1998 E.W.R. Steacie Award Lecture Asymmetric amphiphilic block copolymers in solution: a morphological wonderland[1]

Neil S. Cameron, Muriel K. Corbierre, and Adi Eisenberg

Abstract: Asymmetric amphiphilic diblock copolymers self-assemble in selective solvents. Since 1995, when we first reported the systematic preparation of a sequence of various "crew-cut" aggregate morphologies from this class of copolymer in solution (1), we have identified a vast array of structures and have begun a detailed investigation of the thermodynamic and kinetic parameters that induce morphogenesis. Not only spheres, rods, bilayer and bicontinuous architectures, as well as inverted structures are observed, but also a selection of mixed, combined and much more complex aggregates is documented. All of these aggregates have a phase-separated insoluble core and a crew-cut soluble corona. Thus, all parameters that permit selective modification of the component of either phase or of the interface provide a window for morphological control. By carefully adjusting the polymer chain environment, it has been possible to develop a systematic understanding of morphogenic parameters, which include, among others, polymer composition, common solvent, initial concentration, temperature, type and concentration of added ions, method of preparation, and added homopolymer. To date, more than 30 publications have appeared in the literature from our group alone on this subject. One of the problems inherent with such a complicated system is the taxonomy or classification: which morphologies correspond to equilibrium positions and which are intermediate or trapped? An attempt at a logical presentation of the observed aggregates is given, preceded by a qualitative discussion of the thermodynamic framework for this system. Where possible, the transitions between morphologies are explained in the context of the thermodynamic parameters. Finally, parallels are drawn between the copolymer aggregates and biological architectures.

Key words: crew-cut, morphology, block copolymer, self-assembly, amphiphile.

Résumé : Les copolymères amphiphiles à blocs asymmétriques s'auto-assemblent en présence de solvants sélectifs. Depuis 1995, lorsque nous avons rapporté pour la première fois la préparation systématique d'une séquence de plusieurs morphologies « coupées en brosse » à partir de cette classe de polymères en solution (1), nous avons identifié une grande variété d'aggrégats et avons commencé une étude détaillée des paramètres thermodynamiques et cinétiques responsables de la morphogénèse. Nous avons observé non seulement des sphères, des batonnets, des bicouches et des structures bicontinues ainsi que des structures inversées, mais aussi une sélection de morphologies mélangées, combinées et bien plus complexes. Tous les aggrégats possèdent deux phases distinctes, un coeur insoluble et une couronne coupée en brosse soluble. Par conséquent, tous les paramètres permettant la modification sélective d'un composant d'une des phases ou de l'interface fournissent un moyen de bien contrôler les morphologies. En ajustant avec précaution l'environnement des chaînes de polymère, il a été possible de développer une compréhension systématique des paramètres morphogéniques incluant la composition du polymère, le solvant commun aux deux blocs, la concentration initiale, la température, le type et la concentration d'ions ajoutés, la méthode de préparation et l'ajout d'homopolymère. A ce jour, plus de 30 publications par notre groupe sont apparues dans la littérature sur ce sujet. La classification des divers aggrégats présente un problème inhérent à un système aussi compliqué: quelles morphologies correspondent à des positions d'équilibre, et quelles morphologies sont intermédiaires ou piégées? Suite à une dicussion qualitative sur le cadre thermodynamique de ce système, nous tentons de présenter de manière logique les aggrégats observés. Les transitions entre les morphologies sont expliquées en fonction des paramètres thermodynamiques lorsque cela est possible. Finalement, les similarités entre les aggrégats de copolymères et les architectures biologiques sont présentées.

Mots clés : coupé en brosse (crew-cut), morphologie, copolymère à bloc, auto-assemblage, amphiphile.

1.0. Introduction

Self-assembly of highly asymmetric amphiphilic block copolymers in selective solvents has been of paramount interest in our laboratories since 1994 (2) but morphologies of amphiphilic species, such as small molecule surfactants, have attracted a great deal of interest for many decades (3). The underlying principle is that two fundamentally different sub-units of the amphiphile are driven to phase separate like oil and water, with the limiting condition that they are covalently attached to each other. Molecules, and in our case, *macro*molecules, are therefore thermodynamically driven to self-assemble in order to minimize the contact between the immiscible components (the solvent and the insoluble block). Block copolymer self-assembly in solution has been a topic of active research for more than 30 years (see for example ref. 4). A convenient term for the most commonly observed morphology is the star-micelle. "Star" refers to the fundamental core–corona structure where the core is small and the corona large; micelle reflects the dynamic equilibrium conditions under which these aggregates frequently form. Star micelles can be further divided into two types: regular and reverse. Regular micelles are formed in polar solvents such as water and alcohols; thus, the corona has hydrophilic character. Micelles formed in apolar solvents such as toluene have a hydrophobic corona and are referred to as "reverse." Recently, we have devoted most of our attention to highly asymmetric block copolymers that form aggregates characterized by a large core and a thin coronal shell of the soluble block: the crew-cut systems (1, 2, 5–28).

1.1. Small molecule amphiphiles

Self-assembly of molecules is a rich field for scientific investigation, and a great deal of groundwork has already been completed in the study of small molecule surfactants. Biologically, one of the most important surfactants is the phospholipid that makes up all cell walls. Without highly controlled self-assembly, our living cells could not exist. A typical small molecule surfactant such as sodium dodecyl sulfate (SDS) aggregates at concentrations in excess of 8 mM, the critical micelle concentration (cmc). The free energy of micellization in aqueous media has three components: a favourable hydrophobic component due to the association of the hydrocarbon tails, a surface term that takes into account the opposing requirements to both fully shield the hydrocarbon tails from the polar environment and the electrostatic repulsion inherent for the charged head groups, and also a packing term that determines the morphology (3). Aggregation of surfactants has been described as a start–stop mechanism in that self-assembly occurs until all surfactant molecules are directly involved in the equilibrium morphology whereupon only dynamic chain exchange occurs. Addition of further surfactant molecules induces further self-assembly of aggregates similar to the pre-existing ones.

Many morphologies have been observed for these small molecule amphiphilic systems including simple micelles, rods, planar bilayers, inverted micelles, bicontinuous structures, and vesicles. With increasing surfactant concentration, the morphology spectrum runs from micelles (L_1), through a cubic array of micelles (I_1), hexagonally packed rods (H_1), cubic bicontinuous spheres (V_1), to lamellae (L_3) where phase inversion takes place, and the inverted morphologies develop: Cubic (V_2), Reversed Hexagonal (H_2), Cubic (I_2), and Reversed Micelle (L_2) (29, 30). Furthermore, for systems such as didodecylammonium bromide in oil, micro-emulsions characterized by interconnected tubes are observed (3). The addition of water causes tube dilation until the increased curvature induces droplet formation. Further water addition causes the droplets to grow until the system is no longer able to maintain curvature, and phase separation occurs. Thus, the self-assembly of small molecule surfactants is characterized by relatively high cmc's, three contributions to the free energy of micellization, and dynamic morphology changes.

1.2. Diblock copolymers in the bulk

Diblock copolymers in the bulk also exhibit a spectrum of morphologies analogous to the series observed for small molecule surfactants. Much of the experimental work in this regard has been carried out on polystyrene-*b*-poly(isoprene) (PS-*b*-PI) and polystyrene-*b*-polybutadiene (PS-*b*-PBD). With these systems, it has been possible to study phase separation in the strong segregation limit where $\chi N > 10$.[3] As an example, with increasing volume fraction of PI, the morphological transitions go from body centered cubic (BCC) spheres of PI in a PS matrix through hexagonally packed cylinders of PI in PS, gyroid (G), metastable hexagonally perforated layers (HPL) (31), and finally lamellae (LAM) form when the volume fractions of the two blocks approach equality. As the PI volume fraction increases further, phase inversion occurs, and HPL, G, HEX, and finally BCC morphologies are observed where PI forms the continuous phase. The full spectrum of morphologies is not observed for all polymers, as not only the volume fraction of each block but also the total degree of polymerization plays a role (32).

1.3. Diblock copolymers at the air–water interface

Various morphologies are also observed in two dimensions for block copolymers at the air–water interface. Systems investigated include polystyrene-*b*-poly(4-vinyl pyridine.alkyl iodide) (PS-*b*-P4VP.RI) (33, 34) and the structures identified with changing relative block composition progressed from circles ("starfish") to ribbons and lamellae. Inverted circles (two-dimensional nanofoams) were also observed for polystyrene-*b*-poly(sodium acrylate) (PS(90)-*b*-PANa(32)). The diblock copolymer is dissolved in an organic solvent that is then spread on a water surface in a Langmuir trough. Upon evaporation of the solvent, aggregation occurs. The 2D "films" have been studied by X-ray and neutron scattering (SAXS, SANS) (35), as well as atomic force microscopy (AFM) and transmission electron microscopy (TEM) (36).

1.4. Diblock copolymers in solution

Self-assembly of amphiphilic block copolymers in selective low molecular weight solvents has been studied now for many years. The principle of aggregation of the amphiphilic block copolymers is similar to that undergone by small mol-

[3] The product of the Flory–Huggins segment–segment interaction parameter, χ, and the degree of polymerization, N, is much greater than 10.

© 1999 NRC Canada

ecule amphiphiles in solution; however, the critical micelle concentration (cmc) is usually much lower in the case of block copolymers (6). The dynamics of the chain exchange between the micelles are also different for block copolymers and small molecule surfactants. Indeed, at equilibrium, the micelles exchange chains with one another, and this exchange is fast in the case of small molecules. However, the chain exchange in block copolymer systems is generally much slower, due to a number of factors including the high molecular weight, the low cmc, and the possible entanglement and low mobility of the chains in the core (14). For example, when the glass transition temperature (T_g) of the core-forming chains is very high (T_g of PS ca. 100°C) and no plasticizer is present, the micelles are considered to be "frozen," since the mobility of the core-forming chains is extremely low.

Depending on the relative block lengths, either star or crew-cut micelles are formed. A small core surrounded by a long corona characterizes star micelles, whereas crew-cut micelles consist of a large core and a thin corona. The term crew-cut was originally proposed by Halperin et al. (37). Two features enhance the difference between crew-cut and star micelles: the process of the formation of the micelles and the morphologies of the aggregates. Star micelles can often be prepared by direct dissolution of the block copolymer in a solvent selective for the long block. Thus, the insoluble short blocks associate and form the core, and the soluble long blocks form the corona of the micelles. This process is usually impossible to apply to the formation of crew-cut micelles, since the insoluble blocks represent a very high fraction of the block copolymer. Instead of the direct dissolution process, the diblock copolymers are first dissolved in a solvent good for both blocks, and then a precipitant for the long block is added, resulting in the aggregation of these long blocks. The preparation of crew-cut micelles therefore involves a more delicate process, and the resulting aggregates present a more complicated system than star-like micelles, since they involve solvent mixtures of variable composition. Star micelles are essentially spherical aggregates. Aggregates in the star regime other than small solid spheres have only rarely been observed and have not been studied as extensively (38–45). Very recently, the groups of Winnik and Manners (46) have developed a novel organometallic block copolymer of ferrocenyldimethylsilane and dimethyl siloxane (PFS-*b*-PDMS). This copolymer self-assembles in hot hexane to form wormlike micelles with an iron-rich core.

Starting in 1995 (1), a wide range of different crew-cut morphologies has been observed among aggregates prepared from asymmetric amphiphilic block copolymer systems. The aggregation behaviour shadows small molecule surfactants, where a long hydrophobic tail and a small polar head group generate a wide variety of morphologies in solution. For asymmetric amphiphilic diblock copolymers, the observed morphologies include, but are by no means limited to, spheres, rods, bicontinuous structures, vesicles, lamellae, large compound micelles, large compound vesicles, tubules, "eggshells," baroclinic tubules, porous spheres, and multilamellar vesicles. Overall, we have identified on the order of 30 morphologies (1, 5–28), but their taxonomy presents problems. Some of the morphologies are thermodynamically induced in which case equilibrium trends are observed from simple spheres to inverted micelles; others are kinetically controlled, and their classification is more difficult. Where the mode of aggregation is primarily under thermodynamic control, we observe a spectrum of morphologies (as is also seen both in the bulk and in small molecule surfactant systems) from spheres through rods, bicontinuous rods, bilayers (lamellae and vesicles) to inverse rods and spheres as well as mixtures. Polystyrene-*b*-poly(acrylic acid) (PS-*b*-PAA), polystyrene-*b*-poly-(ethylene oxide) (PS-*b*-PEO), and polystyrene-*b*-poly(4-vinyl pyridine) (PS-*b*-P4VP) are the diblock copolymers that have received the most attention in our studies.

1.5. Others working in the field

More recently, other groups have also studied crew-cut morphologies of copolymers other than simple spheres, including the group of Liu (47), who investigate, among others, polyisoprene-*b*-poly(2-cinnamoylethyl methacrylate) (PI-*b*-PCEMA) in THF with the addition of hexanes, a selective precipitant for PCEMA. They also prepare spherical micelles from polystyrene-*b*-poly(2-cinnamoylethyl methacrylate) (PS-*b*-PCEMA) in THF–cyclohexane or chloroform–cyclohexane mixtures (48). PCEMA-*b*-PAA has also been shown to give various morphologies, including nanofibres (49) and hollow nanospheres, among others (50). One particularly interesting characteristic of PCEMA is that it can be cross-linked, thereby adding stability to the aggregates. The group of Nose (51) has also published examples of crew-cut aggregates.

1.6. Statement of purpose

In this review, the intent is to present and interpret the conditions leading to the formation of aggregates of the various morphologies of highly asymmetric amphiphilic diblock copolymers. The thermodynamic framework as well as parallels to small molecule systems are considered. A detailed review of the various morphogenic parameters including block length, additives, temperature, solvent, and block composition will be presented as a foundation for a survey of the solution morphologies we have observed. Parallels will be drawn between these aggregates and biological subcellular architectures.

2.0. Thermodynamic and experimental parameters

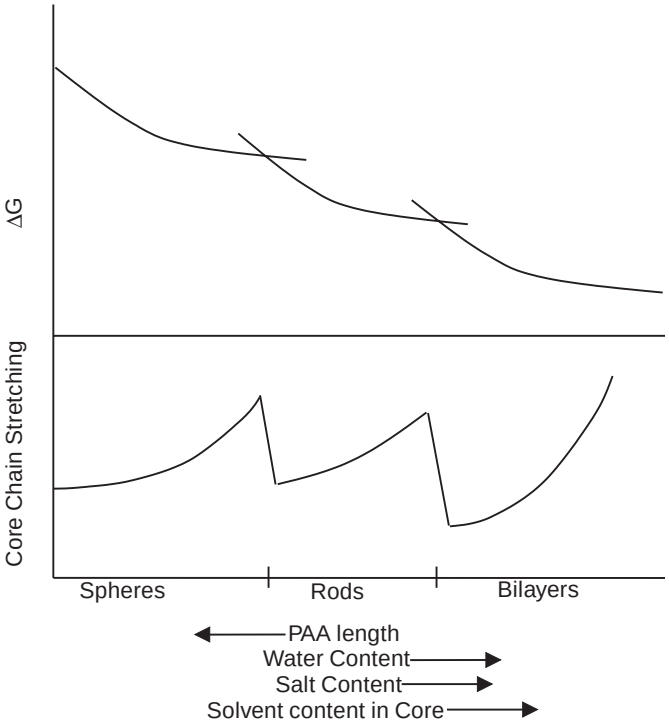
2.1. Three components of the free energy of aggregation

The morphology of self-assembled block copolymer aggregates is governed primarily by three components of the free energy of aggregation: (*i*) core–chain stretching, (*ii*) interfacial energy, and (*iii*) intercoronal chain interactions (21, 37). The effects of these parameters can be more easily understood using the following two examples: in one case, only the hydrophilic block length is varied; in the other, a polymer of constant composition is used in a binary solvent mixture of DMF and water, but we increase the water concentration.

Using a block copolymer with a constant polystyrene block length and starting with a relatively long PAA block, spherical micelles are observed initially. As we decrease the

© 1999 NRC Canada

Fig. 1. Schematic plot of relative free energies and degree of core–chain stretching to indicate morphological boundaries as a function of morphogenic parameters.



PAA length, the repulsive interactions between coronal block chains decrease, thus more chains can aggregate, leading to larger spheres. Some of the polystyrene blocks, however, must reach from the centre of the core to the core–corona interface, and in general, the larger the PS core, the greater the average degree of core–chain stretching. When the aggregates become very large, the entropic penalty of core–block stretching renders simple spheres unfavourable as a low energy morphology, and rods are formed with a decreased core diameter. Reducing the PAA block to an even greater degree leads to an increase in the rod diameter as the aggregation number increases due to reduced coronal block repulsion. Ultimately, in the same manner as for the simple sphere–rod transitions, the core–block stretching term will dictate a further morphological transition to the bilayer structures.

On the other hand, starting with a diblock copolymer of a particular composition in pure common solvent, as we increase the water concentration, we get self-assembly of spheres at some critical concentration (cwc). As the water content increases, the total interfacial energy increases, so the drive is to minimize the total interface surface area. In the limit, a single styrene sphere would minimize the interfacial energy, but the finite styrene block length precludes this option. As soon as the chain stretching and coronal terms exceed the interfacial energy term, a new rod-like morphology with a smaller radius becomes favourable. If the PAA block length is too long, however, then the spherical micelles formed are thermodynamically "stuck" and do not undergo the transition. In this case, the net surface area decrease does not compensate for the electrostatic repulsion implied by the long acrylic acid block. Where the PAA block is short enough, the rod to bilayer morphology change can be induced by more water addition.

If any of these free energy parameters is stressed, for example, by further water addition or reduction of the hydrophilic block length, morphological transition to inverted structures is possible. The PS stretching term and corona–chain repulsion term are balanced by the interfacial term to give a comparatively smooth series of transitions in the total free energy of aggregation[4] (see Fig. 1).

2.2. Preparation of the aggregates

Small molecule surfactants can usually be dissolved directly in a solvent that is good for either the hydrophobic or the hydrophilic component, and due to rapid molecule exchange, equilibrium morphologies are rapidly established (cf. start–stop mechanism). This approach does not work easily for aqueous systems involving amphiphilic PS-*b*-PAA because of the extreme insolubility of polystyrene in water. As mentioned earlier, in an effort to achieve equilibrium conditions, dilute polymer solutions (1% w/w) in dimethyl formamide (DMF) are prepared and then deionized water is slowly added, thereby approaching the critical water concentration (cwc) where self-assembly begins. As the water concentration increases from the cwc, the kinetics of chain exchange slow, and it is possible to trap the then present morphologies. When the water content reaches 25% (w/w), the sample is dialyzed against distilled water to remove DMF. The cwc is usually around 5% H_2O, and at about 10% H_2O, the three-dimensional architectures are considered to be "frozen."

2.3. Environmental parameters

Having detailed the contributing factors to the free energy of aggregation, any parameter that perturbs the core stretching, coronal repulsion, or interfacial energy terms provides a window to morphological control. While the stability of the aggregates, once formed, is very high, the self-assembly of crew-cut PS-*b*-PAA is, in fact, extremely sensitive to the preparative conditions. We have therefore been able to probe the effects of parameter modification that directly affect one or more of the three contributions to the free energy of aggregation: precipitant addition, initial polymer concentration, additives (salt, acid, base and homopolymer), block composition, temperature, and common solvent.

2.3.1. Water addition

Two methods of aggregate preparation are exploited for the DMF–water system. In the vast majority of our samples, aggregation is induced by the water addition method (WA) as described above (Sect. 2.2). The direct dissolution method (DD) in DMF–water mixtures has also been exploited where, for example, the PS-*b*-PAA is dissolved in a solvent mixture containing between 5.5 and 9.5 wt.% water. Table 1 demonstrates the effect of WA from 0 to 7.5% as compared with direct dissolution into a binary solvent mixture at 7.5% water on the aggregate morphology (26).

These methods of sample preparation provide further insight to the thermodynamic and kinetic parameters of morphogenesis. At low water concentrations, the kinetics of exchange are rapid, and therefore, it is the thermodynamically most stable morphology that will dominate. At higher water concentrations, the speed at which aggregation occurs or morphologies change controls the prevalent morphology to a much larger extent. The WA method certainly optimizes chain exchange, since during the onset of aggregation the nonsolvent concentration is low, whereas the DD method is limited by the kinetics of chain exchange at a specific precipitant content. In both cases, the thermodynamics of aggregation appreciably control morphology at low water contents; however, due to the initially high water concentration for DD, rods are possible, for example, in a system that forms simple spheres using the WA method. On the whole, the aggregates formed via DD exhibit more complicated morphologies, whereas the morphologies observed via WA reflect the faster kinetics of chain exchange and the morphologies formed at lower water concentrations, which freeze when the rate of water addition exceeds the dynamics of morphological transition. A possible mechanism for these method-dependent differences depends on the initial state of the polymer. For WA, the polymer is in a molecularly disperse solution of DMF, and aggregation is induced at a low water concentration. At higher water concentration, chain exchange is very slow, and thus, despite the same final water concentration (e.g., 7.5% in Table 1), the exhibited morphology is often the simple sphere. For DD, polymer is added as a solid to a binary solvent mixture, and swelling followed by fission can lead to more complex morphologies that may better reflect thermodynamic equilibrium. In the limit of very slow water addition or very long storage times for direct dissolution, the observed morphologies converge.

2.3.2. Initial polymer concentration

Table 1 not only highlights the effect of water concentration and the preparation method, but also indicates the strong dependence of morphology on the initial polymer concentration. As with most of the trends, which we observe by progressively modifying the aggregation conditions, the morphological progression is from spheres to rods to vesicles and on to inverted and more complicated architectures with various intermediates. Thus, at low initial polymer concentration, simple spheres dominate; however, at higher polymer concentrations, more complicated morphologies become possible (26).

2.3.3. Additives

Water is not the only additive that can have a profound impact on morphology. Any reagent that affects the coil dimensions, inter and intra coronal block interactions, or solvent quality, can be induced to have an effect on aggregation morphology. The results from experiments involving acid, base, and various salts as well as homopolymer are described below. For the ionic additives, the absolute concentration of additive, though important, is not as interesting as the molar ratio, *R*, which relates the number of ions added to the number of coronal repeat units (in our case AA, 4VP, etc.) present. The morphogenic effect of added ions has been investigated over a molar ratio range up to 4.0 (see Table 2) (8, 12). The morphogenic effect of salt has also been studied at millimolar ratios (m*R*) for PS(310)-*b*-P4VP(58). More extraordinary is that *micro*molar ratios (μR) of acid and base induce morphological transitions for this system (24).

2.3.3.1. Salt: The addition of salts induces electrostatic shielding along the partially ionized corona-forming block (for the polyelectrolytes). As the charges along the chain become shielded from one another, the coil dimension decreases thereby reducing steric and electrostatic repulsion among the chains. It is no great surprise then that for a given polymer (e.g., PS(410)-*b*-PAA(25)) the progressive addition of NaCl to a final *R* value of 4.0, while the system is dynamic, can be used to induce the formation of rods, vesicles, or large compound vesicles from a suspension of spheres

PS-*b*-PAA (units)	Homo-PS units	Weight ratio PS-PAA:PS	Morphology	Diameter or wall thickness (nm)
500-*b*-58	—	100:0	Sphere	30
500-*b*-58	180	90:10	Sphere	31
500-*b*-58	180	80:20	Sphere	36
500-*b*-58	180	70:30	Sphere	37
180-*b*-14	—	100:0	Rod	23
180-*b*-14	38	95:5	Sphere	27
200-*b*-8	—	100:0	Vesicle	18
200-*b*-8	38	95:5	Sphere	33

(see Table 2) (8, 12). By adding a divalent cation ($CaCl_2$), bridging becomes possible, and morphological transitions occur at even lower concentrations and *R* values (Table 2). PS(310)-*b*-P4VP(58) follows the same trend from spheres to bilayers on addition of simple electrolytes (24).

2.3.3.2. Acid: The addition of a protic acid is also a potent morphogenic device, since protonation of any anionic acrylate pendant groups will be assured. Thus, protonation provides a valid mechanism for morphological transitions (see Table 2). At a molar ratio (*R*) less than 0.035 HCl per acrylic acid unit for PS(410)-*b*-PAA(25 or 13), only spheres are observed. By raising the molar ratio progressively to 0.050, rods, vesicles, and LCVs are obtained (8, 12). Amphiprotic PS(310)-*b*-P4VP(58) undergoes a sphere–rod transition on the μR addition of HCl. Further addition induces a rod–sphere transition due to increased charge density, and continued addition reverses the trend direction again due to electrostatic shielding (24).

2.3.3.3. Base: The effect of the addition of a strong base is simply to enhance the charge density of the coronal block for PS-*b*-PAA due to deprotonation of the pendant acrylic acid. As charge density increases, coronal repulsion also increases, thus aggregation number and core diameter decrease, and the morphological trend is reversed (Table 2) (8, 12). For the PS(310)-*b*-P4VP(58) system, the situation is more complicated. The micromolar ratio addition of NaOH causes a transition from spheres to rods, but the progressive addition increases charge density due to the abstraction of the α backbone hydrogen so the anticipated sequence of rods to spheres is observed. Still, more NaOH leads to shielding, and the trend is again reversed in the direction of spheres to bilayers (24).

2.3.3.4. Homopolymer (7, 25): The addition of homopolymer to a molecularly disperse solution of PS-*b*-PAA can be used to induce minor variations in diameter within the spherical morphology regime or regime transitions from rods or vesicles to spheres (see Table 3) (7). The effect of added homopolystyrene is to decrease the cwc due to the higher overall content of hydrophobic polymer, but the onset of rod formation is delayed, since the additional homopolymer can volume-fill the core, thereby relieving the core–chain stretch. Experimentally, the block copolymer was dissolved in DMF along with homo-PS, and then water was added in the standard way. It was necessary to use homo-PS samples that were shorter than the PS block of the copolymer in order to avoid premature precipitation of the homopolymer. As long as the copolymer and homopolymer self-assemble before the homo-PS precipitates, then the DMF swollen nascent cores solubilize the homo-PS chains, and therefore, within the spherical regime, the core diameters increase. The addition of homo-PS to samples that form aggregates other than solid spheres may induce spherical morphologies, since it is primarily the inability of the PS block to stretch and completely fill a sphere that leads to nonsphericity in the "native" state (see Table 3).

Table 4. Diblock composition and morphology (7).

PS-*b*-PAA (units)	PAA (mol %)	Morphology
170-*b*-33	16.3	Sphere
180-*b*-28	13.5	Sphere
180-*b*-14	7.2	Rod
410-*b*-20	4.7	Vesicle
410-*b*-16	3.8	Lamella
200-*b*-4	2.0	LCM

2.3.4. Block length (scaling relations)

As discussed within the context of the section on the three components of the force-balance, the block length of each block affects the morphology. Scaling relations have been determined that relate core radius (R_{core}), as well as the related surface area per chain (A_c), and the degree of PS stretching (S_c) within the core for crew-cut primary spheres (7). For example, eq. [1] shows that the radius increases with PS length due to the increased volume of PS in the core.

$$[1] \qquad R_{core} \propto N_{PS}^{0.4} N_{PAA}^{-0.15}$$

With increasing PAA length, however, increasing coronal chain repulsion decreases the aggregation number, therefore, the aggregate size decreases. By varying just the PAA content of the polymer, many of the equilibrium-type morphologies can be induced (see Table 4) (7).

2.3.5. Temperature

The single solvent preparation of aggregates from highly asymmetric diblock copolymers is very desirable not only from the perspective of potential industrial applications but also as a means of simplifying the system in order to control it better. A nontoxic single solvent would be even more desirable if the applications were to have pharmacological

Table 5. Solvent and polymer parameters (52).

Material	Solubility parameter δ	Dielectric constant ε
DMF	24.8	38.2
Dioxane	20.5	2.2
THF	18.6	7.5
Water	47.9	80.1
Styrene	19.0	
Acrylic acid	24.6	

leanings. For PS-*b*-PAA, where the PS block is very much longer than the PAA block, direct preparation in water, even at 200°C and elevated pressure, has proven impossible. However, in less polar low alkanols (methanol, ethanol, *sec*-propanol, and *n*-butanol), elevated temperatures are sufficient to permit at least chain transfer from the bulk to nano and mesoscopic aggregates including spheres, vesicles, tubules, and interconnected vesicles. Given the monodisperse spheres of diameter ~25 nm observed for PS(386)-*b*-PAA(79) formed on cooling in *n*-butanol (0.07 wt.%, 170°C), we infer that while at 170°C, the complete dissolution of the polymer may have been achieved in this solvent, or at least that the kinetics were fast enough for morphogenesis (23). Essentially, this method mimics the effect of water addition to a copolymer solution in a common solvent, since solubility decreases both as the water content increases for binary solvent mixtures and as the temperature decreases for our polymers in single solvent systems.

2.3.6. Common solvent

The role of solvent is crucial to all aspects of the free energy of aggregation. Polymer–solvent interactions determine the coil dimension for each block of a diblock copolymer, which, in turn, has a profound impact on the aggregate dimensions and modes of assembly.

Dissolution of polymers is optimal where the δ values for polymer and solvent are similar (see Table 5) (52). As these values diverge, the polymer chain dimensions decrease. High dielectric constant (ε) values improve the solubility of the corona block. The choice of common solvent therefore permits a qualitative exploration of the principal terms of the free energy of aggregation, since the common solvent directly affects both the core and corona chain dimensions, and the dielectric constant of the nonsolvent affects the coronal chain dimension as well as the interfacial energy.

Solvents common for both blocks in the PS-*b*-PAA system other than DMF and low alkanols have also been investigated. The core dimension of a nascent aggregate during the early stages of water addition is highly dependent on the polymer–solvent interaction parameters. Where the common solvent is better for the core-forming block, during the addition of water, the partition of organic solvent will dictate that the core be more swollen than is the case for DMF. Due to the swelling, more complex morphologies are possible. Some examples of the available morphologies from PS-*b*-PAA copolymers using DMF, dioxane, or THF as a common solvent are given in Table 6. Using just one polymer that exhibits different morphologies in different solvents, any of the intermediate morphologies is made accessible through solvent mixtures (18).

Table 6. Morphology of PS-*b*-PAA from different common solvents (18).

Polymer	PAA content (mol%)	Common solvent		
		DMF	Dioxane	THF

2.3.7. Other block copolymers

Most of the variable parameters discussed above have been presented in the context of PS-*b*-PAA; however, other asymmetric diblock copolymer systems have also been investigated in our laboratories albeit less extensively (see Table 7). The hydrophilic block characteristics change significantly for the different samples; nevertheless, the underlying principles for the self-assembly of asymmetric amphiphilic diblock copolymers are universal. Due to narrow morphological boundaries in their respective phase diagrams, as seen for the polymer bulk morphologies described earlier, it may be that some morphologies are not observable for practical reasons. Some morphologies may not be stable at all for some systems under the conditions of the experiment.

The PS-based systems have a glassy styrene phase at room temperature in water. The other core-forming blocks, poly(caprolactone) (PCL), and poly(butadiene) (PBD), have T_g values of about –65°C (53) and –90 to –8°C (14), respectively. Polyelectrolytic coronae can be formed for PAA and derivatives of poly(4-vinyl pyridine) (P4VP). Uncharged coronae arise from PEO systems. The PS–PMMA–PAA triblock system (20) permitted a preliminary investigation of the effect of a second hydrophobic block on the cwc and subsequent morphologies. Despite the incomplete investigation to date for some of the systems described in Table 7, it is clear that all of these highly asymmetric amphiphilic diblock copolymers follow the same rules. By varying the parameters discussed in some detail above, each system has been induced to form a range of morphologies, and each adds to our understanding of micro-phase separation and aggregation for this particularly rich class of macromolecule.

2.4. Phase diagram and kinetics studies

Summarizing multidimensional phase behaviour is a complicated undertaking; however, we have begun the construction of a ternary phase diagram as a function of water, dioxane, and the polymer PS(310)-*b*-PAA(52).[4] Given the detailed information on the necessary conditions for the formation of the various equilibrium and near-equilibrium morphologies presented in Sect. 3 that can be presented in phase diagrams, it becomes feasible to design systems for desired properties.

A further consideration is the speed at which aggregates can be formed. Early studies started with two populations of solid spheres formed from two different PS-*b*-PAA samples and followed the time scale over which they formed a single population when mixed (13, 54). More recently, attention has been devoted to the formation of complex inverted structures (HHH and TWV, discussed below) from vesicles (17, 22, 27) and bilayers from rods.[5]

3.0. Equilibrium and near-equilibrium morphologies

As a consequence of the kinetics and thermodynamics studies, most aggregates can now be sorted into equilibrium, near-equilibrium, and metastable morphologies. Equilibrium studies have positively identified spheres, rods, and vesicles as well as wide boundary regions between each morphology where, for example, spheres and rods coexist at equilibrium.[4] Furthermore, in a similar fashion to small molecule surfactants and also diblock copolymers in the bulk, a phase inversion occurs in the spectrum of morphologies. In a limited sense to be discussed further, the inverted equilibrium morphologies include hexagonally packed hollow hoops (HHHs) and large compound micelles (LCMs). As observed under the electron microscope, these aggregates represent morphologies at or near equilibrium that were quenched and isolated. Equilibrium and near-equilibrium morphologies (Figs. 2–5) are described below. A discussion of nonequilibrium morphologies (Fig. 6) follow in Sect. 4.0. Some morphologies presented are paradigms from the polymer literature, and some are novel for polymers (e.g., tubules; see below). Still others are novel in their own right, and to our knowledge are without precedent in the self-assembly literature (e.g., pincushions; see below).

3.1. Equilibrium

Simple *spheres*, shown schematically in Fig. 3, of PS-*b*-PAA block copolymer formed in an aqueous environment, consist of a PS core surrounded by PAA coronal chains (1, 2). Usually, PS-*b*-PAA block copolymers with a relatively high PAA content (>10%) form simple spheres. The polydispersity of such micelles is low ($2\sigma_r/d < 5\%$),[6] and the size of the spheres is affected by a number of factors, such as the block lengths, addition of salts (HCl, NaCl, $CaCl_2$) or homopolystyrene to the solution. An obvious restriction for simple spheres is that the total hydrophobic block length in its planar zigzag configuration must not exceed the radius of the core. The entropic penalty of chain stretching dictates, however, that well before the chains become fully extended, a morphological transition is induced. The simple sphere is the parent morphology for all crew-cut aggregates, since under our classical preparative conditions, it is usually the first aggregate to form. We take this morphology as the most basic example of the effect of the force balance equation. The subsequent morphologies are explained as a function of their deviation from this standard where the core–chain stretching, core–corona interfacial energy, and the coronal chain repulsive forces are optimized with respect to the lowest accessible free energy of aggregation available (cf. Fig. 1). Figure 2*A* demonstrates the typically low polydispersity of spherical crew-cut micelles formed, for example, from PS(200)-*b*-PAA(21).

Rods (1, 7, 21) as sketched in Fig. 3, need little description. They are characterized by diameters of the same order of magnitude as those of primary micelles (ca. 30 nm) but can be of widely variable length that can exceed 10 μm (Fig. 2*B*). It should be noted that the energetic contributions to the free energy of aggregation still include core–chain stretching which, at the transition, is decreased slightly relative to the simple sphere, but generally is comparable since the diameters are comparable, and also corona–chain repulsion, which experiences a net decrease due to a decrease in the chain length or due to the addition of simple electrolytes. While the radii of spheres and rods are comparable, the greater length of the rods means that the total aggregate volume increases, thereby reducing the net interfacial energy per chain between the core and the solvent. A further contribution is the end-capping energy arising from the high curvature of the hemispherical caps at rod ends. Under a wide range of conditions, this term is not especially significant although hooped rods ("doughnuts") have been observed. For example, in the case of some of the more complex aggregates presented later, the end-capping energy penalty is sufficiently large that hoops are formed despite the extra curvature energy.

The *bicontinuous rod* morphology (Fig. 2*C*) consists of networks of interconnected branched rods in three dimensions. The diameters of the rods are monodisperse, and the origin of the branch points is the same as for the bicontinuous morphology in the bulk. Disordered bicontinuous rods are schematically represented in Fig. 3. We have observed not only disordered bicontinuous morphologies (25), but also highly ordered examples (28). It is not especially surprising that we find a range of morphologies for asymmetric diblock copolymers in solution. Detailed equilibrium studies have confirmed the status of the simpler solution morphologies; however, due to the fact that this morphology is not seen for all samples, and furthermore, where it is seen, it is only over a very narrow range of parameters, we are unable to categorically assign equilibrium status. It is likely that the highly ordered bicontinuous samples better represent equilibrium.

Bilayers (Figs. 2*D–F*) represent the next step in the arrangement of diblock copolymers as block or environmental parameters change. As shown schematically in Fig. 3, *lamellae* (Figs. 2*D*, 2*E*) and *vesicles* (Fig. 2*F*) are character-

ized by flat or curved bilayer "walls" of polymer. It should be noted that under some preparative conditions, lamellae appear in vesicular suspensions, but under other conditions, pure lamellae can be prepared.[5] Figure 2*D* demonstrates isolated lamellae, whereas Fig. 2*E* shows the superposition of much larger lamellae, in which the different shades of grey represent different numbers of lamellar layers. Vesicles are a particularly versatile morphology, as they can be prepared from many polymers. While small, nearly monodisperse vesicles are often formed, larger, more polydisperse aggregates can also be obtained.

It is highly possible that the *inverse bicontinuous rod* morphology exists under certain equilibrium conditions. To date, we have had only indications of its existence in our studies of the transition from vesicles to the HHH morphology; however, we have not been able to identify it posi-

Fig. 3. Schematic drawings of equilibrium morphologies. Where convenient, coronal chains are indicated; core-forming chains are symbolically represented for the sphere. The surface for HHH represents the interface between hydrophilic and hydrophophic domains. Thus, for PS-*b*-PAA, these hoops contain water swollen PAA, and the whole structure is embedded in a PS matrix.

tively. This morphology is the phase-inverted counterpart of the bicontinuous rod described above (17).

The preparation of *hexagonally packed hollow hoop* structures (*HHH*) (Fig. 2*G*) involves first the formation of small vesicles of PS-*b*-PAA by addition of water; subsequent addition of NaCl ions to the solution of vesicles leads to the assembly and rearrangement of the vesicles into HHH aggregates (17). The HHH structure of the aggregates is depicted in a computer visualization (Fig. 3), and consists of an arrangement of multiple "hollow" concentric rings in a hexag-

onal pattern. The external surface of the aggregates, as well as the internal surface of the hollow hoops, consists of short PAA chains. The hoops are embedded in a PS matrix.

The addition of NaCl to the single vesicles allows for the decrease of the repulsion between them, since NaCl increases the electrostatic screening among the PAA chains, thus reducing the electrostatic repulsion. The vesicles, therefore, come into contact and form large compound vesicles (LCVs). Minimization of the surface free energy and that of chain stretching lead to the formation of HHH aggregates. The end-capping energy of a rod is replaced by a mesoscopic curvature energy on this size scale (i.e., several hundreds of nanometers), imposing the hoop morphology. Indeed, there are two ways of packing rods in a cylindrical space: one consists of a hexagonal packing of straight rods parallel to the direction of the principal axis in which case there is an end-capping energy penalty, resulting from the formation of hemispherical caps at the end of the rods. The other way avoids the end-capping energy penalty by forming hoops, but involves a curvature energy penalty. In the pres-

ent case, for particle sizes less than 1 μm, the end-capping energy is more important than the curvature energy, and hollow hoops are formed in a hexagonal pattern. This morphology may represent equilibrium as long as the particle is isolated, in analogy to the thermodynamic aspects of the vapor pressure of a small drop. Near a large surface, a small drop is unstable due to its higher vapor pressure, however, an isolated small drop can be considered to be at equilibrium.

Secondary copolymer aggregates present a further solution to the problem of how to arrange a large, insoluble block where the solubilizing block is very short. *Large compound micelles* (*LCMs*), illustrated in Fig. 3, bear a strong resemblance to bulk reverse micelles. For LCMs, islands of PAA chains are found in a continuous phase of core-forming polymer (PS) all of which is surrounded by the solvent-soluble PAA corona (1).

It should be noted that LCMs are highly polydisperse (Fig. 2*H*) and that they tend to settle due to gravity because of their large size. Figure 2*I* represents the internal morphology of an LCM obtained by microtoming a sample embedded in epoxy resin. The 60 nm sections were stained with CsOH(aq) and rinsed with deionized water to remove the excess CsOH. Staining increases the contrast between the PAA and PS regions. The elongated shape of the spheres is most likely due to the strong shear force when microtoming (7).

3.2. Aggregates of spheres

HHH is an excellent example of the end result of a morphological rearrangement in that vesicles are induced to form inverse rods on addition of salt. Another type of rearrangement involves coronal and core–chain interactions for simple spheres that, on addition of acid, yields predominantly one-dimensional "*pearl necklaces*" (Fig. 4*A*) in transition from spheres to rods (8). Drying conditions can yield *2D sheets of micelles* (Fig. 4*B* includes sheet folding), which might conceivably be precursors to lamellae[7]; when drying is performed at elevated temperatures (60–80°C), crack patterns develop, which give very large three-dimensional *birefringent needles* (Fig. 4*C*) that resuspend in water to give simple spheres if the PAA block is sufficiently long (1).

3.3. Near equilibrium

We have identified several other discrete morphologies that structurally resemble pure equilibrium morphologies. We are unable to unequivocally classify them; however, it seems clear that the aggregates are at least near equilibrium.

Large rod-shaped compound micelles (*LRCMs*) have been observed (Fig. 5*A*); we believe their internal structure to be identical to that of large compound micelles. Their lengths can reach several micrometers, and their diameters, several hundreds of nanometers (11).

[7] K. Yu. Unpublished data.

© 1999 NRC Canada

Branched short rods (Fig. 5*B*) may be the result of a situation in which the branching energy is comparable to the end-capping energy. Short branched rods may represent an intermediate structure between rods and bicontinuous rods (11).

The hexagonally perforated bilayer morphology obtained in the case of small molecule amphiphiles, where the pores are hexagonally arranged throughout a bilayer of molecules, has not yet been observed for asymmetric diblock copolymers in solution. However, we commonly isolated *disordered perforated bilayers* (Fig. 5*C*) (26).

The *eggshell* morphology (Fig. 5*D*) consists of a bent lamella, and therefore could possibly be an intermediate structure between a lamella and a vesicle (19).

Tubules (Fig. 5*E*) were rarely isolated with PS-*b*-PAA block copolymers except in low polarity solvents (18, 23), but were observed very often with nonionizable PS-*b*-PEO block copolymers (19). The wall thickness of the tubules is typically ca. 20 nm, and their outside diameter is ca. 100 nm. The length of the tubules can reach many micrometers. The difference between rods and tubules is that the latter are hollow. Tubules therefore belong to the family of bilayers; however, it is not yet clear whether they are true equilibrium morphologies.

Branched tubules (Fig. 5*F*) most probably occur when the free energy of the branching points is energetically comparable to the linear midsections. The diameters of branched tubules are similar to the diameters of the single tubules (19).

The "*bagel*" structure (Fig. 5*G*) is an example of many three-dimensional bilayer oddities (19). It can be described as a tubule in which the two ends are connected. This structure was occasionally observed among other bilayer structures for PS-*b*-PEO block copolymers, including structures with several holes that can be considered hollow "pretzels."

Baroclinic tubes (Fig. 5*H*) can be considered to be strings of attached vesicles, and are possibly an intermediary state between tubules and vesicles. This morphology was isolated for several polymers under radically different conditions (19, 23).

Bicontinuous bilayers (called "plumber's nightmare" in small molecule systems) are three-dimensional arrangements of bicontinuous tubes (11, 19). As in Fig. 5*I*, they are observed along with vesicles, which may be the building units for such complicated structures.

3.3.1. Structural parallels

There are many parallels to be drawn between the "solid" and bilayer structures. The theme of morphological transition seems universal among small molecule amphiphiles, copolymers in the bulk, copolymers at the air–water interface, and copolymers in solution. Similarly, there is an obvious parallel to be drawn between the sequence of spheres, pearl necklace, rods, doughnuts, and bicontinuous rods, and the sequence of vesicles, baroclinic tubules, tubules, hollow doughnuts (or "bagels"), and bicontinuous bilayers within the family of copolymers in solution. The formal similarity of the block copolymer bicontinuous architectures to small molecule amphiphilic bicontinuous cubic phases (3) is also noteworthy.

4.0. Nonequilibrium

The equilibrium and near-equilibrium morphologies previously discussed and demonstrated both schematically and in TEM images represent only a fraction of the aggregates we observe. We also observe kinetically trapped morphologies, metastable morphologies, and also various combinations of otherwise stable morphologies. The classification of some of the observed structures into one of these groups is by no means trivial. Furthermore, the definition of each distinct morphology is, in some cases, quite arbitrary, and these morphologies remain open to interpretation and further investigation.

Large compound vesicles, *LCVs*, (8, 12) some of which resemble compartmented spheres or aggregated soap bubbles (Figs. 6*A*, 6*B*) are perhaps among the best examples of a metastable morphology where clear classification is difficult. The inset in Fig. 6*B* is a schematic representation of the internal bilayer structure. Despite the fact that we can choose a polymer and conditions to create a suspension solely of LCVs, the polydispersity remains quite high, and the substructure is highly irregular. Essentially spherical LCVs as well as LCVs with clearly protruding vesicular structures have been observed. It is tempting to conclude that this morphology is in transition. PS(410)-*b*-PAA(13) at 1% initial concentration (w/w) in DMF forms spacious LCVs on the addition of water and very dilute HCl (225 μM). By increasing the HCl concentration to 253 μM, the LCVs formed are much more dense with smaller cavities. As the cavities get smaller, the aggregate begins to resemble more and more the inverse bicontinuous rod or even HHH morphology.

Porous spheres (Fig. 6*C*) are morphologically between LCMs and LCVs, though where exactly they fit in the continuum remains to be seen. The continuous phase is hydrophobic, and there are large cavities within each aggregate, which suggests a "Swiss cheese" analogy. These aggregates form not only from PS-*b*-PEO (11), but also from PS-*b*-PAA with additional homo-PS (25).

Tube-Walled Vesicles (*TWVs*), seen in Fig. 6*D*, are an interesting hybrid of bilayers and inverse rods (22, 27). Although vesicular, the walls are also constructed of hollow tubes. We have many examples of aggregates that follow this motif and believe these aggregates are formed in transition from vesicles to HHH, where for steric reasons the vesicles do not fuse but rather the wall thickens and hollow tubes develop.

"*Onions*"[8] and *entrapped large vesicles* (19) (Figs. 6*E*, 6*F*) are variations on a theme. Multilamellar vesicles have been observed in at least two of our polymer systems and are likely possible in the rest. TEM shadowing experiments confirm the sphericity of the onions that for PS(410)-*b*-PAA(13) are formed from a suspension of vesicles in DMF with 5% water on the addition of salt. Onions have also been observed from PS(260)-*b*-P(4VP.DecI) prepared from a dilute solution in THF by simply adding water dropwise to 50% (w/w) followed by dialysis. Interestingly, there is a precedent for diblock copolymer onions where symmetric diblock copolymers in the bulk have been shown to form

multilamellar spheres when a polymer solution is sprayed, giving small drops that are subsequently dried (55).

An important feature of the large and trapped ("pregnant") vesicles is their size. While nearly monodisperse small vesicles (Fig. 2*F*) are often possible for asymmetrical diblock copolymers, under other conditions, we also observe very much larger vesicles that are usually quite polydisperse. Each large vesicle appears to have an indentation; however, this is an artifact of sample preparation, since each TEM grid is subjected to and released from high vacuum in shadowing, and there is plenty of opportunity for an imbalance of internal and external pressure.

Some samples under certain preparative conditions give *mixed morphologies*. Careful phase diagram work[9] demonstrates appreciably wide equilibrium coexistence regions between the pure sphere and pure rod as well as between the pure rod and pure bilayer regimes. Figures 7*A* and 7*B* are representative examples of such mixed morphologies.

Combined morphologies should be distinguished from the transitional morphologies such as TWVs in that for true combination, simple morphologies are fused. The structural elements of LCMs and rods combine to give a variety of "pincushions" (Figs. 7*C* and 7*D*) where the "pins" can be long or short (11). Rods and lamellae fuse to give "many-armed starfish" (Fig. 7*E*), and vesicles and rods are also occasionally joined (Fig. 7*F*).

4.1. Structurally biomimetic morphologies

It is interesting to note that many of these architectures and their combinations superficially resemble much more complicated biological and cellular systems. Consider the following pairs: lamellae and cell walls, tubules and cellular microtubules, rods and biological filaments, nucleoli and short branched rods or small pincushions, the smooth endoplasmic reticulum and the bicontinuous rod, and finally, microvilli vs. the pincushion. As with lipid-based biosystems, we observe budding transitions at the fusion points for combined morphologies of copolymer aggregates (19). A further point of similarity is the extreme versatility of both biolipids and asymmetric amphiphilic diblock copolymers. In summary, although the biomimetic analogy cannot be taken very far, what remains true is that nature chooses low-energy biological structures, and we observe low-energy architectures that, with small changes in environment, are subject to morphogenesis.

5.0. Conclusions

A morphological wonderland is made possible by asymmetric copolymers that mimic, on a macromolecular level, highly asymmetric small molecule amphiphiles. The critical components of the free energy of aggregation are the core–chain stretching, the coronal chain repulsion, and the interfacial energy. Any parameter that can be induced to modify

[9] H. Shen and A. Eisenberg. Phase Diagram II. Manuscript submitted to Macromolecules.

© 1999 NRC Canada

these terms has a morphogenic effect, and due to the slow kinetics of macromolecules, we have enormous control over their ultimate aggregated morphology. Furthermore, slow kinetics lend themselves to detailed study of morphological transitions better than the kinetics of small molecules, which are fast. The range of equilibrium morphologies is broad and follows, in a sense, the same sort of sequence as observed for small molecule systems as well as diblock copolymers in the bulk. The many near-equilibrium, nonequilibrium, and combined morphologies make unequivocal classification difficult, and furthermore, the definitions of the nonequilibrium morphologies are sometimes arbitrary.

What is a taxonomical nightmare, however, is an engineer's dream as the various morphologies formed by asymmetric diblock copolymers in solution have many potential applications. We are actively pursuing the use of our systems as drug-delivery vehicles (56), but other useful roles include nanoconductors (46) and insulators, nano-filters, timed and chemically induced release capsules (50) as well as nano-reactors (57, 58) for this rich morphological field.

Acknowledgements

N.S.C. and M.K.C. would like to thank Lifeng Zhang and Hongwei Shen for useful discussions during the preparation of this manuscript. A.E. is indebted to the Canadian Society for Chemistry for giving him the EWR Steacie Award for Chemistry, to Sciex Inc. for sponsoring the award, and to the Natural Sciences and Engineering Reseach Council of Canada (NSERC) for funding most of the research, with more recent contributions from the PRF. Most importantly, A.E. deeply is indebted to his current and former graduate students and postdoctoral co-workers, an outstanding group of scientists with whom he has had the good fortune to interact and who have enriched his life both academically and personally for nearly 40 years. For this most recent work, special thanks are due to Zhisheng Gao, Lifeng Zhang, Kui Yu, Yisong Yu, and Hongwei Shen for their seminal contributions.

Dicarbonylcyclopentadienyliridium, $(\eta\text{-}C_5H_5)Ir(CO)_2$, as a ligand

Faming Jiang, Kumar Biradha, Weng Kee Leong, Roland K. Pomeroy, and Michael J. Zaworotko

Abstract: The following complexes, in which $CpIr(CO)_2$ acts as a 2e donor ligand, have been prepared: $Cp(OC)_2IrW(CO)_5$ (**1**), $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$, $Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$ (**2**), $Cp(OC)_2IrOs(CO)_3(X)_2$ (X = Cl, Br (**3**), I). The characterization of the complexes included the crystal structures of **1**, **2**, and **3,** which reveal that all contain an unbridged metal–metal bond. The carbonyl ligands of **1** in solution undergo exchange on the NMR time scale above –40°C. With the exception of **2,** all the complexes dissociate in solution at room temperature, some rapidly so. Only in the case of **3** is an equilibrium with the dissociation products established. The results indicate that $CpIr(CO)_2$ is a weak ligand.

Key words: tungsten, osmium, iridium, binuclear.

Résumé : On a préparé les complexes suivants dans lesquels le $CpIr(CO)_2$ agit comme ligand donneur de $2e^-$: $Cp(OC)_2IrW(CO)_5$ (**1**), $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$, $Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$ (**2**), $Cp(OC)_2IrOs(CO)_3(X)_2$ (X = Cl, Br (**3**), I). La caractérisation des complexes inclus la détermination des structures cristallines des composés **1**, **2** et **3** qui révèlent la présence dans chacun d'une liaison métal–métal non pontée. En solution, au-dessus de –40°C, les ligands carbonyles du composé **1** subissent un échange à l'échelle de temps de la RMN. À l'exception du produit **2**, tous les complexes se dissocient en solution, à la température ambiante; dans certains cas, la dissociation est rapide. On n'a pu établir l'existence d'un équilibre avec les produits de dissociation que dans le cas du composé **3**. Les résultats indiquent que le $CpIr(CO)_2$ est un ligand faible.

Mots clés : tungstène, osmium, iridium, binucléaire.

[Traduit par la Rédaction]

Introduction

Work from this laboratory over the past 15 years has described complexes in which an 18-electron organometallic compound acts as a 2-electron donor ligand to a 16-electron organometallic fragment in much the same way as a conventional ligand such as PPh_3. Typical examples of molecules of this type are $(OC)_5OsOs(CO)_3(GeCl_3)(Cl)$ (1), $(L)(OC)_4OsM'(CO)_5$ (M′ = Cr, Mo, W; L = PR_3 (2), $CNBu^t$ (3)) and $(R_3P)(OC)_4MRu(CO)_3(SiCl_3)_2$ (M = Ru, Os, but not Fe) (4). These complexes contain an unbridged dative bond between two transition metal atoms, which are rare. Only two complexes in this class that are relevant to this study have been reported by others; these are $(\eta^5\text{-}C_5Me_5)[(Pr^iO)_3P](OC)IrRh(CO)[P(OPr^i)_3](Cl)$ (5*a*) and $(\eta\text{-}C_5H_5)(OC)_2RhPt(CO)(C_6F_5)_2$ (5*b*). Complexes with dative metal–metal bonds supported by bridging ligands are more common. Some recent examples are $[RhIr(\mu\text{-dppm})_2(Me)(CO)_3][CF_3SO_3]$ (dppm = $Ph_2PCH_2PPh_2$), $[Pt_2\{Rh(Cl)(CNXyl)\}(\mu\text{-dpmp})_2(CNXyl)][PF_6]_2$ (dpmp = $Ph_2PCH_2P(Ph)CH_2PPh_2$), $(OC)_3(XylNC)Fe(\mu\text{-dppm})Re(CO)_3(Br)$, $Ni(\mu\text{-}S_2fc)(PMe_2Ph)$ (S_2fc = -$(\eta\text{-}SC_5H_4)_2Fe$), and $Mo_2Pd_2(\mu_3\text{-pyphos})_4$ (pyphos = 6-diphenylphosphino-2-pyridonate) (6).

One of the first complexes of this type that we reported was $Cp^*(OC)_2IrW(CO)_5$ (Cp^* = $\eta^5\text{-}C_5Me_5$), which was of marginal stability (7). No attempt was made to prepare the analogous complex in which $(\eta\text{-}C_5H_5)Ir(CO)_2$ acted as a ligand. It was expected that this molecule would be a much weaker donor than its $\eta^5\text{-}C_5Me_5$ analogue. It was known that $Os(CO)_4(PR_3)$ (R = Me, OMe, Ph etc.) were far superior ligands than $Os(CO)_5$ (2). It is presumed that replacing a carbonyl ligand in $Os(CO)_5$ with a stronger σ donor PR_3 ligand increases the electron density on the Os atom and hence increases the dative metal–metal bond strength. More recent studies have, however, revealed that $Os(CO)_3(PR_3)_2$ compounds are weaker ligands than the monosubstituted compounds. For example, although it was possible to isolate $(Me_3P)_2(OC)_3OsW(CO)_5$, the chromium compound could not be prepared (8), whereas $(Me_3P)(OC)_4OsCr(CO)_5$ is an air-stable crystalline solid (2).

The failure to prepare $(Me_3P)_2(OC)_3OsCr(CO)_5$ was attributed to excessive steric interactions between the PMe_3 ligand, which would necessarily be *cis* to the OsCr bond and the radial carbonyls on the Cr atom. This suggested that

complexes with the sterically undemanding $(\eta\text{-}C_5H_5)Ir(CO)_2$ molecule acting as a ligand might be more stable than originally thought. Herein, we report the results of an investigation into this possibility that shows that $CpIr(CO)_2$ can indeed act as ligand, but only with strong acceptor fragments can the resulting complexes be isolated.

Experimental section

Unless otherwise stated, manipulations of starting materials and products were carried out under a nitrogen atmosphere with the use of standard Schlenk techniques. Solvents were thoroughly dried before use. The iridium precursory complex, $(\eta\text{-}C_5H_5)Ir(CO)_2$, was prepared by the reaction of $[Ir(CO)_3(Cl)]_n$ with Tl[Cp] in thf, a minor modification of the original preparation (9). The $W(CO)_5$(thf) (2), *cis*-$Ru(CO)_4(SiCl_3)_2$ (10), $Os(CO)_5$ (11), and *cis*-$Os(CO)_4(I)_2$ (12) were synthesized by literature procedures. The preparations of *cis*-$Os(CO)_4(X)_2$ (X = Cl, Br) (13) and *cis*-$Os(CO)_4(GeCl_3)(Cl)$ (14) are modifications of literature procedures and are given below for completeness.

Infrared spectra were recorded on a Bomen MB100 spectrometer; nuclear magnetic resonance spectra were recorded on a Bruker WM400 or Bruker SY-100 spectrometer; microanalyses were determined by M.K. Yang of the Microanalytical Laboratory of Simon Fraser University. Infrared data and elemental analyses for the new compounds are given in Table 1; ^1H and $^{13}C\{^1H\}$ NMR data are given in Table 2. Because they are unstable, no attempt was made to obtain mass spectra of the new derivatives.

Preparation of *cis*-$Os(CO)_4(GeCl_3)(Cl)$

An autoclave (Parr Instrument Co.; 200 mL) was charged with a solution of $Os(CO)_5$ (~350 mg, ~0.94 mmol) and $GeCl_4$ (2.00 mL, 3.75 g, 17.5 mmol) in hexane (75 mL) and sealed. The autoclave was flushed three times with CO and then pressurized with CO (ultrapure grade; 90 atm (1 atm = 101.3 kPa)). It was then heated at 90°C for 24 h. The bomb was cooled and the gases vented; the pale yellow solution was removed from a white crystalline precipitate, which was washed with hexane and dried under a stream of nitrogen. The resulting solid *cis*-$Os(CO)_4(GeCl_3)(Cl)$ (0.53 g, ~95%) was pure by infrared spectroscopy. (The mother solution yielded 31 mg of yellow crystals that were impure product.) Infrared (warm hexane) ν_{CO}: 2173.5(w), 2106.0(vs), 2083.0(vw), 2061.0(s) cm^{-1}; (CH_2Cl_2) ν_{CO}: 2179.5(m), 2118.5(w,sh), 2110.0(vs), 2069.5(s) cm^{-1}.

Preparation of *cis*-$Os(CO)_4(Cl)_2$

A solution of $Os(CO)_4(H)_2$ in hexane (80 mL) was prepared by the reaction of OsO_4 (1.0 g, 3.9 mmol) in hexane

© 1999 NRC Canada

with CO–H_2 (3:1; total pressure 180 atm) at 170°C overnight (13). After slowly cooling the reaction vessel to room temperature and venting the gases, the solution was transferred to a Schlenk flask. The flask was cooled to 0°C and chlorine gently bubbled through the solution until no more precipitate formed. The solvent was removed from the white precipitate, which was washed with hexane and dried on the vacuum line to give *cis*-$Os(CO)_4(Cl)_2$ in essentially quantitative yield. Infrared (CH_2Cl_2) ν_{CO}: 2189.5(w), 2121.5(vs), 2099.5(ms), 2059.5(s) cm^{-1}. The bromo analogue, *cis*-$Os(CO)_4(Br)_2$, was synthesized in a similar manner. Infrared (warm hexane) ν_{CO}: 2177.0(vw), 2112.0(vs), 2089.0(ms), 2050.5(s) cm^{-1}; (CH_2Cl_2) ν_{CO}: 2182.5, 2115.5, 2098.0, 2059.5 cm^{-1}. The spectra of both derivatives are in excellent agreement with those reported in the literature (13).

Preparation of $Cp(OC)_2IrW(CO)_5$ (1)

A sample of $W(CO)_5$(thf) was prepared from $W(CO)_6$ (40 mg, 0.11 mmol) and the solvent reduced to ~0.5 mL on the vacuum line. A solution of $CpIr(CO)_2$ (~15 mg, ~0.045 mmol) in cold hexane (8 mL) was immediately added to the cold $W(CO)_5$(thf)–thf mixture and the resulting solution stored without stirring at –25°C for 19 h. The solvent was decanted from the solid that had formed, which was dried on the vacuum line. Unreacted $W(CO)_6$ was removed from the solid by sublimation under high vacuum at room temperature to a cold finger. The residue was dissolved in a minimum amount of CH_2Cl_2 at –20°C and quickly filtered through a short column of Florisil (2 × 1 cm) and the solvent was removed on the vacuum line at –20°C. As such, **1** was obtained in low yield as a yellow microcrystalline solid that was analytically pure. In a second preparation the Schlenk flask containing the reagents was kept at –25°C for 6.5 d, whereupon yellow crystals of **1** were obtained that were handpicked from black decomposition material to afford the sample used in the X-ray analysis.

Preparation of $Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$ (2)

A round-bottom flask (~100 mL; fitted with a Teflon valve) was charged with $CpIr(CO)_2$ (~55 mg; 0.18 mmol), *cis*-$Os(CO)_4(GeCl_3)(Cl)$ (100 mg, 0.194 mmol), and hexane (30 mL). The flask and contents were cooled to –196°C and the flask was evacuated; the solution was degassed with three freeze–pump–thaw cycles. The flask was allowed to warm to room temperature and then heated at 60°C for 3 h. The flask was cooled to room temperature and the solvent and excess reagents removed from an off-yellow precipitate. The precipitate was recrystallized from CH_2Cl_2–hexane to yield **2** (83 mg, 59%) as fawn-yellow crystals that appeared stable in air.

Preparation of $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$

A Schlenk tube with *cis*-$Ru(CO)_3(SiCl_3)_2$ (31 mg, 0.064 mmol) and $CpIr(CO)_2$ (15 mg; 0.048 mmol) in hexane (8.0 mL) was stored at –15°C for 6 d. After this period pale yellow crystals had formed along with gray decomposition material. The solvent and excess reagents were removed and the solids washed with a small volume of hexane and dried on the vacuum line. A sample of the yellow crystals of $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$ were immediately hand picked for chemical analysis and an infrared spectrum. The compound decomposes both in solution (in a period of minutes) and in the solid state (after several hours) under nitrogen at room temperature.

Preparation of $Cp(OC)_2IrOs(CO)_3(Br)_2$ (3)

A round-bottom flask with $CpIr(CO)_2$ (~40 mg; 0.13 mmol), *cis*-$Os(CO)_4(Br)_2$ (35 mg, 0.076 mmol), and hexane (20 mL) was evacuated and the solution degassed as described above. The reaction vessel was heated at 55–60°C for ~40 h. The flask was cooled and the solvent removed from a pale yellow precipitate. An IR spectrum of the precipitate indicated that it consisted mainly of **3**, but also of a small amount of $[Os(\mu\text{-}Br)(CO)_3(Br)]_2$. The precipitate was therefore subjected to chromatography on silica (12 × 1 cm) with CH_2Cl_2 as the eluant. The pale yellow fraction was collected, concentrated, and stored at –25°C to afford **3** (41 mg; 72%) as pale yellow crystals. The chloro analogue was prepared in a similar manner. Attempts to prepare the iodo compound gave a red-brown precipitate, an infrared spectrum of which (Table 1) indicated that it contained mainly $Cp(OC)_2IrOs(CO)_3(I)_2$, but the compound rapidly decomposed in solution to give $CpIr(CO)_2$ and $[Os(\mu\text{-}I)(CO)_3(I)]_2$ and could therefore not be further purified.

X-ray structure determination of 1, 2, and 3

The X-ray diffraction data for **1**–**3** were collected on Siemens SMART/CCD diffractometers. Data for **2** were collected with the sample at 20°C, the data for **1** and **3** were collected at –70°C with an LT-II low-temperature device. The diffraction data were corrected for absorption with the SADABS program. The program SHELXTL was used for the structure solution and the refinement was based on F^2 (15). The non hydrogen atoms in the structures were refined anisotropically. Hydrogen atoms were fixed in calculated positions and refined isotropically on the basis of the corresponding C atoms (U(H) = 1.2 U_{eq}(C)). Pertinent crystallographic data are given in Table 3; selected bond lengths and angles for **1**, **2**, and **3** are given in Tables 4–6. Supplementary tables of crystal structure and refinement data, atomic coordinates, thermal parameters, and bond lengths and angles for compounds **1, 2** and **3** have been deposited.[2]

Results and discussion

$Cp(OC)_2IrW(CO)_5$ (1)

Compound **1** was prepared in low yield by the addition of $CpIr(CO)_2$ to $W(CO)_5$(thf) in hexane at low temperature (eq. [1]).

It is a yellow crystalline solid that can be handled for short periods in air, but turns black upon prolonged exposure. In hexane at room temperature **1** decomposed within 20 min to $CpIr(CO)_2$, $W(CO)_6$, and, presumably, tungsten metal. In this respect it is somewhat less stable than $Cp^*(OC)_2IrW(CO)_5$ (**1***) (7). Attempts to prepare $Cp(OC)_2IrCr(CO)_5$ were unsuccessful.

A view of the structure of **1** as determined by X-ray crystallography is shown in Fig. 1; selected bond length and angle data are given in Table 4. As can be seen from the figure, the $CpIr(CO)_2$ molecule is bound to the $W(CO)_5$ unit via an unbridged IrW bond. Given the 18 and 16 electron counts of the respective Ir and W moieties, the bond is considered a dative interaction (Ir →W). The length of the IrW bond in **1** (3.0418(4) Å) is only marginally shorter than that in **1*** (3.054(1) Å) and, as discussed previously for **1*** (7), this is almost 0.2 Å longer than IrW lengths found in cluster compounds of these elements. As in other complexes with dative metal–metal bonds (2–4) and the other structures described here, the carbonyls on the donor metal atom lean toward the acceptor atom. In **1** the appropriate W-Ir-C(CO) angles are 79.9(2)° and 80.9(2)°. (If the Ir moiety had a typical 3-legged piano stool geometry these angles would be ~90°.) Another interesting feature of the geometry adopted by **1** is that the carbonyls on the Ir atom are eclipsed with

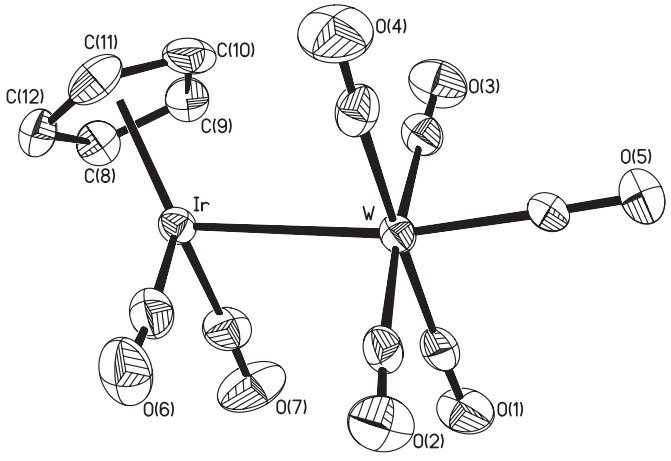
Fig. 1. Molecular structure of $Cp(OC)_2IrW(CO)_5$ (**1**).



two CO ligands on the W atom. The torsion angles between C(1)—W and Ir—C(7), and between C(2)—W and Ir—C(6), are 1.1° and 6.1°, respectively. This is also observed in **1*** but not in other complexes with dative metal–metal bonds (e.g., the structures of **2** and **3** described below).

Shown in Fig. 2 are variable temperature $^{13}C\{^1H\}$ NMR spectra (carbonyl region) of **1** in CD_2Cl_2/CH_2Cl_2. The spectrum at –40°C indicates that the solution structure of **1** is the same as that in the solid state provided there is rapid rotation about the IrW bond. The sample was prepared from ^{13}CO-enriched $W(CO)_5$(thf) (2) and it is apparent that CO exchange has occurred so that the ^{13}CO label is scrambled over all carbonyl sites in the molecule. On warming the solution above –40°C, the carbonyl signals broaden and collapse to the base line (Fig. 2), consistent with the carbonyl exchange taking place on the NMR time scale. This exchange also oc-

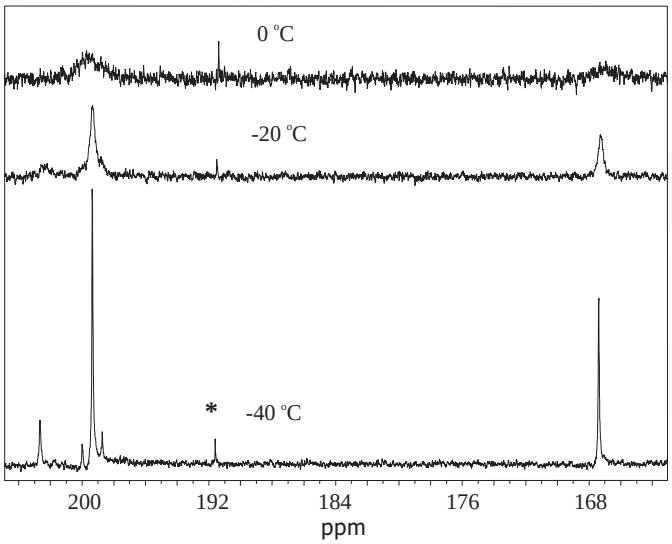
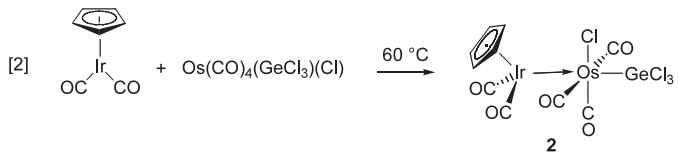
Fig. 2. Variable temperature $^{13}C\{^1H\}$ NMR spectra (CO region) of **1** in CH_2Cl_2/CD_2Cl_2 (4:1). The peak marked with an asterisk is due to $W(CO)_6$.



curs in **1*** such that the carbonyl resonances are virtually collapsed to the base line in the corresponding ^{13}C NMR spectrum at –40°C (7). In other words, the barrier to carbonyl exchange in **1*** is much lower than that in **1**. A similar difference in the barriers to carbonyl exchange is observed in $(\eta^5\text{-}C_5R_5)IrOs_2(CO)_9$ (R = H, Me) (16). For the latter molecules, it was proposed that the pentamethylcyclopentadienyl ligand increases the electron density at the Ir atom, which expands the Ir 5*d* orbitals due to the increased screening of the nuclear charge; this in turn results in better overlap with the empty π^* orbitals on the carbonyl ligands on the adjacent osmium atoms and hence lowers the energy needed to form the presumed intermediate with bridging carbonyls. The same arguments can be used to rationalize the difference in the barriers to CO exchange in **1** and **1***.

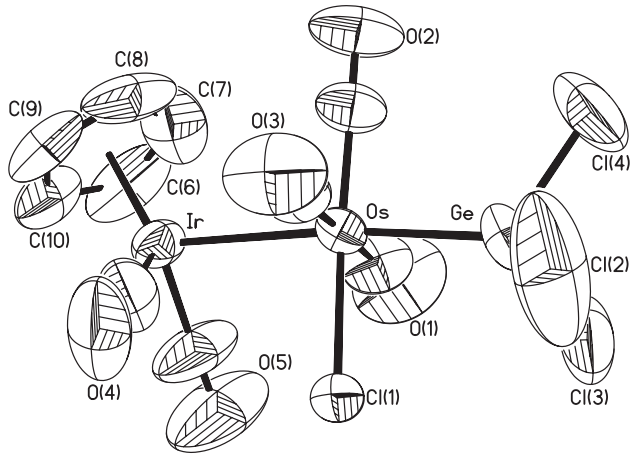
$Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$ (2)

Compound **2** was isolated in moderate yield by the route depicted in eq. [2]. The yellow-fawn crystals of **2** showed no visible sign of decomposition after 2 d of exposure to air.



Similarly, using infrared and NMR spectroscopy, **2** showed no decomposition in CH_2Cl_2 solution (under nitrogen) after 24 h. We had previously found that the $Os(CO)_3(GeCl_3)(Cl)$ fragment is a superior acceptor to the $W(CO)_5$ unit for $Os(CO)_4(L)$ (L = CO, $CNBu^t$) ligands. For example, whereas $(OC)_5OsOs(CO)_3(GeCl_3)(Cl)$ is an air-stable crystalline solid that is stable in solution to at least 60°C (1), we have been unable to prepare $(OC)_5OsW(CO)_5$ (2).

Fig. 3. Molecular structure of $Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$ (**2**).



The infrared spectrum of **2** in CH_2Cl_2 in the carbonyl stretching region exhibits shoulders on the main peaks (Table 1). We attribute this to the presence of two conformers of **2**, one with the Cp ligand in a *cis* orientation to the Cl ligand, the other with a *trans* configuration of these ligands. The $^{13}C\{^1H\}$ NMR spectrum of **2** in CH_2Cl_2/CD_2Cl_2 after an overnight accumulation of spectral data revealed no other species present (Table 2). The ^1H NMR spectrum of **2** in CD_2Cl_2 at –90°C exhibited a singlet for the Cp ligand that was only slightly broadened from that at ambient temperature. Barring accidental degeneracy, the spectra indicate that at –90°C there is still rapid rotation on the NMR time scale about the IrOs bond in **2**.

A view of the structure of **2** is shown in Fig. 3; the structure was determined at 20°C and consequently the thermal ellipsoids are much larger than those for **1** and **3** (see below), which were determined at –70°C. The length of the (unbridged) IrOs bond in **2** is 2.8702(2) Å. We have found that unbridged dative metal–metal bonds are comparable in length to corresponding nondative bonds in dinuclear complexes, but longer than corresponding bonds in cluster compounds (2–4, 17). There does not appear to be any report of a dinuclear complex with an unbridged nondative OsIr bond length to compare with that in **2** and, as expected, the length is significantly longer than those in osmium–iridium carbonyl cluster compounds. For example, in $(\eta^5\text{-}C_5Me_5)(OC)IrOs_2(CO)_8$ the OsIr distances are 2.7902(5) and 2.8124(5) Å (16).

We have previously argued that because of the repulsive $d\pi - d\pi$ interactions between the two transition metal atoms, complexes with dative metal–metal bonds will be more stable, with strong acceptor ligands in both sites *trans* to the bond if steric interactions allow (4). In compound **2** we believe that the $GeCl_3$ unit has excellent acceptor ability, as proposed for the $SiCl_3$ ligand in $(R_3P)(OC)_4MRu(CO)_3(SiCl_3)_2$ complexes mentioned in the Introduction (4). The structural parameters found for the $Os(CO)_3(GeCl_3)(Cl)$ grouping are not significantly different from those in $(OC)_5OsOs(CO)_3(GeCl_3)(Cl)$ (1).

We have found that $Ru(CO)_3(SiCl_3)_2$ is also superior to $W(CO)_5$ as an acceptor fragment (4, 18). Addition of $CpIr(CO)_2$ to *cis*-$Ru(CO)_4(SiCl_3)_2$ in hexane at –15°C produced yellow crystals along with decomposition products. The handpicked crystals gave a satisfactory chemical analy-

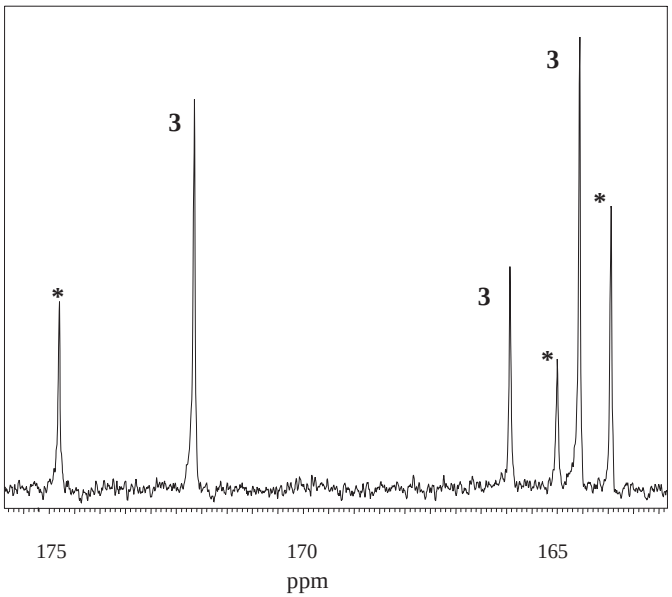
Fig. 4. The $^{13}C\{^1H\}$ NMR spectrum (CO region) of $Cp(OC)_2IrOs(CO)_3(Br)_2$ (^{13}CO in natural abundance) in CH_2Cl_2/CD_2Cl_2 (4:1) after an overnight accumulation of spectral data. The peaks marked with an asterisk are due to dissociation products (see eq. [4] and text).

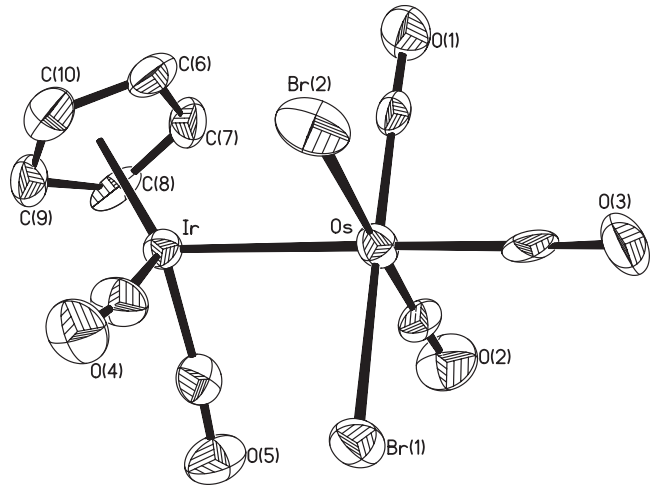


sis and an infrared spectrum (Table 1) expected for $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$, but the compound was too unstable in the solid or in solution (under nitrogen) to characterize further. Because of the smaller covalent radius of Ir compared to Os, dative metal–metal bonds involving iridium are shorter than similar bonds where the donor atom is Os. For example, whereas the IrOs distance in **2** is 2.870 Å, the OsOs lengths in the independent molecules of $(OC)_5OsOs(CO)_3(GeCl_3)(Cl)$ are in the range 2.916(2)–2.931(1) Å (1); in $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)_2$ the OsRu lengths are 2.984(1) and 3.014(1) Å (4). For this reason, it may be that the hydrogen atoms of the cyclopentadienyl ligand in $Cp(OC)_2IrRu(CO)_3(SiCl_3)_2$ make close contact with the $SiCl_3$ ligand, which is by necessity *cis* to the IrOs bond and leads to destabilization of the complex.

