyl)porphyrins

Porphyrin-*N*-oxides have been reported in the literature. Octaethylporphyrin-*N*-oxide (OEP-O) was first prepared by Bonnet et al. (17, 18) by treating OEP with hypofluorous acid (in 64% yield) or a peroxyacid (26% using *m*-CPBA, to 68% using permaleic acid). In studies relating to the active site of cytochrome P-450 enzymes, metal complexes of OEP-O (Ni, Mn, Co, Cu) (19–22), an Fe tetramesitylporphyrin-*N*-oxide complex Fe(TMP-O) (23–26), and a Ti tetraphenylporphyrin-*N*-oxide complex Ti(TPhP-O) (27) have been reported. With OEP-O, the metal was introduced after *N*-oxidation, while Fe(TMP-O) was produced by treating Fe(TMP) with *m*-CPBA, and Ti(TPhP-O) was prepared by photolysis of Ti(TPhP)(O_2). TMP-O was produced by oxidation of TMP, or demetallation of Fe(TMP-O) with HCl–HOAc (23), and Ti(TPhP-O) spontaneously demetallated in ethanol (27). In the metal complexes, the oxygen remains on one face of the porphyrin but, in the free-base porphyrin-*N*-oxides, the oxygen rapidly moves through the center of the porphyrin in a fluxional inversion process (19).

In contrast, (oxidopyridyl)porphyrins have not been reported, although a related compound (**3**) was obtained by Milgrom et al. (28) from the aerial oxidation of a (1-benzyl-4-pyridyl)porphyrin, this procedure leading also to further benzylation of the macrocyclic nitrogens.

Tetraarylporphyrin syntheses

The precursor *meso*-phenyl/pyridyl porphyrins and (aminophenyl)triphenylporphyrin were synthesized according to published procedures (8). The synthesis of (oxidopyridyl)porphyrins via acid-catalyzed condensation of pyrrole, benzaldehyde and 4-pyridinecarboxaldehyde-*N*-oxide was also attempted, but a significant percentage of the oxidopyridyl groups was deoxygenated in refluxing propionic acid. However, acid-catalyzed condensation of pyrrole and 4-pyridinecarboxaldehyde-*N*-oxide did produce at least one porphyrin, probably TOPyP, but this compound was much more conveniently prepared by *N*-oxidation of TPyP.



3

The synthesis of TPyP, via Lindsey conditions was hampered by a side reaction that produced an unidentified, blue compound. It has been noted that under Lindsey conditions, numerous heterocyclic aldehydes fail to give porphyrins but no explanation was suggested (14). *N*-Substitution on the pyridine nitrogen (as in *N*-oxides, and alkyl or acyl pyridinium salts) greatly activates the pyridine ring to nucleophilic addition at the α and γ positions (29). Thus, in situ formation of a pyridinium salt via protonation of (or BF_3 coordination to) the pyridine lone pair under high [H^+] and subsequent reaction (at the pyridine ring and aldehyde substituent) with pyrrole could explain the results obtained here. The side re-

action did not occur using weaker acids (e.g., dichloroacetic acid), but these were not able to catalyze the formation of a porphyrinogen, and thus no TPyP was observed when TCQ was added.

N-Oxidations

N-Oxidation of the pyridyl substitutents was accomplished using *m*-CPBA; the oxidations were sluggish at 0°C, but proceeded readily at r.t. When the peroxyacid was added in small aliquots, only the (oxidopyridyl)porphyrins were obtained, while the single addition of *m*-CPBA generated the corresponding porphyrin-*N*-oxides in low but variable yield, as pyrrole nitrogens were also oxidized. Use of the same conditions with TPhP gave no significant amount of TPhP-oxide, and continued addition of *m*-CPBA only led to the degradation of the porphyrin. As an oxidopyridyl group is more electron-withdrawing than a phenyl group, the (oxidopyridyl)porphyrins are more resistant to oxidative degradation, and thus the (oxidopyridyl)porphyrin-*N*-oxides could be isolated.

Thermal deoxygenation is commonly observed with heterocyclic *N*-oxides (13), but no deoxygenation was observed (by ^{1}H NMR studies) when a solid sample of OPyTrPhP was heated at 100°C overnight in vacuo. Porphyrin-*N*-oxides deoxygenate at milder conditions (18), and were thus kept below 30°C. Deoxygenation was observed in the mass spectra of the (oxidopyridyl)porphyrins and their *N*-oxides. The elemental analyses of these compounds, and the presence of H_2O peaks in their ^{1}H NMR spectra were consistent with water being present; of note, pyridine-*N*-oxide itself is hygroscopic and freely soluble in water (13).

The porphyrin-*N*-oxides are much more soluble in weakly polar solvents (CH_2Cl_2, $CHCl_3$) than their parent oxidopyridyl compounds, and are soluble in MeOH. OPyTrPhP has good solubility in CH_2Cl_2 or $CHCl_3$, but with increasing numbers of oxidopyridyl groups, increasing amounts of MeOH are required as a cosolvent to ensure dissolution. For

example, TOPyP is insoluble in $CDCl_3$ but dissolution (required for ^{1}H NMR measurement) occurs readily on addition of a few drops of CD_3OD. The difference in solubility may be related to less aggregation in the porphyrin-*N*-oxides because of steric effects of the macrocyclic oxygens; also, these oxygens may well be involved in hydrogen-bonding.

X-ray crystallography

The X-ray structure of OPyTrPhP is shown in Fig. 1. The morphology of the porphyrin core and the orientation of the aryl groups do not differ significantly from those of TPhP (30). The porphyrin ring is nearly planar, and the dihedral angle of the oxidopyridyl group and the porphyrin plane is 78°. The N(2)—O(1) bond length (1.299(7) Å) is significantly shorter than that in pyridine-*N*-oxide (1.34 Å), but lies within the range of N—O distances in a variety of substituted pyridine-*N*-oxides (13, 19).

^{1}H NMR spectra

^{1}H NMR spectroscopy (Tables 2, 3) was very useful for characterization of the (oxidopyridyl)porphyrins and enabled the porphyrin-*N*-oxide isomers to be identified.

Oxidopyridyl groups

Compared to the δ_H values for the unoxidized pyridyl group, the 2-*H* and 6-*H* protons of the oxidopyridyl groups were shifted upfield by ~0.4 ppm, while the 3-*H*- and 5-*H*-oxidopyridyl protons were shifted <0.1 ppm (see Fig. 2). Similar shift changes, observed for pyridine-*N*-oxide versus pyridine (13), were rationalized in terms of additional electron density at the 2, 4, and 6 positions resulting from mesomeric structures (Fig. 3). The splitting patterns and δ values for the phenyl and sulfonatophenyl signals of the (oxidopyridyl)porphyrins correspond well to those of the phenyl-(pyridyl)- and (pyridyl)(sulfonatophenyl)porphyrins, respectively (8).

Pyrrole-*N*-oxides

The β-pyrrole protons of the pyrrole-*N*-oxide of the porphyrin-*N*-oxides are shifted upfield to δ ~7.5 compared to those of the nonoxidized pyrroles (Fig. 4, Δ ~ 1.4 ppm). Similar δ values were noted for the β-pyrrole-oxide positions in TMP-O (δ 7.49) (23) and Ti(TPhP-O) (δ 7.26) (27). Based

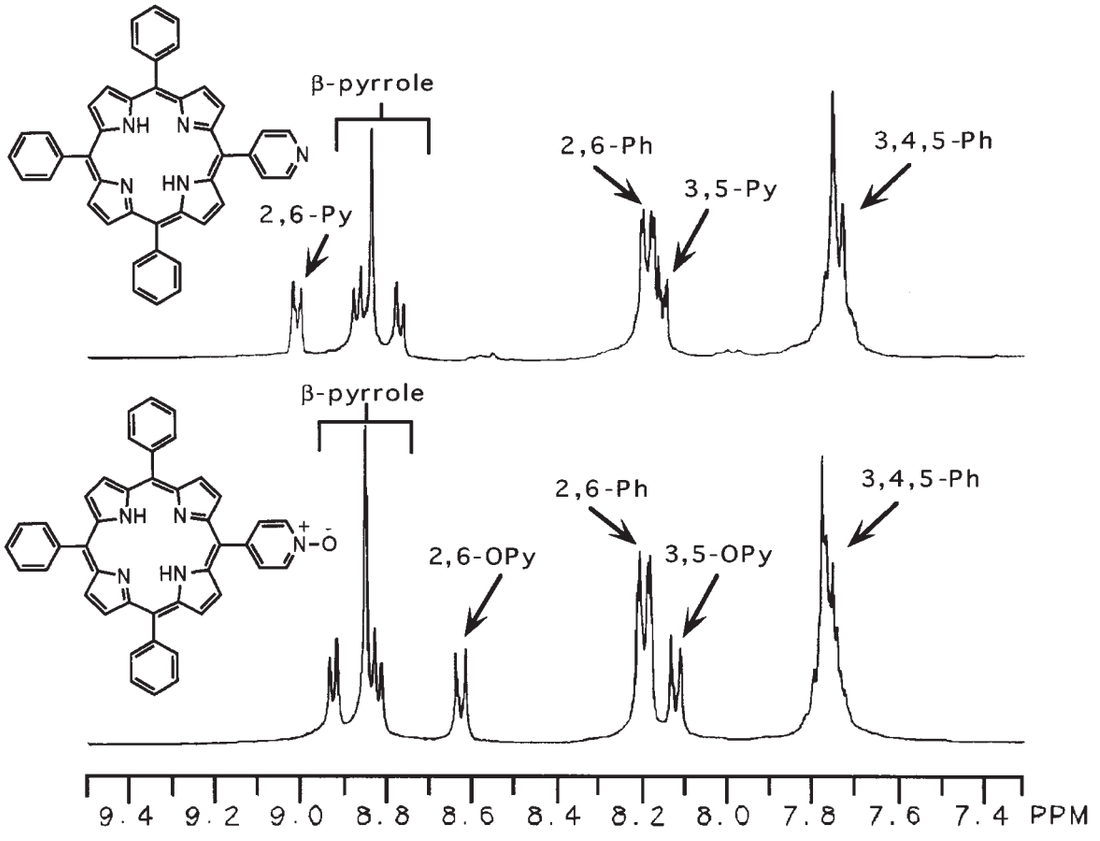

Fig. 3. Mesomeric forms of pyridine-*N*-oxide.

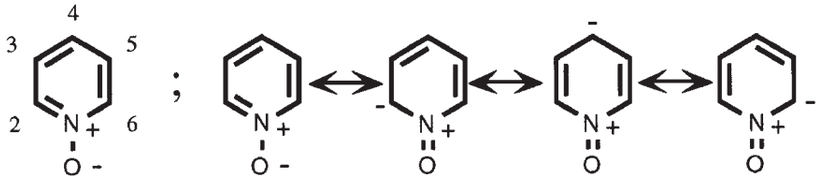

solely on inductive effects, such shifts are opposite to those expected by incorporation of an O-atom, and are unlikely due to partial negative charges for mesomeric forms (cf. Fig. 3), as these would tend to be delocalized over the whole macrocycle. An out-of-plane tilt of the pyrrole-*N*-oxide could explain the upfield shift, as the β-pyrrole protons would then experience less deshielding from the induced ring current. However, in the solid state, the pyrrole-*N*-oxide ring in OEP-O is tipped out of the porphyrin plane only 6.1° (20), which is similar to that of 6.6° found in two of the pyrrole rings of TPhP (30), and such a small tilt in solution is unlikely to explain the large $\Delta\delta$. In the dynamic porphyrin inversion process, in which the oxygen atom moves through the center of the porphyrin (19), the pyrrole groups may be tilted far enough for such a loss of deshielding, and in support of this a similar loss of deshielding is noted for the methylene groups in the Ni(II) complex of OEP-O, where a large pyrrole-*N*-oxide tilt (38.3°) is observed and inversion does not occur (19, 20). A large tilt of the pyrrole-*N*-oxide unit is also expected in Ti(TPhP-O) where a $\Delta\delta$ of ~2 is observed (27).

As in the corresponding pyridyl(phenyl)- and (oxidopyridyl)(phenyl)porphyrin series, the β-pyrrole protons show a singlet when situated between two idendical *meso*-substituents, and an AB spectrum when between two different *meso*-subsituents (8). The rest of the β-pyrrole region is complex because of the inequivalence introduced by the proximity of the oxidopyrrole group and different *meso*-subsitutents.

The inner N-H protons of the porphyrin-*N*-oxides appear as broad singlets at δ ~1.6, which disappear in the presence of D_2O. Compared to the (oxidopyridyl)porphyrins (where δ_{NH} is ~–2.85), the induced ring current is presumably slightly disrupted because of the out-of-plane pyrrole-*N*-oxide ring. The inner N-H signals of OEP-O and TMP-O appear at δ 0.8 (19) and δ 1.75 (23), respectively.

In the ^{1}H NMR spectrum of TOPyP in $CDCl_3$–CD_3OD, the β-pyrrole protons appear as a broad singlet and no N-H

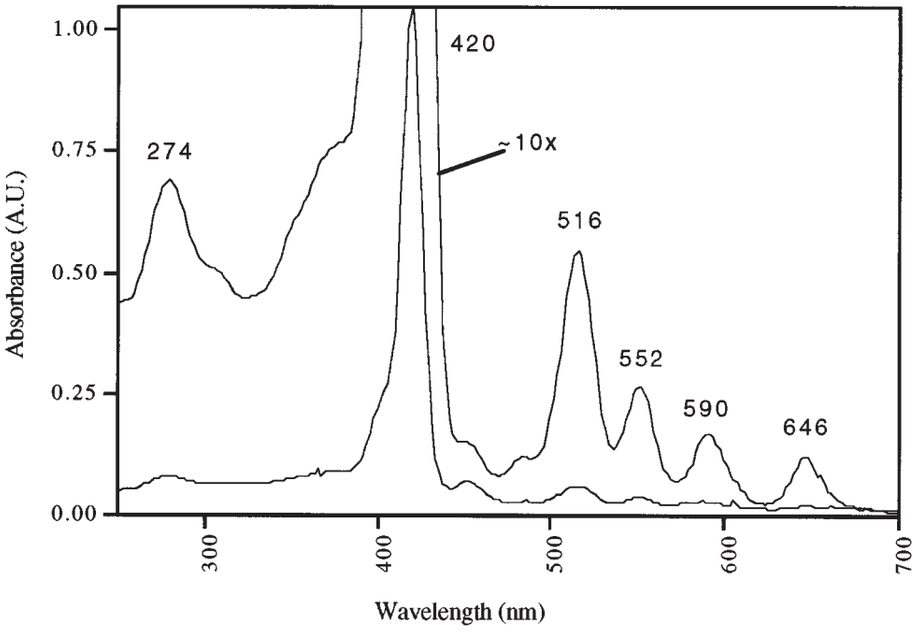

Fig. 7. UV-vis spectrum of OPyTrPhP-23O (~7.6×10^{-6} M) in CH_2Cl_2. (At ~2.8×10^{-5} M, an additional, small peak is observed at 518 nm.)

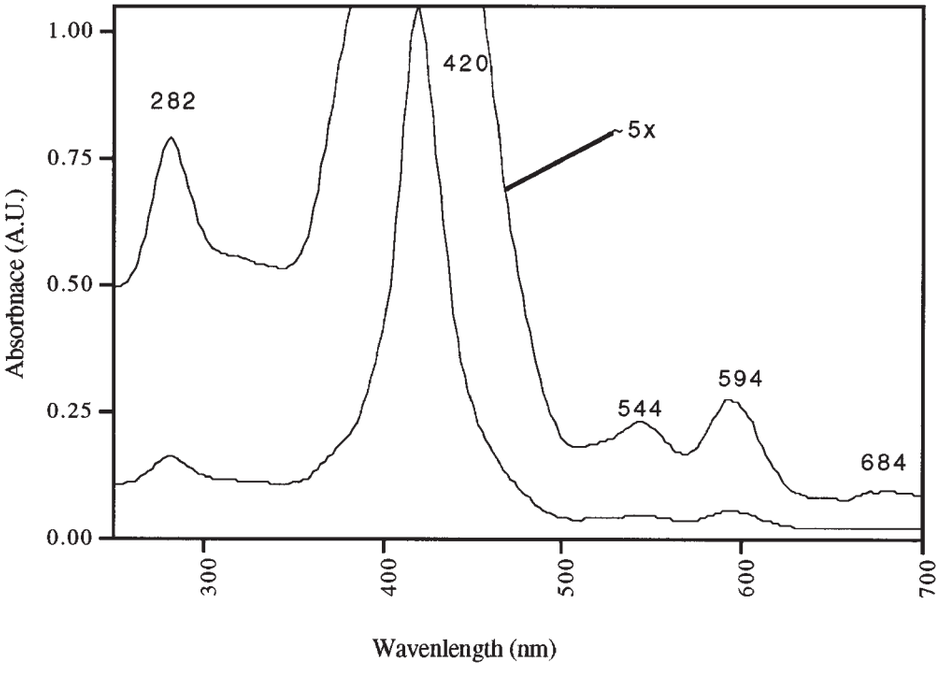


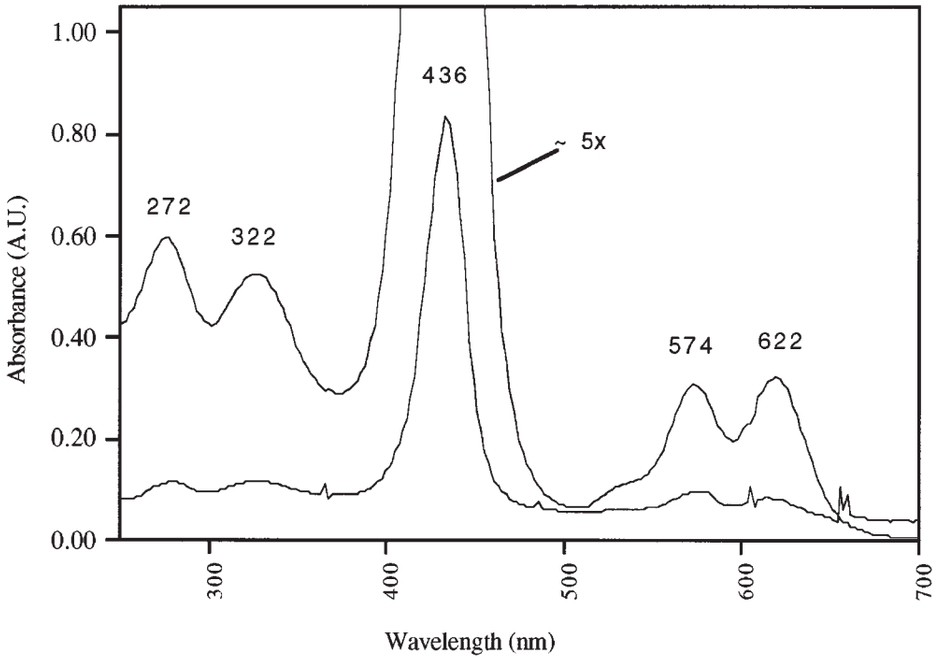
splitting at room temperature; with N-D, the tautomerism is slower (k_H/k_D ~ 12.1 at 35°C) (31), and coupling to the D-atoms broadens the β-pyrrole signals.

UV-vis spectroscopy

Pyridine-*N*-oxide displays an absorbance maximum (log ϵ > 4) in the 255–285 nm region and a weaker (log ϵ ~ 2) absorbance maximum near 350 nm; in polar solvents, the longer wavelength band is blue-shifted and can be hidden by the shorter wavelength absorption maximum (13). The shorter wavelength maximum appears at ~275 nm for the (oxidopyridyl)porphyrins and the corresponding porphyrin-*N*-oxides (see Table 4); and the corresponding longer wavelength band is sometimes observed in the ~310–350 nm

© 1999 NRC Canada

Fig. 8. UV-vis spectrum of OPyTrPhPZn-23O (~1.0×10^{-5} M) in CH_2Cl_2.



region, although this is usually masked by the "background" absorbance from the porphyrin moiety (see Figs. 5 and 6). With the exception of the UV region, the spectra of the (oxidopyridyl)porphyrins are similar to those of free-base tetraarylporphyrins.

The presence of the Soret bands for the porphyrin-*N*-oxides suggests that the conjugation of the macrocycle is uninterrupted (18); however, the Soret bands are broadened, and the Q bands are not as intense as those in the parent (oxidopyridyl)porphyrins (Fig. 7). The Soret and Q-bands in the spectra of OPyTrPhPZn-21O and -23O are similarly broad and diminished in intensity, but the peaks at 320–330 nm are more prominent (see Fig. 8). There is no evidence for a band assignable to any electronic transition of the pyrrole-*N*-oxide group.

Infrared spectroscopy

The *N*-oxide moiety exhibits an intense, characteristic band in the 1200–1350 cm^{-1} region attributed to ν(N-O) (13), and the IR spectra of the (oxidopyridyl)porphyrins show an intense band in the 1221–1261 cm^{-1} region due to the pyridyl-*N*-oxide stretch; for the sulfonated derivatives, the values are about 20 cm^{-1} lower than for the corresponding nonsulfonated porphyrins (see Table S1)[2]. Porphyrin- *N*-oxide stretches for OEP-O (18) and TMP-O (23) appear at 1265 and 1273 cm^{-1}, respectively. Intense bands for the porphyrin-*N*-oxides synthesized here are in the range 1238–1261 cm^{-1}, and these likely result from overlap of the porphyrin- and pyridine-*N*-oxide stretches. The other spectral bands common to the porphyrin ring structure can be assigned according to the literature (32).

Mass spectrometry

The oxidopyridyl groups were deoxygenated using EI and LSIMS techniques and no moleular ion peak was seen, but this could be observed using MALDI-TOF mass spectrometry (using a dihydroxybenzoic acid matrix) (Table 6). Some of the parent peaks for the porphyrin-*N*-oxides were observed under EI ionization conditions (see Fig. 9), and HR-MS analyses were obtained for these species (Table 6).

Sulfonation reactions

Sulfonation of the phenyl groups of OPyTrPhP and *c*-BOPyDPhP was achieved readily in hot, conc. H_2SO_4. Like the pyridyl subsituent, the oxidopyridyl group was not sulfonated under these conditions, and the *N*-oxide was retained. The pyridine nitrogen (or oxygen in the oxidopyridyl group) is certain to be protonated under the sulfonation conditions, thus making the pyridyl group unreactive towards electrophilic addition.

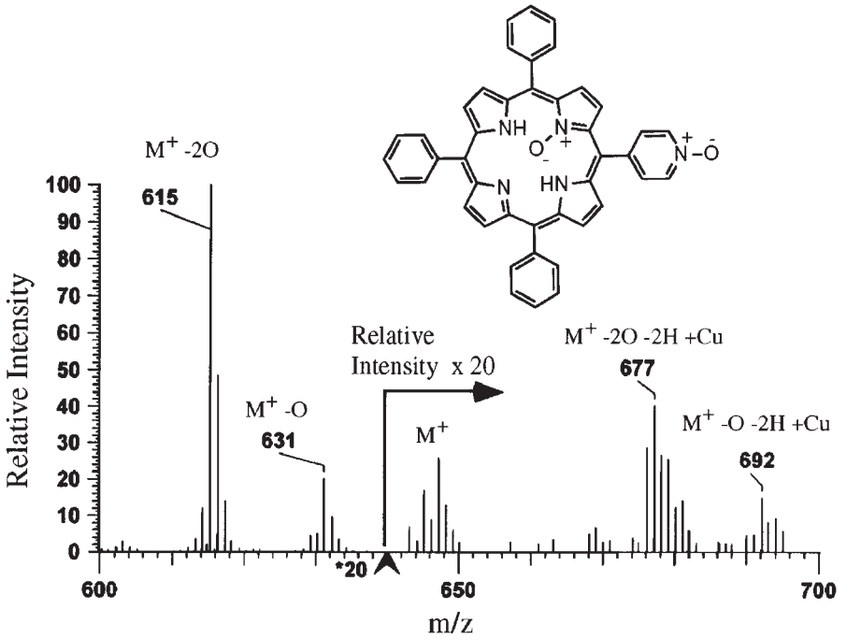
The sulfonated porphyrins, when isolated by solvent removal from an aqueous solution, retained several mole equivalents of water as judged by elemental analysis. This behavior for sulfonated porphyrins has been noted previously by our group (9).

Tirapazamine chemistry

Patents and publications on the biological activity of tirapazamine have appeared (33–35), and the desire to incorporate tirapazamine into a porphyrin was noted in the introduction. The use of triphosgene, a crystalline compound (36), in place of the highly toxic, gaseous phosgene, for reaction with tirapazamine, provided an effective, rapid route to **1**, although the product contained a small amount of tirapazamine. Compound **1** had previously been made in a 4 h reaction using phosgene, and its structure proposed (15) on IR data: ν(C=O) 1814 cm^{-1}, ν(C=N) 1541 cm^{-1}, and the absence of ν(NCO) bands at 2273–2000 cm^{-1} (37). Reaction of an amine with phosgene typically generates an isocyanate, and despite its cyclic structure, **1** does react like an

© 1999 NRC Canada

Fig. 9. Low-resolution mass spectrum (EI) of OpyTrPhP-21O.



isocyanate and produce ureas and carbamates when mixed with amines and alcohols, respectively, undergoing a ring-opening process (15, 33). Also typical of an isocyanate, **1** reacts with water (even on a TLC plate) to regenerate the amine tirapazamine.

The porphyrin bearing an amino group, APhTrPhP, was mixed with **1** to yield **2** in ~50% isolated yield. An IR peak seen at 1225 cm^{-1} due to ν(NO) was not observed in the aminophenyl porphyrin (38). Peaks attributed to tirapazamine appeared in the UV-vis spectrum, but these were in a region of relatively high background absorbance from the porphyrin core.

Conclusions

Porphyrins containing one to four pyridyl groups were synthesized and *N*-oxidized with *m*-CPBA to produce five novel (oxidopyridyl)porphyrins and seven porphyrin-*N*-oxides (including three from a *c*-BOPyBPhP-O mixture). Only three free-base porphyrin-*N*-oxides have been reported previously (OEP-O, TMP-O, and TPhP-O). The (oxidopyridyl)porphyrins and porphyrin-*N*-oxides were well characterized and an X-ray crystal structure of OPyTrPhP was obtained. Sulfonation of OPyTrPhP and *c*-BOPyDPhP was achieved readily under standard conditions with no loss of oxygen from the oxidopyridyl groups.

The product **1** from tirapazamine and triphosgene reacts like an isocyanate, reacting with porphyrins bearing amines and alcohols; the best results were obtained using APhTrPhP to produce the novel porphyrin conjugate **2**. The electrochemical and in vitro evaluation of these porphyrins incorporating *N*-oxide functionalities (39) will be published elsewhere.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council and Medical Research Council of Canada for financial support, and Dr. M. Tracy for the sample of tirapazamine.

Reactions of $(\eta^5\text{-}C_9H_7)Rh(\eta^2\text{-}C_2H_4)_2$ with quinones: molecular structure of $[(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)]$

Stephen A. Westcott, Nicholas J. Taylor, and Todd B. Marder

Abstract: Reactions of $(\eta^5\text{-}C_9H_7)Rh(\eta^2\text{-}C_2H_4)_2$ (**1**) with quinones were investigated. Substitution of the labile ethylene ligands was observed upon addition of either duroquinone (2,3,5,6-tetramethyl-1,4-benzoquinone) or 1,4-benzoquinone to complex **1**. The molecular structure of neutral $(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)$ (**3**), determined by X-ray diffraction, shows that the duroquinone ligand lies in a plane nearly parallel to the indenyl group. The carbonyl moieties of duroquinone lie in a plane incorporating Rh, C2, and the midpoint between C3a and C7a of the indenyl ring. The slip parameter (Δ = *d*(average Rh-C3a,7a) – *d*(average Rh-C1,3)) was calculated to be 0.112(2) Å; whereas a value of ca. 0.05 Å had been obtained previously from film data. Values for the hinge angle (HA = angle between normals to the least-squares planes defined by C1, C2, C3 and C1, C7a, C3a, C3) and fold angle (FA = angle between normals to the least-squares planes defined by C1, C2, C3 and C3a, C4, C5, C7, C7a) are 7.2° and 4.0°, respectively.

Key words: indenyl, rhodium, quinones, ring-slippage, ground-state distortion.

Résumé : On a étudié les réactions du composé $(\eta^5\text{-}C_9H_7)Rh(\eta^2\text{-}C_2H_4)_2$ (**1**) avec les quinones. On a observé la substitution des ligands éthylène labiles lors de l'addition de l'éther duroquinone (2,3,5,6-tétraméthyl-1,4-benzoquinone) ou de la 1,4-benzoquinone sur le complexe **1**. La structure moléculaire du composé neutre $(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)$ déterminée par diffraction de rayons X, révèle que le ligand duroquinone est lié dans un plan quasi parallèle au groupe indényle. Les unités carbonyle de la duroquinone sont liées dans un plan incorporant Rh, C2 et le point milieu entre C3a et C7a du cycle indényle. On a trouvé un paramètre de glissement (Δ = (moyenne Rh-C3a, 7a) – (moyenne Rh-C1,3)) de 0,112 (2) Å; alors qu'on a obtenu antérieurement une valeur d'environ 0,05 Å à partir des données de film. Les valeurs de l'angle d'articulation (AA = angle entre le plan normal et celui des moindres carrés défini par C1, C2, C3 et C1, C7a, C3a) et l'angle de pliement (AP = angle entre le plan normal et celui des moindres carrés défini par (C1, C2, C3 et C3a C4, C5, C7, C7a) sont respectivement de 7,2° et de 4,0°.

Mots clés : indényle, rhodium, quinones, glissement de cycle, distorsion de l'état fondamental.

[Traduit par la Rédaction]

Introduction

Indenylcobalt and rhodium complexes are known to display enhanced catalytic activities compared to their cyclopentadienyl analogues for a number of important organic reactions (1). This rate enhancement, or indenyl effect, (2) occurs in both associative (S_N2) and dissociative (S_N1) reaction pathways and, for the associative process, has been attributed to a low-energy barrier associated with an $\eta^5 \rightarrow \eta^3$ indenyl ring slippage, where the metal centre avoids an unfavourable 20-electron transition state. The relative stability of the η^3-intermediate arises from resonance stabilization of the benzene ring in the indenyl ligand (Fig. 1). Indeed, the molecular structures of several η^3-indenyl metal complexes have been reported (2*c*, 3).

Interestingly, η^5-indenyl d^8-ML_2 complexes all display a certain degree of ground-state distortion towards this allylic bonding mode within the five-membered ring of the indenyl ligand (4, 5). We have been examining the degree of this distortion as a function of the electronic nature of the ancillary ligands (4). While a significant amount of distortion was found for $(\eta^5\text{-}C_9H_7)Rh(CO)_2$ (4*d*), an early report using film data suggested that the slip-fold distortion in $(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)$ was unusually small (6), making this compound the least distorted of all d^8-ML_2-indenyl complexes. As the range of values was important to us, this "limiting" value represented a critical number, and it was thus decided to re-examine the structure of this compound. In this article, however, we report that the degree of distortion in this latter quinone compound is con-

siderably more pronounced than initially reported, thus reducing the range of values known to date.

Experimental

General procedures

NMR spectra were recorded on Bruker WM250 (^{1}H at 250 MHz, $^{13}C\{^1H\}$ at 63 MHz, $^{31}P\{^1H\}$ at 101 MHz), and Nicolet NMC-300 (^{1}H at 250 MHz, $^{13}C\{^1H\}$ at 75.4 MHz, $^{31}P\{^1H\}$ at 121 MHz) spectrometers. ^{1}H NMR chemical shifts are reported in ppm relative to external TMS and were referenced to residual protons in the solvent; coupling constants are in Hz. Multiplicities are reported as (s) singlet, (d) doublet, (t) triplet, (q) quartet, (m) multiplet, (br) broad, and (ov) overlapping. THF and hexane were freshly distilled from sodium benzophenone ketyl. Benzoquinone, duroquinone, and TCNQ (Aldrich Chemical Co.) were used as received. $(C_9H_7)Rh(\eta^2\text{-}C_2H_4)_2$ (**1**) was prepared by established methods (7).

*Preparation of $(\eta^5\text{-}C_9H_7)Rh(C_6O_2H_4)$ (**2**)*

$(\eta^5\text{-}C_9H_7)Rh(C_6O_2H_4)$ was prepared by allowing 1,4-benzoquinone ($C_6O_2H_4$) (119 mg, 1.1 mmol) to react with $(\eta^5\text{-}C_9H_7)Rh(C_2H_4)_2$ (274 mg, 1 mmol) in THF at room temperature. After stirring for 12 h, the solvent was removed in vacuo. The residue was washed with cold hexane (2 × 5 mL) and dissolved in THF/hexane (5/1). An orange–yellow product (271 mg, 83% yield) was obtained after cooling to –10°C. Selected spectroscopic data: IR (CH_2Cl_2, cm^{-1}): 1631 (s sh), 1614 (s), 1578 (m); ^{1}H NMR (CD_2Cl_2) δ: 7.36–7.30 (m), 7.29–7.24 (m), 6.06 (d, J = 3 Hz), 5.74 (q, $J_{H-Rh=H-H}$ = 3 Hz), 5.00 (s); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 160.6 (C=O), 128.9, 121.3, 107.5 (d, J_{C-Rh} = 5 Hz), 90.8 (d, J_{C-Rh} = 7 Hz), 82.1 (d, J_{C-Rh} = 8 Hz), 78.6 (d, J_{C-Rh} = 7 Hz) ppm.

*Preparation of $(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)$ (**3**)*

$(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)$ was prepared by allowing duroquinone ($2,3,5,6\text{-}C_6O_2(CH_3)_4$) (180 mg, 1.1 mmol) to react with $(\eta^5\text{-}C_9H_7)Rh(C_2H_4)_2$ (274 mg, 1 mmol) in THF at room temperature. After stirring for 12 h, the solvent was removed in vacuo. The residue was washed with cold hexane (2 × 5mL) and dissolved in THF/hexane (10/1). Orange–yellow crystals of the product (138 mg, 36% yield) were obtained after cooling to –10°C. Selected spectroscopic data: IR (CH_2Cl_2, cm^{-1}): 1587 (s), 1426 (m), 1369 (m); ^{1}H NMR (CD_2Cl_2) δ: 7.63–7.59 (m), 7.39–7.35 (m), 5.91 (q, $J_{H-Rh=H-H}$ = 3 Hz), 5.68 (d, J = 3 Hz), 2.07 (s) ppm; $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 140.5 (C=O), 123.7, 119.5, 112.3, 91.9 (d, J_{C-Rh} = 5 Hz), 78.8 (d, J_{C-Rh} = 4 Hz), 43.8 (d, J_{C-Rh} = 12 Hz), 12.3 ppm.

Molecular structure determination

Crystals of **3** suitable for X-ray diffraction studies were obtained by crystallization from a THF–hexane solution at –10°C. A summary of the crystal data and parameters for data collection is given in Table 1. Data were collected at room temperature on a Nicolet R3m/V diffractometer using graphite-filtered MoKα radiation (λ = 0.710 73 Å) and the ω scan method. The data and refinement were performed on a VAX 3100 computer using Siemens SHELXTL (VAX) software.[4] The structure was solved using Patterson and

Fourier techniques, and refinement was performed using full-matrix least squares on *F*, with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were located on the Fourier difference electron-density maps and included in the structure model. The maximum residue and hole are proximate to the rhodium atom. Selected bond distances and angles are given in Table 2, and final atomic coordinates are given in Table 3. Complete tables of bond distances and angles, anisotropic thermal parameters for the non-hydrogen atoms, hydrogen atom positions, atomic coordinates, isotropic thermal parameters, crystal data, refinement parameters, and alternative views of **3** have been deposited.[5]

[5] A complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of thermal parameters, these have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Results and discussion

The addition of 1,4-benzoquinone ($C_6O_2H_4$) and duroquinone (2,3,5,6-tetramethyl-1,4-benzoquinone, $C_6O_2(CH_3)_4$) to (η^5-C_9H_7)Rh(C_2H_4)$_2$ (**1**) gave the corresponding metal complexes (η^5-C_9H_7)Rh($C_6O_2H_4$) (**2**) and (η^5-C_9H_7)Rh(2,3,5,6-$C_6O_2(CH_3)_4$) (**3**) (Scheme 1), respectively, where the quinone acts as a four-electron diene ligand.

An early report (6) described only a minimum amount of distortion within the indenyl ring in complex **3**, which is not consistent with data obtained with other (η^5-C_9H_7)RhL_2 complexes where significant slip-fold distortions are observed (1–5). These distortions arise as the ML_2 fragment slips from a pure η^5-bonding mode towards the allylic η^3-mode, whereby the indenyl ring loses planarity, and as result, the six-membered ring folds away slightly from the bulky metal fragment. One spectroscopic tool that has proven useful in determining the degree of slip-fold distortion in solution is $^{13}C\{^1H\}$ NMR spectroscopy (4*f*, 5*b*, 8). The slip distortion has been correlated with the $^{13}C\{^1H\}$ chemical shifts of the ring-junction carbons C3a,7a where larger distortions result in significant downfield shifts. Interestingly, the chemical shifts for the quaternary carbons in benzoquinone complex **2** at δ 107.5 ppm are significantly upfield from starting complex **1** at δ 112.2 ppm (7). This result is significant in that it suggests that the amount of distortion in this quinone complex is much less than that observed in the bis(ethylene) complex (η^5-C_9H_7)Rh(C_2H_4)$_2$.

$^{13}C\{^1H\}$ NMR data have also been used to describe the amount of distortion observed in quinones when these ligands coordinate to metal centres (9). Upon complexation, a marked deviation in the quinone from the D_{2h} symmetry of the free ligand is observed as the carbonyl moieties bend away from the metal. This distortion has been attributed to a repulsive interaction of the metal *d* orbitals with the filled $2b_{1u}$ and empty $2b_{2g}$ orbitals of the quinone (10). As a result of this distortion, the $^{13}C\{^1H\}$ NMR chemical shifts for this carbonyl fragments shift significantly upfield. For instance, the carbonyl groups in (η^5-C_5H_5)Rh($C_6O_2H_4$) are observed at δ 161.6 ppm, compared to free 1,4-benzoquinone at δ 187.0 ppm. A chemical shift at δ 160.6 ppm for **2** suggests that, like (η^5-C_5H_5)Rh($C_6O_2H_4$), only a minor distortion from planarity exists within the quinone ligand for this complex (9).

Although a minimal amount of distortion was reported earlier for (η^5-C_9H_7)Rh(2,3,5,6-$C_6O_2(CH_3)_4$) (**3**) (6), the $^{13}C\{^1H\}$ NMR data for both the indenyl ring and the quinone ligand in this complex suggest otherwise. Indeed, chemical shifts for the indenyl ring-junction carbons at δ 112.3 ppm implies that the degree of slip-fold distortion in **3,** at least in solution, is comparable to complex **1**. Likewise, the carbonyl groups of the quinone ligand have shifted by 36.8 ppm in complex **3** (δ 140.5 ppm) compared to free duroquinone (δ 187.3 ppm). To understand the nature of this discrepancy, we decided to reinvestigate the solid-state structure of **3**.

Figure 2 presents a view of the molecular structure with the atomic numbering scheme. Compound **3** consists of a (η^5-C_9H_7)Rh(2,3,5,6-$C_6O_2(CH_3)_4$) unit with the duroquinone ligand lying in a plane nearly parallel to the indenyl group. The carbonyl moieties of duroquinone lie on a plane incorporating Rh, C2, and the midpoint of the C3a–C7a vector of the indenyl ring. Duroquinone behaves as a 1,4-diolefin where the rhodium–carbon bond distances to the olefinic carbons C9, C10, C12, C13 of 2.194(2), 2.100(2), 2.201(2), and 2.195(2) Å (Rh—C_{ave} = 2.193(2) Å) are typical for those found in other d^8-π-quinone complexes (11). As expected from $^{13}C\{^1H\}$ NMR data, a significant distortion of the quinone ligand away from the plane is observed with the carbonyl groups bending away from the indenylrhodium fragment. The distances Rh—C8 of 2.448 (2) Å and Rh—C11 of 2.450(2) Å are approximately 0.276 Å longer than those to the olefinic carbons. In addition to this distortion from planarity, the unsaturated C=C bond distances within the duroquinone ligand (mean value 1.417 Å) are also elongated considerably compared to free quinone (1.341 Å) (12).

In contrast to previous work, we find that a modest amount of distortion in the indenyl ring is present in the ground-state structure of (η^5-C_9H_7)Rh(2,3,5,6-$C_6O_2(CH_3)_4$), which contains three "short" and two "long" rhodium–carbon distances. The value of the slip-distortion is Δ = 0.112(3) Å, where Δ = *d*(average Rh—C3a,7a) – *d*(average Rh—C1,3). While a hinge angle of 7.2° (HA = angle between planes defined by C1, C2, C3 and C1, C7a, C3a, C3) and a fold angle of FA = 4.0° (FA = angle between planes defined by C1, C2, C3 and C3a, C4, C5, C6, C7, C7a) also suggest a slight distortion towards an allylic bonding mode, there is clearly bonding between the metal atom and ring junction carbons C3a and C7a, as required to attain an 18-electron configuration at the metal. This level of distortion still makes the title compound the least distorted d^8-RhL_2 indenyl complex to have been structurally characterized to date.

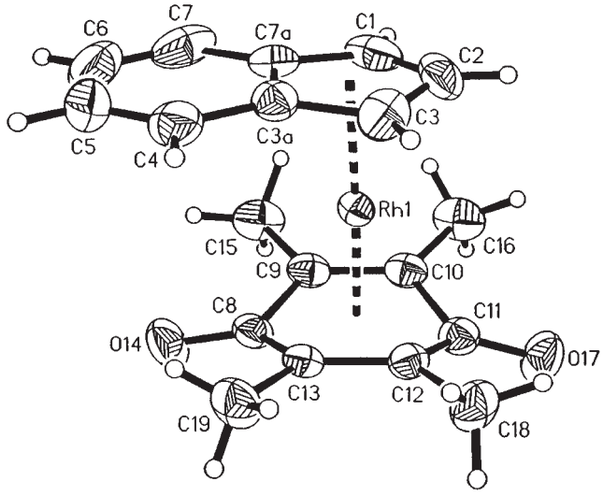
1 **2**, R = H; **3**, R = CH_3

Fig. 2. Molecular structure of (η^5-C_9H_7)Rh(2,3,5,6-$C_6O_2(CH_3)_4$) (**3**).



It is interesting to note that the degree of ground-state distortion in **3** does not correlate well with solution data and is still somewhat less pronounced than in the bis(ethylene) complex **1** (Δ = 0.161 Å, HA = 8.08°, FA = 7.40°) (4*b*, 13). It is plausible that this anomaly arises from the π-accepting ability of the quinone ligand, whereby π-backbonding removes electron density from the Rh(I) centre (towards a formal Rh(III) configuration) and thus strengthening the metal–ligand interactions and affecting the shift correlation. This type of interaction would also result in an increase in contribution from an "aromatic" resonance structure of the quinone ligand, as shown by the pronounced lengthening of the C=C bonds in **3**. Reactions with related 7,7′,8,8′-tetracyanoquinodimethane (TCNQ) gave highly coloured insoluble powders, where the quinone is now so strongly oxidizing that it appears to gives products arising from just charge-transfer chemistry (14[6]). Unfortunately, attempts to grow single crystals of less sterically hindered **2** suitable for X-ray diffraction studies, in order to compare solution and solid-state distortions, proved unsuccessful. In conclusion, the results described herein narrow significantly the range of these distortions, making correlations between ligand electronic and steric parameters and the degree of ground state distortion in d^8-ML_2 indenyl complexes much more difficult to assess.

Synthesis, structure, and solution dynamics of indenyl rhodium complexes containing bulky phosphine ligands: molecular structures of $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)(PCy_3)$ (Cy = cyclohexyl) and $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(dcpe)$ (dcpe = $Cy_2PCH_2CH_2PCy_2$)

Stephen A. Westcott, Ashok K. Kakkar, Nicholas J. Taylor, D. Christopher Roe, and Todd B. Marder

Abstract: Reactions of $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)_2$ with PCy_3 (Cy = cyclohexyl) and 1,2-bis(dicyclohexylphosphino)ethane (dcpe = $Cy_2PCH_2CH_2PCy_2$) gave complexes $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)(PCy_3)$ (**1**) and $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(dcpe)$ (**2**), respectively, in high yields. Complexes **1** and **2** were characterized by x-ray diffraction studies and by multinuclear NMR spectroscopy. Variable temperature $^{31}P\{^1H\}$ NMR spectra allowed for evaluation of energy barriers associated with indenyl ring rotation. While **1** and **2** displayed similar degrees of slip-fold distortion with respect to bonding of the indenyl ligand to the RhL_2 fragment, a lower energy barrier to ring rotation was calculated for the mixed ethylene-phosphine complex **1**. Yellow crystals of **1** are orthorhombic, *Pbca* with 16 molecules per unit cell of dimensions a = 11.341(3), b = 32.915(10), and c = 29.413(9) Å. Yellow crystals of **2** are triclinic, $P\bar{1}$ with two molecules per unit cell dimensions a = 9.327(3), b = 10.117(3), c = 18.934(6) Å, α = 104.28(2)°, β = 101.34(2)°, and γ = 92.99(2)°.

Key words: indenyl, rhodium, phosphines, ring-slippage.

Résumé : Les réactions du $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)_2$ avec le PCy_3 et le 1,2-bis(dicyclohexylphosphino)éthane (dope = $Cy_2PCH_2CH_2PCy_2$) fournissent les complexes $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)(PCy_3)$ (**1**) et $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(dope)$ (**2**) respectivement, avec des rendements élevés. On a caractérisé les complexes **1** et **2** par des études de diffraction des rayons X et par spectroscopie RMN multinucléaire. Les spectres RMN $^{31}P\{^1H\}$ à température variable ont permis d'évaluer les barrières d'énergie associées à la rotation du noyau indényle. Même si les complexes **1** et **2** présentent des degrés semblables de distorsion par glissement/plissement par rapport à la liaison du ligand indényle sur le fragment RhL_2, on a calculé que l'énergie de la barrière à la rotation du cycle est plus faible pour le complexe de l'éthylène phosphine mixte (**1**). Les cristaux du composé **1** sont de couleur jaune, orthorhombiques, de groupe d'espace *Pbca* avec 16 molécules par maille de dimensions a = 11,341(3), b = 32,915(10) et c = 29,413(9) Å. Les cristaux de couleur jaune du complexe **2** sont tricliniques, groupe d'espace $P\bar{1}$ avec deux molécules par maille de dimensions a = 9,327(3), b = 10,117(3) et c = 18,934(6) Å, α = 104,28(2), β = 101,34(2) et γ = 92,99(2)°.

Mots clés : indényle, rhodium, phosphines, glissement de cycle.

Introduction

The enhanced reactivity of η^5-indenyl transition metal complexes compared with their more common η^5-C_5R_5 (R = H, Me) analogues is well documented (1–5) and has been attributed to the facile ring slippage from $\eta^5 \rightarrow \eta^3$ in an associative transition state (2, 5*c*). As part of our ongoing investigation into transition metal indenyl chemistry we have prepared and examined a number of (η^5-indenyl)RhL_2 complexes and examined the factors effecting ground-state distortion and related ligand dynamics (5). While much effort has focused on measuring the energy barriers associated with olefin rotation in indenyl complexes (see ref. 6*c* for leading refs.), relatively few reports describe the barrier to rotation about the metal-ring axis. (4*a*, *b*, *d*, 6) This latter process has a lower activation energy for bis(ethylene) complex (η^5-C_9H_7)Rh(η^2-C_2H_4)$_2$ ($\Delta G_{190}^{\ddagger}$ = 8.5 ± 0.4 kcal mol^{-1}) compared to $\Delta G_{240}^{\ddagger}$ = 10.4 ± 0.4 kcal mol^{-1} observed for olefin rotation (6*c*) (Fig. 1).

Molecular orbital arguments (5*e*, 6*e*, 7) suggest a preferred ground-state conformation where the d^8-ML_2 unit lies parallel to a plane through the C3a-C7a ring-junction carbons of the indenyl ring straddling the C_s mirror plane of the molecule. This orientation best stabilizes the indenyl HOMO while minimizing a four-electron destabilizing π-interaction between the indenyl second HOMO and metal d_{xz}. Rotation of the ML_2 fragment by 90° therefore results in a net destabilization of the molecule. We have prepared a monophosphine complex (η^5-1-CH_3-C_9H_6)Rh(η-C_2H_4)(PCy_3) (Cy = cyclohexyl) (**1**) and a diphosphine analogue, (η^5-1-CH_3-C_9H_6)Rh(dcpe) (dcpe = $Cy_2PCH_2CH_2PCy_2$) (**2**), where incorporation of the methyl substituent at C1 of the indenyl ligand breaks the ground-state C_s symmetry of both molecules. Variable temperature $^{31}P\{^1H\}$ NMR studies have been conducted, allowing us to assess the energy barriers associated with indenyl ring rotation, the results of which, along with the molecular structures of complexes **1** and **2**, are presented herein.

Experimental section

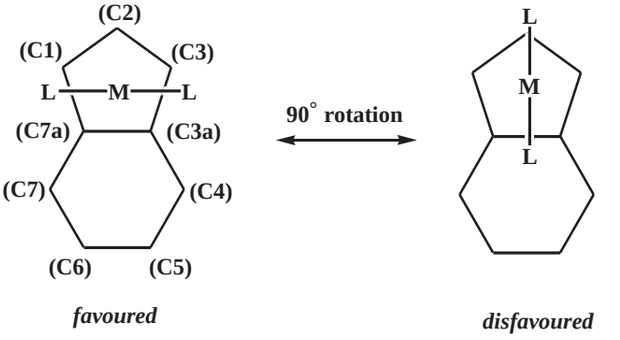
General procedures

NMR spectra were recorded on Bruker WM250 (^{1}H at 250 MHz, $^{13}C\{^1H\}$ at 63 MHz, $^{31}P\{^1H\}$ at 101 MHz), and Nicolet NMC-300 (^{1}H at 250 MHz, $^{13}C\{^1H\}$ at 75.4 MHz, $^{31}P\{^1H\}$ at 121 MHz) spectrometers. ^{1}H NMR chemical shifts are reported in ppm relative to external TMS and were referenced to residual protons in the solvent; coupling constants are in hertz. Multiplicities are reported as (s) singlet, (d) doublet, (t) triplet, (q) quartet, (m) multiplet, (br) broad, and (ov) overlapping. $^{31}P\{^1H\}$ chemical shifts are reported in ppm relative to the external standard 85% H_3PO_4. THF was freshly distilled from sodium benzophenone ketyl. PCy_3 and dcpe (Strem Chemical Co.) were used as received. (η^5-1-Me-C_9H_6)Rh(η^2-C_2H_4)$_2$ was prepared by established methods (6*c*).

Preparation of (η^5-1-CH_3-C_9H_6)Rh(η-C_2H_4)(PCy_3) (1)

A solution of PCy_3 (140 mg, 0.5 mmol) in 10 mL of THF was added dropwise to a solution of (η^5-1-CH_3-C_9H_6)Rh(η^2-C_2H_4)$_2$ (144 mg, 0.5 mmol) in 10 mL of THF at ambient temperature. After stirring for 12 h, the solution was concentrated in vacuo to 5 mL, hexane (20 mL) was added, and the solution cooled to –30°C for 48 h. The resulting orange–red crystals were collected by filtration, washed with hexane (2 × 10 mL), and dried in vacuo to yield 238 mg (88%) of **1**. Selected NMR spectroscopic data: $^{31}P\{H\}$ (THF-d_8, 298 K) δ: 53.9 (d, J_{P-Rh} = 209 Hz); ^{1}H (C_6D_6, 298 K) δ: 0.83–1.19 (br ov m), 1.34 (d, *J* = 5 Hz), 1.40 (br), 1.65 (m), 2.03 (m), 5.47 (d, *J* = 3 Hz, H2, 1H), 5.73 (dd, *J* = 3,1 Hz, H3, 1H), 6.73 (ov m, H4–6, 3H), 7.07 (m, H7, 1H); $^{13}C\{^1H\}$ (THF-d_8, 298 K) δ: 9.6 (d, *J* = 2.3 Hz), 14.3 (s), 23.1 (s), 26.0 (s), 27.2 (s), 28.3 (dd, *J* = 10, 4 Hz), 30.5 (d, *J* = 26 Hz), 32.0 (s), 36.1 (d, *J* = 18 Hz), 38.2 (s), 72.9 (d, *J* = 5 Hz), 83.1 (dd, *J* = 15, 4 Hz), 95.3 (d, *J* = 6 Hz), 114.4 (s), 114.5 (s), 118.3 (s), 119.7 (s), 120.0 (s), 122.5 (s).

Fig 1. ML_2 rotation with respect to the indenyl ligand.



Preparation of (η^5-1-CH_3-C_9H_6)Rh(dcpe) (2)

A solution of dcpe (211 mg, 0.5 mmol) in 10 mL of THF was added dropwise to a solution of (η^5-1-CH_3-C_9H_6)Rh(η^2-C_2H_4)$_2$ (144 mg, 0.5 mmol) in 10 mL of THF at ambient temperature. After stirring for 12 h, the solution was concentrated in vacuo to 5 mL, hexane (20 mL) was added, and the solution was cooled to –30°C for 48 h. The resulting red crystals were collected by filtration, washed with hexane (2 × 10 mL), and dried in vacuo to yield 258 mg (79%) of **2**. Selected NMR spectroscopic data: $^{31}P\{^1H\}$ (THF-d_8, 298 K) δ: 93.7 (d, J_{P-Rh} = 217 Hz); ^{1}H (THF-d_8, 298 K) δ: 0.86–1.34 (br ov m), 1.55–1.88 (br ov m), 2.30 (br s), 5.27 (s, 1H), 5.74 (s, 1H), 6.62 (app q, *J* = 7 Hz, 1H), 6.66 (app q, *J* = 7 Hz, 1H), 6.95 (d, *J* = 8 Hz, 1H), 7.06 (d, *J* = 8 Hz, 1H). $^{13}C\{^1H\}$ (THF-d_8, 298 K) δ: 1.41 (s, CH_3), 23.5 (d t, J_{C-P} = 19 Hz, J_{C-Rh} = 4 Hz), 25.2 (t, *J* = 20 Hz), 27.4 (d, J_{C-P} = 26 Hz), 27.8 (t, *J* = 11 Hz), 29.7 (q, *J* = 14 Hz), 38.5 (app q), 65.2 (d, J_{C-Rh} = 4 Hz), 84.4 (s), 96.2 (d, J_{C-Rh} = 5 Hz), 115.4 (s), 117.0 (s), 117.2 (s), 118.8 (s), 118.9 (s), 119.0 (s).

Molecular structure determination

Crystals of **1** and **2** suitable for X-ray diffraction studies were obtained by recrystallization from THF–hexane solution at –30°C. A summary of the crystal data and parameters for data collection is given in Table 1. Data were collected at room temperature on a Nicolet R3m/V diffractometer using graphite-filtered MoKα radiation (λ = 0.710 73 Å) and the ω scan method. The data and refinement of **1** and **2** were performed on an VAX 3100 computer using Siemens SHELXTL (VAX) software as described elsewhere (5, 8).

[a] $F_o > 6\sigma(F_o)$.

[b] ψ-Scan semi-empirical method.

[c] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $Rw = [\Sigma(w(|F_o| - |F_c|)^2/\Sigma(w|F_o|)^2]^{1/2}$.

[d] $[\Sigma(w(|F_o| - F_c|)^2/(NO - NV)]^{½}$.

The structure was solved using Patterson and Fourier techniques, and refinement was performed using full-matrix least squares on *F*, with anisotropic thermal parameters for all non-hydrogen atoms and isotropic thermal parameters for the hydrogen atoms (riding model). The function minimized was $\Sigma w(F_o - F_c)^2$ with the weights, $w^{-1} = \sigma^2(F)$ for both **1** and **2**. Selected bond distances and angles are given in Table 2, and final atomic coordinates are given in Tables 3 and 4. Crystal data, complete tables of bond distances and angles, atomic coordinates, anisotropic thermal parameters for the non-hydrogen atoms, and hydrogen atom positions, isotropic thermal parameters, and NMR data have been deposited.[5]

Results and discussion

Synthesis of rhodium(I) indenyl complexes

Complexes **1** and **2** were prepared directly by addition of 1 equiv. of the corresponding phosphines to (η^5-1-CH_3-C_9H_6)Rh(η-C_2H_4)$_2$ (**3**) (9). Attempts to prepare the sterically encumbered (η^5-1-CH_3-C_9H_6)Rh(PCy_3)$_2$ by addition of excess PCy_3 to **3** at ambient or elevated temperatures, however, proved unsuccessful, generating only the mixed ethylene–phosphine complex **1** (Fig. 2).

Molecular structures

The crystal structure of **1** contains two independent molecules in the asymmetric unit, which differ in respect to the stereochemistry of the phosphine ligands. Selected bond distances and angles are given in Table 2, and a view of the two molecules is provided in Fig. 3. The two molecules are chemically equivalent with the ethylene and phosphine ligands straddling a plane incorporating Rh and C2 of the indenyl ligand and bisecting the C3a-C7a vector. The ethylene ligands lie directly below the methyl substituent of the indenyl group having an average carbon–carbon bond length of 1.390(11) Å. These bonds are significantly longer than

[5] A complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of anisotropic and isotropic thermal parameters and NMR data, these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Although the substituted indenyl ligand is bound to the rhodium centre in an η^5-fashion, there is a certain amount of distortion towards an η^3-bonding mode. Both rhodium atoms have three short Rh—C distances (average = 2.235(7) Å)

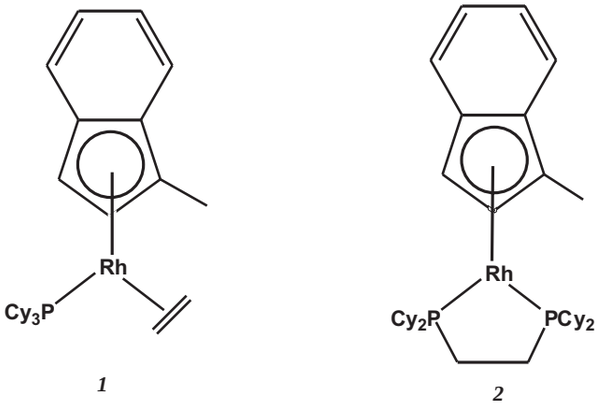
Fig 2. Complexes (η^5-1-CH_3-C_9H_6)Rh(η^2-C_2H_4)(PCy_3) (**1**) and (η^5-1-CH_3-C_9H_6)Rh(dcpe) (**2**).



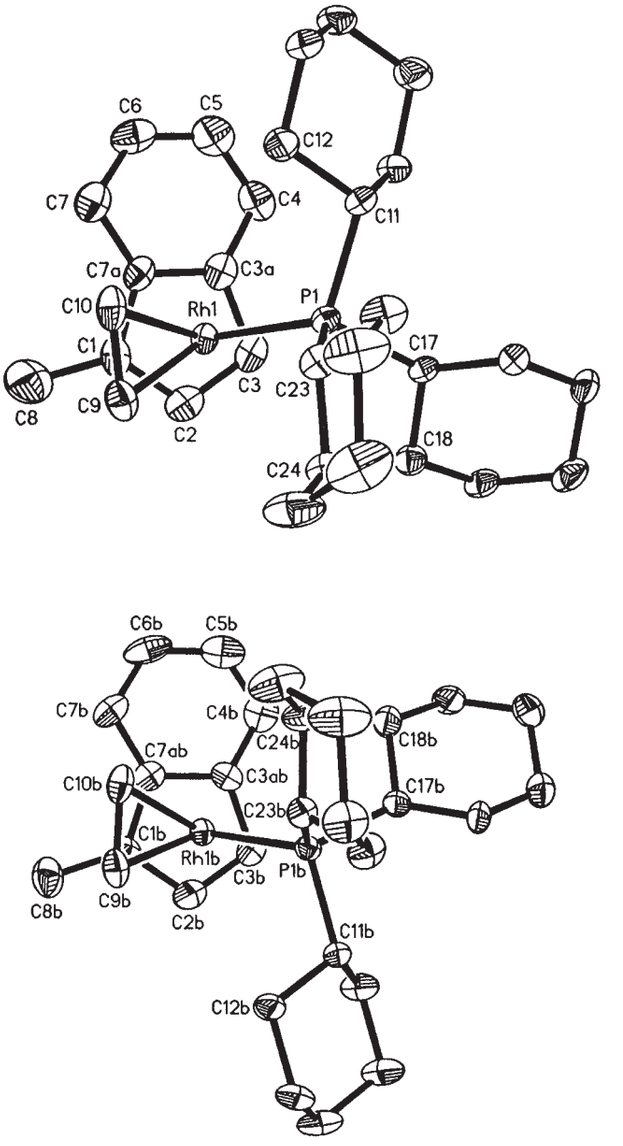
1 *2*

and two longer Rh—C distances (average = 2.427(7) Å); the latter bonds involving the bridge head atoms C3a, C7a. The slip parameter (Δ = *d*(average Rh—C3a,7a) – *d*(average Rh—C1,3)) was calculated to be 0.198(7) Å for molecule A and 0.176(7) Å for molecule B, giving an average value of 0.187(7) Å. Average values for the hinge angle (HA = angle between normals to the least-squares planes defined by C1, C2, C3 and C1, C7a, C3a, C3) and fold angle (FA = angle between normals to the least-squares planes defined by C1, C2, C3 and C3a, C4, C5, C7, C7a) are 8.9 and 10.5°, respectively. Such distortions towards η^3-allyl systems are well-established for d^8-ML_2 compounds (1–6). The degree of distortion in the solid state has been correlated with the electronic nature of the ML_2 fragment where, in general, the greater the electron-donating ability of the fragment, the higher the degree of slip-fold distortion (6*d*).

A fourth type of distortion is also present in **1** as the RhL_2 fragment is skewed slightly towards one side of the five-membered ring of the indenyl ligand. This skew-distortion has been reported recently for analogous nickel indenyl (6*h*) and cyclopentadienyl systems (11). This distortion in **1** appears to be a function of the disposition of the bulky cyclohexyl groups of the phosphine ligand. In molecule A one cyclohexyl ring lies roughly parallel with the Rh—C2 bond under the cyclopentadienyl fragment of the indenyl ring, while in molecule B this ring is rotated approximately 180° and lies under the six-membered ring of the indenyl group. As a result, the Rh—C1 bond (2.206(7) Å) in molecule A is slightly shorter than the corresponding Rh—C3 bond (2.272(7) Å), whereas in molecule B the Rh—C1(b) bond (2.275(7) Å) is somewhat longer than the Rh—C3(b) bond (2.207(7) Å).

Slip-fold distortions are also present in bis(phosphine) complex **2**. Selected bond distances and angles are given in Table 2, and a view of **2** is provided in Fig. 4. The bonding of the RhP_2 fragment is again unsymmetric with respect to the indenyl ligand, containing three short Rh—C distances (average = 2.249(2) Å) and two long Rh—C distances (average = 2.428(2) Å). The slip parameter was calculated to be 0.179(2) Å whereas values for the hinge angle and fold angle are 9.2° and 9.5°, respectively. Interestingly, the degree of slip-fold distortion in **2** is approximately equal to that observed in **1**, where the effect of replacing the second ethylene ligand with a more basic phosphine moiety appears to be minimal at least in the solid state. A pronounced skew-distortion in **2** attests to the influence the unsymmetrical indenyl ligand has on the rhodium–carbon bond distances.

Fig 3. Molecular structure of the two molecules of **1** with the hydrogen atoms omitted for clarity.



NMR spectroscopic studies

It has been reported that two separate resonances are observed in the ^{1}H NMR spectra of d^8-indenyl metal ethylene complexes for the inner and outer protons of the ethylene moiety (6*c*, *e*). The inner ethylene protons are shielded due to their proximity to the overlying indenyl group and are reported at approximately 0.5–2.0 ppm. Conversely, the outer protons are deshielded and resonate at approximately 2.5–3.0 ppm. Unfortunately, unequivocal assignment of the

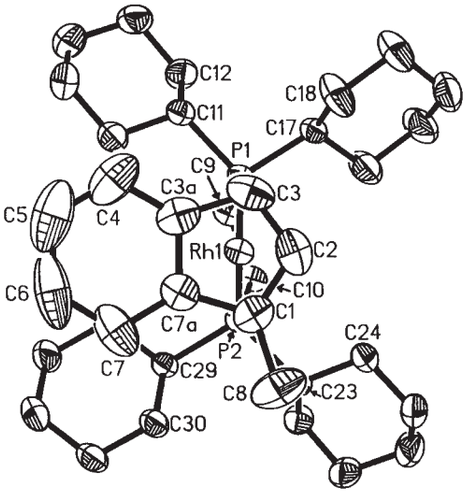
Fig 4. Molecular structure of **2** with hydrogen atoms omitted for clarity.



inner protons is complicated by nearby resonances due to the cyclohexyl groups of the phosphine ligand. For this reason, energy barriers associated with ethylene rotation could not be obtained.

While slippage of the indenyl ring from planar η^5 towards allylic η^3-bonding is observed in the solid state, this distortion is also thought to persist to some extent in solution (1–6, 12). Indeed, $^{13}C\{^1H\}$ NMR spectroscopy can be used as a diagnostic tool to measure the degree of hapticity of the indenyl ligand in solution (4, 6*b*). The chemical shifts of the indenyl ring junction carbons are compared to those for sodium indenide, a standard for planar η^5 bonding (6*b*, 12). The quaternary carbon (C3a, C7a) chemical shifts for **1** are observed at δ 114.5 and 118.3 ppm and are consistent with a slight distortion towards the η^3 form in solution. Likewise, chemical shifts observed for the analogous ring-junction carbons in **2** at δ 117.2 and 118.8 ppm also suggest a certain degree of distortion. For comparison, in the complex $(\eta^3\text{-}C_9H_7)Ir(PMe_2Ph)_3$, which contains a true η^3-indenyl ligand, these carbon resonances are observed at δ 156.7 ppm (13). $^{13}C\{^1H\}$ NMR data pertaining to the indenyl ring for complexes **1** and **2** are provided in Table 5, and are compared to values for the bis(ethylene) complex $(\eta^5\text{-}1\text{-}CH_3C_9H_6)Rh(\eta^2\text{-}C_2H_4)_2$ (**3**). It is interesting to note that addition of a second phosphine moiety has little effect on the carbon chemical shifts as evidenced by similar resonances observed for both the mixed phosphine–ethylene complex **1** and the bis(phosphine) complex **2**. As expected, however, a significant change in chemical shift is observed on going from the strong π-accepting bis(ethylene) complex to the σ-donating phosphine-containing products. The chemical shift difference between indenyl C2 and C3 nuclei is yet another parameter that has been used to measure the degree of distortion within metal–indenyl complexes (4, 6*f*).

Energy barriers to indenyl ring rotation

The 121 MHz $^{31}P\{^1H\}$ spectrum of **1** at room temperature exhibits a doublet (J_{P-Rh} = 209 Hz) at 53.9 ppm split by ^{103}Rh (I = 1/2, 100% abundant). Variable temperature $^{31}P\{^1H\}$ NMR measurements have allowed an evaluation of the barrier to RhL_2 rotation about the indenyl–rhodium axis, where incorporation of the methyl substituent at Cl of the indenyl ligand breaks the ground-state *Cs* symmetry of the molecule. The low temperature limiting spectrum obtained at –100°C displays a pair of doublets with an intensity ratio of approximately 1:2 (δ 54.9 and 53.0 ppm with J_{P-Rh} = 209 Hz). Only minor changes in rotamer populations were observed over the temperature range examined (i.e., 40:60 at –125°C and 44:56 at –75°C). Taking this into account, along with a slight temperature dependence of chemical shifts, a $\Delta G^{\ddagger}_{193}$ value of 8.6 ± 0.05 kcal mol^{-1} has been calculated for indenyl ring rotation. An Eyring plot for the kinetic data for **1** and a linear least-squares analysis of these data gives values of $\Delta H^{\ddagger}$ = 10.5 ± 0.8 kcal mol^{-1} and $\Delta S^{\ddagger}$ = 9.7 ± 4.4 cal mol^{-1} K^{-1}.

It seemed possible that the dynamic process could have involved a hindered rotation about the Rh—P bond, resulting in an exchange of the two distinct species observed in the solid state. Likewise, a dynamic process involving dissociation and flipping the indenyl ring by 180° would also account for the formation of two rotamers. However, the data are completely consistent with the more reasonable explanation of hindered indenyl rotation as observed in all other d^8-ML_2 complexes of 1-Me-indene. Indeed, in a similar study, a barrier of $\Delta G^{\ddagger}_{190}$ = 9.7 ± 0.4 kcal mol^{-1} was measured for rotation about the metal-ring axis in $(\eta^5\text{-}C_9H_7)Rh(\eta\text{-}C_2H_4)_2$ (6*c*). It is interesting to note that a higher energy process ($\Delta G^{\ddagger}_{240}$ = 10.4 ± 0.5 kcal mol^{-1}) was observed in this complex and attributed to an olefin rotation process. As mentioned previously, obstruction of the ethylene resonances in the ^1H NMR by overlapping cyclohexyl resonances from the phosphine ligand precluded similar measurements for complex **1**.

The room temperature $^{31}P\{^1H\}$ spectrum of **2** consists of a doublet at 93.7 ppm (J_{P-Rh} = 217 Hz). The corresponding low-temperature spectrum exhibits two doublet of doublets at δ 98.0 and 89.3 ppm with J_{P-Rh} = 217 Hz arising from the ABX spin systems. While replacement of one of the ethylene moieties with a basic phosphine ligand seems to have little effect on the barrier to indenyl ring rotation, higher energy barriers are observed for bis(phosphine) complexes. Thus, the free energy of activation for ring rotation in **2** was

© 1999 NRC Canada

calculated to be $\Delta G^{\ddagger}_{253} = 10.8 \pm 0.2$ kcal mol^{-1}. This value is comparable to energies observed for the analogous bis(phosphine) complex (η^5-1-CH_3-C_9H_6)Rh(PMe_3)$_2$ ($\Delta G^{\ddagger}_{253} = 11.2 \pm 0.03$ kcal mol^{-1}) (6*d*) and bis(carbonyl) complex (η^5-1-CH_3-C_9H_6)Rh(CO)$_2$ ($\Delta G^{\ddagger}_{213} = 11.27 \pm 0.09$ kcal mol^{-1}) (6*e*). Barriers of approximately 11 kcal mol^{-1} have also been observed in bimetallic Rh–Cr complexes (6*a*, *f*). Although it is difficult to assess the factors governing these energy barriers, it is of interest to note that much lower barriers are obtained for complexes containing ancillary ethylene ligands. Further work is therefore required to gain a better understanding of the factors effecting the barrier to indenyl ring rotation in these systems.

Conclusions

We have prepared the mixed phosphine–ethylene complex (η^5-1-CH_3-C_9H_6)Rh(η-C_2H_4)(PCy_3) (**1**) and bis(phosphine) complex (η^5-1-CH_3-C_9H_6)Rh(dcpe) (**2**) in high yields. Single crystal X-ray diffraction and $^{13}C\{^1H\}$ NMR spectroscopic studies have been used to demonstrate that complexes **1** and **2** show a similar degree of slip-fold distortion in both the solid and solution states, towards an η^3-allylic bonding mode with respect to the indenyl ligand. Variable temperature $^{31}P\{^1H\}$ NMR studies were conducted on both complexes as well. From this data, energy barriers associated with rotation about the indenyl ring – rhodium axis were calculated to be approximately 8.5 and 10.8 kcal mol^{-1} for complexes **1** and **2**, respectively. While $\Delta G^{\ddagger}$ does not appear to be correlated with the degree of slip-fold distortion, lower energies are observed for indenyl rhodium complexes containing ethylene ligands.

Synthesis of 5-phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine and its evaluation as an anticonvulsant agent

Oludotun A. Phillips, K.S. Keshava Murthy, Charles Y. Fiakpui, and Edward E. Knaus

Abstract: The homolytic benzoylation (benzoyl radical) of 5-*tert*-butylcarbonylaminopyrimidine (**6**, 1 equiv.) in the presence of benzaldehyde (3 equiv.), water, sulfuric acid, and acetic acid, upon treatment with $FeSO_4 \cdot 7H_2O$ (3 equiv.) and 70% *t*-BuOOH (3 equiv.) at 5–10°C for 10 min afforded a mixture of 4-benzoyl-5-*tert*-butylcarbonylaminopyrimidine (**7**, 23%), 4,6-dibenzoyl-5-*tert*-butylcarbonylaminopyrimidine (**8**, 44%), and 4-benzoyl-5-*tert*-butylcarbonylamino-6-methylpyrimidine (**9**, 10%). When a similar reaction was performed using 1 equiv. each of PhCHO, $FeSO_4 \cdot 7H_2O$, and *t*-BuOOH, to prevent formation of the 4,6-dibenzoyl product **8**, the monobenzoyl (**7**, 38%) and 4-benzoyl-6-methyl (**9**, 6%) products were obtained. A similar homolytic benzoylation of 5-bromopyrimidine (**10**) using 1.5 equiv. of reagents to generate the benzoyl radical afforded 4-benzoyl-5-bromopyrimidine (**11**, 61%) as the predominant product. Elaboration of **11** via a six-step reaction sequence afforded 2-hydrazino-5-phenyl-3*H*-pyrimido[5,4-*e*][1,4]diazepine (**17**) in 5.2% overall yield. The acid-catalyzed reaction of **17** with triethyl orthoacetate gave the title compound 5-phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine (**18**, 62%). The triazolo compound **18** was more potent than valproic acid (Depakene®) in both the subcutaneous metrazol (scMet) and maximal electroshock (MES) anticonvulsant screens, and more potent than clonazepam in the MES anticonvulsant screen but less potent than clonazepam in the scMet anticonvulsant screen.

Key words: homolytic benzoylation, pyrimidines, pyrimidodiazepines, anticonvulsants.

Résumé : La benzoylation homolytique (radical benzoyle) de la 5-*tert*-butylcarbonylaminopyrimidine (**6**, 1 équiv.), en présence de benzaldéhyde (3 équiv.), d'eau, d'acide sulfurique et d'acide acétique, par réaction avec du $FeSO_4 \cdot 7H_2O$ (3 équiv.) et du *t*-BuOOH à 70% (3 équiv.) à 5–10°C pendant 10 min conduit à un mélange de 4-benzoyl-5-*tert*-butylaminopyrimidine (**7**, 23%), de 4,6-dibenzoyl-5-*tert*-butylaminopyrimidine (**8**, 44%) et de 4-benzoyl-5-*tert*-butylamino-6-méthylpyrimidine (**9**, 10%). Quand on effectue la même réaction en utilisant un équivalent chacun de PhCHO, $FeSO_4 \cdot 7H_2O$ et *t*-BuOOH pour empêcher la formation du produit 4,6-dibenzoylé **8**, on obtient les produits monobenzoyle (**7**, 38%) et 4-benzoyl-6-méthyle (**9**, 6%). Une benzoylation homolytique semblable de la 5-bromopyrimidine (**10**) en utilisant 1,5 équiv. des réactifs pour générer le radical benzoyle conduit à la formation de la 4-benzoyl-5-bromopyrimidine (**11**, 61%) comme produit principal. Une séquence de synthèse en six étapes à partir du produit **11** permet d'obtenir la 2-hydrazino-5-phényl-3*H*-pyrimido[5,4-*e*][1,4]diazépine (**17**) avec un rendement global de 5,2%. La réaction acidocatalysée de **17** avec l'orthoacétate de triéthyle fournit le composé mentionné dans le titre, la 5-phényl-10-méthyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazépine (**18**, 62%). Le composé triazolo **18** est plus actif que l'acide valproïque (Depakenc®) dans les épreuves sous-cutanées métrazel (« scMet ») que dans celles anticonvulsantes avec électrochocs maximaux (« MES »); comparé au clonazépame, il est plus actif dans les épreuves anticonvulsantes MES, mais moins actif dans l'épreuve anticonvulsante scMet.

Mots clés : benzoylation homolytique, pyrimidines, pyrimidodiazépines, anticonvulsants.

[Traduit par la Rédaction]

Introduction

Structure–activity studies for the benzo[1,4]diazepin-2-one class of compounds (**1**) indicated that an electronegative X-substituent at C-7 is an essential requirement for anticonvulsant, sedative, hypnotic, and muscle relaxant activities (1–3). In earlier studies, we showed that the 1,3-dihydro-5-phenyl-2*H*-pyrido[3,4-*e*][1,4]diazepin-2-one (**2**)

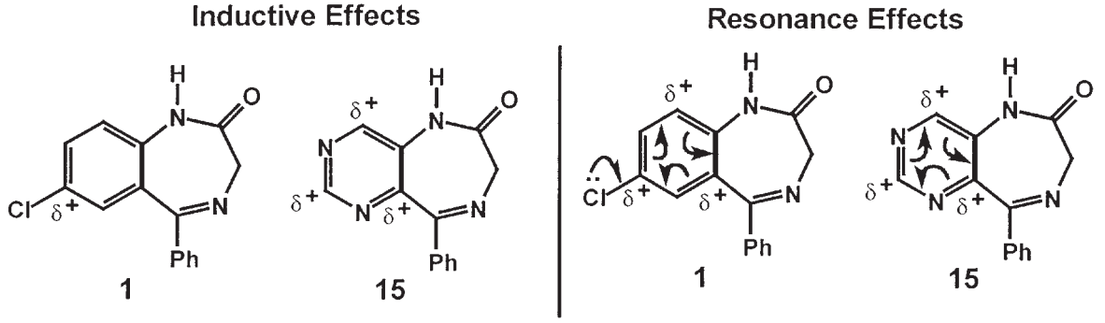
Fig. 1. A comparison of the inductive and resonance effects exhibited by the chlorophenyl substituent in chlorobenzene (**1**) and the ring nitrogens in pyrimidine (**15**).



and 1,3-dihydro-5-phenyl-2*H*-pyrido[3,2-*e*][1,4]diazepin-2-one (**3**) classes of compounds, which are electronically analogous to 7-chloro(nitro)-benzo[1,4]diazepin-2-one (**1**), exhibited anticonvulsant activity (4, 5). It was therefore of interest to extend these structure–activity relationships to include the 1,3-dihydro-5-phenyl-2*H*-pyrimido[5,4-*e*][1,4]diazepin-2-one (**15**) class of compounds, which also are electronically analogous to the chlorophenyl analog (**1**, X = Cl), since they possess similar electron-density profiles at equivalent positions. When the inductive and resonance effects of a chloro substituent (**1**, X = Cl) and the pyrimido ring nitrogen atoms of the pyrimido compound (**15**) are compared, the resulting electron densities are qualitatively similar for the chlorophenyl and pyrimido ring systems at equivalent positions as illustrated in Fig. 1. This study was therefore initiated to determine whether the chlorophenyl and pyrimido ring systems are bioisosteric with respect to anticonvulsant activities, since these ring systems are similar in size and shape (phenyl and pyrimido), and they possess similar electron-density profiles at equivalent positions. Furthermore, the pyrimido nitrogen atom free-electron pairs have the potential to act as H-bond acceptors, which may provide a receptor binding interaction that is not possible with a chlorophenyl ring. Accordingly, it is plausible that the chlorophenyl (**1**) and pyrimido (**15**) classes of compounds could interact with the same receptor site(s) to elicit anticonvulsant activities.

Chemistry

In earlier studies, we developed synthetic methodologies, involving *ortho*-directed lithiation of 3-*tert*-butylcarbonylaminopyridine, that were applicable to the preparation of 3-*tert*-butylcarbonylamino-4-benzoylpyridines (6, 7). In contrast, all attempts to prepare 4-benzoyl-5-*tert*-butylcarbonylaminopyrimidine (**7**) using a similar *ortho*-directed lithiation of 5-*tert*-butylcarbonylaminopyrimidine (**6**), prepared by the Pd/C catalyzed dechlorination of 5-amino-4,6-dichloropyrimidine (**4**), which was elaborated to 5-*tert*-butylcarbonylaminopyrimidine (**6**) upon reaction with trimethylacetyl chloride and Et_3N, were unsuccessful. Although *ortho*-lithiation occurs at the C-4 position of **6**, this lithio, or radical anion, species attacks either the highly electron-deficient C-4, or C-2, position of **6** to exclusively afford bis(5-*tert*-butylcarbonylaminopyrimidine) products prior to addition of an electrophilic reagent such as benzaldehyde. Similar self-condensation coupling reactions of pyrimidine and pyridine derivatives in the presence of lithium diisopropylamide have been reported (8–10).

To overcome the formation of bis(5-*tert*-butylcarbonylaminopyrimidine) self-condensation products during the *ortho*-directed lithiation of 5-*tert*-butylcarbonylaminopyrimidine (**6**), the nucleophilic character of an acyl radical generated in a one-step reaction (11) from an aldehyde in water containing sulfuric acid, *tert*-butylhydroperoxide, ferrous sulfate, and acetic acid reported for the acylation of quinoline (11, 12), 4-cyanopyridine (13), 2-substituted-pyrazines (14, 15), and quinoxaline (16) was investigated. Accordingly, this selective homolytic acylation of protonated heteraromatic bases was used for the benzoylation of 5-*tert*-butylcarbonylaminopyrimidine (**6**). Thus, the homolytic benzoylation of **6** (1 equiv.) in the presence of benzaldehyde (3 equiv.), water, sulfuric acid, and acetic acid, upon treatment with $FeSO_4 \cdot 7H_2O$ (3 equiv.) and 70% *t*-BuOOH (3 equiv.) at 5–10°C for 10 min afforded a mixture of 4-benzoyl-5-*tert*-butylcarbonylaminopyrimidine (**7**, 23%), 4,6-dibenzoyl-5-*tert*-butylcarbonylaminopyrimidine (**8**, 44%), and 4-benzoyl-5-*tert*-butylcarbonylamino-6-methylpyrimidine (**9**, 10%) (see Scheme 1). Introduction of the 6-methyl substituent into **9** likely arises from decomposition of *t*-BuOOH to acetone and a methyl radical which adds to the C-6 position of 4-benzoyl-5-*tert*-butylcarbonylaminopyrimidine (**7**). When the reaction was performed using 1 equiv. each of PhCHO, $FeSO_4 \cdot 7H_20$ and *t*-BuOOH, to prevent the formation of the 4,6-dibenzoyl product **8**, the monobenzoyl prod-

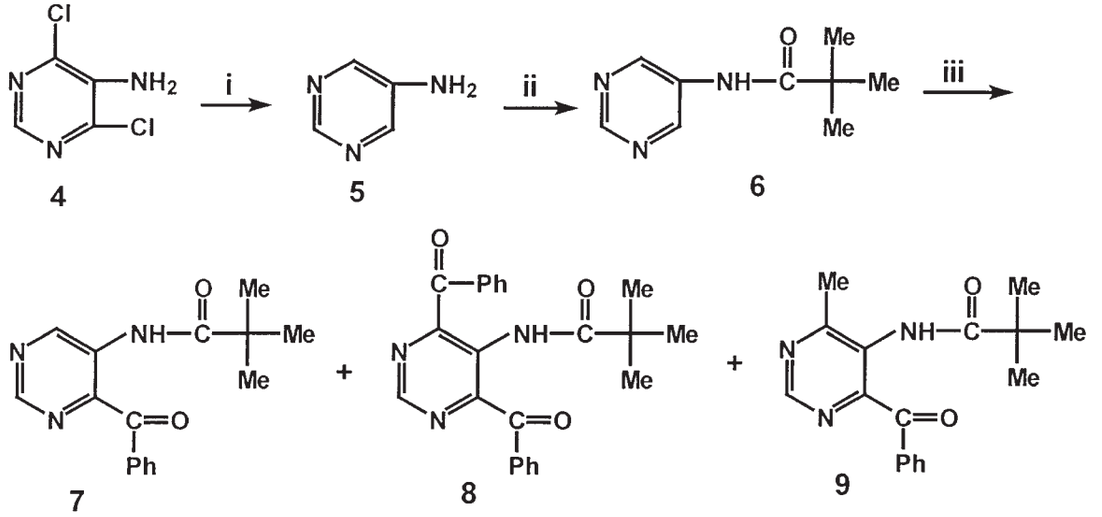
Scheme 1. Reagents: i, 10% Pd/C, 20% w/v aqueous NaOH, H_2 gas at 30 psi, Et_2O, 25°C; ii, Me_3COCl, Et_3N, CH_2Cl_2, 0°C for 30 min and then 25°C for 3 h; iii, H_2O, concentrated H_2SO_4, PhCHO (3 equiv.), HOAc, 0°C and then $FeSO_4 \cdot 7H_2O$ (3 equiv.), 70% w/v *t*-BuOOH (3 equiv.), 5–10°C, 10 min.



uct **7**, the 4-benzoyl-6-methyl product **9**, and unreacted **6** were obtained in 38, 6, and 23% (recovery) chemical yields, respectively. It has been reported that the yield of monoacylation product can be increased by replacement of HOAc with CH_2Cl_2 in homolytic acylation reactions (15). When HOAc is used, the reaction mixture is homogenous. Alternatively, in the absence of HOAc a heterogeneous medium is obtained, which has be proposed to result in the monoacylation product being extracted into the organic layer (CH_2Cl_2) where it is more soluble thereby protecting the monoacylation product from further acylation. However, in this study, replacement of HOAc by CH_2Cl_2 was not successful, since no reaction occurred and the starting material **6** was recovered.

A similar homolytic benzoylation (benzoyl radical) of 5-bromopyrimidine (**10**) was investigated with the objective of increasing the yield of the monoacylation product and preventing the formation of the dibenzoylation (**8**) and methyl radical (**9**) products previously observed upon reaction with 5-*tert*-butylcarbonylaminopyrimidine (**6**). This rationale is based on the premise that (*i*) a bromo substituent should direct predominately *ortho*-substitution and (*ii*) the bromo substituent can be displaced by a nitrogen nucleophile (14). Accordingly, homolytic benzoylation of 5-bromopyrimidine (**10**) with a benzoyl radical, as described previously (see Scheme 1) afforded 4-benzoyl-5-bromopyrimidine (**11**) as the predominant, or exclusive, product which was readily purified by silica-gel column chromatography (61% yield) (see Scheme 2). Amination of **11** using aqueous NH_4OH in the presence of $CuSO_4 \cdot 5H_2O$ yielded 5-amino-4-benzoylpyrimidine (**12**, 22%). The subsequent reduction of **12** with $NaBH_4$ in MeOH gave 5-amino-4-(α-hydroxybenzyl)pyrimidine (**13**, 75%), which was converted to 4-benzoyl-5-benzyloxycarbonylaminomethylcarbonylaminopyrimidine (**14**, 84%) by coupling to the carboxyl group of $PhCH_2OCONHCH_2CO_2H$ in the presence of dicyclohexylcarbodiimide (DCC) and then oxidation of the alcohol using MnO_2. Cyclization of **14** with 33% w/v HBr in HOAc afforded 1,3-dihydro-5-phenyl-2*H*-pyrimido[5,4-*e*][1,4]diazepin-2-one (**15**, 67%), which was elaborated to the corresponding 2-thione derivative (**16**, 70%). Reaction of **16** with $H_2NNH_2 \cdot H_2O$ in MeOH gave the 2-hydrazino-5-phenyl-3*H*-pyrimido[5,4-*e*][1,4]diazepine (**17**, 80%), which was immediately converted to 5-phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine (**18**, 62%) upon reaction with triethyl orthoacetate in the presence of concentrated H_2SO_4.

Biological evaluation of 5-phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine (18) as an anticonvulsant agent

The anticonvulsant activities of 5-phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine (**18**) were determined by the Antiepileptic Drug Development (ADD) Program that is administered by the Section on Epilepsy, United States National Institutes of Health, Bethesda, Md. Anticonvulsant activities against subcutaneous metrazol (scMet) and maximal electroshock (MES) induced seizures, which are models for absence (petit mal) and generalized tonic clonic (grand mal) seizures, respectively, were measured in mice and (or) rats at various time intervals after intraparietoneal (ip), or oral (po), administration of the test compound **18** using procedures previously reported (7). In the Phase II quantitative screen in mice, **18** was moderately active (ED_{50} = 79.5 mg/kg ip at 1 h post drug administration) against MES-induced seizures, very active (ED_{50} = 6.2 mg/kg ip at 15 min post drug administration) against scMet-induced seizures, and it was nontoxic (TD_{50} > 150 mg/kg ip at 15 min post drug administration in mice). The ED_{50} values for the standard reference drugs in these anticonvulsant screens were clonazepam (scMet, ED_{50} = 0.02 mg/kg; MES, ED_{50} = 86.6 mg/kg) and valproic acid (scMet, ED_{50} = 148.6 mg/kg; MES, ED_{50} = 271.7 mg/kg). In

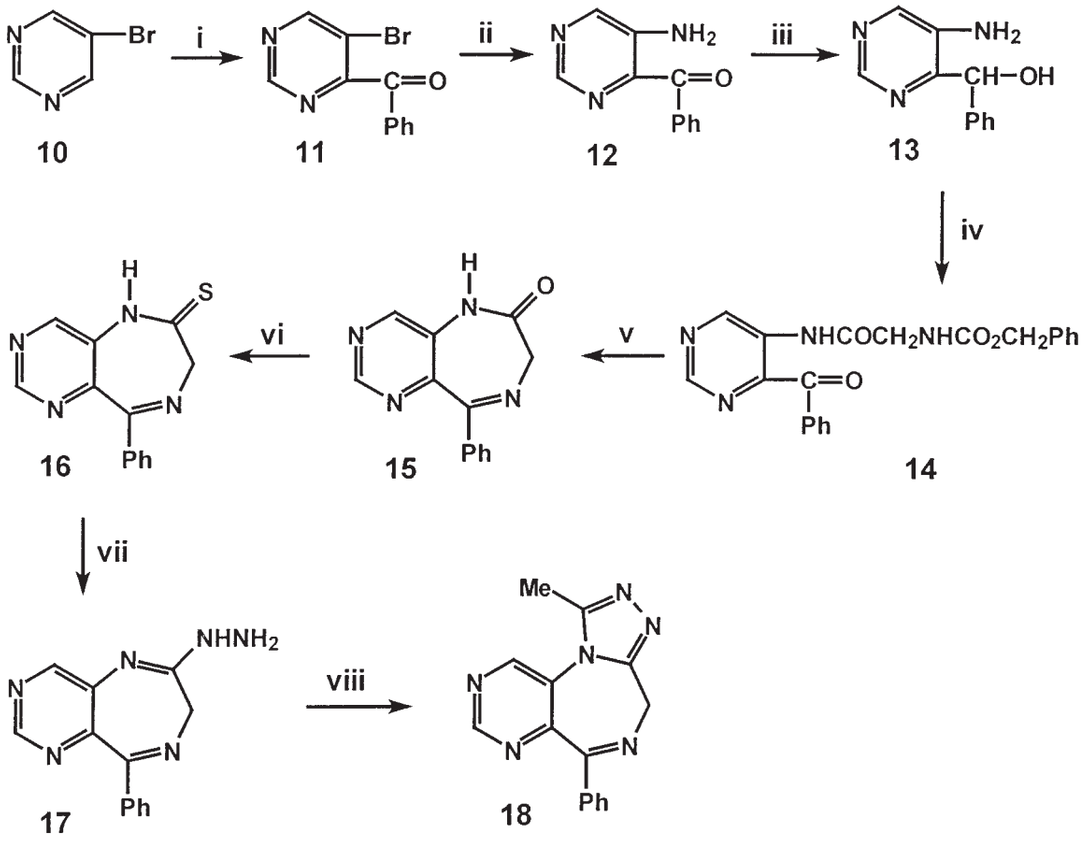
Scheme 2. Reagents: i, PhCHO (1.5 equiv.), HOAc, 4N H_2SO_4 and then $FeSO_4 \cdot 7H_2O$ (1.5 equiv.), H_2O, 70% *t*-BuOOH (1.5 equiv.), 0–5°C for 0.5 h and then 25°C for 2 h; ii, 37% w/v aqueous NH_4OH, $CuSO_4.5H_2O$, 0.5 h at 25°C and then 90°C for 20 h; iii, $NaBH_4$, MeOH, 0–5°C and then 25° for 1.5 h; iv, dicyclohexylcarbodiimide, THF–CH_2Cl_2 (1:1, v/v), $PhCH_2OCONHCH_2CO_2H$, 20 min at 25°C and then 2.5 h at reflux; MnO_2, $CHCl_3$, 25°C, 20 h; v, 33% w/v HBr in HOAc, 25°C, 2.5 h and then Et_2O, 10% w/v aqueous MeOH, NH_4OH, 25°C, 6 h; vi, Lawesson's reagent (2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide), benzene, reflux under argon, 1 h; vii, $H_2NNH_2 \cdot H_2O$, MeOH, 25°C, 2h; viii, triethyl orthoacetate, EtOH, concentrated H_2SO_4, 0°C → 25°C, 4 h.



addition, **18** also exhibited good anticonvulsant activity in the Phase VIa rat oral screen where a 50 mg/kg oral dose protected 2/4, 2/4, and 1/4 rats against seizures at 15 min, 1 h, and 4 h post drug administration, respectively, in the MES screen, and 4/4, 4/4, and 2/4 rats were protected at 15 min, 1 h and 4 h post drug administration, respectively, in the scMet screen.

The ability of **18** to prevent convulsions induced by other convulsion-inducing agents was also investigated in mice at 15 min following an ip dose of **18** (sc bicuculline test: ED_{50} > 10 mg/kg; sc picrotoxin test: ED_{50} = 7.72 mg/kg; and sc strychnine test: ED_{50} > 10 mg/kg). Bicuculline blocks γ-aminobutyric acid (GABA) receptors and this interferes with GABA inhibitory function thereby inducing both clonic and tonic extensor convulsions. Picrotoxin interferes with chloride channels that are regulated by GABA receptors thereby inducing minimal threshold seizures.

The ability of **18** to displace 50% of 10 nM [^{3}H]flunitrazepam from mouse whole brain P_2 pellets (IC_{50} = 72 μM) indicates it has a weaker affinity for the benzodiazepine receptor site(s) as compared to the reference drug clonazepam (5-(2-chlorophenyl)-7-nitrobenzo[1,4]diazepin-2-one, IC_{50} = 0.003 μM).

The results of this study indicate **18** is more potent than valproic acid (Depakene®) in both the scMet and MES screens, more potent than clonazepam in the MES screen, but less potent than clonazepam in the scMet screen.

Experimental

Melting points were determined using a Buchi capilliary apparatus and are uncorrected. Nuclear magnetic resonance spectra (^{1}H NMR, ^{13}C NMR) were determined on a Bruker AM-300 spectrometer. The assignment of exchangeable protons (O*H*, N*H*) was confirmed by the addition of D_2O. ^{13}C NMR spectra were acquired using the *J* modulated spin-echo technique where methyl and methine carbon resonances appear as positive peaks, and methylene and quaternary carbon resonances appear as negative peaks. Infrared (IR) spectra were acquired using a Nicolet 550 Series II Magna FT-IR spectrometer. Silica-gel column chromatography was carried out using Merck 7734 silica gel (60–200 mesh). Preparative

© 1999 NRC Canada

thin-layer chromatography (TLC) was performed using Keiselgel silica-gel (Camag) plates, 1.0 mm in thickness. All reagents were purchased from the Aldrich Chemical Co.

5-Aminopyrimidine (5)

A solution of 5-amino-4,6-dichloropyrimidine (2.0 g, 12.2 mmol) in ether (240 mL) and then 10% palladium-on-charcoal (160 mg) was added to a solution of 20% w/v NaOH (8 g) in water (32 mL) in a low-pressure hydrogenation bottle, and the mixture was agitated at 25°C under hydrogen gas at 30 psi (1 psi = 6.895 kPa) until the uptake of hydrogen gas had ceased. The reaction mixture was filtered through a celite pad which was then washed with warm water (2 × 16 mL). The pH of the combined filtrates was made strongly alkaline by addition of NaOH at less than 5°C. Ether (20 mL) was added, the mixture was extracted by stirring overnight at 25°C, the ether layer was separated, and the aqueous fraction was further extracted with ether (3 × 80 mL). The combined ether extracts were dried ($MgSO_4$), and the solvent was removed in vacuo to give **5** as colorless crystals after recrystallization from benzene containing a few drops of methanol (1.1 g, 95%); mp 170–171°C (lit. mp 171–172°C (17)); ^{1}H NMR ($CDCl_3$) δ: 3.80 (br s, 2H, N*H*$_2$), 8.25 (s, 2H, H-4, H-6), 8.70 (s, 1H, H-2).

5-*tert*-Butylcarbonylaminopyrimidine (6)

A solution of trimethylacetyl chloride (1.67 g, 13.9 mmol) in dry CH_2Cl_2 (1.5 mL) was added dropwise to an ice-cooled solution of **5** (1.2 g, 12.6 mmol) and Et_3N (1.6 g, 15.8 mmol) in dry CH_2Cl_2 (25 mL) at 0°C with stirring during 30 min. The reaction was allowed to proceed with stirring at 25°C for 3 h, and the reaction mixture was poured onto water (40 mL). Extraction with CH_2Cl_2 (2 × 100 mL), washing the combined CH_2Cl_2 extracts with 10% w/v $NaHCO_3$, and then brine (25 mL), drying the CH_2Cl_2 fraction (Na_2SO_4) and removal of the solvent in vacuo gave a yellow–brown viscous oil that was purified by preparative TLC using MeOH–EtOAc (1:20, v/v) as development solvent. Extraction of the band (R_f = 0.56) gave a yellow oil which was recrystallized from EtOAc–hexane (1:3, v/v) to afford **6** as needle-like crystals (1.14 g, 50%); mp 120–121°C; IR ($CHCl_3$): 3442 (NH), 1693 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.36 (s, 9H, C*Me*$_3$), 7.40 (br s, 1H, N*H*), 8.98 (s, 1H, H-2), 9.00 (s, 2H, H-4, H-6). Anal. calcd. for $C_9H_{13}N_3O$: C 60.31, H 7.31, N 23.45; found: C 60.46, H 7.39, N, 23.24.

4-Benzoyl-5-*tert*-butylcarbonylaminopyrimidine (7), 5-*tert*-butylcarbonylamino-4,6-dibenzoylpyrimidine (8) and 4-benzoyl-5-*tert*-butylcarbonylamino-6-methylpyrimidine (9)

A saturated solution of $FeSO_4 \cdot 7H_2O$ (0.93 g, 3.26 mmol) in water (12 mL) and 70% w/v *t*-BuOOH (303 mg, 3.36 mmol) were added simultaneously to a mixture containing **6** (0.20 g, 1.12 mmol), water (2 mL), concentrated H_2SO_4 (80 μL), benzaldehyde (357 mg, 3.36 mmol), and HOAc (3 mL) at 5–10°C with stirring. The reaction was allowed to proceed at 5–10°C for 10 min with stirring prior to neutralization with saturated aqueous $NaHCO_3$ at 0°C. Extraction with EtOAc (3 × 100 mL), drying the EtOAc extract (Na_2SO_4), and removal of the solvent in vacuo yielded an oil which was separated by preparative TLC using benzene–EtOAc (1:1, v/v) as development solvent. Extraction of the band having R_f 0.69 yielded **7** (73 mg, 23%); mp 84–85°C (EtOAc–hexane); IR (CCl_4): 3320 (NH), 2967 (CH), 1742 (C=O), 1703 (CONH) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.54 (t, *J* = 9.0 Hz, 2H, phenyl H-3, H-5), 7.64–7.68 (m, 1H, phenyl H-4), 8.04 (dd, *J* = 2.0, 9.0 Hz, 2H, phenyl H-2, H-6), 9.06 (s, 1H, H-2), 10.24 (s, 1H, H-6), 10.85 (br s, 1H, N*H*). Anal. calcd. for $C_{16}H_{17}N_3O_2$: C 67.82, H 6.05, N 14.83; found: C 68.10, H 6.07, N 14.80. Extraction of the band having R_f 0.86 afforded **8** (190 mg, 44%); mp 166–167°C (EtOAc–hexane); IR (CCl_4): 3361 (NH), 2969 (CH), 1691 (br, C=O and CONH) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.24 (s, 9H, C*Me*$_3$), 7.55 (t, *J* = 8.7 Hz, 4H, phenyl H-3, H-5), 7.68 (t, *J* = 8.7 Hz, 2H, phenyl H-4), 8.08 (d, *J* = 8.7 Hz, 4H, phenyl H-2, H-6), 9.18 (s, 1H, H-2), 10.30 (br s, 1H, N*H*). Anal. calcd. for $C_{23}H_{21}N_3O_3$: C 71.30, H 5.46, N 10.85; found: C 70.93, H 5.34, N 10.67. Extraction of the band having R_f 0.38 yielded **9** (33 mg, 10%); mp 144–145°C (hexane–EtOAc); IR (CCl_4): 3407 (NH), 2968 (CH), 1742 (C=O), 1699 (CONH) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.28 (s, 9H, C*Me*$_3$), 2.56 (s, 3H, C-6 Me), 7.52 (t, *J* = 7.0 Hz, 2H, H-3, H-5), 7.66 (t, *J* = 7.0 Hz, 1H, phenyl H-4), 8.01 (d, *J* = 7.0 Hz, 2H, phenyl H-2, H-6), 8.70 (br s, 1H, N*H*), 9.06 (s, 1H, H-2). Anal. calcd. for $C_{17}H_{19}N_3O_2$: C 68.67, H 6.44, N 14.13; found: C 68.62, H 6.38, N 13.95.

4-Benzoyl-5-bromopyrimidine (11)

Solutions of $FeSO_4 \cdot 7H_2O$ (110 g, 396 mmol) in water (280 mL) and *t*-BuOOH (54 mL of 70% w/v, 394 mmol) were added simultaneously to an ice-cooled solution of **10** (42 g, 264 mmol) and benzaldehyde (40 mL, 394 mmol) in HOAc (280 mL) and sulfuric acid (182 mL of 4.5 N) with stirring during 20 min. After 30 min, the cooling bath was removed, and the reaction was allowed to proceed for 2 h at 25°C. Extraction with EtOAc (4 × 200 mL), and removal of the solvents including acetic acid in vacuo at 40°C gave a residue which was neutralized by treatment with saturated aqueous $NaHCO_3$ solution prior to extraction with EtOAc (4 × 100 mL). The combined EtOAc extracts were washed with water (100 mL), brine (60 mL), and the EtOAc fraction was dried (Na_2SO_4). Removal of the solvent in vacuo gave a residue which was purified by silica-gel column chromatography (4 × 30 cm column) using EtOAc–hexane (1:9, v/v) as eluant to yield **11** (42.2 g, 61%) as an apparently homogeneous oil (silica-gel TLC, EtOAc–hexane (4:1, v/v) as development solvent, R_f = 0.38). This oil, upon standing in hexane at 25°C crystallized as colorless crystals after several hours; mp 41–42°C; IR (KBr): 1680 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.42–7.60 (m, 2H, phenyl H-3, H-5), 7.65 (dt, *J* = 7.5, 1.5 Hz, 1H, phenyl H-4), 7.78–7.80 (m, 2H, phenyl H-2, H-6), 9.00 (s, 1H, H-6), 9.21 (s, 1H, H-2); ^{13}C NMR ($CDCl_3$) δ: 117.02, 128.82 (2C), 130.11 (2C), 133.64, 134.63, 156.26, 159.97, 162.54, 190.73 (*C*=O). Anal. calcd. for $C_{11}H_7BrN_2O$: C 50.22, H 2.68, N 10.65; found: C 49.94, H 2.61, N 10.62.

5-Amino-4-benzoylpyrimidine (12)

A mixture of **11** (12.0 g, 46 mmol), aqueous NH_4OH (100 mL of a 37% w/v solution), and $CuSO_4 \cdot 5H_2O$ (1.1 g, 44 mmol) were placed in a glass pressure flask, and the

© 1999 NRC Canada

reaction was allowed to proceed with stirring at 25°C for 30 min, and then at 90°C for 20 h. After cooling to 10°C, the reaction mixture was transferred to a separatory funnel, the pressure flask was rinsed with chloroform (2 × 40 mL), and the chloroform solution was transferred to the separatory funnel. The organic fraction was separated, and the aqueous fraction was extracted with chloroform (4 × 50 mL). The combined organic extracts were dried (Na_2SO_4), and the solvent was removed in vacuo to give a gummy yellow solid which was purified by silica-gel column chromatography (4.5 × 30 cm column) using EtOAc–hexane (3:2, v/v) as eluant to afford **12** (2.0 g, 22%) as bright yellow needles; mp 109–110°C (ether–hexane); R_f = 0.56 (EtOAc–hexane, 4:1, v/v as development solvent); IR (KBr): 3451, 3328 (NH_2), 1630 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 6.03 (br s, 2H, N*H*$_2$), 7.40–7.60 (m, 3H, phenyl H-3, H-4, H-5), 8.00–8.10 (m, 2H, phenyl H-2, H-6), 8.44 (s, 1H, H-6), 8.64 (s, 1H, H-2); ^{13}C NMR ($CDCl_3$) δ: 127.95 (2C), 130.69 (2C), 132.53, 137.21, 137.26, 142.63, 146.28, 148.92, 196.21 (C=O). Anal. calcd. for $C_{11}H_9N_3O$: C 66.32, H 4.55, N 21.09; found: C 66.12, H 4.60, N 21.07.

5-Amino-4-(α-hydroxybenzyl)pyrimidine (13)

Sodium borohydride (1.5 g, 40 mmol) was added to an ice-cooled solution of **12** (3.0 g, 15 mmol) in methanol (80 mL), and the reaction was allowed to proceed for 1.5 h with stirring. Saturated aqueous NH_4Cl (30 mL) was added, the mixture was stirred for 3 h at 25°C, most of the MeOH was removed in vacuo, and the aqueous residue was extracted with chloroform (6 × 50 mL). The combined chloroform extracts were washed with water (50 mL), brine (50 mL), and the chloroform fraction was dried (Na_2SO_4). Removal of the solvent in vacuo gave a residue which was purified by either recrystallization from chloroform–hexane, or by silica-gel column chromatography using EtOAc as eluant, to afford **13** as a colorless crystalline solid (2.27 g, 75%); mp 148–149°C; IR (KBr): 3425, 3312, 3181, 2853, 1630, 1573 cm^{-1}; ^1H NMR (DMSO-d_6) δ: 5.46 (br s, 2H, N*H*$_2$), 5.79 (d, *J* = 5.0 Hz, 1H, C*H*-OH), 6.37 (d, *J* = 5.0 Hz, 1H, CH-O*H*), 7.15–7.37 (m, 3H, phenyl H-3, H-4, H-5), 7.37–7.50 (m, 2H, phenyl H-2, H-6), 8.10 (s, 1H, H-6), 8.36 (s, 1H, H-2); ^{13}C NMR (DMSO-d_6) δ: 74.40, 126.06 (2C), 127.03, 127.90 (2C), 139.78, 141.72, 143.34, 146.16, 152.64. Anal. calcd. for $C_{11}H_{11}N_3O$: C 65.66, H 5.51, N 20.88; found: C 65.29, H 5.51, N 20.93.

4-Benzoyl-5-benzyloxycarbonyl-aminomethylcarbonylaminopyrimidine (14)

N-Benzyloxycarbonylglycine (10.5 g, 50 mmol) was added in small aliquots to a solution of dicyclohexylcarbodiimide (10.3 g, 50 mmol) in dry THF–CH_2Cl_2 (1:1, v/v, 200 mL) at which time a white solid separated in a few minutes after mixing the two reagents. The resulting suspension was stirred for 20 min at 25°C, **13** (7.0 g, 34.8 mmol) was added as a single aliquot, and the reaction mixture was heated at reflux for 2.5 h. The reaction mixture was cooled to 25°C, the solid was removed by filtration, and the solvent was removed in vacuo to give an oily residue that was purified by silica-gel column chromatography (4.5 × 30 cm column). Elution with EtOAc–hexane (1:1, v/v) eluted impurities which were discarded. Further elution with EtOAc–hexane (9:1, v/v) afforded the hydroxy intermediate as an oil which was dissolved in chloroform (250 mL). Activated MnO_2 (16.0 g, 200 mmol) was added, and the oxidation reaction was allowed to proceed at 25°C for 20 h with stirring. The reaction mixture was filtered through a small celite pad, the celite pad was washed with chloroform (2 × 20 mL), and the chloroform filtrate was filtered. Removal of the solvent in vacuo gave an oily residue which was purified by silica-gel column chromatography (4.5 × 26 cm column) using EtOAc–hexane (7:3, v/v) as eluant to afford **14** (11.5 g, 84%); mp 86–87°C; IR (KBr): 3312, 3058, 1712, 1655, 1565 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 4.05 (d, *J* = 6.0 Hz, 2H, C*H*$_2$NH), 5.14 (s, 2H, OC*H*$_2$), 5.73 (t, *J* = 6.0 Hz, 1H, CH$_2$N*H*), 7.10–7.42 (m, 5H, CH$_2$*Ph*), 7.47 (t, *J* = 7.5 Hz, 2H, benzoyl H-3, H-5), 7.62 (t, *J* = 7.5 Hz, 1H, benzoyl H-4), 7.95 (d, *J* = 8.0 Hz, 2H, benzoyl H-2, H-6), 8.05 (s, 1H, H-6), 9.09 (s, 1H, H-2), 10.86 (br s, 1H, N*H*COCH$_2$); ^{13}C NMR ($CDCl_3$) δ: 45.51, 67.56, 128.21 (2C), 129.48, 131.22 (2C), 133.73, 133.85, 135.68, 135.91, 143.77, 151.95, 152.07, 156.60, 168.72, 195.74. Anal. calcd. for $C_{21}H_{18}N_4O_4$: C 64.61, H 4.65, N 14.35; found: C 64.58, H 4.74, N 14.66.

1,3-Dihydro-5-phenyl-2*H*-pyrimido[5,4-*e*][1,4]diazepin-2-one (15)

A solution of 32% w/v HBr in HOAc (120 mL) was added to **14** (10.0 g, 25.6 mmol), and the reaction was allowed to proceed at 25°C for 2.5 h with stirring. Ether (100 mL) and 10% aqueous NaOH (200 mL) were added, and the mixture was cooled in an ice-bath prior to neutralization with aqueous NH_4OH. The resulting mixture was allowed to stand for 6 h at 25°C, extracted with chloroform (6 × 60 mL), the combined chloroform extracts were dried (Na_2SO_4), and the solvent was removed in vacuo to afford a viscous oil. Purification by silica-gel column chromatography (4.5 × 30 cm column) using EtOAc as eluant gave **15** (4.5 g, 67%); mp 184–185°C (CH_2Cl_2–hexane); IR (KBr): 3156, 1696, 1622 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 4.42 (s, 2H, C*H*$_2$), 7.30–7.50 (m, 3H, phenyl H-3, H-4, H-5), 7.50–7.60 (m, 2H, phenyl H-2, H-6), 8.75 (s, 1H, H-9), 9.08 (s, 1H, H-7), 10.21 (br s, 1H, N*H*); ^{13}C NMR ($CDCl_3$) δ: 56.51, 128.22 (2C), 129.43 (2C), 130.92, 133.50, 136.70, 149.58, 150.94, 153.23, 169.10, 171.71. Anal. calcd. for $C_{13}H_{10}N_4O$: C 65.54, H 4.23, N 23.52; found: C 65.29, H 4.00, N 23.44.

1,3-Dihydro-5-phenyl-2*H*-pyrimido[5,4-*e*][1,4]diazepin-2-thione (16)

A mixture of **15** (5.65 g, 23.7 mmol) and Lawesson's reagent (2,4-bis(4-methoxyphenyl)-1,3-dithia-2,4-diphosphetane-2,4-disulfide) (5.0 g, 12.3 mmol) in benzene (150 mL) was refluxed for 1 h under argon, the resulting dark-colored solution was cooled to 25°C, and EtOAc (150 mL) was added. This mixture was washed with 10% w/v aqueous NaOH (150 mL), water (50 mL), and the aqueous fractions were combined. The combined aqueous fractions were neutralized with 1N HCl, and this mixture was extracted with EtOAc (3 × 50 mL). The combined EtOAc extracts were washed with brine (50 mL) and the EtOAc extract was dried (Na_2SO_4). Removal of the solvent in vacuo at 25°C gave a semi-solid residue which was purified by silica-gel column chromatography (4.5 × 30 cm column) using EtOAc–hexane

© 1999 NRC Canada

(2:3, v/v) as eluant to yield **16** (4.2 g, 70%) as a yellow solid; mp 198–205°C (dec.) (MeOH–hexane); ^{1}H NMR (MeCOMe-d_6) δ: 4.86 (s, 2H, CH_2), 7.32–7.50 (m, 3H, phenyl H-3, H-4, H-5), 7.60–7.70 (s, 2H, phenyl H-2, H-6), 8.97 (s, 1H, H-9), 9.04 (s, 1H, H-7), 11.50 (br s, 1H, N*H*); ^{13}C NMR (MeCOMe-d_6) δ: 64.75, 128.74 (2C), 128.40, 130.38 (2C), 131.25, 135.00, 138.19, 151.59, 151.88, 152.80, 169.14. Product **16** was used immediately in the subsequent reaction for the preparation of **17**.