$Cp(OC)_2IrOs(CO)_3(X)_2$ (X = Cl, Br: 3, I)

The chloro and bromo (**3**, eq. [3]) derivatives were prepared in good yield by using a procedure similar to that for synthesizing **2**. The compounds were isolated as pale yellow

[3] 
Fig. 5. Molecular structure of **3**.



crystals that appeared stable in air. In these reactions the product precipitates from the (nonpolar) hexane solution, which prevents the dissociation described below. In the corresponding reaction of $CpIr(CO)_2$ with *cis*-$Os(CO)_4(I)_2$ a precipitate also formed that gave an infrared spectrum containing bands (Table 1) consistent with the presence of $Cp(OC)_2IrOs(CO)_3(I)_2$, but also bands due to $[Os(\mu\text{-}I)(CO)_3(I)]_2$, identified by analogy to the chloro (19, 20) and ruthenium analogues (20, 21).[3] When the solution was allowed to stand at room temperature there was essentially complete decomposition to $CpIr(CO)_2$ and $[Os(\mu\text{-}I)(CO)_3(I)]_2$ after 1 h.

When **3** was stirred in CH_2Cl_2 (or CD_2Cl_2) there was conversion over 24 h to an apparent equilibrium mixture containing **3** and $CpIr(CO)_2$ and $[Os(\mu\text{-}Br)(CO)_3(Br)]_2$ (eq. [4]), in an approximate 1:1 ratio, by ^1H NMR spectroscopy.

[4] 
(The bromo dimer was similarly identified by comparison of its infrared spectrum[3] with those of the chloro and ruthenium analogues (19–21).) The ratio was unchanged, by infrared spectroscopy, after standing for a further 24 h. The ^{13}C NMR spectrum of **3** (^{13}C in natural abundance) in CH_2Cl_2/CD_2Cl_2 after an overnight accumulation of spectral data at room temperature showed additional peaks besides those due to **3** at 175.0 and 85.8 assigned to $CpIr(CO)_2$ (22) and signals at 165.0 and 163.9 (in a 1:2 ratio) assigned to $[Os(\mu\text{-}Br)(CO)_3(Br)]_2$ (Fig. 4). The signals due to the dissociation products were barely visible in the corresponding spectrum of **3** (^{13}CO enriched)[4] after ~1 h of data accumula-

[3] Infrared for $[Os(\mu\text{-}X)(CO)_3(X)]_2$, ($CH_2Cl_2$) ν_{CO} (X = Cl): 2135(s), 2061(s, br) (20); (X = Br): 2130.5(m), 2057.5(s, br); (X = I): 2119.5(s), 20045.0(s, br) cm^{-1}.

[4] The sample of **3** enriched with ^{13}CO was prepared from ^{13}CO-enriched $Os(CO)_4(Br)_2$, which was in turn synthesized by heating a hexane solution of unenriched $Os(CO)_4(Br)_2$ under ^{13}CO (99%; 2 atm) overnight. The ^{13}C NMR spectrum indicated all carbonyl sites in **3** were equally enriched, consistent with CO exchange on the synthetic time scale.

© 1999 NRC Canada

tion. The equilibrium depicted in eq. [4] is similar to the equilibrium that we have observed for $(OC)_5OsRu(CO)_3(SiCl_3)(Br)$ (18).

The chloro analogue of **3**, $Cp(OC)_2IrOs(CO)_3(Cl)_2$, similarly dissociated in CH_2Cl_2 at room temperature at approximately the same rate as **3**, but there was apparently also decomposition of $[Os(\mu\text{-}Cl)(CO)_3(Cl)]_2$ so that after 24 h an infrared spectrum of the reaction solution showed bands due to $CpIr(CO)_2$, trace amounts of $Cp(OC)_2IrOs(CO)_3(Cl)_2$, and $[Os(\mu\text{-}Cl)(CO)_3(Cl)]_2$, plus unidentified products.

These preliminary results indicate that $Os(CO)_3(Br)_2$ is a better acceptor than the iodo analogue, as might be expected from the electronegativities of the two halogens. That the acceptor abilities of the $Os(CO)_3(X)_2$ (X = Cl, Br) fragments toward $CpIr(CO)_2$ are similar may be rationalized by invoking more $p\pi$ donation from the halogen atoms to the $d\pi$ orbitals of osmium for the chloro fragment compared to the bromo analogue. This would decrease the Lewis acidity of $Os(CO)_3(Cl)_2$ and offset the superior electron-withdrawing ability of the Cl atoms. This is of course similar to the arguments that have been used to explain why BF_3 is a weaker Lewis acid than BCl_3 or BBr_3 (23). Consistent with the view that Cl $p\pi$ donation to Os $d\pi$ orbitals is significant is that the Os—CO length *trans* to the Cl atom in **2** (1.85(1) Å) is considerably shorter than the Os—C distances (1.94(1), 1.95(1) Å) to the carbonyl ligands that are in a mutually *trans* configuration (Table 5).

The structure of **3** reveals (Fig. 5), once again, an unbridged metal–metal bond. The length of the IrOs bond in **3** is 2.8540(7) Å, which is 0.016 Å shorter than the corresponding length in **2**. From a ground state viewpoint, therefore, the IrOs bonds in **2** and **3** are of comparable strength. It has been proposed, however, that transition state stabilization effects are important in determining the lability of dative metal–metal bonds (4, 24). Besides the bond lengths mentioned above, the IrOs distance in **3** may be compared to the OsOs distance of 2.9104(6) Å in the related $(OC)_5OsOs(CO)_3(Cl)_2$ recently prepared in this laboratory. An interesting feature of the structure of **3** is that both the Br atoms are *cis* to the IrOs bond rather than one Br atom *trans* to the bond. Because the Br ligand is a π donor, the electronically preferred position is expected to be *cis* to the dative bond (see above). An alternative view is that the *fac* arrangement of ligands on the acceptor moiety allows each carbonyl ligand to be *trans* to a poor π acceptor ligand and avoids two CO groups competing for the same electron density on the central Os atom. The Os—Br distances in **3** (2.574(2), 2.585(2)Å) are essentially the same as the Os—Br lengths of 2.592(3) Å in $Os_3(CO)_{10}[P(OMe_3)_3]_2(Br)_2$ (25).

Conclusions

The results of this study indicate that $CpIr(CO)_2$ is a weak ligand and only with 16e organometallic fragments that are strong acceptors can complexes be isolated. Except for $Cp(OC)_2IrOs(CO)_3(GeCl_3)(Cl)$, the complexes dissociate in solution, which results in most cases in decomposition. The ligating ability of $CpIr(CO)_2$ therefore appears comparable to that of $Os(CO)_5$ (1, 2). Since $Os(CO)_4(PR_3)$ compounds are better ligands than $Os(CO)_5$ (2*a*, 18), molecules of the type $CpIr(CO)(PR_3)$ with small P ligands will probably act as better donor ligands than the parent $CpIr(CO)_2$. It should also be pointed out that the acceptor fragments employed in this investigation were neutral five-coordinate fragments and it may be that complexes of $CpIr(CO)_2$ with fragments positively charged or of lower coordination numbers (with fewer steric interactions) might be more stable. The stable $(\eta^5\text{-}C_5Me_5)[(Pr^iO)_3P](OC)IrRh(CO)[P(OPr^i)_3](Cl)$ (5*a*) and $(\eta\text{-}C_5H_5)(OC)_2RhPt(CO)(C_6F_5)_2$ (5*b*) complexes mentioned in the Introduction are consistent with the latter suggestion.

Butenolide annelation using a manganese(III) oxidation. A synthesis of chromolaenin (Laevigatin)

Ayhan S. Demir, Zuhal Gercek, Nese Duygu, A. Cigdem Igdir, and Omer Reis

Abstract: A procedure was developed for the annelation of a butenolide to an aromatic ketone that highlighted a manganese(III) oxidation of an aromatic ketone. The merit of this procedure was illustrated in a synthesis of Chromolaenin (Laevigatin) (**1**) from 4,7-dimethyl-1-tetralone (**2c**). Oxidation of tetralone and indanone with manganese(III) acetate in the presence of chloro- or bromopropionic acid or their Mn(II) salts furnished a α-haloesters **3a**–**d**. An Arbuzov reaction of haloesters with triethylphosphite and an intramolecular Horner–Watsworth–Emmons cyclization of the resulting phosphonate gave butenolide **5a**, **b** in 77–79% yield. This methodology was also applied to 4,7-dimethyl-1-tetralone (**2c**), and the corresponding butenolide **6** is synthesized in 85% yield, which was then converted to Chromolaenin (**1**) using DIBAL-H.

Key words: chromolaenin (Laevigatin), manganese(III) acetate oxidation, aromatic ketones, butenolide annelation, lactone, Horner–Watsworth–Emmons cyclization, Arbuzov reaction.

Résumé : On a développé une nouvelle méthode pour l'annélation d'un buténolide à une cétone aromatique qui souligne l'utilité du manganèse(III) pour l'oxydation d'une cétone aromatique. L'intérêt de cette méthode est illustré par une synthèse de la chromolaénine (laevigatine) (**1**) à partir de la 4,7-diméthyl-1-tétralone (**2c**). L'oxydation de la tétralone et de l'indanone par l'acétate de manganèse(III) en présence d'acide chloro- ou bromopropanoïque ou de leurs sels de Mn(II) conduit aux α-halogénoesters **3a**–**d**. Une réaction d'Arbuzov des halogénoesters avec le phosphite de triéthyle et une cyclisation intramoléculaire d'Horner–Watsworth–Emmons sur le phosphonate qui en résulte fournit les buténolides **5a**, **b** avec un rendement de 77–79%. Cette méthodologie a aussi été appliquée à la 4,7-diméthyl-1-tétralone pour conduire au buténolide **6** correspondant (avec un rendement de 85%) qui a été transformé en chromolaenine (**1**) à l'aide de DIBAL-H.

Mots clés : chromolaenine (laevigatine), oxydation à l'aide d'acétate de manganèse(III), cétones aromatiques, annélation en buténolide, lactone, cyclisation de Horner–Watsworth–Emmons, réaction d'Arbuzov.

[Traduit par la Rédaction]

Chromolaenin (Laevigatin) **1** was first isolated in an optically active form of unknown absolute configuration from *Chromolaena laevigata* (Lam.) by King and Robinson (1). Few examples are published for the synthesis of this natural product. Kano et al. (2) started from 4,7-dimethyl-1-tetralone and converted it to 3-alkylideneazetidin-2-one. Isomerization of double bond, epoxidation followed by the reaction with methanesulfonic acid afforded butenolides, which were then converted to a furane ring using DIBAL-H. Juo and Herz (3) synthesized chromolaenin in six steps via photooxygenation of a naphthalene derivative. Racemic and chiral synthesis was established from Chavan et al. (4) starting from racemic and optically pure 4,7-dimethyl-1-tetralone via formation of β,γ-unsaturated ester. Osmylation and oxidative conversion of β,γ-unsaturated acid gave a butenolide, which was reduced to chromolaenin.

In our previous work, we developed a procedure for the acyloxylation of enones in α′-position using manganese(III) acetate in combination either with manganese(II) carboxylate or carboxylic acids, and a general procedure was developed for the annelation of a butenolide to an enone that highlighted a manganese(III) oxidation of enone (5). Using manganese(III) oxidation, we report in this work the simple butenolide anellation on indanone and tetralone as a model system and application of this to an efficient synthesis of chromoleanin.

In an initial study shown in Scheme 1, the oxidation of indanone **(2a)** with 4 equiv. of manganese(III) acetate in combination with 6 equiv. of manganese(II) 2-bromopropanoate, prepared according to the literature procedure (6), or 12 equiv. of 2-bromopropanoic acid furnished the desired 2-(2-bromopropanoyloxy) ketone **3a** in 71–78% yield. Using chloropropanoic acid instead of bromopropanoic acid afforded chloropropanoyloxy derivative **3b** in 68–77% yield. A negligible amount of α-acetoxylated ketone was also obtained in this reaction (5–7% according to GLPC), but separation of the 2-acetoxy and 2-(2-bromo- and chloropropanoyloxy) ketones **3a**, **b** was readily accomplished by column chromato-

graphy. Using the same reaction, starting with tetralone, the corresponding 2-(2-bromopropanoyloxy) derivatives **3c**, **d** are synthesized in good yield (Table 1). The chloro- and bromopropanoyloxy ketones are mainly semisolids and show multiplets of X-CH between δ 4.0 and 4.5.

The highest yield for haloacyloxylation of the ketones was obtained with 12 equiv. of halo acid or 6 equiv. of its Mn(II) salt. Using the free acid gives higher yield than the corresponding Mn(II) salt. Decreasing the bromoacetic acid component increases the yield of acetoxy ketones.

In connection with ongoing research (5), we found that the source of manganese(III) acetate is very important for the yield of the reactions. The anhydrous manganese(III) acetate used in this oxidation was prepared from manganese(II) nitrate and acetic anhydride and dried using phosphorus pentoxide under vacuum prior to use (5*k*, *l*).

The Arbuzov reaction of **3a** with an excess of triethylphosphite proceeded in 79% yield to give the phosphonate **4a**. An intramolecular Horner–Wadsworth–Emmons cyclization of **4a** with sodium hydride in THF gave the desired 3-methyl-8,8a-dihydro-1-oxa-cyclopenta[*a*]inden-2-one (**5a**) in 77% yield. The spectroscopic and physical properties of **5a** are identical in all respects with the reported values (mp 135–137°C, lit. (7) 136–137°C). Using the same reaction sequence starting with tetralone (**2b**), the corresponding 1-methyl-4,5-dihdro-3a*H*-naphtho[2,1-*b*]furan-2-one (**5b**) is synthesized via bromo- and chloroacetoxy ketone **3c**, **3d** and phosphonate **4b** (Scheme 1). The spectroscopic and physical properties of **5b** are identical in all respects with the reported values (mp 152–154°C, lit. (4, 8) 153–154.5°C). With the successful completion of this study, attention was focused on the synthesis of chromolaenin using the same procedure. As shown in Scheme 1, the manganese(III) oxidation of 4,7-dimethyltetralone (**2c**) using manganese(III) acetate in combination with 2-bromopropanoic acid led regioselectively to the bromopropanoyloxy ketone **3e** in 82% yield as a diastereomeric mixture. The use of manganese(II) salt furnished **3e** in 73% yield. The ^1H NMR spectrum of **3e** shows complex splitting from the α-hydrogen at δ 5.16. Completion of the synthesis of chromolaenin involved

© 1999 NRC Canada

an Arbuzov reaction of 2-bromopropanoyloxyketone **3e** with an excess triethylphosphite to give the corresponding phosphonate **4c** in 83% yield. The CH-P proton shows complex splitting around 3.1 ppm. The cyclization of **4c** with sodium hydride in THF furnished the corresponding butenolide **6** as a mixture of diastereomers **6a** and **6b** in 85% yield in a 4:3 ratio, as determined by NMR (9). The ^{1}H NMR spectra of the two diastereomers exhibited signals for α-CH, and CH_3 at different fields. α-CH appears as a ddq at δ 4.91 (J = 12.6, 4.5, 1.7 Hz, **6b**) and δ 5.21 (J = 12.2, 4.1, 1.5 Hz, **6a**). CH_3 protons appear at δ 1.46 (**6b**) and 1.42 (**6a**) (d, J = 7.2 Hz). Since the stereochemistry at the newly created centers was of no consequence as far the synthesis of Chromolaenin is concerned, as they would be destroyed in the subsequent steps, no attempt was made to separate the isomers.

Reduction of butenolide **6** with DIBAL-H (10) in THF at –40°C provided chromolaenin **1** in 83% yield. The spectroscopic and physical properties of chromolaenin thus obtained were found to be identical in all respects with the reported values for **1**, obtained from natural sources (mp 65–67°C, lit. (1) 65–66°C).

As we suggest earlier (5), by the acyloxylation of aromatic ketones, the initial reaction between the manganese(III) acetate and bromopropanoic acid or its manganese(II) salt lead to a mixed manganese(III) complex, which has both acetate and bromopropanoyloxy ligands. This mixed manganese(III) complex may interact with the ketone to form a metal enolate analogous to the enol-lead triacetate intermediate proposed by Corey and Schaefer (11) for the α-acetoxylation reaction of ketones. In accordance with the works of Willams and Hunter (12) and Snider et al. (13), the oxidation of an enolate by Mn(III) yields a α-keto radical (14), which is trapped oxidatively with carboxylate to yield the product.

This work has demonstrated the novel application of manganese(III) oxidation for the synthesis of butenolide from aromatic ketones to the synthesis of chromolaenin. The reactions provide a quick, easy, and mild approach to functionalized butenolide and furane ring systems. This method gives an entry for the chiral synthesis of **1**, starting from known optically pure ketone **2c**.

Experimental

All reagents were of commercial quality, and reagent quality solvents were used without further purification. IR spectra were determined on a Philips model PU9700 spectrometer. ^{1}H NMR spectra were determined on a Bruker AC 80 MHz FT and Varian 200 MHz spectrometers. GC analyses were made on a HP 5890 gas chromatography.

General procedure (representative example) for 2-[(2-chloropropanoyl)oxy] ketone

A mixture of manganese(III) acetate (2.12 g, 10 mmol) and 2-chloropropanoic acid (3.24 g, 30 mmol) or manganese(II) 2-chloropropionate (60 mmol) in benzene (40 mL) was refluxed for 1 h in a Dean–Stark trap. The mixture was cooled, and ketone (2.5 mmol) was added. The mixture was refluxed for 6–12 h, and the reaction was monitored by TLC on silica-gel (EtOAc/hexane 1:3), then cooled to 25°C, diluted with EtOAc, washed with 1 M aqueous HCl, saturated aqueous $NaHCO_3$, and brine, and dried over anhydrous $MgSO_4$. The crude product was purified on preparative thick-layer chromatography silica-gel F-254 plates or by flash column chromatography (15) (EtOAc/hexane 1:3).

General procedure for Arbuzov reaction

A mixture of 2-[(2-chloropropanoyl)oxy] ketone (2.5 mmol) and triethyl phosphite (1.3 g, 8 mmol) was refluxed under argon for 3 h. The reaction was monitored by TLC on silica-gel (EtOAc/hexane 1:1). During this time, an additional triethyl phosphite (1.3 g, 8 mmol) was added at 1 h intervals. The excess triethyl phosphite was removed by distillation under vacuum, and the residue was chromatographed on preparative thick-layer chromatography silica-gel F-254 plates (EtOAc/hexane 1:1) to afford the phosphonate.

General procedure for annulation

To a suspension of NaH (0.096 g, 4 mmol) (washed with pentane) in anhydrous THF (25 mL) at 25°C under argon was added phosphonate (2.5 mmol) dropwise. The mixture was refluxed for 1h and then quenched with H_2O and extracted with EtOAc. The organic layer was washed with brine and dried over anhydrous $MgSO_4$. The residue was chromatographed on preparative thick-layer chromatography silica-gel F-254 plates (EtOAc/hexane 1:5) to afford the butenolide.

A reinterpretation of the substituent effect on the amide barrier. An experimental and theoretical study

Alex. D. Bain, P. Hazendonk, and P. Couture

Abstract: Recent theoretical work on amide systems has brought into question the application of the concept of resonance. In particular, the role of the oxygen atom was questioned, since the calculations showed little change in its properties when the amide bond was rotated. This paper investigates, both experimentally and computationally, the effect of a substituent on the carbonyl carbon on the amide barrier, in order to test this view. The barriers to the amide rotation in seven spiro-fused oxazolidines were measured by NMR, to within 1 kJ mol^{-1}. A subset of three of them was modelled to the 6-31G** level. For all three substituents the computed and measured barriers corresponded to within 7 kJ mol^{-1}. The electron densities were analyzed using the Atoms in Molecules (AIM) theory. The AIM analysis revealed that the oxazolidines behaved similarly to formamide. The substituent effect was described in terms of the atomic populations and energies of the amide C, O, and N. A substituent on the carbonyl carbon caused electron redistributions between N and C, changing their basin attractive energies. Neither the population nor the energy of oxygen changed significantly. When interactions outside the basin of interest were considered, the energy of C was seen to be more sensitive to changing the substituent than the energy of N. However, the atomic parameters from the AIM analysis did not fully reflect the substituent effects observed. For these molecules, the barrier includes contributions from several sources — there is no single, dominant contribution.

Key words: amides, barrier, substituent, nuclear magnetic resonance spectroscopy, chemical exchange, atoms in molecules, slow exchange, NMR lineshape analysis.

Résumé : Un travail théorique récent a remis en question l'application du concept de résonance. En particulier, le rôle de l'atome d'oxygène est remis en question puisque les calculs ont montré qu'il y a peu de changements dans ses propriétés lorsqu'on soumet une liaison amide à une rotation. Dans le but de vérifier cette position, des travaux tant expérimentaux que théoriques ont été effectués pour déterminer l'effet d'un substituant au niveau du carbone du carbonyle sur la barrière à la rotation de l'amide. Faisant appel à la RMN, on a mesuré les barrières à la rotation de l'amide dans sept oxazolidines à fusion spiro avec une précision inférieure à 1 kJ mol^{-1}. On a fait des calculs au niveau 6-31G** sur un sous-ensemble de trois de ces produits. Pour chacun des trois substituants, les barrières calculées et mesurées concordent dans des limites de 7 kJ mol^{-1}. On a analysé les densités d'électron à l'aide de la théorie des atomes dans les molécules (ADM). L'analyse ADM révèle que les oxazolidines se comportent comme le formamide. On décrit l'effet de substituant en fonction de populations atomiques et d'énergies des C, O et N de l'amide. Un substituant sur le carbone du carbonyle provoque une redistribution des électrons entre N et C, ce qui provoque un changement dans leur basin d'énergies d'attraction. Il n'y a pratiquement aucun changement dans la population ni dans l'énergie de l'oxygène. Quand on considère les interactions provenant de l'extérieur du basin d'énergie, on observe que l'énergie de C est plus susceptible au changement de substituant que l'énergie de N. Toutefois, les paramètres atomiques tirés de l'analyse ADM ne reflètent pas complètement les effets de substituant observés. Pour ces molécules, la barrière comprend des contributions de plusieurs sources, sans qu'on puisse discerner de contribution dominante.

Mots clés : amides, barrière, substituant, spectroscopie de résonance magnétique nucléaire, échange chimique, atomes dans les molécules, analyse de la forme des bandes de RMN.

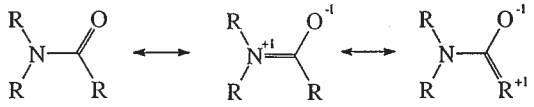
Fig. 1. Resonance structures of an amide including interactions with a substituent on the carbon.



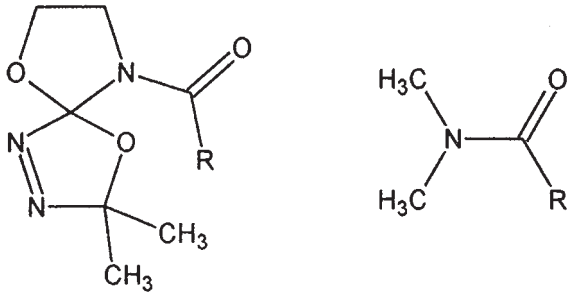
Introduction

Barriers to internal rotational in amides are commonly explained as resulting from resonance between the oxygen and nitrogen (1–13). One of the resonance structures has a double bond between the carbon and the nitrogen, and a negative charge on oxygen, as in Fig. 1. Recent theoretical studies have proposed that this may not be appropriate (8, 9, 14, 15). Instead, they suggest that the barrier is dominated by energy differences in the carbon and nitrogen, and that oxygen is hardly involved. However, this view is still controversial (16–18). One way to test this hypothesis is to look at substituent effects on the barrier and see if they fit into this interpretation. What aspects of the substituent are important to the amide barrier?

Resonance theory predicts that in the planar form of amides there is interaction between the carbonyl π bond and the lone pair on the amide nitrogen (1). This increases the C—N bond order, leading to a net stabilization. In the transition state this interaction is lost, since the orbitals are orthogonal. Substituents on the carbon capable of resonance interactions should reduce the interaction between oxygen and nitrogen (see Fig. 1). As a result, the net stabilization in the planar form is reduced, and the barrier decreases. Recently, the application of the resonance model to formamide has been brought into question (8). These studies employ Atoms in Molecules (AIM) (19) analysis on electron density functions of formamide as the C—N bond is rotated. As the NH_2 group is rotated out of the plane, the main electron transfer is calculated to occur from the nitrogen to the carbon. The calculated atomic population of oxygen is virtually unchanged throughout this process. This disagrees with the resonance model, which requires significant participation of oxygen. As the molecule departs from the planar form, the calculations suggest that the nitrogen pyramidalizes and the C—N bond lengthens. The C=O bond increases only marginally. The calculated energies of the nitrogen and carbon atoms in the molecule dominate the energy changes of the whole system. The energy of oxygen changes insignificantly. Because of the central role of nitrogen, it is perhaps better to view this system as a particular case of an amine rather than a hindered rotation (8, 20).

The AIM theory suggests that in amines, nitrogen is most stable in a planar form (20). However, in this geometry the N—R bonds are shorter than in the pyramidal form, which increases the repulsive energies between the substituents. Furthermore, planar nitrogen is more electronegative, due to higher s character in the N—R bonds. Consequently nitrogen requires a net transfer of charge from the substituents, destabilizing them further. Any consequent stabilization of N in the planar form is overwhelmed by the loss of stability in the substituents, leaving the pyramidal form as most stable (20). Thus the origin of the inversion barrier in amines depends on two factors: (*i*) the stability of nitrogen, and its electronegativity; and (*ii*) the stability of the substituents, especially with regard to changes in repulsive and attractive energies.

Scheme 1. Spiro-fused oxazolidine derivatives and their dimethylaminocarbonyl analogs. R = H, CH_3, OCH_3, $C(CH_3)=CH_2$, Ph, *p*-OCH_3Ph, *p*-NO_2Ph.



In this picture, amides are treated as amines — the carbonyl is just another substituent on the nitrogen. In the planar geometry, nitrogen stabilizes more than the substituents destabilize. In the transition state, nitrogen is predicted to be somewhat pyramidal, where it is least stable. The analysis of the substituent effect on amide barriers should therefore attempt to answer the following questions:

1. Does the substituent alter the charge distribution between C and N, altering their atomic energies?
2. Does the substituent stability drive the changes in the barrier?

In this study, barriers of a series of spiro-fused oxazolidines (see Scheme 1) were measured using a suite of nuclear magnetic resonance (NMR) spectroscopic techniques. The barriers of selected amides were computed and the electron densities were subjected to AIM analysis. The effect of substitution on the amide carbon was assessed by looking for changes in the atomic charges and energy contributions of the nitrogen, carbon, and oxygen.

Methodology

NMR methods

Accurate activation parameters determined by NMR techniques require rate measurements over a wide temperature range (21–23). Several methods can be employed to measure rates, each being optimal in different rate regimes (21, 22, 24–28). Using selective inversion experiments during slow exchange (0.1–10 s^{-1}) (27, 29–31) and lineshape fitting during medium and fast exchange (2, 13, 24, 25, 32–36), it is possible to obtain $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values to within 1 kJ mol^{-1} and 10 J mol^{-1} K^{-1} (22), respectively.

The selective inversion experiments are best applied when the conformer lifetime is of the same order of magnitude as the spin-lattice relaxation time (27, 28, 30). The line corresponding to one site, often the major site, is inverted selectively, and the relaxation of both lines is observed. The exchange rate is extracted by fitting the data to a set of differential equations that describe the relaxation and exchange behaviour.

Lineshape methods are employed most effectively when the rates are comparable with the difference in the Larmor

frequency between the two sites (13, 21, 30). Experimental spectra are compared visually with sample spectra computed with varying exchange rates.

Theoretical methods

Initially, the electron densities (ρ) of selected amides are obtained from the wave functions (Ψ) as in eq. [1].

$$[1] \qquad \rho = N \int \Psi^{*}\Psi \, d\tau$$

Using methods prescribed by the Atoms in Molecules theory (19, 37–39), these densities were analyzed for their topological properties, such as bond critical points (bcp) and bond paths. A critical point occurs where the gradient of ρ vanishes. These critical points are characterized by the properties of eigenvalues of the Hessian matrix at that location. The number of non-zero eigenvalues is its rank, and the sum of their signs is its signature. A bond critical point is a (3,–1) critical point, and nuclear positions are (3,–3) critical points. The path of maximum density connecting two (3,–3) critical points and which passes through the BCP is known as the bond path.

Several properties of ρ at a bcp are commonly used in the analysis of ρ. The density at the bcp is related to the bond order, and the Laplacian at the bcp, $\nabla^2\rho$, indicates whether charge is locally concentrated or depleted (37). A negative Laplacian indicates that charge is locally concentrated, while a positive value suggests that charge is locally depleted.

The next stage of analysis involves searching ρ for interatomic surfaces. These surfaces partition the molecule into atomic domains (Ω), which are used as integration boundaries to calculate atomic properties. Atomic populations, $N(\Omega)$, are calculated by integrating the electron density up to these boundaries (eq. [2]).

$$[2] \qquad N(\Omega) = \int_{\Omega} \rho(r) \, d\tau$$

The atomic energies are computed by invoking an atomic virial theorem (37), as in eq. [3]. For an equilibrium geometry, the total energy of subsystem, $E(\Omega)$, is given in eq. [3].

$$[3] \qquad E(\Omega) = -T(\Omega) = T(\Omega) + V(\Omega)$$

$T(\Omega)$ and $V(\Omega)$ are the kinetic and potential energies, respectively. Thus $E(\Omega)$ and $T(\Omega)$ can be computed by integrating the potential energy within the relevant interatomic surface.

The potential energy of a system can be divided into contributions from repulsive (V_{rp}) and attractive terms in the Hamiltonian. The attractive contribution, $V_{ne}(\Omega)$ (eq. [4]), is the integral of the electron–nuclear potential, with all the nuclei of the system, over the atomic basin.

$$[4] \qquad < V_{ne} > = \sum_{\alpha} Z_{\alpha} e^2 \int_{\Omega} \frac{1}{r} \rho(r) \, d\tau$$

If only the nucleus within the basin is considered, V_{neo} is the basin attractive potential energy, as in eq. [5].

$$[5] \qquad < V_{neo} > = Z_{\Omega} e^2 \int_{\Omega} \frac{1}{r} \rho(r) \, d\tau$$

The contributions from repulsive interactions are computed by integrating the electron–electron potential between electrons within the same basin, $V_{ee}(\Omega,\Omega)$, or a given basin (Ω) and remainder of the electron density (Ω′), $V_{ee}(\Omega,\Omega')$. The repulsion energy is given in eq. [6].

$$[6] \qquad V_{rp} = V_{ee}(\Omega,\Omega) + \frac{1}{2} V_{ee}(\Omega,\Omega')$$

Experimental

Sample preparation

Oxazolidines were prepared by the procedure shown in Scheme 2 (40–42). The semicarbazone of acetone (**1**), prepared by standard methods, was refluxed with 2-

aminoethanol (**2**) in toluene for 7–15 h, to give the substituted semicarbazone (**3**). This compound was oxidized with $PhI(OAc)_2$ in dichloromethane to afford oxazolidines (**4**), which were acetylated or benzoylated by standard methods to afford **6**. A total of seven derivatives were made with the following substituents (R): H, CH_3, OCH_3, $C(CH_3)=CH_2$, phenyl, *p*-nitrophenyl, and *p*-methoxyphenyl. Samples, of approximately 5 mg, were prepared in toluene-d_8 and acetone-d_6, depending on solubility. Tetramethylsilane was used as an internal chemical shift and line-width reference.

NMR measurements

All ^1H NMR measurements were performed on a Bruker AC-300 spectrometer using a 5 mm four-nucleus probe. Temperature control was maintained to within ±0.5°C using a BVT 2000 temperature controller, and was monitored periodically by inserting a copper–constantan thermocouple in a 5 mm NMR tube into the probe. The two readings always agreed to within 0.5°C, and the BVT 2000 reading was used.

The selective inversion experiments were carried out employing the RD–π/2–τ–π/2–VD–π/2–Acq. pulse sequence. The carrier frequency was set to the line to be inverted, typically corresponding to the major site. The delay, τ, was set to $1/(2\Delta\nu_{cis-trans})$, where $\Delta\nu_{cis-trans}$ is the frequency difference (in Hz) between the *cis* and *trans* signals, which varied with substituent from 100 to 489 Hz. The variable delays, VD, were chosen from a range of 10 ms to 5 s, and the relaxation delay (RD) was typically 30 s. Data were transferred over a parallel interface to an SGI INDY workstation for processing. Line intensity measurements of these data were obtained via the XWINNMR package, and were analyzed with CIFIT (28).

Lineshape analysis was performed with the MEX program (24, 25). MEX simulates lineshapes of exchanging systems without scalar coupling. The simulated spectra are directly imported into the Bruker XWINNMR program on a Silicon Graphics Indy computer and compared with experiment using the dual display mode.

Molecular orbital calculations and atoms in molecules analysis

Restricted Hartree–Fock calculations were performed using Gaussian 94 (43) with an IBM RS 6000 470 series computer. Calculations were performed only on the five-membered ring including the amide group and substituents, the second five-membered ring was not included (see Fig. 2). Optimum geometries of both the *cis* and *trans* conformers (see Fig. 3) were calculated with the 6-31G** basis set. Only the H, CH_3, OCH_3, and $C(CH_3)=CH_2$ derivatives were investigated, due to restricted cpu time. The transition state calculations were performed on the H, CH_3, and $C(CH_3)=CH_2$ derivatives using the QST3 method of searching for saddle points in the energy surface, available in Gaussian 94. For the OCH_3 derivative, all attempts at finding the transition state failed.

Topological features of the electron densities were analyzed with EXTREME, which is a program developed in Dr

R.F.W. Bader's laboratory. The parameters $\rho(r)$ and $\nabla^2\rho(r)$ were determined at the bond critical points. The atomic populations and energies were computed using PROAIMV (23), developed by the same group. This software package finds the interatomic surfaces, and uses them for integration boundaries. All integrations were carried out to $L < 0.001$ a.u. Atomic energies were also divided into their contributions from repulsive and attractive potential energy terms.

Results

The Eyring plots of the H, CH_3, OCH_3, $C(CH_3)=CH_2$, and phenyl derivatives in toluene are shown in Fig. 2. Those of H, $C(CH_3)=CH_2$, phenyl, *p*-methoxyphenyl, and *p*-nitrophenyl compounds in acetone are shown in Fig. 3. Note that the graphs include the intercept at $1/T = 0$, to aid in judging the error in the entropy of activation. The equilibrium constants for unequally populated systems were measured at low temperature by integrating the methyl resonances of the major and minor conformers. Due to the large chemical shift differences, it was possible to obtain equilibrium constants at several temperatures, which in turn allowed prediction at high temperature by extrapolation using the van't Hoff isochore. Rate measurements were made over a wide temperature range, ca. 100°C. The activation parameters are shown in Tables 1–3. Uncertainties in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are estimated to be in the range of 1–10 J mol^{-1} K^{-1}, respectively.

To determine whether the ring changes geometry between the *cis* and *trans* forms, the vicinal coupling constants between the methylene protons of the ring were measured for the methyl derivative. This was achieved with XSIM (available from K. Marat, University of Manitoba), a program that simulates static NMR spectra. The iterated spectral parameters are given in Table 4. The simulated spectrum is seen in Fig. 4.

The barriers of the H, CH_3, and $C(CH_3)=CH_2$ derivatives, from MO calculations at the HF/6-31G** level, are shown in Table 1. These are to be compared with the measured enthalpies of activation, $\Delta H^{\ddagger}$. Throughout this analysis, the lowest-energy transition states were used where the carbonyl group was *gauche* to both ring carbons. The electron density and the Laplacian are shown in Tables 5 and 6 (Δ denotes the change in value going from *cis* to the transition state). Table 7 contains atomic populations, and the atomic energies of N, C, and O. These energies are divided into V_{ne}, V_{neo}, and V_{rp}. The values in parentheses represent changes when going to the transition state.

Discussion

Rotational barriers of amides have been studied extensively using NMR methods (2–4, 10–13, 21, 44–51). The effects of substituent (10, 13, 47, 48, 50) and solvent (5, 44, 47, 52–54) have received considerable attention. However, many barrier determinations were performed with few rate measurements. These often covered a narrow temperature range and employed only one experimental technique. As a result most barriers were reported as free energies, without a separation of enthalpy and entropy. Using a combination of selective inversion and lineshape methods, rate measurements can be made over a large temperature range, allowing the enthalpies of the barriers to be reported, since the enthalpies are more compatible with calculations.

In this work, the effects of the substituents on the carbonyl carbon corresponded to previous investigations (6, 10, 13, 44, 47, 48, 54, 55). Replacing H with CH_3 caused the activation enthalpy to decrease by 10 kJ mol^{-1}, which is in line with values between 10 and 13.5 kJ mol^{-1} in the literature

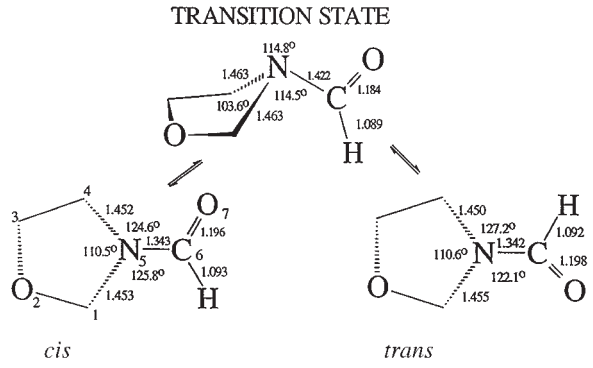
[a]All chemical shift and coupling constants are given in Hz, at a spectrometer frequency of 300.13 MHz. Chemical shifts in parentheses are in ppm with respect to TMS.

Fig. 5. Some geometrical changes in the H derivative during the rotational process predicted by MO calculations.



(6, 13, 44, 56). The barriers were typically lower than in dimethylaminocarbonyl analogs (Table 1 and Scheme 2), which can be attributed to ring strain forcing the nitrogen to take on greater sp^3 character in the low-energy geometries. This is consistent with studies done by Pinto et al. (48), who observed significant variation in amide barriers with changes in ring size. In this study the activation enthalpy for the OCH_3 substituent was 16 kJ mol^{-1} smaller than that of the H derivative, which is quite different from the literature (13). Rather than this molecule being considered as a methoxyl derivative of an amide, it can be regarded as a carbamate ester. Carbamates are known to be similar to amides (57, 58), but they do not behave identically. The $C(CH_3)=CH_2$ substituent lowered the barrier by 24 kJ mol^{-1}, similar to values for analogous systems (59). The phenyl substituents

[a] *E* is the total energy of the basin (in a.u.).

[b] V_{neo} is the basin attractive energy (in a.u.), to its own nucleus only, as given in eq. [5].

[c] V_{no} is the total attractive energy (in a.u.) of the basin as in eq. [4].

[d] V_{rp} is the total basin repulsion energy (in a.u.). The values in parentheses indicate the change in the respective value upon going to the transition state.

decreased the barrier by as much as 25 kJ mol^{-1}, where the effect of the substituents in the *para* position of the ring were as expected. The *p*-nitrophenyl substituent had a barrier 4 kJ mol^{-1} larger than the phenyl substituent and the *p*-methoxyphenyl was 3 kJ mol^{-1} smaller.

The computed barriers correspond reasonably well to experiment, in both trend and absolute value (Table 2). The computed barriers are consistently smaller, by as much as 7 kJ mol^{-1} for the $C(CH_3)=CH_2$ derivative. This may be due to the fact that solvation almost always increases barriers, relative to gas-phase values (55).

The methyl groups in the major conformer are all deshielded with respect to those in the minor site, which suggests that the *trans* form predominates. This was confirmed by one- and two-dimensional NOE experiments, which showed interactions between the N-methyl of the ma-

© 1999 NRC Canada

jor conformer and the two low-frequency ring protons at 2.62 and 2.74 ppm. Changes in the vicinal couplings in the ring between the major and minor conformers indicate small changes in the average conformation of the ring between amide conformations (Table 4). All four vicinal couplings fall within 5–7.5 Hz, which are typical values for five-membered rings (60). These are larger than normal *gauche* couplings and smaller than regular *trans* couplings suggested by Karplus-type relationships (61–64), which implies that the torsional angles are closer to 30° for a *gauche*-like and to 150° for *trans*-like couplings. In both these ranges of dihedral angles, vicinal couplings are similar, thus it is not possible to quantify the change in the ring pucker.

The computed behaviour of the amide portion of the oxazolidines was similar to that of formamide. MO calculations suggest that the nitrogen is planar in the *cis* geometry and pyramidal in the transition state. The C—N bond length increases much more than the C—O bond decreases when going to the transition state from the *cis* form. X-ray crystallographic data of a series of 3,4-dihydro-2-oxo-1,4-propanoquinolines (7, 65, 66), which contain severely distorted amide fragments, indicated similar behaviour.

Further similarities between formamide and these oxazolidines are seen in the electron density at the bond critical point, ρ(bcp), and the Laplacian, $\nabla^2\rho$(bcp). Values of these are given in Tables 5 and 6 for the C—N and C—O bonds. Table 7 gives values of the calculated atomic properties, $E(\Omega)$, $N(\Omega)$, $V_{neo}(\Omega)$, $V_{ne}(\Omega)$, and $V_{rp}(\Omega)$ of C, N, and O in the amide group. The electron density at the bcp of the C—N bond diminishes by about 7% in the transition state with respect to the *cis* form for all derivatives (Table 5). The electron density at the bcp of the C—O bond is left virtually unchanged. The Laplacian at the C—N bcp (Table 6) is nearly identical to that of formamide in both the *cis* and transition forms. In all three derivatives, when going to the transition states there is a net transfer of charge from N to C of ca. 0.2 a.u., and the charge on O changes much less. Nitrogen is destabilized by the loss of charge, which is seen as an increase in V_{neo}(N). Carbon, on the other hand, is stabilized by the gain in charge, thus V_{neo}(C) decreases. As in formamide, the increase in attractive energies on going to the transition state, ΔV_{ne}, is greater than the corresponding decrease in the repulsive energies, ΔV_{rp}. In carbon, the attractive energies decrease more than the repulsive energies increase, causing the carbon to be greatly stabilized.

The Laplacian seems to be the most sensitive to changes in substituent. In the C—N bond of the *cis* conformer, it decreases in the order H, CH_3, $C(CH_3)=CH_2$, but OCH_3 is anomalous (Table 6). The absolute value of the change in the Laplacian from *cis* to the saddle-point geometry decreases in the same order. Unfortunately, the search for the saddle point for the OCH_3 derivative failed, so data are not available for it. In all three derivatives available, the Laplacian in the transition state approaches the same value (ca. –1.2 a.u.).

Similarly, the trends in the atomic properties (Table 7) follow the barriers, but the methoxyl derivative is the exception. In general, there is no single dominant atomic contribution to the energy. The carbon and the nitrogen give the major contribution, but the combination of their energies does not duplicate the trend in the experimental barriers. This may be due to inaccuracies in the atomic integrations, which are good to roughly one part in 1000. For a relatively large system such as this, the energies are determined by a balancing of the energies of all the atoms.

Conclusions

The main goal of this study was to look into the effect of substituents on amide rotational barriers, in order to test recent models. The experimental results on the spiro-fused oxazolidines follow the trends in simpler substituted amides. Calculations on the system, combined with an Atoms in Molecules (AIM) analysis, show similarities to calculations on formamide. However, the trends with substituent are not accurately reflected in the calculated results. For molecules of this size, the AIM analysis is helpful in interpreting the data, but it does not improve on the more traditional resonance model of the barrier.

Acknowledgements

We would like to extend our gratitude to Dr. T. Schaefer in lending us his computational facilities over an extended period, Dr. K. Marat and G. Bernard for assistance with our computations, Dr. Bader for the AIM software, C. Kozak for assisting with the spectrometer work, and the Natural Sciences and Engineering Research Council of Canada (NSERC) for providing financial assistance.

Électrosynthèse de films de polyparaphénylène déposés sur carbones

S. Sadki, J.F. Fauvarque, M.T. Descarsin et P. Simon

Résumé : Des dépôts réguliers et reproductibles de polyparaphénylène (PPP) sur des supports carbonés (tissus et charbons actifs) ont été obtenus par électrosynthèse catalysée et examinés au microscope électronique à balayage. Les propriétés électrochimiques du PPP ainsi préparé, déposé sur des carbones conducteurs, ont été étudiées dans le milieu sulfolane – tétrafluoroborate de tétrabutylammonium. Le dépôt de PPP sur carbone présente bonne une cyclabilité et des densités de courant apparentes (2 mA/cm^2) élevées.

Mots clés : polymères conducteurs, polyparaphénylène, électrodéposition.

Abstract: This present work deals with the formation of polyparaphenylene (PPP) electrodes in which the polymer is associated with conductive carbons. Regular and reproducible coatings of PPP on different types of carbon electrodes were obtained by catalytic electrosynthesis (Fauvarque method) and were examined by electron microscopy. Electrochemical properties of PPP, coated on conductive carbons, were studied in sulfolane–NBu_4BF_4 electrolyte. Coatings on carbon lead to a good cyclability and a high apparent current density (as high as 2 mA/cm^2).

Key words : conductive polymers, polyparaphenylene, electrolytic coating.

1. Introduction

Depuis le début des années 1970, les polymères conducteurs électroniques (1–4) suscitent un intérêt considérable et sont à ce titre l'objet de recherches théoriques et expérimentales interdisciplinaires. Les applications potentielles de ces polymères électroactifs sont liées aux propriétés originales de ces matériaux dans les domaines électrique, électronique, optique ou électrochimique. De nombreuses applications sont envisagées, telles que le blindage électromagnétique (5), les accumulateurs (6, 7), l'affichage électrochrome (8, 9), les composants électroniques (10, 11), les détecteurs à gaz (12)⋯. Cependant, la production de ces matériaux à l'échelle industrielle est peu développée.

Du point de vue fondamental, la connaissance des mécanismes qui confèrent aux polymères électroactifs leurs étonnantes propriétés reste encore succincte (13). Parmi ces matériaux, le polyparaphénylène (PPP) présente à l'état non dopé des propriétés semi conductrices et optiques remarquables et constitue un matériau de choix pour l'industrie électronique (14).

Le PPP peut être aisément obtenu par synthèse chimique (15–19). Il est également synthétisable soit par électro-oxydation (dopage *p*) (20–31), soit par électro-réduction (dopage *n*) (32, 33). Pour réaliser l'électropolymérisation du PPP, nous avons utilisé la réaction électrochimique proposée par Fauvarque et al. (34). Le principe consiste à réaliser la réduction électrochimique d'aryles paradihalogénés catalysés par des complexes de Ni(0) électrogénérés in situ. La réaction globale d'électro-réduction catalytique s'écrit :

[1] 
Cette méthode permet d'obtenir du polyparaphénylène soit sous forme de poudre (34) en utilisant comme électrode de travail une nappe de mercure de grande surface, soit sous forme de films sur des supports métalliques (35, 36) ou de carbone.

Les précédents travaux recensés dans la littérature, réalisés par Aboulkassim et Chevrot (37), ne décrivant les dépôts de polyparaphénylène que sur carbone vitreux, nous nous proposons d'étudier l'électropolymérisation du PPP pour la réalisation de films sur des supports de carbone. Le but de ce travail est la réalisation de dépôts de polymères épais sur des carbones et des graphites de surfaces spécifiques élevées, présentant une bonne conduction électronique, pour une application comme matériau d'électrode dans les supercondensateurs (38, 39). Les matériaux une fois synthétisés seront étudiés par voltampérométrie cyclique et en charge galvanostatique dans un electrolyte sulfolane – tétrafluoroborate de tétrabutylammonium (NBu_4BF_4).

2. Partie expérimentale

Le monomère utilisé au cours de l'électrosynthèse est le 4,4′-dibromobiphényle à la concentration de 0,05 M. Le catalyseur (chlorure de (1.2 (diphénylphosphino)éthane)nickel(II))

de masse molaire 528,05 g/mol est utilisé à la concentration de 0,0025 M. Le solvant est soit du diméthylacétamide seul (DMA), soit un mélange diméthoxyéthane (DME) – hexaméthylphosphorotriamide (HMPT) (70 : 30). Pour les caractérisations électrochimiques des matériaux, le choix s'est porté sur le sulfolane. Ce solvant possède une constante diélectrique assez élevée (40). Le perchlorate de lithium et le tétrafluoroborate de tétrabutylammonium (NBu_4BF_4) sont utilisés comme sel de fond. Les solvants et les sels sont séchés suivant la procédure décrite dans la référence 34.

La pseudo-électrode de référence est une électrode Ag/AgCl plongeant dans une solution de chlorure de potassium saturée dans de l'acide acétique anhydre. La contre électrode est un barreau de magnésium de 12 mm de diamètre et de 40 mm de hauteur.

Différentes types d'électrodes de travail ont été successivement testées pour la réalisation de dépôts de polyparaphénylène : (*i*) des tissus de Carbone–Lorraine® TCM 128. Ces tissus ont une épaisseur de 0,35 mm et de masse 25 mg. Leur surface spécifique est comprise entre 58 et 78 m^2/g; (*ii*) des feuilles poreuses constituées par des grains de carbone de grande surface (Norit®) agglomérés par du polytétrafluoroéthylène (PTFE 20 %) et contenant 10 % en masse de graphite. Le Norit® est un charbon actif constitué de grains de carbone dont la surface spécifique est de 1200 m^2/g (la masse de carbone est de 10 mg).

Pour la réalisation des dépôts de polymères, les électrodes de travail sont découpées en disques de 1 cm de diamètre puis encapsulées dans des grilles en déployé de nickel ou nickel doré. Les électrodes sont séchées pendant 24 h dans une étuve sous vide.

La cellule électrochimique se compose de deux compartiments séparés par un poreux (porosité de 4 Å). La solution est dégazée avec de l'argon U (pureté 99,995 %, impurétés en ppmv : O_2 = 5, N_2 = 20, H_2 = 10, CH_4 = 5, H_2O (5 bar) = 5) avant chaque manipulation (1 bar = 100 kPa).

Mode opératoire

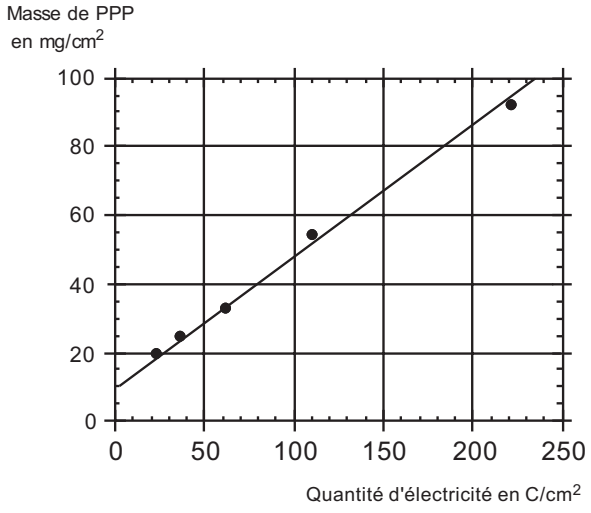
Une pré-électrolyse de 1 h est réalisée sur l'électrode de travail ET à un potentiel de –3 V par rapport à l'électrode de référence, pour réduire l'eau et les impuretés résiduelles. Le catalyseur est ajouté dans le compartiment cathodique à la concentration de 0,0025 M, puis dissout par agitation. La solution est de nouveau dégazée par barbotage de gaz argon. La cathode est portée au potentiel d'électrolyse de –2,5 V. Dès la polarisation de la cathode à ce potentiel, il se forme un dépôt de polyparaphénylène. Simultanément, le courant chute brutalement en fonction du temps de polarisation. Le composite polymère–carbone obtenu est lavé à l'acétone, à l'eau, à l'acide chlorhydrique 5 M, de nouveau à l'eau, puis séché à 50°C pendant 12 h. Une fois séchée, la masse de polymère déposée est déduite par différence avec la masse du support de carbone préalablement pesé.

3. Résultats et discussion

3.1. Dépôts de film de polyparaphénylène sur supports de carbone

3.1.a. Influence du potentiel d'électrolyse

Fig. 1. Masse de PPP déposée sur un tissu de carbone TCM 128 en fonction de la quantité d'électricité mise en ouvre.



L'électrolyse est réalisée à potentiel constant. Le potentiel d'électrolyse conditionnant les propriétés du film de polyparaphénylène déposé, il est indispensable d'en optimiser la valeur en fonction des propriétés recherchées.

La plage de potentiel de formation du polymère est relativement restreinte. Le potentiel optimum trouvé lors de l'électropolymérisation est de –2,5 V. Cette valeur correspond à la réduction du complexe d'insertion Br-$(j)_2$–Ni(dppe)–Br. Dans ces conditions, les films de polymère déposés possèdent de bonnes propriétés d'adhérence vis-à-vis du substrat en carbone. Cette valeur du potentiel est également celle utilisée pour la formation de poudres de polymères.

Pour des valeurs de potentiel comprises entre –2,4 et –2,6 V (autre que –2,5 V) il y a formation de polymère à la surface du carbone mais l'aspect du polymère est granuleux et surtout peu adhérent. Dans cette plage de potentiel, le film est obtenu à l'état neutre isolant de couleur jaune, ce qui peut expliquer les difficultés rencontrées pour la réalisation de films épais.

Pour des potentiels supérieurs à –2,4 V, il n'y a pas de formation de film de PPP sur la surface du carbone du fait de l'absence de régénération de l'espèce électrocatalytique Ni(0).

La synthèse de polymères dopés a également été étudiée en travaillant à des potentiels plus négatifs ($-3\ V < E < -2,6\ V$). Dans ces conditions, le polymère est déposé en subissant de surcroît une réduction électrochimique et un dopage *n* par le cation Li^+. Pour ces valeurs de potentiel, du PPP de coloration bleu, caractéristique du polymère à l'état dopé, se dépose sur le carbone. Le film obtenu est très mince et le rendement de la réaction très faible.

3.1.b. Dépôts sur tissus de carbone

Ces tissus présentent une bonne résistance à la réduction électrochimique (7) quelque soit l'électrolyte organique utilisé (DMA–$LiClO_4$,DME/HMPT–$LiClO_4$, DME/HMPT–NBu_4BF_4).

Les dépôts de polyparaphénylène sont facilement réalisés à la surface du tissu de carbone au potentiel de –2,5 V. La figure 1 représente la masse de PPP déposée en fonction de la quantité d'électricité fournie. Cette figure met en évidence

© 1999 CNRC Canada

l'existence d'une relation linéaire entre la quantité d'électricité Q fournie et la masse de PPP déposée, dans le domaine étudié ($Q < 200$ C). La quantité de PPP introduite dans le composite est donc facilement contrôlable.

La pente de la droite est de 0,5 mg de polymère par coulomb (dans ces expériences, la masse des supports utilisés en carbone est de 50 mg). Lorsque la quantité d'électricité est inférieure ou égale à 3,2 C/cm^2 de surface apparente d'électrode, le PPP se dépose alors. Les photographies des dépôts (fig. 2), réalisées au microscope électronique à balayage (MEB), montrent la présence de points de germination sur les fibres constituant le tissu de carbone (photographies n° 1 et 2).

Pour des quantités d'électricité comprises entre 2,5 C/cm^2 et 50 C/cm^2, les dépôts de PPP sont bien adhérents. La coloration jaune caractéristique du PPP à l'état neutre apparaît.

La photographie MEB n° 3 montre la croissance d'amas de polymère le long des fibres du tissu. Lorsque la masse du polymère déposé est supérieure à 50 mg, les dépôts présentent une structure granuleuse et s'effritent facilement. Mais dans tous les cas, l'encapsulage des électrodes améliore l'homogénéité des dépôts (l'absence de dépôts sur la grille de nickel a été vérifiée au préalable).

3.1.c. Dépôts sur carbones de grandes surfaces

La figure 3 représente la voltampérométrie cyclique d'une électrode en charbon actif de type Norit®, mélangé à du graphite pour améliorer la conductivité électronique. Les courants capacitifs sont élevés. Les capacités obtenues pour le carbone Norit® et le mélange Norit®–graphite sont de l'ordre de 80 F/g de carbone (fig. 3). Il sera donc nécessaire, lors de l'étude du composite polymère – charbon actif, d'utiliser des vitesses de balayage plus faibles pour mettre en évidence les réactions faradiques du polymère.

Les courants d'électrolyse au cours de l'électropolymérisation sont très élevés, de l'ordre de 10 mA/cm^2 de surface apparente d'électrode. La plus grande surface spécifique de ces électrodes, comparativement au tissu, permet d'expliquer ce résultat. La masse de PPP déposée étant toujours proportionnelle à la quantité d'électricité fournie au cours de l'électrolyse, la quantité de polymère déposée sur cette électrode est donc plus importante que celle déposée sur l'électrode en tissu de carbone. Les photographies 4 et 5 montrent que les dépôts de PPP sont compactes et peu visibles sur ces supports (en comparaison à ceux obtenus sur les tissus de Carbone–Lorraine).

En résumé, des dépôts homogènes de polyparaphénylène ont été réalisés sur différents supports de carbone (tissus, et charbons actifs), après optimisation du potentiel de polymérisation. Les quantités de polymères déposées sont facilement contrôlables. Tant que la masse du polymère déposé est inférieure à celle du support, les dépôts présentent une bonne tenue mécanique.

Une caractérisation par voltammétrie cyclique à balayage devrait permettre d'obtenir la contribution faradique du polymère déposé par unité de surface apparente d'électrode. Il sera alors possible entre autre de comparer l'électroactivité des polymères déposés sur chaque type de support. C'est l'objet de la seconde partie de ce travail.

3.2. Propriétés électrochimiques et cyclabilité du polyparaphénylène

Les dépôts de PPP sur supports de carbone obtenus précédemment vont être étudiés en réduction (dopage *n*) puis en oxydation (dopage *p*) électrochimique dans différents électrolytes.

3.2.a. Tissus de Carbone–Lorraine

3.2.a.1. Dopage n. *Voltampérogramme du film* : Les courbes de voltampérométrie cyclique à différentes vitesses de balayage d'un film de polyparaphénylène déposé sur un support en tissu de carbone sont présentées sur la figure 4. Le potentiel de repos est de –0,249 V.

La réaction de dopage–dédopage *n* peut s'écrire de la manière suivante :

$$[2] \qquad (C_6H_4)_x + xy\ NBu_4^+ + xy\ e^- \Leftrightarrow ((C_6H_4)^{-y}(NBu_4^+)_y)_x$$

couleur jaune — couleur bleue

Pour une vitesse de balayage de 10 mV/s, le pic de réduction du PPP situé à –2,2 V, correspondant à la réaction de dopage *n*, est peu visible car masqué par le courant de réduction de l'électrolyte (sulfolane – NBu_4BF_4 0,1 M). Pour cette même vitesse, en balayage retour, le pic apparaissant vers –2 V est lié à la réaction de dédopage.

Le tracé des voltammogrammes à diverses vitesses de balayage (fig. 4) montre un accroissement de la hauteur du pic en fonction de la vitesse de balayage. L'évolution du courant I_p du pic d'oxydation du dépôt de PPP sur tissu de Carbone–Lorraine en fonction de la racine carrée de la vitesse de balayage, visible sur la figure 5, présente un comportement linéaire caractéristique d'un processus diffusionnel. Ce processus est lié à la réaction de dédopage (désinsertion) du cation NBu_4^+ de la matrice polymère (13*a*). Calandra et al. (13*b*) expliquent ce processus par une variation due à un contrôle ohmique compte tenu du fait que la réoxydation a lieu dans une zone où le film redevient isolant. L'explication de la limitation diffusionnel nous semble plus appropriée pour ce processus.

Les intensités mesurées sur le voltammogramme pour la réaction de dopage *n* (pic de ré-oxydation vers –2 V) sont de l'ordre de 100 mA/cm^2 de surface apparente d'électrode. Cette valeur est comparable à celle obtenue précédemment par Aboulkassim et al. (37) lors de l'étude d'un film de PPP déposé sur une électrode en carbone vitreux.

3.2.a.2. Dopage p : La figure 6 représente la voltampérométrie cyclique en dopage *p* d'un film de PPP déposé sur un tissu de Carbone–Lorraine. L'électrode de polyparaphénylène est étudiée en oxydation.

La réaction de dopage–dédopage *p* peut s'écrire de la manière suivante :

$$[3] \qquad (C_6H_4)_x + xy\ BF_4^- \Leftrightarrow ((C_6H_4)^{+y}(BF_4^-)_y)_x + xy\ e^-$$

couleur jaune — couleur rouge

Le pic caractéristique de la réaction de dopage *p* n'est pas visible du fait de l'oxydation du solvant dans la gamme de

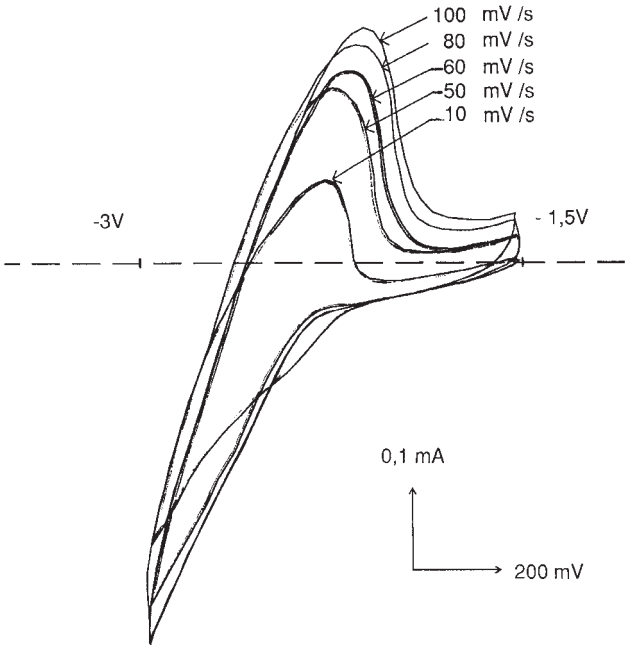

Fig. 5. Étude de l'évolution du courant I_p du pic d'oxydation du dépôt de PPP sur tissu de Carbone–Lorraine® en fonction de la vitesse de balayage en milieu sulfolane – NBu_4BF_4 0,1M, à T = 22°C.

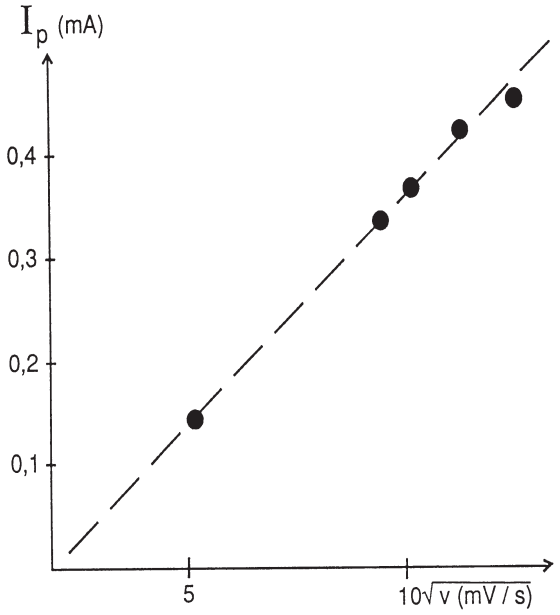

Fig. 6. Voltampérométrie cyclique en dopage *p* d'un film sur tissu de Carbone–Lorraine; v = 18 mV/s; sulfolane – NBu_4BF_4 0,1 M, 22°C.

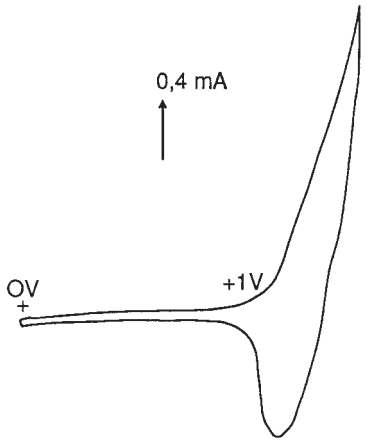


potentiel étudié. Lors du balayage retour, le pic correspondant à la réaction de dédopage apparaît à +1,2 V.

3.2.b. Carbones de grandes surfaces

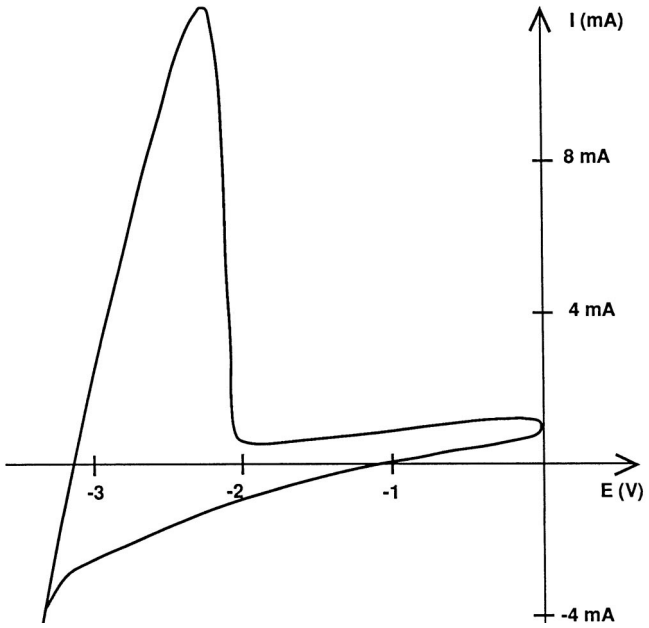
La figure 7 représente la voltampérométrie cyclique en dopage *n* d'un film sur une électrode charbon actif Norit® 70 % – graphite 10 % – PTFE 20 %.

Le pic de réduction correspondant au dopage n'est visible que vers –2,3 V. Le potentiel de ce pic est donc décalé vers les valeurs négatives, comparativement au composite PPP – tissu de carbone. Pour cette raison, le pic d'oxydation n'est pas visible sur le voltammogramme, étant lui aussi décalé vers les valeurs négatives des potentiels.

La valeur de l'intensité mesurée au sommet du pic de dédopage est de 10 mA, ce qui correspond à une densité de courant de 3 mA/cm^2 de surface apparente d'électrode, compte tenu de la contribution du support seul dans le domaine de potentiel étudié (fig. 3). Pour le tissu de carbone, l'extrapolation du courant du pic de dédopage pour une vitesse de 5 mV/s (fig. 5) donne une valeur de 15 mA/cm^2 de surface apparente d'électrode. Il existe donc un facteur 200 entre les densités de courant mesurées sur les deux électrodes. Dans la première partie de cette étude, il apparaissait que les densités de courant utilisées pour le dépôt de PPP étaient très élevés pour l'électrode en charbon actif, c'est à dire que la masse de polymère déposée sur ce support est su-

© 1999 CNRC Canada

Fig. 7. Voltampérométrie cyclique en dopage *n* d'un film de polymère déposé sur une électrode charbon actif Norit® 70 % – graphite 10 % – PTFE 20 %; *v* = 18 mV/s ; milieu DME/HMPT (70/30) – NBu_4BF_4 0,1 M; *T* = 22°C.



périeure à la masse de polymère déposée sur tissu. L'analyse des voltammogrammes confirme que le polymère déposé est bien électroactif.

Ce dernier résultat semble être intéressant dans l'objectif de la réalisation de supercondensateurs : l'utilisation de composites PPP – charbons actifs pourraient permettre d'augmenter la densité de puissance, du fait de la densité de courant de cyclage, et également l'énergie volumique disponible. Pour ce faire, il reste encore à améliorer les qualités de l'électrolyte en réduction, de façon à pouvoir mettre en évidence le pic de dopage *n*. Des travaux sont actuellement en cours au laboratoire.

4. Conclusions

Des dépôts de PPP sont réalisés de manière quantitative sur des supports en tissu de carbone et sur des charbons actifs agglomérés par du PTFE. Il existe dans chaque cas une relation linéaire entre la quantité d'électricité mise en oeuvre et la masse de PPP déposée, ce qui permet de contrôler la quantité de polymère déposée. La présence de PPP est observable par microscopie à balayage. Un dépôt homogène est obtenu sur toute la surface de l'électrode de carbone. Des films de PPP bien adhérents sont réalisés lorsque la masse du dépôt de PPP est inférieure à celle du support de carbone.

Dans le cas de dépôts sur tissu de carbone, les densités de courant de pic mesurées sur le voltammogramme correspondant au dédopage *n* sont de l'ordre de 100 mA/cm^2 de surface apparente d'électrode, valeurs comparables à celles déjà décrites dans la littérature (37).

Dans le cas de dépôts sur des électrodes en charbon actif, les densités de courant d'électrolyse obtenues sont égales à 10 mA/cm^2 de surface apparente d'électrode, et les densités de courant pic de dédopage *n* sont de l'ordre de 3 mA/cm^2. Il y a donc un facteur 200 entre les densités de courant mesurées sur les deux types de composites. Ces résultats semblent prometteurs quant à l'utilisation de composites polyparaphénylène – charbon actif comme matière active dans une application de type supercondensateurs.

Remerciements

Les auteurs tiennent à remercier les Laboratoires d'Alcatel Alsthom Recherche pour leur contribution financière.

Effect of cyclodextrin complexation on the photochemistry of the lignin model α-guaiacoxyacetoveratrone

L.T. Okano, R. Ovans, V. Zunic, J.N. Moorthy, and C. Bohne

Abstract: The photodecomposition of α-guaiacoxyacetoveratrone (GAV) in homogeneous solvents and in aqueous cyclodextrin solutions was studied by following the fluorescence emission of the photoproducts formed. The same qualitative behavior as previously observed for the photodegradation quantum yield measurements was reproduced in the fluorescence studies in dry or wet methanol and acetonitrile. The yield for GAV photodegradation in water is smaller than in the organic solvents. Complexation of GAV to β- and γ-cyclodextrins leads to an increase in the photodecomposition yield, especially during the early part of the photodecomposition kinetics. The transients formed in the photolysis of GAV in water are similar to those observed in acetonitrile, and the lifetime of triplet GAV in water is 130 ns. In addition, solvated electrons were formed when GAV was photolyzed in water. Complexation of GAV to cyclodextrins leads to an increase in the triplet yield compared to the radical yield and a moderate shortening of the triplet lifetime.

Key words: α-guaiacoxyacetoveratrone, cyclodextrin, excited singlet states, excited triplet states, radicals.

Résumé : Utilisant l'émission de fluorescence des photoproduits formés, on a étudié la photodécomposition de l'α-guaïacoxyacétovératrone (GAV) dans des solvants homogènes et dans des solutions aqueuses de cyclodextrine. Dans les études de fluorescence dans le méthanol sec ou aqueux ainsi que dans l'acétonitrile, on a reproduit le même comportement qualitatif que celui observé antérieurement lors de mesures de rendements quantiques pour la photodégradation. Le rendement pour la photodégradation de la GAV dans l'eau est inférieur à celui observé dans les solvants organiques. La complexation de la GAV par les β- et γ-cyclodextrines provoque une augmentation du rendement de photodécomposition, particulièrement au début de la cinétique de photodécomposition. Les espèces transitoires qui se forment lors de la photolyse de la GAV dans l'eau sont semblables à celles observées dans l'acétonitrile et le temps de vie de l'état triplet de la GAV dans l'eau est de 130 ns. De plus, il se forme des électrons solvatés lors de la photolyse de la GAV dans l'eau. La complexation de la GAV par les cyclodextrines provoque une augmentation du rendement de l'état triplet par rapport au rendement en radical ainsi qu'à une diminution modérée du temps de vie du triplet.

Mots clés : α-guaïacoxyacétovératrone, cyclodextrine, états singulets excités, états triplets excités, radicaux.

[Traduit par la Rédaction]

Introduction

The photodecomposition of lignin is responsible for the yellowing observed in paper manufactured from mechanical pulp. In recent years, a significant effort has been made to find efficient inhibition strategies to eliminate or considerably slow down the yellowing of lignin-containing paper. The mechanisms for lignin photodegradation are complex involving several reactive intermediates (1, 2). Most mechanistic studies have been performed in solution employing model compounds because lignin is a high molecular weight polymer that is difficult to handle in solution. Solution studies were important to determine the decomposition pathways, the multiplicity of the excited states involved, and to characterize spectroscopically the reactive intermediates involved (3–13). α-Guaiacoxyacetoveratrone (GAV) has frequently been used as a model compound (8, 9, 13, 14), because it contains key features of lignin. In contrast to other aryl ketones, it was shown that α-phenoxyacetophenones, such as GAV, react from their excited singlet state (8, 11–14) to form the corresponding phenacyl and phenoxy radicals (Scheme 1). This reactivity suggests that the β-cleavage process from the excited singlet state readily competes with intersystem crossing, leading to quantum yields for the latter process that are significantly smaller than unity (13). Compared to α-phenoxyacetophenone (15), the triplet reactivity of GAV is diminished because its lowest triplet state has a π,π^* configuration (9). The triplet lifetime is determined by the efficiency for intramolecular deactivation through β-phenyl quenching, as was observed for β-arylpropiophenone and α-(aryloxy)acetophenones (15–21), and the rate constant for β-cleavage (14). The photodecomposition quantum yields and triplet lifetimes of GAV vary significantly in different solvents (8, 14). This complex behavior is

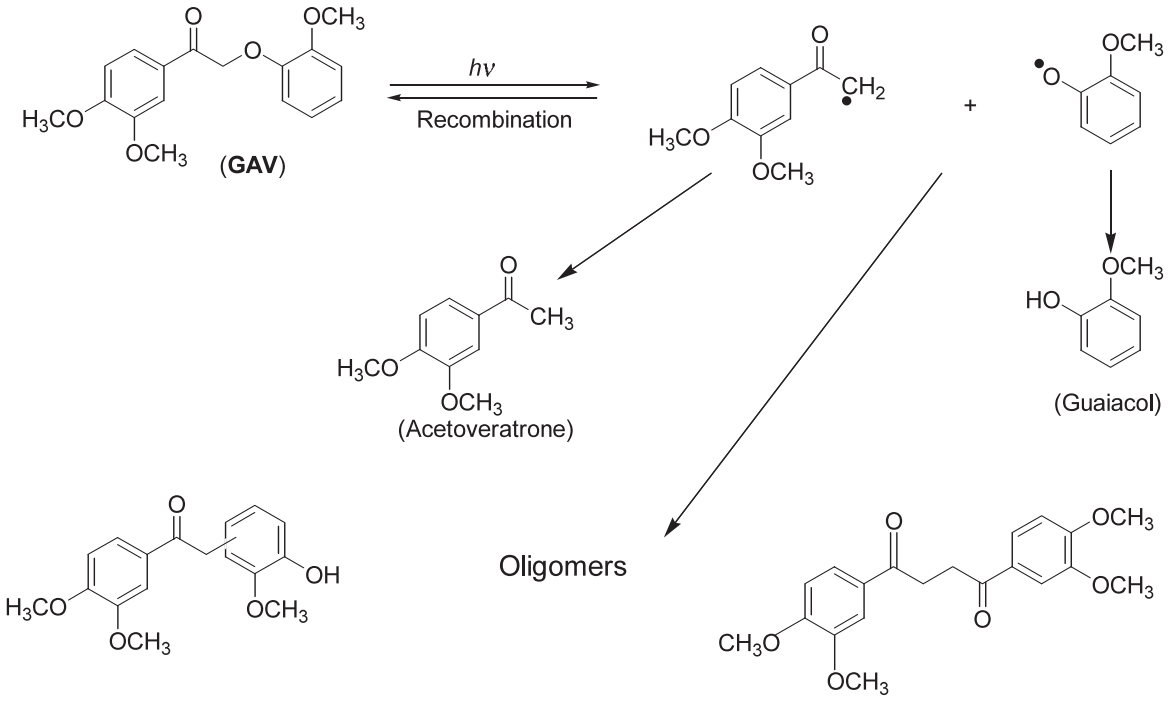
Scheme 1.



related to the reactivity from the GAV singlet excited state and a solvent effect on the intramolecular quenching in the triplet state.

Lignin is located in a constrained environment in the cell wall of wood fibers that influences to a different extent the deactivation pathways of the excited singlet and triplet states when compared to these processes in solution. There are a limited number of studies on the photoreactivity of lignin model compounds in constrained environments or on solid supports. The photodegradation of GAV has been shown to decrease when this compound is adsorbed on paper fibers (9). In addition, GAV is stable in the crystalline state, a fact that was attributed to the formation of excimer-like arrangements in the solid state (6). The photochemistry of α-(aryloxy)acetoveratrones was studied on solid silica gel, Na-X zeolites, and cellulose (4). In the case of cellulose, an inefficient photodecomposition and an enhanced triplet lifetime were observed. These experiments show that the confinement of lignin in the fibers of paper can alter the lignin photoreactivity. Furthermore, the mobility of oxygen through the paper fiber may also be important, since yellow products are only formed in the presence of oxygen (2). In this respect, it has been shown that the quenching of reactive intermediates on cellulose or paper by oxygen is very inefficient (3, 4, 22–24), suggesting that the reaction of reactive intermediates with oxygen may be the rate-limiting step in the photoyellowing process.

The objective of this work is to establish how constrained environments can affect the photochemistry of GAV and the mobility of the radicals formed in its photodecomposition. Since the work on solids has proven to be difficult, we decided to investigate the effect of a constrained environment on the photochemistry of GAV in solution. Cyclodextrins (CDs) were chosen, since they provide a chemical environment similar to cellulose, and the effect of CD inclusion on the photochemistry of β-phenylpropiophenone (25, 26) and α-phenoxyacetophenone (27) have been previously reported. In addition, we chose to work in water, since paper has some moisture (5–10% water), and lignin is probably exposed to a hydroxylic environment.

Experimental

The β- (lot F6080–191) and γ-CDs (lot E 8056) were a kind gift from Cerestar and were used as received. Guaiacol (98%, Aldrich) and 3,4-dimethoxyacetophenone (acetoveratrone) (98%, Aldrich) were distilled under reduced pressure, methanol (ACP, spectrograde) was distilled from CaH_2, and acetonitrile (ACP, HPLC grade) was distilled under N_2 from $LiAlH_4$. Deionized water (SYBRON, Barnstead deionizing system) was used for all aqueous samples. Whatman filter papers (number 1001 125) were used as received.

The α-guaiacoxyacetoveratrone (3′,4′-dimethoxy-α-(2-methoxyphenoxy)acetophenone, GAV) was synthesized by the method previously reported (28). The required synthesis of 3,4-dimethoxy-α-bromoacetophenone was modified from that previously reported in that dimethoxyacetophenone was reacted with pyridinium bromide perbromide in chloroform and under nitrogen (29–33). GAV was purified by repeated recrystallization from ethanol (95%), and its purity was checked by mp (77–80°C) and ^1H NMR measurements.