2-Hydrazino-5-phenyl-3*H*-pyrimido[5,4-*e*][1,4]diazepine (17)

Hydrazine monohydrate (7.4 mL, 151 mmol) was added dropwise using a syringe to a solution of **16** (4.0 g, 15.7 mmol) in MeOH (100 mL) at 25°C with stirring, and the reaction was allowed to proceed at 25°C with stirring for 2 h prior to pouring onto ice-water (100 mL). Methanol was removed from the mixture in vacuo at 25°C, and the aqueous residue was extracted with chloroform (4 × 60 mL). The combined chloroform extracts were washed with water (40 mL), brine (40 mL), and the chloroform fraction was dried (Na_2SO_4). Removal of the solvent in vacuo yielded **17** (3.17 g, 80%) as a yellow solid; ^{1}H NMR ($CDCl_3$) δ: 3.60–4.70 (br m, 5H, N*H*NH_2, H-3), 7.26–7.70 (m, 5H, phenyl hydrogens), 8.74 (s, 1H, H-9), 8.90 (s, 1H, H-7). Since **17** was quite pure (^{1}H NMR) and since it decomposes slowly on standing in air, or in chloroform solution at 25°C, it was used immediately in the subsequent reaction for the preparation of **18**.

5-Phenyl-10-methyl-7*H*-pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine (18)

Concentrated H_2SO_4 (1.2 mL) was added dropwise with stirring to an ice-bath cooled solution of **17** (3.0 g, 11.9 mmol) and triethyl orthoacetate (11.0 mL, 60 mmol) in 98% EtOH (120 mL), and the reaction was allowed to proceed at 25°C for 4 h. The reaction mixture was neutralized with a saturated solution of aqueous $NaHCO_3$ and the mixture was concentrated in vacuo at 25°C. The residue was extracted with chloroform (3 × 50 mL), the combined chloroform extracts were washed with water (50 mL), brine (50 mL), and the chloroform fraction was dried (Na_2SO_4). Removal of the solvent in vacuo, and purification of the product by silica-gel column chromatography using EtOAc–methanol (4:1, v/v) as eluant afforded **18** (2.0 g, 62%); mp 223–224°C (CH_2Cl_2–hexane); ^{1}H NMR ($CDCl_3$) δ: 2.68 (s, 3H, CH_3), 4.19 (d, *Jgem* = 12 Hz, 1H, H-7′), 5.59 (d, *Jgem* = 12 Hz, 1H, H-7″), 7.30–7.50 (m, 3H, phenyl H-3, H-4, H-5), 7.55–7.62 (m, 2H, phenyl H-2, H-6), 9.02 (s, 1H, H-1), 9.35 (s, 1H, H-3); ^{13}C NMR ($CDCl_3$) δ: 12.09, 46.08, 128.25 (2C), 129.17 (2C), 129.39, 131.10, 136.74, 149.94, 151.94, 152.63, 155.02, 156.76, 166.89. Anal. calcd. for $C_{15}H_{12}N_6$: C 65.21, H 4.38, N 30.42; found: C 64.83, H 4.26, N 30.46.

Chemoenzymatic enantioselective synthesis of (–)-enterolactone

Robert Chênevert, Ghodsi Mohammadi-Ziarani, Dave Caron, and Mohammed Dasser

Abstract: Enterolactone, a lignan isolated from biological fluids of animals and humans, was synthesized via enzymatic desymmetrization of 2-(3-methoxybenzyl)-1,3-propanediol.

Key words: enterolactone, synthesis, lipase, desymmetrization, lignan.

Résumé : L'entérolactone, une lignane isolée des fluides biologiques des animaux et des humains, a été préparée via une désymétrisation enzymatique du 2-(3-méthoxybenzyl)-1,3-propanediol.

Mots clés : entérolactone, synthèse, lipase, désymétrisation, lignane.

Introduction

Lignans, naturally occurring secondary plant metabolites consisting of two phenylpropanoid units, are widely distributed in the plant kingdom (1). Enterolactone and enterodiol were the first lignans to be found in humans and animals (2, 3). Enterolactone, like other lignans, exhibits a wide range of biological activity (inhibition of cardiac Na^+, K^+-ATPase, antiestrogenic properties, platelet activating factor antagonist, inhibitor of human estrogen aromatase) and has attracted great interest on account of its cancer-protective properties (4). Epidemiological studies reveal a lowered risk of hormone-dependent cancers (breast, prostate) among vegetarians consuming large amount of lignans. Enterolactone and enterodiol are formed in the intestinal tract by the action of bacteria on precursors present in the diet (5).

Many syntheses of racemic enterolactone have been reported (6) but only a few enantioselective syntheses have been achieved (7). We report here a chemoenzymatic enantioselective synthesis of enterolactone via enzymatic desymmetrization of 2-(3-methoxybenzyl)-1,3-propanediol.

Results and discussion

The known diester **1** (8) was reduced to the diol **2** by lithium aluminum hydride in ether (Scheme 1). Diol **2** was subjected to enzyme-catalyzed esterification (for related desymmetrization of propane-1,3-diol derivatives, see ref. 9) by treatment with *Pseudomonas cepacia* lipase using vinyl acetate as acyl donor and solvent to give the optically active monoester (*R*)-(+)-**3** in quantitative yield. The enantiomeric composition of **3** was measured by ^{19}F NMR (282 MHz, in benzene-d_6) analysis of the corresponding (+)-α-methoxy-α-trifluoromethyl-α-phenyl acetate (MTPA, Mosher's ester). The enantiomeric excess was determined to be 94% (10). (The accuracy of this method is ±3%.) The absolute configuration of monoester **3** (*R*; $[\alpha]_D^{25}$ +26.8 (*c* 2.26, $CHCl_3$)) was determined by correlation with enterolactone **8** of known absolute configuration (the absolute configuration of enterolactone was established by X-ray crystal diffraction (11)). The use of *Pseudomonas fluorescens* lipase gave similar results (quantitative yield, ee = 92%, reaction time = 6.5 h).

Monoester (*R*)-(+)-**3** was treated with mesyl chloride in the presence of triethylamine to give mesylate (*S*)-(+)-**4** (Scheme 2). Displacement of the mesylate with cyanide in DMSO afforded nitrile (*R*)-(–)-**5**. Hydrolysis of the nitrile and the acetate groups in acidic medium was followed by ring closure in a one-pot procedure to give lactone (*R*)-(+)-**6**, $[\alpha]_D^{25}$ +6.15 (*c* 1.86, $CHCl_3$) (lit. (7*e*) $[\alpha]_D^{24}$ 6.06 (*c* 7.92, $CHCl_3$).

The anion of lactone **6** was generated by treatment with lithium diisopropylamide and stereoselectively alkylated with *m*-methoxybenzyl bromide (7*c*) to give lactone (*R*,*R*)-(–)-**7**, $[\alpha]_D^{25}$ –39.0 (*c* 2.5, $CHCl_3$) (lit. (7*a*) $[\alpha]_D^{23}$ –39.2 (*c* 0.78, $CHCl_3$)). Demethylation of lactone **7** with boron tribromide provided enterolactone (*R*,*R*)-(–)-**8**. Comparison of the optical rotation values ($[\alpha]_D^{25}$ –38.4 (*c* 0.37, $CHCl_3$)) for the sample obtained with those reported in the literature (7*a*) ($[\alpha]_D^{23}$ –38.4 (*c* 0.25, $CHCl_3$)) confirmed the absolute configuration of (–)-**8** to be (*R*,*R*), which requires that the enzymatic desymmetrization of **2** leads to diol (+)-**3** with *R* configuration at the newly created stereogenic center.

In conclusion, we have completed the enantioselective synthesis (ee = 94%) of (*R*,*R*)-(–)-enterolactone in seven steps and 35% yield from diester **1**. The key step is the enzymatic desymmetrization of diester **2**.

Experimental section

Melting points were recorded on a Thomas–Hoover apparatus, and are uncorrected. Infrared spectra were recorded

using a Perkin Elmer 781 spectrometer. NMR spectra were recorded in $CDCl_3$ solutions at 300 MHz (^1H), 282 MHz (^{19}F), 75 MHz (^{13}C) on a Bruker AC-300 instrument. Optical rotation values were obtained from a JASCO DIP-300 polarimeter. Column purifications were conducted by flash chromatography on silica gel 60 (230–400 mesh). *Pseudomonas cepacia* lipase and *Pseudomonas fluorescens* lipase were purchased from Amano and Aldrich, respectively.

2-(3-Methoxybenzyl)-propane-1,3-diol (2)

Lithium aluminum hydride (1.825 g, 48.0 mmol) was suspended in anhydrous ether (100 mL) at 0°C under a dry N_2 atmosphere. Diester **1** (3.37 g, 12.0 mmol) was added dropwise and the reaction mixture was stirred at 25°C for 4 h. The mixture was cooled and acidified with 3 N HCl (65 mL), filtered through a bed of Celite, and then extracted with ethyl acetate (2 × 100 mL). The combined extracts were washed with saturated aqueous $NaHCO_3$ (2 × 50 mL) and brine (2 × 50 mL), dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography (ethyl acetate:hexane 2:3, to pure ethyl acetate) to yield diol **2** as a white solid (1.76 g, 75%); mp 82°C (recrystallized from ether) (lit. (6*l*) mp 81–82°C). IR (KBr): 3350, 3020–2800, 1605, 1588, 1491, 1264, 1036, 873, 778, 695 cm^{-1}; ^1H NMR (MeOD): 1.90 (1H, m), 2.61 (2H, d, J = 7.0 Hz), 3.54 (4H, d, J = 5.6 Hz), 3.74 (3H, s), 6.76 (3H, m), 7.15 (1H, m); ^{13}C NMR ($CDCl_3$): 34.17, 43.75, 55.03, 64.49, 111.17, 114.77, 121.55, 129.28, 141.49, 159.49.

Lipase-catalyzed acylation of diol 2. 3-Hydroxy-2-(3-methoxybenzyl)propyl acetate ((*R*)-3)

To a solution of diol **2** (40 mg, 0.167 mmol) in vinyl acetate (3 mL) was added *Pseudomonas cepacia* lipase (35 mg), and the mixture was stirred at room temperature. The prog-

© 1999 NRC Canada

ress of the reaction was monitored by TLC and the reaction was stopped after disappearance of the starting material (26 min). The enzyme was filtered and washed with diethyl ether. The solvent was evaporated and the crude product was purified by flash chromatography (ethyl acetate:hexane, 10:90 to 50:50) to give monoester (*R*)-(+)-**3** as a colorless oil in quantitative yield (ee = 94%). The use of *Pseudomonas fluorescens* lipase gave similar results (quantitative yield, ee = 92%, reaction time 6.5 h). $[\alpha]_D^{25}$ +26.8 (*c* 2.26, $CHCl_3$); IR (neat): 3425, 1738, 1605, 1588, 1491, 1043 cm^{-1}; ^1H NMR ($CDCl_3$): 2.07 (3H, s), 2.10 (2H, m), 2.62 (2H, m), 3.50 (1H, dd, *J* = 11.2 Hz, *J* = 6.2 Hz), 3.60 (1H, dd, *J* = 11.2 Hz, *J* = 4.5 Hz), 3.79 (3H, s), 4.07 (1H, dd, *J* = 11.1 Hz, *J* = 6.5 Hz), 4.18 (1H, dd, *J* = 11.1 Hz, *J* = 4.6 Hz), 6.76 (3H, m), 7.21 (1H, t, *J* = 7.5 Hz); ^{13}C NMR ($CDCl_3$): 20.71, 34.25, 42.22, 55.01, 61.95, 63.92, 111.39, 114.76, 121.31, 129.32, 140.86, 159.63, 171.45; HRMS (EI) calcd. for $C_{13}H_{18}O_4$ (M^+): 238.1205; found: 238.1199.

1-Acetoxy-2-(3-methoxybenzyl)-3-(mesyloxy)propane ((*S*)-4)

A solution of **3** (296.4 mg, 1.244 mmol) in anhydrous THF (10 mL) was prepared under nitrogen. The solution was cooled to 0°C and triethylamine (0.184 mL, 1.32 mmol) was added first, and then methanesulfonyl chloride (0.152 mL, 1.96 mmol) was added dropwise. The solution was stirred for 2 h while the temperature was increased to 25°C. The solvent was evaporated and the residue was taken up in ether. The organic phase was washed with a 1 N HCl solution, with a saturated $NaHCO_3$ solution (three times), dried, and concentrated. The crude product was purified by flash chromatography (silica gel, elution with hexanes:ethyl acetate, 3:1) to yield (*S*)-(+)-**4** (380 mg, 97%) as a colorless oil. $[\alpha]_D^{25}$ 5.40 (*c* 2.34, $CHCl_3$); IR (neat): 3100–3000, 3000–2800, 1738, 1602, 1587, 1490, 1350, 1155 cm^{-1}; ^1H NMR ($CDCl_3$): 1.99 (3H, s), 2.32 (1H, m), 2.63 (2H, d, *J* = 7.4 Hz), 2.91 (3H, s), 3.71 (3H, s), 3.93–4.16 (4H, m), 6.69 (3H, m), 7.14 (1H, t, *J* = 7.8 Hz); ^{13}C NMR ($CDCl_3$): 20.58, 33.78, 36.85, 39.32, 54.96, 62.78, 68.57, 111.83, 114.63, 121.16, 129.52, 139.47, 159.68, 170.54; HRMS (EI) calcd. for $C_{14}H_{20}O_6$ S (M^+): 316.0980; found: 316.0990.

4-Acetoxy-3-(3-methoxybenzyl)butyronitrile ((*R*)-(–)-5)

To a solution of mesylate **4** (152.8 mg, 0.483 mmol) in anhydrous DMSO (5 mL) was added finely pulverized sodium cyanide (31.9 mg, 0.651 mmol). The solution was stirred at 45°C for 12 h. Ethyl acetate (200 mL) was added and the organic layer was washed with water (8 × 50 mL) dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography (silica gel, hexane:ethyl acetate, 3:1) to give nitrile (*R*)-(–)-**5** (118.4 mg, 99%) as a colorless oil. $[\alpha]_D^{25}$–10.77 (*c* 1.96, $CHCl_3$); IR (neat): 3100–3000, 3000–2800, 2250, 1742, 1604, 1589, 1493, 1250–1040 cm^{-1}; ^1H NMR ($CDCl_3$): 2.07 (3H, s), 2.13–2.42 (2H, m), 2.38 (1H, m), 2.66 (1H, dd, *J* = 13.7 Hz, *J* = 7.4 Hz), 2.76 (1H, dd, *J* = 13.7 Hz, *J* = 6.3 Hz), 3.77 (3H, s), 3.98 (1H, dd, *J* = 11.5 Hz, *J* = 6.7 Hz), 4.17 (1H, dd, *J* = 11.5 Hz, *J* = 4.4 Hz), 6.72 (3H, m), 7.22 (1H, m); ^{13}C NMR ($CDCl_3$): 18.94, 20.62, 36.44, 36.61, 55.05, 64.99, 112.06, 114.62, 117.73, 121.13, 129.71, 138.94, 159.80, 170.51; HRMS (EI) calcd. for $C_{14}H_{17}O_3N$ (M^+): 247.1208; found: 247.1200.

4-[(3-Methoxyphenyl)methyl]dihydro-2(3*H*)-furanone ((*R*)-(+)-6)

Nitrile **5** (114 mg, 0.461 mmol) was dissolved in water (5 mL), acetic acid (10 mL), and concentrated sulfuric acid (1 mL). The solution was stirred at 110°C for 2 h. Ethyl acetate (300 mL) and 2 M NaOH (60 mL) were added to the solution and the layers were decanted. The organic layer was washed with water (3 × 50 mL), dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography (silica gel, ethyl acetate:hexane, 1:4) to afford lactone (*R*)-(+)-**6** (89.4 mg, 94%) as a colorless oil. $[\alpha]_D^{25}$ +6.15 (*c* 1.86, $CHCl_3$) (lit. (7*e*) $[\alpha]_D^{24}$ 6.06 (*c* 7.92, $CHCl_3$) (lit. (7*d*) $[\alpha]_D^{20}$ +6.41 (*c* 2.08, $CHCl_3$)). IR (film): 3100–3000, 3000–2800, 1775, 1601, 1584, 1492, 1300–1000 cm^{-1}; ^1H NMR ($CDCl_3$): 2.24 (1H, dd, *J* = 17.5 Hz, *J* = 7.2 Hz), 2.57 (1H, dd, *J* = 17.2 Hz, *J* = 7.6 Hz), 2.71 (2H, dd, *J* = 9.3 Hz, *J* = 3.2 Hz), 2.81 (1H, m), 3.76 (3H, s), 4.00 (1H, dd, *J* = 9.1 Hz, *J* = 6.3 Hz), 4.31 (1H, d, *J* = 8.7 Hz, *J* = 6.9 Hz), 6.74 (3H, m), 7.22 (1H, m); ^{13}C NMR ($CDCl_3$): 34.10, 36.92, 38.78, 55.06, 72.53, 111.73, 114.47, 120.85, 129.68, 139.76, 159.75, 176.77.

3,4-Bis[(3-methoxyphenyl)methyl]-dihydro-2(3*H*)-furanone (3*R*,4*R*)-(–)-7

To lactone **6** (40.2 mg, 0.195 mmol) in anhydrous THF (1.5 mL) at –78°C was added LDA (2 M solution in CH_2Cl_2, 0.176 mL, 0.351 mmol) and HMPA (0.105 mL, 0.585 mmol). The solution was stirred for 0.5 h at –78°C and 3-methoxybenzyl bromide (70.6 mg, 0.351 mmol) in anhydrous THF (0.5 mL) was added in one portion. The mixture was stirred overnight (15 h) at –78°C and then warmed slowly to 0°C. The excess of base was neutralized at 0°C with a saturated aqueous NH_4Cl solution (3 mL) and the mixture was extracted with ether (5 mL) and ethyl acetate (2 × 10 mL). The combined organic layer was washed with water (3 × 20 mL) and brine (10 mL), dried ($MgSO_4$), and evaporated under reduced pressure. The crude product was purified by flash chromatography (pure hexane, to ether:hexane, 15:85) to give lactone **7** (38 mg, 60%) as a colorless oil. $[\alpha]_D^{25}$ –39.0 (*c* 2.5, $CHCl_3$) (lit.(7*a*) $[\alpha]_D^{23}$ –39.2 (*c* 0.78, $CHCl_3$)). IR(neat): 3100–3000, 3000–2800, 1770, 1600, 1585, 1490, 1300–1100, 870, 782, 696 cm^{-1}; ^1H NMR ($CDCl_3$): 2.43–2.64 (4H, m), 2.91 (1H, dd, *J* = 13.9 Hz, *J* = 7.0 Hz), 3.06 (1H, dd, *J* = 13.9 Hz, *J* = 5.0 Hz), 3.76 (3H, s), 3.78 (3H, s), 3.78 (1H, dd, *J* = 15.0 Hz, *J* = 6.2 Hz), 4.10 (1H, dd. *J* = 9.0 Hz, *J* = 6.8 Hz), 6.76 (4H, m), 6.56 (2H, m), 7.20 (2H, m). ^{13}C NMR ($CDCl_3$): 35.01, 38.43, 41.14, 46.22, 55.00, 55.03, 71.05, 111.74, 112.24, 114.39, 114.72, 120.77, 121.47, 129.53, 129.59, 139.42, 139.17, 159.70, 178.32.

3,4-Bis[(3-hydroxyphenyl)methyl]dihydro-2(3*H*)-furanone (enterolactone, 8)

A solution of BBr_3 in CH_2Cl_2 (1 M, 0.421 mL, 0.421 mmol) was added dropwise to a solution of lactone **7** (34.3 mg, 0.105 mmol) in anhydrous CH_2Cl_2 at 0°C. The solution was stirred at 0°C for 1 h and then at –18°C for 12 h. Water (1 mL) was added to the solution and the aqueous

© 1999 NRC Canada

layer was extracted with CH_2Cl_2 (3 × 5 mL). The combined organic layers were washed with brine, dried ($MgSO_4$), and evaporated. The crude product was purified by flash chromatography (ethyl acetate:hexane, 3:7) to yield enterolactone **8** (26.9 mg, 86%) as a white solid; mp 140–142°C (lit. (6*l*) mp 141–143°C). $[\alpha]_D^{25}$ –38.4 (*c* 0.37, $CHCl_3$) (lit. (7*a*) $[\alpha]_D^{23}$ –38.4 (*c* 0.25, $CHCl_3$)). IR (KBr): 3350, 3100–3000, 3000–2800, 1760, 1595, 1485, 1460, 1350, 1230, 875, 785, 698 cm^{-1}; ^1H NMR (acetone-d_6): 2.46–3.01 (6H, m), 3.85–4.08 (2H, m), 6.5–7.2 (8H, m), 8.34 (2H, s); ^{13}C NMR (acetone-d_6): 35.20, 38.57, 42.04, 46.69, 71.38, 114.15, 114.36, 116.34, 117.01, 120.51, 121.36, 130.19, 130.28, 140.72, 141.21, 158.32, 178.65.

A capillary electrophoretic determination of the kinetics of tetradecanedisulfate hydrolysis

Richard A. Walker, D. Gerrard Marangoni, and Truis Smith-Palmer

Abstract: Capillary electrophoresis was used to follow the decrease in concentration of tetradecanedisulfate as a function of time during its hydrolysis in 0.5 M sulfuric acid solution at 60, 75, and 90°C. The hydrolyses were mostly carried out at premicellar concentrations of surfactant, from 1 to 7.5 mM. Large increases of rate occurred at higher concentrations (at least 15 mM). The reaction was found to be first order in tetradecanedisulfate. The activation energy and entropy of activation were calculated to be 97 kJ mol^{-1} and –55 J K^{-1} mol^{-1}, respectively.

Key words: capillary electrophoresis, surfactant, acid hydrolysis, tetradecanedisulfate, activation energy, entropy of activation.

Résumé : On a utilisé l'électrophorèse capillaire pour suivre la diminution de concentration du tétradécanedisulfate en fonction du temps lors de son hydrolyse dans de l'acide sulfurique à 0,5 M, à 60, 75 et 90°C. Les hydrolyses ont été réalisées principalement à des concentrations prémicellaires d'agent de surface, soit de 1 à 7,5 mM. On observe d'importantes augmentations de vitesse aux concentrations les plus élevées (au moins 15 mM). On a trouvé que la réaction est du premier ordre en tétradécanedisulfate. On a calculé que l'énergie et l'entropie d'activation sont respectivement égales à 97 kJ mol^{-1} et –55 J K^{-1} mol^{-1}.

Mots clés : électrophorèse capillaire, agent de surface, hydrolyse acide; tétradécanedisulfate, énergie d'activation, entropie d'activation.

[Traduit par la Rédaction]

Introduction

Despite the tremendous utility of single-headed surfactants in consumer and industrial applications, very little research dealing with the synthesis and properties of surfactants containing two typical anionic head groups such as sulfate, sulfonate, carboxylate, or phosphate has been reported in the literature. Comeau et al. (1) and Boucher et al. (2) have examined the micellar properties of a series of two-headed surfactants: the disodium alkanedisulfates (critical micelle concentration (cmc) values and degrees of counterion binding) and the disodium 3-sulfanato-4-alkylsuccinates (cmc's, aggregation numbers, and degrees of counterion binding). These authors concluded that the addition of the second polar head group made micelle formation thermodynamically less favoured (i.e., the cmc values were higher when compared to their single-headed counterparts). They also concluded that the surface charge densities were higher, while the aggregation numbers were smaller, than those of the single-headed counterparts of comparable chain length. Hence, it appears likely that the structure of the micelles formed by two-headed surfactants is not significantly different from that of the single-headed surfactants, i.e., two-headed surfactants will form small, spherical micelles where the head groups are heavily hydrated.

Sodium alkanedisulfates have been synthesized by El Sawy et al. (3) and in the labs of Marangoni (1) and Smith-Palmer (4) in our department. Two-headed sulfate surfactants offer greater water solubility than their single-headed counterparts, and are more resistant to precipitation in the presence of calcium ions (3, 5). These are properties that could make their use desirable in certain industrial or analytical processes. However, there is some question as to the stability of these species to hydrolysis. One drawback to using SDS, one of the best-known single-headed surfactants, is its propensity to hydrolyze slowly when left to sit in water, and at a considerably faster rate when placed in acid (6–11). Although El Sawy reported that the alkanedisulfates "were completely stable to hydrolysis," the indications in the accompanying data table were that they underwent significant hydrolysis in 40 min in 0.5 M sulfuric acid (3). It was thus of interest to study the stability of these surfactants in various aqueous solutions.

In a previous study, we demonstrated that we were able to separate hydroxy- alkanesulfate and alkanedisulfate using capillary electrophoresis (CE). We were then able to show that the alkanedisulfates were stable in base (but not in acid), and that the constitutional isomers 1-hydroxy-2-alkanesulfate and 2-hydroxy-1-alkanesulfate were able to be hydrolyzed in both acid and base (4).

In this study we determined the rates of acid hydrolysis of tetradecanedisulfate (TDDS) at three temperatures by means of capillary electrophoresis. The results are compared to those reported by El Sawy et al. (3), and to literature rates

for the hydrolysis of various alkanesulfates (6–10). Although CE has already been used to study reaction kinetics (12–15), its utility in this regard is yet to be fully exploited, and the demonstration that we could use CE for this purpose was an important facet of our work. Thermodynamic calculations were also done.

Experimental

Reagents

Chlorosulfonic acid and diethylbarbituric acid were from BDH, Mississauga, Ont.; 1,2-tetradecanediol, anhydrous diethyl ether, and *n*-butanol were from Aldrich, Mississauga, Ont., and sodium hydroxide was from J.T. Baker Chemical Co., Phillisburg, N.J. Ethanol was obtained from Commercial Alcohols, Boucherville, Que., and concentrated sulfuric acid and pure cellulose Soxhlet extraction thimbles were from Fisher Scientific, Nepean, Ont. Sodium chromate tetrahydrate was from Anachemia, Mississauga, Ont. CIA-Pak™ OFM Anion-BT solution was obtained from Waters (Millipore), Milford, Mass.The reverse-phase columns were 15g Supelclean Envi-Carb solid phase extraction columns from Supelco, Bellefonte, Pa.

All water used was 10 MΩ cm resistivity (Millipore 4000S purification system).

Preparation of TDDS: 1,2-Tetradecanediol (2.3 g, 10 mmol) was dissolved in 50 mL ether cooled in an ice bath, and chlorosulfonic acid (1.5 mL, 22 mmol) was added dropwise. The reaction mixture was stirred for 10 min and then neutralised with 8 M sodium hydroxide. The white precipitated surfactant was collected and vacuum dried. A portion (0.083g) was diluted to 25 mL and checked for purity by CE.

Purification by reverse phase extraction columns: The crude product was dissolved in 100 mL water and loaded onto the column, which was then washed with water in 10 50-mL aliquots.

Purification by Soxhlet extraction: Crude product was placed in a thimble and extracted with *n*-butanol. The product remaining in the thimble was then extracted with ethanol.

Instrumentation

Capillary zone electrophoresis (CZE) was carried out on a Waters Quanta 4000 capillary electrophoresis system using a 75 μm fused silica capillary (Polymicro Technologies Inc., Phoenix, Ariz.), hydrostatic injection mode for 30 s, and indirect photometric detection at 254 nm. The data were collected using LabCalc software (Galactic, Salem, N.H.) with 1 V equal to 1 au.

For anion analysis (to check salt content of surfactant preparations), the applied voltage was –20 kV, and the buffer was a chromate solution containing CIA-Pak™ OFM-BT solution, prepared as described by Waters (16). The capillary was 58 cm to the detector.

For surfactant analysis, the applied voltage was +25 kV, and the buffer was a diethylbarbiturate solution prepared by dissolving 0.0554 g diethylbarbituric acid in 30 mL water, adjusting the pH to 8.6, then making the volume up to 50 mL. The pH was readjusted to 8.6 (17), and the buffer was filtered through a 45 μL syringe filter and sonicated for 3 min prior to use. Prior to each run the capillary (52 cm to detector) was rinsed for 2 min with each of 0.1 M sodium hydroxide, water, and buffer.

The water bath was a HAAKE G water circulator employing a digital HAAKE D8 thermostat and containing a 1:1 solution of ethylene glycol and water. A Digi-Sense digital pH/mV/ORP meter was used to record and adjust all pH's.

Hydrolyses

A sulfuric acid solution was prepared from concentrated sulfuric acid and standardized to be 1.002 M using 8.2168 M sodium hydroxide in a Hach model 16900–01 digital titrator (Loveland, Colo.). A 10 mL aliquot was pipetted into a large test tube sealed with a rubber stopper. A balloon on a syringe needle was inserted to allow for expansion and the tube was equilibrated for 10 min at the desired temperature (60, 75, or 90°C). Surfactant solutions of concentrations between 2 and 35 mM were also equilibrated at the chosen temperature for 10 min before a 10 mL aliquot was added to the acid and the time and initial pH recorded. Approximately 2 mL aliquots were taken via syringe from the reaction mix at recorded time intervals. Each aliquot was placed in a 15 mL beaker. From this, 1 mL was pipetted into 30 mL water, the time was noted and the pH was recorded. The 30 mL solutions were neutralized using 1 M and 0.1 M sodium hydroxide and diluted to 50 mL. Samples were analyzed by taking 100 μL of the above solution and running it in the CE as described above. The peak areas and migration times were recorded and the concentration was determined by reference to a standard curve of peak area/migration time versus concentration. This standard curve was prepared by diluting surfactant with sulfuric acid at room temperature and immediately neutralizing and diluting samples as done in the actual hydrolyses experiments.

Results and discussion

Reaction rates of substances are greatly changed when the substances in question are incorporated into micelles. These substances may enter the micelle and thus be held in a more hydrophobic environment where the reagent is more or less soluble, or, as in the case of TDDS, the substance of interest may be the surfactant actually forming the micelles. The charge on the surface of a micelle will strongly attract or repel charged reagents. In the case of acid hydrolysis we would expect the protons to be attracted to the negatively charged surface of the micelle, thus producing rate enhancement at surfactant concentrations above the cmc. Such a phenomenon has been well documented in the case of alkanesulfate hydrolysis (8, 9, 11). Some investigators of alkanesulfate hydrolysis have only used concentrations above the cmc (7) while others have conducted studies at lower concentrations (9–11). It was our intention to carry out our study in a concentration region considerably lower than the cmc in order to avoid micellar rate enhancement. We chose our experimental setup to mimic conditions used by El Sawy et al. (3), so that comparisons would be valid. To this end, we chose TDDS as the substrate because it was the shortest-chain disulfate reported in their paper. Because of having the shortest chain, it was found to have the lowest surface tension and be the best emulsifying agent of the

alkanedisulfates that they prepared. Although we have prepared even shorter-chain analogues, it is more difficult to purify them and so the choice of TDDS as substrate was convenient from all standpoints.

Our method of synthesizing alkanedisulfates involves the reaction of chlorosulfonic acid with the appropriate diol. The end product can contain unreacted diol, singly sulfated product, and chloride and sulfate (4). A variety of ways to purify these surfactants were investigated. The use of C18 reverse-phase columns gave some pure product, but at high cost on a scale sufficient for our kinetic experiments. We believe that the main problem in the purification process is the high solubility conferred by the presence of the second sulfate. The sodium TDDS is extremely soluble in water, and only slightly soluble in ethanol. Sodium chloride is similarly soluble, while sodium sulfate, also very soluble in water, is less soluble in ethanol. As the length of the hydrocarbon tail is decreased, this problem is exacerbated. Soxhlet extractions were found to be the most useful method of purification. The impurity in product tended to vary, but a typical crude product might contain TDDS, hydroxytetradecanesulfate, chloride, and sulfate in a mole ratio of 2.2:1:2:2.4 as determined using CE (using a run in BARB buffer and a run in chromate buffer). As the diol is neutral, it is not separated from the water peak in our buffers. However, the presence of diol is shown by the cloudiness of an aqueous solution of the product. Soxhlet extraction with butanol removed hydroxytetradecanesulfate isomers and unreacted diol into the butanol. The TDDS was separated from inorganic impurities in a subsequent Soxhlet extraction with ethanol. Although longer refluxing times yield more product, the cleanest TDDS (96%) was obtained using a 1 h refluxing time. It was not possible to remove all the chloride.

The final concentration of acid used in the kinetic runs was set at 0.5 M sulfuric, as used by El Sawy et al.(3). This concentration was high enough above the concentrations of surfactant used in the main experiments (1 mM – 7.5 mM) to give us pseudo-first-order conditions.

The reaction was followed by monitoring the disappearance of TDDS as determined by CE using a BARB buffer. Quantitation was by peak area divided by migration time, and an internal standard was not found to be necessary. The reproducibility of runs was generally a few per cent. We assumed that the high concentration of acid being used would override ionic strength effects from using different concentrations of surfactant. Indeed, we checked this assumption by carrying out a run using 10 mL of 10 mM TDDS with an added 0.01 g L^{-1} Na_2SO_4. No significant difference in rate was found.

The presence of the high concentration of sulfuric acid in the reaction mixture necessitated neutralization and dilution of samples before analysis, and limited the concentration of acid that we could use. Hydrolyses of submicellar concentrations of alkanesulfates of interest to us, such as tetradecanesulfate, were not able to be followed by CE using our particular instrument because the sample concentrations were lower than the limit of detection after the necessary neutralisation and dilution of the sulfuric acid reaction matrix. The CMC for tetradecanesulfate in water is 2.2 mM while that for tetradecanedisulfate in water is 11.6 mM (1).

The temperatures were chosen to be well above room temperature so that the reactions went rapidly enough to be followed in reasonable time periods. Preliminary experiments at 40°C, the temperature used by El Sawy et al., gave inconveniently slow reaction rates. They reported the time for cloudiness to appear in a reaction flask containing 5 mM TDDS in 0.5 M sulfuric acid to be 41 min (3). We were not able to duplicate this result. No cloudiness was detected even after 6 days under the prescribed conditions. In their discussion, they stated that the TDDS was stable to hydrolysis, but this is also not completely true, as cloudiness is seen in less than 2 h if the hydrolysis is carried out at 90°C.

The initial rate curves for various concentrations of TDDS at the chosen temperatures of 60, 75, and 90°C were measured, plotted, and the slopes obtained by linear fitting of the points. The fit was very good, with R for the lines ranging from 0.987 to 1.000.

The observed pseudo-first-order rate constant for hydrolysis can be written (18) as

$$k_{obs} = k_0 + k_{H^+}[H^+] + k_{OH^-}[OH^-]$$

We previously reported that we were unable to detect basic hydrolysis of TDDS, and here we are working in acid conditions where $[OH^-]$ will be very low. This is in agreement with the zero values Kurz (7) assigned to the k_{OH}'s for alkanesulfates with carbon chains of 10 and longer. The values of k_0, the first-order rate constant for uncatalyzed hydrolysis, decrease with increasing hydrocarbon chain length for the alkanesulfates and do not seem to be dependent on micellization. The value of k_0 given for SDS at 90°C is 0.27×10^{-7} (7), and thus the value for tetradecanesulfate would be expected to be smaller and even less significant in comparison to k_{H^+}. We will make the assumption that k_0 is also much smaller than k_{H^+} $[H^+]$ for TDDS. Thus we can say

$$k_{obs} = k_{H^+}[H^+]$$

In Fig. 1, the rates obtained from the initial rate curves are plotted as a function of concentration for the three different reaction temperatures. We see a linear dependence on concentration until a concentration of 7.5 mM is reached. We

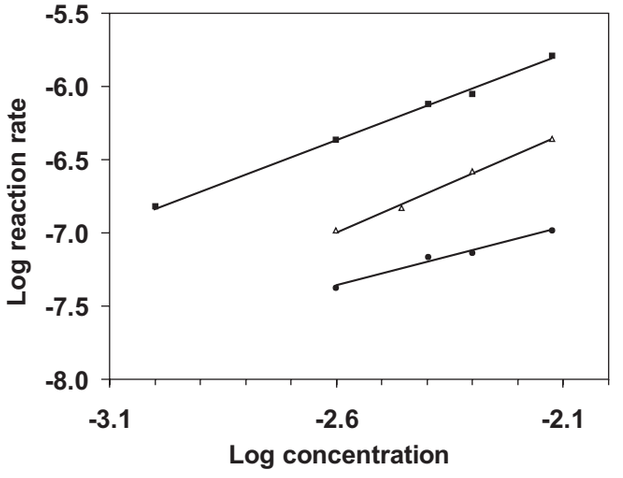

Fig. 3. Plot of ln rate constant versus reciprocal temperature (K^{-1}) for TDDS in 0.5 M sulfuric acid.

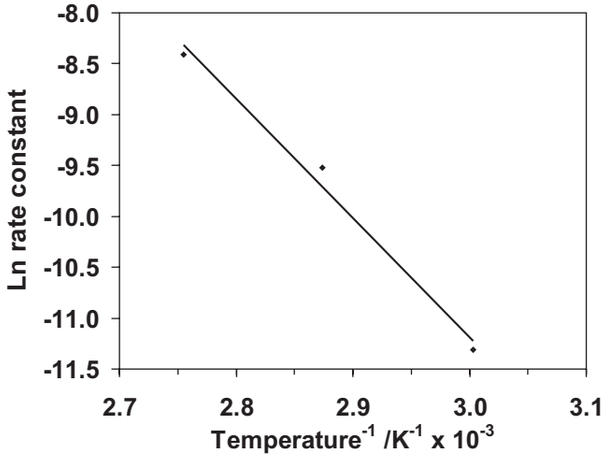

expect that the rate would increase once micelle formation starts to occur because the surface of the micelle would have many negative charges and thus strongly attract the hydrogen ions. Although Marangoni's group reported the cmc to be 11.6 mM for TDDS in aqueous solution (1), the cmc in the 0.5 M sulfuric acid used for the hydrolysis experiment will be quite different. We would expect that the sulfuric acid would act to lower the cmc, as cmc's are known to decrease in the presence of salts. Increasing the temperature generally has the opposite effect (19). To be sure that we were working in the premicellar region under our conditions, one higher concentration was used at each temperature. The increase in rate over that expected shows that micellization was occurring at the higher concentration, and thus we feel confident that our results for 1–7.5 mM are those for premicellar conditions. The sudden jump in rate that is characteristic of micellization occurred between the last two points on each plot shown in Fig. 1. We have not drawn a line between these points, because all we can really say from our results is that there is a change in the rate constant at some point between them.

The premicellar reaction rates at 60, 75, and 90°C were 1.2×10^{-5}, 6.8×10^{-5}, and 2.2×10^{-4} M s^{-1}, respectively. As our concentration of acid ($[H^+]$) is 1 M, these translate to specific acid rate constants of the same numerical value. These k_{H^+}'s are about 10 times larger than corresponding values that have been reported for SDS (9). A better comparison would be with rates for the hydrolysis of tetradecanesulfate, but little information is available. Kurz made some comparisons of hydrolysis rates between SDS and tetradecanesulfate, but the extra carbon never made more than a 50% difference to the rate (7). We can thus assume that the increase in hydrolysis rate as compared to SDS is much more because of the extra sulfate than the extra CH_2. The extra sulfate will increase the electrostatic attraction of the proton to the surfactant. This is the same phenomenon that is responsible for the increase in hydrolysis rate upon micellization, but on a much smaller scale. In addition, the presence of two sulfate groups gives two places for hydrolysis to occur, in a sense doubling the chance of reaction. Once one of the sulfate groups is hydrolyzed, the resulting hydroxytetradecanesulfate hydrolyzes very rapidly, as was previously reported for hydroxydecanesulfate (4).

Plots of log rate versus log concentration for the sets of reactions at 60, 75, and 90°C are shown in Fig. 2. Assuming that the mechanism is the same at all three temperatures, the slopes of 0.86, 1.34, and 1.16, respectively, were averaged to give a value of 1.12. This indicates that the hydrolysis reaction is first order with respect to TDDS. Motsavage and Kostenbauder found that premicellar acid hydrolysis of SDS was first order with respect to SDS at 50 and 70°C (9). Muramatsu and Inoue (10) reported that SDS hydrolysis was second order in surfactant, with the difference being that their results were obtained at 40°C. In addition, they followed the reaction using a radiotracer method after precipitation of sulfate with barium chloride. It seems unlikely that the reaction mechanism changes at this point, and the difference is much more likely to be due to the different methods of obtaining the kinetic data. In addition, the hydrolysis of *s*-butyl hydrogen sulfate is also first order in substrate.

The Arrhenius equation tells us (20) that

$$\ln k = \ln A - E_a/RT$$

where A is the pre-exponential factor and E_a is the activation energy. By plotting $\ln k_{H^+}$ versus the reciprocal of the temperature (Fig. 3) we obtained a value of 96 J mol^{-1} for the activation energy of the hydrolysis reaction. In comparison, an E_a of 120 kJ mol^{-1} was reported for the slower hydrolysis of SDS (9).

The enthalpy of activation in liquid systems can be calculated from the activation energy as follows (21):

$$\Delta H^{o\ddagger} = E_a - RT$$

where R is the gas constant and T is the temperature in degrees Kelvin.

For the acid hydrolysis of TDDS, our calculated values were 94.7, 94.5, and 94.4 kJ mol^{-1} at 60, 75, and 90°C, respectively. Kurz reported an enthalpy of activation of 112

© 1999 NRC Canada

kJ mol^{-1} for SDS at 90°C (7), slightly larger than the value obtained by us for TDDS under the same conditions.

The entropy of activation can be calculated using the following equation:

$$k_{H^+} = kT/\hbar\, e^{-\Delta H_a/RT} e^{-\Delta S_a/R}$$

where k is the Boltzmann constant (21).

The entropy of activation for the hydrolysis of TDDS was thus found to be –55 J K^{-1} mol^{-1}. Such a decrease in entropy on formation of the activated complex is common. A decrease in entropy corresponds to formation of a more ordered configuration in the transition state. A large negative energy may signify an association reaction, where the preliminary binding of the two reagents in a transition state considerably reduces their freedom. A large negative activation entropy may also occur when the activated complex can be more solvated than are the reagents. This electrostriction of water is usually attributed to the distribution of charges in the activated state, suggestive of a bimolecular transition state (22).The more tightly bound the complex, the lower will be its entropy (21). In contrast to our results, Motsavage and Kostenbauder reported a positive entropy of activation of 13 J K^{-1} for hydrolysis of premicellar SDS, with an even more positive value for SDS concentrations above the cmc (9). Positive activation entropies have also been reported for the hydrolysis of steroidal hydrogen sulfate, although solvents other than pure water were used (23). The second charged sulfate group presumably makes a big difference to the electrostriction of water, to the binding of the initial H^+, and to the charge separation in the actual transition state.

Conclusions

CE was used to follow the decrease in concentration of TDDS as a function of time and thus obtain kinetic data for the hydrolysis of TDDS. The hydrolyses were considerably slower than those measured by El Sawy et al. (3) at lower temperature (40°C) but otherwise similar conditions. The majority of the rate measurements were carried out using premicellar concentrations of TDDS. Under these conditions, the rate was found to be first order in TDDS. Hydroxytetradecanesulfate hydrolyzes much more quickly than TDDS, so the hydrolysis of the first sulfate is presumed to be the rate-determining step. Comparison to data in the literature shows that TDDS hydrolyzed more quickly than SDS (and, by inference, more quickly than tetradecanesulfate) under the same conditions. This was attributed to the presence of the second sulfate increasing the overall negative charge (and thus attraction of protons) and providing twice the number of sites for the initiation of hydrolysis. Further rate enhancement is seen at high TDDS concentrations, where we assume micellization has occurred, further increasing the overall negative charge density and the attraction of protons.

The activation energy for the reaction was determined to be 97 kJ mol^{-1}, while the entropy of activation was –55 J K^{-1} mol^{-1}. The high activation energy is in accord with the reaction being very slow, while the entropy change suggests a complex transition state involving restricted motion of the various species involved.

Thermodynamics of the interaction of HCl with D-xylose in water at 278.15–318.15 K

Jianji Wang, Kelei Zhuo, Qiufen Zhang, and Jinsuo Lu

Abstract: The thermodynamic parameters of interaction of HCl with D-xylose in water were determined from electromotive force measurements from 278.15 to 318.15 K. The correlation between the pair interaction Gibbs free energy parameters for HCl–sugar (g_{HCl-S}) and the mean number (n(*e*-OH)) of equatorial hydroxy groups in sugar molecules was found to be g_{HCl-S}/J kg mol^{-2} = (41.2 ± 2.1) + (16.88 ± 0.52)n(*e*-OH). Refractive indices of aqueous D-xylose solutions were measured and used to evaluate the polarizability of D-xylose molecule in water. Several theoretical models were used to calculate the salting constant of D-xylose. The results show that the calculated values are reasonably in agreement with the experimental ones.

Key words: thermodynamics, HCl, D-xylose, interaction parameter, salting constant.

Résumé : Utilisant des mesures de force électromotrice faites entre 278,15 et 318,15 K, on a déterminé les paramètres thermodynamiques de l'interaction HCl avec le D-xylose. On a trouvé que la corrélation entre les paramètres d'énergie libre de Gibbs pour l'interaction de la paire HCl–sucre (g_{HCl-S}) et le nombre moyen de groupes hydroxyles équatoriaux [n(*e*-OH)] dans les molécules de sucre est donnée par l'équation suivante: g_{HCl-S}/J kg mol^{-2} = (41,2 ± 2,1) + (16,88 ± 0,52)n(*e*-OH). On a mesuré les indices de réfraction de solutions aqueuses de D-xylose et on les a utilisées pour évaluer la polarisabilité de la molécule de D-xylose dans l'eau. On a utilisé plusieurs modèles théoriques pour calculer la constante de salaison du D-xylose. Les résultats montrent que les valeurs calculées sont en bon accord avec les données expérimentales.

Mots clés : thermodynamique, HCl, D-xylose, paramètre d'interaction, constante de salaison.

[Traduit par la Rédaction]

Introduction

The hydration of sugars (S) depends on their stereochemistry (1, 2). Several attempts have been made to rationalize the hydration characteristics of sugars (2–4). Franks et al. (5) and Suggett (6) introduced the important distinction between equatorial (*e*-OH) and axial hydroxy (*a*-OH) groups. Uedaira and Uedaira (7*a*) predicted that any properties that depend on the sugar hydration will correlate well with the number n(*e*-OH) of *e*-OH groups in sugar molecules. Examples have been given for diffusion coefficients (7*a*) and partial molar heat capacities (7*b*) of some mono-, di-, and trisaccharides in water.

In an earlier paper (8), we found a linear relation between the pair interaction Gibbs free energy parameters for electrolyte (E) – D-glucose (G) and those for E–sucrose (E = HCl, NaCl, KCl, $MgCl_2$, and $CaCl_2$) at 298.15 K. The slope of this linear equation was calculated to be the mean *e*-OH group number ratio of sucrose to glucose. In our recent papers (9), the thermodynamic parameters of interaction were reported between HCl and some sugars. In this work, we report the interaction parameters for the HCl – D-xylose (X) pair in water from 278.15 to 318.15 K. This not only would provide additional information on the interaction between HCl and D-xylose in water, but also enable us to examine the possible relationship between g_{HCl-S} and n(*e*-OH).

Electromotive forces (emf) measurements of the cells A and B without liquid junction

$$\text{A: Pt, } H_2(g, p^\circ)|\text{HCl}(m_{HCl})|\text{AgCl–Ag}$$

$$\text{B: Pt, } H_2(g, p^\circ)|\text{HCl}(m_{HCl}), \text{X}(m_X)|\text{AgCl–Ag}$$

at m_{HCl}(A) = m_{HCl}(B) were carried out at 10 K intervals from 278.15 to 318.15 K, where p° = 101.325 kPa, m_{HCl} and m_X are the molalities of HCl and D-xylose, respectively, with respect to a kilogram of pure water, m_{HCl} = 0.005–0.1 mol kg^{-1}, m_X = 0.2–0.8 mol kg^{-1}.

Experimental section

D-Xylose (Biochemical reagent, Quzhou Chemical Co.) was purified by recrystallization from aqueous solution of ethanol (80%) at low temperature. Then it was dried under vacuum at 343 K to constant weight and stored over P_2O_5 in a desiccator. The data of elemental analysis (C = 39.927%, H = 6.743%, O = 53.33%) are in good agreement with the theoretical values of xylose (C = 40.002%, H = 6.714%, O = 53.284%). This shows that thus-obtained xylose is anhydrous. Water with specific conductivity of (1.0–1.2) × 10^{-4} Ω^{-1} m^{-1} at room temperature was used in this work. Purification and standardization of hydrochloric acid have been described elsewhere (9).

The AgCl–Ag electrodes were of the thermal electrolytic type (10). They were aged in 0.1 mol kg^{-1} HCl(aq), which was deoxygenated by bubbling hydrogen. Three days after preparation, the finished electrodes were intercompared and the bias potentials were usually less than 0.05 mV. Only those AgCl–Ag electrodes whose bias potentials were less than 0.02 mV were used. Standard potentials of these electrodes in water were determined by the method of Bates and Robinson (11). They are in excellent agreement with the literature values (12) within experimental error. The hydrogen electrodes were lightly coated with platinum black in terms of the Hills and Ives method (13). High-purity hydrogen served as the source of hydrogen. The cells were of all-glass construction with four isothermal presaturators containing the test solution, as described by Yang et al. (14). These cells were thermostated at each temperature with an accuracy of ±0.02 K. The test solutions were freshly prepared. All measures were made using two Ag–AgCl electrodes and two hydrogen electrodes. Equilibrium was reached in about 4–5 h after the initiation of hydrogen bubbling. This allows for the anomeric equilibrium to be reached. The other experimental apparatus and experimental procedures were the same as previously described (9). The observed emf values were corrected to the values at 101.325 kPa of hydrogen. These corrected emf values are listed in Table 1.

Refractive indices of aqueous solutions of D-xylose were measured by a 2WA-J-type refractometer (Shanghai) at 298.15 K from 2 to 24 wt.%.

Results

The transfer Gibbs free energies of electrolyte from water (W) to aqueous nonelectrolyte solutions (W + N) may be expressed as (9)

$$[1]\qquad \Delta_t G_E(W \rightarrow W + N) = -nF\Delta E = 2\nu g_{EN} m_N + 6\nu^2 g_{EEN} m_E m_N + 3\nu g_{ENN} m_N^2$$

where n and F have their usual meaning, ΔE is the difference of the emf values. In the present case, $\Delta E = E_B - E_A$ at $m_E(A) = m_E(B)$; ν is the number of ions into which the electrolyte dissociates; g_{EN}, g_{EEN}, and g_{ENN} are pair and triple interaction Gibbs free energy parameters that take into account for all new sources of nonideality in the ternary system. The higher terms have been neglected in eq. [1]. The Gibbs free energy parameters for the HCl–D-xylose–water system were obtained by least squares and given in Table 2. In this work, we are yet interested in the pair parameters which are most important in dilute solutions.

The relationship between g_{EN} and thermodynamic temperature T can be well represented by the empirical equation (9)

$$[2]\qquad g_{EN} = a + bT + cT^2$$

The coefficients a = 3876.8 J kg mol^{-2}, b = –26.279 J kg mol^{-2} K^{-1}, c = 0.045 714 J kg mol^{-2} K^{-2} were obtained by least squares for the HCl–D-xylose pair, with a standard deviation of the fit of 2.0 J kg mol^{-2}.

Table 2. Interaction free energy parameters for the HCl–D-xylose–water system from 278.15 to 318.15 K.

T (K)	g_{EN} (J kg mol^{-2})	g_{EEN} (J kg^2 mol^{-3})	g_{ENN} (J kg^2 mol^{-3})	δ^a (mV)	R^b
278.15	103±4	37.7±4.7	–0.03±3.96	0.10	0.996
288.15	102±3	27.3±3.4	0.12±2.91	0.07	0.998
298.15	105±3	24.5±3.9	2.23±3.27	0.08	0.998
308.15	118±5	14.7±5.1	–3.55±4.32	0.11	0.996
318.15	144±5	–4.19±5.97	–17.43±5.05	0.12	0.994

[a] δ is the standard deviation of the fit.
[b] R is the correlation coefficient.

Table 3. Pair interaction parameters for HCl–D-xylose from 278.15 to 318.15 K.

T (K)	Ts_{EN} (J kg mol^{-2})	h_{EN} (J kg mol^{-2})	$c_{p,EN}$ (J kg mol^{-2} K^{-1})	k_S (kg mol^{-1})
278.15	236	340	–25.4	0.178
288.15	–19	81	–26.3	0.170
298.15	–292	–187	–27.3	0.169
308.15	–584	–464	–28.2	0.184
318.15	–894	–750	–29.1	0.218

Substituting these coefficients to the following equations (9)

$$[3] \quad s_{EN} = -(b + 2cT)$$

$$[4] \quad h_{EN} = a - cT^2$$

$$[5] \quad c_{p,EN} = -2cT$$

Values of s_{EN}, h_{EN}, and $c_{p,EN}$, which are, respectively, pair interaction entropic, enthalpic, and isobaric capacity parameters for the HCl–D-xylose pair, were calculated and given in Table 3.

The salting constant, k_S, defined by Friedman (15) can be obtained from

$$[6] \quad RTk_S = 2\nu g_{EN}$$

at low values of both m_N and m_E (16, 17). The k_S values for the HCl–D-xylose–water system were obtained and also given in Table 3.

Discussion

Data in Table 2 show that $g_{HCl-X} > 0$ at the temperatures concerned. This means that D-xylose is being salted out by HCl in water (thermodynamic repulsion). Similar phenomena have been found for the HCl–alcohol (17), NaCl–alcohol (18), and HCl–sugar (D-glucose (9*a*), D-fructose (F) (9*b*)) pairs in water. However, the temperature dependence of g_{HCl-X} is different from g_{HCl-G} (see Fig. 1). Similar to g_{HCl-F}, g_{HCl-X} increases with increasing temperature (although it varies slightly from 278.15 to 298.15 K), whereas g_{HCl-G} decreases with increasing temperature. Data in Table 3 show that h_{HCl-X} and Ts_{HCl-X} decrease rapidly with increasing temperature (from positive to negative). Similar tendency exists also for the HCl–alcohol and HCl–sugar pairs in water.

In our previous papers, the structure interaction and electrostatic models were used to interpret the signs and temperature dependence of the interaction parameters for the HCl–alcohol (17) and HCl–D-glucose (9*a*) pairs. Therein, the interactions between HCl and hydroxy compounds were divided into four types: H^+–R (alkyl group); Cl^-–R; H^+–O (O stands for OH, C=O, and -O- groups); and Cl^-–O interactions. It seems that the interaction parameters for the HCl–X pair are mainly determined at low temperature (278.15 K) by the Cl^-–S (Cl^-–R, Cl^-–O) interactions which contribute a positive value to h_{HCl-X} and Ts_{HCl-X}. On the contrary, they are mainly determined at high temperatures (298.15, 308.15, and 318.15 K) by the H^+-O interaction which contributes a negative value to h_{HCl-X} and Ts_{HCl-X}. Meanwhile, the free energy is controlled by enthalpy at lower temperatures (278.15, 298.15 K) and by entropy at higher temperatures (298.15, 308.15, and 318.15 K). On these ideas, the experimental results obtained for the HCl–xylose–water system can be easily understood. In addition, the negative $c_{p,HCl-X}$ values mean that the HCl–X interaction results in a reduction in structure of the solution.

It is also noted that values of g_{HCl-X} are larger than those of g_{HCl-F} over the investigated temperatures, although D-xylose is a pentose, a molecule of which contains a CHOH group less than D-fructose (hexose). This is due to the difference in their stereochemistry as discussed below.

Correlation between pair interaction parameters and the mean number of *e*-OH groups

Hydration of sugars depends on stereochemistry of sugar molecules, especially on the compatibility of their conformation with water structure (1, 5, 6, 19). Therefore, the ratio of *e*-OH and *a*-OH groups seems to be an important factor which determines sugar hydration (7). To calculate the mean number of *e*-OH groups in sugar molecules, we recall the simplified assumption by Lemieux (20; see also ref. 7*a*) that the number of quasi-equatorial hydroxy groups in a molecule for both α- and β-furanose are regarded to be 1.25. On

Fig. 1. Temperature dependence of g_{HCl-S}: ◆, HCl–D-glucose (9*a*); ■, HCl–D-fructose (9*b*); ▲, HCl–D-xylose.

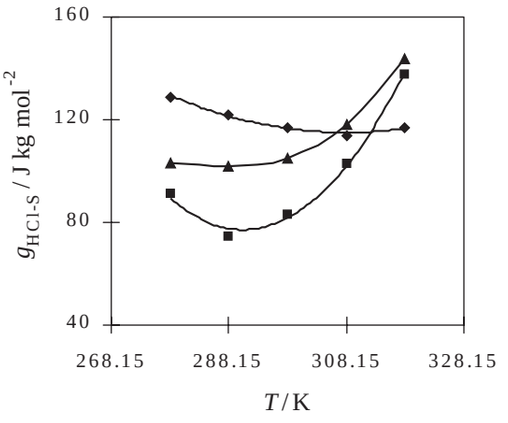

Fig. 2. Correlation between g_{HCl-S} and the mean number n(*e*-OH) of equaterial hydroxy groups in sugar molecules. 1, D-arabinose (unpublished datum from the laboratory of the authors); 2, D-fructose (9*b*); 3, D-xylose; 4, D-glucose (9*a*); 5, sucrose (22).

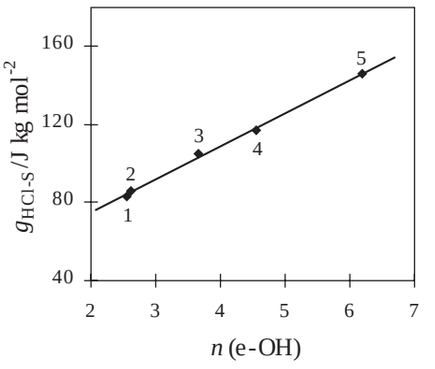

the basis of this assumption and the percentage ratio of anomers in aqueous solutions (1), the values of n(*e*-OH) were calculated as follows: 4.56 for D-glucose, 2.56 for D-fructose, 3.67 for D-xylose, 2.61 for D-arabinose, and 6.2 for sucrose (7*b*, 21).

The g_{HCl-S} values are plotted against n(*e*-OH) in Fig. 2. Evidently, a good linear correlation between g_{HCl-S} and n(*e*-OH) can be observed. By fitting these data to a linear equation, we get

$$[7] \quad g_{HCl-S}/\text{J kg mol}^{-2} = (41.2 \pm 2.1) + (16.88 \pm 0.52)n(e\text{-OH})$$

with a correlation coefficient of 0.999 and a standard deviation of fit of 1.6 J kg mol^{-2}. The equation shows that (*i*) the g_{HCl-S} values are strongly affected by n(*e*-OH); (*ii*) the increase in g_{HCl-S} for each *e*-OH group is about 17 J kg mol^{-2}. This also confirms the suggestion that the hydration characteristics of sugars can be rationalized by the ratio of *e*- to *a*-OH groups (5–7). Furthermore, we can conclude that the dehydration of sugar molecules arising from the interaction between HCl and hydrated sugar molecules should give a significant contribution to g_{HCl-S}. It should be mentioned that such a good correlation is possibly because few data points were used in the fit. More measurements are to be made in the laboratory of the authors.

In previous papers (9), a so-called "H^+-induced structure changes" model was proposed to interpret the interaction of HCl with sugars. In fact, the structure change of sugar molecules will dispel the compatibility between the OH groups on ring sugar molecules and the three-dimensional hydrogen-bonded structure of water, and result in some changes of hydration shell of sugar molecules. This is equivalent to the decrease in the mean number of *e*-OH groups. Accordingly, the g_{HCl-S} values will decrease.

Now return our attention to the difference between HCl–D-xylose and HCl–D-fructose interactions. It can be seen from eq. [7] that the larger value of g_{HCl-X} is due to the larger n(*e*-OH) values of D-xylose compared with D-fructose, although a D-xylose molecule contains one CHOH group less than D-fructose. In other words, because D-xylose is more compatible with water structure, the changes in its hydration shell should contribute a larger value to g_{HCl-X} than would D-fructose.

Theoretical calculation of salting constants

In the preceding paper (22), we calculated the salting constants of three sugars (D-glucose, D-fructose, sucrose) by HCl in water from the Debye–MacAulay theory (DMT) (23), Conway–Desnoyers–Smith theory (CDST) (24), the internal pressure theory (IPT) (25), and the scaled particle theory (SPT) (26). The results showed that the calculated values are reasonably in agreement with the experimental ones.

It has been noted that selecting the required molecular parameters is very important in the calculation. Especially, the parameters of oxonium ion (H_3O^+), such as radius, seriously affect the calculated results. The methods described in the preceding paper (22) for obtaining these molecular parameters have also been used in this work.

The polarizability of D-xylose molecule was obtained by the following processes: first, using the measured refractive indices of pure water (1.3336), the polarizability of water molecule was calculated from the Lorenz–Lorentz equation (27); then, the polarizability of water and the refractive indices of aqueous D-xylose solutions were used to evaluate polarizabilities of D-xylose molecule at various concentrations; finally, the polarizability at infinite dilution for D-xylose was obtained by fitting these data and extrapolating it to zero concentration. The molecular parameters used in the calculation are presented in Table 4.

Using these parameters, the salting constants at 298.15 K calculated from the theoretical models mentioned above are 0.244 (CDST), 0.203 (IPT1),[2] 0.097 (IPT2),[2] and 0.127

[2] IPT1 refers to the equation (25): $[V_n^\circ(V_s - V_s^\circ)]/(RT\beta^\circ)$, where V_n° and V_s° are the standard molal volume (= limiting apparent molal volume V_Φ^∞) of nonelectrolyte and electrolyte, respectively. V_s is the molal volume of the electrolyte as in the molten state and β° the compressibility of pure water. V_{HCl} and V_{HCl}° were, respectively, taken as 20.5 and 18.1 cm^3 mol^{-1} (25*a*). IPT2 refers to the equation (25): $\{[V_n^\circ(V_s - V_s^\circ)]/(RT\beta^\circ)\}[a/(a + b)]$, where a is the average radius of the cation and anion, and b is the radius of the nonelectrolyte (sugar). In the present paper, they were taken as the hydrated radius.

Photochemical reaction of β-ionone derivatives in the presence of oxygen. A convenient synthesis of substituted 1,2,4-trioxanes

Mirta P. Mischne, Silvia N. Huber, and Juan Zinczuk

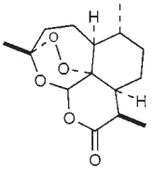
Abstract: This paper describes a simple and convenient method for the preparation of substituted 1,2,4-trioxanes. The scope of the one-pot photooxidation of β-ionones has been extended to include derivatives bearing additional functionalities in the β-ionone ring. The relative stereochemistry of the products has been established by analysis of ^{1}H and ^{13}C NMR spectra.

Key words: 1,2,4-trioxanes, photooxidation, cyclic peroxides, tetrahydrobenzopyranes, antimalarials.

Résumé : Dans ce travail, on décrit une méthode simple et convenable de préparer des 1,2,4-trioxanes substitués. On a élargi la domaine d'application de la réaction d'oxydation photochimique de façon à inclure des dérivés de la β-ionone qui possèdent des fonctionalités additionnelles sur le cycle. La stéréochimie relative des produits a été déterminée par analyse des résultats obtenus par RMN du ^{1}H et du ^{13}C.

Mots clés : 1,2,4-trioxanes, photooxydation, peroxydes cycliques, tétrahydrobenzopyranes, antipaludéens.

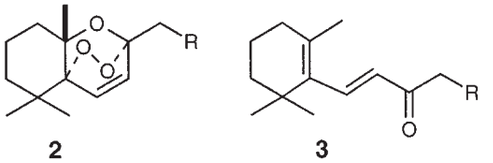
During the last two decades, the recognition of the importance of peroxide-containing natural products possessing biological activities has brought a resurgence in the chemistry of cyclic peroxides and related compounds (1). The discovery that the natural product artemisinin (**1**) is a potent antimalarial drug and that the presence of the 1,2,4-trioxane moiety is responsible for the pharmacological activity (2) has led to new syntheses of compounds containing this oxygenated system.



1

Examples of reported methods for preparing 1,2,4-trioxanes include the trapping of Paterno–Büchi 1,4 diradicals by molecular oxygen (3), autoxidation of imines in the presence of aldehydes (4), cyclization of vicinal hydroxyhydroperoxides with ketones (5), cyclization of hydroperoxyacetals with olefins (6) or epoxides (7), trapping of β-peroxy carbocations or equivalents with aldehydes and ketones (8), cationic ring expansion of ozonides (9), and singlet oxygen addition to pyranes (10). However, in spite of these efforts, there still remains a need to develop more efficient and operationally simple procedures for the preparation of this kind of peroxides.

We have recently reported a simple diastereoselective preparation of the 1,2,4-trioxanes **2a** and **2b** by irradiation of β-ionone type compounds **3a** and **3b** in the presence of oxygen (11).



2 **3**

a R=H
b R=CO_2Me

These compounds were previously prepared by singlet oxygenation of the corresponding tetrahydrobenzopyranes and the stereochemistry of the singlet oxygen addition was assigned by comparing the ^{1}H NMR spectra of the olefinic compounds **2a** and **2b** with their corresponding saturated analogues (10*b*).

Because of the continuous interest on the chemistry and biological activity of cyclic peroxides and in line with our preliminary report, we decided to extend the scope of our methodology to prepare 1,2,4-trioxanes that contain additional functionality. Starting with the readily available ionone

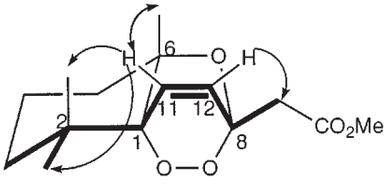
Fig. 1. Relative stereochemistry of compound **2b** and proton–proton through-space connectivities, obtained by NOE difference experiments.



derivatives **4**, a series of 1,2,4-trioxanes **5** was obtained. The stereochemical outcome of the reaction was determined by a careful ^{1}H and ^{13}C NMR analysis of the products, which gives further support to the proposed mechanism for the formation of the trioxane compounds.

Results and discussion

β-Ionone derivatives **4a–4e** were prepared according to literature methods (12*a*–12*d*). Irradiation at λ 350 nm of a 0.01 M toluene solution of **4a–4e** for 6 h, while bubbling oxygen, gave, after purification by column chromatography, compounds **5a–5e** in 35–86% yield. The structures of the products were established based on analytical and spectral data.

a$_e$ R' = eq-OH
b$_a$ R' = ax-OMe
b$_e$ R' = eq-OMe
c$_a$ R' = ax-OAllyl

c$_e$ R' = eq-OAllyl
d$_a$ R' = ax-OAc
d$_e$ R' = eq-OAc
e R' = O

The spectral analysis, necessary for the unambiguous determination of the relative stereochemistry of compounds **5a–5e**, was initiated with the previously described ester **2b**. The ^{1}H and ^{13}C NMR signals of compound **2b** were assigned on the basis of chemical shift considerations, and by HETCOSY, ^{1}H–^{13}C COLOQ, and a series of nuclear Overhauser enhancement (NOE) experiments, which further confirm the relative stereochemistry at C-1, C-6, and C-8 of this compound. Irradiation of the singlet at δ 1.11, attributed to the methyl of C-6, showed NOE with the H-11 signal, while irradiation at δ 6.54 (H-11) enhanced the signals of the C-2α, C-2β, and C-6 methyl protons. In addition, when the signal at δ 6.77 corresponding to H-12 was irradiated, the signal at δ 2.78 attributed to the methylene group of the ester moiety was enhanced (Fig. 1).

These results, which establish the *anti* relationship between the angular methyl group and the peroxide bridge, are in agreement with the conclusion reported previously by using an indirect method (10*b*).

In addition, NOE experiments were performed on compounds **5b**, **5d**$_a$, **5d**$_e$, and **5e**. In particular, strong reciprocal NOE were observed between the signals due to 11-H (δ 6.50) and the methyl groups bonded to C-2 and C-6 (δ 1.00–1.17). No enhancement of these signals was expected in the alternative position of the peroxide bridge. The results support the proposed relative configuration of 1,2,4-trioxanes **5**.

Further evidence for the diastereoselective outcome of the reaction was obtained by analyzing the products of the irradiation of the hydroxy-β-ionone **4a**. In this case, only two of the four possible isomers of 1,2,4-trioxanes were obtained. The resulting trioxanes **5a**$_a$ and **5a**$_e$ were analyzed by ^{1}H and ^{13}C NMR.[3] Thus, alcohol **5a**$_a$ was confirmed as being axial based on its ^{1}H NMR spectral data. While the signal at δ 3.80 is a broad singlet with $W_{1/2}$ = 6.8 Hz, clearly indicating an equatorial methine proton, in compound **5a**$_e$ the corresponding signal appears as a doublet of doublets centered at δ 4.34 (J = 4 and 12 Hz) with characteristic couplings of an axial proton (14). The observed downfield shift of the methine signal could be explained by the deshielding effect of the axial peroxide bridge. Moreover, the distinghishing feature in the ^{1}H NMR spectrum of **5a**$_a$ is a sharp doublet centered at δ 3.56 (J = 6 Hz). This signal, attributed to the hydroxyl proton resonance, is characteristic of an intramolecular hydrogen bond, coupled with the C-5 methine proton and bonded to one oxygen atom of the peroxide bridge. As expected, the signal disappeared upon treatment with deuterium oxide. On the other hand, the corresponding signal of **5a**$_e$ appears as a broad singlet centered at δ 2.45. The presence of an intramolecular hydrogen bond in alcohol **5a**$_a$ is also supported by comparing its IR spectrum with that of **5a**$_e$. The hydroxyl stretching band of **5a**$_a$ at 3575 cm^{-1} agrees with the expected value for an intramolecular hydrogen bond peak. On the other hand, the absorption band for **5a**$_e$ at 3610 cm^{-1} is characteristic of a free hydroxyl group (15). Therefore we must conclude that, in compound **5a**$_a$, the peroxide bridge must be on the same side as the hydroxyl group and, because of the geometrical constraint of the tricyclic system, the angular methyl group must occupy the axial position, which is *anti* to both the hydroxyl group and the peroxide bridge. The conformation of **5a**$_a$, suggested on the basis of the spectral analysis discussed above, is in agreement with conformational calculations performed by the MMX molecular mechanics program (16). The minimum-energy conformation calculated for the alcohol **5a**$_a$ is shown in Fig. 2.

The photooxidation of alkoxy-β-ionones **4b–4c** afforded the corresponding alkoxy-trioxanes **5b–5c** in low yield. The presence of a donor group in the ring makes the substrates more sensible to overoxidation by molecular oxygen and, consequently, to the formation of unidentified products. The formation of the equatorial isomers is preferred with the increasing steric demand of the alkoxy group and the lack of stabilization that is present in the axial isomer **5a**$_a$ because of the intramolecular hydrogen bond. Accordingly, **5b**$_e$ and traces of axial isomer **5b**$_a$ were formed from **4b** (R = OMe),

[3] The spectral data obtained are coincident with those reported by Jeger and co-workers (13) for the same compounds, although no stereochemical assignment was proposed by these authors. In addition, the ^{13}C NMR data of **5a**$_e$ were erroneously assigned to **5a**$_a$.

Scheme 1.

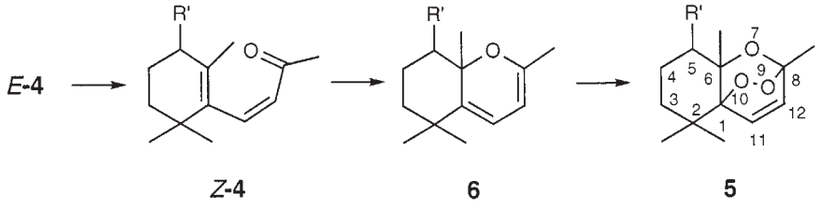

Fig. 2. Projection of the lowest-energy conformation of $\mathbf{5a}_a$ predicted on the basis of molecular mechanics calculations.

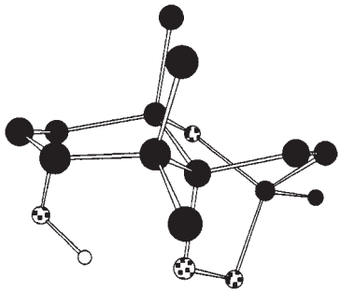


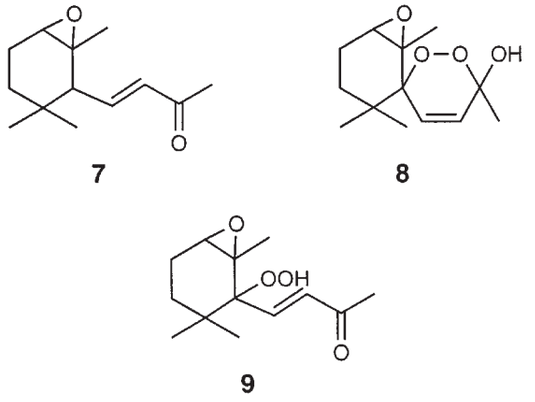
and for **4c** (R = allyloxy) only the equatorial isomer $\mathbf{5c}_e$ was obtained.

Significantly higher yields of 1,2,4-trioxanes were obtained by introducing deactivating groups into the β-ionone moiety. Thus, photooxidation of acetoxy-β-ionone **4d** afforded the corresponding acetoxytrioxanes in 74% yield as a 1:2 mixture of diastereoisomers $\mathbf{5d}_a$ and $\mathbf{5d}_e$. Moreover, the ketotrioxane **5e** was obtained from **4e** with excellent yield (86%).

On the basis of the results described above, the mechanism of formation of 1,2,4-trioxanes **5** could be explained by a rapid *E* to *Z* exocyclic double bond isomerization (*E*-**4** to *Z*-**4**), followed by a tandem process, involving an electrocyclic reaction to give the pyrane intermediates **6** and a Diels–Alder type singlet oxygen reaction addition (Scheme 1).

Although no extra sensitizer was used in the reaction, we conclude that is likely that the substrates may act as sensitizers and generate singlet oxygen.[4] The quantitative formation of **2a** from β-ionone **3a**, bearing an *anti* relationship between the angular methyl group and the peroxide bridge, allowed us to postulate that the oxygen molecule approaches the pyrane **6** (R′ = H) exclusively from the less hindered side. The angular methyl group blocks the attack from one face of the diene system. All the trioxanes obtained, **5a–5e**, show the same relative configuration as **2a** and further support the diastereoselectivity for the oxygen attack. We rationalized the intermediacy of the pyrane based on the reported formation of 1,2,4-trioxanes by sensitized oxygenation of such compounds. In this way, Jeger and co-workers (13) irradiated the epoxy-ionone **7**, to obtain a mixture of hydroxypyranes, **6a** (R′ = OH), which, after purification, were photooxygenated in the presence of a sensitizer to give the trioxanes **5a** in moderate yield.

In our case, when **7** was submitted to reaction with oxygen, the trioxanes **5a** were isolated in very low yield. Instead, the major components of the reaction mixture were the peroxyketal **8** and the hydroperoxide **9** (55% and 10% yield, respectively).



The formation of the spiro-peroxyketal **8** is probably due to the reaction of oxygen with the diradical **10**, formed from *Z*-**7**. The reaction of **10** with oxygen would give the intermediate hydroperoxide **9** that, subsequently, undergoes cyclization to **8**. This pathway is clearly favored over the formation of the hydroxytrioxanes **5a**, which would require the rupture of the C—O bond of the oxirane diradical **10**, necessary to afford the *Z*-hydroxy-β-ionone *Z*-**4a** that would yield the trioxanes **5a** through the intermediacy of the hydroxypyranes **6a** (Scheme 2).

Experimental section

Melting points were determined on an Electrothermal 9100 apparatus and are uncorrected. IR spectra were recorded on a Beckman Acculab 8 spectrometer. The ^{1}H and ^{13}C NMR spectra were measured at 200.1 and 50.3 MHz on a Bruker AC 200-E NMR spectrometer in $CDCl_3$ solutions, with TMS as internal standard. For the COSY, COLOQ, and NOE experiments Bruker standard software was employed. Assignments marked with *, **, or *** may be, correspondingly, interchanged. Column chromatography was performed on silica gel 60H, slurry packed, run under low pressure of nitrogen and employing increasing amounts of EtOAc in hexane as solvent. Analytical TLC was carried out using Kielselgel Merck GF_{254} of thickness 0.20 mm. EI-MS were measured on a ZAB-SEQ4F instrument (LANAIS,

[4] Jeger and co-workers (17) reported the formation of small amounts of the corresponding trioxane, when they photolyzed 7-Me-β-ionone without excluding oxygen from the reaction mixture.

Universidad de Buenos Aires). Elemental analysis were performed by Atlantic Microlab, Inc., Norcross, U.S.A.

General procedure for the photooxidation of 5a–e

The irradiations were performed at λ 350 nm, in a Rayonet RPR 100 photochemical reactor, in which a transparent Pyrex vessel containing a 0.01 M solution of ketone **4** in toluene was placed. A stream of oxygen was bubbled through the solution at room temperature. After 6 h the solvent was evaporated under reduced pressure, and the photoproducts were isolated by column chromatography. The crude products were purified by crystallization to constant mp (solid) or by column chromatography (oily samples).

The following compounds were prepared from this general method.

Conclusions

We report here a convenient and simple route to 1,2,4-trioxanes from substituted β-ionones. The products, which belong to a class of compounds with interesting pharmacological properties, were formed in a one-pot reaction by irradiation in the presence of molecular oxygen. The new compounds were fully characterized by spectroscopic methods. Though we postulated the presence of singlet oxygen in the addition reaction to the pyrane intermediates, no external sensitizer was needed to afford the trioxanes. The diastereoselectivity of the reaction is controlled by the angular methyl group of the in situ generated pyrane intermediate, which directs the approach of the oxygen molecule from the opposite side, giving exclusively the *anti* isomer. High yields of trioxanes were obtained from β-ionones bearing an electron-withdrawing group, which reduces the electron density and prevents the oxidative degradation of the substrate.

The proposed methodology avoids the preparation of the pyranes as starting materials and the use of sensitizers. It also opens up the way for possibile synthesis of properly substituted 1,2,4-trioxanes with potential use as model compounds for biological evaluation.

Préparation du chlorure mercureux et mesure de sa pression de vapeur

Komla Oscar Awitor, Laurent Bernard, Olivier Bonnin, Bernard Coupat, Jean Paul Fournier et Philippe Verdier

Résumé : Le chlorure mercureux (Hg_2Cl_2), ou calomel, a été préparé par synthèse directe à partir de mercure et de chlorure mercurique commerciaux. La fraction massique en chlorure mercurique du produit synthétisé est particulièrement faible. La pression de vapeur du chlorure mercureux a été mesurée entre 353 et 453 K par la méthode d'effusion de Knudsen. Pour exploiter nos mesures, nous avons tenu compte de sa dissociation en phase vapeur, en mercure et chlorure mercurique. Nos résultats sont comparés à ceux existant dans la littérature.

Mots clés : chlorure mercureux, calomel, pression de vapeur, spectrométrie de masse, cellule de Knudsen.

Abstract: Mercurous chloride (Hg_2Cl_2), or calomel, was prepared by direct synthesis from commercial mercury and mercuric chloride. The mercuric chloride mass fraction in the synthesized material is particularly small. The mercurous chloride vapor pressure was measured between 353 and 453 K by the Knudsen cell method. In order to obtain the mercurous chloride vapor pressure, we took into account the dissociation in the vapor phase into mercury and mercuric chloride. Our results are compared with those in the literature.

Key words: mercurous chloride, calomel, vapor pressure, mass spectrometry, Knudsen cell.

1. Introduction

Le chlorure mercureux ou calomel, Hg_2Cl_2, est un matériau aux propriétés physiques remarquables (1). L'utilisation des monocristaux de Hg_2Cl_2 connaît un essor dans le domaine de la polarisation optique et acousto-optique (2), les applications étant limitées par la difficulté d'obtenir un matériau suffisamment pur. Le chlorure mercureux disponible dans le commerce est au mieux pur à 99,5 %, ce qui est insuffisant pour la cristallogénèse. L'objectif de ce travail est d'obtenir un matériau de grande pureté et de stœchiométrie parfaitement maîtrisée pour l'obtention de monocristaux de bonne qualité par croissance à partir de la phase vapeur. Après avoir caractérisé qualitativement la phase gazeuse nous exposons notre méthode de préparation du calomel, basée sur la synthèse directe à partir de mercure et de chlorure mercurique. La pression de vapeur du calomel obtenu a été mesurée entre 353 et 453 K par la méthode d'effusion de Knudsen.

2. Composition de la vapeur du chlorure mercureux

Il n'existe pas d'études expérimentales récentes sur la composition de la vapeur du chlorure mercureux, cependant il est sûr que la vapeur n'est pas formée de molécules HgCl qui, contenant un nombre impair d'électrons, seraient paramagnétiques (3). Des études anciennes ont montré que des traces d'humidité influencent fortement la vaporisation (4, 5).

Plus récemment, pour l'étude de la cristallogénèse du calomel à partir de sa phase vapeur, N.B. Singh et al. (6–11) supposent que la sublimation est congruente. Cette supposition, qui est à la base de tous leurs modèles de transport de matière en phase gazeuse, n'a pas été vérifiée.

Opperman et al. (12) ont montré, en comparant leurs mesures de pression de vapeur du calomel avec les données thermodynamiques, que la vapeur était complètement dissociée en mercure et chlorure mercurique pour des températures supérieures à 200°C.

Nous avons réalisé des analyses qualitatives par spectrométrie de masse à partir du produit commercial (Aldrich Chemical Company, Inc. 99,5+ %) longuement desséché sur anhydride phosphorique. Nous avons utilisé la méthode d'ionisation par impact électronique. Les mesures sont réalisées en augmentant la température de 30 à 500°C à raison de 1°C/s, une acquisition étant effectuée toutes les 5 s. L'énergie d'ionisation de 70 eV, couramment utilisée en spectrométrie de masse pouvant fragmenter d'éventuelles molécules Hg_2Cl_2, nous avons également travaillé à 50 et 12 eV.

Les spectres de masse correspondant à une température de 140°C sont présentés sur la figure 1, chaque massif étant repéré par son identité. Les abondances isotopiques relatives

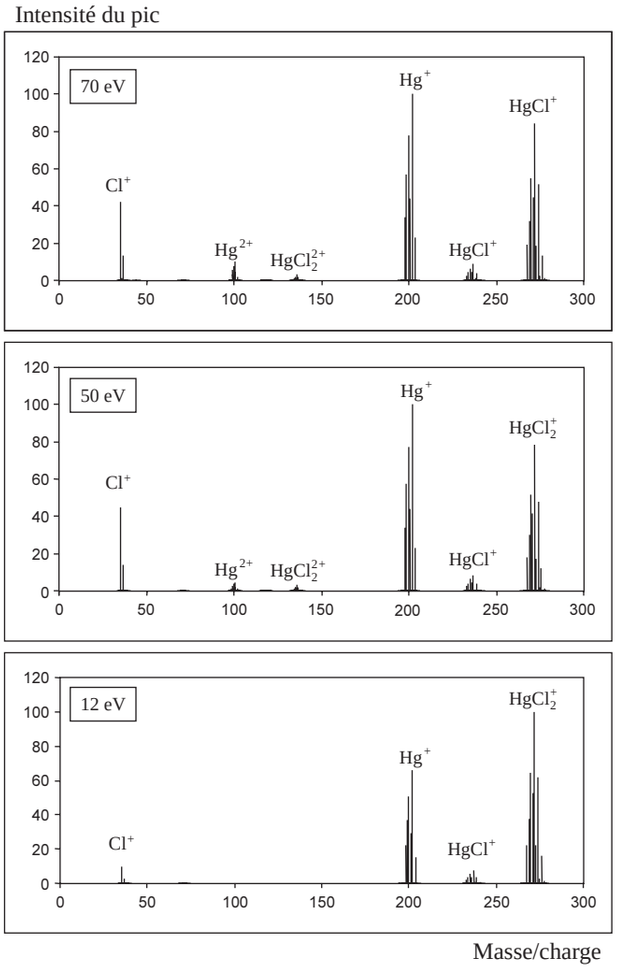
Fig. 1. Spectres de masse du calomel pour différentes énergies d'ionisation.



au mercure et au chlore, utiles pour interpréter les spectres de masse, sont données dans le tableau 1. Nous remarquons que le nombre de massifs diminue en même temps que l'énergie d'ionisation. Pour une énergie électronique de 12 eV, on ne détecte aucune masse supérieure à 300, ce qui élimine la présence de Hg_2Cl_2. Le massif aux environs de 237 correspond à l'ion $HgCl^+$ et non pas à l'ion doublement chargé $Hg_2Cl_2{}^{2+}$, car dans ce cas on devrait observer des rapports masse/charge demi-entiers et une répartition isotopique différente. Ces ions $HgCl^+$ ainsi que les ions Cl^+ proviennent de la fragmentation de molécules $HgCl_2$ par le faisceau d'électrons. De cette étude, il ressort que dans le domaine de température 30–500°C, le calomel est totalement dissocié en phase vapeur, la vapeur étant composée d'un mélange de mercure et de chlorure mercurique.

calomel commercial Aldrich Chemical Company Inc. à 99,5+ %, nous avons observé la formation de gouttelettes de mercure, ce qui laisse penser que le produit final n'est pas stœchiométrique. Ce problème nous a conduit à entreprendre la synthèse directe du calomel à partir des produits commerciaux Aldrich Chemical Company Inc. Le chlorure mercurique a une pureté de 99,999 %, celle du mercure étant de 99,9995 %, ce qui est bien supérieur à celle du calomel commercial.

Le protocole de la synthèse et de la purification est schématiquement représenté sur la figure 2. On commence par charger le compartiment de queue d'un tube Pyrex® à deux compartiments de façon équimolaire en mercure et chlorure mercurique (soit 6,5 g de mercure pour 8,8 g de chlorure mercurique). Après dégazage, les produits sont transportés vers le compartiment suivant par chauffage à 110°C sous vide secondaire dynamique. Le produit condensé est un mélange de calomel, de mercure et de chlorure mercurique. Les impuretés les plus volatiles sont évacuées vers le système de pompage et les moins volatiles isolées par scellage du compartiment de queue. L'ampoule est à nouveau dégazée durant 24 h et scellée sous vide secondaire.

On récupère dans le compartiment de chargement des impuretés de couleur noire provenant certainement en majeure partie de l'affinité du chlorure mercurique pour l'eau. Ces dépôts étant très peu abondants, il est difficile de les analyser et de les quantifier. Par ailleurs, une certaine quantité de mercure et de chlorure mercurique part vers le système de pompage durant les différentes phases de dégazage et de transport. Ces pertes vers le système de pompage sont certainement plus importantes en mercure qu'en chlorure mercurique et sont très difficiles à évaluer.

L'ampoule est ensuite insérée au 9/10^e dans un four maintenu à 200°C, l'extrémité étant laissée à l'air libre. Les produits sont transportés de la zone chaude vers la zone froide et se combinent lors de leur condensation. Lorsque le transport est terminé, l'ampoule est retournée pour un nouveau transport. Chaque étape de sublimation–condensation nécessite 24–72 h, la durée de l'opération augmentant en fonction de la proportion de calomel synthétisé. Après trois opérations, n'observant plus de traces de mercure, nous considérons que quatre transports suffisent.

Les premières analyses thermiques différentielles effectuées sur les produits de synthèse ont révélé que le produit final était un mélange de calomel et de chlorure mercurique. Pour éliminer l'excès de chlorure mercurique, nous effec-

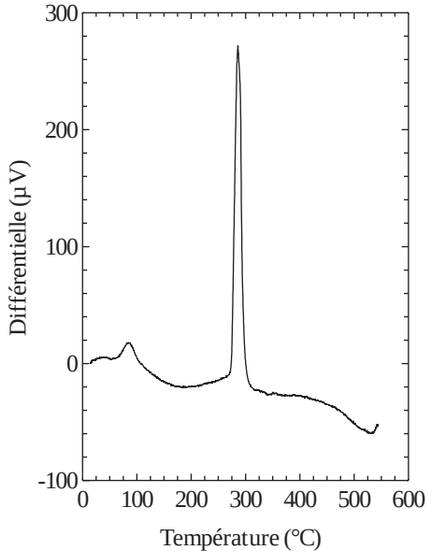

Fig. 4. Analyse thermique différentielle du calomel synthétisé.

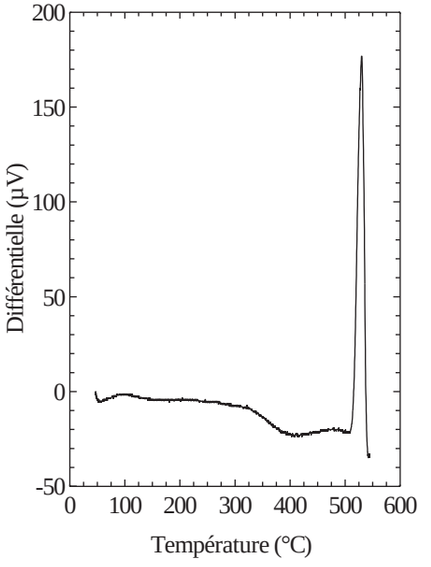

tuons un dernier transport pendant 24 h dans un four à deux zones isothermes maintenues respectivement à 165 et 145°C. Compte tenu des différences très importantes entre les pressions de vapeur du chlorure mercureux et du chlorure mercurique, ce dernier se condense majoritairement dans la zone froide de l'ampoule avec une faible partie du produit synthétisé. L'analyse thermique différentielle effectuée sur le matériau condensé dans la zone froide (fig. 3) montre qu'il s'agit bien de chlorure mercurique, le seul pic qui apparaît correspondant à la fusion de $HgCl_2$ aux environs de

© 1999 CNRC Canada

285°C. L'analyse du produit synthétisé (fig. 4) montre par ailleurs qu'il y a peu de chlorure mercurique, le pic près de 530°C correspondant à la transformation de Hg_2Cl_2 en deux phases liquides (13).

Nous avons déterminé précisément la fraction massique en chlorure mercurique des produits préparés (14). L'excès de chlorure mercurique est extrait par solubilisation dans l'éther et la quantité extraite est mesurée, après fixation des ions mercuriques sur un papier échangeur de cations, par spectrométrie d'émission de rayons X sur la raie $L\alpha_1$ du mercure. La fraction massique du chlorure mercureux synthétisé est de l'ordre de (3–4) × 10^{-5}.

4. Mesure de la pression de vapeur

4.1 Étude de la méthode

La méthode d'effusion, développée par Knudsen (15), repose sur la mesure de la perte de masse de la substance à travers un orifice vers une enceinte à basse pression. L'interprétation du phénomène met en jeu l'effusion moléculaire associée à un flux hydrodynamique, l'importance relative des deux termes dépendant de la pression mesurée et de la géométrie de l'orifice. Dans le cas du calomel, les pressions attendues sont très faibles, et compte tenu des caractéristiques de nos cellules de mesure, le terme hydrodynamique est négligeable.

Dans cette hypothèse, le flux d'effusion des molécules qui s'échappent d'une enceinte par un orifice de longueur L et de rayon r, exprimé en mol m^{-2} s^{-1} a pour expression (15, 16) :

$$[2] \qquad J = \frac{pW}{\sqrt{2\pi MRT}}$$

avec

p : pression de vapeur à l'intérieur de la cellule en pascal
M : masse molaire de la substance étudiée en kg mol^{-1}
R : constante molaire des gaz (8,314 J mol^{-1} K^{-1})
T : température en kelvin
W : facteur de Clausing dépendant de L et r (17)

Dans le cas du calomel, la formule [2] montre que le flux d'effusion du mercure est supérieur à celui du chlorure mercurique si leurs pressions partielles sont égales. Si par ailleurs la sublimation du matériau est stœchiométrique, l'apport à la phase gazeuse est équimolaire. Le régime d'effusion sera permanent si les flux d'effusion sont égaux au flux de sublimation du matériau et dans ce cas, les pressions partielles des deux espèces dans la cellule doivent, quant à elles, être différentes.

Si p désigne maintenant la pression de vapeur du calomel :

$$[3] \qquad p_{Hg} \cdot p_{HgCl_2} = \frac{p^2}{4}$$

et compte tenu de la relation [2] qui donne

$$[4] \qquad \frac{p_{Hg}}{\sqrt{M_{Hg}}} = \frac{p_{HgCl_2}}{\sqrt{M_{HgCl_2}}}$$

les pressions d'équilibre à l'intérieur de l'enceinte sont donc

$$[5] \qquad p_{Hg} = \frac{p}{2}\left(\frac{M_{Hg}}{M_{HgCl_2}}\right)^{1/4} \quad \text{et} \quad p_{HgCl_2} = \frac{p}{2}\left(\frac{M_{HgCl_2}}{M_{Hg}}\right)^{1/4}$$

Si n_c moles de calomel sont vaporisées par seconde, la variation du nombre de moles de l'espèce i (Hg ou $HgCl_2$) à l'intérieur de la cellule s'exprime :

$$[6] \qquad dn_i = n_c\, dt - J_i S\, dt$$

où S est l'aire de l'orifice.
Si V représente le volume de la cellule :

$$[7] \qquad J_i = \frac{Wn_i}{V}\sqrt{\frac{RT}{2\pi M_i}}$$

et ainsi

$$[8] \qquad dn_i = (n_c - \alpha_i n_i)\, dt \text{ avec } \alpha_i = \frac{WS}{V}\sqrt{\frac{RT}{2\pi M_i}}$$

À l'intérieur de la cellule :

$$n_{Hg} n_{HgCl_2} = \frac{p^2}{4}\left(\frac{V}{RT}\right)^2 = \beta \quad \text{donc}$$

$$[9] \qquad n_{Hg}\, dn_{HgCl_2} + n_{HgCl_2}\, dn_{Hg} = 0$$

En utilisant [8] on obtient :

$$[10] \qquad n_c = \frac{(\alpha_{Hg} + \alpha_{HgCl_2}) n_{Hg} n_{HgCl_2}}{n_{Hg} + n_{HgCl_2}}$$

Et en reportant cette valeur dans l'expression [8] on obtient l'équation différentielle :

$$[11] \qquad dn_{Hg} = \left(\frac{n_{Hg} n_{HgCl_2} \alpha_{HgCl_2} - n_{Hg}^2 \alpha_{Hg}}{n_{Hg} + n_{HgCl_2}}\right) dt$$

En intégrant cette expression on obtient l'équation :

$$[12] \qquad t + \frac{1}{2\alpha_{Hg}} \ln(n_{Hg}^2 \alpha_{Hg} - \beta\alpha_{HgCl_2}) + \frac{1}{2\alpha_{HgCl_2}} \ln\left(\frac{n_{Hg}^2 \alpha_{Hg} - \beta\alpha_{HgCl_2}}{n_{Hg}^2}\right) + C = 0$$

où la constante C peut être déterminée par la condition limite à $t = 0$.

Nous présentons sur la figure 5, pour une pression de vapeur du calomel égale à 0,53 Pa, l'évolution des pressions partielles du mercure et du chlorure mercurique dans une cellule de 3 cm^3 de volume et dont l'orifice mesure 0,085 mm de diamètre et 1 mm de longueur. Le temps d'établissement du régime permanent, de l'ordre de 100 s, est tout à fait négligeable par rapport aux temps de mesure de plusieurs heures que nous avons utilisés.

Dans ces conditions, la pression de vapeur du calomel s'exprime, en fonction de la masse effusée m et du temps de mesure t :

$$[13] \qquad p = \frac{\sqrt{8\pi RT}}{W}\frac{m}{tS}\frac{(M_{Hg} M_{HgCl_2})^{1/4}}{M_{Hg_2Cl_2}}$$

4.2 Résultats

Le dispositif expérimental et l'étalonnage des cellules de Knudsen ont fait l'objet d'une publication (18). Nous rappelons les dimensions des cellules utilisées (tableau 2).

Les pressions de vapeur du chlorure mercureux obtenues avec les trois cellules sont reportées dans le tableau 3 et représentées sur la figure 6. Le lissage du logarithme népérien en fonction de l'inverse de la température en kelvin conduit à

Fig. 6. Pression de vapeur du calomel.

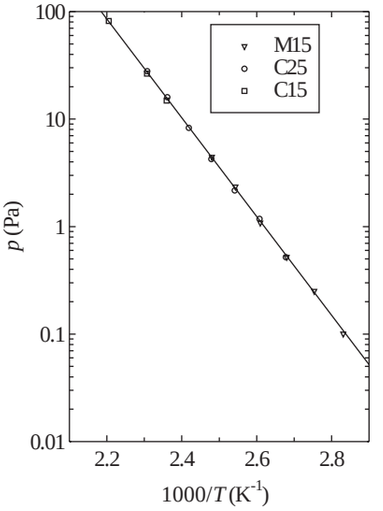

Fig. 7. Comparaison des données de la littérature avec nos valeurs expérimentales.

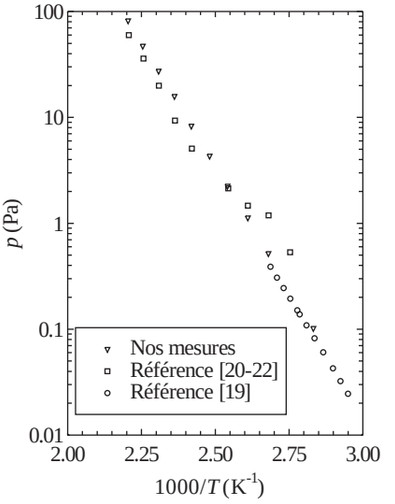

$$[14] \quad \ln p(\text{Pa}) = 27{,}7 - \frac{10571}{T(K)}$$

ce qui correspond à une enthalpie de sublimation égale à 87,9 kJ mol^{-1}.

Sur la figure 7, nous comparons nos résultats avec les pressions de vapeur mesurées par Neumann (19), Niederschulte (20), Niederschulte et Matthies (21) et Wiedemann et al. (22). Nous constatons un écart de 18 % à 363 K entre nos mesures et celles de la référence 19, l'écart avec celles des références 20–22 étant de 55 % à la même température.

Les pressions de vapeur mesurées par Oppermann et al. (12), pour les températures supérieures à 473 K, conduisent à

$$[15] \quad \ln p(\text{Pa}) = 27{,}8 - \frac{10546}{T(K)}$$

ce qui est très proche de nos résultats pour le domaine 353–453 K.

© 1999 CNRC Canada

5. Conclusion

La méthode de préparation du calomel que nous avons mise au point par synthèse directe à partir de mercure et du chlorure mercurique conduit à du calomel dont la fraction massique en chlorure mercurique est particulièrement faible. Nous avons confirmé la dissociation du calomel en phase vapeur, en mercure et chlorure mercurique, et mesuré sa pression de vapeur de 353 à 453 K. Ces résultats nous permettront de mieux maîtriser le transport et la croissance en phase vapeur pour l'obtention de monocristaux dont les études seront publiées prochainement.

Energétique des liaisons inter- et intramoléculaires dans les trois acides carboxypyridiniques (acides picolinique, nicotinique et isonicotinique)

Raphaël Sabbah et Safi Ider

Résumé : Le présent travail porte sur l'étude thermodynamique des trois acides carboxypyridiniques de formule générale : $C_6H_5NO_2$. Il a été réalisé en utilisant quatre techniques : la calorimétrie de combustion de faibles quantités de substance (quelques milligrammes par essai), la calorimétrie de sublimation, la mesure de capacités calorifiques par la méthode de chute et l'analyse thermique différentielle. Cette étude nous a permis : de déterminer les enthalpies de combustion, de sublimation, de formation et de fusion de ces composés ainsi que la température de leur point triple; de préciser la stabilité relative des trois isomères et de les comparer à celle d'autres dérivés de la pyridine; de déterminer les énergies de conjugaison et de les comparer à celles d'autres dérivés de la pyridine; de déterminer les enthalpies d'atomisation des trois composés et la valeur enthalpique des liaisons du groupe (C-N=C); de déterminer qualitativement et quantitativement les interactions intermoléculaires.

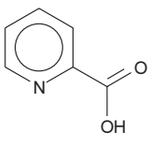
Mots clés : thermodynamique, calorimétrie, analyse thermique différentielle, acides carboxypyridiniques, acide picolinique, acide nicotinique, acide isonicotinique, enthalpie de combustion, de sublimation, de fusion, de formation, des liaisons inter- et intramoléculaires, énergie de conjugaison, température du point triple, substance d'intercomparaison.

Abstract: The present work is concerned with a thermodynamic study of the three carboxypyridinic acids (general formula: $C_6H_5NO_2$). It was achieved using four techniques: combustion calorimetry of small amounts of substance (a few milligrams), sublimation calorimetry, heat capacity measurements by the drop method, and differential thermal analysis. From this study, it was possible to determine the enthalpies of combustion, sublimation, formation, and fusion of these compounds and their triple point temperatures; to discuss the relative stability of the three molecules and to compare it to those of other pyridine derivatives; to determine the resonance energy and to compare it to those of other pyridine derivatives; to determine the atomization enthalpies of our compounds and an enthalpy value for the bonds of the group (C-N=C); to determine the nature and the enthalpy of the intermolecular bonds.

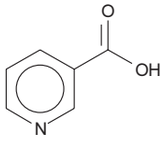
Key words: thermodynamics, calorimetry, differential thermal analysis, carboxypyridinic acids, picolinic acid, nicotinic acid, isonicotinic acid, enthalpy of combustion, of sublimation, of fusion, of formation, of inter- and intramolecular bonds, resonance energy, triple point temperature, reference material.

1. Introduction

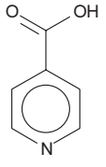
Dans le cadre de nos études sur l'énergétique des liaisons inter- et intramoléculaires dans les substances organiques visant la mise en évidence du lien existant entre grandeurs énergétiques et structure, nous avons souhaité nous intéresser à l'étude des trois acides picolinique, nicotinique et isonicotinique. Cette étude fait suite à celle que nous avons entreprise sur les trois isomères de l'aminopyridine (1).



Acide picolinique
(isomère *ortho*)



Acide nicotinique
(isomère *méta*)



Acide isonicotinique

Sur le plan pratique l'acide nicotinique et ses dérivés, la nicotinamide par exemple, font partie du groupe de la vitamine B. Ils sont principalement utilisés en pharmacie et comme additifs dans l'alimentation humaine et animale. On évalue les besoins mondiaux en acide nicotinique et ses dérivés à environ 100 000 t/an (2). Entrant dans la constitution de certains coenzymes (NADH, NADP), une carence alimentaire en acide nicotinique induit une pathologie : la pellagre associant aux lésions dermatologiques et digestives d'importants troubles mentaux (3). Signalons, au passage, que l'acide nicotinique a été étudié, au cours de ces dernières années, par calorimétrie de combustion dans le but de le proposer comme substance d'intercomparaison dans ce domaine calorimétrique pour les substances azotées (4).

Cette étude a été réalisée par calorimétrie de combustion de faibles quantités de substance, de sublimation et par analyse thermique différentielle : mesure du degré de pureté de l'échantillon soumis à l'étude, de son enthalpie de fusion ainsi que de la température de son point triple. Elle nous a permis, dans un premier temps, de déterminer certaines grandeurs énergétiques liées à la structure des molécules étudiées : énergie de conjugaison, enthalpie d'atomisation. À partir de cette dernière grandeur, il nous a été possible de déterminer l'enthalpie des liaisons du groupement (C-N=C). Une étude sur la stabilité relative des acides carboxypyridiniques et d'autres dérivés de la pyridine a aussi été réalisée. Elle a permis de mettre en évidence l'effet du substituant.

Enfin, à partir de l'enthalpie de sublimation, nous avons pu tirer des conclusions quantitatives relatives aux liaisons hydrogène inter- et intramoléculaires présentes dans les cristaux des trois acides.

Les données dans la littérature concernant les grandeurs thermodynamiques des substances étudiées sont inexistantes à l'exception de l'acide nicotinique pour lequel l'enthalpie de combustion et de formation à l'état condensé sont connues (5, 6). Par ailleurs, quelques résultats concernant la structure cristalline sont consignés dans les références 7 à 13.

2. Partie expérimentale

2.1. Produits

L'acide picolinique est un produit Aldrich. L'analyse thermique différentielle de l'échantillon de cet acide ayant donné un degré de pureté égal à 99,65 mol %, nous avons été amenés à repurifier le produit en le recristallisant trois fois dans l'éthanol absolu puis séché en l'abandonnant 8 h environ dans un dessiccateur à potasse maintenu sous pression réduite. Nous avons trouvé pour le produit ainsi purifié un degré de pureté de (99,92 ± 0,01) mol %.

L'acide nicotinique est un produit Fluka. Son analyse thermique différentielle ayant fourni un résultat satisfaisant pour son degré de pureté : (99,98 ± 0,01) mol %, nous l'avons utilisé tel que.

L'acide isonicotinique est un produit Fluka dont le degré de pureté, signalé sur le flacon, est ≥99 %. Compte tenu de son point de fusion élevé (592 K (14)) et de sa décomposition à la fusion, il ne nous a pas été possible de réaliser son analyse thermique différentielle. Selon la référence 13, l'acide isonicotinique pur est incolore. Comme notre produit avait une légère couleur brunâtre, nous l'avons repurifié à partir de quatre recristallisations dans l'eau distillée et déminéralisée suivies d'un séchage identique à celui qui a été pratiqué dans le cas de l'acide picolinique.

2.2. Appareillages, techniques et modes opératoires

2.2.1. Analyse thermique différentielle

Nous avons utilisé la version moyenne température de l'analyseur thermique différentiel et les cellules expérimentales en verre décrites dans la référence 15.

Dans toutes nos expériences : (*i*) la vitesse de montée en température du four a été de 0,2 K min^{-1}; (*ii*) la masse de substance utilisée a été d'environ 100 mg, déterminée par double pesée à l'aide d'une balance « Mettler», type M5, sensible au μg et dont l'exactitude des pesées est de ±2 μg; (*iii*) la préparation des échantillons et leur mise en container ont été conduites de la façon décrite dans la référence 15.

La mesure des températures a été faite à l'aide de deux thermocouples (thermocoax, type 2ABI 15), l'un est solidaire de l'échantillon, l'autre de la référence (alumine-α). La différence entre les f.é.m. délivrées par ces deux thermocouples est amplifiée par un microvoltmètre AOIP, type EVA, sensibilité 100 μV pleine échelle. Le signal ainsi amplifié est envoyé simultanément à un enregistreur Sefram, type Gépérac, pour le visualiser, et à un multimètre Keithley, modèle 175, pour le digitaliser. Un autre multimètre Keithley, modèle 196, sensibilité 300 mV (résolution 100 nV) est utilisé pour mesurer la f.é.m correspondant à la température de l'échantillon. Les données issues de ces deux multimètres sont envoyées vers un ordinateur en vue de leur traitement à l'aide d'un programme écrit et mis au point au laboratoire. En appliquant l'équation de Clausius–Clapeyron et la loi de Raoult, ce programme permet de déterminer la pureté de l'échantillon, son enthalpie de fusion ainsi que la température de son point triple.

Comme indiqué dans la référence 15, l'étalonnage (*i*) en température, de notre analyseur thermique a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque, diphénylacétique et anisique, de carbazole et d'anthraquinone, dont la température de leur point triple est bien connue dans la littérature; (*ii*) en énergie, a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque et diphénylacétique, dont l'enthalpie de fusion est bien connue dans la littérature.

2.2.2. Calorimétrie de combustion

Les enthalpies de combustion de nos composés ont été déterminées en utilisant un calorimètre isotherme, à flux thermique, monopile, basculant, CRMT (sensibilité : 0,0623 V W^{-1}) équipé d'une microbombe en acier inoxydable (Superimphy 625) de volume interne égal à 42,9 cm^3 à la température ambiante.

Le signal issu du calorimètre est amplifié par un microvoltmètre électronique AOIP, modèle EVA, sensibilité 30 mV pleine échelle, avant son envoi simultané sur un intégrateur électronique, conçu, réalisé et mis au point au laboratoire, qui détermine l'aire des thermogrammes $dQ/dt = f(t)$, et sur un enregistreur potentiométrique Sefram, modèle Servotrace, qui le visualise.

© 1999 CNRC Canada

La rotation du calorimètre suivant plusieurs plans permet à toutes les génératrices de la bombe d'être lavées par l'eau déminéralisée placée en son fond (1 cm^3).

Comme indiqué dans la référence 16, les substances à étudier sont mises sous forme de pastilles. À cet effet, nous avons utilisé un ensemble piston-moule façonné dans un acier trempé, ce qui a pour effet d'éviter l'entraînement dans les pastilles de traces de métal et d'augmenter ainsi la qualité des résultats.

Les pesées ont été effectuées sur une microbalance « Mettler», modèle UM3, équipée d'un jeu de poids étalonnés par le N.I.S.T. Sa portée est de 3 g et sa sensibilité de 0,1 µg. L'erreur commise avec cette balance sur une pesée de quelques milligrammes est de l'ordre de ±0,2 µg. Dans toutes nos pesées, nous avons tenu compte des corrections de poussée de l'air pour calculer les masses réelles.

Une fois garnie, la bombe est remplie d'oxygène sous une pression de 3,04 MPa. L'oxygène N45, utilisé à cet effet, provient de l'Air Liquide et son degré de pureté est supérieur à 99,995 % (fraction molaire d'azote $<10^{-5}$). La durée d'une expérience a toujours été de 90 min à partir du moment de la mise de feu.

Après chaque expérience, nous avons déterminé, dans la phase aqueuse, la concentration d'acide nitrique par titrage acido-basique en présence de phénolphtaléine avec une solution de soude préalablement titrée à l'aide de solutions d'acide oxalique de concentrations connues et avons vérifié, à l'aide des tubes de Dräger, l'absence d'oxyde de carbone et d'oxydes d'azote (NO, NO_2) dans la phase gazeuse (sensibilité des tubes <1 ppm pour CO et <0,1 ppm pour NO et NO_2).

2.2.3. Calorimétrie de sublimation

Nous avons utilisé un calorimètre Tian–Calvet (sensibilité 0,0188 V W^{-1} à 328,75 K et 0,0160 V W^{-1} à 362,15 K) associé à un montage différentiel doté de cellules d'effusion de Knudsen pour déterminer les enthalpies de sublimation de nos composés. L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après chaque série d'expériences. Le mode opératoire a été décrit dans la référence 17. Précisons que :

(*i*) le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147, sensibilité 30 µV pleine échelle, puis digitalisé par un multimètre numérique Keithley modèle 175 et enregistré sur un enregistreur potentiométrique Sefram, modèle Servotrace;

(*ii*) compte tenu de la faible pression de vapeur saturante de nos composés, l'isomère *ortho* a été étudié à 328,75 K et les deux autres isomères à 362,15 K. De plus, nous avons admis l'identité $\Delta_{sub}H_m(T) \equiv \Delta_{sub}H°_m(T)$;

(*iii*) le diamètre des trous d'effusion, pratiqués dans des joints en téflon de 0,3 mm d'épaisseur, sont respectivement de 0,5, 1 et 2,5 mm dans le cas des isomères *ortho*, *méta* et *para*.

(*iv*) l'ouverture et la fermeture de l'orifice d'effusion des cellules sont pilotées par l'ordinateur;

(*v*) toutes les pesées ont été effectuées à l'aide d'une balance « Mettler », type UM3.

L'acquisition et le traitement des données sont réalisés à l'aide de l'ordinateur et d'un programme conçu et mis au point au laboratoire. Il permet, entre autres, de déterminer la pression de vapeur saturante, l'aire des thermogrammes et, à partir du coefficient d'étalonnage, l'enthalpie de sublimation de nos composés à la température de l'expérience $\Delta_{sub}H°_m(T)$.

2.2.4. Mesure des capacités calorifiques

Pour calculer $\Delta_{sub}H°_m$ (298,15 K) à partir de $\Delta_{sub}H°_m(T)$, il est nécessaire de connaître : (*i*) le comportement thermique de nos substances entre 298,15 K et *T*. Nous nous sommes donc assurés que nos substances ne présentaient aucun changement de phase dans cet intervalle; (*ii*) la capacité calorifique à pression constante des phases condensée et gazeuse des substances étudiées à 298,15 K et *T* de façon à pouvoir appliquer la relation suivante :

$$\Delta_{sub}H°_m(298{,}15\ \mathrm{K}) = \Delta_{sub}H°_m(T) + \int_T^{298{,}15K} [C°_{p,m}(g) - C°_{p,m}(cr)]dT$$

La différence enthalpique $H°_m(T) - H°_m(298{,}15\ K)$ à l'état solide a été calculée par la méthode de chute à l'aide d'un calorimètre Tian–Calvet et d'un four maintenus respectivement à 298,15 K et *T*. Le calorimètre a été préalablement étalonné en utilisant des échantillons d'alumine-α.

Quant aux valeurs des capacités calorifiques à l'état gazeux $C°_{p,m}(g)$ et aux températures 298,15 K et *T*, elles ont été déterminées à partir d'une méthode incrémentale en utilisant, à chacune de ces deux températures, les capacités calorifiques à l'état gazeux des molécules de benzène et de l'acide benzoïque (18). Ceci nous a permis, dans un premier temps et à chacune de ces deux températures, de déterminer la part du chaînon COOH, puis de calculer une valeur moyenne de $C°_{p,m}$ pour les trois acides en ajoutant cette quantité au $C°_{p,m}$ de la pyridine.

Les différents calorimètres et analyseur thermique, leurs périphériques ainsi que les balances sont placés dans des salles thermorégulées à (19,0 ± 0,2)°C.

3. Résultats

Les constantes physiques des trois acides ayant fait l'objet de ce mémoire sont rassemblées dans le tableau 1.

3.1. Analyse thermique différentielle

Les résultats obtenus sont consignés dans le tableau 2. Les trois isomères se décomposent à la fusion en prenant une coloration brune. L'acide isonicotinique n'a pas pu être étudié car sa décomposition entraînait une explosion de l'ampoule.

Le manque de données de la littérature relatives à l'enthalpie de fusion de ces acides ne nous a pas permis d'en faire une comparaison avec nos valeurs expérimentales.

Quant aux températures de leur point triple, la référence 14 indique les valeurs suivantes : acide picolinique : 409–410 K, acide nicotinique : 509–510 K et acide isonicotinique : 592 K. Comme nous pouvons le constater, nos résultats expérimentaux sont tout à fait compatibles avec ces données.

3.2. Calorimétrie de combustion

L'équivalent énergétique du système calorimétrique (U_{calor}) a été déterminé à partir de sept combustions d'acide benzoïque échantillon 39 i du N.I.S.T. pour lequel $\Delta_c u°$(cr, 298,15 K) = (–26 414 ± 3) J g^{-1} (21). Dans chaque expérience, nous avons utilisé environ 5 mg d'acide et 0,2 mg de

Tableau 1. Grandeurs physiques des substances utilisées à 298,15 K.

Substance	Formule	M [a] / g mol^{-1}	ρ / g cm^{-3}	$-(\partial U/\partial P)_T$ / J g^{-1} MPa^{-1}
Acide benzoïque	$C_7H_6O_2$	122,1234	1,32(19)	0,12(19)
Coton	$CH_{1.791}O_{0.850}$	27,4157	1,50(19)	0,29(19)
Acide picolinique	$C_6H_5NO_2$	123,1112	1,571 [b]	0,13 [c]
Acide nicotinique	$C_6H_5NO_2$	123,1112	1,333 [b]	0,13 [c]
Acide isonicotinique	$C_6H_5NO_2$	123,1112	1,488(13)	0,13 [c]

[a]Calculée à partir du tableau des masses atomiques de 1993 (20).
[b]Valeurs déterminées par nos soins.
[c]Valeurs estimées.

coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur $\Delta_c u°$(cd, 298,15 K) = (–16 399 ± 23) J g^{-1} (22). Nous avons trouvé U_{calor} = (16,028 ± 0,004) J V^{-1} s^{-1}.

Les enthalpies standard de combustion de nos composés concernent la réaction suivante :

$$C_6H_5NO_2(cr) + 25/4\ O_2\ (g) \rightarrow 6\ CO_2\ (g) + 5/2\ H_2O\ (l) + 1/2\ N_2\ (g)$$

et sont calculées, à l'aide de l'ordinateur et d'un programme écrit et mis au point au laboratoire, à partir de nos valeurs expérimentales en tenant compte des corrections dites de Washburn.

La combustion des trois isomères s'est révélée complète, aucune trace de cendre ne subsistant dans le corps de la bombe et dans le creuset, une fois l'expérience terminée et les dosages par tubes colorimétriques de Dräger n'ayant révélé aucune présence de CO et d'oxydes d'azote dans la phase gazeuse.

Les résultats relatifs à ces manipulations sont rassemblés dans les tableaux 3–5.

L'enthalpie de formation à l'état condensé de nos trois acides a été calculée à partir de leur enthalpie de combustion et des valeurs de l'enthalpie de formation de l'eau : $\Delta_f H°_m$(l, 298,15 K) = (–285,830 ± 0,042) kJ mol^{-1} et du dioxyde de carbone : $\Delta_f H°_m$(g, 298,15 K) = (–393,51 ± 0,13) kJ mol^{-1} (23).

Nous avons remarqué qu'environ 12 % de l'azote contenu dans nos composés se trouvaient, à l'issue de la combustion, sous forme d'acide nitrique. L'expérience a montré que la quantité d'acide nitreux formé est excessivement faible et peut être négligée.

Comme nous l'avons précisé dans l'introduction, seul l'acide nicotinique a fait l'objet de deux études réalisées par calorimétrie de combustion en bombe statique en vue de sa proposition comme substance d'intercomparaison dans ce domaine calorimétrique pour les substances azotées. C'est ainsi que Johnson propose en 1975 (5) la valeur $\Delta_f H°_m$(cr, 298,15 K) = (–2730,67 ± 0,57) kJ mol^{-1} et Sato-Toshima et al. proposent en 1983 (6) la valeur $\Delta_f H°_m$(cr, 298,15 K) = (–2730,83 ± 0,48) kJ mol^{-1}. Comme nous pouvons le constater ces deux valeurs sont tout à fait compatibles à la nôtre $\Delta_f H°_m$(cr, 298,15 K) = (–2731,19 ± 0,79) kJ mol^{-1}.

Tableau 2. Analyse thermique différentielle des acides étudiés.

Substance	Pureté / mol %	T_{pt} [a] / K	$\Delta_{fus}H_m$ / kJ mol^{-1}
Acide picolinique	99,92±0,02	410,23±0,04	14,47±0,11
Acide nicotinique	99,98±0,01	509,16±0,01	13,01±0,32

[a] Températures du point triple définies par rapport à l'EIT-90.

3.3. Calorimétrie de sublimation.

L'ensemble des résultats est consigné dans le tableau 6. Malheureusement le manque de données dans la littérature relatives à l'enthalpie de sublimation et à la pression de vapeur saturante des trois acides carboxypyridiniques ne nous a pas permis d'en faire une comparaison avec nos valeurs expérimentales. À partir de nos essais, il nous a été possible d'évaluer la pression de vapeur saturante de nos trois acides en utilisant la relation :

$$P(T) \approx \Delta P = \mathrm{d}m/\mathrm{d}t\ (2\pi RT / M)^{1/2} 1/aF$$

dans laquelle ΔP est la pression de part et d'autre du trou d'effusion; $P(T)$, la pression mesurée par effusion à la température T; $\mathrm{d}m/\mathrm{d}t$, la masse effusée par unité de temps; R, la constante des gaz parfaits; M, la masse molaire de la substance; a, l'aire de l'orifice d'effusion; F, le facteur de Clausing.

3.4. Enthalpie de formation à l'état gazeux

En utilisant les résultats expérimentaux obtenus par calorimétrie de combustion et de sublimation, nous avons calculé l'enthalpie molaire standard de formation à l'état gazeux de chacun des trois isomères. Celle-ci est égale à (–245,0 ± 0,9) kJ mol^{-1}, (–239,3 ± 1,0) kJ mol^{-1} et (–240,3 ± 1,0) kJ mol^{-1} respectivement pour les isomères *ortho*, *méta* et *para*.

3.5. Enthalpie d'atomisation

À une température donnée, la réaction d'atomisation des acides étudiés dans ce mémoire s'écrit :

$$C_6H_5NO_2(g) \rightarrow 6\ C(g) + 5\ H(g) + N(g) + 2\ O(g)$$

En conséquence, à 298,15 K, l'enthalpie liée à cette réaction est égale à :

$$\Delta_a H°_m(g) = 6\Delta_f H°_m C(g) + 5\Delta_f H°_m H(g) + \Delta_f H°_m N(g) + 2\Delta_f H°_m O(g) - \Delta_f H°_m C_6H_5O_2N(g)$$

Aminopyridines	107,5	141,4	125,9	1
Hydroxypyridines			–30,3	25
Carboxypyridines	–245,0	–239,3	–240,3	Ce travail

Dans le présent travail, l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, $\sigma_m = \pm\{\Sigma(x - x_0)^2 / n(n-1)\}^{1/2}$, x étant chacune des n valeurs entrant dans le calcul de la moyenne x_0. Lorsque la valeur expérimentale est fonction de plusieurs variables, l'incertitude calculée tient compte de l'erreur sur chacune de ces variables.

4. Discussion

4.1. Enthalpie de formation à l'état gazeux

Nous avons voulu comparer entre elles les valeurs de l'enthalpie de formation à l'état gazeux et à 298,15 K des trois isomères de différents dérivés de la pyridine se différenciant par la nature du substituant. Ces différentes valeurs sont rassemblées dans le tableau 7. Cette comparaison nous permet de faire les constatations suivantes :

1. Les substances étudiées dans le présent travail sont les plus stables. Les valeurs de leur $\Delta_fH^\circ_m$(g, 298,15 K) sont négatives et élevées (en valeur absolue). La stabilité semble décroître dans l'ordre suivant : carboxypyridines, hydroxypyridines, méthylpyridines et aminopyridines.

2. Quelle que soit la famille considérée, l'isomère *ortho* paraît être le plus stable. Comme il en sera question plus loin dans le texte, ceci peut être dû à la présence d'une liaison hydrogène intramoléculaire entre l'atome d'hydrogène de la fonction acide et l'atome d'azote de l'hétérocycle créant ainsi un second cycle et renforçant, de ce fait, la conjugaison. Par ailleurs, cette stabilité décroît dans le sens *ortho*, *para*, *méta*.

4.2. Liaisons intramoléculaires dans les acides carboxypyridiniques

Par définition, l'enthalpie d'atomisation d'une molécule est égale à la somme des liaisons intramoléculaires compte tenu des facteurs de stabilisation et de déstabilisation.

À partir de cette grandeur thermodynamique et compte tenu du principe de transférabilité, nous avons pu déterminer la valeur enthalpique de l'ensemble des liaisons comprises

Tableau 8. Energie de conjugaison des trois isomères de différents dérivés de la pyridine.

Dérivé	E_{conj} kJ mol^{-1}		
	ortho	*méta*	para
Méthylpyridines	169,9	153,6	160,5
Aminopyridines	182,6	168,2	182,9
Hydroxypyridines			161,9
Carboxypyridines	252,9	240,1	241,1

dans le groupement (C-N=C) dans chacun des trois acides. Pour ce faire, nous avons défalqué de $\Delta_a H°_m$(298,15 K) la valeur des différentes autres liaisons intramoléculaires précédemment déterminées au laboratoire (26) : H(C_b—C_b) = 504,97 kJ mol^{-1}, H(C_b—H) = 415,88 kJ mol^{-1}, H(C_b—C) = 351,56 kJ mol^{-1}, H(COOH) = 1657,35 kJ mol^{-1}. Nous trouvons pour H(C-N=C) la valeur moyenne 910,22 kJ mol^{-1} qui est en très bon accord avec les valeurs trouvées précédemment au laboratoire pour ce même ensemble (902,18 kJ mol^{-1} (26), 924,2 kJ mol^{-1} (27)) ou consignées dans la littérature (valeur moyenne 903 kJ mol^{-1} (28)).

4.3. Energie de conjugaison

L'énergie de conjugaison est la différence entre l'énergie réelle de la molécule et l'énergie qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Pratiquement, pour la déterminer, il suffit d'utiliser les enthalpies standard de combustion à l'état gazeux de la molécule réelle et de la molécule fictive non conjuguée. La première de ces grandeurs s'obtient expérimentalement et la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages qui est consignée dans la référence 29 compte tenu des modifications relatives aux liaisons C—N et C=N indiquées dans la référence 30.

Les valeurs de l'énergie de conjugaison des trois acides étudiés dans ce mémoire sont consignées dans le tableau 8 avec celles de différents dérivés de la pyridine. Ce tableau nous permet de faire les constatations suivantes :

1. Les carboxypyridines sont les dérivés les plus conjugués. Ceci est vraisemblablement dû au fait que le groupement (COOH), donneur d'électrons, consolide la conjugaison du cycle.

2. Quelle que soit la famille considérée, l'isomère *ortho* est plus le conjugué.

3. L'énergie de conjugaison des aminopyridines est plus élevée que celles des hydroxypyridines (à noter que la littérature ne propose de valeur sûre que pour l'isomère *para*). Ceci peut s'expliquer si l'on considère l'électronégativité des atomes d'azote de la fonction amine (NH_2) et d'oxygène de la fonction hydroxyle (OH). En effet, le doublet électronique porté par chacun de ces deux atomes est plus délocalisé dans le cas de NH_2 que dans celui de OH.

4. Le groupement CH_3 ne participant éventuellement à la conjugaison que par l'effet d'hyperconjugaison fait que les méthylpyridines apparaissent comme les dérivés les moins conjugués.

4.4. Liaisons intermoléculaires dans les acides carboxypyridiniques

4.4.1. Liaisons hydrogène intermoléculaires

L'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires comprenant la part énergétique due aux forces de van der Waals (de dispersion et dipolaires) et, le cas échéant, celle qui est relative aux liaisons hydrogène.

Un procédé de calcul, plusieurs fois utilisé avec succès au laboratoire (1, 31–38), nous a permis de déterminer la part énergétique due aux liaisons hydrogène intermoléculaires. Il consiste, dans notre cas, à comparer l'enthalpie de sublimation de nos molécules à celle d'une molécule isoélectronique (ici la molécule de nitrobenzène) possédant les mêmes forces de dispersion et d'interactions dipolaires. Ce composé étant liquide à 298,15 K, nous avons déterminé son enthalpie de sublimation à partir de son enthalpie de vaporisation à 298,15 K et de son enthalpie de fusion à T_{fus} = 278,85 K en utilisant, en première approximation, la relation suivante :

$$\Delta_{sub}H°_m(298{,}15\ \text{K}) = \Delta_{vap}H°_m(298{,}15\ \text{K}) + \Delta_{fus}H_m(298{,}15\ \text{K})$$

avec $\Delta_{vap}H°_m$(298,15 K) = 55,0 kJ mol^{-1} (24) et $\Delta_{fus}H_m$(278,85 K) = 11,59 kJ mol^{-1} (39). Cette dernière valeur a été ramenée à 298,15 K en appliquant la relation de Sidgwick (40) :

$$\Delta_{fus}H_m(298{,}15\ \text{K}) = \Delta_{fus}H_m(278{,}85\ \text{K}) - 0{,}055\ (278{,}85 - 298{,}15)$$

Nous obtenons $\Delta_{fus}H_m$(298,15 K) = 12,65 kJ mol^{-1} et $\Delta_{sub}H°_{m.}$(298,15 K) = 67,65 kJ mol^{-1}. Cette dernière valeur correspond, en première approximation, à la part des forces de dispersion et dipolaires dans le cristal des trois acides carboxypyridiniques. Malheureusement, il ne nous a pas été possible de départager ces deux types d'interactions. En effet, la littérature ne propose aucune valeur de l'enthalpie de vaporisation et de fusion du 2-phénylpropène qui nous auraient permis de déterminer son enthalpie de sublimation à 298,15 K. Cette grandeur est, rappelons-le, en première approximation égale à la part énergétique due aux forces de dispersion dans les cristaux des acides carboxypyridiniques. Il s'en suit que la part énergétique due aux liaisons hydrogène intermoléculaires dans les isomères *ortho*, *méta* et *para* est respectivement égale à 25,07 kJ mol^{-1}, 37,52 kJ mol^{-1} et 43,63 kJ mol^{-1}.

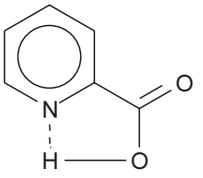
Si l'on considère la molécule d'isomère *para* dans laquelle il ne peut y avoir que des liaisons hydrogène intermoléculaires, la part énergétique due à ces liaisons est relativement élevée par rapport à celles qui ont été trouvées jusqu'ici au laboratoire (41) ou consignées dans la littérature (42). On pourrait expliquer cette anomalie si l'on considère les rares résultats de la littérature à propos de la structure cristalline des trois acides carboxypyridiniques (10, 11, 13). En effet, ces résultats font tous état de liaisons hydrogène intermoléculaires entre l'atome d'azote d'une molécule et l'atome d'oxygène de la fonction OH d'une molécule voi-

© 1999 CNRC Canada

sine. D'après Takusagawa et Shimada (13), à ces liaisons viennent s'ajouter, dans le cas de l'acide isonicotinique (isomère *para*), deux autres faibles liaisons hydrogène entre chacun des atomes de carbone du cycle, situés de part et d'autre de l'atome d'azote, et l'atome d'oxygène de la fonction carbonyle de molécules voisines. En estimant que la liaison N···H—O, ayant une longueur N···H de 1,51 Å (13), possèderait une enthalpie de 29 kJ mol^{-1} (42), à chacune des deux liaisons C—H···O, ayant une longueur O···H de 2,46 Å (13), serait associée une enthalpie d'environ 7,5 kJ mol^{-1}.

4.4.2. Liaisons hydrogène intramoléculaire dans l'isomère ortho

À la suite de leur travail sur la structure de l'acide picolinique, Pâris et al. (7) concluent que cet acide présente une chélation à l'état solide par formation d'une liaison hydrogène intramoléculaire entre l'atome d'azote de l'hétérocycle et l'atome d'hydrogène de la fonction carboxylique.



Un moyen simple de pouvoir quantifier cette chélation consiste à comparer entre elles les valeurs de l'enthalpie de sublimation des isomères *ortho* et *para*. La différence observée, dans le cas présent, est de 18,56 kJ mol^{-1} et doit être attribuée, compte tenu de la chélation, au fait que la molécule d'acide picolinique possède moins de liaisons hydrogène intermoléculaires que les deux autres isomères. La valeur trouvée est tout à fait compatible avec celles qui ont été précédemment déterminées au laboratoire dans le cas des acides hydroxybenzoïques (17,8 kJ mol^{-1} (43)), des acides aminobenzoïques (11,2 kJ mol^{-1} (44)) et des nitrophénols (20,1 kJ mol^{-1} (33)).

D'autres observations faites sur les propriétés physicochimiques de l'acide picolinique tendent à prouver l'existence de cette liaison intramoléculaire.

1. À partir de nos expériences de sublimation, il s'avère que la pression de vapeur saturante de l'isomère *ortho*, est, quelle que soit la température, toujours supérieure à celle des deux autres isomères.

2. La température du point triple et l'enthalpie de fusion sont plus faibles dans le cas de l'isomère *ortho* qu'elles ne le sont dans celui des deux autres isomères (cf. tableau 2).

3. La valeur du pK_a de l'acide picolinique (5, 32) est supérieure à celle des deux autres acides (nicotinique : 4,81, isonicotinique : 4,86) (45).

4. Au cours de nos expériences, nous avons constaté que la solubilité de l'acide picolinique dans un solvant apolaire comme le benzène est plus forte que celle de l'isomère *para* dans le même solvant.

4.5. Peut-on ériger l'acide nicotinique au rang de substance d'intercomparaison en calorimétrie de combustion des substances azotées ?

À la suite de leurs travaux, plusieurs chercheurs (5, 6, 46, 47) ont en fait la proposition.

L'étude des trois acides carboxypyridiniques nous a montré qu'ils sont stables à température ambiante, non hygroscopiques et ont une faible pression de vapeur saturante. Par contre, les expériences réalisées avec ces substances par calorimétrie de combustion nous ont permis de constater que :

1. les pastilles d'acide isonicotinique ont tendance à s'effriter;
2. des combustions incomplètes ont quelquefois été observées avec l'acide picolinique.

Enfin, on trouve dans le commerce des échantillons d'acide nicotinique très purs, ce qui permet de les utiliser sans purification.

Compte tenu de ce qui précède, nous pensons aussi que l'acide nicotinique peut être retenu comme substance d'intercomparaison en calorimétrie de combustion des substances azotées dont le rapport N/C est faible.

Ether synthesis using trifluoromethanesulfonic anhydride or triflates under mild reaction conditions

Tomihiro Nishiyama, Hideaki Kameyama, Hideki Maekawa, and Kouhei Watanuki

Abstract: Reactions of magnesium alkoxides with trifluoromethanesulfonic anhydride or triflates gave corresponding symmetrical or unsymmetrical ethers in moderate to good yields under mild reaction conditions. The scope and limitations of the reaction are discussed.

Key words: ethers, trifluoromethanesulfonic anhydride, triflates, magnesium alkoxides.

Résumé : Les réactions des alcoolates de magnésium avec l'anhydride trifluorométhanesulfonique ou avec les triflates dans des conditions douces conduit aux éthers symétriques ou non symétriques avec des rendements qui vont de modérés à bons. On discute de la portée et des limitations de la réaction.

Mots clés : éthers, anhydride trifluorométhanesulfonique, triflates, alcoolates de magnésium.

[Traduit par la Rédaction]

Introduction

Conversion of an alcohol to the corresponding ether is a widely used functional transformation in organic synthesis, and several methods are available to accomplish an *O*-alkylation reaction under a variety of conditions. For example, the Williamson ether synthesis, with its modifications (1, 2), is one of the most useful synthetic methods for the formation of a carbon–oxygen bond. The attack of alkoxides on alkyl halides, however, is synthetically useful only when the alkyl halide is primary (3). Moreover, the standard Williamson ether synthesis requires rigorous reaction conditions. The condensation of alcohols and their salts with aldehydes (4), olefins (5), *p*-toluene sulfonic acid (6), nitro compounds (7), and dialkyl phosphates (8) are also reported to be useful methods for the *O*-alkylation reaction.

Other approaches have been demonstrated by either the trimethylsilyl triflate- or trimethylsilyl iodide-catalyzed reductive coupling of carbonyl compounds with trialkylsilanes (9). Noyori and co-workers (10) have shown that acetals can be conveniently reduced to ether with trimethylsilane catalyzed by trimethylsilyl trifluoromethanesulfonate. This method is extremely mild and provides nearly equal quantitative yields of symmetrical and unsymmetrical ethers from the corresponding acetals.

In this paper, we report a simple procedure for the preparation of symmetrical and unsymmetrical ethers by the reaction of magnesium alkoxides with trifluoromethanesulfonic anhydride (Tf_2O) or triflates (Scheme 1). The scope and limitations of this procedure are also discussed.

Results and discussion

Table 1 summarizes the products and yields obtained from the reaction of magnesium alkoxides with Tf_2O, and scope of the present method. The reaction of Tf_2O in dry ether with in situ generated magnesium di(benzyl alcoholate) proceeded smoothly to yield dibenzyl ether **2a**. The reaction was completed in 30 min at 5°C, and an 80% isolated yield of dibenzyl ether could be obtained. In this reaction, a stoichiometric amount of Tf_2O was necessary for the reaction. After treatment of magnesium di(benzyl alcoholate) with 0.5 equiv. of Tf_2O, the isolated yield of symmetrical ether decreased to 35% (entry 2). The trifluoromethanesulfonic acid (TfOH) and toluene-4-sulfonic anhydride (TS_2O) were less effective (entries 3 and 4), and the reaction required longer reaction times and a higher temperature to attain a comparable yield (entry 4). With other magnesium alkoxides such as 2-phenylethanol **1b** and hexanol **1c**, the corresponding symmetrical ethers, diphenethyl ether **2b** and dihexyl ether **2c**, were obtained in high yields. The reactions of magnesium alkoxides with Tf_2O were usually carried out at 5°C for 30 min, although in one case, a higher temperature provided better yields. When a mixture of magnesium di(hexanolate) and Tf_2O was stirred at 40°C for 1h, **2c** was obtained in 90% yield. Similarly, a branched primary magnesium alkoxide gave the symmetrical ether **2d** as a mixture of diastereomers (ratio 1:1) in 60% yield (entry 7). In contrast to results obtained with primary magnesium alkoxides, the reactions with secondary magnesium alkoxides such as 2-hexanol **1e** and

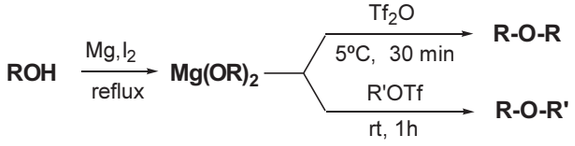
Scheme 1.



3-phenyl-2-propanol **1f** gave bis(2-hexyl) ether **2e** and bis(3-phenyl-2-propyl) ether **2f** as a mixture of diastereomers (ratio 1:1) in low yields. However, tertiary alcohol and phenol failed to give the corresponding ethers. No product was obtained upon heating magnesium di(1,1-dimethyl-2-phenylethanolate) and Tf_2O, even after several hours.

We next turned our attention to the synthesis of unsymmetrical ethers. An unsymmetrical ether can be obtained in moderate yields when an alkyl triflate is used in place of Tf_2O in the reaction. These results are summarized in Table 2. The addition of 1 equiv. of pentyl triflate in dry ether to magnesium di(benzyl alcoholate) in benzyl alcohol **1a** solution at room temperature for 1 h gave benzyl pentyl ether **3a** in 87% yield. The reaction is much less successful with mesylate or tosylate than with triflate. In the case of pentyl mesylate, the reaction required longer reaction times and a higher temperature to obtain an unsymmetrical ether (entry 2). Pentyl tosylate did not give an unsymmetrical ether even at 60°C for 17 h (entry 3). The treatment of 2 equiv. of magnesium di(2-phenylethanolate) with ditriflate at room temperature for 6 h gave symmetrical bis(phenethoxy)butane **3c** in 60% yield. When branched magnesium di(2-phenyl-1-propanolate) was used, the corresponding pentyl 2-phenyl-1-propyl ether **3d** was obtained in 88% yield. For the reactions of secondary magnesium alkoxides with triflate, the corresponding ethers **3e** and **3f** were isolated in 85 and 76% yields, respectively (entries 7 and 8). With tertiary magnesium alkoxide such as 1,1-dimethyl-2-phenylethanol **1h**, the yield was not satisfactory (entry 9). The results in Table 2 indicate that this reaction sequence is applicable to primary and secondary magnesium alkoxides in moderate yields.

In conclusion, we report a simple procedure for the preparation of symmetrical and unsymmetrical ethers by the reaction of magnesium alkoxides with Tf_2O or triflates. This method has the advantage that the reaction rapidly and cleanly takes place under mild reaction conditions.

Experimental

General methods

NMR spectra were recorded in $CDCl_3$ on a JEOL GSX-400 spectrometer operating at 400 and 100 MHz for ^1H and ^{13}C, respectively. Chemical shifts for NMR spectra were referenced to internal $(CH_3)_4Si$. Mass spectra were measured

with a Perkin–Elmer model 910 spectrometer operating in the electron impact mode (70 eV). IR spectra were recorded on a Perkin–Elmer model 1600 spectrophotometer. Gas chromatography was carried out on a 20 m × 0.22 mm capillary column packed with methyl silicone.

Materials

Triflates, mesylates, and tosylates were prepared in the same manner as described in the literature (11, 12). All reagents were reagent grade materials purchases obtained from Tokyo Kasei Kogyo Co. Ltd. (Tokyo) and used without further purification.

General procedure for the synthesis of symmetrical ethers

The following experimental procedure is representative. The precursor, the magnesium alkoxides, were prepared by using a slight modification of the procedure described in the literature (13). A mixture of benzyl alcohol **1a** (2.16 g, 0.02 mol), magnesium (0.24 g, 0.01 mol), and iodine (50 mg, 0.2 mmol) was stirred at 60°C for 1 h. To this solution were added **1a** (2.16 g, 0.02 mol), and the reaction mixture was refluxed until the magnesium was digested. After the reaction mixture cooled to ice-water temperature, a solution of Tf_2O (2.8 g, 0.01 mol) in dry ether (10 mL) was added, and the mixture was then stirred continuously for 30 min at 5°C. The reaction was quenched by the addition of water and extracted with ether. The extract was washed with water, and concentrated in vacuo. The residue was chromatographed on silica gel using hexane/ethyl acetate (80/20) to give dibenzyl ether **2a** in 80% yield as a colorless oil.

General procedure for the synthesis of unsymmetrical ethers

Unsymmetrical ethers were prepared using triflates in place of Tf_2O. To a solution of magnesium di(benzyl alcoholate), generated in situ from **1a** (2.16 g, 0.02 mol), magnesium (0.24 g, 0.01 mol), and iodine (50 mg, 0.2 mmol) in benzyl alcohol (2.16 g, 0.02 mol) was added dropwise a solution of pentyl triflate (2.2 g, 0.01 mol) in 5 mL of dry ether. The mixture was stirred at room temperature for 1 h, the reaction was quenched by the addition of water. After the usual work-up, chromatography of the residue with hexane/ethyl acetate (80/20) afforded benzyl pentyl ether **3a** (1.55 g, 87%).

Benzyl pentyl ether (3a) (17)

α-Halogenohydrazides: useful starting material for the synthesis of hydrazinoazapeptides and azauracils

Catherine Barré, Sophie Carret, Michel Guerro, Philippe Le Grel, and Michèle Baudy-Floc'h

Abstract: An efficient method for the synthesis of pseudodipeptides, which combines an aza glycine residue with various hydrazinoacid moieties by simple substitution of the halogen of α-halohydrazides, is described. Some of these hydrazinoazapeptides lead to hydrazones by oxidation or to azaaminouracils by cyclization.

Key words: hydrazinohydrazides, hydrazones, hydrazinoazapeptides, azaaminouracils, pseudopeptides.

Résumé : Une méthode de synthèse efficace de pseudopeptides, combinant une unité azaglycine avec divers hydrazinoacides, est décrite. Celle-ci consiste en une simple réaction de substitution de l'halogène de divers α-halohydrazides. Nous montrons également que certains de ces hydrazinoazapeptides peuvent conduire à des hydrazones par oxydation et par cyclisation intramoléculaire à des hétérocyles très peu représentés, les azaaminouracils.

Mots clés : hydrazinohydrazides, hydrazones, hydrazinoazapeptides, azaaminouracils, pseudopeptides.

Introduction

Following our studies on the high lability of the chloro or bromo atom of α-halogenohydrazides **1** (1, 2), which occurs under basic conditions with rapid substitution of the halogen by nucleophiles, we focussed our attention on the reaction of various substituted hydrazines. Here is a full report of the reaction of hydrazines, hydrazides, or carbazates **2** with α-halogenohydrazides **1**, which affords hydrazinoazapeptides **3**, **4**, or azauracils **9**. Such pseudopeptides are interesting since hydrazinopeptides (3), as well as azapeptides (4), are analogues of peptides in which the modification of the amide bond decreases the enzymatic biodegradability (5). Moreover, though azauracils are well known compounds (6), only a few of them are *N*-amino substituted and they have been shown to act as herbicidal agents (7).

Results

α-Hydrazinohydrazides **3** or **4** are readily obtained via a simple procedure that involves stirring the starting α-halogenohydrazides **1** with an excess of nucleophiles **2** (typically 3- to 6-fold excess) at room temperature. The basicity of most of the hydrazine derivatives **2** means that only in the case of the lowest basic hydrazides or carbazates must some additional base (NEt_3) be added to promote the reaction.

Most of the cases we have examined give moderate to good yields (Tables 1 and 2). It is interesting to note that monoalkylated hydrazines **2** react either exclusively (R^3 = Me, CH_2Ph; R^4 = H; only one isomer **4** is observed by ^1H NMR spectra of the crude reaction mixture) or predominantly ($R^3 = CH_2CF_3$; R^4 = H) through the substituted nitrogen, the most nucleophilic one being due to the electron donor substituent (Table 2). In the former case, both isomers **3** and **4**, which can be separated by column chromatography, are formed in the proportion 3:7. The structure **4** was proved by NMR spectroscopy as well as by condensation with an aldehyde or a ketone to give **5** (Scheme 1).

Some exceptions to the general reaction must be noted. (*i*) The use of *N*-aminotriazole **6** affords the triazolium salt **7** instead of the expected α-hydrazino compound (Scheme 2). This structure was confirmed by ^1H NMR spectroscopy; in particular, the CH at 6.75 ppm is in accord with a proton in the α position of a pyridinium salt (8). (*ii*) The reaction with phenylhydrazine **2** (R^3 = Ph, R^4 = H) leads to the corresponding hydrazone **8** (*syn* and *anti*) probably via the oxidation of an α-hydrazino intermediate **3** (Scheme 3). (*iii*) In some cases (Table 3), if the reaction is run in refluxing toluene, the formation of *N*-aminoazauracil **9** was observed even under a nitrogen or argon atmosphere. This reaction probably takes place through the oxidation of the primary α-hydrazinohydrazide **3**. It was possible to isolate **3** at room temperature and to show that the α-hydrazinohydrazide can be oxidized by DDQ to yield the hydrazone **8**, which affords *N*-aminoazauracil **9** by cyclization in the presence of NEt_3 (Scheme 4).

Regarding the peptidomimic properties of the resulting compounds **3** and **4**, it appears that a lot of them are interesting pseudopeptidic building blocks that combine an

azaglycine residue (ester form) with various hydrazinoarylglycine moieties in racemic form (Scheme 5). Such association of aza aminoacids and hydrazino acids has not been previously reported; moreover, substituted phenylglycine derivatives have been described as potent agonists or antagonists of the glutamate receptors of the central nervous system (9).

It is important to note that although the presence of an additional nitrogen makes their incorporation into peptidic backbones (10) difficult, such pseudodipeptides **(3** and **4)** could be linked to aminoacids (3*b*). For example the *N* extremity could be coupled with the free carboxylic acid function of protected aminoacids or peptides. Alternatively, the Boc-hydrazino (11) or Bz-hydrazino (12) moiety could be deprotected, leading to an hydrazido extremity that could react with isocyano aminoester (13). Of course these two aspects could be combined to integrate the pseudodipeptides into elaborated peptidic analogues. This last promising aspect is under investigation in our laboratory.

Experimental section

General procedures

^1H NMR spectra were recorded at 80 MHz on a Bruker WP 80 or at 300 MHz on a Bruker AM 300 spectrometer and ^{13}C NMR spectra at 75 MHz on a Bruker AM 300 spectrometer with tetramethylsilane as internal reference. Mass spectra were determined with a Varian Mat 311 spectrometer from the Centre Régional de Mesures Physiques de l'Ouest. IR spectra were determined with a Perkin–Elmer 225 or 1420 spectrometer. Elemental analyses were performed by the analytical laboratory, CNRS (Lyon). Melting points were taken with a Kofler hot stage apparatus. α-Halohydrazides **1** (X = Cl or Br) were prepared as previously described (14).

Preparation of hydrazinoazapeptides 3a–3e

A mixture of α-halohydrazide **1** (8 mmol), methylhydrazinocarboxylate **2** ($R^3 = CO_2Me$, $R^4 = H$) (32 mmol), and NEt_3 (32 mmol) was stirred for 16 h in CH_3CN (50 mL). After removal of the solvent under reduced pressure, the residue was diluted in CH_2Cl_2 (100 mL), and the organic layer was washed with an aqueous solution of HCl (100 mL) and water (100 mL) and then dried (Na_2SO_4). Evaporation afforded the α-hydrazinohydrazide **3**.

3a *(R^1 = pClC_6H_4, $R^2 = Ph$, $R^3 = CO_2Me$, $R^4 = H$)*: Yield 70%, mp 144°C ($CHCl_3$–Et_2O). IR (Nujol), ν: 3270, 3200, 3100, 1695, 1655 cm^{-1}. ^1H NMR (80 MHz, DMSO-d_6), δ: 3.57 (s, 3 H), 4.72 (s, 1 H), 5.27 (br, 1 H), 7.45–7.95 (m, 9 H), 8.45 (br, 1 H), 10.12 (s, 1 H), 10.40 (s, 1 H). Anal. calcd. for $C_{17}H_{17}N_4O_4Cl$: C 54.18, H 4.52, N 14.87, Cl 9.43%; found: C 54.41, H 4.82, N 15.08, Cl 9.36%.

3b *(R^1 = pMeC_6H_4, $R^2 = Ph$, $R^3 = CO_2Me$, $R^4 = H$)*: Yield 72%, mp 105°C ($CHCl_3$–Et_2O). IR (Nujol), ν: 3220, 1720, 1685, 1645 cm^{-1}. ^1H NMR (80 MHz, DMSO-d_6), δ: 2.30 (s, 3 H), 3.57 (s, 3 H), 4.65 (s, 1 H), 5.12 (br, 1 H), 7.10–7.92 (m, 9 H), 8.42 (br, 1 H), 10.02 (br, 1 H), 10.40 (br, 1 H). Anal. calcd for $C_{18}H_{20}N_4O_4$: C 60.66, H 5.65, N 15.72%; found: C 60.31, H 5.73, N 15.14%.

Preparation of α-hydrazinohydrazide 3o

To a solution of *N*-aminomorpholine **2** (R^3, R^4 = -$(CH_2)_2O(CH_2)_2$-) (25 mmol) in CH_3CN (10 mL) was added the α-halohydrazide **1** (5 mmol). After 16 h stirring at room temperature the solvent was removed under reduced pressure, the residue was partially dissolved in CH_2Cl_2 (10 mL), the halohydrate of *N*-aminomorpholine was filtered, and the filtrate saturated by addition of petroleum ether. Cooling afforded a precipitate of α-hydrazinohydrazide **3o.**

3o *(R^1 = 2,4-$Cl_2C_6H_3$, R^2 = OMe, R^3, R^4 = -$(CH_2)_2O(CH_2)_2$-)*: Yield 40%, mp 149°C (CH_2Cl_2 – petroleum ether). IR (Nujol), ν: 3362, 3270, 3227, 1728, 1700 cm^{-1}. ^1H NMR (80 MHz, $CDCl_3$ + CF_3CO_2H), δ: 2.72 (m, 4 H), 3.57 (m, 4 H), 3.60 (s, 3 H), 4.87 (s, 1 H), 7.28–7.77 (m, 3 H), 9.00 (br s, 1 H), 9.85 (br s, 1 H). Preparation of triazolium salt 7

To a solution of 4-amino-4*H*-1,2,4-triazole **6** (28 mmol) in CH_3CN (20 mL) was added α-halohydrazide **1** (9 mmol) under stirring, and the solution was then heated (water bath) for 30 min. After 16 h stirring at room temperature the precipitate of salt **7** was filtered, and washed with hot CH_3CN.

IR (Nujol), ν: 3260, 3110, 3020, 1690, 1612 cm^{-1}. ^1H NMR (DMSO–$CDCl_3$), δ: 3.57 (s, 3 H), 6.75 (s, 1 H), 7.10 (br, 2 H), 7.57 (A_2B_2, 4 H, ^3J = 8 Hz), 9.20 (br, 2 H), 10.25 (s, 1 H), 10.52 (s, 1 H). ^{13}C NMR (DMSO-d_6), δ: 52 (q, ^1J = 147 Hz), 65 (d, ^1J = 146 Hz), 129 (d, ^1J = 169 Hz), 131 (d, ^1J = 160 Hz), 130, 134, 143 (d, ^1J = 229 Hz), 145 (d, ^1J = 228 Hz), 156, 164. Anal. calcd. for $C_{12}H_{14}N_6O_3BrCl$: C 35.5, H 3.45, N 20.70, Cl 18.75, Br 19.73%; found: C 35.68, H 3.59, N 20.38, Cl 8.81, Br 19.25%.

Preparation of hydrazone 8

NEt_3 (20 mmol) was added to a solution of α-halohydrazide **1** (7 mmol) and phenylhydrazine **2** (R^3 = Ph, R^4 = H) (20 mmol) in toluene (20 mL) and refluxed for 65 h. The solvent was then removed and the residue was dissolved in Et_2O (60 mL) and washed with water (2 × 50 mL). The organic layer was dried (Na_2SO_4), and concentrated by evaporation of the solvent. The oil was resolved by silica gel chromatography, eluted by 50:50 Et_2O:petroleum ether to afford *syn* and *anti* **8**. It was not possible to determine which was the *syn* or the *anti* isomer.

8 *(R^1 = pMeC_6H_4, R^2 = OMe, R^3 = Ph)*: R_f 0.38, yield 38%. Preparation of azaaminouracils 9

General procedure

NEt_3 (12 mmol) was added to a mixture of α-halohydrazide **1** (4 mmol) and hydrazine **2** (R^3 = OMe, R^4 = H) (12 mmol) in toluene (25 mL) and refluxed for 20 h. After cooling, the solvent was removed and the residue dissolved in CH_2Cl_2 (60 mL). Addition of acidified water (4 N HCl) afforded a precipitate of **9**.

Via the hydrazone 8

NEt_3 (14 mmol) was added to hydrazone **8** (7 mmol) in toluene (80 mL) and refluxed for 24 h. After cooling, the azaaminouracil **9** was filtered.

9a *(R^1 = pClC_6H_4, R^2 = Ph)*: Yield 61%, mp > 260°C (ethyl acetate). An ether-linked tetrafunctional acylating reagent and its cross-linking reactions with hemoglobin

Ronald Kluger, Krisztina Paal, and J. Gordon Adamson

Abstract: A new type of tetrafunctional reagent for cross-linking proteins has been prepared and used to modify human hemoglobin A. DPEE (1,2-bis{2-[3,5-bis(3,5-dibromosalicyloxycarbonyl) phenoxy]ethoxy}ethane)) has two separate pairs of reacting sites connected by a flexible tetraether chain. DPEE is capable of connecting a cross-link within a protein to another cross-link, either within the same protein molecule or between molecules. DPEE was readily prepared by esterification of a tetraether-linked bisphthalate (prepared by coupling of 1,2-bis(2-iodoethoxy)ethane and 5-hydroxyisophthalic acid). DPEE reacts with deoxy hemoglobin to produce a mixture of modified proteins. Ion-exchange HPLC was used to separate the modified proteins in the mixture. The most abundant products were selected for structural analysis, which used data from reverse-phase chromatography and tryptic peptide mapping. To prevent dissociation of the modified proteins during analysis, the products were further reacted with the bifunctional reagent, bis(3,5-dibromosalicyl) fumarate, which produces fumaryl cross-links between α-subunits. From peptide analysis of the separated products, the major modified protein from DPEE was identified as a novel species with four links within the same $\alpha_2\beta_2$ tetramer. In addition, a minor product that involves cross-links in two different proteins was observed. These results imply that the reagent reacts primarily in a folded state within the protein.

Key words: acylation: cross-linking, multifunctional, hemoglobin, reaction pattern.

Résumé : On a préparé un nouveau type de réactif tétrafonctionnel pour effectuer la réticulation des protéines et on l'a utilisé pour modifier de l'hémoglobine humaine A. Le DPEE (1,2-bis{2-[3,5-bis(3,5-dibromosalicyloxycarbonyl) phénoxy]éthoxy}éthane) possède deux paires séparées de sites réactionnels liés par une chaîne tétraéther flexible. Le DPEE peut relier une réticulation à l'intérieur d'une protéine avec une autre réticulation de la même molécule de protéine ou entre des molécules. On peut facilement préparer le DPEE par estérification d'un bisphtalate relié à un tétraéther (préparé par couplage du 1,2-bis(2-iodoéthoxy)éthane et de l'acide 5-hydroxy-isophtalique). Le DPEE réagit avec la désoxyhémoglobine pour produire un mélange de protéines modifiées. On a fait appel à la CLHP par échange d'ions pour séparer les protéines modifiées présentes dans le mélange. On a choisi les produits les plus abondants pour réaliser une analyse structurale en utilisant des données obtenues par chromatographie en phase inversée et par cartographie d'un peptide tryptique. Dans le but d'empêcher la dissociation des protéines modifiées au cours de l'analyse, on a fait réagir les produits avec le réactif bifonctionnel, fumarate de bis(3,5-dibromosalicyle) qui produit des réticulations fumaryles entre les sous-unités α. Sur la base de l'analyse peptidique des produits séparés, on a déterminé que la protéine principale découlant de la modification par le DPEE est une nouvelle espèce comportant quatre liaisons à l'intérieur du même tétramère $\alpha_2\beta_2$. On a aussi observé la présence d'un produit mineur qui comporte des réticulations dans deux protéines différentes. Ces résultats impliquent que le réactif agit principalement dans un état replié de la protéine.

Mots clés : acylation : réticulation, multifonctionnel, hémoglobine, patron de réaction.

[Traduit par la Rédaction]

Introduction

Human hemoglobin A is an $\alpha_2\beta_2$ tetramer that reversibly dissociates into αβ dimers (1, 2). Cross-linking prevents dissociation into dimers while providing the possibility for systematic alteration of the protein's properties (3-8). Cross-linked hemoglobins are of special interest since they may have clinical significance as red cell substitutes in transfusion medicine (9–11). A minimal reagent that prevents hemoglobin from dissociating into dimers contains two reactive functional groups that create a cross-link (12–14). The properties of the resulting altered protein depend on the sites that are connected and the structure of the link (7, 14–18). Reagents with three reactive functional groups can produce a cross-link between two sites within a protein, leaving a functional group available for bioconjugation (19). Alternatively, all three groups can react within the protein, creating a novel cross-linked structure (7, 20, 21).

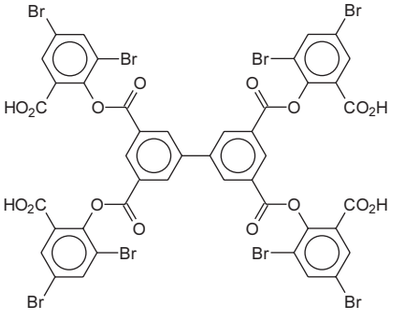
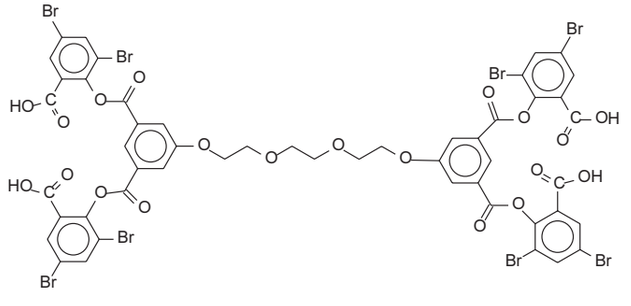
Reagents with four reactive centers present additional possibilities for creating novel modified proteins (22, 23). A reagent that has two pairs of connected reactive sites can produce two cross-links that are connected by the core of the reagent. Depending on the geometry of the core, the two cross-links can form within one protein molecule or in two separate molecules, resulting in modified-connected proteins. If one or two functional groups of the reagent remain intact in the reaction with the protein these sites can be utilized for further conjungation reactions.

We have reported that a relatively small reagent with four reactive groups, BTDS (3,5,3′,5′-biphenyltetracarbonyl tetrakis(3,5-dibromosalicylate)), reacts with deoxy hemoglobin to give principally a product that has a stable cross-link between the β-subunits. The two additional reactive groups of the reagent do not combine with the protein (22). It is likely that once reaction has occurred at two of the groups, the geometric relationship of the remaining groups prevents them from being in proximity to nucleophiles in the same protein or in a second protein.



BTDS

To arrive at new types of altered proteins from a reagent with four reactive groups, we therefore assumed that a greater separation of the groups is necessary. In this paper we report the synthesis of DPEE (1,2-bis{2-[3,5-bis(3,5-dibromosalicyloxycarbonyl) phenoxy]ethoxy}ethane). DPEE contains isophthalyl dibromosalicylate reaction sites, as in BTDS, but they are connected in a longer, more flexible, and more hydrophilic array.



DPEE

Chemically modified hemoglobins are readily amenable to ion spray mass spectral analysis (21, 24, 25). Combining the results of such an analysis for separated materials with results from size-exclusion chromatography and tryptic peptide mapping (26) enables us to propose structures for the major modified proteins that result from reaction of DPEE and hemoglobin.

Experimental

Commercial reagents and chemicals were used without further purification. Solvents were dried prior to use. Reagents for preparation of buffers were analytical grade or better. Purified human hemoglobin A was from Hemosol, Inc. Proton NMR spectra were obtained at 400 MHz or 200 MHz and ^{13}C NMR spectra at 100 MHz.

The structures of the materials associated with the synthesis of the DPEE are shown in Schemes 1 and 2 in the Results section. The synthesis of the linked esters follows the general procedure of Collman et al. (4).

Synthesis of 1,2-bis{2-[3,5-bis(ethoxycarbonyl) phenoxy]-ethoxy}ethane (2)

Diethyl 5-hydroxyisophthalate (0.95 g, 0.0040 mol) and potassium *tert*-butoxide (0.47 g, 0.0042 mol) were stirred in 20 mL anhydrous tetrahydrofuran at room temperature for 30 min. A solution of 0.74 g (0.0020 mol) of 1,2-bis(2-iodoethoxy)ethane (**1**) in 20 mL anhydrous tetrahydrofuran was added and the reaction mixture was refluxed for 48 h under nitrogen. Water was added and the product was extracted with ether. The solution was dried over magnesium sulfate, filtered, and the solvent removed. Separation on a silica column (3 cm × 30 cm, hexanes – ethyl acetate 1:1) produced a white powder (0.60 g, 51%). ^1H NMR ($CDCl_3$) δ: 8.25 (2 H, t, J = 1.2 Hz, ArH), 7.74 (4 H, d, J = 1.2 Hz, ArH), 4.36 (8 H, q, J = 6.9 Hz, CH_2), 4.20 (4 H, t, J = 5.6 Hz, CH_2), 3.87 (4 H, t, J = 5.6 Hz, CH_2), 3.75 (4 H, s, CH_2), 1.36 (12 H, t, J = 6.9 Hz, CH_3).

1,2-Bis[2-(3,5-dicarboxyphenoxy) ethoxy]ethane (3)

The tetraethyl ester (0.60 g, 0.0010 mol, **2**) was dissolved in 30 mL ethanol. The solution was heated to 65°C. Then 0.25 g (0.0060 mol) sodium hydroxide dissolved in 1 mL water was added and the reaction mixture kept at 65°C for 22 h. The resulting white precipitate was filtered and dissolved in 10 mL of water. The tetraacid (**3**) was precipitated by addition of concentrated hydrochloric acid and filtered. The product was dried under vacuum (0.46 g, 95%). ^1H NMR (DMSO-d_6) δ: 8.05 (2 H, s, ArH), 7.62 (4 H, s, ArH), 4.19 (4 H, s, CH_2), 3.75 (4 H, s, CH_2), 3.60 (4 H, s, CH_2); a broad band is also present under the three high-field signals.

1,2-Bis{2-[3,5-bis(chlorocarbonyl) phenoxy]ethoxy}-ethane (4)

The tetraacid (0.23 g, 0.0047 mol, **3**) was dissolved in 15 mL thionyl chloride containing three drops of dimethylformamide. The solution was refluxed under nitrogen for 5 h and then the solvent was evaporated. The product (yellow oil) was dried under vacuum and solidified overnight (0.26 g, 100%). ^1H NMR ($CDCl_3$) δ: 8.43 (2 H, t, J = 1.6 Hz, ArH), 7.90 (4 H, d, J = 1.6 Hz, ArH), 4.24 (4 H, t, J = 5 Hz, CH_2), 3.89 (4 H, t, J = 5 Hz, CH_2), 3.74 (4 H, s, CH_2). This tetraacid tetrachloride was used without further purification.

1,2-Bis{2-[3,5-bis(3,5-dibromosalicyloxycarbonyl) phenoxy]ethoxy}ethane (DPEE, 6)

tert-Butyl 3,5-dibromosalicylate (0.66 g, 0.0019 mol) (27, 28) and potassium *tert*-butoxide (0.21 g, 0.0019 mol) were stirred in 15 mL anhydrous tetrahydrofuran at room temperature for 30 min. Then a solution of 0.26 g (0.00047 mol) of **4** in 15 mL anhydrous tetrahydrofuran was added and the reaction mixture was stirred at room temperature overnight. Water was added and the product was extracted with ether. The extract was dried over magnesium sulfate, filtered, and the solvent removed, leaving the tetra *tert*-butyl ester (**5**). The white solid was dissolved in 15 mL anhydrous trifluoroacetic acid (to convert the *tert*-butyl ester to the free acid) and left at room temperature for 2.5 h. Dry ether was added (15 mL) and a white precipitate formed. The product (**6)**, DPEE, was filtered and dried in vacuum (white powder, 0.55 g, 74%). IR (KBr): 3177 (br s, ν_{OH}), 1736 (s, $\nu_{C=O}$), 1195 (s, $\nu_{C—O}$) cm^{-1}; ^1H NMR (DMSO-d_6) δ: 8.36 (2 H, t, J = 1.4 Hz, ArH), 8.33 (4 H, d, J = 2.5 Hz, ArH), 8.09 (4 H, d, J = 2.5 Hz, ArH), 7.98 (4 H, d, J = 1.4 Hz, ArH), 4.31 (4 H, br s, CH_2), 3.79 (4 H, br s, CH_2), 3.63 (4 H, s, CH_2); a broad band is also present under the three high-field signals; ^{13}C NMR (acetone-d_6) δ: 163.57, 163.25, 160.59, 148.36, 140.13, 134.68, 131.79, 128.06, 124.54, 122.12, 120.29, 120.06, 71.50, 70.29, 69.47; MS (negative FAB), M – 1 calcd. for $C_{50}H_{30}Br_8O_{20}$: 1589; found: 1589.

Reactions of human hemoglobin A with DPEE were carried out as described previously (22). A typical example is described here. A solution of carbonmonoxy hemoglobin (2.0 mL, 1.25 mM, 0.000025 M) in 50 mM Bis-Tris buffer (pH 6.5) was passed through a Sephadex G-25 column (2.5 × 15 cm) equilibrated with 50 mM sodium borate buffer (pH 8.0). The carbonmonoxy hemoglobin was converted to oxy hemoglobin by irradiation under flowing oxygen at 0°C for 2 h. The solution was then kept under flowing nitrogen at 37°C for 2 h to convert the hemoglobin to the deoxy form. DPEE (0.0080 g, 5.0×10^{-6} mol) was dissolved in 1.0 mL of dioxane, and 3.0 mL of 50 mM sodium borate buffer (pH 8.0) was added. Oxygen was removed from the solution by evacuation followed by addition of nitrogen. This was repeated three times. The material was then added under nitrogen to the deoxy hemoglobin solution. The reaction mixture was kept at 37°C for 20 h with humidified nitrogen flowing through the rotating flask. The flask was then flushed with carbon monoxide. The solution of modified carbonmonoxy hemoglobin was passed through a Sephadex G-25 column (2.5 × 15 cm) equilibrated with 50 mM sodium phosphate buffer (pH 7.5) to remove residual reagent. (The resulting material is referred to as DPEE-Hb.) C-4 reverse-phase HPLC columns were used to separate heme and the various modified and native globin chains under denaturing conditions. Hemoglobins of different molecular weights were resolved using gel filtration chromatography, both with high concentrations of magnesium salt that lead to dissociation into $\alpha\beta$ dimers (29) as well as under nondissociating conditions where the tetramers remain intact.

Analysis of modified hemoglobin

General procedures for structural analysis were as previously reported (22). The product mixture was separated on a C-4 reverse-phase HPLC column. In addition to known peaks corresponding to heme and native globin chains, new peaks appeared that correspond to cross-linked globin chains. The molecular weights of these materials were determined by ion spray mass spectrometry (30, 31). The sites of modification were deduced by comparison of peptide patterns (reverse-phase HPLC) from digestion of native and modified chains with trypsin and endoproteinase Glu-C (14, 22, 32–34) along with ion spray mass spectral results as has been described in detail for other cross-linked hemoglobins (24, 27). Reference data for weights and mass spectra of native globin chains are conveniently summarized in the work of Adamczyk and Gebler (25). Size exclusion chromatography was used to distinguish materials by their approximate molecular weights (35). Columns were calibrated with cross-linked and oligomerized hemoglobin.

The formation of a cross-link between α-subunits of DPEE-Hb with fumaryl bis(3,5-dibromosalicylate) was accomplished by the procedure described for production of doubly cross-linked hemoglobin (14). After the 20 h incubation period of deoxy hemoglobin with DPEE (described above), a deoxygenated solution of fumaryl bis(3,5-dibromosalicylate) (0.0035 g, 5.0×10^{-6} mol) in 4.0 mL 50 mM sodium borate buffer (pH 8.0) was added to the hemoglobin reaction solution under nitrogen. (This reagent should introduce a cross-link between the ε-amino groups of the α-99 lysyl residues of hemoglobin (14, 16). It is effective if the sites in the β-subunits that make up the DPG-binding site (3, 36) are blocked.) The mixture was kept at 37°C for 2 h and then the flask was flushed with carbon monoxide. The solution of twice-modified carbonmonoxy hemoglobin was passed through a Sephadex G-25 column (2.5 × 15 cm) equilibrated with 50 mM sodium phosphate buffer (pH 7.5) in order to remove residual reagent. (The resulting material is referred to as XL2-Hb.) C-4 reverse-phase HPLC columns were used to separate the hemes and the globin chains. In another set of analyses of XL2-Hb, gel filtration chromatography was used to separate modified hemoglobins by their gross molecular weight (size). We used size-exclusion columns under conditions that dissociate the $\alpha\beta$ dimers from hemoglobin that is not cross-linked between these dimers, and also used conditions under which hemoglobin remains tetrameric ("nondissociating conditions"). Elution was under isocratic conditions. The nondissociating eluent was 0.050 M pH 7.0 sodium phosphate with 0.15 M sodium chloride flowing through a PSEC-12 column at 0.5 mL min^{-1}. The dissociating eluent was 0.025 M pH 7.2 Tris with 0.5 M magnesium chloride flowing through a TSK G2000 swxl column at 0.2 mL min^{-1}.

Results

The synthesis of DPEE efficiently introduces the necessary paired reactive functional groups for cross-linking onto a flexible linking chain. The route could be extended to produce a reagent library by varying the length of the polyether linker. The synthesis of the ether is based on Collman's method for producing a tetraether-linked tetraester (4). The reactive groups are conveniently introduced by Klotz's procedure for forming dibromosalicylates (28) (Schemes 1 and 2).

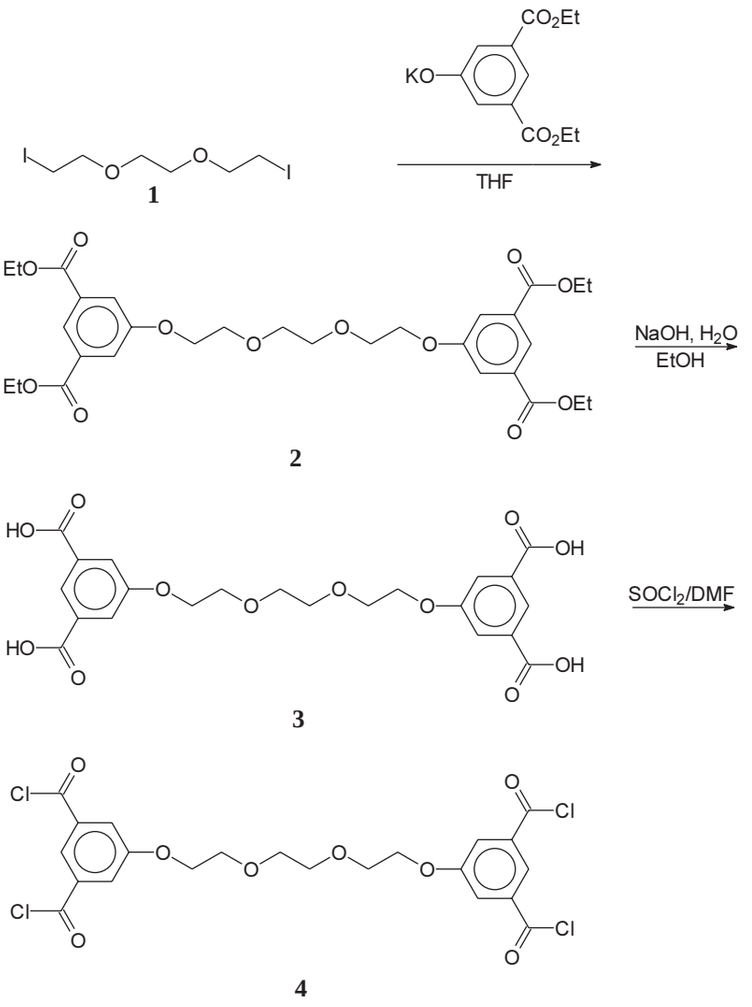
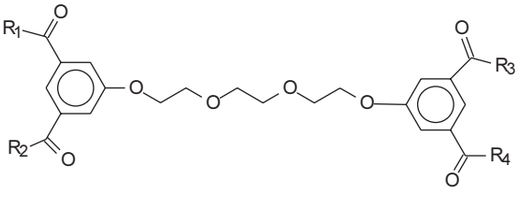
Scheme 1.



DPEE reacts with deoxy hemoglobin but not with carbonmonoxy hemoglobin, based on analysis of the resulting globin chains by C-4 reverse-phase HPLC. This is consistent with reaction occurring at the binding site for DPG in hemoglobin, which is more accessible in the deoxy form (37). The observed product pattern of the reaction remained constant as the ratio of the reagent to hemoglobin was varied from 1:2 to 2:1 and temperature was changed from 37 to 50°C. The reaction mixture appears to contain a considerable variety of altered protein products. The relative amounts were estimated based on peak areas in the chromatograms. We chose the materials in the largest peaks for structural analysis.

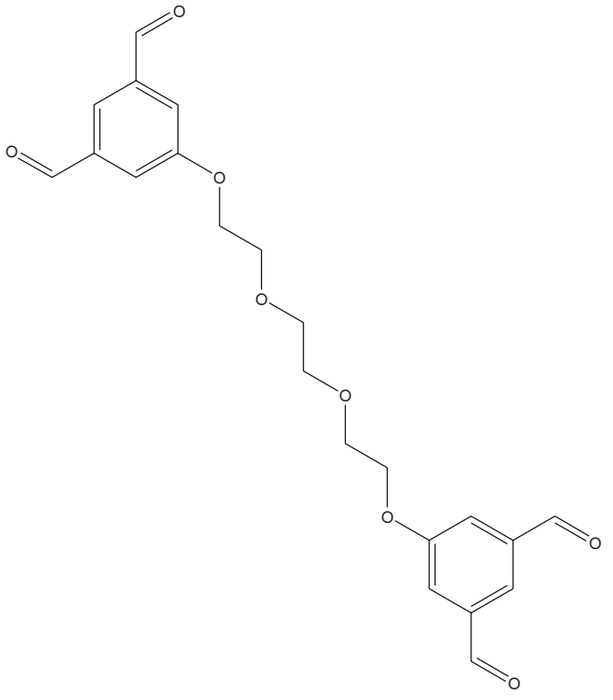
The heme and globin chains were separated on a C-4 reverse-phase HPLC column (see Fig. 1). The products in the largest peaks were detected and their molecular weights were determined from the parent peaks of ion spray mass spectra. Table 1 summarizes the ion spray mass spectral assignments associated with major peaks that were observed on reverse-phase HPLC analysis. The product from the largest chromatographic peak (**7**) is a tetraamide formed by acylation at four amino groups of two β-subunits. Products from other peaks retain one or more 3,5-dibromosalicyl (DBS) esters from DPEE or are partially hydrolyzed. Structures consistent with the observed masses are indicated as substituted derivatives of the core structure below:



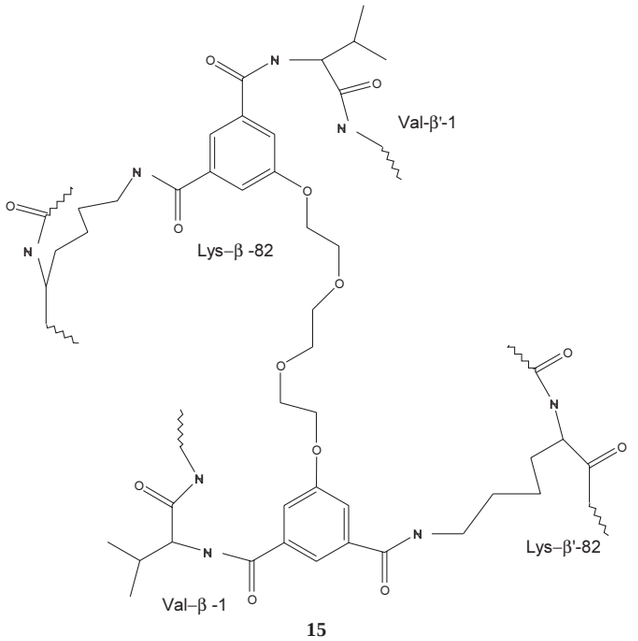
7–13

The mass of the linked globin chain that is proposed as the structure of the major product (**7**) is consistent with the electrospray mass spectral peak. This is a dimer of two β-subunits linked by four amide connections derived from the core of DPEE (**14**), which has a molecular mass of 410. The molecular mass of a β-subunit is 15 868 and that of the α-subunit is 15 126. Combining the masses of two β-subunits and **14**, less the mass of hydrogens that are dissociated from

© 1999 NRC Canada



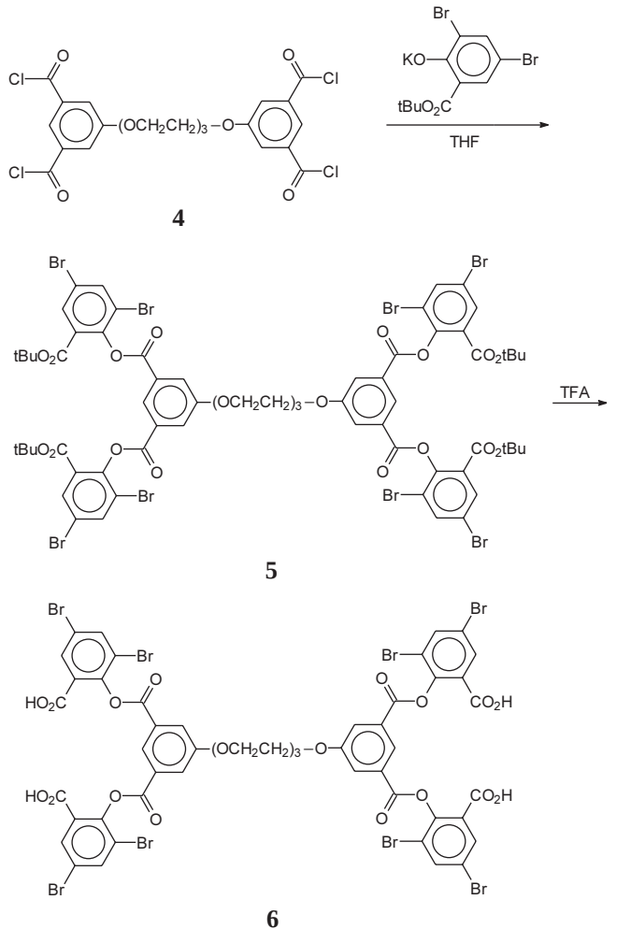
14



15

each resulting amide, gives a predicted mass of 32 142 for **7**. This is consistent with what is observed.

Scheme 2.



4

5

6

To determine the residues within hemoglobin that are modified by DPEE in **7**, the material from the peak corresponding to the cross-linked β-subunits was subject to tryptic digestion and peptide mapping. The products of digestion were separated by C-18 reverse-phase HPLC and the peptides were compared to those from digestion of the unmodified β chain (26). Three fragments of the native β digest were absent from that of the modified β-subunits: β-T1, β-T9, and β-T10a′. β-T1 is the amino terminus (Val-β-1) and β-T9 is connected to β-T10a′ through the β-Lys-82 residue, indicating that the amino termini of both β-subunits as well as the ε-amino groups of both β-Lys-82 residues are acylated by DPEE (Fig. 2). (The other peaks listed in Table 1 represent smaller quantities and the structural assignments are based on masses, with attachment sites based on the consistent patterns of modification seen with other reagents with similar functionality. Digests were not performed for these.) The results for **7** indicate that there are two sets of cross-links connecting positions 1 and 82 of β-subunits introduced by a single tetrafunctional reagent (**15**).

Formation of bis tetramers

The four functional groups of DPEE are arranged so that it is possible for them to produce a connection between tetramers. If we assume that reaction occurs at positions 1 or

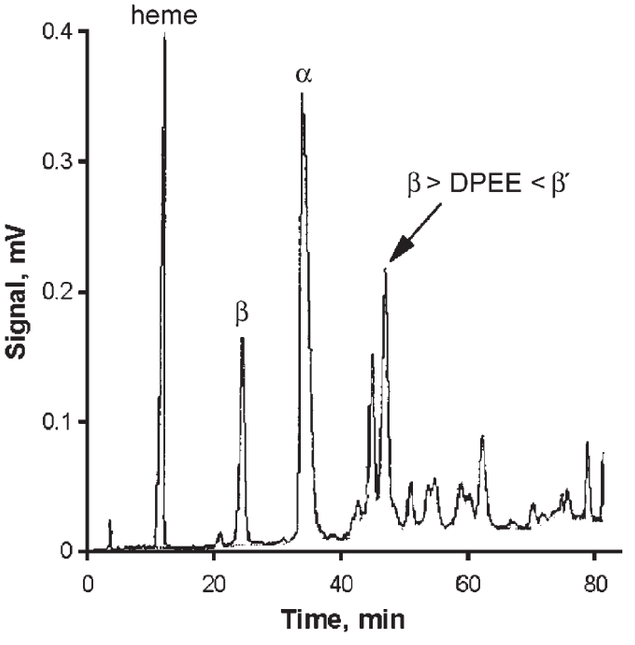
Fig. 1. Globin chain separation after reaction of deoxy hemoglobin with DPEE: 20 h at pH 8.0 and 37°C



82 of β-subunits, and the product is symmetrical, schematic structures **16** or **17** are possible. To determine whether any bis tetramer formed, we analyzed the reaction solutions on size exclusion columns that give an indication of mass based on calibrated globular size. Since hemoglobin tetramers (64 000 Da) are in equilibrium with αβ dimers (32 000 Da) (38), cross-linking between two β-subunits or between two α-subunits prevents dissociation while a link within a subunit does not. Addition of magnesium chloride to the solution influences the equilibrium toward dissociation into dimers (29). Thus, **16** will dissociate into dimers while **17** will not.

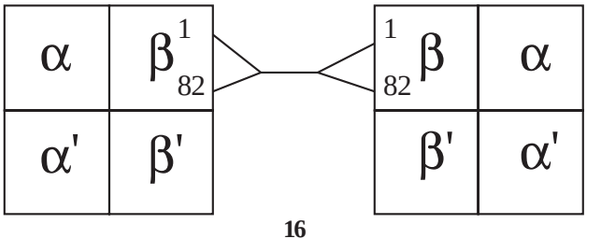
Hemoglobins that are doubly cross-linked, with a link in between α- as well as β-subunits, can be prepared by addition of the reagent bis(3,5-dibromosalicyl)fumarate (DBBF), to a ββ-cross-linked hemoglobin (14). Thus when the α-subunits of **16** are subsequently cross-linked by reaction with DBBF, the tetrameric protein will no longer dissociate into dimers. In the possible cross-linked tetrameric structures, shown as **18** and **19,** reaction with all four sites of DPEE

Table 2. Expected masses (kDa) of peaks of modified hemoglobins. Addition of 0.5 M magnesium chloride causes dimers that are not cross-linked to separate from tetramer. See text for details (indicated as "dissociating").

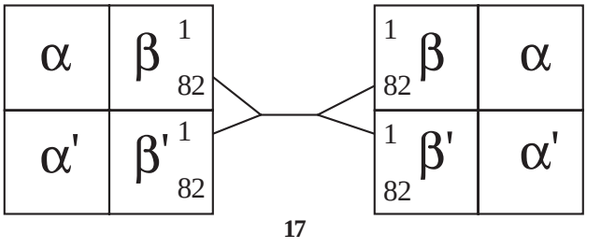
Structure	Mass	Mass (dissociating)	Mass (dissociating) after formation of α–α cross-link
16	128	64, 32	128
17	128	128	128
18	64	64	64
19	64	64	64

will give material that does not dissociate into dimers. Therefore, introducing the α–α cross-link should not change the effect of adding magnesium chloride. These possibilities are summarized in Table 2.

We note that α–α cross-linking permits separations that



16



17

distinguish **16** from **17**. Structure **17** has cross-links between β-subunits, preventing dissociation into dimers. Cross-linking between the α-subunits does not change the results for dissociation. Therefore, formation of **17** should not change the apparent product–mass distribution. However, two of the four αβ dimers of **16** can dissociate. If an α–α cross-link is

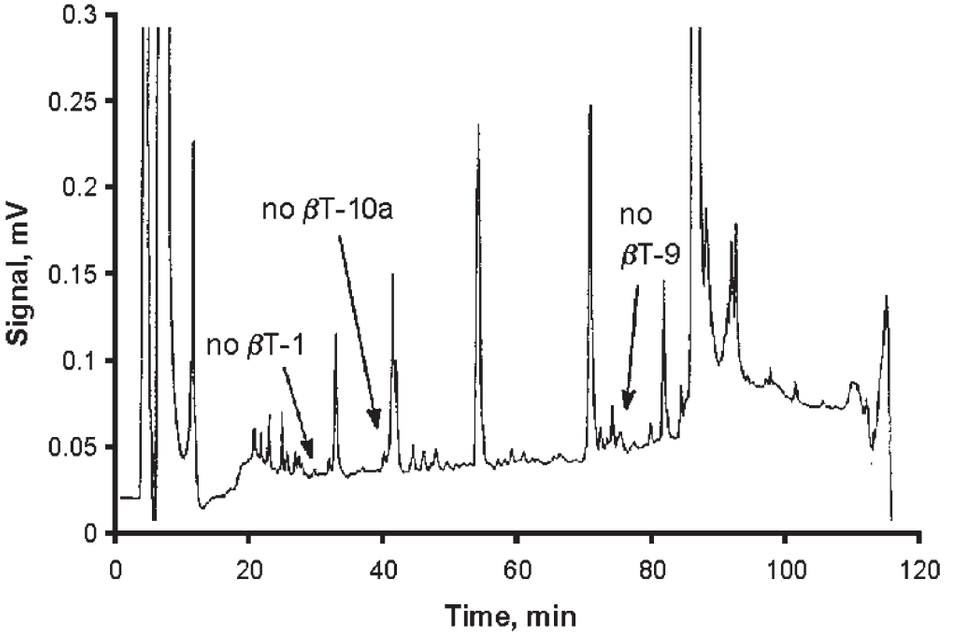
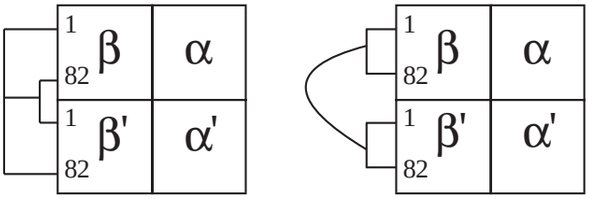
Fig. 2. Tryptic-Glu-C peptides of the β-subunits linked at four sites by DPEE. Comparison is noted against native protein digest.



introduced, there will be a decrease in the amount of 32K material present.

Structures **18** and **19** are both capable of generating the major product. Both are fully cross-linked and will not dissociate into dimers. Both have a molecular mass of 64K. Both have all the β-1 and β-82 amino groups converted to amides.



18

19

Separation of the globin chains by C-4 reverse-phase HPLC, before and after treatment of the reaction product with DBBF, shows that the reagent completely converts all native α-subunits in the product solution. The results of analysis by size exclusion chromatography are given in Table 3.

Discussion

DPEE appears to react with amino groups in the β-subunits of deoxyhemoglobin within its DPG-binding site as do other 3,5-dibromosalicylate esters. However, unlike BTDS, which reacts at only two of its four ester sites, major products include species in which all four esters are converted to amide derivatives of hemoglobin. The reaction of DPEE with deoxy hemoglobin gives one major product (>50%) and several minor products, including β–β, α–β, and α–α cross-linked products. Even after a long reaction period, considerable amounts of native protein subunits are found on reverse-phase HPLC analysis. The rates of the reactions between hemoglobin and DPEE are considerably slower than with other reagents that have the same dibromosalicyl leaving groups on aromatic hydrocarbon cores (trimesyl and biphenyl) (22, 27). These cross-linkers readily react with hemoglobin and reactions go to completion within a few hours. It is very likely that the slow reaction of DPEE would be the result of the hydrophobic end groups of DPEE stacking on one another, blocking its accessibility, and controlling its reaction patterns.

Our data show that the major product is a β–β′ cross-linked tetraamide containing one tetraacyl unit derived from DPEE. Several different modified hemoglobins could give data consistent with our results. From the mass and tryptic digestion analyses we know that cross-links are only between β-subunits, and all four amino groups from β-Val-1 (N-terminal α-amino group) and β-Lys-82 (ε-amino group) of both chains must be acylated. From the reaction patterns of other reagents, we know that the acyl groups on *meta* positions of a substituted benzene can connect ε-amino groups of the lysyl residues at position 82 of each β-subunit. They also can connect the α-amino group of the N-terminal valine of one β-subunit and the ε-amino group of Lys-82 of the other β-subunit. The same amino groups can also be connected within the same subunit. The β-Val-1 amino groups are too far apart to be connected by the *meta*-substituent groups.

If one end of DPEE has reacted between amino groups of Val-1 and Lys-82 on different β-subunits, then the other end must react with the alternative Val-1 and Lys-82 amino groups (**18**). The schematic diagrams for **20** and **21** (for **18** and **19**) are shown in terms of functional groups (following page).

The alternative products (**19** and **21**)) have the *meta*-substituted dicarbonyls from one end of DPEE connected as amides on the same β-subunit to Val-1 and Lys-82. The other end of DPEE is then connected to the other β-subunit in the

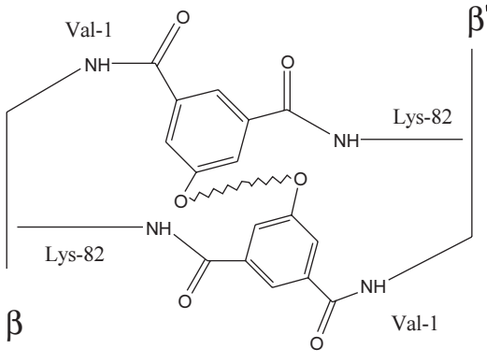
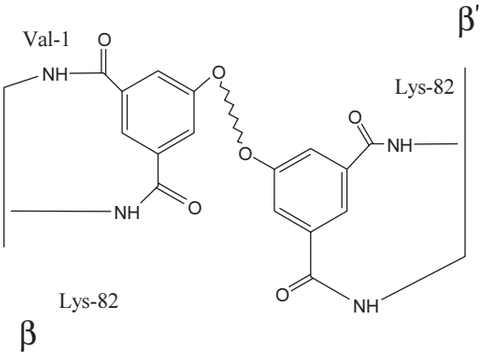
Table 3. Size exclusion chromatography analysis of relative amounts of various modified hemoglobins (DPEE-Hb) and those that have been reacted further to cross-link their α-subunits (HBXL2). Results are for distribution of relative amounts, according to their mass. Dissociating conditions refer to the presence of 0.5 M magnesium chloride.

Hemoglobin	Conditions	% ≥128 kDa	% 64 kDa	% 32 kDa
Native (human)	Dissociating	0.7	15.3	82.0
DPEE-Hb	Dissociating	2.5	89.3	8.2
DPEE-Hb	Nondissociating	5.7	87.7	6.6
HBXL2	Dissociating	5.2	82.4	12.4
HBXL2	Nondissociating	6.1	86.3	7.6



20



21

same manner. Based on the reaction patterns of other isophthalyl-DBS esters, we know that the ε-amino group of a β-Lys-82 is most likely to be converted to an amide. Since the α-amino groups of each N-terminal β-Val-1 are also modified in the product, and the *meta*-substituted reagent cannot span the distance between the two N-termini, these must react more quickly than does the other β-Lys-82 ε-amino group with the same end of DPEE. The reagent must arrange itself within the DPG binding site in order to achieve this selectivity, perhaps directed by hydrogen-bonding interactions.

The data in Table 3 show that a portion of the reaction products consists of two connected β-subunits, derived from different tetramers, producing a bis tetramer (mass: 128 kDa). Such a species of connected tetramers should be of interest for studies of cooperativity (1) as well as for analysis of physiological effects. Approximately half of the 128 kDa material found in DPEE-Hb under nondissociating conditions is converted to 64 and 32 kDa species under dissociating conditions (Table 3). This scenario is consistent with structure **16** (Table 2). The portion of 128 kDa species that is present under dissociating conditions could be explained by structure **17**, which should be stable under such conditions.

The introduction of cross-links between α-subunits holds the tetrameric structure together regardless of whether cross-linking has occurred between the β-subunits (14, 18). Stabilization of DPEE-Hb by α–α cross-linking, giving HBXL2, makes the 128 kDa species stable under dissociating conditions. These findings are also consistent with structure **16**. In such a case, the reagent would have had to join Val-1 and Lys-82 on the same subunit within each tetramer. Structure **17** remains intact under dissociating conditions, requiring that the cross-linking of each tetramer be between different β-subunits. The results from size exclusion chromatography confirm that at least one of the minor but significant products is a bis tetramer.

While these assignments are self-consistent, we know that other difunctional *meta*-substituted DBS reagents react between the ε-amino groups of each of the β-Lys-82 residues only (14, 22, 27, 33). The formation of such a product within one tetramer would require that the two β-Val-1 amino groups be connected at *meta* substituents. This is most unlikely since the distance between the amino termini of the two β chains of hemoglobin is too great (18.4 Å in the deoxy and 19.9 Å in the oxy conformation) (37) to be spanned by the isophthalyl group. No reagent that we have examined, even with a larger span (32), connects the N-termini of two β-subunits.

The slow rate of the reaction of DPEE with deoxyhemoglobin is consistent with either of the four-way cross-linked tetramers (**18** and **19**) being the product. Since movement of the bulky reagent inside the DPG binding site is likely to be restricted, it should be in a folded conformation as it enters the cavity. In addition, there is probably a limited orientation by which DPEE can get into the DPG site, once it is in an appropriate overall conformation.

Conclusion

The reaction of DPEE with deoxy hemoglobin is slower than that of smaller reagents, suggesting that the reagent is less accessible to the protein, presumably because it exists in a folded state. This has consequences in the reaction pattern as well. The major product from the reaction of DPEE with hemoglobin has four amino groups of the $\alpha_2\beta_2$ tetramer, two from each β-subunit, modified and cross-linked by a single molecule of reagent. In contrast, the rigid reagent derived from a symmetrical biphenyl tetracarboxylate (BTDS), which is unable to fold onto itself, reacts with hemoglobin primarily at only two sites in any modification process. The "knotted" species from the DPEE reaction may present an

© 1999 NRC Canada

interesting basis for studies of the protein's structural dynamics. Our results show that DPEE is sufficiently long to produce bis tetramers but the product is not present to a large extent, consistent with a predominant folded state of the reagent. A long but rigid reagent will give such products in greater proportion.

1998 W.A.E. McBryde Medal Lecture Searching for the Holy Grail in analytical separations[1]

Charles A. Lucy, Ken K.-C. Yeung, Shilin Fu, Dongmei Li, Tracey L. Henselwood, and Royale S. Underhill

Abstract: This paper describes the chemistry presented during the W.A.E. McBryde Medal address given at the 81st Chemistry in Canada Conference held in Whistler. The narrative chronicles our Quest to perform isotopic separations in the solution phase using as our Excalibur, capillary zone electrophoresis. The narrative takes you through the highs of our early success in separating $^{35}Cl^-$ and $^{37}Cl^-$. This separation was achieved by adjusting the electroosmotic flow to be equal in magnitude but opposite in direction to the chloride mobility. The narrative then takes you through the dark days, when we could not extend the isotopic separations to cationic species or even explain why there was an isotopic effect on mobility. Since those dark days, we have made numerous discoveries that have aided our Quest. Firstly, the development of mixed surfactant wall coating procedures yielded control of the reversed electroosmotic flow. This control enabled us to perform isotopic separations of systems such as ^{15}N-/^{14}N-aniline and $^{15}NH_4^+/^{14}NH_4^+$. In terms of understanding electrophoretic mobility, we demonstrate the importance of dielectric friction to mobility. Further, the effect of ionic strength in capillary zone electrophoresis is explained using the Pitts treatment, which is analogous to the extended Debye–Hückel equation for ionic activity. So, have we completed our Quest? Read on.

Key words: capillary zone electrophoresis, isotopic, electroosmotic flow, mobility modeling, ionic strength.

Résumé : Ce travail décrit la chimie décrite au cours de la conférence W.A.E. McBryde présentée lors de la 81ème Conférence de chimie au Canada qui s'est tenue à Whistler. La narration fait la chronique des événements qui ont accompagné notre quête en vue de réaliser des séparations isotopiques en solution en utilisant comme Excalibur l'électrophorèse en zone capillaire. Cette narration vous guide vers les sommets de nos succès préliminaires dans la séparation du $^{35}Cl^-$ et du $^{37}Cl^-$. Cette séparation a été effectuée en ajustant l'écoulement électroosmotique de façon à rendre son amplitude égale, mais direction opposée, à la mobilité des ions chlorures. Cette narration vous entraîne ensuite vers les jours sombres vécus lorsque nous avons été dans l'impossibilité d'étendre la portée des séparations isotopiques à des espèces cationiques ou même d'expliquer pourquoi il n'y avait pas d'effet isotopique sur la mobilité. Depuis ces jours sombres, nous avons fait de nombreuses découvertes qui nous ont aidés dans notre quête. Premièrement, le développement des méthodes impliquant le recouvrement des surfaces avec des agents de surface mixtes a permis de contrôler l'écoulement électroosmotique inversé. Ce contrôle nous a permis d'effectuer des séparations isotopiques de systèmes telles que les ^{15}N-/^{14}N-anilines et $^{15}NH_4^+/^{14}NH_4^+$. En termes de compréhension de la mobilité électrophorétique, on a démontré l'importance de la friction diélectrique pour la mobilité. De plus, on a expliqué l'effet de la force ionique dans l'électrophorèse en zone capillaire en faisant appel au traitement de Pitts qui est analogue à l'équation étendue de Debye–Hückel pour l'activité ionique. Nous avons donc complété notre quête. Lisez.

Mots clés : électrophorèse en zone capillaire, isotopique, écoulement électroosmotique, modélisation de la mobilité, force ionique.

Introduction

The nature of research, like that of quests, depends heavily upon the character and the background of the protagonist. This particular quest had its beginnings during Dr. Lucy's time with Atomic Energy of Canada Ltd. (AECL Research) in Chalk River, Ont. AECL Research produces a wide array of radioisotopes for medicinal and other peaceful applica-

Received October 21, 1998.

tions. For instance, AECL produces most of the world's molybdenum-99 which is used to generate technicium-99m for radiodiagnostic scans of the brain, bones, heart, lungs, gall bladder, and virtually every other organ of the body.

At AECL Dr. Lucy developed production methods for new radioisotope products. During this time Dr. Lucy became intrigued by the work of Tanaka et al. (1) and by technique of capillary electrophoresis. Tanaka et al. (1) demonstrated that isotopic induced differences in acid dissociation constants for species such as aniline and benzoic acid could be used to separate the isotopic species using high-performance liquid chromatography, albeit the separations took hours. At the same time, the scientific literature was rife with papers on capillary zone electrophoresis (CZE). CZE offers 10–100 times the separation power of high-performance liquid chromatography.

Thus, when Dr. Lucy joined the faculty at The University of Calgary in 1992, his "Holy Grail" was to separate isotopic species using as our "Excalibur" capillary zone electrophoresis. This paper details our efforts towards that goal, and some of the integral tangents that arose from this work. Indeed the work has taken many tangents, which through the skills, perseverance, and ingenuity of the "knights and squires" in our laboratory, have lead to many fascinating and unexpected results.[3]

Introduction to capillary zone electrophoresis

Electrophoresis is simply defined as the migration of ions in an applied electric field. Anions will migrate towards the anode (positive electrode), and cations toward the cathode (negative electrode). The rate of migration will be a function of the size of the ions, and the net charge on the ion. This is illustrated by the Hückel equation

$$[1] \qquad \mu_e = \frac{q}{6\pi\eta r_s}$$

where μ_e is the electrophoretic mobility of an ion, q is the charge on the molecule, η is the solvent viscosity, and r_S is the Stokes or hydrated radius of the ion. The time necessary to perform a separation is related to the velocity with which the ions move. This ion velocity (ν) is a simple function of the ionic mobility (μ) and the applied voltage V

$$[2] \qquad \nu = \frac{\mu V}{L_t}$$

where L_t is the total length of solution over which the voltage is applied. In classical electrophoresis, such as used for DNA fingerprinting, about 300 V is applied and yields separations in hours to days.

In *capillary zone electrophoresis* (CZE) the goal is to perform separations in minutes. Thus, as shown in Fig. 1, 5 000–30 000 V are applied across the capillary, causing the ions to migrate rapidly. Unfortunately, such high voltages generate significant Joule heating, such that the solution will heat or even boil. The use of narrow (10–100 μm) capillaries effectively dissipates that heat, making possible the use of high voltages.

A typical CZE experiment starts with the voltage off. The left-hand buffer vial is replaced with a sample vial, and a pressure (0.5 psi) is applied for a few seconds to hydrodynamically push a few nanoliters of sample onto the capillary. The sample vial is then replaced with the buffer vial, and the voltage (5–30 kV) is applied. Ions are then separated based on differences in their electrophoretic mobilities, i.e., effectively their *charge-to-mass* ratios, as depicted by the vectors in Fig. 1. Near the right-hand end of the capillary, a detector monitors the absorbance of the ion bands.

The resultant signals are known as *electropherograms*. Electropherograms, such as those presented in Fig. 2, appear very much like traditional *chromatograms*. The features that distinguish electropherograms from chromatograms are the rapid separation times (Fig. 2*A*) and the extremely high separation efficiencies (Fig. 2*B*). In Fig. 2, the solutes range from inorganic anions to macromolecules. Furthermore, these separations are complete in minutes and display efficiencies as high as 300 000 plates. The performance in Fig. 2 is by no means unusual. CZE separations have been performed in as little as a millisecond (2) and can achieve efficiencies over 1 000 000 theoretical plates (3).

So, this is the Excalibur with which we were going to take up the quest for the Holy Grail in analytical separations, the separation of isotopic species. However, as with any weapon as powerful as Excalibur, it is essential to understand its subtleties to fully exploit its power. The most important subtlety in CZE is that a flow is generated within the capillary when a voltage is applied. This *electroosmotic flow* (EOF) is caused by the intrinsic negative charge on the capillary walls. This negative charge arises from the weakly acidic silanol (-SiOH) groups on the surface of the fused silica. An excess of cationic charge will build up in the solution near

the capillary wall. When a voltage is applied, these excess cations within the diffuse layer of the solution migrate towards the cathode (to the left in Fig. 1). As the cations in the diffuse layer move toward the cathode, they drag with them their hydration spheres. These hydration spheres in turn generate a viscous drag on the bulk solution within the capillary. The net effect is a plug flow of buffer towards the cathode that is larger in magnitude that the mobility of most anions. The velocity of this flow can be described in terms of an electroosmotic mobility (μ_{eof}).

The electrophoretic mobilities and the electroosmotic flow mobility are vectoral functions. The net or apparent mobility ($\mu_{apparent}$) is the sum of the two mobilities:

$$[3] \quad \mu_{apparent} = \mu_e + \mu_{eof}$$

where μ_e is the electrophoretic mobility of the ion (eq. [1]), and μ_{eof} is the electroosmotic flow mobility.

With a bare fused silica capillary, the electroosmotic flow mobility is large and towards the cathode. The electroosmotic flow is so large that almost all ions are swept towards the cathode. Thus, if an injection is made at the anode and the detector is positioned at the cathode (opposite configuration to that shown in Fig. 1), cations, neutral molecules, and slow anions can all be detected in the same electropherogram. Only small inorganic anions such as chloride and sulfate have an electrophoretic mobility greater than the electroosmotic flow. Thus only these anions migrate towards the anode. As such, fast anions such as chloride and sulfate are injected at the cathode and migrate to the detector positioned at the anode to generate the electropherogram in Fig. 2*A*. This is the instrument configuration used for most of the work discussed herein.

Seeking the Holy Grail

In capillary electrophoresis, the resolution between two peaks is expressed as (4)

$$[4] \quad R_S = \frac{\sqrt{N}}{4}\frac{\Delta\nu}{\bar{\nu}}$$

where N is the average number of theoretical plates as defined in chromatography, $\Delta\nu$ is the difference in the peak velocities, and $\bar{\nu}$ is the average peak velocity. Recalling that the electromigration is accompanied by electroosmotic flow, the zone velocity is given by (3)

$$[5] \quad \nu = (\mu_e + \mu_{eof})\frac{V}{L_t}$$

where V is the applied voltage and L_t is the total length of the capillary.

Typical efficiencies in capillary electrophoresis are on the order of 100 000–1 000 000 theoretical plates. However, even such high efficiencies by themselves are not sufficient to separate isotopic species. With isotopic separations, the difference in the electrophoretic mobilities will be very small. For instance, there is only a 0.12–0.26% difference in the zone velocity ($\Delta\nu$) between $^{35}Cl^-$ and $^{37}Cl^-$ (5). Nonetheless, Avdalovic et al. (6) had observed a partial separation of $^{35}Cl^-$ and $^{37}Cl^-$ using capillary electrophoresis with suppressed conductivity detection. The key to performing ultrahigh resolution capillary electrophoretic separations is to adjust the average zone velocity ($\bar{\nu}$) in eq. [4] to near zero (7). As indicated by eq. [5], a near zero zone velocity can be achieved by adjusting the electroosmotic flow to be equal in magnitude but opposite in direction to the ionic migration of the sample.

In an untreated capillary, the electroosmotic flow coefficient is given by (8)

$$[6] \quad \mu_{eof} = \frac{\sigma_{SiO^-}\kappa^{-1}}{\eta}$$

where σ_{SiO^-} is the surface charge density which is related to the degree of ionization of the silanol groups on the capillary wall, η is the viscosity, and κ^{-1} is the double layer thick-

ness which is inversely related to the square root of the buffer ionic strength. Based on eq. [6], Tracey Henselwood (née McDonald) adjusted the ionic strength (altering κ^{-1} in eq. [6]) and pH (altering σ_{SiO^-}) of a chromate buffer to match the electroosmotic flow to the mobility of chloride ions. The resultant separation is shown in Fig. 3.

We achieved baseline separation of the isotopes of chloride based solely on the intrinsic mobility differences of the isotopes (9)! The response to this result was overwhelming. The work was highlighted in Chemical and Engineering News (10), and a copy of Fig. 3 was incorporated into popular undergraduate texts in analytical chemistry with the caption *This impressive separation was done by an undergraduate student at the University of Calgary* (see Fig. 18–14 in ref. 11).

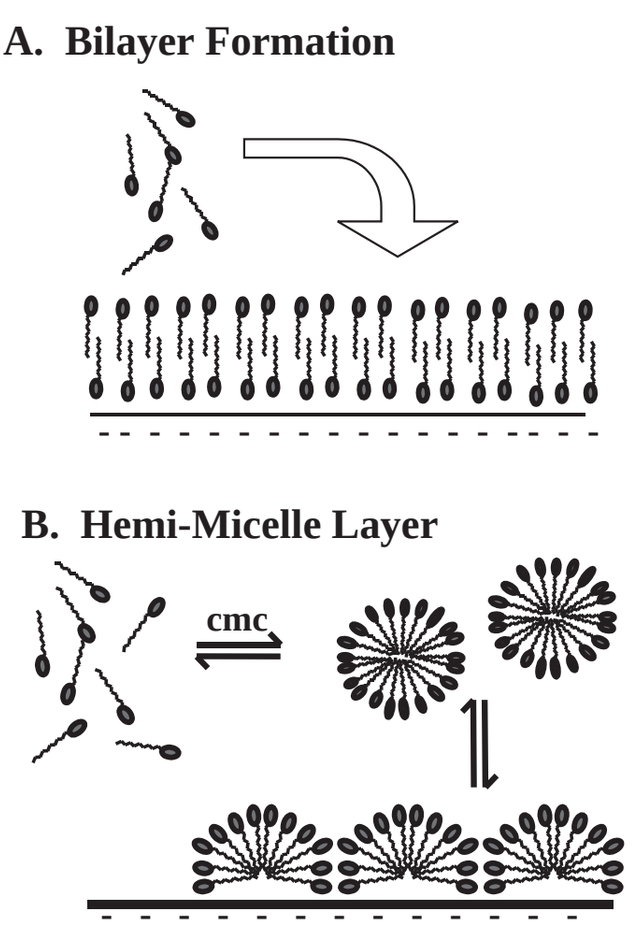
We had achieved our Holy Grail of isotopic separations in the solution phase…

The dark days

…but just as quickly doubts started to descend upon the lab. You see, it should have been possible to extend ultra-high resolution capillary electrophoresis to cations. Indeed, the isotopic difference in mobility between $^{39}K^+$ and $^{41}K^+$ is almost twice that of chloride (5). But we could not do it. One of the primary reasons that we could not perform cation isotopic separations is that we could not control the electroosmotic flow in the opposite direction.

To make matters worse, we really could not explain why the separation of the chloride isotopes was even possible! Why did one isotope migrate faster than another did? One could simply say "charge-to-mass," but mass does not appear in the expressions for electrophoretic mobility (e.g., Hückel equation, eq. [1]). To account for isotopic fractionation in geological groundwaters, geologists had invoked the concept of ion filtration (12) and even Graham's law (5, 13). While these arguments successfully predicted that the lighter isotope migrates faster, they were ineffective at given a clear understanding of the factors that control mobility.

Fig. 4. Models for reversal of electroosmotic flow by cationic surfactants. *(A)* Bilayer model and *(B)* hemi-micelle model. See text for details.



So, at this point we had to retrench. We set out three goals. Firstly, to gain control of reversed electroosmotic flow. Secondly, to achieve isotopic separations of cationic species. Finally, to gain an understanding of the factors affecting electrophoretic mobility.

Seeking control of reversed electroosmotic flow

Figure 1 depicts the migration of anions in an untreated capillary. With cationic separations, the migration of the ions will be reversed. Therefore, similarly it is necessary to reverse the electroosmotic flow. It had been reported that addition of cationic surfactants such as cetyltrimethylammonium bromide (CTAB) and tetradecyltrimethylammonium bromide (TTAB) to the electrophoretic buffer reverses the electroosmotic flow (14). The conventional explanation for this electroosmotic flow reversal was as depicted in Fig. 4*A*. The cationic surfactants adsorb onto the anionic capillary wall to form a *bilayer.* That is, there is a first monolayer of surfactant in which each cationic head group is associated with

© 1999 NRC Canada

a silanol on the wall. The hydrophobic tail of the surfactant is left extending out into solution. A second monolayer of surfactants associates their tails with those of the first monolayer, leaving their cationic head groups extending out into the solution. The net result of such bilayer formation is that each anionic site on the wall is replaced with a positive charge.

So, the bilayer model was our initial model for the reversal of electroosmotic flow. We reasoned that, given this model, it should be possible to alter the magnitude of the reversed flow simply by varying the pH of the buffer. Alteration of the pH would change the anionic charge on the capillary wall. This in turn would alter the population of cationic surfactant in the bilayer. Thus, simply varying the pH of CTAB containing buffers should adjust the magnitude of the reversed electroosmotic flow. It did not work! Varying the buffer pH had almost no effect on the magnitude of the reversed electroosmotic flow (15).

Thus, a new model of the cationic surfactant induced electroosmotic flow reversal was needed. Extensive review of the colloid and interface literature indicated that a "hemi-micelle model" should be a better descriptor of this behavior. In the hemi-micelle model, no reversal of the electroosmotic flow is expected below the critical micelle concentration of the surfactant. Indeed, little alteration of the flow was observed below the critical micelle concentration (15). However, once the critical micelle concentration was exceeded, micelles form in the buffer solution (Fig. 4*B*). These polycationic micelles are attracted to the negative capillary wall, and condense onto the wall to form a "hemi-micelle" layer (Fig. 4*B*). The properties of this hemi-micelle layer are then governed by the properties of the micelle and surfactant, and not affected by the underlying anionic charge (so long as there is sufficient anionic wall charge to anchor the micelles to the wall).

Thus, the hemi-micelle model explained why the surfactant-induced electroosmotic flow reversal was pH independent. Further it was found that variation of other conditions such as the buffer anion and the surfactant length had little effect on the magnitude of the reversed electroosmotic flow (15).

Still questing for control of reversed electroosmotic flow

Thus, while we now understood the mechanism for flow reversal using cationic surfactants, we still required a means to easily alter the magnitude of the reversed electroosmotic flow. Fortunately, we realized that the electroosmotic flow resulting from the hemi-micelle layer was a function of the electrostatic properties of the layer. The electrostatic properties of the hemi-micelle layer could be altered by adding another surfactant bearing a different charge, i.e., create a mixed surfactant system. The zwitterionic surfactant coco amidopropylhydroxyldimethyl sulfobetaine (CAS U, Witco) was successfully incorporated into the cationic hemi-micelle to alter the effective wall charge. Variation of the CAS U to cationic surfactant ratio (at concentrations above the critical micelle concentrations of the surfactants) allowed monotonic variation in the electroosmotic flow from near zero to full reversed (16). Thus, we had achieved the first of the three challenges that we foresaw — control of reversed electroosmotic flow. We have successfully applied this reversed electroosmotic flow to the optimization of separations of inorganic anions (16) and cationic proteins (17).

Meandering along the path to the Holy Grail

One surprising aside from this work was the observation that CAS U itself adsorbed onto the capillary walls to form a hemi-micelle. This hemi-micelle formation reduced the electroosmotic flow to ~10% of its normal (i.e., untreated capillary) value (18). We believe the hemi-micelle formation increased the ionic strength in the vicinity of the capillary wall, as depicted in Fig. 4*B*. The hemi-micelle formation lowers the double layer thickness (κ^{-1}), and thus the electroosmotic flow (eq. [6]). The hypothesis of a localized high ionic strength was very important.

Cationic proteins are very difficult to separate by capillary electrophoresis. The strong electrostatic attraction between these proteins and the anionic capillary wall results in severe peak distortion and even irreversible loss of the protein. One solution to this problem was to use extremely high ionic strength buffers (>2 M) (19). Despite the *Herculean* nature of this approach, it has been commercialized by Waters as Z1 Methyl Additive, and is widely used. We argued that if our zwitterionic surfactant hemi-micelle layer increases the localized ionic strength at the capillary walls, might it not also prevent adsorption of cationic proteins. Indeed addition of 0.002 M CAS U to our buffers yielded over 750 000 plates per meter for lysozyme and α-chymotrypsinogen A, as evident in Fig. 2*B* (18). This was the highest efficiency ever reported for separation of these proteins. Further, recoveries of protein from the capillary were quantitative (18).

Retrieving the Holy Grail

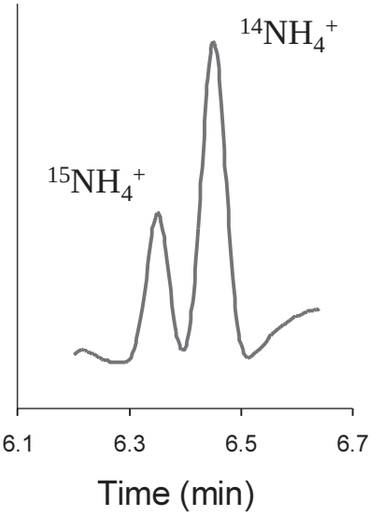
To perform isotopic separations of cationic species we needed an electroosmotic flow that was equal in magnitude, but opposite in direction to the migration of the cations. The zwitterionic–cationic surfactant systems described above gave us the electroosmotic flow control needed for this application.

But what cationic isotopic separation should we apply this technique to? The advent of Inductively Coupled Plasma – Mass Spectroscopy (ICP–MS) has rekindled the use of tracers, albeit stable isotopes, by once again demonstrating their great value in practical applications such as environmental studies (20). However, ICP–MS and other mass spectroscopic techniques are expensive, and so are all too often unavailable to experimentalists, thus limiting the use of stable-isotope labeling. Also, with isotope species like $^{15}NH_4^+/^{14}NH_4^+$ sample handling can be complex (21). Thus it would be extremely useful if capillary electrophoresis could be used to separate isotopically labeled ammonium. Further, the work of Tanaka et al. (1) has demonstrated that there is an isotope-induced shift in the pK_a of amines that can be exploited for such separations.

Figure 5 shows a preliminary separation of $^{15}NH_4^+$ and $^{14}NH_4^+$ achieved by Ken Yeung using mixed surfactant hemi-micelle wall coatings to control the reversed electroosmotic

© 1999 NRC Canada

Fig. 5. Separation of isotopically labeled ammonium ($^{15}NH_4^+$) from natural ammonium ($^{15}NH_4^+$). Experimental conditions: applied voltage, –15 kV; capillary, 47 cm of 50 μm i.d. (40 cm to detector); temperature, 25°C; detection, indirect at 214 nm; buffer, 10 mM borate with 0.5 mM CAS U with pH adjusted to 9.55 using benzyltributyl ammonium hydroxide; sample, 0.1 mM $^{15}NH_4^+$ and 0.2 mM $^{14}NH_4^+$.



flow. As predicted (1), the ^{15}N retains its hydrogen more strongly, and so has a slightly higher effective charge than $^{14}NH_4^+$, and thus migrates more quickly. Further work is being done to fully characterize this analysis (22). The same approach has been applied to other ^{15}N-labeled compounds such as aniline (23).

Thus, we now have overcome two of the hurdles that we foresaw. Firstly, we have gained control over the magnitude of the reversed electroosmotic flow. Secondly, we have used that flow control to separate cationic isotopic species. The only quest that yet remains is an understanding of what actually controls electrophoretic mobility.

Questing for an understanding of electrophoretic mobility

The mobility of an ion is a function of its charge (z) and a frictional drag (f):

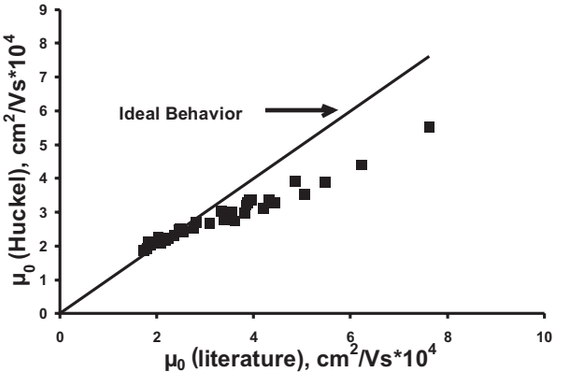
$$[7] \qquad \mu \alpha \frac{z}{f}$$

The most common hydrodynamic model for mobility is related to the Stokes–Einstein diffusion model, and is known as the Hückel equation:

$$[8] \qquad \mu_0 = \frac{ze}{6\pi\eta r_s}$$

where z is the valence number of the molecule, e is the charge of an electron, η is the viscosity of the solution, and r_S is the Stokes radius. The denominator is the frictional coefficient (f) as predicted by Stokes law for moving a hypothetical spherical molecule of radius r_s at a uniform velocity through a continuum of viscosity η.

Fig. 6. Correlation of the mobilities predicted using the Hückel equation (eq. [8]) with the infinite dilution mobilities for 34 aliphatic monoamines. The line is the expected behaviour for perfect correlation between the literature and predicted values. Reprinted with permission from ref. 24. Copyright 1998 American Chemical Society.



While the Hückel equation is widely quoted, it is not highly effective even for simple organic ions, as is shown in Fig. 6. Figure 6 shows the infinite dilution mobilities calculated using the Hückel equation (eq. [8]) plotted versus the literature mobilities for 34 aliphatic monoamines (24). The Stokes radii were derived from the van der Waals volume of the molecule calculated using the Bondi increments. The line in Fig. 6 indicates the ideal correlation (i.e., if the calculated mobilities precisely matched the literature mobilities). Clearly, the mobilities determined using the Hückel equation (eq. [8]) deviate significantly from the literature values. The average relative error in mobility prediction using the Hückel equation (eq. [8]) is 13.9% (24).

In retrospect, it seemed obvious why the Hückel equation failed. Molecules are not spherical! Thus, our second attempt at modeling the mobility of these simple aliphatic monoamines was to use the Perrin model (25). In the Perrin model, the shape of the molecule is approximated as an ellipsoid. Generally the frictional resistance of the ellipsoid is expressed relative to the resistance of moving a sphere of the same volume (i.e., f/f_0 where f is the frictional coefficient of the ellipsoid, and f_0 is the frictional coefficient for a sphere of the same volume). Thus Perrin's equation has the form:

$$[9] \qquad \mu = \frac{ze}{6\pi\eta r_s(f/f_0)}$$

The frictional ratio factor (f/f_0) is related to the dimensions of the ellipsoid (length, width, and depth) through elliptical functions of the first kind. So, molecular modeling was used to determine the dimensions of the molecule, and then nontrivial mathematics were used to convert these dimensions into a frictional factor.

After all this effort, the Perrin ellipsoidal model provided little improvement over the Hückel model (24). The average relative error of mobilities predicted for the aliphatic monoamines by the Perrin model was 10.0% (24). Furthermore, use of the Perrin model induced greater deviation in

© 1999 NRC Canada

the prediction of the mobility of large monoamines, where shape was expected to be most important!

At times like these one forsakes the wisdom of Merlin, and relies on the brawn of Lancelot. Numerous empirical expressions have been developed for predicting electrophoretic mobility (26). A common feature of these is that the mobility is found to depend upon the molecular volume to a power greater than the minus one third suggested by the Hückel equation (eq. [8]). Similarly, empirical expressions for diffusion, which is related to electrophoretic mobility through the Einstein relation, have consistently yielded surprisingly high power dependencies on the radius and (or) volume (27). Therefore, it was decided to try to fit the literature mobilities for the aliphatic monoamines to an expression in which the dependence on volume was allowed to vary. The resultant expression for monoamines (z = +1) was (24)

$$[10] \quad \mu_0 = \frac{3.66 \pm 0.27 \times 10^{-3}}{V^{0.481 \pm 0.016}} \quad (\mathrm{cm^2\ V^{-1}\ s^{-1}})$$

where V is the van der Waals volume of the molecule calculated using the Bondi increments. The average error for infinite dilution mobilities predicted using eq. [10] was 6.6%. This error was much reduced from that of the Hückel (eq. [8]) (13.9%) or Perrin (eq. [9]) (10.0%) equations.

However, there were still significant problems with our mobility predictions. Firstly, eq. [10] was purely empirical. In all likelihood the power dependence on volume was biased by other factors affecting mobility. Secondly, there are significant errors in the mobilities predicted by eq. [10]. Surprisingly, these errors did not seem to relate to shape. What else could influence mobility? Well, obviously hydration! An ion in solution will cause water molecules to reorient in response to the ion charge. Generally, we refer to the first shell of such solvation as the "*primary hydration sphere*." But how do you calculate the primary hydration sphere for an organic molecule? Fortunately, our molecular modeling program (Molecular Modeling Pro™, Version 1.44, WindowChem Software, Fairfield, Calif.) provided the McGowan waters of hydration. In this procedure, each functionality within a molecule is associated with a certain number of waters of hydration. For instance, CH_n has 0 waters, ROH has 1, NH_4^+ has 12, R-NH_3^+ has 9, $R_2NH_2^+$ has 6, R_3NH^+ has 3, and R_4N^+ has 3. The summation of such increments over the functional groups of a molecule gives the total waters of hydration for that molecule.

Allowing for the influence of hydration on mobilities of ions, the general expression for mobility (eq. [7]) becomes

$$[11] \quad \mu \propto \frac{z}{f_{\mathrm{hydrodynamic}} + f_{\mathrm{hydration}}}$$

where $f_{\mathrm{hydrodynamic}}$ is the frictional drag due to the volume of the ion, and $f_{\mathrm{hydration}}$ is the frictional drag caused by the waters of hydration. Incorporating the McGowan waters of hydration (H) into our empirical expression for the mobility of aliphatic monoamines (z = +1) yielded

$$[12] \quad \mu_0 = \frac{(7.8 \pm 1.2) \times 10^{-3}}{V^{(0.619 \pm 0.028)} + (0.286 + 0.087)H} \quad (\mathrm{cm^2\ V^{-1}\ s^{-1}})$$

This expression significantly lowered the error in our predicted mobilities, to about 5% (24). Further, this expression was the most effective predictor for mobilities of a test set of other aliphatic monoamines (5.2%) (24).

So, we seem to have identified the primary factors governing mobility — the volume-related hydrodynamic friction and the hydration friction. We decided to test this model on another class of ions, aliphatic carboxylates. It is obvious that more than just hydrodynamic friction governs the mobility of carboxylates. For instance, CCl_3COO^- and n-$C_4H_9COO^-$ have about the same molecular volume (104.3 and 105.3 Å^3, respectively). However, the infinite dilution mobility of CCl_3COO^- (3.62×10^{-4} cm^2 V^{-1} s^{-1}) is much higher than that of n-$C_4H_9COO^-$ (2.98×10^{-4} cm^2 V^{-1} s^{-1})). Thus, it would appear that a hydration friction is operative with carboxylates, as well as with the amines discussed above. However, the McGowan waters of hydration list carboxylates as 5 waters of hydration. There is no variation. It is then not possible to explain the mobility differences between CCl_3COO^- and n-$C_4H_9COO^-$.

At about this same time we started to become aware of the "semi-empirical" nature of the McGowan waters of hydration. This is not surprising since even with simple ions such as K^+ and F^- there is tremendous variation in the quoted hydration numbers (see Table 15 in ref. 28). Thus, while the McGowan waters of hydration worked very effectively for the aliphatic monoamines (24), it was evident that we needed to find a more sophisticated or appropriate manner to describe the charge induced friction of an ion.