UV-vis absorption spectra were measured on Cary 1 or Cary 5 spectrometers from Varian. Induced circular dichroism spectra were measured on a Jasco J-720 spectropolarimeter. Fluorescence was measured with a PTI QM-2 fluorimeter at 20.0 ± 0.5°C. Most samples were excited at 280 nm, however, when necessary the excitation wavelength was shortened to avoid the Raman emission from the solvents. Emission spectra were collected before and after the photodecomposition kinetics to monitor prod-

© 1999 NRC Canada

uct formation. Narrow slits (bandwidth 1–2 nm) were employed to measure the emission spectra to minimize the photodecomposition of GAV. The photodecomposition kinetics of GAV was monitored simultaneously by the product emission at 310 and 350 nm. The rate of decomposition was dependent on the excitation intensity and bandwidth (5 or 7 nm) employed for the excitation slits. Solutions were contained in 10 × 10 mm quartz cells and were purged with N_2 or O_2 for 30 min before the fluorescence measurements were performed. Solid samples were either mounted on a triangular metal support or were suspended within the sample holder. In both cases, the excitation beam and detector were in a 90° arrangement, and for the solid samples, the surface of the paper was placed at a 45° angle with respect to the excitation beam.

The laser flash photolysis system used for the transient studies has been previously described (34). Samples at 20 ± 2°C were excited either with a Lumonics excimer laser at 308 nm (<30 mJ/pulse, 5 ns pulse width) or a Spectra Physics Nd:YAG laser at 266 nm (<20 mJ/pulse, 6 ns pulse width). A program written with Labview 4.0™ (National Instruments) was used to control the laser flash photolysis systems, acquire the data, and for initial analysis of the decay curves. A flow cell (7 × 7 mm Suprasil) was employed for solutions purged with N_2 and O_2 (30–40 min) so that a fresh portion of the solution was irradiated at each laser pulse. The solution in the reservoir before entering the flow cell was covered with aluminum foil to avoid photodecomposition by ambient light. A 7 × 7 mm Suprasil cell stoppered with a rubber septum was used for N_2O purged (20 min) solutions. The photodecomposition in the static samples was followed by UV-vis absorption, and the sample was subjected to a small number of laser shots so that only limited decomposition of GAV occurred.

Solutions of GAV in all solvents except water were prepared by dissolving the solid in the respective solvent. Aqueous solutions were prepared by the injection of a small amount (<1%) of the methanolic GAV solution into water. In all cases, the concentration of GAV was 15.8 μM. The CD solutions were prepared by dissolving, in the aqueous GAV solution, the appropriate amounts of β- and γ-CD to reach final concentrations of 10 and 30 mM, respectively. These solutions were warmed in hot water for 5 min and were left stirring for at least 12 h. Some insoluble material was removed by filtering the solutions through 40 μm Millipore filters. For this reason, it is likely that the GAV and CD concentrations quoted are somewhat lower than stated. During preparation and storage, all solutions were shielded as much as possible from ambient light.

Filter paper samples (5 × 1.1 cm) containing GAV were prepared by using either the drop or immersion methods (35). For the drop method, 0.15–0.5 mL of a methanolic or methanol–water solution of GAV (≤0.01 M) was slowly dropped with a microsyringe on samples mounted in Delrin frames. Two samples were always prepared from the same GAV solutions. After application of GAV, the samples were protected from light and were dried for at least 12 h. In the case of the immersion method, two samples were simultaneously placed for 20 min in Petri dishes containing GAV solutions (≤0.01 M). After the immersion period, the paper samples were mounted on Delrin frames and were dried as described above. The immersion method leads to a more homogeneous distribution of additives in paper (35). The amount of GAV added was established by comparing the weight of each paper sample before and after the application of GAV. Filter papers without any treatment were employed as a reference. The samples were irradiated for 1 h in front of a 75W Xe lamp (PTI).

Results

Several spectroscopic techniques can be employed to establish the complexation of guest molecules with CDs. The primary consideration in choosing a technique is that a change of a spectroscopic property has to be observed for the free and complexed guest molecule. The formation of the GAV–CD complexes was observed by circular dichroism spectroscopy. GAV in water does not show a circular dichroism signal because it is achiral. In the presence of β- or γ-CD, induced circular dichroism signals were observed in the spectral region where GAV absorbs (Fig. 1). These experiments clearly show that GAV is incorporated to some extent into both CD cavities. Unfortunately, circular dichroism could not be employed to determine the equilibrium constants values and the complexation stoichiometries due to the poor signal-to-noise ratio observed and the fact that some photodestruction (<10%) occurs upon irradiation in the spectrometer. Likewise, ^1H NMR could not be employed to determine the complexation efficiency because of the low solubility of GAV in water (<20 μM).

Fluorescence is, in principle, an ideal technique to establish the complexation of guest molecules with CDs, because fluorescence properties, such as the emission quantum yields

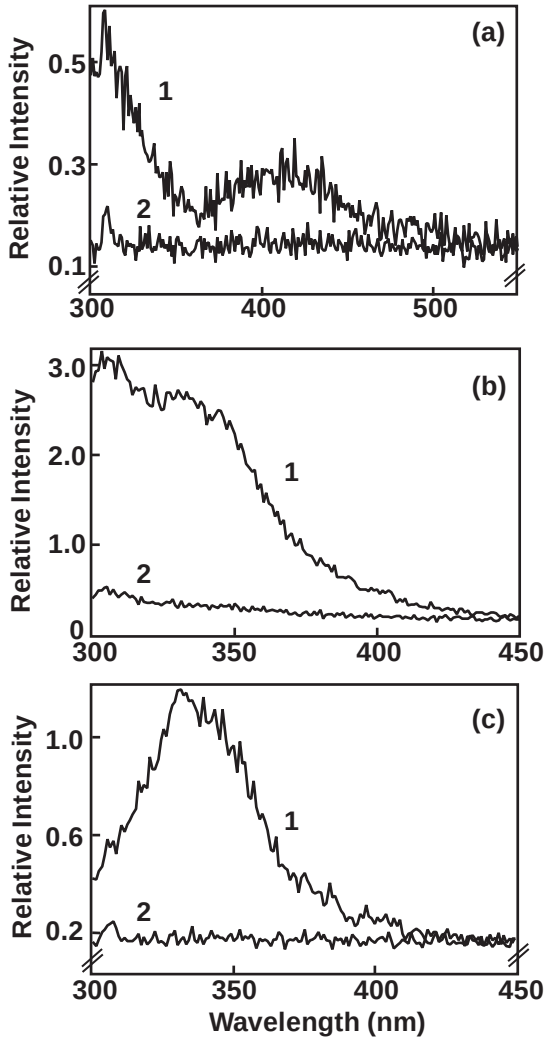
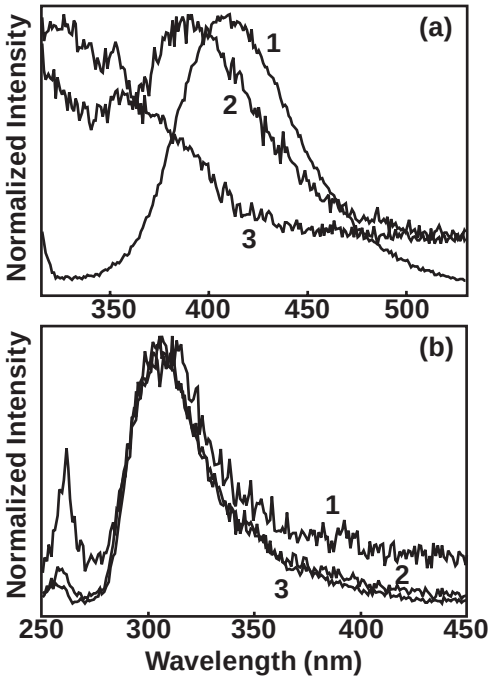
Fig. 2. Emission spectra before (2) and after (1) irradiation of 15.8 μM GAV for 1 h at 280 nm in (*a*) water, (*b*) methanol, and (*c*) acetonitrile.



and lifetimes, can be very sensitive to the environment around the fluorophore. The first approach tried to establish the complexation of GAV to β and γ-CD was fluorimetry, since an emission assigned to the fluorescence of GAV in methanol had been previously reported (6). Unfortunately, we established that GAV does not fluoresce when the samples are shielded from the exposure to ambient light (Fig. 2). Appreciable fluorescence is only observed after the samples are exposed to the excitation beam in the fluorimeter (Fig. 2). This emission was assigned to the fluorescence of photoproducts. The spectral distribution of the emission is solvent dependent. The emission observed in water and methanol between 310 and 320 nm, after exposure of the sample to the excitation beam, is not due to Raman emission of the solvent because the spectra are the same at different excitation wavelengths.

Guaiacol and acetoveratrone are likely products in the photolysis of GAV (Scheme 1). For this reason, their fluorescence spectra in various solvents was measured (Fig. 3). Guaiacol has a higher fluorescence quantum yield by about one order of magnitude than acetoveratrone. In addition, the

Fig. 3. Fluorescence spectra of 15.8 μM acetoveratrone (*a*, λ_{ex} = 280 nm) and guaiacol (*b*, λ_{ex} = 240 nm) in water (1), methanol (2), and acetonitrile (3). The sharp peak at 260 nm (*b*) corresponds to the Raman emission of the solvent.



fluorescence spectra for guaiacol were the same for all three solvents, and its emission efficiency in acetonitrile and methanol was somewhat higher (ca. 2) than in water. In contrast, the acetoveratrone emission is very solvent dependent with emission maxima at 420, 390, and ca. 330 nm, respectively, in water, methanol, and acetonitrile, and the emission quantum yield is higher in water than in the organic solvents.

The decomposition quantum yields of GAV in homogeneous solution are very dependent on the nature of the solvent and the presence of water (8). For this reason, we used the appearance of the photoproduct emission to measure relative photodecomposition yields of GAV in different solvents. The kinetic traces for the appearance of photoproducts were measured at 310 and 350 nm (Fig. 4). The rate of appearance was faster in methanol than in acetonitrile. At 310 nm, the photoproduct formation rate follows a fairly linear relationship, whereas at 350 nm, a considerable slowdown is observed as the photodecomposition of GAV proceeds. Most kinetic traces showed initially a fast increase in the fluorescence intensity. This burst kinetics appears as an initial jump in the traces shown in Fig. 4. The initial jump also incorporates any product formed when spectra were collected with narrow slits before the kinetic run and any product formed due to exposure to ambient light during sample preparation and handling.

Relative yields for the formation of products were estimated from the initial slopes of the photodecomposition kinetics after the burst phase (Table 1). In the absence of oxygen, the rate for appearance of photoproduct emission at 310 nm is highest in methanol and comparable in acetonitrile and water. At 350 nm, the photodecomposition

Fig. 4. Kinetics for the appearance of photoproduct emission for the photolysis (λ_{ex} = 280 nm) of 15.8 μM GAV monitored at 310 (*a*) and 350 (*b*) nm in methanol (1), acetonitrile (2), and water (3). The opening of the shutter leads to the initial jump in the emission intensities.

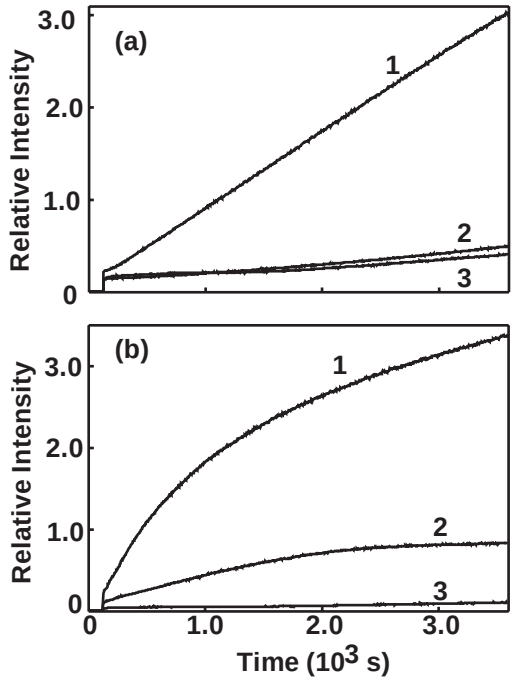

Fig. 5. Kinetics for the appearance of photoproduct emission for the photolysis (λ_{ex} = 280 nm) of 15.8 μM GAV monitored at 310 (*a*) and 345 (*b*) nm in the presence of 10 mM β-CD (1), 30 mM γ-CD (2), 10 mM γ-CD (3), 5 mM β-CD (4), and in water (5). The traces in (*a*) show the kinetics after the initial jump, while the experiments in (*b*) show the burst kinetics at short times.

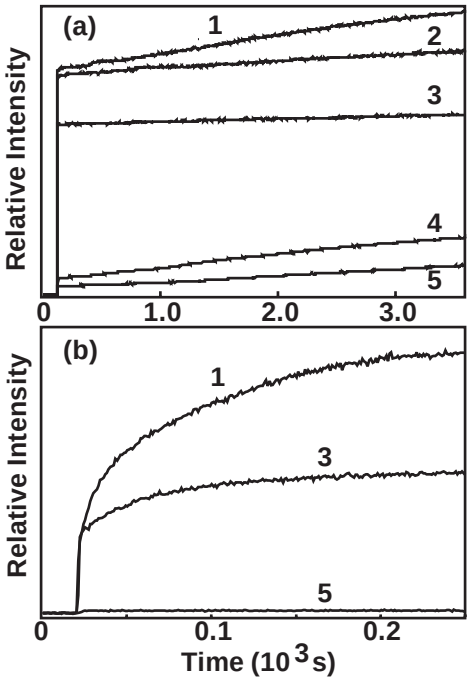

rate is highest in methanol and lowest in water (Fig. 4). The presence of oxygen has only a small effect on the rate of product appearance in water, due to the low solubility of oxygen in this solvent (1.4 mM) (36). In methanol and acetonitrile, the presence of oxygen led to a marked decrease in the rate of emission of the photoproducts, suggesting that oxygen efficiently quenched the excited state responsible for product formation.

The presence of water in methanol was shown to decrease the degradation quantum yield of GAV, whereas the opposite effect was reported for the photolysis in acetonitrile (8). The relative rates for photoproduct emission showed a similar trend. The emission rate at 310 nm in methanol was only decreased at a high water content (60%), whereas a more significant decrease of the rate was measured at 350 nm (Table 1). In the case of GAV photolysis in acetonitrile, an increase of the photoproduct formation was observed in the presence of water (Table 1).

The emission spectrum of GAV in the presence of β- and γ-CD is similar to that observed for GAV in water. However, the contribution of the emission at 450 nm is higher in the presence of CDs. The complexation of GAV to β- and γ-CD led to a slight increase in the rate of appearance of the photoproduct emission when monitored at 310 and 350 nm (Fig. 5, Table 2). Some of this enhancement is quenched in the presence of oxygen. A more significant effect of the CD complexation is observed on the initial jump corresponding to the burst phase (Table 3). The enhancement of the initial jump increases when the β-CD concentration is raised, and this enhancement is not sensitive to the presence of oxygen. In contrast, the enhancement in the presence of γ-CD is sensitive to the presence of oxygen (Table 3).

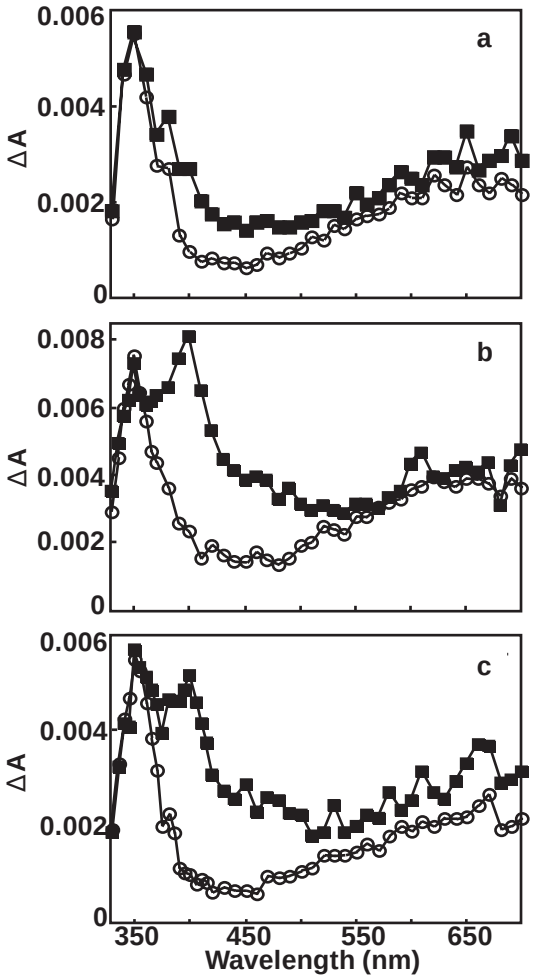
The emission of filter paper with and without GAV was measured to determine whether fluorescence spectroscopy could be employed to monitor the photodecomposition of GAV absorbed into the paper matrix. The filter paper without GAV showed some background emission. In the presence of GAV (≤3% w/w), the same emission spectra were observed when the sample was excited at 270, 280, or 310 nm. The emission spectra were also measured after the reference and paper sample containing GAV were irradiated for 1 h. The emission intensities measured for the reference and GAV samples were nonreproducible. In some cases, an increase of the emission intensity was observed, whereas for duplicate samples prepared from the same GAV solution a decrease of the intensity was measured. The same pattern was observed for samples prepared either by the drop or the immersion methods. Although the contradictory results on the emission intensity are difficult to explain at this point, it was observed that the magnitude of the enhancement or the decrease is dependent on the amount of GAV adsorbed into the paper and the duration of the irradiation of the sample.

Laser flash photolysis was employed to study the transient species formed in the photolysis of GAV. All transient studies, with the exception of those in the presence of N_2O, were performed using flow cells. When static cells were employed, a higher yield of radicals compared to the triplet yield was observed. This is particularly noticeable when GAV is excited in the presence of CDs. The higher yield of radicals is probably due to the accumulation of long-lived radicals after subsequent laser shots.

The transient phenomena observed after excitation at 308 nm of GAV in acetonitrile were similar to those previously reported (5, 7, 8, 13). The short-lived triplet (τ = 254 ns) was observed around 400 nm, and the weak transient absorption in the 400–500 nm region of the phenacyl radical was also present. Both these transients were efficiently quenched by oxygen. The remaining transient absorption in the 300–400 nm region in the presence of oxygen is due to the guaiacoxy radical.

Fig. 6. Transient absorption spectra of 15.8 μM GAV/N_2 after excitation at 308 nm in water (*a*, (■) 90 and (○) 570 ns delays), in the presence of 10 mM β-CD (*b*, (■) 70 and (○) 360 ns delays), and in the presence of 10 mM γ-CD (*c*, (■) 80 and (○) 640 ns delays).



The transient phenomena of GAV in water have not been previously described. The same transients as observed in acetonitrile were also present in water (Fig. 6*a*). In addition, in water we observed the formation of solvated electrons that absorb above 600 nm. The solvated electrons are probably formed in a two-photon process leading to the photoionization of GAV. The presence of solvated electrons was established by the disappearance, in the presence of N_2O, of the short-lived absorption measured at 640 nm. The triplet lifetime of GAV in water was (130 ± 10) ns, and it is shortened to (76 ± 3) ns in oxygen saturated solutions. This result is consistent with a diffusional quenching rate constant by oxygen, taking into account the oxygen solubility in water (1.4 mM).

Complexation of GAV to 10 mM β- or γ-CD leads to a larger yield of triplets when compared to the radical yield measured for the photolysis of GAV in water (Fig. 6). The triplet GAV lifetime in the presence of β-CD is (110 ± 3) ns and (104 ± 4) ns in the absence and presence of oxygen, whereas in the presence of γ-CD the respective triplet lifetimes are (97 ± 5) and (88 ± 7) ns. The residual absorption

Table 4. Average ratios for the solvated electron yield formed in the photolysis at 308 nm of GAV in the presence of CDs and in water. The number in parentheses corresponds to the number of experiments averaged.

CD	Solvated electron ratio (CD/H_2O)
10 mM β-	1.4 ± 0.2 (5)
10 mM γ-	1.2 ± 0.1 (5)
30 mM γ-	1.3 ± 0.2 (2)

observed after the decay of the triplet corresponds to the guaiacoxy radical, which is very long lived (>100 μs).

In the presence of CDs, an increase was observed for the yield of solvated electrons. The amount of solvated electrons formed was estimated by subtracting the ΔA values at 640 nm in the presence of N_2O, where all solvated electrons are quenched, from the value determined in the presence of N_2. Since the photoionization of GAV is likely to be a two-photon process, the absolute yield for solvated electron formation is very dependent on the laser energy that excites the sample. For this reason, the yields for solvated electron formation have to be compared for measurements performed for the same experimental conditions. Although the absolute values for these yields changed between experiments performed on different days, it was always observed that the yields in the presence of β- and γ-CD were higher than those measured in water (Table 4). Experiments performed by exciting GAV at 266 nm in the presence of 10 mM of both CDs led to the same ratios for solvated electron formation as observed for the excitation at 308 nm.

Discussion

The photodecomposition of GAV in homogeneous solution leads to the formation several products (Scheme 1) (8, 13, 14). Some of these photoproducts fluoresce, and since fluorescence spectroscopy is a very sensitive technique, a small amount of product formation can be detected before any decomposition is visible by other spectroscopic techniques, such as UV-vis absorption and NMR. The spectral distribution for the photoproduct emission following the photolysis of GAV is very dependent on the nature of the solvent. This difference could be due to changes in the product distribution or different emission quantum yields for each product in the different solvents. Since the emission quantum yields of guaiacol or acetoveratrone were shown not to vary by more than a factor of 2, we explain the different spectra observed to be due to different product distributions.

The products from the photolysis of GAV will have different fluorescence spectra as exemplified for guaiacol and acetoveratrone. The coupling products shown in Scheme 1 are expected to have a fluorescence emission that is similar to that of acetoveratrone, since the chromophore of the latter is present in these compounds. The emission between 300 and 320 nm observed for the photoproduct formation of GAV in methanol and water is assigned to the formation of guaiacol. This spectral feature is absent for the photolysis of GAV in acetonitrile, suggesting that guaiacol is not formed in this solvent. The lack of detection of guaiacol is not due to a sensitivity problem, since the guaiacol emission quantum yield is about one order of magnitude higher than that for acetoveratrone. The emission observed at 420 nm in water and between 320 and 340 nm in methanol and acetonitrile is assigned to products with the acetoveratrone moiety. This blue shift of the emission maxima was also observed when the fluorescence of acetoveratrone was measured in these organic solvents. The larger blue shift observed for the photoproduct emission of GAV could be due to a more significant solvent effect on the emission spectra of the coupling products when compared to the shift for acetoveratrone.

A brief comment on the fact that acetoveratrone fluoresces is justified because it has implications on why GAV is reactive from the excited singlet state. The fluorescence of some methoxy substituted aryl ketones in water has been previously reported (37), but in most cases, ketones do not fluoresce because their intersystem crossing quantum yield is close to unity (38). The intersystem crossing efficiency depends on the configurations and the energy difference between the singlet and triplet states involved in the transition. The configuration of the excited states of ketones can be influenced by the presence of electron-donating substituents that stabilize π,π^* states compared to n,π^* states (39). In the case of acetoveratrone, the presence of two methoxy substituents will stabilize the π,π^* states in the singlet and triplet manifold, leading to a decrease of the intersystem crossing rate constant by either switching the configuration of S_1 to a π,π^* one or by influencing the S_1–T_n energy gap involved in the intersystem crossing process. This decrease of the intersystem crossing quantum yield leads to lengthening of the excited singlet lifetime and the observation of fluorescence. This stabilization in the case of GAV leads to a less reactive triplet state when compared to ketones with n,π^* triplets (13). Furthermore, the GAV photophysics will primarily be determined by the acetoveratrone moiety. This ensures that the rate constant for intersystem crossing of GAV is lower than for other ketones (13) and that the GAV excited singlet state can undergo a β-cleavage reaction. In contrast to acetoveratrone, GAV does not fluoresce in solution, suggesting that the rate constant for β-cleavage is larger than the radiative rate constant responsible for fluorescence. The emission of the photoproducts of GAV in methanol was previously assigned incorrectly to the fluorescence of GAV (6), and based on this assignment, the authors explained the crystalline GAV emission with a maximum at 450 nm to be due to an excimer formed from two adjacent acetoveratrone moieties. The emission observed in the solid state may be due to the emission of GAV, since this emission occurs in the spectral region where acetoveratrone fluoresces in water. However, other evidence previously reported (6) supports this emission to be due to excimer formation. A definite assignment of this emission is problematic, since the emission spectra of acetoveratrone was shown to depend on the solvent polarity, and a similar effect is expected to be observed for GAV.

The objective of the kinetic studies for photoproduct appearance was to investigate if the relative rates observed in the fluorescence measurements can be correlated to the reported photodegradation quantum yields (8). It is important to take into account that the fluorescence intensity is directly proportional to the emission quantum yield of the excited

© 1999 NRC Canada

fluorophores. For this reason, the presence in solution of any substance that quenches the emission of the fluorophore will lead to a decrease of the measured fluorescence intensity. For example, if during the photolysis of GAV one of the products is an efficient quencher of the fluorescence from a second product, the emission intensity of the latter will be decreased. Due to this possible quenching effect, any analysis of the shape of the kinetic trace (i.e., linear at 310 nm and curved at 350 nm) was not attempted. Furthermore, the photolysis of GAV leads to a mixture of products that can fluoresce. At each wavelength, the intensity measured is a function of the concentration of each product, its absorption coefficient at the excitation wavelength, and its emission quantum yield at the wavelength where the kinetics is being monitored; we did not expect to observe the same relative rates when the photoproduct formation was monitored at 310 and 350 nm. Clearly, no quantitative information is available from the kinetic studies performed. However, the relative ordering of the photodegradation yields in methanol and acetonitrile as well as the effect of water addition to these solvents were reproduced. This adequate qualitative correspondence of the photodegradation quantum yield with the relative fluorescence rates shows that fluorescence can be used as a first screening technique to determine the photodecomposition yields of lignin model compounds. The advantage of using fluorescence for preliminary studies is that the experiments are much quicker to perform than the determination of quantum yields, and fluorescence can be employed for the screening of different experimental conditions before performing quantum yield measurements.

The fluorescence experiments were employed to estimate the GAV photodecomposition quantum yield in water, since this value has not been previously reported. The quantum yield in water is much smaller than in methanol and is probably also smaller than in acetonitrile. The emission spectra for the photoproducts indicate that the product distribution observed in water is closer to that in methanol than the product distribution observed in acetonitrile. These experiments show that the photodecomposition pattern of GAV in water, and probably other lignin model molecules, cannot be extrapolated from studies in organic solvents. This is an important point when trying to understand the photodegradation of lignin because the paper matrix contains some water.

We tried preliminary experiments to explore the fluorescence of product formation for the decomposition of GAV when incorporated into paper. These experiments were inconclusive, suggesting that the decomposition rate and (or) the emission properties of the photodecomposition products are affected by the incorporation in the paper matrix. Moreover, these experiments show the complexity of the behavior of fluorophores in paper and that degradation of lignin may have a quenching effect when fluorescent brightners are employed to counteract the yellowing of paper made from mechanical pulp.

The complexation of GAV to β- and γ-CD was established by the appearance of an induced circular dichroism signal when GAV was solubilized in the presence of CD. The direction and strengths of the induced circular dichroism signals of an achiral guest in the CD cavity can be related to the position of the guest within the CD cavity (40–42). The fact that the same direction was observed for the induced circular dichroism signals of GAV in β- and γ-CD suggests that the guest is incorporated in a similar environment in both cavities. No detailed information on the complexation environment could be obtained because the signal-to-noise ratio of the spectra is too poor to warrant any further analysis. The complexation of α-phenoxyacetophenone with β-CD has been previously reported (27), and a 1:1 complex in which the benzoyl moiety is encapsulated was proposed. GAV is too large to completely fit within the β-CD cavity, and for 1:1 complexes, part of the molecule will be exposed to the aqueous phase. However, the possibility exists that at higher β-CD concentrations, a 1:2 (GAV:CD) complex is formed that protects the guest from the aqueous environment. In the case of the larger γ-CD, the benzoyl and phenoxy moieties could be included in the same cavity as was previously proposed for the inclusion of β-phenyl-*p*-methoxypropiophenone (25).

In principle, the complexation of GAV to CDs could lead to either a decrease or increase of the photodegradation rate. In the case of a 1:2 (GAV:CD) complex, we would expect a decrease of the photodegradation rate, since separation of the radicals would be inhibited, leading to an increase in the probability for GAV regeneration. Since such an increase was not observed, it is likely that 1:2 complexes are not present to an appreciable amount. In contrast, the entrapment of one of the radical moieties within the CD cavity and efficient release of the second radical could lead to an enhancement of the GAV photodecomposition quantum yield. Surprisingly, most of the enhancement effect is observed on the initial jump and not on the relative rates at longer times. The relative rates are increased moderately (2–6) by the presence of CDs, indicating that complexation of the radicals to the CD cavity does not affect significantly the rate of product formation after the burst phase (initial jump). In the laser flash photolysis studies, we established that at least the phenoxy radicals are very long lived (>100 μs). Since the exit rate constants of guests from CD cavities are of the order of 10^5–10^6 s^{-1} (43, 44), the long radical lifetimes ensure that radicals formed from the GAV photoreaction can exit and enter CD cavities for many times before they are involved in recombination reactions. Consequently, the entrapment of the radicals does not lead to a significant alteration of the rate for product formation.

The most pronounced effect of CD complexation on the GAV photodecomposition was observed on the enhancement of the amount of product formed during the burst phase. The magnitude of this effect depends on the CD concentration, indicating that this enhancement is due to the complexation of GAV to CDs. This increase is not due to an inhibition of the recombination probability of the phenacyl and guaiacoxy radicals to regenerate GAV, since this inhibition would mean that the exit of one of the radicals from the CD cavity is faster than the separation of the radicals in the solvent cage formed in water. This is an unlikely scenario because it was shown that polar molecules such as triplet xanthone, which are not completely included in the CD cavity (45), have an exit constant of 8.4×10^6 s^{-1} (46), which is much slower than the separation of encounter complexes of neutral molecules in aqueous solution. For this reason, it is likely that the phenacyl and guaiacoxy radicals remain in close contact within the CD cavity for a longer period of time than an en-

© 1999 NRC Canada

counter complex in the aqueous phase. In this case, the enhanced emission intensity is due to a larger yield of coupling product formation in the CD cavities when compared to the reaction in the bulk phase.

An increase of the intersystem crossing quantum yield of GAV when this molecule is complexed to the CDs could also be responsible for the increase of products formed during the burst phase. The laser flash photolysis data suggest that the intersystem crossing quantum yield increased, since a higher triplet to radical concentration is observed for GAV in the presence of CDs than in water. The triplet lifetimes of GAV in β- (110 ns) and γ-CD (97 ns) are short enough that some β-cleavage will occur within the CD cavity. The radical pair formed from the cleavage of a triplet excited state has triplet multiplicity, and an intersystem crossing process has to occur before these radicals can react. For this reason, it is likely that one of the radicals will have to escape the CD cavity before any of the recombination or coupling reactions can occur. In this respect, the increased intersystem crossing for GAV leads to a decrease of the probability for the recombination of GAV and an enhancement of the product formation.

A puzzling effect was observed when oxygen was added to the solutions containing GAV and CDs. The initial jump for the fluorescence experiments decreased when GAV was complexed to γ-CD, but no effect was observed in the presence of β-CD or for GAV solubilized in the aqueous phase. Since the excited triplet state of GAV is quenched in the aqueous phase, the lack of oxygen quenching in the homogeneous solution suggests that the products formed in the initial burst are mainly due to the reactivity from the excited singlet GAV. The same explanation can be employed for the results with β-CD. In the case of γ-CD, the quenching by oxygen indicates that some of the products formed during the burst phase involve a long-lived transient that can react with oxygen. The triplet lifetime of GAV when complexed to γ-CD is decreased by a factor of 1.1 when oxygen is present in solution. This decrease is much smaller than observed for the quenching of triplet GAV in water, and it suggests that the triplet GAV complexed to γ-CD is mainly protected from the interaction with oxygen. This eliminates the triplet as the candidate for the transient being intercepted by oxygen. The phenacyl radical is the other transient in the GAV photolysis that reacts readily with oxygen (7). Thus, the oxygen effect in the presence of γ-CD could be explained by the trapping of this radical when it exits the CD cavity. Although we cannot fully explain the oxygen result, it is worth noting that the GAV complexes with β- and γ-CD must have sufficiently different geometries to lead to the photochemical behavior observed.

The transients formed in the photolysis of GAV in water were studied by laser flash photolysis. As already emphasized above, the comparison of the photochemistry of GAV in water to the previously reported reactions in organic solvents is relevant, since lignin will be exposed to an aqueous like environment in paper. The same transients, i.e., excited triplet state, and phenacyl and guaiacoxy radicals as observed in acetonitrile were also detected in water. The triplet lifetime of GAV in water is shorter than observed in the organic solvents (8). This result explains why the GAV triplet lifetimes in alcohols containing water are shorter than in the pure alcohols leading to a decrease of the photodecomposition quantum yield of GAV (8). The triplet lifetime of GAV in water is also shorter than in pure acetonitrile. In contrast to the results in alcohols, a slight increase (ca. 1.25) (8) was observed for the triplet lifetime in acetonitrile containing 40% water, which is accompanied with a significant increase (2.6) of the photodecomposition quantum yield (14). Our qualitative fluorescence results indicate that the photodegradation rate is smaller in water than in acetonitrile, which is in line with the shorter triplet lifetimes. The fluorescence results also show the same trend as previously reported (8) for the GAV degradation in acetonitrile–water mixtures. These results show that it is not easy to predict the photochemistry of GAV in mixed solvents.

In addition to the formation of the excited triplet states and radicals, we also observed that GAV in water is photoionized, leading to the observation of solvated electrons in the laser flash photolysis experiments. This photoionization reaction is common for ketones in aqueous solution and is augmented when the ketone is complexed to supramolecular structures, such as SDS micelles and bile salt aggregates (47). The same effect was observed for GAV when complexed to both CDs, suggesting that incorporation of GAV into the CD cavity leads to a more efficient separation of the solvated electron and the GAV radical cation. No transient signals were observed for the GAV radical cation probably because its decomposition is very fast. A similar effect has been reported for other ketones (47). Since the photoionization process involves the sequential absorption of two photons, this process can only contribute to the yellowing of paper made from mechanical pulp when very high irradiation intensities are employed. In most applications this reaction will not be relevant.

In summary, complexation of GAV to β- and γ-CD leads to an increase of the initial product formation but has only a small effect on the rate following the burst kinetics. This result indicates that the constrained environment around lignin within the paper matrix could determine the ratio between coupling of the radicals at different positions of the phenol ring and recombination to reform GAV, which will influence the degree of photoyellowing of the paper. The small effect observed for the relative rates after the initial burst are a consequence of the fast entry and exit dynamics of the radicals compared to the time domain for the radical–radical reactions. A more viscous environment will have to be employed to study how the decrease of the mobility of radicals by encapsulation into constrained environments affects the photochemistry of GAV. Finally, we report that GAV does not fluoresce in homogeneous solution, but the fluorescence of the products of GAV photolysis can be employed to gain qualitative information on the photodegradation kinetics.

Successive photocyanation of highly chlorinated aromatic compounds

Alexandre D. Konstantinov, Andrea N. Johnston, and Nigel J. Bunce

Abstract: Successive photocyanation was found to be a general reaction when chlorinated aromatic compounds were photolyzed with sodium cyanide. The products were polycyanated hydroxychloro compounds with various degrees of chlorine replacement. Although the products from some substrates could be isolated, identified, and characterized, most reactions proceeded with low regioselectivity, which limits their synthetic potential. Quantum yields of substrate disappearance increased with the number of chlorine substituents on a substrate, and followed the expected relationship $\phi^{-1} \propto [CN^-]^{-1}$. In some cases, ϕ depended also on the concentration of the chloro compound, indicating the involvement of excimers, although the major reaction channel appears to be S_N2Ar^*. Sensitization and quenching experiments established the triplet excited state to be reactive for all substrates tested.

Key words: photocyanation, chlorinated aromatic compounds.

Résumé : On a trouvé que la photocyanuration successive est une réaction générale lorsqu'on soumet des composés aromatiques chlorés à une photolyse avec du cyanure de sodium. Les produits obtenus sont les composés hydroxylés, chlorés et polycyanurés ayant donné lieu à des degrés divers de remplacement du chlore. Même s'il a été possible d'isoler, d'identifier et de caractériser les produits obtenus à partir de certains substrats, les réactions se font généralement avec des faibles régiosélectivités et cette caractéristique limite leur potentiel en synthèse. Les rendements quantiques pour la disparition du substrat augmentent avec le nombre d'atomes de chlore substituant un substrat et ils peuvent être décrits par la relation attendue: $\phi^{-1} \propto [CN^-]^{-1}$. Dans un certain nombre de cas, ϕ dépend aussi de la concentration du composé chloré; ceci indique une implication des excimères, même si la voie de réaction principale semble être S_N2Ar^*. Des expériences de sensibilisation et de désactivation ont permis de démontrer que l'état triplet excité est réactif pour chacun des substrats étudiés.

Mots clés : photocyanuration, composés organiques chlorés.

[Traduit par la Rédaction]

Introduction

Recently (1), we reported a novel nucleophilic polysubstitution reaction of hexachlorobenzene (HCB) with cyanide ion in acetonitrile–water. Successive photocyanations of HCB occurred with high quantum yield ($\phi_{diss} \rightarrow 0.18$) without the need for an electron acceptor, giving polycyano(chloro)phenols as products. The phenol functional group is introduced by competing hydrolysis of the polycyanochlorinated benzenes. Sensitization and quenching experiments indicated a triplet reactive excited state. Variation of $[CN^-]$ at constant [HCB] followed the expected relationship $\phi_{diss}^{-1} \propto [CN^-]^{-1}$, but variation of [HCB] at constant $[CN^-]$ showed that the reaction becomes less efficient with increasing [HCB], consistent with the formation of an unproductive excimer.

The objectives of the present research were to examine the scope of the new reaction for various classes of highly chlorinated aromatic compounds, to investigate its reaction mechanism further, and to evaluate its possible synthetic potential.

Experimental

Chemicals

Chlorinated benzenes, 1,2-dicyanobenzene, 1,2,4,5-tetracyanobenzene, and hexafluorobenzene were purchased from Aldrich; polychlorobiphenyls, octachloronaphthalene, and octachlorodibenzo-*p*-dioxin from AccuStandard. HPLC grade acetonitrile, methanol, and ethyl acetate were obtained from Fisher. All solvents were used as received. 2,3,4,5,6-Pentachlorobenzonitrile[2] was obtained by cyanation of pentachloroiodobenzene[3], which was synthesized by iododeamination of 4-chloroaniline (4) followed by polychlorination of 1-iodo-4-chlorobenzene[4] (5).

Irradiations

Solutions were photolyzed in 8 mm o.d. Pyrex® test tubes in a Rayonet RPR photochemical reactor equipped with 16 RPR-3000 low-pressure mercury lamps that emit a band at 300 nm with a bandwidth of 25 nm at a half-intensity. When necessary, samples were degassed and sealed on a vacuum manifold using four freeze–pump–thaw cycles (last two cycles using an oil-diffusion pump, $P < 0.01$ Torr (1 Torr = 133.3 Pa)). Preparative photocyanations were done using up to four 30 mm o.d. Pyrex® test tubes sealed with rubber septa and placed in a Rayonet merry-go-round photoreactor (Table 1).

Analytical methods

Reactions were monitored by HPLC equipped with Waters U6K injector, Waters 600E system controller, and Waters 486 tunable absorbance detector, and Waters μ-Bondapack C_{18} 3.9 × 300 mm column, using acetonitrile/water (9/1) as the mobile phase. Calibration curves for analytes ($r^2 = 0.99$) were built using Millennium II software. Absorption spectra of analytes and transmittance spectra of optical filters were acquired on a double-beam Shimadzu UV-vis recording spectrophotometer (Model UV-160A). Carbon Nuclear Magnetic Resonance (^{13}C NMR) and Hydrogen Nuclear Magnetic Resonance (^1H-NMR) spectra were recorded at 100.6 MHz and 400 Hz, respectively, on Avance400 Bruker spectrometer, using acetonitrile-d_3 as a solvent.

Electrospray mass spectral analyses of the photoproducts (negative ionization) were obtained using a VG Quattro II (Fisons U.K. Ltd.) triple quadrupole mass spectrometer equipped with an atmospheric pressure ion source, and MassLynx™ software package. The sample solutions were introduced into the mass spectrometer via a 10 μL Rheodyne™ 7010 injection valve. The mobile phase (50/50 v/v NANOpure water (Barnstead) and acetonitrile (Caledon)) was delivered using a Hewlett Packard 1090 Series II/L binary LC pump at 15 μL/min. The mass spectra were acquired and averaged over at least 8 scans in multi channel analysis (MCA) data acquisition mode by scanning the first quadrupole in 0.1 u increments from m/z 100 to 800 in 1.2 s.

Measurement of quantum yields

Quantum yields of substrate disappearance were determined by potassium ferrioxalate actinometry (6) using solutions of potassium chromate and nickel sulphate (7) as an optical filter. The actinometer in water and the test solution in acetonitrile, containing 5% water, were placed in 8 mm o.d. test Pyrex® tubes that were positioned coaxially in 25 mm o.d. Pyrex® test tubes filled with optical filter. The filter transmitted in the 285–335 nm region, with maximum transmittance of approximately 20% at 313 nm. The actinometer and test solutions were irradiated simultaneously in the photoreactor using the merry-go-round to assure equal light intensity incident on all solutions. All the light was absorbed by the actinometer, and the photon intensity absorbed by the actinometer ($I_o = 7.09 \times 10^{-7} \pm 7.55 \times 10^{-8}$ mol min^{-1}) was calculated based on $\phi_{313} = 1.24$ for potassium ferrioxalate (8). The light flux absorbed by the test solution I_{abs} was calculated using the following equation:

$$I_{abs}\ (\text{mol}) = I_o\ (\text{mol min}^{-1}) \times \text{time (min)} \times (1 - 10^{-A})$$

Solutions of substrates (1.00×10^{-5} to 4.00×10^{-4} mol L^{-1}) and NaCN (0.18–0.25 mol L^{-1}) in acetonitrile–water (5% H_2O) were irradiated for time intervals ranging from 10 min to 2 h. After irradiation, substrate disappearance was determined by HPLC analysis (averaged results of triplicate experiments are presented in supplementary materials)[5]. The apparent quantum yields were calculated and plotted against time.

Sensitization of photocyanation by acetone and acetophenone and oxygen removal

Concentrations of acetone and acetophenone were chosen such that most of the incident light was absorbed by the sensitizers. In a typical experiment, eight substrate solutions in acetonitrile–water (5% H_2O) containing NaCN were prepared, with two having acetone (0.125 mol L^{-1}, $A_{300} = 0.78$) and the other two having acetophenone (1.12×10^{-2} mol L^{-1}, $A_{300} = 0.57$) added. The samples, except two of those without sensitizers, were degassed by four freeze–pump–thaw cycles, sealed under vacuum, and irradiated at 300 nm for 7–20 min in the merry-go-round photoreactor. The results of HPLC analysis of duplicate samples are presented in supplementary materials.

Quenching of photocyanation by ferrocene

In a typical experiment, eight sample tubes, each containing 1.0 mL aliquots with various concentrations of ferrocene and fixed concentrations of substrate and sodium cyanide,

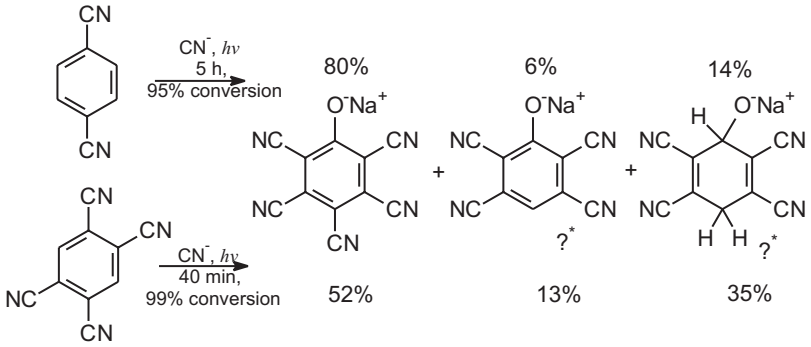
Fig. 1. Photocyanation of 1,4-dicyano- and 1,2,4,5-tetracyanobenzenes; *, possible structures; products not isolated.



were irradiated for 4–30 min in a merry-go-round photoreactor and analyzed by HPLC. The concentrations of ferrocene were selected to maintain the absorbance of ferrocene <0.1 at 300 nm.

Preparative photocyanation of 2,3,4,5,6-pentachlorobiphenyl

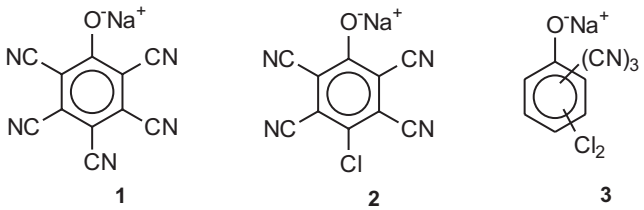
Forty-one milligrams (1.25×10^{-4} mol) of 2,3,4,5,6-pentachlorobiphenyl and 0.5 g (10 mmol) of NaCN were dissolved in 50.0 mL of acetonitrile – 5% water. The solution was placed in two 30 mm Pyrex® tubes, sealed with rubber septa, and irradiated at 300 nm for 24 h. The resultant yellow liquid was treated with 3.2 g Dowex® 50W and extracted with 3 × 20 mL hexane. Approximately 30 mg of starting material, which was recovered from hexane, was redissolved in 50 mL of acetonitrile – 5% water with 0.5 g of NaCN and irradiated for additional 48 h. After treatment with Dowex® 50W and hexane extraction, 18 mg of the starting pentachlorobiphenyl was recovered. The product, a tetracyanochlorohydroxybiphenyl, was isolated by flash chromatography (ethyl acetate: acetonitrile = 4:1). Yield: 12.5 mg, 4.12×10^{-5} mol (59% based on reacted material). ^{1}H NMR (δ, CD_3CN): 7.41, dd, J = 7.4 Hz, ^4J = 2 Hz, 1H (H3′); 7.49, ddd, J = 7.4 Hz, J = 7.6 Hz, ^4J = 1.4 Hz, 1H (H4′); 7.52, ddd, J = 7.6 Hz, J = 8.0 Hz, ^4J = 2 Hz, 1H (H5′); 7.60, dd, J = 8 Hz, ^4J = 2 Hz, 1H (H6′). ^{13}C NMR (partial spectrum) (δ, CD_3CN): 125.7 (C2′), 128.6 (C4′), 131.1(C6′), 131.4 (C3′), 132.6 (C5′), 151.3 (C1′). Mass spectrum, *m*/*z* (%): 303 (M – H) (100), 266 (10.5), 241(9.5) 224 (5.9); MS/MS, daughters of *m*/*z* 303, *m*/*z* (%): 293 (142), 213(29), 201(14) 188 (26), 163 (10.5), 35 (56).

Results and discussion

Scope of the reaction

Chlorinated benzenes

Our previous work showed that irradiation of HCB with excess NaCN at 300 nm in aqueous acetonitrile results in rapid disappearance of the title compound and the formation of pentacyanophenol **1** (14%), 4-chloro-2,3,5,6-tetracyanophenol **2** (54%), and a tricyanodichlorophenol **3** (29%) as highly polar sodium salts. Similar irradiations of penta and less-chlorinated benzenes with NaCN resulted in the disappearance of the starting materials and formation of polar products, visually similar (yellow–greenish solutions) to those formed in photocyanation of HCB. ES–MS analysis of the products of photocyanation revealed that pentacyanophenol was the major product for all congeners, except pentachlorobenzene for which 4-chloro-2,3,5,6-tetracyanophenol predominated. The rate of the reaction decreased in parallel with the number of chlorine substituents; 20 h were required to reach 95% conversion of dichlorobenzene, compared with 2 h for pentachlorobenzene and 1 h for HCB. In penta and less-chlorinated benzenes, both hydrogen and chloro substituents were replaced by cyanide (reactions take place in air, which acts as an oxidant for the H^- that is formally replaced (9–11)).



1 **2** **3**

Polycyanobenzenes

Irradiation of 1,4-dicyanobenzene in the presence of NaCN gave pentacyanophenoxide **1** as a major product (Fig. 1). ES–MS analysis of the reaction products at 95% conversion also revealed the presence of small amounts of products with *m*/*z* 193 and 195 in the ratio of 1:2.5. These products correspond to a tetracyanophenoxide ($C_6H(CN)_4O^-$) and a dihydrotetracyanophenoxide ($C_6H_3(CN)_4O^-$). The formation of a dihydro product is often observed when hydrogen is replaced by CN in the absence of oxidants (10, 12). Photocyanation of 1,2,4,5-tetracyanobenzene gave similar products, except that more dihydro product was formed (Fig. 1).

Although CN^- did not react with 1,4-dicyanobenzene in the dark, a dark reaction was observed upon addition of 0.1 mol L^{-1} solution of NaCN in 9:1 acetonitrile:water to 1,2,4,5-tetracyanobenzene in acetonitrile. The starting material disappeared rapidly (50 min) with development of a deep purple colour. ES–MS analysis of the reaction mixture showed peaks at *m*/*z* 384 (71%), 406 (26%), and 455 (3%) of which *m*/*z* 384 corresponds to the molecular mass of octacyanodiphenoquinone.

Polychlorinated biphenyls

Photolysis of decachlorobiphenyl (DCB) with NaCN in aqueous acetonitrile gave a complex mixture of hydroxybiphenyls bearing from one to eight cyano groups according

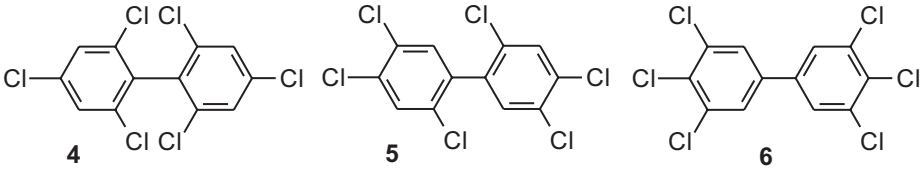
m/*z*	466	457	448	439	430	421	412	403
Relative abundance, %	7	12	20	24	16	8	7	6



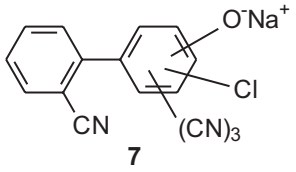
to ES–MS (Table 2). No attempt was made to isolate products, but we can draw the following conclusions:

(*i*) Introduction of an hydroxy group can occur at early stages of reaction, when just one or two chlorines have been substituted by CN^-, possibly inhibiting further cyanation.

(*ii*) Cyano substitution can occur on both rings of decachlorobiphenyl, since biphenyls bearing >5 CN substituents were formed.

(*iii*) Simultaneous hydroxylation of both aromatic rings of highly cyanated biphenyls is unlikely, since no dihydroxy products were found.[6]

Although the symmetrically substituted biphenyls **4**, **5**, and **6** also gave complex mixtures, photocyanation of 2,3,4,5,6-pentachlorobiphenyl, which has one ring fully chlorinated and the other unsubstituted, gave 80% (ES–MS) of a single substance with *m*/*z* 303 and a one-chlorine pattern corresponding to $C_{12}H_4Cl(CN)_4O^-$ (**7**). The minor products included *m*/*z* 337 (a two-chlorine pattern, $C_{12}H_3Cl_2(CN)_4O^-$) and *m*/*z* 294 (no chlorines, $C_{12}H_4(CN)_5O^-$). Continuous irradiation of the product mixture for 48 h resulted in the decrease of relative intensity of the ion *m*/*z* 303, with formation of single-ring products (*m*/*z*: 218, 193, and 195). These were tentatively identified as **1**, a tetracyanophenoxide ($C_6H(CN)_4O^-$), and a dihydrotetacyanophenoxide ($C_6H_3(CN)_4O^-$), respectively.



Compound **7** was isolated in 59% yield as the sodium salt from a large-scale photocyanation of 2,3,4,5,6-pentachlorobiphenyl. Attempts to protonate this salt by treatment with 20% hydrochloric acid resulted in decomposition, while less concentrated acid failed to cause protonation (based on the UV spectrum of the product); attempts to crystallize this salt for X-ray analysis were also unsuccessful.

The partial structure of **7** was deduced from ES–MS, ES–MS–MS. and 2D NMR. The molecular formula of **7** indicates that during the photocyanation of 2,3,4,5,6-pentachlorobiphenyl, one hydrogen was substituted by CN^- ($C_{12}H_5Cl_5$ has five substituents, $C_{12}H_4Cl(CN)_4O^-$ has six). The MS–MS spectrum showed a fragment with *m*/*z* 201 corresponding to $C_6(CN)_3ClO^{\cdot -}$ in which the biphenyl bond of **7** has cleaved. Proton NMR (400 MHz) for $C_{12}H_4Cl(CN)_4O^-$ exhibited a complex coupling pattern that could be interpreted as an ABCD pattern with the aid of COSY and HSQC experiments ($J_{A–B} \approx J_{B–C} \approx J_{C–D} \approx 7.4–7.6$ Hz, $J_{A–C} \approx J_{B–D} \approx 1.4–2$ Hz). COSY data were compatible only with a 3,4,5,6 pattern of C—H bonds, hence the CN group had been incorporated at the 2 position.

Heteronuclear connectivity was established from HSQC NMR (supplementary material). With the aid of a long-range proton to carbon coupling experiment (HMBC, supplementary material) chemical shifts for carbon 1′ (δ = 151.3 ppm, downfield due to the phenoxide substituent) and carbon 2′ (δ = 125.7.3 ppm, upfield due to the CN substituent) were determined. Cross signals between H_A and C1′, and between H_D and C6′ indicate that H_A is on the position 3′, and H_D is on the position 6′ of the biphenyl ring. One-dimensional ^{13}C NMR data could not determine the placement of the substituents in the second aromatic ring, and 2D ^{13}C experiments like DQF_PS COSY or INADEQUATE were infeasible due to insufficient quantity of **7**.

Octachloronaphthalene and octachlorodibenzo-p-*dioxin*

Photolysis of octachloronaphthalene (OCN) and octachlorodibenzo-*p*-dioxin (OCDD) with NaCN both gave highly complex product mixtures, and no attempts to isolate the cyanated products were made. According to ES–MS, a tetrachlorotricyanonaphthol (*m*/*z* 354) and a pentachlorodicyanonaphthalene (*m*/*z* 363) predominated in the product mixture from OCN; only traces of higher cyanated naphthalenes were found. Knowing the strong preference of naphthalene derivatives for α rather than β substitution (13), we speculate that the low reactivity of β-chlorines may inhibit further photocyanation.

Hexafluorobenzene

Fluorine is considered the best leaving group among halogens in photochemical nucleophilic substitution (10). At 300 nm, where C_6F_6 is transparent, photolysis was slow

[6] Under the conditions of negative ionization, the possible dihydroxy products would form dianions with *m*/*z* corresponding (FW-2)/2. Careful examination of the ES–MS spectra revealed the absence of peaks near *m*/*z* 220, which would correspond to polychloro-polycyano-dihydroxybiphenyls.

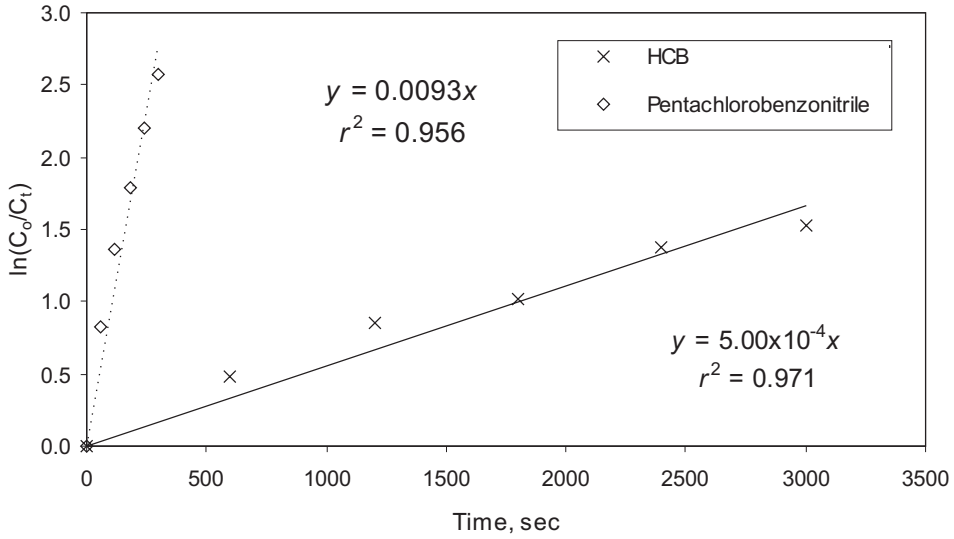
Fig. 2. Pseudo-first-order kinetics in photocyanation of HCB and pentachlorobenzonitrile.



(55% conversion in 47 h). Irradiation of an 8.75×10^{-4} mol L^{-1} solution of C_6F_6 in the presence of 0.05 mol L^{-1} NaCN at 254 nm ($A_{C_6F_6} = 0.136$) resulted in rapid disappearance of the starting material. Analysis of the reaction mixture by ES–MS revealed a product mixture rather analogous to that that obtained from hexachlorobenzene, principally a difluorotetracyanobenzene (*m*/*z* 214), with trace amounts of **1** (*m*/*z* 218), a difluorotricyanophenoxide (*m*/*z* 204), a tetrafluorocyanophenoxide (*m*/*z* 190), and pentafluorophenoxide (*m*/*z* 183).

Reaction kinetics and quantum yields

Photocyanation was pseudo-first order in substrate (under conditions of low absorbance $I_{abs} = I_0(1 - 10^{-A}) \sim 2.303 I_0 A$) for all compounds studied, with rate constants ranging from 1.1×10^{-3} s^{-1} to 6.7×10^{-5} s^{-1}. The only exception was hexafluorobenzene at 254 nm for which the reaction did not follow pseudo-first order kinetics, and 85% conversion was reached within 5 min of irradiation.

As observed previously for HCB (1), the apparent quantum yields of substrate disappearance declined with conversion. Extrapolation to zero conversion gave the limiting value $\phi_{diss} = 0.26$ for decachlorobiphenyl ($\phi = \phi_0 - 0.013$ min^{-1} × time).[7] The quantum yield is higher than that of HCB (0.14). The quantum yields of disappearance of OCN and OCDD were rather small, 2×10^{-4} and 0.001, respectively.

For all the above compounds, reductive dechlorination competed with photocyanation, and significant amounts of reductive dechlorination products were found by GC–MS. The relative rate constants for substrate disappearance in the absence and the presence of 0.25 mol L^{-1} NaCN indicated that ~15% each of DCB and OCN was consumed by reductive dechlorination, but for OCDD photocyanation and dechlorination occurred at almost equal rates.

Photolysis of DCB at a range of concentrations of NaCN gave the relationship $1/\phi_{diss} \propto 1/[NaCN]$; the limiting (low conversion) ϕ_{diss} ranged from 0.29 to 0.07 as [NaCN] changed from 0.285 to 0.020 mol L^{-1}. Thus, photocyanation is first order in both excited DCB and sodium cyanide, and is even more efficient photochemically than the reaction with HCB (1).

Increasing the water content of the solvent decreased ϕ_{diss} for DCB, but the effect was less profound than for HCB, where increasing $[H_2O]$ from 1.4 to 14% caused a threefold drop in ϕ_{diss} (1). The plot of ϕ_{diss} vs. $[H_2O]$ was linear (r^2 = 0.973), and from the intercept at $[H_2O] \rightarrow 0$, $\phi_{diss} = 0.27$ at $[NaCN] = 2.55 \times 10^{-2}$ mol L^{-1}, and $[DCB]^\circ = 2.63 \times 10^{-5}$ mol L^{-1} (supplementary material). ϕ_{diss} for OCDD and OCN also decreased with increasing water content in the solvent.

Photocyanation steps beyond replacing the first chlorine must proceed with successively higher quantum yield, because no mono- or dicyano products were detected in any of the product mixtures. We determined the quantum yield for the secondary cyanation of HCB by comparing the rates of disappearance of HCB and pentachlorobenzonitrile at constant substrate concentration, nucleophile concentration, and solvent composition (Fig. 2). The quantum yield of disappearance of pentachlorobenzonitrile ϕ_s was calculated to be 0.51 from eq. [1], using ϕ_{diss} for HCB = 0.14, and the absorbances of HCB ($A_{313} = 0.054$) and pentachlorobenzonitrile ($A_{313} = 0.278$). This is an example of a photochemical autoacceleration reaction in which each consecutive step occurs with the higher quantum efficiency. Therefore, the total photon efficiency of photocyanation of HCB is very high.

$$[1] \qquad \phi_s = \phi_{HCB} \frac{\left\{(c_0 - c_t) - \frac{1}{\varepsilon l} \ln\left[\frac{(1 - e^{-2.303\varepsilon c_t l})}{(1 - e^{-2.303\varepsilon c_0 l})}\right]\right\}^s}{\left\{(c_0 - c_t) - \frac{1}{\varepsilon l} \ln\left[\frac{(1 - e^{-2.303\varepsilon c_t l})}{(1 - e^{-2.303\varepsilon c_0 l})}\right]\right\}^{HCB}}$$

The photoefficiency of photocyanation of chlorinated benzenes depends directly on the number of electron-withdrawing chlorine substituents. HCB, pentachlorobenzene, and 1,2,3,4-tetrachlorobenzene were irradiated with NaCN at equal substrate absorbances, so that the pseudo-

[7] $\phi_0 = 0.259$; time in minutes; $r^2 = 0.955$.

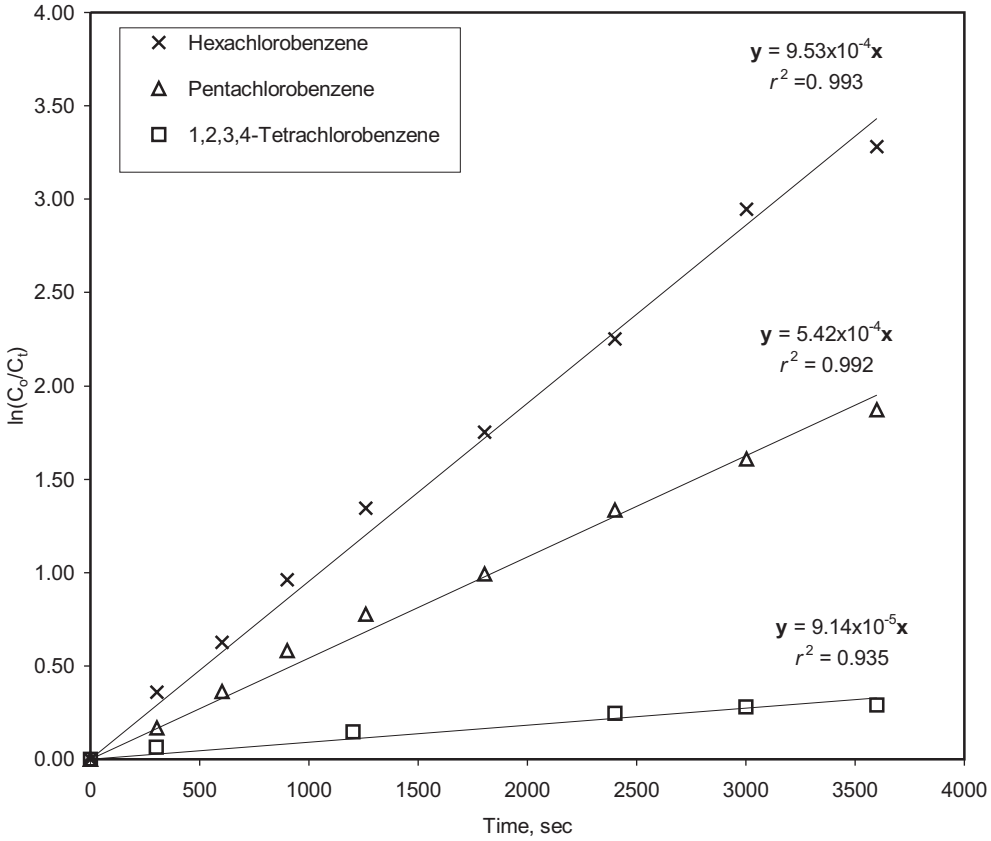
Fig. 3. Measurement of pseudo-first-order rate constants for photocyanation of HCB, pentachlorobenzene, and 1,2,3,4-tetrachlorobenzene in solutions with equal absorbancies.



first-order rate constants for substrate disappearance (Fig. 3) would be proportional to ϕ_{diss}. HCB, pentachlorobenzene, and 1,2,3,4-tetrachlorobenzene had ϕ_{diss} under these conditions 0.14, 0.07, and 1.4×10^{-2}, respectively.

Chlorinated biphenyls show a strong *ortho* effect in reductive dechlorination, because steric interference between the substituents raises the energy of the (planar) excited state (14). The *ortho* effect is also observed in photocyanation, as shown by studying the hexachlorobiphenyls **4**, **5**, and **6**, which have four, two, and no *ortho* chlorines, respectively. Rates of homolysis were an order of magnitude smaller than those for photocyanation of all three hexachlorobiphenyls and at equal substrate concentrations, ϕ_{diss} values calculated using eq. [1] were in the ratio 1:0.45:0.05 for **4**, **5**, and **6**.

Reactive excited state

Sensitization and quenching experiments provided evidence that photocyanation of DCB, like that of HCB, is a triplet state process. The ϕ_{diss} value increased in the presence of acetone and acetophenone, and when oxygen was removed by freeze–pump–thaw. A Stern–Volmer plot of the quenching of decachlorobiphenyl photocyanation by ferrocene had a positive slope of 784 mol^{-1} L with r^2 = 0.975. From the slope, the triplet lifetime of DCB is 80 ns, assuming that the quenching of the DCB photocyanation is diffusion-controlled. Sensitization experiments with acetophenone and acetone suggest that photocyanations of OCN and OCDD are also triplet state reactions, but attempts to quench these photolyses by ferrocene failed; increasing the concentration of ferrocene resulted in the enhancement of the reaction in both cases. Examination of the half-wave reduction potentials for OCN ($E_{1/2}$ = 1.29 V, ref. 15) and ferrocene ($E_{1/2}$ = 1.33 V, ref. 16) revealed that the electron transfer from ferrocene to excited OCN is possible. Although the half-wave reduction potential for OCDD is not reported in the literature, electron transfer is likely to occur, since the addition of electron donors significantly enhances photolysis of OCDD in hydrocarbon solvents (17). Electron transfer from ferrocene to DCB is less favourable (for DCB $E_{1/2}$ = 1.76 V, ref. 15). All substrates examined to date therefore appear to exhibit triplet state reactivity.

Reaction mechanism

The candidate mechanisms for photocyanation reactions are S_N2Ar^*, photoionization, excimer-mediated, and electron-acceptor assisted (18).

S_N2Ar^*

$ArX^* + CN^- \rightarrow ArXCN$ (σ-complex)

$ArXCN \rightarrow ArCN + X^-$

Photoionization

$ArX^* \rightarrow ArX^{\cdot+} + e^-_{diss}$

$ArX^{\cdot+} + CN^- \rightarrow ArXCN^{\cdot}$

$ArXCN^{\cdot} \rightarrow ArCN + X^{\cdot}$

© 1999 NRC Canada

Excimer

$ArX^* + ArX \rightarrow \{ArX^{\cdot+}\ ArX^{\cdot-}\}^*$

$ArX^{\cdot+} + CN^- \rightarrow ArXCN^{\cdot}$

$ArXCN^{\cdot} \rightarrow ArCN + X^{\cdot}$

When X = H: $2ArHCN^{\cdot} \rightarrow ArCN + \text{“Ar”}H_2CN$ (a dihydro product)

$S_{ET}Ar^*$, or exciplex

$ArH- \xrightarrow{hv} {}^1ArH^*$

$^1ArH^* + 1,4\text{-DCB} \rightarrow ArH^{+\cdot} + 1,4\text{-DCB}^{-\cdot}$

$Ar^{+\cdot} + CN^- \rightarrow ArH\text{-}CN^{\cdot}$

$2\ ArH\text{-}CN^{\cdot} \rightarrow H\text{-}ArH\text{-}CN + ArCN$

$ArH\text{-}CN^{\cdot} + DCB^{-\cdot} \rightarrow ArH\text{-}CN^- + DCB$

$ArH\text{-}CN^- + H^+ \rightarrow H\text{-}ArH\text{-}CN$

$ArH\text{-}CN^{\cdot} + Ox \rightarrow ArCN + OxH^{\cdot}$

1,4-DCB is 1,4-dicyanobenzene (an array of other e^- donors can be used)

Photoionization can be ruled out based on the observation that in the benzene series, ϕ_{diss} increases with the number of Cl substituents. We showed previously that the excimer of HCB, though formed, appears to be unproductive (1). By contrast, increasing the initial concentration of OCN results in higher ϕ_{diss}, (Fig. 4), suggesting that photocyanation of OCN may proceed in part via the intermediacy of an excimer. Low solubility in acetonitrile precluded a test of the dependence of ϕ_{diss} on the concentration of DCB; however, an excimer involvement in the photocyanation mechanism in this case is unlikely due to low initial concentration of the reactant (2.5×10^{-5} mol L^{-1}). Assuming a μs lifetime for the excited state, even a diffusion-controlled encounter between the excited and ground state molecules could not compete significantly with first-order decay of the excited state.

Regarding the initial step of photocyanation, the S_N2Ar^* mechanism is most probable. At this stage, there are no available electron-accepting substances available in the reaction mixture to promote the $S_{ET}2Ar^*$ mechanism (11); this is not true once photocyanation is under way, and cyanoaromatic compounds, which are well known electron acceptors, are present in solution. Autoacceleration of the disappearance of the original substrate due to the involvement of electron-accepting products has been observed previously in the photocyanation of naphthalene (19).

The $S_{ET}2Ar^*$ mechanism also accounts for the replacement of -H by -CN in the photocyanation of penta and less-chlorinated benzenes, since replacement of -H by -CN usually occurs by this mechanism (11). After accepting an electron, the cyano compound undergoes parasitic reactions leading to loss of material balance (20) except, as in our system, when an oxidant (O_2) is present to reoxidize $ArCN^{\cdot-}$ to ArCN. Indirect evidence for this proposal is observation of dihydro by-products, typical for $S_{ET}2Ar^*$ during photolysis of 1,4-dicyanobenzene and 1,2,4,5-tetracyanobenzene on the presence of CN^- (Fig. 1).

Conclusions

Successive photocyanation can be achieved for a wide variety of polyhaloaromatic compounds, including polychlorinated benzenes, biphenyls, naphthalenes, and dioxins, and probably also their polyfluorinated analogs. Unfortunately, the synthetic potential of the successive photocyanation is low. Most substrates undergo the reaction with low regioselectivity, giving complex mixtures of products, and even when some selectivity exists, the photocyanation products can only be isolated as their conjugate bases because of the high acidity of polycyanophenols.

All compounds studied undergo photocyanation from the triplet excited state. The initial replacement of -Cl by -CN can generally be rationalized by the S_N2Ar^* mechanism, but subsequent steps involving substitution of -CN for -H are more likely $S_{ET}2Ar^*$ reactions. In either case, autoacceleration of the reaction is observed because increasing the number of -CN substituents makes the molecule more susceptible to nucleophilic attack.

Fig. 4. A double reciprocal relationship of the quantum yield of disappearance of OCN and the initial concentration of OCN.

A novel photorearrangement of 1,3-diketonatoborinate: a photoinduced intramolecular alkylation on a conjugated carbonyl system

Jun-ichi Ishiyama and Yuan L. Chow

Abstract: Irradiation of borinates derived from 9-borabicyclo[3,3,1]nonane and 1,3-diketones at their π–π* transition band caused a rearrangement from their triplet excited state to give boronate intermediates that could be hydrolyzed to the corresponding aldols. The primary photolysis involves the scission of one of the B—C bonds followed by a 1,3- or 1,5-migration and the formation of a more stable B—O bond by radical pathways. The triplet state reaction was established by quenching and heavy atom effect experiments. The overall reaction pattern is an irreversible 1,2- or 1,4-addition of an alkyl-boron group to an α,β-conjugated ketone system by radical processes. Evidence showed that the non-isolated boronates also underwent secondary photoreactions followed by hydrolysis to afford enones corresponding to dehydration products of aldols; mechanisms are suggested for these secondary steps. The photoreaction was more facile in nonpolar solvents than in polar solvents; different solvents also gave different product compositions. In the presence of dilute acetic acid, the photolysis gave a high yield of aldols, suggesting a rapid acetolysis of the B—C bond in boronates to acetylborates. Under oxygen, the photolysis was complicated by radical oxidation to give totally different products.

Key words: borinate photochemistry, charge transfer absorption, alkylborane addition, boronate intermediates, B—C bond homolytic scission.

Résumé : L'irradiation de borinates dérivés du 9-borabicyclo[3.3.1]nonane et des 1,3-dicétones au niveau de leur bande de transition π–π* provoque un réarrangement à partir de leur état excité triplet pour conduire à des boronates intermédiaires que l'on peut hydrolyser en aldols correspondants. La photolyse primaire implique la scission de l'une des liaisons B—C, suivie d'une migration 1,3 ou 1,5 et la formation d'une liaison B—O plus stable par le biais de voies radicalaires. On a établi l'implication d'une réaction de l'état triplet à l'aide d'expériences de désactivation et d'effets isotopiques. Le schéma de la réaction globale est une addition, 1,2 ou 1,4 irréversible, d'un groupe alkyl-bore sur un système cétonique α,β-insaturé par des processus radicalaires. Les données montrent que les boronates qui n'ont pas été isolés subissent aussi des photoréactions secondaires qui, suivies d'une hydrolyse, fournissent les énones qui correspondent aux produits de déshydratation des aldols; on suggère des mécanismes pour ces étapes secondaires. La photoréaction est plus facile dans les solvants non polaires; les divers solvants donnent aussi des compositions de produits différentes. En présence d'acide acétique dilué, la photolyse fournit un rendement élevé d'aldols; ceci suggère que, dans les boronates, il se produit une acétolyse rapide de la liaison B—C pour donner des acétylboronates. En présence d'oxygène, la photolyse est compliquée par une oxydation radicalaire qui conduit à des produits totalement différents.

Mots clés : photochimie du borinate, absorption du transfert de charge, addition d'alkylborane, intermédiaires boronates, scission homolytique de la liaison B—C.

[Traduit par la Rédaction]

Introduction

We observed some 10 years ago that dialkylborinates derived from simple 1,3-diketones (such as **5–7** in Scheme 1, see below) underwent photolysis to give rearranged products. The work has been left dormant since we noted that two short communications on the photoreaction of allied borinates (where the bicyclononane ring in **5–7** is replaced by di-*n*-butyl or dicyclohexyl groups) had already been published in 1986 (1). These works were a study based on suggestions derived from an earlier communication by another group (2). While an additional related communication was

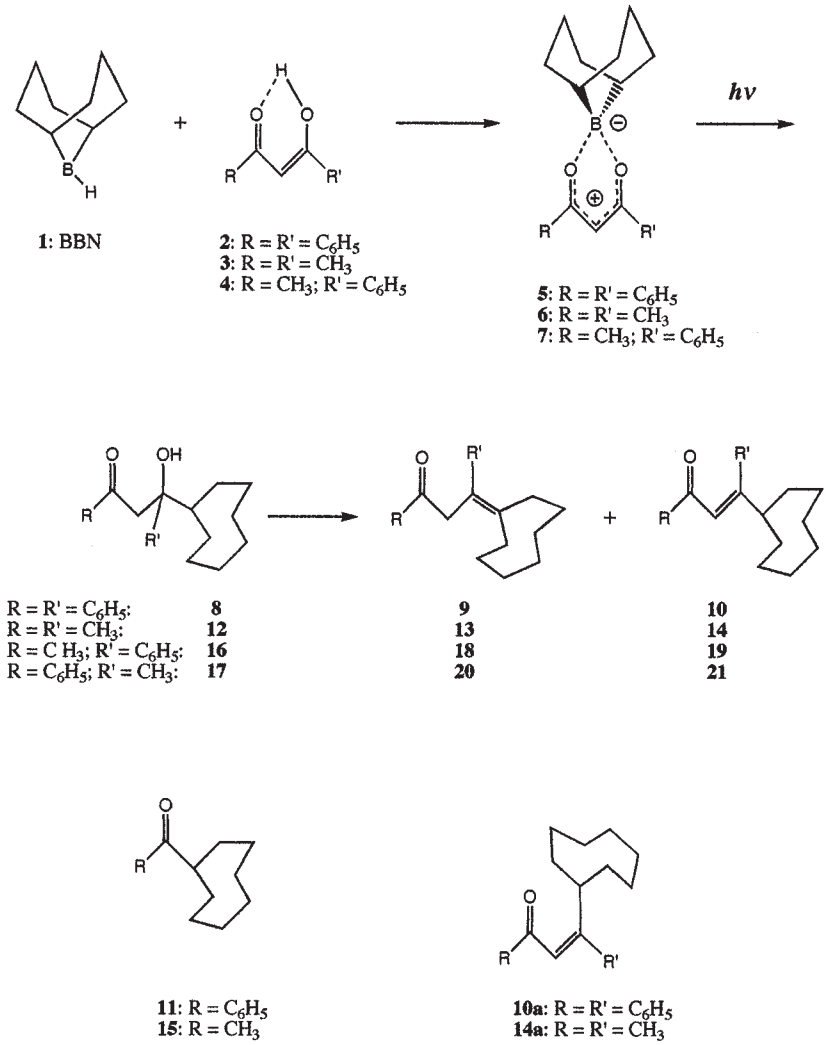
Scheme 1.



published later (3), the detailed photochemical reaction of allied borinates has not, to our knowledge, been described. In the meantime, the photochemistry and photophysics of boron compounds continue to attract investigations, and interesting results have been published in relation to photoinduced electron transfer (4), photo-cycloadditions (5), exciplex formations (5), and unusual emission patterns (6, 7). We were attracted by the abnormally deep-colored appearance of these borinates, and were puzzled by what appeared to be an unusually strong CT band in their UV–visible spectra. More recently, we undertook an in-depth investigation of borinates **5–7**, and discovered that our results were not in total agreement with the earlier communications (1). The chemical and physical behavior of these borinates is interesting and promises to stimulate new studies of allied boron compounds, particularly in relation to their excited states and radical reactions. We wish to describe the results from our group.

Results

The reaction of 9-borabicyclo[3,3,1]nonane (BBN, **1**) with a 1,3-diketone (**2–4**) in THF readily gave the corresponding *B*-diketonato-9-borabicyclo[3,3,1]nonane, **5–7**, in high yields (8); these borinates were abbreviated as AABBN (for *B*-acetylacetonato-, **6**) (8*b*), BABBN (for *B*-benzoylacetonato-, **7**) and DBMBBN (for *B*-dibenzoylmethanato-, **5**). They were prepared equally easily from 9-methoxy-BBN (**1**, H = OCH_3) and 9-(2-aminoethanolato)-BBN (**1**, H = $NH_2CH_2CH_2O$) in comparable yields. These colored (from yellow to orange) crystalline dialkylborinates **5–7** prominently showed strong UV absorption that is slightly blue-shifted from that of the parent diketone (6); this UV band was red-shifted in more polar solvents and must arise from a π–π* transition. They also showed a broad and weaker but well-defined band that was assigned as a CT transition (Fig. 1). Since the intensity of these absorption bands obeyed the Beer–Lambert law in cyclohexane and methylene chloride, it was concluded that these borinates existed as monomers up to 0.1 M. The borinates showed a strong IR absorption band for the B—O bond at 1376–1378 cm^{-1} and a ^{13}C NMR signal for the C-B carbon at about 23 ppm, which was slightly broadened owing to the boron quadrupole couplings. It should be noted that whereas the chemical shift of olefinic hydrogen moved downfield in the order **6–7–5**, the ^{13}C chemical shift of the corresponding

olefinic carbon moved upfield in the same order. The reversed order of chemical shifts could be related to the ring current generated by resonance involving the borinate ring.

DBMBBN **5** gave a broad (380–500 nm) fluorescence band with λ_{max} 415 nm in methylene chloride on excitation at the π–π^* transition at 330 nm, but no emission on excitation at the CT band. AABBN **6** in cyclohexane (and methylene chloride) showed a narrow fluorescence peak at 280 nm on excitation at 259 nm, and at 393 on excitation of the CT band at 353 nm. In both spectra weak emission humps at longer wavelengths (e.g., those at 320 and 370 nm in the former and at 432 and 507 nm in the latter) were assumed to arise from decomposed intermediates. While these fluorescence spectra were stable in cyclohexane, those in acetonitrile showed complex shapes and changed with time lapses. Their study remains to be continued later.

Irradiation of DBMBBN **5** in methylene chloride at 350 nm gave unconjugated enone **9** and a mixture of isomeric enones **10** in addition to a smaller amount of aldol **8**; the amount of all enones increased at the expense of **8** during isolation. Injection of this sample into GC showed that **9** and **10** were present in 14 and 30%, respectively, but **8** was thermally decomposed to give a new peak showing M^+ = 217 by a CI mode. By the EI mode, this GC peak showed the major *m*/*e* fragment at 216 (M^+), 133 ($C_6H_5COCH_2CH_2$), 105 (C_6H_5CO, 100%), and 77 (C_6H_5); this MS pattern is compatible with the structure of **11**,which could be easily formed from the retro-aldol reaction of **8** on injection into GC. Similar photolysis of **5** in a solution containing 0.2% of acetic acid (by volume) afforded aldol **8**, in a 41% isolated yield, but no enones **9** and **10**; the yields of the latter two were small as shown by GC analysis. However, in the presence of methanol (<1%) or acetic anhydride, analogous photolysis caused marginal effects. On the other hand, similar photolysis of **5** in a mixture of methylene chloride and acetonitrile (1:4) gave only enones **9** and **10** in 38 and 36% yield, respectively. While enone **9** could be isolated by chromatography, enone **10** decomposed during the operation.

In the initial stage, AABBN **6** was photolyzed in a mixture of cyclohexane and methylene chloride (9:1) under a blanket of dry nitrogen with 300 nm light in order to obtain a higher yield of aldol **12** at a reasonable rate. Irradiation with 254 nm light was faster by a factor of two than that with 300 nm light, but irradiation with 350 nm light (i.e., excitation of the CT band), on the contrary, caused no significant decomposition in 24 h. Photolysates were chromatographed to give aldol **12** and enones **13** and **14** in yields of 54, 7 and 1%, respectively, by 254 nm irradiation, and 54, <1, and 14%, respectively, by 300 nm irradiation. The GC spectrum of the crude product showed these and other product peaks, including those of acetylcyclooctane (**15**) and the geometric isomer **14a**; both of them were too small to be isolated (see Table 1). As is typical of a radical reaction, there were also several small by-product peaks that

[a]See text for details of the solutions; the irradiation time was 4 h for tubes 1–4 and 2.5 h for tubes 7 and 8; the corresponding factor for products to the internal standard (hexadecane) was arbitrarily set at 10:1.
[b]This peak is derived from **12** upon injection of photolysates.
[c]Tube 3 contains 0.167 M acetic acid.
[d]Tubes 3 and 4 contain phenyl bromide, 0.0082 and 0.0041 M, respectively.
[e]Tubes 7–9 contain 1,2-dibromoethane, 0.02, 0.04, and 0.08 M, respectively.

were more visible in the 254 nm irradiation. GC–MS and (or) the coinjection of authentic samples identified these minor GC peaks as those of cyclooctane, cyclooctene, 1,1′-bicyclooctyl, and cyclooctanone. In the presence of <1% acetic acid, a similar 300 nm photolysis of AABBN **6** gave predominantly aldol **12** and only trace amounts of enones **13–14**, though the rate of AABBN conversion was scarcely affected (Table 2); indeed **12** was prepared in good yield by this procedure. Aldol **12** was partially decomposed on GC injection to give the peaks of itself and **15** in a 6:4 ratio; GC–MS by the CI mode showed two peaks to have M^+ at 213 and 155. The latter GC peak exhibited the *m*/*e* at 154 (M^+), 139, 111, 69 (100%), and 43, which supported the structure of **15**. Aldol **12** also slowly decomposed to **15** either in solution or neat; decomposition was more rapid on heating, during which enones **13** and **14** were also formed in small amounts as shown by GC and NMR monitors. In dilute acidic (HCl) methanol, **12** decomposed slowly to **14** and **15** at room temperature, but rapidly and mainly to enone **13** on refluxing. The enone distribution suggested that unconjugated enone **13** is thermally more stable than the conjugated **14**, probably because of steric crowding.

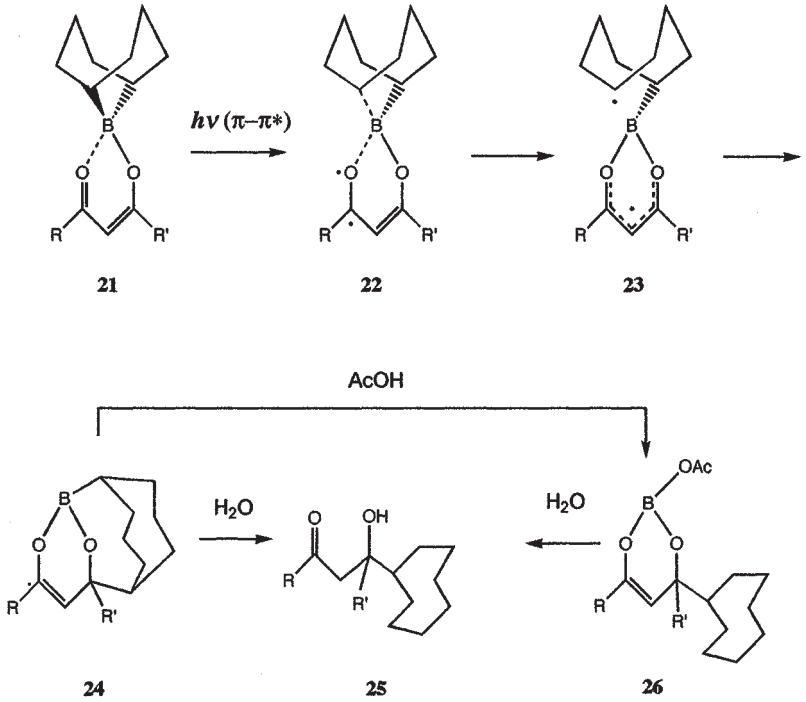
BABBN **7** in methylene chloride was irradiated with 300 nm light to give low yields of four enones that could be derived from aldols **16** and **17**; these aldols continued to decompose during separation. With difficulty, enones **20–21** were finally isolated only in semi-pure states by preparative TLC. The same solution containing 1% of acetic acid was irradiated under similar conditions to give aldol **16** (46%) and a small amount of a mixture containing the alternative aldol **17**. Aldol **16** when injected into the GC gave only one peak, which showed the MS pattern corresponding to **11** both by EI and CI modes. The fact that both aldols **8** and **16** decomposed to give the common ketone **11** provided a rationale for the structural correlation among them. The GC injection of the impure fraction of **17** under the same conditions gave the major peak corresponding to **15** as shown by the R_T and MS pattern. A crude product obtained from terminating a 60% photoreaction of **7** at 300 nm irradiation was subjected to GC analysis conditions as above to record the ketone peaks of **11** and **15** in a 27%/15% ratio in the absence, and in a 56%/20% ratio in the presence, of acetic acid. Similar photoreaction at 350 nm irradiation either in the presence or absence of acetic acid recorded the ketone peaks in a ratio of 12:10 by GC analysis. As the ratio of **11:15** virtually represents the ratio of **16:17** in the crude product, the latter must be coalescing to the 1:1 ratio.

AABBN **6** was used as a model to study the excited state reaction of these borinates. Photolysis of **6** with 300 nm light in various solvents showed the decreasing efficiency order of cyclohexane >> THF ~ benzene > acetonitrile > methylene chloride in the ratio of 1.00:0.74:0.71:0.60:0.49. When the photolysis was carried out in the presence of a trace amount of water (i.e., using purging nitrogen directly from a cylinder without drying), it was noteworthy that this ratio was nearly leveled, although cyclohexane and benzene were still the better solvents. GC examinations showed that the major product was aldol **12** for the reaction in methylene chloride and enone **14** for those in cyclohexane and benzene. Sensitized photodecomposition of **6** with benzophenone by 350 nm irradiation was an ideal setup since the sensitizer absorbed strongly in the 350 nm region where **6** showed no photoreactivity; this irradiation caused much more efficient decomposition than that by direct irradiation at 300 nm, and resulted in enormously accelerated disappearance of **6** as well as the efficient formation of enones **13** and **14a** in addition to a few unknown GC peaks. The reaction was complicated by the sensitizer itself being consumed, but the occurrence of triplet energy transfer was indicated by the absence of benzopinacol in the crude product; this implied that triplet excited benzophenone had been quenched (9). While the interpretation was not unambiguous, this observation, coupled with the efficient product yields, supported that efficient sensitization must have occurred. Under the oxygen blanket, the photolysis of **6** was not totally quenched but instead slightly accelerated, and gave oxidation products obviously due to the participation of O_2 in the product formation as is often observed in free radical reactions (10). While the result was inconclusive, in view of the smallness in the rate increase, oxygen quenching had probably occurred but was masked by the enhanced radical reactions.

The photoreaction of **6** was quenched efficiently by 1,3-pentadiene at the 3.5 mM level, and also by vinyl ethyl ether and furan (at 5 mM). The former diene is a typical triplet quencher, but the latter ethers do quenching by some other mechanisms, most likely intercepting the singlet state by electron transfer (9). No new compound was formed from these quenching experiments. Further, the consumption of **6** was accelerated by more than an order of magnitude in the presence of bromobenzene (4 mM) and 1,2-dibromoethane (5 mM). In both cases, both enones **13** and **14**, particularly the former unconjugated one, were produced in significantly increased amounts with increasing bromide concentrations, while the yield of aldol **12** was affected little, as shown in Table 2. The fluorescence peak of AABBN **6** in cyclohexane at 280 nm by excitation at λ_{ex} 259 nm was quenched by the presence of increasing concentrations of 1,2-dibromoethane. The Stern–Volmer plot was a straight line with the slope (K_{sv}) of 20.0. This demonstrated that singlet excited **6** interacted with the bromide and mutated rapidly to the triplet state by heavy atom effects (11). Similar spectroscopic ex-

© 1999 NRC Canada

Scheme 2.



periments with bromobenzene and 1,3-pentadiene could not be carried out owing to the overlap of the absorption in the 260 nm region.

The structure of the products was primarily determined from NMR spectral evidence, in some cases with partially pure samples. The primary photoproducts were obviously aldols **8**, **12**, **16**, and **17**, which served as the source for the observed products, enones and acylcyclooctanes, derived from the secondary reactions as shown in Scheme 1. The isolated aldols showed, among other required signals, the following key NMR signals to define the structure unambiguously. Firstly, they showed a pair of AB quartets due to the diastereotopic proton of -CO-CH_2-, with the chemical shifts progressively moved downfield as a CH_3 group was replaced by a C_6H_5 group. Secondly, they had the carbonyl ^{13}C signal at 211 ppm for the acetyl and at 202 ppm for the benzoyl group. Finally, the monosubstituted cyclooctyl group showed eight ^{13}C signals indicating that the eight carbons are nonequivalent, that is, in each pair the corresponding -CH_2- groups were diastereotopic to one another due to the vicinal chiral centers. The unconjugated enones **9**, **13**, and **20** showed (*i*) a two-proton singlet in the 3.0–4.0 ppm region and a carbonyl ^{13}C signal at 199–208 ppm for the CH_2-CO, and (*ii*) eight ^{13}C signals (including one olefinic at about 137 ppm) for the cyclooctylidene group. Among the conjugated enones, only **14**, **14a**, and **21** were isolated, the last two as mixtures. Both **14** and **21** were always formed as the major isomer and assigned to the configuration shown for steric reasons. Both enones **10** and **19** (and (or) their isomers) could be detected with GC–MS but could not be isolated because of decomposition during column chromatography. The isomeric enone pair **14** and **14a** showed nearly identical spectral patterns not only in MS but also in the ^{13}C and ^{1}H NMR spectra, which gave little evidence to assign the *cis–trans* isomerism. These two conjugated enones and **21** exhibited (*i*) an olefinic proton singlet at 6.05, 6.05, and 6.72 ppm, (*ii*) a set of pertinent ^{13}C signals for an α,β-unsaturated carbonyl system, and (*iii*) five ^{13}C signals for the cyclooctyl group due to its rapid rotation. In addition, the NMR spectra of these enones also showed the required signals with appropriate chemical shifts.

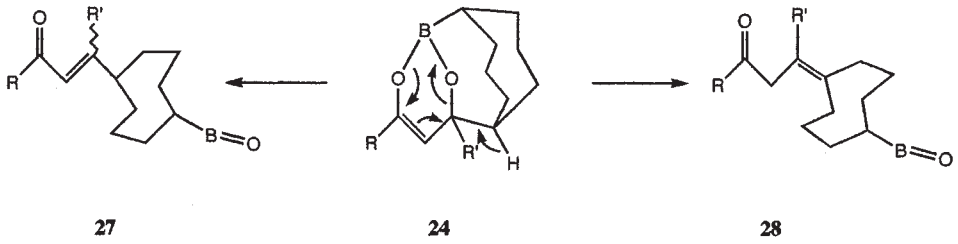
Discussion

The overall reaction resembles the well-known classic 1,2- or 1,4-addition of an alkylborane onto α,β-unsaturated carbonyl compounds (12), except that the present reaction is promoted by light and occurs intramolecularly through free radical mechanisms. Thus, electronic excitation provides an alternative pathway to promote this alkylborane addition. The failure for excitation in the CT band to promote the reaction must imply that this excited state is rapidly deactivated to the ground state, i.e., that is the only channel available. These borinates **5–7** undergo a deep-seated rearrangement upon excitation of the π–π* transition band in a wide range of solvents; the photolytic efficiency is better in nonpolar than in polar media and the product patterns vary widely depending on reaction conditions. The overall result indicates that the products are formed in consecutive multistep processes involving intermediates that are sensitive to the photolysis conditions. The overall reaction is approximated as the primary photoinduced rearrangement to give the precursors of aldols **8**, **12**, **16**, and **17**, followed by secondary decomposition of the precursors under the photolysis conditions.

The experimental probes described provide good qualitative evidence that the primary photoreaction is derived from the triplet excited state of these borinates **5–7**. Two of these probes are unambiguous; that is, efficient triplet quenching (9) by 1,3-pentadiene, and a heavy atom effect to enhance

© 1999 NRC Canada

Scheme 3.



27 **24** **28**

the population of the triplet state induced by bromine-containing compounds (11). The other two, the benzophenone sensitization and oxygen quenching, are complicated by the participation of the reagents in the reactions; the former, which cannot be analyzed quantitatively owing to the change in the product pattern, also supports triplet state energy transfer on the basis of the detailed observations.

In the previous communications (1), the authors stated that the photoreaction of some similar dialkylborinates could not be quenched by either oxygen or 1,3-pentadiene, which led them to suggest a singlet state reaction. Though the present dialkylborinates **5–7** are not exactly the same as theirs, the corresponding results for these two quenchers are just the opposite to, and more complicated than, those stated in their reports. It is interesting to compare details of the two experimental descriptions.

The reaction mechanism is proposed in Scheme 2, in which the carbonyl triplet excited state **22**, as represented by the diradical model (9), is the species initiating the radical pathway. The step **22** to **23** is analogous to the homolytic substitution of a borane by an alkoxy radical, the driving force of which is derived from a bond energy gain of about 30–40 kcal/mol in the conversion of a B—C bond to a B—O bond (13). Triplet excited state biacetyl has been shown to interact with borane either directly or through the acetyl radical (14). The intramolecular attack in **22–23** should be more facile than any intermolecular attacks. The subsequent recombination of the radical pair **23** can occur at the carbon of either O—C bond; the direction is controlled by the nature of the R groups to give boronate **24**. The migration can be highly regiospecific if the R and R′ groups possess a large electronic gradient (1). Thus, the primary photolysis is assumed to terminate on the formation of **24**. Its simple hydrolysis should give aldols **25**, the process of which appears to be relatively sluggish under the photolysis conditions; thus GC analysis at times shows poor reproducibility depending upon sampling times. As will be discussed below, the conversion of **24–25** can also involve an excitation step. However, the work-up does not require highly nucleophilic hydrogen peroxide anion (1) to hydrolyze borate esters. While the efficiency of the borinate photodecomposition does not correlate strictly with solvent polarity, its rate is generally faster in hydrocarbons than in polar solvents. It is noteworthy that water, even in a trace amount, can retard the efficiency; the retardation is more significant in cyclohexane. The mechanism may be related to the coordination process at the boron center and remains to be elucidated. Efforts to isolate boronate **24** for an intermediate identification under anhydrous conditions have not been successful in providing a workable sample.

The mechanistic studies have been encumbered by unpredictable variations of the product pattern on changing the photolysis conditions; their effects have been traced to the secondary reactions and the reactivity of accompanying intermediates. The probable concurrence of thermal as well as photolytic pathways for intermediates adds further complexity that poses a formidable problem in portraying the mechanism(s). Nevertheless, certain observations can be explained with obvious and straightforward rationales. First of all, about 1% acetic acid does not affect the rate of photolysis, as shown in Table 2, but may rapidly attack boronate **24** by a pre-rate-determining nucleophilic coordination (15, 16) to form acetyl-borate **26**, which should be more easily hydrolyzed than **24** to afford **25.** Unless absorbing excitation light, both **25** and **26** are not photolabile and can afford good yields of aldols such as is the case for **8** and **12**, which are obtained clean even after prolonged irradiation under the given conditions. In contrast, the photolysis of borinate **7** generates borate **26** with R = C_6H_5 and R′ = CH_3 (corresponding to aldol **17**), which possesses the α-boratoxystyryl chromophore and must be labile to 300 nm irradiation, but not to 350 nm irradiation. Indeed, two observations support this argument; they are the formation of much less **17** than **16** (as measured by the GC peak of **15** and **11**) under the former (300 nm) irradiation and that of as much **17** as **16** under the latter (350 nm) irradiation. The high yield of aldol **8** in the photolysis of **5** under 350 nm irradiation must have a similar cause. Likewise, if aldols **25** with R = C_6H_5 are formed by adventitious water, they will be sensitive to 300 nm light and may cause a further complication to product patterns. To avoid these uncertainties, photolysis should be carried out under dry conditions. Further, there is no doubt that ketones **11** and **15** are formed by thermal and (or) acid-catalyzed retro-reactions from the aldols, slowly during isolation and more rapidly on injection in the GC port; when the port is cleaned the decomposition of **12** is drastically reduced.

Explanations of other observations are less straightforward and must rely on indirect rationales. In view of the sluggish acid-catalyzed dehydration of **12** at a room temperature (16), enone formation through simple thermal reactions cannot make a substantial contribution to high yields of enones such as those shown in Table 1. On the basis of the following evidence, we propose, as the cause of the enone formation, that boronate **24** undergoes photo-rearrangement followed by hydrolysis (Scheme 3). Firstly, the photoreaction of borinates **5–7** affords lower yields of aldols in the absence of acetic acid than in the presence, suggesting that exposure of **24** to light causes photoreactions to give enones (e.g., see Table 2). The borinate photoreactions car-

© 1999 NRC Canada

ried to a high conversion always furnish more enones. Secondly, the photolysis of **7** with 300 nm irradiation always gives much less **17** than 1**6**, particularly in the absence of acetic acid. This is a good indication that the intermediate **24** (R = C_6H_5, R′ = CH_3), corresponding to **17**, having an α-boronatostyryl chromophore, can absorb more light energy from 300 nm irradiation and undergo photolysis more extensively. The corroborating evidence is the formation of nearly the same amount of **16** and **17** in 350 nm irradiation, in which both corresponding intermediates **24** are scarcely irradiated. Thirdly, the dominance of either **13** or **14**, depending on the wavelength of excitation (see Table 1), supports the participation of an excited state of **24,** which is the intermediate in the absence of acetic acid. Finally, in the presence of benzophenone as a sensitizer or a bromide as a triplet enhancer, enones **13** and **14** are disproportionately increased in comparison to aldol. We speculate that the excited state of either promoter interacts with intermediates, through exciplexes or otherwise, which may increase either conjugated **14** (e.g., in the presence of bromobenzene) or unconjugated enone **13** (e.g., in the presence of 1,2-dibromoethane) **12,** as shown in Table 2.

While **24** is not available for study at this stage, the bond reorganization as shown in Scheme 3 is suggested to account for the photochemical transformations to give the enone precursors **27** and **28**. The former, **27,** can be arrived at by a retro-Diels–Alder reaction; the latter, **28**, by a 1,3-hydrogen shift from **24**. The alkyl B=O bond may be regarded as an analogue of an acyl carbonium ion, and is expected to react with water vigorously to give the observed enones. The proposed boronate intermediates in Scheme 3 involve much unexplored chemistry of their ground and excited states, which promises to open up a new area of investigation. In this regard, the origin of the broad CT absorption band must be related to the electronic structure of borinates **5–7** and will be studied.

Experimental section

Materials and instrumentation

Commercial 1,3-diketones (Aldrich) were recrystallized or distilled, but 9-borabicyclo[3.3.1]nonane (9-BBN, 0.5 M solution in THF) was used as received. For preparative photolysis, reagent grade solvents were distilled with proper dehydrating agents. Solvents of spectroscopic grade (BDH) were used for optical spectra. Benzophenone, 1,3-pentadiene, bromobenzene, and 1,2-dibromoethane were purified as described in earlier publications (5, 10, 11). The sample of 1,3-pentadiene was a mixture of *trans/cis* 55:45 by GC.

Melting points were determined on a Fisher–Johns block and not corrected. Infrared spectra were recorded with a Perkin–Elmer model FT1605 spectrometer, ultraviolet and visible spectra with a Varian–Cary 210 spectrophotometer, fluorescence spectra with either a PTI LS-1 or Perkin–Elmer MPF-44B, and GC–MS with a Hewlett–Packard 5985B. NMR spectra were taken with Bruker AMX-400 or AMX-600 using TMS as the internal standard. Gas chromatography was carried out at the injection port temperature of 150–250° C with a Hewlett–Packard 5790 equipped with a 15 m × 0.2 mm BB-1 or OV-1 capillary column and HP 3390A integrator.

Irradiation was carried out in a Rayonet Photochemical Reactor in quartz (for 254 and 300 nm irradiation) or Pyrex (for 350 nm irradiation) test tubes (12 × 100 mm) placed in a "merry-go-round." A bottom fan circulated the air to maintain a constant temperature of 30–34°C. For analytical and sensitized photolysis, solutions were added with a known concentration of hexadecane or eicosane as the internal standard before irradiation. The corresponding factor of AABBN to hexadecane was determined for each column to calculate percent conversions.

Preparation of borinates 5–7

To a solution of a 1,3-diketone in THF, a calculated amount of 9-BBN was added by syringe under a nitrogen blanket at room temperature while the solution was stirred magnetically. The precipitate in nearly a quantitative yield was filtered and recrystallized under nitrogen purging. 9-Methoxy-9-borabicyclo[3,3,1]nonane (1.0 M solution in hexane) or 9-(2-aminoethyleneoxy)-9-BBN was also used to give nearly quantitative yields.

DBMBBN (5)

The precipitate was recrystallized in CH_2Cl_2 and hexane (2:1) or THF and hexane (2:1) and cooled to –20°C to give deep red crystals, mp 266–267°C; IR (Nujol): B–O stretching at 1376.5 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.00 (2H, br s), 1.55–1.65 (2H, m), 1.70–1.80 (4H, m), 1.90–2.10 (6H, m), 6.90 (1H, s), 7.50 (4H, t), 7.60 (2H, t), 8.10 (4H, d); ^{13}C NMR ($CDCl_3$) δ: 23.0 (br), 24.91, 31.41, 92.67, 128.24, 128.86, 133.73, 134.14, 183.11; MS (EI) *m*/*e* (relative intensity): 344 (16, M^+), 287 (18), 261 (28), 248 (43), 235 (17), 105 (100). Anal. calcd. for $C_{23}H_{25}BO_2$: C 80.23, H 7.27; found: C 80.32, H 7.35. This compound is soluble in THF and methylene chloride but much less soluble in benzene and acetonitrile.

BABBN (7)

The precipitate was recrystallized in THF and diethyl ether (1:1) by cooling to –20°C to give brilliant red crystals, mp 196–197°C; IR (Nujol): B–O stretching at 1377.7 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.90 (2H, br s), 1.50–1.60 (2H, m), 1.60–1.70 (4H, m), 1.80–2.00 (6H, m), 2.25 (3H, s), 6.30 (1H, s), 7.45 (2H, t), 7.60 (1H, t), 7.95 (2H, d); ^{13}C NMR ($CDCl_3$) δ: 23.0 (br), 24.79, 24.83, 24.98, 31.14, 31.36, 96.42, 128.15, 128.78, 133.53, 133.63, 181.79, 191.84; MS (EI) *m*/*e* (relative intensity): 282 (22, M^+), 239 (13), 225 (35), 199 (55), 186 (100), 173 (40). Anal. calcd. for $C_{18}H_{23}BO_2$: C 76.61, H 8.21; found: C 76.75, H 8.45.

AABBN (6)

The precipitate was recrystallized in degassed hexane to give bright yellow crystals, mp 121–122° C; IR(Nujol): B–O stretching at 1376.6 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.80 (2H, br s), 1.40–1.50 (2H, m), 1.58–1.66 (4H, m), 1.70–1.90 (6H, m), 2.10 (6H, s), 5.55 (1H, s); ^{13}C NMR ($CDCl_3$) δ: 23.0 (br), 24.29, 24.73, 31.07, 100.63, 190.44; MS (EI) *m*/*e* (relative intensity): 220 (25, M^+), 177 (12), 163 (50), 137 (80), 124 (100), 111 (31). Anal. calcd. for $C_{13}H_{21}BO_2$: C 70.91, H 9.55; found: C 70.68, H 9.45. **6** is soluble in cyclo-

hexane and benzene but less soluble in methylene chloride and acetonitrile.

Preparative photolysis of borinates

DBMBBN

A solution of **5** (0.10 g, 0.29 mmol) in anhydrous THF (50 mL) was distributed in 12 Pyrex tubes, sealed with septa, and purged with dry nitrogen for 5 min. The tubes were rotated in a merry-go-round under irradiation with RPR 3500 A lamps (24 W × 16) for 24 h. The photolysate gave two major GC peaks, at R_T 3.60 and 4.20. The crude product was chromatographed on a short column of silica gel 60 (20 cm^3) to afford an impure fraction of the former peak that was rechromatographed to give **9**; ^{1}H NMR ($CDCl_3$) δ: 1.50–1.80 (10H, m), 2.11 (2H, br t), 2.30 (2H, br t), 4.10 (2H, s), 7.20–7.60 (8H, m), 7.81 (2H, m); MS (EI) *m*/*e*: 318 (5, M^+), 213 (11), 105 (100), 91 (15), 77 (25); MS (CI) *m*/*e*: 319 (100, M^++1). Anal. calcd. for $C_{23}H_{26}O$: C 86.75, H 8.23; found: C 86.95, H 8.64.

When the photolysis was carried out in a mixture of methylene chloride and acetonitrile (1:1), the GC spectra showed both peaks in 38 and 36% yields. The fraction of R_T 4.20 (**10**) decreased rapidly on chromatography; one of its impure fractions showed ^{1}H NMR ($CDCl_3$) δ: 0.90 (2H, m), 1.50–2.00 (12H, m), 2.72 (1H, m), 6.60 (1H, s), 7.11 (2H, m), 7.22 (3H, m), 7.30 (2H, m), 7.70 (2H, m), 8.01 (H, m); MS (EI) *m*/*e* (relative intensity): 318 (60, M^+), 207 (5), 192 (5), 105 (100), 91 (11), 77 (31); MS (CI) *m*/*e*: 319 (100, M^++1).

In a separate photolysis, DBMBBN (0.17 g) in methylene chloride (50 mL) containing acetic acid (0.5 mL) was irradiated in a similar way to afford a 65% conversion. Repeated chromatography on a long silica gel column (40 cm^3) gave **8** as colorless crystals; ^{1}H NMR ($CDCl_3$) δ: 1.20–1.80 (14H, m), 1.96 (1H, q), 3.25 and 3.95 (AB quartet, diastereotopic -CH_2-, J = 16.3 Hz), 4.88 (1H, br s), 7.12 (1H, t), 7.23 (2H, t), 7.40 (2H, d), 7.43 (2H, t), 7.55 (1H, t), 7.84 (2H, d); ^{13}C NMR ($CDCl_3$) δ: 26.31, 26.40, 26.70, 26.93, 27.08, 27.76, 28.03, 44.13, 47.49, 79.43, 125.75, 126.34, 127.79, 127.98, 128.59, 133.49, 137.35, 146.19, 202.56. Anal. calcd. for $C_{23}H_{28}O_2$: C 82.10, H 8.39; found: C 82.45, H8.12. This compound on injection to GC–MS gave a single peak for **11**, at an early R_T of 1.77 min, which showed M^++1 = 217 by the CI mode, and *m*/*e*: 216 (M^+, 10%), 133 (12), 120 (12), 105 (100), and 77 (35) by the EI mode.

BABBN

A solution of **7** in methylene chloride was irradiated for 24 h with RPR 3000A lamps, and the crude product was chromatographed to give four fractions, each containing a major component, that showed the R_T of the major component at 7.6, 8.5, 8.8, and 9.7 min and M^++1 = 257 of the major peak by the CI mode. Fraction one contained mostly **20** (R_T 8.8); ^{1}H NMR ($CDCl_3$) δ: 1.50–1.68 (10H, m), 1.69 (3H, s), 2.20 (2H, br t), 2.31 (2H, br t), 3.75 (2H, s), 7.40 (2H, m), 7.51 (1H, t), 7.95 (2H, m); ^{13}C NMR ($CDCl_3$) δ: 19.30, 16.19, 26.22, 26.67, 26.99, 27.56, 31.41, 32.11, 44.38, 121.92, 128.09, 128.52, 132.70, 132.76, 137.63, 198.96; MS (EI) *m*/*e*: 256 (15, M^+), 241 (3), 105 (100), 95 (21), 77 (31); MS (CI) *m*/*e*: 257 (M^++1). Fraction two contained **21** (R_T 9.7) as the major component; ^{1}H NMR ($CDCl_3$) δ: 1.50–1.80 (14H, m), 2.18 (3H, s), 2.35 (1H, tt), 6.71 (1H, br s), 7.45 (2H, m), 7.51 (1H, m), 7.90 (2H, m); ^{13}C NMR ($CDCl_3$) δ: 18.09, 26.08, 26.43, 26.70, 31.78, 41.19, 118.73, 123.38, 128.14, 139.09, 139.76, 166.44, 192.22; MS (EI) *m*/*e*: 256 (5, M^+), 241 (6), 171 (12), 145 (71), 105 (100), 77 (41); MS (CI) *m*/*e*: 257 (M^++1). Fraction three contained **18** (R_T 7.6); ^{1}H NMR ($CDCl_3$) δ: 1.50–1.70 (10H, m), 2.05 (3H, s), 2.10 (2H, br t), 2.35 (2H, br t), 3.45 (2H, s), 7.05 (2H, m), 7.20 (3H, m); MS (EI) *m*/*e*: 256 (60, M^+), 241 (100), 238 (26), 213 (45), 198 (25), 143 (51), 131 (80), 117 (75), 91 (90); MS (CI) *m*/*e*: 257 (100, M^++1), 239 (25), 199 (81). Fraction four contained **19** (R_T 8.5); ^{1}H NMR ($CDCl_3$) δ: 1.40–1.60 (10H, m), 1.61 (2H, m), 1.70 (3H, s), 1.81 (2H, m), 2.60 (1H, m), 6.05 (1H, s), 7.10 (2H, m), 7.30 (3H, m); MS (EI) *m*/*e*: 256 (15, M^+), 241 (3), 105 (100), 95 (22), 77 (32); MS (CI) *m*/*e*: 257 (M^++1).

In a similar experiment, **7** (0.142 g, 0.51 mmol) in a solution of methylene chloride (50 mL) and acetic acid (0.5 mL) was irradiated for 23 h, and the photolysate was neutralized with K_2CO_3. The crude product was chromatographed twice on a silica gel column to give a small fraction containing **17** and a fraction of **16** (0.026 g). ^{1}H NMR ($CDCl_3$) δ: 1.20–1.90 (15H, m), 1.98 (3H, s), 2.87 and 3.22 (AB quartet, diastereotopic -CH_2-, J = 16.3 Hz), 4.45 (1H, br), 7.19 (1H, m), 7.28 (2H, m), 7.36 (2H, m); ^{13}C NMR ($CDCl_3$) δ 26.20, 26.35, 26.72, 26.85, 27.04, 27.20, 27.46, 27.79, 32.22, 46.99, 49.88, 79.06, 125.61, 126.43, 127.65, 145.94, 211.72. The injection of **16** to GC gave a single peak at R_T 1.77 min, and the fragmentation pattern of **11**. The former fraction containing **17** was contaminated by benzoylacetone, and showed, on GC–MS determination, a peak at R_T 1.45 and the fragmentation pattern of **15** (vide infra).

A solution of **7** (0.023 g, 0.081 mmol) and eicosane (0.02 g, 0.071 mmol) in methylene chloride (10 mL) was divided in two quartz tubes; acetic acid (10) was added to the second one. These tubes, sealed with septa and purged with dry nitrogen, were irradiated with RPR 3000A for 19 h to give 70% conversions. The GC analysis of the photolysates (injection temperature 250°C) gave two peaks at 1.40 min (for **15**) and 1.59 min (for **11**) with a yield of 27%/15% for the first and 56%/20% for the second tube (with acetic acid).

Separately, two tubes of methylene chloride solution containing **7** (0.0078 M) and eicosane (0.0071 M), one with the presence (10 μL) and the other with the absence of acetic acid, were irradiated under similar conditions except for using RPR 3500A lamps for 24 h to cause a 40% conversion. The GC analysis gave a yield for **15**/**11** of 12%/10%, within experimental error, for both photolysates.

AABBN

A solution of AABBN **6** (0.048 g, 0.22 mmol) in a mixture of cyclohexane and methylene chloride (9:1, 20 mL) was distributed in four quartz tubes and sealed under nitrogen. The solution was irradiated with RPR 2540A lamps for 8 h to cause about 80% conversion. A separate solution prepared from 0.04 g of **6** was irradiated with RPR 3000A lamps under the same conditions for 18 h to cause a 75% conversion. Both solutions were examined by GC–MS analysis to afford the major peaks shown in Table 1. A similar experiment was carried out with RPR 3500A lamps for 24 h

© 1999 NRC Canada

to give a 15% conversion of **6**. The crude product from 254 nm irradiation was chromatographed on silica gel columns with *n*-hexane elution to give unreacted **6**. With increasing amounts of methylene chloride in *n*-hexane, **13** (7.8 mg), **14** (trace amount), and **12** (18 mg, 54%) were isolated. The physical data of **12**: IR (Nujol): 3488 (O–H stretching), 1699.7 (C=O stretching), 1171.8 (*tert*-C–O stretching) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 1.12 (3H, s), 1.15–1.25 (2H, m), 1.35–1.83 (13H, m), 2.19 (3H, s), 2.55 and 2.66 (diastereotopic -CH_2-, J = 16.3 Hz); ^{13}C NMR ($CDCl_3$) δ 23.36, 26.40, 26.53, 26.98, 27.14, 27.75, 29.01, 32.10, 46.60, 50.04, 75.09, 211.52. Anal. calcd. for $C_{13}H_{24}O_2$: C 73.54, H 11.39; found: C 73.82, H 11.48. The injection of **12** into GC at 250°C gave two peaks at R_T 1.85 and 6.04 min in the ratio of 6:4. The former peak arising from **15** showed M^++1 at 155 by theCI mode, and *m*/*e* at 154 (1), 139 (1), 111 (10), 97 (14), 69 (100%), 43 (60) by the EI mode. The latter peak was due to **12** itself and showed *m*/*e* by the CI mode at 213 (M^++1, 2), 195 (31), 155 (100) and by the EI mode at 197 (1), 111 (10), 101 (100), 69 (21), 43 (61). The physical data of **13**: ^1H NMR ($CDCl_3$) δ: 1.40–1.55 (6H, m), 1.15–1.72 (4H, m), 1.68 (3H, s), 2.10 (3H, s), 2.14–2.20 (2H, m), 2.20–2.26 (2H, m), 3.13 (2H, s); ^{13}C NMR ($CDCl_3$) δ: 19.18, 26.07, 26.22, 26.70, 26.90, 27.59, 29.15, 31.29, 32.02, 49.80, 121.58, 138.15, 207.56; MS (EI) *m*/*e*: 194 (15, M^+), 179 (16), 151 (10), 136 (12), 109 (26), 95 (100), 81 (35), 69 (42). Anal. calcd. for $C_{13}H_{22}O$: C 80.35, H 11.41; found: C 80.11, H 11.58.

The crude product from 300 nm photolysis was worked up similarly to give **13** (trace amount), **14** (4.3 mg), and **12** (14.3 mg, 54%). **14** showed the following physical constants: ^1H NMR ($CDCl_3$) δ: 1.40–1.78 (14H, m), 2.09 (3H, d, J = 1.5 Hz), 2.16 (1H, br s), 2.18 (3H, s), 6.05 (1H, q, J = 1.5 Hz); ^{13}C NMR ($CDCl_3$) δ: 17.47, 26.02, 26.39, 26.59, 31.65, 48.84, 121.60, 166.11, 199.32; MS (EI) *m*/*e*: 194 (10, M^+), 179 (41), 151 (10), 136 (15), 111 (41), 109 (55), 98 (30), 95 (81), 81 (45), 69 (75), 43 (100). Anal. calcd. for $C_{13}H_{22}O$: C 80.35, H 11.41; found: C 80.28, H 11.21.

Sensitized photolysis of AABBN 6

AABBN (0.101 g, 0.46 mmol), hexadecane (0.05 mmol), and benzophenone (0.042 g, 0.23 mmol) in a mixture of cyclohexane and methylene chloride (9:1, 50 mL) were irradiated with RPR 3000A as above for 6 h to cause a 76% conversion of **6**. GC analysis of the photolysate showed the peak % of **15**, **14a**, **13**, **14**, and **12** to be 4.3, 11, 16, 3.1, and 4.2%. Separately, a cyclohexane solution of **6** (0.0052 M), hexadecane (0.00033 M), and benzophenone (0.0032 M) was irradiated with RPR 3500A for 2.6 h to give a 60% conversion; the control experiment without benzophenone gave a <2% conversion. The GC analysis gave the peak % for **15**, **14a**, **13**, **14**, and **12** of 0.5, 3.5, 6.1, 3.2, and 0.5%. In both GC analyses the benzophenone peak decreased and several minor peaks were observed in R_T >10 min. Examination of the crude products with HPLC gave no benzopinacol peak by coinjection.

The former solution was worked up in the usual way to give **13** (5.4 mg, 8%), **14** (10.0 mg, 15%), **12** (30.3 mg, 42%), and a mixture of **14a** and benzophenone. This mixture showed ^1H NMR ($CDCl_3$) δ: 1.40–1.80 (14H, m), 2.08 (3H, d, J = 1.2 Hz), 2.15 (3H, s), 6.05 (1H, br s); ^{13}C NMR δ: 17.42, 26.34, 26.54, 25.97, 31.60, 31.82, 48.80, 121.56, 165.09, 199.31. This sample showed a GC peak at R_T 3.7 in contrast to that of 5.4 for **14**; the GC–MS of the former peak showed MS (EI) *m*/*e*: 194 (40, M^+), 179 (42), 151 (10), 136 (12), 123 (25), 109 (71), 95 (100), 81 (50), 69 (40), 43 (98).

Quantitative analysis of the photoreaction of AABBN 6

A solution of **6** (7.2 mg, 0.0364 mmol) in cyclohexane (25 mL) was divided between five test tubes (5 mL each); tubes 3 and 4 also contained acetic acid (2 μL). Tubes 1–4 were sealed under dry nitrogen and kept in a dark place. Tube 5 was sealed under dry oxygen. After 5 days, GC analysis showed a peak at R_T 1.23 min, in trace amounts, for tubes 1 and 5, and 2% for tube 3; after 8 days the intensity was 2–3% for all tubes.

Solutions of **6** (0.054–0.056 M) in cyclohexane, benzene, THF, methylene chloride, and acetonitrile were prepared to contain fixed concentrations of hexadecane (0.0131–0.0121 M). These solutions, placed in quartz tubes and sealed under nitrogen dried over solid $CaCl_2$ and NaOH pellets, were irradiated with RPR 3000A lamps for 21 h. The photolysates were analyzed by GC, and the % conversion of **6** was determined to give >96, 71, 74, 52, and 61% with respect to the internal standard. A set of similar experiments purged with nitrogen directly from a tank without drying gave the % conversion of 60, 64, no data, 41, and 56%.

Four tubes of a solution of **6** (0.007 M) in cyclohexane containing hexadecane as the internal standard and 1,3-pentadiene (45:55 mixture of *cis/trans*) at 0.014, 0.007, 0.0035, and 0.0 M were prepared and sealed under nitrogen. A solution containing the same substrate concentrations in a mixture of cyclohexane and methylene chloride was also prepared and distributed in four tubes to make the second set. They were irradiated for 5 h, and analyzed by GC for the % conversion of **6** to give 21, 22, 23, and 60% for the first set in cyclohexane, and 16, 19, 20, and 64% for the second set in the mixture. No new reaction product with the dienes was detected.

Five tubes of solution in a mixture of cyclohexane and methylene chloride (9:1) containing **6** (0.0082 M) and hexadecane (0.0046 M) were prepared. Tube 1 served as the control run. Acetic acid (0.167 M) was added to tube 2, and phenyl bromide (0.0082 and 0.0041 M) to tubes 3 and 4, respectively. These tubes were sealed under dry nitrogen except for tube 5, which was bubbled with a slow stream of dry oxygen while all of them were irradiated with RPR 3000 lamps. GC analysis of the photolysates showed the remaining % of **6** in each tube to be 100, 100, 85, 88, and 90%, respectively, at 1 h irradiation, and 88, 84, 44, 46, and 52%, respectively, at 4 h irradiation. The details of GC analysis of photolysates 1–4 after 4 h irradiation are given in Table 2. The photolysate of **6** under oxygen contained completely different products of highly oxidized materials with R_T 2–5 min; column chromatography failed to give pure products.

Four tubes of similar solutions containing **6** (0.0088 M) and hexadecane (0.0034 M) were prepared as tubes 6–9, to which were added 1,2-dibromoethane at 0.0, 0.02, 0.04, and 0.081 M, respectively. These tubes were irradiated as above. GC analysis of the photolysates gave % of remaining **6** to be 100, 67, 63, and 52%, respectively, after 1 h irradiation, and 98, 47, 46, 29%, respectively, after 2.5 h irradiation. The de-

© 1999 NRC Canada

tailed product analyses of the 2.5 h photolysate by GC for tubes 7–9 are given in Table 2, but those for the control run (tube 6) were too small and are assumed to be similar to that shown for tube 1.

Étude du système U-Sr-O par diffraction X à haute température

André Pialoux et Bernard Touzelin

Résumé : La diffractométrie de rayons X à chaud ($293 \leq T(K) \leq 1773$) est utilisée pour étudier la réaction entre monoxyde de strontium et dioxyde d'uranium sous atmosphère contrôlée ($10^5 \geq P_{O_2}(Pa) \geq 10^{-24}$), avec mesure des paramètres cristallins et évaluation de la composition des divers uranates formés. C'est ainsi qu'avec un échantillon de rapport Sr/U = 1, prennent naissance les phases successives : (*a*) α-« $SrUO_4$ » orthorhombique dont la réduction ($3{,}67 \geq O/U \geq 3{,}62$) se traduit par l'observation d'un volume de maille constant ($V = 0{,}367$ nm^3) entre 1173 et 1373 K; (*b*) β-« $SrUO_4$ » rhomboédrique qui manifeste une forte variation de composition entre la forme oxydée (β-$SrUO_{3,60}$) métastable en dessous de 1108 K et la forme réduite (β′-« $SrUO_{3,11}$ ») stable à toute température; (*c*) « $SrUO_3$ » de composition constante ($O/U \approx 3$) entre 293 et 1533 K puis variable ($O/U < 3$) au-dessus de 1533 K, avec pour cette pérovskite déformée une probable transition du second ordre (α-*Pnma*, β-*Imma*) au voisinage de 1073 K; (*d*) $U_{1-\delta}Sr_\delta O_{2-\delta}$ de structure fluorine et dont la teneur maximale en SrO ($\delta \approx 0{,}25$) provoque à 1673 K un accroissement du paramètre de 0,5 % par rapport à celui de l'$UO_{2,00}$. Un diagramme de phases est proposé pour le système pseudo-binaire « $SrUO_3$ » – « $SrUO_4$ ». Avec un échantillon de rapport Sr/U = 3, la pérovskite « Sr_3UO_6 » monoclinique se montre stable sous $P_{O_2} \approx 10^5$ Pa jusqu'à 1373 K. Par contre, en milieu réducteur ($P_{O_2} \leq 10^{-19}$ Pa), elle cède la place à la phase « Sr_3UO_5 » orthorhombique de paramètres beaucoup plus grands quelle que soit la température.

Mots clés : diffraction X à haute température, réactivité des oxydes métalliques, système U-Sr-O, combustibles nucléaires.

Abstract : High-temperature X-ray diffraction ($293 \leq T(K) \leq 1773$) is used to investigate the reaction between strontium monoxide and uranium dioxide under controlled atmosphere ($10^5 \geq P_{O_2}(Pa) \geq 10^{-24}$), with lattice parameter measurements and composition estimates of the different uranates obtained. Thus, with a Sr/U = 1 sample, we successively observe the phases: (*a*) orthorhombic α-"$SrUO_4$", whose reduction ($3.67 \geq O/U \geq 3.62$) is shown by a constant volume of the cell ($V = 0.367$ nm^3) between 1173 et 1373 K; (*b*) rhombohedral β-"$SrUO_4$", which shows a large composition variation between the metastable oxidized form (β-$SrUO_{3.60}$) below 1108 K and the stable conjugate reduced form (β′-$SrUO_{3.11}$) at whatever temperature; (*c*) "$SrUO_3$" of constant composition ($O/U \approx 3$) between 293 and 1533 K, then variable ($O/U < 3$) above 1533 K, with a probable second-order transformation (α-*Pnma*, β-*Imma*) for this distorted perovskite near 1073 K; (*d*) fluorite type $U_{1-\delta}Sr_\delta O_{2-\delta}$ solid solution for which a maximal account in SrO ($\delta \approx 0.25$) induces a 0.5 % thermal expansion parameter in comparison with $UO_{2.00}$. A pseudo-binary "$SrUO_3$"–"$SrUO_4$" phase diagram is propounded. With a sample compound of Sr/U = 3, the monoclinic "Sr_3UO_6" perovskite is stable under $P_{O_2} \approx 10^5$ Pa up to 1373 K. On the other hand, in reducing atmosphere ($P_{O_2} \leq 10^{-19}$ Pa), it becomes orthorhombic "Sr_3UO_5" with much greater lattice constants at every temperature.

Key words: high-temperature X-ray diffraction, reactivity in metallic oxides, U-Sr-O system, nuclear fuels.

Introduction

Il est bien connu que les propriétés physicochimiques et cristallographiques des composés du strontium sont intermédiaires entre celles des composés homologues du calcium et du baryum. Pour illustrer ce fait, il suffit par exemple de comparer la stabilité des trois monoxydes alcalino-terreux (de structure type NaCl), que l'on se réfère aux valeurs des enthalpies libres de formation standard à 298 K ($\Delta_f G^0$ (CaO) = –646,5 kJ mol^{-1}, $\Delta_f G^0$ (SrO) = –608,9 kJ mol^{-1} et $\Delta_f G^0$ (BaO) = –574,8 kJ mol^{-1} (1)) ou à celles des paramètres cristallins (*a* (CaO) = 0,4811 nm, *a* (SrO) = 0,5160 nm et *a* (BaO) = 0,5523 nm (2)). Une évolution similaire est donc prévisible chez les divers oxydes mixtes susceptibles de se former au-dessus de 1273 K et sous des pressions d'oxygène variables par réaction des phases CaO, SrO et BaO sur le dioxyde d'uranium. C'est bien à ce genre de conclusion qu'ont abouti les études de Lang et al. (3) (pour les phases $Me(U,Me)O_x$ ou « $BaUO_3$ » et $U_{1-\delta}Me_\delta O_{2-\delta}$ respectivement de structures types pérovskite et fluorine), Rietvield (4)

(pour la perovskite « Me_3UO_6 »), Loopstra et Rietveld (5) (pour l'oxyde α-« $MeUO_4$ » orthorhombique), Cordfunke et Loopstra (6), Tagawa et al. (7–9) puis Takahashi et al. (10) (pour les phases α-« $MeUO_4$ » et β-« $SrUO_4$ » rhomboédrique,[2] ainsi que Voronov et Sofronova (11–13) (pour l'ensemble des phases stables au-dessus de 1673 K). Mais si les études en question se montrent en règle générale complémentaires, voire en bon accord sur le plan cristallographique, l'emploi exclusif de produits trempés fait qu'elles sont émaillées de fréquentes contradictions tant sur les conditions de formation que sur la composition des phases examinées. Il arrive même, comme c'est le cas pour l'étude cristallographique de Zachariasen (14) sur les oxydes β-« $CaUO_4$ » et β-« $SrUO_4$ », qu'aucune indication ne soit fournie quant à la différence de stabilité, pourtant très grande, qui existe entre ces deux composés. On peut en outre regretter que les recherches approfondies de Brisi et de son équipe sur les systèmes U-Sr-O (15, 16) et U-Ca-O (17) n'aient pas été étendues au système U-Ba-O. Aussi nous est-il paru intéressant d'appliquer notre technique de diffractométrie de rayons X à haute température à l'étude des oxydes mixtes d'uranium et de strontium, ainsi que nous l'avions fait précédemment pour leurs homologues à base de baryum (18) et de calcium (19). Une telle étude in situ, inédite sur le système U-Sr-O, était d'autant plus souhaitable qu'elle devrait permettre de préciser les caractéristiques structurales et la composition des diverses phases coexistant dans ce système au-dessus de 1273 K, en vue de compléter les précédents résultats obtenus à 293 K (3–17) et ainsi faciliter une comparaison ultérieure avec le système U-Ba-O (18) notamment. L'importance technologique de ces deux systèmes mérite en effet d'être soulignée, du fait que les éléments Sr et Ba sont les produits majeurs de fission du dioxyde d'uranium utilisé comme combustible nucléaire (20, 21).

Conditions expérimentales

Comme précédemment (18, 19), nous employons deux ensembles diffractométriques complémentaires, chacun d'entre eux étant pourvu de son propre four pour rayons X. Le premier de ces fours, de marque Rigaku–Denki (R.D.) possède une résistance de platine rhodié assurant son fonctionnement jusqu'au voisinage de 1423 K dans un courant gazeux oxydo-réducteur de 24 $dm^3\ h^{-1}$ et sous une pression partielle d'oxygène contrôlée ($10^{-19} \le P_{O_2}$(Pa) $\le 10^5$). Le second est un four dont la résistance de graphite permet de travailler entre 293 et 2273 K dans un milieu fortement réducteur ($10^{-1} \le P_{CO}$(Pa) $\le 10^5$, $P_{O_2} \le 10^{-19}$ Pa), que l'on opère sous vide entretenu ($10^{-4} \le P$ (Pa) $\le 10^{-1}$) ou sous pression atmosphérique d'azote avec un lent débit gazeux ($V_{N_2} \approx 0{,}5\ dm^3\ h^{-1}$).

Les échantillons polycristallins utilisés au cours de cette étude sont confectionnés à partir de dioxyde d'uranium Koch–Light à 99,97 % et de carbonate de strontium Johnson–Matthey de qualité « Specpure ». Ils se distinguent par leurs compositions globales et leurs modes de préparation comme suit :

(*i*) Échantillons de compositions $1UO_2 + 1SrCO_3$ et $1UO_2 + 3SrCO_3$ obtenus par broyage puis compression uniaxiale (pastilles cylindriques de diamètre 8 mm et de hauteur 3 mm) en vue d'examens exclusivement effectués dans le four à graphite.

(*ii*) Échantillons de compositions approximatives $SrUO_{3,7}$ (phase α-« $SrUO_4$ » orthorhombique (5, 6, 10, 13, 16, 22, 23) pure) et $Sr_3UO_{5,7}$ (mélange de l'uranate « Sr_3UO_6 » monoclinique (4) avec moins de 5 % des oxydes α-« $SrUO_4$ » et « Sr_2UO_5 » monoclinique (24)) préparés dans un four annexe à partir des mélanges $1UO_2 + 1SrCO_3$ et $1UO_2 + 3SrCO_3$ chauffés pendant 48 h à 1273 K sous courant d'oxygène.

(*iii*) Échantillons constitués par la phase β-« $SrUO_4$ » (de rapport $3{,}30 \le O/U \le 3{,}70$ (6, 16)) et obtenus, toujours dans le four annexe, après 2 h de réduction à 1273 K de l'α-« $SrUO_4$ » par un mélange gazeux $H_2 + N_2$ à 10 % d'hydrogène.

Chaque essai consiste à contrôler aux rayons X l'évolution structurale que provoque, à la surface de l'échantillon, soit une modification de la température ($293 \le T$(K) ≤ 1773) dans un potentiel d'oxygène constant au cours de paliers successifs espacés d'une cinquantaine de K toutes les 2 h environ, soit un maintien à température constante (avec un éventuel changement de P_{O_2}) aussi longtemps qu'on le juge utile. L'échantillon est alors progressivement refroidi jusqu'à 293 K (four R.D.) ou trempé, examiné à l'ambiante et conservé sous vide, dans l'attente de recuits ultérieurs (jusqu'à 6 recuits dans le four à graphite).

Résultats et discussion

Le premier traitement sous vide d'un comprimé $1UO_2 + 1SrCO_3$ dans le four à graphite nous a permis d'observer successivement :

(*i*) La dissociation totale du carbonate orthorhombique en monoxyde de strontium dès 1073 K et la formation progressive, à partir de 1173 K, des uranates β-« $SrUO_4$ » et « $SrUO_3$ ».

(*ii*) La coexistence des quatre oxydes UO_2, SrO, β-« $SrUO_4$ » et « $SrUO_3$ » entre 1173 et 1513 K.

(*iii*) La disparition des phases β-« $SrUO_4$ », SrO et « $SrUO_3$ » aux températures respectives de 1513, 1588 et 1663 K au profit de la seule solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$ dont le paramètre cristallin à 1663 K (a = 0,5570 nm) est plus grand que celui de l'oxyde $UO_{2,00}$ (a = 0,5547 nm).

Les températures de formation obtenues dans ces conditions extrêmes ($P_{O_2} \le 10^{-19}$ Pa) pour les oxydes SrO, β-« $SrUO_4$ », « $SrUO_3$ » et $U_{1-\delta}Sr_\delta O_{2-\delta}$, de même que celles précédemment signalées pour les composés homologues du Ba (18) et du Ca (19), ainsi que pour l'α-« $BaUO_4$ » (18), ont été indiquées dans le tableau 1. On pourra notamment constater que la réactivité du dioxyde d'uranium avec chacun des trois monoxydes CaO, SrO et BaO est d'autant plus importante que l'élément alcalino-terreux considéré est lourd. À noter l'absence des phases α-« $CaUO_4$ », β-« $BaUO_4$ » et $U_{1-\delta}Ba_\delta O_{2-\delta}$, alors qu'au contraire la présence des deux oxydes α- et β-« $SrUO_4$ » souligne le caractère intermédiaire du système U-Sr-O par rapport aux systèmes U-Ba-O et U-Ca-O. Il est vrai qu'en raison de son instabilité

[2] Conformément aux usages et à l'inverse des auteurs japonais (7–10), nous utilisons la lettre β pour distinguer la phase « $MeUO_4$ » la plus réduite (et aussi la plus ancienne (14)) de la plus riche en oxygène (α-« $MeUO_4$ »), en principe la moins stable à haute température.

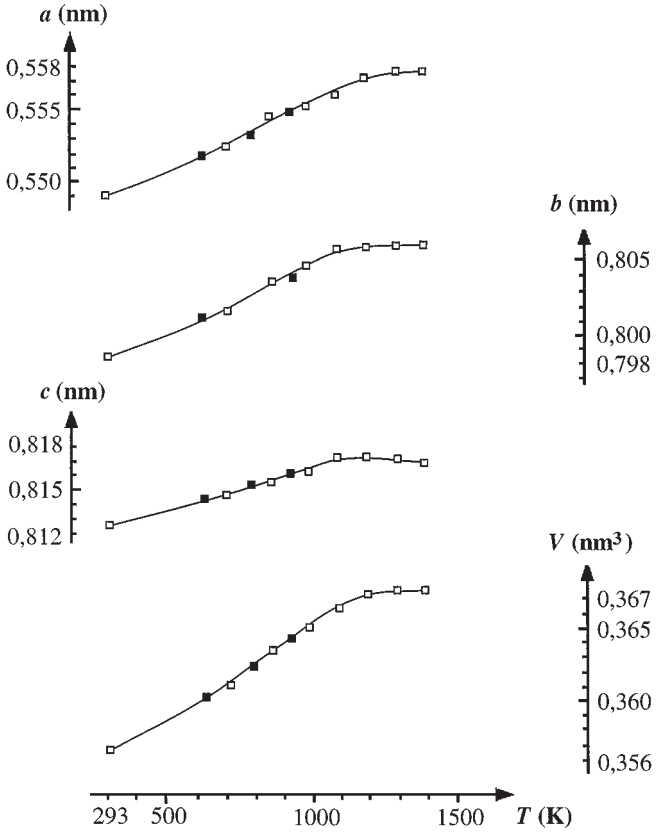
Fig. 1. Variations des paramètres cristallins de la phase α-« $SrUO_4$ » en fonction de la température. □, α sous oxygène pur; ■, α dans l'air (four R.D.).



dans le four à graphite, l'oxyde α-« $SrUO_4$ » fait l'objet d'une mention spéciale au tableau 1. Aussi commencerons-nous par préciser le comportement de cet oxyde en fonction de la température (fig. 1), avant d'étudier celui des uranates β-« $SrUO_4$ » (fig. 2), « $SrUO_3$ » (fig. 3) et $U_{1-\delta}Sr_\delta O_{2-\delta}$ (fig. 4), les mesures de paramètres cristallins relatives aux deux phases « Sr_3UO_6 » et « Sr_3UO_5 » ayant été jointes à celles de « $SrUO_3$ » (fig. 3), afin de faciliter la comparaison entre ces trois pérovskites.

Étude des oxydes « $SrUO_4$ »

La phase α-« $SrUO_4$ » dite basse température

Stable dans l'oxygène pur, la phase α-« $SrUO_4$ » orthorhombique (groupe spatial *Pbcm*, 4 groupements formulaires par maille (5, 23)) est de couleur jaune, comme le sont aussi les phases α-« $BaUO_4$ » et β-« $CaUO_4$ » formées dans les mêmes conditions ($P_{O_2} \approx 10^5$ Pa à 1273 K). À température ambiante, les paramètres cristallins de ce monouranate (a = 0,5491 nm, b = 0,7980 nm et c = 0,8126 nm) sont en parfait accord avec ceux qui ont été proposés par de nombreux auteurs (5, 6, 10, 13, 16, 22, 23).

Comme le montre la fig. 1, les trois constantes réticulaires, ainsi que le volume de la maille orthorhombique, augmentent de façon continue jusqu'au voisinage de 1123 K, avec de faibles écarts positifs par rapport à la linéarité pour chacune des quatre courbes d'expansion obtenues. Après quoi, celles-ci demeurent horizontales dans l'intervalle de température compris entre 1123 et 1373 K. Un tel comportement, en tout point comparable à ceux que manifestent les phases α-« $BaUO_4$ » (18) et β-« $CaUO_4$ » (19), s'interprète par un changement de composition de l'oxyde examiné. Contrairement à ce qui se produit avec l'α-« $BaUO_4$ », tout risque d'évaporation doit toutefois être écarté pour l'α-« $SrUO_4$ », la tension de vapeur de l'oxyde BaO étant environ 10^3 fois plus élevée que celle de l'oxyde SrO (1). Si bien qu'il convient d'envisager, par analogie avec l'oxyde « U_3O_8 » (25), et ainsi que nous l'avons déjà fait pour la phase β-« $CaUO_4$ » (19), un départ d'oxygène avec création simultanée de lacunes plus ou moins ionisées au sein du cristal orthorhombique de α-« $SrUO_4$ ». La composition de cet uranate ne devrait donc pas varier entre 293 et 1123 K, avec un rapport O/U ≈ 3,67, égal à celui de « U_3O_8 » (O/U = 2,67 (25)) augmenté de celui de la chaux (O/Ca = 1,00). Par contre, elle devrait évoluer entre $SrUO_{3,67}$ à 1123 K et $SrUO_{3,62}$ à 1373 K (25). Dès lors, nous sommes conduits à admettre a posteriori que la constance des paramètres cristallins de l'α-« $BaUO_4$ » est indépendante de la vaporisation et doit être associée à la même diminution du rapport O/U (3,67 ≥ O/U ≥ 3,62) que celle de l'α-« $SrUO_4$ ». Cette conclusion est en totale contradiction avec les affirmations des précédents auteurs (5, 6, 8–10, 13, 16, 22, 23) d'après lesquelles ces oxydes ne s'écartent pratiquement pas de la composition stœchiométrique (O/U ≈ 4).

Signalons qu'une toute autre interprétation que la nôtre a été proposée pour justifier l'existence de « plateaux naturels d'expansion » et de dilatations négatives qui caractérisent d'autres oxydes, à des températures beaucoup moins élevées que les précédentes toutefois. De récentes études de diffraction de neutrons entre 10 et 450 K (26, 27) ont permis notamment d'attribuer la dilatation négative des composés $Sc_2(WO_4)_3$ et $Lu_2(WO_4)_3$ à un déplacement thermique des atomes d'oxygène dans les liaisons Me-O-W. Ces déplacements semblent être reliés à des mouvements oscillatoires que subissent les polyèdres présents dans l'édifice cristallin, à condition que ceux-ci puissent se déformer.

La phase « β-$SrUO_4$ » dite haute température

Formée par réduction de l'α-« $SrUO_4$ » au voisinage de 1273 K, la phase β-« $SrUO_4$ » rhomboédrique ($R\bar{3}m$, $z = 1$ (14)) existe elle-même sous deux formes distinctes :

(*i*) La forme oxydée β identifiée exclusivement dans le four R.D. sous courant d'azote pur ($10^{-1} \leq P_{O_2}$(Pa) ≤ 1);

(*ii*) La forme réduite β′ observée aussi bien dans le four R.D. sous atmosphère d'hydrogène dilué à 10 % dans l'azote que dans le four à graphite fonctionnant sous vide ($P_{O_2} \leq 10^{-19}$ Pa).

Quelle que soit la forme de l'oxyde examiné, nous considèrerons la maille hexagonale correspondante (constituée de 3 groupements formulaires $SrUO_4$), afin de faciliter la comparaison entre nos mesures pour $293 \leq T$(K) ≤ 1718 (fig. 2) et celles que les précédents auteurs (7, 10, 13, 14, 16) ont effectuées à 293 K (tableaux 2 et 3).

(a) La forme oxydée β-« $SrUO_4$ » : Le tableau 2 permet de constater la dispersion considérable qui se manifeste sur les valeurs des paramètres cristallins proposés pour cet oxyde à 293 K par les différents auteurs et par nous-mêmes (écarts entre les valeurs extrêmes de *c*, *a*, *c*/*a* et *V* atteignant respectivement 0,8, 2,2, 3,3 et 5,2 %). Une telle dispersion est d'autant plus surprenante qu'elle est pratiquement inexistante pour la forme oxydée de β-« $CaUO_4$ » (19) isomorphe de β-« $SrUO_4$ » mais stable dans l'oxygène pur (écarts sur les paramètres ne dépassant pas 0,13 % à 293 K). Les valeurs que nous avons attribuées à ces paramètres à chaud (fig. 2, symboles ■ et ▲) se montrent d'ailleurs tout autant dispersées entre 293 et 1108 K que les précédentes à 293 K, une atténuation de ce phénomène se produisant toutefois au-dessus de 1108 K. C'est ainsi que les plus faibles valeurs du rapport *c*/*a* (symboles ■, ▲ et □) obéissent à une loi de variation en fonction de *T* qui est totalement déconcertante : obtention de la courbe (1) tour à tour croissante entre 293 et 758 K, décroissante pour $758 \leq T$(K) ≤ 1108, puis de nouveau croissante de 1108 à 1343 K. Indépendamment de l'anisotropie qui caractérise cette structure (19), il n'est pas douteux qu'une telle courbe $c/a = f(T)$ doive être associée à de fortes variations de composition de l'oxyde examiné. Comme celles-ci se montrent en outre imprévisibles, incontrôlables et difficilement reproductibles, on doit admettre que la forme oxydée β-« $SrUO_4$ » est métastable entre 293 et 1108 K. Cette métastabilité est de plus étayée par l'obtention simultanée des deux formes β oxydée et β′ réduite de « $SrUO_4$ » à l'ambiante (à la suite d'une trempe de la forme oxydée sous azote depuis 1363 K), puis entre 293 et 498 K lors de recuits ultérieurs. Ajoutons que, contrairement à toute attente, ces recuits ont eu pour effet de provoquer une homogénéisation de l'oxyde rhomboédrique dans sa forme réduite β′ pour $498 \leq T$(K) ≤ 593 en présence d'azote (symbole ■) et pour $478 \leq T$(K) ≤ 783 dans l'air (symbole ▲). Après quoi, les diminutions observées sur le rapport *c*/*a* entre 593 et 1108 K dans l'azote (symbole ■) et de 783 à 1073 K dans l'air (symbole ▲) n'ont fait que traduire une réoxydation progressive de l'échantillon jusqu'à l'obtention de la forme oxydée β-« $SrUO_4$ » dans le premier cas et de l'α-« $SrUO_4$ » dans le second.

Fig. 2. Variations des paramètres cristallins et du volume de la maille hexagonale des phases β et β′-« $SrUO_4$ » en fonction de la température. Dans le four R.D. : ■, β seule sous N_2 pur; ▲, β seule par oxydation sous air de β′; □, β′ seule sous H_2. Dans le four à graphite : ●, β′ + UO_2 + SrO + $SrUO_3$; ○, β′ + $SrUO_3$; △, β′ + UO_2; ▽, β′ + UO_2 + $SrUO_3$.

Quant à l'accroissement linéaire que subit le rapport *c*/*a* entre 1108 et 1343 K, il s'interprète, ainsi que nous l'avons fait pour β-« $CaUO_4$ » (19), par un début de réduction de la forme oxydée β-« $SrUO_4$ », le changement du nombre d'oxydation de quelques atomes d'uranium (passage U^{VI}/U^{V}, voire U^{VI}/U^{IV}) devenant prépondérant devant la création de lacunes d'oxygène.

C'est donc à partir de 1108 K que cette forme oxydée β devrait se manifester à l'état thermodynamiquement stable, avec une composition qui ne devrait pas trop s'éloigner de $SrUO_{3,60}$ entre 1108 et 1343 K, si l'on se réfère aux compositions limites adoptées pour l'α-« $SrUO_4$ » dans un intervalle de température voisin.

Signalons qu'à trois reprises, de précédents auteurs (7, 8, 13) ont envisagé la phase β-« $SrUO_4$ » comme étant métastable en dessous d'une température limite comprise entre 973 et 1073 K et, par conséquent, peu éloignée de la nôtre (T = 1108 K). D'autres auteurs ont en outre observé les deux formes β et β′ coexister à 293 K, à la suite de trempes qui avaient été effectuées respectivement depuis 1173 K sous H_2 (Corfunke et Loopstra (6)) et 1673 K dans l'air (Brisi et al. (16)). En revanche, selon Takahashi et al. (10), il existe une solution solide continue β rhomboédrique à toute température (3,978 ≥ O/U ≥ 3,597), les phases limites s'étant vues attribuer pour $\Delta_f H^0(298)$ des valeurs comprises entre –1890 et –1990 kJ mol^{-1} et pour paramètres cristallins des valeurs proches des nôtres (tableaux 2 et 3).

(b) La forme réduite β′-« *$SrUO_4$* » : Les valeurs des paramètres cristallins obtenues pour cet oxyde sont moins dispersées que les précédentes, tant à l'ambiante (tableau 3) qu'entre 293 et 1713 K (fig. 2, symboles □, ●, ○, △, et ▽). D'une manière générale, elles se montrent les plus fortes à toute température, exception faite des valeurs anormalement faibles du paramètre *c* et du rapport *c*/*a* dont l'obtention pour 293 ≤ T(K) ≤ 873 (symbole □) doit être attribuée à la réduction progressive des échantillons partiellement oxydés lors de leur transfert du four annexe au four R.D. en début d'essai. On peut notamment constater que le rapport *c*/*a* s'accroît peu avec la température (4,69 ≤ *c*/*a* ≤ 4,71 pour 293 ≤ T(K) ≤ 1713) mais que, pour une température donnée, l'augmentation que subit ce rapport entre les deux formes β et β′de « $SrUO_4$ » est considérable. Ainsi, pour T = 1108 K, le rapport passe de 4,59 ± 0,01 à 4,70 ± 0,01, soit une variation relative de 2,2 % encore plus élevée que celle de 1,8 % précédemment obtenue pour l'oxyde β-« $CaUO_4$ » à 1373 K (19). Si donc l'on admet que ces valeurs sont consécutives à la même diminution du rapport O/U (soit Δ(O/U) = 0,49 (19)), ainsi que la composition $SrUO_{3,60}$ pour la forme oxydée β-« $SrUO_4$ », la réduction de celle-ci devrait se traduire par l'obtention du composé β′-$SrUO_{3,11}$ dès 1108 K. Cette composition ne devrait d'ailleurs guère évoluer entre 1108 et 1713 K, compte tenu de la faible variation du rapport *c*/*a*, et cela que la forme réduite β′ soit seule (symbole □) ou coexiste avec les diverses phases UO_2, SrO et $SrUO_3$ (symboles ●, ○, △ et ▽). En tout état de cause, le rapport O/U = 3,11 est de loin le plus faible qui ait été proposé (tableau 3) pour la forme réduite β′-« $SrUO_4$ », celui qui s'en rapproche le plus (O/U = 3,30) étant dû à Cordfunke et Loopstra (6). Du fait que la phase β′-$SrUO_{3,11}$ subit parfaitement l'effet de trempe (symboles ●, ○, △ et ▽) et prend systématiquement naissance aux dépens de l'oxyde β-$SrUO_{3,60}$ entre 293 et 783 K, nous estimons qu'elle est thermodynamiquement stable à toute température. Bien que non confirmée par nos mesures, l'existence d'une solution solide β rhomboédrique entre les deux composés limites n'est possible qu'au-dessus de 1108 K et non pas dès 293 K comme l'ont prétendu Takahashi et al. (10). Une toute autre interprétation de nos résultats sera toutefois suggérée dans le dernier chapitre de cette discussion.

La transition (α,β) entre les oxydes « $SrUO_4$ »

À notre connaissance, il n'existe pas de relation cristallographique entre les deux structures α orthorhombique et β rhomboédrique de l'oxyde « $SrUO_4$ » (28). Comme en outre, l'une et l'autre se manifestent dans un grand intervalle de température (293 ≤ T(K) ≤ 1373), mais jamais simultanément, nous préférons considérer les oxydes α et β « $SrUO_4$ » comme étant des phases distinctes plutôt que des variétés polymorphes. De ce point de vue, il existe une certaine analogie entre le comportement de ces oxydes (1,83 ≥ Δ(O/U+Sr) ≥ 1,55) et celui des sesquinitrures α et β « U_2N_3 » (1,75 ≥ Δ(N/U) ≥ 1,45) (29, 30). De précédents auteurs (8, 13, 17) ont néanmoins admis l'existence de la transition polymorphique α-« $SrUO_4$ » ⇄ β-« $SrUO_4$ » comme se produisant dans l'air ($P_{O_2} \approx 2 \times 10^4$ Pa) à la température de 1523 ± 30 K, données que nous n'avons pu vérifier en raison du fonctionnement limité du four R.D. Cependant, la constance des paramètres cristallins de l'α-« $SrUO_4$ » observée dans l'oxygène pur ($P_{O_2} \approx 10^5$ Pa) entre 1173 et 1373 K (fig. 1) s'interprète, nous l'avons vu, comme un début de réduction de cet oxyde et constitue, somme toute, un signe prémonitoire de la transition annoncée. De plus, nous avons observé les deux transformations β → α et α → β s'amorcer à

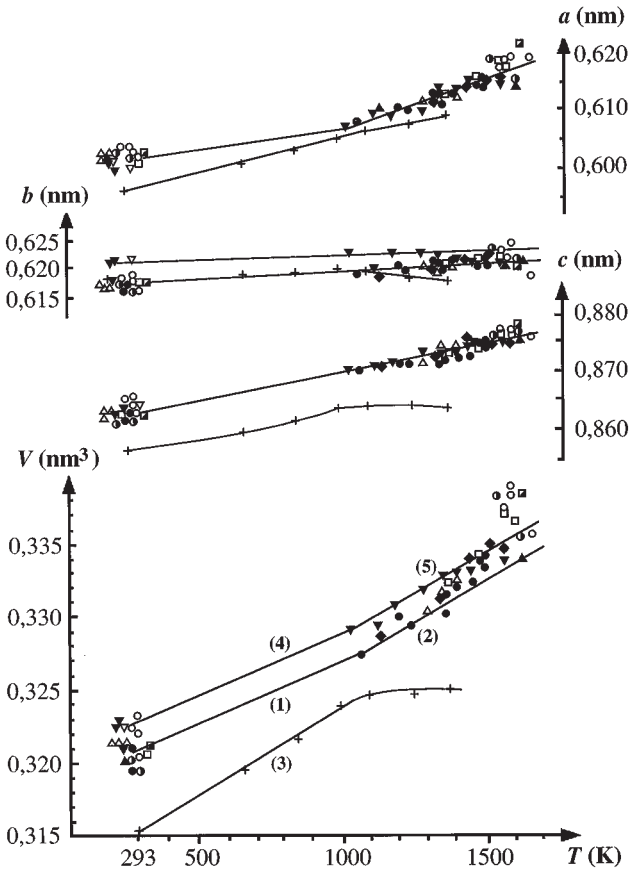
Fig. 3. Variations des paramètres cristallins des phases « $SrUO_3$ », « Sr_3UO_5 » et « Sr_3UO_6 » en fonction de la température. Dans le four à graphite : phase « $SrUO_3$ » en présence de : ●, UO_2 + SrO + β′-« $SrUO_4$ »; ◑, UO_2 + SrO; ○, UO_2; □, β′-« $SrUO_4$ »; ◪, UO_2 + β′-« $SrUO_4$ »; phase « Sr_3UO_5 » en présence de : ▼, SrO + β′-« $SrUO_4$ »; △, UO_2 + SrO + β′-« $SrUO_4$ »; ◆, UO_2 + SrO; ▲, seule à 1633 K; ▽, seule à 293 K. Dans le four R.D. : +, phase « Sr_3UO_6 » seule sous O_2.



la même température de 1363 K respectivement sous courant d'air et sous courant d'azote ($P_{O_2} \leq 1$ Pa). On peut donc admettre que la transition (α,β) devient réversible à 1523 K dans l'air, les uranates concernés ayant des compositions voisines ($3{,}62 \geq O/U \geq 3{,}60$).

Étude des pérovskites mixtes d'uranium et de strontium

La phase « $SrUO_3$ »

Apparue dès 1173 K et formée progressivement sous $P_{O_2} \leq 10^{-19}$ Pa aux dépens des oxydes « UO_2 », SrO et β′-« $SrUO_4$ » jusqu'à 1663 K, la phase « $SrUO_3$ » orthorhombique (*Pnma*, $z = 4$ (15)) n'a jamais pu être préparée isolément, et cela quelle que soit la composition de départ ($1UO_2 + 1SrCO_3$ ou $SrUO_{3,7}$). Comme néanmoins les proportions en oxydes résiduels « UO_2 » et SrO se confondaient le plus souvent, on peut estimer avec Brisi (15) que la pérovskite « $SrUO_3$ » ne s'écarte guère de la composition stœchiométrique, ce qui est d'ailleurs aussi le cas de ses isomorphes à base de baryum au-dessus de 1423 K (18) ou de calcium entre 293 et 1723 K (19).

Les paramètres cristallins que nous attribuons à la maille élémentaire de « $SrUO_3$ » à 293 K (sur la base d'une moyenne de 10 déterminations) sont respectivement : a = 0,6030 nm, b = 0,6175 nm, c = 0,8630 nm et V = 0,321 nm^3. Ils sont en parfait accord avec ceux (a = 0,603 nm, b = 0,618 nm, c = 0,862 nm et V = 0,321 nm^3) de Brisi (15), eux-mêmes légèrement plus grands que les paramètres (a = 0,601 nm, b = 0,617 nm, c = 0,860 nm et V = 0,319 nm^3) initialement proposés par Lang et al. (3) pour le composé $Sr(U,Sr)O_x$.