And as is often the case with such incantations, we found the answer in old lost scrolls. In 1920 Max Born proposed a model to explain the mobilities of the alkali metal ions ($K^+ > Na^+ > Li^+$). He postulated that an additional *dielectric* friction is caused by the orientation of the solvent dipoles in response to the ionic charge. After the ion passes, energy is dissipated during the relaxation of the solvent to its equilibrium polarization. This additional energy dissipation enhances the overall friction experienced by the ion. That is, the mobility of an ion is governed by both a hydrodynamic ($f_{\mathrm{hydrodynamic}}$) and a dielectric friction ($f_{\mathrm{dielectric}}$):

$$[13] \quad \mu_0 \propto \frac{z}{f_{\mathrm{hydrodynamic}} + f_{\mathrm{dielectric}}}$$

The hydrodynamic friction is related to the molecular volume, while the dielectric friction is related to the ion charge.

Born's idea has been further developed by numerous workers using the assumption of point charges within a continuum medium (29). The most advanced formulations of this approach are the Zwanzig and Hubbard–Onsager expressions, which have the general form:

$$[14] \quad \mu_0 = \frac{ze}{6\pi\eta r_i + \left(\frac{B'\eta}{r_i^3}\right)}$$

where z is the valence number of the ion charge, e is the charge on the electron, η is the solvent viscosity and r_i is the crystallographic radius. The constant B' is

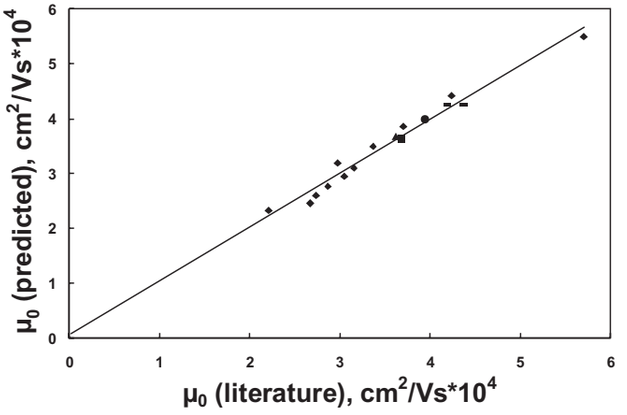
Fig. 7. Correlation of the mobilities predicted using eq. [16] with the infinite dilution mobilities for 15 aliphatic carboxylates. The symbol ◆ indicates nonhalogenated aliphatic carboxylates, and other symbols indicate halogenated aliphatic carboxylates. The line is the linear regression between the predicted and literature mobilities. Reprinted with permission from ref. 31. Copyright 1998 Royal Society of Chemistry.



$$[15] \quad B' = H(ze)^2 \frac{\tau}{\eta} \frac{\varepsilon_0 - \varepsilon_\infty}{\varepsilon_0^2}$$

where τ is the solvent dielectric relaxation time, and ε_0 and ε_∞ are the low- and high-frequency dielectric constants, respectively. The constant H is 3/8 for the Zwanzig model and 1/16.5 for the Hubbard–Onsager model (29).

One of the most striking features of eqs. [14] and [15] is that the dielectric friction is related to z^2/r^3. This is, in effect, a charge density. So, if we can calculate the charge density of an amine or a carboxylate functionality, we should be able to predict the mobility of the molecule. However, such calculations would be long and tedious. It would be much more straightforward and simple to use nature's explicit statement of the charge density in a functional group — the acid dissociation constant (30). For instance, for acetic acid the charge can only be distributed within the carboxylate. As a result, the pK_a is quite high, 4.72. With chloroacetic acid, the chloro group helps disperse the carboxylate charge. This stabilizes the conjugate base form of the molecule, and lowers the pK_a to 2.87.

Based on the above rationale, we developed expressions for mobility incorporating the volume to reflect the hydrodynamic friction and the pK_a to reflect the charge density that governs the dielectric friction. The resultant expression for carboxylates was (31)

$$[16] \quad \mu_0 = \frac{(6.8 \pm 1.2) \times 10^{-3}}{V^{(0.62 \pm 0.04)} + (0.66 \pm 0.24) \mathrm{p}K_a} \quad (\mathrm{cm}^2\ \mathrm{V}^{-1}\ \mathrm{s}^{-1})$$

Volumes were calculated using the Bondi increments, and pK_a values were taken from the literature. This expression successfully described the infinite dilution mobilities of aliphatic carboxylates, as can be seen in Fig. 7. The average relative error between the predicted and literature absolute mobilities is only 3.7%. This is approximately the error associated with the literature absolute mobilities.

However, what was more exciting than the accuracy of the predictions given by eq. [16] was the commonalities between this expression for aliphatic carboxylates, and that determined for aliphatic monoamines (31):

$$[17] \quad \mu_0 = \frac{(7.8 \pm 1.3) \times 10^{-3}}{V^{(0.62 \pm 0.03)} + (0.66 \pm 0.23) \times \mathrm{p}K_b} \quad (\mathrm{cm}^2\ \mathrm{V}^{-1}\ \mathrm{s}^{-1})$$

and that for sulfonates (32):

$$[18] \quad \mu_0 = \frac{(5.5 \pm 0.6) \times 10^{-3}}{V^{(0.57 \pm 0.02)} + 0} \quad (\mathrm{cm}^2\ \mathrm{V}^{-1}\ \mathrm{s}^{-1})$$

In eq. [17], the pK_b is used as the measure of the charge density on the amine.

There are numerous points of commonality within eqs. [16]–[18]. Firstly, the numerators are similar. Secondly, the power dependence on volume is statistically equivalent in the three cases. The only differences in the equation lies in their dielectric friction terms. The use of pK_a and pK_b as measures of the charge density on ionized carboxylates and amines make chemical sense (31). The lack of a dielectric friction term for the sulfonates requires a bit more reflection. Sulfonates are fully dissociated in aqueous solution. Thus, their pK_a will be very low (≈0). Thus, in analogy to eq. [16], such a low pK_a would make the dielectric effect negligible.

The strong commonalities between eqs. [16]–[18] suggest that we have reduced the mobility behaviour down to its fundamental form. But, as has been discussed previously, it is the physical significance of the parameters and not the quality of fit that is the true test of a model (33). So what is the significance of the parameters in eqs. [16]–[18]? Well, the power dependence on volume is probably the most interesting. In eqs. [16]–[18], the mobility of aliphatic carboxylates, amines, and sulfonates depends on $\sim V^{-0.6}$. This is very close to the $V^{-0.66}$ that is theoretically predicted if the mobility of these ions were governed by the radius of gyration of the flexible tail of these aliphatic molecules (31). But what then of aromatic molecules. Their structure is much more rigid, and so will not be free to gyrate. Preliminary results with aromatics indicate that their mobility is well modeled by the Perrin equation (eq. [9]) modified to include the effect of dielectric friction (34).

Thus, we now have a better understanding of the form of the hydrodynamic friction for organic molecules and an appreciation for the importance of dielectric friction. We are now in a position to estimate the mobility of organic ions at infinite dilution.

Is the knowledge of Merlin useful to Lancelot?

The work described in the last section all focused on predicting mobilities at infinite dilution. However interesting and worthwhile this might be, practical analysts must work in more concentrated buffers — generally 5–100 mM in concentration. At such concentrations ionic strength and ion association will alter the observed mobilities from that observed at infinite dilution. As can be seen in Fig. 8*A*, the

mobility of ions, and particularly highly charged ions, decrease rapidly as the buffer concentration is increased.

Traditionally in capillary electrophoresis, the effect of ionic strength has been described using the Onsager law. This model is analogous to the Debye–Hückel limiting law for ionic activity. It is postulated that the ion is a point charge surrounded by an ionic atmosphere of opposite charge. Based on these assumptions, the apparent mobility ($\mu_{apparent}$) is related to the square root of the buffer ionic strength ($\sqrt{I}$). Figure 8*B* replots the mobility observed in Fig. 8*A* in this fashion (36). Nonlinearity is still apparent in Fig. 8*B*. Thus, the Onsager equation was only partially successful in correcting for the effect of ionic strength.

What is needed to fully correct for the effect of ionic strength on mobility is an allowance for the size of the central ion. In discussions of ionic activity, such allowances are made in the Debye–Hückel extended law. In this model, the central ion is considered to have a finite radius and is then surrounded by an ionic atmosphere. The mobility model that is equivalent to the Debye–Hückel extended law once again comes from the ancient scrolls (1950s) and is known as the Pitts equation (35). The predicted ionic strength dependence is then

$$[19] \quad \mu \propto \frac{\sqrt{I}}{1 + Ba\sqrt{I}}$$

where I is the ionic strength, B is a constant for a given solvent related to the dielectric constant, temperature and viscosity, and a is an ionic size parameter related to the hydrated radius of the ion. While eq. [19] is simple, I do not want to trivialize this expression. Generation of this expression from Pitts' work required 2 months of effort using Mathematica.

For aromatic carboxylates, the constant Ba was found to have an empirical value of 2.4 (36). Figure 8*C* shows the mobility data from Fig. 8*A* replotted using the Pitts equation (eq. [19]). This expression successfully linearized the ionic strength behaviour. Furthermore, the slope of the ionic strength dependence in Fig. 8*C* was within 20% of that predicted by the Pitts equation (36). This is remarkable when one considers that the Pitts equation was actually derived to describe equivalent conductivity. That is, it was derived to describe the mobility of the *buffer*, not the mobilities of *analytes* within a buffer.

While the success of the Pitts equation is remarkable, the uncertainty in the predicted behaviour is still sufficient to allow the relative mobilities of similar ions to reverse. There remain numerous factors which can alter selectivity including ion association and other secondary equilibrium effects. Thus, we are not yet at the stage where we can predict the absolute migration order of ions within a buffer. Nonetheless, our work acts as a guide to help analytical chemists understand some of the key factors affecting electrophoretic mobility.

Conclusions

So concludes our narrative for today. Were we successful in our quest? Well, we have achieved control of the reversed electroosmotic flow, and we have demonstrated separations of isotopic species ranging from chloride to ammonium. We have even made progress in understanding the factors affecting the mobility of ions, albeit we still cannot explain the isotopic effect on mobility.

But then none of this was really what the quest was all about. In reality, the quest for the Holy Grail has always symbolized the quest for knowledge. For it is only with knowledge and understanding that one can wield the full

© 1999 NRC Canada

power of an Excalibur such as capillary electrophoresis. In that quest we have had some success, as is being recognized by the W.A.E. McBryde Medal. However, it is not a quest that we have completed, nor ever hope to complete.

Finally, given the theme of this presentation, I suspect a number of you now know what my middle initial stands for.

Acknowledgments

The foundations for this work were laid during my squireship under the tutelage of Prof. Fred Cantwell at the University of Alberta and Prof. Pete Carr at the University of Minnesota (Minneapolis). However, many other individuals including Janis Gulens, Howard Yeager, and Penny Codding greatly aided me with their sage advise and wisdom.

The work described herein has had many patrons. These include the Natural Sciences and Engineering Research Council of Canada (NSERC), The University of Calgary, the Province of Alberta, the Government of Canada, and Syncrude Research. This support is gratefully acknowledged. K.K.-C.Y. also thanks NSERC, the Killam Foundation, and Glaxo Wellcome for their support. Finally, I would like to thank Hewlett–Packard for sponsoring the W.A.E. McBryde Medal, and for their support of the Canadian Analytical Chemistry Community in general.

Theoretical studies of heterofullerenes $C_{68}X_2$ (X = N, B)

Zhongfang Chen, Keqin Ma, Yinming Pan, Xuezhuang Zhao, and Auchin Tang

Abstract: A systematic investigation on the molecular structures of the possible energetically favored isomers of $C_{68}X_2$ (X = N, B) have been performed using the semiempirical MNDO, AM1, and PM3 methods. The most stable isomer of $C_{68}X_2$ was computed, and the static properties such as heats of atomization, ionization potentials, electron affinities, absolute electronegativities, and global hardness have been predicted theoretically. The proposition that the changes of hybridization from sp^2 to sp^3 are the predominant factors of the regiochemistry for both $C_{60}X_2$ and $C_{58}X_2$ are supported by the calculations, and the regioselectivity of the doped fullerenes may be deduced in light of the knowledge of the fullerene adducts based on this proposition.

Key words: $C_{68}N_2$, $C_{68}B_2$, MNDO, AM1, PM3.

Résumé : Utilisant des méthodes de calculs semi-empiriques, comme MNDO, AM1 et PM3, on a effectué une étude systématique des structures moléculaires des isomères énergétiquement favorisés possibles pour le $C_{68}X_2$ (X = N, B). On a déterminé par calcul la nature de l'isomère le plus stable du $C_{68}X_2$ et l'on a prédit d'une façon théorique ses propriétés statiques, telle que chaleur d'atomisation, potentiel d'ionisation, affinité électroniques, électronégativité absolue et dureté globale. L'hypothèse selon laquelle les changements d'hybridation de sp^2 à sp^3 sont les facteurs prédominants dans la région chimie tant du $C_{60}X_2$ que du $C_{58}X_2$ est supportée par les calculs et, en utilisant cette hypothèse, on peut déduire la régiosélectivité de fullerènes dopés à la lumière d'une connaissance des adduits du fullerène.

Mots clés : $C_{68}N_2$, $C_{68}B_2$, MNDO, AM1, PM3.

[Traduit par la Rédaction]

1. Introduction

The synthesis and characterization of the so-called heterohedral fullerenes, which have one or more of the carbon atoms substituted by other elements such as boron and nitrogen, have become the new hot topic soon after the discovery of C_{60} (1–13), since the incorporation of heteroatoms into the fullerene skeleton is expected to modify its structural and electronic properties. The first substituted fullerenes $C_{60-x}B_x$ (x = 1–6) were produced by Smalley and co-workers (1) in 1991. Later in the same year Rao and co-workers (2) reported the preparation of a number of C_nN_m fullerenes. The production of the first substituted fullerenes in 1991 opened up new avenues in materials science and organic chemistry, raised new fundamental questions about their ability, morphology, electronic behavior, and the basic features of the chemical bonding. All of these revealed another inspiring world for scientists to explore. Since then much experimental and theoretical work has been done in this new field. The verification of $C_{59}N$ was reported by Mattay and co-workers (3) in 1995, and the fullerenes substituted with one nitrogen atom $C_{59}N$ were synthesized and characterized by Yu et al. (4) at about the same time. Also in this year, the synthesis of $C_{59}N$ in the dimer form $(C_{59}N)_2$ was achieved by Hummelen et al. (5). Later the synthesis and isolation of heterofullerenes $(C_{59}N)_2$ and $(C_{69}N)_2$ and their adducts $RC_{59}N$ and $RC_{69}N$ were achieved by Nuber and Hirsh (6) in 1996. The potassium-intercalated $K_6C_{59}N$ solid was prepared and structurally characterized by Prassides et al. (7) with $(C_{59}N)_2$ as precursor. The hydrogenated azafullerene $C_{59}NH$, which can be a suitable source of $C_{59}N$ radical when it is deprotonated, was isolated and fully characterized by Wudl and co-workers (8) in 1997. The derivatization of $C_{59}N$ has been achieved from $(C_{59}N)_2$ and $C_{59}NH$ also by Wudl and his group (9) in 1997. More recently Nuber and Hirsch (10) reported the successful synthesis of arylated heterofullerenes $ArC_{59}N$ with $(C_{59}N)_2$ as precursor. The experimental work about boron-substituted fullerenes will also make great progress with the macroquantivity synthesis of $C_{60-n}B_n$ and $C_{70-n}B_n$ (11).

On the theoretical side, the stabilities, electronic properties, band structures, and the third-order polarizability of the heterohedral fullerenes have been studied, and some intriguing properties different from the all carbon fullerenes are predicted (14–32). However, theoretical studies on the molecular properties, including all the static properties and most kinetic properties, largely depend on the accuracy and reliability of the equilibrium geometries, the properties of

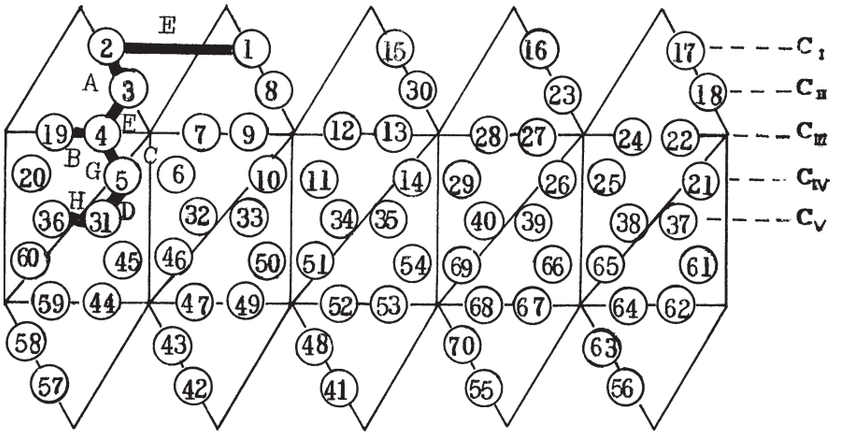
Fig. 1. The planar nets of C_{70}. (The numbers of the circles are used to characterize the 70 carbon atoms of C_{70}. C_I, C_{II}, C_{III}, C_{IV}, and C_V are defined as the five unique carbon atoms in C_{70}.)



the heterofullerenes predicted so far are all based on the arbitrarily assigned geometries, which often give ambiguous and contradictory results. Hence, it is an urgent task for us to determine the stable species of the doped fullerenes.

In our previous work (32), heterofullerenes $C_{58}X_2$ (X = N, B) have been investigated systematically. The aim of the present theoretical work is to extend our investigations on heterofullerenes to the studies of $C_{68}X_2$ (X = N, B) to find the most stable isomers and predict their electronic properties. The semiempirical MNDO, AM1, and PM3 methods were used to perform a systematic investigation on the molecular structures of the possible energetically favored isomers of $C_{68}X_2$ (X = N, B). The equilibrium geometrical structures, heats of formation, HOMO–LUMO gap energies, heats of atomization, ionization potentials, electron affinities, absolute electronegativities, and global hardness will be predicted theoretically.

2. Computational details

Closed-shell SCF calculations were performed with the standard MNDO, AM1, and PM3 parameters as implemented in the MOPAC 6.0 program,[2] using the PRECISE option in order to decrease the gradient norm. The full optimizations were carried out without any symmetry constraints in Cartesian coordinates, and initial input geometries were based on the optimized C_{70} with specific carbon atoms displaced by B and N. The ab initio 3-21G computations on the two lowest energy isomers of $C_{68}X_2$ were performed with the G94 program package (33) in the optimized MNDO geometries as single-point calculations only.

3. Results and discussion

There are 143 structurally distinct isomers for $C_{68}X_2$. Time required for the computation makes it impossible to calculate all the isomers of the systems studies in this paper. Nevertheless, in our previous studies (32) we have found that the isomer corresponding to 1,4-substitution to the cyclohexatriene unit is the most stable isomer among 23 possible isomers of $C_{58}X_2$ (X = N, B), and the stabilities decrease with the increasing of the distance between the heteroatoms. These results permit a reliable search of the ground state of $C_{68}X_2$ with little effort. All the isomers resulting from 1,2-substitution across the 6,6-fusion and from the 1,4-substitution across 6-rings will be calculated; the other isomers, except 1,2- and 1,4-substitution to the cyclohexatriene units, will also be considered in this paper. These isomers are listed in Table 1 and designed as follows. First, the carbon atoms are numbered as indicated in the planar net of C_{70}. An isomer of $C_{68}X_2$ is characterized by the position of the substitution, and a comma is used for 1,2-isomers, a slash (/) is used for 1,4-isomers, a semicolon (;) is used for other isomers except 1,2- and 1,4-substitution to the cyclohexatriene units. For example, $C_{68}X_2(2,3)$ means that the carbon atoms numbered 2 and 3 in C_{70} are substituted by X atoms, and this isomer is 1,2-substitution. $C_{68}X_2(2/19)$ means that the carbon atoms numbered 2 and 19 in C_{70} are substituted by X atoms, and this isomer is 1,4-substitution (see Fig. 1).

3.1. Heats of formations and HOMO–LUMO energy gaps

The heats of formation and HOMO–LUMO gap energies of $C_{68}X_2$ are listed in Table 1. All the calculations indicate that $C_{68}X_2(6/45)$ and (2/19), which correspond to 1,4-substitution to the cyclohexatriene unit, have the lowest heats of formation among all the isomers that resulted from substitution to the cyclohexatriene units, thus the most stable isomers. The isomer 6/45 is favored by several kcal/mol over 2/19 according to both semiempirical and ab initio calculations, and is predicted to be the ground state.

In our previous paper (32) we have proposed that the changes of hybridization from sp^2 to sp^3 may be the underlying reason why 1,4-substitution is favored in $C_{58}N_2$ and $C_{58}B_2$. Our recent calculations of $C_{58}P_2$ also confirmed this proposition. Therefore, the most stable isomers may be found out in the light of the regioselectivity of $C_{60}X_2$, since the same hybridization changes occur at the carbon atoms where the addends are added in $C_{60}X_2$. Now let us try finding the most stable isomers of $C_{68}X_2$ in light of the regioselectivity of $C_{70}X_2$. Up to now, many theoretical stud-

[a]Note that the heats of formation of $C_{68}N_2$(31,36) and (2/19) obtained by AM1 are almost the same, the single point energies (3-21G) based on the optimized geometries of $C_{68}N_2$(31,36) and (2/19) are –2668.5070 and –2668.5438 au, respectively. The energy order is not consistent with AM1 results but agrees with the MNDO and PM3 results.

ies on $C_{70}X_2$ have been performed. For example, Henderson et al. (34) have found that 4 of 143 $C_{70}H_2$ isomers have particularly low heats of formation based on the PM3 results, and these isomers represent either 1,2-addition across 6:6 ring fusion or 1,4-addition across a six-membered ring. It is feasible to find the most stable isomer of $C_{68}X_2$ from the four isomers in which the heteroatoms substitute the carbon atoms where the H atoms are added in the four most stable isomers of $C_{70}H_2$. Considering that the N—N and B—B bonds will tend to destabilize the structures and should be avoided, we can draw the conclusion that the two isomers of 1,4-substitution across a six-membered ring, i.e., $C_{68}X_2$(2/19), $C_{68}X_2$(6/45), are the most energetically favored. Hence, the knowledge of the regioselectivity of fullerenes can be useful to find the stable isomers of the doped fullerenes.

If the carbon C2 in C_{70} was substituted by heteroatom X, and the substitution positions of the second heteroatom fall approximately on the circumference connecting C2 and C42, the distance between the heteroatoms can be approximately represented by the number of C—C bonds between the two heteroatoms. The dependence of H_f and *E*(HOMO)/*E*(LUMO) obtained by MNDO method on the number of

Fig. 2. Dependence of H_f on the number of C—C bond separating the heteroatoms in $C_{68}N_2$ (top) and $C_{68}B_2$ (bottom).

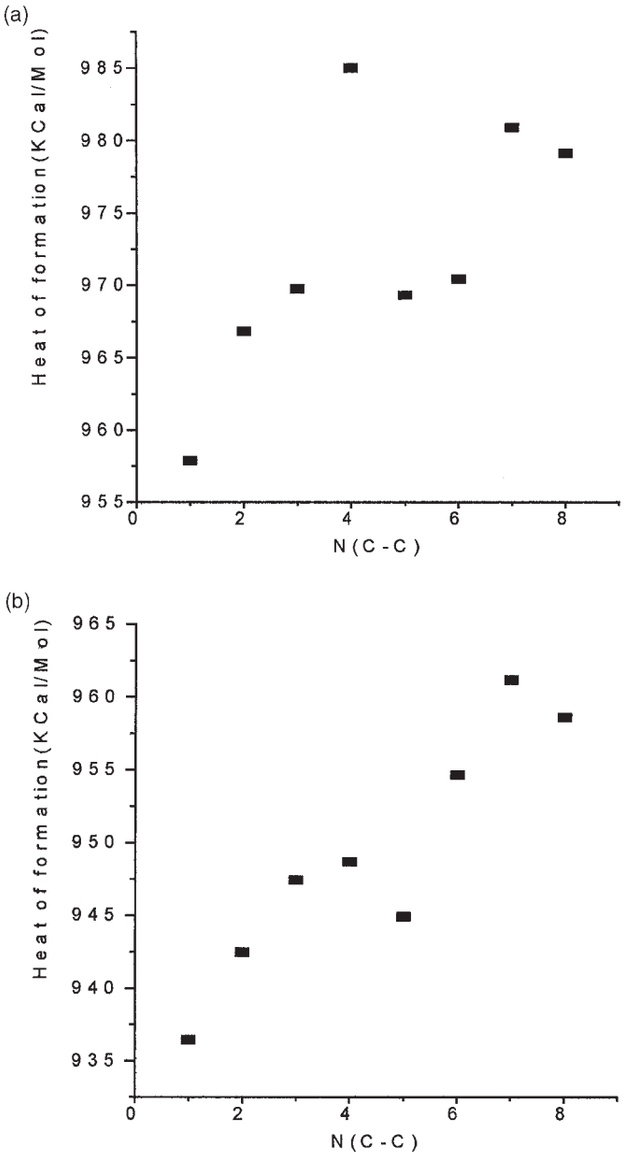

Fig. 3. Dependence of E(HOMO)/E(LUMO) on the number of C—C bonds separating the heteroatoms in $C_{68}N_2$ (top) and $C_{68}B_2$ (bottom).

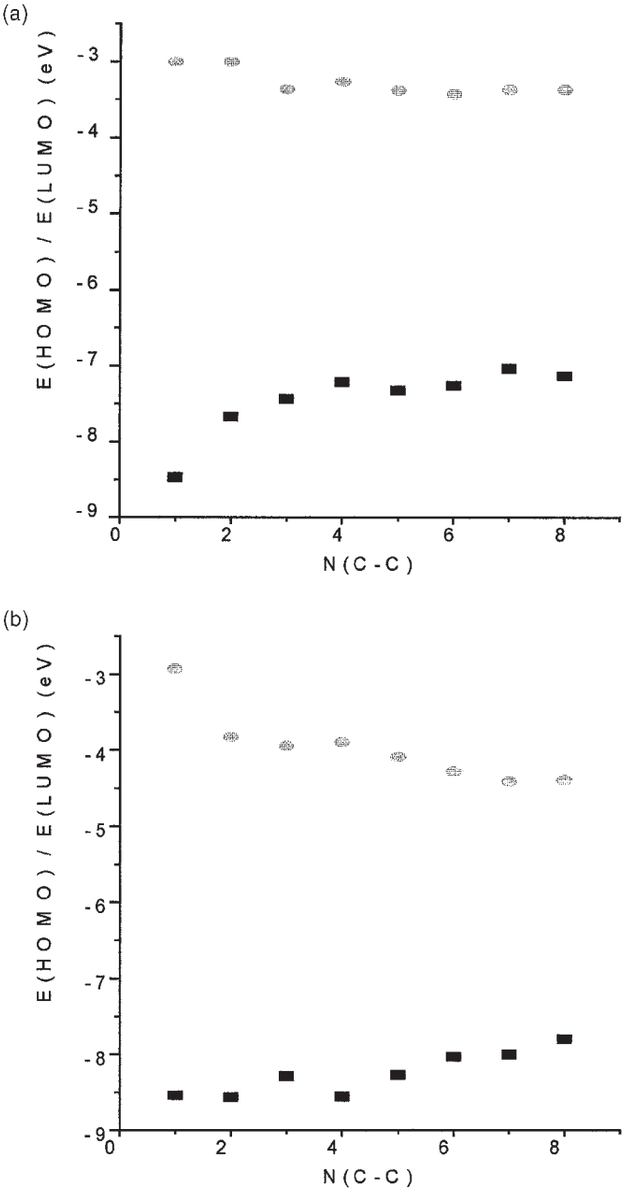


C—C bond separating the heteroatoms in $C_{68}X_2$ were shown in Figs. 2 and 3, respectively. Although there are some oscillations, the general trend is that the heats of formation increase (or stabilities decrease), and the HOMO–LUMO gap energies decrease with increasing number of intervening bonds. This indicates that the stabilities of $C_{68}X_2$ (X = N, B) decrease with increasing the distance between the heteroatoms, which is similar to the findings for the analogous $C_{58}X_2$ (X = N, B) systems (32). These results can also be seen as further confirmation of the stability order.

The HOMO–LUMO energy gapes are associated with chemical stabilities against electronic excitation. Generally speaking, the larger the gap, the more chemically stable the compound is. The HOMO–LUMO energy gaps of the most stable species of $C_{68}X_2$ are all smaller than that of C_{70}. This means that it is easier to excite the electrons in $C_{68}X_2$ from the HOMO to the LUMO than in C_{70}; in other words, the electrons in the HOMO of $C_{68}X_2$ are easier to remove from its molecular potential surfaces than C_{70} by some distance.

3.2. Heats of atomization of $C_{68}X_2$ and C_{70}

For hetero-clusters, the stability should be indicated by a greater negative value of the heat of atomization H_{at}. The heat of formation H_{at} can be calculated according to the gas-phase reaction: nC + mX = C_nX_m; this means that $H_{at}(C_nX_m) = H_f(C_nX_m) - nH_f(C) - mH_f(X)$. The heats of atomization of

© 1999 NRC Canada

the most stable isomers of $C_{68}X_2$ (X = B, N) and C_{70} are summarized in Table 1. Similar to C_{60} and its substituted fullerenes, C_{70} also can not be stabilized by doping nitrogen or boron atoms, and the nitrogen-doped species are more stable than their boron-doped analogues. Considering the successful synthesis of $C_{68}B_2$ (11), it is reasonable to expect that $C_{68}N_2$ would be synthesized and detected experimentally if appropriate synthetic protocols can be achieved. The preparation of heteroatom-doped fullerenes has been one of the challenges in the fullerene field. Up to now there are several experimental methods to prepare heterofullerenes. One convenient way is the contact-arc vaporization method. For instance, the nitrogen-doped fullerenes have been synthesized by arcing a graphite rod in a pure nitrogen atmosphere (4). Some macroscopic amounts of boron-doped fullerenes such as $C_{60-n}B_n$ and $C_{70-n}B_n$ (n = 1, 2, 3) have been synthesized by the DC arc-burning method using highly pure graphite rod and B_4C/graphite composite rod as electrodes (11). The alternative method may be the derivativation of some suitable precursors for the doped fullerenes. A good example for this procedure is the ongoing investigation on the uses of the pyrrole-embedded [60]fullerenes as potential precursors for $C_{58}N_2$ derivatives formed by an azide addition–dechlorination sequence (35).

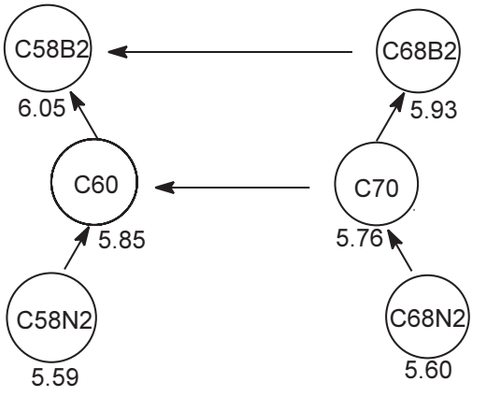
3.3. Frontier orbital energies, ionization potentials, electron affinities, global hardness, and absolute electronegativities

The substitutional perturbation affects both HOMO and LUMO orbitals of $C_{68}X_2$. In general, the HOMO become less bound while the LUMO become more bound with increasing H_f (i.e., decrease in stabilities).

Now we discuss the reactivities of $C_{68}X_2$ based on the Frontier Orbital (FO) theory of Fukui (36). This theory considers the distribution of the HOMO density as being most important for electrophile attack, and the LUMO density for neucleophile attack. For the most stable species of $C_{68}X_2$ and C_{70}, the energy sequence of HOMO is $C_{68}N_2$ (–8.26 eV) > C_{70} (–8.67 eV) > $C_{68}B_2$ (–8.73 eV), while the energy sequence of LUMO is $C_{68}B_2$ (–3.13 eV) < $C_{68}N_2$ (–2.94 eV) < C_{70} (–2.85 eV). Thus towards an electrophile, $C_{68}N_2$ is the more reactive than C_{70}, and C_{70} is more reactive than $C_{68}B_2$; towards a nucleophile, both $C_{68}B_2$ and $C_{68}N_2$ are more reactive than all-carbon fullerene C_{70}, and $C_{68}B_2$ is the most reactive.

IP and EA are two well-known quantities and are of considerable interest from a theoretical viewpoint. The ionization potentials and electron affinities from Koopmans theorem for $C_{68}X_2$ (X = N, B) are summarized in Table 1. It can be seen that for the most stable species both $C_{68}N_2$ and $C_{68}B_2$ have bigger affinity energies than C_{70}, which suggests that $C_{68}X_2$ can obtain electrons easier to form anions, i.e., it is more easier to reduce $C_{68}X_2$ relative to C_{70}. While the sequence of ionization potentials is $C_{68}N_2$ < C_{70} < $C_{68}B_2$, which suggests that $C_{68}N_2$ loses electrons more readily to form positive ions than C_{70}, i.e., it is more easier to oxide $C_{68}N_2$, while $C_{68}B_2$ loses electrons difficultly to some extent. In our previous work we have found that $C_{58}X_2$ (X = N, B) have somewhat smaller ionization potentials and bigger electron affinities compared with C_{60} (32), which indicates that it is more easy to oxidize and reduce $C_{58}X_2$ relative to C_{60}. Thus we can draw the conclusion that doping may have different effects in substituted C_{60} systems and substituted C_{70} systems.

Fig. 4. The absolute electronegativities of the doped fullerenes. (The arrows show the electron transfer directions when the dimers are formed.)



Recently the concept of chemical hardness has been of great interests (37). The quantities of the global hardness (η) and absolute electronegativity (χ) have been defined as $\eta = (1/2)(\partial^2 E/\partial N^2)$ and $\chi = (\partial E/\partial N)$ where E being the energy and N being the number of electrons in the system considered. In a finite difference approximation using integer values for N, the expressions can be rewritten as η = (IP – EA)/2 and χ = (IP + EA)/2. The hardness is the resistance of the chemical potential to change in the number of electrons, the absolute electronegativity is a good measure of the ability of the molecule to attract electrons to itself. Table 1 summarizes the calculated global hardness and absolute electronegativity of the heterofullerenes $C_{68}X_2$ (X = N, B). It can be found that the most stable isomer has the biggest global hardness among all the 1,4-isomers. This is consistent with the principle of maximum hardness (PMH) (37). Since Choho et al. (38) have found that the reactivity of the larger fullerenes can still be governed by the hard–hard interactions as described in the HSAB principle (39), i.e., hard acids prefer to coordinate to hard bases and soft acids to soft bases, the global hardness is also considered here to study the reactivities of the heterofullerenes. The sequence of the most stable species of the doped fullerenes under investigation according to the global hardness can be found in Table 1. For both $C_{68}N_2$ and $C_{68}B_2$, the most stable isomer has smaller hardness as compared to C_{70}, and the sequence of hardness is C_{70} > $C_{68}B_2$ > $C_{68}N_2$. If we take the global hardness as the measure for the reactivity, $C_{68}X_2$ (X = N, B) should have smaller reactivity towards a nucleophile relative to C_{70}; this is contrary to the reactivity order based on the Frontier Orbital theory. The local hardness may be better descriptor of the reactivity of $C_{68}X_2$, and the reactivity sequence similar to that of FO theory is expected, based on the local hardness because the reactions occur only at specific positions.

From Table 1 we can find that there are remarkable differences between the absolute electronegativities of the doped fullerenes. Since the absolute electronegativity is a good measure of the ability of the molecule to attract electrons to

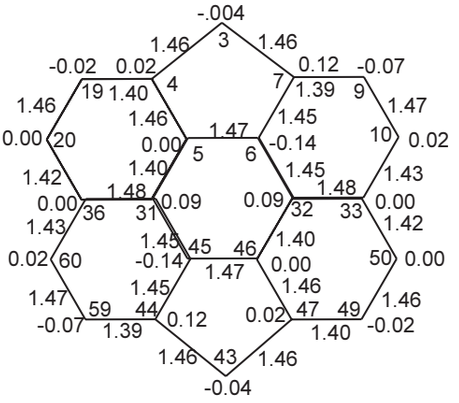
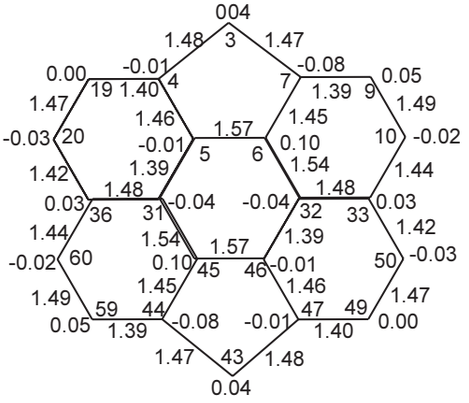
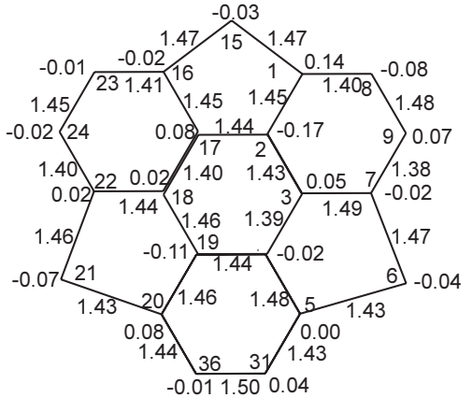
Fig. 5. Calculated bond lengths (Å) and atomic charges of $C_{68}X_2$.



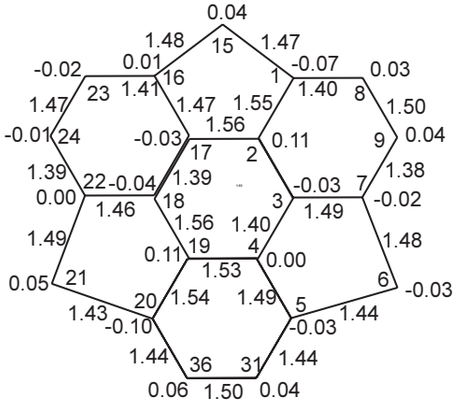
$C_{68}N_2(6/45)$



$C_{68}B_2(6/45)$



$C_{68}N_2(2/19)$



$C_{68}B_2(2/19)$

itself, the existence of these differences suggests that there should be electron transfer when the dimers such as $C_{68}N_2$–$C_{68}B_2$, $C_{68}N_2$–C_{70} are formed. These dimers formed should be donor–acceptor salts. The absolute electronegativities of the most stable doped fullerenes under investigation were summarized in Fig. 4 from which we can see the electron transfer directions. There should be significant electron transfer in the complexes between the all carbon fullerenes and B- or N-doped fullerenes or between the boron-doped fullerenes and their nitrogen analogues. Moreover we can find that the electrons will flow from C_{70} and its B-doped fullerene to C_{60} and its B-doped fullerene when the dimers between them are formed.

3.4. Geometric structures of $C_{68}X_2$ (X = N, B)

The cluster geometry is seriously affected by the substitution. The significant distortion occurs at the heteroatom site for all the isomers of the doped fullerenes. We mainly discuss the structures of two lowest energy isomers of $C_{68}X_2$ (isomer 6/45 and 2/19) obtained by MNDO method.

The calculated bond lengths and atomic charges of $C_{68}N_2$ and $C_{68}B_2$ are shown in Fig. 5 for the region where the heteroatoms substitute the carbon atoms. In $C_{68}N_2$ (6/45), the calculated angle sums for N6 and N45 are 332.2° and 332.3°, respectively. In $C_{68}B_2$(6/45), the calculated angle sums for B6 and B45 are 346.7° and 346.8°, respectively, whereas the corresponding values in C_{70} are 348.3° and 353.0°. Significant deviations from the values for C_{70} indicates that the heteroatoms lie well outside the mean surface of the fullerene skeleton. Hence, some angle strain in C_{70} is relieved upon the substitution, similar to the addition of a double bond of C_{70}. In both cases, heteroatom substitution or addition, the hybridization states change from sp^2 to sp^3. As expected, the comparison of charge density distributions in C_{70} and $C_{68}X_2$ clearly demonstrates the larger amount of charges around the N and B nuclei, since there are differences between the electronegativities of boron, nitrogen, and that of carbon element. The calculated atomic charges of –0.14*e* for each nitrogen atom in $C_{68}N_2$ and +0.10*e* for each boron atom in $C_{68}B_2$ can be found.

The geometries of $C_{68}X_2$(2/19) show the same deformation as shown in $C_{68}X_2$(6/45), with the angle sums of the heteroatoms smaller than those of the corresponding carbons in C_{70}. For $C_{68}N_2$, the calculated angle sums for N2 and N19 are 339.2° and 327.2°, respectively. For $C_{68}B_2$, the calculated angle sums for B2 and B19 are 346.0° and 343.6°,

© 1999 NRC Canada

respectively, whereas the corresponding values in C_{70} are 347.2 and 348.3. For $C_{68}N_2$, the atomic charges at N2 and N19 are –0.17*e* and –0.11*e*, respectively, and the carbon atoms connecting the nitrogen atoms show positive charges. For $C_{68}B_2$, the atomic charges at boron atoms are +0.11*e* on each, and the neighboring atoms show negative charges. The charge distribution in $C_{68}X_2$(2/19) can also be explained by the differences between the electronegativities of the heteroatoms and those of the carbon atoms.

Symmetry lowering with respect to C_{70} is also responsible for the existence of permanent dipole moments in heterofullerenes. The calculated values (MNDO) are 1.132 D for $C_{68}N_2$(6/45), 1.303 D for $C_{68}N_2$(2/19). The dipole moments for $C_{68}B_2$ are relatively smaller, 0.417 and 0.340 D for isomers 6/45 and 2/19, respectively.

4. Conclusions

The equilibrium geometrical structures of $C_{68}X_2$ (X = N, B) were fully optimized at MNDO, AM1, and PM3 level. The heats of formation, HOMO–LUMO gap energies, heats of atomization, ionization potentials, electron affinities, absolute electronegativities, and global hardness for doped fullerenes $C_{68}X_2$ (X = N, B) have been predicted theoretically. The calculation results show that the heterofullerenes $C_{68}X_2$ are less stable than their all carbon analogue C_{70}, and the nitrogen-doped fullerenes $C_{68}N_2$ should be of greater thermodynamic stabilities than their boron analogues $C_{68}B_2$. The isomers 6/45 and 2/19, which correspond to 1,4- substitution to the cyclohexatriene unit, are the most stable isomers for both $C_{68}N_2$ and $C_{68}B_2$, and the isomer 6/45 is the ground state. Although there are some oscillations, the stabilities decrease with the increasing of the distance between the heteroatoms. The redox characteristics of fullerenes can be enhanced by doping. The reactivities towards a nucleophile or electrophile attack are considered according to the frontier molecular orbital (FMO) theory and the HSAB principle. Based on the absolute electronegativities the electron transfer directions in dimer fullerenes are predicted. Our previous proposition that the changes of hybridization from sp^2 to sp^3 are the predominant factors of the regiochemistry for both $C_{60}X_2$ and $C_{58}X_2$ are supported by the calculation results presented in this paper. The regioselectivity of the doped fullerenes may be deduced in light of the knowledge of the fullerene adducts based on this proposition.

Excess molar volumes of liquid 1-bromoalkane + alkane mixtures. Nitta–Chao characterization of the bromine–bromine and bromine–methylene interactions in binary 1-bromoalkane + alkane mixtures

J. García, M.J. Comuñas, L. Lugo, E.R. López, and J. Fernández

Abstract: Excess molar volumes at 298.15 K for the binary mixtures of a 1-bromoalkane with a *n*-alkane are reported. The V^E values were obtained from measurements of the density with an Anton Paar densimeter. Literature data of excess Gibbs energies, excess enthalpies, excess volumes, and activity coefficients at infinite dilution for this kind of mixtures together with molar volumes and vaporization enthalpies of pure bromoalkanes were used to calculate the characteristic parameters of the Nitta–Chao group contribution model. With the obtained parameters, this model consistently describes the experimental data of the 1-bromoalkane + *n*-alkane mixtures. Furthermore, we have determined the energetic parameters for the Larsen version of the UNIFAC model.

Key words: liquids, mixtures, thermodynamics, group contributions.

Résumé : On presente les volumes molaires d'excès, V^E, à 298.15 K des mélanges binaires de 1-bromoalcane avec un *n*-alcane. Les valeurs de V^E ont éte obtenues a partir des mesures de densité faites avec un densimètre Anton–Paar. Les données disponibles dans la littérature relatives aux énergies de Gibbs en excès, aux enthalpies en excès, aux volumes en excès et aux coefficients d'activité à dilution infini pour cette type de melanges aussi bien que les volumes molaires et les enthalpies de vaporisation ont été uti1lisees pour determiner les paramètres characteristiques du modèle de contribution de groupe de Nitta–Chao. Ce modèle décrit d'une façon consistante les données expérimentales des mélanges 1-bromoalcane + *n*-alcane. Nous avons determiné aussi les paramètres energetiques pour la version de Larsen du modèle de UNIFAC.

Mots clés : liquides, mélanges, thermodynamique, contributions de groupes.

1. Introduction

In previous papers (1, 2), thermodynamic properties of mixtures involving a 1-chloroalkane or a α,ω-dichloroalkane with a *n*-alkane were used to determine the characteristic parameters of the chlorine group and of its interaction with the methyl and methylene groups for the Nitta–Chao (3) model. To continue with the study of mixtures containing other halogenoalkanes, we have determined in this paper, for the first time, the characteristic parameters of the bromine group and of its interaction with the methyl and methylene groups, using the Nitta–Chao model and the Larsen et al. (4) version of UNIFAC. Moreover, in the present work we have measured the excess volumes at 298.15 K and atmospheric pressure of 1-bromoheptane + hexane, heptane, and dodecane and of 1-bromooctane + hexane, octane, and dodecane, since we have not found excess molar volumes in the literature for 1-bromoalkane + alkane systems. The obtained experimental values are compared with those predicted by the Nitta–Chao model.

Kehiaian and Velasco (5) have presented a literature survey until 1987 of the VLE, excess enthalpy, and activity coefficients at infinite dilution. These authors have also determined the dispersive and quasichemical parameters for bromine–bromine and bromine–methylene interactions using the DISQUAC model (6). After 1987, we have only found in the literature VLE data of 1-bromobutane + (hexane, heptane) measured by Rambabu et al. (7) and of 1-bromopropane + heptane obtained by Wisniak et al. (8).

Concerning the UNIFAC model, there are parameters available of bromine–methylene interactions for the original (9), Dang and Tassios (10), and Gmehling et al. (11) versions, whereas there are not published parameters for the Larsen et al. (4, 12) version. In this paper we compare the

predictions of the UNIFAC versions (Tassios, Gmehling, and Larsen) and the DISQUAC and Nitta–Chao models.

2. Experimental

The sources and the purities of the chemicals were *n*-hexane, *n*-heptane, *n*-octane (Fluka, puriss 99.5%), *n*-dodecane, 1-bromooctane (Aldrich, puriss 99%), and 1-bromoheptane (Fluka, puriss >98%). All liquids were used without purification, but prior to the measurements they were kept over Union Carbide 0.4 nm molecular sieves (Fluka) and degassed. The purities of the chemical products were verified by measurement of the densities at 298.15K, which were in agreement with literature values (13–16).

Excess molar volumes were calculated from density measurements made using an Anton–Paar DMA 60/602HP densimeter at 298.15 K. The temperature inside the vibrating tube was measured with an Anton Paar CKT 100 thermometer and was regulated to better than ±0.01 K using a Polyscience PS 9110 thermostat.

Before each series of measurements the instrument was calibrated at atmospheric pressure with air, heptane, and water, which was purified using a Milli-Q Plus System. Liquid mixtures were prepared by weight using a precision digital Sartorius 210-P balance with an accuracy of $\pm 10^{-5}$ g. The possible error in the mole fractions is estimated to be less than 10^{-5}, and the precision of V^E was estimated better than ±0.002 cm^3 mol^{-1}. All molar quantities are based on the IUPAC relative atomic mass table.

3. Experimental results and discussion

The experimental results for the excess molar volumes at 298.15 K are listed in Table 1. A Redlich–Kister equation was fitted to the excess volume values for the binary systems:

$$[1] \qquad V^E/(\text{cm}^3\ \text{mol}^{-1}) = x(1 - x)\ \Sigma A_i(2x - 1)^i$$

where x is the mole fraction of the 1-bromoalkane. The coefficients A_i and the standard deviations given in Table 2 were calculated by the unweighted least-squares method, the degree of the polynomial having been optimized by applying the *F*-test. A graphical representation of the experimental values together with the fitted curves is shown in Fig. 1. We have not found in the literature V^E data for any 1-bromoalkane + alkane mixture.

The excess molar volumes of 1-bromoheptane and 1-bromooctane + alkane present a similar behaviour. The $V^E(x)$ curves are quite symmetrical about $x = 0.5$. Furthermore, the V^E data increase when the size of the alkane grows, being negative for the shorter alkanes and positive for the dodecane. The trend of the excess molar volumes with the bromoalkane length is opposite to the trend with the alkane size, and thus, the V^E values increase when the alkane length increases and the bromoalkane size decreases.

In the literature (4, 17, 18), contrary to the excess volumes, the excess enthalpies for all the mixtures of this type are positive over the whole range of composition. The positive values of the excess enthalpies indicate that the breaking of the pure bromoalkanes and the dispersive interactions of the pure alkanes are more important than the negative contributions due to the formation of dipole–dipole interactions in the bromoalkanes. Besides, the excess enthalpies for the 1-bromoalkane + alkane systems decrease when the length of the 1-bromoalkane chain decreases and the alkane chain increases.

4. The Nitta–Chao model

4.1. Theory

It is a remarkable characteristic of the Nitta–Chao model (3) that the same set of interaction parameters can be used to represent rather accurately the thermodynamic properties of

the mixtures: excess Gibbs energies, G^E, excess enthalpies, H^E, excess volumes, V^E, heat capacities, $C_p{}^E$, and activity coefficients at infinite dilution, γ^∞; as well as thermodynamic properties of the pure liquids such as molar volumes and vaporization enthalpies.

In the Nitta–Chao model (3) the hard-core volume V_i^* has a temperature dependence given by the empirical expression:

$$[2] \qquad V_i^* = V_{i0}^* \exp\left[a_i\left(\frac{1}{T} - \frac{1}{T_0}\right)\right]$$

where V_{i0}^* is the hardcore volume at temperature T_0 (normally 298.15 K), and a_i gives the dependence of V_i^* with the temperature. Both parameters (V_{i0}^*, a_i) and the number of ex-

ternal degrees of freedom of the group (c_i) are determined by fitting the theoretical equations to the experimental data.

The energy of pairwise interaction between groups (Φ_{ij}) is the sum of two contributions:

$$[3] \qquad \Phi_{ij} = -\frac{\varepsilon_{ij}}{\tilde{\nu}} \exp\left(\frac{\kappa}{\tilde{\nu}}\right) - \sigma_{ij}$$

with ε_{ij} being the dispersive interaction energy parameter, κ a constant whose value is 0.7, and σ_{ij} being the nondispersive energy which is temperature dependent and given by

$$[4] \qquad \frac{\sigma_{ij}}{T} = \frac{\sigma^0_{ij}}{T_0} + \sigma'_{ij}\left(\frac{1}{T} - \frac{1}{T_0}\right)$$

where σ^0_{ij} and σ'_{ij} are characteristic parameters of this model. For nonassociating pairs $\sigma_{ij} = 0$, and all the energy is dispersive. However, for associating pairs or polar–polar interactions $\varepsilon_{ij} \neq 0$, and the dispersive energy still gives a contribution.

4.2. Estimation of the characteristic parameters of the Nitta–Chao model and Larsen version of UNIFAC

As for the DISQUAC (6) model and the Tassios and Gmehling versions of UNIFAC (9–11) model, the bromoalkanes were considered, in the Nitta–Chao model, as being formed by a bromine group (Br) and methyl (CH_3) and methylene (CH_2) groups. The number of the contacts of the groups, q_i, is determined by means of the Bondi (19) method. The hardcore volumes, the number of external degrees of freedom of these groups, and the energetic parameter, ε_{CH2CH2}, were taken from Nitta et al. (3). For this reason, only the V^*_{Br}, a_{Br}, c_{Br}, ε_{BrBr}, ε_{BrCH2}, σ^0_{BrBr}, σ'_{BrBr}, parameters need to be fitted to the thermodynamic properties of pure bromoalkanes and of bromoalkanes + alkanes mixtures.

Similarly to what is done in the Larsen version for the chlorine group ($ClCH_2$) we have considered the bromine group as $BrCH_2$.

Furthermore, as in other group contribution models, the energetic parameters involving the groups CH_2 and CH_3 have the same values. In order to keep a low number of characteristic parameters we have made all them independent of the length of the 1-bromoalkanes.

In both models the parameters (Tables 3, 4) were fitted using a database containing the thermodynamical properties of the 1-bromoalkane + alkane systems and a Marquardt (20) optimization algorithm. For the Nitta–Chao model, the constraints imposed by the physical significance of the parameters (1), have also been considered.

The database contains excess Gibbs energies (5, 7, 8), excess enthalpies (5), and activity coefficients at infinite dilution (5) of 1-bromoalkane + alkane mixtures for the two models. Furthermore, for the Nitta–Chao model, vaporization enthalpies (21), excess molar volumes (this work), and molar volumes (15) of pure 1-bromoalkanes have been introduced in the database.

We have not included thermodynamical properties of 1-bromoalkane + cycloalkane systems for the determination of the group parameters, because the methylene group of a cycloalkane is different from the methylene group of a normal alkane in both models.

To analyze the significance of the parameters obtained in the case of the Nitta–Chao model, we have compared the energetic parameters of the chlorine and bromine groups. It is important to point out that the dispersive interaction energies increase in the order Cl < Br, and the nondispersive interaction energies decrease in the order Cl > Br, for 1-halogenoalkanes + alkanes mixtures. These sequences are the

same as those previously obtained by Kehiaian and Velasco (5) for the dispersive and quasichemical interchange energies of the DISQUAC model. These authors explained these trends by taking into account the dipole moments of the molecules and the cohesive energy density of the pure liquids.

5. Theoretical results and discussion

To compare the predictions of all the thermodynamic properties with the Nitta–Chao model with the Larsen version, and with other group contribution models, we have used the percentage mean deviation, PMD defined by

$$[5] \qquad \mathrm{PDM} = \frac{100}{N_Y} \sum \frac{\left| Y_{\mathrm{exp}} - Y_{\mathrm{theo}} \right|}{\left| Y_{\mathrm{exp}} \right|}$$

where Y_{exp} and Y_{theo} are, respectively, the experimental and predicted values for the thermodynamic property Y and N_Y is the number of experimental values for this property.

Pure liquids

The percentage mean deviations between experimental (15, 21) and predicted values for the molar volumes, V_m, and the vaporization enthalpies, H_v, are about 0.9 and 1.2%, respectively. It can be seen in Figs. 2 and 3 that the Nitta–Chao model with the parameters calculated in this work gives a very good representation of the variation of these properties with the length of the 1-bromoalkane chain and with the temperature.

Mixtures

In Tables 5–7 the theoretical predictions obtained in this work for equimolar composition of the mixing properties of the 1-bromoalkane + alkane systems, using the parameters calculated by us, are presented. For comparison we have also listed the theoretical predictions using DISQUAC and the Tassios and Gmehling versions of the UNIFAC model.

The overall percentage mean deviations obtained for the excess Gibbs energies, G^E, are 13, 21, 21, and 26% for the Nitta–Chao model and the Larsen version with our parameters, the DISQUAC model, and the Gmehling version, respectively. In Table 5 we can see that all models reproduce the temperature dependence of the excess Gibbs energy for 1-bromopentane + pentane; this property decreases when the temperature increases. In Fig. 4 we show that the Nitta–Chao and DISQUAC models reproduce remarkably well the magnitude and the symmetry of the $G^E(x)$ curves.

For the excess enthalpies, H^E, the percentage mean deviations are 8% for the Nitta–Chao model with our parameters, DISQUAC model, and Tassios version, 9% for the Larsen version with our parameters, and 19% for the Gmehling version. In Table 6 it is possible to observe that the Nitta–Chao model and the Larsen version correctly predict the sequences with the length of the 1-bromoalkane and alkane chains. The other models reproduce also the above mentioned sequences. Figure 5 shows the predictions obtained

for two examples. The symmetry of the curves is reproduced quite well by the Nitta–Chao model.

In the case of the logarithm of the activity coefficients at infinite dilution, the percentage mean deviations are 19, 37, 79, and 21% for the Nitta–Chao model and Larsen version with our parameters, DISQUAC model, and Gmehling version, respectively.

The excess molar volumes (Table 8) measured in this work present a percentage mean deviation of about 14% with the Nitta–Chao model and the parameters calculated by us. The poorer results are obtained in systems containing hexane, as can be seen in Figs. 1 and 6. The mean deviation is reduced until 5% if the mixtures containing *n*-hexane are excluded. We think that the Nitta–Chao model can not reproduce well the excess volumes for the systems that present a great packing effect, such as the systems composed by a large 1-halogenoalkane and a short alkane. In fact, for 1-chloroalkane + alkane mixtures (1), the overall mean deviations for V^E were 21%, but for the case with the bigger packing effect for which there are available V^E data (1-chlorohexane + hexane), the deviation increases until 100%.

Finally, we can see that the Nitta–Chao model, for all properties, gives the best description and that only this model is able to predict excess molar volumes. Although the

DISQUAC model predicts excess Gibbs energies and excess enthalpies with a precision better than the Larsen and Gmehling versions, for the activity coefficients at infinite dilution the best results are obtained with this last version. These results confirm that the Nitta–Chao and DISQUAC models are more appropriate for mixtures containing a polar molecule, bromoalkanes in this case, due to the inclusion in the expression for the interaction energies of a nondispersive term (σ^0_{BrBr} and σ'_{BrBr} for the Nitta–Chao model and C^{quac} for the DISQUAC model).

6. Conclusions

We have determined, for the Nitta–Chao model, the structural parameters for the bromine group and its interaction with the methyl or methylene groups for 1-bromoalkane + alkane binary systems by using an updated database of excess enthalpies, excess Gibbs energies, and excess volumes for the mixtures, together with vaporization enthalpies and molar volumes of the pure 1-bromoalkanes. Moreover we have calculated, for the first time in the literature, the energetic parameters between the bromine and methyl or methylene groups of the Larsen version of UNIFAC.

Compared with other group contribution models such as DISQUAC and UNIFAC (in Tassios, Larsen, and Gmehling versions), the Nitta–Chao model with our parameters is distinguished, since this model gives the best results and the other models cannot predict the excess volumes, vaporization enthalpies, and molar volumes.

In the future, we will try to extend the parameter matrix for the Nitta–Chao model, by determining the structure-dependent interaction parameters for the α,ω-dibromoalkane + alkane mixtures in order to improve the predictions for this kind of mixtures, as was done for α,ω-dichloroalkane + alkane systems (2). In addition, we will extend this study to mixtures containing other halogenoalkanes (iodoalkanes and fluoroalkanes).

Oxidation of secondary alcohols and ethers by dimethyldioxirane

Alfons L. Baumstark, Franci Kovac, and Pedro C. Vasquez

Abstract: The oxidation of several series of secondary alcohols **2**–**9**, ethers **10**–**17**, and related derivatives **18** and **19**, by dimethyldioxirane, **1**, in acetone at 25°C produced the corresponding ketones in good to excellent yields for all but two cases. (The exceptions: oxidation of 1-methoxy-2-methyl-1-phenylpropane (48%) and 1-methoxy-2,2-dimethyl-1-phenylpropane (24%).) The oxidation of the secondary alcohols was found to yield k_2 values that were roughly 10-fold greater than those of the corresponding methyl ethers. The rate constant for oxidation of a silyl ether was slightly lower than that for the corresponding methyl ether while that for the ester derivative was roughly half the value. For oxidation of alcohols and methyl ethers, the k_2 values became smaller as the R″ series (Me, Et, *n*Pr, iPr, and *t*Bu) increased in steric bulk ($\rho^* = 1.7$; $r = 0.998$ and $\rho^* = 3.2$; $r = 0.95$, respectively). The Hammett study for the oxidation of the methyl ethers of α-methyl-*p*-benzyl alcohols (**10**, **20**–**25**) yielded a ρ value of –0.74. The activation parameters for oxidation of the parent compound of the ether series (1-methoxy-1-phenylethane) were $\Delta H^{\ddagger} = 14.8 \pm 0.5$ kcal/mol, $\Delta S^{\ddagger} = -21.9$ eu, $\Delta G^{\ddagger} = 21.3$ kcal/mol, k_2 (25°C) = 1.6×10^{-3} M^{-1} s^{-1}. The mechanistic aspects of the oxidation are discussed in relation to two mechanistic extremes: (*a*) direct insertion of the oxygen atom into the C—H bond and (*b*) direct abstraction of the H by dimethyldioxirane to yield a caged-radical pair, with subsequent coupling to hemi-ketal intermediates that fragment to yield acetone, alcohol or water, and ketone as the final products.

Key words: dimethyldioxirane, oxidation.

Résumé : L'oxydation de plusieurs séries d'alcools secondaires (**2**–**9**), d'éthers (**10**–**17**) et de dérivés apparentés (**18** et **19**), par le diméthyldioxirane (**1**) dans l'acétone, à 25°C, conduit aux cétones correspondantes avec des rendements allant de bons à excellents (à l'exception des deux cas suivants : 1-méthoxy-2-méthyl-1-phénylpropane (48%) et 1-méthoxy-1-phénylpropane (24%)). On a observé que les valeurs de k_2 des alcools secondaires sont environ 10 fois plus élevées que celles des éthers méthyliques correspondants. La constante de vitesse d'oxydation d'un éther silylé est légèrement inférieure à celle de l'éther méthylique correspondant alors que celle du dérivé ester est approximativement égale à la moitié de la valeur. Pour l'oxydation des alcools et des éthers méthyliques, les valeurs de k_2 deviennent de plus en plus faibles avec une augmentation de l'empêchement stérique (Me, Et, *n*Pr, iPr, *t*-Bu) de la série R″ ($\rho^* = 1{,}7$; $r = 0{,}998$ et $\rho^* = 3{,}2$; $r = 0{,}95$ respectivement). Une étude de Hammett pour l'oxydation des éthers méthyliques des alcools benzyliques **10** et **20–25** conduit à une valeur de ρ de –0,74. Les paramètres d'activation pour l'oxydation du produit parent de la série des éthers (1-méthoxy-1-phényléthane) sont: $\Delta H = 14{,}8 \pm 0{,}5$ kcal/mol, $\Delta S = 21{,}9$ ue; $\Delta G = 21{,}3$ kcal/mol et k_2 (25°C) = $1{,}6 \times 10^{-3}$ M^{-1} s^{-1}. On discute des aspects mécanistiques de l'oxydation en relation avec deux mécanismes extrêmes : (*a*) insertion directe de l'atome d'oxygène dans la liaison C—H et (*b*) enlèvement direct de l'hydrogène par le diméthyldioxirane, conduisant à une paire de radicaux en cage, suivie d'un couplage subséquent formant des intermédiaires hémicétals qui se fragmentent ensuite pour donner de l'acétone, de l'alcool ou de l'eau et la cétone comme produits finals.

Mots clés : diméthyldioxirane, oxydation.

[Traduit par la Rédaction]

Introduction

Dimethyldioxirane, **1**, has become an extremely versatile reagent for the fast, mild oxidation of a great variety of organic substrates (for reviews, see ref. 1) since the initial report of its isolation and characterization (2, 3). Although considerably less reactive than methyl(trifluoromethyl)dioxirane (4), dimethyldioxirane is often the reagent of choice because of its facile, inexpensive preparation. For example, dimethyldioxirane has been shown to be useful (1) for olefin epoxidation, heteroatom oxidation, and oxidation of C—H bonds of saturated hydrocarbons, phenyl-substituted hydro-

carbons, aldehydes, and alcohols (5). In addition, there have been several reports on the use of **1** for the removal of benzyl protecting groups of alcohols (6) as well as the oxidation of other ethers, acetals, and orthoesters (7). Similar conversions have been carried out with methyl(trifluoromethyl)dioxirane (8). An earlier study (5*e*) of the reaction of **1** with benzaldehydes to produce benzoic acids indicated that the formal CH insertion process involved radical intermediates. Recently, a mechanistic study (5*f*) on the reaction of substituted α-methylbenzyl alcohols with dimethyldioxirane yielded results that could be interpreted as consistent with a direct reaction to yield caged-radical pairs. CH insertion studies on more difficult-to-oxidize positions by dioxiranes have been interpreted (8) to be consistent with a concerted insertion process. We report here a study of the oxidation of a series of secondary alcohols, the corresponding ethers, and related compounds by dimethyldioxirane in acetone.

Results

The reaction of excess dimethyldioxirane, **1**, with secondary alcohols (1-phenylethan-1-ol, **2**; 1-phenylpropan-1-ol, **3**; 1-phenylbutan-1-ol, **4**; 1-phenyl-2-methylpropan-1-ol, **5**; 1-phenyl-2,2-dimethylpropan-1-ol, **6**; benzhydrol, **7**; α-cyclopropylbenzyl alcohol, **8**; 1-phenyl-2-propanol, **9**), corresponding methyl ethers, **10**–**17**, and related compounds (1-trimethylsilyloxy-1-phenylethane, **18**; 1-acetoxy-1-phenylethane, **19**; 1-(*p*-anisyl)-1-methoxyethane, **20**; 1-(*p*-tolyl)-1-methoxyethane, **21**; 1(*p*-fluorophenyl)-1-methoxyethane, **22**; 1-(*p*-chlorophenyl)-1-methoxyethane, **23**; 1-(*p*-bromophenyl)-1-methoxyethane, **24**; 1-(*p*-trifluoromethylphenyl)-1-methoxyethane, **25**) produced the corresponding ketones in good to excellent yields in most cases (reaction [1]). Generally, under similar conditions the yields of ketones were higher from the oxidation of alcohols **2**–**9** than from that of the methyl ethers **10**–**17**.

In most cases, at least a threefold excess of **1** was necessary to achieve efficient conversion. For all but the slowest oxidation reactions, use of an inert (N_2) atmosphere resulted in product yields within experimental error of those obtained when open to the atmosphere. Low yields of ketones were obtained in two cases, the dimethyldioxirane oxidation of 1-methoxy-2-methyl-1-phenylpropane, **13**, and 1-methoxy-2,2-dimethyl-1-phenylpropane, **14** (48% and 24%, respectively). The products (ketones) were isolated and identified by comparison of NMR and GC–MS data with those of authentic samples. The product yields are listed in Table 1.

Kinetic studies of the oxidation of **2**–**19** were carried out in acetone at 25°C by UV techniques. Excellent linear correlations were obtained under pseudo-first-order conditions with either the dioxirane or the substrate in at least a 10-fold

[b] Pseudo-first-order conditions with 10-fold excess of dioxirane.

excess. Either approach yielded k_2 values within experimental error (±5%) as expected for this second-order reaction. For convenience, most experiments were carried out with a 10-fold excess of dioxirane. Reproducibility between duplicate runs was excellent (generally 1–2%). In general, the k_2 values for oxidation of the alcohol series were at least 10-fold greater than those for the corresponding methyl ether series. The k_2 values for **13** and **14**, the only compounds for which the product yields were poor, were the lowest in the entire set of data. Formal replacement of the methyl ether in **10** by either the trimethylsilyl ether (**18**) or the acetate (**19**) yielded k_2 values that were slightly lower with excellent product yields. Formal replacement of the phenyl group in compounds **2** and **10** by a benzyl group (**9** and **17**) produced k_2 values that were three- and twofold slower, respectively. Oxidation of both the alcohol and methyl ether series showed the same general trend: as the alkyl group in the α-position (R″, Table 1) becomes bulkier, the k_2 value becomes smaller (Me > Et > *n*Pr > iPr > *t*Bu). An excellent correlation (r = 0.998) was obtained for a plot of log k_2 vs. σ* with a Taft ρ* value of 1.7 for compounds **2**–**6**. The corresponding methyl ether series, **10**–**14**, showed a marginal correlation (r = 0.95) with a ρ* of 3.2. The k_2 value for R″= cyclopropyl in both series is only slightly lower than for R = methyl, and higher than for R″ = ethyl. A minor discrepancy between the two series is for R″ = phenyl: k_2 for **7** falls between **5** (R″ = iPr) and **6** (R″ = *t*Bu); and k_2 for **15** is slightly faster than that for **10** (R″ = Me). The kinetic data (second-order rate constants k_2) are summarized in Table 1.

The oxidation reaction of 1-methoxy-1-phenylethane (**10**) and *p*-substituted analogs **20**–**25** by dimethyldioxirane was chosen for futher characterization. Unlike epoxidation reactions (5*e)* with **1**, the ether oxidations did not show large changes in rate upon addition of water to the solvent. This result is similar to that found (5*f*) for the dimethyldioxirane oxidation of α-methylbenzyl alcohols. Rate accelerations that correlated with the hydrogen bond donor capacity of the medium have been noted (5*c*) for the reaction of **1** with *cis*-1,2-dimethylcyclohexane. Additional solvent effect studies including some intramolecular hydrogen-bonding effects have been described (*5g*). The rate constants for the oxidation of **10** were determined at 5° intervals from 20° to 45°C (see Table 2). The activation parameters determined by the Arrhenius method were found to be $\Delta H^{\ddagger}$ = 14.8 ± 0.5 kcal/mol; $\Delta S^{\ddagger}$ = –21.9 e.u.; $\Delta G^{\ddagger}$ = 21.3 kcal/mol; k_2 (25°C) = 1.63 × 10^{-3} M^{-1} s^{-1}. In addition, the oxidation of *p*-substituted analogs of **10** showed that electron-donating groups increased the rate of oxidation while electron-withdrawing groups decreased it. A Hammett plot of the second-order rate constants at 25°C for oxidation of **10** and **20**–**25** by **1** showed an excellent LFER against σ_p constants with a ρ value of –0.74 ± 0.03. These data are shown in Table 3.

Discussion

The oxidations of secondary alcohols and hydrocarbons by **1** and methyl(trifluoro-methyl)dioxirane have been interpreted (1, 5*a*–*d*, 8) in terms of direct reaction without involvement of a chain process. Recently, Ingold and coworkers (9) have shown, based on radical rearrangement arguments, that the oxidation of 2-cyclopropylpropane by **1** is not a free-radical chain process. Historically, the AIBN catalyzed O_2 oxidation of benzyl methyl ether was found (10*a*) to be faster than that of benzyl alcohol. The direct reaction of **1** with secondary methyl ethers also shows different characteristics from those of free-radical chain processes. The results clearly show that the oxidation of secondary alcohols by **1** is at least 10-fold faster than that of the corresponding methyl ethers and related derivatives. The Hammett ρ value of –0.74 for oxidation of methyl ethers **10** and **20**–**25** by **1** is essentially equivalent to that of –0.7, as was obtained (5*f* : note, the ρ value reported was off by 2.303; correct value is –0.7) for the oxidation of alcohol **2** derivatives. Free-radical reactions on benzyl ethers, hydrogen atom abstraction by alkyl peroxy radicals on benzyl phenyl ether (5, 9*a*), or by benzoyloxy radicals on dibenzyl ether (5, 10*b*), were found to show ρ values of –0 and –0.65, respectively. The direct reaction of *p*-nitroperbenzoic acid with substituted benzyl

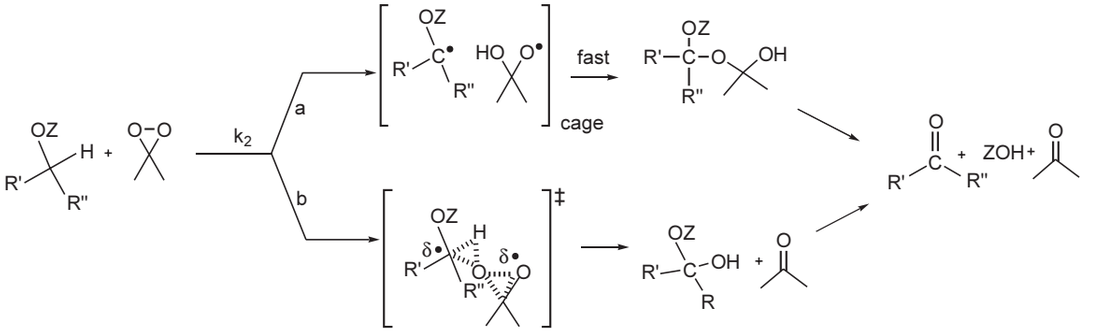
Scheme 1.



methyl ethers was found (11*a*) to show a ρ^+ value of –0.9. The differences in activation parameters for oxidation of the secondary methyl ethers by **1** vs. those of the secondary alcohols (5*f*) are roughly an increase of 3 kcal/mol in $\Delta H^{\ddagger}$ and a decrease in $\Delta S^{\ddagger}$ (less negative). A $\Delta S^{\ddagger}$ of approximately –15 eu has been estimated (8) for the oxidation of cyclohexanol by methyl(trifluoromethyl)dioxirane. The relative reactivity as a function of R″ within the alcohol and methyl ether series shows similar trends. Plots of log k_2 vs. σ^* constants give reasonable correlations with the greater sensitivity found in the ether series. The sign of the ρ^* is opposite that of the Hammett ρ value and opposite that found (11*b)* for ρ^* for the reaction of *p*-nitroperbenzoic acid with substituted alkenes. The ρ^* of reaction [1] presumably is strongly influenced by steric effects. The data showed a poor correlation with the Taft steric parameter (E_S). The lower reactivity of methyl ether series coupled with the larger range of relative reactivity could be viewed as a steric effect. Alternatively, it could be argued that the alcohols undergo faster oxidation by **1** due to hydrogen bonding with **1** and (or) the solvent. Our deuterium isotope effect study (5*f*) for the oxidation of **2** with dimethyldioxirane has shown a k_{OH}/k_{OD} value of 1.09. This value could represent a large secondary effect or perhaps an extremely small primary effect, indicative of a hydrogen bond between the alcohol OH and the dioxirane in the transition state.

The reaction of dimethyldioxirane with secondary alcohols, ethers, and related derivatives can be viewed in terms of two mechanistic extremes: (*a*) a direct insertion process and (*b*) a caged-radical process (Scheme 1). The direct insertion process has been postulated (1, 8) to involve an "oxenoid" atom insertion into the side of the C—H bond via a multicentered transition state. Our previous study (5*f*) of the oxidation of α-methylbenzyl alcohols by **1** was interpreted in terms of a caged-radical process in which direct reaction of **1** and the substrate yields a singlet pair of radicals that are not solvent separated. For the caged-radical process to be valid, combination of the radicals must be faster than both rearrangement of the carbon-based radical and escape from the cage. In addition, for the oxidation of methyl ethers (Z = Me), the caged-radical process must yield a hemiketal, which would be expected to rapidly fragment to the final products. The concerted process has been favored (8) as the simplest explanation due, in part, to the lack of detection of (hemiketal) intermediates for secondary alcohol and hydrocarbon oxidation. At present, the data do not clearly distinguish between these two possibilities. Note that for secondary ether oxidation, hemiketal intermediates must be formed regardless of pathway. The two mechanisms are not necessarily mutually exclusive. The trajectory of approach of the dioxirane to the C—H bond remains to be elucidated.

In conclusion, the oxidation of secondary alcohols, methyl ethers, and related derivatives with excess dimethyldioxirane generally produces high yields of ketones. Reaction times are convenient if a 10-fold excess of dioxirane is employed. The differences in reactivity with each series and between different series of compounds show the method to be of synthetic utility.

Experimental

A. General

Infrared spectra were recorded on a Perkin–Elmer system 2000 FT-IR spectrophotometer. All ^{1}H NMR and ^{13}C NMR spectra were obtained in chloroform-d_1 at 30°C on a Varian 300 MHz spectrometer. The GS–MS data were obtained on a Shimadzu GC-17A gas chromatograph coupled to a Shimadzu QP-5000 mass spectrometer.

All solvents were either spectral or HPLC grade (Aldrich). Dimethyldioxirane (**1**) was prepared and isolated by a modified version (12) of the general method developed by Murray and Teyaraman (3*a*). The redistilled acetone solution (≤0.1 M) of **1** was stored at –20°C with little or no decomposition after several weeks (over $MgSO_4$). Initial dioxirane concentration was determined by NMR techniques (integration of thioanisole and oxidation product signals) for reaction of the stock solution with a known quantity of thioanisole. The value was within experimental error (±5%) of that determined by monitoring the change in absorbance at 330 nm before and after reaction with excess 2,3-dimethyl-2-butene (added neat via syringe) and dividing by the ε value of 12.9. All the final products (ketones) and alcohols **2**, **3**, **6**, **7**, and **9** were commercially available (Aldrich) and were used without further purification. Alcohols **4**, **5**, and **8** were prepared from the corresponding ketones (Aldrich) by conventional $NaBH_4$ reduction and were purified by vacuum distillation. Methyl ethers **10**–**17** and **20**–**25** were prepared in ~65% yields by a two-step procedure: first, the parent ketones of alcohols **2–9** were converted to their corresponding dimethyl ketals (13) by treatment with methyl orthoformate in methanol (HCl catalyst); after purification by vacuum distillation the dimethyl ketals were converted to the corresponding methyl ethers (14*a*) by treatment with $AlCl_3$ in ethyl ether, followed by $LiAlH_4$; the methyl ethers were purified by vacuum distillation. The boiling points of the methyl ethers were in good agreement with literature values (14). Silyl

© 1999 NRC Canada

ether **18** and acetate **19** were prepared from alcohol **2** by standard silylation (Me_3SiCl–Et_3N) and acylation (Ac_2O) procedures, and were purified by vacuum distillation. All compounds were characterized by physical and spectral (^1H NMR, IR, and GC–MS) data.

B. Kinetic studies

Kinetic experiments were performed using a Shimadzu UV-3101PC UV-VIS-NIR scanning spectrometer. The cell temperature (25°C unless specified) was maintained via a constant temperature circulating bath (± 0.3°C) and was checked before and after each kinetics run using a YSI model 425C telethermometer with a number 423 probe. The following is a general, representative procedure for the kinetics studies: dimethyldioxirane solutions (1.000 mL, 10 equiv.) of known concentration (≤0.100 M) in dried acetone were placed in a 1 cm UV cell at the desired temperature. After temperature equilibration, 1.0 equiv. of the substrate in 0.100 mL acetone was added via syringe and the solution was rapidly mixed by bubbling air via disposable pipet. The reaction was monitored by measuring the change in absorbance at 380 nm vs. time (pseudo-first-order conditions). The ε value at 380 nm for **1** is 4.51 ± 0.03. The value of the relative absorbance was determined by subtraction of the final value from the instantaneous value as a function of time. The pseudo-first-order rate constants (k_{obs}) were calculated by plotting the ln (relative absorbance) versus time and were linear for at least two half-lives. The second-order rate constants (k_2) were calculated by dividing the pseudo-first-order rate constant (k_{obs}) by the initial concentration of dimethyldioxirane. Reproducibility between runs was generally better than 5% of the k_2 value. Correlation coefficients were excellent for all experiments. Several experiments were repeated under pseudo-first-order conditions with the substrate in 10-fold excess. The rate constants were found to be essentially identical (within experimental error) to those determined with **1** in excess, confirming the validity of the approach.

C. Product studies

The products from the reaction of compounds **2**–**25** with 3 equiv. of isolated dimethyl-dioxirane at room temperature (~1.5 mmol of substrate) were analyzed after 6–24 h by GC–MS. The GC–MS data showed the ketones to be formed in high yield in all cases except for oxidation of **13** and **14**. The GC–MS data were in excellent agreement with those of authentic ketone samples. After removal of the solvent (acetone), the residue was taken up in $CDCl_3$ and then was analyzed by ^1H NMR spectroscopy. The ^1H NMR data were in agreement with those of authentic (commercial) ketone samples. For most cases (within experimental error), little or no reduction in final ketone yields was observed for reactions carried out under inert (N_2) atmosphere. The percentage yields (±4%) were determined (with anisole as added internal standard) from the ^1H NMR spectral data.

One-dimensional ribbons of solvated Ag sulfonates

George K.H. Shimizu, Gary D. Enright, Gabriela S. Rego, and John A. Ripmeester

Abstract: Single crystal X-ray structure determinations of two solvated silver sulfonates have been obtained and these compounds have been shown to adopt infinite one-dimensional motifs. $\{AgOTs(MeCN)\}_\infty$ (OTs = *p*-toluenesulfonate) crystallizes in the monoclinic space group, $P2_1$, a = 8.4278(5) Å, b = 5.7413(3) Å, c = 12.1057(7) Å, β = 109.24(1)°. $\{Ag(NDSA)(MeCN)_2(H_3O)(H_2O)_2\}_\infty$ (NDSA = 1,5-naphthalenedisulfonate) crystallizes in the triclinic space group, $P\bar{1}$, a = 8.3407(4) Å, b = 10.4374(5) Å, c = 12.3399(6) Å, α = 101.941(8)°, β = 109.24(1)°, γ = 102.190(8)°. Despite one compound containing a monosulfonate and the other a disulfonate, both complexes form infinite one-dimensional arrays.

Key words: silver, sulfonates, coordination polymer.

Résumé : Une détermination de structure de deux sulfonates d'argent solvatés par rayons X sur un cristal unique montre que ces composés adoptent un motif infini unidimensionnel. Le composé $\{AgOTs(MeCN)\}_\infty$ (OTs = *p*-toluènesulfonate) cristallise dans le groupe d'espace monoclinique $P2_1$, avec a = 8,4278(5) Å, b = 5,7413(3) Å, c = 12,1057(7) Å, β = 109,24(1)°. Le composé $\{Ag(NDSA)(MeCN)_2(H_2O)_2\}_\infty$ (NDSA = 1,5-naphtalènedisulfonate) cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec a = 8,3407(4) Å, b = 10,4374(5) Å, c = 12,3399(6) Å, α = 101,941(8)°, β = 109,24(1)°, γ = 102,190(8)°. En dépit du fait qu'un composé soit un monosulfonate et l'autre un disulfonate, les deux complexes forment une chaîne infinie à une dimension.

Mots clés : argent, sulfonates, polymère de coordination.

Introduction

The coordinate covalent bond is increasingly being recognized as a powerful tool in the generation of ordered solid state arrays (1). We are in the process of probing the chemistry of silver(I) with sulfonate anions (2). These compounds form a layered network bearing a strong structural analogy to the much studied Zr phosphonates (3). A characteristic of silver(I) is its rather pliant coordination sphere. Coordination numbers ranging from two to four are common and even five- and six-coordinate complexes have been observed (4). In a positive light, this imparts an element of versatility to the frameworks. However, this flexibility comes at the cost of predictability of the overall structure, a crucial factor for crystal engineering (5). Elucidation of the fundamental bonding interactions, which exist in solution prior to crystallization, is critical if a true element of structural control is to be achieved.

Silver *p*-toluenesulfonate, AgOTs, forms an infinite lamellar structure containing 7-coordinate silver(I) and a fivefold bridging sulfonate group (2). This crystal structure was obtained from relatively non-coordinating solvents (MeOH, ether). As part of our ongoing examination of solvent effects on the structures of silver sulfonates, we present the coordination polymer structures of two silver sulfonates, $\{AgOTs(MeCN)\}_\infty$, **1**, and $\{Ag(NDSA)(MeCN)_2(H_3O)(H_2O)_2\}_\infty$ (NDSA = 1,5-naphthalenedisulfonate), **2**, grown from solutions of a coordinating nitrile solvent. Despite one compound containing a monosulfonate and the other a disulfonate, both complexes form infinite one-dimensional arrays.

Results and discussion

Crystallographic data for **1** and **2** are presented in Tables 1–5.

Structure of $\{AgOTs(MeCN)\}_\infty$, 1

Commercially available AgOTs was dissolved in MeCN and single crystals were grown by the slow diffusion of isopropyl ether into this solution. Figure 1 shows the structure of the resulting one-dimensional array. Each Ag(I) ion adopts a distorted tetrahedral geometry comprising three sulfonate oxygen atoms (Ag—O distances are 2.308(2), 2.364(3), and 2.438(3) Å), each from a different OTs group, and a nitrogen donor from a coordinated MeCN molecule (2.187(2) Å). Bond angles around Ag range from 94.94(9)°

to 131.9(1)°. Each toluenesulfonate ion is coordinated, via two of the oxygen atoms, to two different silver(I) centers. Figure 2 shows the packing, along the *b* axis, of the one-dimensional arrays. There are no interactions, save for van der Waals' contacts, between adjacent 1-D polymers. It should be noted that the MeCN in this structure is lost quite readily to afford a white solid. This desolvated product has been determined, by powder X-ray diffraction, to have the same layered structure as single crystals grown from a methanolic solution.

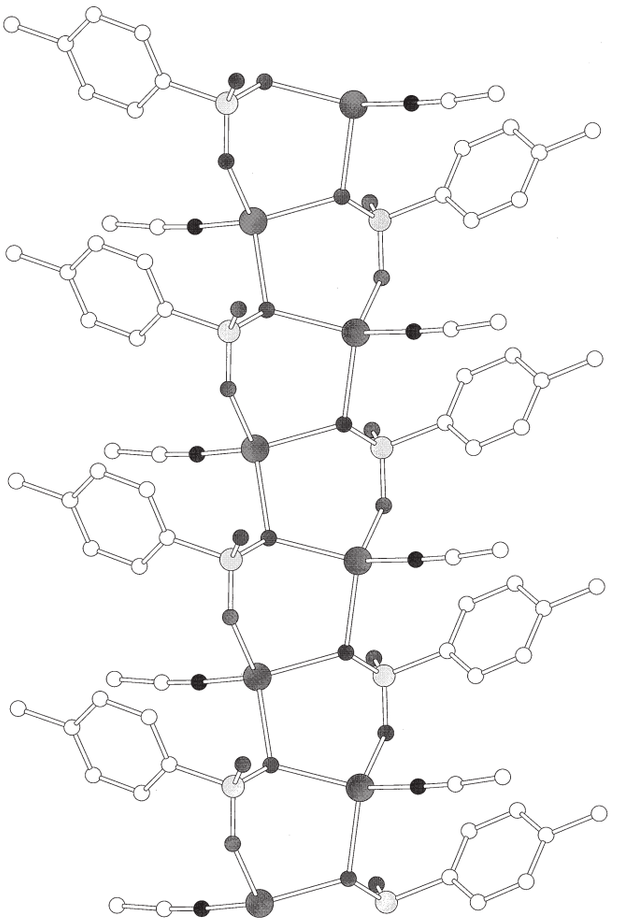
sodium salt of 1,5-naphthalenedisulfonic acid tetrahydrate. Interestingly, the formulation of the crystals contains only a 1:1 ratio of metal to disulfonate. To achieve charge balance, a single hydronium ion, originating from the hydrate molecules of the starting sulfonate salt, is present in the unit cell.

The structure of **2** reveals another one-dimensional polymeric structure. The nature of the extended system is fundamentally different than that in **1** as, in this case, there are two different sulfonate groups on each ligand. Figure 3 shows that each sulfonate group functions in a monodentate manner coordinating to a single silver(I) center (Ag—O = 2.380(2) and 2.439(2)Å). In **1**, the multidentate coordination mode of the SO_3 groups is the basis of the polymeric architecture. The coordination environment around silver is a tetrahedron comprised of two sulfonate oxygen atoms, from different disulfonate molecules, and two MeCN molecules (Ag—N = 2.204(3) and 2.220(2)Å). As the sulfonate ligand is dianionic and only a single silver(I) ion is present for each of these molecules, a hydronium ion (H_3O^+) is also present. The hydronium ion, along with two water molecules, forms part of a hydrogen-bonded $H_7O_3^+$ bridge between sulfonyl oxygen atoms of adjacent $Ag(NDSA)^-$ ribbons, as shown in Fig. 4. O—O distances in the H-bonded array range from 2.459(2) to 2.703(2) Å. Figure 5 shows the overall packing motif of **2**, where $(Ag\text{-}NDSA)^-$ layers alternate with layers of $H_7O_3^+$ units.

Fig. 1. Single crystal X-ray structure of **1**, showing the infinite one-dimensional array and coordination of MeCN at silver(I). Hydrogen atoms omitted for clarity.



Crystals of **2** lose solvent readily, as did the crystals of **1**, to afford a white powder. Our attempts to index the powder X-ray diffraction pattern of this compound have not been successful, possibly indicating the presence of lower symmetry. However, the present results lend encouragement towards the prospect of forming infinite lamellar networks with the disulfonate ligands, where the disulfonate moieties would act to "pillar" the interlayer region (6). Further studies on the effects of different solvents and anhydrous conditions are in progress.

Preparation, isolation, and characterization of permethylated galactosides and fucosides

Daniel D. Asres and Hélène Perreault

Abstract: Sugar analysis involving permethylation followed by methanolysis can lead to significant results, given that permethylated monosaccharide standards are available for comparison of spectral and chromatographic data. Such standards are not readily commercially available, especially the furanoside forms. This note describes the isolation and characterization of permethylated pyranoside and furanoside species of D(+)-galactose and L(–)-fucose. Separation of the isomers was optimized using a combination of column chromatography and continuous elution thin-layer chromatography (TLC). TLC, gas chromatography – mass spectrometry, and ^{1}H nuclear magnetic resonance (NMR) spectroscopy were used as the characterization methods. The isolation of furanosides is emphasized, since no specific NMR data have been reported on those to date, while several reports have already discussed the structural aspects of pyranosides.

Key words: permethylation, monosaccharide, GC–MS, TLC, NMR.

Résumé : Une analyse des sucres faisant intervenir une perméthylation suivie d'une méthanolyse peut donner des résultats significatifs en autant que des standards de monosaccharides perméthylés soient disponibles pour comparer les données spectrales et chromatographiques. De tels standards ne sont pas facilement accessibles commercialement surtout en ce qui a trait aux formes furannosides. Ce travail décrit l'isolement et la caractérisation de furannosides et de pyrannosides perméthylés du D(+)-galactose et du L(–)-fructose. On a optimisé la séparation des isomères en utilisant une combinaison de chromatographie sur colonne et de chromatographie en couche mince avec élution continue (TLC). On a utilisé comme méthodes d'analyse : la TLC, la chromatographie en phase gazeuse couplée avec la spectrométrie de masse et la RMN du ^{1}H. On a mis l'accent sur l'isolement des furannosides pour lesquels aucune donnée spécifique de RMN n'existe jusqu'à ce jour dans la littérature, alors que l'on dispose de plusieurs données relatives aux aspects structuraux des pyrannosides.

Mots clés : perméthylation, monosaccharide, GC–MS, TLC, RMN.

Introduction

Methylation analysis has, for more than 40 years, played an important role in the characterization of carbohydrates. Methylated sugar derivatives are in general less polar and more volatile than their unmodified analogs, which makes their characterization more feasible by a variety of methods. Gas chromatography – mass spectrometry (GC–MS) is one of the most popular techniques used to identify and quantify methylated sugars. Several methylation procedures have been established, some yielding partially methylated products (1–3) and others producing permethylation (4–8). Several articles (e.g., refs. 9–12) reported that permethylation of a monosaccharide produces at least two, and up to four isomers, which are five- and six-membered ring compounds. The formation of seven-membered ring permethylated sugars has also been discussed (13).

In our hands, using the Ciucanu and Kerek permethylation method (7), mainly furanosides and pyranosides are obtained (12). We recently reported on the influence of permethylation reaction conditions upon the isomeric ratios obtained for two monosaccharides, D(+)-galactose and L(–)-fucose (12). We can take advantage of these experimental conditions and apply them to permethylation toward preparation of pure, single galactosides and fucosides. In this paper, we report on inexpensive methods of preparing pure permethylated hexosides of D(+)-galactose and L(–)-fucose. These methods include (*i*) permethylation of commercially available methyl pyranosides, and (*ii*) permethylation of hexoses followed by separation of isomers by column chromatography or continuous elution thin-layer chromatography (TLC). Such separations of permethylation products of monosaccharides have already been reported (14–18), although the emphasis was on recovery of permethylated pyranoside isomers and no

mention was made about isolation of the furanosides (15–18). The initiative for achieving this work thus came from the great difficulty in locating reference ^{1}H nuclear magnetic resonance (NMR) and mass spectral data for the furanoside isomers produced by permethylation of galactose and fucose. Extensive ^{1}H and ^{13}C NMR studies on permethylated pyranosides have been reported (15–18), and their electron impact mass spectra are available from a library (19).

Experimental

Materials

D(+)-Galactose and L(–)-fucose were purchased from Sigma (St. Louis, Mo.). Methyl iodide (CH_3I) was obtained from Aldrich Chemicals (St. Louis, Mo.). The α and β forms of methyl galacto- and fucopyranoside were from Sigma. The α and β forms of methyl galactofuranoside and methyl-β-fucofuranoside were purchased from Color Your Enzyme (Kingston, Ont.). Dimethyl sulfoxide (DMSO) was obtained from Pierce Chemicals (Rockport, Ill.). The other solvents were glass-distilled or HPLC grade and obtained from Mallinckrodt (Paris, Ky.). Water was obtained from a Barnstead Nanopure II^{TM} purification system fed with water purified by reverse osmosis. Small TLC plates were cut from aluminium sheets coated with silica gel 60 F_{254} (E. Merck, Darmstadt, Germany). Silica gel 60, 230–400 mesh, 40–63 μm, used for column chromatography was obtained from Mallinckrodt. The large TLC plates (20 cm × 20 cm, glass coated with a 1 mm thick layer of silica gel 60) were obtained from E. Merck.

Permethylation of the hexoses and preparation of reference standards

D(+) Galactose and L(–) fucose were permethylated based on the method developed by Ciucanu and Kerek (7), and specific sets of experimental conditions as reported by us previously (12) were used. Permethylation of methyl glycoside standards of known anomericity was also effected using conditions based on the method developed by Ciucanu and Kerek (7). Essentially no epimerization or degradation was observed.

GC–MS

The apparatus used consisted of a Varian 3400 chromatograph and Finnigan Mat Ion Trap Detector 800. A 30 m long DB-5 column (95% methyl-, 5% phenyl-silicon, J&W Scientific) with 250 mm i.d. and 0.25 μm film thickness was used. The oven temperature programming was as follows: initial temperature of 80°C kept constant for 10 min, followed by linear ramp to 270°C at the rate of 7°C/min, and final temperature of 270°C maintained constant for 10 min. The data system used was a Finnigan Mat ITDS, version 4.10.

TLC

Characterization experiments were carried out with silica-coated aluminum plates with 8 to 12 successive elutions. The solvent system was 1:9:40 isopropanol – ethyl acetate – hexanes.

Column chromatography

A 0.7 × 20 cm glass column packed with 10 g of silica was used. The solvent was 3:1 cyclohexane – ethyl acetate. The amount of sample applied to the column for one separation was of the order of 5–7 mg.

Continuous elution TLC

The solvent was 1:9:40 isopropanol – ethyl acetate – heptane. The galactose isomers required 12–15 h of continuous development, whereas in the case of fucose only 7–9 h were necessary.

^{1}H NMR

The instrument used was a Bruker AM 300 FT spectrometer (Bruker Inc., Billerica, Mass.). Samples were in concentrations of 1 mg/mL or less. The solvent used was deuterated chloroform, $CDCl_3$.

Results and discussion

Although a number of reports mention the use of TLC and silica column chromatography for the separation of monosaccharide permethylation mixtures (15–18), no details are given about elution order, chromatographic behavior, or resolution. We wish to provide more details on these procedures, which constitute an important step in the preparation of permethylated monosaccharides.

In a previous report (12), we discussed the relative abundances of permethylated galactoside and fucoside isomers formed with different sets of reaction conditions. The permethylated galactoside isomers observed by GC–MS were, in increasing order of retention time: β-galactofuranoside

(**1**), β-galactopyranoside (**2**), α-galactopyranoside (**3**), and α-galactofuranoside (**4**). In the case of the fucosides, the GC retention order was similar, i.e.: β-fucofuranoside (**5**), β-fucopyranoside (**6**), α-fucopyranoside (**7**), and α-fucofuranoside (**8**).

For the work discussed here, permethylation reaction conditions were chosen to favor production of (*a*) selective isomer(s), as described previously (12). However, a variation of the conditions did not have a significant influence on the amounts of **1**, **3**, and **5** obtained. The three latter were produced in very low amounts (≤4% of the products) and thus were difficult to isolate as pure substances at the low-milligram level.

Gee (14) observed that the TLC separation of products **1–4** on silica was restricted by the tendency of **2** and **4** to coelute. In our hands, the compounds were eluted as follows: **1**, R_f = 0.280; **4**, R_f = 0.195; **2**, R_f = 0.190; **3**, R_f =

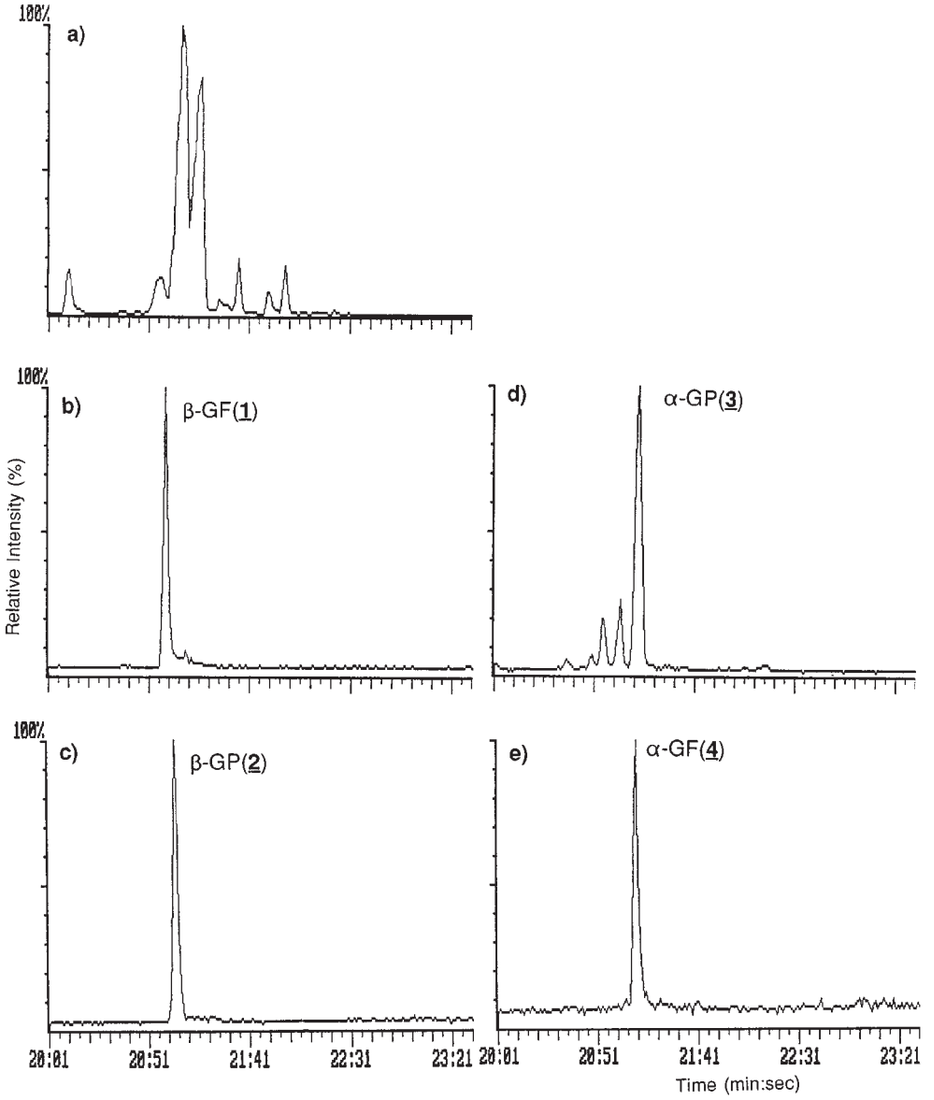
Fig. 3. GC–MS total ion chromatograms of the permethylation products of D(+)-galactose. (*a*) Product mixture, (*b*) β-galactofuranoside (β-GF) isolated from mixture, (*c*) β-galactopyranoside (β-GP) isolated from mixture, (*d*) α-galactopyranoside (α-GP) isolated from mixture, and (*e*) α-galactofuranoside (α-GF) isolated from mixture.



0.145, for the galactosides, and **5**, R_f = 0.565; **8**, R_f = 0.310; **6**, R_f = 0.245; **7**, R_f = 0.150, for the fucosides. Figure 1*a* shows the TLC elution pattern obtained for the permethylated galactoside isomers and emphasizes the difficulty of separating **2** and **4**. This separation is, however, better than reported by Gee (14). Figure 1*b* shows the elution pattern of the permethylated fucoside isomers, whose separation was easier to achieve.

Column chromatography of the mixture of permethylated galactosides allowed isolation of pure **1** and **3**; however, **2** and **4** could not be separated when 5–7 mg of products were applied to the column. The fucoside isomers could be separated more easily under the same conditions.

In our hands, continuous elution TLC was the most efficient method of separating the isomers. This technique yielded reasonably good separation of **2** and **4**, with quantities of material ranging from 5 to 30 mg. The fucoside isomers were separated using the same method. For either galactosides or fucosides, the fastest moving isomer had to be discarded, due to its migration to the top of the plate along with the impurities. Table 1 lists each of the eight compounds discussed in this study, along with the method that we considered the most efficient for its isolation.

The use of reversed phase high-performance liquid chromatography (HPLC) as a preparative method for the separation of the isomers was also investigated. Detection based on ultraviolet absorption was made difficult by the absence of suitable chromophores on the galactosides, and refractive index detection became possible only when milligram quantities of sample were loaded onto the column, at which point no separation was obtained. The only way to detect a good separation of the four isomers was by on-line HPLC – electrospray mass spectrometry, and injections of less than 1 picomol of each component were necessary to baseline-

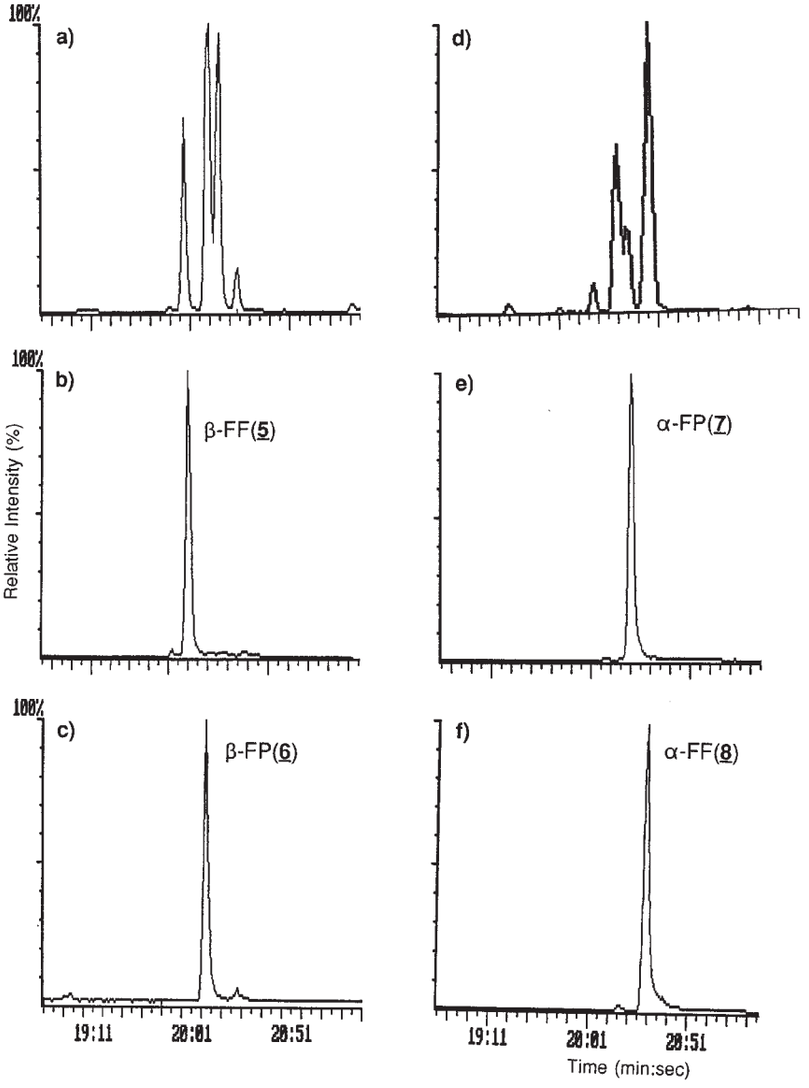
Fig. 4. GC–MS total ion chromatograms of the permethylation products of L(–)-fucose and of the permethylated fucoside standards. (*a*) Mixture of the four standards named as those isolated: (*b*) β-fucofuranoside (β-FF) isolated from permethylation mixture, (*c*) β-fucopyranoside (β-FP) isolated from permethylation mixture, (*d*) permethylation products of L(–)-fucose, (*e*) α-fucopyranoside (α-FP) isolated from permethylation mixture, and (*f*) α-fucofuranoside (α-FF) isolated from the permethylation mixture.



resolve the isomers. The practicability of this approach was questioned, and finally we decided not to use this method for the purposes of the present report.

Figure 2*a* shows the GC–MS total ion current (TIC) traces obtained for a mixture of the four permethylated galactoside standards.Traces (*b*)–(*e*) show the elution of each standard, once isolated, according to the methods listed in Table 1. Compound **1** was isolated with the highest purity level, while compounds **2**, **3**, and **4** contained very low levels of the other components due to band broadening on column or TLC.

Figure 3*a* shows the GC–MS TIC trace obtained for the permethylation products of D-(+)-galactose, and traces (*b*)–(*e*) correspond to the products isolated using the same methods as the standards. Compound **3** was the least abundant with each permethylation condition set used (12), and thus it was impossible to perfectly isolate this product from the rest of the permethylated mixture.

Figure 4*a* shows the elution (GC–MS) of the four permethylated fucoside standards. The first one, **5**, contained a high proportion of **8** from an impurity of methyl α-fucofuranoside in the starting material. Figure 4*d* shows the GC–MS trace obtained for the permethylation products of fucose, in one specific set of permethylation conditions (12). The isolation of the four main components from this product mixture resulted in the chromatograms presented in Fig. 4, (*b*), (*c*), (*e*), and (*f*). We successfully isolated milligram quantities of **7**, which we could not readily obtain from a commercial source. The production of compound **5** by permethylation of fucose was very difficult to enhance and

was maximized as shown in Fig. 4*d*. Therefore, we collected enough of this compound for a GC–MS analysis (Fig. 4*b*), but insufficient for NMR characterization.

Each of the separated isomers of permethylated D(+)-galactose and L(–)-fucose were subjected to ^{1}H NMR analysis. The results obtained for the pyranoside isomers are presented in Table 2. The values related to the methoxy groups closely matched those already reported by Streefkerk and Stephen (15) with $CDCl_3$ as the solvent. For other non-methoxy protons, values were available from the literature but only with acetonitrile-d_3 or benzene-d_6 as the solvent (16, 17), while we used $CDCl_3$. The values presented in Table 3, to our knowledge, are the first NMR data to have been reported on permethylated galacto- and fucofuranosides. Our assignments of the ring proton peaks (H2, H3, and H4) were made based on their respective coupling constants. In the case of compound **1**, the assignment of the peaks due to these protons was only possible within a range, since the peaks of interest were burried under the methoxy proton peaks. In general, the chemical shift of the H1 signal and its associated coupling constants were sufficient to identify the hexoside under investigation.

Conclusions

We have described an inexpensive method for the preparation of single isomers of permethylated D(+)-galactosides and L(–)-fucosides, to be used as standards in GC experiments as part of methylation analysis. Starting from D(+)-galactose and L(–)-fucose, we can control to some extent the proportions of the four isomers obtained in each case, by varying parameters in the permethylation reaction. Most products can then be separated in milligram quantities by silica column chromatography or continuous elution TLC. Two of the galactosides, β-galactopyranoside and α-galactofuranoside, were difficult to separate and were not recoverable as pure species on a column. They were isolated as almost pure compounds, however, using continuous elution TLC. The fucoside isomers lent themselves better to separation, although there was still a slight overlap between β-fucopyranoside and α-fucofuranoside; however, this was much less than for the galactoside isomers. We are in the process of using this method for preparing single permethylated hexoside isomers for glucose, *N*-acetylgalactosamine, *N*-acetylglucosamine, sialic acid, and mannose.

Acknowledgments

The authors wish to thank W. Buchannon of the Chemistry Department, University of Manitoba, for technical assistance during the GC–MS experiments. We acknowledge the help of D. Kunec in preparing some of the permethylated compounds of interest to this study. Thanks are also addressed to P. Hultin for advice regarding chromatographic methods using silica, and to R. Wallace for kindly scanning and editing pictures for Fig. 1. Finally, the authors wish to thank the Natural Sciences and Engineering Research Council of Canada and the University of Manitoba for their financial support.

Free radicals formed by H(Mu) addition to pyrene

Paul W. Percival, Brenda Addison-Jones, Jean-Claude Brodovitch, Khashayar Ghandi, and Joachim Schüth

Abstract: Muonium addition to pyrene has been investigated by means of transverse field muon spin rotation and muon level-crossing spectroscopy. Two hydropyrenyl radicals are produced and easily detected while a third is formed in low abundance. Muon and proton hyperfine constants were experimentally determined and compared with semiempirical and ab initio calculations. It is concluded that the radicals are of cyclohexadienyl type, i.e., the Mu adds only to carbon atoms that can assume a tetrahedral -CHMu- configuration without distorting the planar carbon skeleton of pyrene.

Key words: muonium, pyrene, radical, hyperfine.

Résumé : L'addition du muonium au pyrène a été étudiée à la fois par la spectroscopie de rotation du spin du muon en champ transverse et par celle de résonance de croisement de niveaux en champ longitudinal. Parmi les radicaux hydropyrényles qui sont produits, deux sont facilement détectés alors qu'un troisième n'est formé qu'en très faible quantité. Les valeurs des constantes hyperfines du muon et du proton obtenues expérimentalement ont été comparées à celles fournies par des calculs semi-empiricaux et ab initio. On en déduit que les espèces observées sont des radicaux cyclohexadiényles, ou encore, que Mu ne s'additionne qu'aux atomes de carbone dont la position permet au groupe -CHMu- de prendre un configuration tétrahédrale sans déformation du plan défini par les atomes de carbone du pyrène.

Mots clés : muonium, pyrène, radical, hyperfine.

Introduction

It has been well established that fullerene, C_{70}, has five chemically distinct carbon atoms. Hence, up to five isomeric radicals could be formed by addition of a single hydrogen atom or other free radical. Four of the H adducts have been detected by electron spin resonance (ESR) (1) and four (2) or five (3) of the muonium adducts have been detected by muon spin rotation (μSR). Assignment of the structures is not at all straightforward, and there is disagreement (1, 4, 5) on whether addition occurs at the "equatorial" carbon (labelled E in Fig. 1(*a*)). This carbon differs from the others (A–D) in being at the intersection of three six-membered rings. As such, it is similar to the central carbons, 15 and 16, of pyrene (see Fig. 1(*b*)). The A–D fullerene sites each involve two six- and one five-membered ring. It is the latter that provide curvature to the fullerene skeleton, and not surprisingly the curvature in C_{70} is least at E. The question of how curvature of the carbon skeleton influences reactivity has prompted us to extend our μSR studies of fullerene radicals (2, 6, 7) to planar and curved polyaromatics, selected to represent sub-units of the C_{70} molecule. In this context, the pyrene molecule may be considered a fragment of C_{70} (as emphasized in Fig. 1), and its reactivity may guide us in understanding the behaviour of the fullerene.

Pyrene is a planar polycyclic aromatic hydrocarbon with five chemically distinct carbons. In an ESR study of γ-irradiated pyrene single crystals Kawakubo (8) concluded that two H-adduct radicals are formed (1-hydro- and 4-hydropyrenyl). In contrast, a more recent pulse radiolysis study of pyrene in liquid methanol was interpreted (9) in terms of a single radical product, 1-hydropyrenyl. By drawing analogies with the benzene H adduct, cyclohexadienyl (10), and the two radicals formed from naphthalene (11), we might expect three radicals from pyrene, corresponding to addition at sites 1, 2, and 4, where the resulting radicals can have a tetrahedral C-CH_2-C configuration without disturbing the planarity of the carbon skeleton. The remaining two sites (11 and 15) are considered less likely because of the rigidity of the planar carbon skeleton at the points of ring fusion. On the other hand, in the case of fullerenes, whose framework is an assembly of curved unsaturated carbon rings, it is precisely these trigonal carbon sites that are attacked.