Pour ce qui concerne les mesures effectuées à chaud, la fig. 3 permet de constater (symboles ●, ◑, ○, □ et ◪), outre leur dispersion caractéristique de l'anisotropie de cette structure (19), que le paramètre a est celui qui augmente le plus entre 293 et 1553 K ($\Delta a/a \approx 3{,}3$ %) par rapport aux paramètres c et b ($\Delta c/c \approx 1{,}7$ % et $\Delta b/b \approx 0{,}8$ %). Quant aux valeurs du volume entre 293 et 1553 K, elles permettent de définir deux droites (**1**) et (**2**) s'interceptant à 1073 K puis, pour $1553 \leq T(K) \leq 1663$, elles se distribuent nettement au-dessus de la droite (**2**). Les droites (**1**) et (**2**) conduisent respectivement aux coefficients moyens de dilatation volumique $\overline{\alpha}_1 = 28 \times 10^{-6}$ K^{-1} et $\overline{\alpha}_2 = 43 \times 10^{-6}$ K^{-1}. Ces coefficients se montrent voisins de ceux ($\overline{\alpha}_1' = 33 \times 10^{-6}$ K^{-1} et $\overline{\alpha}_2' = 45 \times 10^{-6}$ K^{-1}) précédemment déterminés (19) pour la phase « $CaUO_3$ » monoclinique dont l'angle β subit une brutale diminution de 90,1° à 90,0° précisément au voisinage de 1073 K, sans que pour autant cette pérovskite ne devienne orthorhombique (transition α-orthorhombique, β-monoclinique observée à 1773 K (19)). Or la cassure de pente qui se manifeste dans le cas de « $SrUO_3$ » (fig. 3) s'accompagne soit de la disparition au-dessus de 1073 K du pic indexé (111) dans le système orthorhombique (15), soit de sa réapparition systématique à l'ambiante après une trempe. Ce pic (111) de faible intensité ($I/I_0 \approx 10$ selon Brisi (15) et ≤ 5 d'après nos mesures) est le seul pic (*hkl*) dont la somme des indices de Miller soit impaire et qui soit bien séparé (angle ≈ 23° 2θ de Bragg) des autres pics enregistrés dans nos diffractogrammes. Il implique l'appartenance de l'oxyde au réseau orthorhombique primitif (mode *P*). La disparition de ce pic, conforme à la règle de sélection ($h + k + l = 2n$ (31), équivaut donc à l'obtention d'un réseau centré (mode *I*), avec changement simultané de groupe spatial au sein du même groupe ponctuel 2/*m*2/*m*2/*m*. La cassure de pente observée à 1073 K ne fait donc que traduire l'existence d'une discrète transition du second ordre qui pourrait s'écrire (31) :

[1] α-« $SrUO_3$ » (*Pnma*) ⇌ β-« $SrUO_3$ » (*Imma*)

À noter encore que la proximité des valeurs prises par les paramètres cristallins a et b de la phase orthorhombique (a = 0,618 ± 0,004 nm et b = 0,623 ± 0,003 nm) aux températures les plus élevées de nos essais ($1553 \leq T(K) \leq 1663$) annonce l'existence d'une seconde transition (β-orthorhombique, γ-quadratique) de la pérovskite « $SrUO_3$ ». Aucune vérification de cette transition n'a cependant pu être effectuée, nos examens ayant dû se limiter à la température de 1663 K, du fait que la solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$ se formait alors en grande quantité. En tout état de cause,

© 1999 CNRC Canada

l'augmentation constatée sur le volume de la maille au-dessus de 1553 K (symboles ○, ◐, □ et ◪) est significative d'un début de réduction de l'oxyde « $SrUO_3$ », selon un processus similaire à celui que nous avons proposé pour les phases UO_{2-x}, ThO_{2-x} et $CaUO_3$ (19), le départ d'oxygène étant probablement compensé par la substitution de quelques ions U^{4+} (r_i = 0,100 nm) par des ions U^{3+} légèrement plus gros (r_i = 0,106 nm) (31) et répartis au hasard dans le réseau centré de cette pérovskite orthorhombique.

La phase « Sr_3UO_6 »

Après avoir été préparée sous $P_{O_2} \approx 10^5$ Pa dans le four annexe fonctionnant à 1273 K, la phase « Sr_3UO_6 » monoclinique ($P2_1$, z = 2 (4)) est transférée dans le four R.D. puis examinée sous le même potentiel d'oxygène entre 293 et 1373 K. C'est ainsi que nous proposons, pour la maille monoclinique à 293 K, des paramètres cristallins (a = 0,596 nm, b = 0,618 nm, c = 0,856 nm, β = 90,1° et V = 0,315 nm^3) qui sont très proches de ceux (a = 0,5959 nm, b = 0,6179 nm, c = 0,8553 nm, β = 90,19° et V = 0,3149 nm^3) précédemment indiqués par Rietveld (4). La qualité de nos enregistrements est toutefois insuffisante pour préciser à mieux de ±0,1° près la valeur de l'angle β. Comme cet angle a toute chance de diminuer encore avec l'accroissement de T (19), nous considèrerons la phase « Sr_3UO_6 » comme étant pseudo-orthorhombique à toute température. Dans ces conditions, la fig. 3 permet de constater que les paramètres ainsi obtenus (symbole +) sont les plus faibles de tous, avec cependant un volume de maille augmentant plus vite entre 293 et 1073 K pour « Sr_3UO_6 » (droite (**3**), $\bar{\alpha}_3 = 33 \times 10^{-6}$ K^{-1}) que pour « $SrUO_3$ » (droite (**1**), $\bar{\alpha}_1 = 28 \times 10^{-6}$ K^{-1}), puis se montrant constant au-dessus de 1073 K. Ces différences de paramètres et de coefficients de dilatation sont dues au changement du nombre d'oxydation des atomes d'uranium (de U^{VI} à U^{IV}) présents dans ces deux pérovskites. Quant à la constance du volume observée entre 1073 et 1373 K, elle s'explique, de la même manière que nous l'avons fait pour l'α-« $SrUO_4$ », par une réduction progressive de la phase « Sr_3UO_6 » se traduisant par une légère variation de composition ($5{,}67 \geq O/U \geq 5{,}62$), avec formation simultanée de lacunes d'oxygène ionisées et sans diminution du degré d'oxydation des atomes d'uranium.

La phase « Sr_3UO_5 »

Il était intéressant de connaître le comportement de la pérovskite « Sr_3UO_6 » dans l'atmosphère réductrice ($P_{O_2} \leq 10^{-19}$ Pa) du four à graphite. À notre vive surprise, et contrairement à ce que nous avions réalisé avec la phase isomorphe « Ca_3UO_6 » (19), aucune mesure n'a cependant été possible sur l'oxyde « Sr_3UO_6 », sa pression d'oxygène étant selon toute vraisemblance trop élevée. On peut en effet constater sur la fig. 3 que les valeurs des paramètres cristallins obtenues dans ces conditions, notamment celles du volume (symboles ▽ et ▼), se distribuent toutes au-dessus non seulement de la courbe (**3**) caractéristique de « Sr_3UO_6 » (symbole +), mais aussi des droites (**1**) et (**2**) caractéristiques de « $SrUO_3$ » (symboles ●, ◑, ○, ◪ et □). Par la suite, ces résultats ont été confirmés par l'examen des phases formées à la surface d'un échantillon $1UO_2 + 3SrCO_3$ progressivement réduit sous vide entretenu entre 293 et 1633 K, les mesures effectuées lors de cet essai (symboles △, ◆et ▲), ainsi que les précédentes (symboles ▽et ▼) ayant permis de tracer les nouvelles droites (**4**) et (**5**) sensiblement parallèles aux droites (**1**) et (**2**).

Précisons que cet essai est le seul nous ayant permis de préparer une pérovskite de strontium à l'état pur, les oxydes « UO_2 » et SrO avec lesquels elle coexistait depuis 1183 K ayant fini par disparaitre simultanément à la température de 1633 K. Cette pérovskite répond donc bien à la composition Sr_3UO_5, conformément aux observations antérieures que Charvillat et al. (32) ont réalisées à 293 K sur des produits trempés depuis une température maximale de 1173 K.

Comme nos propres observations permettent en outre de constater (fig. 3) l'existence d'une cassure de pente entre les droites (**4**) et (**5**) se produisant au voisinage de 1073 K, ainsi que l'absence du pic (111) de la structure orthorhombique au-dessus de 1073 K, il y a tout lieu d'admettre que les deux phases Sr_3UO_5 et « $SrUO_3$ » sont isomorphes et manifestent la même transition (α,β) du second ordre. La diminution du nombre d'oxydation de l'uranium (de U^{VI} à U^{IV}), ainsi que la substitution d'un ion U^{4+} (r_i = 0,100 nm) sur deux par un ion Sr^{2+} (r_i = 0,116 nm) dans le sous-réseau cationique de la pérovskite simple, conditionnent les passages respectifs « Sr_3UO_6 » → Sr_3UO_5 et « $SrUO_3$ » → Sr_3UO_5 (ou $Sr_2(Sr,U)O_5$). Elles sont responsables de l'accroissement des dimensions réticulaires et des variations d'intensité relative que l'on observe entre ces trois composés.

Le domaine monophasé de type pérovskite ainsi délimité se distingue de ceux précédemment mis en évidence pour les systèmes U-Ba-O (18) et U-Ca-O (19) par le fait que, des trois phases Sr_3UO_5, « Ba_3UO_5 » et « Ca_3UO_5 », seule la première est identifiable à 293 K, la seconde ne subissant pas l'effet de trempe et la troisième demeurant un composé hypothétique du fait qu'elle est indiscernable de l'oxyde « $CaUO_3$ » monoclinique par notre technique.

Le rôle intermédiaire de l'ion Sr^{2+} (r_i = 0,116 nm) par rapport à ceux des ions Ba^{2+} (r_i = 0,136 nm) et Ca^{2+} (r_i = 0,100 nm) (31) est particulièrement mis en lumière par l'évolution structurale des trois types de pérovskites doubles examinées :

(*i*) La symétrie monoclinique, commune aux oxydes de calcium, ne subsiste qu'avec « Sr_3UO_6 » pour faire place à la symétrie orthorhombique de Sr_3UO_5, « $SrUO_3$ » et « $BaUO_3$ » (33), puis à la symétrie quadratique, voire cubique pour $T \geq 1063$ K, de « Ba_3UO_5 » et « Ba_3UO_6 » (18, 32, 34).

(*ii*) Au composé « Me_3UO_5 » correspond toujours la plus grande maille pérovskite, mais alors que le volume de la maille diminue dans l'ordre « Me_3UO_5 », « $MeUO_3$ », « Me_3UO_6 » pour Me = Ca et Sr, il y a permutation de « $MeUO_3$ » et « Me_3UO_6 » dans le cas du baryum.

Étude de la solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$

À notre connaissance, seuls les travaux de Lang et al. (3) et de Voronov et Sofrana (11) font état de l'existence de la phase $U_{1-\delta}Sr_\delta O_{2-\delta}$ désordonnée ($Fm3m$, z = 4) résultant de la miscibilité partielle des oxydes UO_2 et SrO à une température au moins égale à 1273 K. Mais alors que les auteurs américains (3) proposent une teneur maximale en monoxyde de strontium de 25 % au voisinage de 2073 K, d'après l'équipe soviétique (11), cette teneur dépendrait de la tempé-

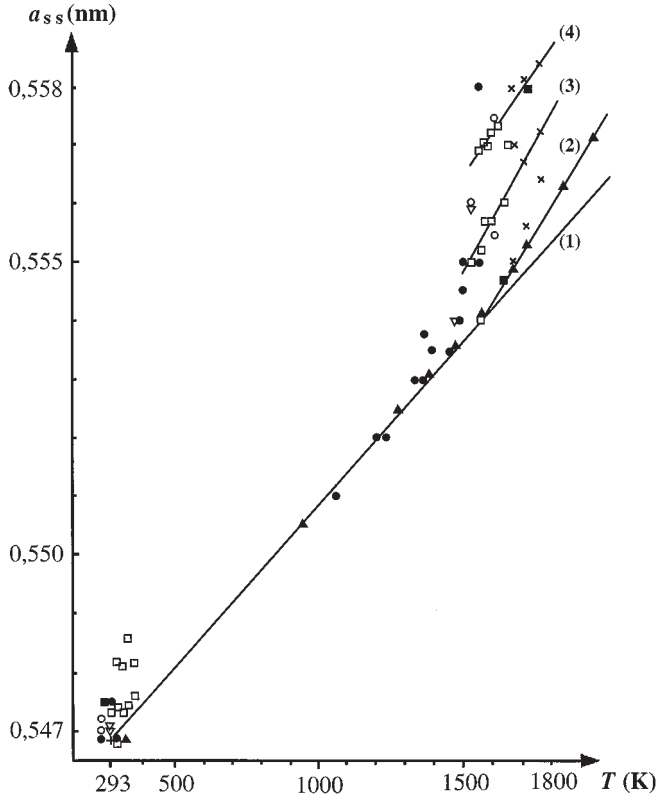
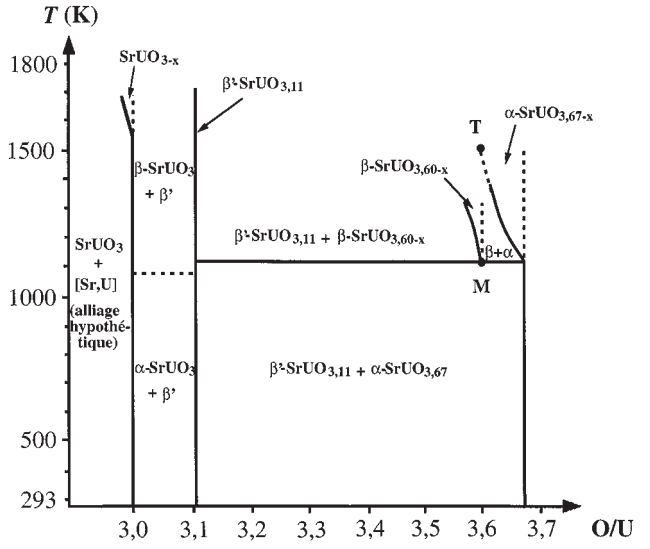
Fig. 4. Variation du paramètre cristallin de la solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$ en fonction de la température. Étude dans le four à graphite : +, UO_2 + $SrCO_3$ à 293 K; ● $(s.s.)_1$ + éventuelle $(s.s.)_2$ + SrO + $SrUO_3$ + β′-« $SrUO_4$ »; ○, $(s.s.)_1$ + éventuelle $(s.s.)_2$ + SrO + $SrUO_3$; □, $(s.s.)_1$ + éventuelle $(s.s.)_2$ + $SrUO_3$; ■, $(s.s.)_1$ + β′-« $SrUO_4$ »; ▽, $(s.s.)_1$ + $SrUO_3$ + β′-«,$SrUO_4$ »; ×, $(s.s.)_1$ + $(s.s.)_2$ + $(s.s.)_3$. Précédente étude (35) : ▲, $UO_{2,00}$ (droite **1**) et UO_{2-x} (droite **2**) en présence de C, α-« UC_2 » et CO.



rature ($9 \leq SrO(\%) \leq 20$ pour $1273 \leq T(K) \leq 1773$) et s'accompagnerait d'une légère diminution du paramètre cristallin ($0{,}5465 \geq a(nm) \geq 0{,}5460$).

Cette dernière conclusion s'avère en totale contradiction avec nos résultats expérimentaux. La fig. 4 permet en effet de constater qu'aussi bien à l'ambiante qu'à température élevée ($1373 \leq T(K) \leq 1773$), le paramètre de la phase « UO_2 » en la présence éventuelle des oxydes SrO, β′-« $SrUO_4$ » et « $SrUO_3$ » (symboles ●, ○, □, ■, ▽ et ×) se montre systématiquement plus grand que celui de l'$UO_{2,00}$ (droite (**1**)) et supérieur ou égal à celui de l'UO_{2-x} (courbe (**2**), symbole ▲) qui coexiste avec les phases C, CO et α-« UC_2 » (35). Un examen minutieux des diagrammes de diffraction aux grands angles permet en outre de constater la coexistence fréquente de deux phases de type fluorine (courbes (**3**) et (**4**), symboles ●, ○ et □) en présence des autres oxydes, voire de trois de ces phases c.f.c. (courbes (**2**), (**3**) et (**4**), symbole ×) en l'absence de toute autre phase. Ces observations, au demeurant plus aisées à chaud qu'à 293 K, soulignent la difficulté de maintenir la structure cubique désordonnée dans un état bien cristallisé après trempe. Elles s'interprètent, de même que nous l'avons fait pour la phase $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$ (19), par l'existence d'un domaine homogène de solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$ encadré par les domaines

Fig. 5. Diagramme de phases du système pseudo-binaire « $SrUO_3$ » – « $SrUO_4$ ».



diphasés | s.s.(courbe (**3**)) + UO_{2-x} (courbe (**2**)) | et | s.s.(courbe (**4**)) + « $SrUO_3$ » |. La résolution des différentes composantes entrant dans la constitution des pics diffractés par la phase $U_{1-\delta}Sr_\delta O_{2-\delta}$ est toutefois plus délicate à réaliser en raison d'une moindre dissolution de SrO et d'une diminution concomitante de l'angle de Bragg, au lieu d'un accroissement de cet angle dans le cas de $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$.

Il n'est pas douteux que les variations opposées que manifestent les paramètres cristallins des solutions solides $U_{1-\delta}Sr_\delta O_{2-\delta}$ et $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$ soient dues à la différence de rayon entre les ions Sr^{2+} et Ca^{2+} lorsque ceux-ci se substituent progressivement aux ions U^{4+}, la substitution U^{4+}/Sr^{2+} apparaissant de ce fait plus limitée que la substitution U^{4+}/Ca^{2+}, alors que la substitution U^{4+}/Ba^{2+} est pratiquement interdite par la taille excessive de l'ion Ba^{2+} ($\delta < 0{,}01$ d'après Kleykamp (20)).

Afin d'évaluer l'indice de substitution δ de la phase $U_{1-\delta}Sr_\delta O_{2-\delta}$, nous avons adopté comme référence un indice δ′ connu (19) pour la phase $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$. Après quoi, nous avons admis que ces indices étaient dans le même rapport que celui des variations relatives de paramètres auxquelles ils donnaient lieu, et cela indépendamment du sens de ces variations. C'est ainsi que ces calculs approximatifs ont été effectués à deux reprises pour chacune des limites de phases à 1673 K (fig. 4) correspondant aux courbes (**3**) ($\Delta a/a$ = 0,23 %) et (**4**) ($\Delta a/a$ = 0,51 %), sur la base d'un indice δ′ prenant les valeurs successives 0,25 ($\Delta a/a$ = 0,54 %) et 0,45 ($\Delta a/a$ = 0,90 %) (19). Ils conduisent aux teneurs limites en monoxyde SrO respectivement égales à 11,0 ± 0,5 % (courbe (**3**)) et 25 ± 1 % (courbe (**4**)), en bon accord avec les teneurs limites en chaux qui ont été proposées pour la solution solide $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$ en dessous de 1523 K (19). Aucune réaction de type péritectoïde n'a toutefois pu être observée entre les composés $U_{1-\delta}Sr_\delta O_{2-\delta}$, « $SrUO_3$ » et SrO.

Le diagramme de phases du système pseudo-binaire « $SrUO_3$ » – « $SrUO_4$ »

Compte tenu de nos résultats expérimentaux et de quelques hypothèses simplificatrices, nous suggérons le dia-

gramme représenté sur la fig. 5. Il permet de préciser et éventuellement de corriger un certain nombre de données bibliographiques (3, 6, 8–13, 15, 16) sur les points suivants.

Il n'existe que trois uranates thermodynamiquement stables à 293 K : ce sont les composés α-$SrUO_{3,67}$ orthorhombique, β′-$SrUO_{3,11}$ rhomboédrique et $SrUO_{3,00}$ de structure pérovskite.

L'uranate intermédiaire β-$SrUO_{3,60}$, isomorphe de β′-$SrUO_{3,11}$, ne se montre stable qu'au-dessus de 1108 K. Sa formation (point M sur la fig. 5) correspond donc à une réaction de type monotectoïde que l'on peut écrire :

[2] $\beta'\text{-}SrUO_{3,11} + \alpha\text{-}SrUO_{3,67} \rightleftharpoons \beta\text{-}SrUO_{3,60}$

Si la décomposition monotectoïde de β-$SrUO_{3,60}$ ne provoque jamais l'apparition de l'α-$SrUO_{3,67}$ à 293 K, ce sont probablement des contraintes qui en sont responsables. Un tel comportement a d'ailleurs été signalé sur d'autres systèmes tels que le système U–C, avec la réaction eutectoïde :

[3] U_2C_3 (c.c.) + C $\rightleftharpoons$ α-UC_2 (quadratique)

dont la réversibilité à 1793 K par précipitation du sesquicarbure d'uranium est impossible à vérifier par diffraction X à chaud quelle que soit la durée des recuits (36, 37).

Le diagramme proposé montre en outre que, des quatre oxydes examinés, seul l'oxyde β′-$SrUO_{3,11}$ ne subit pas de variation de composition entre 293 et 1713 K et, qu'à ce titre, il doit être considéré comme un véritable composé défini.

À gauche, il coexiste avec l'oxyde « $SrUO_3$ », le diagramme rappelant que cette pérovskite est le siège d'une transition du second ordre à 1073 K (représentée en pointillés dans le domaine diphasé $SrUO_3$ + β′-$SrUO_{3,11}$) et devient légèrement sous-stœchiométrique ($3{,}00 \geq O/U \geq 2{,}97$) entre 1553 et 1663 K.

À droite, le composé β′-$SrUO_{3,11}$ est en équilibre soit avec l'oxyde α-$SrUO_{3,67}$ entre 293 et 1108 K, soit avec son isomorphe β-$SrUO_{3,60-x}$ dont l'accroissement du rapport *c*/*a* atteste d'une légère diminution de la teneur en oxygène entre 1108 et 1343 K. Une limite droite verticale ($O/U \approx 3{,}60$) est, par contre, admise pour la phase monotectoïde qui coexiste avec l'oxyde α-« $SrUO_4$ » de composition variable ($3{,}67 \geq O/U \geq 3{,}62$) entre 1108 et 1373 K.

On voit que l'existence de la solution solide rhomboédrique ($3{,}98 \geq O/U \geq 3{,}60$) que Takahashi et al. (10) ont annoncée sur la base de leur étude de produits trempés est en totale contradiction avec le présent diagramme de phases. D'après celui-ci, une telle solution solide n'est guère concevable avant 1523 K, température pour laquelle se produirait la transformation (α,β) de la phase « $SrUO_4$ » (point T sur la fig. 5), peut-être à la suite d'une réaction de type péritectoïde.

Conclusions

Le présent travail de diffraction X à haute température a permis d'étudier les diverses phases solides qui prennent naissance au-dessus de 1073 K lorsque l'on fait réagir en proportions variables et sous pression d'oxygène contrôlée le dioxyde d'uranium et le monoxyde de strontium.

Pour chacune de ces phases (α-« $SrUO_4$ » orthorhombique, β et β′-« $SrUO_4$ » rhomboédriques, « $SrUO_3$ », « Sr_3UO_6 » et Sr_3UO_5 de structure pérovskite, ainsi que $U_{1-\delta}Sr_\delta O_{2-\delta}$ cubique), nous avons déterminé les paramètres cristallins et évalué les variations de composition dans l'intervalle de température compris entre 293 et 1713 K.

Compte tenu de ces évaluations, nous pouvons proposer les diagrammes de phases qui correspondent respectivement aux systèmes pseudo-binaires UO_2–SrO et « $SrUO_3$ » – « $SrUO_4$ ». Le premier de ces diagrammes se déduit immédiatement de celui précédemment attribué au système UO_2–CaO (19), à la différence près que la teneur minimale en oxygène de la solution solide $U_{1-\delta}Sr_\delta O_{2-\delta}$ est constante à toute température ($2 - \delta \approx 1{,}75$ au lieu de $1{,}75 \geq 2 - \delta \geq 1{,}45$ pour $U_{1-\delta'}Ca_{\delta'}O_{2-\delta'}$), et que la transformation péritectoïde de $CaUO_3$ à 1663 K disparait dans le cas de $SrUO_3$. Quant au second diagramme (fig. 5), il est pour l'essentiel basé sur l'existence de la phase monotectoïde β-« $SrUO_4$ » à 1108 K, la solution solide rhomboédrique précédemment annoncée (10) étant par conséquent métastable à 293 K.

Postface

Avec ce troisième mémoire consacré aux oxydes mixtes d'uranium et de métaux alcalino-terreux s'achève un long travail, commencé 35 ans plus tôt sur les oxydes d'uranium eux-mêmes (38), puis poursuivi sur de nombreux composés (oxydes, carbures, nitrures...) aussi bien de l'uranium et du thorium que d'autres métaux de transition. Tout au long de nos publications, nous avons tenté de faire partager au lecteur l'intérêt exceptionnel qu'offre, au triple point de vue structural, thermodynamique et cinétique, l'étude de l'état solide par diffraction X à haute température sous atmosphère conditionnée. Il y a en effet quelque chose de fascinant dans le fait que de petites modifications provoquées tant sur la température que sur une pression partielle gazeuse suffisent pour faire défiler les structures dans le temps et de manière réversible, ce qui donne à la matière cristallisée une véritable apparence de vie. Souhaitons que les recherches en ce domaine se perpétuent pour la plus grande satisfaction de leurs auteurs.

NMR conformational analysis on cyclic decapeptide template molecule

Zhenghong Peng

Abstract: We report the synthesis and conformational analysis of a series of cyclic and bicyclic decapeptide templates for combinatorial chemistry. The peptides were synthesized via solid phase synthesis and followed by solution cyclization. The conformation of the peptides was studied by proton NMR spectroscopy in DMSO and in TFE–water. The structure of the peptide template was calculated with the program DIANA and followed by SA from the NMR experimental constraints. The peptide adopts a fold comprising two β-strands and two type II β-turns. The design of such a restained cyclic decapeptide template will be discussed along with Template Assembled Synthetic Proteins (TASP).

Key words: solid phase peptide synthesis, cyclic decapeptide, NMR, conformational analysis, β-sheet.

Résumé : On a réalisé la synthèse d'une série de gabarits décapeptidiques cycliques et bicycliques pour la chimie combinatoire et on en a fait l'analyse conformationnelle. On a synthétisé les peptides par synthèse en phase solide et on a réalisé leur cyclisation en solution. On a étudié la conformation des peptides par spectroscopie RMN du proton en solution dans le DMSO ou dans des mélanges de TFE–eau. On a calculé la structure du gabarit peptidique à l'aide des programmes « DIANA », puis « SA », à partir des contraintes RMN expérimentales. Le peptide se replie avec deux brins β et deux plis β de type II. On discute de la conception d'un tel gabarit décapeptidique cyclique contraint ainsi que des protéines de synthèse assemblées à l'aide d'un gabarit (« TASP »).

Mots clés : synthèse peptidique en phase solide, décapeptide cyclique, RMN, analyse conformationnelle, feuillet-β.

[Traduit par la Rédaction]

Introduction

Topological templates that contain well defined functional groups are well known for protein de novo design and combinatorial chemistry (1–6). One approach of peptide library assembly, rather than being linked via a linear polypeptide fashion, the secondary structure forming peptide building blocks is assembled by covalent attachment to a template molecule (7–11). The template plays a determining role with the respect to the interaction of building blocks, the topological packing of the TASP, and predetermining the number, type, and spatial arrangement of its functional groups.

We report solid phase synthesis and conformational analysis for a series of decapeptide template molecules (Fig. 1). The model of the template is cyclic KXKPGKXKPG (X is any amino acid), where the orthogonal protecting groups of lysine side chain can be used to assemble secondary peptides as well as application to combinatorial chemistry. The templates were anticipated to provide conformationally well-defined structure based on two linked type II beta turns, by analogy with systems like the naturally occurring cyclic decapeptide antibiotic, gramicidin S4 (12). The templates have also been studied extensively in Mutter's group (3, 13, 14). However, they find out that the conformations of these molecules were initially inferred from considerations of their amino acid sequence, and several families of favored conformations were found, some of which had the lysine side chains pointing to both sides of the template in a random fashion. The template molecule is difficult to study partially because it contains four lysyl residues, and the highly symmetric molecule leads to considerable loss of information for NMR conformational analysis. Therefore, we assembled peptides with the sequence XXXPGXXXPG (X is any amino acid) or XXXPGXXXFP where XXX is designed to mimic the structure of KXK and to examine the conformations of these molecules from different amino acid sequences. We use XPGX sequence to adopt a type I or type II β-turn, which is also present in the GPGR sequence, a tight turn for the central conservative loop region of HIV-1 (15, 16). On the other hand, we use the XFPX sequence to adopt likely a type VI β-turn, which is present in the VFPA sequence of *RS-AFP*1, an antifungal protein isolated from radish seeds (17, 18). To define a more rigid structure, we further model the template by disulfide bond formation in the center of the template (Fig. 1).

Materials and methods

Peptide synthesis and purification

The linear peptides (NH2-XCXPGXCXPG-COOH) were prepared from solid phase synthesis according to the Fmoc strategy. Highly acid-labile resin (HALH or 2-Cl-Trt resin) was employed, thus allowing the completed linear peptides

to be detached from the solid phase resin under very mild conditions, with 1% TFA in DCM for HALH resin and 10% acetic acid for 2-Cl-Trt resin. Mild conditions both in peptide assembly and cleavage gave the degree of flexibility needed to incorporate various protecting groups of the peptide side chain (Boc, *t*-Bu, Acm, Trt). The protecting groups are intact after cleavage from the solid support, and the linear peptide was subsequently cyclized in high dilution with HBTU–DIPEA. The disulfide bond was formed via air oxidation or iodine oxidation (19–21).

Synthesis details

A complete synthesis strategy of the bicyclo-[KCIPGSCNPG] decapeptide (No. 2b) is shown in Fig. 2. The first residue Fmoc-Gly-OH 0.2 g (0.3 mmol) was dissolved in 5 mL dry DCM (a few drops of DMF was added just enough to dissolve Fmoc-Gly-OH), then the solution together with DIPEA (0.21 mL, 1.2 mmol) was added to 0.5 g 2-Cl-Trt resin (1.05 mmol/g substitution, 0.53 mmol total). The mixture was shaking mechanically for 25 min, the resin was filtered, and end capped with three times 10 mL of DCM/MeOH/DIPEA (17:2:1 vol.), followed by wash steps with 10 mL of 3 × DCM, 2 × DMF, 2 × DCM, and 2 × MeOH. Finally, the solvent was removed under suction, and the resin was dried by vacuum. A substitution of 0.56 mmol/g resin was obtained according to the UV detection of the deprotection of the Fmoc group. The Fmoc-Pro-OH, Fmoc-Asn(Trt)-OH, Fmoc-Cys(Acm)-OH, Fmoc-Ser(*t*-Bu)-OH, Fmoc-Gly-OH, Fmoc-Pro-OH, Fmoc-Ile-OH, Fmoc-Cys(Acm)-OH, Fmoc-Lys(Boc)-OH were sequentially assembled onto the Fmoc-Gly-Trt resin, employing the peptide synthesizer. Freshly distilled DMF was the unique solvent; 2.5 equiv. of Fmoc – amino acid, 2.5 equiv. of HBTU, 5 equiv. of DIPEA relative to the resin were preactivated in 5 mL DMF for 2 min, added to the reaction column, magnetic stirring intermittently for 30 min. The integration of the Fmoc deprotection peak was used to examine the completeness of the coupling reaction. The Fmoc group was removed with 3 mL of 20% piperidine in DMF for 3 min, repeated five times, after the peptide chain was assembled on the resin, the *N*-terminal Fmoc group was removed, the resin-bound side chain protected peptide was treated with 20 mL of acetic acid/TFE/DCM (1:1:8 by vol.) at room temperature for 30 min, the filtrate was concentrated under reduced pressure (300 mg, >90% pure by RP HPLC).

The linear protected peptide NH_2-Lys(Boc)-Cys(Acm)-Ile-Pro-Gly-Ser(*t*-Bu)-Cys(Acm)-Asn(Trt)-Pro-Gly-OH, 150 mg (0.1 mmol), was dissolved in 4 mL of DMF and added

through a capillary by siphonage to a solution of HBTU (152 mg, 0.4 mmol) and of DIPEA (70 μL, 0.4 mmol) in DMF (100 mL) at room temperature over 30 min. The cyclization was complete after an additional 30 min, as determined from the analytical RP HPLC (22, 23). The solution was concentrated under reduced pressure. The Boc and *t*-Bu protecting groups were removed with a mixture of 20 mL of 95% TFA, 2.5% TIS, 2.5% water for 2 h, and the reaction was monitored by analytical RP HPLC (24). The solvent was evaporated, and the peptide was then dissolved in 75% aqueous methanol (250 mL), 35 mg iodine in 75 mL methanol was added dropwise into the peptide solution over 60 min, and the reaction proceeded overnight. The crude product was separated by RP HPLC with pharmacia C18 0.95 × 50 cm column, linear gradient A: 0.1 TFA in water, B CH_3CN from 10~50%, over 25 min, flowrate 4 mL/min; 16 mg of peptide No. 2b was obtained.

The peptides Nos. 3b, 4m, and 4b were prepared under similar conditions, the chemical structure of the peptides was further identified by the complete assignments of the ^{1}D NMR spectra.

The peptide No. 1b was prepared on hyper-acid labile (HALH) resin. The preparation of the HALH resin is shown in Fig. 3 (25).

4-Hydroxymethyl-3-methoxyphenoxybutyric amino – methyl copolystyrene – divinyl benzene was prepared as amino methylated resin. First, the resin (Nova Biochem, substitution: 0.81 mmol/g) 5 g (4.05 mmol), was swollen in DMF–

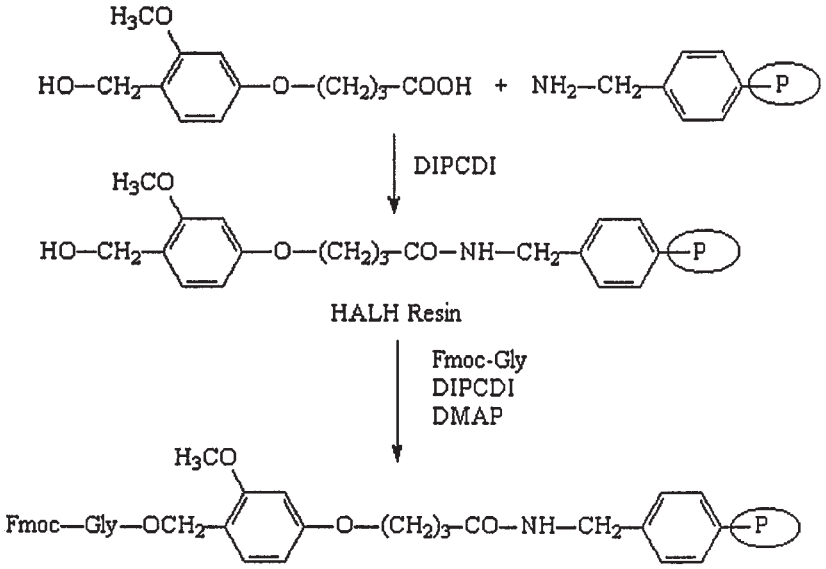
Fig. 3. The preparation of the Fmoc-Gly-HALH resin.



CH_2Cl_2 washed successively with 10 mL of DMF, 3 × 1 min, 20% piperidine in DMF, 1 × 3 min, 1 × 7 min, DMF, 3 × 1 min, CH_2Cl_2, 3 × 1 min. To the swollen resin was added a mixture of 2.9 g (12.15 mmol) of 4-(4-hydroxymethyl-3-methoxyphenoxyl)butyric acid and 0.2 mL (1.2 mmol) of diisopropylcarbodiimide (DIPCDI). The reaction mixture was swirled at room temperature for 1 h, then the resin was collected, washed with DMF, CH_2Cl_2, and ethyl ether each three times, dried in a vacuum desiccator over P_2O_5 overnight; weighed 5.873 g, substitution based on the weight increase was 0.78 mmol/g.

The first load of Fmoc-Gly onto HALH the resin

Fmoc-Gly, 2.4 g (8.1 mmol), was dissolved in CH_2Cl_2/DMF (1:1), with stirring. DIPCDI, 0.63 mL (4.05 mmol), was added to the solution. After 10 min, the above prepared dry resin, 2 g (1.62 mmol), was added, followed by addition of 100 mg (0.8 mmol) of DMAP. After swirling at room temperature for 1 h, the resin was drained, washed successively with DMF, CH_2Cl_2, CH_3OH, diethyl ether; dried resin weighed 2.424 g, substitution: 0.76 mmol/g.

The solid phase synthesis of the linear peptide was proceeded with similar conditions described above. After the peptide chain was assembled on the resin, the *N*-terminal Fmoc group was removed, followed by thorough washes with DMF, DCM, MeOH, and ethyl ether, dried in a vacuum desiccator over P_2O_5, weighed 1.008 g, weight increase 500.8 mg (0.2 mmol).

The resin-bound protected peptide was treated with 25 mL of 1.0% TFA in DCM at room temperature for 40 min, the filtrate was collected into 1.5 mL of prechilled DMF, the coloured resin was washed with 10 mL of MeOH, the combined filtrate was concentrated to ca. 2 mL by evaporation in vacuum, and directly separated on a RP-phase HPLC; column: pharmacia C18 10u 0.98 × 50 cm; linear gradient: A: 0.1% TFA in water, B: CH_3CN, B from 40 to 95% over 25 min; flow rate: 4 mL/min UV dual monitoring at 214 and 254 nm. The main peak, which was eluted at 21 min, was pooled, lyophilized to give a white powder, weighed 300 mg.

The following reaction of head-to-tail cyclization and deprotection from the side chain and disulfide bridge formation was prepared under similar conditions described in the synthesis of peptide No. 2b. Peptide No. 1m was also synthesized via HALH resin and purified using RP HPLC and proved by ES – mass spectroscopy and NMR.

NMR measurements

All the degassed samples had a final peptide concentration of 15 mM in DMSO-d_6,

The NMR spectra were recorded on a Bruker AM-500 spectrometer at 315 K. DQF-COSY (26, 27), TOCSY (28, 29), NOESY (30), and ROESY (31–33) spectra, with a spectral width of 6024.10 Hz, were recorded using standard pulse sequences. Phase-sensitive acquisition in t_1 was achieved by TPPI (34). The digital resolution in t_2 was 5.8 Hz/point and in t_1 was 11.6 Hz/point. Two-dimensional spectra were obtained with 2048 real data points and 512 t_2-increments (64–128 scans and 4 dummy scans per experiment). The spin lock in the TOCSY spectrum with field strength of 8.4 kHz was achieved with a MLEV-17 sequence preceded by a 1.5 ms trim pulse (28). In the ROESY spectra, continuous irradiation with field strength of 3.8 kHz was used for spin lock during 150 ms.

The data were processed on a X32 workstation with the UXNMR program. A $\pi/2$ shifted squared sine window function in the F2 dimension and a $\pi/2$ shifted sine window function in the F1 dimension was used. A polynomial baseline correction was performed in both dimensions.

The temperature coefficients of the amide proton resonance were extracted from a series of 1D spectra taken at several temperatures within the range of 295–325 K. Approximate hydrogen–deuterium exchange rates of the amide protons were measured from a series of 1D 16K spectra (96 scans and 4 dummy scans) with a spectral width of 6024.10 Hz after addition of two drops D_2O into the DMSO-d_6 solution. An E.COSY spectrum of the D_2O/DMSO-d_6 sample was recorded with a spectral width of 3496.50 Hz

© 1999 NRC Canada

under similar conditions as above. $^3J_{HN\alpha}$ interproton coupling constants were measured from 1D spectrum after a Lorentz to Gauss multiplication (GB = 0.15, LB = –3) and from the DQF-COSY spectrum at 315 K. $^3J_{\alpha\beta}$ interproton coupling constants were extracted from the 1D and E.COSY spectra. The NOESY buildup curve was sampled at the mixing times of 80, 120, 160, 200, 250, and 300 ms and was still linear up to 160 ms, therefore, the NOE cross-peak volumes were extracted from the NOESY spectra with the mixing time of 160 ms. Based on the two-spin approximation and the NOE contacts between the geminal C_α-protons of glycine (with a fixed distance of 1.78 Å), the NOE cross-peak intensities were calibrated versus distances (35). The upper limits of the distances $d_{N\alpha}$ (i, i), $d_{\alpha N}$ (i, i + 1), and d_{NN} (i, i + 1) were smaller than 3.0, 3.6, and 4.5 Å, respectively. For the lower limit, the VDW radius of 1.8 Å was used. The calculated distances were multiplied by a factor of 1.1 in order to achieve upper limits and to correct for possible experimental errors. Pseudoatom corrections were applied for the methyl groups and not the stereospecific assigned prochiral groups (36). A total of 76 distance constraints comprising 42 intraresidual, 19 sequential, and 16 transannular were used in the structure calculation. In addition, two constraints for the disulfide $2.0 < S_i^\gamma - S_j^\gamma < 2.2$ Å, $2.8 < C^\beta_i - S_j^\gamma < 3.3$ Å and one constraint for head-to-tail cyclization (1.23 < N1-C10 < 1.50 Å) were included.

The 10% TFE–water (by vol.) sample has a peptide concentration of 12.6 mM at pH 4.2. DSS was added as an internal chemical shift reference. The 20 and 30% (by vol.) TFE–water solutions are obtained by adding appropriate amounts of TFE to the 10% TFE–water sample. Two TOCSY spectra were recorded in 10% TFE and 30% TFE, respectively, under similar conditions as above.

Structure calculations

Stereospecific assignments for the prochiral β-methylene groups were obtained with the program Habas based on 31 distance constraints and 19 vicinal interproton coupling constants (37). These, together with the allowed ranges for the ϕ, φ, and χ^1 dihedral angles and the distance constraints, were used in all structure calculations, which are performed with the program DIANA version 2.1 (38). Additional stereospecific assignments were obtained with the program GLOMSA (38), using the 20 conformers with the lowest target function from the first DIANA calculation. The new assignments together with the other data were subjected to a new DIANA calculation. A subset of the 30 conformers with the lowest target function was further optimized by simulated annealing (SA protocol) in the AMBER force field (39). All distance constraints and dihedral angles were enforced through the usual harmonic "pseudo" energy terms with force constants of 32 kcal mol^{-1} $Å^{-2}$ (40) and 100 kcal mol^{-1} rad^{-2} respectively (41). A Lennard–Jones potential and a distance dependent dielectric constant in the coulombic energy term were used throughout. The structures were first energy minimized in 150 iterations by steepest descent and 500 iterations by conjugate gradients followed by heating of the molecule to 1000 K in 2 ps and kept there during 18 ps. The time steps were always 1 fs. In eight steps, the molecule was cooled to 300 K (850, 750, 675, 600, 525, 425, and 375 K) and finally energy minimized by 500 iteration of steepest descent and 5000 iterations of conjugate gradients. The cutoff was always 13 Å except for the two last steps (15 Å). The SA protocol was executed with in InsightII/Discover (Insight II and Discover User Guide, version 3.0, Biosym Technologies, San Diego, 1995, and NMRchitect 95.0).

Results

Conformation of the peptides

The proton resonance signals for the synthetic decapeptides were assigned from a combination of DQF-COSY, TOCSY, ROESY, and NOESY spectra following the standard assignment procedure of Wüthrich (42). The individual spin system connectivities were traced in the DQF-COSY and TOCSY spectra, and the sequence specific assignments of the spin systems were obtained from NOESY and ROESY spectra.

In the case of cyclo-[IAYPGHDSPG] peptide No. 1m (Fig. 1), two isomers are present, more precisely, a *cis* and *trans* conformation of the peptide bond Ser8–Pro9 with a ratio of 30/70. The *trans* conformation is evidenced by the presence of the strong $d_{\alpha\delta}$ (Ser8, Pro9) contact and the absence of the $d_{\alpha\alpha}$ (Ser8, Pro9) contact, while *cis* conformation is supported by the strong $d_{\alpha\alpha}$ (Ser8, Pro9) contact and the absence of $d_{\alpha\delta}$ (Ser8, Pro9) contacts. The peptide bond Tyr3–Pro4 adopts exclusively a *trans* conformation. For both isomers, all the resonance signals were assigned and are on the NMR time scales in slow exchange with each other as established from the ROESY spectrum.

Since peptide No. 1m adopts two conformations, the bicyclic form of bicyclo-[ICYPGHCSPG] peptide No. 1b was tested (Fig. 1). The NMR results reveal a single structure with a (*trans*, *trans*) conformation of the Ser8–Pro9 and Tyr3–Pro4 peptide bond as evidenced by the strong sequential NOE contacts $d_{\alpha\delta}$ (Tyr3, Pro4) and $d_{\alpha\delta}$ (Ser8, Pro9). No other isomers are observed. Strong sequential $d_{\alpha N}$ NOE contacts reveal the extended structure of the template and the strong interstrand NOE contacts d_{NN} (Ile1, Ser8), $d_{N\alpha}$ (Ile1, Pro9), $d_{\alpha N}$ (Pro4, His6), and d_{NN} (Tyr3, His6) confirm the antiparallel β-sheet orientation (42–44). The close contact between the phenyl ring of Tyr3 and methyl group of Ile1 shows that the side chains are oriented to the same side of the template. The chemical shift temperature coefficient patterns for the interproton of peptide No.1b, No. 2b, and No. 3b are shown in Fig. 4. In the case of peptide No. 2b, the slightly positive temperature coefficient of Ser1 (1.26 ppb/K) and Lys6 (1.1 ppb/K) prove the existence of the hydrogen bonds between the amide protons and the carbonyl group of, respectively, Ser1-NH and Ile8-CO, Lys6-NH and Asn3-CO, which is a common feature in β-turns. The value of Asn3 (–4.01 ppb/K) and Ile8 (–4.2 ppb/K) indicates weak hydrogen bonds between the Asn3-NH and Lys6-CO, Ile8-NH and Ser1-CO. The data shows that the four NH protons were hydrogen bonded in the β-sheet. Similar hydrogen bonding patterns were observed in peptide No. 1b and No. 3b. Thus, in contrast to the result of Floegel and Mutter (13), we obtained a well-defined conformer despite their different amino acids constitution of the bicyclic template molecule.

The results of bicyclic templates (Nos. 1b–3b) reveal a single structure and that the Xxx-Pro-Gly-Xxx β-turn adopts exclusively *trans* conformation when the disulfide bridge is

presented. We further test the Val-Phe-Pro-Ala β-turn where the Phe–Pro peptide bond adopts *cis* conformation, as the type VI β-turn observed in *RS-AFP*1 (17). More than two conformers can be identified from 1D NMR spectra for the cyclo-[NYVFPAHKPG] peptide No. 4m. Two isomers can be identified from bicyclo-[NCVFPACKPG] peptide No. 4b. The peptide bond Phe4–Pro5 adopts both a *cis* and *trans* conformation, while the peptide bond Lys8–Pro9 adopts only a *trans* conformation. The ratio of the *cis* and *trans* conformation is about 50:50, as measured from the integration of the methyl groups of Val3 and Ala6 from both isomers in the 1D spectrum. The $d_{\alpha\alpha}$ (Phe4, Pro5) contact proves the presence of the *cis* conformation. The typical strong upfield shifts of the chemical shifts of Pro5 protons are consistent with a nearby aromatic ring of the side chain of Phe4, which stabilizes a type VI β-turn by hydrophobic interactions with Pro5 (14, 44–46). In contrast, for the *trans* isomer, the $d_{\alpha\delta}$ (Phe4, Pro5) contact is observed, and the upfield shift of 0.5 ppm for the methyl protons of Val3 indicates the aromatic ring current contact of Phe4, which is not observed for Pro5.

In conclusion, the Val-Phe-Pro-Ala β-turn adopts both conformations, even though the disulfide bridge is presented in peptide No. 4b, while the Xxx-Pro-Gly-Xxx β-turn adopts only a *trans* conformation when the disulfide bridge is presented. Since only peptides Nos. 1b, 2b, and 3b are presented as a single isomer and have also similar structural properties, further structure determination will be focused on peptide No. 2b.

Chemical shifts and $^3J_{HN\alpha}$ coupling constants for peptide No. 2b are shown in Table 1. The chemical shifts of the amide protons show a good dispersion, over a range of 1.8 ppm in DMSO and 1.3 ppm in TFE–water. No line broading effect was observed at different temperatures, indicative of the absence of conformational exchange on the NMR time scale. The prochiral C_α protons of Gly10 and Gly5 have a $\Delta\delta$ value of 0.7 and 0.3 ppm, indicating that the protons are not in the same environment. The relatively large $^3J_{HN\alpha}$ coupling constants of Cys2, Asn3, Cys7, and Ile8 indicate the β sheet conformation (Table 1). The $^3J_{HN\alpha}$ coupling constants of Ser1 and Lys6 have averaged values indicative for possible flexibility in the segments Asn3-Pro4-Gly5-Lys6 and Ile8-Pro9-Gly10-Ser1 where Ser1 and Lys6 are located at the end of the type II β-turn structure.

The α-proton Wishart Chemical Shift Index (CSI) is a fast and simple method for the preliminary assignment of protein secondary structure by NMR spectroscopy (47). The results of the α-proton chemical shift difference between the observed value and the typical random coil value are shown for different solvents in Fig. 5. The large downfield shifts of the α-protons of Cys2, Asn3, Cys7, and Ile8 are in agreement with a β-strand conformation. In comparison with the different solvents (DMSO, 10, 20, 30% TFE–water), the Wishard CSI does not change significantly, which proves that the conformation of the peptide is preserved in different solvents.

In conclusion, the NOE contacts, the $^3J_{HN\alpha}$ coupling constants, the hydrogen bonding pattern, and the chemical shifts of α-protons at different solvents proves that the synthesized decapeptide adopts a β-sheet conformation and two type II β-turns.

Solution structure of the peptide No. 2b

Using the program DIANA, 250 starting conformers were calculated with the following structural constraints: 71 interproton distances extracted from the NOE crosspeaks, 23 torsion angles from 19 vicinal coupling constants, and 5 distance constraints from disulfide bridge and ring closure. From the 150 structures with a final target function value

Table 2. Target function, residual violations on the constraints, energies and rmsd values for the 30 best DIANA structures and the 20 best structures after simulated annealing for peptide No. 2b.

Parameter	DIANA[a,b]	DIANA-SA[b,c]
Target function (Å^2)	(3.26 ± 2.90) × 10^{-5}	— [d]
Upper limit violations		
Number >0.2 Å	0	0
Number >0.1 Å	0.03 ± 0.18	0.60 ± 0.68
Sum of violations (Å)	0.12 ± 0.07	0.40 ± 0.07
Maximum violation (Å)	0.06 ± 0.03	0.10 ± 0.01
Lower limit violation	0	0
Dihedral angle violations		
Number >5°	0	0
Sum of violations (°)	0.20 ± 0.64	2.18 ± 0.88
Maximum violation (°)	0.20 ± 0.64	0.99 ± 0.43
AMBER energy (kcal mol^{-1})		
Bond energy	78.57 ± 4.17	2.29 ± 0.21
Valence angle energy	30.08 ± 5.50	16.86 ± 1.53
Improper energy	57.70 ± 7.33	19.08 ± 1.42
van der Waals energy	23.67 ± 5.57	–8.60 ± 1.08
Electrostatic energy	–55.59 ± 4.34	–96.41 ± 4.61
Total energy	133.66 ± 16.83	–69.85 ± 4.52
rmsd value (Å)		
Backbone atoms	0.34 ± 0.10	0.51 ± 0.16
All atoms	1.40 ± 0.36	1.46 ± 0.53

[a]The structures after the final DIANA calculation.

[b]The given numbers are the mean ± standard deviation. The rmsd values are the average pairwise rmsd taken over all structure pairs.

[c]The structures after simulated annealing.

[d]The target function is not defined for the simulated annealing structures, since they do not have the standard ECEPP geometry any more.

smaller than 0.1 Å^2, only 30 best structures were selected. None of these structures exhibited violation of experimental distance constraints by more than 0.2 Å, and for torsional angle constraints, more than 5°. The good convergence of the structures was clear from the small rmsd value, (0.34 ± 0.10 Å) for the backbone atoms and (1.40 ± 0.36 Å) for all atoms. After the energy optimization by SA, none of the structures exhibited large violation of the experimental data (distance constraints by more than 0.2 Å and torsional angle constraints more than 5°). The selection of the 20 solution SA structures (Fig. 6) is based on the values of the total energies. From the statistical analysis of the DIANA and DIANA/SA final structures (Table 2), it is clear that the SA structures gave substantial improvement of the van der Waals energy, which on average drops by 33.27 kcal mol^{-1}, and more important, is going from a positive to a negative value. Also, the electrostatic contribution to the energy decreases by 40.82 kcal mol^{-1}, showing that the distribution of

[b]Not observable.

Fig. 7. Ramachandran plot of the 20 SA structures of peptide No. 2b. (■) Gly5 and Gly10; (▲) Pro4 and Por9; (◆) Ser1, Cys2, Asn3, Lys6, Cys7, and Ile8.

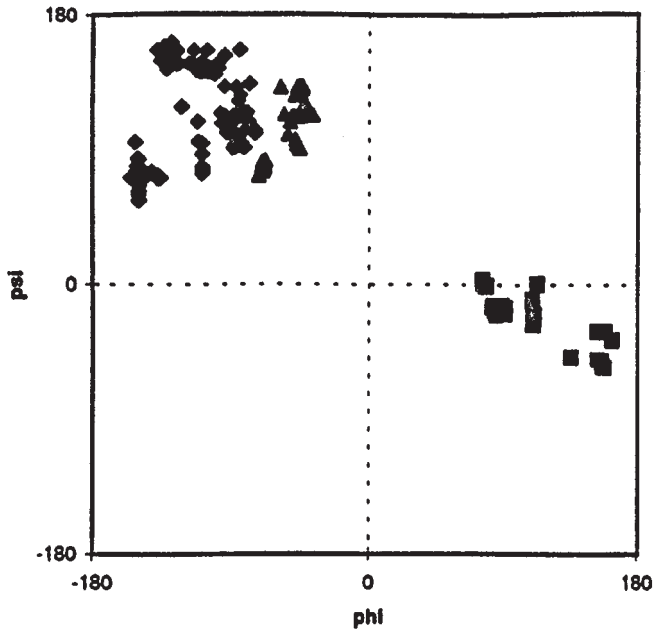

Fig. 8. Average rmsd deviations for each residue over the 20 SA structures to the average structure. (◆) backbone atoms; (■) all atoms.

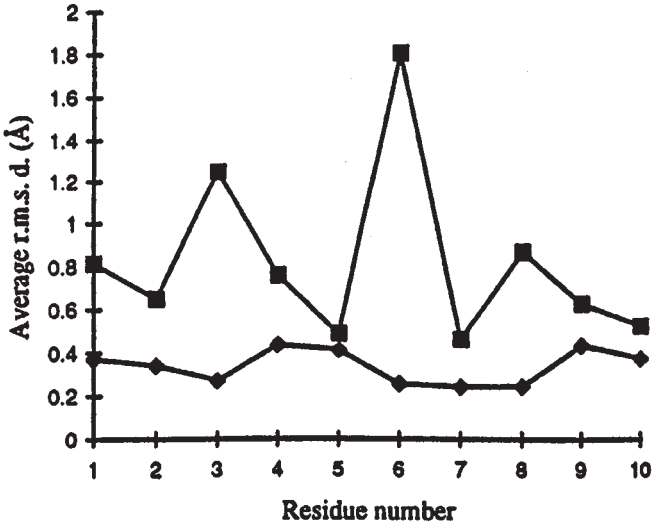

the charges in the conformer is significantly improved. The decrease of the bond energies, valence angle energy, and improper energy were achieved without a significant increase of the residual violations of the experimental constraints as compared with the DIANA conformers. More remarkably, the geometry of most hydrogen bonds in the individual structures was improved as a result of the electrostatic term in the force field. Finally, the narrow range of the rmsd values (0.51 ± 0.16 Å for the backbone atoms and 1.46 ± 0.53 Å for all atoms) implies that the obtained solution structures are identical so as to be in a single family.

The Ramanchandran plot for all the residues in the 20 refined conformers (Fig. 7) (48) clearly indicates the overall quality, and gives an impression of the main structural elements presented in the peptide. These are an antiparallel β-sheet conformation with β-strand I: Ser1-Cys2-Asn3 and β-strand II: Lys6-Cys7-Ile8, two β-turns centered around residues Pro4-Gly5 and Pro9-Gly10. This is clearly dictated by the central Cys2–Cys7 disulfide bridge.

The ϕ, φ values of Ser1, Cys2, Asn3, Lys6, Cys7, Ile8 clearly falls into the antiparallel β-sheet region with 53% in the most favored regions and 47% in the additional allowed regions (the Ramanchandran plot, data not shown) (48). Hydrogen bonds between Ser1-NH and Ile8-CO, Asn3-NH and Lys6-CO, Lys6-NH and Asn3-CO, Ile8-NH and Ser1-CO were identified in the solution structures using the criteria that the distance between the donor hydrogen and the acceptor oxygen must be less that 2.5 Å and that the angle between the donor–proton, donor atom, and the acceptor atom must be larger than 155°. These hydrogen bonds are in agreement with the small chemical shift temperature coefficient and the reduced amide exchange rates and confirm the interstrand hydrogen bonds of antiparallel β-sheet conformation (Table 3). The ϕ, φ values of the prolyl residues are in the region of (–70, –40) for ϕ angles and (70, 130) for φ angles; and the ϕ, φ values of the glycyl residues are in the region of (60, 175) for ϕ angles and (–50, 0) for φ angles. These values are characteristic for type-II β-turn. Hydrogen bonds between Ser1-NH and Ile8-CO, Asn3-NH and Lys6-CO are characteristic features of 1← 4 hydrogen bonding in the β-turn.

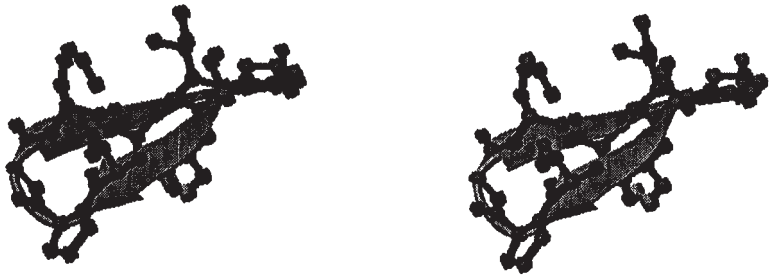
Fig. 9. Stereoview of the average of the 20 SA structures (heavy atoms). The ribbon is generated with MolMol (49).



The average rmsd value for each residue in the 20 SA structures is shown in Fig. 8. It is clear that the backbone from Ser1 to Asn3 and from Lys6 to Ile8, which is a β-sheet region, is better defined than the segment of Pro4-Gly5 and Pro9-Gly10, which are the central residues of the β-turn. The large rmsd value for all atoms of Ser1, Asn3, Lys6, and Ile8 indicate the side chain of these residues are ill defined, and they are all solvent exposed.

In conclusion, the solution structure of the decapeptide bicyclo-[SCNPGKCIPG] consists of an antiparallel β-sheet with dimensions of ~13 Å for the extension of the β-strands and ~4 Å for the interstrand distance. Strand I extends from Ser1 to Asn3 and is followed by the type II β-turn around Pro4 and Gly5. Strand II runs from Lys6 to Ile8 and is followed by the other type II β-turn around Pro9 and Gly10 to make the ring closure of the peptide. The stereoview of the average of the final best 20 SA-refined structures is shown in Fig. 9. It is clearly that the side chain of Ser1, Asn3, Lys6, and Ile8 extends one side of the template, while the disulfide bridge is formed from the other side. The conformation of this bicyclic template molecule is devoid of different amino acids constitutions and reserves a rigid core central scaffold. The orientation of the side chain functional groups has been rigorously determined. The solution structure of these decapeptides presents an excellent model for orthogonal protected template bicyclo-[KCKPGKCKPG]. Cyclic peptide templates containing four orthogonal protecting groups have been already used as scaffolds for preparation of chemical libraries with a positional scanning format (9). In the area of de novo protein design, the different peptides building blocks can be attached and oriented to the template and give rise to different types of TASP molecule (3). Ongoing efforts in the group are focused to the solution synthesis of the template molecule and anchor it to the solid phase for the application of protein de novo design and combinatorial chemistry.

Determination of trace silicon in zirconium matrices and steels by inductively coupled plasma – atomic emission spectrometry

Kwang-Soon Choi, Kih-Soo Joe, Steven L. Mitchell, Candace J. Everall, and Keith R. Betty

Abstract: The determination of trace silicon by inductively coupled plasma – atomic emission spectrometry in samples containing HF is inhibited by the high blank caused by attack of the quartz torch. Use of a proprietary commercial amine to neutralize the HF and increase the pH to between 7 and 7.5 allows the simultaneous determination of silicon and other impurities in zirconium or zircaloy samples. The determination of silicon in steels requires the addition of an auxiliary complexing agent to the amine solution to prevent precipitation of iron(III). The analytical results obtained for several Standard Reference Materials (SRMs) with and without the amine reagent agree well with one another, and also with the certified values.

Key words: silicon, zirconium, zirconium alloys, steel, amine neutralization.

Résumé : La détermination de traces de silicium, par spectrométrie d'émission à plasma atomique couplé de façon inductive, dans des échantillons contenant du HF est inhibée par la valeur élevée du blanc causée par l'attaque de la torche de quartz. L'utilisation d'une amine commerciale de formule déposée permet de neutraliser le HF, d'augmenter le pH à des valeurs variant de 7,0 à 7,5 et de déterminer de façon simultanée le silicium et les autres impuretés contenues dans le zirconium ou dans des échantillons de zircaloy. La détermination du silicium dans les aciers nécessite l'addition d'un agent complexant auxiliaire à la solution d'amine afin de prévenir la précipitation du fer(III). Les résultats analytiques obtenus pour plusieurs matériaux de référence standard (MRS), avec et sans amine, sont en bon accord les uns avec les autres ainsi qu'avec les valeurs certifiées.

Mots clés : silicium, zirconium, alliages de zirconium, acier, amine, neutralisation.

Silicon is a minor or trace constituent of many alloys, and its determination is often necessary to ensure that the alloy specifications are met. Zirconium metal and zircaloy (an alloy of zirconium and tin) are used in the nuclear industry for fuel cladding, and in the CANDU®[2] reactors, a Zr – 2.5% Nb alloy is used for pressure tubes. The levels of trace impurities in Zr metal and its alloys are closely controlled to ensure they meet the specification values. The analysis of zirconium metals and alloys is often performed by Inductively Coupled Plasma – Atomic Emission spectrometry (ICP–AES) (1, 2). These alloys must be dissolved with the aid of HF, which has been reported to cause high and irreproducible silicon blanks and memory effects (3) when ICP–AES is used for silicon determinations, even when an "HF-resistant" torch, nebulizer, and spray chamber are used. We also were not able to obtain acceptable results for silicon with a commercial "HF-resistant" torch, but these blanks can be reduced by neutralizing the solution with tertiary amines (3) or with the addition of ammonia and an auxiliary complexing agent (4) prior to analysis. Although the determination of silicon in zirconium can also be performed colorimetrically with molybdenum blue (5), the procedure is very technique dependent. We have also encountered a low bias in the determination of silicon in steels with aqua regia dissolution using the procedure of Ward and Marciello (6) unless HF is added to the solutions. We have investigated the use of a new commercial amine neutralization reagent for the determination of silicon and other impurities in zirconium and zirconium alloys, and for the determination of trace silicon in stainless steel.

Experimental

Apparatus

Measurements were performed on an ARL 3520B ICP spectrometer using the operating conditions given in Table 1. A mass flow controller (Model FC-2805, Tylan General) was used to control nebulizer gas flow rate. A two-head

Table 1. Operating conditions for the ARL 3520B spectrometer.

System	Sequential type
Focal length	1 m
Mounting	Paschen–Runge
Grating	1080 grooves mm^{-1}
Light path	Vacuum
Slits	Entrance slit 20 μm
	Exit slit 20 μm
Torch	Fassel type
Nebulizer	Perkin–Elmer conespray
Spray chamber	Quartz, Scott type
Outer gas flow	12 L min^{-1}
Intermediate gas flow	0.8 L min^{-1}
Injector gas flow	1 L min^{-1}
Sample uptake rate	2 mL min^{-1}
Incident power	1200 W
Integration time	3 × 5 s
Observation height	15 mm above load coil

peristaltic pump (Gilson Minipuls 2) was used both for sample uptake and to pump the spray chamber drain. Plastic laboratory ware was used to avoid silicon contamination from glassware.

Reagents

All the reagents were of analytical reagent grade and were used without further purification. Nitric acid, hydrofluoric acid, and ammonium hydroxide were obtained from J.T. Baker (Phillipsburg, N.J., U.S.A.). A proprietary mixture of water-soluble amines ("amine reagent," Unisolve UNS-100, Inorganic Ventures, Lakewood, N.J., U.S.A.) was used to neutralize the HF. Zirconium oxychloride octahydrate, $ZrOCl_2 \cdot 8H_2O$, was obtained from Teledyne Wah Chang Albany (Albany, Oreg., U.S.A.) for use in matrix-matched zirconium standards. Tartaric acid was obtained from Aldrich (Milwaukee, Wisc.), citric and oxalic acids from Anachemia (Montreal, Canada), and EDTA (disodium salt of ethylenediamine tetraacetic acid) was obtained from Sigma (St. Louis, Mo.). Standard 1000 mg/L stock solutions were obtained from Spex (Edison, N.J.), Plasmachem (Farmingdale, N.J.), Inorganic Ventures (Lakewood, N.J.) and High Purity Standards (Charleston, S.C.). Zirconium and zircaloy Standard Reference Materials (SRMs) 360a, 360b, and 1234–1239, and steel SRMs 8j, 36a, and 101f were obtained from the National Institute of Standards and Technology (Gaithersburg, Md., U.S.A.). Zircaloy Certified Reference Materials Z11, Z12, Z21, Z22, and Z23 were obtained from the Japan Atomic Energy Research Institute (JAERI, Tokai-mura, Ibaraki-ken, Japan).

Sample dissolution

Zirconium and zircaloy

Place a known amount of sample (0.5 g) into a PTFE beaker. Add 10 mL of distilled deionized water (DDW) and 2 mL of concentrated nitric acid. Carefully add 0.5 mL of 48% hydrofluoric acid. Swirl gently to mix and cover with a PTFE watch glass. After cooling add three additional increments of 0.5 mL of 48% hydrofluoric acid at 30 min intervals, swirling after each addition. Quantitatively transfer the sample into a 50 mL plastic volumetric flask and add 0.25 mL of 1000 ppm of scandium stock solution as an internal standard (preliminary experiments showed that Sc gave better results as an internal standard than did Zr). Add 12.5 mL of Unisolve UNS-100 UHC amine reagent and swirl to mix. Let cool to room temperature and dilute to the mark with DDW. Mix and let cool.

Steel

Place a known amount of sample (0.2 g) into a PTFE beaker. Add 9.5 mL of 24% (v/v) aqua regia and wait for the reaction to subside. Cover with a PTFE watch glass. Place on a hot plate and boil for 20–30 min. Let cool to room temperature. Add 0.5 mL of 48% HF and let stand overnight. Quantitatively transfer the sample into a 200 mL plastic volumetric flask. Add 4 mL of 1 M tartaric, citric, or oxalic acid, or 40 mL of 0.1 M EDTA. Add 40 mL of 25% v/v UNS-100 UHC amine reagent and swirl to mix. Let cool to room temperature and dilute to the mark with DDW. Mix and let cool.

Standard preparation

Zirconium

Matrix matching of standards is desirable during analysis of zirconium to compensate for spectral interferences and background shifts (1, 2). Zirconium standard solutions were matrix-matched at a final concentration of 10 g/L Zr. Although zirconium samples containing 1–2% Sn were stable in solution for several weeks, it was found that Sn in the standards was not stable in the presence of HF for more than a few days. Since the nominal concentrations of HF are identical in the samples and standards, it is believed that HF is sparged from the samples by the copious amounts of hydrogen released during their dissolution. To eliminate this problem of instability of the standards, two different stock solutions were made as follows: (*i*) To matrix-match the standards for the determination of all elements except Sn, to a 1000 mL plastic volumetric flask add 70.74 g of $ZrOCl_2 \cdot 8H_2O$, 40 mL of concentrated HNO_3 and 75 mL of 48% HF. Make to volume with DDW and mix. (*ii*) For matrix-matching the Sn standards, to a 100 mL volumetric flask add 7.074 g of $ZrOCl_2 \cdot 8H_2O$ and 17.5 mL of concentrated HNO_3. Make to volume with DDW and mix.

Standards were prepared by adding the appropriate amount of 1000 ppm stock solution, 25 mL of matrix-matching solution, 0.25 mL of 1000 mg/L Sc, and 12.5 mL of amine to a 50 mL plastic volumetric flask. The amount of nitric acid added to the standards was reduced from that added to the samples to account for the acid consumed during sample dissolution.

Steel

Silicon standards for steel analysis were matrix-matched to contain the same amount of amine and complexing agent as the samples. The pH was adjusted to between 7 and 7.5 with NH_4OH.

Line selection

The complex spectrum of zirconium causes considerable difficulties in selecting emission lines for the determination of impurities (1). Additional problems were encountered in

this work because of band spectra produced by the amine, which inhibit line selection at wavelengths below 200 nm. The wavelengths found to be free of interferences or problems and thus used in these analyses are listed in Table 2.

Results and discussion

Zirconium

Although Steffan and Vujicic (1) used a zirconium concentration of 20 g/L for zirconium analysis, we found that this zirconium level clogs the torch injector tube after several hours of operation. We therefore adopted a zirconium concentration of 10 g/L for this work. A rinse solution of 0.1% NH_4OH was found to give a lower silicon blank than did a DDW rinse. Method Detection Limits (MDLs) in µg/g solids basis with and without amine reagent are given in Table 2. For elements other than Cr, Fe, and Sn, the MDLs were calculated as three times the standard deviation determined from the dissolution and measurement of 13 SRM 360b samples. The MDLs for Cr, Fe, and Sn, which are present in significant quantities in SRM 360b, were calculated as three times the standard deviation determined from the measurement of 18 processed reagent blank solutions containing 10 g/L Zr and 25% v/v of amine reagent. This procedure for estimating MDLs may underestimate the detection limits that can be achieved in practice, but is in accord with common practice. The addition of amine causes a loss in sensitivity of approximately 40%, resulting in generally higher detection limits. The presence of Na in the amine substantially raises its detection limit. The detection limit for P is raised by spectral interference from the amine.

The results must be corrected for residual impurities in the zirconium used for matrix matching the standards. The only significant known impurity, based on the certificate obtained from the manufacturer, is hafnium. The hafnium content of the $ZrOCl_2 \cdot 8H_2O$ as determined by ICP–AES was calculated to be the difference between the measured ICP–AES values and the certified hafnium values for SRMs 1234–1239 and CRMs Z11 and Z12. The hafnium result for SRM 360b was not included as part of this calculation because of a higher uncertainty in its certified hafnium concentration. The hafnium values for the other SRMs and CRMs are shown in Table 3, and agree well with values obtained by neutron activation analysis (NAA) and inductively coupled plasma – mass spectrometry (ICP–MS) determinations.

The results of analysis of SRMs and CRMs are given in Tables 4 and 5. The relative standard deviation (RSD) of Ni in JAERI-Z21 and JAERI-Z23 is high because the value is very close to the MDL. For the determination of all other elements certified in the SRMs and CRMs, the RSDs vary from 0.4% for Fe in the SRM 360a to 13% for Hf in the JAERI-Z22. The RSD depends on the concentrations and elements. The analytical results obtained with and without the amine reagent agree well with one another, and also with the certified values.

for masking this precipitation were tested. Oxalic acid did not inhibit the precipitation reaction. Although tartaric acid, citric acid, and EDTA all inhibit precipitation, the lower solubility of the EDTA and the slow rate of formation of the iron–EDTA complex make its use inferior. The MDLs were determined as three times the standard deviation of a set of seven processed reagent blank solutions, and are included in Table 2. Results of silicon determinations in steel SRMs

with amine neutralization and with tartaric or citric acid masking are shown in Table 6. The results are in excellent agreement with each other and with the certified values.

Conclusions

The use of a commercial high-capacity amine reagent to raise the pH allows the determination of silicon in zirconium and zircaloy standards by ICP–AES with a quartz spray chamber and torch, thus allowing replacement of the time consuming colorimetric procedure. Several other impurities can also be determined with no significant bias observed between the results with and without the amine procedure. However, the presence of sodium in the amine substantially raises the detection limit for Na, and spectral interference from the amine significantly raises the detection limits for phosphorous. Use of the amine reagent prior to the determination of silicon in stainless steels by ICP–AES requires an auxiliary complexing agent. Either tartaric or citric acid was found suitable.

Acknowledgments

The assistance of M.M. Totland, P.A. Robinson, and R. Ryan for NAA and ICP–MS determinations, and of K. Watanabe of JAERI in supplying CRMs Z21, Z22, and Z23, is gratefully acknowledged.

A versatile approach to the synthesis of oligonucleotide analogs containing neutral 5′-thioformacetal internucleoside linkages

Yves Ducharme and Kimberly A. Harrison

Abstract: Activation of nucleoside donors **5** by sulfuryl chloride followed by the addition of 5′-thionucleoside acceptors **3** yields 5′-thioformacetal dinucleotide analogs **6** with in situ trapping of liberated methanesulfenyl chloride with cyclohexene. Purine as well as pyrimidine derivatives can be part of a coupling reaction as nucleoside donors or acceptors. The dimethoxytrityl protecting group is compatible with the present coupling methodology allowing differential 3′,5′-end protection. The synthesis of longer oligonucleotides is also possible as shown by the preparation of trinucleotide analog **23**.

Key words: oligonucleotides, 5′-thioformacetal.

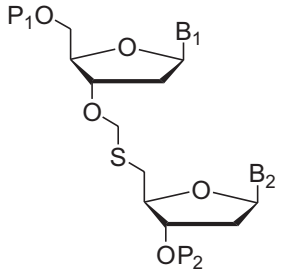
Résumé : L'activation de donneurs nucléosides (**5**) à l'aide de chlorure de sulfuryle, suivie d'une addition d'accepteurs 5′-thionucléosides (**3**), conduit aux analogues dinucléotide 5′-thioformacétal (**6**) avec piégeage in situ du chlorure de méthanesulfényle libéré à l'aide de cyclohexène. Les dérivés de la purine aussi bien que ceux de la pyrimidine peuvent faire partie d'une réaction de couplage comme nucléosides donneurs ou accepteurs. Le groupe protecteur diméthoxytrityle est compatible avec la présente méthodologie de couplage ce qui permet une protection différentielle des extrémités 3′ et 5′. La synthèse d'oligonucléotides plus longs est aussi possible comme on l'a démontré par la préparation de l'analogue trinucléotide **23**.

Mots clés : oligonucléotide, 5′-thioformacétal.

[Traduit par la Rédaction]

Introduction

In view of their potential use as antisense agents (1), numerous efforts have recently been devoted to the synthesis of oligonucleotide analogs with modified backbones (2). In the course of our study on the molecular recognition properties of oligonucleotide analogs, we required access to a variety of dinucleotide derivatives **1** containing a neutral 5′-thioformacetal internucleoside linkage, acid labile protecting groups P_1 and P_2, and where the nucleic bases B_1 and B_2 would be indiscriminately thymine, cytosine, guanine, or adenine.



1

The only previous synthesis of a 5′-thioformacetal dinucleotide analog was reported by Matteucci et al. (3*a*) who have prepared dimer **4** by activating nucleoside donor **2** with molecular bromine followed by the addition of nucleoside acceptor **3t** (Scheme 1). While this method is very useful for the coupling of nucleoside derivatives bearing pyrimidine bases, it is inefficient for the preparation of dinucleotide analogs containing purine bases. We now report an efficient and versatile method for the synthesis of 5′-thioformacetal oligonucleotide analogs containing purine as well as pyrimidine nucleic bases (part of this work was published as a communication: see ref. 3*b*).

Results and discussion

The methylthiomethyl ether function found in nucleoside donor **2** is known to be transformed into a α-chloromethyl ether upon treatment with sulfuryl chloride (4). A previous report (5) on the use of this reaction in the context of nucleic acid chemistry suggested to us its potential utility for the synthesis of 5′-thioformacetal dinucleotide analogs. In a preliminary experiment, the coupling of nucleoside donor **5a**, a purine derivative, with nucleoside acceptor **3t** by sulfuryl chloride activation was attempted (Scheme 2). Thus, treatment of 2′-deoxyadenosine derivative **5a** with sulfuryl chloride (1.1 equiv.) in the presence of *N*,*N*-diisopropylethylamine (1.1 equiv.) for 10 min followed by the ad-

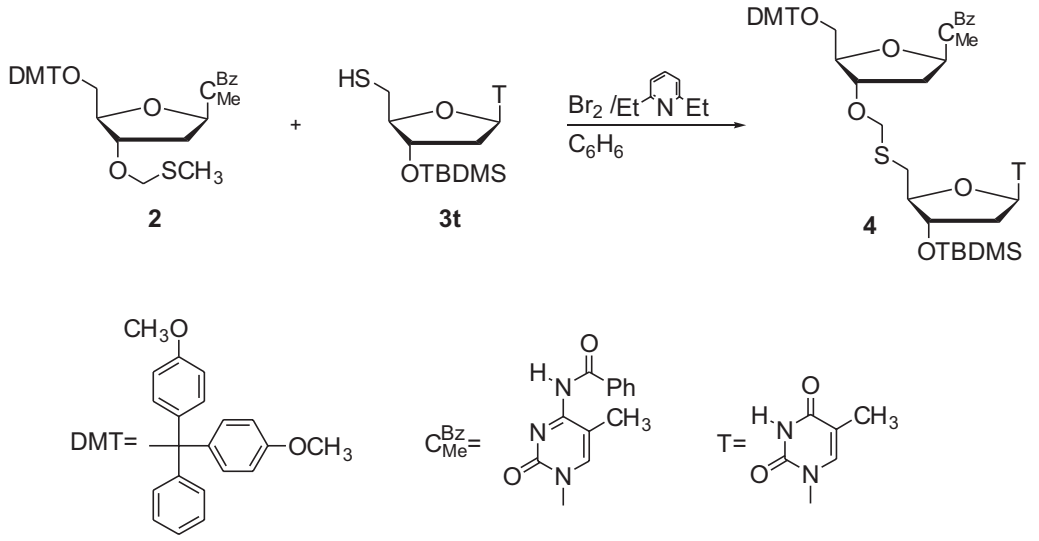
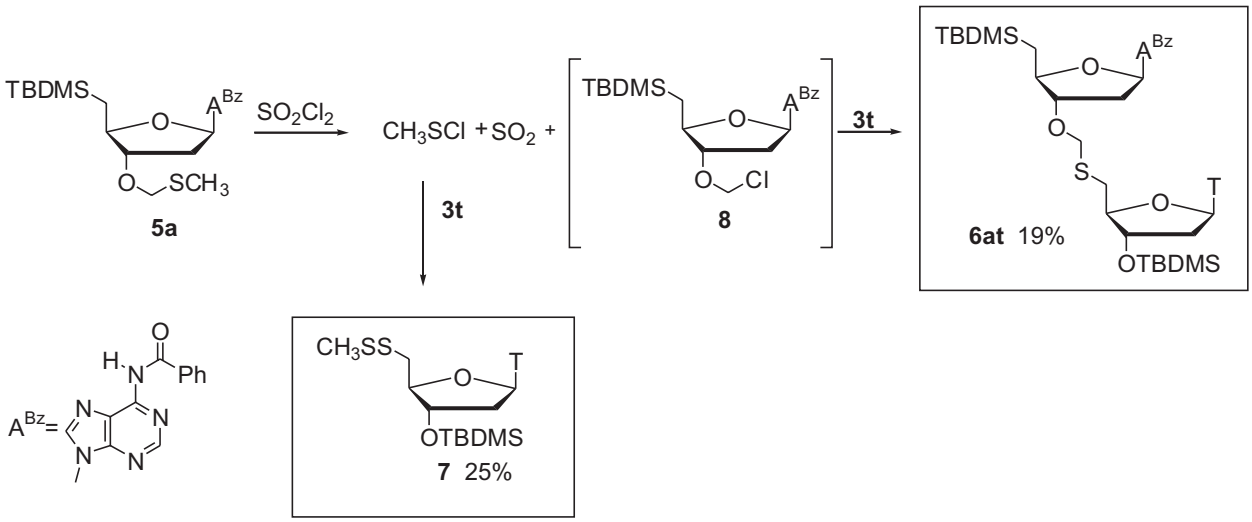
Scheme 1.



Scheme 2.



dition of 5′-thiothymidine (**3t**) (1.0 equiv.) and *N*,*N*-diisopropylethylamine (1.1 equiv.) afforded the desired dinucleotide analog **6at** albeit in a low 19% yield. A careful analysis of the reaction mixture revealed the presence of asymmetric methyl disulfide **7** (25%). The formation of this unwanted disulfide results from the liberation of highly electrophilic methanesulfenyl chloride upon reaction of methylthiomethyl ether **5a** with sulfuryl chloride. Reaction of mercaptan **3t** with methanesulfenyl chloride forms disulfide **7**. The yield of desired dinucleotide analog **6at** is greatly improved by trapping the liberated methanesulfenyl chloride with cyclohexene (4*a*) prior to the addition of nucleoside acceptor **3t**. In a typical reaction, sulfuryl chloride (1.3 equiv.) is added dropwise to a 0°C mixture of nucleoside donor **5a** (1 equiv.), *N*,*N*-diisopropylethylamine (1.4 equiv.), and 3 Å molecular sieves in dichloromethane. After 2 min, cyclohexene (2 equiv.) is added, and the reaction mixture is allowed to reach room temperature. Ten minutes later, a solution of nucleoside acceptor **3t** (1.3 equiv.) and *N*,*N*-diisopropylethylamine (1.4 equiv.) in dichloromethane is added, and the reaction mixture is stirred under nitrogen for 3 h. After an aqueous work-up and a purification by flash chromatography, the desired dinucleotide analog **6at** is obtained in 68% yield. The versatility of the method is demonstrated by the results presented in Table 1. Purine as well as pyrimidine derivatives can be part of a coupling reaction as nucleoside donors **5** or acceptors **3**. 5′-Thioformacetal dinucleotide analogs containing two purines such as **6aa** and **6ag** are easily obtained.

The required nucleoside donors and acceptors were prepared in the following ways. A Pummerer reaction (6) on N^6-benzoyl-5′-*O*-*tert*-butyldimethylsilyl-2′-deoxyadenosine (**9**) (7) gave access to donor **5a** (Scheme 3). Nucleoside donor **5t** was prepared by the alkylation of 5′-*O*-*tert*-butyldimethylsilylthymidine (**10**) (7) with chloromethyl methyl sulfide. The four nucleoside acceptors **3a**, **3c**, **3g**, and **3t** were prepared by the method of Kawai et al. (8) (Table 2). Mitsunobu coupling of suitably base-protected deoxynucleosides **11** (9) with thiolacetic acid afforded the 5′-*S*-acetyl nucleoside derivatives **12**. Silylation of the sec-

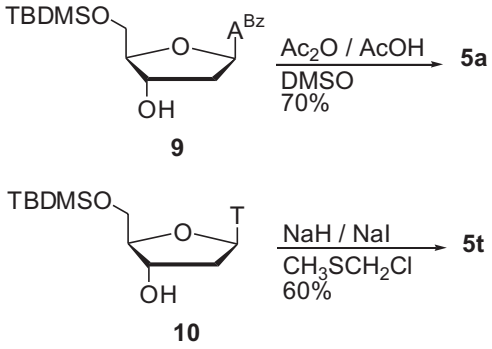
ondary alcohols with *tert*-butyldimethylsilyl chloride gave fully protected nucleosides **13**. Methanolysis of the thioesters finally provided the desired nucleoside acceptors **3**.

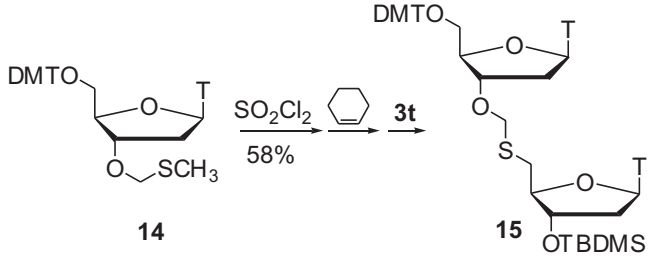
The dimethoxytrityl protecting group is compatible with the present coupling methodology as shown by the coupling of donor **14** (10) with acceptor **3t** to afford 3′,5′ differentially protected dinucleotide analog **15** in 58% yield (Scheme 4).

The synthesis of longer oligonucleotides is also possible as shown by the preparation of trinucleotide analog **23**

Scheme 3.



Scheme 4.



(Scheme 5). The 5′-dimethoxytrityl protecting group of thymidine derivative **14** (10) was selectively removed by treatment with *p*-toluenesulfonic acid in 85% yield. Mitsunobu coupling of the resulting primary alcohol **16** with thiolacetic acid gave thioester **17** (96% yield). This nucleoside donor was activated by sulfuryl chloride to be coupled with acceptor **3a** and thus provided dinucleotide an-

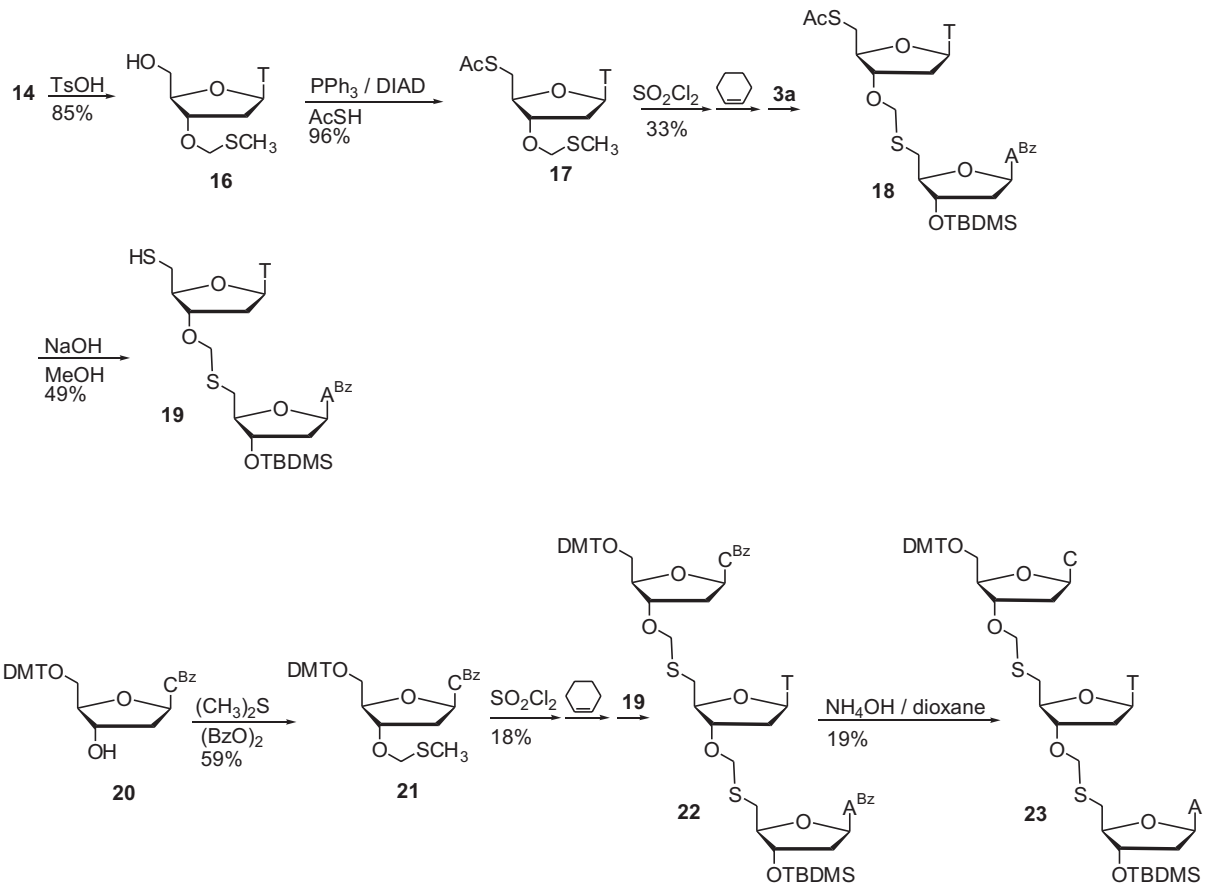
Scheme 5.



alog **18** in 33% yield. Methanolysis of the 5′-thioacetate group (50% yield) provided dinucleotide acceptor **19**. The 5′-dimethoxytrityl protected cytidine donor **21** was prepared by the treatment of secondary alcohol **20** (9) with dimethyl sulfide and benzoyl peroxide (11) in 59% yield. Sulfuryl chloride promoted coupling of donor **21** with dinucleotide acceptor **19**, then afforded trinucleotide analog **22** in 18% yield. Since the 3′ and 5′ terminus of trimer **22** are conveniently protected with acid labile *tert*-butyldimethylsilyl and dimethoxytrityl groups, it was possible to selectively liberate the benzoylated nucleic bases with aqueous ammonia to afford 5′-thioformacetal trinucleotide **23** in 19% yield.

Conclusions

A versatile methodology for the synthesis of oligonucleotide analogs containing 5′-thioformacetal internucleoside linkages has been developed. The 5′-thioformacetal link is formed by the activation of nucleoside donors bearing a 3′-methylthiomethyl ether moiety by sulfuryl chloride followed by the addition of 5′-thionucleoside acceptors with in situ trapping of liberated methanesulfenyl chloride by cyclohexene. Using this methodology, purine as well as pyrimidine derivatives can be part of a coupling reaction as nucleoside donors and acceptors. The dimethoxytrityl protecting group is compatible with the present methodology, allowing differential 3′,5′-end protection. The synthesis of longer oligonucleotides is possible as shown by the preparation of trinucleotide analog **23**.

Experimental section

General

Proton NMR spectra were recorded on Varian Gemini 200, Bruker AMX 300, or Bruker ARX 400 spectrometers, and proton chemical shifts are relative to tetramethylsilane as internal standard. Carbon NMR spectra were recorded on a Bruker AMX 400 spectrometer, and chemical shifts are relative to residual solvent signals. Low-resolution mass spectra were recorded by Oneida Research Services, Whitesboro, N.Y. High-resolution mass spectra were recorded by the Biomedical Mass Spectrometry Unit of McGill University, Montreal.[3]

[3] Copies of ^{1}H NMR spectra of compounds **3**, **5**, **6**, **12**, **13**, **15**–**19** and **21**–**23** (27 pages) have been deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

Preparation of nucleoside acceptors 3

Step 1

5′-S-*Acetyl*-N^6-*benzoyl-2′,5′-dideoxy-5′-thioadenosine* ***(12a)***: Diisopropyl azodicarboxylate (7.4 mL, 37.6 mmol) was added to a 0°C solution of triphenylphosphine (9.85 g, 37.6 mmol) in THF (70 mL). The mixture was stirred for 30 min at 0°C. *N*^{6}-Benzoyl-2′-deoxyadenosine (9) (**11a**) (7.0 g, 19.7 mmol), THF (40 mL), and thiolacetic acid (2.7 mL, 37.8 mmol) were consecutively added, and the reaction mixture was stirred for 30 min at 0°C and 90 min at room temperature. The volatiles were then evaporated, and flash chromatography of the residue (silica gel; dichloromethane/methanol (90/10)) afforded thioester **12a** (6.2 g, 76%) as a colorless gum: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.35 (s, 3H), 2.60 (m, 1H), 2.95 (m, 1H), 3.30 (m, 2H), 4.15 (m, 1H), 4.50 (m, 1H), 6.45 (t, 1H), 7.50 (m, 2H), 7.60 (m, 1H), 8.05 (m, 2H), 8.20 (s, 1H), 8.80 (s, 1H), 9.15 (s, 1H); MS (CI): 414 (MH^+), 240.

5′-S-*Acetyl*-N^4*-benzoyl-2′,5′-dideoxy-5′-thiocytidine* ***(12c)***: The procedure used to prepare thioester **12a** applied to *N*^{4}-benzoyl-2′-deoxycytidine (**11c**) (9) gave thioester **12c** (41%) as a white solid: ^{1}H NMR (200 MHz, CD_3OD) δ: 2.25 (m, 1H), 2.40 (s, 3H), 2.55 (m, 1H), 3.30 (m, 2H), 4.10 (m, 1H), 4.25 (m, 1H), 6.20 (t, 1H), 7.60 (m, 6H), 8.00 (d, 1H), 8.30 (d, 1H).

5′-S-*Acetyl*-N^2*-isobutyryl-2′,5′-dideoxy-5′-thioguanosine* ***(12g)***: The procedure used to prepare thioester **12a** applied to *N*^{2}-isobutyryl-2′-deoxyguanosine (9) (**11g**) gave thioester **12g** (94%) as a white solid: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.25 (d, 6H), 2.35 (s, 3H), 2.50 (m, 1H), 2.85 (m, 2H), 3.10 (m, 1H), 3.50 (m, 1H), 4.10 (m, 1H), 4.30 (bs, 1H), 4.65 (m, 1H), 6.20 (t, 1H), 7.85 (s, 1H).

5′-S-*Acetyl-5′-deoxy-5′-thiothymidine* ***(12t)*** *(8)*: The procedure used to prepare thioester **12a** applied to thymidine (**11t**) gave thioester **12t** (8) (42%) as a white solid. This compound showed spectroscopic properties identical to those published in the literature (8).

Step 2

5′-S-*Acetyl*-N^6*-benzoyl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thioadenosine* ***(13a)***: A solution of alcohol **12a** (5.80 g, 14.0 mmol), imidazole (4.03 g, 59.2 mmol), and *tert*-butyldimethylsilyl chloride (6.09 g, 40.4 mmol) in DMF (80 mL) was stirred at room temperature for 20 h before EtOAc (1000 mL) was added. The organic phase was washed with water (3 × 500 mL) and brine, dried ($MgSO_4$), and evaporated. Flash chromatography of the residue (silica gel; hexane/EtOAc (50:50)) afforded compound **13a** (6.68 g, 91%) as a white solid: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.15 (d, 6H), 0.95 (s, 9H), 2.35 (s, 3H), 2.45 (m, 1H), 3.00 (m, 1H), 3.25 (dd, 1H), 3.35 (dd, 1H), 4.10 (m, 1H), 4.50 (m, 1H), 6.45 (t, 1H), 7.55 (m, 2H), 7.60 (m, 1H), 8.05 (d, 2H), 8.20 (s, 1H), 8.80 (s, 1H), 9.20 (s, 1H); MS (CI): 528 (MH^+), 289, 240.

5′-S-*Acetyl*-N^4*-benzoyl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thiocytidine* ***(13c)***: The procedure used to prepare compound **13a** applied to thioester **12c** gave compound **13c** (92%) as a white solid: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.10 (s, 6H), 0.90 (s, 9H), 2.15 (m, 1H), 2.40 (s, 3H), 2.60 (m, 1H), 3.25 (d, 2H), 4.10 (m, 2H), 6.20 (t, 1H), 7.55 (m, 4H), 7.90 (d, 2H), 8.10 (d, 1H), 8.65 (bs, 1H).

5′-S-*Acetyl*-N^2*-isobutyryl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thioguanosine* ***(13g)***: The procedure used to prepare compound **13a** applied to thioester **12g** gave compound **13g** (78%) as a white solid: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.10 (s, 6H), 0.90 (s, 9H), 1.30 (t, 6H), 2.30 (m, 1H), 2.40 (s, 3H), 2.70 (m, 1H), 3.05 (m, 2H), 3.90 (m, 1H), 4.10 (m, 1H), 4.50 (m, 1H), 6.20 (t, 1H), 7.75 (s, 1H), 9.05 (bs, 1H); MS (CI): 510 (MH^+), 279.

5′-S-*Acetyl-3′*-O-tert-*butyldimethylsilyl-5′-deoxy-5′-thiothymidine* ***(13t)*** *(8)*: The procedure used to prepare compound **13a** applied to thioester **12t** gave compound **13t** (8) (98%) as a colorless oil. This compound showed spectroscopic properties identical to those published in the literature (8).

Step 3

N^6*-Benzoyl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thioadenosine* ***(3a)***: A methanolic sodium hydroxide solution (0.5 N; 49 mL, 24.5 mmol) was added to a deoxygenated solution of thioester **13a** (6.68 g, 12.7 mmol) in methanol (120 mL). The reaction mixture was stirred at 0°C for 1 h before it was neutralized by the addition of acidic Amberlyst 15 resin. The resin was filtered and washed thoroughly with methanol, and the filtrate was evaporated. Flash chromatography of the residue (silica gel; hexane/EtOAc (50:50)) afforded thiol **3a** (3.18 g, 52%) as a white solid: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.14 (s, 3H), 0.15 (s, 3H), 0.94 (s, 9H), 1.56 (t, 1H), 2.46 (m, 1H), 2.77–3.02 (m, 3H), 4.12 (m, 1H), 4.65 (m, 1H), 6.44 (t, 1H), 7.53 (m, 2H), 7.61 (m, 1H), 8.02 (m, 2H), 8.22 (s, 1H), 8.80 (s, 1H), 8.95 (s, 1H); MS (CI): 486 (MH^+), 382, 240.

N^4*-Benzoyl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thiocytidine* ***(3c)***: The procedure used to prepare compound **3a** applied to thioester **13c** gave thiol **3c** (56%) as a white solid: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.10 (s, 6H), 0.90 (s, 9H), 1.55 (t, 1H), 2.15 (m, 1H), 2.60 (m, 1H), 2.85 (m, 2H), 4.10 (m, 1H), 4.30 (m, 1H), 6.25 (t, 1H), 7.55 (m, 3H), 7.60 (m, 1H), 7.90 (d, 2H), 8.20 (d, 1H), 8.80 (bs, 1H).

N^2*-Isobutyryl-3′*-O-tert-*butyldimethylsilyl-2′,5′-dideoxy-5′-thioguanosine* ***(3g)***: The procedure used to prepare compound **3a** applied to thioester **13g** gave thiol **3g** (64%) as a white solid: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.15 (s, 6H), 0.95 (s, 9H), 1.30 (dd, 6H), 1.55 (t, 1H), 2.40 (m, 1H), 2.65 (m, 2H), 2.80 (m, 2H), 4.05 (m, 1H), 4.50 (m, 1H), 6.20 (t, 1H), 7.85 (s, 1H), 8.50 (bs, 1H); MS (CI): 468 (MH^+), 279, 222.

3′-O-tert-*Butyldimethylsilyl-5′-deoxy-5′-thio-thymidine* ***(3t)*** *(8)*: The procedure used to prepare compound **3a** applied to thioester **13t** gave thiol **3t** (8) (82%) as a white solid. This compound showed spectroscopic properties identical to those published in the literature (8).

Preparation of nucleoside donors 5

N^6-*Benzoyl-5′*-O-tert-*butyldimethylsilyl-3′*-O-*methylthiomethyl-2′-deoxyadenosine (**5a**)*: A solution of *N*^{6}-benzoyl-5′-*O-tert*-butyldimethylsilyl-2′-deoxyadenosine (7) (**9**) (9.51 g, 20.2 mmol), acetic acid (20 mL), and acetic anhydride (66 mL) in DMSO (100 mL) was stirred at room temperature for 17 h before it was slowly poured in a 0°C solution of potassium carbonate (100 g) in water (1 L). The aqueous phase was extracted with chloroform (3 × 200 mL), and the combined organic phases were washed with water and brine, dried ($MgSO_4$), and evaporated. Flash chromatography of the residue (silica gel; hexane/EtOAc (30:70)) afforded methylthiomethyl ether **5a** (7.52 g, 70%) as a white solid: ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.11 (s, 6H), 0.92 (s, 9H), 2.18 (s, 3H), 2.68 (m, 2H), 3.86 (m, 2H), 4.21 (m, 1H), 4.66 (m, 1H), 4.70 (ABq, 2H), 6.52 (t, 1H), 7.52 (m, 2H), 7.60 (m, 1H), 8.03 (d, 2H), 8.34 (s, 1H), 8.80 (s, 1H), 9.12 (bs, 1H); MS (CI): 530 (MH^+), 240.

5′-O-tert-*Butyldimethylsilyl-3′*-O-*methylthiomethylthymidine (**5t**)*: Sodium hydride (97%; 0.78 g, 31.4 mmol) was added to a 0°C solution of 5′-*O-tert*-butyldimethylsilylthymidine (7) (**10**) (2.00 g, 5.6 mmol) in THF (66 mL). The mixture was stirred for 20 min at 0°C. Sodium iodide (0.92 g, 6.1 mmol), HMPA (5.6 mL), and chloromethyl methyl sulfide (0.52 mL, 6.2 mmol) were then consecutively added, and the reaction mixture was stirred at room temperature for 1.5 h before water was added slowly. EtOAc was added, and the organic phase was washed successively with saturated aqueous NH_4Cl, aqueous 5% $NaHCO_3$, water, and brine. The organic phase was then dried ($MgSO_4$) and evaporated. Flash chromatography of the residue (silica gel; hexane/EtOAc (50:50)) afforded methylthiomethyl ether **5t** (1.40 g, 60%) as a colorless gum: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.15 (s, 6H), 0.90 (s, 9H), 1.95 (s, 3H), 2.00 (m, 1H), 2.15 (s, 3H), 2.40 (m, 1H), 3.85 (m, 2H), 4.10 (m, 1H), 4.50 (m, 1H), 4.65 (AB q, 2H), 6.30 (dd, 1H), 7.50 (s, 1H), 8.35 (bs, 1H); MS (CI) *m*/*e*: 417 MH^+, 291.

Preparation of 5′-thioformacetal dinucleotide analogs 6 and 15

5′-O-tert-*Butyldimethylsilyl-3′*-O-*methylenethymidylyl-(3′→5′)-3′*-O-tert-*butyldimethylsilyl-5′-deoxy-5′-thiothymidine (**6tt**)*: To a mixture of 5′-*O-tert*-butyldimethylsilyl-3′-O-methylthiomethylthymidine (**5t**) (83 mg, 0.20 mmol), *N*,*N*-diisopropylethylamine (49 μL, 0.28 mmol), and 3 Å molecular sieves (100 mg) in dichloromethane (1.5 mL) stirred at 0°C was added sulfuryl chloride (21 μL, 0.26 mmol). After 2 min, cyclohexene (41 μL, 0.40 mmol) was added, and the cold bath was removed. After 10 min at room temperature, a solution of 3′-*O-tert*-butyldimethylsilyl-5′-deoxy-5′-thiothymidine (**3t**) (97 mg, 0.26 mmol) and *N*,*N*-diisopropylethylamine (49 μL, 0.28 mmol) in dichloromethane (1.0 mL) was added to the reaction mixture. After 3.5 h, aqueous 5% $NaHCO_3$ was added, and the aqueous phase was extracted twice with dichloromethane. The combined organic phases were washed with water and brine and then dried ($MgSO_4$). Evaporation and flash chromatography of the residue (silica gel; hexane/EtOAc (25:75)) afforded dinucleotide analog **6tt** (89 mg, 60%) as a pale yellow solid: ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.10 (s, 6H), 0.12 (s, 6H), 0.90 (s, 9H), 0.93 (s, 9H), 1.92 (d, *J* = 0.9 Hz, 3H), 1.94 (s, 3H), 1.95 (m, 1H), 2.15 (m, 1H), 2.25 (m, 1H), 2.43 (dd, *J* = 12.2, 5.5 Hz, 1H), 2.85 (dd, *J* = 13.8, 5.9 Hz, 1H), 2.96 (dd, *J* = 13.8, 4.9 Hz, 1H), 3.78 (dd, *J* = 11.2, 2.5 Hz, 1H), 3.87 (dd, *J* = 11.2, 3.0 Hz, 1H), 4.02 (m, 1H), 4.10 (bs, 1H), 4.29 (m, 1H), 4.45 (d, 1H), 4.72 (s, 2H), 6.20 (m, 1H), 6.27 (dd, *J* = 8.6, 5.5 Hz, 1H), 7.27 (s, 1H), 7.46 (s, 1H), 9.08 (bs, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 12.48, 12.60, 17.85, 18.28, 25.64, 25.86, 32.23, 37.84, 40.35, 63.44, 72.24, 73.62, 84.86, 84.96, 85.59, 110.97, 111.16, 135.07, 135.53, 150.26, 150.44, 163.83, 163.92; HRFABMS *m*/*e* calcd. for $C_{33}H_{57}N_4O_9SSi_2$ (MH^+): 741.3385; found: 741.3382.

Preparation of 5′-thioformacetal trinucleotide analog 23

3′-O-*Methylthiomethylthymidine* ***(16)***: *p*-Toluenesulfonic acid monohydrate (444 mg, 2.33 mmol) was added to a 0°C solution of 5′-*O*-dimethoxytrityl-3′-*O*-methylthiomethylthymidine **14** (10) (596 mg, 0.99 mmol) in dichloromethane (7 mL) and methanol (3 mL). After being stirred at 0°C for 15 min, the reaction mixture was treated with saturated aqueous sodium bicarbonate and extracted with dichloromethane. The organic layer was dried ($MgSO_4$) and evaporated. Flash chromatography of the residue (silica gel; hexane/EtOAc (10:90)) afforded primary alcohol **16** (252 mg, 85%) as a

Mechanism of silylene extrusion reaction in cyclic polysilane via triplet energy surface: a direct MO dynamics study

Hiroto Tachikawa, Yoshihisa Yamada, and Tetsuji Iyama

Abstract: Dynamics of photoreaction of permethylcycloheptasilane $(Me_2Si)_7$ on the triplet state surface, $(Me_2Si)_7$ (T_1) $\rightarrow$ $(Me_2Si)_6$ + Me_2Si (T_1), has been investigated by means of the direct MO dynamics method in order to elucidate mechanism of silylene extrusion from the Si-ring following the triplet energy transfer from a carbonyl compound. Full dimensional potential energy surface calculated at the PM3 method was employed in the dynamics calculation: the total energy and energy gradient on each atom were calculated at each time step during the reaction. The calculations showed that the seven-membered Si-ring is spontaneously changed to the six-membered ring without activation barrier on T_1 surface. The photoreaction of $(Me_2Si)_7$ is significantly fast (reaction is completed within 1.0 ps), although heavy molecule (silylene radical) is dissociated. This is due to the fact that the T_1 surface is strongly repulsive for the coordinate between the silylene and the Si-ring. The mechanism of the silylene extraction from the Si-ring was discussed on the basis of theoretical results.

Key words: direct MO dynamics, polysilane, photoreaction, permethylcycloheptasilane, silylene.

Résumé : Faisant appel de la méthode de la dynamique d'OM directe, on a étudié la dynamique de la photoréaction du perméthylcycloheptasilane $(Me_2Si)_7$ sur la surface de l'état triplet, $(Me_2Si)_7$ (T_1) $\rightarrow$ $(Me_2Si)_6$ + Me_2Si (T_1) dans le but d'élucider le mécanisme de l'extrusion du silylène du cycle de silicium à la suite d'un transfert d'énergie triplet à partir d'un composé carbonylé. Pour les calculs dynamiques, on a utilisé une surface d'énergie potentielle à pleine dimension calculée par la méthode PM3: l'énergie totale et le gradient d'énergie de chaque atome ont été évaluées pour chaque étape temporelle de la réaction. Les calculs ont montré que, sur la surface T_1, le cycle à sept chaînons de silicium se transforme spontanément en un cycle à six chaînons, sans barrière d'activation. La photoréaction du $(Me_2Si)_7$ est assez rapide (la réaction est complète en dedans de 1,0 ps), même s'il se produit une dissociation d'une molécule lourde (radical silylène). Ceci est dû au fait que la surface T_1 est fortement répulsive pour la coordination entre le silylène et le cycle de silicium. On discute du mécanisme d'extraction du silylène du cycle de silicium sur la base des résultats théoriques.

Mots clés : dynamique d'OM directe, polysilane, photoréaction, perméthylcyclopentasilane, silylène.

1. Introduction

Polysilanes are σ-conjugated polymers composed of Si-Si backbone and organic side groups. Photochemical property and electronic structure of polysilanes have received much attention from both experimental and theoretical points of view, because they play an important role in photoresists, one-dimensional conductors, high-density optical data storage materials (1). Current interest has been focused on the localization and delocalization mechanism of electron (hole) in polymer chain (2–4) and on the photoreaction of polysilanes. (5).

Cyclic polysilane $(R_2Si)_n$ (where R is alkyl-group) is one of the photosensitive polysilanes in which silylene extrusion occurs in the excited electronic state. Also, it is known that $(R_2Si)_n$ is an intermediate in synthesis of the oligosilanes. Studying of the reaction of the cyclosilanes in the excited electronic state provides detailed information on the photochemistry of polysilane.

Permethylcyclohexasilane $(Me_2Si)_6$ is one of the cyclic polysilanes, and the photoreaction causes a silylene extrusion reaction expressed by

$$(Me_2Si)_6 \xrightarrow{h\nu} (Me_2Si)_5 + Me_2Si$$

Drahnak et al. (5) reported that the silylene extrusion reaction is occurred in 3-methylpentane/methylcyclohexane matrices at 77 K. They detected the products (Me_2Si and $(Me_2Si)_5$) by means of UV-visible and infrared spectroscopes. The reaction was also observed in argon matrix at 77 K. It has been considered from the experiment that this reaction mainly proceeds via singlet state (5). This originates only from the experiment that silylene radical Me_2Si has a singlet electronic state. However, a recent experiment (6) showed that a cyclic polysilane $(Me_2Si)_6$ quenches effi-

ciently the triplet excited states of carbonyl compound $^3(R_2C{=}O)$ in benzene. The triplet energy transfer can be expressed by

$$(Me_2Si)_6 + {}^3(R_2C{=}O) \rightarrow (Me_2Si)_6\ (T_1) + {}^1(R_2C{=}O)$$

where $^3(R_2C{=}O)$ and $^1(R_2C{=}O)$ are carbonyl compounds at the triplet and singlet states, respectively. As a course of reaction of $(Me_2Si)_6$ (T_1), the silylene extrusion reaction,

$$(Me_2Si)_6\ (T_1) \rightarrow (Me_2Si)_5 + Me_2Si$$

may consequently take place on the triplet state surface as well as on singlet state. It is experimentally known that the silylene radical is also generated from photoirradiation of other number of rings, namely, the photoirradiation of the cyclosilanes $(Me_2Si)_n$ (n = 5 and 7) gives the smaller sized ring $(Me_2Si)_{n-1}$ and Me_2Si.

In previous papers, we investigated the photoreactions of $(Me_2Si)_n$ (n = 5 and 6) at triplet state by means of direct MO dynamics method (7, 8). The calculations show that the extrusion reaction spontaneously occurred on the T_1 state and is completed within 1.0 ps, which is much faster in spite of the heavy atom (silylene radical Me_2Si) extrusion processes. This is due to the fact that the bonding nature of Si—Si bond is strongly changed to a repulsive surface in the excited electronic state. Also, we showed that the reaction via S_1 state has an activation barrier.

In the present study, in order to obtain the general feature of the photoreactions of cyclic polysilanes in the excited electronic state, we extend direct MO dynamics calculation to the similar photochemical reaction of $(Me_2Si)_7$, which possesses a less steric energy than for reactions with n = 5 and 6. The reaction is expressed by

$$[1] \qquad (Me_2Si)_7\ (T_1) \rightarrow (Me_2Si)_6 + Me_2Si$$

For this reaction system, Ishikawa and Kumada (9) reported that the photochemical reaction of $(Me_2Si)_7$ was observed in cyclohexane solution at 318 K as well as in $(Me_2Si)_6$. Studying reaction [1] would provide more detailed information on photochemistry of cyclic polysilanes.

2. Method of the calculations

Usually, the classical trajectory (10) is performed on an analytically fitted potential energy surface as previously carried out by us (11). However, it is not appropriate to predetermine the reaction surface of reaction [1] due to the large number of degrees of freedom ($3N - 6 = 57$ where N is number of atoms in the reaction system). Therefore, in the present study, we applied the direct trajectory calculation with all degrees of freedom (12). The energy gradients on all atoms were calculated at the PM3-MO level at each time step.

In the trajectory calculation, we used optimized geometry of $(Me_2Si)_7$ as an initial structure. At a starting point of the trajectory calculation, atomic velocities for all atoms were adjusted to give a temperature of 300 K. The potential energy (total energy) and energy gradients at each time step was calculated at the PM3-MO level (8). The program code to calculate the trajectory and the program for the dynamics calculation were created by our group (12).

In the calculation of the classical trajectory, we assumed that each atom moves as a classical particle on the PM3 multidimensional potential energy surfaces. The equations of motion for n atoms in a molecule are given by

$$m_i\, dv_{\mu i}/dt = F_{\mu i}$$

$$dx_{\mu i}/dt = v_{\mu i}$$

where $x_{\mu i}$ (μ = 1, 2, 3) are the three Cartesian coordinates of the ith atom with mass m_i, $F_{\mu i}$ values are the three components of the force acting on the ith atom. These equations were numerically solved by the Runge–Kutta method. No symmetry restriction was applied in the calculation of the gradients in the Runge–Kutta method. The time step size chosen was 0.2 fs. The drift of the total energy was confirmed to be less than 0.1% for an entire trajectory. It was also confirmed that the momentum of the center of mass and the angular momentum around the center of mass retained their initial value of zero. The present reaction system has a large degree of freedom ($3N - 6 = 57$), so that a backflow from the kinetic energy to the potential energy was not observed.

3. Results

A. Structures of $(Me_2Si)_7$ for the ground and excited electronic states

The structure of $(Me_2Si)_7$ in the ground state (S_0) is determined by the energy gradient method under no-symmetry restriction. Fully optimized structure is illustrated in Fig. 1. The distance of Si—Si atoms is calculated to be 2.4280 Å for all Si—Si bonds, while the angle of Si-Si-Si is 108.7°. These are normal angle and distance in cyclic silane. It should be noted that the interatomic distance between Si_2 and Si_3 atoms is calculated to be 3.9443 Å.

The structure for the excited electronic state (T_1 state) is fully optimized by the same manner. The result is illustrated in Fig. 1. The optimized structure for the triplet (T_1) state is much different from that of S_0 state. The interatomic distance between Si_2 and Si_3 atoms is calculated to be 2.4887 Å, which is significantly shorter than that of S_0 state (3.9443 Å). Furthermore, the angle of Si_2-Si_1-Si_3 at T_1 state is strikingly smaller than that at S_0 state (58.2° vs. 108.7°). These results suggest that the silylene radical (Me_2Si radical) can be dissociated from $(Me_2Si)_7$ and smaller Si ring $(Me_2Si)_6$ is formed at T_1 state. However, the silylene radical is not completely dissociated from $(Me_2Si)_6$, because the radical is weakly bound to $(Me_2Si)_6$ and forms an intermediate complex $(Me_2Si)_6...Me_2Si$.

B. Dynamics of reaction [1]

As described in the previous section, the PM3 calculations showed that the structure of $(Me_2Si)_7$ is strongly deformed at T_1 state. Also, it is expected that silylene radical is extruded from the ring. In this section, in order to elucidate the dynamics of the silylene extrusion reaction, the direct MO dynamics calculation is carried out for the triplet state surface. The initial geometry used in the dynamics calculation is chosen by the optimized structure of $(Me_2Si)_7$ obtained at S_0 state.

The results of the dynamics calculation are given in Fig. 2. Potential energy (PE) of the system calculated as a function of reaction time is plotted in Fig. 2*A*. PE is sud-

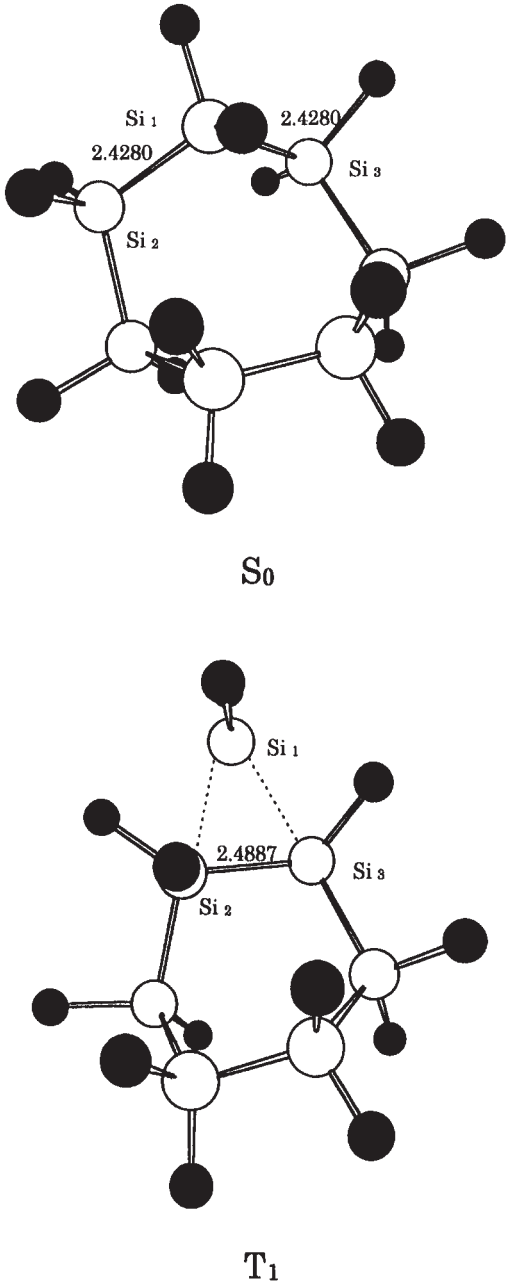
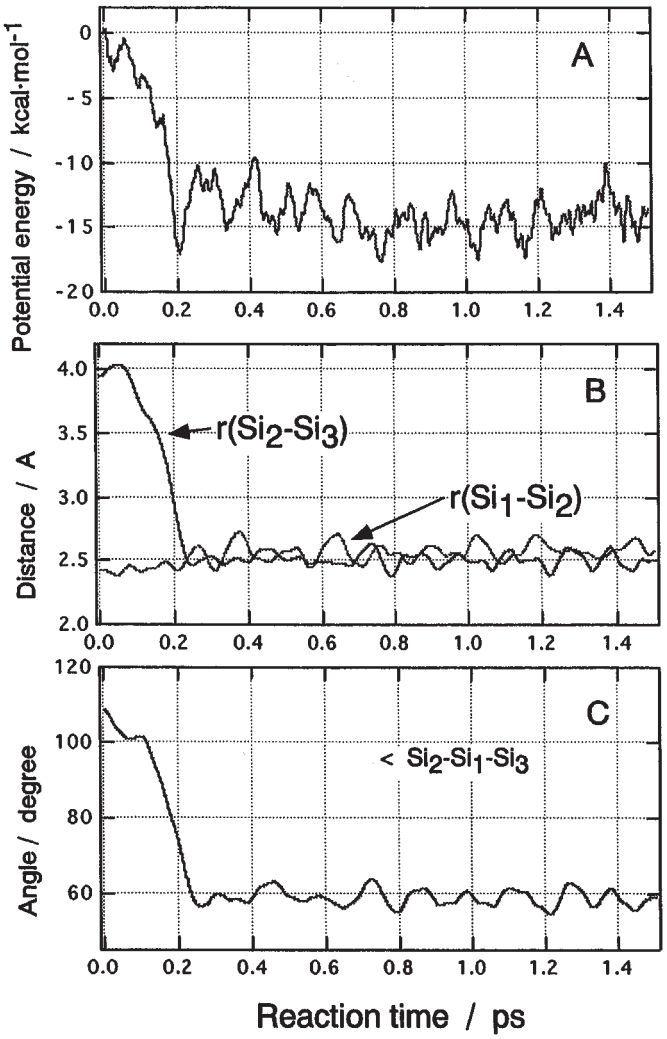
Fig. 1. Optimized structures of $(Me_2Si)_7$ in the ground state (S_0), and triplet state (T_1) calculated by PM3-CI method. Bond lengths and angles are in angstroms and degrees, respectively. Open and closed circles mean silicon and carbon atoms, respectively. Hydrogens in methyl group are omitted.



denly down in short time region (0.0–0.2 ps). The lowest energy is –17.3 kcal/mol with respect to the initial point at time zero. At the middle time region (0.2–1.0 ps), PE is gradually and slightly lowered. The interatomic distances calculated as a function of time are plotted in Fig. 2*B*. The distance between Si_1 and Si_2 is almost constant throughout, while a normal vibration of Si-Si stretching mode is observed around 2.50 Å. On the other hand, the interatomic distance between Si_2 and Si_3 is significantly changed: the distance is shortened from 3.90 to 2.50 Å. In addition, the

Fig. 2. Sample trajectory calculated by the direct PM3-MO dynamics method with T_1 potential energy surface. (*A*) Potential energy, (*B*) interatomic distances, and (*C*) angle of Si_2-Si_1-Si_3 versus reaction time.



angle of Si_2-Si_1-Si_3 is largely changed from 108.0° to 60.0°. These results indicate strongly that seven-membered ring is spontaneously changed to six-membered ring on T_1 surface. As shown in Fig. 2, the silylene radical was not completely dissociated from the six-membered ring. Instead, the intermediate complex $(Me_2Si)_6$...Me_2Si is formed. This complex is precursor in reaction [1].

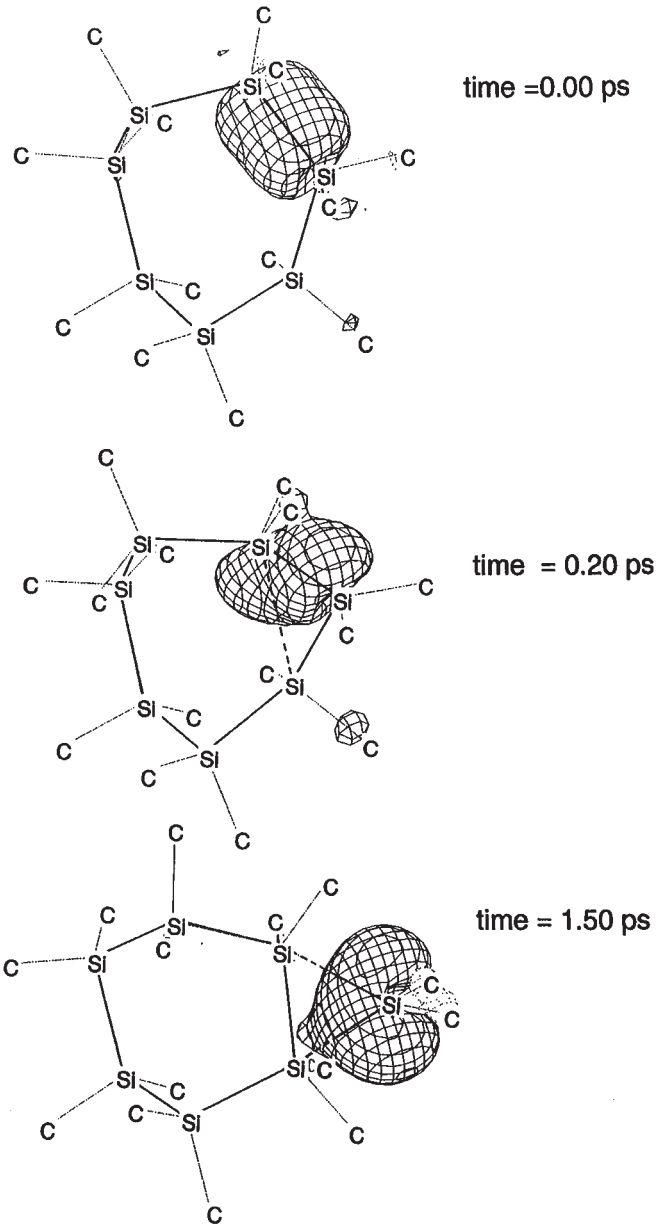
C. Bond alternation as a function of reaction time

A simple Mulliken population analysis is useful to describe the bonding nature in molecules. Therefore, Mulliken populations for all Si—Si bonds are monitored as a function of reaction time. The results are summarized in Table 1. A normal value of population between Si—Si bond in the ground state (S_0) is calculated to be 0.349, which is comparable to that of $(Me_2Si)_6$. The value for the Si_2—Si_3 bond is –0.040, which is close to zero, suggesting that there is no interaction between Si_2 and Si_3 atoms at S_0 state.

In contrast, the population of Si_1—Si_3 bond is a negative sign (–0.941) at T_1 state, meaning that the bond of Si_1—Si_3

© 1999 NRC Canada

Fig. 3. Snapshots of the structures of the system and spin orbitals in $(Me_2Si)_7$ on the triplet state surface.



is strongly repulsive. This may cause the bond breaking for Si_1—Si_3 bond. The population of Si_1—Si_2 bond is calculated to be 0.254, which is close to the normal value of Si—Si bond (0.349). It should be emphasized that the bond population between Si_2 and Si_3 is not zero, but a positive value (0.036) in spite of the long separation (3.95 Å). After 1.50 ps (final stage of the reaction), the populations of Si_1—Si_2 and Si_1—Si_3 bonds are –0.436 and –0.253, respectively, meaning that Me_2Si can be dissociated from the ring. Thus, the population analysis also indicates that the silylene extrusion is spontaneously occurred on T_1 surface.

D. Spin orbitals

Snapshots of the structures and spin orbitals are illustrated in Fig. 3. At time zero, the spin orbital is localized on one of the Si—Si bonds as clearly seen in Fig. 3 (time = 0.0 ps). At time of 0.20 ps, the orbital is slightly expanded by the deformation of Si-skeleton. At time of 1.00 ps (figure is not given), the spin orbital concentrates to one of silylene groups so that unpaired electron is localized mainly on the Si atom. As seen in Fig. 3 (time = 1.50 ps), the spin orbital is composed of π-orbital of silylene radical, and the unpaired electron is fully localized on silylene group. The reaction is terminated at this point.

Table 1. Bond populations calculated as a function of reaction time.[a]

		Bond population		
State	Time/ps	Si_2—Si_3	Si_1—Si_2	Si_1—Si_3
S_0	0.0	–0.040	0.349	0.349
T_1	0.0	0.036	0.254	–0.941
	0.10	0.038	0.251	–0.826
	0.20	–0.090	0.261	–0.653
	0.50	0.244	–0.570	–0.106
	1.00	0.362	–0.433	–0.297
	1.50	0.366	–0.436	–0.253

[a]Dissociating silylere is composed of Si_1 atom.

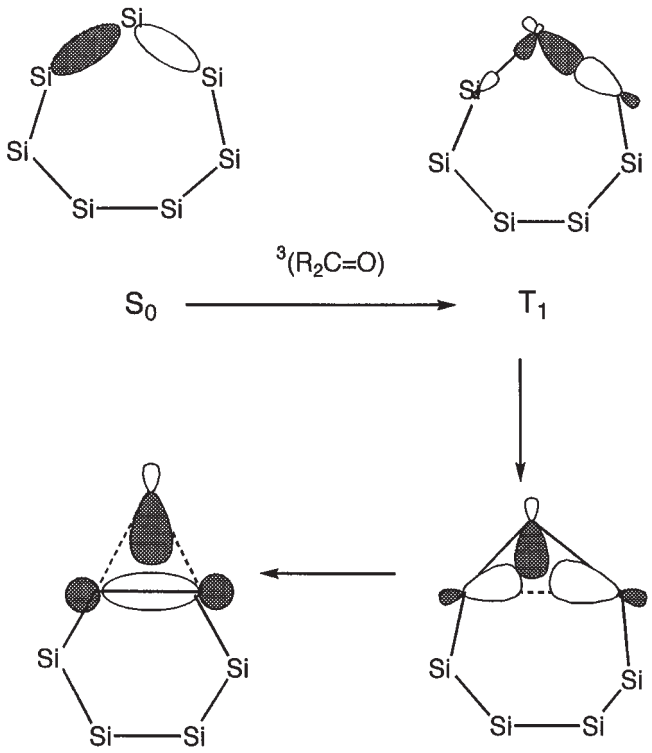
4. Discussion

In previous papers (7, 8), we proposed reaction model on the photoinduced silylene extrusion reaction in $(Me_2Si)_6$ (T_1) following the triplet energy transfer from carbonyl compound on the basis of direct MO dynamics calculation. The potential energy surface for T_1 state calculated by us is favored for the silylene extrusion to occur: T_1 surface is strongly repulsive for interaction between Me_2Si and $(Me_2Si)_5$. Hence, the silylene extrusion proceeds efficiently on T_1 surface. In the present study, we have extended the direct dynamics calculation to a larger cyclic silane compound $(Me_2Si)_7$. The present results are essentially similar to that obtained for $(Me_2Si)_6$ system (7). This means that the model presented by us may be general in photoreaction of cyclic polysilane compounds.

Here, let us discuss the photoreaction mechanism of $(Me_2Si)_7$ following the triplet energy transfer in terms of the orbital interaction. Schematic representation of the orbital interaction on the Si_2-Si_1-Si_3 moiety during the photoreaction process is illustrated in Fig. 4. In the ground state (S_0), the highest occupied molecular orbital (HOMO) shows that all Si—Si bonds have a bonding nature, suggesting that the regular cyclic structure is most stable. When the triplet energy transfer from $^3(R_2C{=}O)$ to the polysilane takes place, the electronic state of $(Me_2Si)_7$ is suddenly changed from S_0 to T_1 state. At the T_1 state, the orbital interaction of Si—Si bonds is composed of anti-bonding type, and the unpaired electrons are localized on one of Si—Si bonds. After that, the silylene extrusion occurs on this state. The interaction between Si_1 and Si_j (j = 2 or 3) is composed of strong anti-bonding interaction. Magnitude of the anti-bonding interaction may be enough for the elongation of Si_1—Si_j bond to occur. Accompanying the slight elongation of Si_1—Si_j bond, the Si_2—Si_3 bond is newly formed because of the same orbital phase. After more elongation of the Si_1—Si_j bonds, the

© 1999 NRC Canada

Fig. 4. Schematic representation of orbital interactions of the Si atoms in the T_1 excited electronic state. $^3(R_2C{=}O)$ means a carbonyl compound at the triplet state (T_1).



Si_2—Si_3 bond is completely formed, and silylene radical is dissociated from seven-membered ring. This mechanism is in reasonable agreement with our previous model for the photoreaction mechanism proposed for $(Me_2Si)_n$ (T_1) $\rightarrow$ $(Me_2Si)_{n-1}$ + Me_2Si (T_1) (where n = 5 and 6) (7, 8). The present calculation indicates that the silylene radical is also extruded from the seven-membered ring $(Me_2Si)_7$ at the T_1 state, and this reaction proceeds in terms of the same mechanism as that of $(Me_2Si)_6$.

From the basis of Woodward–Hoffmann selection rule, Ramsey suggested that both singlet and triplet excited states, denoted respectively by $^1(\sigma\sigma^*)$ and $^3(\sigma\sigma^*)$, correlate to silylene radical dissociation channel (14). This is consistent with the present model.

Several approximations to calculate the potential energy surface and to treat the reaction dynamics were introduced in the present study. Firstly, we assumed that $(Me_2Si)_7$ (T_1) has no excess energy at the initial point of the trajectory calculation (time = 0.0 ps). This may cause a slight change of lifetime for $(Me_2Si)_6$...Me_2Si intermediate in which the silylene radical weakly interacts with $(Me_2Si)_6$. Hence, the present calculation shows that the trajectory was trapped in the intermediate region, while the silylene radical did not escape from $(Me_2Si)_6$. The dissociation of Me_2Si may occur in the case of higher excess energy. This effect was not considered in the present calculations. It should be noted therefore that the present model is limited in the case of no excess energy. Furthermore, we did not consider the solvent effect in the dynamics calculation, although almost all experiments for reaction [1] have been carried out in condensed phase. The solvent effects may play an important role in the dissociation of Me_2Si from $(Me_2Si)_7$.

Secondary, we assumed PM3 multidimensional potential energy surface in the trajectory calculations throughout. A more accurate wave function may provide deeper insight in the dynamics. Despite several assumptions introduced here, the results enable us to obtain valuable information on the photoreaction process in $(Me_2Si)_7$.

Polynuclear Co(II) and Cu(II) complexes of tetraacetylethane: $Cu^{II}_2(dpa)_2(tae)(O_2CCF_3)_2$, $\{[Cu^{II}_2(dpa)_2(tae)(4,4'\text{-bipy})](O_2CCF_3)_2\}_n$, and $[Co^{II}_2(dpa)_4(tae)](O_2CCH_3)_2(H_2O)_2$, dpa = 2,2′-dipyridylamine, tae = tetraacetylethane dianion

Yousheng Zhang, Steven R. Breeze, Suning Wang, John E. Greedan, N.P. Raju, and Lijuan Li

Abstract: The syntheses and structures of copper(II) and cobalt(II) complexes employing tetraacetylethane as the bridging ligand have been investigated. The reaction of $Cu(O_2CCF_3)_2$ with tetraacetylethane (tae) and 2,2′-dipyridylamine (dpa) yielded a dinuclear complex $Cu^{II}_2(dpa)_2(tae)(O_2CCF_3)_2$ (**1**), which has an extended hydrogen-bonded chain structure in the solid state. The reaction of 4,4′-dipyridyl (4,4′-bipy) with compound **1** resulted in the formation of a polymeric compound $\{[Cu^{II}_2(dpa)_2(tae)(4,4'\text{-bipy})](O_2CCF_3)_2\}_n$ (**2**), where the dinuclear unit is cross-linked by the 4,4′-dipyridyl ligand. The reaction of $Co(O_2CCH_3)_2$ with tetraacetylethane and 2,2′-dipyridylamine yielded a helical dinuclear complex $[Co^{II}_2(dpa)_4(tae)](O_2CCH_3)_2(H_2O)_2$ (**3**), which forms a hydrogen-bonded band architecture in the solid state. The three-dimensional structure of **3** has molecular sieve-like channels that host methanol molecules reversibly. While only either negligible or weak magnetic exchanges appear to be present in compounds **1** and **2**, there appears to be a significant ferromagnetic exchange in **3**, which is likely caused by orbital orthogonality of the Co(II) ions, as supported by the crystal structure and EHMO calculations.

Key words: cobalt, copper, polynuclear, tetraacetylethane complex, magnetism.

Résumé : On a réalisé la synthèse et on a examiné les structures des complexes de cuivre(II) et de cobalt(III) impliquant le tétraacétyléthane comme ligand de pont. La réaction du $Cu(O_2CCF_3)$ avec le tétraacétyléthane (tae) et la 2,2′-dipyridylamide (dpa) conduit à un complexe dinucléaire, $Cu(II)_2(dpa)_2(tae)(O_2CCF_3)_2$ (**1**), qui, à l'état solide, comporte une structure en chaîne avec liaison hydrogène étendue. La réaction du 4,4′-dipyridyle (4,4′-bipy) avec le composé **1** conduit à la formation d'un composé polymérique, $\{[Cu(II)_2(dpa)_2(tae)(4,4'\text{-bypy})](O_2CCF_3)_2\}_n$ (**2**), dans lequel l'unité dinucléaire est réticulée par le ligand 4,4′-dipyridyle. La réaction du $Co(O_2CCH_3)_2$ avec le tétraacétyléthane et la 2,2′-dipyridylamine fournit un complexe dinucléaire hélicoïdal, $[Co(II)_2(dpa)_4(tae)](O_2CCH_3)_2(H_2O)_2$ (**3**), qui, à l'état solide, donne lieu à une architecture en bande avec liaisons hydrogènes. La structure tridimensionnelle du composé **3** comporte des canaux semblables à ceux des tamis moléculaires qui permettent d'accueillir des molécules de méthanol de façon réversible. Même si on ne peut détecter que des échanges magnétiques faibles ou négligeables dans les composés **1** et **2**, il semble exister un échange ferromagnétique important dans le composé **3**; celui-ci découle vraisemblablement de l'orthogonalité de l'orbitale des ions Co(II) qui serait supportée par la structure cristalline et les calculs d'OM.

Mots clés : cobalt, cuivre, polynucléaire, complexe tétraacétyléthane, magnétisme.

[Traduit par la Rédaction]

Introduction

Polynuclear metal complexes containing paramagnetic metal ions are an important class of molecules because they not only provide the opportunity for the study of magnetic exchange mechanisms involving several metal ions, but also provide the fundamentals for the systematic assembly of extended structures that may have a long-range magnetic ordering (1). Previously, we studied the assembly of polynuclear copper(II) complexes by using amino alcohols or hydroxypyridines as the bridging ligands. We have found that antiferromagnetic exchanges are dominant in most of the amino alcohol or hydroxypyridine complexes (2). Recently, we explored the synthesis of polynuclear metal com-

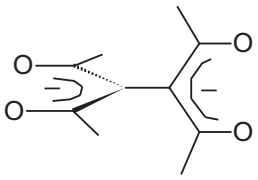
Fig. 1. The tae ligand.



plexes by using the doubly deprotonated tetraacetylethane ligand (tae, Fig. 1). As demonstrated by previously reported Ni(II) and Cu(II) dinuclear complexes (3) that contain the tae ligand, steric constraint forces the two diketone portions of the tae ligand to be non-coplanar but about 90° to each other, which, when bonded to two metal ions, may promote ferromagnetic exchange via orthogonal orbitals (1*e*, 4). In addition, the ~90° twisting of the ligand could also promote the formation of dinuclear helical structures when bonded by two octahedral metal ions, which is also an area of much interest (5). In our studies we have obtained new copper(II) and cobalt(II) compounds containing the tae ligand with structures ranging from dimers, one-dimensional polymers, to chiral molecular squares (6). The common feature of these new compounds is that they all have extended structures in the solid state via either hydrogen bonds or covalent bonds, in contrast to the discrete dinuclear Ni(II) and Cu(II) molecules reported previously (3). We report herein the syntheses, structures, and properties of three new Co(II) and Cu(II) complexes containing the tae ligand.

Experimental section

All reactions were carried out by using standard Schlenk vacuum line techniques under nitrogen atmosphere. Tetraacetylethane was synthesized according to published procedures (7). All other chemicals were purchased from Aldrich Chemical Co. Elemental analyses were performed at Canadian Microanalytical Service. Ltd, Delta, B.C. The EPR spectra were recorded at 100 K on a Bruker 420 spectrometer. Magnetic susceptibility data were collected at 1 kG on a SQUID instrument from Quantum Design in the temperature range 2–300 K. Thermogravimetric analyses were performed on a Perkin–Elmer TGA-7 analyzer.

Synthesis of $Cu_2(tae)(dpa)_2(CF_3CO_2)_2$ (1)

$Cu(CF_3CO_2)_2$ (200 mg, 0.69 mmol) was dissolved in 15 mL of methanol. With stirring, tetracetylethane (68 mg, 0.35 mmol) was added to the flask. A green solution was obtained immediately. After the addition was complete, the mixture was stirred for 2 h, and 2,2′-dipyridylamine (118 mg, 0.69 mmol) was added to the solution. The solution immediately turned dark green. After being stirred for an additional 4 h, the solution was filtered and concentrated in vacuo to about 5 mL. Dark green thin plate crystals were harvested after the solution was kept standing at room temperature for 1 week. Yield 262 mg (84%); mp 215–220°C. Anal. calcd. for vacuum-dried sample, $C_{34}H_{30}N_6O_8F_6Cu_2$: C 45.60, H 3.62, N 9.39; found: C 45.30, H 3.61, N 9.48%.

Synthesis of $[Cu_2(tae)\ (dpa)_2(4,4'\text{-bipy})](CF_3CO_2)_2$ (2)

Method A

$Cu(CF_3CO_2)_2$ (200 mg, 0.69 mmol) was dissolved in 15 mL methanol.Tetraacetylethane (68 mg, 0.35 mmol) was added to the solution with stirring. The color of the solution immediately changed to green. After 2 h, 2,2′-dipyridylamine (118 mg, 0.69 mmol) was added to the solution. The color changed to dark green. After stirring for another 4 h, 4,4′-dipyridyl (54 mg, 0.34 mmol) was added without further color change. The mixture was stirred for 24 h, and then concentrated to 5 mL. Diethyl ether (2 mL) was added. Upon standing at room temperature for 1 week, dark green block crystals were obtained (249 mg, yield, 69%).

Method B

$Cu_2(tae)(dpa)_2(CF_3CO_2)_2$ (1) (200 mg, 0.22 mmol) was dissolved in 15 mL methanol. 4,4′-Dipyridyl (35 mg, 0.22 mmol) was added. No obvious color change of the solution was observed. The mixture was stirred for ~24 h, and then concentrated to 5 mL. Ether (2 mL) was added and the solution was kept standing at room temperature. After 1 week, dark green block crystals of compound **2** were harvested (207 mg, yield, 90%), mp 195°C. Anal. calcd.: C 50.34, H 3.84, N 10.67; found: C 50.12, H 3.67, N 10.56%.

Synthesis of $[Co_2(tae)(dpa)_4](CH_3CO_2)_2(H_2O)_2/CH_3OH$ (3)

$Co(OAc)_2{\cdot}4H_2O$ (200 mg, 0.80 mmol) was dissolved in 15 mL of methanol. With stirring, tetraacetylethane (79 mg, 0.40 mmol) was added to the flask. The solution immediately turned red. After the addition was complete, the mixture was stirred for 1 h, and 2,2′-dipyridylamine (275 mg, 1.61 mmol) was added to the solution. The solution immediately turned dark red. After being stirred for an additional 2 h, the solution was filtered and concentrated invacuo to about 5 mL. After adding 2 mL diethyl ether to the solution, the solution was kept standing at room temperature for 2 days. Red thin plate crystals of compound **3** were obtained. Yield 392 mg (vacuum-dried sample, 87%), mp 198–200°C. Anal. calcd. for the vacuum-dried sample, $C_{54}H_{58}N_{12}O_{10}Co_2$: C 56.26, H 5.04, N 14.59; found: C 56.38, H 4.80, N 14.28%.

X-ray diffraction analysis

The crystal of **2** was mounted on glass fibers with epoxy glue while the crystals of **1** and **3** were sealed inside glass capillaries with the saturated methanol solution. Data were collected over the ranges $2° < 2\theta < 45°$ for **1** and **3** and $2° < 2\theta < 50°$ for **2** on a Siemens P4 single-crystal X-ray diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) operated at 50 kV and 40 mA at 23°C. No significant decay was observed for all crystals. Data were processed on a Pentium PC using Siemens SHELXTL (version 5.0) software package.[2] An empirical absorption correction based on azimuthal scans of several reflections was applied for all crystals. The data were corrected for Lorentz polar-

ization effects. Neutral atom scattering factors were taken from Cromer and Waber (8). The crystal of **2** belongs to the monoclinic space group $P2_1/c$, uniquely determined by systematic absences ($0k0$, $k = 2n + 1$, $h0l$, $l = 2n + 1$). The systematic absences for compounds **1** and **3** agree with both *Cc* and *C*2/*c* space groups. The structural solution and refinement confirmed that *C*2/*c* is the correct choice for both compounds. All structures were solved by direct methods. Full-matrix least-squares refinements minimizing the function $\Sigma w(F_o^2 - F_c^2)^2$ were applied to all compounds. Both compounds **1** and **3** contain a disordered methanol solvent molecule in the crystal lattice (one methanol per dimer), which could not be fully modeled. The fluorine atoms of one of the $CF_3CO_2^-$ groups in compound **2** showed a twofold rotational disorder. The carbon atoms and oxygen atoms on this trifluoroacetate group also showed some degree of disorder that could not be modeled. The positions of hydrogen atoms except those of water and methanol molecules were calculated and their contribution was included in structural factor calculations. The data of crystallographic analysis are given in Table 1.

Results and discussion

Synthesis and structure of $Cu_2(tae)(dpa)_2(CF_3CO_2)_2$ (1)

Compound **1** was obtained in good yield from the reaction of $Cu(O_2CCF_3)_2$ with 2,2′-dipyridylamine and tetraacetylethane in a 2:2:1 ratio in methanol. The neutral tetraacetylethane molecule became the dianion, tae, in the product. The driving force for the formation of the tae dianion could be attributed to the chelating effect of the tae ligand. Complexes of tae involving Ni(II) and Cu(II) have previously been reported by Fukuda et al. (3*a*). Recently the structure of a dinuclear copper(II) compound, $[Cu_2(tae)(tmed)_2](NO_3)_2$, was also reported (3*c*). Single-crystal X-ray diffraction and elemental analyses established the composition and structure of compound **1**. A diagram showing the molecular structure of **1** is given in Fig. 2. Selected bond lengths and angles are listed in Table 2.

Compound **1** has C_2 symmetry where the two Cu(II) units are related by a twofold rotation axis with the Cu(1) and Cu(1A) separation distance being 7.968 Å. The tae ligand acts as a bridging ligand to the two copper(II) centers. As observed previously in Ni(II) and Cu(II) compounds, the tae ligand in compound **1** is not planar. The twisting angle of the two diketone portions of the tae ligand is 81.5°, smaller than that (84.6°) of $[Cu_2(tae)(tmed)_2](NO_3)_2$ (3*c*). The Cu—O (tae) bond lengths are comparable to those of previously reported acetylacetonato copper(II) compounds (9). The dpa ligand is chelated to the copper(II) center through the two pyridyl groups with normal Cu—N bond lengths. The fifth position of the copper center is occupied by a trifluoroacetate ligand with a long Cu—O bond (Cu(1)—O(3) = 2.331(9) Å). While the O(2)-Cu(1)-N(3) angle is nearly linear (173.0(3)°), the O(1)-Cu(1)-N(1) angle of 145.3(3)° deviates significantly from linearity. The geometry of the Cu(II) ion can therefore be best described as a distorted square pyramid. The amino N(2) atom is coplanar with the two pyridyl rings (the dihedral angle between the N(2)C(6)N(3) and N(2)C(5)N(1) planes is 1.3°) and the N(2)—C(5) and N(2)—C(6) bond lengths (1.378(12), 1.365(12) Å) are close to that of N—C double bonds, indicative of the N(2) conjugation with the two pyridyl rings. The structure of the dinuclear unit of **1** resembles that of $[Cu_2(tae)(tmed)_2](NO_3)_2$ (3*b*).

The amino N(2) group plays an important role in the extended solid state structure of **1**. The proton on N(2) forms a hydrogen bond with the noncoordinating O(4) atom of the acetate from the neighboring dimer, as evident by the N(2)···O(4A) distance of 2.81(2) Å. The two dpa ligands and the two trifluoroacetate ligands form a hydrogen-bonded box as shown in Fig. 2. As a consequence of the hydrogen bonds, compound **1** forms an extended one-dimensional chain struc-

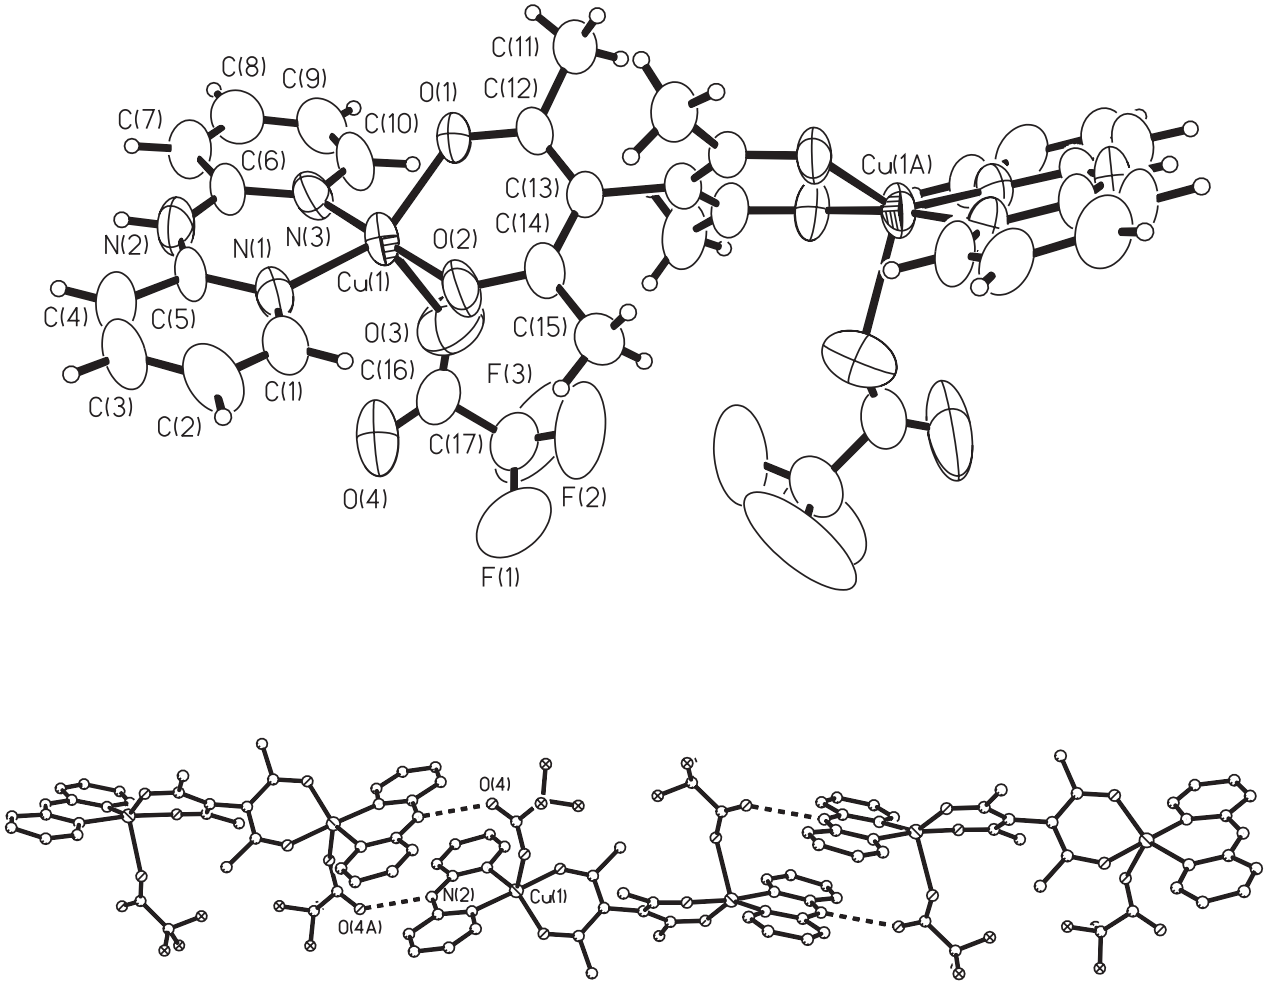
Fig. 2. Top: a diagram showing the structure of **1** with 50% thermal ellipsoids and labeling scheme. Bottom: A diagram showing the hydrogen bonds between the dinuclear units of **1**.



ture in the solid state (Fig. 2, bottom). Hydrogen-bonded extended structures involving copper(II) ions have been observed frequently (10). The geometry of the dpa ligand allows it to function as a chelating ligand and a proton donor as well, making it an ideal candidate for the building of complexes with extended hydrogen-bonded structures.

Synthesis and structure of $[Cu_2(tae)(dpa)_2(4,4\text{-bipy})](CF_3CO_2)_2$ (2)

The copper(II) ion in compound **1** is five-coordinate. Since a Cu(II) ion can also have a six-coordinate pseudo-octahedral geometry, we anticipated that it may be possible to link the dinuclear unit together through covalent bonds by introducing a cross-linking ligand at the unoccupied axial position. The ligand we chose is 4,4′-dipyridyl. Indeed, the reaction of compound **1** with 1 equiv. of 4,4′-dipyridyl produced a polymeric compound **2**, $[Cu_2(tae)(dpa)_2(4,4'\text{-bipy})](CF_3CO_2)_2$,in good yield. Compound **2** can also be obtained directly from the reaction of $Cu(O_2CCF_3)_2$, di-2-pyridylamine, tetraacetylethane, and 4,4′-bipy in a 2:2:1:1 ratio. The crystal structure of **2** was determined by single-crystal X-ray diffraction analysis. A diagram showing the structure of the dinuclear unit of **2** is given in Fig. 3. Selected bond lengths and angles are given in Table 2.

As shown in Fig. 3 (top), the structure of the dinuclear unit of **2** has some resemblance to that of **1**. Each copper(II) center is coordinated by a chelating dpa ligand and linked to the other copper(II) center by the bridging tae ligand. The twisting angle between the two diketone planes is 89.7°, much larger than that in compound **1**. As a consequence, the two planar Cu(II) units are essentially orthogonal to each other (the dihedral angle between the Cu(1)O(1)O(2)N(1)N(3) and Cu(2)O(3)O(4)N(4)N(6) planes is 94.4°). In contrast to compound **1** where the trifluoroacetate ligand occupies the axial position, the two trifluoroacetates in **2** are not bound to the copper centers but form hydrogen bonds with the amino hydrogen atoms (N(2), N(5)) of the dpa ligands as indicated by the N(2)···O(5) (2.74 Å) and N(5)···O(8) (2.76 Å) distances. As anticipated, the 4,4′-bipy ligand occupies the axial position of the copper center (Cu(1)—N(7) = 2.278(6) Å, Cu(2)—N(8A) = 2.274(6) Å), thus linking the dinuclear units together to form a one-dimensional polymer (Fig. 3, bottom). The deviation of Cu(1) from the O(1)O(2)N(1)N(3) plane is 0.085 Å while the deviation of Cu(2) from the O(3)O(4)N(4)N(6) plane is 0.137 Å. The geometry of each copper(II) center is therefore square pyramidal. Due to the orthogonality of the Cu(1) and Cu(2) planar units, the two neighbouring 4,4′-dipyridyl bridging ligands are also at ap-

proximately right angles with respect to one another. The Cu(1)—Cu(2) distance in the dinuclear unit is 8.027 Å, comparable to that in **1**, while the Cu(1)—Cu(2A) distance between the dimer is 11.618 Å. The hydrogen-bound trifluoroacetate molecules are situated in the cavities between the polymer chains. 4,4′-Dipyridyl bridged polynuclear copper(II) complexes have been reported previously (11*a*). The most notable utility of 4,4′-dipyridyl is as a spacer in tetranuclear compounds with square or extended ladder structures (11*b*–11*e*). In order for 4,4′-dipyridyl to link compound **1** to form a square or rectangular structure, the two copper(II) units in **1** have to be coplanar. The orthogonal arrangement of the two copper(II) units in **1** appar-

ently precludes the formation of such a structure but favors the formation of the polymer structure in **2**.

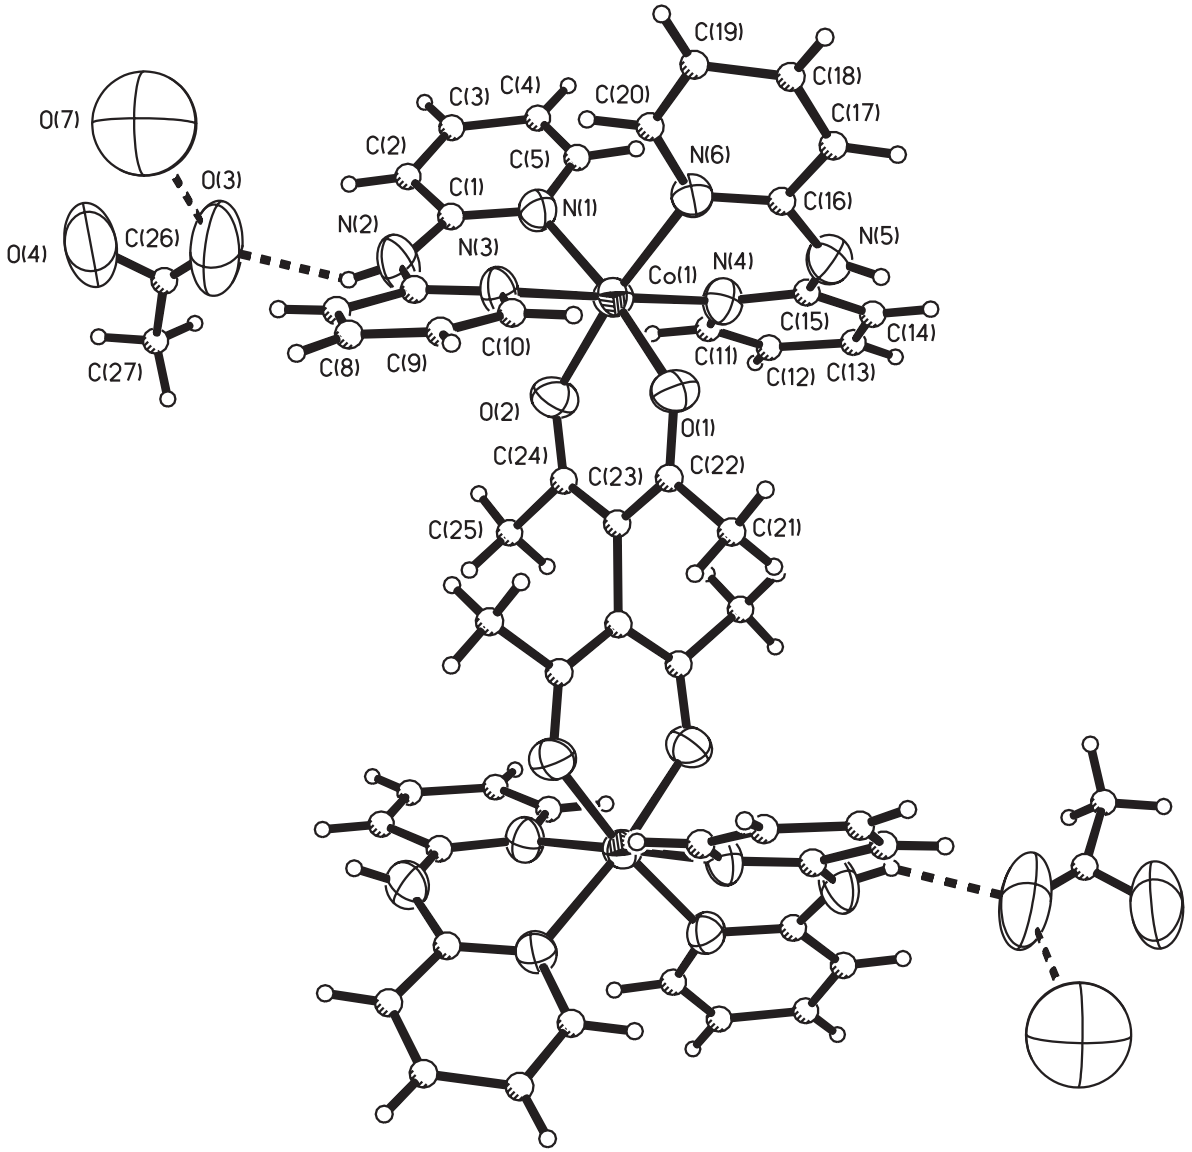
Synthesis and structure of $[Co_2(tae)(dpa)_4](CH_3CO_2)_2(H_2O)_2$ (3)

The dinuclear cobalt(II) compound was obtained in good yield from the reaction of $Co(O_2CCH_3)_2(H_2O)_4$ with 2,2′-dipyridylamine and tetraacetylethane in a 2:4:1 ratio in methanol. The crystal structure of **3** was determined by a single-crystal X-ray diffraction analysis. Selected bond lengths and angles are given in Table 2.