In our investigation, pyrenyl radicals were generated from the parent pyrene molecule by addition of muonium (Mu) instead of the H atom. Muonium is the single-electron atom with a positive muon as nucleus and can be considered a light isotope of hydrogen. The short lifetime of the muon (2.2 μs) and the availability of spin-polarized beams (the muon has spin 1/2) makes it particularly suited as a probe of transient radicals (12). Although the experimental probe (the muon) and the data acquisition techniques have their roots in particle physics, the principles of μSR are the same as magnetic resonance (12, 13). In particular, the hyperfine interac-

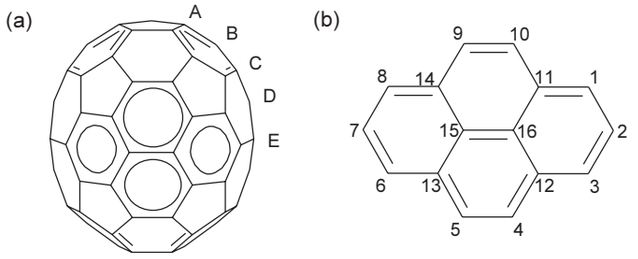
Fig. 1. (*a*) Classification of C_{70} carbon atoms. (*b*) The pyrene numbering system used in this paper.[3]



tion between a muon and the unpaired electron of a free radical can be deduced from the frequencies of muons precessing in a magnetic field transverse to their spin polarization (transverse-field muon spin rotation, TF-μSR). A related technique, muon level-crossing resonance (μLCR) can be used to determine the hyperfine constants (hfcs) for other magnetic nuclei in the muonium-labelled molecule, here, specifically, the protons of a pyrenyl radical. Thus, these two μSR techniques complement each other to provide information similar to ESR. An advantage of μLCR over conventional ESR is the ready determination of the sign of the hfc.

Muon spin rotation and muon level-crossing resonance experiments

Experiments were performed at one of the muon beam lines of the TRIUMF cyclotron in Vancouver. TF-μSR and μLCR measurements were made with the same sample, a degassed 1.04 M solution of pyrene in tetrahydrofuran (THF), sealed in a stainless steel vessel fitted with a thin foil window (14). Both types of measurements were made in the same spectrometer, HELIOS, based on a superconducting solenoid magnet arranged such that the muon beam travels along its axis and stops in the sample placed at its centre. A plastic scintillator detector in front of the sample signals muons incident on the sample, while other scintillators are used to detect the muon decay positrons. For TF-μSR the spin polarization of the muon beam was rotated roughly 90° from its momentum, and four positron detectors were arranged around the sample in a circular array perpendicular to the beam. For μLCR measurements, the spin polarization was kept parallel to the beam momentum; the positron detectors were moved in a downstream direction and used with an upstream set to provide a forward–backward counter geometry (13, 14).

In TF-μSR the elapsed time between the stop of each muon and the detection of its decay positron is measured, and the data are collected as a histogram of frequency of occurrence (counts) against time. The probability of detecting the decay positron in a given direction varies with time due to the radioactive decay of the muon and, more interestingly, to the muon spin precession in the magnetic field. Thus the μSR histogram obtained from each positron detector contains oscillations in the muon lifetime spectrum, and these oscillations correspond to the time dependence of the muon spin polarization. The general form of the histogram is

$$[1] \qquad N(t) = B_g + N_0 e^{-t/\tau_\mu}[1 + A(t)]$$

where B_g represents a small constant background count, N_0 is a normalization factor, τ_μ is the muon lifetime, and $A(t)$ is a sum of decaying oscillations — the precession signals. $A(t)$ may be Fourier transformed to provide a frequency spectrum similar to NMR and ESR spectra.

For typical organic solvents, such as the THF used in this work, roughly two thirds of the incoming muons become incorporated in diamagnetic molecules (15). The resulting diamagnetic signal precesses at the muon Larmor frequency, $\nu_\mu = \gamma_\mu H$ ($\gamma_\mu = 0.01355$ MHz G^{-1}). The remaining muons form muonium, which rapidly reacts with unsaturated molecules such as pyrene. Muons in free radicals are subject to a hyperfine interaction with the unpaired electron in addition to the Larmor interaction with the external magnetic field. At high magnetic fields two precession frequencies ensue:

$$[2] \qquad \nu_{R1} = \nu_{mid} - \tfrac{1}{2}A_\mu \text{ and } \nu_{R2} = \nu_{mid} + \tfrac{1}{2}A_\mu$$

where

$$[3] \qquad \nu_{mid} = \tfrac{1}{2}\{[A_\mu^2 + (\nu_e + \nu_\mu)^2]^{1/2} - \nu_e + \nu_\mu\}$$

is close to the muon Larmor frequency. A_μ is the isotropic muon hyperfine constant; ν_e and ν_μ are the electron and muon Larmor frequencies. The experimentally measurable quantities are ν_μ, ν_{R1}, and ν_{R2}. Equations [2] and [3] show that A_μ can be determined from the difference of ν_{R1} and ν_{R2} or from a combination of one of these and the diamagnetic frequency.

If A_μ is larger than $2\nu_{mid}$, then ν_{R1} is negative, i.e., precession occurs in the opposite sense to the diamagnetic muon signal. Whether this can be detected in practice depends on the experimental setup. In our experiments data from four positron detectors were combined to produce time signals in quadrature, thus permitting use of complex Fourier transformation and providing the ability to distinguish negative frequencies.

The symmetrical placement of radical frequencies around the diamagnetic peak is evident in the Fourier transform TF-μSR spectrum shown in Fig. 2. The presence of two pairs of peaks clearly signals the existence of two radicals (**I** and **II**) with different hyperfine constants. The low intensity of the high-frequency peaks is due to limited time resolution of the apparatus. Careful inspection of a series of spectra revealed consistent weak signals that we interpret as a third radical (**III**). One of the peaks due to **III** can be seen in the expanded portion of the figure; the corresponding peak on the high-frequency side of the diamagnetic signal is too weak to detect.

Quantitative data evaluation was done by fitting histograms in the time domain, using initial parameters derived from the Fourier transform. Comparison of the statistically independent results from the four detectors provided a consistency check that further confirmed the third radical signal. The hyperfine frequencies (A_μ) determined at 20° C are **I**: 263.44 ± 0.01 MHz; **II**: 347.06 ± 0.01 MHz; **III**: 530.52 ±

[3] The carbons labeled 11–16 here correspond to 10a, 3a, 5a, 10c, and 10b, respectively, according to standard rules for numbering fused rings.

15.073	–17.62		

[a] Uncertainty ≤3 G.
[b] Uncertainty ≤0.06 MHz.
[c] Doubly degenerate.

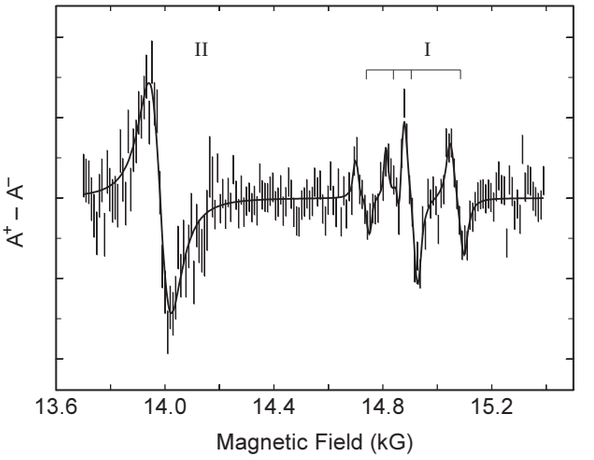
0.07 MHz. The relative radical abundances derived from the fitted signal amplitudes are **I** : **II** : **III** = 1.00 ± 0.02 : 0.71 ± 0.02 : 0.08 ± 0.03.

In contrast to TF-μSR, which involves spin precession in a fixed magnetic field, in μLCR the longitudinal muon spin polarization is monitored as the magnetic field is swept. The polarization is determined from the difference in decay positrons detected in the forward and reverse directions with respect to the applied field. Resonances occur at values of the magnetic field where a muon transition frequency is matched to that of some other nucleus in the coupled spin system of a radical. The mixing of a pair of otherwise degenerate levels results in an avoided crossing. This mixing couples the muon and nuclear spin functions, with the net result that there is an effective loss of muon spin polarization integrated over the muon lifetime. The field at resonance is primarily determined by the difference between the hyperfine constants of the muon and that (A_n) of the nucleus (or magnetically equivalent nuclei) involved in the resonance:

$$[4] \qquad B_{LCR} = \frac{1}{2}\left[\frac{A_\mu - A_n}{\gamma_\mu - \gamma_n} - \frac{A_\mu^2 - 2MA_n^2}{\gamma_e(A_\mu - A_n)}\right]$$

where M is the z-component of the total spin, γ_e, γ_μ, and γ_n refer to the magnetogyric ratios of the electron, muon, and other nucleus, respectively, and $\gamma_e \gg \gamma_\mu, \gamma_n$. It is possible to use μLCR to determine ^{13}C hyperfine constants (7, 16) if ^{13}C-enriched samples are available, but in this study of pyrene radicals only proton hfcs were determined.

Fig. 3. Part of the μLCR spectrum obtained from 1 M pyrene in tetrahydrofuran. The resonance labelled **II** is assigned to the -CHMu- group of radical **II**, while the set of four resonances marked **I** are due to different -CH- sites in radical **I**.



μLCR investigation of the sample of pyrene in tetrahydrofuran revealed at least nine resonances in a range of fields from 8 to 22 kG (see Table 1). Part of the spectrum is shown in Fig. 3. (The differential lineshape of the resonances is a consequence of the field modulation used to suppress baseline fluctuations.) On the basis of the TF-μSR results it is assumed that only radicals **I** and **II** give rise to the μLCR signals. Nevertheless, there is inherent ambiguity in using eq. [4] to deduce the proton hyperfine constants, since it is not known a priori to which radical (therefore which value of A_μ) a given resonance belongs.

Part of the problem is resolved by predicting the proton hfcs of the methylene (-CHMu-) groups on the basis of results for cyclohexadienyl (12, 17). After accounting for the "trivial" isotope effect caused by the ratio of magnetic moments of the muon and the proton (3.183) the "reduced" muon hyperfine constant, $A_\mu' = A_\mu / 3.183$, in cyclohexadienyl is 28% larger than the proton hfc. By assigning the 14 kG pyrenyl resonance (see Fig. 3) to radical **II** we deduce an isotope effect of 27%. Similarly, assignment of a resonance detected at 10.5 kG to radical **I** results in an isotope effect of 23%. No other assignment gives acceptable values.

The remaining resonances must all be due to α protons (protons attached to a carbon carrying significant unpaired spin density) whose hfcs are typically negative (17, 18). By rejecting atypical alternatives we assigned the resonances to radicals **I** and **II** as shown in Table 1. In one case, the resonance at 14.9 kG, the signal intensity did not match prediction until two protons were assumed (details of the method are given in ref. 19).

The uncertainties of the calculated proton hfcs are dominated by the calibration and reproducibility of the magnetic field, estimated to be about 3 G, which corresponds to 0.06 MHz in hfc.

Computation and discussion

The foregoing analysis of experimental results clearly shows that two of the five possible Mu adducts of pyrene are readily formed, and a third isomer is formed in low abundance. To assign individual structures it is necessary to turn to model calculations. We employed both semiempirical RHF-PM3 (20) and ab initio density functional (DFT) methods (21). Relevant results are summarized in Tables 2–4, and compared with the experimentally determined hyperfine constants to justify our assignments.

Consideration of the relative heats of formation of the isomeric radicals immediately suggests that the two abundant radicals, **I** and **II**, correspond to 1-Mu- and 4-Mu-pyrenyl, and that **III** could be 2-Mu-pyrenyl. Further support and, in particular, evidence to distinguish between the 1-Mu and 4-Mu isomers comes from the predictions of unpaired electron spin distribution (Table 2). It is well established that α-proton hyperfine constants in π-radical systems are proportional to the unpaired spin density on the carbons to which they are bound (18):

$$[5] \qquad A_H = Q_\alpha \rho_\alpha, \quad Q_\alpha \approx -75 \text{ MHz}$$

Given that only carbons 1–10 have attached protons, the expected pattern of negative hyperfine constants is four medium and one small for 1-Mu-pyrenyl; one very large and two medium for 4-Mu-pyrenyl; two degenerate values for 2-Mu-pyrenyl; two large for 11-Mu-pyrenyl; and a single large value for 15-Mu-pyrenyl. The first two patterns match the experimental results for radicals **I** and **II** (Table 1), respectively.

The unpaired electron spin estimates can also be used to predict the methylene (-CHMu-) hfcs in the β position, although the relationship is more complicated. Whiffen showed (22) that the CH_2 proton hfcs in cyclohexadienyl depend on the π-orbital coefficients of the two neighbouring carbons; we extended his argument to predict how the proton hfc in $C_{60}H$ depends on the unpaired spin densities of the three carbons adjacent to the CH site (6):

$$[6] \qquad A_\beta \propto \left(\rho_{\alpha 1}^{1/2} + \rho_{\alpha 2}^{1/2} + \rho_{\alpha 3}^{1/2}\right)^2$$

A difficulty in applying eq. [6] to the hydropyrenyls is that the proportionality constant is expected to vary with the local molecular geometry, because the hfc depends on the degree of orbital overlap between the C—H bond and the π orbital containing the unpaired electron. (This is also affected by the curvature of the carbon skeleton, as noted by Borghi et al. (5)). However, with these considerations in mind it is still instructive to predict the trend in hfcs. The

I II

spin factors listed in Table 3 correspond to the right-hand side of eq. [6]. In the next line of the table the spin factors have been converted to hfc predictions with a proportionality factor chosen so that the muon hfc in 1-Mu-pyrenyl is 275 MHz, the value for the most abundant C_{70}Mu radical (2, 23). Once again, the conclusion is that radicals **I**, **II**, and **III** should be assigned as 1-Mu-, 4-Mu-, and 2-Mu-pyrenyl, respectively.

An alternative to the above semiempirical calculations of spin density is direct calculation of hyperfine constants ab initio. We performed unrestricted open-shell calculations using the UB3LYP density functional provided with the Gaussian 94W package (21). The geometry of each hydropyrenyl isomer was first optimized using the STO-3G basis set, and then the hyperfine constants were computed in a single-point Fermi contact analysis using the 6-31G** basis. The program outputs values of spin density at each nucleus. These were converted from atomic units to hyperfine constants with the conversion factors 14229.0 MHz for Mu and 4469.9 MHz for H (24). Muon hfcs were then adjusted by a factor of 1.20 to account for the isotope effect. Similarly, a correction factor of 0.94 was applied to the proton hfc of the -CHMu- group to mimic the isotope effect found for the muonium-substituted cyclohexadienyl (12, 16).

Considering the different methods employed, there is remarkable accord (see Table 3) between the density functional calculations of muon hfcs and the semiempirical estimates. The DFT results for all the hfcs of 1-Mu- and 4-Mu-pyrenyl are listed in Table 4. The α-H values do not match the experimental results quite as well as the β-H and muon values, but the correspondence still provides convincing evidence for the assignment of these two isomers.

Conclusions

Addition of muonium to pyrene results in 1-Mu-pyrenyl and 4-Mu-pyrenyl in large abundance and a small amount of 2-Mu-pyrenyl. Taking into account degeneracies (there are twice as many sites equivalent to carbons 1 and 4 as for carbon 2), the relative reactivities of carbons 1, 4, and 2 are 1.00 ± 0.02 : 0.71 ± 0.02 : 0.16 ± 0.06.

Having assigned the spectra, it is possible to deduce the distribution of unpaired π-spin density in the radicals from the experimentally determined hyperfine constants. Figure 4 shows the results for the two principal pyrenyls.

There is no evidence for addition at one of the trigonal carbon sites (15 and 16 in Fig.1(*b*)). This supports the conclusion that the HC_{70} isomer not detected by ESR (1) corresponds to addition at the E carbon (Fig.1(*a*)).

Complete determination of the solid (RI)–liquid equilibria of four consecutive *n*-alkane ternary systems in the range $C_{14}H_{30}$–$C_{21}H_{44}$ using only binary data

Valérie Metivaud, Fazil Rajabalee, Harry A.J. Oonk, Denise Mondieig, and Yvette Haget

Abstract: The liquidus surfaces and thermal windows of four ternary systems implying consecutive *n*-alkanes (for *n* between 14 and 21 carbon atoms) have been studied combining Differential Scanning Calorimetry (DSC), X-ray experiments, and calculation using the program Txy-CALC. From the DSC measurements, the transition temperatures as well as the melting enthalpies have been determined. X-ray experiments performed at temperatures just below melting have shown that there is almost complete syncrystallization in the rotator form RI. The calculation of the RI → L liquidus surfaces has been made with temperature-independent as well as temperature-dependent excess Gibbs energies. In both cases, the agreement between experimental and calculated data is very good, the average temperature difference being within the uncertainty of the former.

Key words: *n*-alkanes, ternary mixtures, liquidus and solidus surfaces, rotator phase, thermodynamic analysis.

Résumé : Les surfaces de liquidus et les fenêtres thermiques de quatre systèmes ternaires impliquant des alcanes normaux consécutifs (de 14 à 21 atomes de carbone) ont été étudiées en combinant l'analyse enthalpique différentielle (AED), les mesures aux rayons X et le calcul thermodynamique. Les températures et les enthalpies de fusion ont été déduites des mesures AED. Les expériences aux rayons X, réalisées à des températures proches de la fusion, ont montré qu'il y a syncristallisation quasi-totale sous forme rotatoire RI. Les surfaces de liquidus RI → L ont été calculées en utilisant les énergies de Gibbs d'excès aussi bien indépendantes que dépendantes de la température. Dans les deux cas l'accord calcul–expérience est excellent, l'écart moyen entre les températures restant dans la limite des erreurs expérimentales.

Mots clés : *n*-alcanes, alliages ternaires, surfaces de liquidus et de solidus, phase rotatoire, analyse thermodynamique.

Introduction

The study of *n*-alkanes and their mixtures, which is one of the main research topics in our group, is of great interest both from a fundamental and a practical point of view. Fundamental because knowledge of the behaviour of *n*-alkanes and their systems can serve as a basis for understanding the behaviour of systems composed of more complex molecules, such as alkanes with one or more characteristic groups. Practical because the systems of *n*-alkanes lead to MAPCM (Molecular Alloy Phase Change Materials), which are suitable for the storage of energy and for thermal protection (1–4). One of the main characteristics of MAPCM is that they are thermo-adjustable by means of their composition. High-performance MAPCM that can be used for the applications mentioned must meet two important criteria, which are (*i*) a transition with an important latent heat, in combination with (*ii*) a narrow thermal window (temperature difference between solidus and liquidus at a certain composition). Research is necessary to investigate which compositions of what system of *n*-alkanes have these characteristics. Because many combinations of *n*-alkanes are possible, it would be useful to have a thermodynamic model to make reliable predictions of the desired characteristics. With such a model,

suitable systems could be selected without the need of testing all systems in detail experimentally.

The present work concerns the experimental determination and thermodynamic calculation of four ternary systems of consecutive *n*-alkanes from $C_{14}H_{30}$ to $C_{21}H_{44}$ (hereafter denoted by C14 to C21): the systems C14-C15-C16,[2] C16-C17-C18, C18-C19-C20, and C19-C20-C21. This paper focuses on solid–liquid equilibria. From the application point of view, these systems cover a large temperature range, roughly from 0 to 50 degrees Celsius.

Experimental

The compounds were purchased from Aldrich (C14, C16, C17, and C20) and from Fluka (C15, C18, C19, and C21), with purity grades >99% as certified by gas chromatography and mass spectrometry.

For the systems implying at least one solid component at room temperature, mixtures were prepared according to the melting–quenching method: the components are weighed in the desired proportion, melted, mixed to get an entirely homogeneous sample, and then quenched into liquid nitrogen (in the case of the system C14-C15-C16, the components are already liquid at room temperature).

Calorimetric measurements were carried out using a Perkin–Elmer DSC7 differential scanning calorimeter, operating in the subambient mode. The instrument was calibrated with substances of known transition temperatures and enthalpies (indium, naphthalene, and water). Samples were introduced at room temperature in aluminium pans, which were subsequently hermetically closed. The following conditions were adopted: sample weight ≈4.0 mg, each time, precision ±0.1 mg; heating rate, 2 K/min; at least four independent measurements for each composition.

Liquidus temperatures were determined from the DSC curves using the shape-factor method (6, 7). The random part of the uncertainties was estimated using Student's method with 95% threshold of reliability.

X-ray experiments were performed at specified constant temperatures using a Siemens D500 vertical powder diffractometer, which operates in the reflection mode with CuK α radiation (λ = 1.5406 Å). The temperature was controlled with a low-temperature Anton Paar KG device. The data were collected with 0.04° 2θ–step and 3 s interval time.

Pure component properties

The structural and thermodynamic properties of the *n*-alkanes considered in this work have been described previously in detail (8–10). In the range $n \leq 21$, *n*-alkanes can be divided into two groups according to the parity of the number of carbon atoms.

Odd-numbered alkanes have an orthorhombic crystal structure Oi at low temperature (space group *Pcam*, $Z = 4$). With increasing temperature, the structure becomes face-centred orthorhombic (*Fmmm*, $Z = 4$). This form, which is called rotator I (RI), presents orientational disorder (11, 12). Even-numbered alkanes have a triclinic structure Tp ($P\bar{1}$, $Z = 1$), the RI form being metastable.

Stable and metastable (RIm → L) melting points ($T_{melting}$) and enthalpies of melting ($\Delta H_{melting}$) of the pure components are reported in Table 1, together with the entropies of melting ($\Delta S_{melting} = \Delta H_{melting}/T_{melting}$). Thermophysical characteristics relative to the Oi → RI transition are given elsewhere (8).

Table 1. Thermophysical characteristics of the pure components ($T_{melting}$ are in K, $\Delta H_{melting}$ in kJ mol^{-1}, and $\Delta S_{melting}$ in J mol^{-1} K^{-1}).

	308.7±0.5	44.9±1.0	145±3	RI* → L
C21	313.0±0.3	46.6±1.1	149±4	RI → L

* is related to the metastable form RI.

The constituent binary systems

Experimental data

The solid–liquid phase diagrams of the 11 binary subsystems are represented in Fig. 1. The diagrams C14-C15, C15-C16, C14-C16, C18-C19, and C18-C20 are taken from refs. 5, 9, and 13).

In all cases, the mixed crystalline state in the rotator I form is stable over a large part of the composition range, even when both components do not show that stable phase (C14-C16 and C18-C20). When the two components present the RI phase, the miscibility is total (C19-C21). One could say that compositional disorder tends to stabilize forms with orientational disorder.

Calculation

The equilibria between solid (RI) and liquid were analysed using the program LIQFIT (which stands for LIQuidus FITting) (14): an iterative method of thermodynamic phase diagram analysis, with intermediate phase diagram calculation, in which the calculated liquidus curve is made to pass through the experimental liquidus points. It provides a thermodynamically sound solidus together with the difference in excess Gibbs energy between the liquid and the solid state for the mean temperature of the solid–liquid two-phase region (eq. [1]).

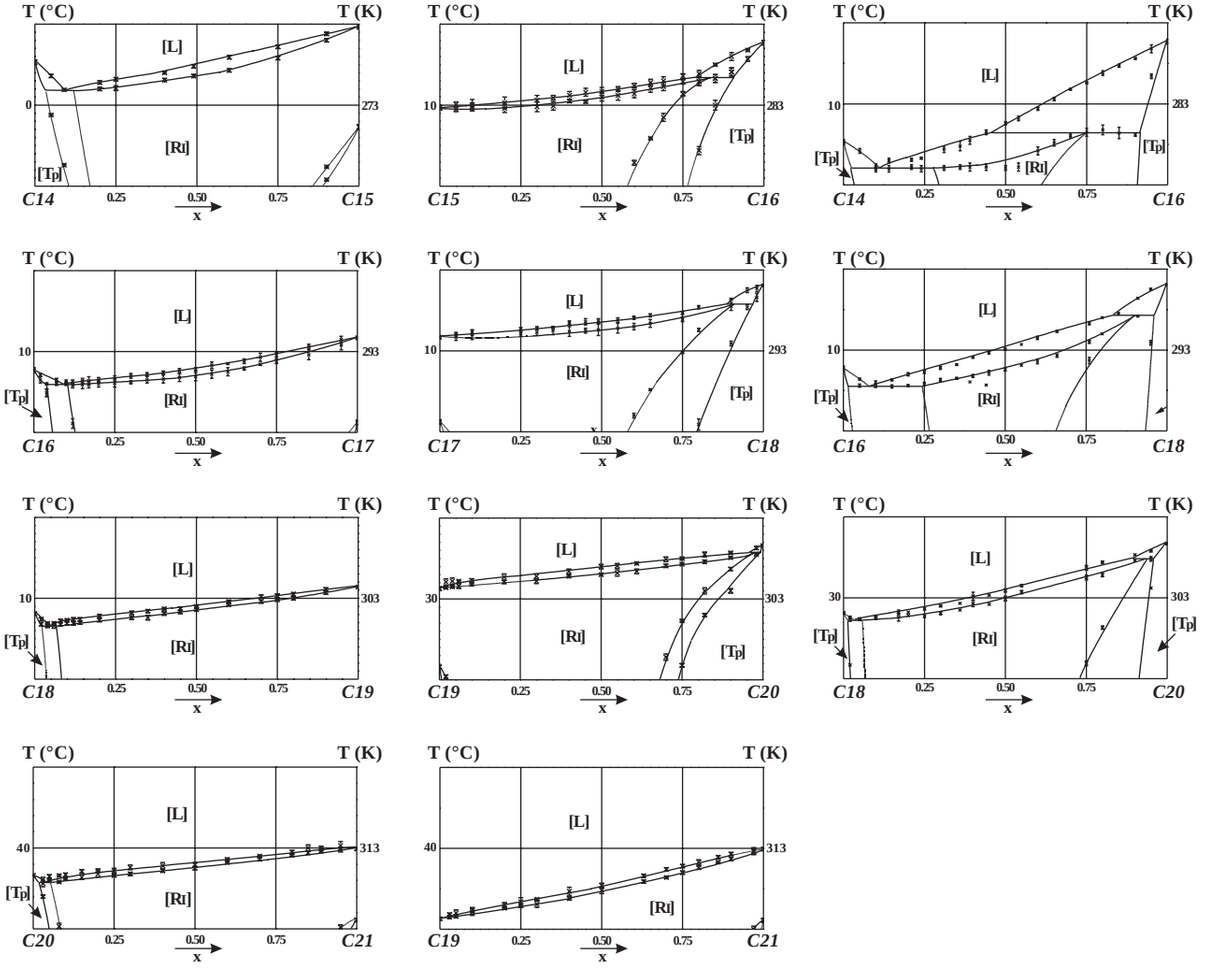
$$[1] \qquad \Delta^{liq}_{sol} G^E(T,x) = G^{E,liq}(T,x) - G^{E,sol}(T,x)$$

If the excess Gibbs energy of one of the states is known, then the excess Gibbs energy difference function provides the excess Gibbs energy of the other state. In the case of *n*-alkane systems, the thermodynamic excess functions of liquid mixtures are so small that these mixtures can safely be taken as ideal, i.e., $G^{E,liq=0}$. Then, as expressed in eq. [2]:

$$[2] \qquad \Delta^{liq}_{sol} G^E(T,x) = -G^{E,sol}(T,x)$$

© 1999 NRC Canada

Fig. 1. Experimental solid–liquid phase diagrams of the binary systems involved in the four ternary systems.



The calculation of the solid state excess Gibbs energy by means of LIQFIT was made in two different ways, hereafter denoted by case 1 and case 2.

In case 1 (eq. [3]), the excess Gibbs energy is taken to be independent of temperature.

$$[3] \qquad G^{E,sol}(T,x) = G^{E,sol}(x)$$

And it means that the outcome of the computation corresponds to an excess Gibbs energy function that is representative of the mean temperature of the input data.

In case 2 (eq. [4]), the excess Gibbs energy is taken to be linearly dependent upon temperature.

$$[4] \qquad G^{E,sol}(T,x) = H^{E,sol}(x) - TS^{E,sol}(x)$$

In this case, the experimental $H^{E,sol}$ (excess enthalpy depending on heat of mixing) is part of the input for LIQFIT and the program is used to calculate the excess entropy ($S^{E,sol}$).

The thermodynamic excess functions were expressed as a second-order Redlich–Kister polynomial (eq. [5], (15)).

$$[5] \qquad Z^E = x(1 - x)[Z1 + Z2(1 - 2x)]$$

In eq. [5], Z^E stands for any thermodynamic excess function such as G^E, H^E, or S^E, x is the mole fraction of the component with the greatest number of carbon atoms, and $Z1$ and $Z2$ the so-called Redlich–Kister coefficients of the excess property.

Solid (RI) excess coefficients of most of the binary systems involved in this work have already been determined previously within our research group and published by Mondieig et al. (16) and Oonk et al. (17). However, recent complementary studies performed on pure *n*-alkanes have allowed a refinement of the even alkane metastable (RI $\rightarrow$ L) transition temperatures. These metastable values have been used as input for new LIQFIT computations in order to refine excess coefficients. The results of the computations for case 1 (eq. [3]) are given in Table 2. Uncertainties relative to these excess parameters are about 20 J mol^{-1} for $G1$ and 40 J mol^{-1} for $G2$. For case 2 (eq. [4]), the computed entropy coefficients are given in Table 3 along with the input enthalpy coefficients. Uncertainties relative to the $H1$ and $H2$ experimental excess values and to the $S1$ and $S2$ computed values are about 0.5 kJ mol^{-1}, 0.8 kJ mol^{-1}, 10 J mol^{-1} K^{-1}, and 20 J mol^{-1} K^{-1}, respectively.

Table 2. Computed Redlich–Kister coefficients of excess Gibbs energy valid for the mean temperatures of the individual systems ($G1$ and $G2$ are in J mol^{-1}).

Binary systems	$G1$	$G2$
C14-C15	930	150
C15-C16	760	–360
C14-C16	2070	100
C16-C17	680	–90
C17-C18	310	–170
C16-C18	1370	300
C18-C19	200	0
C19-C20	–160	150
C18-C20	500	0
C20-C21	–290	–160
C19-C21	360	–90

Table 3. Computed Redlich–Kister coefficients of excess entropy along with the experimental coefficients of the excess enthalpy used as input for the computations ($H1$ and $H2$ are in kJ mol^{-1}, $S1$ and $S2$ in J mol^{-1} K^{-1}).

Binary systems	$H1$	$H2$	$S1$	$S2$
C14-C15	6.5	0.2	20	1
C15-C16	5.0	2.8	15	11
C14-C16	13.4	–18.3	41	–66
C16-C17	4.7	1.8	14	7
C17-C18	5.2	1.2	17	5
C16-C18	12.2	0.3	37	1
C18-C19	3.6	0.0	11	0
C19-C20	4.7	3.7	16	12
C18-C20	11.2	8.3	35	28
C20-C21	4.8	1.6	16	6
C19-C21	10.3	7.0	32	23

Although these new values are slightly different from those published in refs 16 and 17, the conclusions given in these two papers remain totally the same.

The ternary solid–liquid equilibria

Experimental

For each ternary system, experiments were carried out for at least 11 ternary compositions. Liquidus temperatures and thermal windows were determined from the DSC curves. The expected existence of large ternary stability regions of the rotator I mixed crystalline state was confirmed by X-ray diffraction. As an example, in Fig. 2, X-ray patterns corresponding to a central composition are given for the four systems.

Calculation

Calculations of the RI $\rightarrow$ L equilibria of the different ternary systems were performed using the program Txy-CALC (18, 19). In common practice, the ternary excess Gibbs energy needed for the calculations is composed of the binary functions and eventually extended with ternary interaction functions. The latter, as a rule, are added if the ensemble of binary functions fails to yield a correct description of the equilibria for compositions inside the ternary triangle. Out of the various methods of adding binary excess functions (20), we opted for the method proposed by Kohler (21).

As was done for the binary systems, two different approaches were considered. In the first case, the excess Gibbs energy was taken as temperature independent and in the second case as temperature dependent. Two main parameters were calculated: the liquidus surfaces and the thermal windows. The comparison between experimental and calculated temperatures is given in Tables 4–7 for the systems C14-C15-C16, C16-C17-C18, C18-C19-C20, and C19-C20-C21, respectively. Isotherm liquidus lines calculated in case 1 are represented in Figs. 3*a*–6*a* for the systems C14-C15-C16, C16-C17-C18, C18-C19-C20, and C19-C20-C21, respectively, together with the analysed compositions. Lines of thermal windows of equal width calculated in case 1 are represented in Figs. 3*b*–6*b*.

Discussion

The average differences between experimental and calculated liquidus temperatures are reported for each system in Table 8.

The agreement between experimental and calculated data is very good in all cases, the maximum average difference being 0.3 K. All these differences are within the experimental uncertainties of the liquidus temperatures. Moreover, no systematic shift is observed; in other words, it was not necessary to introduce a ternary interaction parameter. From Fig. 7, in which the experimental thermal windows are plotted against the calculated ones, it can be concluded that the agreement between the two is quite satisfactory. It means, among other things, that the experimental procedures for the melting process in the alkane systems, in combination with the shape-factor method, are capable of giving consistent solidus and liquidus temperatures.

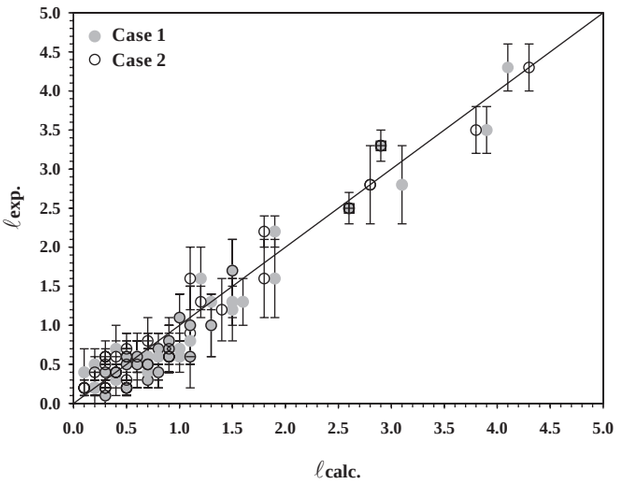
Table 8. Average differences between experimental and calculated liquidus temperatures.

	Liquidus temperatures	
Ternary systems	Case 1	Case 2
C14-C15-C16	0.2	0.2
C16-C17-C18	0.1	0.1
C18-C19-C20	0.3	0.2
C19-C20-C21	0.2	0.2

Another observation that can be made, in the case of the melting in alkane systems, is that, for predictive computations from binary data, it is not necessary to take into account the temperature dependence of the excess Gibbs energies. This follows from the fact that the case 2 calculations did not produce better results than the case 1 calculations. In addition, computations made earlier on the system C15-C16-C17 gave rise to the same conclusions (22).

© 1999 NRC Canada

Fig. 7. Experimental thermal windows (l_{exp}) against the calculated ones (l_{calc}).



The general conclusion of the underlying research could be that the equilibria between solid and liquid in ternary systems of consecutive *n*-alkanes can be reliably predicted from the binary data, i.e., without the need of experimentally verifying the computational results.

The properties of a family of two-headed surfactant systems: the 4-alkyl-3-sulfosuccinates 2. Surface properties of alkyl sulfosuccinate micelles

Judith A. MacInnis, Greg D. Boucher, R. Palepu, and D. Gerrard Marangoni

Abstract: The micellar properties of a family of two-headed surfactants, the alkyl sulfosuccinates, were investigated employing fluorescence, ultra-violet spectroscopy, and acid–base titrations, as a function of the chain length of the surfactant. Polarity of the micellar interior was investigated using pyrene and the ionic probe 8-anilino-1-naphthalensulfonic acid ammonium salt (ANS). Pyrene I_1/I_3 ratios were used to probe the microenvironment of the probe in the palisade layer of the micelle. The pK_a values of both of the anionic head groups were determined using acid–base titrations. Surface potential measurements were obtained from the measurement of the pK_a of the hydrophobic indicator, 7-hydroxycoumarin, at the sulfosuccinate micellar interface. All of these results were used to examine the surface properties of the alkyl sulfosuccinate micelles and the polarity of the micellar interior.

Key words: micellization, pK_a, surface potential, surface charge density, 7-hydroxycoumarin, pyrene.

Résumé : Faisant appel à la fluorescence, à la spectroscopie ultraviolette et à des titrages acide/base, on a étudié les propriétés micellaires d'une famille d'agents de surface à deux têtes, les sulfosuccinates d'alkyle, en fonction de la longueur de la chaîne de l'agent de surface. On a étudié la polarité de l'intérieur de la micelle en utilisant le pyrène et une sonde ionique, le sel d'ammonium de l'acide 8-anilinonaphtalène-1-sulfonique (ANS). On a utilisé les rapports I_1/I_3 du pyrène pour évaluer le microenvironnement de la sonde dans la couche palissade de la micelle. On a déterminé les valeurs des pK_a des deux têtes ioniques à partir de mesures de pK_a de la 7-hydroxycoumarine, un indicateur hydrophobe, à l'interface micellaire du sulfosuccinate. On a utilisé l'ensemble de ces résultats pour étudier les propriétés superficielles des micelles de sulfosuccinate d'alkyle et la polarité de l'intérieur de la micelle.

Mots clés : micellisation, pK_a, potentiel de surface, densité de charge de surface, 7-hydroxycoumarine, pyrène.

1. Introduction

Micelles in ionic detergent solutions are generally considered to be excellent models for the study of colloidal and detergent properties due to the ease of creating stable colloidal aggregates with definite surface properties. There have been a number of papers in the literature describing the synthesis and micellar and solution properties of novel two-headed surfactant systems (1–4). However, much of this work has focused on the synthesis, critical micelle concentration values (cmc), and the degrees of counter ion binding (β values) of two-headed surfactants. Although the β values provide some information on the surface charge densities of the micelles, direct measurements of the surface properties of the two-headed surfactants are essential to evaluate the unique structure of the interface between water and the micelles of these two-headed surfactants (5–17). Surface potential measurements using solubilized pH indicators have often been used to examine the properties of micelles and model lipid membranes. The micelle–water interface possesses properties that are distinctly different from those of the bulk solution and the micellar interior. Understanding the surface properties of micelles may play an important role in applications such as micellar catalysis, transport phenomena, anesthetic properties, and colloid stability in mixed electrolyte solutions, where surface micellar effects have been recognized as being important. Surface potential measurements may also shed some light on the hard-water tolerance of two-headed surfactants (3). The present paper involves the examination of a family of two-headed surfactants, the disodium 4-alkyl 3-sulfosuccinate surfactants (Fig. 1). These two-headed surfactants are of interest because the addition of a second negatively charged head group adjacent to an existing anionic surfactant increases the cmc and lowers the Kraft point of the two-headed surfactants (1–4). The alkyl sulfosuccinate surfactants have negatively charged sulfonate and carboxylate groups separated by two carbon atoms on the alkyl chain (4), and hence may also have interesting micellar properties as a function of the pH.

In this paper, the micellar surface properties and the micropolarity of a family of two-headed surfactants, the alkyl sulfosuccinates, were investigated using fluorescence

spectroscopy, ultra-violet spectroscopy, and acid–base titrations of surface solubilized indicator 7-hydroxycoumarin. As a first step in determining the micellar properties of the sulfosuccinate surfactants, as a function of pH, we have also determined the pK_a values of both of the anionic head groups of the alkyl sulfosuccinates, employing acid–base titrations. Pyrene I_1/I_3 ratios and the luminescent intensities of ANS were used to determine the polarity of the microenvironment of the micelle. The measurement of the pK_a of hydrophobic indicator, 7-hydroxycoumarin, at the sulfosuccinate micellar surface, was used to determine the micellar surface potentials. All of these properties are discussed in terms of the influence of having two negatively charged head groups on the surfactant chain. Nuclear magnetic resonance spectroscopy was also used to investigate the location of a typical aromatic probe (benzene) in the surfactant micelles.

2. Experimental

The alkyl sulfosuccinates were synthesized using the following general procedure. Equimolar amounts of maleic anhydride and an alcohol were heated for 20 min, with constant stirring, in a 500 mL round bottom flask. An equimolar amount of an aqueous sodium metabisulfite solution was added, and the mixture was neutralized to pH ≅ 7–9. The mixture was then allowed to reflux for 20–24 h. The progress of the reaction was monitored by running a UV spectrum on the reaction mixture to confirm the absence of the maleic anhydride double bond. The resulting surfactants were purified through Soxhlet extraction with diethyl ether for at least 72 h. The structures of these surfactants were confirmed by nuclear magnetic resonance and FT-IR spectroscopy.

The pK_a values of the respective anionic head groups were determined as follows. Aqueous surfactant solutions, with concentrations twice the critical micelle concentration, were titrated with standardized sodium hydroxide (0.10 M, Fisher Scientific A.C.S.) and were used to obtain the titration curve data. The pH of the solution was measured using a glass electrode and a Cole–Palmer Digi-Sens pH/mv meter. The electrode was calibrated using pH 4 and 10 buffer solutions (Fisher Scientific). The pH values were reproducible to ±0.15 pH units.

The luminescence probing experiments to obtain the pyrene I_1/I_3 ratios in the sulfosuccinate micellar interior were carried out as follows. Pyrene (Aldrich, 99%) was purified through sublimation and recrystallization (twice) with ethanol. The pyrene probe was held at a constant concentration of 2×10^{-5} M. A small amount of a pyrene–ethanol solution was placed in a small flask, and the solvent was allowed to evaporate, depositing the pyrene as a monolayer at the bottom of the flask.

The stock aqueous solution of the surfactant was added to the flask containing the pyrene; this solution was stirred overnight to ensure complete dissolution of the pyrene in the surfactant solution. Steady-state pyrene emission spectra were recorded on a Perkin–Elmer MPF-66 spectrophotometer, using an excitation wavelength of 338 nm and scanning the emission spectra from 350 to 500 nm. The intensities of the first and third peaks of the emission spectra were recorded and used to determine the I_1/I_3 ratio and hence, an estimate of the micropolarity of the micellar interior.

The ANS polarity studies were carried out as follows: 8-anilino-1-naphthalenesulfonic acid ammonium salt was purchased from Aldrich and was used as received. A stock solution of the probe (10^{-5} M) was prepared in absolute ethanol. Micellar solutions of ANS were prepared by taking an aliquot of the stock solution and adding the surfactant solution. The resulting solutions were sonicated for 5 min. Fluorescence measurements were made using an excitation wavelength of 389 nm and the emission spectra was obtained from 400 to 525 nm.

The nmr spectra (^{1}H and proton decoupled ^{13}C) were obtained on a Bruker AC-200. D_2O was used as a solvent for all of the sulfosuccinate experiments. The ^{1}H spectra were referenced to the HOD peak (δ = 4.81 ppm), while the ^{13}C chemical shift signals were referenced to the deuterium lock signal. Two sets of nmr experiments were carried out to determine the location of a typical aromatic probe (benzene) in the surfactant micellar interior.

(*a*) Benzene solubilization studies: The alkyl sulfosuccinate solutions were prepared, at a concentration of twice the critical micelle concentration. To 1 mL of each of these solutions was added 10 or 20 μL of benzene (Aldrich), and the mixture was stirred for 30 min.

(*b*) Surfactant Studies: At least five solutions, up to twice the critical micelle concentration were prepared in D_2O. To 1 mL of each of these solutions was added 10 mL of benzene.

Surface potential measurements were carried out as follows. Sodium dodecyl sulfate (Aldrich, 99%) was recrystallized twice from absolute ethanol. The nonionic surfactant octaethylene glycol decyl ether ($C_{10}E_8$) was supplied by Fluka and was used without further purification. The acid–base indicator 7-hydroxycoumarin was obtained from Aldrich Chemical Co. and was used without further purification. The pH was adjusted by NaOH (A.C.S. Reagent Fisher Scientific) or HCl (A.C.S. Reagent Fisher Scientific). NaCl (A.C.S. Fisher Scientific) was used to adjust the ionic strength of the surfactant solutions. Solutions were titrated from high pH to low pH by the addition of small amounts of NaOH or HCl solutions (0.10 M). After the addition of either NaOH or HCl the pH of the solution was recorded, and the degree of ionization of the indicator was

obtained by measuring the intensities of the peak at 373 nm as a function of pH using the HP 8450A diode array spectrophotometer.

3. Results

3.1. pK_a determination

Aqueous solutions of the alkyl sulfosuccinates were prepared at twice the critical micelle concentration, and the resulting solutions were titrated using 0.1 M NaOH. The pK_a values for the carboxylate and the sulfonate anionic head groups were determined from the apparent breaks that occur in the titration curves (Fig. 2), and these values are given in Table 1.

The pK_a values (Fig. 3) increase with increasing carbon number for both the carboxylate and sulfonate head groups. There is an observed dependence on increasing chain length for the pK_a values, and these values are in agreement with the literature values. These pK_a values depend slightly on the alkyl chain length (18). Hence, we can clearly see from Fig. 1 that when the pH is high (>9.6), the sulfosuccinates are in the form of two-headed anionic surfactants. Varying the pH of the solution should change the properties of the sulfosuccinate micelles as the degree of ionization of the ionizable carboxylate head group is changed; this is currently under investigation.

sulfosuccinates and the alkyl sulphate surfactants is shown in Fig. 5.

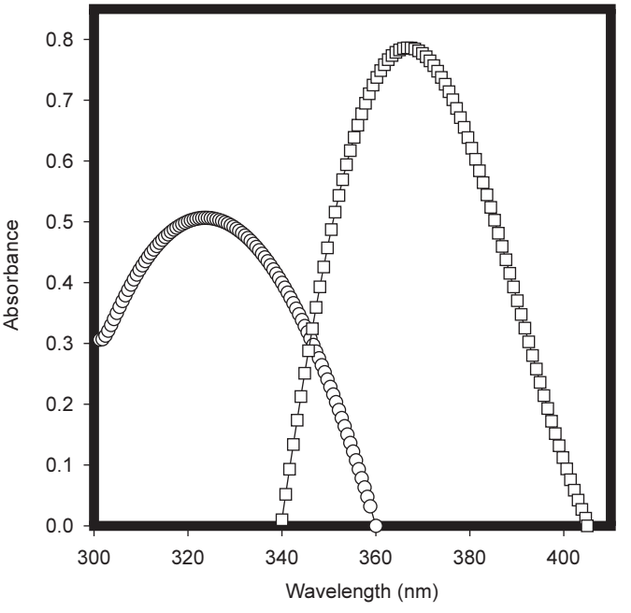
3.3. Surface potential measurements

The measurement of the surface potential of a micellar system will provide information on the surface charge density – surface potential relationships for these novel two-headed surfactants. 7-Hydroxycoumarin and its derivatives have been used, in the literature, to investigate the interfacial microenvironment of a large number of monolayers (8–12). The electrostatic surface potential of a charged interface can be calculated using the following expression:

$$[1] \qquad \Psi_0 = \frac{2.303RT}{F}(pK_a^i - pK_a^{obs})$$

where ψ_0 is the surface potential, pK_a^{obs} is the apparent pK_a value of the 7-hydroxycoumarin at the charged surface, pK_a^i is the apparent pK_a of the 7-hydroxycoumarin at the surface when $\psi_0 = 0$ and F, R, and T are the Faraday constant, the universal gas constant, and the absolute temperature, respectively. The pK_a values of 7-hydroxycoumarin are a function of the dielectric constant of the medium. The pK_a^i of the indicator is determined from the pK_a^{obs} in the presence of a nonionic surfactant. The nonionic surfactant micelle acts as a zero potential reference state for determining the pK_a^i values of 7-hydroxycoumarin in anionic micelles. The absorption spectrum of 7-hydroxycoumarin was obtained as a function of pH; the UV spectrum shows two characteristic peaks that are pH dependent (Fig. 6).

Fig. 6. UV/vis adsorption spectrum for 7-hydroxycoumarin in aqueous solution at a pH of 2.0 (λ_{max} = 320 nm) and a pH of 10.0 (λ_{max} = 370 nm).



The protonated 7-hydroxycoumarin (pH < 6) exhibits an intense absorption band with λ_{max} at 324–330 nm, with a log $\varepsilon \sim 4.1$. In basic solution (pH > 8) the absorption band that appears at λ_{max} 365–370 nm, with log $\varepsilon \sim 4.2$, is assigned to the anionic form of the indicator that is formed from the dissociation of the acidic phenolic proton at position seven (19).

The results for the λ_{max} of the acid form and the λ_{max} of the anionic form of the indicator are in excellent agreement with the literature. The absorbance spectrum (1.0 cm cells) of a 6.0×10^{-5} M solution as a function of pH at 370 and 320 nm is given in Fig. 7.

The observed pK_a for 7-hydroxycoumarin was determined from the absorption spectra using the following equation:

$$[2] \qquad pK_a = pH - \log\left(\frac{\alpha}{100 - \alpha}\right)$$

where α is the percentage of 7-hydroxycoumarin that has been ionized. The maximum absorbance of the 7-hydroxycoumarin at the λ_{max} of the probe, as a function of the solution pH, was taken as the 100% ionization value and the minimum absorbance as the 0% ionization value. At least six different a values between 0 and 100 were examined for each solution.

For the alkyl sulfosuccinate surfactants the ionic strength, I, of the bulk solution is given by

$$[3] \qquad I = 10^{(pH_i - 14)} + [NaCl] + cmc + 1/2(\Sigma Z^2\ cmc)$$

© 1999 NRC Canada

Fig. 7. Absorbance of 7-hydroxycoumarin as a function of pH at 320 and 370 nm.

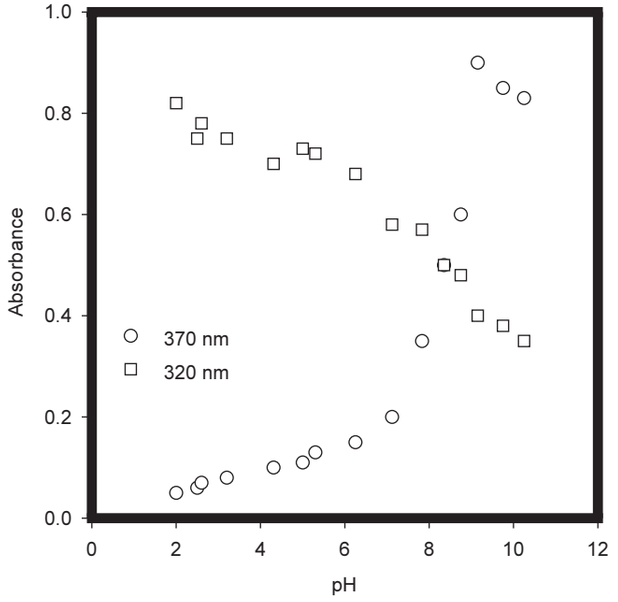


Fig. 8. Surface potentials of sodium dodecyl sulphate at various ionic strengths.

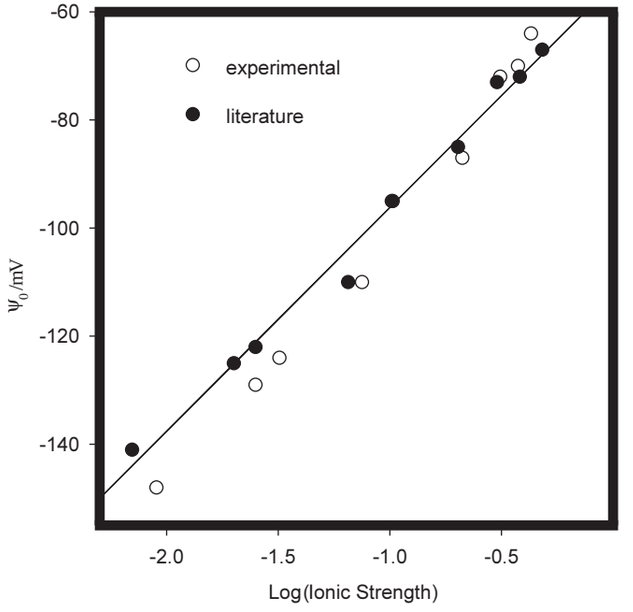

where pH_i is the initial pH, [NaCl] is the concentration of added NaCl, and the last term is due to the contributions of the negatively charged head groups ($Z = -2$). This equation neglects the contribution to the ionic strength from the micelles and the dissociated counter ions (6).

The experimental surface potentials of 0.02 M SDS solutions, of varying ionic strength, were determined using the above method. The measured values for SDS are in excellent agreement with those reported in the literature. These are shown in Fig. 8. The potentials were calculated using

Fig. 9. Surface potentials of the alkyl sulfosuccinates at varying ionic strength.

eq. [1] based on the pK_a of 7-hydroxycoumarin, in 5×10^{-3} mol/L $C_{10}E_8$, of 9.12 ± 0.15 (pK_a^0). This value was found to be constant by up to an ionic strength of 4 M NaCl. The experimental surface potentials for the alkyl sulfosuccinates are shown in Fig. 9, and as both the un-ionized and ionized forms of the indicator partition into the micellar phase and reside within the interfacial region of the anionic micelles (8, 9, 11, 12), the differences between pK_a^i and pK_a^0 should reflect the difference in the surface potential of the two-headed surfactants vs. the nonionic reference micelle. The above expression assumes that the dielectric constant of the medium directly surrounding the probe is relatively the same in both micellar systems. This has been verified for SDS and DTAB micelles (8, 12, 14) and should be a reasonable assumption for the sulfosuccinate micelles.

The surface charge density was calculated using the following equation:

$$[4] \qquad \sigma_0 = \frac{-eN_s(1-\beta)}{4\pi a^2}$$

where N_s is the aggregation number, and β is the fraction of surfactant ions in the micelle that are electrically neutralized by the specific binding of a counter ion. These values are given in Table 3 (Fig. 10).

© 1999 NRC Canada

Fig. 10. Surface charge density of the alkyl sulfosuccinates.

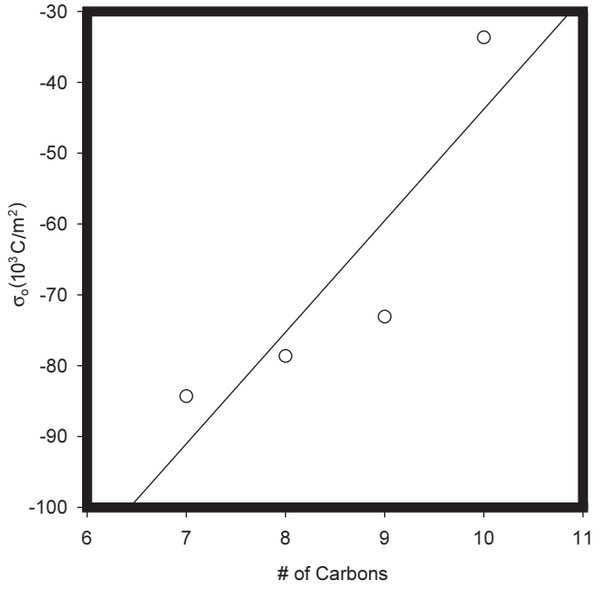

Fig. 11. Surface area per head group alkyl sulfosuccinates.

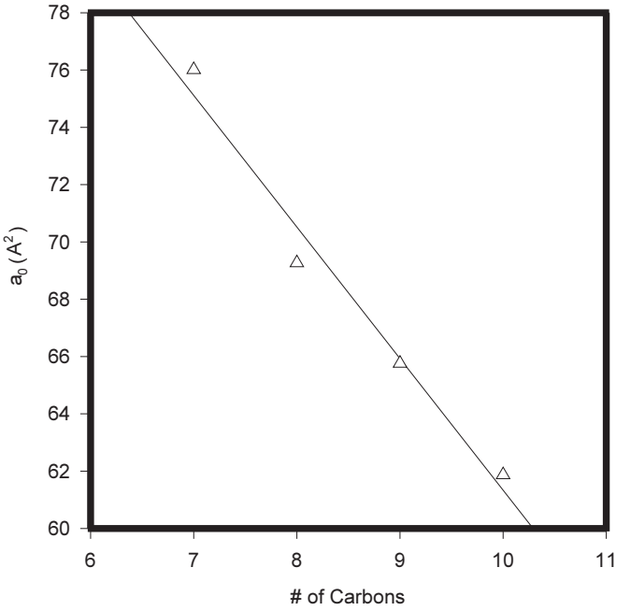

4. Discussion of results

The pK_a values of the sulfonate and carboxylate head groups of the alkyl sulfosuccinates increase as the number of carbons is increased on the hydrocarbon chain (Table 2, Fig. 3). The titration of the alkyl sulfosuccinates produces a curve that is similar to that of a weak acid titrated with a strong base. The break points that occur in the curve are due to the neutralization of the carboxylate and sulfonate head groups. The pK_a values are in good agreement with those for the aliphatic carboxylic acids (18). The pK_a values for the sulfonic acid group is slightly higher than the pK_a values for benzenesulfonic and toluenesulfonic acids (18). There is also an observed dependence on increasing chain length for the pK_a values, which is in reasonable agreement with the literature.

The use of luminescence probing experiments to determine a number of important properties of surfactant micelles is well established (19–29). The ability of pyrene to sense the polarity of its microenvironment is also well established (22–29). Since the pyrene I_1/I_3 ratios reflect the polarity of the microenvironment around the probe, it can, therefore, detect changes in polarity in micelles. Analysis of the pyrene I_1/I_3 ratios (Table 2, Fig. 4) gives information about the polarity of the microenvironment surrounding the solubilized probe in the micelle. It is known that pyrene is solubilized in the palisade layer of micelles, near the polar head groups, where it senses a relatively high polar environment (30). In the present study, it is evident that the pyrene senses a very similar degree of polarity in the microenvironment surrounding the probe in all of the sulfosuccinate micelles. This may be attributed to the inability of the pyrene to penetrate deeply into the micelle, and hence the pyrene senses the same degree of polarity due to the location of the pyrene near the micelle–water interface.

The surface area per head group for the sulfosuccinate micelles has been estimated as follows. The hydrophobic chain volume of the micelle (v) and the critical chain lengths (l_c) were obtained using Tanford equations (30):

[5] $v = 27.4 + 26.9n$ (Å^3)

[6] $l_c = 1.5 + 1.265n$ (Å)

where n is the number of carbon atoms of the chain. The micellar radius, r, and the surface area per head group (a_0) were obtained assuming spherical shape. The aggregation numbers were determined by fitting the C-13 measurements to the mass action model (1). The values of r and a_0 ($(4\pi r^2)/N_{agg}$) along with the critical packing parameter ($v/(a_0 l_c)$), which is a parameter-controlling micelle shape, are presented in Table 3 (30). The increase in the critical packing parameter indicates the formation of larger spherical micelles; however, we estimate that the surface area per head group decreases linearly with an increase in carbon number. This is shown in Fig. 11.

The ionic probe, ANS, has been known to interact with anionic micelles such as sodium dodecyl sulphate (31). The spectral behavior of ANS is interesting because the emission properties are sensitive not only to the polarity of the microenvironment but to the microviscosity of the environment of the probe. ANS is almost nonfluorescent in aqueous solutions, but it exhibits a fluorescence enhancement upon binding to the micellar surface. This fluorescence enhancement is due to the polarity-dependent twisted intramolecular charge transfer (TICT) (32). When the ANS molecules are transferred from the highly polar aqueous media to the relatively nonpolar micellar surface, the reduction in polarity and the increase in microviscosity leads to a decrease in the rate of the TICT process. Inhibition of nonradiative TICT pathways results in an increase of the emission quantum yield lifetime.

In examining Fig. 5 it can be seen that the members of the alkyl sulfosuccinate family experience the same polarity in the microenvironment surrounding the ANS probe. The same

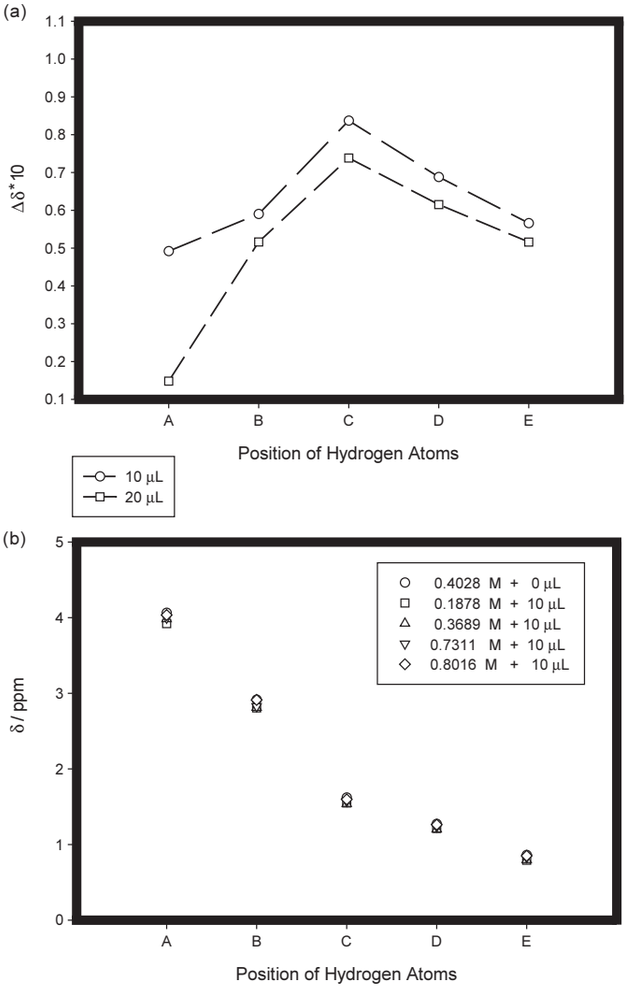
Fig. 12. (*a*) Changes in proton chemical shifts upon addition of benzene (C8SS). (*b*) Changes in proton chemical shifts upon increasing surfactant (C8SS) concentration (benzene concentration = 10 μL/mL).



is also true for the alkyl sulfate surfactants. These results agree with those obtained from the pyrene polarity study.

Before we discuss the surface potentials of the sulfosuccinate surfactants, certain facts must be considered when examining the use of a probe for surface potential measurements. To calculate the surface charge density the radius of the micelle hydrophobic core is needed. Because of changes at the micelle surface, its shape is not known exactly (22, 23); also the exact position of the 7-hydroxycoumarin at the micelle surface is also not known. If the indicator resides outside the micelle surface it will sense a surface potential lower than the true value (1). There have been extensive nmr studies carried out with aromatic molecules solubilized in SDS micelles (33) in the literature. These studies have indicated that the aromatic molecules with ionizable hydroxy groups sit in the plane of the sulphate head groups in the SDS micelle. Therefore, it is reasonable to assume in our present investigation that the 7-hydroxycoumarin indicator will also sit in this plane and hence, respond to the true surface potential.

E CH_3	0.8436	0.3200	0.6150

Although the locus of solubilization may not be the same for benzene and other aromatic molecules (pyrene or 7-hydroxycoumarin), one should be able to obtain a fairly reasonable qualitative estimate of the location of aromatic molecules in the sulfosuccinate surfactant micelle interior from the nmr studies of benzene solubilized in the alkyl sulfosuccinate micelles. It can be seen from Fig. 12(*a*) that the magnitude of the alpha proton chemical shift (i.e., head group region) are greater than those of the other proton shifts, that occur due to added benzene (Table 4), suggesting that the benzene is residing in the head group region of the micelle. The second area of the nmr study involved keeping the benzene concentration constant and increasing the surfactant concentration. From this study it was concluded that the proton chemical shifts are not influenced by the increasing surfactant concentration (Fig. 12(*b*)). These studies indicate, in the range of ion concentrations studied, that the benzene is located within the head group region of the surfactant micelle. From this we can conclude that the acid–base indicator 7-hydroxycoumarin should also be located in the same region of the micelle.

It is clear from the surface potential values, in the anionic sulfosuccinate micelles, that these surfactants must have relatively low degrees of counter ion binding, as the surface potential values are two to three times larger than those of sodium dodecyl sulphate at comparable ionic strengths. In addition, the dependence of the surface potential on ionic strength is significantly different for these two-headed surfactants vs. the single-headed surfactants. In the case of the two-headed surfactants, the ψ_0 values decrease with an increase in ionic strength, whereas for the single-headed surfactants, the ψ_0 values increase with increasing ionic strength. This may indicate a significant difference in the properties of two-headed surfactant micelles, as a function

© 1999 NRC Canada

of increasing salt concentration, vs. single-headed surfactant micelles like sodium dodecyl sulphate.

It is also important to note that the differences in the surface potential values between the members of the alkyl sulfosuccinate family are due to several important factors:

1. The various micellar solutions have different ionic strengths due to the fact that the members of the sulfosuccinate family have different cmc values.

2. The degree of counter ion binding is different for each member of the sulfosuccinate family.

3. The sulfosuccinate micelles may have slightly different sizes and shapes.

5. Conclusions

It has therefore been shown that the alkyl sulfosuccinate surfactants exhibit characteristics that are distinctive of a family of surfactants that contain two negatively charged head groups.

The micellar properties of these two-headed anionic surfactants have therefore been shown to be influenced by the pH of the solution. Also the presence of this second negatively charged head group affects not only the polarity of the microenvironment of the micelle, but it also increases the surface potential of the head-group region.

Acknowledgments

The financial support of the Natural Science and Engineering Research Council of Canada (NSERC) and St. F.X. University in the grant of a James Chair Research Fellowship to R.P. are greatly appreciated. The authors would also like to thank Andrew P. Rodenhiser of Dalhousie University for supplying the sample of the nonionic surfactant octaethylene glycol decyl ether ($C_{10}E_8$) used in this study.

Energetics of the encapsulation of *o*-, *m*-, and *p*-hydroxybenzoic acids by β-cyclodextrin and its methylated and hydroxypropylated derivatives in aqueous solution

Elena Junquera, Valentin G. Baonza, and Emilio Aicart

Abstract: A fully computerized potentiometric technique has been used to analyze the energetics of the encapsulation of *o*-, *m*-, and *p*-hydroxybenzoic acids by β-cyclodextrin (β-CD) and (or) two of its most used derivatives: 2,6-di-*O*-methyl-β-cyclodextrin (DIMEB) and hydroxypropyl-β-cyclodextrin (HPBCD). The study has been carried out by measuring the pH of aqueous solutions of the three hydroxyacids in the absence of cyclodextrin at 25°C, and in the presence of cyclodextrin at several temperatures ranging from 15 to 40°C, keeping constant the concentration of the guest. The dissociation constant of the acids and the binding constants of the inclusion complexes formed have been simultaneously determined at all the temperatures by using a model previously derived by us. The carboxylic forms have been found to bind the CD with higher affinities than the carboxylate partners do, irrespective of the temperature, the cyclodextrin used, and the position of the substituents on the guest molecules. The formation of the inclusion complexes studied in this work has been found to be enthalpy driven, with a favorable enthalpic term dominant over an unfavorable entropic one. The effect of the substituents of both guest and host molecules on the thermodynamics of the inclusion processes has been analyzed.

Key words: binding constant, β-cyclodextrin, hydroxybenzoic acid, inclusion complex, substituent effect.

Résumé : On a utilisé une technique potentiométrique entièrement automatisée pour analyser le bilan énergétique de l'inclusion des acides *o*-, *m*- et *p*-hydroxybenzoïques dans la β-cyclodextrine (β-CD) et (ou) dans deux de ses dérivés les plus utilisés : la 2,6-di-*O*-méthyl-β-cyclodextrine (DIMEB) et la hydroxypropyl-β-cyclodextrine (HPBCD). On a réalisé l'étude en mesurant le pH des solutions aqueuses de trois hydroxyacides en l'absence de la cyclodextrine à 25°C, et en présence de la cyclodextrine à différentes températures allant de 15 à 40°C, tout en maintenant constante la concentration de l'entité moléculaire invitée. On a déterminé simultanément, à toutes les températures, la constante de dissociation des acides et la constante de liaison des complexes d'inclusion formés, en utilisant un modèle mis au point antérieurement dans ce laboratoire. On a trouvé que les formes carboxyliques sont liées dans la CD avec des affinités plus grandes que les formes carboxylates quelles que soient la température, la cyclodextrine utilisée et la position des substituants sur la molécule-hôte. On a trouvé que la formation des complexes d'inclusion étudiés dans ce travail dépend de l'enthalpie avec un terme enthalpique favorable qui a préséance sur un terme entropique défavorable. On a étudié l'effet des substituants, aussi bien sur la molécule hôte que sur la molécule invitée, sur le bilan thermodynamique du processus d'inclusion.

Mots clés : constante de liaison, β-cyclodextrine, acide hydroxybenzoïque, complexe d'inclusion, effet de substituant.

Introduction

Non-covalent interactions, with water solvent playing an important and decisive role, are known to be the main driving forces in most recognition processes at the biological level (1, 2). Highly specific biological processes make extensive use of molecular complexation. It is thus necessary to have as much information as possible regarding the contribution of, for example, of van der Waals contacts, hydrophobic and solvent effects, electrostatic interactions, etc., in the energetics of these processes (3). However, this is not a simple task, and very often scientists turn to designing sim-

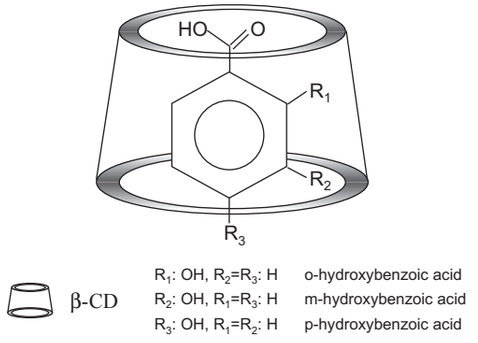
Scheme 1.



ple synthetic model systems that somehow mimic the biological interaction (4, 5). In this context, cyclodextrins (CDs) have been widely used as simple model receptors to study the nature of the binding process of apolar organic molecules in aqueous solutions (6). These cyclic oligosaccharides are well known for including a wide variety of guest molecules in their toroidal cavity with only the concurrence of non-covalent intermolecular forces, and with clearly changing effects on the physicochemical properties of the guest. This feature has been profitably used by the cosmetic, agro-alimentary, and pharmaceutical industries (6–8) to improve the bioavailability of their products.

A number of structural and thermodynamic studies have been carried out in the last decade with different experimental techniques to elucidate the rules that govern the association process in these model systems (9–14). Parameters such as stoichiometry of the complex (*A*), binding constant ($K_{CD:Substrate}$), and enthalpy ($\Delta H°$), entropy ($\Delta S°$), and heat capacity (ΔC_p^o) changes upon binding are of crucial importance to understand how the different intermolecular forces contribute to the overall free energy of complexation ($\Delta G° = -RT \ln K_{CD:Substrate}$). Several methods and mathematical models for determining association constants can be found in the literature (6, 15), while the thermodynamic magnitudes ΔH^o and ΔS^o can be obtained either directly from calorimetric experiments, or indirectly from van't Hoff plots, which give $-\Delta H^o$ as the slope and $\Delta S°$ as the intercept of a plot of $R \ln K$ vs. $1/T$. Some authors use the comparison of ΔH^o obtained from both calorimetric and van't Hoff methods to extract information about the possible contribution of concomitant processes to the associations studied (10*c*, 16–21).

We recently (13) derived a model to obtain simultaneously the binding constants for the inclusion of the non-ionized and ionized forms of the guest into the CD cavity from pH potentiometric data when the guest is an acid–base conjugated system. In the present work, this model has been applied to study the encapsulation of three derivatives of benzoic acid, the *o*-, *m*-, and *p*-hydroxybenzoic acids, by the β-CD and two derivatives, DIMEB and HPBCD (see Scheme 1, as an example). Previous studies (11, 22–34) on the complexation of benzoic acid and phenol derivatives by CDs revealed that the thermodynamic parameters of the association process are quite sensitive to the type, position, and orientation of the substituents introduced in both host and guest molecules. However, systematic studies have not been done with the hydroxy derivatives of benzoic acid. We expect that the determination of the association constants of the inclusion complexes studied in this work as a function of temperature will improve our understanding of the effect of substitution and position of substituents on the energetics of the CD:hydroxybenzoic acid interaction.

Experimental

Materials

The *o*-, *m*-, and *p*-hydroxybenzoic acids, with purities greater than 99%, were purchased from Sigma. β-CD was from Aldrich; HPBCD, containing an average of 0.4 hydroxypropyl groups per glucopyranose unit, was from Janssen Biotech, and DIMEB was from Cyclolab. β-CD, HPBCD, and DIMEB have been found (through a thermogravimetric (TG) analysis) to consist of 13.6%, 3.4%, and 1.7% mass of water content, respectively, which was used to calculate solute concentrations. Distilled water was further treated with a Super Q Millipore ion exchange purification system. To assure the homogeneity of the initial solutions, they were sonicated during 1 h in an ultrasonic bath.

Potentiometric measurements

Potentiometric data were collected with a Metrohm 713 ion meter, using a combined glass electrode filled with 3 M KCl solution. Calibration of both the asymmetry potential and the Nernst slope of the electrode was made daily using three Metrohm buffer solutions at pH = 1, 4, and 7. The equipment and the experimental procedure have been described in detail elsewhere (13). Mixtures were prepared with a Metrohm digital burette, whose cylinder was kept at the same constant temperature as that of the measuring cell. The pH ion meter and the burette were operated via RS-232C interfaces. The whole measuring process is controlled through a computer program developed by us. The accuracy on the molarity of the solutions is better than 1×10^{-5} M, in both the cell and the burette. The thermostatic system holds the temperature constant within ±1 mK. The pH data, obtained as an average of 250 measurements for each concentration, are reproducible within 0.0003 units. pH measurements were made as a function of cyclodextrin concentration, keeping constant the guest concentration around 4 mM. Cyclodextrin concentrations were chosen to cover at least 80% of the saturation curve to guarantee a proper determination of binding constants (35).

Determination of the association constants from potentiometric data

Several models have been developed in the literature to determine the binding constants of host–guest systems from pH potentiometric measurements (13, 22, 36, 37). Particularly when the guest is an acid–base conjugated system, both acid (HA) and base (A^-) species are present in the aqueous solution and can be included by the cyclodextrin. Several equilibria are then involved in the encapsulation process: (*a*) those for the association of both acid and base species of the guest with the cyclodextrin, and (*b*) those for the dissociation of the acid species in both their free and complexed forms, as indicated in the following scheme:

© 1999 NRC Canada

Scheme 2.

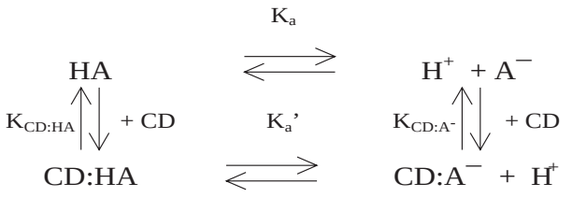


Fig. 1. Plot of pH vs. the concentration of *o*-, *m*-, and *p*-hydroxybenzoic acid, in aqueous solution at 25°C.

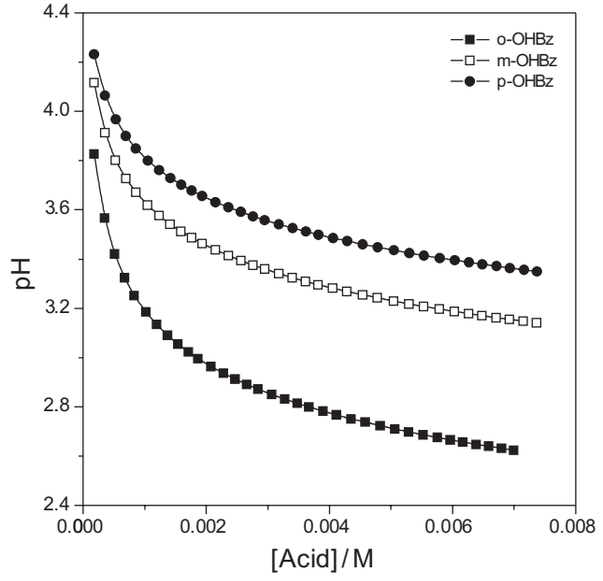


The equilibrium constants that govern these equilibria can be expressed as a function of the activity of the species as follows,

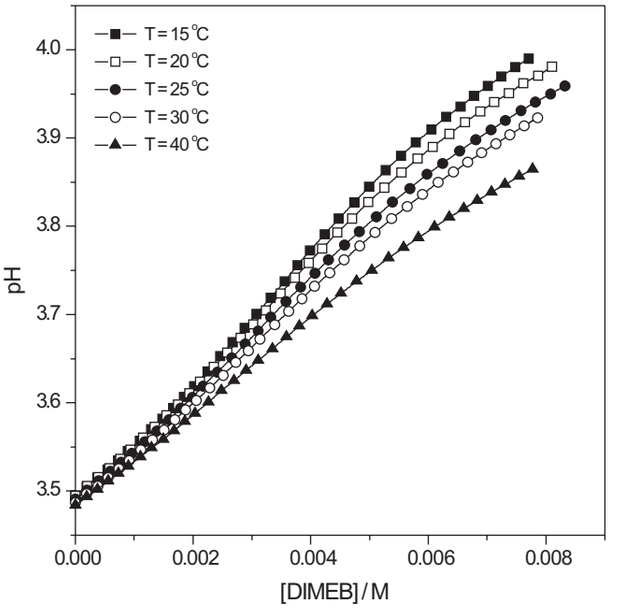
[1] $K_a = (a_{H+}a_{A}\text{-})/a_{HA}$

[2] $K_{CD:HA} = a_{CD:HA} / (a_{CD}\, a_{HA})$

[3] $K_{CD:A}\text{-} = a_{CD:A}\text{-} / (a_{CD}\, a_{A}\text{-})$

The dissociation constant for the complexed acid species (K_a') is related to the previous equilibrium constants by a simple expression. Any valuable model must check the formation of complexes with stoichiometries different than those shown in the previous scheme. In our model, eqs. [1]–[3], those for the activity coefficients (using the Debye–Hückel theory), and the corresponding mass and charge balances, allow for simultaneous determination of these binding constants and the dissociation constant of the uncomplexed hydroxyacid by fitting the experimental pH data with a nonlinear regression method (NLR), based on a Marquardt algorithm. The numerical procedure includes the determination of uncertainties due to pH measurements and statistical errors inherent in the NLR method. These uncertainties are 5% in the dissociation constants for the pure acids and 10–25% in the constants for the ternary systems. This model (13) was derived on the basis of that of Gelb et al. (22), although improvements were successfully included, the most relevant being: (*i*) the numerical procedure assigns negligible values to those binding constants of association processes (1:1, 1:2, 2:1, etc.) that either do not take place or occur with negligible affinities; and (*ii*) the simultaneous determination of the dissociation constant of the guest (K_a) constitutes a control for the suitability of the method, since these values can be compared either with literature values or with those obtained for the pure acids in the absence of cyclodextrin.

Fig. 2. Plot of pH vs. [DIMEB] for aqueous solutions of *p*-hydroxybenzoic acid where [*p*-OHBz] is kept constant at ~4 × 10^{-3} M, at different temperatures ranging from 15 to 40°C.



Results and discussion

The pH of the aqueous solutions of *o*-, *m*-, and *p*-hydroxybenzoic acids has been measured in the absence of cyclodextrin at 25°C, and in the presence of β-CD, DIMEB, or HPBCD at 15, 20, 25, 30, and 40°C, at constant hydroxyacid concentration.

Figure 1 shows the data for pH as a function of *o*-, *m*-, and *p*-hydroxybenzoic acid concentration at 25°C. From the experimental pH data, the dissociation constants of the three hydroxyacids have been determined for our model in its simplest version. There is only one fitting parameter, K_a, provided that only one equilibrium must be considered in the absence of cyclodextrin. Values of 2.9, 4.1, and 4.6 have been obtained, at 25°C, for the pK_a of *o*-, *m*-, and *p*-hydroxybenzoic acids, respectively. The acid character increases with the proximity of the -OH and -COOH groups in the aromatic ring, since the formation of a hydrogen bond between the hydroxyl and carboxylic groups stabilizes the ionized species.

Figure 2 shows, as an example, the pH curves of an aqueous solution of *p*-hydroxybenzoic acid, at a constant concentration of ~4 mM, as a function of DIMEB concentration, the temperature ranging from 15 to 40°C. In contrast with Fig. 1, when the DIMEB is added several equilibria are

involved, since both non-ionized (*p*-OHBz) and ionized (*p*-$OHBz^-$) forms of the guest can be encapsulated by DIMEB, the pH data in Fig. 2 being the result of shifting of the equilibria with the addition of cyclodextrin. The binding constants, $K_{CD:OHBz}$ and $K_{CD:OHBz^-}$, as well as K_a of the guests, were determined by fitting the pH data as a function of cyclodextrin concentration using our model (13). The results obtained are shown in Tables 1–3, and can be summarized as follows: (*i*) stoichiometries higher than 1:1 have not been found in any of the complexes, confirming the validity of Scheme 1; (*ii*) values of $K_{CD:guest}$ smaller than 5 are not considered representative, since they are within the uncertainty of the fit; (*iii*) the dissociation constants of *o*-, *m*-, and *p*-hydroxybenzoic acid (K_a) are in excellent agreement with those found in the study made in the absence of cyclodextrin, confirming the suitability of the method; and (*iv*) the carboxylic species are encapsulated by either β-CD or its derivatives with a higher stability than their ionized counterparts in all the systems studied.

The behavior described above has been previously observed (22, 31, 38, 39) for other carboxylic derivatives, and is explained in terms of the way these guest molecules penetrate the cyclodextrin cavity. It is believed that carboxylic species are encapsulated with the carboxylic group end first,

which means that the ionizable group is inside the cavity. Some authors (38) attribute the lower stability of the CD:carboxylate complexes to the random character of the inclusion and (or) to the energy balance of transferring species from the bulk to the CD cavity, and others (31) to the repulsive interaction between the negative charge on the anionic species and the negatively charged end of the CD dipole, which is located at the wider end of the cavity. In a previous article (13), we pointed out slight differences in the entropic balance upon binding, related to the water structure-breaking character of carboxylate anions, as an additional factor for such a pattern.

Table 4 compares the values of the association constants found in the literature for some of the systems studied in this work with the values obtained here. It must be emphasized that whenever the binding constants obtained with different experimental techniques are to be compared, the same interval of the degree of saturation must be covered, preferably within the optimum range (20–80%) (35), and in experimental conditions that are as similar as possible (40). Keeping this in mind, the values in Table 4 call for some comment. First of all, it can be observed that those *K* values obtained from experiments where the solution is unbuffered (Lach and Cohen (23), Harata (24), and Kajtar et al. (41)) are always intermediate between the binding constants for the inclusions of the acid and basic forms. Actually, those values correspond to apparent constants that average both inclusion processes. The values obtained by Sideris et al. (32) for the β-CD:*o*-OHBz complex determined at pH = 1.5, and by Kamiya et al. (29) for the β-CD:*p*-$OHBz^-$ complex determined at pH = 6.2, are affected by a certain contribution of both the base and acid forms, since the fixed pH is not different enough (34) from the pK_a of the guest. On the other hand, those association constants obtained under such condi-

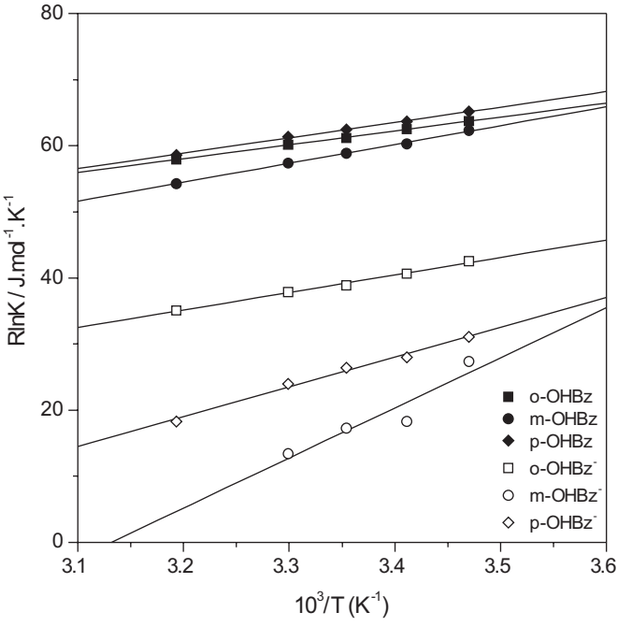
tions that only the acid (or the base) form of the guest is present are in better agreement with the values reported herein, the level of agreement depending mainly on the degree of saturation covered in each experiment.

Van't Hoff analysis

As shown in Tables 1–3, the dissociation constants of the three monohydroxybenzoic acids are temperature independent within the uncertainty of the K_a values, while $K_{CD:OHBz}$ and $K_{CD:OHBz}$- decrease with temperature independently of the position of the substituents on the guest or the cyclodextrin. In all cases, valuable thermodynamic information can be extracted through the corresponding van't Hoff plots ($R \ln K$ vs. $1/T$). Figure 3 shows, for example, this plot for the system formed by DIMEB with *o*-, *m*-, and *p*-hydroxybenzoic acids in both the non-ionized and ionized forms. It is well known (16) that this procedure assumes that both $\Delta H°$ and $\Delta S°$ are independent of temperature, which means that the association process runs with no change in the molar heat capacity $\Delta C_p^o (\sim 0)$, an assumption that is not always correct (10, 14, 17, 42). In any case, if a reasonable linearity is observed for the plot over a given range of temperatures, it can be assumed that both $\Delta H°$ and $\Delta S°$ are essentially constant in the temperature range of the experiments.

Table 5 reports the $\Delta H°$ and $\Delta S°$ values determined for all the complexes studied in this work. These data reveal that both non-ionized and ionized species, irrespective of the *ortho*, *meta*, and *para* position of the substituents in the aromatic ring, bind to β-CD or DIMEB with a favorable enthalpic term ($\Delta H° < 0$) and an unfavorable entropic term ($\Delta S° < 0$). In the case of HPBCD, the non-ionized and ionized forms of the *ortho* isomer, and only the non-ionized forms of the *meta* and *para* isomers bind and have similar characteristics. Thus, the encapsulation processes are exothermic and enthalpy driven ($|\Delta H°| > T|\Delta S°|$), following the behavior found for associations of small guest molecules and cyclodextrins in aqueous solution (9–14). This thermodynamic pattern, which contrasts with a typical hydrophobically driven process (43), has been attributed (9–14) to the contribution of different driving forces to the overall free energy of binding: the hydrophobic effect, van der Waals contacts between the host and the guest, and the solvent reorganization. A clear trend for $\Delta H°$ of the non-ionized complexes with respect to the ionized ones is not found in Table 5. However, negative values are always obtained for $\Delta S°$, being more negative for the complexed anions. This energy balance translates into a decrease of the overall stability of the ionized complexes with respect to the non-ionized ones. This picture indicates that the difference found between the entropic terms could be responsible for such a pattern, as previously reported for other CD:carboxylate systems (13). This behavior has been attributed to the water structure-breaking character of carboxylate anions, which tend to orient water molecules radially with respect to their electrostatic field (44).

Fig. 3. van't Hoff plots for the associations of DIMEB with the nonionized and the ionized forms of *o*-, *m*-, and *p*-hydroxybenzoic acids.



Effect of the position of the substituents of the guest molecule

The data in Tables 1–3 show that the stability of the inclusion complexes CD:OHBz and CD:OHBz$^-$ (CD is β-CD or HPBCD or DIMEB) decreases in the order *p*-OHBz > *o*-OHBz > *m*-OHBz, and *o*-OHBz$^-$ > *p*-OHBz$^-$ > *m*-OHBz$^-$, irrespective of the temperature and the cyclodextrin. Some different and probably opposite contributions may be responsible for such a pattern for the stability of the complexes, depending on the positions of the substituents on the guest molecule. It seems clear that the *m*-hydroxybenzoic, in both the ionized and non-ionized forms, is the guest that binds a cyclodextrin with less affinity, pointing to the important role of a steric factor in the interactions of CD:hydroxybenzoic derivatives. In addition, the slightly higher

© 1999 NRC Canada

stability of the inclusion complexes formed with the *p*-hydroxybenzoic with respect to the *o*-hydroxybenzoic in the acid forms (inverted in the case of the anionic forms) could be related to the presence or absence of the hydrogen bond between the -OH and -COOH groups of these molecules.

Effect of the substituents of the β-CD molecule

The binding constants reported in Tables 1–3 reveal that, independently of the temperature and of the position of the substituents on the guest molecule, the trend observed for the acid species is $K_{\text{DIMEB:OHBz}} > K_{\beta\text{-CD:OHBz}} \approx K_{\text{HPBCD:OHBz}}$. The higher affinity found for the DIMEB:OHBz inclusion complexes may be reasonably explained in terms of the substitution of 14 H per β-CD molecule by 14 CH_3 groups. The methyl groups increase the hydrophobicity of the CD cavity by providing an extension of the cavity when introducing nonpolar methyl groups at the 2 and 6 positions of the glucopyranose units. This cavity lengthening may promote van der Waals contacts between the host and the guest. However, it seems that the substitution of 3 H per β-CD molecule by 3 hydroxypropyl groups (β-CD → HPBCD) does not affect the interaction with the guest very much. In contrast, for a given cyclodextrin, clear stabilizing effects have been reported (40) when the guests are elongated rather than globular molecules, as in the case of surfactant molecules. This feature indicates that 3 hydroxypropyl "tails" on the CD cavity entrance clearly favor van der Waals contacts with the guest when it is long enough, but in the case of globular molecules the steric hindrance of the hydroxypropyl groups and the rigidity of the macrocycle (45) could be competing with its ability to extend the hydrophobic cavity. On the other hand, a clear trend cannot be found for the *K* values of the ionized species, revealing the differences in the molecular mechanism that governs the inclusion process with respect to their non-ionized counterparts, although some structural information would be clarifying.

Conclusions

The results reported can be summarized as follows: (*i*) the three monohydroxybenzoic acids are encapsulated by β-CD, DIMEB, and HPBCD with 1:1 stoichiometries. Higher stoichiometries have not been found; (*ii*) in all cases, the carboxylic forms of the guests bind a cyclodextrin with higher affinities than do the carboxylate partners, independently of the temperatures and of the substituents of both host and guest molecules; (*iii*) all the association processes have been found to be exothermic and enthalpy driven, with favorable enthalpic terms dominant over unfavorable entropic terms. The affinities of binding decrease with increasing temperature, indicating the contribution of van der Waals contacts, hydrophobic effect, and solvent reorganization as the main driving forces governing the interactions; (*iv*) the higher affinity shown by the acid forms on binding the DIMEB, relative to β-CD and HPBCD, has been attributed to the lengthening of the apolar CD cavity by the substitution of 14 H atoms by 14 methyl groups. On the other hand, the anionic forms present a more random behavior, with the particularity shown by HPBCD, which does not encapsulate the *m*-$OHBz^-$ and *p*-$OHBz^-$; (*v*) the effect of a steric factor, and possibly the presence of hydrogen bonding between the -OH and -COOH groups of the guest molecules, depending on their position, could be beyond the trends found for the CD:OHBz or CD:$OHBz^-$ affinities; and (*vi*) it is worth noting the importance of analyzing the encapsulation processes of non-ionized and ionized forms of the guest, when they occur, if clear and reasonable conclusions are required.

Tetraorganodichalcogenoimidodiphosphinato derivatives of dimethyltellurium(IV) compounds. Crystal structures of $Me_2Te[(SPPh_2)_2N]_2$, $Me_2TeCl[(SPPh_2)_2N]$, $Me_2TeI[(SPPh_2)_2N]$, and $Me_2TeCl[(OPPh_2)(SPPh_2)N]$

John E. Drake, Robert J. Drake, Anca Silvestru, and Jincai Yang

Abstract: Isolation of $Me_2Te[(SPPh_2)_2N]_2$, $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, and the halo derivatives $Me_2TeX[(SPPh_2)_2N]$ and $Me_2TeX[(OPPh_2)(SPPh_2)N]$, where X = Cl, Br, I, was attempted. Four of these were characterized by single crystal X-ray diffraction, while the formation of the others was confirmed by multinuclear NMR spectroscopy. $Me_2Te[(SPPh_2)_2N]_2$, **1**; $P2_1/n$ (No. 14) with cell parameters a = 14.908(3) Å, b = 11.122(5) Å, c = 30.384(6) Å, β = 92.67(2)°, V = 5032(2) Å^3, Z = 4, R = 0.0661, R_w = 0.0696. $Me_2TeCl[(SPPh_2)_2N]$, **2**; $P\bar{1}$ (No. 2) with cell parameters a = 10.553(2) Å, b = 15.512(2) Å, c = 8.769(3) Å, α = 103.19(2)°, β = 94.27(2)°, γ = 85.76(2)°, V = 1391.3(7) Å^3, Z = 2, R = 0.0377, R_w = 0.0328. $Me_2TeI[(SPPh_2)_2N]$, **4**; $P\bar{1}$ (No. 2) with cell parameters a = 10.954(3) Å, b = 15.580(3) Å, c = 8.751(3) Å, α = 103.49(2)°, β = 93.11(3)°, γ = 87.33(2)°, V = 1449.3(7) Å^3, Z = 2, R = 0.0586, R_w = 0.0613. $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**; $P2_1/c$ (No. 14) with cell parameters a = 10.441(9) Å, b = 13.672(10) Å, c = 19.521(9) Å, β = 97.16(6)°, V = 2764(3) Å^3, Z = 4, R = 0.0546, R_w = 0.0572. The immediate environment about Te is that of a sawhorse structure in which the lone pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid. In **1**, **2**, and **4**, one sulfur atom of $(SPPh_2)_2N$ occupies an axial position. If the second sulfur atom is included in the coordination sphere, then the environment about Te becomes distorted octahedral, for **1**, and square pyramidal, for **2** and **4**. By contrast, in $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, the oxygen atom, rather than sulfur, is bound to tellurium in the axial position, with the S atom, at best, having a very weak interaction with Te.

Key words: structure, tellurium, methyl, tetraphenyldichalogenoimidodiphosphinates.

Résumé : On a tenté d'isoler le $Me_2Te[(SPPh_2)_2N]_2$, le $Me_2Te[(OPPh_2)_2(SPPh_2)N]_2$ et les dérivés halogénés $Me_2TeX[(SPPh_2)_2N]$ et $Me_2TeX[(OPPh_2)(SPPh_2)_2N]$ dans lesquels X = Cl, Br, I. On a caractérisé quatre de ces complexes par diffraction des rayons X de monocristaux alors que la formation des autres a été confirmée par spectroscopie RMN multinucléaire. $Me_2Te[(SPPh_2)_2N]_2$ (**1**), $P2_1/n$ (No. 14), avec a = 14,908(3), b = 11,122(5) et c = 30,384(6) Å, β = 92,67(2)°, V = 5032(2) Å^3, Z = 4, R = 0,0661 et R_w = 0,0696. $Me_2TeCl(SPPh_2)_2N]$ (**2**), $P\bar{1}$ (No. 2), avec a = 10,553(2), b = 15,512(2) et c = 8,769(3) Å, α = 103,19(2)°, β = 94,27(2)° et γ = 85,76(2)°, V = 1391,3(7) Å^3, Z = 2, R = 0,0377, R_w = 0,0328. $Me_2TeI(SPPh_2)_2N]$ (**4**), $P\bar{1}$ (No. 2), avec a = 10,954(3), b = 15,580(3) et c = 8,751(3) Å, α = 103,49(2)°, β = 93,11(3)° et γ = 87,33(2)°, V = 1449,3(7) Å^3, Z = 2, R = 0,0586, R_w = 0,0613. $Me_2TeCl(OPPh_2)_2(SPPh_2)_2N$ (**6**), $P2_1/n$ (No. 14), avec a = 10,441(9), b = 13,672(10) et c = 19,521(9) Å, β = 97,16(6)°, V = 2764(3) Å^3, Z = 4, R = 0,0546 et R_w = 0,0572. L'environnement immédiat autour du Te correspond à une structure en chevalet dans laquelle la paire d'électron non pairée est apparemment stéréochimiquement active alors qu'elle occupe une position équatoriale dans une bipyramide trigonale déformée. Dans les composés **1**, **2** et **4**, un atome de soufre du groupe $(SPPh_2)_2N$ occupe une position axiale. Si le deuxième atome de soufre est inclus dans la sphère de coordination, l'environnement autour du Te devient alors un octaèdre déformé (composé **1**) et une pyramide carrée (composés **2** et **4**). Par opposition, dans le composé $Me_2TeCl(OPPh_2)_2(SPPh_2)_2N$ (**6**), c'est l'atome d'oxygène plutôt que l'atome de soufre qui est lié en position axiale du tellure; dans les meilleures conditions, l'atome de S n'offre qu'une faible interaction avec le Te.

Mots clés : structure, tellure, tétraphényldichalcogénoimidodiphophinates.

Introduction

The importance of supramolecular associations in molecular compounds of tellurium complexes with sulfur ligands has been recently reviewed (1). Several reports have appeared on organotellurium(IV) derivatives with 1,1-dithio ligands including *O*-alkyl dithiocarbonates (2–7), *N*,*N*-dialkyl dithiocarbamates (5–16), pyrrolidyl and piperidyl dithioformates (17), and dithiophosphates (18). Many of these sulfur-bonding derivatives of diorganotellurium(IV) display varying tendencies to undergo reductive elimination. The bonding can usually be described as anisobidentate (one strong and one weaker interaction with tellurium) and the ligands have similarly restricted bite lengths. We were therefore interested to see whether such features would be maintained using tetraphenylmono- and -di-thioimidodiphosphinates, which have relatively unrestricted bite lengths. We have reported on the molecular structures of triphenyltellurium derivatives $Ph_3Te[(SPPh_2)_2N]$, $Ph_3Te[(OPPh)_2(SPPh_2)N]$ and $Ph_3Te[(OPPh_2)_2N]$ (19, 20), and we now describe attempts to synthesize and spectroscopically characterize the dimethylbis(tetraorganodichalogenoimidodiphosphinato)tellurium(IV) compounds, $Me_2Te[(SPPh_2)_2N]_2$ and $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, as well as the corresponding halodimethyl compounds, $Me_2TeX[(SPPh_2)_2N]$ and $Me_2TeX[(OPPh_2)(SPPh_2)N]$, where X = Cl, Br, I. X-ray crystal structures are included for $Me_2Te[(SPPh_2)_2N]]_2$, **1**, $Me_2TeCl[(SPPh_2)_2N]$, **2**, $Me_2TeI[(SPPh_2)_2N]$, **4**, and $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**.

Experimental

Materials

$TeCl_4$, and Me_4Sn were obtained from Aldrich, and $TeBr_4$ and Me_2TeI_2 from Alfa and Organometallics, Inc., respectively, all starting materials being used as supplied. Me_2TeCl_2 and Me_2TeBr_2 were prepared by adaptation of the method described in the literature for the preparation of Ph_2TeCl_2 (21) involving the reaction of $TeCl_4$ or $TeBr_4$ with Me_4Sn in toluene at 60°C under reflux for 4 h. The salts $K[(SPPh_2)_2N]$ and $Na[(OPPh_2)(SPPh_2)N]$ were prepared as described previously (22, 23). All solvents were dried and distilled prior to use and all reactions were carried out under anhydrous conditions. Elemental analyses were performed at Guelph Chemical Laboratories, Guelph, Ontario.

Preparation of $Me_2Te[(SPPh_2)_2N]_2$, 1, and $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, 5

Typically, Me_2TeCl_2 (0.048 g, 0.167 mmol) and $K[(SPPh_2)_2N]$ (0.170 g, 0.350 mmol) were placed in a flask followed by the addition of toluene (15 mL). The mixture was stirred at room temperature for 1 h before being filtered to remove KCl and unreacted materials. The filtrate was concentrated by pumping off the solvent, followed by the addition of *n*-hexane (5 mL), and then left in the refrigerator at 5°C to allow the formation of $Me_2Te[(SPPh_2)_2N]_2$, **1**; yellow crystals; mp (dec.) 152°C, 0.153 g, 0.140 mmol, yield 84%. ^{1}H NMR ($CDCl_3$) δ: 2.42 (6H, Te-CH_3), 7.29 (24H, P(S)-C_6H_5, *m* + *p*), 7.85 (16H, P(S)-C_6H_5, *o*). ^{13}C NMR ($CDCl_3$) δ: 22.03 (Te-CH_3), 128.14 (C_m, P(S)-C_6H_5), 130.64 (C_p, P(S)-C_6H_5), 131.18 (C_o, P(S)-C_6H_5). ^{31}P NMR ($CDCl_3$) δ: 35.8 (*P*(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 566. Anal. calcd. for $C_{50}H_{46}N_2P_4S_4Te$: C 56.94, H 4.40, N 2.66; found: C 57.15, H 4.48, N 2.65. Similarly, starting with Me_2TeCl_2 and a twofold excess of $Na[(OPPh_2)(SPPh_2)N]$, was formed $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, **5**; yellow viscous material. ^{1}H NMR ($CDCl_3$) δ: 2.69 (6H, Te-CH_3), 7.28 (P(O)-C_6H_5, *m* + *p*, and P(S)-C_6H_5, *m* + *p*), 7.68 (8H, P(O)-C_6H_5, *o*), 7.94 (8H, P(S)-C_6H_5, *o*), along with peaks attributable to toluene. ^{13}C NMR ($CDCl_3$) δ: 25.80 (Te-CH_3), 127.94 (C_m, P(O)-C_6H_5), 128.20 (C_m, P(S)-C_6H_5), 130.82, 130.95 (C_p, P(O)-C_6H_5 and P(S)-C_6H_5), 131.29, 131.42 (C_o, P(O)-C_6H_5 and P(S)-C_6H_5), along with peaks attributable to toluene. ^{31}P NMR ($CDCl_3$) δ: 21.3 (*P*(O)-C_6H_5), 39.7 (*P*(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 571. Attempts to recrystallize as described above did not yield X-ray quality crystals, but resulted in decomposition.

Preparation of $Me_2TeCl[(SPPh_2)_2N]$, 2, and $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, 6

Typically, Me_2TeCl_2 (0.039 g, 0.135 mmol) and $K[(SPPh_2)_2N]$ (0.066 g, 0.135 mmol) were placed in a flask followed by the addition of toluene (15 mL). The mixture was stirred at room temperature for 2 h before being filtered to remove KCl and unreacted materials. The filtrate was concentrated by pumping off solvent, followed by the addition of *n*-hexane (5 mL) and then left in the refrigerator at 5°C to allow the formation of $Me_2TeCl[(SPPh_2)_2N]$, **2**; colorless crystals; mp (dec.) 106°C, 0.075 g, 0.117 mmol, yield 87%. ^{1}H NMR ($CDCl_3$) δ: 2.72 (6H, Te-CH_3), 7.31 (12H, P(S)-C_6H_5, *m* + *p*), 7.86 (8H, P(S)-C_6H_5, *o*). ^{13}C NMR ($CDCl_3$) δ: 23.39 (Te-CH_3), 128.16 (C_m, P(S)-C_6H_5), 130.10 (C_p, P(S)-C_6H_5), 131.20 (C_o, P(S)-C_6H_5). ^{31}P NMR ($CDCl_3$) δ: 43.2 (*P*(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 618. Anal. calcd. for $C_{26}H_{26}NP_2S_2ClTe$: C 48.67, H 4.08, N 2.18; found: C 48.88, H 4.01, N 2.01. Similarly, starting with Me_2TeCl_2 (0.101 g, 0.350 mmol) and $Na[(OPPh_2)(SPPh_2)N]$ (0.159 g, 0.350 mmol), was formed $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**; colorless crystals; mp (dec.) 130°C, 0.189 g, 0.302 mmol, yield 86%. ^{1}H NMR ($CDCl_3$) δ: 2.80 (6H, Te-CH_3), 7.30 (12H, P(O)-C_6H_5, *m* + *p*, and P(S)-C_6H_5, *m* + *p*), 7.70 (4H, P(O)-C_6H_5, *o*), 7.90 (4H, P(S)-C_6H_5, *o*). ^{13}C NMR ($CDCl_3$) δ: 26.00 (Te-CH_3), 128.10 (C_m, P(O)-C_6H_5), 128.34 (C_m, P(S)-C_6H_5), 129.13, 129.75 (C_p, P(O)-C_6H_5 and P(S)-C_6H_5), 131.23, 131.94 (C_o, P(O)-C_6H_5 and P(S)-C_6H_5). ^{31}P NMR ($CDCl_3$) δ: 21.8 (*P*(O)-C_6H_5), 39.8 (*P*(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 580. Anal. calcd. for $C_{26}H_{26}NOP_2SClTe$: C 49.92, H 4.19, N 2.24; found: C 49.68, H 4.12, N 2.18.

Formation of $Me_2TeBr[(SPPh_2)_2N]$, 3 and $Me_2TeBr[(OPPh_2)(SPPh_2)N]$, 7

Typically, Me_2TeBr_2 (0.062 g, 0.195 mmol) and $K[(SPPh_2)_2N]$ (0.095 g, 0.195 mmol) were placed in a flask followed by the addition of toluene (15 mL). The mixture was stirred at room temperature for 2 h before being filtered to remove KBr and unreacted materials. The solvent was pumped off to give $Me_2TeBr[(SPPh_2)_2N]$, **3**, a yellow viscous material that darkened with time. ^{1}H NMR ($CDCl_3$) δ: 2.77 (6H, Te-CH_3), 7.37 (12H, P(S)-C_6H_5, *m* + *p*), 7.89 (8H, P(S)-C_6H_5, *o*), along with peaks attributable to toluene. ^{13}C NMR ($CDCl_3$) δ: 22.64 (Te-CH_3), 128.55 (C_m, P(S)-C_6H_5), 130.68 (C_p, P(S)-C_6H_5), 131.12 (C_o, P(S)-C_6H_5), along with peaks attributable to toluene. ^{31}P NMR ($CDCl_3$) δ: 43.3

(P(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 590. Similarly, starting with Me_2TeBr_2 and an equimolar amount of Na[($OPPh_2$)($SPPh_2$)N], was formed Me_2TeBr[($OPPh_2$)($SPPh_2$)N], **7**, a pale yellow viscous material that darkened with time. ^{1}H NMR ($CDCl_3$) δ: 2.87 (6H, Te-CH_3), 7.33 (12H, P(O)-C_6H_5, m + p, and P(S)-C_6H_5, m + p), 7.79 (4H, P(O)-C_6H_5, o), 7.864 (4H, P(S)-C_6H_5, o), along with peaks attributable to toluene. ^{13}C NMR ($CDCl_3$) δ: 25.29 (Te-CH_3), 128.36 (C_m, P(O)-C_6H_5 and C_m, P(S)-C_6H_5), 130.80, 130.99 (C_p, P(O)-C_6H_5 and P(S)-C_6H_5), 131.15, 131.24 (C_o, P(O)-C_6H_5 and P(S)-C_6H_5), along with peaks attributable to toluene. ^{31}P NMR ($CDCl_3$) δ: 20.3 (P(O)-C_6H_5), 39.7 (P(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 578. Attempts to recrystallize **3** and **7** as described above for **2** and **6** resulted in decomposition.

Preparation of $Me_2TeI[(SPPh_2)_2N]$, 4, and $Me_2TeI[(OPPh_2)(SPPh_2)N]$, 8

Typically, Me_2TeI_2 (0.125 g, 0.304 mmol) and K[$(SPPh_2)_2$N] (0.148 g, 0.304 mmol) were placed in a flask followed by the addition of toluene (15 mL). The mixture was stirred at room temperature for 1 h before being filtered to remove KI and unreacted materials. The filtrate was concentrated by pumping off solvent, followed by the addition of *n*-hexane (5 mL), and was then left in the refrigerator at 5°C to allow the formation of $Me_2TeI[(SPPh_2)_2N]$, **4**, yellow crystals, mp (dec.) 105°C, to form a brown solid that darkened considerably at 230°C, 0.190 g, 0.259 mmol, yield 86%. ^{1}H NMR ($CDCl_3$) δ: 2.76 (6H, Te-CH_3), 7.35 (12H, P(S)-C_6H_5, m + p), 7.88 (8H, P(S)-C_6H_5, o). ^{13}C NMR ($CDCl_3$) δ: 20.74 (Te-CH_3), 128.44 (C_m, P(S)-C_6H_5), 131.04 (C_p, P(S)-C_6H_5), 131.18 (C_o, P(S)-C_6H_5). ^{31}P NMR ($CDCl_3$) δ: 33.6 (P(S)-C_6H_5). ^{125}Te NMR ($CDCl_3$) δ: 557. Anal. calcd. for $C_{26}H_{26}NP_2S_2ITe$: C 42.60, H 3.58, N 1.91; found: C 42.76, H 3.62, N 1.83. Similarly, starting with Me_2TeI_2 and an equimolar amount of Na[($OPPh_2$)($SPPh_2$)N] was formed, Me_2TeI[($OPPh_2$)($SPPh_2$)N], **8**; brown viscous material. ^{1}H NMR ($CDCl_3$) δ: 2.84 (6H, Te-CH_3), ca. 7.20 (P(O)-C_6H_5, o), 7.40 (4H, P(S)-C_6H_5, o), 7.60 (8H, P(O)-C_6H_5, o and P(S)-C_6H_5, o). ^{13}C NMR ($CDCl_3$) δ: 23.39 (Te-CH_3), 127.68 (C_m, P(O)-C_6H_5), 127.88 (C_m, P(S)-C_6H_5), 128.60 (C_p, P(O)-C_6H_5), 130.62 (C_p, P(S)-C_6H_5), 131.42, 131.90 (C_o, P(O)-C_6H_5 and P(S)-C_6H_5)]. ^{125}Te NMR ($CDCl_3$) δ: 525. Attempts to recrystallize as described above resulted in decomposition.

Physical measurements

^{1}H and ^{13}C {H} NMR spectra were recorded on a Bruker 300 FT/NMR spectrometer at 300.133 and 75.471 MHz, respectively, in $CDCl_3$ using Me_4Si as internal standard. The ^{31}P and ^{125}Te NMR spectra were recorded on a Bruker 200 FT/NMR spectrometer in $CDCl_3$ using 85% H_3PO_4 and Me_2Te, respectively, as external standard. All NMR spectra were run at ambient temperature under standard operating conditions. The melting points were determined on a Fisher–Johns apparatus.

X-ray crystallographic analysis

Yellow block crystals of $Me_2Te[(SPPh_2)_2N]_2$, **1**, and $Me_2TeI[(SPPh_2)_2N]$, **4**, and colorless block crystals of $Me_2TeCl[(SPPh_2)_2N]$, **2**, and $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, were mounted on glass fibres and sealed with epoxy glue. Data were collected on a Rigaku AFC6S diffractometer, with graphite-monochromated Mo Kα radiation operating at 50 kV and 35 mA. Cell constants corresponded to monoclinic (for **1** and **6**), and triclinic (for **2** and **4**) cells whose dimensions are given in Table 1, along with other experimental parameters. Based on the appropriate systematic absences for **1** and **6**, statistical analyses of intensity distributions, and the successful solution and refinement of the structures, the space groups were determined to be $P2_1/n$ and $P2_1/c$ (No. 14) for **1** and **6**, respectively, and $P\bar{1}$ (No. 2) for **2** and **4**. The data were corrected for Lorentz and polarization effects and an empirical absorption correction was applied. The structures were solved by direct methods (24) and all calculations were performed using the TEXSAN (25) crystallographic software package of the Molecular Structure Corp.[2] For **1**, the phenyl groups were treated as fixed rings with the C—C distances set at 1.40 Å. Hydrogen atoms attached to carbon were included in their idealized positions with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. All non-hydrogen atoms were refined anisotropically for **2** and **6**, all non-hydrogen atoms except carbon for **1**, and only the tellurium and iodide atoms for **4**.

The unweighted and weighted agreement factors and standard deviations of an observation of unit weight[3] are given in Table 1. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, sin θ/λ, and various classes of indices showed no unusual trends. Selected distances and bond angles are given in Tables 2–4 and ORTEP diagrams in Figs. 1 and 2. Additional crystallographic data are available as supporting information. Tables of final atomic coordinates and equivalent isotropic thermal parameters for the non-hydrogen atoms, final anisotropic thermal parameters of non-hydrogen atoms, final fractional coordinates and thermal parameters of hydrogen atoms, and all bond distances and angles have been deposited.[4]

Calculation of Pauling partial bond orders

We have introduced an adjustment to Pauling's calculation of partial bond orders (26), which was essentially based on the C—C single bond, to readily obtain estimates of the partial bond orders within these tellurium complexes (2). Thus,

[2] Least squares: function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/(Lp)^2$, S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, Lp = Lorentz-polarization factor, and p = p factor.

[3] Standard deviation of an observation of unit weight: $\Sigma w(|F_o| - |F_c|)^2/N_o - N_v)^{1/2}$, where N_o = number of observations and N_v = number of variables.

[4] Copies of material deposited (tables of fractional atomic coordinates, isothermal parameters and anisotropic thermal parameters, interatomic bond distances and angles) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada. Tables of atomic coordinates and of bond distances and angles have also been deposited with the Cambridge Crystallographic Centre, and can be obtained on request from The Director, Cambridge Crystallographic Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, UK. Structure factor amplitudes are no longer being deposited and may be obtained directly from the author.

Pauling's relationship is modified so that for $n = 10^X$, $X = [1.54(d - d_n)/d]/0.6$ or $X = 2.57(d - d_n)/d$, where d_n is the bond length for bond number *n*, and *d* is the length of the single bond of the same type. Based on the assumption that in these compounds the appropriate Te—S single bond length has an average value of 2.62 Å in **1**, **2**, and **3**, typical calculated values of the lengths of Te—S partial bonds for various values of *n* are as follows: 2.62 Å (*n* = 1.0), 2.75 (0.75), 2.93 (0.50), 3.24 (0.25), and 3.64 Å (*n* = 0.10). Similarly, based on the assumption that the appropriate Te—Cl, Te—Br, and Te—I single bond lengths are those found in the corresponding Me_2TeX_2 compounds of 2.51, 2.68, and 2.92 Å, respectively, for X = Cl, Br, and I, typical calculated values of the lengths of Te—X partial bonds for various values of *n* are as follows: for Te—Cl, 2.51 Å (*n* = 1.0), 2.63 (0.75), 2.80 (0.50), 3.10 (0.25), and 3.49 Å (*n* = 0.10); for Te—Br, 2.68 Å (*n* = 1.0), 2.81 (0.75), 2.99 (0.50), 3.31 (0.25), and 3.71 Å (*n* = 0.10); and for Te—I, 2.92 Å (*n* = 1.0), 3.06 (0.75), 3.26 (0.50), 3.60 (0.25), and 4.06 Å (*n* = 0.10). The corresponding "valences" for partial bonds, which were calculated for the Te—I bonds in TeI_4, gave 3.16 (0.40) and 3.50 Å (0.20) (27).

Results and discussion

Preparation of the tetraphenyldi- and -mono-thioimidodiphosphinate bis derivatives of dimethyltellurium(IV), $Me_2Te[(SPPh_2)_2N]_2$, **1**, and $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, **5**, is achieved by the reaction of an excess of the potassium or sodium salt of the appropriate imidodiphosphinate with dimethyltellurium dichloride in toluene in accord with eq. [1]:

[1] $$Me_2TeCl_2 + 2M[(EPPh_2)(SPPh_2)N] = Me_2Te[(EPPh_2)(SPPh_2)N]_2 + 2MCl$$

(M = Na or K; E = S or O)

Halodimethyl(tetraphenyldi- and -mono-thioimidodiphosphinato)tellurium(IV) compounds, $Me_2TeCl[(SPPh_2)_2N]$, **2**, $Me_2TeBr[(SPPh_2)_2N]$, **3**, $Me_2TeI[(SPPh_2)_2N]$, **4**, $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, $Me_2TeBr[(OPPh_2)(SPPh_2)N]$, **7**, and $Me_2TeI[(OPPh_2)(SPPh_2)N]$, **8**, can be similarly prepared by the reaction of equimolar amounts of the appropriate salt with dimethyltellurium dihalide in accord with eq. [2]:

[2] $$Me_2TeX_2 + M[(EPPh_2)(SPPh_2)N] = Me_2TeX[(EPPh_2)(SPPh_2)N] + MX$$

(X = Cl, Br, or I; M = Na or K; E = S or O)

However, four of these products, notably **3**, **5**, **7** and **8**, were not isolated in a pure state totally free of solvent because of a tendency to decompose when attempts were made to recrystallize or remove the last traces of solvent. By contrast, **1**, **2**, **4**, and **6** were isolated in good yields (ca. 85%) and were obtained as X-ray quality crystals on recrystallization from mixed toluene–*n*-hexane solvents. None showed signs of decomposition during X-ray data collection, which was carried out at room temperature.

[a]Symmetry equivalent position (2 – *x*, –*y*, –*z*) denoted by a prime and (2 – *x*, *y* – 1/2, ½ – *z*) denoted by a double prime.

Crystal structures of $Me_2Te[(SPPh_2)_2N]_2$, 1, $Me_2TeCl[(SPPh_2)_2N]$, 2, $Me_2TeI[(SPPh_2)_2N]$, 4, and $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, 6

$Me_2Te[(SPPh_2)_2N]_2$, **1**, crystallizes in the space group $P2_1/n$. The ORTEP diagram in Fig. 1*a* illustrates that the immediate environment about tellurium is the sawhorse structure typical of tellurium(IV) compounds, at least in the gas phase, in which the lone pair is assumed to be active stereochemically and occupying an equatorial position in a distorted trigonal bipyramid approximately at the location of the Te(1) label. The two methyl groups occupy the other two equatorial positions with the Te—C bond length of 2.13(3) Å essentially the same as those in related dithio derivatives. The C(1)-Te(1)-C(2) bond angle of 90(1)° is much closer to 90° than is normally found, as exemplified by angles of 96.2(2)°, 97.1(1)°, and 96.6(3)°, respectively, for $Me_2Te[S_2COEt]_2$ (2), $Me_2Te[S_2CN(CH_2)_3CH_2]_2$ (17), and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ (18). The axial positions are occupied by one sulfur atom from each of the $(SPPh_2)_2N$ groups. The S(1)-Te(1)-S(3) bond angle of 169.6(2)° is the same as in $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$, close to those in $Me_2Te[S_2CN(CH_2)_4CH_2]_2$ (17) and $Me_2Te[S_2POCMe_2CMe_2O]_2$ (18), (173.1(1) and 173.26(7)°, respectively) and larger than in $Me_2Te[S_2CN(CH_2)_3CH_2]_2$, 162.2(3)°. The average length of these axial Te—S bonds, 2.64(1) Å, is longer than has generally been reported for related dithio derivatives and one of these bonds is clearly longer than the other. When the two Te—S bond lengths differ, the sulfur atom of the longer bond has frequently been associated with the tellurium atom of an adjacent molecule at contact distances less than the sum of the van der Waals radii of 3.86 Å. However, this is not the case in **1**, as has also been found for other derivatives with bulky ligands such as $Me_2Te[S_2CN(CH_2)_4CH_2]_2$, $Me_2Te[S_2CN(CH_2)_3CH_2]_2$, $Me_2Te[S_2POCMe_2CMe_2O]_2$, and $Me_2Te[S_2POCH_2CEt_2CH_2O]_2$ (17, 18).

The apparently nonbonded S(2) and S(4) atoms are both oriented toward the tellurium center at Te—S distances of 3.345(8) and 3.572(6) Å, which are at the high end of the

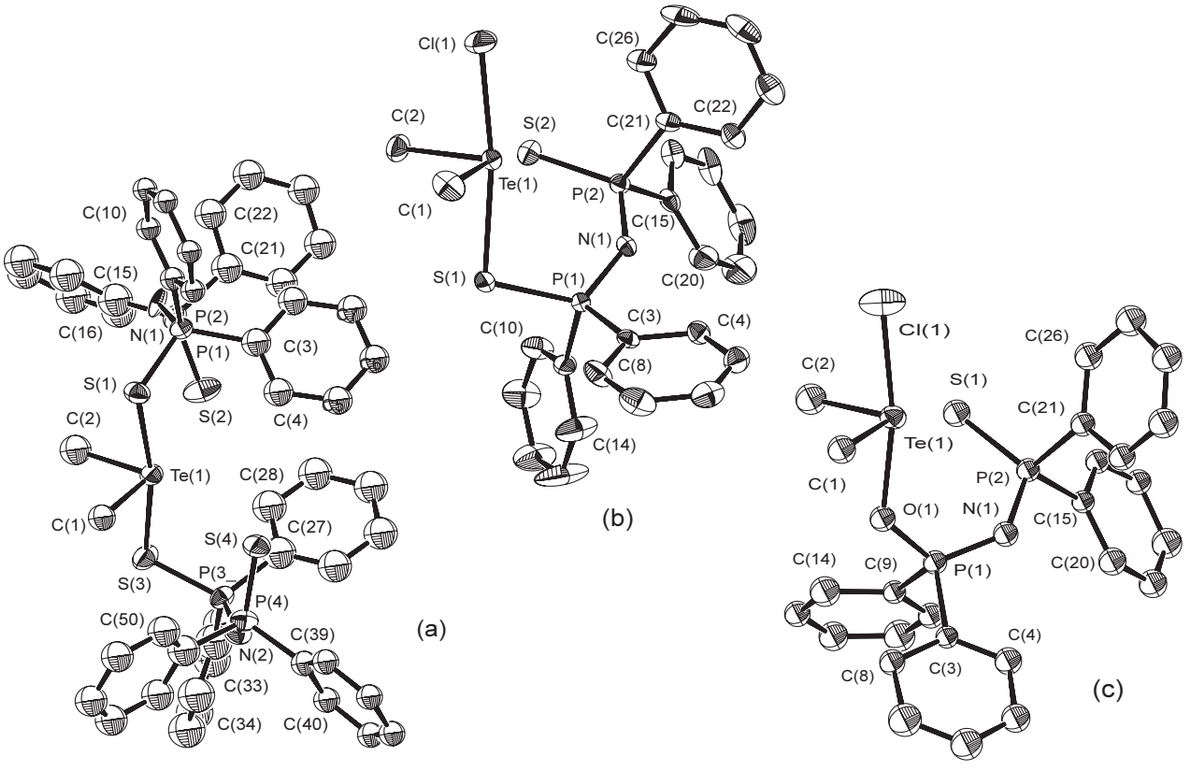
Fig. 1. ORTEP plots of the molecules (*a*) $Me_2Te[(SPPh_2)_2N]_2$, **1**; (*b*) $Me_2TeCl[(SPPh_2)_2N]$, **2**; and (*c*) $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, showing the immediate environment about tellurium. Atoms are drawn with 30% probability ellipsoids and spheres with hydrogen atoms omitted for clarity.



range of those found in related dithio derivatives, 3.162(4)–3.33(1) Å. These distances correspond to normalized Pauling partial bond orders of less than 0.25, but are still compatible with their being part of the coordination sphere as demonstrated in Fig. 2*a*. The orientation of the two unsymmetrical bidentate or anisobidentate $(SPPh_2)_2N$ groups results in a distorted octahedral environment about Te(1), the distortion being much less than has been previously found in, for example, $Me_2Te[S_2CN(CH_2)_4CH_2]_2$ (17), suggesting an essentially inactive lone pair, or one with a high percentage of *s*-character. The Te-S-P angles of the two ligands are 107.7(3)° and 108.2(3)°, leading to S-Te—S bite angles of 90.1(2)° and 88.4(2)° and S—S bite lengths of 4.27(1) and 4.343(9) Å. This is in contrast to typical bite angles and lengths of ca. 60° and ca. 2.99 Å, respectively, found with the more restricted S_2COR and S_2CNR_2 ligands (2, 8, 15, 17). The more flexible $(SPPh_2)_2N$ fragments should be capable of forming bidentate ligands but instead appear to establish similar anisobidentate distances with the Te—S anisobond essentially *trans* to a methyl group and *cis* to the "fully bonded" sulfur atom of the adjacent ligand with S(2)—Te(1)-S(3) and S(4)—Te(1)-S(1) being 94.3° and 98.3(2)°, respectively. In $Me_2Te[S_2CN(CH_2)_4CH_2]_2$, the corresponding angles are more distorted from 90°, with values of 123.1(1)° and 121.6(1)° (17).

$Me_2TeCl[(SPPh_2)_2N]$, **2**, and $Me_2TeI[(SPPh_2)_2N]$, **4**, both crystallize in the space group $P\bar{1}$. The ORTEP diagram of **2** in Fig. 1*b* illustrates that, as for **1**, the immediate environment about tellurium for **2** and **4** is again the sawhorse structure but with the halogen atoms now occupying one of the axial positions to give X(1)-Te(1)-S(1) angles of 172.18(6)° and 172.7(2)°, respectively, for **2** and **4**. The average Te—C bond length of 2.12(1) Å is essentially the same as in **1**, but the C(1)-Te(1)-C(2) angles, with an average of 95.2(2)°, are no longer as close to 90° as they were in the bis compound. The average Te(1)—S(1) distance of 2.62(2) Å in **2** and **4** is similar to those in **1**, whereas in the corresponding $Me_2TeX[S_2COEt]$ and $Me_2TeX[S_2CN(CH_2)_nCH_2]$ species there was considerable shortening of the Te—S bond, with distances of ca. 2.51 Å indicating much stronger bonds in these halo derivatives with estimated bond orders of up to 1.30 (17, 28). In $Me_2TeX[S_2COEt]$ and $Me_2TeX[S_2CN(CH_2)_nCH_2]$ derivatives, the Te—X bonds were found to be distinctly longer than in related R_2TeX_2 species, an average of 2.670(7) Å for Te—Cl bonds compared to 2.51(4) Å for Me_2TeCl_2 (29), and an average of 3.05(3) Å for Te—I bonds compared to a range of 2.885(3) to 2.994(3) Å in Me_2TeI_2 (30). This shortening of the Te—S bond and lengthening of the Te—X bonds appeared to be a general example of the *trans* influence operating on a main group metal for such derivatives of tellurium. Therefore, by contrast and, surprisingly, in $Me_2TeX[(SPPh_2)_2N]$, the Te(1)—Cl(1) bond in **2** is, within experimental error, the same length as in Me_2TeCl_2, and the Te(1)—I(1) bond in **4** at 2.900(3) Å is within the range of the bond lengths in Me_2TeI_2. This suggests that the sulfur atoms in $(SPPh_2)_2N$ have far less *trans*

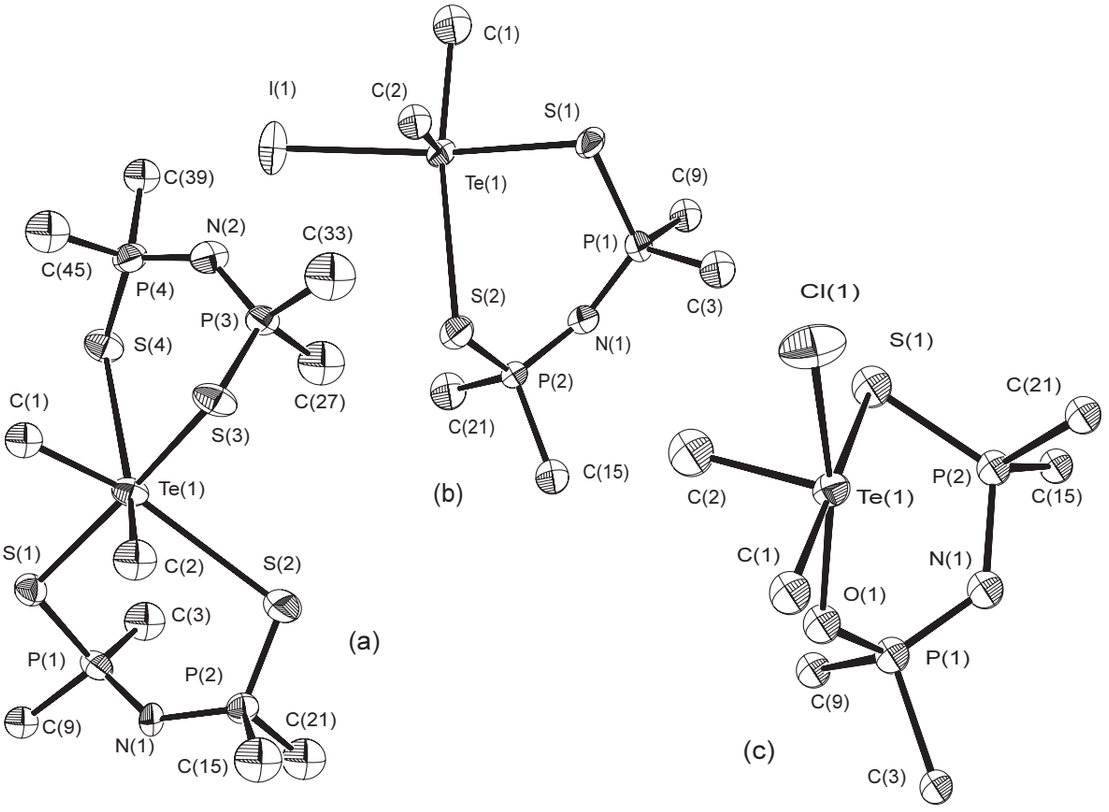
Fig. 2. ORTEP plots of the molecules (*a*) $Me_2Te[(SPPh_2)_2N]_2$, **1**; (*b*) $Me_2TeI[(SPPh_2)_2N]$, **4**; and (*c*) $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, showing the stereochemistry about tellurium when the intramolecular interactions leading to unsymmetrical bidentate ligands are included. The atoms are drawn with 30% probability ellipsoids and spheres. Hydrogen atoms and the carbon atoms of the phenyl rings other than those attached to phosphorus are omitted for clarity.



influence than in halo-dithiocarbonates and -dithiocarbamates and the Te—S bonds are generally weaker in these dithioimido compounds.

As with **1**, the $(SPPh_2)_2N$ group in **2** and **4** can be treated as an unsymmetrical bidentate ligand with the pendant S atom as part of the coordinating sphere to give Te—S anisobonds of similar length, Te(1)—S(2) 3.367(2) Å in **2** and 3.361(8) Å in **4**, respectively. The orientation of the phosphorus ligand is identical in **2** and **4**, giving rise to a distorted square pyramidal arrangement about tellurium in both cases or a distorted pseudo-octahedral arrangement if the lone pair is now assumed to be occupying the position *trans* to C(2), as is illustrated for **4** in Fig. 2*b*. The Te-S-P angles in **2** and **4** of 103.49(7)° and 102.7(4)°, respectively, are slightly smaller than in **1**, resulting in smaller S(1)-Te(1)—S(2) bite angles of 79.43(5)° and 80.4(2)°, respectively, and S(1)—S(2) bite lengths of 3.862(2) and 3.91(1) Å, respectively. As with **1**, the P—S(Te) bonds are longer, 2.045(7) Å for **1**, 2.047(2) Å for **2**, and 2.05(1) Å for **4**, than those of the aniso *P*=S—(Te) bonds, 1.962(3) for **1**, 1.964(2) Å for **2**, and 1.97(1) Å for **4**.

The weak intramolecular Te—S interactions, which range from 3.345(8) to 3.527(6) Å in **1**, **2**, and **4**, are of the same magnitude as in $Ph_3Te[(SPPh_2)_2N]$, 3.331–3.655 Å (19). The short and long tellurium–sulfur distances correspond with long and short phosphorus–sulfur bonds, which are typical for P—S single and P=S double bonds (P—S (avg.) 2.047(5) Å, P=S (avg.) 1.965(4) Å); cf. $MeS\text{-}PPh_2\text{=}N\text{-}Ph_2P\text{=}S$:[5] P—S 2.069(3) Å, P=S 1.9563(3) Å). Consequently, the phosphorus–nitrogen bond lengths are also different, corresponding to P=N double and P—N single bonds (P=N (avg.) 1.563(17) Å, P—N (avg.) 1.615(13) Å); cf. $MeS\text{-}PPh_2\text{=}N\text{-}Ph_2P\text{=}S$:[5] P=N 1.568(4) Å, P—N 1.610(4) Å). As expected, the PNP unit in the dithioimidodiphosphinato ligands is angular and the magnitude of the P-N-P angle, which ranges from 129(1)° in **1**, to 139.1(3)° in **2**, is consistent with the high flexibility of the SPNPS fragment. The resulting TeS_2P_2N rings display different conformations (Table 5). Thus in **1**, both six-membered rings may be discussed in terms of a boat with a variable degree of distortion (Fig. 3*a*, *b*), while in both halo derivatives the TeS_2P_2N rings are folded along the S(1)—-S(2) axis (Fig. 3*c*, *d*) as was found in the $Ph_3Te[(SPPh_2)_2N]$ derivative (Fig. 3*e*) (19). The TeS_2/S_2P_2N dihedral angle is 104.9° in **2**, 104.4° in **4**, and 114.4° in $Ph_3Te[(SPPh_2)_2N]$.

$Me_2TeCl[(OPPh_2)(SPPh_2)N]$, **6**, crystallizes in the space group $P2_1/c$ and the ORTEP diagram, Fig. 1*c*, illustrates that, as with **2** and **4**, the immediate environment about tellurium is the sawhorse structure with the chlorine atom now occupying one of the axial positions. However, in contrast to

S(3)Te(1)S(4)P(4)	–18.3						

[a]In **1**, one ring is a boat with S(2) and P(1) on vertices.

[b]In **1**, the second ring is a twisted boat with S(4) and P(3) on vertices.

[c]In **2**, **4**, and $Ph_3Te[(SPPh_2)_2N]$ the ring is folded about the S(1)—-S(2) axis.

[d]In **6** the ring is folded about the O(1)—-S(1) axis.

[e]In $Ph_3Te[(OPPh_2)(SPPh_2)N]$ the ring is folded about the N(1)—-S(1) axis.

the halo-dithioimidodiphosphinato derivatives and any other related monothio derivatives such as the $Me_2TeX[SCONEt_2]$ (31) and $Me_2TeX[SCO_2R]$ series (32), the oxygen atom in **6** forms the primary bond in the axial position to give a Cl(1)-Te(1)-O(1) angle of 168.9(4)° with the sulfur atom forming a Te—S aniso-bond. This is also contrary to what was observed in $Ph_3Te[(OPPh_2)(SPPh_2)N]$ where neither chalcogen forms a short bond. However, it is consistent with the generally weaker Te—S bonds in the $Me_2TeX[(SPPh_2)_2N]$ species and the lack of a *trans* influence. The Te—O distance of 2.14(2) Å is similar to the lengths of the primary Te—O bonds in $Ph_2Te(O_2CCH_3)_2$ (2.160 Å) (33) and $Ph_2Te(O_2CCCl_3)_2$ (2.156 Å) (34). The Te—Cl bond (2.464(8) Å) is clearly not longer than in Me_2TeCl_2 (2.51(4) Å), confirming that the imidodiphosphinato ligands are demonstrating different behavior from other monothio derivatives because the Te—Cl bonds in $Me_2TeCl[SCONEt_2]$ and $Me_2TeCl[SCO_2Me]$ are considerably longer at 2.792(2) and 2.703(3) Å, respectively.

When the relatively long Te(1)—S(1) aniso-bond (3.413(7) Å) is included in the coordination sphere it gives rise to the same distorted square pyramidal arrangement about tellurium as was found with **2** and **4** (see Fig. 2*c*). The primary coordination of $(OPPh_2)(SPPh_2)N$ through oxygen is consistent with the length of the P(1)—O(1) bond (1.56(1) Å), which is typical for a single P—O bond, whereas the P(2)—S(1) bond length (1.973(8) Å) is similar to that of the aniso-bonded sulfur atom in **1**, **2**, and **4**, and is typical for a P=S bond (cf. $PPh_2(=S)OMe$ (35): P—O 1.60(2) Å; $(OPPh_2)(SPPh_2)NH$ (23): P=O (avg.) 1.503(16), P=S (avg.) 1.925(14) Å; $Na(OPPh_2)(SPPh_2)N$ (36): P=O 1.494(7), P=S 1.979(4) Å). Again, the different phosphorus–nitrogen bond lengths are consistent with P=N double and P—N single bonds (P(1)=N(1) 1.56(2) Å, P(2)—N(1) 1.64(2) Å); cf. $MeS\text{-}PPh_2{=}N\text{-}Ph_2P{=}S$:[5] P=N 1.568(4), P—N 1.610(4) Å). The conformation of the $TeOSP_2N$ ring is similar to those displayed by the $Me_2TeX[(SPPh_2)_2N]$ derivatives (Table 5) being folded along the O(1)—-S(1) axis (Fig. 3*f*), but quite different from that observed for $Ph_3Te[(OPPh_2)(SPPh_2)N]$ where the ring is folded about the N(1)—-S(1) axis (Fig. 3*g*). This behavior again confirms the high flexibility of the XPNPY fragment in this class of ligands.

Nuclear magnetic resonance spectra

The ^1H, ^{13}C, ^{31}P, and ^{125}Te NMR spectra presented in the experimental section are assigned based on the spectra taken as quickly as possible immediately after dissolving the compounds in $CDCl_3$. For **1**, **2**, **4**, and **6** the integration of the peaks in the ^1H NMR spectra confirms the presence of the assigned compound in solution and the absence of other peaks indicates greater than 99% purity relative to other H-containing species. The integration also confirms the presence of **3**, **5**, **7**, and **8**, the overlap with the toluene peaks being somewhat limited. In general, the quality of the ^{31}P and ^{125}Te NMR spectra was much poorer for **3**, **5**, **7**, and **8**. In the ^1H NMR spectra, all of the derivatives show a sharp peak attributable to the methyl group attached to tellurium, and the C*H*$_3$-Te chemical shift of 2.42 ppm in $Me_2Te[(SPPh_2)_2N]_2$, **1**, is close to the values observed for Me_2TeL_2 species, where L = $S_2P(OPh)_2$ (18) (2.40 ppm), S_2CNR_2 (15, 17) (2.46–2.49 ppm), and S_2COR (2) (2.52–2.55 ppm), but somewhat lower than for S_2POGO (18) (2.68–2.69 ppm for G = CMe_2CMe_2, CHMeCHMe, $CH_2CMe_2CH_2$, and $CH_2CEt_2CH_2$) all of which have anisobidentate ligands, with short and long Te—S distances similar to those in **1**. The chemical shifts of the $Me_2TeX[(SPPh_2)_2N]$ species **2**–**4** range from 2.72 to 2.77 ppm, which is a similar range to those observed for the Me_2TeXL species, where L = S_2CNR_2 (15, 17) (2.75–2.81 ppm) and S_2COR (28) (2.79–2.87 ppm). By contrast with the chemical shift of **1**, that of $Me_2Te[(OPPh_2)(SPPh_2)N]_2$, **5**, is 2.69 ppm, putting it near the range of many partially halogenated species. But for the exception of the $Me_2Te[S_2POGO]_2$ species, it would be reasonable to suggest that this reflects the fact that, in contrast to **1** and the

other Me_2TeL_2 species, the primary bond may well be with the more electronegative oxygen atom, as it is in the solid state structure of **6**. In other related monothio derivatives such as $Me_2Te[SCONR_2]_2$ (31) and $Me_2Te[SCO_2R]_2$ (32),

© 1999 NRC Canada

where the primary bond is Te—S, the chemical shifts are again closer to 2.42, at ca. 2.45 and 2.57 ppm, respectively. The ^{125}Te–^{1}H coupling, with *J*(TeH) ca. 26-29 Hz, is observed in the spectra of the $(SPPh_2)_2N$ derivatives but not in those of $(OPPh_2)(SPPh_2)N$. The peaks in the phenyl region of the spectra are similar to those found for other tetraphenyldichalcogenoimidodiphospinato derivatives, but are more poorly resolved.

In the ^{13}C NMR spectra of the Me_2TeL_2 species, the *C*H_3-Te chemical shifts are ca. 14.8, 15.1, 15.5, 17.0, and 19.2 ppm, respectively, for L = $SCONR_2$, SCO_2R, S_2COR, S_2CNR_2, and S_2POGO, respectively. The values of 22.03 and 25.80 ppm for **1** and **5** appear to be an extension to the series. The corresponding Me_2TeXL series range from ca. 18.9 to 16.9, 20.0 to 17.3, 21.4 to 18.0, and 20.7 to 18.2 for L = $SCONR_2$, SCO_2R, S_2COR, and S_2CNR_2, respectively, as X goes from Cl to I, so, relatively, the range of shifts in **2–4** and **6–8** of 26.00 for **6** to 20.74 for **4** is as might be expected. The peaks in the phenyl region of the spectrum are similar to those found for other tetraphenyldichalcogenoimidodiphospinato derivatives (19, 20, 23, 36) but are again more poorly resolved so that the phosphorus–carbon coupling was ill defined and the *ipso* carbon signals were not observed. The chemical shifts for C_m, C_p, and C_o are similar in $Me_2Te[(OPPh_2)(SPPh_2)N]_2$ and the $Me_2TeX[(OPPh_2)(SPPh_2)N]$ series to those reported for $Me_2Sn[(OPPh_2)(SPPh_2)N]_2$ (36) in which the imidodiphosphinate groups are clearly bidentate, but are much broader than in the tin analogue. The chemical shifts differ from those in $Ph_3Te[(OPPh_2)(SPPh_2)N]$ (20) in which there are no short Te—S or Te—O bonds. The ^{31}P NMR signals were not always of good quality, presumably at least in part because of decomposition. The chemical shift for Ph_2PO is quite close to that of $Me_2Sn[(OPPh_2)(SPPh_2)N]_2$ (δ_P 20.0) but the shift for Ph_2PS is in general closer to that of $Me_3Sn[(OPPh_2)(SPPh_2)N]$ (δ_P 39.7) (36). The values of the ^{125}Te NMR chemical shifts cover similar ranges to those of the previously studied Me_2TeL_2 and Me_2TeXL species, as exemplified by the $Me_2TeX[S_2CO(i\text{-}Pr)]$ series where δ_{Te} ranges from 577 to 525 for X = Cl and I, respectively, compared to 580 for **6** to 525 for **8**. The resonance for **6** is shielded by 38 ppm relative to that for **2**. In contrast, the resonance for **5** is slightly deshielded relative to that for **1**, suggesting that in **5** the diphosphinates might be S-bonded rather than O-bonded.

Concluding comments

This study was initiated to examine the differences that might result from the use of more flexible ligands with the potential for a wide range of bite lengths and angles in the formation of Me_2TeL_2 and Me_2TeXL species as compared to the many dithio and monothio ligands that we had studied previously. Despite the flexibility for both L = $(SPPh_2)_2N$ and $(OPPh_2)(SPPh_2)N$, the ligands are still anisobidentate. However, the bite angles and lengths are larger so that, although the Te—S aniso bonds are still long (avg. 3.40(7) Å), the angles about Te are less distorted. In previous studies with Me_2TeXL dithio derivatives, there was a marked "*trans* influence" in the shortening of the Te—X bond and lengthening of the Te—S bond but no such effect was observed in this study. With $Me_2TeCl[(OPPh_2)(SPPh_2)N]$, the primary bond is Te—O rather than Te—S, which is contrary to what has been observed in related monothio derivatives such as $Me_2TeX[SCONEt_2]$ (31) and $Me_2TeX[SCO_2R]$ (32), where Te—S is the primary bond.

Computational study on small water clusters using a semiempirical valence bond approach

Youliang Wang and John R. Gunn

Abstract: Small clusters of water $(H_2O)_n$, $n = 3$–8, are studied using a semiempirical valence bond approach to investigate the bonding energy contribution and hydrogen-bonding structure in the most stable conformation. The energy contribution was decomposed into electron pair–pair interactions and valence-bond energy for each water monomer. Our study shows that there is significant bonding difference between small clusters ($n \leq 5$) of water and larger clusters ($n > 5$). In the larger clusters, there are structures containing tetravalent oxygen centers, which is impossible in the small clusters. The contribution to the binding energy from each H-bond varies from −4.7 kcal/mol to −7.3 kcal/mol in the water clusters considered here. The contribution of −5.9 kcal/mol per H-bond in the cubic octamer is comparable to the experimental value (−6.7 kcal/mol) of the binding energy in ice.

Key words: semi-empirical, valence bond, hydrogen bonding, water clusters.

Résumé: On a étudié des petits agrégats d'eau $(H_2O)_n$, $n = 3$–8, en utilisant une méthode semi-empirique de liaison de valence afin d'évaluer les contributions à l'énergie des liaisons et de la disposition des ponts hydrogène dans les structures les plus stables. L'énergie a été décortiquée en énergie de liaison des doublets et interaction entre doublets pour chaque monomère. Notre étude démontre qu'il y a une différence significative entre les plus petits ($n \leq 5$) et les plus grands ($n > 5$) agrégats d'eau. Dans ce dernier cas, il existe des atomes d'oxygène liés à quatre hydrogènes, ce qui est impossible dans les petits agrégats. La contribution à l'énergie due à chaque pont hydrogène varie de −4,7 kcal/mol jusqu'à −7,3 kcal/mol dans les agrégats considérés ici. La contribution de −5,9 kcal/mol par pont hydrogène dans l'octamère cubique se compare avec la valeur expérimentale de −6,7 kcal/mol pour l'énergie de liaison dans la glace.

Mots clés: semi-empirique, liaison de valence, pont hydrogène, agrégats d'eau.

1. Introduction

Small clusters of water molecules are of great interest due to the importance of water as a universal solvent. An understanding of the water–water interactions is fundamental to the problems of solvation and hydration in chemistry, ice structures in physics, and enzymatic mechanisms and protein and RNA folding in biology. The structural properties and cooperative effects of intermolecular interactions have also been studied in the case of small neutral water clusters $(H_2O)_n$ ($n = 2$–6) (1–4), where the magnitudes of the two- through six-body energy terms and their contribution to the interaction energy have been calculated at various levels of theory. Hydrogen-bonded water complexes $H^+(H_2O)_n$ ($n = 2$–6) have been used as models to study the mechanism of proton transport through biological membranes (5–9). It is known that the potential energy surface (PES) is extremely flat and anharmonic along the motion of the proton in both the dimer and trimer, which may be adequately described with the treatment of electron correlation at the second-order Møller–Plesset perturbation (MP2) level (10,11). However, it is unrealistic to carry out a dynamics calculation at that level due to the computational expense.

Water–water effective pair potentials have been widely used for liquid water simulations. In the model "Transferable Intermolecular Potential" functions (TIPS2, TIP3P, TIP4P) by Jorgensen et al. (12), the water–water interaction energy is calculated from the electrostatic energy between the point charges on the atoms and a Lennard–Jones (LJ) interaction between oxygen atoms, based on the experimental H_2O geometry. In the model of "Empirical Potential using Electrons and Nuclei" (EPEN) by Scheraga and co-workers (13), the empirical potential was developed by the charge distribution of their pair potentials, which involves the nuclei of oxygen and hydrogen, the binding electron pairs and the lone pairs. A number of researchers have derived potential schemes based on ab initio calculations, such as the MCY potentials (14), and ASP (for anisotropic potential) (15).

Most of those potentials are based directly on simple physical models rather than on principles of chemical bonding. High-level ab initio calculations (MP2 and density functional (DFT) with large basis sets including basis-set superposition error (BSSE) correction) are also making it more and more difficult to relate energies to qualitative ideas about chemical bonding. It is necessary to explore the conceptual interpretations that allow for the development of a corresponding chemical intuition. It was Pauling (16) who first gave a proper description of the structures of water and water clusters based on valence bond (VB) theory, introducing the hybridization and hydrogen bond concepts. Classical valence bond theory

is very successful in providing a qualitative explanation for many aspects. Chemists are familiar with the localized molecular orbitals and the classical VB resonance concepts. When modern accurate wave functions are represented in terms of such well-known concepts, chemical intuition and experience can be given a firm theoretical basis.

Most theoretical structural studies have been based on ab initio calculations but these have been limited, especially for large clusters where such calculations are very demanding. Both empirical potential and ab initio calculations (1–4, 17–25), as well as far-infrared spectroscopic results (26–28) have indicated that the trimer, tetramer, and pentamer have the cyclic structure as the most stable structure. However, the water hexamer is much harder to characterize since a large number of nearly isoenergetic minima are too close for the most stable structure to be definitely determined theoretically. A recent combined experimental and theoretical study (far-infrared and diffusion Monte Carlo, respectively) has identified a "cage" structure. Based on the ASP potential, a diffusion quantum Monte Carlo calculation by Gregory and Clary (29) has confirmed that a noncyclic cagelike structure is the most stable for the hexamer due to a relatively low zero-point energy (ZPE). Their calculation gave similar results for the 3D prismatic structure, which is also found to be the absolute minimum in the extended MP2 analysis on the water hexamer of Tsai and Jordan (30). The cagelike structure is consistent with the far-infrared spectrum, which shows a prolate symmetric top and has been used (31) to extract geometrical parameters for the structure of Gregory and Clary. However, a recent DFT calculation by Estrin et al. (32) reported that the optimized 3D prismlike structure is lower by 1.4 kcal/mol than the energy of the cyclic structure when no corrections are applied. The zero-point energy correction is larger than the value for the cyclic structure, and by including the BSSE correction, the energy is -38.0 kcal/mol (D_0) compared to -39.8 kcal/mol (D_0) for the chairlike geometry, in contradiction to the results of other theoretical methods. Although the ZPE correction is clearly important in resolving the exact energy differences among these structures, it has not been calculated in the present work. The contribution of the ZPE to the cluster binding energies is largely due to the intermolecular (H-bond) modes, which are notoriously flat and anharmonic. For this reason, an estimate using harmonic normal modes would not be appropriate and a thorough sampling of the energy surface is required. This is beyond the scope of the present work, and the results presented here will therefore be compared with classical potential minima whenever possible.

It has been observed that the O—O distances decrease as the number of water molecules increases in the cyclic structures, in agreement with experiment, giving values of 2.84, 2.80, and 2.76 Å for the trimer, tetramer, and pentamer, respectively (31). As expected, different binding energies result from different methods for the clusters ($n = 2$–8). For instance, for the water cyclic hexamer, the plane-wave-DFT simulation yields $D_0 = -45.5$ kcal/mol and the Hartree–Fock (HF) $D_0 = -20.6$ kcal/mol, to be compared with $D_0 = -39.9$ kcal/mol from DFT–PP (Perdew–Perdew gradient-corrected exchange-correlation functional) (32).

Due to the inconsistent results for the binding energy and stable structures of the larger water clusters, it is of interest to investigate the structural characteristics from the viewpoint of the chemical bonds. To study the characteristic features in the different conformations, we derive a semiempirical valence bond method for water clusters based on LMP2/6-31G** (localized MP2 with the 6-31G** Gaussian basis set) calculations and investigate the individual contributions from each electron pair, especially from the H-bonds, contributed from each water monomer. This will also be useful in establishing the principles that underly the formation of different types of structures, thereby determining guidelines for predicting the likely minima for larger clusters. This would also greatly simplify the search for the global minimum by reducing the number of possibilities that need to be considered.

Section 2 briefly outlines the computational method. The benchmark calculation results and discussion of the water trimer are given in Sect. 3. Section 4 presents the results and discussion for the water tetramer, pentamer, hexamer, and octamer. The conclusions are given in Sect. 5.

2. Computational method

A semiempirical scheme for generalized valence bond (GVB) calculations of large systems has been proposed, based on a GVB wave function and fitted to high-level ab initio potential energy surfaces. Although the details of this methodology have been given previously (33), it is useful to give a brief description of the basic features of the VB wave function, energy decomposition, and semiempirical evaluation formula.

2.1. Valence bond wave function

With the assumption that each atom has only *s* and *p* atomic orbitals in its valence shell, a set of four hybrid atomic orbitals is generated based on the local geometry. The assigned hybrid orbitals are oriented along the internuclear vectors, forming σ bonds, and the hybrid orbitals on each atom are related to one another by orthonormality.

The GVB wave function for an A–B bond is thus constructed directly from two atomic hybrid orbitals ϕ_A and ϕ_B,

$$[1] \quad \psi_{AB} = [\sigma_1(\phi_A\phi_B + \phi_B\phi_A) + \sigma_2\phi_A\phi_A + \sigma_3\phi_B\phi_B](\alpha\beta - \beta\alpha)$$

where each term corresponds to the electronic structures A–B, $A^- B^+$, and $A^+ B^-$, respectively, with the coefficients (σ_i, $i = 1, 3$) being determined variationally by solving a 3×3 secular matrix equation.

In general, this VB wave function for a three-body fragment A–X–B is

$$[2] \quad \psi_{A-X-B} = \mathcal{A}[\psi_{A-X}\psi_{B-X}]$$

©1999 NRC Canada

which is a multiconfiguration form. Typically for a three-center four-electron hydrogen bond system, for instance, $[F–H–F]^-$, our VB wave function has a total of 6 degrees of freedom with 9 configurations, as compared to 2 degrees of freedom with 3 configurations in the extended valence bond (EVB) model (34,35). In addition, our VB wave function has a strong orthogonality restriction imposed as in the GVB–PP (perfect pairing) wave function (36). However, with more degrees of freedom in determining configurations in our procedure, only the configuration coefficients are variationally determined, as opposed to optimizing both the starting orbitals and configuration coefficients, resulting in a substantial cut in the computing time.

2.2. Energy components

For a closed-shell system, the seGVB total energy is calculated by summing the valence-bond energies over all pairs of electrons and the interactions between the different pairs of electrons. The general expression for the seGVB total energy is therefore

$$[3] \qquad E = E_{\mathrm{nr}} + \sum_{\mu} E_{\mu} + \sum_{\mu<\nu} E_{\mu\nu}$$

where E_μ is the GVB pair energy for each electron pair (bonding or lone pair), $E_{\mu\nu}$ the interaction between the different pairs of electrons, and E_{nr} the internuclear repulsion. The energy contributed by a specific electron pair μ can be calculated by the sum of its GVB pair energy E_μ and its interactions with all other pairs of electrons,

$$[4] \qquad E'_{\mu} = E_{\mu} + \sum_{\nu} E_{\mu\nu}$$

where E'_μ is the quantity that is variationally minimized.

The advantages of this energy expression are (i) the transferability of a valence bond can be used to compute the energy for large systems; (ii) a distance cutoff can be employed in evaluating the pair–pair interactions to substantially decrease the computing time; and (iii) the characteristic change in the potential energy surface in conformational changes and reactions can be easily analyzed. The first two advantages have been used in other VB or similar methods (35, 37). For the third, many energy decomposition schemes (38) have been applied to hydrogen-bonded systems. Virtually all decompose the total energy into components such as Coulomb interaction, polarization, exchange repulsion, charge transfer, and electron density deformation. The method of localized charge distributions has been used to analyze the localized MP2 pair energies for the hydrogen bond in the water dimer (39). The energy form used in our scheme is rather different in that it highlights the characteristic contribution from each pair of electrons.

In this study of water clusters, the following energy terms have been defined. The total bonding energy of each water monomer (e.g., monomer 1) in clusters was calculated as $\sum_{\mu\in \mathrm{O1}} E_\mu$, which is the bonding energy of the four pairs of electrons of each oxygen in the water cluster. The total pair–pair interaction energy between water monomers in a cluster was calculated as $\sum_{\mu\in \mathrm{O1},\nu\in \mathrm{O2}} E_{\mu\nu}$. The total binding energy is defined as $\Delta E = E[(H_2O)_n] - nE[H_2O]$.

2.3. Semiempirical evaluation and parameterization

The calculation of the Hamiltonian in the secular equation is based on the evaluation of the one-center and two-center energy integrals. The one-center energy integrals (h_{AA}, J_{AA}) are calculated using similar formulae to those in AM1 (40,41) and PM3 (42). The functional forms for evaluating two-center energy integrals and overlap integrals used in our previous work (33) have been modified for a better description of the angular dependence. Defining $\boldsymbol{\mu}_\mathrm{A}$ and $\boldsymbol{\mu}_\mathrm{B}$ as unit vectors in the direction of the major lobes of each hybrid orbital in an A–B bond and $\boldsymbol{R}_{\mathrm{AB}}$ as the separation vector between centers A and B, the two-center energy integrals can be generally expressed as

$$[5] \qquad T_{\mathrm{AB}} = F(n_\mathrm{A}, n_\mathrm{B}, \boldsymbol{\mu}_\mathrm{A}, \boldsymbol{\mu}_\mathrm{B}, \boldsymbol{R}_{\mathrm{AB}})$$

where n_A and n_B are used to quantify the hybridization of sp^n-type orbitals. This function can be simplified by using the angles θ_A, θ_B, and θ_{AB} with the definition that $\cos\theta_\mathrm{A} = \cos\theta_\mathrm{B} = \cos\theta_{\mathrm{AB}} = 1$ for "head-to-head" σ bonding, such that

$$[6] \qquad T_{\mathrm{AB}} = F_1(n_\mathrm{A}, n_\mathrm{B}, \cos\theta_\mathrm{A}, \cos\theta_\mathrm{B}, \cos\theta_{\mathrm{AB}}) F_2(R_{\mathrm{AB}})$$

Therefore, the approximation formulae for two-center energy integrals and overlap integrals are

$$[7] \qquad h_{\mathrm{AB}} = \frac{\alpha^{ss}_{\mathrm{AB}} + \sqrt{n_\mathrm{A}}\cos\theta_\mathrm{A}\alpha^{ps}_{\mathrm{AB}} + \sqrt{n_\mathrm{B}}\cos\theta_B\alpha^{sp}_{\mathrm{AB}} + \sqrt{n_\mathrm{A}n_\mathrm{B}}\cos\theta_{\mathrm{AB}}\alpha^{pp}_{\mathrm{AB}}}{1 + \sqrt{n_\mathrm{A}} + \sqrt{n_\mathrm{B}} + \sqrt{n_\mathrm{A}n_\mathrm{B}}} f_1(R_{\mathrm{AB}})$$

$$[8] \qquad J_{\mathrm{AB}} = \frac{\beta^{ss}_{\mathrm{AB}} + n_\mathrm{A}\cos^2\theta_\mathrm{A}\beta^{ps}_{\mathrm{AB}} + n_\mathrm{B}\cos^2\theta_\mathrm{B}\beta^{sp}_{\mathrm{AB}} + n_\mathrm{A}n_\mathrm{B}\cos^2\theta_{\mathrm{AB}}\beta^{pp}_{\mathrm{AB}}}{1 + n_\mathrm{A} + n_\mathrm{B} + n_\mathrm{A}n_\mathrm{B}} \left(f_2(R_{\mathrm{AB}}) + C_{-1}\frac{1}{R_{\mathrm{AB}}} \right)$$

©1999 NRC Canada

$$[9] \quad K_{AB} = \frac{\gamma_{AB}^{ss} + n_A \cos^2\theta_B \gamma_{AB}^{ps} + n_B \cos^2\theta_B \gamma_{AB}^{sp} + n_A n_B \cos^2\theta_{AB} \gamma_{AB}^{pp}}{1 + n_A + n_B + n_A n_B} f_3(R_{AB})$$

$$[10] \quad S_{AB} = \frac{S_{AB}^{ss} + \sqrt{n_A}\cos\theta_A S_{AB}^{ps} + \sqrt{n_B}\cos\theta_B S_{AB}^{sp} + \sqrt{n_A n_B}\cos\theta_{AB} S_{AB}^{pp}}{1 + \sqrt{n_A} + \sqrt{n_B} + \sqrt{n_A n_B}} f_4(R_{AB})$$

The function $f(R_{AB})$ is

$$f(R_{AB}) = e^{-\zeta_{AB} R_{AB}} (c_0 + c_1 R_{AB} + c_2 R_{AB}^2 + \cdots + c_5 R_{AB}^5)$$

The bonding orbital exponent ζ_{AB} in the expression for $f(R_{AB})$ is defined as

$$[11] \quad \zeta_{A-B} = \frac{\zeta_{AB}^{ss} + \sqrt{n_A}\cos\theta_B \zeta_{AB}^{ps} + \sqrt{n_B}\cos\theta_B \zeta_{AB}^{sp} + \sqrt{n_A n_B}\cos\theta_{AB} \zeta_{AB}^{pp}}{1 + \sqrt{n_A} + \sqrt{n_B} + \sqrt{n_A n_B}}$$

The parameters α_{AB}, β_{AB}, γ_{AB}, S_{AB}, and ζ_{AB} are obtained by fitting to model ab initio calculations, for instance, LMP2/6-31G** calculations in most cases due to the vast amount of available data and their reliability.

In our work, the model ab initio calculations at the LMP2/6-31G** level were carried out using the PSGVB (43) programs. Due to the BSSE in ab initio calculations of the total energy for complexes, the interaction energy with counterpoise corrections is the target to be fit by our seGVB parameterization.

3. Benchmark calculations of water trimer

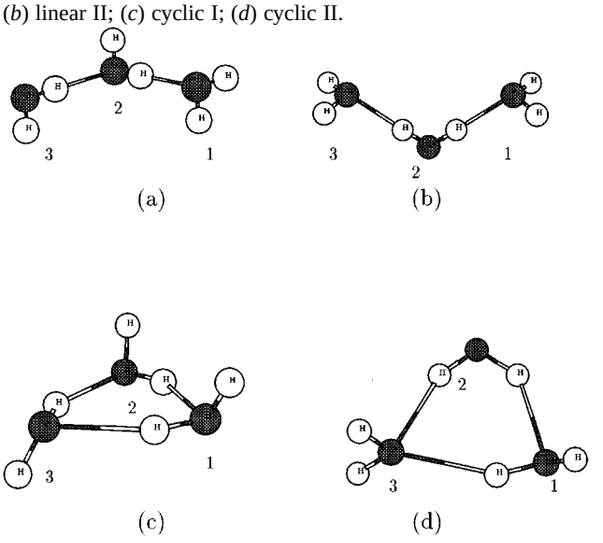
The seGVB potential energy functions are evaluated based on their ability to reproduce the LMP2/6-31G** geometries and energies for the water monomer and dimer. The parameters that have been given in an earlier paper (33) are used here for calculating the water clusters. In this section, the results and discussion of the benchmark calculations of the water trimer are given.

There have been a number of previous ab initio theoretical studies on the water trimer. Notably, the early studies by Clementi and co-workers (44) had already established a cyclic structure as the global minimum; in the minimum energy structure one O—H bond from each monomer contributes to a hydrogen bond to form a nearly equilateral triangle, with the other O—H bond remaining free. Two of the free O—H bonds are above the O–O–O plane, the third below, i.e., (uud). Mó et al. (18) recently investigated the PES over a wide range of configurations at the MP4 level. In addition to the cyclic minimum, the linear water chain can be considered as a model for the study of proton transfer along a proton wire and in the study of the binding energy for water clusters (33).

As a benchmark calculation, we analyzed the energy contributions in seGVB calculations for four different typical structures of water trimer, which are labeled as linear I, linear II, cyclic I, and cyclic II as shown in Fig. 1. H_2O has the experimental geometry, and each H-bond distance is 1.95 Å.

To simplify the analysis, each of the valence bond electron pairs can be described as one of four types: free O—H bonds (OH); free lone pairs (LP); and hydrogen bonds, which consist of an O—H donor (OH-D) and a lone pair acceptor (LP-A). Each water monomer thus comprises two pairs of type OH or OH-D and two pairs of type LP or LP-A, giving a total of nine distinct molecule types. These can be labeled as hydrogen-bond donors (D) and acceptors (A), as well as the combinations AA, DA, DD, DAA, and DDA. The remaining two possibilities correspond to free and bulk configurations.

Fig. 1. The equilibrium structures of water trimers. (*a*) Linear I; (*b*) linear II; (*c*) cyclic I; (*d*) cyclic II.



The electron-pair binding energies are shown in Table 1 for each of the trimers, listed according to pair type. These terms represent the two-electron VB energy levels. The total binding energies for each monomer are given in Table 2, along with the intra- and inter-molecular pair–pair repulsion energies. These are the sums of the two-pair terms, $\sum_{\mu,\nu} E_{\mu\nu}$, for all μ and ν on the same center in the case of intramolecular repulsions,

©1999 NRC Canada

and for all μ on one center and all ν on a second center, as described in Sect. 2.2, in the case of intermolecular repulsions.

The results clearly show the direct effects of the formation of a hydrogen bond. The energies of the interacting pairs, OH-D and LP-A, are lower than the corresponding OH and LP energies. In addition, the intramolecular pair repulsion energies are lower in both the donor and acceptor due to the delocalization of electron density into the bonding region. This effect is greater for the acceptor because the lone pairs represent the dominant contribution to the repulsions. For an isolated water molecule, this term is 5.44 a.u., which indicates that the effects of the hydrogen bond are very nearly additive, roughly 0.35 and 0.95 a.u. for the donor and acceptor, respectively. Larger clusters also give values for the DDA and DAA monomers that follow the same trend.

There is a significant difference, however, between the total binding energies of the donor and acceptor molecules. For the donor, the difference with respect to an isolated water molecule, which has a binding energy of −30.711 161 a.u., is 0.317 529 a.u., which is entirely due to the difference between the OH and OH-D pairs. For the acceptor, on the other hand, the energies of all VB pairs are lowered with respect to an isolated molecule. In fact, the energy of an OH pair in an H-bond acceptor is actually lower than that of an OH-D. This suggests that the effect of the polarization of the acceptor by the shared hydrogen is more important than the contribution of the bonds that are directly involved. The linear I trimer was constructed with monomers of types A, DA, and D forming two hydrogen bonds that are held to be perfectly linear with an O—O distance of 2.907 Å. Although this structure collapses readily to the cyclic structure described below, it is an important benchmark for describing cumulative hydrogen bonds. The binding energy for this trimer structure is −12.2 kcal/mol, or −6.1 kcal/mol per H-bond. At the same geometry, the sum of the binding energies for two isolated H-bonded dimers is −8.8 kcal/mol, showing that the nonadditive energy contribution due to the cooperative effect is −3.4 kcal/mol in the trimer. Again, this is due to the increased polarization of the central molecule.

The linear II structure with three monomers of types A, DD, and A forming two hydrogen bonds, as shown in Fig. 1 (*b*), is different from the linear I structure in that monomer 2 of type DD maintains two O—H bonds and two lone pairs as in H_2O, while it is connected to monomer 1 of type A and monomer 3 of type A through H-bonds. Despite the difference in connectivity, the individual VB pairs are virtually the same as in the linear I structure, with the only difference being between the terminal and central LP-A pairs, the latter being absent in the linear II case. The binding energy is virtually the same, −12.0 kcal/mol, or −6.0 kcal/mol per H-bond, giving a nonadditive contribution of −3.2 kcal/mol. The dominant feature of both linear structures is the presence of two different acceptor molecules.

The other possible linear structure, with a D, AA, D connectivity, would be expected to be much higher in energy because even though there are the same number of H-bonds, there is only one (double) acceptor molecule and, therefore, fewer pairs next to the LP-A pairs, which are themselves neighbors. In fact, this structure is not even a local minimum with respect to the cyclic II structure, which is itself higher in energy than the other linear structures despite the presence of a third H-bond. The preference for accepting rather than donating hydrogen bonds can be understood in terms of the nucleophilicity of water, which is known to be greater than its electrophilicity (18). The fact that structures with multiple acceptors are less stable than those with multiple donors does not contradict this principle — monomers which are multiple acceptors are indeed lower in energy. However, the underlying driving force is to maximize the total number of acceptor *molecules* and, since the total number of acceptor and donor *sites* are necessarily equal, this leads to a preference for single acceptors and multiple donors rather than the inverse.

The most stable structure for water trimer is the cyclic I structure with three monomers of type DA forming three hydrogen bonds. In this structure, each water monomer of type DA is connected to the two others, acting as both an H-bond donor and acceptor. With one more H-bond formed in the cyclic structure, the binding energy becomes −15.0 kcal/mol, or −5.0 kcal/mol per H-bond. As compared to the linear structures, the stability of each H-bond is actually decreased due to the increase in the pair–pair interaction as the calculated results of VB energy decomposition indicated; however, this cost is offset by the addition of the third hydrogen bond. The pair–pair repulsion in this case is simply a reflection of the nonlinearity of the H-bonds; while the OH–D and LP–A distances remain the same, the two oxygen centers are closer together along with all other electron pairs that do not participate in the H-bond. The advantage of having a third acceptor molecule is partially offset by the increased intermolecular repulsions due to the confined geometry. The linear is therefore not the stable equilibrium structure, and will go instead to the cyclic structure through a transition state as calculated by Mó et al. (18) on the full potential energy surface.

In the cyclic II structure with three monomers of types DA, DD, and AA forming three hydrogen bonds, monomer 2 of type DD maintains two O—H bonds and two lone pairs as in H_2O. This structure is energetically not as stable as the cyclic I, even though they both have three H-bonds. Our results give a binding energy of −11.9 kcal/mol, or −4.0 kcal/mol per H-bond. In comparing the two cyclic structures, the large difference is clearly seen to be due to the presence of only two acceptor molecules instead of three. Although the LP-A energies are lower in the AA molecule, giving it the lowest binding energy (−34.413 207), this can only partially compensate for the higher pair energies in the DD molecule that lose the secondary stabilization.

No experimental indications of the trimer binding energy have been reported so far although the cyclic structure has been confirmed experimentally (26). For the stable cyclic structure, the most recent high-level ab initio calculations give a binding energy of −12.71 kcal/mol (DFT with ZPE and BSSE correction) (44), −16.6 kcal/mol (MP2), −11.2 kcal/mol(MP2 with

4. Results and discussion

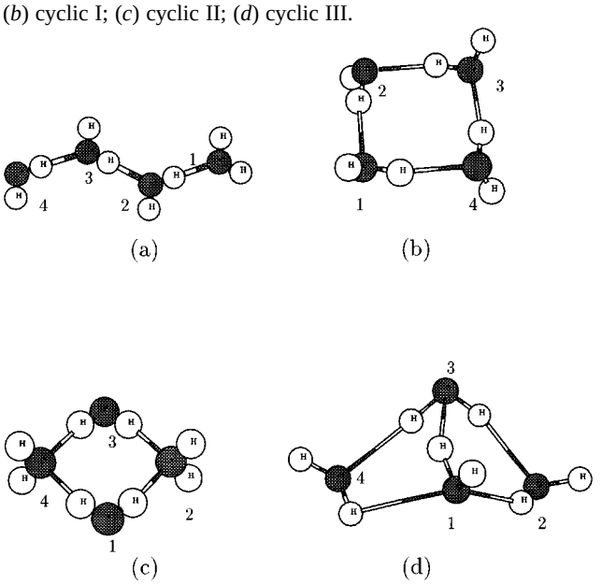
Our benchmark calculations of the water trimer are not only in good agreement with the previous high-level calculations, but also allow the electronic structure to be interpreted in terms of the stability and interactions of individual chemical bonds. Based on these results, this investigation can now be extended to larger water clusters. In this study, some typical structures of water tetramer, pentamer, hexamer, and octamer have been considered, with the goal of studying the relationship between bonding structure and energy. H_2O has the experimental geometry, and each H-bond distance is 1.95 Å.

4.1. Water tetramer

It is known that the cyclic water tetramer is the most stable structure, with shorter H-bonds than in the trimer (27). Four water tetramer structures were calculated in this work: the linear and three different cyclic structures as studied earlier by Clementi et al. (1). These structures are illustrated in Fig. 2.

The energy decomposition (Table 3) shows that the same valence-bond energies observed for the trimer are generally transferable to the tetramer. The linear structure contains four monomers of types A, DA, DA, and D forming three hydrogen bonds, analogous to the trimer. The total bonding energies for monomers 1, 3, and 4 are virtually the same as those of monomers 1, 2, and 3 in the trimer, respectively. The difference arises for monomer 2 in the tetramer, which, although still of type DA, has another DA as a donor rather than a D as is the

Fig. 2. The equilibrium structures of water tetramers. (*a*) Linear; (*b*) cyclic I; (*c*) cyclic II; (*d*) cyclic III.



case for monomer 3. The calculated binding energy for the linear tetramer is −20.4 kcal/mol, or −6.8 kcal/mol per H-bond, with a cooperative effect of −8.2 kcal/mol. Compared to the linear I trimer, the fourth water monomer stabilizes the cluster by 0.7 kcal/mol per H-bond. The average H-bond strength has been increased in going to the linear tetramer from the linear trimer, due to the cumulation of the H-bonds.

The most stable structure is the cyclic I structure with four

monomers of type DA forming four hydrogen bonds, as shown in Fig. 2(*b*). In this form, each water monomer is connected to two others through H-bonds as in the cyclic I trimer, acting as both an H-bond donor and acceptor. As in the trimer, the individual H-bonds are weaker than in the linear structures, but there is an overall stabilization due to the additional H-bond. The calculated binding energy is −23.9 kcal/mol, or −6.0 kcal/mol per H-bond. Compared to the cyclic I trimer, the fourth water monomer stabilizes the cluster by 1.0 kcal/mol per H-bond. The cyclic structure also benefits from reduced repulsion in a more relaxed geometry.

The cyclic II structure, as shown in Fig. 2 (*c*), has two monomers of type AA and two of type DD. As is the case in the trimer, the energy of the LP pairs of the donors is higher, and is not completely compensated by the adjacent LP-A pairs of the acceptors. Although the total number of H-bonds is the same as in cyclic I, the total bonding energy is smaller. The calculated binding energy is −20.6 kcal/mol, or −5.2 kcal/mol per H-bond.

The cyclic III structure with four monomers of types DAA, DA, DDA, and DA forms five hydrogen bonds, as shown in Fig. 2 (*d*). The formation of an additional H-bond lowers the monomer energies relative to the cyclic I structure, since each monomer is still at least a single acceptor, and the DAA monomer 1 has the lowest monomer energy of any structure. However, the pair repulsion is also increased, and in particular the nuclear repulsion is higher due to the central hydrogen. The resulting binding energy is −21.2 kcal/mol, or −4.2 kcal/mol per H-bond. The higher coordination of the DAA and DDA monomers in this case leads to a strained geometry; however, as is the case with the cyclic structures, this would be expected to be more favorable in a larger cluster.

HF, MP2, and DFT calculations all give similar cyclic structures as the equilibrium conformation. The binding energy varies from −24.6 to −29.1 kcal/mol (44). With BSSE and ZPE correction, MP2 gives a binding energy of −16.1 kcal/mol. There is no experimental binding energy value to compare with. The energy spread reported in the literature for the tetramer shows that the binding energy is very sensitive to the level of theory.

4.2. Water pentamer

The most stable pentamer is cyclic (28). The results for the cyclic and linear (Fig. 3) pentamers are listed in Table 4. For the linear structure as shown in Fig. 3 (*a*), the binding energy is −27.2 kcal/mol, or −6.8 kcal/mol per H-bond, which is similar

to that in the linear tetramer. For the cyclic structure with five monomers of type DA forming five hydrogen bonds, as shown in Fig. 3 (*b*), the calculated binding energy is −33.7 kcal/mol or −6.7 kcal/mol per H-bond. Compared with the cyclic tetramer, the fifth water stabilizes the cluster by 0.7 kcal/mol per H-bond. The H-bond strength has been substantially increased in the five-water cyclic structure from the four-water cyclic structure. The nearly identical values for the H-bond energies in the linear and cyclic structures indicates that the ring strain is minimal in this case and that the H-bond geometries are nearly optimal.

Although many other types of structures have been calculated, none has been found so far to have a lower energy than the cyclic structure. This includes structures having a triply H-bonded monomer, consistent with our above observation that this type of bonding will lead to a twisted structure that will only be stable in a larger, more relaxed system.

4.3. Water hexamer

The water hexamer has served as a prototype for analyzing the bonding in ice. It is well known that there exist a number of distinct and almost isoenergetic structures for the hexamer based on a number of theoretical studies. This cluster is particularly interesting because it represents the transition between two- and three-dimensional H-bonding networks with a near trade-off between the additional energy of new H-bonds and the repulsion associated with the geometrical strain and nonlinearity. Four different characteristic structures are investigated in this work: the linear, cyclic, prism, and book structures as shown in Fig. 4. The analysis of VB energy decomposition are listed in Table 5.

For the linear structure in Fig. 4 (*a*), the binding energy is −35.2 kcal/mol, or −7.0 kcal/mol per H-bond. Compared with the linear pentamer, the sixth water stabilizes the cluster by 0.2 kcal/mol H-bond. The binding energy is −41.0 kcal/mol for the cyclic structure as shown in Fig. 4 (*b*), or −6.8 kcal/mol per H-bond. Compared with the cyclic pentamer, the sixth water stabilizes the cluster by 0.1 kcal/mol per H-bond. This structure consists of six nearly equivalent DA monomers, with H-bond energies approaching those of the linear chain, indicating minimal strain as in the case of the pentamer.

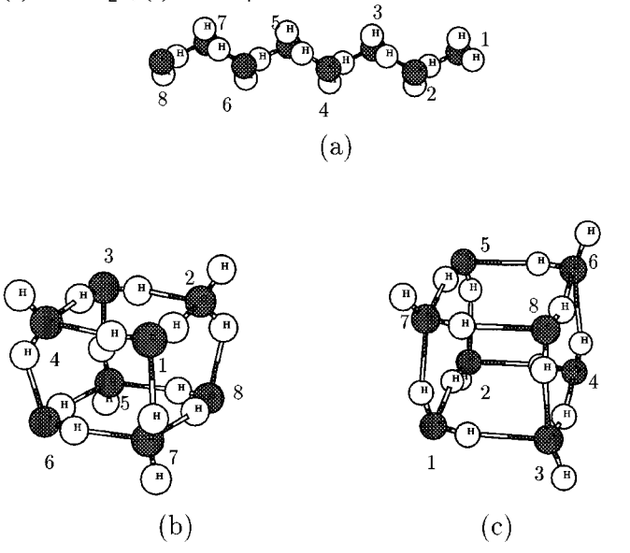
The book structure shown in Fig. 4 (*d*) adds one additional H-bond with the creation of a bridgehead pair of DDA and DAA monomers. As expected, these monomers have a greater bonding energy (the double acceptor in particular); however, this is offset by the additional repulsion caused by a more compact geometry. The binding energy is −39.3 kcal/mol, or −5.6 kcal/mol per H-bond.

The prism structure shown in Fig. 4 (*c*) consists of all DDA and DAA monomers, with a total of nine H-bonds. The repulsion is again increased, but in this case the marginal cost is less than the benefit of the added H-bonds. The value of the binding energy drops to −4.7 kcal/mol; however, the total of −42.6 kcal/mol surpasses that of the cyclic structure. The intermediate case, with two DA, two DAA, two DDA monomers, and a total of eight H-bonds, corresponds to the cage structure proposed by Gregory and Clary (29), which they found to be intermediate in energy between the book and prism forms. Their conclusion that the cage structure would be the ground state was based on a detailed calculation of the zero-point energy using diffusion Monte Carlo (DMC) with an empirical potential surface. Such effects are clearly important when the differences in energy minima are so small; however, this calculation was not carried out in the present work in which the goal is to reproduce the underlying potential energy surface with the seGVB calculation.

There is a large spread in the binding energies for the hexamer as reported in the literature. MP2 calculations for the cyclic and prism structures, respectively, give $D_e = -47.4$ and −46.1 kcal/mol (29) and $D_e = -39.8$ and −40.2 kcal/mol (30). The corresponding DFT-PP values are $D_e = -52.0$ and −52.4 kcal/mol (32), and the ASP results are $D_e = -45.8$ and −50.2 kcal/mol (29). Our results are in relatively good agreement with the MP2 calculations, as would be expected since MP2 results for the dimer were used in the parameterization. Estimates of the ZPE correction, for the cyclic and prism structures, respectively, range from 17.6 and 17.0 kcal/mol from the DMC simulations to 14.4 and 12.1 kcal/mol from harmonic analysis of the DFT-PP frequencies.

Fig. 5. The equilibrium structures of water octamers. (*a*) Linear; (*b*) cubic D_2d; (*c*) cubic S_4.



4.4. Water octamer

We have investigated three structures of the water octamer: one linear and two cubic structures, of D_{2d} and S_4 symmetry, as shown in Fig. 5 and listed in Table 6. The binding energy for the linear octamer is −51.0 kcal/mol, or −7.3 kcal/mol per H-bond.

For the D_{2d} and S_4 structures, four monomers are of type DDA and four others of type DAA. The sum of the binding energies for monomers of type DDA (−34.350 144 a.u. for D_{2d} and −34.345 135 a.u. for S_4) is smaller than that for monomers of type DAA (−35.560615 a.u. for D_{2d} and −35.477 311 a.u. for S_4), respectively, as would be expected. Both cubic structures have 12 hydrogen bonds, with very similar binding energies of −70.4 and −71.1 kcal/mol, respectively, or −5.9 kcal/mol per H-bond. Since the valence bond structure is the same in both cases, the small difference is likely due to struc-

tural relaxation and reduced repulsion in the lower symmetry structure.

The binding energy varies from −59 to −70 kcal/mol in ab initio HF, MP2, and DFT calculations. The energy contribution of −5.9 kcal/mol from each H-bond in the cubic octamer is of the order of the experimental value (−6.7 kcal/mol) of the binding energy in ice (45).

5. Conclusions

Based on the valence bond calculations, several basic principles emerge that determine the structures and relative energies of small water clusters. The energy of a hydrogen bond is largely determined by the polarization of the acceptor by the donor. For this reason small clusters form cyclic structures in which the hydrogen bonds are aligned with each molecule acting as both donor and acceptor, and structures with multiple donors and acceptors are less favorable. There is also a nonadditive energy due to the fact that the charge transfer that occurs in hydrogen bonding is stabilized by the presence of other molecules. This has the effect of increasing the effective acidity or basicity of molecules that are already hydrogen bonded, as observed by Mó et al. (18). There is also a secondary next-nearest-neighbour effect, which favours "head-to-tail" H-bonding patterns.

In larger clusters, more hydrogen bonds can be formed by creating polycyclic structures; however, the individual bonds are weaker. Again, structures with each molecule acting as both donor and acceptor are favored in order to maximize the nonadditive energy. Because the polycyclic structures have a higher electronic and nuclear repulsion, only structures with a high connectivity (prism, cube) will be lower in energy than the cyclic structures, although the energy differences are often quite small.

Although water clusters generally maximize the number of hydrogen bonds, because of the polarization effects the energy of each bond depends strongly on the geometry and pattern of connectivity. In the systems studied here, the contribution to the binding energy from each H-bond varies from −4.7 to −7.3 kcal/mol. The contribution of −5.9 kcal/mol per H-bond in the cubic octamer can be compared to the experimental value (−6.7 kcal/mol) of the binding energy in ice.

Cyclic voltammetry of ferrocene-containing β-diketones as a tool to obtain group electronegativities. The structure of 3-ferrocenoyl-1,1,1-trifluoro-2-hydroxyprop-2-ene

W.C. (Ina) du Plessis, Johannes J.C. Erasmus, Gert J. Lamprecht, Jeanet Conradie, T. Stanley Cameron, Manuel A.S. Aquino, and Jannie C. Swarts

Abstract: Formal reduction potentials ($E^{\circ\prime}$ values vs. Ag/Ag^+ given in parentheses) in acetonitrile of 1-ferrocenyl-4,4,4-trifluorobutane-1,3-dione (ferrocenoyltrifluoroacetone, Hfctfa, 0.394 V), 1-ferrocenyl-4,4,4-trichlorobutane-1,3-dione (ferrocenoyltrichloroacetone, Hfctca, 0.370 V), 1-ferrocenylbutane-1,3-dione (ferrocenoylacetone, Hfca, 0.313 V), 1-ferrocenyl-3-phenylpropane-1,3-dione (benzoylferrocenoylmethane, Hbfcm, 0.306 V), and 1,3-diferrocenylpropane-1,3-dione (diferrocenoylmethane, Hdfcm, 0.265 and 0.374 V for the two electrochemically nonequivalent ferrocenyl groups) were determined. A linear relationship between observed group electronegativity, χ, and $E^{\circ\prime}$ as well as observed infrared carbonyl stretching frequencies of methyl esters of the type RCOOMe resulted in average χ-values, on the Gordy scale, of 1.87 for the ferrocenyl group and 2.82 for the ferrocenium group. A single crystal X-ray structure determination of Hfctfa (monoclinic, $P2_1/n$, $Z = 4$, $R = 0.029$) showed that this β-diketone crystallizes in the enol form. Asymmetric enolization in a direction furthest from the aromatic ferrocenyl group was observed.

Key words: ferrocene, β-diketone, group electronegativity, cyclic voltammetry.

Résumé : On a déterminé les potentiels de réduction formelle (valeurs de $E^{\circ\prime}$ en fonction de Ag/Ag^+ données entre parenthèses), dans l'acétonitrile, des 1-ferrocényl-4,4,4-trifluorobutane-1,3-dione (ferrocényltrifluoroacétone, Hfctfa, 0,394 V), 1-ferrocényl-4,4,4-trichlorobutane-1,3-dione (ferrocényltrichloroacétone, Hfctca, 0,370 V), 1-ferrocénylbutane-1,3-dione (ferrocénylacétone, Hfca, 0,313 V), 1-ferrocényl-3-phéhylpropane-1,3-dione (benzoylferrocénylméthane, Hbfcm, 0,306 V) et 1,3-diferrocénylpropane-1,3-dione (diferrocénylméthane, Hdfcm, 0,265 et 0,374 V respectivement pour les deux groupes ferrocényles électrochimiquement non équivalents). On a observé une relation linéaire entre l'électronégativité des groupes, χ, et $E^{\circ\prime}$ ainsi qu'avec les fréquences d'élongation du carbonyle observées dans l'infrarouge pour les esters méthyliques du type RCOOMe; sur l'échelle de Gordy, les valeurs moyennes de χ seraient respectivement 1,82 pour le groupe ferrocényle et 2,82 pour le groupe ferrocénium. On a déterminé la structure cristalline du Hfcta par diffraction des rayons X (monoclinique $P2_1/n$, $Z = 4$, $R = 0,029$); elle montre que cette β-dicétone cristallise sous la forme énolique. On observe une énolisation asymétrique dans la direction opposée au groupe ferrocényle aromatique.

Mots clés : ferrocène, β-dicétone, électronégativité d'un groupe, volvampérométrie cyclique.

[Traduit par la Rédaction]

Introduction

β-Diketones may exist in equilibrium with two possible enol isomers according to eq. [1].

[1] $$R'C(OH)=CHCOR \rightleftharpoons R'COCH_2COR \rightleftharpoons R'COCH=C(OH)R$$

Two driving forces that will determine the preferred enol isomer were recently (1) defined. The first is labelled an electronic driving force in which the formation of the preferred enol isomer is controlled by the group electronegativity of the substituents R and R′ on the β-diketone $R'COCH_2COR$. Regarding the keto isomer (eq. [1]), when the group electronegativity of R′ is less than that of R, the

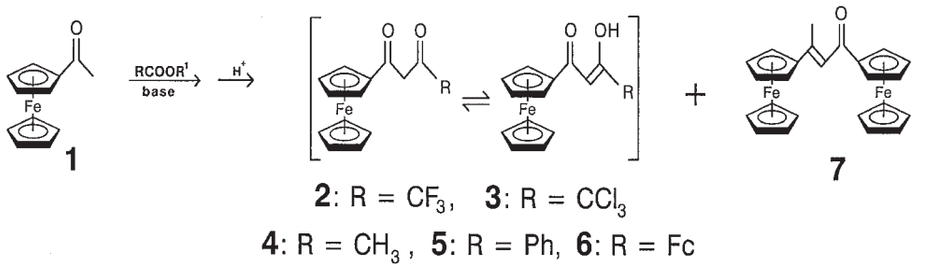
Scheme 1. Claisen condensation of acetylferrocene (**1**) with appropriate esters to give β-diketones Hfctfa (**2**, R = CF_3), Hfctca (**3**, R = CCl_3), Hfca (**4**, R = CH_3), Hbfcm (**5**, R = phenyl), and Hdfcm (**6**, R = ferrocenyl). ^{1}H NMR studies indicated that asymmetric enolization as shown dominates. Aldol self-condensation of **1** leads to the side product **7**. The base used was either sodium ethoxide or lithium diisopropylamide. Abbreviations are defined in the abstract.



carbon atom of the carbonyl group adjacent to R′ will be less positive in character than the carbon atom of the other carbonyl group. Consequently, from an electronic point of view, the dominant enol isomer should be R′C(OH)=CHCOR. However, this driving force was not found to apply to β-diketones with R′ = ferrocenyl or phenyl. In a recent paper (1) we have shown that, in chloroform solutions, the only observable enol isomer of β-diketones of the type $FcCOCH_2COR$ (Fc = ferrocenyl, R = CF_3, CCl_3, CH_3 (Me), phenyl (Ph), and Fc) is FcCOCH=C(OH)R. In the same paper, apparent group electronegativities, χ, measured on the Gordy scale, for all R groups were obtained from a linear relationship between χ and apparent pK_a' determinations of the β-diketones and also from a linear relationship between χ and carbonyl IR stretching frequencies of esters of the type RCOOMe. The term "apparent pK_a'" is used because no distinction is made between the pK_a of enol and keto isomers. Rather, pK_a' refers to the acidic behaviour of the conjugated keto–enol system. The apparent group electronegativity, χ, of the ferrocenyl group was found to be lower than χ for all the indicated R substituents of $FcCOCH_2COR$. Hence, if the electronic driving force was dominant in this system, the expected enol isomer should be FcC(OH)=CHCOR and not the one found. Consequently, the existence of a second driving force, the resonance driving force, was defined. The resonance driving force implies that the formation of different canonical forms of a specific enol isomer will lower the energy of this specific isomer enough to allow it to dominate over the existence of other isomers. Indirect evidence for the canonical forms was from the crystal structure determination (2) of the enol form of Hfca, FcCOCH=C(OH)Me. However, the apparent Gordy group electronegativities of the ferrocenyl and methyl groups of Hfca are not that different (χ_{Fc} = 1.87 and χ_{Me} = 2.34). There is a need to demonstrate that the resonance driving force arguments put forward by us (1) are also valid for ferrocene-containing β-diketones in which the other β-diketone substituent, R, has a marked larger group electronegativity than that of the ferrocenyl group. Hfctfa, with R = CF_3, would be particularly suitable for this purpose because the CF_3 group has one of the largest group electronegativities known. However, there exists an uncertainty in the group electronegativity of the CF_3 group (estimated values vary between 3.01 (1) and 3.35 (3)) primarily because of the method of group electronegativity determination. With respect to ref. 1, this uncertainty is due to the uncertainty of the structure of CF_3-containing β-diketones (1) in basic aqueous solutions, which resulted in an unreliable apparent pK_a' for $FcCOCH_2COCF_3$. The CF_3 group electronegativity obtained from IR carbonyl measurements was more satisfactory, but still open to criticism since CF_3COOMe is too volatile for convenient experiments. Instead, the ethyl ester was used. This makes direct comparisons with the other methyl esters unsatisfactory. We now demonstrate that cyclic voltammetry can be used to determine accurate apparent group electronegativities, including that of the CF_3 group. From the crystal structure determination of $FcCOCH=C(OH)CF_3$ we conclude that the resonance driving force overrules the electronic driving force in determining the preferred enol isomer of β-diketones where different canonical forms lower the energy of a specific enol isomer even if group electronegativities are markedly in favour of the electronic driving force.

Results and discussion

Claisen condensation of acetylferrocene, **1**, with an appropriate ester according to the general procedure outlined in Scheme 1, gave the β-diketones Hfctfa, **2**, Hfctca, **3**, Hfca, **4**, Hbfcm, **5,** and Hdfcm, **6**. β-Diketones **2–6** exist in solution (1) predominantly as one enol tautomer. The aldol condensation product, **7**, was invariably isolated when lithium diisopropylamide was the base used to initiate Claisen condensation.

Cyclic voltammetry results are summarized in Table 1. The difference in peak anodic, E_{pa}, and peak cathodic, E_{pc}, potentials, ΔE_p, for all β-diketones indicates reasonable electrochemical reversibility: Electrochemical reversibility (4) of a one-electron process at 25°C is characterized by ΔE_p = 59 mV and is independent of scan speed. The biggest E_{pa} drift detected was 6 mV for E_{pa} of Hfctca when the scan rate was increased from 50 to 200 mV s^{-1}, but this did not influence $E^{o'}$. All $E^{o'}$ values remained constant between scan rates of 50 and 200 mV s^{-1} and indicate that the group electronegativities obtained from formal reduction potentials are independent of scan rates within the indicated range. The ratio i_{pc} / i_{pa} (i_{pc} and i_{pa} are the peak cathodic and anodic currents) was in all cases close to unity, implying that the electrochemical oxidation of the iron(II) nucleus of the ferrocenyl groups is not followed by a chemically induced reduction (5) of the Fe(III) nucleus of the ferrocenium group by the hydroxyl group of the enol form of the β-diketone, a reaction that has been observed in other ferrocenyl / hydroxyl

[a] The first set of electrochemical data refers to the electrochemical process taking place when the first ferrocenyl group is oxidized, while the second set of data refers to the oxidation of the second ferrocenyl group.

systems (6). Since i_{pc} could not always be measured with accuracy, the i_{pc} / i_{pa} ratio was estimated using eq. [2] with $i_{pc,0}$, the peak cathodic current, measured from the base line (i.e., where zero current flows) and $i_{pa,0}$, the current flowing at the potential where the sweep is reversed, also measured from the baseline (7).

$$[2] \qquad \frac{i_{pa}}{i_{pc}} = \frac{i_{pc,0}}{i_{pa}} + \frac{0.485 i_{pa,0}}{i_{pa}} + 0.086$$

That Hdfcm shows two formal reduction potentials ($E^{\circ\prime}$ = ½(E_{pc} + E_{pa})), one at 0.266 and one at 0.375 V versus Ag/Ag$^+$ (Fig. 1, Table 1), is in contrast to ^{1}H NMR measurements (1) that could not differentiate between the two ferrocenyl groups. The observed inequality is most likely due to the improbability of both ferrocenyl groups of the same molecule, Hdfcm, coming simultaneously in reaction contact with the electrode to invoke two simultaneous one-electron transfer processes. Therefore, when only one of the ferrocenyl groups is oxidized, the newly formed intermediate is the mixed valent β-diketone $FcCOCH_2COFc^+$. Good communication between Fc and Fc^+ for this intermediate leads to oxidation of the second ferrocenyl group at a different potential than was observed for the first ferrocenyl oxidation in Hdfcm. Electrochemical inequality of the ferrocenyl groups was also observed for **7** (Fig. 2, $E^{\circ\prime}$ = 0.183 and 0.348 V vs. Ag/Ag$^+$, respectively) and various other diferrocenyl-containing compounds (8). The spread of formal reduction potentials of the ferrocenyl group of β-diketones **2–6** is large. The least positive formal reduction potential is 0.266 V for Hdfcm whereas the most positive is 0.395 V for Hfctfa. This large spread in $E^{\circ\prime}$ is the result of good communication between the ferrocenyl group and the R substituent on β-diketones **2–6** via the backbone of the pseudo-aromatic β-diketone core. The ferrocenyl group on **2–6** becomes increasingly difficult to oxidize the more electron density is withdrawn from it by the substituent, R. This observation implies that communication between the ferrocenyl group and the other β-diketone substituent R is sufficient to allow determination of group electronegativities of the R groups by measuring formal reduction potentials, $E^{\circ\prime}$, of the ferrocenyl group on these β-diketones by means of cyclic voltammetry. Of great interest is the large positive potential required to oxidize the second ferrocenyl group on Hdfcm (and **7**) compared to the oxidation of the first. The formal reduction potential of the more difficultly oxidized ferrocenyl group of Hdfcm is only 20 mV less positive than that of the ferrocenyl group of Hfctfa. This indicates that the electron-withdrawing properties of the positively charged ferrocenium radical-cation, formed during the easy oxidation of the first ferrocenyl group of Hdfcm, is almost as powerful as that of the trifluoromethyl group. The relative ease of oxidation of the first ferrocenyl group of Hdfcm as compared to that of all the other β-diketones investigated here further indicates that the electron-donating properties of the ferrocenyl group substantially overshadow those of the other β-diketone side groups, R, used in this study.

The formal reduction potentials obtained for the ferrocenyl and ferrocenium groups of **2–6** were used to determine group electronegativities, χ_R, on the Gordy scale for

Fig. 1. Cyclic voltammograms of 2 mmol dm^{-3} solutions of ferrocene, Fc, and β-diketones in acetonitrile containing 0.100 mol dm^{-3} tetrabutylammonium hexafluorophosphate at 25°C at a scan rate of 50 mV s^{-1}on a Pt working electrode.

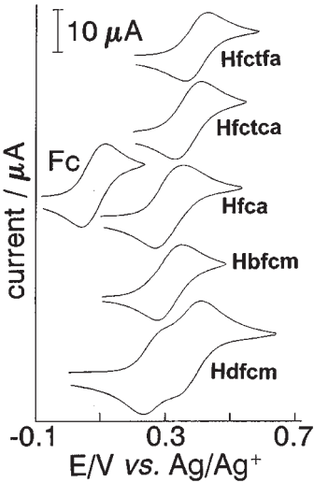

Fig. 2. Cyclic voltammograms of 1-ferrocenoyl-2-ferrocenylprop-2-ene, **7**, in CH_3CN (1.3 mmol dm^{-3}) containing 0.100 mol dm^{-3} tetrabutylammonium hexafluorophosphate at scan rates of 50 (smallest i_p values), 100, 150, 200, 250, 300, and 350 mV s^{-1} on a Pt working electrode at 25°C.

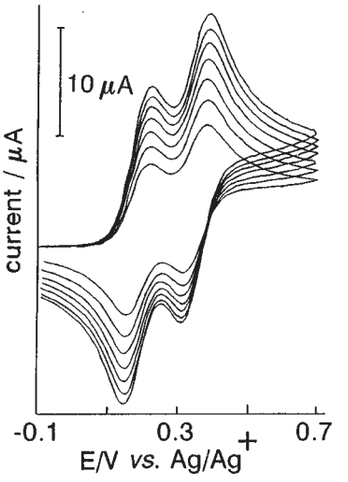

the substituents R on the β-diketone as well as the ferrocenium radical-cation. (3) Utilizing literature values (1, 3) for apparent group electronegativities, a straight line was generated by the linear fit of $E^{\circ\prime}$ (vs. Ag/Ag^+) and χ_R (R = Ph, CH_3 and CCl_3). It should be noted that χ_{Ph} was the observed value (1), χ_{Ph} = 2.21, and not the original value obtained from the IR spectra of $O{=}PPh_3$ or Ph-H (3*a*, *c*, *d*). The linear relationship obtained, $E^{\circ\prime}$ = 115.5χ_R + 47.9 mV, allowed the determination of the apparent group electronegativities of the ferrocenyl, ferrocenium radical-cation and the CF_3 group as $\chi_{ferrocenyl}$ = 1.87, $\chi_{ferrocenium}$ = 2.82, and $\chi_{trifluoromethyl}$ = 3.01, respectively. The results obtained for the ferrocenyl and CF_3 groups are mutually consistent with values obtained by utilizing the linear relationship, $\nu(C{=}O)_R$ = 74.5χ_R + 1560.7 cm^{-1}, between the carbonyl stretching frequency, $\nu(C{=}O)_R$, of methyl esters of the indicated R groups (Fig. 3) and apparent group electronegativities, χ_R. A polarographically determined group electronegativity for the ferrocenyl group was reported (9) to be 2.08. Since $E°$ and pK_a are thermodynamic quantities linked by the equation (10) $E° = (RT/nF)\ln(K_a)$ or, rearranged, $pK_a = -(nF/2.303RT)E°$, a graph of $E^{\circ\prime}$ versus pK_a' should be linear (by using $E^{\circ\prime}$ rather than $E°$ and also pK_a' rather than pK_a, the slope of the graph would be affected but not its linearity). The validity of the pK_a' values determined (1) is demonstrated by the linear relationship obtained (Fig. 4). In particular, it appears as if a pK_a' value of 5.65 for Hfctfa would be more appropriate than the observed (1) value of 6.53. The reason for the scattering of pK_a' values of CF_3-containing β-diketones is probably centred on the reversible formation of new CF_3 complexes when the β-diketone interacts with the base used to titrate it, as described elsewhere (1, 11). The pK_a' value of the mixed valent β-diketone $FcCOCH_2COFc^+$ ($Hdfcm^+$) is estimated as 6.80. Spectroscopic, pK_a', and group electronegativity results are summarized in Table 2.

The X-ray crystal structure of [Rh(fca)(cod)] has been reported (12*a*). Two molecules *within the same* unit cell were observed, one of which (molecule A) approached very closely the extreme case of asymmetric coordination with rhodium. As a result, for molecule A, the geometry of the coordinated fca ligand is very similar to that found for the asymmetrically enolized free (uncoordinated) ligand (2), Hfca. The geometry of the fctfa ligand coordinated to the Rh(I) centre is also known (12*b*). It was established spectroscopically (1) that uncoordinated Hfctfa enolizes in a direction away from the ferrocenyl group. Here we confirm this spectroscopic result by reporting the structure of Hfctfa (**6**, R = CF_3). Crystal data are summarized in Table 3, selected bond lengths and angles can be found in Table 4, and a perspective view of Hfctfa showing atom labelling is presented in Fig. 5. Unlike what was found (12*b*) in [Rh(fctfa) $(CO)(PPh_3)$], the trifluoromethyl group in free Hfctfa is disordered. The bond length C12—C13 (1.345(6) Å) is notably shorter than C11—C12 (1.432(6) Å), indicating that Hfctfa, like Hfca (2), is enolized asymmetrically in a direction away from the ferrocenyl group. Angle C11-C12-C13 (120.0(4)°) is, within experimental error, the theoretical value (120°) expected for sp^2 hybridization. The O1—O2 distance of 2.549(6) Å provides further support for the enolic structure of Hfctfa. β-Diketones in the keto form have O—O distances (12*c*) of ca. 3.05 Å. From the difference map, H11 is shown to be approximately 0.33 Å further away from O1 than from O2 with H11—O2 ca. 1.15 Å. The cyclopentadienyl rings of the ferrocenyl group deviated only 2.17(1)° (Fig. 5) from an eclipsed conformation although the energy barrier to cyclopentadienyl rotation (12*d*) in ferrocene (which includes conversion from the eclipsed to the staggered conformation) is very small (4 ± 1 kJ mol^{-1}). The structural details that may be used to explain the spectroscopically observed (1) direction of asymmetrical enolization are, however, centred on the longer bond length C13—C14 (1.515(7) Å) as compared to C11—C1 (1.448(6) Å) and the dihedral angle of 7.84° between the pseudo-aromatic system forming plane 1 defined by atoms O1-C11-C12-C13-O2 (Fig. 5) and the planar cyclopentadienyl ring of the aromatic ferrocenyl moiety bound to it. These two structural details emphasize the effective

Fig. 3. Apparent group electronegativities, χ_R, obtained by spectroscopic techniques, viz., the stretching frequency of the carbonyl group in methyl esters of the type $RCOOCH_3$ (right axis, lower graph), or electrochemical techniques, viz., cyclic voltammetry to obtain formal reduction potentials, $E^{o\prime}$ (left axis, upper graph), of β-diketones of the type $FcCOCH_2COR$ are mutually consistent. R = ferrocenyl (Fc), phenyl (Ph), H, CH_3, $CHCl_2$, CCl_3, Cl, ferrocenium (Fc^+), and CF_3 as indicated.

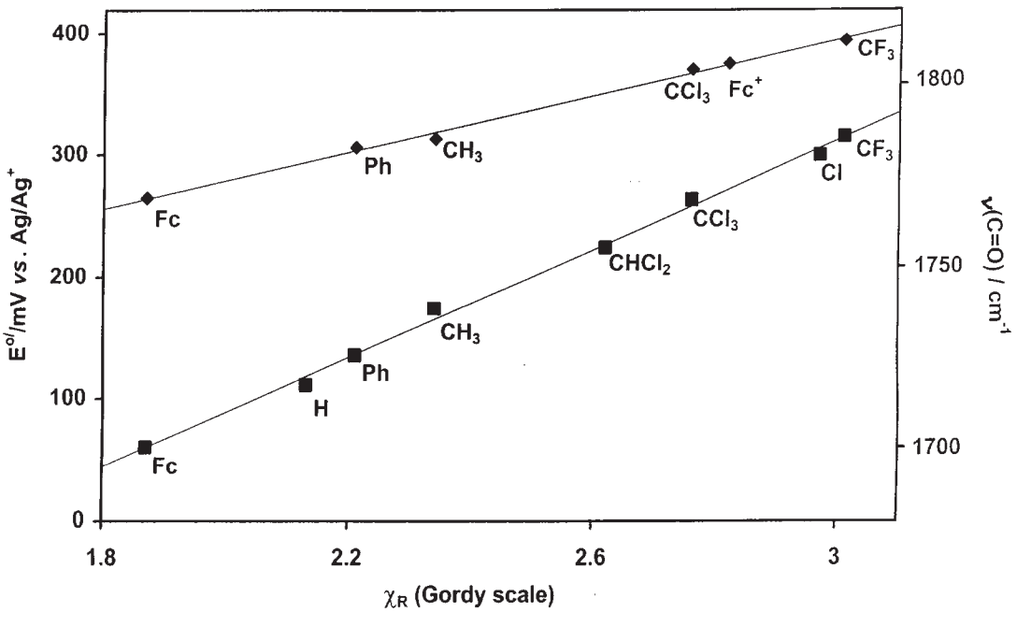

Fig. 4. The linear dependence of pK_a' of β-diketones with respect to formal reduction potential, $E^{o\prime}$ (points indicated as ■), predicts an apparent pK_a' of 5.65 for Hfctfa ($FcCOCH_2COCF_3$) and 6.80 for $FcCOCH_2COFc^+$ (points indicated as ●). The point indicated as ▲ is the measured pK_a' of Hfctfa (6.53).

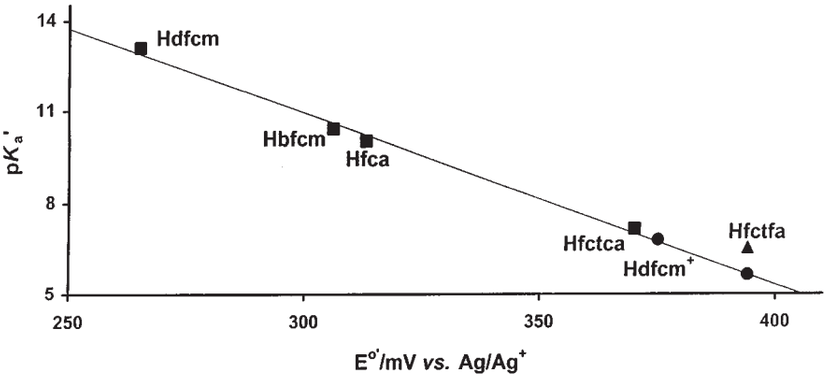

conjugation by the ferrocenyl group into the pseudo-aromatic system of plane 1. This conjugation can take place in at least two ways, as demonstrated with the formation of canonical forms **III** and **IV** of the two theoretically possible enol forms **I** and **II** of Hfctfa (Scheme 2). Either the enol isomer **I** can convert to one of its canonical forms, **III**, or isomer **II** will convert to canonical form **IV**. Both these conversions will lower the energy of the system. To decide which of these energy-lowering processes is favoured, the bond lengths O1—C11 (1.277(5) Å) and O2—C13 (1.297(5) Å) play a pivotal role. Typical β-diketone C=O bond lengths are 1.206 Å (see, for example, ref. 12*c*), whereas C—O (enol) bond lengths are in the region of 1.300 Å. For Hfctfa, C13—O2 (1.297(5) Å) is perfectly normal, but C11—O1 (1.277(5) Å) does not remotely resemble typical β-diketone C=O bond lengths. In fact, this bond is so long that it approaches typical single, enol, C—O, bond lengths, a situation that can only arise if canonical form **IV** makes a large contribution to the overall structure of Hfctfa. We therefore conclude as before (1) that, despite the large difference in group electronegativities of the ferrocenyl and trifluoromethyl groups, resonance driving forces always will carry priority over electronic driving forces to determine which enol form of a β-diketone possessing aromatic side groups is favoured. Zwitterionic canonical structures resembling **IV** are key intermediates in the enolization process of ferrocenyl- and phenyl-containing β-diketones. It should be noted that, although the canonical forms indicated in Scheme 2 explain the ^1H NMR and crystallographically observed dominance of isomer **II** over **I**, they by no means

[a] $R = \Sigma\ ||F_o| - |F_c|| / \Sigma|F_o| = 0.029$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma wF_o^2]^{0.5} = 0.030$.

imply that other canonical forms and relationships do not also exist.

The geometry of Hfctfa as a free ligand and coordinated to the Rh(I) nucleus in [Rh(fctfa)(CO)(PPh_3)] follows the same general trends, especially the carbon–carbon bond lengths. In the complex, the CF_3 group is also further from the pseudo-aromatic β-diketone core than the ferrocenyl group. Like C12—C13, the corresponding bond length in the complex is also shorter than the other C—C bond of the β-diketone skeleton. The only obvious difference lies in the C—O bond lengths. In the complex, these bond lengths are equal (1.266(5) and 1.264(5) Å, respectively). This is expected and normal (12*e*) for β-diktone complexes of rhodium(I). It appears that, even in complexed form, canonical structures resembling **IV** (Scheme 2) play an important role. The structure of **7**, Scheme 1, is discussed elsewhere (12*f*).

Experimental

Materials

Solid reagents (Merck, Strem, or Aldrich) were used without further purification. Liquid reactants and solvents were distilled prior to use; water was double distilled. Dry, air-free acetonitrile was obtained by refluxing under nitrogen over calcium hydride, distilled onto alumina for storage, and redistilled just prior to use.

Spectroscopy

Proton NMR spectra at 298 K were recorded either on a Bruker AM-300 or a WP-80 instrument while chemical shifts are presented as δ values referenced to $SiMe_4$ at 0.00 ppm. IR spectra (KBr pellets or chloroform solutions) were recorded on a Hitachi model 270–50 spectrometer with data processor.

Cyclic voltammetry

Measurements on ca. 2 mmol dm^{-3} β-diketone solutions in acetonitrile with 0.100 mol dm^{-3} tetra-*n*-butylammonium hexafluorophosphate (Fluka, electrochemical grade) as supporting electrolyte were conducted under a blanket of purified argon at 25.0°C utilizing a BAS model CV-27 voltammograph interfaced with a personal computer. A three-electrode cell, which utilized a Pt auxiliary electrode, a Pt working electrode with surface area 0.0707 cm^2, and a Ag/Ag^+ (0.0100 mol dm^{-3}, $AgNO_3$) reference electrode (13) mounted on a Luggin capillary (4, 5), was employed. Data,

© 1999 NRC Canada

uncorrected for junction potentials, were collected with an Adalab-PC™ and Adapt™ data acquisition kit (Interactive Microwave, Inc.) with locally developed software, and analysed with Hyperplot (JHM International, Inc.). All temperatures were kept constant to within 0.5°C.

Structure determination

Crystals of Hfctfa were obtained by recrystallizing from acetone–hexane (1:5 by volume). A dark red crystal was mounted on a glass fiber and intensity data were collected on a Rigaku AFC5R diffractometer using graphite monochromated Cu-K_α radiation and a rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $62.88° < 2\theta < 74.41°$. Data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied. The structure was solved by direct methods (14) and expanded using Fourier techniques (15). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The locations of H10 and H11 (Fig. 5) were estimated from a difference Fourier synthesis (see supplementary material).[2] Neutral atom scattering factors were taken from Cromer and Waber (16). Anomalous dispersion effects were included in F_{calc} (17); the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (18). The values for the mass attenuation coefficients are those of Creagh and Hubell (19). All calculations were performed using the teXsan (20) crystallographic software package of the Molecular Structure Corporation. Crystallographic detail and refinement parameters are reported in Table 3.

Table 4. Bond lengths (Å) and angles (deg) for Hfctfa. The standard deviation of the last decimal is given in parentheses.

Synthesis

Hfctfa (**2**), Hfca (**4**), Hbfcm (**5**), and Hdfcm (**6**) were synthesized according to published (1) procedures. The procedure for Hfctca is as follows: A light yellow solution of $LiNPr^i_2$ was prepared under nitrogen by adding *n*-butyllithium (20 cm^3 of a 1.6 mol dm^{-3} solution in hexane) to an ice-cooled solution of freshly distilled diisopropylamine (3.41 g, 33.6 mmol) in dry THF (60 cm^3). The $LiNPr^i_2$ solution was added at 0°C to a solution of acetylferrocene (6.81 g, 29.87 mmol) in THF (50 cm^3) and stirred at room temperature for 20 min before methyl trichloroacetate (5.00 g, 3.36 cm^3, 28 mmol) dissolved in 40 cm^3 THF was added. Stirring of the resulting reaction mixture continued for 4 h before it was shaken with 250 cm^3 of 1 mol dm^{-3} HCl and immediately extracted with ether (5×200 cm^3). The combined ether extracts were thoroughly washed with water and dried ($MgSO_4$), and the solvent was removed under reduced pressure. Chromatography of the residue (R_f = 0.58) on Sephadex with eluant ethanol:hexane (1:6 by volume) afforded spectroscopically pure Hfctca (1.78 g, 16%) as a dark purple liquid that crystallized over 3 weeks at 4°C, mp 52°C. ν_{max}(KBr)/cm^{-1}: 1620 (C=O); δ_H (300 MHz, $CDCl_3$): 4.14 (0.1 H, s, keto-CH_2), 4.22 (5 H, s, C_5H_5), 4.62 (2 H, t, C_5H_4), 4.86 (2 H, t, C_5H_4), and 6.35 (0.95 H, s, enol CH). Anal. calcd. for $C_{14}H_{11}FeCl_3O_2$: Fe 14.95; found: Fe 14.8%. Compound **7** was isolated from the reaction mixture in yields up to 10%, mp116°C. ν_{max}(KBr)/cm^{-1}: 1630 (C=O); δ_H (300 MHz, $(CD_3)_2CO$): 2.55 (3 H, d, CH_3), 4.19 (5 H, s, C_5H_5 on the alkenyl side), 4.22 (5 H, s, C_5H_5 of ferrocenoyl), 4.46 (2 H, t, C_5H_4 on the alkenyl side), 4.57 (2 H, t, C_5H_4 of ferrocenoyl), 4.79 (2 H, t, C_5H_4 on the alkenyl side), 4.88 (2 H, t, C_5H_4 of ferrocenoyl) and 6.89 (1 H, q, CH). Anal. calcd. for $C_{24}H_{22}Fe_2O$: Fe 26.21; found: 26.1 %.

Summary

The formal reduction potentials, $E^{\circ\prime}$, of five different synthesized ferrocene-containing β-diketones and the carbonyl IR stretching frequencies of eight different methyl esters independently extrapolate to mutually consistent group electronegativities whereas the single crystal structure deter-

[2] Supplementary material (a complete X-ray structure report for $C_{14}H_{11}O_2FeF_3$ including experimental details, tables of atomic coordinates, bond lengths and angles, anisotropic displacement parameters, torsion angles, and least-squares planes) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the tables of anisotropic displacement parameters, torsion angles, and least-squares planes, this material has also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

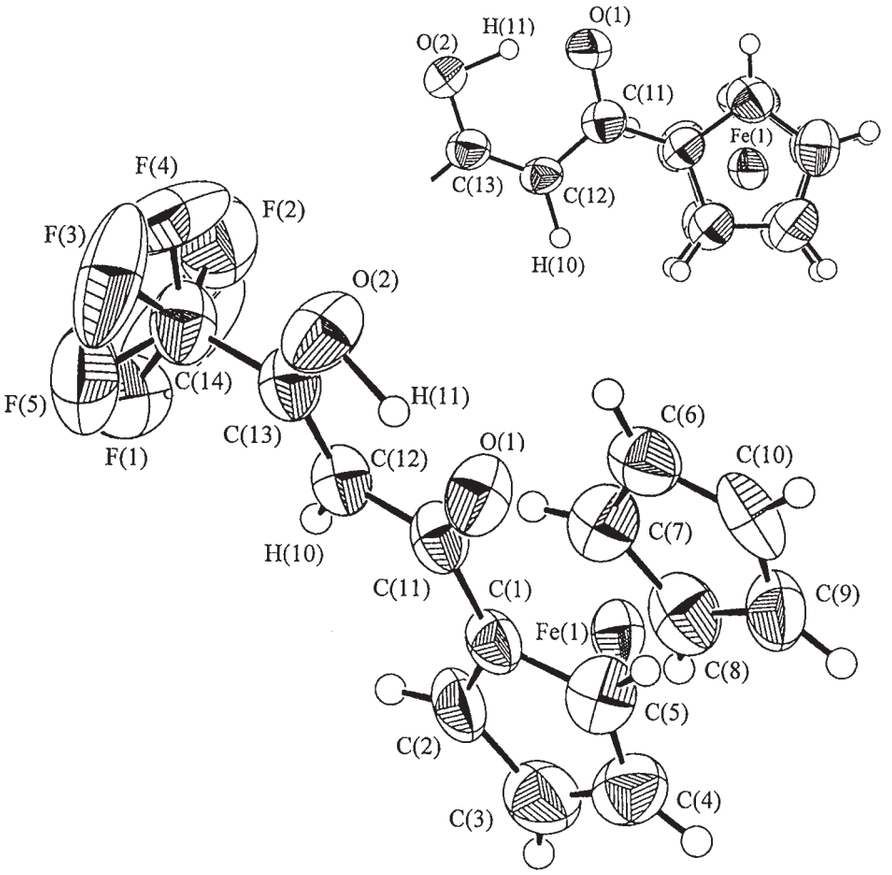
Fig. 5. A perspective view of Hfctfa showing atom labelling. The view from above down the C_5 ferrocenyl axis (top right) highlights the eclipsed conformation of the ferrocenyl group and the asymmetric enolization of the molecule.



Scheme 2. Electronic considerations in terms of electronegativity, χ, favour **I** as the enol form of Hfctfa. However, structure **II** was shown by crystallography and NMR to be dominant, implying that the equilibrium between **I** and **II** lies far to the right. A dihedral angle of 7.84° between the aromatic ferrocenyl group and the pseudo-aromatic β-diketone core imply that energy-lowering canonical forms such as **IV** make a noticeable contribution to the overall existence of Hfctfa. For clarity, the ferrocenyl group in **II** and **IV** is shown in just one canonical form but in both cases the iron atom can be bound to any of the five cyclopentadienyl carbon atoms as indicated in **I.** Likewise, the positive charge of **IV** is also not confined to the single position shown but rather oscillates between C(2) and C(5) (it cannot be on C(1), atom numbers are indicated next to individual atoms) to give rise to four different canonical forms as indicated in **III**. $\chi_{trifluoromethyl} = 3.01$, $\chi_{ferrocenyl} = 1.87$.

mination of the CF_3 derivative confirms that asymmetric enolization takes place in a direction away from the ferrocenyl group.

Apparent molar volumes of glycine, L-alanine, and L-serine in water + ethanol mixtures at 298.15 K

Xiaoling Ren, Ruisen Lin, Yaming Ni, and Hanxing Zong

Abstract: Densities of glycine, L-alanine, and L-serine have been measured with an oscillating-tube densimeter at 298.15 K in water + ethanol (EtOH) mixtures ranging from pure water to 45% ethanol by mass. From these densities, apparent molar volumes and limiting apparent molar volumes of the three amino acids in the mixtures have been calculated. Transfer volumes are interpreted in terms of the structure-making or structure-breaking effects of water on addition of these amino acids in the mixtures. The relative contributions of hydrophilic and hydrophobic interactions in these solutions have been inferred.

Key words: glycine, L-alanine, L-serine, water + ethanol mixtures, densities.

Résumé : Opérant à 298,15 K et faisant appel à un densimètre à tube oscillant, on a mesuré les densités de solutions de glycine, de L-alanine et de L-sérine dans des mélanges d'eau + éthanol (EtOH) contenant de 0 à 45% (en poids) d'éthanol. Utilisant ces densités, on a calculé les volumes molaires apparents et les volumes molaires apparents limites de ces trois acides aminés dans les mélanges. On interprète les volumes de transfert en fonction des effets de formation ou de bris de structures provoqués par l'eau lors de l'addition de ces acides aminés dans les mélanges. On a déduit les contributions relatives des interactions hydrophiles et hydrophobes dans ces solutions.

Mots clés : glycine, L-alanine, L-sérine, mélanges eau + éthanol, densités.

[Traduit par la Rédaction]

Introduction

Amino acids are the monomers that constitute proteins and are considered to be model compounds for proteins. There are extensive volumetric property studies of aqueous amino acid systems, but few of amino acids in mixed aqueous solvents (1–4). Water + alcohol mixtures have proved to be the most interesting due to the unique structural relationship of alcohols with pure water. The present work reports the apparent molar volumes of some amino acids in H_2O + ethanol (EtOH) mixtures.

Experimental

Analytical reagent grade glycine, L-alanine, and L-serine were recrystallized twice from ethanol + water mixtures. The materials were used after drying at 100°C for 6 h and then in vacuo over silica gel at room temperature for a minimum of 24 h. Ethanol (purity > 99.9 mass percent) was controlled by GLC. Freshly prepared twice-distilled water was used in all experiments. H_2O + EtOH mixtures were prepared by mass. The mass percentage of ethanol in these mixtures ranged in 10% increments from 5% to 45%. Solutions of amino acids were made by mass on the molality concentration scale. They were stored in sealable vials prior to use. Uncertainties in solution concentrations were estimated at ±0.000 02 mol kg^{-1} in calculations.

The sample densities were measured with an Anton Paar DMA 55 densimeter thermostatted to better than ±0.01°C. The temperature inside the densimeter cell was monitored with an Anton Paar DT 100-20 digital thermometer. The densimeter was calibrated with twice-distilled water and dry air. The accuracy of density values was $\pm 10^{-5}$ g cm^{-3}. The density of pure water at 298.15 K was taken as 0.99705 g cm^{-3} (5).

Results and discussion

Densities for solutions of glycine, L-alanine, and L-serine in H_2O + EtOH mixtures are shown in Tables 1–3. For the variation of densities of H_2O + EtOH mixtures with ethanol content, the results obtained in this work are in good agreement with those of Naize et al. (6), Sandhu et al. (7) and Bateman (8) (see Fig. 1). Our measured density of pure ethanol is 0.785 12, the value found by Treszczanowicz et al. (9) is 0.785 12, and that of Marsh et al. (10) is 0.785 08. Apparent molar volumes V_ϕ are calculated from these data (11) using the equation:

$$[1] \qquad V_\phi = \frac{1}{m}\left[\frac{1000 + mM}{d} - \frac{1000}{d_0}\right]$$

where m is the molality, M is the molecular weight of solute, and d_0 and d are the densities of solvent and solution, respectively. Calculated apparent molar volumes for amino acids are also listed in Tables 1–3. The results can be fitted by the equation

$$[2] \qquad V_\phi = V_\phi^0 + b_v m$$

where V_ϕ^0 is the apparent molar volume at infinite dilution and b_v is an experimentally determined parameter.

V_ϕ^0 and b_v values of eq. [2] have been evaluated by least squares and are listed in Table 4. Literature values for V_ϕ^0 and b_v of the three amino acids in water are also given in Table 4. The agreement between V_ϕ^0 values in water obtained in this work and those reported in the literature is good.

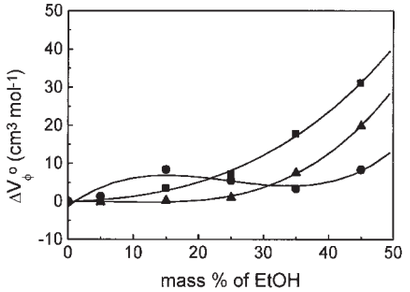
Fig. 2. Transfer volumes ΔV_ϕ^0 of amino acids versus mass% of EtOH at 298.15 K: (■) L-Gly, (▲) L-Ala, (●) L-Ser.



Transfer volumes of amino acids, ΔV_ϕ^0, from H_2O to H_2O + EtOH mixtures are calculated from

[3] $$\Delta V_\phi^0(H_2O \rightarrow H_2O + EtOH) = V_\phi^0(\text{in } H_2O + EtOH) - V_\phi^0(\text{in } H_2O)$$

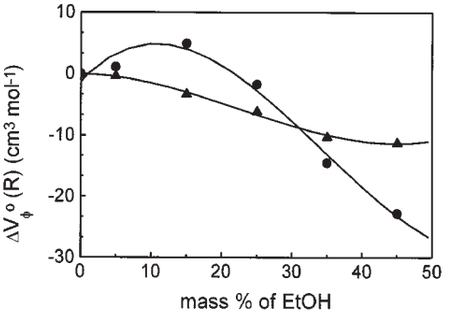
The results are illustrated in Fig. 2.

It is well known that at infinite dilution solute–solute interactions are absent and, therefore, the observed transfer volumes are due to the solute–cosolvent–solvent interactions. As can be seen in Fig. 2, transfer volumes of the three amino acids are positive except one for L-alanine at 5 mass% of ethanol. Addition of a small amount of ethanol in water enhances the structure of water, resulting in a more structured solvent (15). When ethanol molecules interact with the charged centers of amino acids, some of the previously electrostricted water molecules around these centers return to their normal structure due to the hydration cosphere overlap effect. This decrease in electrostriction gives rise to an increase in volume, and demonstrates that the three amino acids are "structure makers" for the water in H_2O + EtOH mixtures.

Transfer volumes of glycine and L-alanine increase monotonically with increasing ethanol content in mixed solvents (Fig. 2). This suggests that the decrease in electrostriction

© 1999 NRC Canada

Fig. 3. Contribution of R groups to transfer volumes ΔV_ϕ^0(R) versus mass% of EtOH at 298.15 K: (▲) L-Ala, (●) L-Ser.



increases rapidly and the structure-making effects of water on addition of glycine and L-alanine increase rapidly with increasing ethanol content in mixed solvents.

Besides the electrostricted water around the charged zwitterionic centers, there exists a hydrophobic hydration cosphere for the -CH_3 side chain of L-alanine. In the case of overlap of the ethanol cosphere with that of L-alanine, some water molecules are also released from the cosphere of the side chains, making a negative contribution to ΔV_ϕ^0. This gives rise to a decrease in the ΔV_ϕ^0 of L-alanine against glycine. The structure-making effect of water on addition of L-alanine is weaker than that on addition of glycine. At 5 mass% of ethanol, the negative contribution is bigger than the positive contribution to ΔV_ϕ^0 of L-alanine in mixed solvents. This results in a small decrease in volume and L-alanine has a small effect on the structure breaking of water.

It can be seen that the variation of ΔV_ϕ^0 of L-serine with ethanol content is complex. The values first increase to a maximum at 15 mass% of ethanol, and then decrease to a minimum at 35 mass% of ethanol (Fig. 2). Besides the electrostricted water around the charged zwitterionic centers, there exists a hydrophilic hydration cosphere for the -CH_2OH sidechain of L-serine. In the case of overlap of ethanol cospheres with that of L-serine, some water molecules are also released from the cosphere of the side chains, making a positive contribution to ΔV_ϕ^0. This positive contribution is dominant in the "rich" water region and reaches a maximum at 15 mass% of ethanol. L-Serine has the strongest effect on making water structure at 15 mass% of ethanol. The collapse of the hydrophobic hydration co-sphere of ethanol due to charged portions of L-serine gives rise to a decrease in volume in the region of rich ethanol. At 35 mass% of ethanol, this negative contribution to ΔV_ϕ^0 is maximum and L-serine has the weakest effect on "making" water structure. As compared with glycine and L-alanine, L-serine contributes more effectively to enhancing water structure in the region of rich water (L-serine > glycine > L-alanine), but is less effective in the region rich in ethanol (glycine > L-alanine > L-serine) (Fig. 2).