As shown in Fig. 4, the tae ligand bridges two cobalt(II) ions in the same manner as observed in **1** and **2**. The Co(1) and Co(1A) separation distance (8.286 Å) is, however, longer than those in **1** and **2**, attributable to the relatively long Co–ligand bond lengths, in comparison to those of the Cu–ligand bonds. The molecule of **3** has a C_2 symmetry. The Co—O(tae) bond lengths are similar to the previously reported Co(II)—O bonds (12). The twisting angle (88.9°) between the two diketone portions of the tae ligand is much larger than that in **1**, but similar to that in **2**, which results in a 85.6° dihedral angle between the Co(1)O(1)O(2)N(1)N(6) and Co(1A)O(1A)O(2A)N(1A)N(6A) planes. Unlike compounds **1** and **2**, where the copper(II) centers are chelated by one dpa ligand, in compound **3** the cobalt(II) ion is coordinated by two chelating dpa ligands with typical Co—N bond lengths. The geometry around the cobalt center is almost an ideal octahedron, as indicated by the bond angles of O(2)-Co(1)-N(6) = 173.3(3)°, O(1)-Co(1)-N(1) = 173.7(3)°, and N(3)-Co(1)-N(4) = 179.5(3)°. In contrast to compounds **1** and **2**, where the dpa ligands are essentially planar, the dpa ligands in compound **3** are buckled. The dihedral angle between the two pyridyl rings is 17.3° for the N(2) dpa ligand

© 1999 NRC Canada

Fig. 4. A diagram showing the molecular structure of **3** with 50% thermal ellipsoids and labeling scheme. All carbon atoms are shown as ideal spheres for clarity.



and 22.0° for the N(5) dpa ligand. The buckling of the dpa ligand in **3** can be attributed to the increased crowdedness of the cobalt ion, in comparison to the copper ions in **1** and **2**, and the relatively long Co—N bonds.

As observed in compound **2**, the dinuclear portion of compound **3** is a dication. The two acetate ligands are not coordinated to the metal centers. One interesting feature of the dication is that it has a helical chiral structure as shown by the space-filling diagram of Fig. 5. The two Co(II) units linked by the tae ligand have the same chirality, i.e., (Λ, Λ) or (Δ, Δ). Both enantiomers co-crystallize in the solid state. We have not been able to isolate any of the (Λ, Δ) diastereomer from the same reaction. The helical structure of **3** is apparently promoted by the nonplanarity of the tae ligand. The fact that the (Λ, Λ) and (Δ, Δ) isomers were obtained in >80% yield suggested to us that these isomers must be thermodynamically more favorable than the (Λ, Δ) isomer. Coordination compounds with helical structures have been reported previously (5). The simplicity of the tae ligand makes it very attractive for the synthesis of helical coordination compounds involving octahedral metal ions.

Another interesting feature of **3** is the formation of an extended hydrogen-bonded architecture. The acetate forms two hydrogen bonds with two amino groups from two dications, as indicated by the bond distances of N(2)···O(3) = 2.821 Å and N(5A)···O(4) = 2.726 Å. Unlike compound **1**, where the dimers are linked via hydrogen bonds in a head-to-tail fashion, the (Λ, Λ) dication in **3** is linked via hydrogen bonds to the (Δ, Δ) dication via two acetate ligands in a parallel head-to-head and tail-to-tail fashion to form a one-dimensional band (Fig. 6). In the cavity between two hydrogen-bonded bands are water molecules that are hydrogen bonded to the acetate (O(6)···O(3) = 2.948 Å). The box formed by the two acetates and two dianions is about 8 Å × 11 Å in two dimen-

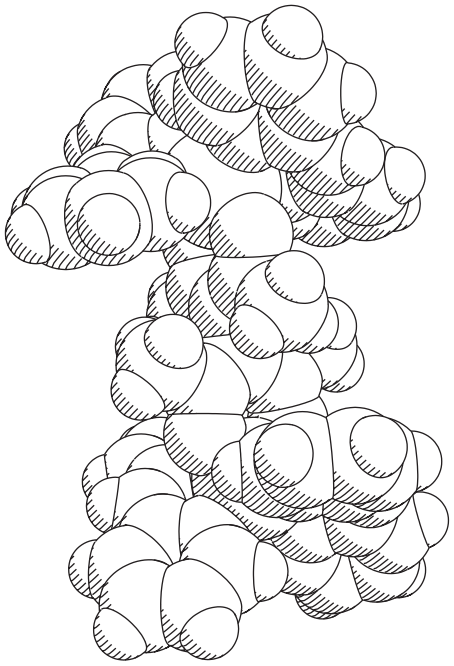
Fig. 5. A space-filling diagram showing the helical structure of the (Δ,Δ) enantiomer of **3**. The acetate groups are omitted for clarity.



sions and extends along the third dimension to form a one-dimensional channel. Disordered methanol solvent molecules are located in these channels (Fig. 6).

The molecular sieve-like behavior of 3

Most interestingly, the methanol guest molecules in the lattice of **3** go in and out of the channel reversibly, as established by TGA experiments. The freshly prepared compound **3** loses 2.7% weight in the temperature range 20–38°C, consistent with the loss of methanol solvent molecule (2.7%, one methanol per compound **3**). Compound **3** also readily loses the methanol solvent molecule, without loss of crystallinity, when subjected to vacuum. The vacuum-dried sample has no significant weight loss in the temperature range 20–60°C. However, after being exposed to the methanol vapor, the vacuum-dried sample shows a similar TGA curve to that of the freshly prepared sample, indicative of the reabsorption of the methanol guest molecule. Examples of inorganic complexes that host organic solvent molecules in the crystal lattice are abundant (11). However, most crystal lattices of these complexes collapse when the guest molecules leave the lattice, resulting in an irreversible loss of the guest molecule. In fact, inorganic complexes that absorb organic molecules in the lattice in a reversible fashion are still a rare occurrence. The behavior of compound **3** resembles that of molecular sieves (1*k*, 13), which prompted us to examine the utility of the crystals of compound **3** in hosting small organic molecules other than methanol, such as ace-

Fig. 6. A packing diagram showing the three-dimensional hydrogen-bonded extended structure of **3**. The disordered methanol solvent molecules are in the large channels (shown in the middle of the diagram).

tonitrile. However, at present, methanol is the only known guest molecule that can be reversibly hosted by the crystals of compound **3**.

Magnetic properties of compounds 1–3

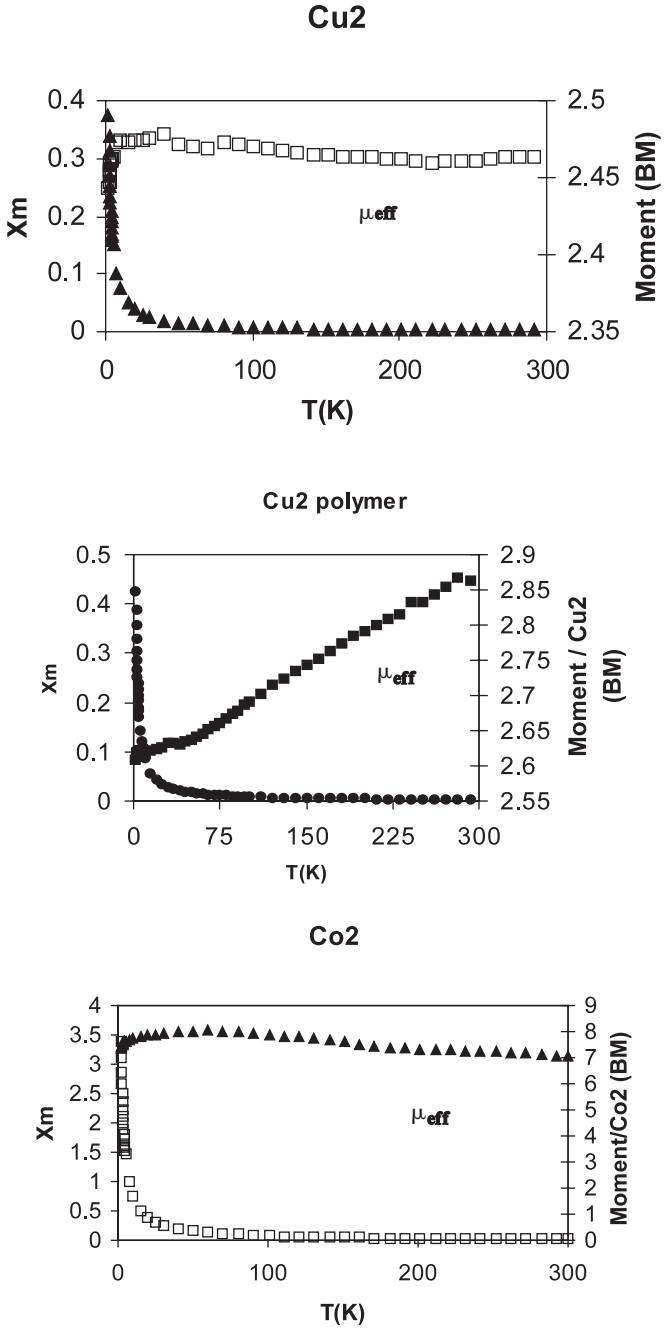
The paramagnetic metal ions in the dinuclear units of compounds **1–3** are about 8 Å away from each other. It is therefore of interest to see if there is any magnetic exchange between the two metal ions. In addition, the tae ligand links the two mononuclear units together in an approximately orthogonal fashion, which could result in either weak ferromagnetic exchange or no exchange at all (1, 3, 14). Previous studies on dinuclear copper(II) tae complexes by Lim et al. (3*c*) indicated that antiferromagnetic exchanges dominate in their compounds. The difference between our copper(II) compounds and Lim's copper(II) compounds lies in the fact that our compounds have either a hydrogen-bonded or covalently bonded extended structure in the solid state while Lim's compounds are discrete dinuclear molecules. To determine the presence and nature of possible magnetic exchange in **1–3**, magnetic susceptibility data of compounds **1**–**3** were measured over the temperature range 2–300 K. The data were corrected for diamagnetism by using Pascal constants.

As shown in Fig. 7 (top), compound **1** is a nearly ideal paramagnet in the temperature range 20–300 K. The drop of magnetic moment at temperatures below 20 K is likely caused by intermolecular antiferromagnetic exchange. The behavior of compound **1** contradicts that of Lim's compound where significant intramolecular antiferromagnetic exchange appears to be present. The cause for this discrepancy has not been understood. The magnetic moment vs. temperature plot (Fig. 7, middle) for compound **2** clearly indicates that antiferromagnetic exchanges dominate. The plot of moment vs. *T* (Fig. 7, bottom) for compound **3** shows a gradual increase of moment with decrease in temperature, indicative of the presence of weak ferromagnetic exchanges.

EHMO calculations

To further understand the magnetic exchange in compound **3**, we performed molecular orbital calculations by using the extended Hückel molecular orbital methods (EHMO) (15). The molecular geometry was established by using the crystallographic coordinates of compound **3**. The result of the EHMO calculations showed that the HOMO (**1b**) and LUMO (**1a**) levels consist mostly of the two $d(x^2 - y^2)$ atomic orbitals from the two Co(II) ions. There are also considerable contributions from the coordinating atoms to these two molecular orbitals. The energy difference between the HOMO and the LUMO level (–10.180 eV vs. –10.179 eV) is negligible. Thus, the HOMO and LUMO can be considered as one doubly quasi-degenerate molecular orbital, consistent with a ferromagnetic exchange ground state. As shown in Fig. 8, the $d(x^2 - y^2)$ orbitals of the two Co(II) ions at the HOMO level are orthogonal with a dihedral angle of 85.6°. The ferromagnetic exchange in compound **3** could be therefore attributed to the orbital orthogonality of the two Co(II) ions, imposed by the tae ligand. Other mechanisms such as spin-orbital couplings may also be responsible for the magnetic behavior of **3**, which requires further theoretical investigations.

Fig. 7. Diagrams showing χ_M vs. *T*(K) and μ_{eff} vs. *T* plots of **1–3**.



Conclusion

The nonplanarity of the tae ligand appears to promote helical structures of complexes containing octahedral metal ions and ferromagnetic exchange in the dinuclear Co(II) complex as well. The dpa ligand is a good bifuctional ligand and promotes the formation of extended hydrogen-bonded structures in the solid state by interacting with proton acceptors such as acetate via the noncoordinating amino site. Compound **3** is one of the rare examples of hydrogen-bound extended structures that hosts methanol solvent molecules reversibly.

Crystal structures of dihydroquercetin 3-acetate and dihydroquercetin 3,3′,4′,7-tetraacetate: hydrogen bonding in 5-hydroxyflavanones

Eberhard Kiehlmann, Kumar Biradha, Konstantin V. Domasevitch, and Michael J. Zaworotko

Abstract: The molecular structures of dihydroquercetin 3-acetate **3** and dihydroquercetin 3,3′,4′,7-tetraacetate **4** were determined by single crystal X-ray analysis. Comparison of their crystal data with those of 16 known 5-hydroxyflavanones shows intramolecular O(5)-H···O(4)=C hydrogen bonding, preference for nearly perpendicular orientation of the two aromatic rings and preferred sofa conformation of the heterocyclic ring. The major stabilizing force in the crystal packing pattern of **3** is intermolecular hydrogen bonding.

Key words: crystal structure, dihydroquercetin, flavanones, hydrogen bonding.

Résumé : On a déterminé les structures moléculaires du 3-acétate de dihydroquercétine (3) et du 3,3′,4′,7-tétraacétate de dihydroquercétine (4) par diffraction des rayons X sur des cristaux uniques. Une comparaison de leurs structures cristallines avec celles de seize autres 5-hydroxyflavones connues démontre l'existence d'une liaison hydrogène intramoléculaire O(5)-H···O(4)=C, d'une préférence pour une orientation pratiquement perpendiculaire des deux noyaux aromatiques et d'une préférence pour la conformation sofa du cycle hétérocyclique. La liaison hydrogène intramoléculaire est la principale force stabilisante dans le patron d'empilement cristallin du composé **3**.

Mots clés : structure cristalline, dihydroquercétine, flavones, liaison hydrogène.

[Traduit par la Rédaction]

Introduction

Dihydroflavonols (2-aryl-3-hydroxy-2,3-dihydrobenzopyran-4-ones) are widely distributed in the plant kingdom and exhibit a large variety of physiological effects (1). Dihydroquercetin (3,3′,4′,5,7-pentahydroxyflavanone, **1**) (dhq), the most common member of this group of flavonoids, occurs in Douglas fir bark and has been found in *O*-methylated, *O*-acetylated, and glycosidic forms in many other plants. The close similarity in the chemical and spectral properties of various partially derivatized dhq isomers has led to inconsistent and erroneous structural (2) and spectral assignments (3) in the past. Following the synthesis of 22 of the 31 possible dhq acetates (4), we now report the crystal parameters of dhq 3-acetate **3** and dhq 3,3′,4′,7-tetraacetate **4**, the only two that yielded single crystals of sufficient size for X-ray diffraction studies, and compare them to those of 16 known 5-hydroxyflavanones.

Discussion

(2*R*,3*R*)-Dihydroquercetin 3-acetate **3**, the sweet principle of several subtropical plants (3, 5–7), was prepared by exhaustive acetylation of (+)-dihydroquercetin with excess acetic anhydride and pyridine (8, 9) and subsequent deacetylation of the pentaacetate **2** with sodium sulfite in aqueous methanol (4) (Scheme 1). Integration of its ^{1}H NMR spectrum showed the product to be a monoacetate, with the following characteristic proton chemical shifts (in Me_2CO-d_6) indicating the presence of an aliphatic rather than an aromatic ester: δ 1.96 (3-O*Ac*, vs. 2.26 and 2.28 for ArO*Ac* of **2** and **4**), 5.82 (H-3, vs. 4.4–4.8 for 3-C*H*OH of **1**), and 11.57 ppm (5-O*H*, H-bonded to >C=O). The absolute configurations of **3** and **4** follow from their optical activity, the proven stereochemistry of the (+)-dhq (10) used as starting material, and the known retention of configuration at the chiral centers during mild base-catalyzed *O*-acetylation (11) and *O*-deacetylation (12) of flavonoids.

The 3,3′,4′,7-tetraacetate **4** is obtained as major acetylation product of dhq when only catalytic amounts of pyridine are used as base catalyst (4, 8). It can be readily separated from the pentaacetate **2** formed as byproduct by crystallization from methanol. Contrary to a previous literature report (2), acid-catalyzed deacetylation of **2** yields the isomeric 3,3′,4′,5-tetraacetate. The structure with the free hydroxyl

group at C-5 (**4**, systematic name: (2*R*,3*R*)-3,7-bis(acetyloxy)-2-[3,4-bis(acetyloxy)phenyl]-2,3-dihydro-5-hydroxy-4*H*-1-benzopyran-4-one) was first proposed by Aft (8, 13) on the basis of IR- and UV-spectral evidence and is consistent with the results of our NMR and X-ray crystallographic studies.

Comparison of the chemical shifts of its aromatic protons and C-13 nuclei with those of **2** and other flavanone acetates (4, 14) shows that the A-ring is monoacetylated, and the downfield position and sharpness of the OH peak (11.35 ppm in Me_2CO-d_6, 11.28 ppm in $CDCl_3$) in the ^1H NMR spectrum are typical of a strongly hydrogen-bonded proton. Since this proton exchanges slowly, it broadens the signals of adjacent C-13 nuclei, a feature which has been previously exploited for the unambiguous assignment of tertiary and quaternary carbons in the ^{13}C NMR spectra of 5-hydroxyflavanones (15, 16) and 5-hydroxyisoflavones (17). Thus, in the proton-coupled ^{13}C NMR spectrum of **4**, the broad singlet at 163.8 ppm must be assigned to the hydroxyl-substituted C-5, the sharp triplet at 160.1 ppm to the acetoxy-substituted C-7 (coupled to H-6 and H-8) and the broad triplet at 105.8 ppm to C-4a. Likewise, the broadened double doublet at 104.5 ppm (^1J = 166 Hz, $^3J_{H8}$ = 3.8 Hz) is due to C-6 and can be readily distinguished from the sharp C-8 double doublet at 102.9 ppm.

Single-crystal X-ray diffraction analysis confirmed the structure of **3** as *trans*-2-(3,4-dihydroxyphenyl)-2,3-dihydro-3-acetoxy-5,7-dihydroxy-4*H*-1-benzopyran-4-one, with one organic molecule and two molecules of water comprising the asymmetric unit (Fig. 1). The 3-acetoxy group and the B-ring are linked to the pyranone ring equatorially (angle C1′-C2-C3-OAc 64°), placing H-2 and H-3 into *trans*-diaxial position, in good agreement with the large ^1H NMR coupling constant (J_{23} = 12.0 Hz) observed in solution. The heterocyclic ring adopts a sofa conformation, with C-2 as the only atom deviating significantly (by 0.61 Å; C-3 deviates by 0.04 Å) from the mean plane defined by O-1, the six carbon atoms of the A-ring and C-4. The plane of the pendant catechol ring (B) forms a torsional angle of 73° with the A-ring. This appears to be energetically more favorable than a parallel alignment because it minimizes repulsive steric interactions between the *ortho* hydrogens (H-2′ and H-6′) and the bulky 3-acetoxy substituent. The 5-OH proton is displaced by 0.18 Å from the O5-CCC-O4 mean plane, and the large C5-O5-H bond angle of 136(5)° places it into a relatively unfavorable position for efficient intramolecular hydrogen bonding to the carbonyl oxygen (O4) via a puckered six-membered ring. Intermolecular hydrogen bonding forces, on the other hand, are strong (O···H distances <2.0 Å) and account for the stability of the crystal. They involve the 3′-, 4′-, and 7-OH groups as donors, 4′-OH, 5-OH, and the ester carbonyl as acceptors, and the water of hydration. Each water molecule is tetrahedrally connected to two others and two phenolic OH groups: one links OH-4′ and OH-7, the other OH-3′ and OH-5 of adjacent organic moieties (Fig. 2). In addition, a hydrogen bond between OH-4′ and the carbonyl oxygen of the acetoxy group links molecules related by the screw axis. The H-bonding parameters are summarized in Tables 1 and 2.

The tetraacetate **4** crystallizes in the triclinic *P*1 space group and exhibits three-center bifurcated hydrogen bonding. Its asymmetric unit comprises two residues (Fig. 3). In the crystal lattice, each hydroxyl proton is hydrogen-bonded to two pyranone carbonyl oxygen atoms (one intra-, the other intermolecularly), and each of the carbonyl oxygens in turn is surrounded by two hydroxyl protons. Although the hydrogen atoms are positioned slightly above the O5-CCC-O4 plane (as in **3**), the smaller C5-O-H angles of 116(4)° and 98(4)° (vs. 136° for **3**) indicate that in this case intramolecular attractive forces predominate. The heterocyclic ring adopts a half-chair conformation with C-2 above (0.46, 0.47 Å) and C-3 below (–0.25, –0.41 Å) the mean plane defined by the A-ring, O-1 and C-4. As in **3**, ring B is nearly orthogonal (75°, 73°) to ring A, and the two hydrogens of ring C are again *trans*-diaxial. Large Ar-OCO (63°–90°) and small ArO-CO torsional angles (2°–10°), as found in most aryl acetate crystal structures (18), suggest that the lone electron pairs of the three acetylated phenolic oxygens are delocalized mainly into the carbonyl groups. Crystal data,

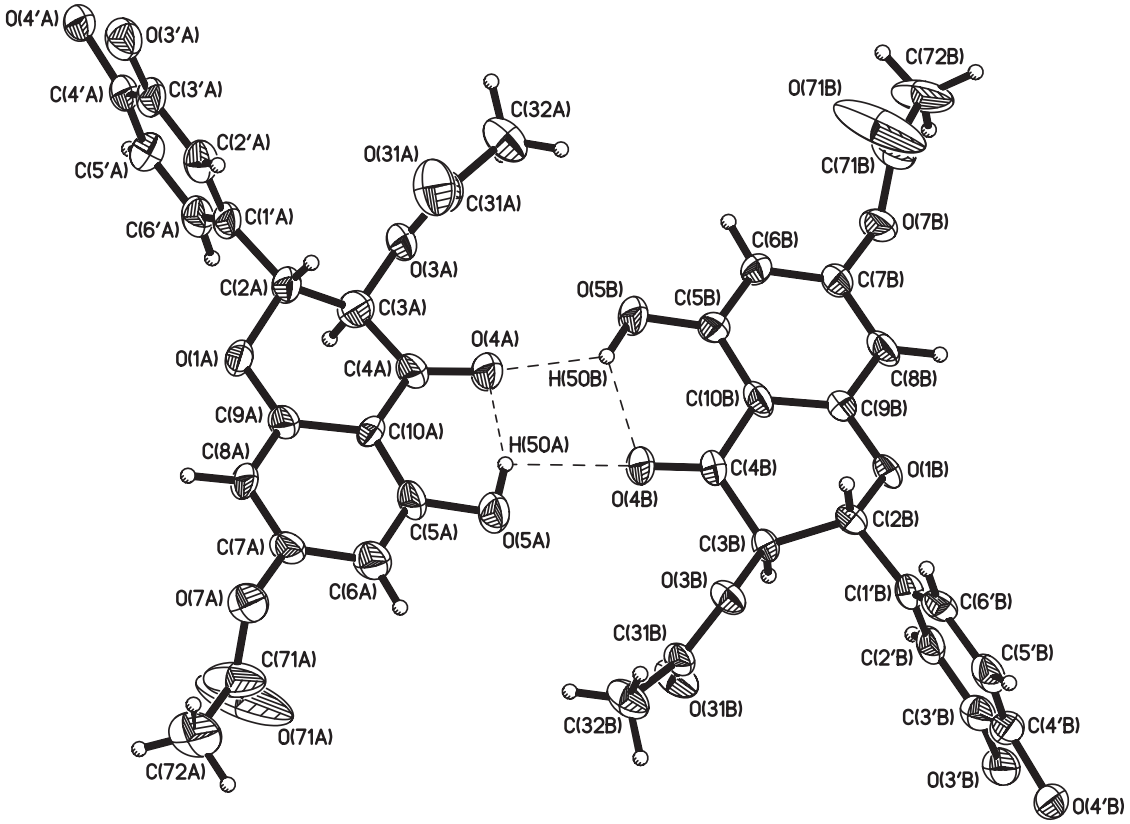
[a]Intramolecular hydrogen bonds are listed in Table 2.

Fig. 3. ORTEP diagram of **4** with atomic numbering scheme. Perspective projection of the dimeric moiety, with 40% probability thermal ellipsoids. The acetyl groups attached to atoms O(3′A), O(4′A), O(3′B), and O(4′B) are omitted for clarity.



structure refinement parameters, and selected bond lengths and angles of **3** and **4** are listed in Tables 3 and 4, the refined atomic coordinates in Tables 5–7.

The Cambridge Crystallographic Database[2] contains 16 5-hydroxy-flavanones: 10 (**5***a–j*, Scheme 2) (19) with and 6 (16, 20) without hydrogen coordinates. Comparison of their crystal parameters with those of **3** and **4** (Table 2) permits the following generalizations about the conformational preferences that are common to this class of compounds and applicable to both the solid and solution state.

The pyranone ring prefers the sofa over the half-chair conformation in all compounds except **4**, **5b**, and **5e**. In silybin (**5k**, R_3 = OH, $R_{3'}$-$R_{4'}$ = O-CH(CH_2OH)-CHAr-O, ref. 20*a*) and uvarinol (**5l**, R_8 = 2-hydroxybenzyl, R_6 = 2-hydroxy-5-(2-hydroxybenzyl)-benzyl, ref. 20*b*), one residue of the asymmetric unit is a slightly distorted sofa, the other a half-chair, demonstrating the flexible response of the

heterocyclic ring to packing forces. In all cases, H-2 and H-3 are *trans*-diaxial, and except for hesperetin hydrate (**5c**) and naringin hydrate (**5e**), the plane of the equatorial B-ring is oriented nearly perpendicular (71–113°) to that of the A-ring.

Strong intramolecular hydrogen bonding with planar six-membered ring geometry (21) is characteristic of all 5-hydroxyflavanones. The OH(5)···O(4) distances are short (1.43–1.92 Å), the bond angles at the hydrogen atom have a mean value of 143° (esd 9°), and the Ar-OH torsional angles are close to zero (1°–12°). In addition, all molecules with extra phenolic hydroxyl groups form intermolecular hydrogen bonds. The carbonyl oxygen of each of the nine anhydrous compounds accepts two OH protons in bifurcated fashion, while in the three hydrated structures **3**, **5c**, and **5e**, water serves as acceptor, and the 5-OH proton is engaged in three-center hydrogen bonding. Thus, in the presence of water, inter- rather than intramolecular hydrogen bonding appears to determine the crystal geometry. Hesperetin hydrate **5c** is the only structure that may also be stabilized by aromatic ring stacking: its two benzene rings lie in the same plane, and successive molecular layers are approximately 3.6 Å apart.

Experimental

Acetylation of (+)-dhq, extracted from Douglas fir bark as described previously (22), with excess acetic anhydride in the presence of a catalytic amount of pyridine (4) gave the 3,3′,4′,7-tetraacetate **4** in 50% yield, mp 144–6° (MeOH). Proton-coupled ^{13}C NMR (Bruker AMX-400, chemical shifts relative to Me_2CO-d_6 at 29.80) δ (ppm): 169.4 (3-OAc), 168.7–168.4 (ArOAc), 163.8 (br, C-5), 162.6 (d, ^2J = 4 Hz, C-8a), 160.1 (t, ^2J = 4 Hz, C-7), 144.2/143.4 (C-3′/4′), 134.9 (br d, ^2J = 9 Hz, C-1′), 126.4/124.7/124.0 (^1J = 164 Hz, ^3J = 4/8 Hz, H-2′/5′/6′), 105.8 (br t, ^3J = 5 Hz, C-4a), 104.5 (br dd, ^1J = 166 Hz, ^3J = 4 Hz, C-6), 102.9 (dd, ^1J = 169 Hz, ^3J = 4.6 Hz, C-8), 81.1 (m, ^1J = 151 Hz, C-2), 73.3 (dd, ^1J = 147 Hz, ^2J = 2.3 Hz, C-3), 21.0 (q, J = 130 Hz, 7-OAc), 20.5 (q, J = 130 Hz, 3′/4′-OAc), and 20.1 (q, J = 130 Hz, 3-OAc). MS (HP-5985 quadrupole instrument) *m*/*z* (% intensity): 472 (0.7, M), 412 (1.3, M – HOAc), 388 (1.7, M – 2 ketene), 370 (3.1, M – ketene – HOAc), 346 (3.5, M – 3 ketene), 328 (14.4, M – 2 ketene – HOAc), 286 (24.3, M – HOAc – 3 ketene), 250 (4.5, M – ring B – CHO), 237 (3.0), 236 (3.6, RDA fragment with ring B – ketene), 223 (3.8), 208 (7.8), 195 (25.1), 194 (20.3, RDA fragment with ring A), 192 (15.1), 153 (100), 152 (73.8, RDA fragment with ring A – ketene), 150 (54.1, $(HO)_2C_6H_3CH{=}CO^{+\cdot}$), 123 (20.9, $(HO)_2C_6H_3CH_2^+$). $[\alpha]_D^{22}$ +41° (Autopol II polarimeter, c 1.07, Me_2CO) (lit. (8) +18.6°, c 1.07). (2*R*,3*R*)-Dihydroquercetin 3-acetate **3** was obtained in 70% yield by deacetylation of the pentaacetate **2** with sodium sulfite in aqueous methanol (41 h/25°) as described previously (4), pale yellow needles, mp 125–7° (aq. MeOH).

Crystal structure determination

The X-ray diffraction data for **3** and **4** were collected on a Siemens SMART/CCD diffractometer equipped with an LT-II low-temperature device, using monochromatic Mo K_α radiation (λ = 0.710 73 Å). Diffracted data were corrected

for absorption using the SADABS program, SHELXTL was used for the structure solution,[3] and full-matrix least-squares refinement was based on F^2. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms attached to carbon were fixed at calculated positions and refined isotropically on the basis of corresponding C-atoms (U(H) = 1.2 Ueq (C)); those of O-H groups were located and refined isotropically. Pertinent crystallographic details are given in Tables 3–6. Supplementary tables of crystal structure and refinement, atomic coordinates, bond lengths and angles, anisotropic thermal parameters, and hydrogen coordinates have been deposited.[4]

Dendritic aryl imides containing the tetrahydro[5]helicene unit: synthesis, characterization, electrochemical behavior, and comparison with a linear oligoimide analogue

Timothy P. Bender, Yu Qi, Pierre Desjardins, and Zhi Yuan Wang

Abstract: Herein, we describe the synthesis, characterization, and electrochemical behavior of dendritic aryl imides derived from a core compound 3,12-dinitro-5,6,9,10-tetrahydro[5]helicene-7,8-dicarboxylic anhydride (**3**). Compound **3** is an AX_2 type system (where X is a masked or protected group), possesses a well-defined spatial orientation, is conformationally rigid, and contains a conjugated *o*-terphenyl moiety as part of its molecular structure. This compound is used as a building block in the construction of dendritic aryl imides using a divergent synthetic approach. Dendrons from generations one through three were synthesized, and their identities were confirmed. A comparison of the properties of the dendrons, several model compounds, and a linear oligoimide, all containing either the tetrahydro[5]helicene or *o*-terphenyl units, has been made. There are differences in their hydrodynamic volume, glass transition temperature, and electrochemical behaviour. All dendrons are electrochemically active and exhibit well-defined and reversible redox cycles. Furthermore, all dendrons are fluorescent, and the intensity of the fluorescent emission is dependent on the generation of the dendron.

Key words: dendrimer, dendron, electrochemistry, helicene, tetrahydro[5]helicene.

Résumé : On décrit la synthèse, la caractérisation et le comportement électrochimique d'aryl imides dendritriques dérivés d'un composé commun, l'anhydride de l'acide 3,12-dinitro-5,6,9,10-tétrahydro[5]hélicène-7,8-dicarboxylique (**3**). Le composé **3** est un système du type AX_2 (dans lequel X est un groupe caché ou protégé), il possède une orientation spatiale bien définie, il est conformationnellement rigide et sa structure moléculaire comporte une partie *o*-terphényle. Ce composé est utilisé comme bloc dans la construction d'aryl imides dendritiques par une approche synthétique divergente. On a synthétisé des « dendrons » des générations un à trois et on a confirmé leurs identités. On a fait une comparaison des propriétés des dendrons avec celles de plusieurs composés modèles et un oligoimide linéaire qui contenaient tous des unités tétrahydro[5]hélicène ou *o*-terphényle. On a noté des différences dans leur volume hydrodynamique, leur température de transition vitreuse et leur comportement électrochimique. Tous les dendrons sont électrochimiquement actifs et ils présentent tous des cycles redox réversibles bien définis. De plus, tous les dendrons sont fluorescents et l'intensité de l'émission fluorescente dépend de la génération du dendron.

Mots clés : dendrimère, dendron, électrochimie, hélicène, tétrahydro[5]hélicène.

[Traduit par la Rédaction]

Introduction

The incorporation of functionalized [5]helicene derivatives into macromolecular systems has been a focus of our research group for some time now. More specifically, we have found that the tetrahydro[5]helicene moiety, a known precursor to [5]helicene (1, 2), provides a unique and versatile building block for several compounds, all suitable for incorporation into a variety of macromolecular systems (3). All of the compounds we have investigated thus far can be derived from a single core molecule, 5,6,9,10-tetrahydro[5]helicene-7,8-dicarboxylic anhydride (**1**, Scheme 1). This C_2 symmetric molecule has a rigid polycyclic aromatic structure and contains a helical *o*-terphenyl moiety as part of its molecular structure. We have previously shown that compound **1** (Scheme 1) can be selectively derivatized to give an AB-type amino anhydride (**10**, Scheme 2) as well as AA-type diamine and difluoride monomers. Subsequent polymerization of these monomers gave high molecular weight polyimides and poly(ether sulfone)s, respectively (3). In these

studies, a markable increase in the solubility of the polyimides containing the tetrahydro[5]helicene unit, as compared to the same containing a [5]helicene unit, was observed. Furthermore, the tetrahydro[5]helicene unit was shown to increase the glass transition temperature, proportionally to its content, in a series of random copoly(ether sulfone)s (3*d*). Wide angle X-ray diffraction (WAXD) experiments performed on the polyimide derived from the AB-type amino anhydride monomer **10** showed it to be completely amorphous.[2]

High molecular weight polymers containing the [5]helicene moiety were readily obtained from precursor polyimides containing the tetrahydro[5]helicene unit by post polymer transformation using elemental bromine or atmospheric oxygen (3*a*, *b*); whereas we were unable to obtain high molecular weight polyimides that contained the [5]helicene moiety by direct solution polymerization of the corresponding monomer, presumably due to its rigidity and low solubility in the polymerization medium. Through the use of molecular modeling, it is speculated that although both the tetrahydro[5]helicene and [5]helicene moieties occupy the same molecular level spacial volume, the tetrahydro[5]helicene unit is more flexible within that volume and therefore imparts greater solubility to the macromolecules for which it is a part (3*c*). Additionally, due to the bridging carbons at positions 5, 6, 9, and 10 (see numbering Scheme 1) the *o*-terphenyl moiety within the tetrahydro[5]helicene unit remains conformationally locked so as to allow a state of conjugation between these benzene rings.

Having explored the properties and characteristics of linear macromolecules containing the tetrahydro[5]helicene unit, it would now be of interest to study the properties of the same unit within a macromolecule having dendritic architecture (for a general reference on dendrimers and dendrimer synthesis, see ref. 4). The synthesis of regular dendritic aryl imides would allow not only for the study of such molecules, but gives a direct avenue for the comparison of such dendritic molecules with their linear analogues, which we have previously synthesized and studied (3*a*). For example, the dendrimer should also possess a relatively lower glass

transition temperature (T_g) as compared to its linear analogue. Disc-shaped dendritic poly(aryl ether)s have been previously used to modify the properties of poly(*p*-phenylene) (5). Furthermore, given the dendrimer's extended array of *o*-terphenyl moieties, one may expect these dendritic macromolecules to possess some unique and interesting electrochemical properties as compared to their monomeric and oligomeric counterparts. Therefore, we have set out to construct dendritic aryl imides containing the tetrahydro[5]helicene unit using a divergent synthetic sequence, as presented herein.

Experimental section

Nomenclature

G1-den (Scheme 1), **G2-den** (Scheme 3), and **G3-den** (Scheme 3) refer to the first, second, and third generation dendrons, respectively. **G1** and **G2** refer to the first and second generation dendrimers, respectively.

Materials

The synthesis and characterization of compounds **1**, **2**, **6**, and **10** were previously reported (3*a*). Compound **7** was made according to our established synthesis for compound **1** (3*a*). Compounds **8** (6) and **9** (7) are known. Oligoimide **11** was synthesized using the published method except that the polycondensation was time-controlled so as to produce low molecular weight polyimide (3*a*). Fractionation of the produced oligoimide, to give material containing 4–10 repeat units, was accomplished from chloroform solution with methanol. Chlorobenzene and *N*,*N*-dimethylformamide (DMF) were reagent grade (Aldrich) and dried over 4 Å molecular sieves prior to use. Ethanolamine, iron powder, *m*-cresol, isoquinoline, 1,3,5- benzenetricarbonyl trichloride, *N*,*N*-dimethyl-4-aminopyridine (DMAP), and toluene were reagent grade (Aldrich) and used as received. Spectrophotometric grade DMF (Aldrich), NMP (1-methyl-2-pyrrolidinone, Aldrich), and Bu_4NPF_6 (Sigma) were used as received. Purification of dendrons and dendrimers was done using a gravity fed preparative size exclusion chromatogra-

phy (SEC) column packed with Bio-Beads SX-3 (purchased from Bio-Rad). Flash chromatography was performed using standard grade silica gel (Merck).

Characterization

^{1}H and ^{13}C NMR spectra were recorded on either a Varian Gemini-200 or a Bruker-400 instrument using tetramethylsilane as an internal reference. Infrared measurements were performed on a Bomen Michelson 120 FTIR spectrometer. Low- (EI) and high-resolution mass spectra were obtained on VG 7070E and Kratos Concept IIH spectrometers, respectively. Melting points were obtained with a Fisher–Johns apparatus and are uncorrected. Gel permeation chromatography (GPC) was performed using chloroform at ambient temperature at a flow rate of 1.0 mL per min; a UV detector set at 254 nm wavelength was used for detection. The glass transition temperatures were determined on a Seiko 220C DSC at a heating rate of 10°C/min under nitrogen flow (200 mL/min). MALDI-TOF mass spectra were obtained on a Kratos Kompact MALDI 3 time-of-flight mass spectrometer, using a dithranol/lithium bromide (20:1 by weight) or dithranol/silver trifluoroacetate (20:1 by weight) matrix. Electrochemical measurements were performed on a custom-made electrochemical workstation using a silver wire pseudo-reference, BAS MF2013 platinum disc working electrode, and platinum wire counter electrode. Measurements were made in DMF or NMP solution containing 0.1 M Bu_4NPF_6. The solutions were deoxygenated with argon for at least 15 min prior to measurements. All electrochemical potentials were corrected versus SCE using the position of the $Fe(cp)_2^{+/0}$ couple determined in DMF solution, by relation to the position of the $Co(cp)_2^{+/0}$ couple (8). Molecular modeling was performed on a personal computer using HyperChem version 5.01. Models were optimized using the MM+ molecular mechanics method.

3,12-Dinitro-5,6,9,10-tetrahydro[5]helicene-7,8-dicarboxylic anhydride (3)

Compound **2** (30.0 g) was dissolved in 1.0 L of chloroform to which was added 300 mL of acetic acid. The nitrating agent (275 mL of 70% nitric acid and 250 mL of concentrated sulfuric acid in 450 mL of acetic acid) was added dropwise with vigourous stirring at room temperature (22°C) over a 0.5 h period. The reaction continued for 3 days until TLC showed no more starting material. Stirring was stopped, and the organic phase (top) was separated from the acid phase (bottom). Extraction of the acid phase with chloroform gave no product. The organic phase was washed with water (6 × 250 mL, until the washings were pH 5 to litmus) and 10% $KHCO_3$ solution (2 × 250 mL) and dried over $MgSO_4$. After removal of the solvent, the residual solid was dissolved in hot CH_2Cl_2 (450 mL), which upon slow recrystallization gave compound **3** as yellow crystals: 14.0 g (43% yield); mp > 300°C; IR (KBr, C=O): 1762, 1835 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.19 (d, 1H, ^4J = 2.3 Hz), 7.75 (dd, 1H, ^3J = 8.6 Hz, ^4J = 2.3 Hz), 7.13 (d, 1H, ^3J = 8.6 Hz), 4.0 (d, 1H, ^2J = 15.5 Hz), 3.1 (d, 1H, ^2J = 12.1 Hz), 2.9 (td, 1H, ^2J = 12.1 Hz, ^3J = 3.3 Hz), 2.6 (t, 1H, ^2J = 15.5 Hz) ppm; ^{13}C NMR (100 MHz, $CDCl_3$) δ 163.2, 148.6, 141.9, 141.7, 140.5, 139.19, 132.0, 128.1, 124.5, 122.4, 29.1, 24.8 ppm; MS (EI, *m*/*e*, relative intensity %) 442 ($M^{\cdot+}$, 100); HRMS calcd. for $C_{24}H_{14}N_2O_7$: 442.0801; found: 442.0808.

G1-den

To a suspension of compound **1** (6.0 g, 15.0 mmol) in DMF (60 mL) was added ethanolamine (2.0 mL, 30 mmol). After stirring at room temperature for 1 h, the solution was clear and homogeneous at which point it was set to reflux overnight. The solution was cooled to room temperature and added dropwise with vigourous stirring to an HCl aqueous solution (10%, 300 mL). The resulting yellow precipitate was filtered, washed with water (until the washings were neutral to litmus). and dried in vacuo overnight (80°C, 5 mmHg (1 mmHg = 133.3 Pa)) to give **G1-den**: 5.8 g (97% yield); mp > 300°C; IR (KBr): 3536 (OH), 1757, 1706 (C=O) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.33 (d, 2H), 7.15–7.25 (m, 4H), 6.95 (t, 2H), 4.1 (b, 2H), 3.9 (m, 2H), 2.9 (m, 4H), 2.5 (b, 2H) ppm; ^{13}C NMR (100 MHz, $CDCl_3$) δ 176.6, 170.1, 139.8, 139.51, 134.18, 130.9, 129.09, 128.44, 126.5, 119.3, 62.2, 41.3, 29.2, 24.9 ppm; MS (EI, *m*/*e*, relative intensity %): 395 ($M^{\cdot+}$, 100); HRMS calcd. for $C_{26}H_{21}NO_3$: 395.1521; found: 395.1512.

G1

A solution of **G1-den** (2.7415 g, 6.94 mmol), 1,3,5-benzenetricarbonyl chloride (0.6142 g, 2.27 mmol), and DMAP (1.3866 g, 11.40 mmol) in dichloromethane (50 mL) was set to stir under argon atmosphere overnight. The dichloromethane solution was washed with HCl (1 M, 2 × 50 mL) and water (2 × 50 mL). The insoluble materials were filtered, and the filtrate was dried and concentrated to give **G1** as a yellow glass: 2.54 g (65% yield); IR (KBr): 1759, 1732, 1704 (C=O) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.67 (s, 1H), 7.22 (d, 2H), 7.03–7.12 (m, 4H), 6.82 (t, 1H), 4.41–4.50 (m, 2H), 3.92–3.97 (m, 4H), 2.78–2.87 (m, 4H), 2.3–2.5 (m, 2H) ppm; ^{13}C NMR (100 MHz, $CDCl_3$) δ 170.1, 169.2, 139.8, 139.6, 139.4, 135.7, 134.2, 131.6, 130.9, 129.1, 128.4, 126.7, 126.4, 63.5, 37.1, 29.2, 24.9 ppm; MS (MALDI-TOF-MS, dithranol/LiBr matrix, *m*/*e*, relative intensity %) calcd. for $C_{87}H_{63}N_3O_{12}$: 1341.4; found: 1348.0 (M + Li^+, 100).

G2-den

To a solution of compound **3** (2.00 g, 4.52 mmol) in chlorobenzene (25 mL) in a round-bottomed flask fitted with a Dean–Stark trap was added ethanolamine (0.41 g, 1.5 equiv, 6.80 mmol) in DMF (0.3 mL). The solution was stirred at room temperature for 1 h and then set to reflux overnight. The chlorobenzene solution was concentrated, then precipitated into *n*-pentane, and the resulting yellow solid was filtered (2.06 g, 95%). IR, ^{1}H and ^{13}C NMR, and MS confirmed the identity of the product. This imide product (4.70 g, 9.5 mmol) was placed in a mixture of THF (80 mL), ethanol (40 mL), water (20 mL), and conc. HCl (1 mL). To this was added iron powder (18 g), and the mixture was sonicated at 60°C (water bath) for 1 h. The iron–oxide powders were filtered and then washed with boiling ethyl acetate (150 mL). The combined solutions were partitioned, and the aqueous layer was extracted with ethyl acetate (2 × 50 mL). The combined organic phases were dried over $MgSO_4$ and concentrated to give a red solid that was

© 1999 NRC Canada

further purified by flash column chromatography (60/40 v/v ethyl acetate/hexane then ethyl acetate) to give compound **4** (1.57 g, 39%). IR, ^{1}H and ^{13}C NMR, and MS confirmed the identity of the product. Compounds **4** (1.06 g, 2.5 mmol) and **1** (1.98 g, 5.6 mmol, 2.2 equiv.) were dissolved in *m*-cresol (15 mL) with isoquinoline (0.5 mL) and heated at 200°C under argon flow overnight. The reaction mixture was precipitated into methanol (50 mL), and the resulting yellow precipitate was filtered. The yellow compound was further purified by preparative SEC (toluene). Removal of the solvent and drying overnight (80°C, 5 mmHg) gave **G2-den**: 1.79 g (65% yield); IR (KBr): 3439 (OH), 1756, 1710 (C=O) cm^{-1}; ^{13}C NMR (50 MHz, $CDCl_3$) δ 169.3, 167.7, 140.1, 139.4, 139.2, 138.9, 138.6, 133.5, 132.7, 131,8, 130.8, 130.4, 130.3, 128.5, 127.8, 126.4, 126.1, 125.9, 125.8, 125.7, 125.6, 124.1, 28.7, 28.6, 24.2, 24.1 ppm; MS (MALDI-TOF-MS, dithranol/LiBr matrix, *m*/*e*, relative intensity %) calcd. for $C_{74}H_{51}N_3O_7$: 1093.3; found: 1093.1 (M^+, 100).

G2

A solution of **G2-den** (0.602 g, 0.55 mmol), 1,3,5-benzenetricarbonyl chloride (50.1 mg, 0.18 mmol), and DMAP (0.1284 g, 1.00 mmol) in dichloromethane (20 mL) was stirred at room temperature for 3 days under argon atmosphere. The dichloromethane solution was washed with aqueous HCl solution (1 M, 2 × 50 mL), water (2 × 50 mL), dried over $MgSO_4$, and concentrated to give a yellow–orange glassy compound. The compound was further purified by preparative SEC (toluene). Removal of the solvent and drying overnight gave **G2** as a yellow–orange glass: 0.428 g (68% yield); IR (KBr): 1760, 1734, 1706 (C=O) cm^{-1}; MS (MALDI-TOF-MS, dithranol/LiBr matrix, *m*/*e*, relative intensity %) calcd. for $C_{231}H_{153}N_9O_{24}$: 3436.1; found: 3445.0 ($M + 1 + Li^+$, 100).

G3-den

As described for the synthesis of **G2-den**, compound **3** was imidized with **4** in *m*-cresol at 200°C, followed by reduction with iron powder to give compound **5**. Subsequent imidization of **1** with **5** afforded **G3-den** in 70% yield after purification by SEC (toluene). IR (KBr): 3442 (OH), 1763, 1711 (C=O) cm^{-1}; MS (MALDI-TOF-MS, dithranol/LiBr matrix, *m*/*e*, relative intensity %) calcd. for $C_{170}H_{111}N_7O_{15}$: 2489.8; found: 2496.1 ($M + Li^+$, 100); T_g = 346°C.

Results and discussion

Synthesis

We have previously reported the synthesis of **2** from compound **1** (Scheme 1) (3). Nitration of this product under mild conditions gave the dinitrated product **3** and a structural isomer of which **3** could be isolated in moderate yield (43%) after recrystallization from dichloromethane. Direct dinitration of **1** gave a mixture of nitrated compounds, which were difficult to separate by recrystallization and other common means. The first generation dendron (**G1-den**, Scheme 1) could be made by reaction of compound **1** with ethanolamine in refluxing DMF. Assembly of this dendron around the trimesic acid (1,3,5-benzenetricarboxylic acid) core was accomplished by reaction with 1,3,5-benzenetricarbonyl trichloride in dichloromethane using DMAP as a base. After purification, the first generation dendrimer **G1** was obtained as a yellow glassy solid in good yield (65%).

Imidization of dinitro compound **3** with ethanolamine in chlorobenzene and DMF followed by reduction with iron powder gave compound **4** in moderate yield (Scheme 1). It was found that the anhydride group of compound **1** (as well as compound **3**) either remains unreactive towards alcohols or the ester–acid derivative reverts back to the free alcohol and anhydride during work-up or under the reaction conditions. Therefore, imidization of compound **4** with compound **1** in *m*-cresol at 200°C (Scheme 3) afforded the second generation dendron (**G2-den**) in good yield after purification by SEC. Assembly of **G2** was accomplished by reaction of **G2-den** with 1,3,5-benzenetricarbonyl trichloride for 3 days in dichloromethane.

Synthesis of the third generation dendron (**G3-den**) began with imidization of compound **4** with compound **3**, followed by reduction with iron powder to give compound **5** (Scheme 3). Imidization of compound **1** with compound **5** in *m*-cresol at 200°C gave the third generation dendron (**G3-den**, Fig. 1) in good yield (70%) after purification by SEC. However, this dendron could not be assembled around the trimesic acid core, even after the coupling reaction was carried out for 28 days, under similar conditions used for the assembly of the second generation dendrimer. The highest molecular weight compound, isolated from the reaction mixture by SEC, had a mass corresponding to a trimesic acid core having only two dendrons assembled around it (*m*/*e* = 5289, MALDI-TOF-MS, dithranol/silver trifluoroacetate matrix). It is postulated that due to steric crowding, **G3-den** cannot get close enough in space to the trimesic acid core to couple.

Structural characterization

Gel permeation chromatography (GPC) was performed on each dendron from generation one (**G1-den**, Scheme 1) to three (**G3-den**, Fig. 1), which showed an increase in apparent molecular weight for increasing generation and the expected monodispersity. However, comparing these molecular weight profiles against polystyrene standards provided no useful information regarding molecular weight. This is not unexpected, given the obvious difference in molecular conformation between polystyrene and these rigid aryl dendrites. Figure 1 illustrates both stick and space-filled molecular models of **G3-den**. From this model, the conformation of each of the tetrahydro[5]helicene units as well as the shape and conformation of the dendron itself is illustrated.

The identity of each dendron and dendrimer was confirmed using IR spectroscopy, and its mass was confirmed using MALDI-TOF mass spectrometry. In each case, the mass spectrum was used as the primary means for structural determination, since for every dendron and dendrimer higher than generation one, the ^{1}H NMR spectra were cluttered and not easily interpretable. A single peak was observed in the MALDI-TOF mass spectrum, corresponding to the mass of the parent molecular species plus Li^+ (from the matrix) except for **G2-den**, which had only its parent molecular ion.

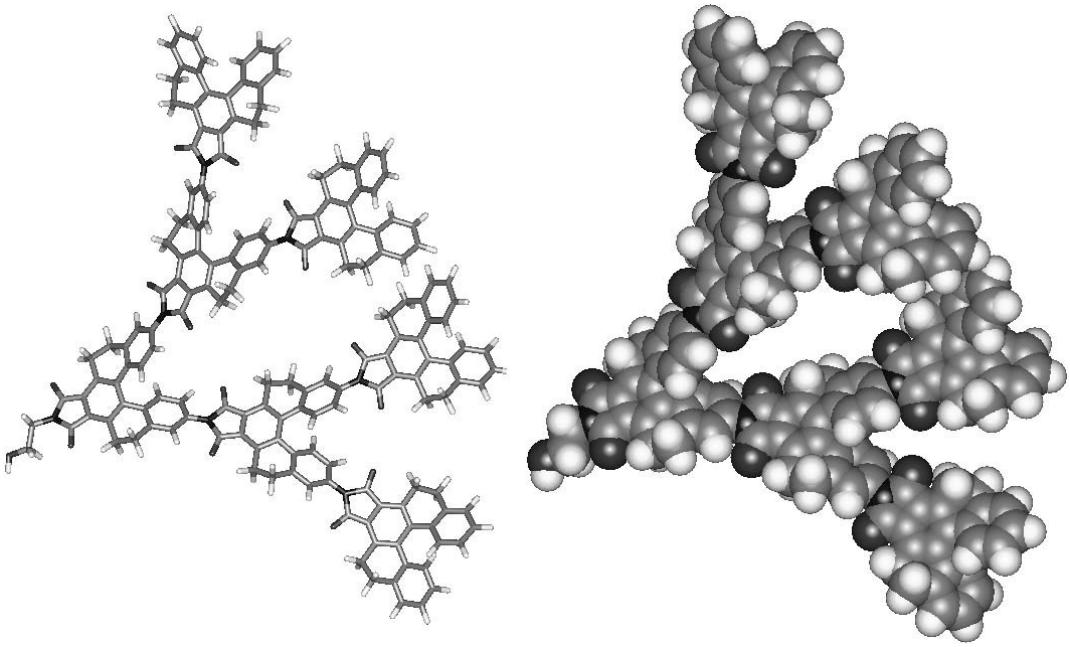

Fig. 2. MALDI-TOF mass spectra (dithranol/silver trifluoroacetate matrix) of oligoimide **11**. Peaks indicated are M + Ag^+ for a given number (*n*).

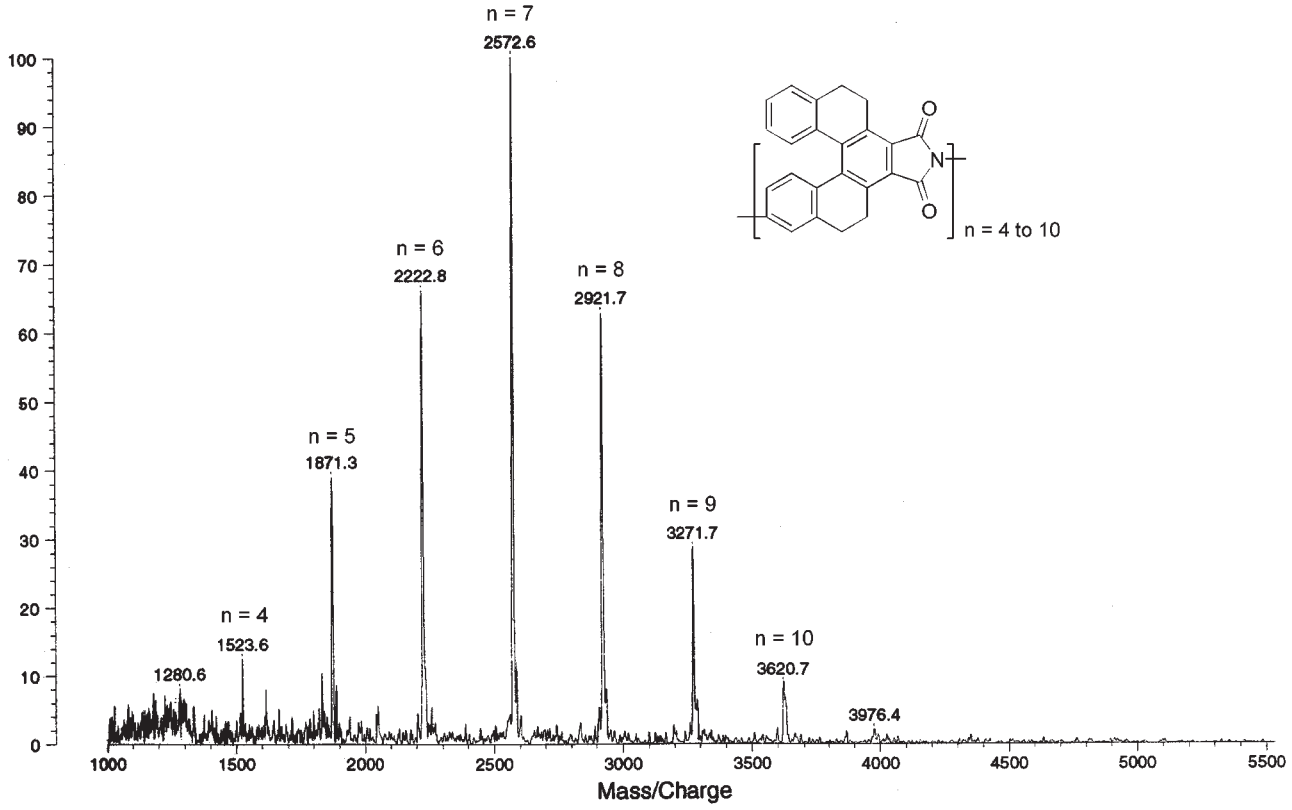

Physical properties

To compare the physical properties of these dendritic aryl imides with analogous linear imides, oligoimides were needed of approximately the same molecular weight that contained only the tetrahydro[5]helicene unit. Consequently, the synthesis of oligoimide **11** was accomplished using our published method, except the polymerization reaction was time controlled so as to produce the oligoimides (3*a*). The produced oligoimides were fractionated using chloroform (good solvent) and methanol (poor solvent). A fraction was obtained that had a distribution of oligomers corresponding to oligoimide **11** with 4–10 repeat units, which was confirmed by its MALDI-TOF mass spectrum (Fig. 2). The distribution of molecular weights for oligoimide **11** was

centered around $n = 7$ and a mass of $m/e = 2461$, which were close to that of **G3-den** ($n = 7$, $m/e = 2489$).

Figure 3 illustrates GPC traces of oligoimide **11** and **G3-den**. Both compounds have similar absolute molecular weights by MALDI-TOF. However, oligoimide **11** showed a higher apparent molecular weight, which can be attributed to its rigid-rod conformation and consequently larger hydrodynamic volume. This difference in hydrodynamic volume is a direct indication that the presented dendritic aryl imides would have a lower solution and melt viscosity when compared with their linear counterparts. These observations further confirm a widely held opinion for which there has only recently been direct evidence (9). DSC measurements showed that **G3-den** possessed a detectable glass transition (T_g) at 346°C, whereas oligoimide **11** did not show a glass transition up to 450°C. The measured lower T_g suggests that the dendritic aryl imide is more flexible than the linear aromatic oligoimide. Both of these properties suggest that dendritic aryl imides could be used to modify the properties of traditional linear polyimides.

Fluorescence study

Figure 4*a* illustrates the UV-vis absorption spectra of the dendrons **G1-den**, **G2-den**, and **G3-den** as well as oligoimide **11**, taken in dichloromethane solution at a concentration of 3×10^{-5} M.[3] Each compound exhibits two maximum absorptions at about 290 and 370 nm. The repeat unit equivalent molar extinction coefficients for each dendron at each $\lambda_{max,abs}$ are approximately equal. However, when the same series of compounds are irradiated at either wavelength, they fluoresce, and both the wavelength and intensity of the fluorescent emission vary widely among the compounds (Fig. 4*b*). For example, the emission intensity of **G1-den** ($\lambda_{max,em}$ = 480 nm) is over 30 times greater than the emission intensity of **G2-den** ($\lambda_{max,em}$ = 477 nm), which is itself 5 times larger than that of **G3-den** ($\lambda_{max,em}$ = 501 nm). The shift of the fluorescent emission of **G3-den** compared to **G2-den** indicates a loss of radiant energy by some pathway. Furthermore, there is a progressive decrease in the emission intensity with increasing dendron generation. Additionally, the linear oligoimide **11** exhibits larger emission intensity (although shifted to longer wavelength) than **G3-den**. Coupling these observations leads to the conclusion that within the higher generation dendrons intermolecular quenching of the emitted radiation takes place. One may expect these observations, given the dendritic structure and conformation of **G3-den**. It would be more likely to undergo intramolecular quenching, as compared to its linear rod-like analogue, given that any intermolecular quenching would have to be a result of the *o*-terphenyl moieties overlapping and interacting in solution.

Electrochemical behavior

Given the indication that the tetrahydro[5]helicene units of the higher generation dendrons are capable of interacting in solution, it would be of interest to see whether or not there exists a redox activity, not observed in isolated *o*-terphenyl moieties, tetrahydro[5]helicene units, or imide functionalities, that does exist within the higher generation dendrons (**G2-den** and **G3-den**). Thus, cyclic voltammetry was performed in DMF solution, using tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) as the supporting electrolyte, in order to examine the electrochemical behaviour of the dendritic aryl imides (**G1-den**, **G2-den**, and **G3-den**).

[3] The absorptions and emissions have been corrected by a factor equal to the repeat unit equivalent molar concentration for each compound.

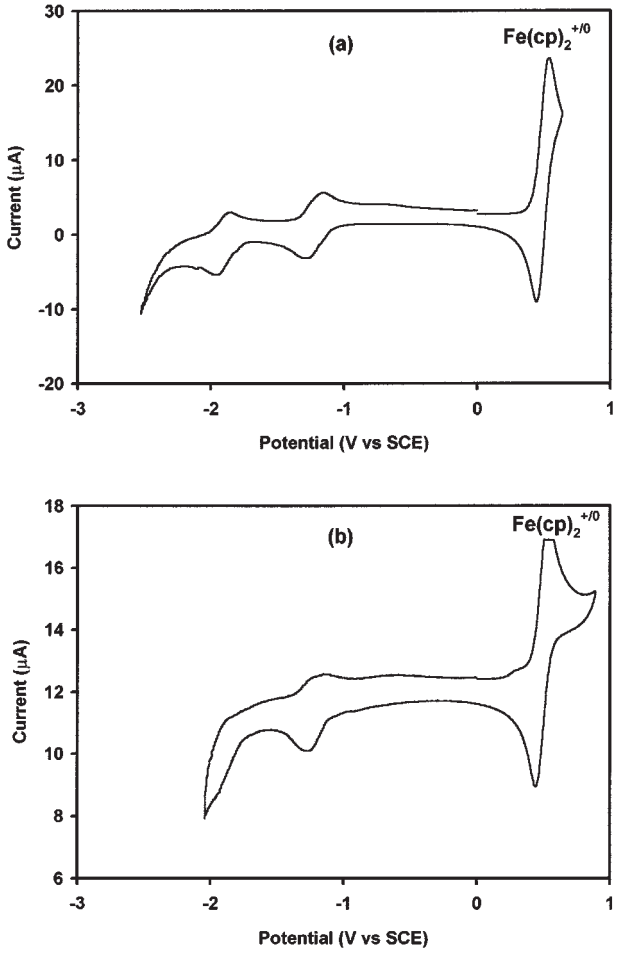
Fig. 5. Cyclic voltammograms of **G3-den** (*a*) and oligoimide **11** (*b*).



All the three dendrons exhibited electrochemical activity, although only one reversible[4] redox couple was observed for **G1-den** (at –1.28 V), whereas two were observed for **G2-den** and **G3-den** (Fig. 5, Table 1). The first reversible redox couple at approximately –1.28 V was consistently present for all the dendrons. If **G1-den** was submitted to potentials more negative than –1.3 V, a second redox couple was observed. However, under these conditions, neither the first nor the second redox couples were reversible, indicating that chemical degradation occurred at the more negative potentials.

To explain these observations and the nature of this electrochemical behaviour, cyclic voltammograms for a series of compounds (Fig. 6) containing both *o*-terphenyl and anhydride moieties were obtained. Within compound **1**, the *o*-terphenyl moiety is bridged and held in place by the ethylene unit (at positions 5–6 and 9–10). The twist angle of the *o*-terphenyl moiety within compound **1** is approximately 32° as shown by X-ray diffraction analysis of a single crystal.[5] Compounds **7**– **9** differ in the degree of conjugation within the *o*-terphenyl moiety, brought about by the difference in the number of bridging carbon atoms as compared with

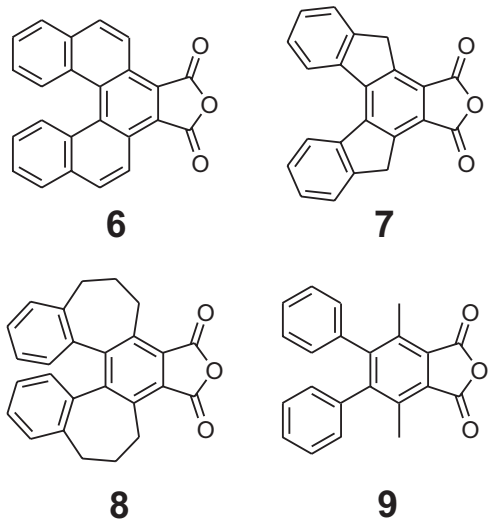
Fig. 6. Analogs of compound **1**, containing both *o*-terphenyl and anhydride moieties.



compound **1**. The *o*-terphenyl moiety within compound **9** is not bridged at all and therefore is least conjugated within this series. Whereas, compound **6** ([5]helicene-7,8-dicarboxylic anhydride) contains an *o*-terphenyl moiety, which is bridged by a vinylene group and is therefore the most conjugated within the series. Therefore, this series of compounds can be thought to undergo a shift in the degree of conjugation of the *o*-terphenyl moiety as follows: **6** ≥ **7** > **1** > **8** > **9** ≈ *o*-terphenyl.

All the compounds illustrated in Fig. 6, except for *o*-terphenyl itself, exhibited electrochemical activity, with redox couples in the range of –0.70 to –2.00 V vs. SCE (Table 1). For compounds **1**, **8**, and **9**, only one reversible redox couple was observed. Compounds **6** and **7** exhibited two reversible redox couples, with the second couple at more negative potential. The first redox couple is shifted to more positive potentials as the degree of conjugation increases, in

[4]Reversible couple is defined in this work as the ability of the molecule to undergo identical redox couples (i.e., superimposable CV waves) over 12 consecutive scans within the applied potential range.
[5]T.P. Bender and Z.Y. Unpublished results.

the order **6** > **7** > **1** > **8** > **9**. Furthermore, when compound **1** was submitted to higher negative potentials, it underwent an additional reductive process at approximately –1.9 V. However, this reduction was not reversible and resulted in the degeneration of the measured current over consecutive scans and a shift of the reduction potential for both the first and second redox couples, behaviour similar to that observed for **G1-den**.

Based on these observations and by analogy to compounds **1** and **6**–**9**, the electrochemical behaviour of the tetrahydro[5]helicene containing dendrons (**G1-den**, **G2-den**, and **G3-den**) can be partially explained. The presence and approximate position of the first redox couple is consistent within the dendrons (**G1-den**, **G2-den**, and **G3-den**) and the model compounds (**1**, **6**–**9**). The potential of the first redox couple is invariant with generation. Therefore, the first redox couple must be attributed to a redox process occurring at the anhydride–imide functionality. This is consistent with the reported findings from the electrochemical study of soluble linear polyimides (10). Since the first redox couple moves to more negative potential on the series **6** > **7** > **1** > **8** > **9**, its position is directly proportional to the degree of conjugation present within the *o*-terphenyl moiety (which is attached to the anhydride–imide functionality). The lower the degree of conjugation within the aromatic ring system, the more difficult the reduction of the anhydride carbonyl group becomes. For compounds **6** and **7**, a second reversible redox couple at more negative potential was also observed. These two compounds possess the highest degree of conjugation within the series of model compounds. Thus, this second redox couple must originate within the *o*-terphenyl moiety and is stabilized within these compounds due to their increased degree of π-conjugation.

Two reversible reductive processes were observed for the higher generation dendrons (**G2-den** and **G3-den**, Fig. 5). Although within these dendrons, there is an extended array of tetrahydro[5]helicene units (and consequently the *o*-terphenyl moieties), they cannot be in a state of extended conjugation because of the imide functionality. Given the presence of a nonreversible reductive process at approximately –1.90 V for compound **1** and **G1-den**, the second reduction of the higher dendrons at –1.93 and –1.92 V, for **G2-den** and **G3-den**, respectively, must originate within the *o*-terphenyl moiety. Furthermore, due to its reversibility, the intermediate of the second reduction must be stabilized by interaction with other *o*-terphenyl moieties within the dendritic structure itself. This is consistent with the observations made using fluorescence spectroscopy, which indicated an interaction between tetrahydro[5]helicene units of the higher generation dendrons in solution. Further to this, linear oligoimide **11**, which on average has the same number of repeat units as **G3-den**, exhibits only one, all be it broad, redox couple at –1.23 V when measured in NMP solution (Table 1, Fig. 5). The presence of only one redox couple for linear oligomer **11** further implies that the second redox couple observed for **G3-den** is attributed to the dendritic structure of the molecule. Further spectroelectrochemical investigation of the higher dendrons may help determine the exact nature of the second redox couple.

Conclusions

In conclusion, we have shown that a new tetrahydro[5]helicene derivative, compound **3** containing a conformationally locked *o*-terphenyl moiety, can be used in the synthesis of dendritic aryl imides by a divergent synthetic approach. First and second generation dendrons could be assembled around a trimesic acid core to give first and second generation dendrimers, **G1** and **G2**, respectively. In each case, MALDI-TOF-MS and spectroscopic methods were used to confirm the identity of each dendron and dendrimer. Each of the dendrons underwent either one or two electrochemical reductions on the range –1.2 to –2.1 V vs. SCE. When a dendritic aryl imide was compared with its linear analog, differences were found in the hydrodynamic volumes, glass transition temperatures, and fluorescence and electrochemical behaviour.

Acknowledgments

The authors would like to thank Dr. A.S. Hay's group (McGill University, Montreal) for performing the MALDI-TOF-MS analysis, Dr. Chuncai Yang for the synthesis of the oligoimide (**11**), and Dr. Wen Lu for the useful discussions on electrochemistry. This work was financially supported by the Natural Sciences and Engineering Research Council (NSERC) of Canada. T.P.B. would like to acknowledge the financial support of NSERC through a PGS-A.

1998 J.C. Polanyi Award Lecture Fullerene ions in the gas phase: chemistry as a function of charge state[1]

Diethard K. Böhme

Abstract: Results of recent measurements in the Ion Chemistry Laboratory at York University using the Selected-Ion Flow Tube (SIFT) technique are surveyed for reactions of singly, doubly, and triply charged buckminsterfullerene C_{60}^{n+} cations proceeding at room temperature in helium buffer gas at 0.35 Torr (1 Torr = 133.3 Pa). Measured rate coefficients and observed product channels for reactions with a variety of inorganic and organic molecules depend strongly on the charge state of the reactant ion. The measured rate coefficients span more than four orders of magnitude. Primary product channels observed include attachment, dissociative attachment, dissociative attachment with charge separation, single-electron transfer, dissociative single-electron transfer, and two-electron transfer. A qualitative description of the potential-energy profiles associated with these reaction channels is provided. The observed higher order chemistry of derivatized C_{60}^{n+} cations and of atomic exohedral adduct ions is also described. This chemistry includes cation-transfer reactions, surface derivatization, and "ball-and-chain" polymerization. Finally, results are presented that provide insight into the influence of surface strain on the reactivities of fullerene ions.

Key words: fullerenes, ions, electron transfer, charge separation, surface derivatization.

Résumé : On présente une revue des résultats de mesures récentes effectuées dans le « Ion Chemistry Laboratory at York University », utilisant la technique du tube à écoulement d'ions choisis (« SIFT »), pour des réactions des cations buckminsterfullerènes portant une, deux ou trois charges, C_{60}^{n+}, se produisant à la température ambiante, dans de l'hélium à 0,35 Torr agissant comme gaz tampon. Les coefficients de vitesse mesurés et les voies observées pour les produits de réactions avec une grande variété de molécules inorganiques et organiques dépendent fortement de la charge de l'ion qui réagit. Les coefficients de vitesse observés s'étalent sur quatre ordres de grandeur. Les principales voies observées pour les produits comprennent la fixation, la fixation dissociative, la fixation dissociative avec séparation de charge, le transfert d'un seul électron, le transfert dissociatif d'un seul électron et le transfert de deux électrons. On fournit une description qualitative des profils d'énergie potentielle reliées à ces voies réactionnelles. On décrit aussi la chimie d'ordre élevée observée pour les cations C_{60}^{n+} dérivatisés et pour les ions adduits exoédriques atomiques. Cette chimie inclut des réactions de transfert de cation, de dérivatisation en surface et de polymérisation en collier de perle avec bâtonnets. Enfin, on présente des résultats qui permettent de comprendre l'influence de la tension de surface sur les réactivités des ions fullerènes.

Mots clés : fullerènes, ions, transfert d'électron, séparation de charge, dérivatisation en surface.

[Traduit par la Rédaction]

1. Introduction

One of the many remarkable features of the isolated buckminsterfullerene molecule, C_{60}, is its stability as a multiply charged cation against Coulomb explosion. Tilmann Märk and his group at the University of Innsbruck have been able to produce and identify mass-spectrometrically C_{60} with up to 7 electrons removed from the ocean of 240 valence electrons that surround its hollow cage of 60 carbon atoms in this molecule (1). This has been achieved in a dedicated ion source that delivers high electron currents at high electron energies. In the Ion Chemistry Laboratory at York University we have found that it is straightforward to remove up to three electrons from C_{60} in the conventional electron-impact ion source that delivers ions into our selected-ion flow tube (SIFT) apparatus (2). The SIFT apparatus is a flow reactor designed to measure reaction-rate coefficients and product-ion distributions for reactions between gas-

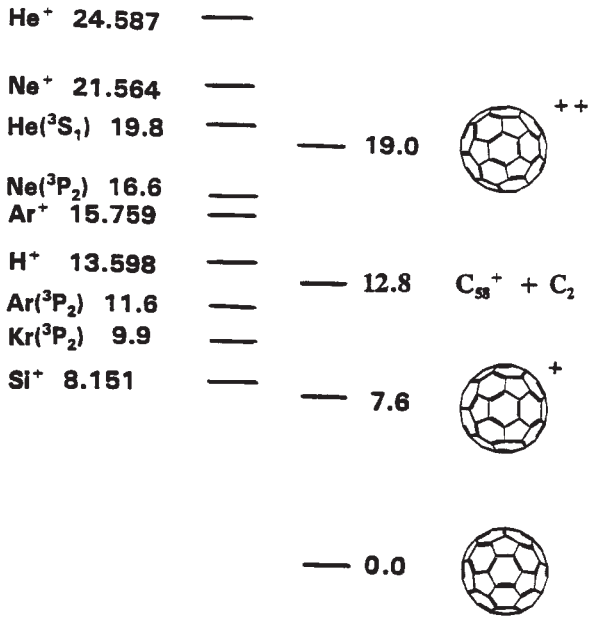
Fig. 1. Energy-level diagram for various charge states of C_{60}, a selection of singly charged atomic ions, and several rare-gas metastable atoms.



phase ions and neutral molecules. The ease of production of the first three ionized states of C_{60} has prompted us to explore systematically the uncharted chemistry of C_{60}^{n+} as a function of charge state from n = +1 to +3. Investigations of reactivity as a function of charge state are unprecedented in the greater world of gas-phase ion chemistry, in part because many molecular ions explode by intramolecular Coulombic repulsion already in the second charge state. We shall see in this overview that C_{60}^{n+} carbocations are extensively reactive in the gas phase at room temperature and more so as the charge state increases. New reaction pathways become accessible at higher degrees of ionization as, in a sense, physics increasingly preempts the occurrence of chemistry.

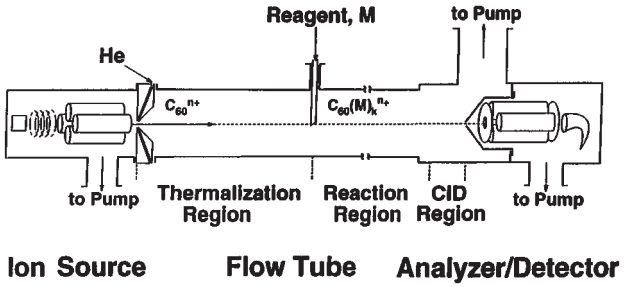
This overview is restricted to the research on the chemistry of fullerene ions performed in the author's own laboratory since 1991. No attempt has been made to review the larger body of gas-phase fullerene ion chemistry nor the gas-phase chemistry and physics of multiply charged ions generally that has been reported in the literature.

2. Electron transfer and chemi-ionization of C_{60}

Before embarking on measurements of the chemistry of C_{60}^{n+} ions, we first attempted the gas-phase ionization of C_{60} with methods other than electron-impact ionization. These early experiments showed that metastable atoms of He, Ne, Ar, and Kr induce the loss of electrons from C_{60} in the gas phase *at room temperature* in chemi-ionization (or Penning ionization) reactions of type [1] (3).

[1] $X^* + C_{60} \rightarrow C_{60}^+ + X + e$

Fig. 2. Schematic view of the Selected-Ion Flow Tube (SIFT) apparatus.



As shown in Fig. 1, these metastable atoms all have energies that lie above the first ionization energy of C_{60}, IE(C_{60}) = 7.61 ± 0.02 eV (4). The mechanism of reaction (1) can be understood in terms of the formation of an excited quasi-molecule $(XC_{60})^*$ that undergoes autoionization (3). We also found that C_{60} is readily ionized at room temperature in electron-transfer reactions of type [2] with ions that have a recombination energy (RE) larger than IE(C_{60}).

[2] $X^+ + C_{60} \rightarrow C_{60}^+ + X$

Such reactions have been observed in our laboratory with the atomic ions listed in Fig. 1 (5). While exothermic dissociative electron transfer leading to the rupture of C_{60}^+ through loss of C_2 was not observed to compete under our experimental operating conditions, we did see novel electron transfer/electron emission reactions of type [3] with X^+ = He^+ and Ne^+.

[3] $X^+ + C_{60} \rightarrow C_{60}^{2+} + X + e$

The mechanism of this novel reaction is not known. It has been suggested[3] that it proceeds by the initial transfer of a deeply embedded electron in C_{60} followed by an Auger emission of a second electron in a manner analogous to that which is known to occur when metals are exposed to slow beams of He^+ ions (6). The occurrence of reaction [3] may therefore be a manifestation of the metallic character of C_{60} due to the ocean of electrons that surround its hollow cage of 60 carbon nuclei.