It is of interest to examine the contribution to transfer volumes of R groups on the α-carbon of amino acids. For this purpose, the V_ϕ^0 of glycine is subtracted from that of the other two amino acids

$$[4] \qquad V_\phi^0(\mathrm{R}) = V_\phi^0(\text{amino acids}) - V_\phi^0(\text{glycine})$$

where V_ϕ^0(R) is the R group contribution to V_ϕ^0. In this calculation, it is being assumed that the volume contribution of the -H in glycine can be neglected. The results are shown in Fig. 3.

Contributions of the -CH_3 of L-alanine to transfer volumes are significant and negative. With increasing ethanol content in mixed solvents, the values of ΔV_ϕ^0(-CH_3) decrease rapidly, and the structure-making effect of water on addition of L-alanine increases rapidly.

The contributions of the -CH_2OH of L-serine to transfer volumes are significant and positive up to 22.5 mass% of ethanol. At 15 mass% of ethanol, the ΔV_ϕ^0(-CH_2OH) value is maximum, and the structure-making of water on addition of L-serine is also maximum. The positive ΔV_ϕ^0(-CH_2OH) values indicate that L-serine is a more effective water structure maker than glycine in the region of rich water. After 22.5 mass% of ethanol, the values of ΔV_ϕ^0(-CH_2OH) decrease rapidly.

Estimation of hydrocarbon types in light gas oils and diesel fuels by ultraviolet absorption spectroscopy and multivariate calibration

Peter D. Wentzell, Darren T. Andrews, Jennifer M. Walsh, Jean M. Cooley, and Paige Spencer

Abstract: Ultraviolet absorption spectra are used in conjunction with multivariate calibration methods to predict the percent content of saturates (61–99%), monoaromatics (1–34%), diaromatics (0–5%), and polyaromatics (0–1%) in light gas oil and diesel fuel samples. A total of 114 samples taken from three pilot plant studies between 1992 and 1994 were used to develop the calibration models. Supercritical fluid chromatography with flame ionization detection was employed as the reference method for quantifying hydrocarbon types. Several multivariate calibration methods (classical least squares, multiple linear regression, principal components regression (PCR), and partial least squares (PLS)) were examined. PCR and PLS gave the best overall performance, with root-mean-squared errors of prediction (absolute) of 0.9% (saturates), 0.8% (monoaromatics), 0.2% (diaromatics), and 0.05% (polyaromatics) based on 44 prediction samples. Relative errors (absolute × 100/range) for these same species were 2.4%, 2.4%, 3.2%, and 5.3%.

Key words: light gas oil, diesel, hydrocarbon content, UV spectroscopy, multivariate calibration, aromatics, petroleum.

Résumé : On a utilisé conjointement les spectres d'absorption ultraviolets et des méthodes de calibration à multivariables pour prédire le pourcentage de produits saturés (61–99%), monoaromatiques (1–34%), diaromatiques (0–5%) et polyaromatiques (0–1%) contenus dans des échantillons de diesel et de gazole léger. Pour développer les méthodes de calibration, on a utilisé cent quatorze (114) échantillons recueillis à partir de trois usines pilotes entre 1992 et 1994. On a fait appel à la chromatographie fluide supercritique avec détection à ionisation de flamme comme méthode de référence pour la quantification des divers types d'hydrocarbures. On a étudié plusieurs méthodes de calibration à multivariables (moindres carrés classiques, régression linéaire multiple, régression des principaux composants (RPC) et moindres carrés partiels (MCP). Les méthodes RCP et PLS donnent les meilleures performances globales avec des erreurs quadratiques moyennes de prédiction (absolues) de 0,9% (saturés), 0,8% (monoaromatiques), 0,2% (diaromatiques) et 0,05% (polyaromatiques) sur la base de quarante-quatre (44) échantillons de prédiction. Pour les mêmes espèces, les erreurs relatives (absolues × 100/écart) sont respectivement 2,4%, 2,4%, 3,2% et 5,3%.

Mots clés : gazole léger, contenu en hydrocarbures, spectroscopie UV, calibration à multivariables, aromatiques, pétrole.

1. Introduction

Transportation fuels such as gasoline, diesel, and jet fuels must meet detailed specifications for their quality. Such specifications ensure, for example, that the fuel will be suitable for the engine for which it is intended, will be stable over a reasonable time frame, and will meet certain environmental standards. Some of the analytical tests developed to monitor adherence to these specifications are rapid, simple, and require very little sample, while other assays require a more significant amount of fuel and specialized test equipment. Obviously, it is desirable to replace the latter test with the former wherever possible, not only to reduce costs and delays in analysis, but also to facilitate more efficient quality control at the processing stage.

One specification for transportation fuels that is becoming more important is the quantity of aromatic compounds present. This is often measured by fluorescent indicator analysis (FIA) (ASTM D1319 or UOP 501), a classical technique that is time consuming and, for the higher boiling samples (e.g., diesel), is difficult to perform reliably. A more recently developed method to measure aromatic content is based on analysis by supercritical fluid chromatography (SFC) (1, 2). In addition to being more rapid and reliable, this technique has the advantage of being able to speciate aromatics into mono-, di- and polyaromatics. However, it requires more

complex instrumentation than techniques like FIA and is not available in many labs. Other techniques, such as high-performance liquid chromatography, mass spectrometry, and nuclear magnetic resonance spectroscopy, have also been used to determine aromatic content, but these methods face similar drawbacks.

An alternative approach to predict the aromatic content, as well as other properties of refinery products, is the use of spectroscopic techniques, and such methods have been widely reported in the literature. Near-infrared, Fourier transform infrared (FTIR), and Raman spectroscopy have been used most extensively for this purpose, especially with gasoline, aviation fuel, and other light products (3–10). Typically, these spectroscopic methods are used in conjunction with a variety of multivariate calibration techniques that can extract the desired information from the mixtures. The general consensus of these studies is that spectroscopy can be used as a rapid and simple means to predict certain properties of hydrocarbon mixtures provided that a training set of samples that is representative of future samples is available.

Fewer studies on the spectroscopic prediction of properties from heavier refinery products such as diesels have been carried out (11, 12). Quantitation of the hydrocarbon types in diesel fuels is becoming more important since future regulations on diesel properties may make it necessary to reduce the aromatic content in order to meet fuel specifications. A few studies have examined the application of ultraviolet absorption spectroscopy to the prediction of diesel and gas oil properties (13–15). These studies have been limited in scope and often restricted to a few wavelengths, without taking full advantage of multivariate calibration methods.

In this paper, a method for the spectroscopic determination of hydrocarbon types in light gas oils and diesel fuels is evaluated. The present study can be distinguished from many of the earlier works in three ways: (*i*) it utilizes ultraviolet (UV) absorption measurements as opposed to the more commonly employed IR or NIR measurements, (*ii*) it is applied to middle distillates as opposed to gasoline, (*iii*) aromatic content is subdivided into mono-, di-, and polyaromatics (saturated hydrocarbon content is also determined), and (*iv*) a large number of chemically diverse samples with a wide range of aromatic content were available for calibration. Five methods of multivariate calibration are applied to the spectroscopic data and compared for their ability to predict the four properties of interest.

2. Multivariate calibration techniques

Multivariate calibration techniques are now widely used in many practical applications, not the least of which is the petroleum industry. Whereas traditional univariate calibration relies on a single scalar measurement for each sample, multivariate calibration methods utilize a vector (or matrix) of data for each sample, such as a spectrum, which permits analysis in the presence of multiple interferences. In general, the object is to obtain an $n\times1$ vector of regression coefficients, **b**, such that

$$[1] \qquad \hat{y}_{unk} = \mathbf{x}^{T}\mathbf{b}$$

where $\hat{y}_{unk}$ is the estimated value of the property of interest (e.g., % monoaromatics) for an unknown sample and **x** is an $n\times1$ vector of responses for the sample measured at n channels (e.g., the spectrum measured at n wavelength channels). (In this paper, scalars will be indicated by lower case italic symbols, vectors by boldface lower case symbols, and matrices with boldface upper case symbols. The superscript "T" will be used to indicate the transpose of a matrix or vector.) A wide range of calibration techniques are now available, with the main differences being the methods that they employ to determine the regression vector, **b**.

In most cases, the calibration procedure is as follows. First, a set of samples is obtained that is representative of the range of compositions that are likely to be encountered in practice. Spectra (or other vectorial measurements) are then recorded for each sample. The property of interest is also measured for each of these samples by an independent reference method (in this work, supercritical fluid chromatography). The samples are then divided into two groups, one that is used to build the calibration model (the training or calibration set) and another that is used to independently assess the performance of the model (the validation or prediction set).

This study focuses on the evaluation of a few key multivariate calibration methods for the problem of interest. These are: (*i*) classical least squares (CLS), (*ii*) forward selection multiple linear regression (FS-MLR), (*iii*) stepwise selection multiple linear regression (SS-MLR), (*iv*) principal components regression (PCR), and (*v*) partial least-squares regression (PLS). These techniques have been reviewed in the literature (16–21), but will be described briefly here in the context of the present study.

2.1. Classical least squares

Classical least squares (CLS), also known as the K-matrix method, assumes that the observed responses are linearly related to the component concentrations and that the concentrations of all components in the mixtures are known for the calibration set. The most common example of this is the multivariate form of Beer's Law, which relates a matrix of spectra, **X**, to a matrix of concentrations, **Y**, through:

$$[2] \qquad \mathbf{X} = \mathbf{YK}$$

Here, **X** is an $m\times n$ matrix of mixture spectra (m samples measured at n wavelength channels), **Y** is an $m\times p$ matrix of component concentrations (p components for each of m samples), and **K** is the $p\times n$ matrix of pure component spectra (molar absorptivities, assuming a unit path length). Unless pure component spectra are known, **K** is normally calculated from the calibration data by solving the system of linear equations. From there it is a straightforward procedure to obtain the regression vectors for each component.

CLS can be an effective method when all components in the mixture contributing to the spectra have been identified and can be quantitated, but it is less useful when these conditions are not met because the model is incomplete. Furthermore, the model really only applies when the property of interest (e.g., concentration) can be associated with a component with a clearly defined spectrum, and its utility for more general properties (e.g., cetane number) is questionable. In the present study, it might be argued that the properties measured (saturates and aromatics) approximate a

© 1999 NRC Canada

complete set of "components" for UV spectroscopy, so the potential of CLS was explored.

2.2. Multiple linear regression

Perhaps the most serious deficiency of CLS is that it requires a knowledge of all of the components in the mixture, while there may be only a few properties of interest. Multiple linear regression (MLR), sometimes called the P-matrix method, circumvents this problem by assuming a model of the form:

$$\mathbf{Y} = \mathbf{XP} \quad [3]$$

where **Y** is the $m \times p$ matrix of properties to be estimated (p properties for m samples), **X** is the $m \times n$ matrix of spectra, and **P** is the $n \times p$ matrix of regression coefficients. This is sometimes referred to as the "inverse model," since **X** and **Y** are reversed from the CLS model in eq. [2], and MLR is sometimes referred to as inverse least squares. A distinct advantage of MLR is that it permits the determination of the regression vector (**b** in eq. [1]) for a desired component or property without requiring a complete knowledge of all components. It is therefore possible to apply this equation using only reference values for the property of interest. Unfortunately, reliable estimation requires that m, the number of samples in the calibration set, is substantially greater than n, the number of wavelength channels. Since modern spectrometers can have hundreds to thousands of channels, this condition is seldom met and it is necessary to select a much smaller subset of the wavelength channels. The channel selection is key, and in this work two common methods of variable selection were used: forward selection (FS) and stepwise selection (SS).

Forward selection is a screening procedure that selects the best variables (wavelength channels in this case) and adds them to the regression model one at a time until no additional improvement in model performance is found (17). This point is often determined using a standard F-test, but with a large number of wavelength channels, this test breaks down due to the statistical problem of multiple testing (17, 22). In this work, the alternative approach of internal validation was used. In this procedure, the calibration set is further subdivided into two parts, one that is used to build the models (calibration subset) and the other that is used to determine when to stop adding variables (prediction subset). Note that the latter is not the same as the prediction set described earlier, since the calibration procedure must remain blind to the data set used for validation. Variables are added to the calibration model by FS using the calibration subset as described above. For each new set of variables, the regression vector is calculated and the prediction subset is used to calculate the root-mean-squared standard error of prediction (rmsep) from:

$$\text{rmsep} = \sqrt{\frac{\left(\mathbf{y}_{\text{pred}} - \mathbf{X}_{\text{pred}}\hat{\mathbf{b}}\right)^{\text{T}}\left(\mathbf{y}_{\text{pred}} - \mathbf{X}_{\text{pred}}\hat{\mathbf{b}}\right)}{n_{\text{pred}}}} \quad [4]$$

where n_{pred} is the number of samples in the prediction subset. Note that in this case, the rows of **X** do not contain the full spectra of the prediction samples, only those variables selected by the FS procedure. The rmsep is a measure of the predictive ability of the model and will generally pass through a minimum when plotted against the number of variables added to the model, indicating that additional variables are overfitting. The minimum is used to determine the optimum number of wavelength channels. The FS procedure is then repeated using the full calibration set and terminating at this number of variables.

The technique of stepwise selection is fundamentally the same as FS for the addition of variables, but it allows one to check the significance of previously added variables after a new one is added (17). As with FS-MLR, the internal validation procedure was used to select the optimum number of variables for SS-MLR.

2.3. Principal component regression

Principal component regression (PCR) has emerged as one of the tools of choice for the multivariate calibration problems in chemistry. In PCR, the overall dimensionality of the data is reduced to only a few variables, thereby addressing the rank deficiency problem inherent in MLR. Unlike the variable selection procedures used for MLR, variable reduction in PCR occurs by combining those variables that exhibit strong correlations into *latent variables*, so information is not lost through the elimination of wavelength channels. The first step in PCR is to decompose the $m \times n$ matrix of calibration responses, **X**, using principal component analysis (PCA) to give scores and loadings matrices:

$$\mathbf{X} = \mathbf{TL} \quad [5]$$

Assuming that $m < n$, PCA returns the scores matrix, **T** ($m \times m$), and the loadings matrix, **L** ($m \times n$). In order to retain p latent variables for the regression, these matrices are then truncated by removing the right-hand columns and bottom rows to give $\tilde{\mathbf{T}}$ ($m \times p$) and $\tilde{\mathbf{L}}$ ($p \times n$). The latent variables selected in this way form an orthogonal set and are the linear combinations of the original variables that account for the largest amount of variance in the data. Because of this, these variables are likely to be useful in developing a model. The matrix $\tilde{\mathbf{T}}$ is analogous to the matrix **X**, except that it has fewer columns, making it more readily employed in MLR. The corresponding regression model is:

$$\mathbf{y} = \tilde{\mathbf{T}}\mathbf{q} \quad [6]$$

where **q** is the $p \times 1$ vector of regression coefficients. Solution of eq. [6] for **q**, the regression vector for the scores, and its transformation to **b**, the regression vector in terms of the original variables, is straightforward.

An important consideration in PCR is the number of latent variables used in the regression. In this work, this parameter was determined by *leave-one-out cross-validation*. In this procedure, the calibration is carried out using all but one of the calibration samples. This sample is then predicted using the model determined and the difference between the predicted and reference values of y is determined. This process is repeated m times, each time leaving out a different calibration sample. All of the prediction errors are then combined to give the root-mean-squared error of cross-validation (rmsecv):

© 1999 NRC Canada

$$[7] \qquad \text{rmsecv} = \sqrt{\sum_{i=1}^{m} (y_i - \hat{y}_i)^2 / m}$$

Here y_i is the observed value of the property of interest for calibration sample i, $\hat{y}_i$ is the predicted value of the property, and m is the number of calibration samples. A plot of the rmsecv vs. the number of latent variables should pass through a minimum at the optimum number of latent variables. This approach is similar to the internal validation procedure used for variable selection in MLR, but is often considered more reliable because more samples are used to build the model. For MLR, cross-validation cannot generally be used for variable selection, since a new group of variables may be selected on each iteration of the process.

2.4. Partial least-squares regression

One weakness of PCR is that it extracts the latent variables, which are linear combinations of the original variables, on the basis of the amount of variance in **X** that they encompass. Therefore, wavelength channels with large variations in response over the calibration set tend to be weighted most heavily. However, these wavelengths are not necessarily the ones that are most useful in predicting the desired property. To mitigate this problem, the technique of partial least-squares regression (PLS) can be used (16). In recent years, PLS has become one of the most widely used regression techniques in chemistry. In many instances, PCR and PLS produce comparable results, but in certain cases PLS will exhibit superior performance and often can produce a model with fewer latent variables.

Regression with PLS is very similar to PCR, with latent variables being extracted from the calibration data and used in the regression model. However, while PCR extracts the latent variables to maximize the variance in **X**, PLS generates the latent variables by maximizing the covariance between **X** and **y**. In this way, variables that have good predictive abilities are given a greater weight. The latent variables, or scores, in PLS can be calculated by a variety of algorithms (16), the details of which will not be discussed here. As with PCR, it is necessary to determine the optimum number of latent variables by cross-validation.

3. Experimental

3.1. Data

There were a total of 115 samples from pilot plant studies available for study in this work. These consisted of two sets of light gas oil samples (boiling range 195–343°C) and one set of diesel samples (boiling range 177–343°C). Fifty-nine light gas oil samples were obtained from a pilot plant program conducted at Syncrude Canada Ltd. to evaluate three different catalysts. The project consisted of 20 mass balances and included temperatures ranging from 320 to 400°C, pressures ranging from 6.9 to 13.8 MPa, and liquid hourly space velocities ranging from 0.7 to 1.3 mL L^{-1} mL^{-1}. A further 26 samples were obtained from a subsequent program, which used a different feed as well as different catalysts. Finally, 30 diesel samples were obtained from a third pilot study that involved very severe treating of light gas oil samples with an aim of significantly reducing aromatic content. The use of three separate pilot plant studies ensured chemical diversity in the samples studied.

The reference values for percentages of saturates, monoaromatics, diaromatics, and polyaromatics were determined by supercritical fluid chromatography (1) using an HP model G1205A supercritical fluid chromatograph (Hewlett–Packard, Palo Alto, Calif.) equipped with an autosampler. The oils were separated neat on a 250 × 4.6 mm HP hydrocarbon group separation column using carbon dioxide as the carrier (2 mL min^{-1}). The oven temperature was 35°C and the outlet pressure was 150 bar. Quantitation was performed with a flame ionization detector (FID). To obtain the weight percentages of each of the four groups, the FID signal was integrated over ranges specified by the CGSB for each group. This area was then ratioed to the total area for the chromatogram. The ranges obtained for the samples were as follows: saturates, 60.6–99.0%; monoaromatics, 0.8–34.1%; diaromatics, 0–5.0%; polyaromatics, 0–0.9%. The wide range of concentrations is an asset in the construction of reliable models.

For the spectral analysis, approximately 0.12 g of each sample was accurately weighed into a 25 mL volumetric flask and diluted with HPLC grade cyclohexane. This solution was further diluted by a factor of 1/200 with cyclohexane before running the spectra. (In preliminary studies, higher concentrations had also been employed, but the lower concentrations were found to be more useful.) Spectra were obtained on a Cary 3 UV–visible spectrophotometer (Varian Instruments, San Fernando, Calif.) in a 1 cm flow-through cell. Scanning parameters were: spectral band width, 0.5 nm; signal averaging time, 0.1 s; data interval, 0.35 nm; scan rate, 21 nm min^{-1}; range, 200–400 nm. There were a total of 572 points acquired for each spectrum. Each spectrum was normalized to an initial concentration of 0.1 g/25 mL by multiplying the absorbance readings by 0.1/(sample mass).

3.2. Data pretreatment

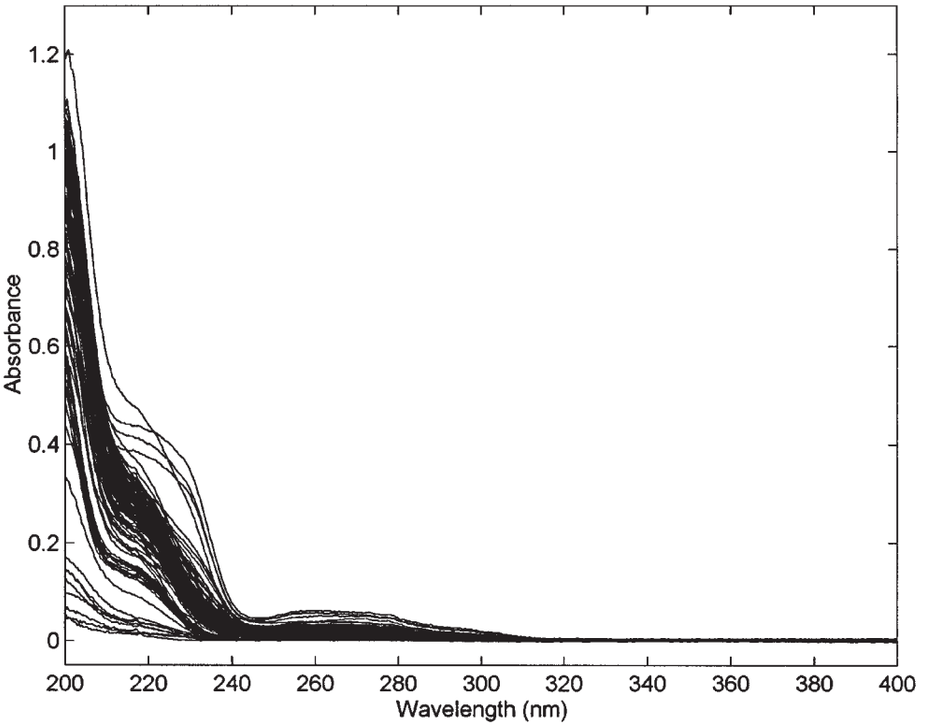
The data for the original 115 samples were first analyzed to identify the presence of outliers using the procedure outlined by Martens and Næs (16). In this procedure, samples that are highly influential (high leverage) and have large studentized residuals are flagged as outliers. Only one sample was identified as an outlier and eliminated from subsequent analysis. This corresponded to a feed sample that was expected to have a considerably different composition from the other samples. The UV spectra for the remaining 114 samples used in this work are shown in Fig. 1.

Prior to regression analysis, the spectra were adjusted by subtracting the mean absorbance at each wavelength from all of the measurements at that wavelength. This preprocessing step, called column mean-centering, is commonly employed with spectroscopic data to eliminate intercept terms from the model. Likewise, each of the four groups of reference measurements was centered about its mean value. In the final prediction, a correction for the offset was made.

For the regression analysis, it was necessary to divide the full data set into a calibration set and a prediction set for purposes of validation. For this work, the sizes of the calibration and prediction sets were chosen to be 70 and 44 samples, respectively. To ensure that each set is representative of the other, the subset selection procedure of Kennard

© 1999 NRC Canada

Fig. 1. Spectra of 114 samples used in the study (outlier excluded). Spectra were normalized to a concentration of 0.02 g L^{-1}.



and Stone was used (23) to split the data. Visual verification of the representativity was also made by examining two-dimensional projections of the samples after PCA. For FS-MLR and SS-MLR, further splitting of the calibration set was necessary for internal validation, giving a calibration subset of 50 samples and a prediction subset of 20 samples. The same method was used for obtaining these subsets.

3.3. Computational aspects

All of the results presented here were obtained on a Pentium-based personal computer using programs written in Matlab v4.2x (The Math Works, Natick, Mass.). All programs were written by the authors, except for the PLS routines, which were taken from the PLS Toolbox for Matlab (Eigenvector Research Inc., Manson, Wash.). Computation times for building the models varied with the regression technique, but all were under an hour. Once the regression coefficients are computed, calcualtion of results for new samples is computationally trivial.

4. Results and discussion

Initially, the feasibility of using UV spectroscopic data to predict aromatic content was evaluated by calculating the correlation coefficient between the absorbance at each wavelength and the reference value for each of the four properties to be predicted. The data were mean-centered for these calculations. Figure 2 shows the correlation coefficient plotted as a function of wavelength for the four properties. Each of the properties exhibits regions where there is a high degree of positive or negative correlation, indicating that these data may be useful in the development of a regression model. For the three classes of aromatics, correlation is high at short wavelengths and the maximum shifts to longer wavelengths with increasing aromaticity. This is consistent with the observed transitions for aromatic compounds and the bathochromic shift that occurs with increasing conjugation. For saturates, there is a strong negative correlation in this region, since these compounds do not absorb in this part of the spectrum and the content is essentially correlated with the absence of aromatics. For all constituents, the degree of correlation falls off with increasing wavelength until it is effectively zero above 350 nm.

Despite the high degree of correlation found, attempts to use single wavelengths to model the properties of interest were unsuccessful, generally resulting in nonlinear plots. This led to the application of the multivariate methods described above.

Table 1 summarizes the results obtained by the various calibration methods. The table is divided by constituent and calibration method and gives the prediction errors in each case, along with other relevant parameters. The errors presented in the table are rmsep values obtained using the prediction set of 44 samples, which were completely excluded from the calibration process. Therefore, these values should be good estimates of the true predictive ability of each model in this sample domain. Both absolute errors (% content of constituent) and relative errors (% of range of predicted value) are shown. The relative error is often a better means of evaluating the predictive ability of the model since it takes into account the range of values to be predicted. Also given in the table are the number of wavelength channels selected, the corresponding wavelengths (MLR), and the number of latent variables used (PCR and PLS). The

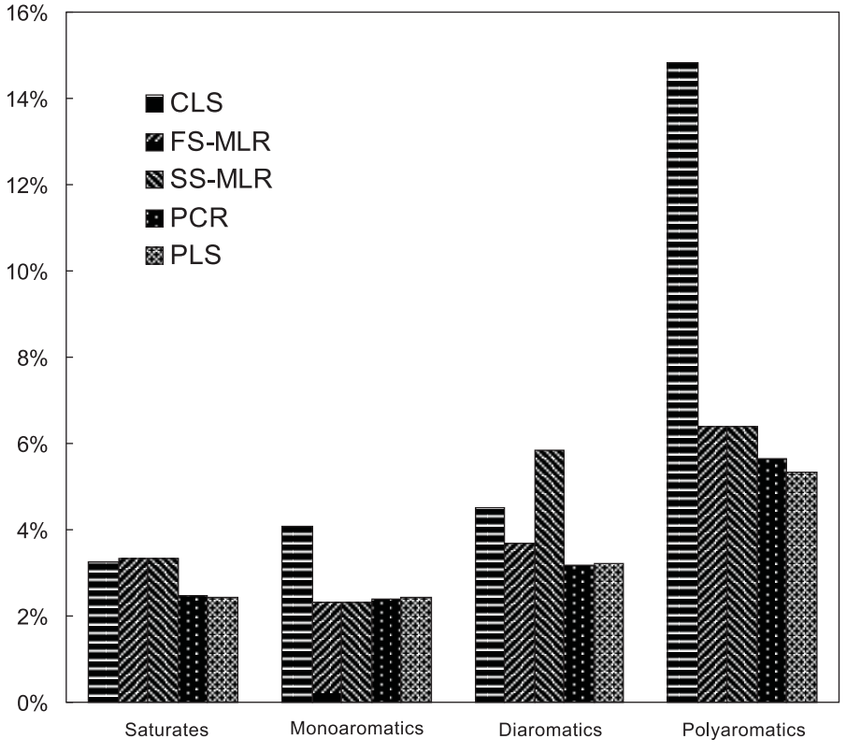
Fig. 3. Graphical comparison of relative prediction errors from multivariate calibration.



wavelengths have been rounded to the nearest nanometre to save space. The predictive abilities are also summarized in the bar chart in Fig. 3 for easy comparison.

All of the methods used were able to quantitate the four hydrocarbon types reasonably well, with the possible exception of the polyaromatic content, which was below 1% in all of the samples examined. For the other three groups of compounds, all of the relative prediction errors are below 6% and often below 4%. CLS performed better than expected, probably because the aromatic classes approximate a complete set of absorbers in the UV. FS-MLR and SS-MLR yielded the same wavelength subsets (and hence the same predictive abilities) in all cases except the diaromatics, with SS generating a subset of the FS case with poorer predictive ability. Only two wavelengths were selected for the monoaromatics and a single wavelength was found to be sufficient for the polyaromatics. While it is tempting to try to interpret the selected wavelengths from a chemical perspective, this is difficult to do because the wavelengths with the best predictive ability do not necessarily correspond to the peak maximum for a given class of compounds in a complex mixture.

In general, PCR and PLS performed the best of the five methods tested, but the improvement was only marginal. These two methods gave similar results but, as is common, PLS often required fewer latent variables. The regression vectors obtained by PCR and PLS can often yield information about important regions of the spectrum and suggest critical measurement regions for lower resolution instruments. These regression vectors are plotted for each of the hydrocarbon classes in Fig. 4. There appears to be good agreement in the general shape of the regression vectors (with the possible exception of the monoaromatics), which explains their similar performance. These plots suggest that shorter wavelengths are more important, as expected. Beyond this, it is difficult to say much about the shape of the curves, but it is likely that the oscillating structure of the regression coefficients is the result of regularly spaced bands for the aromatic species present. It is possible that restricting the wavelength range to shorter wavelengths prior to calibration may further improve the results, but this was not attempted in this work.

Finally, as a typical example, Fig. 5 shows results for predicted vs. measured properties for the PLS method. The plot distinguishes among calibration and prediction samples and the three different data subsets in order to convey information about the distribution of samples. Note that the correlation between measured and predicted values is very good for the first three constituents and there is no suggestion of bias. The agreement is not as good for the polyaromatics, but the figure makes it clear that one of the reasons for this is digitization error in the reference method arising from the low concentrations of these species within the samples, which is anticipated for light gas oils.

5. Conclusions

The results presented here demonstrate that UV spectroscopic measurements, in conjunction with multivariate calibration methods, can be used to predict the aromatic content of intermediate petroleum distillates with good reliability. The models were constructed and validated using two differ-

ent sets of light gas oil samples and one set of diesel samples. In addition to different boiling ranges, the samples are also chemically different due to severe hydrotreating/ hydrocracking of the diesel samples. Therefore, this data set should represent a fairly rigorous test of the multivariate modeling methods. Furthermore, unlike some earlier studies that only quantified total aromatics, this work was able to differentiate among three different classes of aromatic compounds. With the exception of polyaromatic content, which suffered from imprecision in the reference method, relative prediction errors for PCR and PLS were around 3%, which is quite good for this type of analysis and comparable to current methods for diesel aromatics. The absolute errors were similar to the repeatability specifications for the SFC method, suggesting that uncertainty in the reference method may be a significant contributor to the prediction error.

The use of an ultraviolet spectrometer to measure aromatic content has potential advantages over SFC and other techniques. UV spectrometers are relatively inexpensive, rugged, and simple to use, making them more suitable for on-site measurements. In this work, spectroscopic measurements were carefully made on a high-quality instrument to ensure reliable data. It is likely, however, that comparable results can be obtained with faster scans on lower resolution instruments. Of course, steps would need to be taken to ensure that the calibration models exhibit good long-term reliability with changes in plant operating conditions and feedstocks. Nevertheless, this study has shown the feasibility of estimating hydrocarbon content through UV spectroscopy.

The adsorption of carbon dioxide by tertiary alkanolamines

M. Teresa S.R. Gomes, Cristina M.F. Barros, M. Graça O. Santana-Marques, and João A.B.P. Oliveira

Abstract: The quantification of gaseous carbon dioxide, CO_2, adsorbed by tertiary alkanolamines was performed using a quartz crystal microbalance. Carbon dioxide was injected over piezoelectric quartz crystals coated with different amounts of *N*,*N*,*N*′,*N*′-tetrakis(2-hydroxyethyl)ethylenediamine (THEED), *N*,*N*,*N*′,*N*′-tetrakis(2-hydroxypropyl)ethylenediamine (Quadrol), and triethanolamine (TEA), and the frequency decrease of the crystals was recorded. The nature of the interaction of the alkanolamines with CO_2 was investigated by nuclear magnetic resonance spectroscopy (NMR), Fourier transform infrared spectroscopy (FTIR), fast atom bombardment mass spectrometry (FABMS), and mass spectrometry/mass spectrometry (MS/MS).

Key words: alkanolamine, quartz crystal microbalance, piezoelectric quartz crystal.

Résumé : On a déterminé la quantité de dioxyde de carbone gazeux absorbé par les alcanolamines tertiaires à l'aide d'une microbalance à cristal de quartz. On a injecté le dioxyde de carbone sur un cristal de quartz piézoélectrique enrobé de différentes quantités de *N*,*N*,*N*′,*N*′-tétrakis(2-hydroxyéthyl)éthylènediamine (THEED), de *N*,*N*,*N*′,*N*′-tétrakis(2-hydroxypropyl)éthylènediamine (Quadrol) et de triéthanolamine (TEA), et on a enregistré la diminution de fréquence des cristaux. Pour déterminer la nature des interactions des alcanolamines avec le CO_2, on a utilisé la spectroscopie de résonnance magnétique nucléaire (RMN), la spectroscopie infrarouge avec transformation de Fourrier (IR FT), la spectrométrie de masse à bombardement par des atomes rapides (FABMS) et la combinaison spectrométrie de masse/spectrométrie de masse (MS/MS).

Mots clés : alcanolamine, microbalance à cristal de quartz, cristal de quartz piézoélectrique.

[Traduit par la Rédaction]

Introduction

N,*N*,*N*′,*N*′-Tetrakis(2-hydroxyethyl)ethylenediamine (THEED) interacts in a reversible way with carbon dioxide, and previous studies have shown that THEED is a suitable coating for piezoelectric quartz crystals used for carbon dioxide monitoring (1–3).

Although amines are widely used for CO_2 adsorption in a variety of industrial processes, there is a lack of information on the nature of the interaction of amines with CO_2, in the absence of water.

Tertiary amines do not react with carbon dioxide in the absence of water (4, 5), but tertiary alkanolamines can react with CO_2, due to the presence of the hydroxyl groups, and form alkyl carbonates, $R_2NROCOO^-$. However, these carbonates are not stable at pH values lower than 10 and, in an acidic, neutral, or slightly basic medium, the hydroxyl group can be regarded as inert (6–10). This is why, in aqueous solutions, triethanolamine (TEA), $(HOCH_2CH_2)_3N$, showed qualitatively the same behaviour as triethylamine, $(CH_3CH_2)_3N$, when reacting with CO_2 (8). In the absence of solvent either a small interaction between TEA and CO_2 (1) or no interaction at all (11, 12) has been reported.

In the absence of water a very small interaction between *N*,*N*,*N*′,*N*′-tetrakis(2-hydroxypropyl)ethylenediamine (Quadrol) and CO_2 has been reported in the literature (12, 13). The similarity of structures (Scheme 1) and of the chemical and physical properties of TEA, THEED, and Quadrol makes the study of their interactions with CO_2 particularly interesting.

The quartz crystal microbalance (QCM) is known for its remarkable sensitivity and was used to monitor the mass change of a crystal coated with known quantities of these alkanolamines in the presence of CO_2. The results obtained allowed the comparison of the three alkanolamines in terms of the extent of their interactions with CO_2. To obtain information about the nature of these interactions, in the absence of solvents, nuclear magnetic resonance spectroscopy (NMR), Fourier transform infrared spectroscopy (FTIR), fast atom bombardment mass spectrometry (FABMS), and mass spectrometry/mass spectrometry (MS/MS) were used.

Experimental

Reagents

N,*N*,*N*′,*N*′-Tetrakis(2-hydroxyethyl)ethylenediamine (THEED) and *N*,*N*,*N*′,*N*′-tetrakis(2-hydroxypropyl)ethylenediamine (Quadrol) were purchased from Fluka, and triethanolamine (TEA) from Merck. The three alkanolamines were used

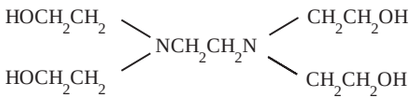
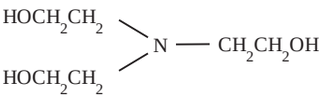
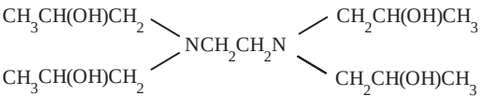
Scheme 1.



THEED



TEA



Quadrol

without further purification. In all experiments no solvent was added to the amines, except for spray coating, for which they were dissolved in absolute ethanol (purchased from Merck). Nitrogen was R grade, carbon dioxide was N45, and both were purchased from ArLíquido.

Apparatus

Each piezoelectric crystal was coated with a solution of the alkanolamine in absolute ethanol on one of its faces, using a commercial air brush and a rotating plate with orifices that held the crystal upright. After coating, the crystal was placed in a glass cell through which a constant nitrogen flow of 50 cm^3 min^{-1} was maintained. The flow rate was controlled with a variable area flow meter (Cole Parmer). Both the spraying device and the glass cell have been described elsewhere (14).

CO_2 was injected into the nitrogen flow, through an Omnifit septum injector fitted in front of the crystal cell. The syringes were SGE (Scientific Glass Engineering, Ltd), gas tight, with valve.

The piezoelectric crystals were 9 MHz (SIWARD) and the frequency was monitored with a frequency counter (Leader).

The infrared spectra were recorded on a Nicolet Magma 550 Fourier transform infrared spectrometer. The sample was introduced into a liquid cell (Spectra Tech) with CaF_2 windows.

The NMR spectra were obtained using a Bruker AMX 300 spectrometer tuned at 75 MHz to detect ^{13}C. The sample was placed in a 5 mm NMR tube with a coaxial tube for the external reference of $CDCl_3$.

FAB mass spectra and MS/MS spectra were acquired with a VG AutoSpecQ used as a EBE geometry instrument. It was equipped with a cesium ion gun, and the intensity of the Cs^+ beam was 3 μA at 15 kV. The applied accelerating voltage was 8 kV. The mass spectrometer was operated at a nominal mass resolution of 1000 (10% valley).

Samples were placed directly on the probe tip. MS/MS spectra were acquired with and without collision gas (Ar, 50% of signal attenuation). Precursor ion spectra were obtained by a linked scan of B^2/E.

Procedure

Quartz crystal microbalance measurements

The frequency of three new and similar crystals, which had been previously washed with absolute ethanol and dried, was measured under a nitrogen flow of 50 cm^3 min^{-1}.

One of the quartz crystals was sprayed on one of its faces with a 1% (w/v) solution of one of the alkanolamines in absolute ethanol. The coated crystal was again placed in the glass cell, through which the nitrogen flow was maintained. The frequency of the crystal was continuously monitored and a sudden rise in the frequency, corresponding to solvent evaporation, was observed. After frequency stabilization, corresponding to complete solvent evaporation, the frequency of the coated crystal was recorded. The frequency decreases due to coating were calculated by subtracting the recorded stabilized value from the initial frequency of the uncoated crystal.

After complete evaporation of the solvent, 5.0 cm^3 of CO_2 was injected into the nitrogen flow, and, as soon as it reached the crystal, a sudden decrease in the frequency was observed and recorded.

The crystal was washed and dried and its frequency monitored, to insure that the initial frequency of the uncoated crystal was reached. It was then coated with a different amount of the same amine, by varying the exposure of the crystal to the spray, and the experiment with CO_2 was repeated as before.

The overall procedure was repeated for the other two alkanokamines and, to prevent contamination, a new crystal was used for each amine.

NMR spectra

The NMR tube was filled with THEED, and nitrogen was bubbled in to displace atmospheric CO_2. An external reference of $CDCl_3$ was placed inside the coaxial tube, to prevent contact with the amine. The ^{13}C NMR spectrum of THEED was then recorded. The spectrum of THEED with CO_2 was recorded after bubbling CO_2 into the previous sample.

Fig. 1. Frequency of a crystal coated with THEED when 5.0 cm^3 of CO_2 are injected into the nitrogen flow.

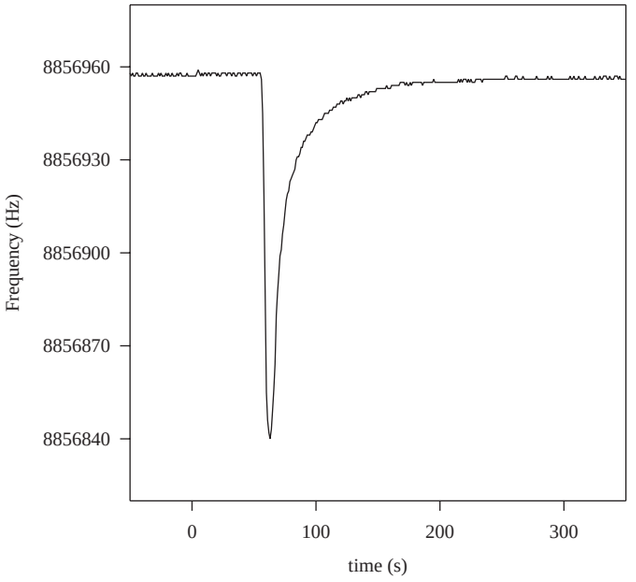

Fig. 2. Frequency decrease of a crystal coated with THEED with successive injections of different amounts of CO_2.

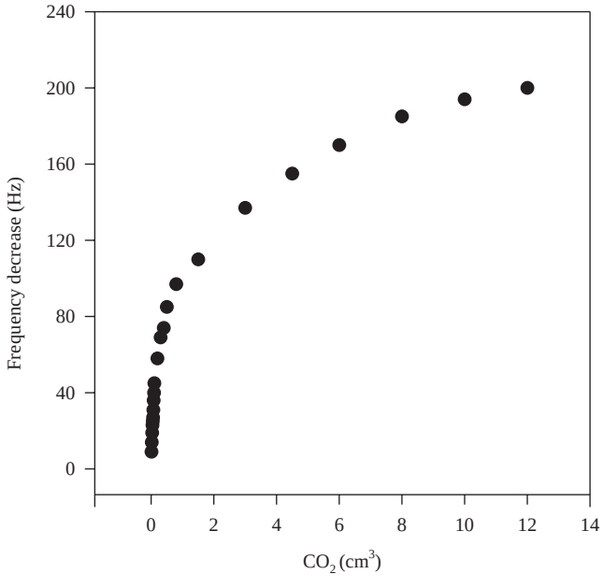
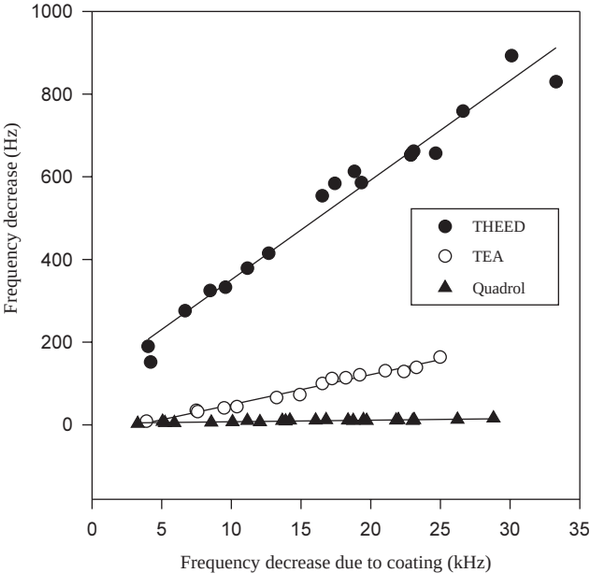


MS spectra

FAB mass spectra were recorded after bubbling N_2 and CO_2 into aliquots of the alkanolamine. The samples were applied directly to the tip of the FAB probe without adding matrix or cosolvent. Positive and negative ion spectra were recorded.

MS/MS experiments, both in the positive and in the negative mode, were performed, selecting the ions with the EB section of the mass spectrometer. Product ions of the metastable or collision-induced decompositions of the selected ions were obtained by a scan of the second electric sector.

Fig. 3. Frequency decrease observed when 5.0 cm^3 of CO_2 are injected over crystals coated with different amounts of THEED, TEA, and Quadrol.



Precursor ion spectra were obtained by a linked scan of B^2/E.

FTIR spectra

THEED was introduced into the liquid cell and either N_2 was passed through the cell, or CO_2 was introduced through a Luer fitting.

The single beam IR spectra were saved after fixed time intervals. The resolution was 4 cm^{-1} and 100 interferograms were accumulated for each spectrum.

Results and discussion

Quartz crystal microbalance experiments

Figure 1 shows the frequency of a piezoelectric crystal coated with THEED, when 5.0 cm^3 of CO_2 was injected into the nitrogen carrier gas passing through the crystal cell, and impinging on both faces of the crystal. The frequency of the crystal decreases, after CO_2 injection, due to the increase of mass on the surface of the electrodes. As the nitrogen continues to flow through the crystal cell, CO_2 is slowly displaced from the coated crystal, and the frequency rises to the base-line value, which corresponds to the initial frequency of the crystal. The reversibility of the interaction of CO_2 with THEED, as long as coating stability is maintained, allows successive injections of different amounts of CO_2. As can be seen in Fig. 2, the observed frequency is proportional to the amount of injected CO_2, as long as saturation of the coating is prevented.

Figure 3 shows the response of crystals coated with different amounts of the three alkanolamines to 5.0 cm^3 CO_2 injections. For the same amount of injected CO_2, the frequency decrease is proportional to the coating amount. Although the precision of the data shown in Fig. 3 is not as good as that of Fig. 2, the coating procedure used is repro-

© 1999 NRC Canada

ducible enough, as far as concerns the coating distribution over the electrode area of the piezoelectric crystal, to allow us to compare the response of the three amines to CO_2 injection. If other widely known coating procedures, such as smearing, dipping, or syringe deposition, were used, no comparison would be possible. The plots in Fig. 3 show that THEED has the highest sensitivity to CO_2 and that the interaction with CO_2 of both TEA and Quadrol is very weak, especially in the case of Quadrol, which can be regarded as practically inert.

The higher sensitivity of THEED when compared with the other two alkanolamines is obviously related to its surface physicochemical properties. Parameters such as the diffusivity of the gas in the liquid film should be taken into account. The latter is inversely proportional to the viscosity of the liquid.

All experiments were carried out at room temperature, and the viscosities of the alkanolamines decrease in the following order: Quadrol > THEED > TEA, so the highest adsorption should be expected for TEA. This implies that other parameters must be taken into account.

Primary and secondary amines can react directly with CO_2 in the absence of water, forming carbamates ($RNHCOO^-$ or R_2NCOO^-) but, as mentioned before, tertiary amines do not react with CO_2 in the absence of water. If the observed interaction between THEED and CO_2 is chemical, either it occurs with HCO_3^- formation (eq. [1]) from absorbed water, because the alkanolamines are hygroscopic, or it involves the hydroxyl groups of the alkanolamines, probably leading to formation of an alkylcarbonic acid or alkyl carbonate (eq. [2]).

$$[1] \qquad CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+$$

$$[2] \qquad R_2NROH + CO_2 \rightleftharpoons R_2NROCOOH$$

Although the amines were used without any previous purification or drying procedure, and contact with the atmosphere during spraying could not be avoided, it is not probable that the observed interaction is only, or even predominantly, due to the presence of absorbed water. Even when the quartz crystals coated with THEED were kept for several days at 44°C with a constant flow of N45 impinging on the coated face, the magnitude of the signals obtained after CO_2 injection showed only a slight decrease in comparison with those obtained at room temperature, already expected in exothermic processes governed by adsorption.

NMR and IR spectroscopy experiments

Figure 4 shows the NMR spectra of THEED after bubbling in N_2 (*a*), and CO_2 (*b*). The acquisition time for the spectrum in Fig. 4*b* was longer (1 night) than the acquisition time for the spectrum in Fig. 4*a* (2 h) due to a lower signal-to-noise ratio caused by the increased viscosity of the sample after CO_2 bubbling. In Fig. 4*b* we can observe a signal at 163.877 ppm that does not appear in Fig. 4*a*. This signal cannot be assigned to gaseous CO_2 (15, 16), but the possibility of the signal being due to HCO_3^- cannot be excluded (15, 16). On the other hand, the presence of H_2CO_3 is out of the question, as the signal of H_2CO_3 as reported in the literature would appear at 153 ppm (16). This signal can also be due to alkyl carbonate formation (17).

Figure 5 shows the infrared spectra of a THEED sample recorded in a sequence of different experiments, and Fig. 6 a detail of the same spectra in the range from 1000 to 1800 cm^{-1}. After the spectrum of the THEED sample in contact with the atmosphere was recorded, a flow of CO_2 through the cell was maintained for 5 min, after which a new spectrum was acquired. A third spectrum was acquired after 120 min of constant nitrogen flow through the infrared cell.

A few changes induced by CO_2 can be observed by comparing the spectra. The presence of gaseous CO_2 is easily recognised by the two signals at 2340 and 2362 cm^{-1}. A signal due to HCO_3^- would have appeared at 1360 ± 3 cm^{-1}; however, no significant change is observed in this region. This is evidence that formation of HCO_3^- from absorbed water does not occur to a significant extent.

The wide absorption band near 3300 cm^{-1}, from the OH stretching vibration, shows considerable broadening, downward frequency shift, and intensification with CO_2, which is characteristic of hydrogen bonding (18).

The two intense bands at 1069 and 1040 cm^{-1} can be attributed to C–N vibration (doublet for tertiary amines) (19), and the band at 1040 cm^{-1} to C–O stretching and O–H deformation, characteristic of primary alcohols (18). The decrease in the intensity of the band at 1040 cm^{-1} with CO_2 introduction can be interpreted as evidence of the involvement of the OH group in the interaction with CO_2.

Near 1300 cm^{-1} an absorption band that can be attributed to C–O stretching (20), and also to C–N vibration, increases with CO_2 introduction. This increase is consistent with alkyl carbonate formation.

Two bands at 1643 and 1574 cm^{-1}, which are almost nonexistent in the absence of CO_2, show a marked increase with its introduction. The band at 1643 cm^{-1} can be attributed to carbonyl group stretching, shifted to lower frequencies because of random formation of hydrogen bonds with the neighbouring molecules; if we assume that the compound also exists as the β-ammonium carboxylate zwitterion, the band at 1574 cm^{-1} can be assigned as the antisymmetrical stretching vibration.

The appearance of both the ionized and non-ionized carboxyl absorptions in the infrared spectra is not common, but has been reported before for noncrystalline aminoacids (18).

Zwitterionic forms also appear for EDTA (ethylenediaminetetraacetic acid) and related compounds in aqueous solution as their α-ammonium carboxylates, with carboxylate antisymmetrical stretching frequencies in the range 1630–1620 cm^{-1} (21). This shift is due to the inductive effect of the positive charge in the α quaternary nitrogen, and would not be expected to occur to the same extent for the β-ammonium carboxylates.

The data recorded in the literature for alkyl carbonates report carbonyl group absorptions from 1787 cm^{-1} up to 1819 cm^{-1}. Although these are not observed in our experiments, this does not exclude the formation of an alkyl carbonate type compound with the neutral carbonic acid in equilibrium with its zwitterion.

The spectrum obtained after the N_2 flow confirms the reversibility of the interaction between THEED and CO_2, already demonstrated by the quartz crystal microbalance experiments, although reversibility was not complete in 120 min.

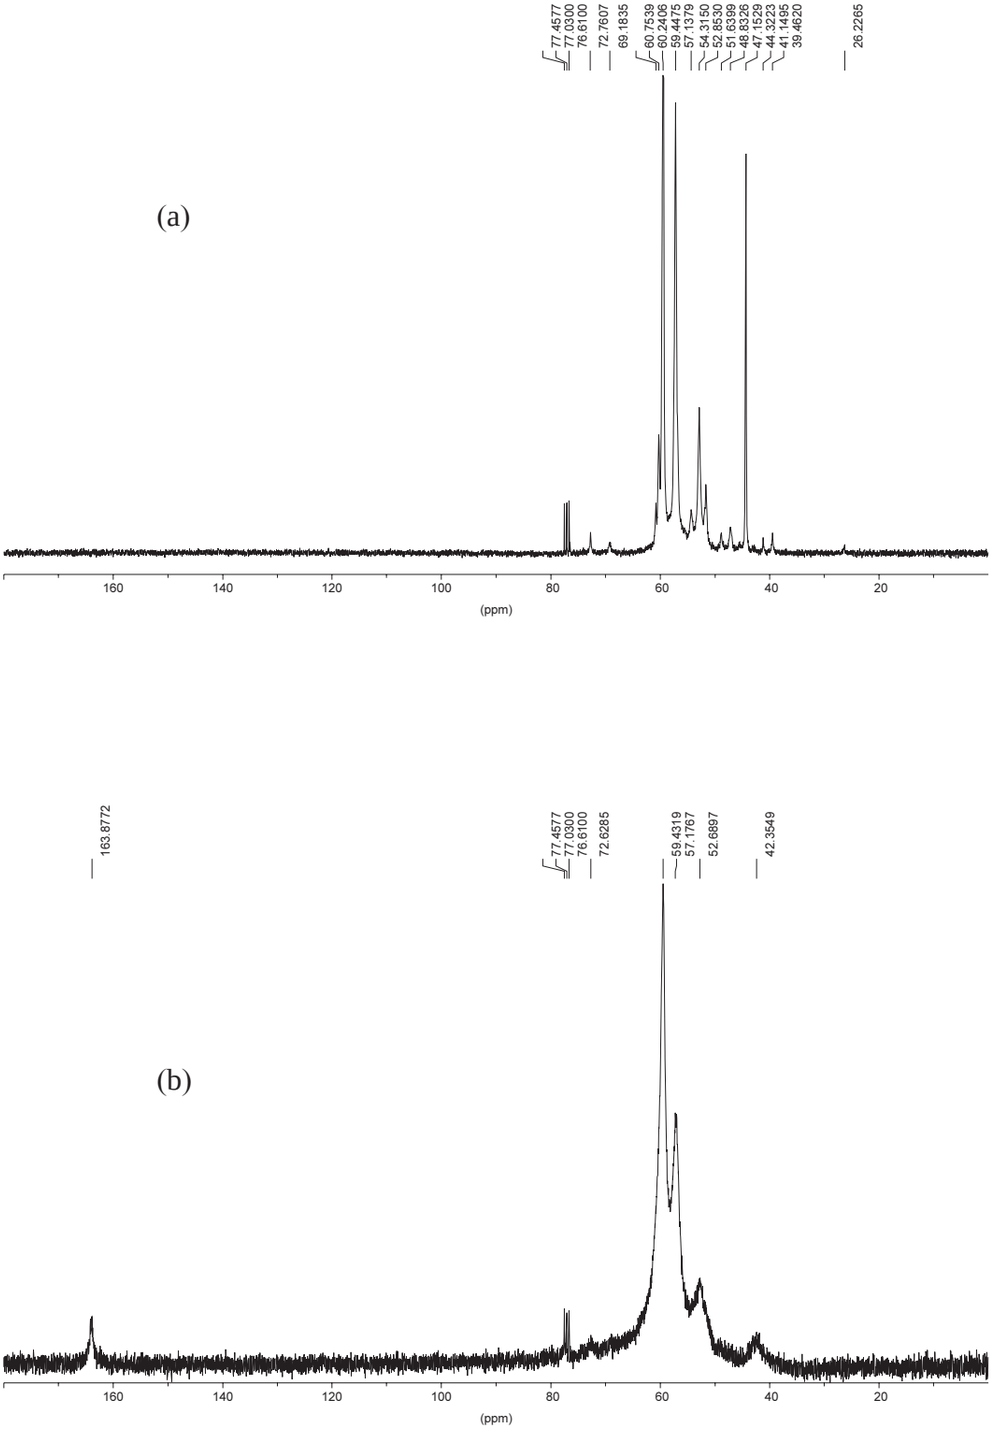
Fig. 4. ^{13}C NMR spectra of THEED (*a*) after bubbling in N_2; (*b*) after bubbling in CO_2.



Mass spectrometry experiments

Figure 7 shows the positive ion FAB mass spectrum of THEED after CO_2 was bubbled in. The protonated THEED molecule, $[M + H]^+$, of *m/z* 237, is the third most abundant ion in the spectrum. The base peak is the ion of *m/z* 132 and the second most abundant ion is that of *m/z* 118. The spectrum also shows two ions of *m/z* 281 and of *m/z* 325, with masses, respectively, 44 and 88 Da higher than the mass of the protonated molecule of THEED, the last ion having a low relative abundance.

In the FAB mass spectrum of TEA, obtained after CO_2 was bubbled in, and using the same experimental conditions, no ions with masses 44 and 88 Da higher than the mass of the protonated molecule are observed. The positive ion mass

© 1999 NRC Canada

Fig. 5. Infrared spectra of THEED in different environments.

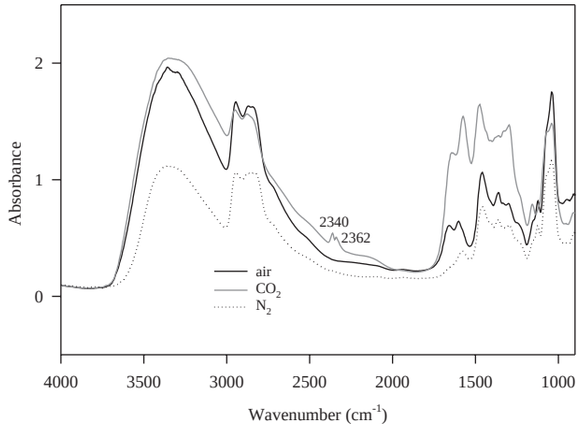


Fig. 6. Detail of the spectrum of Fig. 5 in the frequency range from 1000 to 1800 cm^{-1}.

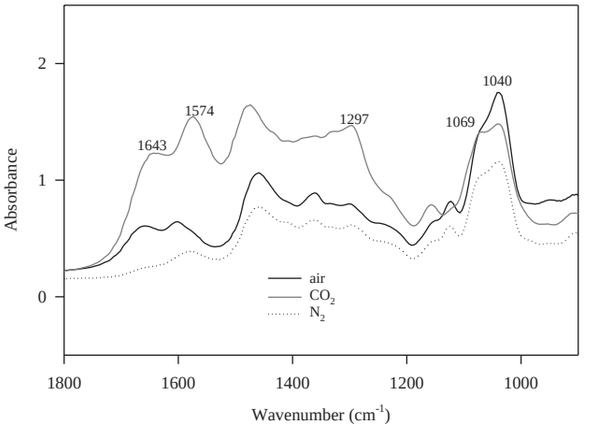
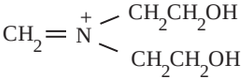
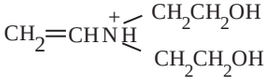


spectrum of TEA shows the protonated molecule $[M + H]^+$, of *m/z* 150, which is the base peak, and the other three most abundant ions are the $[M - H]^+$ ion, of *m/z* 148, and ions of *m/z* 132 and of *m/z* 118.

The collisionally activated MS/MS spectra of the ions of *m/z* 118 formed from both TEA and THEED are identical, and the same occurs for the collisionally activated MS/MS spectra of the ions of *m/z* 132. Based on these data we propose the following structures for these ions:

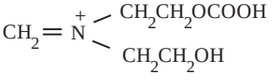


118

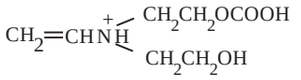


132

The collisionally activated MS/MS spectra of the ions of *m/z* 281, $[M + H + 44]^+$, and of *m/z* 325, $[M + H + 88]^+$, from THEED, both show abundant product ions of *m/z* 162 and of *m/z* 176. These data and the data from the collisionally activated MS/MS spectra of the ions of *m/z* 162 and of *m/z* 176, allow us to propose the following structures for the ions:



162



176

The proposed structures are consistent with the hypothesis of alkyl carbonate formation, and are the carbonated homologues of the structures proposed above for the ions of *m/z* 118 and of *m/z* 132.

The collisionally activated MS/MS spectrum of the ion of *m/z* 325 also shows other two product ions of *m/z* 206 and of *m/z* 220, with lower relative abundances, and with masses 44 Da higher than those of the ions of *m/z* 162 and of *m/z* 176, respectively. These other two product ions, of *m/z* 206 and of *m/z* 220, can be explained by the reaction of a second OH group with CO_2, with formation of a second alkyl carbonate group. If we compare the relative abundances of the ions of *m/z* 281 and of *m/z* 325 in Fig. 7, the second alkyl carbonate group is formed to a much smaller extent than the first alkyl carbonate group.

Figure 8 shows the spectra obtained by subtracting the negative ion FAB spectra of THEED, acquired without bubbling CO_2, from the spectra acquired after CO_2 was bubbled. The changes due to CO_2 are shown in this spectrum and the most important change is the formation of the ion of *m/z* 103, which was absent in the negative ion mass spectrum of THEED before CO_2 was bubbled in. The ion of *m/z* 339, also absent in the negative ion mass spectrum of THEED before CO_2 was introduced, can be observed, although with much lower relative abundance than the ion of *m/z* 103. An increase in the relative abundances of the ions of *m/z* 147 and *m/z* 191 is also observed.

The precursor ion spectrum of the ion of *m/z* 103 shows that this ion is formed by fragmentation of the ions of *m/z* 147 and of *m/z* 339. The ion of *m/z* 339 is probably the proton-bound dimer of the ions of *m/z* 103 and $[M - H]^-$ (of *m/z* 235). The precursor ion spectrum of the ion of *m/z* 147 shows that its main precursor ion is the ion of *m/z* 191.

The fragmentation of the $[M - H]^-$ ion of THEED, of *m/z* 235, can be rationalized by successive elimination of CH_2CH_2O, with hydrogen migration to the nitrogen atoms. On the basis of these data and the data obtained from the precursor ion spectra, we propose for the ions of *m/z* 191 and *m/z* 147 the following structures:

$H_2NCH_2CH_2N(CH_2CH_2OH)CH_2CH_2OCOO^-$

m/z 191

$H_2NCH_2CH_2NHCH_2CH_2OCOO^-$

m/z 147

The structure of the ion of *m/z* 103 is not obvious, although one possibility is the distonic ion $H_2NCH_2\dot{C}HOCOO^-$.

From analysis of the data from the negative ion spectra it is clear that a reaction between THEED and CO_2 occurs. The data are not inconsistent with alkyl carbonate formation, notwithstanding the fact that the ions, with masses 44 and 88 Da higher than the mass of the $[M - H]^-$ ion, are not observed in the negative ion spectra. The reason is perhaps a

Fig. 7. FAB positive ion mass spectrum of THEED after CO_2 interaction.

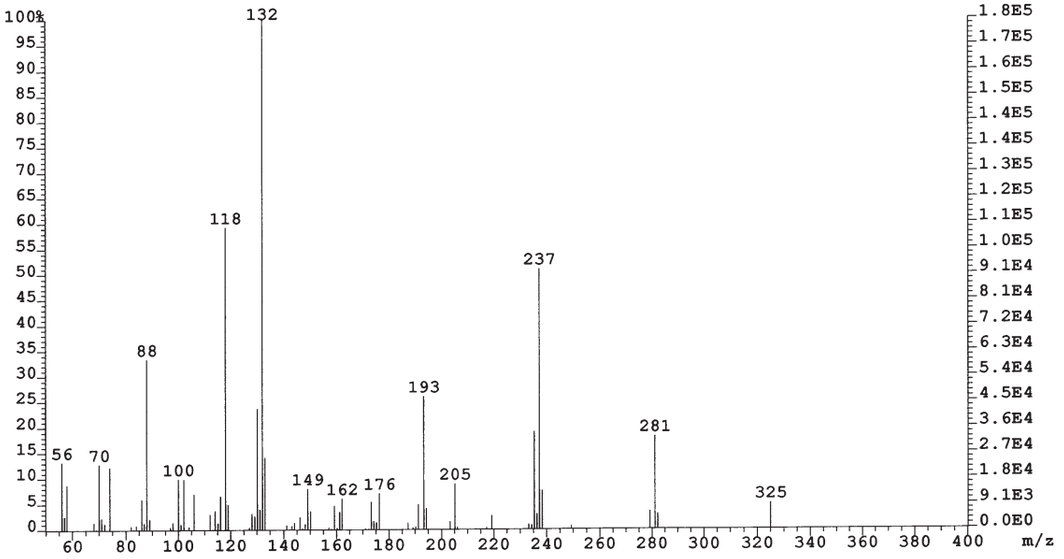

Fig. 8. Spectrum obtained by subtracting the FAB negative ion mass spectrum of THEED before CO_2 interaction from the FAB negative ion mass spectrum of THEED after CO_2 interaction.

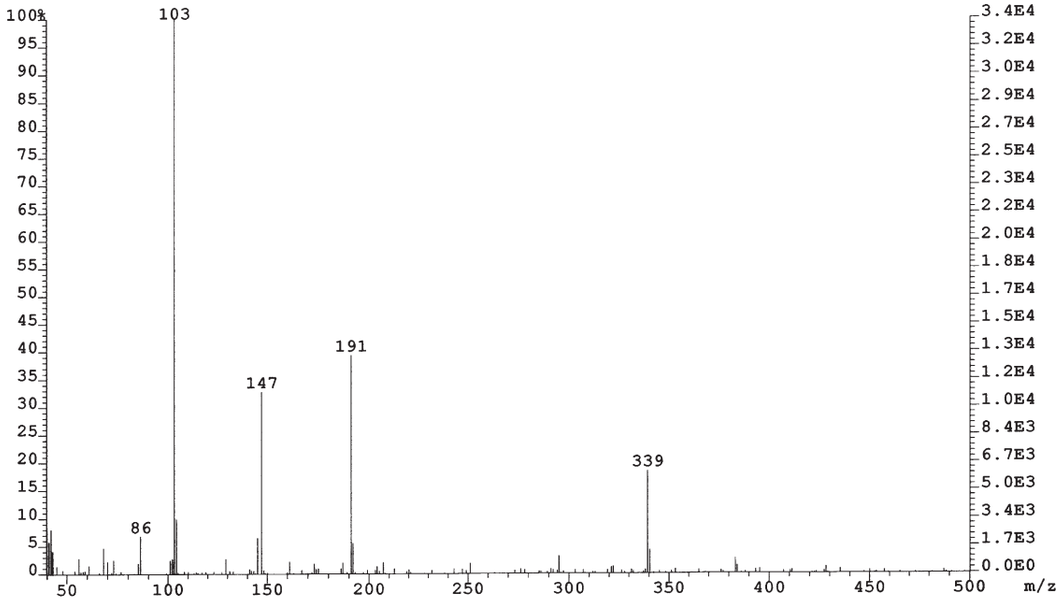


more extensive fragmentation in the negative mode, occurring mainly by successive elimination of CH_2CH_2O.

To test whether the ions observed were the result of FAB-induced "delayed chemistry" (22), we plotted the total ionic current and the currents of the ions of *m*/*z* 103 and *m*/*z* 339, formed after CO_2 absorption, vs. the elapsed time (Fig. 9). The ionic currents are approximately constant for the duration of the experiment (94 s), showing that the ions are not the result of a delayed chemistry process. They may exist as preformed ions in the condensed phase or they are formed in the selvedge in a "prompt chemistry process." Either way, they are much more closely related to their counterparts in the condensed phase than would be the case if they were the result of a FAB-induced delayed reaction.

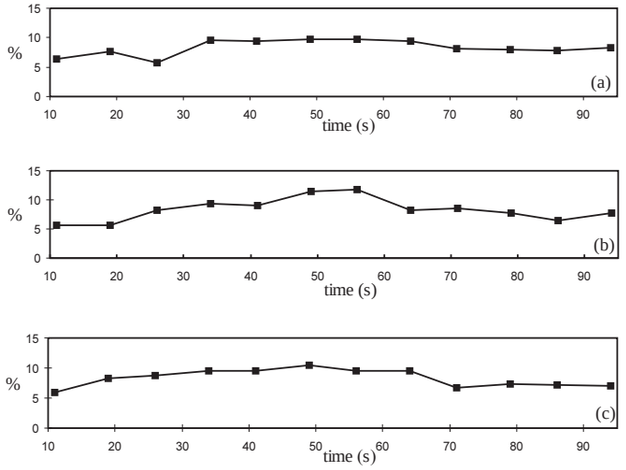
The FAB mass spectrum of Quadrol, obtained without bubbling in of CO_2, has a very low signal-to-noise ratio, and no significant information could be retrieved from it. No spectrum could be obtained after introducing CO_2, because the signal-to-noise ratio is even lower.

Conclusions

THEED in the absence of water interacts reversibly, and to a great extent, with CO_2. Alkyl carbonate formation is a

© 1999 NRC Canada

Fig. 9. Ionic current: (*a*) total ion current; (*b*) current of the ion *m*/*z* 339; (*c*) current of the ion *m*/*z* 103.



hypothesis that agrees with the results obtained. The other two tertiary alkanolamines TEA and Quadrol interact to such a small extent with CO_2 that for TEA no evidence of the interaction was found by using mass spectrometry, and for Quadrol practically no mass increase with CO_2 injections was detected. Quadrol has a high viscosity, which makes the bubbling of CO_2 difficult. Also the FAB mass spectrum of Quadrol has a very low signal-to-noise ratio, and no reliable information could be obtained from it.

An effective balance between physical and chemical parameters is perhaps the explanation for the highest sensitivity of THEED. Quadrol is the most viscous of the three alkanolamines, so the diffusivity of CO_2 is low. The highest diffusivity in TEA is probably overcome by the lesser availability of its OH groups, because TEA possess more intramolecular hydrogen bonding than THEED.

The ranking of the three alkanolamines in relation to the extent of their interaction with CO_2 was inferred from QCM experiments. However, we have to bear in mind that the QCM responds not only to mass change but also to changes in viscosity. This is not a problem when the interaction of CO_2 with a single alkanolamine is used, because it increases the sensitivity to the changes, but it can influence comparison of results obtained with different alkanolamines.

One should also note the differences in molecular organization depending upon whether the experiments were carried out with the QCM or with the spectrometers. In the first case the reaction took place at the surface, while in the second it occurred in the bulk of the alkanolamine.

Abstract: Acid leaching (with 1 mol dm^{-3} HNO_3) was combined with slurry nebulization in inductively coupled plasma mass spectrometry, with mixed-gas plasmas and flow injection, in an attempt to facilitate the quantitative analysis of heterogeneous materials such as soils. Matrices analyzed ranged from marine sediment to metal-contaminated soil, and were chosen for their variety in elemental composition and matrix structure. Slurries were prepared by first grinding the material to less than 3 μm in high-purity water and then diluting to 0.1% (w/v) with 1 mol dm^{-3} HNO_3, which served as both a dispersing and a leaching agent. The resulting slurries were injected (0.25 cm^3) into a deionized distilled water carrier. Under these conditions, the sensitivity was about 85% of that achieved by continuous nebulization. Multivariate optimization of the nitrogen percentage, forward torch power, and aerosol carrier gas flow rate was conducted to find conditions maintaining sensitivity constant between different slurries. Since no set of conditions was optimal for all elements, a compromise set was selected, which resulted in accurate results for La and Pb in a series of reference materials, by calibrating with aqueous standards. On the other hand, the results for V and Cr were almost systematically low, indicating that the compromise plasma conditions did not allow complete atomization/ionization of these elements.

Key words: inductively coupled plasma mass spectrometry, slurry nebulization, flow injection, mixed-gas plasma.

Résumé : Un lessivage acide (par HNO_3 1 mol dm^{-3}) fut combiné à la nébulisation de suspension, les plasmas mixtes et la technique d'injection en flot continu dans le but de façiliter l'analyse quantitative de matériaux hétérogènes, tels que des sols, par la spectrométrie de masse à plasma couplé inductivement. Les matrices analysées vont des sédiments marins aux sols contaminés par des métaux; elles furent choisies pour leur variété en composition élémentaire et en structure. Des suspensions furent préparées en broyant d'abord chaque matériau jusqu'à moins de 3 μm dans de l'eau de haute pureté, et en diluant ensuite jusqu'à 0.1% (m/v) avec HNO_3 1 mol dm^{-3} qui servit d'agent de dispersion et de dissolution. Les suspensions résultantes furent injectées (0.25 cm^3) dans un flot d'eau distillée déionisée. Dans ces conditions, la sensibilité était environ 85% de celle obtenue par nébulisation continue. Une optimisation multifactorielle du pourcentage d'azote, de la puissance appliquée et du débit du gaz de nébulisation fut conduite afin de déterminer des conditions maintenant la sensibilité constante pour diverses suspensions. Comme aucun ensemble de conditions ne s'est révélé optimal pour tous les éléments, un ensemble compromis fut selectionné et donna des résultats exacts pour La et Pb dans une série de matériaux de référence, par étalonnage avec des solutions étalons. D'un autre côté, les résultats pour V et Cr furent presque systématiquement bas, ce qui indique que les conditions compromises du plasma n'ont pas permis une atomisation/ionisation complète de ces éléments.

Mots clés : spectrométrie de masse à plasma couplé inductivement, nébulisation de suspension, injection en flot continu, plasmas mixtes.

Introduction

Inductively coupled plasma mass spectrometry (ICP-MS) is a method with low detection limits, a wide linear dynamic range, and high sample throughput (1). However, the accuracy of results obtained using solutions of rocks or minerals depends on the dissolution method, which can cause loss of volatile analytes (2). Incomplete transfer of elements to solution is also possible for mineral phases that are highly resistant to acid attack, such as chromium or vanadium oxides (2).

Although ICP-MS was originally designed to analyze solutions, analysis of other matrices is possible, as long as the

Resolution (at 10% peak height)	1.1

[a] Optimum conditions for the analysis of slurries.

sample can be introduced into the gas flow (3). In particular, slurry analysis is similar enough to solution analysis that conventional instruments can be used with little modification and calibration may be accomplished with aqueous standards (4). The approach was recently thoroughly reviewed by Ebdon et al. (4).

Slurry preparation, which can be as simple as the "bottle-and-bead" approach of Williams et al. (5), has the advantage of involving few chemicals. In comparison to total dissolution approaches, sample preparation is simplified, so slurry nebulization can be used to avoid analyte loss, contamination, incomplete dissolution, and the hazardous use of $HClO_4$ and (or) HF (6).

ICP-MS analysis of some slurry-nebulized reference soils was carried out previously using continuous nebulization (5) and flow injection (FI) (7). No sampler cone blockage occurred during the continuous nebulization of 0.05% w/v slurries of soil with particle sizes of <3 μm (5). Of the six trace elements determined using an external calibration with aqueous standards, the results for V, Cr, and Ni were in agreement with the certified values whereas those for Cu, Co, and Zn were higher than expected.

Flow injection (7) allowed the analysis of 1% w/v slurries, which would have resulted in blockage after about 30 min of continuous nebulization (5). Furthermore, under appropriate conditions, 0.5 cm^3 injections provided the same signal as for continuous nebulization of the same solutions, while reducing sample consumption and eliminating blockage problems (7). Under these conditions, accurate analysis of two reference soil slurries could be achieved, using a conventional calibration with standard solutions (7). However, only two trace elements, V and Cu, were determined.

For a calibration using standard solutions to be successful for the analysis of slurries, several parameters have to be considered (4). Amongst the most important are the particle size, the dispersion, i.e., colloidal stability of the slurry, and the ICP system (i.e., nebulizer, spray chamber, and torch injector), which determine the particle size that will ultimately reach the plasma (4). Ideally, to minimize transport interferences, a single particle should be present within each aerosol droplet, and the size of that particle should be such that the overall density of the droplet is not significantly different from that of a particle-free droplet (8). Under these conditions, the slurry aerosol would behave like a solution aerosol in the sample introduction system.

Because of the heterogeneous nature of soils and the varying density of the particles, segregation of different analyte-containing phases may occur during aerosol transport to the plasma. The smallest possible solid particle size is therefore recommended, to minimize variations in densities amongst the resulting aerosol droplets (8). One way to reduce particle size further from that achieved by grinding is to perform a leaching of the slurry with an acid. This approach was recently used for the quantitative determination of As in cigarette tobaccos by hydride generation atomic absorption spectrometry (9).

It is combined here to ICP-MS with FI for sample introduction of the slurries into a mixed-gas plasma. The latter has indeed been demonstrated to reduce atomization interferences during the ICP-AES (atomic emission spectroscopy) analysis of highly refractory firebrick particles (10). The intent of this paper is therefore to minimize transport effects by using FI of acid-leached slurries and to minimize atomization interferences with the mixed-gas plasma so as to provide a fast, reliable ICP-MS method for trace-element determination in soils by calibration using standard aqueous solutions.

Experimental

Reagents

Multielemental standard solutions were prepared by dilution of 1000 ± 5 mg dm^{-3} monoelemental stock solutions (Spex Industries, Edison, N.J.) with high-purity nitric acid (Seastar, Sidney, B.C.) and deionized distilled water (DDW) (Milli-Q+, Millipore, Mississauga, Ont.).

Standard reference materials (SRMs)

A variety of SRMs were used: soils GSS-1, -2, -4, and -7 from the Institute of Geophysical and Geochemical Prospection (IGGE), Ministry of Geology, and the Institute of Rock and Mineral Analysis (IRMA) in China; soils SRM-2710 and -2711 from the U.S. National Institute of Standards and Technology (NIST); marine sediment PACS-1 from the National Research Council of Canada (NRC). Two rock SRMs were also included in the study: basalt SRM-688 from NIST and syenite SY-2 from the Canadian Certified Reference Materials Project (CCRMP) of the Canada Centre for Mineral and Energy Technology (CANMET).

Slurry preparation

The bottle-and-bead method (5), with 30 cm^3 stoppered polypropylene bottles and 1.4–3.35 mm (in diameter) zirconia beads (Geneq Inc., Montréal, Que.), was used for slurry preparation. The bottles and zirconia beads were rinsed with 1 mol dm^{-3} HNO_3, before 0.25 g soil, 5 g zirconia beads, and 10 cm^3 DDW were placed in each bottle. Shaking was accomplished with a wrist action shaker for 24 h. The slurries were recovered into 250 cm^{-3} volumetric flasks that were filled to volume with 1 mol dm^{-3} HNO_3. The beads

[a]No expected concentration was available.

were removed by decanting the slurry and rinsing the bottle at least 3 times, with each rinse also decanted into the volumetric flask. The slurries were then transferred to polypropylene bottles. An ultrasonic bath was employed to keep the slurries dispersed during ICP-MS analysis. Controls were prepared by following exactly the same procedure without soil.

Acids other than HNO_3 were not tried, since most would contribute additional peaks to the background spectrum and thereby result in spectroscopic interferences on many trace elements determined. More concentrated HNO_3 solutions than 2 mol dm^{-3} were also avoided since they would not only increase corrosion of the MS interface, but would also increase sample preparation cost.

Some slurries were centrifuged at 10 000 G (Beckman induction drive centrifuge, model J2–21M, used with Beckman Rotor JA-14, Spinco Division of Beckman Instruments Inc., Palo Alto, Calif.) for 1 h and decanted for supernatant analysis to determine the efficiency of the acid leaching.

Equipment

An ELAN 500 ICP-MS instrument (Perkin–Elmer SCIEX, Thornhill, Ont.) was used, with several modifications. A homemade x–y–z translation stage under the torch box allowed precise alignment of the plasma with respect to the interface. A low-flow PlasmaTherm (SCP Science, Montreal, Que.) torch was used instead of the standard ICP-MS one. The standard Meinhard C-3 concentric nebulizer (which is connected to a Scott double-pass spray chamber) was replaced by a Conespray nebulizer (Perkin–Elmer, Norwalk, Conn.). A mass flow controller (model 1259B, MKS Instruments, Andover, Mass.) regulated the aerosol carrier gas flow rate. A specified N_2 percentage was added to the outer plasma gas using a gas proportioner (model 7371, Matheson of Canada Ltd., Whitby, Ont.). A peristaltic pump (Minipuls 3, Gilson Medical Electronics Inc., Middleton, Wis.) kept the sample uptake or carrier flow rate constant at 3 cm^3 min^{-1}.

Flow injection setup

A single-line FI manifold was used, which consisted of a valve (model 5020, Rheodyne Inc., Cotati, Calif.) installed on an automatic switching module (Universal module, Anachem, Luton, U.K.) downstream of the peristaltic pump. The sample injection valve was connected to the nebulizer with 1 m of 0.8 mm i.d. Teflon tubing, similarly to the earlier FI study (7). The sample injection loop was filled by suction into a syringe directly from the sample bottle, to prevent contaminations incurred by syringe injection. The

© 1999 NRC Canada

input line to the FI loop was cleaned by flushing with 1 mol dm^{-3} HNO_3 between injections to minimize memory effects. All FI-ICP-MS operating conditions are summarized in Table 1.

Initial optimization

An Ar plasma was ignited at 1.2 kW with 9 dm^3 min^{-1} outer gas flow rate, which was then increased to either 12 dm^3 min^{-1} or 15 dm^3 min^{-1} upon ignition. The highest flow rate was used whenever power was increased and (or) a mixed-gas plasma was formed, to avoid torch melting. A 100 μg dm^{-3} standard solution of Li^+, Rh^+, and Pb^+ in 1% v/v HNO_3 was aspirated while manual triaxial plasma–MS interface alignment was conducted to optimize the Rh^+ signal. The voltages to the ion lenses were then adjusted, if needed, to equalize the Li^+ and Pb^+ signals. Then, the aerosol carrier gas flow rate was adjusted to maximize all three ion signals. This resulted in the best compromise conditions for multielemental analysis of supernatant solutions.

For the analysis of slurries, the optimization was performed similarly, except that the optimal aerosol carrier gas flow rate was determined by repeated injection of a slurry at various aerosol carrier gas flow rates. The flow rate giving maximum transient peak height for most analytes was selected.

Mixed-gas plasma formation

Nitrogen was slowly added to the outer gas stream of an already ignited Ar plasma, until the desired N_2 percentage was reached. Care was required to prevent plasma extinction as a result of the sudden plasma shrinkage that occurred when N_2 was initially added. Reflected power was kept lower than 15 W by manual fine tuning.

Experimental design

The percentage of N_2 in the outer plasma gas (5, 10, or 15%), forward power (1.2, 1.3, or 1.4 kW), and nebulizer gas flow rate (0.800, 0.900, or 1.00 dm^3 min^{-1}) were optimized together, because they were critically interdependent. Three values were considered sufficient to detail the effects of each parameter, with the addition of a 1.2 kW Ar-only plasma as a reference. To minimize instrumental drift, conditions were randomly selected from the 36 possible parameter combinations until all had been tested, while maintaining the optimum conditions previously determined for other experimental parameters (see Table 1). The study was carried out for each of three SRMs (GSS-7, PACS–1, and NIST-2710). For each set of conditions, the relative standard deviation (RSD) of the average sensitivity obtained for the three slurries was calculated for each element.

Data acquisition and processing

The "Graphics" program of the Elan 5000 multielement data acquisition software, Version 2, was used in the "Measurement" scanning mode, with 50 ms dwell time, 1 sweep per reading, and 1 measurement per peak (at the assumed peak centre).

In-house DOS GWBASIC programs were used to process the FI peaks. Polynomial smoothing was first performed with a seven-point moving window. Background-subtracted peak height was then determined (using the background on both sides of the peak to linearly interpolate that corresponding to the peak maximum).

The analysis of soil slurries was carried out by injecting a solution blank followed by the corresponding standard solution, a control, and then the slurries. Each blank or control count rate was then subtracted from the corresponding solution or slurry count rates.

Given the wide linear dynamic range of ICP-MS, sensitivity was determined for soil SRM slurries, using a one-point calibration. All sensitivity comparisons were carried out during the same day to minimize instrumental drift and changes in sensitivity associated with regular instrumental maintenance (i.e., change or cleaning of torch, sampler, skimmer, etc.). Detection limits (expressed with respect to the undiluted solid) were calculated as three standard deviations of the control count rate divided by the sensitivity.

Results and discussion

Slurry preparation

The grinding time was selected by examining backscattered electron images of ground samples and comparing them to that of a reference grid. Samples of sandy soil, but not of other soils, were ground down to 3 μm in 2 h. However, after 24 h of grinding, no samples (including peat- and clay-rich samples) had particles larger than 3 μm. Increasing the grinding time to 48 h had no significant effect on either the particle size or the signal obtained from the slurry. Thus, 24 h (overnight) was used for the remainder of the work.

Although the addition of acid to the dispersing agent during the grinding of geochemical materials has been reported to significantly improve analyte recoveries (11, 12) or reduce the size of some especially difficult mineral phases (13), this approach was not selected here. Only DDW was used during grinding, with acid added afterward, to minimize background metal levels originating from the grinding beads (13). The relatively low signal obtained for a control compared to an uncontaminated soil SRM (GSS-1) in Fig. 1 shows that this procedure was adequate.

Nitric acid was used to leach out metals and to, possibly, further reduce the particle size through partial dissolution (although the particle size after leaching was not actually measured in this study). Table 2 shows that 1 mol dm^{-3} HNO_3 leached metals out of soils and sediments. Since 2 mol dm^{-3} HNO_3 did so to a similar extent, all slurries were made up in 1 mol dm^{-3} HNO_3 thereafter. This medium also provided the best compromise in terms of precision (i.e., RSD of seven injections), detection limit, sensitivity, and sensitivity equality between different slurries. This is in agreement with the literature since, at the corresponding slurry pH of approximately 1.5, the zeta potential is expected to be far away from the isoelectric point (i.e., the stability of the suspension is ensured through an electrostatic stabilizing mechanism (14)). The best signal-to-noise ratio in ICP–AES and stability (i.e., no aggregation or flocculation) were similarly obtained for an alumina slurry by adjusting the pH away from the isoelectric point, without using any other dispersant (15).

The leaching efficiency was also checked as a function of time. However, supernatants of slurries that were allowed to settle for 2 months showed essentially the same concentra-

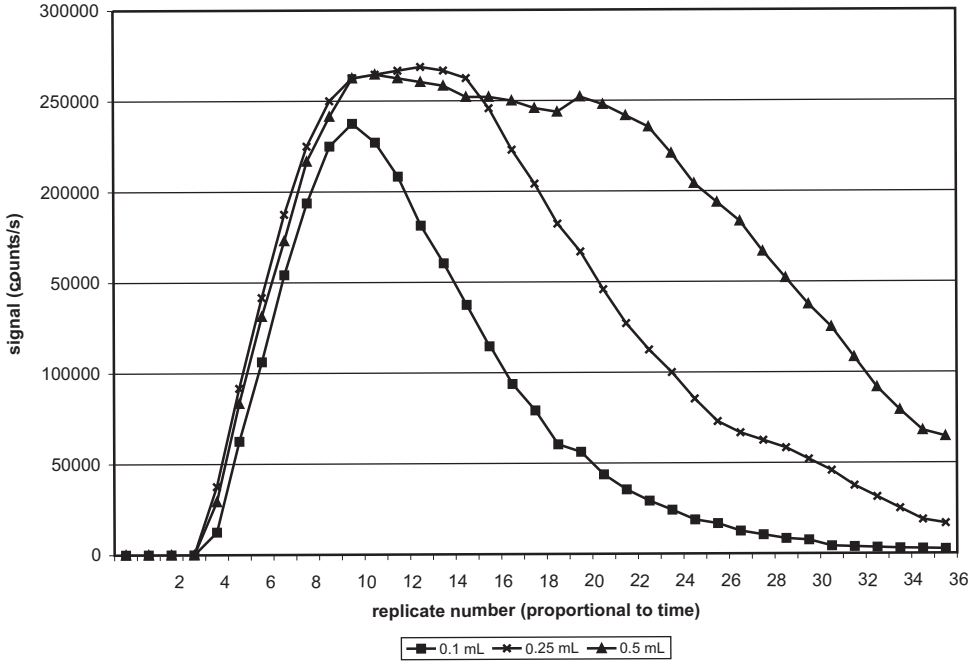
Fig. 2. Examples of typical flow injection peaks that were obtained with sample injection volumes of 0.1 (■), 0.25 (▲), and 0.5 (×) cm^3. Here Zn was monitored during injections of a slurry of NIST-2710.



tion of metals as those of slurries that were immediately centrifuged. Very little signal was detectable in supernatant for some elements (e.g., V) due to the inability of these concentrations of HNO_3 to attack the silicates or relatively insoluble oxides in which they are found, while other elements are partially or fully leached. (The greater than 100% recoveries observed in some cases were the result of spectroscopic interferences, as discussed in greater detail below.)

Slurry flow injection

No blockage of either the sampler cone or the Conespray nebulizer was ever observed. However, despite the continuous rinsing by the DDW carrier, the first control injection immediately after a slurry sample injection was typically elevated in metal concentration, and was visually rejected in favour of an extra control injection.

Nonetheless, as shown in Fig. 2, a typical transient FI peak was observed upon injection of a 0.1 cm^3 (or 0.05 cm^3) aliquot of slurry. Larger volumes (0.25 and 0.5 cm^3) led to a wider transient signal, with a tendency to level into a plateau at its top. The plateau is particularly evident with 0.5 cm^3 injections, and was close to the signal that would be obtained if the slurry was continuously nebulized. Since, ideally, maximum sensitivity (i.e., that of continuous nebulization) is desired with the regular wash-out feature of flow injection, a 0.25 cm^3 loop was selected and used for the remainder of this work. It provided a dispersion coefficient (defined as the ratio of the steady-state signal from continuous nebulization over the height of the FI peak) of about 1.2 (as opposed to 1.7 for the 0.1 cm^3 loop), i.e., only a small sacrifice in sensitivity.

Wash-out time and peak reproducibility were the deciding factors when the DDW carrier flow rate was determined. Flow rates from 1 to 3 cm^3 min^{-1} resulted in similar signal intensity. (Even higher carrier flow rates were possible, but would have resulted in erratic nebulization since the nebulizer was designed to operate with 2–3 cm^3 min^{-1} sample uptake. Although a nebulizer can be starved, to an extent, by decreasing the sample uptake rate from its optimal value without a major sacrifice in sensitivity (16), it cannot be flooded.) However, 3 cm^3 min^{-1} gave more reproducible peaks than 2 cm^3 min^{-1}, and also provided faster wash-out times. It was therefore selected for the remainder of this study.

Table 3. Operating conditions resulting in the lowest relative standard deviation (RSD) in sensitivity between three slurries (or the next-to-lowest, in parentheses).

$\%N_2$	Rf power /kW	Aerosol carrier gas flow /cm^3 min^{-1}	Analytes
15	1.4	900	V, Cu, Zn, (Pb), (Mo)
0	1.2	800	Mo, Cr, Co
5	1.3	800	La, Co, (Ni)

Injection peak signals using 0.25 cm^3 sample loop volume, 3 cm^3 min^{-1} carrier flow rate, 900 cm^3 min^{-1} nebulizer gas flow rate, and an Ar-only plasma, showed that peak shape, width at half height, and the dispersion coefficient were very similar for solutions and soil slurries. This is in agreement with the dispersion behaviour reported for solid particles injected in a straight tube where, at a sufficiently high flow rate for the solid particle size, the soil slurry behaved like a solution (17). It further encouraged an attempt to calibrate soil slurries with aqueous solution standards.

Mixed-gas plasmas

Co-optimization of the percentage of N_2, the forward power, and the aerosol carrier gas flow rate, which was carried out

[b]Errors on certified values for the GSS series are 15% relative uncertainties (20% for Mo).

to minimize the difference in sensitivities between 3 SRMs (PACS-1, GSS-7, and NIST-2710), did not result in a single set of optimal conditions for all the elements tested (V, Pb, Mo, La, Cr, Ni, Co, Cu, Zn). Factorial analysis was also unsuccessful (i.e., no suitable model could be found to fit the data). Table 3 shows three different sets of conditions that resulted in the least variation in sensitivity (or the next-to-least, in parentheses) for the various elements tested in the three slurries.

Analysis of SRMs

Compromise conditions were therefore required for multielemental analysis. The set of conditions providing the lowest average RSD for all the elements was selected: 15% N_2, 1.2 MW of torch power, with 800 cm^3 min^{-1} of aerosol carrier gas flow rate. Nine slurries were analyzed under these conditions, using an aqueous standard solution for external calibration. The results are summarized in Tables 4–6. In each case, averages that fall within the confidence limits of the corresponding certified value are highlighted in bold.

No accurate determination of Co, Ni, or Cu could be carried out using $^{59}Co^+$, $^{60}Ni^+$, and $^{63}Cu^+$ because of spectroscopic interferences from polyatomic species ($^{43}Ca^{16}O^+$ on $^{59}Co^+$, $^{44}Ca^{16}O^+$ on $^{60}Ni^+$, and $^{40}Ar^{23}Na^+$ on $^{63}Cu^+$) arising from the matrix. In fact, since Co is monoisotopic and all of the Ni isotopes are interfered with by CaO and (or) CaOH, the determination of these elements is precluded in Ca-containing matrices unless the Ca is removed. In the case of Cu, it may be possible to use $^{65}Cu^+$, with a concurrent sacrifice in sensitivity.

Table 4 shows that Pb and La may be accurately determined by this method. The results are particularly impressive for La where all the concentrations fall within the confidence interval of the certified values. Using five control replicates, detection limits in the solid of 7.1 μg g^{-1} for Pb and 2.7 μg g^{-1} for La were calculated. Calibration by a SRM (GSS-1) chosen for its uncontaminated, intermediate metal concentrations was also tried but was less accurate than calibration by aqueous standard for both Pb and La. This is not surprising since it is very likely that, for heterogeneous slurries, "elements will not be distributed uniformly and the particle size distributions and densities of elements within the sample may not be comparable to those for the slurry being analysed" (4).

In the case of Zn (Table 5), a positive bias was observed in most cases, as is also evident in the results obtained by continuous nebulization of soil slurries (5). This bias is very likely a result of spectroscopic interferences from the matrix. For instance, a $^{50}Ti^{16}O^+$ interference on $^{66}Zn^+$ led to 249 and 312 μg g^{-1} instead of 142 and 210 μg g^{-1} for GSS-7 and GSS-4, respectively, which are the two soils with the highest Ti content (2.01 and 1.08% w/w, respectively). Another positive bias may come from the interference of $^{40}Ar^{26}Mg^+$. Quantitative analysis (using $^{66}Zn^+$) is therefore possible only if the level of these sources of interferences is relatively low (as in GSS-2 and the two rock SRMs, NIST-688 and SY-2). An alternative would be to use $^{68}Zn^+$ for the determination, albeit with a sacrifice in sensitivity. Results in closer

Table 6. Comparison of the V and Cr concentrations found[a] (n = 5) and the certified (suggested) value (± confidence limits, 95% level[b]) in μg g^{-1} (in the solid).

SRM	Certified V	V found	Certified Cr	Cr found
NIST-2711	81.6 ± 2.9	36	(47)	37
NIST-2710	76.6 ± 2.3	25	(39)	27
GSS-1	86 ± 13	49	62 ± 9	48
GSS-2	62 ± 9	35	47 ± 7	38
GSS-4	247 ± 37	381	370 ± 56	**366**
GSS-7	245 ± 37	438	410 ± 62	**364**
PACS-1	127 ± 5	66	113 ± 8	64
NIST-688	(250)	67	332 ± 9	93
SY-2	50 ± 8	3	9.5 ± 2.9	1

[a]The relative standard deviation was 2–10% for Cr and V.

[b]Errors on certified values for the GSS series are 15% relative uncertainties.

agreement with the certified values were obtained for Mo (Table 5). Although the Mo level was in general too low for accurate quantitative analysis, semi-quantitative analysis (i.e., within a factor of 2 of the expected concentration) was nonetheless possible.

In contrast, the V and Cr results were almost systematically low compared to the expected values (Table 6). The results for Cr were closer (or in agreement, for GSS-4 and GSS-7) than those for V, which is consistent with the higher percentage of Cr that was leached out (Table 2). A comparison of Table 6 with Table 2 also reveals that, at least for PACS-1, NIST-2710, and NIST-2711, the measured concentration corresponds to 12–33% more than the leachable concentration of these elements but the total is, in general, less than 100%. It suggests that the selected operating conditions did not allow complete atomization/ionization of the solid particles. However, quantitative analysis may still be possible if the optimal conditions found for these elements (see Table 3) were to be used instead of the compromise conditions. They indeed correspond to an increase in residence time in the plasma and should therefore reduce atomization interferences. A torch with a wider injector (than the 1 mm injector used in this work) could also be used to increase both the residence time in the plasma and the mean particle droplet size of the aerosol entering the plasma (4). Indeed, a 3 mm bore injector was previously used for the successful determination of V (5, 7) and Cr (5) in two SRM soils.

Conclusions

In comparison to earlier work on the analysis of soils by slurry nebulization ICP-MS (5, 7), the proposed approach allowed the quantitative determination of Pb and La, two elements that had not been previously looked at in this matrix. The determination of Zn and Mo should also be possible, based on the similar or better leaching efficiency observed for these elements in comparison to Pb and La (Table 2), provided that an interference-free isotope is used for the determination of Zn and the level of Mo can be detected (alternately, the concentration of the slurry could be increased to 1% w/v since the FI system can handle it).

On the other hand, the proposed approach degraded the determination of V and Cr, which had been successfully determined before. The most important difference between this work and previous studies is the smaller bore of the injector (1 mm vs. 3 mm), which restricted the mean particle droplet size reaching the plasma. Although acid-leaching the slurry was attempted to further reduce its particle size, and mixed-gas plasmas were used to minimize atomization differences between the various particles, the wider bore injector may be nonetheless required and will be the subject of a future study.

Specific intramolecular interactions C—H···N in heteroaryl vinyl ethers and heteroaryl vinyl sulfides studied by ^{1}H, ^{13}C, and ^{15}N NMR spectroscopies and by ab initio calculations on molecular structures as well as on nuclear shieldings

Abstract: ^{1}H,^{13}C, and ^{15}N NMR spectra have been measured for a series of isostructural aryl (heteroaryl) vinyl sulfides and compared with analogues of vinyl ethers. It was found that "intramolecular interaction" of the α-hydrogen of the vinyl group with endocyclic nitrogen takes place in 2-vinylthiopyridines. This is in common with the findings for 2-vinyloxypyridine and the intramolecular interaction is shown to have a profile characteristic of hydrogen bonding. Also, the NMR spectral data show that this type of interaction is more intense (~1.5 times) in 2-vinyloxypyridine than in 2-vinylthiopyridine. This is probably due to the greater electronegative effect of oxygen compared to that of sulfur. To discuss these findings further in detail, ab initio calculations have been made, and the conformational energy map and the NMR chemical shifts have been discussed. The ab initio calculations, which were carried out on the D95++(d,p) basis set at the B3LYP level, confirm the planar structure of 2-vinyloxy- and 2-vinylthiopyridines, while other analogues of these ethers and sulfides were essentially nonplanar. Gauge-Independent Atomic Orbital (GIAO) calculations of the shielding constants, based on the same basis set, support the extraordinary low-field shift of the α-hydrogen in the vinyl group when it is situated close to endocyclic nitrogen. All these calculations support our proposal that the vinyl proton is involved in intramolecular hydrogen bonding in 2-vinyloxy- and 2-vinylthiopyridines.

Key words: NMR, intramolecular hydrogen bonding, ab initio calculation, GIAO.

Résumé : On a déterminé les spectres RMN du ^{1}H, du ^{13}C et du ^{15}N d'une série de sulfures d'aryle (hétéroaryle) et de vinyle et on les a comparés avec ceux de leurs analogues oxygénés. On a trouvé que, avec les 2-vinylthiopyridines, il se produit une « interaction intramoléculaire » de l'hydrogène-α du groupe vinyle avec l'azote endocyclique. Ceci se rapproche des observations faites avec la 2-vinyloxypyridine et l'interaction intramoléculaire est mise en évidence par un profil caractéristique de liaison hydrogène. Les données de spectroscopie RMN montrent aussi que ce type d'interaction est environ 1,5 fois plus intense dans la 2-vinyloxypyridine que dans la 2-vinylthiopyridine. Ce résultat est probablement dû à un effet électronégatif plus grand pour l'oxygène que pour le soufre. Dans le but d'analyser ces données plus en détail, on a effectué des calculs ab initio et on discute de la carte d'énergie conformationnelle et des déplacements chimiques en RMN. Les calculs ab initio, effectués au niveau B3LYP avec un ensemble de base D95++(d,p), confirment que les 2-vinyloxy- et 2-vinylthiopyridines existent dans une structure planaire alors que les autres analogues de ces éthers et de ces sulfures sont essentiellement non planaires. Les constantes d'écran calculées par la méthode « Gauge-Independent Atomic Orbital (GIAO) » en utilisant le même ensemble de bases sont en accord avec le fait que l'hydrogène α du groupe vinyle subit un déplacement extraordinaire vers les bas champs lorsqu'il est près de l'azote endocyclique. Tous les calculs théoriques sont en accord avec notre hypothèse selon laquelle le proton vinylique peut être impliqué dans une liaison hydrogène intramoléculaire dans la 2-vinyloxy- et la 2-vinylthio-pyridine.

Mots clés : RMN, liaison hydrogène intramoléculaire, calculs ab initio, « GIAO ».

Introduction

Spectral (1) and crystallographic (2) data give evidence that polar C—H groups can form a weak hydrogen bond with heteroatom X (usually, X = N or O). For example, crystallographic data show that the H···X distance is significantly shorter than the sum of van der Waals radii in certain molecules, indicating the presence of inter- or intramolecular C—H···X hydrogen bonding (2). The clear nature of crystallographic data makes these investigations very attractive, but crystallographic data are not suited to detailed quantitative study and other spectroscopic studies necessary for discussion of all properties relevant to the C—H···X hydrogen bonding. It should also be stressed that the C—H···N interaction has not been investigated in detail although an overwhelming majority of studies have dealt with the C—H···O interaction (2). This paper is an attempt to compensate for this gap.

Hitherto, downfield shifts have been observed in the ^{1}H NMR signal (1*d*–1*h*) when hydrogen bonding of the type C—H···X (X = N or O) occurred. This trend is in common with the standard case of hydrogen bonding, O—H···X. Changes in the infrared frequencies have also been detected for the same case of hydrogen bonding C—H···X (1*a*–1*d*, 1*g*). However, such NMR and IR spectral effects are very small in the case of C—H···X compared to those observed in the standard case of O—H···X. This leads to ambiguity in an extended interpretation of the C—H···X hydrogen bonding. Probably, this C—H···X hydrogen bonding is weak and occupies a middle position on the energy scale between standard hydrogen bonding and nonspecific van der Waals interaction. Therefore it may be important to discuss such weak hydrogen bonding on the basis of advanced methods in molecular spectroscopy and molecular calculations.

Large numbers of aryl and heteroaryl vinyl ethers have recently been investigated by ^{1}H, ^{13}C, ^{15}N, and ^{17}O NMR spectroscopy and semiempirical quantum-chemical calculations (3). Statistical analysis of this quantity of structural data disclosed the presence of an anomaly in the NMR spectra. The anomaly, which appeared in the NMR parameters of the molecules under investigation, may be ascribed to the presence of weak intramolecular hydrogen bonding between the α-hydrogen of the vinyl group and the pyridine nitrogen atom (3).

Modern high-field NMR spectroscopy has proven to be an exceptionally powerful technique for detection of the weak interactions that occur between different molecules. Also, ab initio calculations in quantum chemistry are now becoming sufficiently accurate for the quantitative discussion of weak interactions in molecules (4, 5). Advances in these two different fields have promoted extensive studies on molecular properties and interactions in recent years. For example, the shielding tensor σ in nuclear magnetic resonance spectroscopy is one of the most important properties of a molecule, one that is closely related to the fine structure and chemical nature of the molecule, and hence has long been studied from the theoretical as well as the experimental point of view. As a consequence, a number of Hartree–Fock and post-Hartree–Fock calculations on the σ of different molecules have appeared in the literature. Among these, the GIAO method (6, 7) is very attractive to chemists since it is known to yield very accurate calculational results (8, 9). It was also shown (10) that density functional theory (DFT) tends to give more robust results than does the Hartree–Fock method: it provides calculations on geometrical structures, vibrational frequencies, and electronic structures that are reasonable compared with the results of experiment while the Hartree–Fock calculations fail to do so. Friedrich et al. (8) were the first to combine the GIAO method of Ditchfield (6) with DFT.

In the present study we investigated several isostructural molecules of 2-vinyloxypyridine and 2-vinylthiopyridine, 2-vinyloxyquinoline, and 2-vinylthioquinoline, together with other aromatic vinyl ethers and sulfides, and ab initio calculations were carried out to investigate how the intramolecular C—H···N interaction influences the molecular structure of 2-vinyloxy- and 2-vinylthiopyridines. Furthermore, the GIAO calculation of magnetic shielding tensors was applied on the basis of the ab initio wave functions, and the experimental data of ^{1}H, ^{13}C, ^{15}N, and ^{17}O NMR were discussed in relation to specific intramolecular hydrogen bonding.

Results and discussion

NMR data

The ^{1}H and ^{13}C NMR parameters of the vinyl group of ethers **1–15** and sulfides **16–28** (Scheme 1) are presented in Tables 1, 2, and 3.

The spectral anomalies in the ^1H_X, $^{13}C_\alpha$, and ^{15}N chemical shifts as well as the $^1J_{C_\alpha H_X}$ coupling constants were encountered in heteroaryl vinyl ethers **1** and **13–15**, which

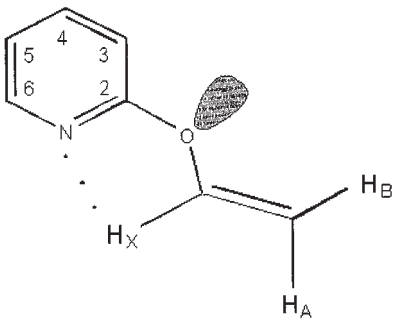
[b]The increments of ^{15}N chemical shifts are presented in square brackets.

[c]These data are taken from ref. 23.

[d]**2** denotes the 2-vinyloxyl group and **4** denotes the 4-vinyloxyl group.

Scheme 2.



have a vinyloxyl group attached to the atom that is neighbour to the endocyclic nitrogen (Table 1). The spectral data listed suggest the presence of intramolecular hydrogen bonding between the pyridine nitrogen and the H_X proton in the s-*trans* conformation and a *syn* arrangement of nitrogen to the vinyl group as shown in Scheme 2. Various statistical treatments have been used to distinguish the effect of hydrogen bonding from the pure electronic effect of the aromatic system (3). The hydrogen bonding leads to a downfield shift of the α-proton signal by 1 ppm, and an upfield shift of the α-carbon and ^{15}N signals by 4–5 and 17–20 ppm, respectively. The increase in the $^1JC_\alpha H_X$ coupling constants amounts to 6-7 Hz.

The one-bond ^{13}C–^{13}C coupling constants in the aromatic ring of ethers **1–7**, **9**, and **12** are included in Table 2. The increment from the unsubstituted pyridine and benzene rings is also included in Table 2 (in parentheses). This increment is larger in all compounds listed in the Table 2 when the pertinent carbon is attached by such electronegative groups as vinyloxyl, halogen, and NO_2. This is due to the electronegative effect of the attached atoms (11, 13). This increment amounts to 11.6–13.0 Hz for compounds **2–7**, **9**, and **12**, but a much larger increment (18 Hz) is observed for compound **1**. It has been suggested (14) that the oxygen lone-pair electrons have introduced an additional positive contribution to the one-bond ^{13}C–^{13}C coupling constant when these lone-pair electrons are situated *cis* to this ^{13}C—^{13}C bond. The oxygen lone pair occupies just such a *cis* position relative to the C_2—C_3 bond in an s-*trans* conformation of a vinyloxyl group in the *syn* arrangement of the pyridine ring in 2-vinyloxypyridine (Scheme 2). It causes an additional positive contribution (5–6 Hz) to the $^1JC_2C_3$ coupling constant that results in an unusually large increment in this coupling. On the other hand, 3-vinyloxypyridine **2** should exist

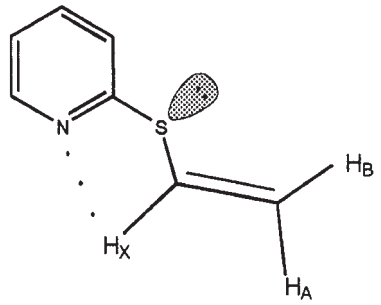
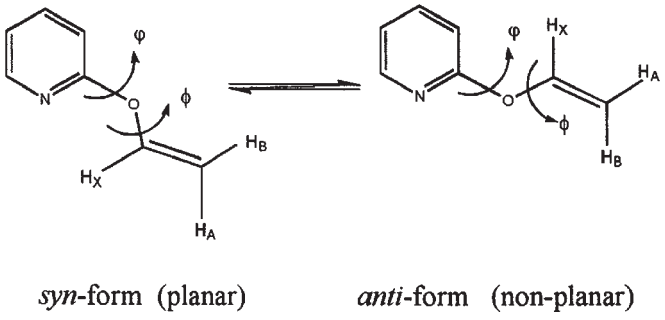


Scheme 5.

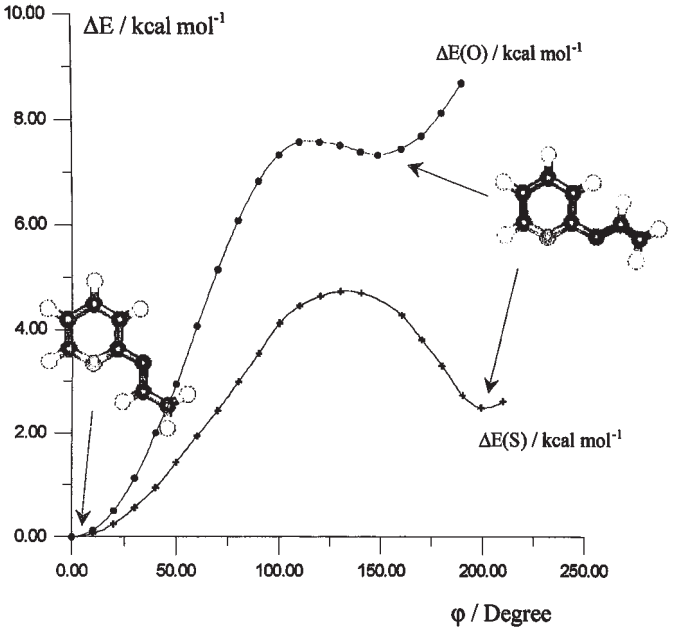


molecule is considered to have different local minima in the rotational equilibrium. Therefore, the extra contributions of the oxygen lone pair to the $^1JC_2C_3$ and $^1JC_3C_4$ coupling constants almost disappear. This situation is common to all the other compounds (**3**–**7**, **9**, and **12**).

The H_X signal in molecules **16** and **28**, in which the vinylthio group is attached to the *ortho* carbon of pyridine nitrogen, is found to be displaced by 0.6–1.0 ppm to the lower field with reference to other compounds **17–27** (Table 3). This characteristic result also supports the presence of intramolecular hydrogen bonding in this type of compound (Scheme 4).

It may be important to compare quantitatively the magnitude of the spectral anomalies observed in the intramolecularly hydrogen-bonded compounds of ethers **1** and **13** and sulfides **16** and **28**. The H_X signal is shifted to lower field by 0.95 and 1.28 ppm in ethers **1** and **13**, respectively, compared to other non-hydrogen-bonded compounds, since the average value of δH_X is 6.60 ppm for ethers **2**–**12** whereas in molecules **1** and **13** δH_X is equal to 7.55 and 7.88 ppm, respectively. This difference is reduced to 0.58 and 0.95 ppm for the sulfides when the data of **16** and **28** are compared with the averaged data (6.53 ppm) of **17–27**. Therefore the

Fig. 1. The function of potential energy of internal rotation in 2-vinyloxypyridine **1** and 2-vinyl-thiopyridine **16** around the C_2—O bond (D95 basis set).



ratio of the downfield shift of δH_X is said to be larger by a factor of ca. 1.6 in ethers **1** compared to that in the sulfides. A similar ratio is observed for other spectral parameters: 1.4 times for the deviation in $\delta^{13}C_\alpha$ and 1.5 times for the deviation in the $^1JC_\alpha H_X$. Thus it is concluded that specific intramolecular hydrogen bonding will cause spectral changes in the ethers that is about 1.5 times stronger than that in the sulfides. A similar tendency may be expected in the difference of the interaction energy, which will be discussed below.

To estimate an additional contribution to the ^{15}N increment, the dependence of $\delta^{15}N$ increments for pyridine and quinolines ($\Delta\delta^{15}N$) versus ($\Delta\delta^{13}C$) for benzenes and naphthalenes upon the same substituents has been compared (3). Based on this dependence it is expected that the increment of the ^{15}N chemical shift for 2-vinylthiopyridine **16** would be 2.7 times larger in absolute magnitude than that for the C_3 carbon ($\delta^{13}C_3$, Table 3) (3). However, the observed value is 9 ppm less than this expectation (taking into consideration the sign of the increments). This suggests that the positive contribution to the ^{15}N shielding constant occurs because of the intramolecular C—H···N interaction. According to the theory of Li and Chesnut (15, 16) the shielding effect on the ^{15}N nucleus indicates the attractive nature of the interaction under discussion. The value of the positive contribution to the ^{15}N shielding constant is about 2 times smaller in 2-vinylthiopyridine **16** than that in 2-vinyloxy-pyridine **1**.

Ab initio calculations

To understand how the interaction under discussion influences the spatial structure of 2-vinyloxy- and 2-vinylthiopyridines ab initio calculations were carried out. The ab initio calculation is inevitable for the exact discussion of conformational energies as well as the NMR chemical shifts of sulfur compounds, especially when the sulfur is situated

in a conjugated state with an aromatic ring, although for the discussion of the ether compounds in our previous study (3) a semiempirical AM1 calculation can offer a reasonable estimate of the conformational energy. The aryl and heteroaryl vinyl ethers have two degrees of freedom with regard to the flexible rotation angle. There is rotation around the O—C heteroaryl (aryl) bond and the O—C vinyl bond (the torsion angles φ and ϕ, respectively, Scheme 5). The search for the minimum in the potential energy hypersurface was carried out using the D95 basis set at full optimization of geometrical parameters. The global energy minimum in compounds **1, 13**, and **16** corresponds to a planar structure, i.e., both torsion angles φ and ϕ are equal to 0°. For comparison, the AM1 calculation of the global minimum gave φ and ϕ equal to 31° and 11°, respectively (3).

The segment of potential energy hypersurface was calculated in molecules **1** and **16** under varying torsion angles φ and full optimization of another geometry parameter. The results are shown in Fig. 1. The second energy minimum was found in the field of φ = 150°–160°. The local energy minimum is 7.3 kcal/mol higher in energy than the global one for 2-vinyloxypyridine **1**. The energy difference is reduced to 2.4 kcal/mol for 2-vinylthiopyridine **16**. The magnitudes of energy difference ensure that the population with the *anti* conformation is quite minor for both molecules (17), and compounds **1** and **16** are predominantly in the *syn* form.

The structure of the *anti* conformer differs considerably from that of the *syn* conformer in planarity, since the *anti* conformer is essentially nonplanar whereas the *syn* conformer is planar. The torsion angles φ and ϕ are equal to 30° and 31°, respectively, in the *anti* form of **1**. These angles are changed to φ = 20° and ϕ = 50° in compound **16**. To compare the structures of the other compounds under discussion, the equilibrium geometries were calculated for 3-, 4-vinyloxypyridines (**2** and **3),** phenyl vinyl ether **4**, 3-, 4-vinylthiopyridines (**17** and **18**), and phenyl vinyl sulfide **19**. The calculations are summarized in Table 4. The structures of these compounds are similar to those of the *anti* conformer of 2-vinyloxypyridine **1** and 2-vinylthiopyridine **16** but are strikingly different from those of the *syn* conformer.

The molecule of 3-vinyloxypyridine **2** should also have two distinguishable stereo orientations of the vinyloxyl group relative to the pyridine ring (Scheme 3). Indeed, the D95 calculation reveals two energy minima, which differ by only 0.26 kcal/mol, the *syn* conformer being lower in energy. Thus, the energy difference between *syn* and *anti* conformers is very small in 3-vinyloxypyridine **2** and the compound is considered to be present as a rotating mixture where rotation angles φ and ϕ are distributed over rather wide ranges.

To achieve a better description of the hydrogen-bonding interaction, diffuse functions were used (18) in the computation at the D95++(d,p) level. An appreciable reduction of the energy difference between the *syn* and *anti* conformers is observed in molecule **1** as well as molecule **16** in the extended basis set calculation: a reduction from 7.3 to 4.7 kcal/mol and from 2.6 to 1.3 kcal/mol is observed for **1** and **16**, respectively. To take into account an electron correlation effect, density functional theory was applied (19). No important change was observed in the equilibrium geometry of molecules **1** and **16** when calculations at the B3LYP/D95++(d,p) (19) as well as the HF/D95++(d,p) levels are compared with those at the HF/D95 basis set (Table 4).The computation for 3-vinyloxypyridine **2** at the B3LYP/D95++(d,p) level shows results similar to the computation at the D95

basis set: the torsional angles in both conformers differ only slightly and the energy difference amounts to only 0.16 kcal/mol (Table 4).

Another essential indication of the C—H···N interaction is the interatomic distance between H_X and nitrogen. The equilibrium distance H_X···N in 2-vinyloxypyridine **1** lies in the range 2.29–2.39 Å (depending on the basis set of the calculation) whereas the distance in 2-vinylthiopyridine **16** gives values between 2.31 and 2.38 Å (Table 4). The distance in 2-vinyloxyquinoline **13** is equal to 2.33 Å. The distance HX···N in all these molecules is much less than the sum of the van der Waals radii (2.75 Å) (2*a*). The short distance and planar structure of molecules **1**, **13**, and **16** completely support an attractive rather than a repulsive nature between C—H and N.

The NMR chemical shift can be discussed on the basis of ab initio theory in quantum chemistry through the use of an advanced version of nuclear shielding calculations. The calculations of shielding constants (SC) as a function of internal rotation for 2- and 3-vinyloxypyridines, **1** and **2**, and 2-vinylthiopyridine **16** by the GIAO method (9) are summarized in Table 5. The rotation of the vinyloxyl group seems not to affect the shielding constant in 3-vinyloxypyridine **2**: the changes in SC of H_A, H_B, and H_X are within 0.1 ppm. But closer examination of the calculated values discloses a few tendencies that are included in the calculation. The SC of $^{13}C_\beta$ is decreased by 0.40 ppm in the *anti* conformer compared to that in the *syn* conformer. This reflects an alteration in the *p*–π conjugation between the pyridine ring and the vinyloxyl group due to the change in spatial orientation. This decrease in the SC of $^{13}C_\beta$ is accompanied by an increase in the SC of $^{13}C_\alpha$, and it corresponds to the weakening of the *p*–π conjugation between the pyridine ring and the vinyl group. This tendency is in complete agreement with the observed experimental data (20). Very small changes in the SC of the *syn* and *anti* conformers of 3-vinyl-oxypyridine **2** indicate that these SC values can be treated as a suitable standard for the SC values, including no extra specific intramolecular interaction. When SC values calculated for 2-vinyloxypyridine **1** are compared on the basis of that standard, several characteristic profiles may be deduced. The H_X shielding constant is decreased by 2 ppm in the *syn* conformer of **1** while the H_A and H_B shielding constants remain almost unchanged. A decrease in the shielding constant means that the downfield chemical shift, and hence the experimentally observed downfield shift of the H_X proton (0.95 ppm), is supported by the theoretical calculations. It should also be noted that the H_X shielding constant in the *anti* conformer of 2-vinyloxypyridine **1** corresponds well with those calculated for the *syn* and *anti* conformers of 3-vinyloxypyridine **2** where a specific intramolecular interaction between the H_X proton and the nitrogen lone pair is impossible because of geometrical remoteness. The SC values of the C_α and C_β carbons in the *syn* conformer are increased relative to those in the *anti* conformer by 3.6 and 2.9 ppm, respectively. The increase in C_β shielding should be attributed to the intensification of the *p*–π conjugation with the vinyloxyl group in the planar *syn* conformation. However, the intensification of the *p*–π conjugation leads to the deshielding rather than the shielding of the C_α carbon (vide supra). The C_α atom shielding in the *syn* conformer comes from the intramolecular C—H···N interaction. The experimental shift of the C_α carbon and the change of shielding constants in the GIAO method are in an excellent agreement.

An important result is that the GIAO method predicts the increase of the ^{15}N SC by 24.6 ppm in going from the *anti* to the *syn* conformer of 2-vinyloxypyridine **1**. Therefore, the empirical estimate of the $\delta^{15}N$ upfield shift by 17–20 ppm is confirmed by the calculated data.

It is interesting to consider a hypothetical case in which the *syn*-conformer of 2-vinyloxypyridine **1** takes the "usual" structure, i.e., both torsional angles φ and ϕ are equal to 30°. The calculations for this hypothetical case are also given in Table 5. The increase in torsional angles results in an increase of intramolecular H_X···N distance (2.68 Å). Taking into account the angular factor (2*h*), this prevents hydrogen bond formation. In consequence, one can mark the sharp change of SC for atoms involved in the C—H···N interaction. The shielding constants of the H_X and C_α nuclei increase by 1.7 and 3.2 ppm, respectively, and have a value slightly different from that of the *anti* conformer. An increase in the torsional angles leads to the significant decrease of the ^{15}N shielding constant (13.3 ppm, see Table 5), indicating "release" from the attractive C—H···N interaction. The ^{17}O shielding in the hypothetical conformer is increased by 2.8 ppm, relative to that in the *syn* conformer. This supports the proper interpretation of the ^{17}O downfield shift in molecule **1** as a result of planar molecular structure (3). Similar regularities emerge from the comparison of calculated shielding constants in the *syn* and *anti* conformers of 2-vinylthiopyridine **16** (Table 5).

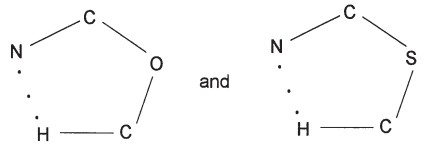
In Table 6 changes in the NMR parameters estimated for the hypothetical *syn* and *anti* conformers are compared with

© 1999 NRC Canada

Table 6. Comparison of the estimated changes in the NMR chemical shifts (ppm) between the *syn* and *anti* conformers.[a]

	$\delta H_X^{syn} - \delta H_X^{anti}$	$\delta C_\alpha^{syn} - \delta C_\alpha^{anti}$	$\delta N^{syn} - \delta N^{anti}$
Compound **1**	–2.06	2.87	24.61
Compound **16**	–1.57	1.76	16.48
Ratio	1.3	1.6	1.5

[a]An estimate is given only for those atoms that are common to the compounds and which can form an acyclic arrangement in the intramolecular hydrogen-bonded system:



the nuclei that are directly engaged in intramolecular hydrogen bonding. The calculations are compared for compounds **1** and **16**. This *ratio* is based on the GIAO calculations and supposes that a change in the shielding constant of the *syn* conformer relative to that of the *anti* conformer of 2-vinyloxypyridine **1** is about 1.5 times larger than would be the case in 2-vinylthiopyridine **16**. This result corresponds well with the observed changes in the NMR parameters.

Experimental

Spectral measurements

The NMR spectra were recorded on a Bruker WP 200 SY spectrometer using ASPECT 2000 software system operating at 200 MHz for ^{1}H and 50.3 MHz for ^{13}C. All spectra were obtained under the same conditions. The solvent was $CDCl_3$ and the internal reference was given by HMDS. The concentration of solute molecules was 5% for the ^{1}H and 30% for the ^{13}C NMR experiments. The typical spectrometer conditions were as follows: ^{1}H NMR, spectral width 2500 Hz, pulse width 2 μs, flip angle 30°, number of scans 4, data points 32K; ^{13}C NMR, spectral width 10 000 Hz, pulse width 2.5 μs, flip angle 45°, relaxation delay 3 s, number of scans 100–400, data points 32K.

The proton-coupled spectra were obtained by gated decoupling techniques (21). The spectral width was contracted to 1000 Hz to reach the accuracy of ^{13}C–^{1}H coupling constant measurements, not less than ±0.1 Hz. The simulations of proton-coupled spectra were effected using Bruker's PANIC program. Some of the compounds were recorded on Tesla BS 567 A and Varian VXR 500 spectrometers (100 and 499.8 MHz for ^{1}H, 25.1 and 125.7 MHz for ^{13}C, respectively) under the same conditions as mentioned above. The conditions for ^{15}N and ^{17}O spectral measurements are given in ref. 3.

Computational details

All calculations were performed using Gaussian 94 (22) on a Silicon Graphics Indigo^2 computer at the Genome Information Research Center of Osaka University. The ab initio calculations were performed using D95 and D95++(d,p) basis sets at the Hartree–Fock level and at the B3LYP level of density functional theory (19). The geometries were fully optimized without any symmetry constraints. The shielding constants were calculated by the GIAO method (9) using the B3LYP/D95++(d,p) basis set.

Abstract: Crystals of [Fe(2-methylimidazolate)$_2$·0.13(FeCp$_2$)]$_x$, **1**, are orthorhombic, a = 8.0654(11), b = 15.3504(5), c = 19.3388(9) Å, Z = 8, space group *Pnnm*. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R (F, $I \geq 3\sigma(I)$) = 0.057 (R_w (F^2, all data) = 0.142). The structure involves tetrahedral iron(II) centers linked in chains by single imidazolate ligand bridges. The chains are cross-linked by additional imidazolates to generate a complex 3-D network of linear channels in which ferrocene molecules are trapped. [Cu(1,2,4-triazolate)$_2$]$_x$, **2**, is shown by indirect evidence to have a polymeric structure in which copper(II) ions are bridged by triazolate ligands. Magnetic susceptibilities were measured on powdered samples over the temperature range 2–300 K at applied fields of 0–55 000 G. Both materials exhibit antiferromagnetic exchange at temperatures above a magnetic phase transition: 27 K for **1** and 35 K for **2**. At temperatures below these transitions the compounds exhibit weak ferromagnetism, likely resulting from canted spin structures. Cycling the applied magnetic field between +55 000 G and –55 000 G at 4.8 K generates hysteresis loops for both materials. Remnant magnetizations of 200 and 55 cm^3 G mol^{-1} and coercive fields of 5000 and 2500 G are obtained for **1** and **2**, respectively.

Key words: iron, 2-methylimidazolate, copper, 1,2,4-triazolate, canted spins, ferromagnets.

Résumé : Les cristaux du [Fe(2-méthylimidazolate)$_2$·0.13(FeCp$_2$)]$_x$, **1**, sont orthorhombiques, groupe d'espace *Pnnm*, avec a = 8,0654(11), b = 15,3504(5) et c = 19,3388(9) Å et Z = 8. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R (F, $I \geq 3\sigma(I)$) = 0,057 (R_w (F^2, toutes les données = 0,142). La structure implique des centres de fer(II) tétraédriques liés en chaînes par des ponts impliquant un seul ligand imidazolate. Les chaînes sont réticulées par des imidazolates additionnels qui génèrent un réseau tridimensionnel complexe de canaux linéaires dans lesquels les molécules de ferrocène sont enfermées. On a montré, grâce à des données indirectes, que le [Cu(1,2,4-triazolate)$_2$]$_x$, **2**, possède une structure polymérique dans laquelle les ions de cuivre(II) sont reliés par des ligands triazolates. On a mesuré les susceptibilités magnétiques d'échantillons en poudre à des températures allant de 2 à 300 K, à des champs appliqués allant de 0 à 55 000 G. Les deux matériaux donnent lieu à un échange antiferromagnétique aux températures supérieures à une transition de phase magnétique; 27 K pour le composé **1** et 35 K pour **2**. À des températures à ces transitions, ces composés présentent un faible ferromagnétisme qui résulte vraisemblablement de structures à spin oblique. En faisant faire un cycle au champ magnétique appliqué entre +55 000 G et –55 000 G, à 4,8 K, il y a génération d'un cycle d'hystérésis avec chacun des matériaux. On a observé des magnétisations résiduelles de 200 et 55 cm^3 G mol^{-1} et des champs coercifs de 5000 et 2500 G respectivement pour les composés **1** et **2**.

Mots clés : fer, 2-méthylimidazolate, cuivre, 1,2,4-triazolate, spins obliques, ferroaimants.

[Traduit par la Rédaction]

Introduction

The ability of diazolate ligands to bridge metal ions and to mediate magnetic interactions between paramagnetic centers is well documented (1–3). Studies on binary copper(II), cobalt(II), nickel(II), and manganese(II) pyrazolates show that the 1,2 positioning of the nitrogen atoms in the ligands leads to 1-D linear chain structures with double azolate bridges and antiferromagnetically coupled metal centers (4–9). In contrast, as has been recently discussed (10), the 1,3 positioning of the donor nitrogens in imidazolate ligands results in steric constraints that are likely to prevent the formation

[b]Includes crystal decay (if any), absorption, and scaling corrections performed in a single step.

of double azolate bridges. These ligands may then be expected to singly bridge metals with the potential of forming higher dimensional 2-D or 3-D structures and long-range magnetic interactions. As we reported previously, these structural and magnetic characteristics are exhibited by $[Fe_3(imid)_6(imidH)_2]_x$ (where imidH = imidazole), a compound in which iron(II) ions are singly bridged by imidazolate ligands in an extended 3-D lattice (10). Magnetic studies on this compound revealed antiferromagnetic coupling and a canted spin structure, leading to weak ferromagnetism and long-range magnetic ordering below a critical temperature of 17 K.

There is considerable interest in materials such as $[Fe_3(imid)_6(imidH)_2]_x$ (termed molecular magnets) from the joint perspectives of understanding factors that generate them and of their potential information storage applications (11). Hence we are expanding our studies on complexes of azolates, particularly those ligands in which the potentially bridging donor nitrogens are separated by one carbon in the heterocyclic ring. We report here the X-ray determined structure and magnetic characterization of an iron(II) complex of 2-methylimidazolate, $[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$ (2-meimid = 2-methylimidazolate and Cp = cyclopentadienyl), **1**. Stoichiometrically and structurally this compound is distinct from its imidazolate analogue, $[Fe_3(imid)_6(imidH)_2]_x$; nonetheless, it too is found to exhibit the properties characteristic of molecular magnets.

The 1,2,4 triazolate ligand (1,2,4-trz) is related to the imidazolates in that it too has two potentially bridging donor nitrogens separated by one carbon in the heterocyclic ring; it differs, of course, in that it has a third ring nitrogen. We are interested in studying complexes of this ligand and in making structural and magnetic comparisons with related imidazolate complexes. We chose to study first the known complex, Cu(1,2,4-trz)$_2$, **2**, since earlier magnetic characterization had involved only high-temperature measurements (12). In addition we hoped to determine its molecular structure. Unfortunately, in spite of repeated attempts involving a synthetic route that has been utilized very successfully to obtain single crystals of related copper(II) pyrazolate complexes (5*a*), we have been unable to obtain crystals of the compound suitable for single crystal X-ray studies. We have nonetheless completed extensive magnetic studies on this material. The magnetic properties parallel very closely those of **1**.

Experimental

Syntheses

Ferrocene (from Strem) and 2-methylimidazole (2-meimidH) and 1,2,4-triazole (1,2,4-trzH) (from Aldrich) were used as supplied. Copper metal beads were cleaned immediately prior to use by washing in 12 M HCl, followed by a thorough water wash and finally an acetone rinse. Solvents used were reagent grade and were dried and distilled under an atmosphere of dry dinitrogen before use.

$[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$, ***1***

Ferrocene (0.50 g, 2.6 mmol) and 2-methylimidazole (3.0 g, 37 mmol) were combined and sealed under vacuum in a Carius tube. The mixture was heated for 4 days at 160°C. Over this period the bright orange of the original solution of ferrocene in the molten 2-meimidH (mp 142°C) was discharged and pale yellow crystals were deposited from the solution. The product and excess 2-meimidH were allowed to cool to room temperature and the Carius tube was opened under a dinitrogen atmosphere. The excess 2-meimidH was extracted with dry and oxygen-free acetonitrile solvent and the remaining crystals were washed with benzene and hexanes. The product was isolated as pale yellow crystals. Anal. calcd. for $C_{9.3}H_{11.3}N_4Fe_{1.13}$: C 46.1, H 4.7, N 23.1; found: C 47.1, H 4.8, N 23.3.

$[Cu(1,2,4\text{-trz})_2]_x$, ***2***

Clean copper beads (ca. 1 g) were placed in a 20 mL round bottom flask. 1,2,4-Triazole (3 g, 0.15 mmol) was added to the flask, which was then fitted with a reflux condenser. The reaction mixture was heated under a dioxygen atmosphere to 140°C, causing the triazole to melt. The mixture was maintained at this elevated temperature, without stirring, for 5 days, during which time the copper beads became coated with a purple solid. The reaction mixture was

[a] $B_{eq} = (8/3)\pi^2 \Sigma \Sigma (U_{ij} a_{i*} a_{j*} (\mathbf{a}_i . \mathbf{a}_j))$.

allowed to cool and solidify, and the unreacted triazole was removed by vacuum sublimation. The product was then physically separated from the copper beads as a purple powder. Anal. calcd. for $C_4H_4N_6Cu$: C 24.1, H 2.0, N 42.1; found: C 24.4, H 2.0, N 41.7.

Physical characterization

Differential scanning calorimetry (DSC; 35°C to 600°C) and thermal gravimetric analysis (TGA; 35°C to 800°C) measurements were made using a TA Instruments TGA 51 unit. Electronic spectra (200–3000 nm) were obtained at room temperature on Nujol mulls pressed between quartz plates using a Varian Cary 5 UV–Vis–NIR spectrophotometer. Infrared spectra (4000–400 cm^{-1}) were recorded at room temperature on a Bomen FTIR spectrophotometer using KBr disc samples.

Magnetic properties were examined using a Quantum Design (MPMS) SQUID magnetometer. Magnetic susceptibilities were measured at 500 and 10 000 G over the temperature range 2–300 K, magnetization studies as a function of field strength (0–55 000 G) were made at several temperatures, and hysteresis magnetization data were obtained by oscillating the applied magnetic field between +55 000 G and –55 000 G at 4.8 K. A specially designed sample holder, as described previously (5*d*), was used to minimize the background signal. Magnetic susceptibilities were corrected for background and for the diamagnetism of all atoms; corrections of 125×10^{-6} and 79.0×10^{-6} cm^3 mol^{-1} were employed for $[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$ and $[Cu(1,2,4\text{-trz})_2]_x$, respectively. Data reported here are on a per mole of monomer basis.

X-ray crystallographic analysis of $[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$, 1

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares based on 16 071 reflections with $2\theta = 4.0$–63.8. The data were processed,[2] and corrected for Lorentz and polarization effects, and for absorption (semiempirical, multi-scan, based on analysis of symmetry-equivalent data).

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. A cavity in the structure is partially occupied by ferrocene. The site occupancy of the ferrocene iron atom (Fe(2), which lies at the intersection of two mirror planes) was refined and its final value of 0.130(1) corresponds to 52% of the maximum value of 0.25. One of the 2-methylimidazolate ligands (containing N(4)) was modeled as 1:1 twofold disordered with respect to rotation about a twofold axis. Bond length restraints (six in total) were imposed for the disordered 2-methylimidazolate moiety. The poorly resolved ferrocene carbon atoms were refined with isotropic thermal parameters while all remaining non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2B_{bonded\ atom}$. No corrections for secondary extinction were necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (13). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles

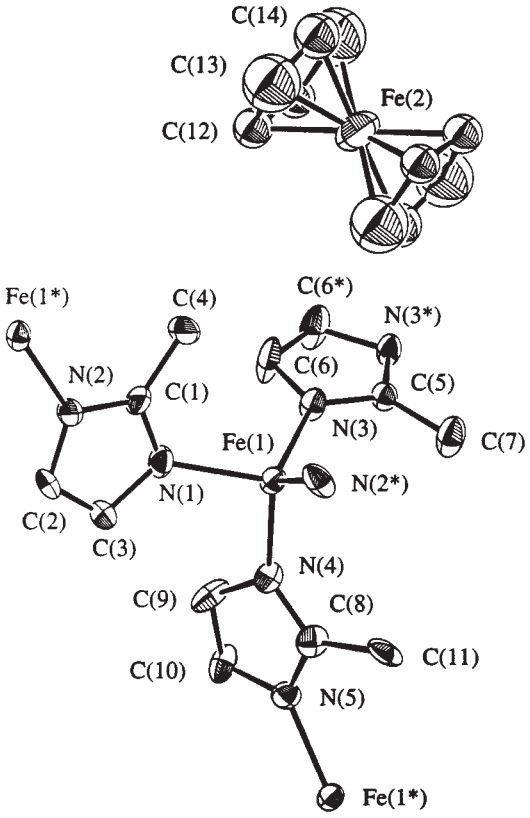
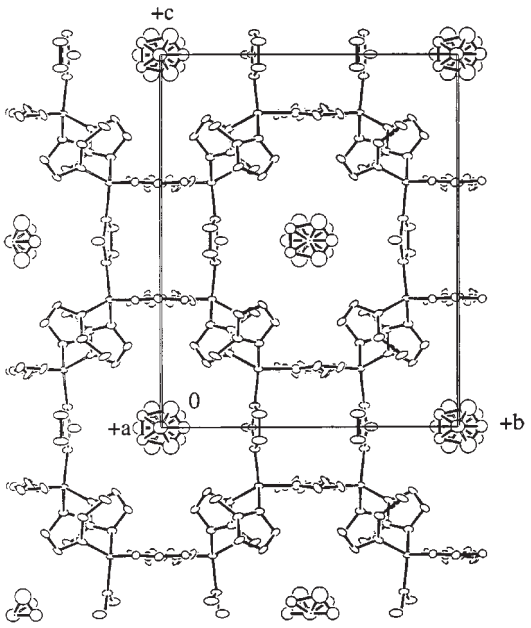
Fig. 1. View of the repeat unit of **1** and atom numbering scheme (33% ellipsoids, 0.13 occupancy for ferrocene).



method for preparing divalent metal azolate polymers (9, 10). In the present work the reaction between ferrocene and excess molten 2-methylimidazole has afforded a crystalline polymeric Fe(II) material, $[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$, **1**, in which tetrahedral Fe(II) ions are linked via 2-methylimidazolate bridges. The electronic spectrum of **1** shows an absorption maximum at 1300 nm with a shoulder at about 1800 nm. This we assign to the $^5E \rightarrow {}^5T_2$ transition for (distorted) tetrahedral Fe(II) (14). The absence of a ν_{N-H} stretching vibration in both this spectrum and the infrared spectrum is indicative of the absence of neutral 2-methylimidazole in the product sample. Thermal gravimetric analysis (TGA) of the compound shows it to be thermally stable to 310°C. From 310 to 640°C the compound decomposes with a total weight loss over this range corresponding to 70% of the initial mass. This compares favorably with a 74% loss in mass that would occur if only iron metal remained after decomposition. Interestingly, the thermal analysis indicates that the ferrocene molecules trapped in the lattice (see below) are firmly held, at least up to 310°C. Loss of these, through sublimation for example, would be expected to result in a weight loss of 15% of the initial mass followed by decomposition of the covalent lattice material and further weight loss at higher temperatures. The carbon microanalysis was not in particularly good agreement with the value expected on the basis of the stoichiometry as determined by X-ray crystallography, suggesting the possibility that different crystals might have slightly different amounts of trapped ferrocene. However, both hydrogen and nitrogen analyses were in excellent agreement with the

Fig. 2. View of the crystal structure of **1** along the *a* axis. The stoichiometry is not shown as the ferrocene sites are only partially occupied, as described in the text.



X-ray determined stoichiometry and hence this stoichiometry was used in the analysis of the magnetic data.

The structure of **1** was determined by single crystal X-ray diffraction and a section of it is shown with the atom numbering scheme in Fig. 1. Each of the tetrahedral Fe(II) ions is linked via single 2-meimid bridges to four other Fe(II) ions to form the 3-D polymer. A portion of the polymer structure is shown in Fig. 2. This structure again demonstrates how the 1,3 positioning of the nitrogens has prohibited the formation of a linear chain polymer with double azolate bridges between the M(II) ions as seen in previously described metal pyrazolate materials (4–9). Further insights into the nature of the 3-D lattice can be obtained from the iron atom connectivity diagram (Fig. 3). The structure involves the interconnection of 4-, 6- and 8-sided rings containing iron ions. A novel feature of this structure is the ferrocene molecules trapped in the lattice. These molecules may play a role in stabilizing the structure. Repeated preparations always generated the same material and, as described above, the ferrocenes cannot be removed by thermolysis without complete decomposition of the material.

$[Cu(1,2,4\text{-trz})_2]_x$, **2**, was prepared by the copper shot – molten azole method, which has been employed to obtain several copper(II) pyrazolate complexes, some in crystalline form suitable for X-ray structure determinations (5*a*, 5*d*). Unfortunately, all attempts to obtain the triazolate in a form suitable for definitive X-ray analysis were unsuccessful. These attempts generally involved modifications designed to reduce the rate of the reaction. This involved procedures such as lowering the temperature of the reaction (below that of the melting point of the azole) by adding small amounts of benzene or xylenes to the reaction mixture and reducing the concentration of dioxygen by employing atmospheric concentrations instead of a pure O_2 atmosphere. Although such attempts did produce the desired product, no macroscopic

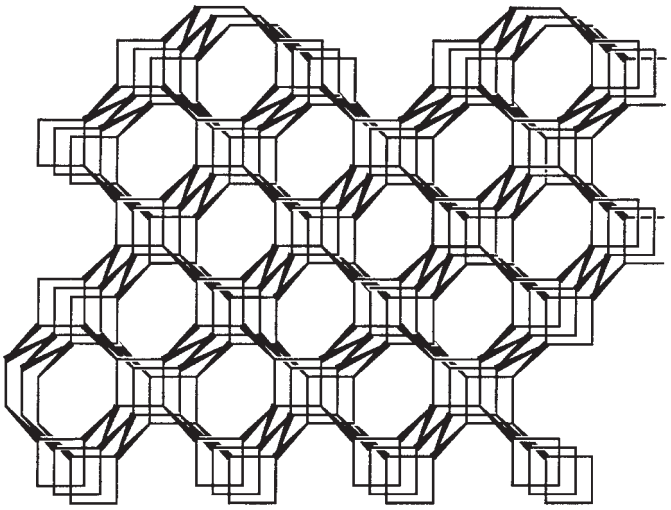
Fig. 3. Iron ion connectivity diagram for **1**.

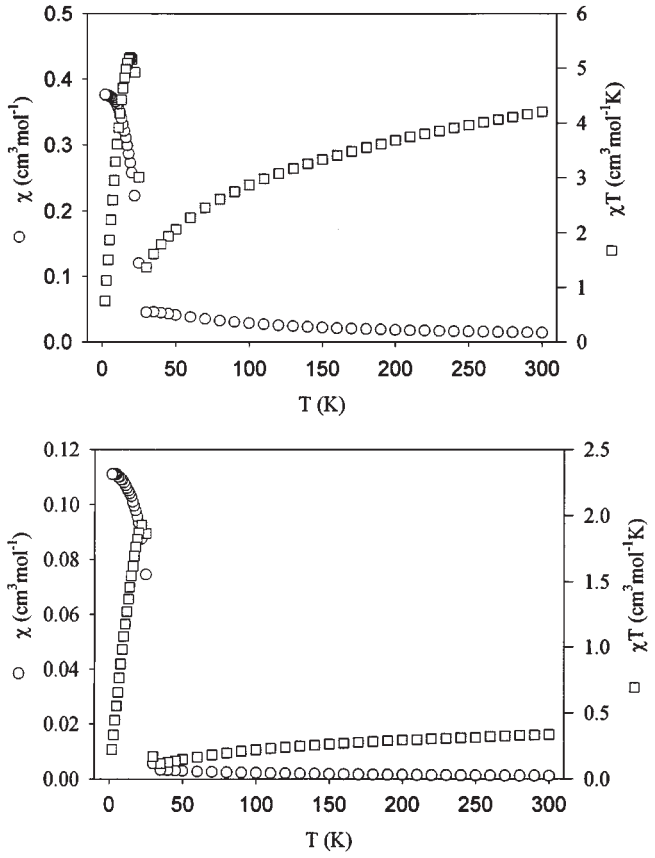


single crystals were obtained. The previously published route to this compound involving the reaction of an aqueous solution of the azole with an ammoniacal copper(II) sulfate solution (15) was also explored but yielded only microcrystalline powder.

Although the exact structure of **2** remains unknown, the polymeric nature of the material is indicated by its physical properties. The compound is stable both in air and in contact with moisture. It is insoluble in water and common organic solvents, involatile, and thermally robust. It dissolves with decomposition in concentrated mineral acids. Thermogravimetric analysis shows no mass loss due to thermal decomposition or sublimation below 320°C. Thermal decomposition appears to take place in two stages. There is a relatively rapid loss of about 40% of the initial mass between 320 and 380°C. The second stage is more gradual with about 30% of the initial mass being lost between 380 and 560°C. The 30% of the mass remaining corresponds closely to the 32% expected for a residue of copper metal.

The infrared spectrum of **2** does not contain the bands generated by ν_{N-H} stretching vibrations, thus indicating that all of the triazole is present in its deprotonated form. The electronic spectrum consists of an absorption at 35 700 cm^{-1} assigned to charge transfer and another at 17 400 cm^{-1} assigned to d→d transitions. Hathaway (16) published a correlation between band energies and stereochemistry for CuN_{4-6} chromophores. The value of 17 400 cm^{-1} obtained for the triazolate compound is consistent with six-coordination. This could be achieved if all three of the azolate nitrogen atoms are involved in binding to copper in a structure involving a 3-D covalent lattice. It should be noted, however, that two possible structures for this material were previously proposed based on evidence obtained from broad-line proton magnetic resonance spectroscopy (17). Both of these structures involved lower dimensional lattices and four coordinate copper ions.

Fig. 4. Magnetic susceptibility and χT versus temperature plots at 500 G for **1** (top) and **2** (bottom).



Magnetic properties

Magnetic susceptibility (χ) and χT versus T data on powdered samples of **1** and **2** in an applied field of 500 G are shown in Fig. 4. For both compounds χT decreases with decreasing temperature from 300 K to a critical temperature, T_c, (27 K and 35 K for **1** and **2**, respectively). Below T_c, χT increases abruptly to a maximum value (5.19 cm^3 mol^{-1} K at 19 K for **1** and 1.93 cm^3 mol^{-1} K at 22 K for **2**) before decreasing again as the temperature decreases to 2 K. The magnetic transition at T_c is also seen in the χ versus T plots (Fig. 4). The susceptibility, which increases with decreasing temperature below 300 K, shows an incipient maximum just above T_c for both compounds. Below T_c the susceptibility rises abruptly as the temperature decreases before levelling off and approaching a saturation value at the lowest temperatures studied. This magnetic behavior is very similar to that reported for $[Fe_3(imid)_6(imidH)_2]_x$ (10). It suggests a form of antiferromagnetic coupling in which perfect antiparallel alignment of spins on neighboring metal ions does not occur because of a canting of the spins. This leads to a residual spin on the metal centers and long-range ferromagnetic ordering of the spins generates weak ferromagnetism at low temperatures. Ferromagnetism is also evident in the magnetization versus field plots at several temperatures (Fig. 5). For both compounds these plots are linear above T_c and extrapolate to zero magnetization at zero applied field while below T_c they show extrapolated net magnetization at zero field. That these compounds are behaving as long-range or-

Fig. 5. Magnetization versus applied field plots at different temperatures for **1** (top) and **2** (bottom).

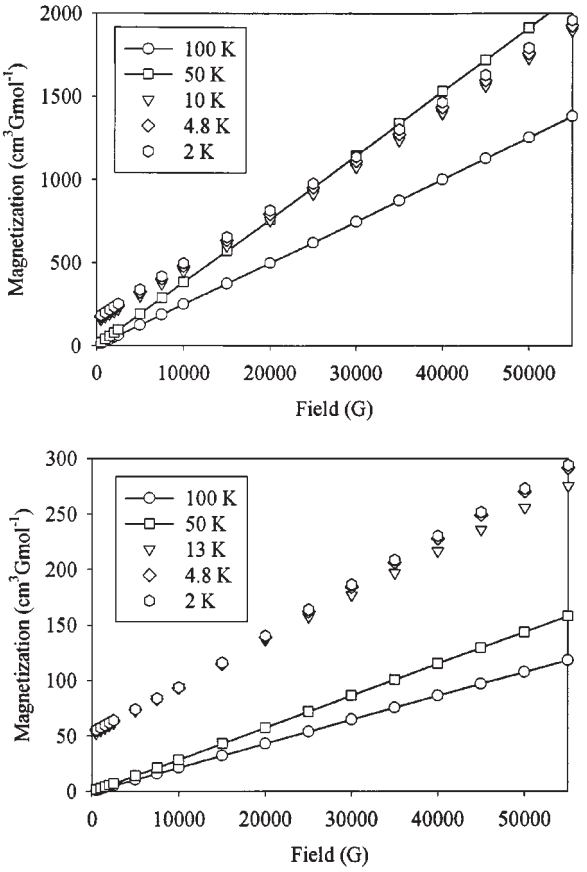

Fig. 6. Magnetic hysteresis plots at 4.8 K for **1** (top) and **2** (bottom).

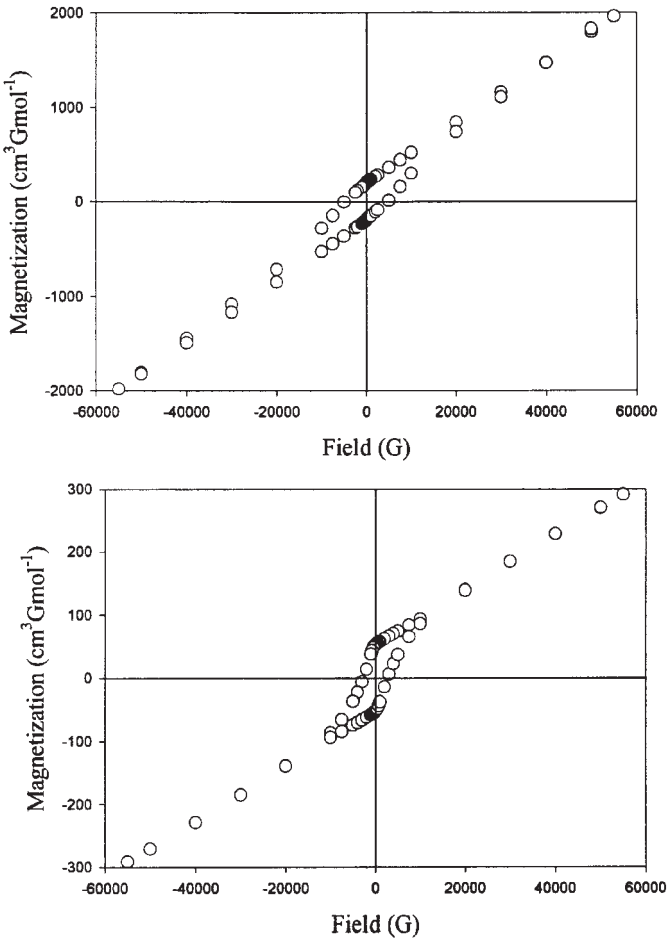

dered molecular magnets below T_c is further illustrated by hysteresis studies. In these studies, the magnetization was measured as the applied field was cycled between +50 000 G and –50 000 G at 4.8 K. The resulting hysteresis loops are shown in Fig. 6. These loops give remnant magnetizations of 200 and 55 cm^3 G mol^{-1} and coercive fields of 5000 and 2800 G for **1** and **2**, respectively.

Since the structure of **1** is known, the possibility exists of analyzing the antiferromagnetic exchange in the material by modeling the magnetic data at temperatures above T_c as was done earlier for $[Fe_3(imid)_6(imidH)_2]_x$ (10). Unfortunately, no theoretical expression is available for modeling the magnetism of a 3-D extended array of $S = 2$ ions. The structure itself revealed a feature that suggested the use of a simpler model. There are three different Fe–ligand–Fe distances in the compound: Fe···Fe = 5.95 Å (a chain along the *a* axis), and 6.06 and 6.19 Å (in the 4- and 8-membered rings). The structure is such that it can be considered as consisting of chains of ligand-bridged iron ions joined together by weaker Fe–ligand-bridged–Fe interactions. While exchange likely occurs via all three pathways, we considered the possibility that the shortest pathway dominates. Accordingly, we examined fits of the magnetic susceptibilities over the temperature range 30–300 K to the expression for a linear chain of antiferromagnetically coupled $S = 2$ centers (18). Employing an isotropic Hamiltonian of the form $H = -2\,J\,S_1S_2$ the equation for the magnetic susceptibility is

$$\chi = (Ng^2\beta^2/kT)\left[\frac{2 + 71.938x^2}{1 + 10.482x + 955.56x^3}\right]$$

where $x = |J|/kT$, J is the exchange coupling constant, g is the Landé factor, and the other symbols have their usual meaning.

To analyze the antiferromagnetic interactions in **1** using the above equation we employed susceptibility data obtained at 10 000 G. At this higher field the ferromagnetic ordering is repressed as evidenced by a less pronounced anomaly at 27 K in both the susceptibility and χT plots (Fig. 7). The best fit to these susceptibility data was obtained with $J = -2.75$ cm^{-1}, $g = 2.20$ (with $F = 0.010$), where F is the value of the function (given below) that was minimized in the fitting procedure. F also provides a measure of the goodness of fit.

$$F = \left[\frac{1}{n}\sum_{i=1}^{n}\left[\frac{\chi^i_{calc} - \chi^i_{obs}}{\chi^i_{obs}}\right]^2\right]^{1/2}$$

In the above expression n is the number of data points. The experimental and calculated susceptibility and χT data are compared in Fig. 7. In spite of the obvious limitations of

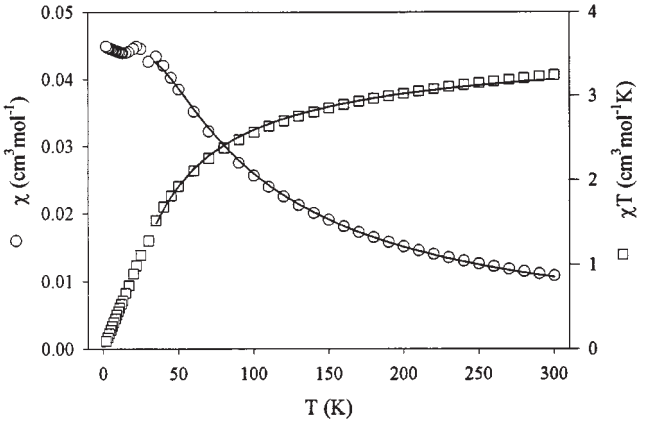
Fig. 7. Plots of magnetic susceptibility and χT versus temperature at 10 000 G for **1**. The solid lines are calculated from theory, for the temperature range 30–300 K, as described in the text.



the model, which ignores interchain exchange, the agreement between experiment and theory is good. However, because of the limitations of the model not too much importance should be attached to the actual value of *J*. That *J* is, at least, a qualitative measure of the strength of the antiferromagnetic coupling, however, is indicated by the fact that it is of the same order of magnitude as that determined previously for $[Fe_3(imid)_6(imidH)_2]_x$ in which interacting Fe(II) centers are linked by single imidazolate bridges ($J = -2.3$ cm^{-1}) (10).

Magnetic parameters for five azolate compounds, including **1** and **2** and three other azolate compounds (10, 19, 20) that exhibit low-temperature ferromagnetic ordering and canted spin antiferromagnetism, are given in Table 5. The three compounds that have structures determined from X-ray studies illustrate the fact that the phenomenon is not restricted to covalent lattices of a particular dimensionality since the antiferromagnetic exchange processes in $[Fe_3(imid)_6(imidH)_2]_x$ (10), $[Fe(4\text{-imidazolacetate})_2]_x$ (19), and **1** are considered to involve 1-D, 2-D, and 3-D pathways, respectively. Unfortunately the number of compounds of this class with known structures is too small at this time to try to correlate magnetic parameters with detailed structural features.

In summary, the studies on **1** have supported the previously stated contention (10) that azolate ligands that bridge through nitrogen atoms separated by one carbon in the heterocyclic ring will generate structures with single azolate bridges and extended arrays. Moreover, it appears this bridge geometry can generate a systematic alternation in the relative orientation of neighboring metal chromophores. These characteristics facilitate a canting of spins and long-range magnetic ordering (10). The 1,2,4-triazolate ligand may have these desirable structural features also, although confirmation of this will require the X-ray structural determination of **2** or a related system.

Abstract: The room-temperature reaction of Me_3Ga with benzimidazole 2-carboxylic acid in xylene solvent has yielded a novel crystalline hexameric gallium compound with "MeGa" moieties bridged by the doubly depronotated ligand precursor. Crystals of $[MeGa(4,5\text{-benzimidazolato-2-carboxylato})]_6{\cdot}(C_6H_6){\cdot}(m\text{-}Me_2C_6H_4)_2$ are monoclinic, a = 18.091(2), b = 17.094(2), c = 13.2215(5) Å, Z = 2, space group $C2/m$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R (F, $I \geq 3\sigma(I)$) = 0.064 (R_w (F^2, all data) = 0.134). The hexameric Ga complex contains a six-membered ring of Ga atoms, bridged by the benzimidazolate ligands with the benzo rings projecting alternately above and below the Ga plane, thus forming a ball-shaped molecule. The complex could have ideal D_{3d} symmetry, but it contains an encapsulated molecule of benzene, which distorts the regularity of the Ga_6 hexagon, and reduces the symmetry of the complex to the crystallographically observed C_{2h}. The coordination geometry at each of the two independent GaO_2N_2C centres approximates a trigonal bipyramid, with a N_2C trigonal plane, and the O atoms above and below; average dimensions are Ga—O = 2.176(2), Ga—N = 1.973(3), Ga—C = 1.927(5) Å, O-Ga-O = 165°. The unit cell also contains four *m*-xylene solvent molecules (outside the molecular cage).

Key words: gallium, crystal structure, benzene intercalate, benzimidazolecarboxylic acid.

Résumé : La réaction du Me_3Ga avec l'acide benzimidazole-2-carboxylique en solution dans le xylène, à la température ambiante, conduit à un nouveau composé hexamérique cristallin comportant des portions « MeGa » reliées par de ligand précurseur doublement déprotoné. Les cristaux du $[MeGa(4,5\text{-benzimidazolato-2-carboxylato})]_6{\cdot}(C_6H_6){\cdot}(m\text{-}Me_2C_6H_4)$ sont monocliniques, groupe d'espace $C2/m$, avec a = 18,091(2), b = 17,094(2) et c = 13,2215(5) Å et Z = 2. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R (F, $I \geq 3\sigma(I)$) = 0,064 (R_w (F^2, toutes les données = 0,134). Le complexe hexamère du Ga contient un cycle à six chaînons d'atomes de Ga reliés par ligands benzimidazolates dans lesquels les noyaux benzo sont projetés alternativement au-dessus et au-dessous du plan des Ga formant ainsi une molécule en forme de balle. Le complexe pourrait avoir une symétrie idéale D_{3d}; elle contient toutefois une molécule de benzène encapsulée qui déforme la régularité de l'hexagone Ga_6 et qui réduit ainsi la symétrie observée cristallographiquement du complexe à C_{2h}. La géométrie de coordination de chacun des deux centres GaO_2N_2C indépendantes correspond approximativement à une bipyramide trigonale avec un N_2C trigonal plan et les atomes d'O au-dessus et au-dessous; les dimensions moyennes sont : Ga—O = 2,176(2), Ga—N = 1,973(3), Ga—C = 1,927(5) Å et O-Ga-O = 165°. La maille élémentaire contient aussi quatre molécules du solvant (*m*-xylène) (en dehors de la cage moléculaire).

Mots clés : gallium, structure cristalline, benzène intercalé, acide benzimidazolecarboxylique.

[Traduit par la Rédaction]

Introduction

Our interest in ligands capable of giving polymeric transition metal complexes is well documented, particularly with pyrazolate and imidazolate bridging ligands (1–5). The present study was undertaken to explore the possibility of utilizing the 4,5-benzimidazole-2-carboxylic acid molecule as a ligand precursor. Reaction with 2 molar equivalents of Me_3Ga was anticipated to yield the bis-Me_2Ga complex, **A**, shown in eq. [1]:
since it is well documented that Me_3Ga readily loses one Me group in its reactions with active hydrogen species (6), whereas

the "Me_2Ga" moiety is quite robust and resists attack even by water (7). It was somewhat surprising, therefore, that the crystalline product isolated was a hexameric species containing only MeGa units bridged by doubly deprotonated ligand precursors (see Fig. 1). The entrapment of benzene molecules (from the xylene solvent) was also unexpected.

Experimental

Materials were handled in a conventional high-vacuum line or in a glove box under an atmosphere of oxygen-free dry dinitrogen. Solvents were dried and distilled before use. Gas volumes are at STP. Trimethylgallium was prepared as described previously, from gallium and dimethylmercury (8). The benzimidazole-2-carboxylic acid monohydrate (a gift from Dr. P.N. Preston of Heriot-Watt University, Edinburgh) was prepared by the method of Bistrzycki and Przeworski (9). The anhydrous compound was obtained by vacuum treatment of the hydrate at ~70ºC (N.B. Even at 100ºC the anhydrous material is prone to decarboxylation).

Preparation of $[MeGa{\cdot}C_8H_4N_2O_2]_6(C_6H_6)(m\text{-}Me_2C_6H_4)_2$

The anhydrous benzimidazole-2-carboxylic acid (0.162 g; 1.0 mmol) was transferred to a 250 mL round-bottomed flask fitted with break-seal side arm. Xylene solvent was added and the reaction flask was then cooled to –196ºC and

[a]Temperature 180 K, Rigaku/ADSC CCD diffractometer, Mo K_α (λ = 0.7109 Å), graphite monochromator, takeoff angle 6.0°, aperture 94.0 × 94.0 mm at a distance of 39.15(3) mm from the crystal, $\sigma^2(F^2) = (C + B)/Lp2$ (C = scan count, B = background count), function minimized $\Sigma w(|F_o^2| - |F_c^2|)^2$ where $w = 1/\sigma^2(F_o^2)$, $R(F) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w(F^2) = (\Sigma w(|F_o^2| - |F_c^2|)^2/\Sigma w|F_o^2|^2)^{1/2}$, and gof = $[\Sigma w(|F_o^2| - |F_c^2|)^2/(m - n)]^{1/2}$.

[b]Includes crystal decay (if any), absorption, and scaling corrections performed in a single step.

evacuated. Me_3Ga (0.229 g; 2.0 mmol) was vacuum transferred into the reaction vessel, which was then flame-sealed. The contents of the flask were then warmed slowly to room temperature during which time gas evolution was observed. After remaining at room temperature overnight the product mixture was cooled to –196°C, the break-seal on the flask opened, and the volume of methane evolved in the reaction measured using a Toepler pump (found: 45.1 mL; calcd.: 44.8 mL (for 2 mmol)). The contents of the flask were then warmed to room temperature. The clear solution of the product was reduced in volume under vacuum and then placed in the glove box. Slow evaporation of further solvent led to the collection, in high yield, of colorless crystals of the solvated product $[MeGa{\cdot}C_8H_4N_2O_2]_6(C_6H_6)(m\text{-}Me_2C_6H_4)_2$. Anal. calcd.: C 51.9, H 3.9, N 9.6; found: C 52.3, H 4.2, N 9.7%. The air-stable colorless crystals were subjected to single crystal X-ray analysis (see below). The mass spectrum of the product did not show detectable signals due to the parent hexamer ion, but a weak group of signals around m/e 1228 corresponds to the $[MeGa.C_8H_4N_2O_2]_5^+$ cluster ion. A strong signal due to the monomeric species, $[MeGaC_8H_4N_2O_2]^+$ was also detected. The ^{1}H NMR spectrum of the complex in C_6D_6 solution showed one signal for the MeGa groups at δ 0.40, together with xylene Me signals at δ 2.20 and aromatic ring proton signals at δ ~7.0. The infrared spectrum (KBr disc) showed a characteristic Ga–C stretching vibration at 598 cm^{-1}. A thermal gravimetric analysis experiment revealed the compound to be thermally stable to 150°C. All solvated xylene and entrapped benzene were lost by ~230°C, and major cage breakdown was evident after ~320°C.

X-ray crystallographic analysis of $[MeGa(4,5\text{-benzimidazolato-2-carboxylato})]_6{\cdot}(C_6H_6){\cdot}(m\text{-}Me_2C_6H_4)_2$

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares based on 18 744 reflections with 2θ = 4.0°–60.2°. The data were processed,[2] corrected for Lorentz and polarization effects, and for absorption (semiempirical, multi-scan, based on analysis of symmetry-equivalent data). Space group *C2/m* was deduced from the systematic absences, a statistical analysis of the intensity distribution, and successful solution and refinement of the structure.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2\ B_{bonded\ atom}$. No corrections for secondary extinction were necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (10). Final atomic coordinates and equivalent isotropic thermal parameters are in Table 2, and a summary of important bond lengths and angles in Table 3. Complete tables of atomic coordinates, anisotropic thermal parameters, bond lengths and angles, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[3]

Results and discussion

The reaction of Me_3Ga with ligands containing acidic hydrogen yields adducts that readily eliminate methane to produce cyclic products containing Me_2Ga moieties (6). The degree of association of the product materials is determined by a balance between steric effects, valency angle strain, and entropy factors (6, 11, 12). Thus, for example, the reaction

of pyrazoles with Me_3Ga yields, via methane elimination, dimeric products, $[Me_2Gapz]_2$, which contain six-membered Ga_2N_4 rings (13–15). On the other hand, the reaction of 2-methylimidazole or water with Me_3Ga results in the formation of the tetrameric products $[Me_2Ga{\cdot}Meimid]_4$ (16) and $[Me_2GaOH]_4$ (17), respectively.

The present study was designed to investigate the feasibility of using the doubly deprotonated benzimidazole-2-carboxylic acid dianion as a bridging ligand in the preparation of polymeric transition metal complexes. It was anticipated that in the 2:1 reaction (eq. [1]), each molecule of Me_3Ga would lose one Me group, resulting in the product **A**. It was somewhat surprising, therefore, when the isolated compound contained only MeGa moieties linked together by the deprotonated ligand precursor. (A 1:1 reaction also yielded the cyclic hexamer.) The observed cyclic hexamer (Fig. 1) was also unique in that within its central cavity was entrapped a benzene molecule. In addition, the isolated crystals contained two *m*-xylene molecules of crystallization per hexameric unit in the lattice; the encapsulated molecule is definitely benzene, with no electron-density peaks that could be interpreted as (ordered or disordered) xylenes.

Crystals of the product are built from hexameric molecules (Fig. 1) that contain a planar six-membered ring of Ga atoms, bridged by coordination with the N and O atoms of the benzimidazolate ligands. The benzo rings of the ligands project alternately above and below the Ga plane, thus forming a ball-shaped molecule, with the six Ga atoms around a central seam. The molecule could have ideal D_{3d} symmetry (Fig. 1 is a view along the possible C_3 axis), but it contains an encapsulated molecule of benzene, which distorts the regularity of the Ga_6 hexagon into an elliptical shape; the Ga···Ga distances remain all nearly equal at about 5.4 Å, but the Ga···Ga···Ga angles increase to 132° at the two Ga1 atoms, and decrease to 114° at the four Ga2 atoms. The symmetry of the complex is thus the crystallographically

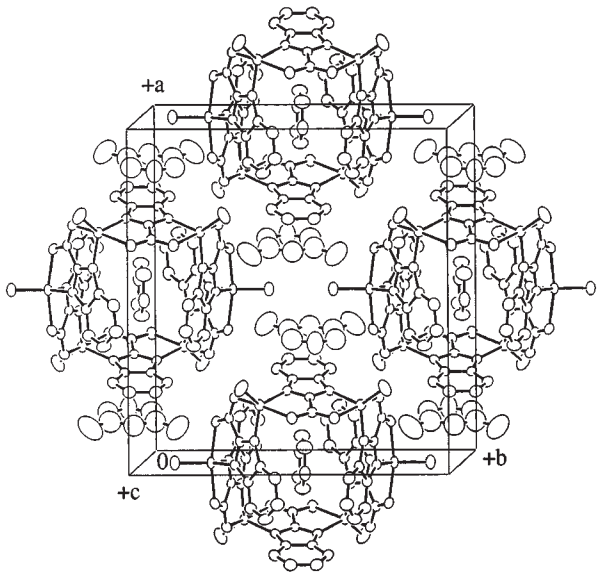
Fig. 2. View of the unit cell of the hexameric Ga complex; the positive direction of the *c*-axis points away from the viewer.



imposed C_{2h}, with the molecule and the encapsulated benzene situated on the 2/*m* site. The benzene is held in position only by van der Waals forces; the shortest C(benzene)···C(hexamer) distances are in the range 3.443–3.589(6) Å. Nevertheless the presence of benzene (or other possible intercalated molecule) may be crucial to formation of the hexamer.

The coordination geometry at each of the two independent GaO_2N_2C centres approximates a trigonal bipyramid, with a N_2C trigonal plane, and the O atoms above and below. Average dimensions are Ga—O = 2.176(2), Ga—N = 1.973(3), Ga—C = 1.927(5) Å, O-Ga-O = 165°; the O atoms are displaced away from the methyl C atoms. All the five- and six-membered rings in the molecule, including the chelate rings, are essentially planar (there are some minor foldings that are statistically significant, but not chemically important).

The crystal also contains *m*-xylene solvate molecules, which occupy positions across the mirror plane, but outside the Ga complex (Fig. 2). These solvate molecules exhibit rather high thermal parameters (Table 2), and their dimensions are less accurately determined.

These results are encouraging in that they demonstrate both the bridging capabilities and the flexibility of this novel ligand system. Currently work is in progress to incorporate magnetically interesting transition metal ions with this bridging anion in new polymeric materials.

Abstract: Reaction of pyridinium and phosphonium 2-carboxy-1-formyl-2-oxoethylides with oxybis(diphenylborane) yields 5-(2-oxo-1-(pyridinio or phosphonio)ethylidene)-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanones, which represent novel types of boron nitrogen and boron phosphorus betaines, respectively. Crystals of 5-(2-oxo-1-pyridinioethylidene)-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, **1***a*, are monoclinic, a = 15.589(3), b = 12.366(2), c = 20.1869(11) Å, β = 111.227(2)°, Z = 8 (two independent molecules), space group $P2_1/a$; and those of 5-[2-oxo-1-(triphenylphosphonio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclo-pentanone, **11**, are monoclinic, a = 9.6922(7), b = 25.027(2), c = 11.3041(4) Å, β = 92.1418(13)°, Z = 4 (two independent molecules), space group $P2_1$. The structures were solved by direct methods and refined by full-matrix least-squares procedures to R (F, $I \geq 3\sigma(I)$) = 0.047 and 0.042 (R_w (F^2, all data) = 0.096 and 0.088), respectively, for **1***a* and **11**.

Key words: pyridinium ylides, phosphonium ylides, bisacyl methylide diphenylboron chelates, boron nitrogen betaines, boron phosphorus betaines, organoboron compounds, crystal structures.

Résumé : Les réactions des 2-carboxy-1-formyl-2-oxoéthylures de pyridinium et de phosphonium avec l'oxybis(diphénylborane) conduisent aux 5-(2-oxo-1-pyridinio ou phosphonio)éthylidène)-2,2-diphényl-1,3-dioxa-2-borata-cyclopentan-4-ones respectivement qui correspondent à de nouveaux types de bétaïnes bore azote et bore phosphore. Les cristaux de la 5-(2-oxo-1-pyridinioéthylidène)-2,2-diphényl-1,3-dioxa-2-borata-cyclopentan-4-one, **1***a*, sont monocliniques, groupe d'espace $P2_1/a$, avec a = 15,589(3), b = 12,366(2) et c = 20,1869(11) Å, β = 111,227(2)° et Z = 8 (deux molécules indépendantes); celles de la 5-[2-oxo-1-(triphénylphosphonio)éthylidène]-2,2-diphényl-1,3-dioxa-2-borata-cyclopentan-4-one, **11**, sont monocliniques, groupe d'espace $P2_1$, avec a = 9,6922(7), b = 25,027(2) et c = 11,3041(4) Å, β = 92,1418(13)° et Z = 4 (deux molécules indépendantes). On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R (F, $I \geq 3\sigma(I)$) = 0,047 et 0,042 (R_w (F^2, toutes les données = 0,096 et 0,088) respectivement pour **1a** et **11**.

[Traduit par la Rédaction]

Introduction

From a ring-opening reaction of pyridinium and phosphonium betaines of squaric acid the corresponding bisacyl methylides, **2** and **10**, were obtained (1). In these compounds both a formyl and an oxalyl group flank the ylidic carbon atom and contribute to the resonance stabilization. In the course of our investigations on stable boron nitrogen betaines (2), and also on the grounds of interest in zwitterionic boron phosphorus compounds (3), we employed these pyridinium and phosphonium ylides as bidentate ligands in reactions with diphenylborinic acid. Several modes of chelation are possible. The oxalyl moieties in **2** or **10** might lead to the formation of five-membered boron chelates[3] by replacement

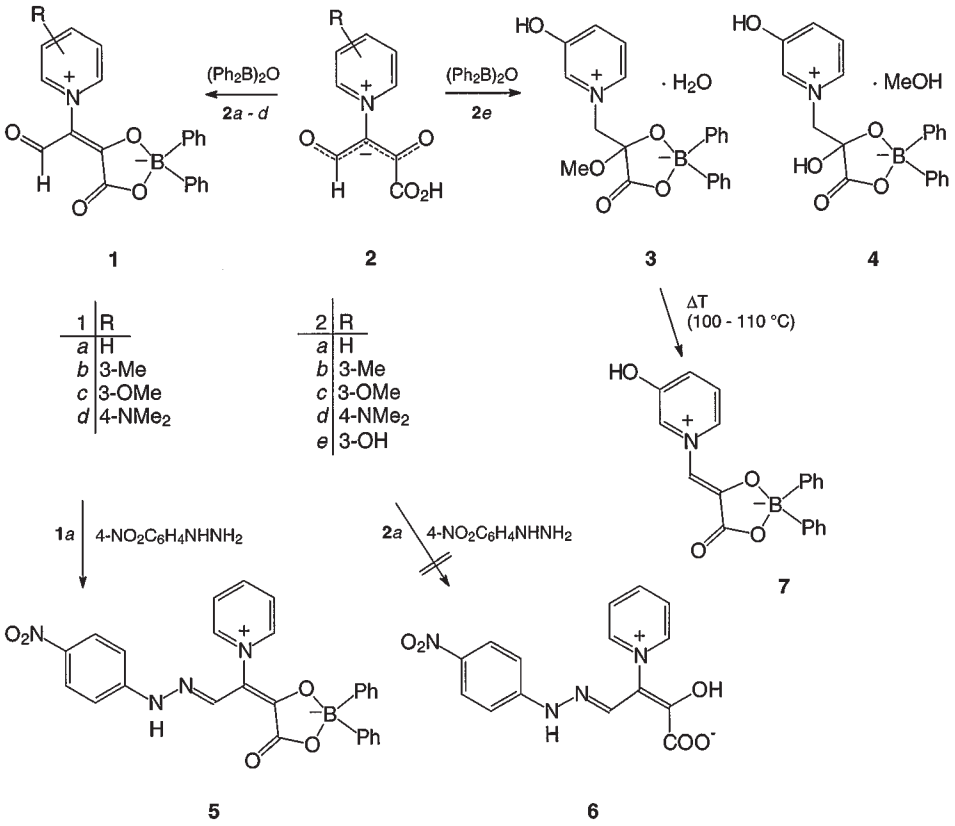
[3]Here and elsewhere in this work the term "boron chelate" refers to a "chelate" of the Ph_2B^+ moiety. Considering the diphenylborenium moiety as a "pseudometal" explains much of the chemistry of these systems even though the bonding is (necessarily) quite different from that in metal complexes.

 © 1999 NRC Canada



of the proton with a diphenylborenium (Ph_2B^+) ion, causing the migration of the (formal) negative charge from the mesomeric ylide system to the boron chelate ring and resulting in the hypothetical *B,N*- and *B,P*-betainic structures **1** and **11**, respectively. In addition to a five-membered chelate **1**, six- or seven-membered chelate rings as depicted in the pyridinium compounds **8** or **9**, and the analogous phosphonium derivatives, had to be taken into consideration. In the present study we describe the preparation of the desired diphenylboron chelates, some of their chemical and physical properties, and the unambiguous proof of two of the molecular structures by X-ray crystallographic analysis.

Experimental

General procedures

Compounds **2***a-e* and **10** were synthesized as described in the literature (1). Oxybis(diphenylborane) was prepared according to literature methods (4). All reactions were carried out under normal conditions, without protective gas atmosphere. Melting points (uncorrected): Linström apparatus. IR (KBr): Pye Unicam SP 3-100 and SP 3-200. ^{1}H and ^{13}C NMR: Bruker AM 400. ^{11}B and ^{31}P NMR: Bruker AC 200. MS: Finnigan MAT 8430. Elemental analyses: Carlo Erba CHNO elemental analyzer 1106-1 and 1106-2.

5-(2-Oxo-1-pyridinioethylidene)-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 1*a*

Pyridinium (2-carboxy-1-formyl-2-oxoethylide) **2***a* (0.97 g, 5.0 mmol) is dissolved in 20 mL of methanol with heating and stirring. After addition of a solution of oxybis(diphenylborane) (0.87 g, 2.5 mmol) in 5 mL of methanol and refluxing with stirring for 15 min, the solvent is removed in vacuo to a residue of ca. 5 mL. The product crystallizes on cooling. Yield: 1.4 g (78%) of yellowish crystals; mp 215–217°C (dec.; from chloroform – diethyl ether). Infrared (KBr, cm^{-1}): 1735 (C=O), 1620 (C=C); ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 7.11–7.24 (m, 10 aromatic H), 8.30–8.34 (m, 2 aromatic H), 8.73–8.77 (m, 1 aromatic H), 8.99–9.01 (m, 2 aromatic H), 10.62 (s, CH=O). ^{13}C NMR (100 MHz, DMSO-d_6 –TMS), δ (ppm): 123.94 (s), 126.29 (d), 127.05 (d), 128.33 (d), 131.35 (d), 131.55 (s), 147.09 (d), 147.28 (d), 159.60 (s), 162.84 (s), 181.70 (d, CH=O). ^{11}B NMR (64.2 MHz, DMSO-d_6–Et_2OBF_3), δ (ppm): 9.9 ($W_{1/2}$ = 642 Hz). Mass spectrum (EI, 70 eV, 180°C), *m/z*: 357 (3%, M^+), 328 (3%, M^+ – CHO), 312 (7%, M^+ – CO_2H), 280 (100%, M^+ – Ph). Anal. calcd. for $C_{21}H_{16}BNO_4$: C 70.62, H 4.52, N 3.92; found: C 70.46, H 4.37, N 3.76.

The product gives a blue-colored solution upon the addition of diphenylcarbazone in ethanol, indicating the presence of the chelated diphenylborenium (Ph_2B^+) ion (5). Crystals suitable for X-ray analysis were obtained by slow crystallization from tetrahydrofuran – diethyl ether.

5-[2-Oxo-1-(3-methylpyridinio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 1*b*

3-Methylpyridinium (2-carboxy-1-formyl-2-oxoethylide) **2***b* (1.0 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) as described above for **1***a*. Yield: 1.3 g (72%) of yellowish crystals; mp 186–187°C (dec.; from tetrahydrofuran – diethyl ether). Infrared (KBr, cm^{-1}): 1730 (C=O), 1615 (C=C); ^{1}H NMR (400 MHz, DMSO-d_6 –TMS), δ (ppm):

1*b* gives a blue-colored solution upon addition of diphenylcarbazone as described for **1***a*.

5-[2-Oxo-1-(3-methoxypyridinio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 1*c*

3-Methoxypyridinium (2-carboxy-1-formyl-2-oxoethylide) **2***c* (1.1 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) as described above for **1***a*. Yield: 1.2 g (62%) of yellowish crystals; mp 190–191°C (dec.; from methanol – diethyl ether). Infrared (KBr, cm^{-1}): 1735 (C=O), 1615 (C=C). ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 3.99 (s, CH_3), 7.11–7.25 (m, 10 aromatic H), 8.22–8.25 (m, 1 aromatic H), 8.37–8.39 (m, 1 aromatic H), 8.62 (d, 1 aromatic H), 8.92 (d, 1 aromatic H), 10.60 (s, CH=O). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 57.48 (q, CH_3), 124.18 (s), 126.27 (d), 127.02 (d), 128.57 (d), 131.38 (d), 132.01 (d), 134.83 (d), 139.60 (d), 158.27 (s), 159.92 (s), 162.87 (s), 181.50 (d, CH=O). Mass spectrum (EI, 70 eV, 170°C), *m/z*: 387 (3%, M^+), 358 (2%, M^+ – CHO), 310 (100%, M^+ – Ph). Anal. calcd. for $C_{22}H_{18}BNO_5$: C 68.24, H 4.69, N 3.62; found: C 67.74, H 4.70, N 3.49.

1*c* gives a blue-colored solution upon addition of diphenylcarbazone as described for **1***a*.

5-[2-Oxo-1-(4-dimethylaminopyridinio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 1*d*

4-Dimethylaminopyridinium (2-carboxy-1-formyl-2-oxoethylide) **2***d* (1.2 g, 5.0 mmol) is reacted with oxybis(diphenylborane) (0.87 g, 2.5 mmol) as described above for **1***a*. Yield: 1.7 g (83%) of yellowish crystals; mp 258–260°C (dec.; from tetrahydrofuran – diethyl ether). Infrared (KBr, cm^{-1}): 1720 (C=O), 1640, 1610 (C=C). ^{1}H NMR (400 MHz, DMSO-d_6 –TMS), δ (ppm): 3.22 (s, CH_3), 7.08–7.26 (m, 12 aromatic H), 8.08 (d, 2 aromatic H), 10.60 (s, CH=O). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 39.91 (q, CH_3), 107.42 (d), 122.59 (s), 126.15 (d), 126.99 (d), 131.37 (d), 143,66 (d), 156.01 (s), 160.10 (s), 163.46 (s), 183.20 (d, CH=O). Mass spectrum (EI, 70 eV, 230°C), *m/z*: 400 (2%, M^+), 371 (3%, M^+ – CHO), 323 (100%, M^+ – Ph). Anal. calcd. for $C_{23}H_{21}BN_2O_4$: C 69.02, H 5.29, N 7.00; found: C 68.92, H 5.43, N 6.81.

1*d* gives a blue-colored solution upon addition of diphenylcarbazone as described for **1***a*.

5-[2-(4-Nitrophenylhydrazono)-1-pyridinioethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 5

1*a* (0.36 g, 1.0 mmol) is dissolved in 20 mL of ethanol with heating and stirring. After addition of a hot solution of 4-nitrophenylhydrazine (0.15 g, 1 mmol) in 10 mL of ethanol and storage at room temperature for 7 days, the precipitated product is collected. Yield: 0.45 g (91%) of yellow crystals; mp 241–242°C (dec.; dimethylformamide–methanol). Infrared (KBr, cm^{-1}): 1690 (C=O), 1625 (C=C). ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 6.67 (d, 2 aromatic H), 7.07–7.22 (m, 8 aromatic H), 7.99 (d, 2 aromatic H), 8.36–8.39 (m, 2 aromatic H), 8.84 (t, 2 aromatic H + CH=N), 9.20 (d, 2 aromatic H), 11.51 (s, exchangeable, NH). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 110.55 (d), 119.33 (s), 125.70 (d), 125.98 (d), 126.74 (d),

5-Methoxy-5-(3-hydroxypyridiniomethyl)-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone-hydrate, 3

3-Hydroxypyridinium (2-carboxy-1-formyl-2-oxoethylide) **2***e* (1.0 g, 5.0 mmol) is suspended in 20 mL of methanol with heating and stirring. After addition of a solution of oxybis(diphenylborane) (0.87 g, 2.5 mmol) in 5 mL of methanol and refluxing with stirring for 15 min, the solvent is removed in vacuo to a residue of ca. 5 mL. The product crystallizes on cooling. Yield: 1.3 g (66%) of colorless crystals; mp 90–100°C (from methanol). Infrared (KBr, cm^{-1}): 3400, 2750, 2640 (OH), 1695 (C=O). ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 2.89 (s, CH_3), 3.35 (s, broad, exchangeable, H_2O), 4.55–4.64 (q, CH_2), 6.89–7.08 (m, 8 aromatic H), 7.30–7.34 (m, 2 aromatic H), 7.45–7.49 (m, 1 aromatic H), 7.53–7.56 (m, 1 aromatic H), 8.10 (m, 2 aromatic H), 11.66 (s, broad, exchangeable, OH). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 50.48 (q, CH_3), 63.92 (t, CH_2), 99.96 (s, *C*-OCH_3), 124.40 (d), 125.96 (s), 126.18 (d), 126.32 (d), 127.16 (d), 130.08 (d), 130.59 (d), 130.85 (d), 133.30 (d), 136.46 (d), 155.71 (s), 172.43 (s, C=O). Anal. calcd. for $C_{21}H_{22}BNO_6$: C 63.82, H 5.61, N 3.54; found: C 64.47, H 5.46, N 3.42.

5-(3-Hydroxypyridiniomethylene)-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 7

3 (0.20 g, 5.0 mmol) is heated for 10 min, without solvent, to ca. 100–110°C. The residue is washed with hot methanol. Yield: 0.16 g (93%) of a pale yellow powder; mp 217–219°C (dec.; from tetrahydrofuran – diethyl ether). Infrared (KBr, cm^{-1}): 3420, 2840, 2720 (OH), 1680 (C=O), 1620 (C=C). ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 7.09–7.21 (m, 6 aromatic H), 7.28 (s, CH=), 7.36–7.38 (m, 4 aromatic H), 7.79–7.81 (q, 1 aromatic H), 7.93–7.97 (q, 1 aromatic H), 8.96 (d, 1 aromatic H), 9.22 (t, 1 aromatic H), 11.98 (s, broad, exchangeable, OH). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 104.21 (d), 125.83 (d), 126.86 (d), 128.33 (d), 129.09 (d), 129.47 (d), 131.40 (d), 132.99 (d), 145.85 (s), 156.65 (s), 166.39 (s). Anal. calcd. for $C_{20}H_{16}BNO_4$: C 69.60, H 4.67, N 4.06; found: C 69.42, H 4.60, N 3.94.

5-[2-Oxo-1-(triphenylphosphonio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 11

2,4-Dioxo-3-(triphenylphosphoranylidene)butanoic acid **10** (1) (0.38 g, 1.0 mmol) is dissolved in 20 mL of ethanol with heating and stirring. After addition of a solution of oxybis-(diphenylborane) (0.17 g, 0.5 mmol) in 5 mL of ethanol and refluxing with stirring for 15 min, the precipitated product is separated. Yield: 0.53 g (98%) of colorless crystals; mp 260–261°C (dec.; from 2-propanol – diethyl ether). Infrared (KBr, cm^{-1}): 1740 (C=O), 1650 (C=C). ^{1}H NMR (400 MHz, DMSO-d_6 –TMS), δ (ppm): 6.78–6.80 (m, 4 aromatic H), 7.02–7.06 (m, 6 aromatic H), 7.59–7.81 (m, 15 aromatic H), 10.96 (d, J = 22.1 Hz, CH=O). ^{13}C NMR (100 MHz, DMSO-d_6–TMS), δ (ppm): 119.92 (d, J = 91.1 Hz, =C-P), 125.90 (d), 126.63 (d), 129.46 (d), 129.59 (d), 130.70 (d), 133.55 (d), 133.65 (d), 133.74 (d), 133.77 (s), 188.57 (d, CH=O). ^{31}P NMR (81 MHz, DMSO-d_6–H_3PO_4), δ (ppm): 14.8. Mass spectrum (EI, 70 eV, 200°C), *m/z*: 540 (3%, M^+), 463 (100%, M^+ – Ph), 435 (12%, 463 – CO). Anal. calcd. for $C_{34}H_{26}BO_4P$: C 75.57, H 4.85; found: C 75.14, H 4.80.

Crystals suitable for X-ray analysis were obtained by slow crystallization from chloroform – diethyl ether.

5-[2-(4-Nitrophenylhydrazono)-1-(triphenylphosphonio)ethylidene]-2,2-diphenyl-1,3-dioxa-2-borata-4-cyclopentanone, 12

11 (0.54 g, 1.0 mmol) is dissolved in 20 mL of dichloromethane with heating and stirring. After addition of a hot solution of 4-nitrophenylhydrazine (0.15 g, 1.0 mmol) in 10 mL of ethanol and refluxing with stirring for 1 h, the solution is evaporated in vacuo to dryness. The solid residue is washed with methanol. Yield: 0.27 g (40%) of a yellow powder; mp 228–229°C (dec.; from dimethylformamide–methanol). Infrared (KBr, cm^{-1}): 1695 (C=O). ^{1}H NMR (400 MHz, DMSO-d_6–TMS), δ (ppm): 6.77–6.79 (m, 2 aromatic H), 6.97–7.02 (m, 4 aromatic H), 7.09–7.15 (m, 4 aromatic H), 7.39 (d, 2 aromatic H), 7.51–7.65 (m, 10 aromatic H), 7.74–7.86 (m, 8 aromatic H), 9.33 (d, CH=), 11.11 (s, broad, exchangeable, NH). Anal. calcd. for $C_{40}H_{31}BN_3O_5P$: C 71.12, H 4.63, N 6.22; found: C 70.57, H 4.49, N 6.19.

X-ray crystallographic analyses of 1*a* and 11

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares based on 9640 reflections with 2θ = 4.0°–60.1° for **1***a* and 19 997 reflections with 2θ = 4.0°–60.2° for **11**. The data were processed,[4] corrected for Lorentz and polarization effects, and for absorption (based on analysis of symmetry-equivalent data).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. There are two independent molecules in the asymmetric units of both **1***a* and **11**. For **11** the structure analysis was initiated in the noncentrosymmetric space group $P2_1$ on the basis of the *E*-statistics, this choice being validated by subsequent calculations. The two independent molecules in the asymmetric unit of **11** are mirror images of one another and are related by a non-crystallographic inversion centre. The non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and B_H = 1.2 $B_{\text{bonded atom}}$. No corrections for secondary extinction were necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (6). Parallel refinement of the mirror image of **11** resulted in marginally greater residuals (*R* and R_w ratios: both 1.001). This small difference is not unexpected in view of the pseudo-inversion centre and the small anomalous scattering effect. Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, selected bond angles, and intra-annular

[a]Temperature 180 K, Rigaku/ADSC CCD diffractometer, Mo K_α (λ = 0.71069 Å), graphite monochromator, takeoff angle 6.0°, aperture 94.0 × 94.0 mm at a distance of 39.2 mm from the crystal, $\sigma^2(F^2) = (C + B)/Lp^2$ (C = scan count, B = background count), function minimized $\Sigma w(|F_o^2| - |F_c^2|)^2$ where $w = 1/\sigma^2(F_o^2)$, R (F) = $\Sigma||F_o| - |F_c||/\Sigma|F_o|$, R_w (F^2) = $(\Sigma w(|F_o^2| - |F_c^2|)^2/\Sigma w|F_o^2|^2)^{1/2}$, and gof = $[\Sigma w(|F_o^2| - |F_c^2|)^2/(m - n)]^{1/2}$.

[b]Two independent molecules.

[c]Includes crystal decay (if any), absorption, and scaling corrections performed in a single step.

[d]Includes Friedel pairs, 7586 are unique.

torsion angles appear in Tables 2–5, respectively. Complete tables of bond lengths and angles, hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes are available as supplementary material.[5]

Results and discussion

Reaction of the pyridinium ylides **2***a*–**2***d* with oxybis(diphenylborane) gives crystalline compounds having elemental analyses and ^{1}H NMR spectroscopic data consistent with the postulated diphenylboron chelate structure **1** as well as isomeric structures such as **8** and **9**. A chelate system with a tetracoordinated boron nucleus is also indicated by the ^{11}B NMR spectrum of **1***a*, displaying a typical ^{11}B NMR signal at $\delta(Et_2OBF_3)$ = 9.9 ppm. The intact diphenylboron moiety is confirmed by a color reaction with diphenylcarbazone, indicating the presence of the Ph_2B^+ ion via rechelatization (5). Strong absorption bands between 1720 and 1735 cm^{-1} in the infrared spectra indicate either free aldehyde groups as in **1**, and (or) boryloxyacyl moieties (B-O-C=O) as in **1** and **9**, respectively. Similar C=O stretching frequencies between 1700 and 1750 cm^{-1} have been noted for various diphenylboron chelates with one carboxylate ligand involved (7). Diphenylboron chelates of 1,3-dicarbonyl compounds, comparable to structure **8**, however, do not show any intense C=O absorptions at all in the range between 1600 and 2000 cm^{-1} (8). To provide a means of distinguishing be-

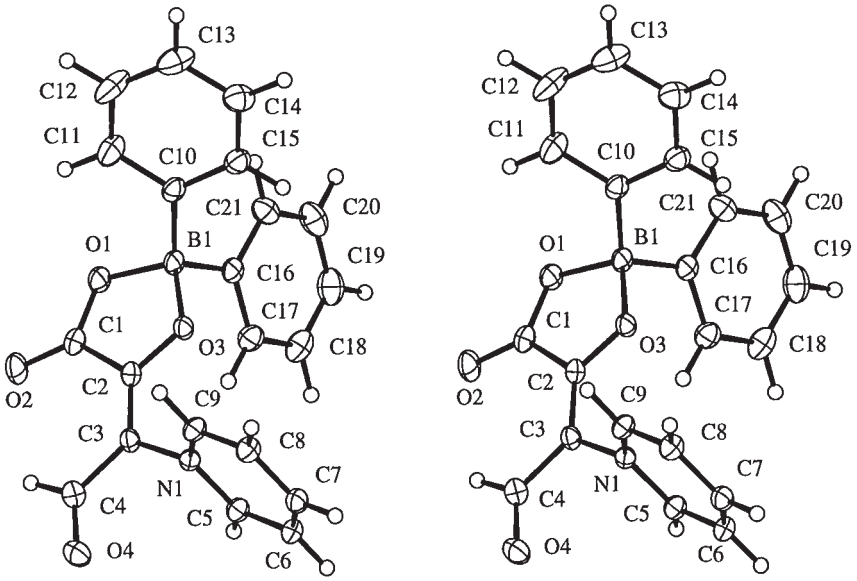
[a] $B_{eq} = (8/3)\pi^2 \Sigma \Sigma(U_{ij}a_{i*}a_{j*}(\mathbf{a}_i.\mathbf{a}_j))$.

Fig. 1. Stereoview of one of the two independent molecules of **1***a*; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.



tween the possible isomers, an X-ray crystallographic analysis was performed on compound **1***a*, which gave suitable single crystals.

The X-ray analysis establishes the molecular structure **1***a* (Fig. 1), containing a five-membered boron chelate ring formed by the oxalyl residue of the ligand **2***a*.[6] The ylidic structure **2** has thus been transformed into the zwitterionic structure of **1**, a completely new type of boron nitrogen betaine (2*a*). Chelate structures analogous to **1***a* can also be ascribed with high probability to the substituted derivatives **1***b*–**1***d*.

The (*Z*)-configuration at the C(2)—C(3) double bond (C(23)—C(24) for the second independent molecule) allows an intramolecular C-H···O interaction between the formyl

[6] The chelating properties of the pyridinium ylides **2** might also be involved in the formation of a colored complex with $FeCl_3$ and the precipitation of reaction products with Cu(II), Ni(II), and Zn ions in aqueous solution (1).

C(29)—B(1)	1.599(4)	C(63)—B(2)	1.608(4)

group involving C(4)—H(1) (C(25)—H(17)) and the carboxyl oxygen atom O(2) (O(6)). The geometry of this interaction is consistent with the presence of an intramolecular hydrogen bond with some contribution to the molecular arrangement (9) (C···O = 3.048(2) (3.025(2)) Å, H···O = 2.41 (2.39) Å, C-H···O = 122° (122°)).

The observed bond lengths are consistent with the distribution of double bonds depicted in formula **1**. Compared to the free ligand **2***a*, which displays nearly equal C—C bond lengths between the ylidic center carbon atom and both of the flanking carbonyl carbon atoms (average 1.405 Å) (1), the chelate **1***a* shows a short C—C bond with considerable double bond character between the (former) ylidic center carbon and the chelate ring carbon atom: C(3)—C(2) (C(24)—C(23)) = 1.350(2) Å (both), whereas the bond from the (former) ylidic center to the formyl group is lengthened: C(3)—C(4) (C(24)—C(25)) = 1.450(2) (1.449(2)) Å. The C=C bond length lies between the average C=C-OH (1.362 Å) and C=C-C=O (1.340 Å) bonds reported, and the C—C(formyl) single bond is similar to the average C—C distance for conjugated carbonyl compounds (1.464 Å) (10). Corresponding to the substantial double bond character of the C(3)—C(2) (C(24)—C(23)) bond, the C(2)—O(3) (C(23)—O(7)) bond shows a reduction of its carbonyl character with a bond distance of 1.309(2) Å (for both molecules), corresponding to a π-bond order of only 0.47, as estimated from a bond length vs. HMO–π-bond order plot (11) and calculated (12). This shift of electron density in the chelate **1**, relative to the ligand **2**, is coincident with the increase of the double bond character of the carbonyl C=O of the formyl group: C(4)—O(4) (C(25)—O(8)) = 1.222(2) (1.225(2)) Å, compared with 1.240 Å for the ligand **2***a* (1). The enhanced carbonyl activity of the formyl group in the chelate **1***a*, compared to the ligand **2***a*, is also confirmed by chemical means. The reaction of **2***a* with the carbonyl-detecting reagent 4-nitrophenylhydrazine did not lead to a corresponding hydrazone derivative **6** whereas **1***a* gave the hydrazone **5** under mild conditions. This indicates the enhanced reactivity of the aldehyde function, which interacts less with the adjacent (conjugated) groups in the chelate **1** than it does in the ylide **2**. An additional indication of the strengthened aldehyde function in **1** is given by the ^{1}H NMR

spectra, which display the signal of the formyl proton at about 10.6 ppm, whereas the ligand **2** has the analogous signal in an upfield area around 9.2 ppm (1).

Unlike the formation of **1***a*–**1***d*, the reaction of the ylidic ligand **2***e* with diphenylborinic acid leads to the five-membered boron chelate **3**. This might originate from a solvolytic splitting off of the formyl group from **1** or **2** (presumbably as formic acid or methyl formate) with subsequent addition of the involved solvent methanol. Crystallizing with 1 mol of water, the compound **3** represents the diphenylboron chelate of a semi-acetal of an α-oxocarbonic acid derivative. The possible isomeric structure **4**, caused by the addition of water and crystallization with solvate methanol can be excluded by NMR spectroscopic observations. A distinct cross-correlation between the methoxy group and the acetalic carbonyl carbon atom can be seen in the C,H-COLOC spectrum. This proves the participation of methanol in the acetal group, and thus the structure **3**.

This deviating behavior in the reaction of **2***e* with oxybis(diphenylborane) might possibly be caused by the

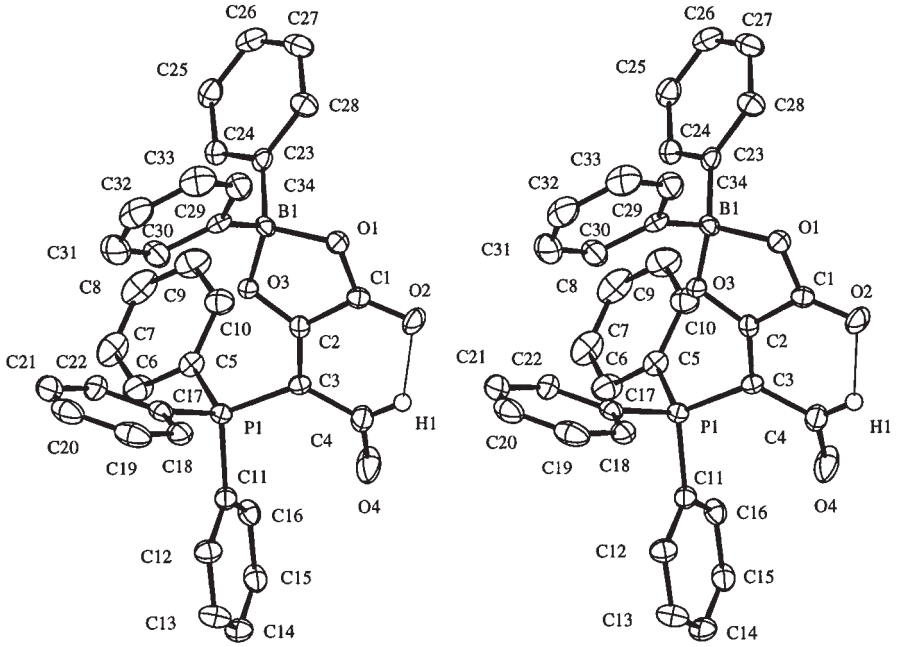
Fig. 2. Stereoview of one of the two independent molecules of **11**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.



acidity of the free phenol group. All of the compounds of type **2** are hydrolyzed in acidic solution, giving formic acid and an α-oxocarbonic acid or its hydrate (1), a reaction that had already been observed by Kröhnke (13) with various bisacyl pyridinium ylides. Heating of **3** to ca. 110°C results in the elimination of methanol and the loss of solvate water, giving the very stable diphenylboron chelate **7**.[7]

The phosphonium ylide **10** reacts analogously to **2** with oxybis(diphenylborane) giving the *B,P*-betainic diphenylboron chelate **11** in high yield. In the ^{1}H NMR spectrum of **11** the signal of the formyl group proton appears at 10.96 ppm, distinctly downfield from the corresponding signal produced by the formyl proton of the uncomplexed ylide **10** at 8.72 ppm. This points to the enhanced aldehyde function of the formyl group, similar to that in the type **1** chelates, which is further supported by the formation of the 4-nitrophenylhydrazone **12**. The ^{31}P NMR spectrum of **11** shows only a minor change with respect to that of the ligand **10** (1), emphasizing the insignificant influence of the chelatization on the phosphonium moiety.

The X-ray analysis of **11** establishes the proposed molecular structure (Fig. 2), which is analogous to **1**. To the best of our knowledge, compound **11** represents a new type of boron chelate with a boron phosphorus betaine structure. As in **1***a*, an intramolecular C-H···O interaction is conspicuous. The C···O distances of 2.959(4) and 2.979(4) Å, respectively, for the two independent molecules, H···O distances of 2.24 and 2.30 Å, and the corresponding C-H···O angles of 129.6° and 125.6° might suggest somewhat stronger intramolecular hydrogen bonds between C(4) and O(2), and C(38) and O(6), than those existing in **1***a*.

In the triphenylphosphonium residue of **11** the P—C(phenyl) bond distances of about 1.800 Å (1.793(3)–1.815(3) Å) are of the same order as those observed in the

[7] A facile elimination of methanol and the formation of **7** can be observed even during storage at room temperature, monitored by infrared spectroscopy. A readdition of methanol is not achieved by the treatment of **7** with heated methanol.

triphenylphosphonium methylide adduct of boraadamantane (14). The P(1)—C(3) and P(2)—C(37) distances of 1.793(3) and 1.786(3) Å, respectively, are somewhat longer than the comparable P—C bond in the above-mentioned ylide adduct (14) (1.766 Å). Steric factors as well as loss of the ylide character might be responsible for the lengthening of this P—C bond in **11**. Free triphenylphosphonium methylide has a distinctly shorter comparable P—C bond of 1.661 Å (15), as does triphenylphosphonium dimethylallylide, P—C = 1.677 Å (16). The four substituents around the phosphorus atom are arranged in a nearly tetrahedral manner, the phenyl rings being oriented in a propeller arrangement.

The overall geometry of the boron chelate ring in **11** is similar to that observed for **1***a*. Obvious differences can be seen at the formyl group: C(4)—O(4) = 1.222(2) Å and C(25)—O(8) = 1.225(2) Å in **1***a*; C(4)—O(4) = 1.206(3) Å and C(38)—O(8) = 1.219(3) Å in **11.** The increased double bond character of the carbonyl C=O bond, having an estimated π-bond order of 0.85 (from a bond length vs. HMO–π-bond order plot (11)), points to the weaker influence of the phosphonium substituent in **11**, compared to the pyridinium substituent in **1***a*, upon the conjugated system that ends with the electron-withdrawing diphenylborinate moiety. The geometry around the boron nuclei in both compounds, **1***a* and **11,** is very similar, both displaying normal bond lengths and angles.

The structures of both **1***a* and **11** consist of discrete molecules, the most significant intermolecular interactions in the solid state corresponding to weak C-H···O interactions (C···O = 3.147(3)–3.441(2) Å, H···O = 2.44–2.53 ÅC–H···O = 125°–163°).

Abstract: In weakly acidic, aqueous buffer ($MeCO_2^-$+ bipy), the complex ion $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+}$, **1** (bipy = 2,2′-bipyridine), coexists in rapid equilibrium with its hydrolytic derivatives, $[Mn_2^{IV}(\mu\text{-}O)_2(bipy)_2(H_2O)_4]^{4+}$, **2**, and $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)(H_2O)_4]^{3+}$, **3**. The solution quantitatively oxidizes hydrogen peroxide to oxygen and ascorbic acid to dehydroascorbic acid, itself being reduced to Mn^{II}. In the presence of excess reductant, the reactions follow simple first-order kinetics with no evidence for the accumulation of a significant amount of any intermediate manganese complex. The ascorbate anion shows overwhelming kinetic dominance over ascorbic acid, but no evidence is available for deprotonation of hydrogen peroxide. The preferred intimate mechanism for hydrogen peroxide is inner sphere but that for ascorbic acid is uncertain. For both reductants, increased extent of aquation leads to increased kinetic activity in the order: **1** < **2** < **3**.

Key words: kinetics, manganese, ascorbic acid, hydrogen peroxide, 2,2′-bipyridine.

Résumé : En milieu faiblement acide, tampon aqueux (acétate + bipyridine), le complexe ionique $[Mn(IV)_2(\mu\text{-}O)(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+}$ (**1** dans lequel bipy = 2,2'-bipyridine) coexiste en équilibre rapide avec ses dérivés d'hydrolyse, $[Mn(IV)_2(\mu\text{-}O)(bipy)_2(H_2O)_4]^{4+}$ (**2**) et $[Mn(IV)_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_4]^{3+}$ (**3**). La solution oxyde quantitativement le peroxyde d'hydrogène en oxygène et l'acide ascorbique en acide déhydroascorbique alors que le manganèse est réduit en Mn(II). En présence d'un excès de réducteur, les réactions suivent une cinétique du premier ordre simple, sans accumulation de quantités significatives de complexes de manganèse intermédiaires. L'anion ascorbate présente une dominance cinétique importante par rapport à l'acide ascorbique, mais on n'a pas pu mettre en évidence de déprotonation du peroxyde d'hydrogène. La sphère interne correspond au mécanisme intime préféré pour le peroxyde d'hydrogène; celui pour l'acide ascorbique est toutefois incertain. Pour les deux réducteurs, une augmentation de l'aquation conduit à une activité cinétique accrue dans l'ordre **1** < **2** < **3**.

Mots clés : manganèse, acide ascorbique, peroxyde d'hydrogène, 2,2′-bipyridine.

Introduction

The oxygen-evolving complex (OEC) in photosystem II (PS II) consists of a manganese cluster that binds substrate water molecules and accumulates oxidizing equivalents in a cyclic sequence of reactions known as the Kok or the S-state cycle (1). The OEC is made up of four manganese ions (2), held together by μ-oxo and carboxylate bridges, and a tetrameric structure was recently proposed on the basis of EXAFS and EPR data (3). ESSEM $^{14}N/^{15}N$ labelling studies (4) and ^{15}N ENDOR spectroscopy (5) have shown that nitrogen-containing ligands are bound to manganese in PS II. Oxo- and carboxylato-bridged manganese dimers (6) containing N-donor ligands are therefore considered as "molecular bricks" for the OEC. Investigation of the kinetics, equilibrium, and mechanism of the ligand substitution and redox reactions of such complexes is intrinsically interesting.

In addition to their significance in light-driven oxidation of water molecules to oxygen, these complexes are novel oxidants useful for the mechanistic studies of electron transfer reactions of higher-valent manganese in solution. We recently investigated the kinetics of reduction of two dioxo-bridged manganese(III,IV) dimers (7) and the tribridged $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+}$ ion (**1**; bipy = 2,2′-bipyridine; see Fig. 1) in aqueous media (8–10). We thus found that the Mn_2^{IV} species in excess bipy generate a $Mn^{III}Mn^{IV}$ dimer, $[(bipy)_2Mn^{IV}(\mu\text{-}O)_2Mn^{III}(bipy)_2]^{3+}$, as intermediate while reacting with thiosulfate and hydrazine but not with nitrite. From the observed proton dependence, the intimate mechanism for hydrazine appeared to be inner sphere. In this paper, we report the kinetics of reduction of **1** and its aqua derivatives by ascorbic acid (H_2A) and hydrogen peroxide in an attempt to further explore the reactivity pattern of higher-valent oxo-bridged manganese complexes.

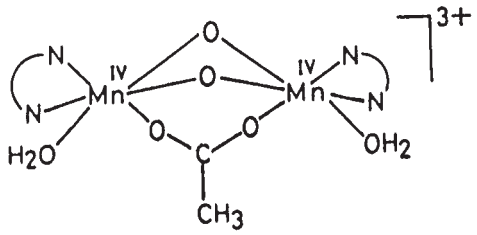
Fig. 1. Graphical structure for **1** drawn on the basis of its crystal structure.



Experimental

Materials

The solutions of hydrogen peroxide were prepared by dilution of 30% (w/v) stabilizer-free hydrogen peroxide (G.R., E. Merck) and were standardized by iodometry using starch indicator (11). L-Ascorbic acid (A.R., S.R.L) was used without further purification. All other materials including the complex ion **1** have been described earlier (8). Solutions were prepared in doubly distilled water, generally just before use.

Physical measurements and kinetics

Kinetics were measured with a stopped-flow spectrophotometer (HITECH SF-51), interfaced with an Apple-II GS personal computer for data acquisition and analysis of absorbance–time data for the first-order rate constants. Five hundred and twelve data points were collected by the stopped-flow apparatus for each experiment. Excess reducing agent maintained pseudo-first-order conditions in a mixed ($MeCO_2H/MeCO_2^-$ + $Hbipy^+$/bipy) aqueous buffer medium in the pH range 4.2–5.5. Each reported first-order rate constant is the average of three to five replicate measurements for a given reaction mixture. We measured the solution pH with an Elico (L 1120) pH-meter (8, 12). The linearity of the electrode was established using pH 4, 7, and 9 buffers. The electrode was calibrated to read –log [H^+] directly using a series of acid solutions at the ionic strength used for kinetic measurements. Kinetics was measured at 25.0°C for hydrogen peroxide, but at 15.0°C for fast-reacting ascorbic acid.

Stoichiometries were determined under the kinetic conditions. An excess of a reducing agent, hydrogen peroxide or ascorbic acid, was added in a single portion to a solution of the Mn_2^{IV} complex **1**. The amount of hydrogen peroxide remaining after complete reaction was determined iodometrically(11). Ascorbate concentration in spent reaction mixtures was determined iodimetrically using starch indicator near the end point in a dilute sulphuric acid medium (13). Standard iodine solution rapidly and quantitatively oxidized ascorbic acid to dehydroascorbic acid (13, 14). Other materials present in the mixture did not interfere.

Results and discussion

Stoichiometry and reaction products

Each mole of the complex consumed two moles of H_2O_2 and thus suggests quantitative oxidation of H_2O_2 to O_2 (Table 1). The 1:2 stoichiometry was also observed for ascorbic acid (H_2A), indicating that dehydroascorbic acid (A), the most common oxidation product (14, 15) of H_2A, is produced in the present experiments.

[a] C_{bipy} = 35.0; all concentrations are in mmol dm^{-3} ; total volume, 100 mL.

Solution equilibria

The crystal structure of the complex salt $\mathbf{1}(ClO_4)_3 \cdot H_2O$ shows a bridging ethanoate ligand, a bis(μ-oxo) bridge, and two water molecules, each directly coordinated to one manganese(IV) ion (16). The ethanoate bridge and a bipy ligand are labile and dissociate in aqueous solution according to eqs. [1] and [2] (8).

[1] $$[Mn_2^{IV}(\mu-O)_2(\mu-MeCO_2)(bipy)_2(H_2O)_2]^{3+} + 2H_2O$$
$$\mathbf{1}$$
$$\overset{K_{12}}{\rightleftharpoons} [Mn_2^{IV}(\mu-O)_2(bipy)_2(H_2O)_4]^{4+} + MeCO_2^-$$
$$\mathbf{2}$$

[2] $$\mathbf{1} + 2\ H_2O \overset{K_{13}}{\rightleftharpoons} [Mn_2^{IV}(\mu-O)_2(\mu-MeCO_2)(bipy)(H_2O)_4]^{3+} + bipy$$
$$\mathbf{3}$$

[3] $$MeCO_2H \overset{K_{ea}}{\rightleftharpoons} MeCO_2^- + H^+$$

[4] $$Hbipy^+ \overset{K_{Hbipy}}{\rightleftharpoons} H^+ + bipy$$

The solution is otherwise stable under the present experimental conditions.

A labile ethanotate bridge is found also in the dinuclear Mn(III,IV) complex $[Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(\textit{fac}\text{-bpea})_2]^{2+}$ (bpea is *N*,*N*-bis(2-pyridylmethyl)ethylamine) and in its diferric analogue, $[Fe_2(\mu\text{-}O)(\mu\text{-}MeCO_2)_2(L)_2]^{2+}$ (L is substituted bpea) (17–19).

The chelating ligands in the complexes $[L'_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}L'_2]^{3+}$ (L′ = 2,2′-bipyridine and 1,10-phenanthroline) are also labile (7, 20). The binding sites in the S_3-state (the S-state notation (1) identifies the number of oxidizing equivalents stored in the manganese cluster in the water oxidation

complex of PS II) are labile and exchange ^{18}O-labeled water in less than 1 s (21). However, the bridging oxo-ligands are kinetically inert (22, 23). Interestingly, equilibrium as well as kinetic studies (8, 10) suggest that the coordinated water molecules in **1** and its aqua derivatives do not deprotonate, at least up to pH 5.5. Weak acidity of coordinated water is known also for $[Mn_3^{IV}(\mu\text{-}O)_4(bipy)_4(H_2O)_2]^{4+}$ (24) and $[Mn(pd)_2(H_2O)_2]^+$ (pd is pentane-2,4-dione). The latter complex has a pK_a value of 7.3 (25–27). The weak acidity observed is consistent with recent findings that the O—H bond strength in water coordinated to higher-valent manganese is comparable to the phenolic O—H bond strength in tyrosine (28, 29).

Kinetics and reaction schemes

All reactions in the presence of excess reducing agent obeyed first-order kinetics for at least 90% reaction. The first-order rate constants, k_0 for H_2O_2 and k_0' for ascorbic acid (see Table 2), increased with increasing concentration of the reducing agent but decreased with increasing [bipy] and [$MeCO_2^-$] at a fixed pH. However, pH change affects k_0 and k_0' differently. Increased pH decreases k_0 but increases k_0' (Fig. 2). The variations in k_0 can be explained on the basis of only equilibria [1]–[4], provided the hydrolytic derivatives **2** and **3** are kinetically more active than their parent, **1**. We therefore propose Scheme 1 as a simple model for the reaction of H_2O_2.

The pH dependence of the reactions of ascorbic acid can be reasonably explained if one assumes, along with equilibria [1]–[4], the deprotonation equilibrium of H_2A, eq. [8] (15), and an overwhelming kinetic dominance of the ascorbate ion, HA^-, over ascorbic acid, H_2A. (Scheme 2, eqs. [8]–[11]).

Table 2. (*concluded*).

pH	[bipy]	[$MeCO_2^-$]	[R]	k_0/s^{-1}
4.50	19.1	36.3	4.5	16.2 (16.0)
4.50	19.1	36.3	5.0	17.8 (17.8)

[a]Temperature, 25.0°C for H_2O_2; 15.0°C for ascorbic acid. [Mn_2^{IV}] = 0.10; all concentrations are in mmol dm^{-3} except I = 1.0 mol dm^{-3} ($NaNO_3$); λ, 420 nm for H_2O_2; 380 nm for ascorbic acid. Values in parentheses are calculated rate constants.

Schemes 1 and 2 lead to eqs. [12] and [13], respectively.

$$[12]\quad k_0 = \frac{\{k_A[MeCO_2^-][bipy] + k_BK_{12}[bipy] + k_CK_{13}[MeCO_2^-]\}[H_2O_2]}{[MeCO_2^-][bipy] + k_{12}[bipy] + k_{13}[MeCO_2^-]}$$

$$[13]\quad k_0' = \frac{\{K_ak_A'[MeCO_2^-][bipy] + K_ak_B'K_{12}[bipy] + K_aK_{13}k_C'[MeCO_2^-]\}C_a}{\{[H^+] + K_a\}\{[MeCO_2^-][bipy] + K_{12}[bipy] + K_{13}[MeCO_2^-]\}}$$

where C_a (= [H_2A] + [HA^-]) is the total analytical concentration for ascorbic acid. Equation [12] leads to eq. [14] and eq. [13] leads to eq. [15].

$$[14]\quad k_0([MeCO_2^-][bipy] + K_{12}[bipy] + K_{13}[MeCO_2^-])/[H_2O_2] = k_A[MeCO_2^-][bipy] + k_BK_{12}[bipy] + k_CK_{13}[MeCO_2^-]$$

$$[15]\quad k_0'([H^+] + K_a)([MeCO_2^-][bipy] + K_{12}[bipy] + K_{13}[MeCO_2^-])/C_aK_a = k_A'[MeCO_2^-][bipy] + k_B'K_{12}[bipy] + k_C'K_{13}[MeCO_2^-]$$

$[MeCO_2^-] = C_{ea}K_{ea}/([H^+] + K_{ea})$ and $[bipy] = C_{bipy}K_{Hbipy}/([H^+] + K_{Hbipy})$, where C_{ea} = ([$MeCO_2^-$] + [$MeCO_2^-$]) and C_{bipy} = ([$Hbipy^+$] + [bipy]) are the total analytical concentration of ethanoate and 2,2′-bipyridine, respectively. Values for the left-hand sides of eqs. [14] and [15] may be calculated using known rate constants (Table 2) and equilibrium constants (Table 3). The calculated left-hand sides of eqs. [14] and [15] each yielded excellent straight lines (Figs. 3 and 4) when plotted against [bipy] or [$MeCO_2^-$], thus justifying the proposed schemes. The slopes and intercepts of the straight lines yielded the specific rate constants k_A, k_B, k_C, k_A', k_B' and k_C' displayed in Table 4 along with known rate constants for comparable reactions. The rate law derived for an equivalent scheme admitting significant kinetic contribution from H_2A contains an additional term, first order in [H^+]. Such a rate law does not fit the experimental data.

The K_{12} and K_{13} values are available only at 25.0°C and were used in computing the k_n' values for ascorbic acid at 15.0°C. This difference in temperature is unlikely to introduce serious error. We verified that a simultaneous increase or decrease to the extent of 50% in K_{12} and K_{13} changes k_1' by only 12% even when k_2' and k_3' are kept fixed to see what happens if the whole thrust of the change in the two equilibrium constants are put on k_1' alone. Similar were the cases for k_2' and k_3'.

Intimate mechanism

Ascorbic acid can act both as an inner-sphere as well as an outer-sphere reducing agent (30). In the present study, labile coordination sites present in the metal complexes may induce an inner-sphere mechanism but it is not a trivial matter to pinpoint the mechanism. For example, Bansch et al. (31) have shown that oxidation of ascorbic acid by $[Fe(H_2O)_6]^{3+}$ ion follows an outer-sphere path, and oxidation by the $[Fe(H_2O)_5(OH)]^{2+}$ ion proceeds by an H-atom transfer from HA^- although both H_2A and HA^- are known (32) to be good ligands for Fe(III). Obviously, presence of a labile coordination site and the ability of the reductant to bind to a metal centre are insufficient information to decide in favour of one of the two intimate mechanisms — inner sphere or outer sphere. However, an H-atom transfer mechanism may be discarded since the Mn_2^{IV} complexes have no OH group.

The simple first-order kinetics observed by us, without any indication of rate saturation, only implies the validity of the inequality, $Q_x[HA^-] << 1$ for every individual value of Q_x, the formation quotient for adducts that may form between HA^- and the $Mn^{IV}{}_2$ complexes, **1**, **2**, **3**. In our experiments the maximum value for [HA^-] is 3.6×10^{-3} mol dm^{-3}. The inequality, therefore, imposes an upper limit on Q_x, 30 dm^3 mol^{-1}. The observed situation is similar to those for reduction of $[Mn_2^{III,IV}(\mu\text{-}O)_2(bipy)_4]^{3+}$, **4**, by hydroquinone and HSO_3^-. No rate saturation was observed in these two reactions, as was also the case in the reaction between HSO_3^- and **4**, and that between HA^- and the one-electron reduced $Mn^{III}{}_2$ form of **4** (33). However, the $(Mn^{III}{}_2)$–HSO_3^- adduct (Q = 450 dm^3 mol^{-1}), as well as that formed from **4** and ascorbic acid, is strong enough to permit their kinetic detection (33). Apparently, the Q values may be sufficiently different to evade rationalization even in closely related systems.

Oxidation of hydrogen peroxide is generally inner sphere (34) excepting when the oxidant is very powerful and coordinatively saturated, such as $[Ni^{III}(bipy)_3]$ (35). For example, the reactions of H_2O_2 with moderately oxidizing (36)

[a]Reference 8 in the text.

[b]Reference 43. Change in temperature little affects the value; e.g, for $I \rightarrow 0$, the value over the temperature range 15–25°C is 4.756 ± 0.002 (44).

[c]Reference 45. Effect of *I* on p*K* is small; ±0.01 unit for a change in *I* from 0.33 to 0.1 mol dm^{-3}; cf. ref. 46.

[d]Reference 47. This value was used in calculations for ascorbic acid. Comparison with footnote *c* shows that the effect of temperature on p*K* is small.

[e]Reference 15 in the text.

complexes such as $[Mn(cydta)(H_2O)]^-$ (cydta is cyclohexyl ethylenediaminetetraacetate) (37) and solvolyzed **4** follow the inner-sphere path (7*d*, 36). Oxidation of potassium peroxymonosulfate to O_2 with solvolyzed **4** and its close analogues also follows the inner-sphere mechanism (38), and the same mechanism appears very likely for the reactions under the present investigation. Earlier examples of the inner-sphere mechanism for the Mn_2^{IV} complexes are their reactions with $N_2H_5^+$ (10).

In this study, no evidence is available for deprotonation of H_2O_2, though an inner-sphere mechanism implies a coordinated H_2O_2 and enhanced acidity. We recall that water molecules coordinated to Mn(IV) in **1** and its hydrolytic derivatives release no H^+ in the experimental range of pH. Similar behaviour is definitely expected for coordinated H_2O_2 and is not in contradiction with the proposed mechanism.

Table 4 shows that the kinetic activity of the Mn_2^{IV} complexes towards various reducing agents increases with increased extent of aquation in the order: **1** < **2** < **3**. Limburg et al. (38) as well as Banerjee and co-workers (7) noticed that, kinetically, **4** is a much inferior oxidant than its solvolyzed derivatives. Again, in a recent model for the mechanism of the OEC in PS II, it has been assumed that only the two terminal manganese atoms containing coordinated water in a ⊂-shaped tetranuclear cluster are redox active; the two central Mn^{4+} ions without coordinated water are inactive (23). A rationale for the greater kinetic activity of the aqua complexes was presented earlier (9).

Reduction of the Mn_2^{IV} complexes by $S_2O_3^{2-}$ and $N_2H_5^+$ produced the $Mn^{IV}Mn^{III}$ complex, **4**, as an intermediate, which subsequently oxidized additional molecules of reductant and thus decayed to Mn^{II}. No intermediate manganese complex could be detected in the present experiments. This, and the observed exponential profiles along with the absence of any absorbance drops immediately after mixing, suggests that generation of **4** and its subsequent reactions with ascorbic acid and hydrogen peroxide are kinetically insignificant in the present systems. It may be that the one-electron transfer products, the radicals $HO_2^\bullet$ and $A^{-\bullet}$ (generated in the rate-determining steps) rapidly react with the $Mn^{IV}Mn^{III}$ species. This is a strong possibility if the reactions are inner sphere, when rapid further reduction of the successor complex might

occur before the radicals can escape into the bulk solvent (kind suggestion of a reviewer; see also ref. 39).

Such a mechanism, where the radicals are generated and consumed within the coordination sphere of the metal complex, is, however, closely analogous to and rarely distinguishable from a simultaneous two-electron transfer mechanism, proposed for different multinuclear manganese complexes. For example, Wieghardt et al. (40) isolated a peroxo-bridged complex, $[L_2'Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}O_2)]^{2+}$ (L′ = trimethyl-1,4,7-triazacyclononane), which releases molecular oxygen rapidly in aqueous solution at 20°C by an intramolecular two-electron oxidation of coordinated O_2^{2-} with concomitant reduction of Mn_2^{IV} to a binuclear Mn_2^{III} complex. Peroxo-bridged Mn_4 clusters have recently been proposed to represent the S_4 state, in which intramolecular two-electron oxidation of the peroxo-bridge produces O_2 and the S_0 state is regenerated (23). The S_3 to S_4 transition may also be described as a probable two-electron oxidation of substrate ligands according to the Hoganson and Babcock model (23). It appears that a mechanism involving a pair of electron acceptors becomes necessary when the driving force for electron transfer from a multielectron donor becomes too small for free-radical production (41). In such situations, binuclear complexes may provide a low-energy pathway for two-electron transfer. Nevertheless, ascorbic acid rarely undergoes two-electron transfer (42). One suggested example involves a ferriporphyrin dimer(41).

Conclusions

Rapid reduction of the complex ion $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+}$ and its hydrolytic derivatives with hydrogen peroxide seems to be inner sphere, but the intimate mechanism for the reduction by ascorbic acid is uncertain. An increased number of coordinated water molecules in-

© 1999 NRC Canada

creases the kinetic activity of the host Mn(IV) site in these model complexes, as in the OEC.