3. The Selected-Ion Flow Tube (SIFT) apparatus

Our SIFT apparatus shown in Fig. 2 is essentially a tandem-quadrupole mass spectrometer in which the two quadrupoles are separated by a flow tube (2). Fullerene cations are generated in a conventional "open" electron-impact source at electron-impact energies from 60 to 100 eV, depending on the desired charge state: C_{60}^+ at ca. 50 eV, C_{60}^{2+} at ca. 80 eV, and C_{60}^{3+} at ca. 100 eV. The cations are selected upstream with the first quadrupole mass filter, injected through an aspirator-type inlet into He carrier gas at 0.35 Torr, allowed to thermalize to room temperature with ca. 10^5 collisions with He bath gas atoms, and then reacted with a desired reagent added into the flow tube. A large variety of stable gases and vapors of volatile liquids were added

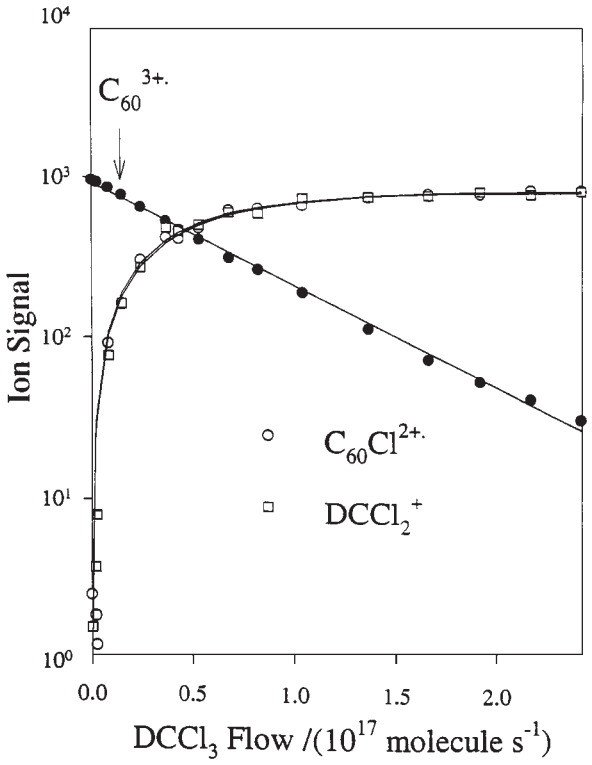
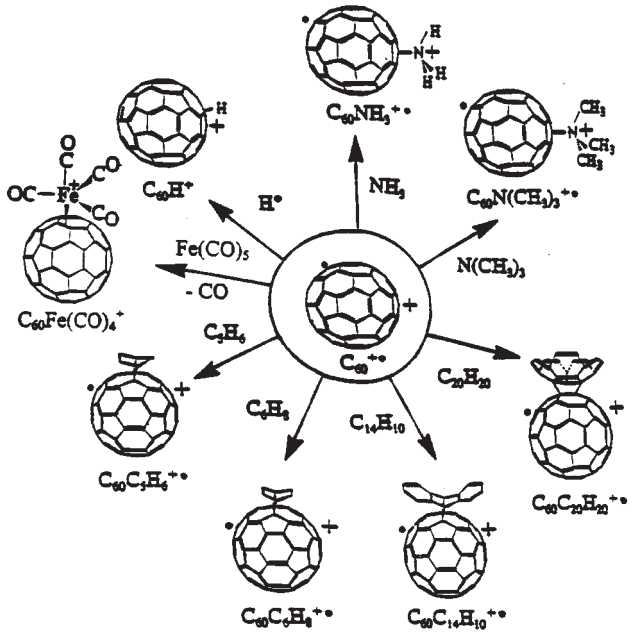
Fig. 3. Experimental data for the chemistry initiated by the reaction of $C_{60}^{\cdot 3+}$ with deuterated chloroform. $C_{60}^{\cdot 3+}$ was produced in a low-pressure ion source by electron impact at 100 eV with C_{60} vapour derived from a fullerene powder. The lines represent fits to the experimental data with solutions of the systems of differential equations appropriate for the observed reactions.



as reagents. Also, reagent hydrogen atoms were generated by the action of a microwave discharge upon a mixture of (5%) hydrogen and helium. The reacting mixture communicates with a second quadrupole mass spectrometer downstream and an electron multiplier, which monitor the reagent and product ions as a function of the flow of the neutral reagent. The reaction time is fixed at a few milliseconds by the buffer-gas flow velocity and the positions of the inlet and sampling ports.

Reaction profiles are obtained by monitoring reactant and product ions as a function of the flow of the neutral reagent. These profiles can be analyzed to provide rate coefficients for primary and secondary (or higher order) reactions as well as ion-product distributions. Representative reaction profiles for the chemistry initiated by C_{60}^{3+} in deuterated chloroform (7) are shown in Fig. 3. Bond connectivities in the product ions can be investigated in multicollision induced dissociation (CID) experiments by raising the sampling nose–cone voltage from 0 to –80 V while concomitantly varying the potentials of front and rear quadrupole focussing lenses so as not to introduce mass discrimination (8). The latter voltages are predetermined manually and then delivered with a programmable power supply.

Fig. 4. An overview of derivatization reactions of C_{60}^+ observed at a room temperature of 294 ± 2 K and a helium pressure of 0.35 ± 0.01 Torr. The assigned structures are speculative.



4. The chemistry of C_{60}^{n+} cations

A. Reactions of C_{60}^+

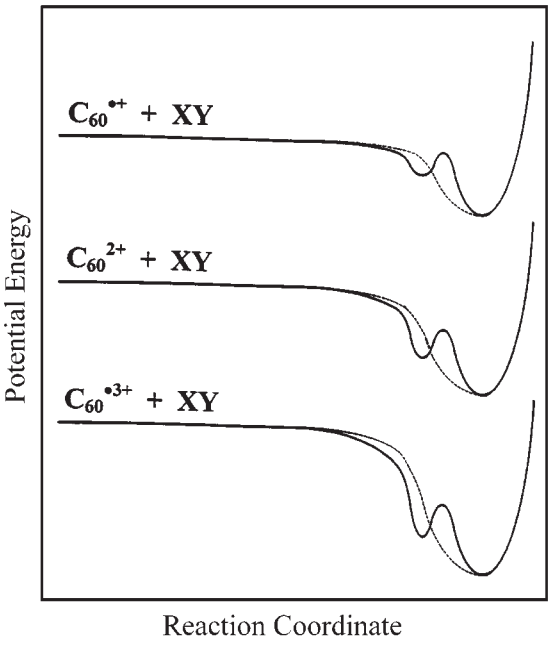
C_{60}^+ is generally quite nonreactive under SIFT conditions: we have found C_{60}^+ to be nonreactive towards more than 50 nonpolar, but also polar, inorganic and organic molecules. Electron transfer is rare because of the low electron-recombination energy of C_{60}^+ (7.6 eV (4)). The few chemical reactions of C_{60}^+ that we have observed so far under SIFT conditions are largely *termolecular* addition reactions that lead to chemical-bond formation with the carbonaceous surface of C_{60}^+. These are summarized in Fig. 4. We have found that C_{60}^+ can be derivatized with H atoms (9, 10), strong nucleophiles such as ammonia and aliphatic amines (11), and with molecules capable of Diels–Alder additions such as 1,3-cyclopentadiene, 1,3-cyclohexadiene, anthracene, and corannulene (12). A reaction of C_{60}^+ with iron pentacarbonyl produces $C_{60}Fe(CO)_4^+$ (13) and is the only example of a *bimolecular* derivatization reaction with C_{60}^+ that we have observed to date.

A remarkable trend is observed for the reactions of C_{60}^+ with amines: ammonia adds only slowly, but the rate of addition approaches the collision rate with increasing alkyl substitution. This behaviour is consistent with a trend in inductive electron donation (the Lewis basicity of the amine) and a trend in the number of degrees of freedom in the intermediate adduct ion effective in energy dispersal (11).

Here is how we envisage the progress of chemical reactions with singly charged C_{60}^+ (14). At long range the charge on the *isolated* cation, initially delocalized over the entire C_{60} surface, will become localized due to electrostatic interaction with the induced and (or) permanent dipole of the incoming molecule. Chemical attack at short separations should occur at the carbon site of a localized charge. For re-

© 1999 NRC Canada

Fig. 5. Schematic view of the increasing well depth of the potential-energy well leading to adduct formation, and of the barrier to covalent-bond formation in the double-well model, with increasing charge state.



action to take place, a transition is required from largely sp^2 to largely sp^3 hybridization at the C-atom which becomes bonded. This requires surface deformation and so will involve an activation barrier that we estimate to be ca. 15 kcal mol^{-1}. Although this barrier can be overcome by electrostatic interaction with an incoming molecule, its presence can account for the relatively low reactivity of C_{60}^{+} at room temperature. The barrier is presumably located between the initial electrostatically bound complex and the ultimate chemically bound adduct, and should be easier to overcome if the electrostatic interaction is larger (see Fig. 5).

B. Reactions of C_{60}^{2+}

C_{60}^{2+} is much more reactive than C_{60}^{+} in both electron transfer and chemical bonding. We have attributed this enhanced reactivity to the higher recombination energy of C_{60}^{2+}, RE = 11.36 ± 0.05 eV (15), and to the stronger electrostatic interaction between molecules and C_{60}^{2+} that may serve to overcome the energy barrier associated with the change in hybridization required at the site of bonding (14), respectively. Figure 6 summarizes derivatization reactions observed with C_{60}^{2+}. The chemistry of C_{60}^{2+} has been explored with H atoms (9, 10), ammonia, and aliphatic amines (11), nitriles (16), water, alcohols, and ethers (17), aldehydes, ketones, carboxylic acids, and esters (18), cyclic aliphatic oxides (19), and unsaturated hydrocarbons (20–23). Electron transfer is an important competitive channel for

Fig. 6. An overview of derivatization reactions of C_{60}^{2+} observed at a room temperature of 294 ± 2 K and a helium pressure of 0.35 ± 0.01 Torr. The assigned structures are speculative.

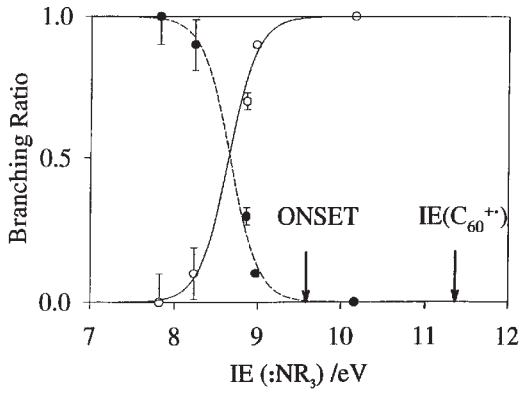
Fig. 7. Competition between electron transfer (broken line) and adduct formation (solid line) observed for reactions of C_{60}^{2+} with ammonia and amines at room temperature 294 ± 2 K and a helium pressure of 0.35 ± 0.01 Torr.



some of the observed derivatization reactions and, for molecules with sufficiently low ionization energies, becomes the only reaction channel. However, electron transfer with C_{60}^{2+} occurs in the presence of an activation barrier that arises from Coulomb repulsion between the charged product ions (24, 25). This is evident in Fig. 7 that shows a delayed onset for competing electron transfer at about 9.6 eV, which is well below the recombination energy of C_{60}^{2+} (11.36 ± 0.05 eV). Electron transfer must be exothermic by at least 1.8 eV in order to compete effectively.

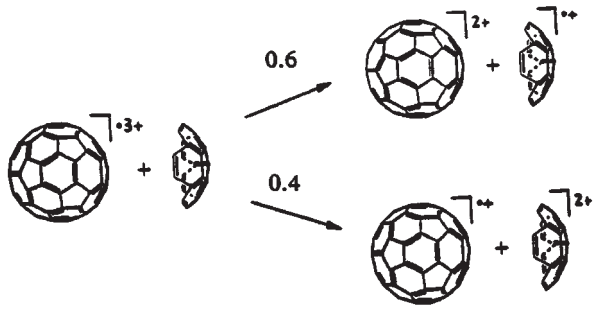
C. Reactions of C_{60}^{3+}

Derivatization reactions also have been observed with C_{60}^{3+}, but electron transfer is even more competitive than with C_{60}^{2+}. For example, although we have observed ammonia to add to C_{60}^{3+}, only electron transfer has been seen with amines (11). The ionization-energy threshold for electron transfer to C_{60}^{3+} lies 4.4 eV below the thermodynamic threshold of RE (C_{60}^{3+}) = 15.6 eV (15). This threshold is higher in energy than observed for electron transfer to C_{60}^{2+} and again can be rationalized in terms of an energy barrier arising from Coulombic repulsion between the product ions (24, 25). We have also observed C_{60}^{3+} cations to abstract *two* electrons from corannulene and the PAH molecules anthracene, pyrene, and benzo[*rst*]pentaphene in reactions of type [4] (26).

$$[4] \qquad C_{60}^{3+} + M \rightarrow M^{2+} + C_{60}^{+}$$

All of these PAH molecules have sufficiently low first and second ionization energies to make double-electron transfer thermodynamically and kinetically favourable. The mechanism of the two-electron transfer reaction [4], whether electron transfer is concomitant or sequential, is not known. Reaction [4] occurs in competition with single-electron transfer. It was observed as a minor channel (<5%) with anthracene, corannulene, and pyrene and occurs in almost equal amounts with benzo[*rst*]pentaphene, which requires the lowest energy for double ionization of these four PAH molecules. The single and two-electron transfer observed with corannulene is illustrated in eq. [5]. (The structure of corannulene is assumed not to change upon ionization.)

[5]



Reactions of C_{60}^{3+} have been investigated with H atoms (9, 10), nitriles (16), water, alcohols, and ethers (17), aldehydes, ketones, carboxylic acids, and esters (18), cyclic aliphatic oxides (19), and unsaturated hydrocarbons (20–23). Figure 8 provides a summary of addition reactions observed. New, charge separation, channels appear for some of the reactions with C_{60}^{3+}. For example, dissociative electron transfer to produce $C_{60}^{2+}/CH_2NH_2^+$ and C_{60}^{2+}/CH_3^+ is the dominant reaction channel with ethylamine [12]. Also, dissociative addition reactions such as hydride and hydroxide transfer, become more effective. This is the case with water, some alcohols, and some alkanes. Halide transfer from HCl and HBr also has been observed. HCl reacts both by Cl^- transfer to produce, remarkably, a free proton as the second ion product (88%) and by hydride transfer (12%) according to reaction [6]. HBr also reacts by halide transfer, but the competing channel in this case is dissociative electron transfer (27).

$$[6a] \qquad C_{60}^{3+} + HCl \rightarrow C_{60}Cl^{2+} + H^+$$

$$[6b] \qquad \rightarrow C_{60}H^{2+} + Cl^+$$

5. Trends with charge state

Reactions [7*a*]–[7*f*] summarize the various types of reactive encounters we have observed between the first three charge states of C_{60}^{n+} and some 30 different reactive molecules that we have surveyed. These include addition [7*a*], dissociative addition [7*b*], dissociative addition with charge separation [7*c*], single-electron transfer [7*d*], dissociative single-electron transfer [7*e*], and two-electron transfer [7*f*].

$$[7a] \qquad C_{60}^{n+} + XY \rightarrow C_{60}XY^{n+}$$

$$[7b] \qquad \rightarrow C_{60}X^{n+} + Y$$

$$[7c] \qquad \rightarrow C_{60}X^{(n-1)+} + Y^+$$

$$[7d] \qquad \rightarrow C_{60}^{(n-1)+} + XY^+$$

$$[7e] \qquad \rightarrow C_{60}^{(n-1)+} + X^+ + Y$$

$$[7f] \qquad \rightarrow C_{60}^{(n-2)+} + XY^{2+}$$

Both the nature of the product channel and the rate of reaction were observed to be a function of the charge state of C_{60}^{n+}. This is indicated qualitatively in Fig. 9. A unified model for these reactive encounters in terms of schematic potential-energy profiles is given in Fig. 10 (28). An analogous model was originally introduced by Herman (29) to account for the observed reactivities of other, smaller doubly

Fig. 8. An overview of derivatization reactions of C_{60}^{3+} observed at a room temperature of 294 ± 2 K and a helium pressure of 0.35 ± 0.01 Torr. The assigned structures are speculative.

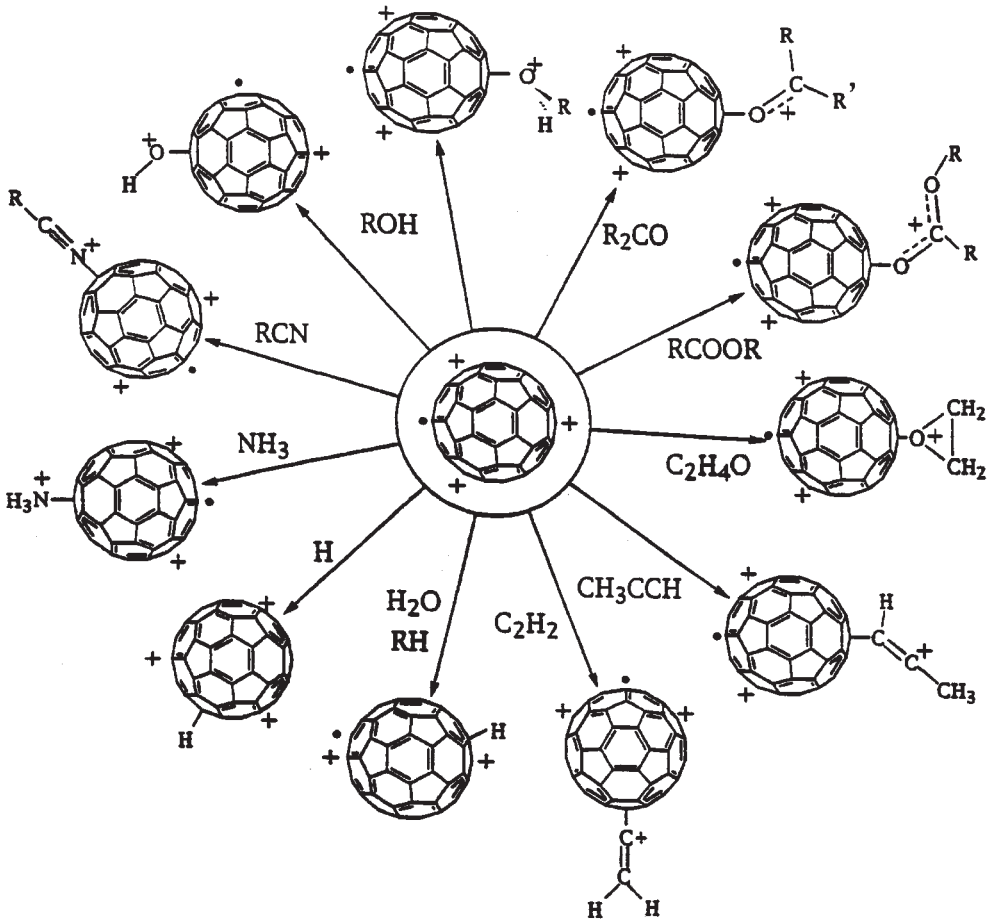

Fig. 9. Qualitative overview of the trend in the reactivity of C_{60}^{n+} cations with charge state. The predominant reaction channels that were observed are indicated in the order of general importance. RE is the recombination energy.

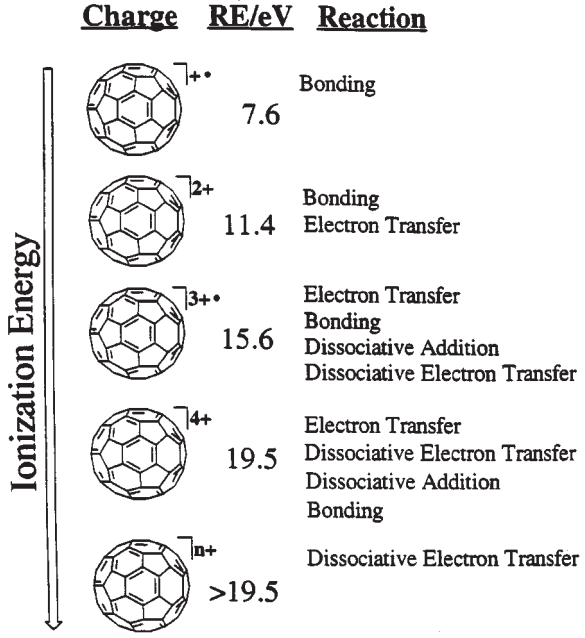

charged ions. As reactants approach each other within this model, a multiply charged fullerene cation encounters single, double, and dissociative electron-transfer potential-energy curve crossings first whereupon a nonadiabatic transition may occur leading to the transfer of an electron. Those C_{60}^{n+}-M pairs that survive the electron-transfer crossings may undergo inelastic collisions with He buffer-gas atoms to produce stable adduct ions $C_{60}M^{n+}$. Failing that, bond redisposition may occur by dissociative addition with or without charge separation. The opportunity for electron transfer increases with increasing charge state. In a sense, chemistry is increasingly preempted by physics with increasing charge state.

6. Higher order chemistry

We have shown that C_{60}^{n+} cations may be derivatized in primary addition or dissociative addition reactions of types [7*a*], [7*b*], and [7*c*]. Now we explore the higher order chemistry of these derivatized ions. Figure 11 provides an overview of this chemistry.

A. Cation-transfer reactions

A number of secondary reactions have been observed with derivatized fullerene cations that involve the transfer of a

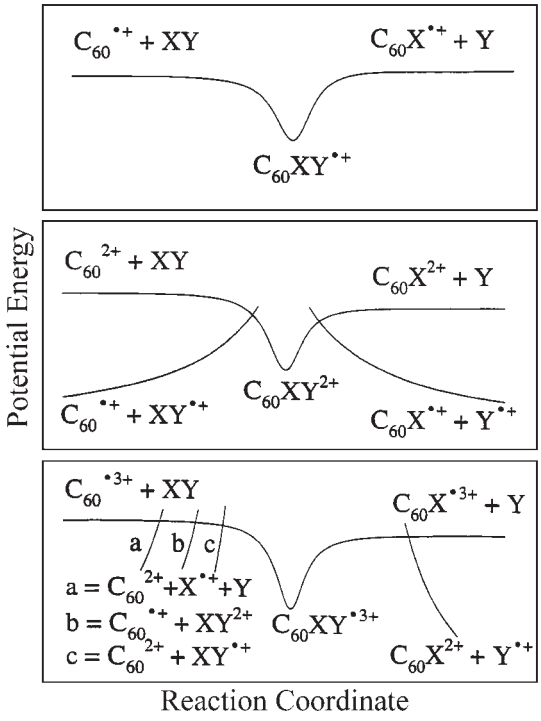
Fig. 10. Summary of plausible potential-energy profiles for reactions [6*a*]–[6*f*] as a function of charge state. The minima in these profiles represent bound adducts $C_{60}M^{n+}$. The repulsive curves on the left represent charge separation channels corresponding to single, double, and dissociative electron transfer. Those on the right represent bond formation by dissociative addition with or without charge separation.

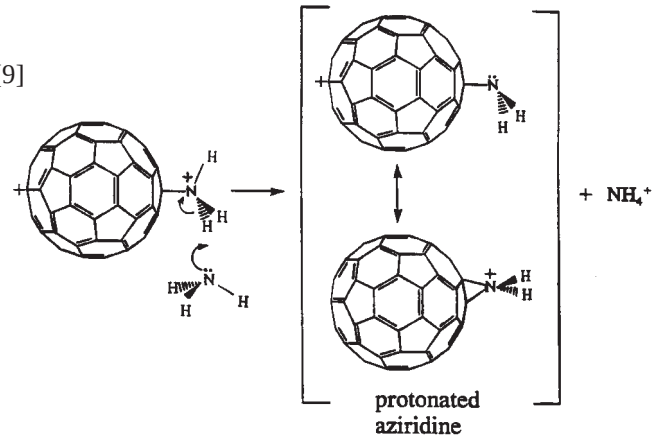


proton, a methyl cation, or the entire ionized substituent. When the substituent contains a hydrogen atom, $C_{60}XH^{n+}$ may undergo partial or complete proton transfer with a suitable proton acceptor. Thus, secondary reactions of singly charged $C_{60}XH^{+}$ ions produce proton-bound adducts of the type $C_{60}X\cdots H^{+}\cdots XH$ with XH = NH_3, CH_3NH_2, $C_2H_5NH_2$, and $(CH_3)_2NH$ (13). Doubly charged derivatized $C_{60}(XH)_m^{2+}$ (m = 1, 2) cations have been observed to undergo rapid proton-transfer reactions of type [8] with XH = ammonia, amines, alcohols, carboxylic acids, ketones, and cyanides (30).

[8] $C_{60}(XH)_m^{2+} + XH \rightarrow C_{60}(XH)_{m-1}X^{+} + XH_2^{+}$

Reaction [9] provides one example of such a proton transfer for XH = NH_3 and m = 1.

[9]



We have assessed this proton-transfer reactivity in terms of an apparent gas-phase acidity of the dicationic species $C_{60}(XH)_m^{2+}$ and have taken the first steps towards establishing a gas-phase acidity ladder for derivatized fullerene cations (30). Also, we have established the gas-phase acidity of $C_{60}H^{2+}$ from the occurrence and nonoccurrence of proton-transfer reactions with this cation (31).

Reactions with methyl formate and methyl acetate involve the transfer of a methyl cation according to eq. [10] proceeding in competition with adduct formation and proton transfer (18).

[10] $C_{60}(XCH_3)^{3+} + XCH_3 \rightarrow C_{60}(X)^{2+} + X(CH_3)_2^{+}$

Fig. 11. Overview of the higher order chemistry of C_{60} adduct ions, designated as $C_{60}AB^{n+}$, with molecules M.

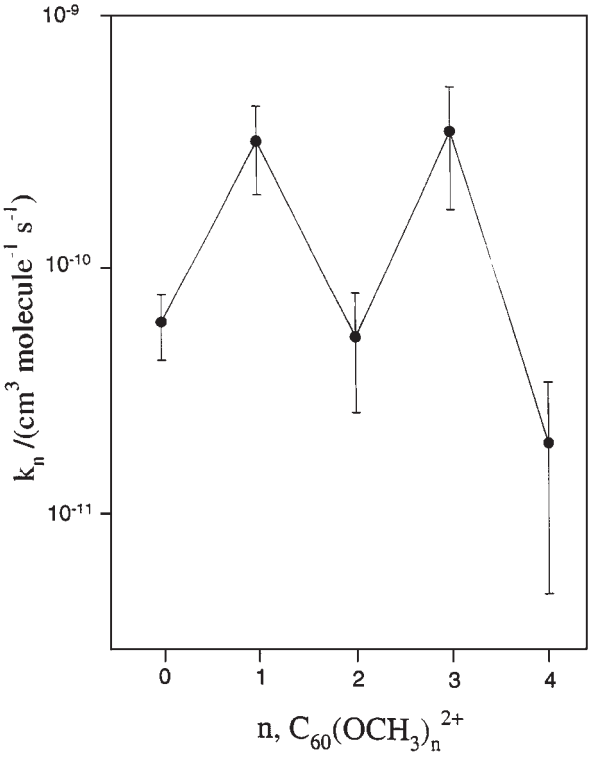
Fig. 12. Variation in the rate coefficient measured for the sequential methoxylation reaction of C_{60}^{2+} with methyl nitrite at room temperature in helium buffer gas at 0.35 Torr.



Also, we have observed several reactions of derivatized fullerene cations that involve the complete transfer of the ionized substituent according to eq. [11] with R = CN, C_2H_3, C_3H_3, and CH_2CN (16).

[11] $C_{60}(NCR)^{3+} + RCN \rightarrow C_{60}^{2+} + (RCN)_2^+$

Presumably such reactions are driven by the stability of the product dimer cation.

B. Surface derivatization

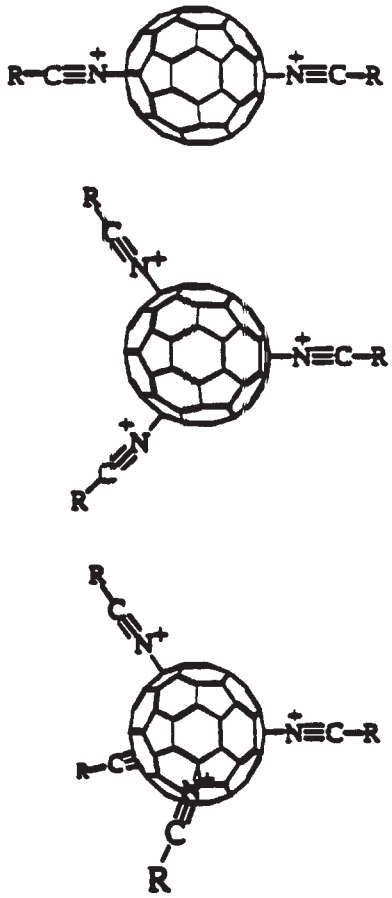
A number of higher order reactions have been observed in our laboratory that result in the sequential derivatization of the *surface* of the fullerene cation to produce what have been called "fuzzy ball" structures. H atoms were seen to add sequentially to the first three charge states of C_{60}^{n+} to produce $C_{60}H_m^{n+}$ according to reaction [12], with *m* up to 9 and constrained only by the number density of H atoms that we were able to generate in the flow tube experimentally (8, 9).

[12] $C_{60}H_m^{n+} + H \rightarrow C_{60}H_{m+1}^{n+}$

Several aliphatic nitriles have been observed to add rapidly to C_{60}^{n+} in numbers equal to the number of charges on C_{60}^{n+} to produce adducts according to reaction [13], with *n* up to 4 (16).

[13] $C_{60}(NCR)_m^{n+} + RCN \rightarrow C_{60}(NCR)_{m+1}^{n+}$

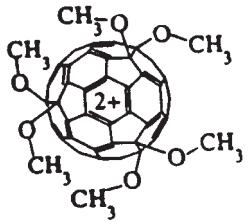
These adducts have the following plausible structures (16).



Also, C_{60}^{2+} has been observed to react with methyl nitrite in sequential bimolecular reactions leading to the sequential transfer of at least 15 methoxy groups according to reaction [14] (31).

[14] $C_{60}(CH_3O)_m^{2+} + CH_3ONO \rightarrow C_{60}(CH_3O)_{m+1}^{2+} + NO$

The addition kinetics exhibits periodicities of 2 and 4 that have been attributed to periodicities in the stabilities of the resulting surface-derivatized cations of which the following structure is representative.



The occurrence of surface derivatization was deduced from observations of the collision-induced dissociation of the $C_{60}(CH_3O)_{m+1}^{2+}$ product ions that indicated loss of a single CH_3O group for all values of *m*. The periodicity in reaction rate is shown in Fig. 12. The higher reactivities of the odd-numbered $C_{60}(CH_3O)_m^{2+}$ adduct ions have been attributed to their radical nature. The lower reactivities of the 4th and 8th adducts have been ascribed to an aromatic character for these cations as they contain $(4n + 2)$ π electrons (32).

Fig. 13. Data for the sequential addition of allene to C_{60}^{2+} observed at a room temperature of 294 ± 2 K and a helium pressure of 0.35 ± 0.01 Torr.

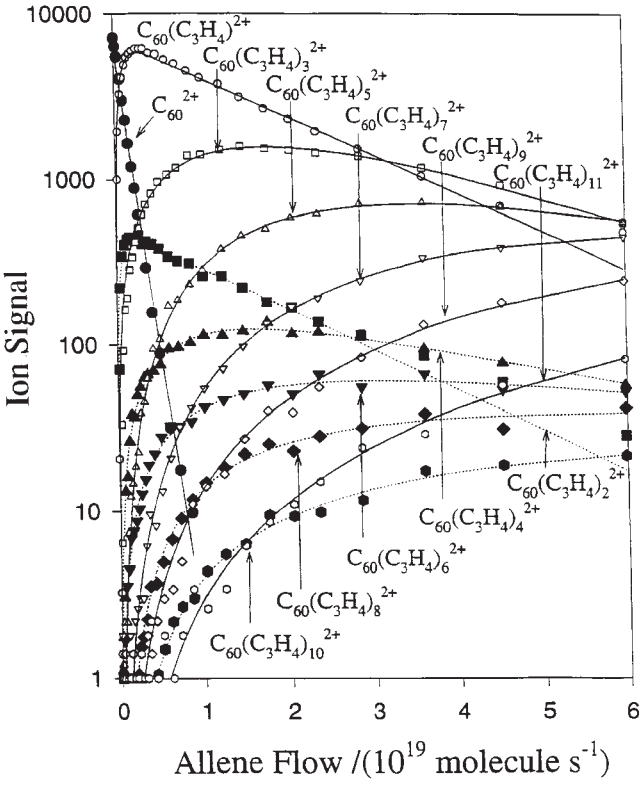

Fig. 14. Measured profiles for the multicollision-induced dissociation of $C_{60}(allene)^{2+}$ at an allene flow of 4.5×10^{19} molecules s^{-1} in 10% argon–helium at a total pressure of 0.30 ± 0.01 Torr and 294 ± 2 K.

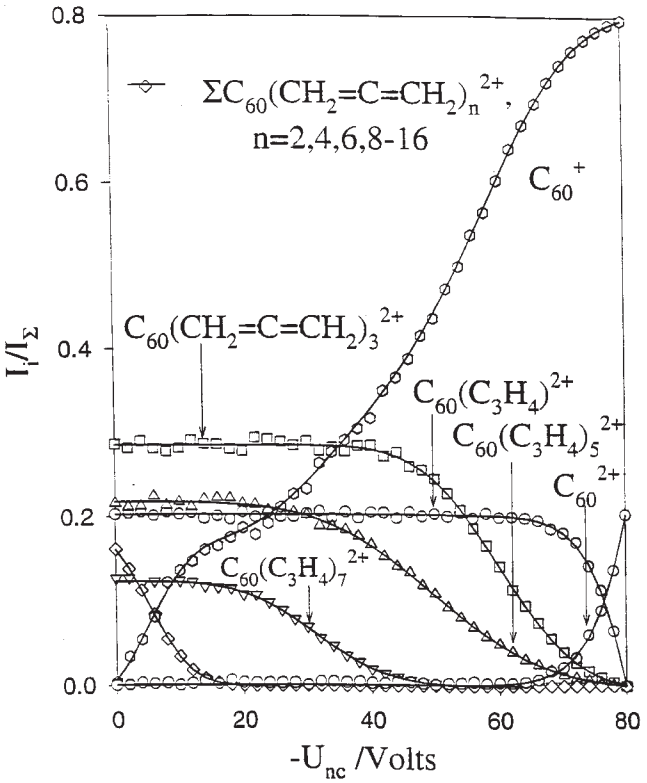

C. Ball-and-chain propagation

With some molecules we have observed multiple derivatization that we suggest leads to chain propagation or ball-and-chain formation in the manner indicated by reaction [15].

[15] 
We have proposed such reactions for C_{60}^{2+} reacting sequentially with ethylene (33), propene, allene (33), 1,3-butadiene (21), *cis*, and *trans*–1,3-pentadiene, acetylene (33), methyl acetylene (34), diacetylene, cyanoacetylene, ethylene oxide (19), and propylene oxide. Many of these molecules are well known as monomers in traditional polymer chemistry. Indeed, reaction [15] may be regarded as an ion-induced polymerization reaction. A noteworthy feature of reaction [15] is the concomitant intramolecular charge separation. We have postulated that one of the charges is propagated along the substituent driven by Coulombic repulsion, which directs chain growth away from the C_{60} surface (21).

The chemistry of C_{60}^{2+} and allene is of particularly interest, since the sequential addition exhibits a striking periodicity in reactivity, with the *even*-numbered adducts reacting about 10 times faster than the *odd*-numbered adducts (see Fig. 13). We have managed to probe the bond connectivity in these adducts using multicollision induced dissociation. Figure 14 shows that the first allene molecule comes off intact by *heterolytic* dissociation to regenerate the C_{60}^{2+} dication. Higher adducts appear to completely eliminate polymers of allene in one step by *homolytic* dissociation, leading to charge separation and formation of singly charged C_{60}^{+}. Also, Fig. 14 shows that the odd adducts have a higher stability than the even adducts, which exhibit a much lower threshold for dissociation. Taken together, the kinetic and collision-induced dissociation results have led us to propose a mechanism involving the alternating formation of *charge-localized even-numbered acyclic allyl cations*,which can be expected to be more reactive, and the formation of *charge-delocalized cyclic odd-numbered allyl cations*, which would be less reactive. The following semi-empirical MP3 structure calculated for $C_{60}(allene)_7^{2+}$ is representative of an odd-numbered allyl cation.

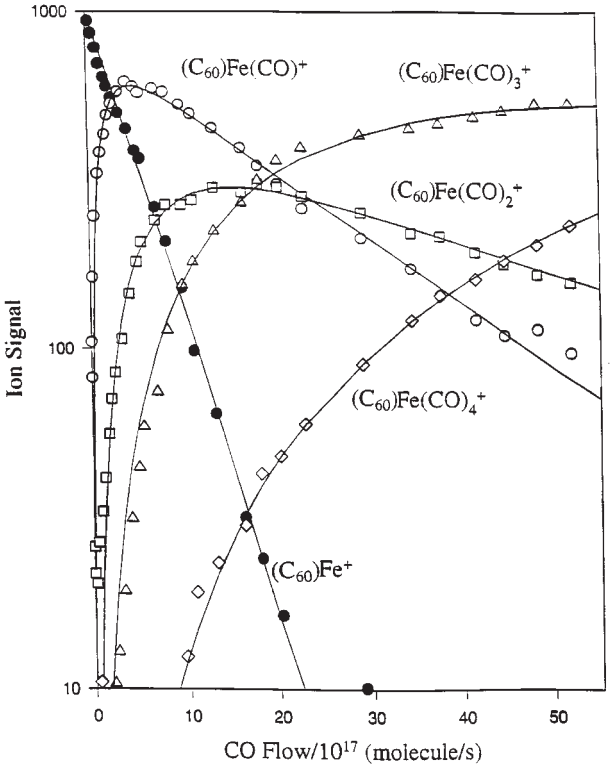
Fig. 15. Experimental data for the reaction of $C_{60}Fe^+$ with CO in helium buffer gas at a total pressure of 0.30 ± 0.01 Torr and 294 ± 2 K. The fifth adduct, $C_{60}Fe(CO)_5^+$ could not be detected.



7. Reactions of atomic exohedral adduct ions

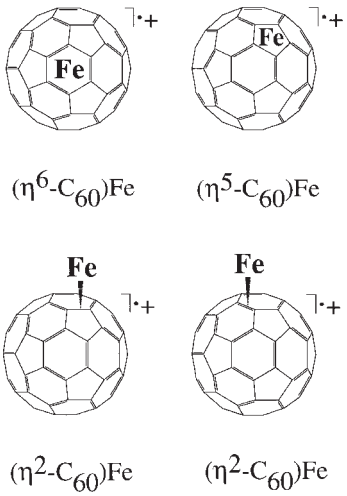
Recently we have become interested in elucidating the influence of C_{60} as a ligand on the reactivity of metal ions. Atomic ions readily can be attached to C_{60} upstream in the flow tube of our SIFT apparatus by attachment reactions of type [16], and the chemistry of the adduct ion then can be followed downstream.

[16] $A^+ + C_{60} + He \rightarrow C_{60}A^+ + He$

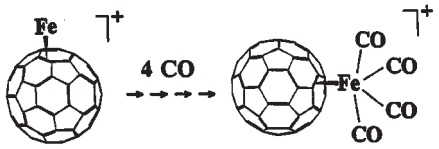
For example, we have already observed the attachment of Si^+, Fe^+, and Mg^+ to C_{60} under SIFT conditions. Questions arise regarding the nature of the bonding in $C_{60}A^+$ and the location of A^+ on the C_{60} surface. Possible sites for the location of Fe^+ on the C_{60} surface are illustrated below.

We hypothesized that a comparative study of the chemical reactivity of Fe^+ ligated to C_2H_4, *c*-C_5H_5, C_6H_6, and C_{60} would provide insight into the mode of bonding in $C_{60}Fe^+$. Indeed, reactivity measurements with CO and N_2O indicated a match between $(C_2H_4)Fe^+$ and $C_{60}Fe^+$ that suggests that the $(\eta^2\text{-}C_{60})Fe^+$ structures are preferred for $C_{60}Fe^+$ generated under SIFT conditions (35).

A comparison of the reactivities of $C_{60}Fe^+$ and the unligated Fe^+ ion provides a measure of the influence of the C_{60} ligand on chemical reactivity. Thus the addition reaction of CO with Fe^+, which does not occur measurably for the isolated cation ($k < 10^{-14}$ cm^3 molecule^{-1} s^{-1}), proceeds rapidly in the presence of C_{60} ($k = 1.3 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}). Three more molecules add sequentially (see Fig. 15), presumably to the Fe center according to reaction [17].

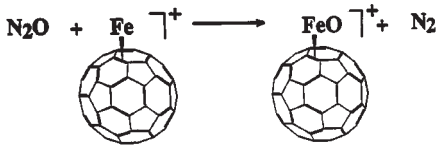


[17]



Also, the rate of the bimolecular O-atom transfer reaction of nitrous oxide with Fe^+ ($k = 3.1 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}) is enhanced by a factor of more than three in the presence of C_{60} ($k = 1.0 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}). Again, the O-atom transfer presumably occurs at the Fe site as shown in reaction [18].

[18]



8. On the influence of surface strain on the reactivities of fullerene ions

Fullerene molecules, and presumably also their ions, provide a range of reactive C sites with different degrees of hybridization and strain (36). We have made some progress in investigating the influence of such surface features on the chemical reactivity of fullerene cations. Our early investigations of addition reactions of fullerene cations C_{56}^+, C_{58}^+, and C_{60}^+ with NH_3, of addition reactions of C_{56}^{2+}, C_{58}^{2+}, and C_{60}^{2+} with C_2H_4 and CH_3CN, and of hydride-transfer reactions of C_{56}^{2+}, C_{58}^{2+}, and C_{60}^{2+} with *n*-C_4H_{10}, revealed an enhanced reactivity for the adjacent-pentagon fullerene ions of C_{56} and C_{58} relative to those of C_{60} (37). Adjacent pentagons enhance the curvature of the carbon surface and the sp^3 character of selected C sites (37). More recent systematic studies of addition reactions of C_{56}^+, C_{58}^+, C_{60}^+, C_{70}^+, corannulene$^+$, and coronene$^+$ with cyclopentadiene and 1,3-cyclohexadiene indicated that the efficiency of bond forma-

Fig. 16. Semi-logarithmic plot for the dependence of reaction efficiency on the square of the POAV angle and the strain energy for reactions with cyclopentadiene in helium buffer gas at 0.35 Torr and 294 ± 2 K. k_{obs} is the measured rate coefficient and k_c is the collision rate coefficient, which is estimated to be 10^{-9} cm^3 molecule^{-1} s^{-1}. The horizontal bars represent the range in strain energy presented by the various cations, which could not be resolved, since the exact C site(s) being bonded could not be determined.

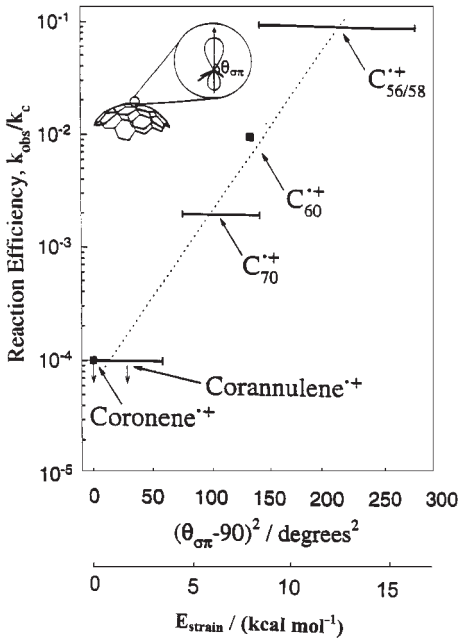

Table 1. POAV angles for various sites on selected carbonaceous molecules.

POAV angle, θ_x (deg)	C_{60}	C_{70}	Corannulene	Coronene
θ_1	11.6[a]	12.0[a]	7.7[b] (8.2)[c]	0
θ_2	—	11.9[a]	3.0[b] (3.8)[c]	0
θ_3	—	11.5[a]	0	0
θ_4	—	10.0[a]	—	—
θ_5	—	8.9[a]	—	—

[a]Reference 39.
[b]Reference 40.
[c]Reference 41.

tion with these two molecules also depends strongly on the curvature of the carbonaceous surface of the reacting cation (38).

On a carbonaceous surface the strain energy will depend upon the π orbital axis vector (POAV) angle, θ (36): the angle between the π-orbital at the bonding C site and one of the σ bonds on the adjacent carbonaceous surface minus 90° (see Fig. 16). For a planar sp^2 carbon atom this angle is 0°, and for a tetrahedral sp^3 carbon atom it is 19.47°. The POAV angles for the different sites in C_{60} and C_{70} and the related corannulene and coronene molecules shown below are given in Table 1. C_{70} has five different types of C sites with different surface strain, while C_{60} has only one such site. There is no strain in the flat PAH coronene whereas the bowl-shaped corannulene molecule has three types of C sites including one without strain.

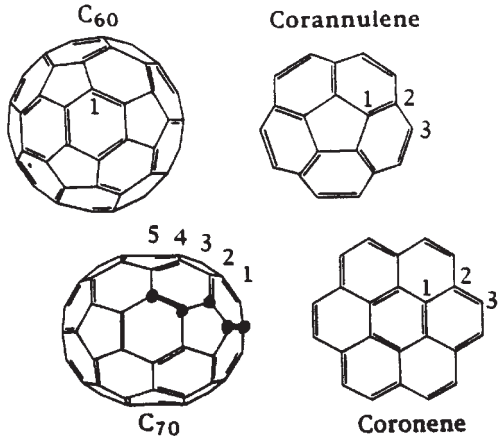

Figure 16 shows that the Diels–Alder addition with cyclopentadiene is faster with the smaller, more strained fullerenes and that the efficiencies of addition to the less-strained corannulene cation and the flat coronene cation are immeasurably small. Apparently the addition is driven by the relief of strain energy. The correlation presented in Fig. 16 leads to the following approximate dependence of the rate coefficient for addition on strain energy *E*, in kcal mol^{-1}, over the range in POAV angle explored.

[19] $k = 6.0 \times 10^{-14}\ e^{0.595E}$

These results also suggest a preference in reactivity for C sites with the highest strain energy (or the site with the highest local curvature) in those cations with more than one site of different strain as is the case, for example, with C_{70}^+ and corannulene$^+$. Such regioselectivity has been identified in earlier solution studies of the osmylation of C_{70} (42).

Conclusions

I have surveyed here much of the remarkable chemistry of buckminsterfullerene cations that has been revealed by our laboratory measurements using the SIFT technique since we began our studies in 1991. The charge state of C_{60}^{n+} has been shown to be decisive in determining the nature of this chemistry. Multiple derivatization, both of the C_{60} surface and in a ball-and-chain fashion, is an important feature of the higher order chemistry, particularly in the chemistry initiated by C_{60}^{2+} and C_{60}^{3+}. But, as the electron recombination energy of C_{60}^{n+} increases with increasing ionization, the transfer of one or more electrons from a reacting molecule eventually dominates.

Singly charged fullerene ions are known to be produced naturally in certain hydrocarbon flames where they have been shown to add hydrogen atoms (43). We have proposed elsewhere that mechanisms exist for the production of singly and doubly charged fullerenes from neutral fullerenes thought to be present in interstellar clouds and circumstellar atmospheres (44). The chemistry of these fullerene ions may have important consequences in these environments. For example, additions of hydrogen atoms to ionized fullerenes

© 1999 NRC Canada

that we have observed under SIFT conditions are expected to be efficient and may lead to the production of *fulleranes* (hydrogenated fullerenes) upon neutralization or even to the formation of molecular hydrogen by hydrogen-atom recombination on the fullerene-ion surface. Furthermore, additions of a variety of other known interstellar and circumstellar atoms and molecules to ionized fullerenes, particularly to doubly charged fullerenes, as well as additions of ions to neutral fullerenes are also likely. Finally, our results in the gas phase for the chemistry of C_{60}^{n+} should serve as a useful benchmark for the chemistries of fullerene cations in solution. These chemistries have not yet been elucidated, although persistent singly and multiply charged cations of C_{60} and other fullerenes have been observed in solution (45–47).

Acknowledgements

A number of graduate students and postdoctoral fellows have participated in the fullerene-ion research over the years, and I am grateful for their contributions. Special thanks go to Dr. Simon Petrie, Dr. Reza Javahery, and Dr. Vladimir Baranov for their inspiring collaboration. Also, I wish to thank the Natural Sciences and Engineering Research Council of Canada for ongoing financial support and the Canada Council for a Killam Research Fellowship during the formative part of this research.

Solubility of phenanthrene in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon Mobile Order theory

Carmen E. Hernández, Karina M. De Fina, Lindsay E. Roy, Tina L. Sharp, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for phenanthrene dissolved in 41 different organic nonelectrolyte solvents containing ether, carbonyl, hydroxy, chloro, amino, ester, methyl and *tert*-butyl functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 31 solvents for which predictions could be made, computations show that Mobile Order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 41.3% (excluding acetonitrile). In comparison, the average absolute deviation is 1610% when ideal solution behavior is assumed. Also reported are experimental solubilities at 26°C for pyrene dissolved in 1-hexanol, 1-heptanol, ethylbenzene, aniline, and 2-butanone.

Key words: phenanthrene solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : Opérant à 25°C, on a déterminé les solubilités expérimentales du phénanthrène en solution dans 41 solvants organiques non électrolytiques différents comportant les substituants et groupes fonctionnels suivants : éther, carbonyle, hydroxyle, bromo, amino, ester, méthyle et *tert*-butyle. On a utilisé les résultats de ces mesures pour évaluer les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Les 31 solvants pour lesquels il est possible de faire des prédictions par calculs permettent de démontrer que la théorie de l'ordre mobile fournit des évaluations assez raisonnables des solubilités en fraction molaire de saturation. La déviation absolue moyenne entre les valeurs observées et calculées est de 41,3% (en excluant l'acétonitrile). Par comparaison, la déviation absolue moyenne est de 1610% lorsqu'on assume un comportement de solution idéale. On rapporte aussi les solubilités expérimentales, à 26°C, du pyrène en solution dans l'hexan-1-ol, l'heptan-1-ol, l'éthylbenzène, l'aniline et la butan-2-one.

Mots clés : solubilités du phénanthrène, solvants organiques non électrolytiques, prédictions de la solubilité.

[Traduit par la Rédaction]

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and hetero-atom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application, however, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the data base contain as many different functional groups as possible, preferably with adequate representation from both mono- and multi-functional solute/solvent molecules to permit evaluation of potential synergistic effects. The data base should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham et al. (12, 13) recently developed a general solvation equation that can be used in the correlation and understanding of physicochemical and biochemical phenomena.

Physical properties that have been correlated include gas–solvent partition coefficients (as log L):

$$[1] \quad \log L = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + d\log L^{16}$$

and water–solvent partition coefficients (as log P):

$$[2] \quad \log P = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + vV_x$$

where R_2 and V_x refer to the molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, L^{16} is the solute's gas–liquid partition coefficient on hexadecane, and $\sum\alpha_2^H$ and $\sum\beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity. For any given solvent, numerical values of the seven curve-fit coefficients (c, r, s, a, b, d, and v) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported curve-fit coefficients for water (12, 13) and a few select organic solvents (13).

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs) and polycyclic aromatic nitrogen hetero-atoms (PANHs). In the present communication, we report phenanthrene solubilities in 41 different organic solvents at 25°C and pyrene solubilities in 1-hexanol, 1-heptanol, ethylbenzene, aniline, and 2-butanone at 26°C. Results of the phenanthraene measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory. Subsequent studies will use the experimental phenanthrene and pyrene solubilities in developing gas–liquid partition and water – organic solvent partition correlations based upon eqs. [1] and [2].

Materials and methods

Phenanthrene (Aldrich, 98%) and pyrene (Aldrich, 99+%) were recrystallized several times from methanol. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), dibutyl ether (Aldrich, 99%), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Company, absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), cyclopentanol (Aldrich, 99%), ethylene glycol (Aldrich, 99.8%, anhydrous), acetonitrile (Aldrich HPLC, 99.93+%), 1,4-dioxane (Aldrich, 99.8%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), carbon tetrachloride (Aldrich HPLC, 99.9+%), 2-butanone (Aldrich HPLC, 99.5+%), ethylbenzene (Aldrich, 99.8%, anhydrous), aniline (Aldrich, ACS Reagent, 99.5+%), cyclohexanone (Aldrich, 99.8%), ethyl acetate (Aldrich HPLC, 99.9%), butyl acetate (Aldrich HPLC, 99.8%), and 2,2,2-trifluoroethanol (Aldrich, 99+%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol% or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated phenanthrene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with 2-propanol for spectrophotometric analysis at 347 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert Law absorbance versus concentration working curve for nine standard solutions. The concentration of phenanthrene in the standard solutions varied from 2.29×10^{-3} to 7.64×10^{-3} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\varepsilon \approx 212$ L mol^{-1} cm^{-1} (2.29×10^{-3} M) to $\varepsilon \approx 191$ L mol^{-1} cm^{-1} (7.64×10^{-3} M).

Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of phenanthrene, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert Law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental phenanthrene solubilities, X_A^{sat}, in 41 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%. Also measured were the solubilities of pyrene at 26°C in 1-hexanol (X_A^{sat} = 0.012 73), 1-heptanol (X_A^{sat} = 0.016 94), ethylbenzene (X_A^{sat} = 0.064 24), aniline (X_A^{sat} = 0.033 98), and 2-butanone (X_A^{sat} = 0.067 52). Pyrene solubilities were measured spectrophotometrically at 372 nm.

Results and discussion

Solubility data for phenanthrene are available in the chemical literature for 8 of the 41 solvents listed in Table 1. Doane and Drickamer (14) previously reported the solubility

[a]Numerical values represent the average of between four and eight independent determinations with the measurements being reproducible to ±1.5%.

[b]Deviations (%) = 100 $[(X_A^{sat})^{calc} - (X_A^{sat})^{exp}]/(X_A^{sat})^{exp}$.

of phenanthrene in several saturated hydrocarbon solvents as a function of pressure. At a pressure of P = 1 atm (= 101.3 kPa), the measured mole fraction solubilities were X_A^{sat} = 0.0326, X_A^{sat} = 0.0401, and X_A^{sat} = 0.0464 for hexane, heptane, and octane, respectively. Our experimental values listed in Table 1 differ from the published values by less than ±5%. Differences in chemical purities and experimental methodologies (static versus dynamic methods) can lead to differences of a few percent between values determined by two different research groups.

Speyers (15) measured the solubility of phenanthrene in ethanol as a function of temperature. The five temperatures studied by the author ranged from 273.2 K to 343.4 K, and did not include 298.15 K. The mole fraction solubility at 298.15 K can be obtained by curve-fitting the experimental data to

$$[3] \qquad \ln X_A^{sat} = 50.276 - 30{,}302/T + 4\,167\,980/T^2$$

a 1/T polynomial. Three terms were needed to accurately describe the experimental values. Using the above mathematical representation, we calculate a mole fraction solubility of X_A^{sat} = 0.011 44 at 298.15 K, which is in excellent agreement with our measured value of X_A^{sat} = 0.011 14.

Three experimental values were found for the solubility of phenanthrene in cyclohexane. McLaughlin and Zainal (16), Choi et al. (17), and Gordon and Scott (18) determined the solubility of phenanthrene as a function of temperature. Temperatures for the first two studies ranged from 300 K to 340 K. The latter study covered a slightly larger temperature range of 286 K to 340 K. Least-squares analysis of the three sets of experimental data gave the following three polynomials:

$$[4] \qquad \ln X_A^{sat} = 15.405 - 5{,}611.0/T$$

$$[5] \qquad \ln X_A^{sat} = 13.666 - 5{,}071.0/T$$

$$[6] \qquad \ln X_A^{sat} = 62.745 - 35{,}818/T + 4\,803\,930/T^2$$

from which we calculate extrapolated/interpolated mole fraction solubilities of X_A^{sat} = 0.032 89, X_A^{sat} = 0.035 37, and X_A^{sat} = 0.035 17 at T = 298.15 K. Our experimental value of X_A^{sat} = 0.036 48 is only slightly larger than the values reported by both Choi et al. and Gordon and Scott.

McLaughlin and Zainal (19) also studied the solubility behavior of phenanthrene in carbon tetrachloride at five temperatures from T = 305.6 K to T = 319.2 K. Least-squares analysis of the published solubility data yielded the following correlation:

$$[7] \qquad \ln X_A^{sat} = 9.9251 - 3{,}562.8/T$$

from which we calculate an extrapolated mole fraction solubility of X_A^{sat} = 0.1246 at T = 298.15 K. Our experimental value of X_A^{sat} = 0.1262 is again in good agreement with the published literature data.

Niimi (20) reported the millimolar solubility of phenanthrene in 1-octanol at 277.15 K, 285.15 K, and 293.15 K. From a plot of log molar solubility versus 1/T we extrapolate the published solubility data to T = 298.15 K, obtaining a numerical value of C_A^{sat} = 0.3226 M. There is some uncertainty in this extrapolation because three experimental data points did not fall on a straight line. A slightly larger value of C_A^{sat} = 0.3579 M is obtained if the value at T = 277.15 K is excluded from the least-squares analysis. Molar solubilities can be converted to mole fractions using $V_{octanol}$ = 158.30 cm^3 mol^{-1} and V_{phenan} = 155.8 cm^3 mol^{-1} (21), and by assuming that the excess volume is negligible. Performing this computation, mole fraction solubilities of X_A^{sat} = 0.051 02 and X_A^{sat} = 0.056 60 were calculated for phenanthrene dissolved in 1-octanol. Our experimental solubility of X_A^{sat} = 0.054 18 falls in between the two extrapo-

© 1999 NRC Canada

lated values. Finally, Li et al. (22) reported activity coefficients and mole fraction solubilities of six aromatic hydrocarbons in acetonitrile at 298.15 K. No details were given regarding the chemical purities and experimental methodology. Our measured value of $X_A^{sat} = 0.032\,67$ is slightly less than the published literature value of $X_A^{sat} = 0.035$.

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (23–30) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume V of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen bonding, as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as (26–30)

$$[8]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5\,(1 - V_A/V_{solvent})\,\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi^2_{solvent}\, V_A(\delta'_A - \delta'_{solvent})^2\,(RT)^{-1} - r_{solvent}\,(V_A/V_{solvent})\,\phi_{solvent}$$

where the $r_{solvent}\,(V_A/V_{solvent})\,\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated (25) based upon

$$[9]\quad r_{solvent} = \frac{K_{solvent}\,\phi_{solvent}/V_{solvent}}{1 + K_{solvent}\,\phi_{solvent}/V_{solvent}}$$

with a numerical value of $K_{solvent} = 5000$ cm^3 mol^{-1} assumed for all monofunctional alcohols.

If complexation does occur between the crystalline solute and solvent (26–30):

$$[10]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5\,(1 - V_A/V_{solvent})\,\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi^2_{solvent}\, V_A(\delta'_A - \delta'_{solvent})^2\,(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ'_A and $\delta'_{solvent}$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid}

$$[11]\quad \ln a_A^{solid} = -\Delta H_A^{fus}\,(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T) \ln (T_{mp}/T) - (\Delta S_A^{trans}/RT)(T_{trans} - T)$$

can be computed (17, 31, 32) from the solute's molar enthalpy of fusion, ΔH_A^{fus}, and heat capacity difference, $\Delta C_{p,A}$, at the normal melting point temperature, T_{mp}. The last term in eq. [11] accounts for the additional first-order phase transition that occurs at $T_{trans} \approx 339.2$ K. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi^2_{solvent}\, V_A(\delta'_A - \delta'_{solvent})^2\,(RT)^{-1}$ term. Ruelle et al. (26–30) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Predictive application of eqs. [8] and [10] is relatively straightforward. First, an average numerical value of $\delta'_{phenan} = 20.45$ MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent} = 0$ and (or) $K_{ASolvent} = 0$) perfectly describes phenanthrene mole fraction solubility data in *n*-hexane ($\delta'_{phenan} = 20.57$ MPa$^{1/2}$), *n*-heptane ($\delta'_{phenan} = 20.39$ MPa$^{1/2}$), and *n*-octane ($\delta'_{phenan} = 20.39$ MPa$^{1/2}$). The numerical value of $a_A^{solid} = 0.2596$ is calculated using eq. [11] with $\Delta H_A^{fus} = 16\,474$ J mol^{-1}, $\Delta C_{p,A} = 12.586$ J mol^{-1} K^{-1}, $T_{mp} = 372.4$ K, $\Delta S_A^{trans} = 3.853$ J mol^{-1} K^{-1}, and $T_{trans} = 339.2$ K (32). A numerical value of $V_{phenan} = 155.8$ cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute. The numerical value of $V_{phenan} = 155.8$ cm^3 mol^{-1} corresponds to the experimentally determined partial molar volume of phenanthrene in carbon tetrachloride (21).

Table 1 summarizes the predictive ability of Mobile Order theory for the 31 different organic solvents for which both phenanthrene solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (26, 27, 29, 30), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (33) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does pro-

Ethyl acetate	98.5	20.79
Butyl acetate	132.5	19.66
Phenanthrene[b]	155.8[c]	20.45[d]

[a]Tabulated values are taken from a compilation given in Ruelle et al. (26, 27, 29, 30).

[b]The numerical value of a_A^{solid} = 0.2596 was calculated from eq. [11] using ΔH_A^{fus} = 16,474 J mol^{-1}, $\Delta C_{p,A}$ = 12.586 J mol^{-1} K^{-1}, T_{mp} = 372.4 K, ΔS_A^{trans} = 3.853 J mol^{-1} K^{-1}, and T_{trans} = 339.2 K (32).

[c]Numerical value of V_{phenan} = 155.8 cm^3 mol^{-1} corresponds to the experimentally determined partial molar volume of phenanthrene in carbon tetrachloride (21).

[d]Numerical value was calculated using the measured phenanthrene mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [8] and [10]; with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0.

vide fairly reasonable estimates of the solubility behavior of phenanthrene in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 62.2%.

The next to last entry in Table 1 shows that Mobile Order theory grossly overpredicts the solubility of phenanthrene in acetonitrile. Similar failures were noted previously in the case of anthracene (34), fluoranthene (35), and pyrene (35). We suspect that the overprediction results from either failure of the Scatchard–Hildebrand solubility parameter theory to describe the nonspecific interactions between acetonitrile and these four polycyclic aromatic hydrocarbon solutes, or perhaps from an incorrect value for this solvent's modified solubility parameter. If acetonitrile is excluded from the comparison, the average absolute deviation is reduced to 41.3%. This results in a significant improvement in the predictive ability. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly non-ideal, and that the experimental solubility data cover over a 250-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid}$ = 0.2596 for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 1610% between predicted and observed values.

Kinetic and equilibrium studies of the acid dissociation of the cobalt(II) complexes of *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamine ligands

Hongwei Sun, Zhifen Zhou, Huakuan Lin, Guanghua Zhao, Shourong Zhu, Xuncheng Su, and Yunti Chen

Abstract: The complexation property and the acid dissociation kinetics of four *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamine complexes with cobalt(II) were studied using a pH meter and a stopped-flow spectrophotometer. In 6.6×10^{-3}~0.5 mol dm^{-3} HCl (I = 0.5 mol dm^{-3} HCl + NaCl), the dissociation rate follows the law $k_{obs} = kK_2[H^+]/(1 + K_2[H^+])$. The acid dissociation can be rationalized in terms of a four-step kinetic process involving two rapid pre-equilibrium protonations and rate-determining cleavage of the Co(II)—N(phenanthroline) bond. The temperature dependence of the rate was determined, and the appropriate thermodynamic parameters were obtained. The linear relationship between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ suggests that an isokinetic temperature, T_{iso} of 282 ± 2 K exists.

Key words: *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamine, complexation property, acid dissociation kinetics, mechanism, cobalt(II) complex.

Résumé : Faisant appel à un pH-mètre et un spectrophotomètre à écoulement interrompu, on a mesuré les propriétés de complexation et la cinétique de dissociation acide de quatre complexes *N,N′*-dialkyl-1,10-phénanthroline-2,9-dimathamine avec le cobalt(II). Dans le domaine de concentration de $6{,}6 \times 10^{-3}$ à 0,5 mol dm^{-3} de HCl (I = 0,5 mol dm^{-3} HCl + NaCl), la vitesse de dissociation obéit à la loi: $k_{obs} = kK_2[H^+]/(1 + K_2[H^+])$. On peut rationaliser la dissociation acide en termes d'un processus cinétique en quatre étapes impliquant deux protonations rapides de prééquilibre et un clivage cinétiquement limitant de la liaison Co(II)—N(phénanthroline). On a déterminé la relation entre la température et la vitesse de la réaction et on en a tiré les paramètres thermodynamiques appropriés. La relation linéaire entre le ΔH et le ΔS suggère l'existence d'une température isocinétique, T_{iso} = 282 ± 2 K.

Mots clés : *N,N′*-dialkyl-1,10-phénanthroline-2,9-dimathanamine, propriété de complexation, cinétique de la dissociation acide, mécanisme, complexe du Co(II).

[Traduit par la Rédaction]

Introduction

Acid-assisted dissociation kinetics of open-chain and macrocyclic polyamine complexes hav been extensively studied (1–7), and many of these works have been reviewed (8, 9). Recently, there has been renewed interest in this field. Many experiment results were studied and the possible mechanisms for the reactions, the factors influencing the rates, and the factors affecting the relative importance of each of the possible pathways were discussed (10–16). Nearly all such studies support the general mechanism proposed by Read and Margerum (9). We mentioned that almost all the systems studied are linear or macrocyclic aliphatic polyamines, which are excellent electron donors, and the coordinated nitrogens are of similar basicity. The corresponding kinetics of acid-assisted dissociation of linear and microcyclic ligands with different type of nitrogens have received little attention (17).

1,10-Phenanthroline have been extensively used as ligands in both analytical and preparative coordination chemistry (18). The π-electron deficiency makes phenanthroline excellent π acceptors. If amine was assembled on the 1,10-phenanthroline, the ligands would contain both soft and hard sites. Recently, we have prepared a series of *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamine ligands (Fig. 1) with two electron deficient nitrogens (phenanthroline) and two electron donor nitrogens (alphatic amine) (19). It was of interest to learn the effects of different coordinated nitrogens on the dissociation kinetics of the cobalt(II) complexes. In this paper, we report the results of our systematic studies on the complexation property and the acid dissociation reaction of cobalt(II) complexes of our novel *N,N′*-dialkyl-1,10-

phenanthroline-2,9-dimathanamine ligands in order to determine the effect of different coordinated nitrogens and some important kinetic parameters to gain an insight into the reaction mechanism.

Experimental

Reagents

The *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamine ligands were prepared according to our novel synthesis methods (19). All other chemicals used in this work were of GR grade. NaCl was recrystallized before use. Redistilled water was used for all solutions.

Instruments

Electronic spectra were recorded on a Shimadzu UV-240 spectrophotometer. Protonation constants of *N,N′*-dialkyl-1,10-phenanthroline-2,9-dimathanamines and complex formation constants of cobalt(II) complexes were determined by potentiometric pH titration using a Beckman Φ71 pH meter. The kinetics of the acid-catalyzed dissociation of the cobalt complexes were studied with a Union Giken RA-401 stopped-flow spectrophotometer equipped with a Union-415 rapid-scan attachment.

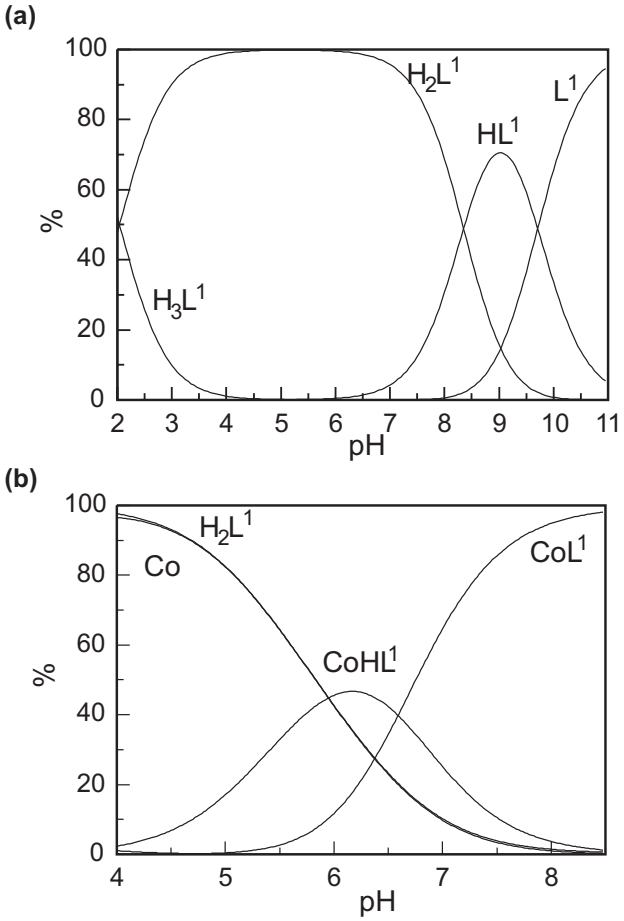
Potentiometric measurements

Potentiometric titrations of the ligands in the absence and presence of cobalt(II) (as nitrate salt) were carried out with a Beckman pH meter Model Φ71. The apparatus and procedure have been described before (20). Computation of equilibrium constants was made using the SCMAR (21) program. Species–distribution curves were calculated and plotted with DP (21) program. For each system at least two titration were performed, each titration contained about 50 experimental points.

Kinetic measurements

Pseudo-first-order conditions were maintained by using at least a 20-fold excess of acid in each run. Complex conc. = 1.0×10^{-4} mol dm^{-3} (I = 0.5 mol dm^{-3} NaCl), conc. acid = 6.6×10^{-3}~0.5 mol dm^{-3} HCl (I = 0.5 mol dm^{-3} HCl + NaCl). Good first-order kinetics were observed in all cases. The reaction has excellent reproducibility. Complex solutions were prepared by mixing equimolar quantities of the ligand and standard $CoCl_2$, followed by adjustment of pH to 8.0 with NaOH at which point the complex is fully formed in the form CoL (Fig. 2*b*). Absorbance vs. time data were collected at 295 nm and temperature maintained at 10 ± 0.1, 20 ± 0.1, 30 ± 0.1, and 40 ± 0.1°C under a N_2 atmosphere. Reaction time ranges from 50 to 2000 ms. Each kinetic run has been repeated at least six times.

Fig. 2. Distribution curves for the protonated L^1 species (*a*) and Co(II)–L^1 system (*b*) as a function of pH in 0.1 mol dm^{-3} $NaNO_3$ solution at 298.15 K.



Results and discussion

Protonation and cobalt(II) complex equilibria

The protonation constants of L^1 to L^4 were determined by potentiometric pH titration at I = 0.1 ($NaNO_3$) and 25°C. Table 1 summarizes the protonation constants as logarithmic values. In the pH range investigated (2.5~11), equilibria involve three protonation steps related to the phenanthroline nitrogen and two amino nitrogens (defined in eqs. [1]–[3]). K_1 and K_2 are the protonation constants of the amino nitrogens. The second amine protonation step of the ligands involves a decrease of the log K value (1.3~1.4) due to electrostatic repulsive effects. For the same reason, log K_3 values that corresponded to the protonation of 1,10-phenanthroline are smaller than that of 1,10-phenanthroline (log K = 4.748 (ref. 22)). The basicity of two amines is mainly determined by inductive effects of N-substituted alkyls. The order is $L^1 < L^2 < L^3 < L^4$.

Fig. 3. Plot of k_{obs} vs. [H^+] for the dissociation of $[CoL^1]^{2+}$ at 10, 20, 30, and 40°C. The solid lines are calculated from eq. [14].

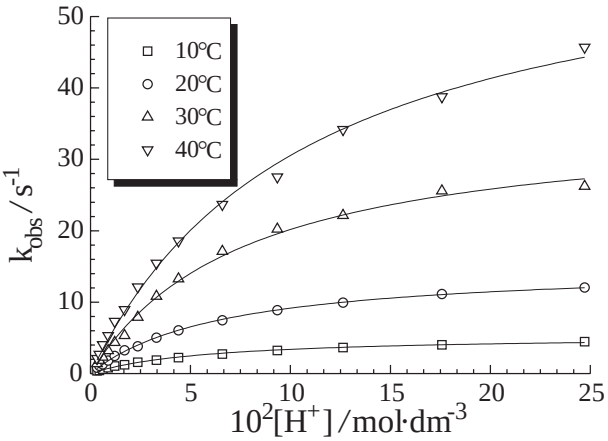

Fig. 4. Plot of k_{obs}. vs. [H^+] for the dissociation of $[CoL^4]^{2+}$ at 10, 20, 30, and 40°C. The solid lines are calculated from eq. [15].

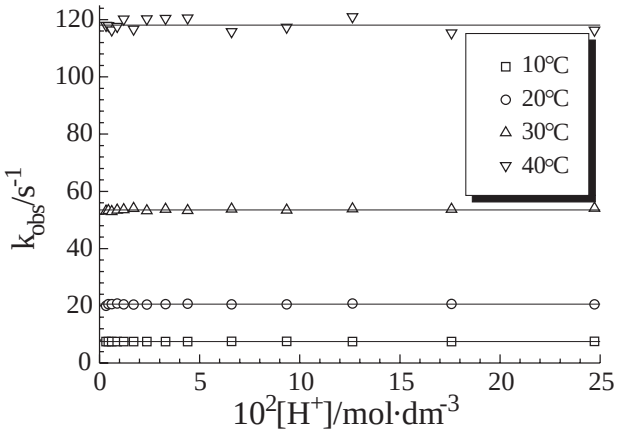

[2] $H^+ + HL \rightleftharpoons H_2L^{2+}, \quad K_2 = [H_2L^{2+}]/[H^+][HL^+]$

[3] $H^+ + H_2L^{2+} \rightleftharpoons H_3L^{3+}, \quad K_3 = [H_3L^{3+}]/[H^+][H_3L^{2+}]$

The incorporation of Co^{2+} by the ligands in aqueous solution was studied to identify the species formed and to evaluate the complexation constants of these compounds. The following reactions were found to take place:

[4] $Co^{2+} + L \rightleftharpoons CoL^{2+}, \quad \log\beta_{110} = [CoL^{2+}]/[Co^{2+}][L]$

[5] $Co^{2+} + L + H^+ \rightleftharpoons CoHL^{3+}, \quad \log\beta_{111} = [CoHL^{3+}]/[Co^{2+}][L][H^+]$

As shown in Table 1, for CoL^{2+} and $CoHL^{3+}$ species, complexes of Co^{2+} with L, shown the stability order $L^1 > L^2 > L^3 > L^4$, indicated that steric effects play a more important role than electron inductive effects.

Kinetic measurements

At 295 nm where the dissociation reactions of the complexes were monitored, perchlorate and nitrate have absorption, so sodium chloride was used to maintain the ionic strength, and hydrochloric acid to change the pH.

Under the experimental conditions of constant hydrogen concentration, the dissociation reaction of these complexes was found to proceed to completion and to occur by a single stage. A first-order reaction with respect to the concentration of complex was observed. The rate equation can be expressed by eq. [6].

[6] $-d[CoL^{2+}]/dt = k_{obs}[CoL^{2+}]$

Figure 3 shows the dependence of the rate constants k_{obs} on the concentration of hydrogen ion at different temperature for CoL^1 complex. As shown in Fig. 3, the observed rate constants k_{obs} increases with the increase of [H^+] and tends to attain limiting values at high acidities. Same phenomenon appears for CoL^2 and CoL^3 complex. From a mathematical view, the tendency coincides with the hyperbolical function (eq. [7]) where a and b are constants.

[7] $k_{obs} = a[H^+]/(1 + b[H^+])$

As shown in Fig. 4, the observed rate constants k_{obs} for CoL^4 keeps invariable with the increase of [H^+]. From a mathematical view, the tendency also coincides with eq. [7] under the condition of $b[H^+] >> 1$.

The phenomenon of complexes we studied is quite different from that of copper(II) complexes with linear aliphatic tetraamine. For linear tetramine copper(II) complexes, the plot of k_{obs} vs. [H^+] gives a straight line; the rate-determining step for the dissociation reactions is the breakage of the first copper–nitrogen bond according to Chao and Chun (15). The ligands we studied show a different behaviour compared to linear tetraamine. For linear tetraamine cobalt(II) complexes, the four coordinated amino nitrogens are of similar property. For the complexes we studied, the basicity of two nitrogens of phenanthroline is significantly weaker than that of two amino nitrogens, and the π backdonor

bond exists between cobalt(II) and two phenanthroline nitrogens (23). The first protonation process of complex CoL must be the protonation of amino nitrogen. As shown in Table 1, the intermediates $CoLH^{3+}$ can exist stably in the solution. The equilibrium constants log K of the following reaction (eq. [8]) range from 6.6 to 7.4 for the complexes with the four ligands studied (Table 1).

$$[8] \qquad CoL^{2+} + H^+ \overset{K}{\rightleftharpoons} CoLH^{3+}$$

In strongly acidic, aqueous media, the two amino nitrogens are easier protonated than that of phenanthroline; the protonation rates are very fast, therefore, the first two protonation processes of amino nitrogens are pre-equilibrium processes. Being the most difficult, the third step, the breakage of the cobalt–nitrogens (phenanthroline) bond, is the rate-determining step. After three steps, the products are solvated cobalt(II) ion and partly protonated ligand. Finally, the ligand is quickly fully protonated in the acid solution. We proposed the following acid-dissociation mechanism (eqs. [9]–[12]):

According to the mechanism, we obtained

$$[13] \qquad k_{obs} = \frac{kK_1K_2[H^+]^2}{1 + K_1[H^+] + K_1K_2[H^+]^2}$$

From Table 1 we can see that even at the lowest concentration of acid used ($[H^+] = 3.3 \times 10^{-3}$ mol dm^{-3}), the product of K and $[H^+]$, $K[H^+] \approx 1.3 \times 10^4 >> 1$. Considering that the eq. [8] is the same as eq. [9], we assumed that $1/(K_1[H^+]) << 1$. Consequently, under the conditions used in this study the limiting rate law that operates is

$$[14] \qquad k_{obs} = \frac{kK_2[H^+]}{1 + K_2[H^+]} = \frac{k[H^+]}{1/K_2 + [H^+]}$$

The eq. [14] is exactly the same as the experimental rate law (eq. [7]). Therefore, the mechanism proposed by us is reasonable. For CoL[4], when we assume $1/K_2 << [H^+]$, we can obtain

$$[15] \qquad k_{obs} = k$$

which coincides with the phenomenon in Fig. 4.

The rate constant k and the pre-equilibrium constant K_2 can be calculated from eqs. [14] and [15], the results have been listed in Tables 2 and 3. From Figs. 3 and 4, we can see

[9] 
[10]

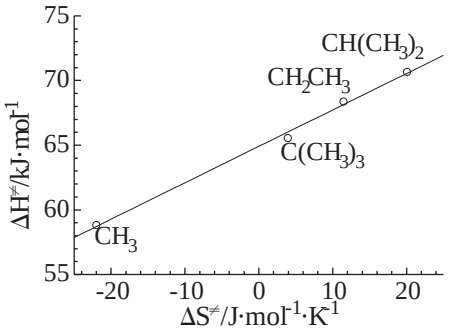
Fig. 5. The isokinetic relationship of reaction [11].



that the experimental points are coincident with those of calculations from eqs. [14] and [15].

From Eyring's equation

$$\ln (k/T) = -\Delta H^{\neq}/RT + \Delta S^{\neq}/R + \ln (R/N_A h)$$

Regression of ln (k/T) vs. 1/T, activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of the rate-determining step can be obtained. The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are summarized in Table 2. Regressing of ln K_2 vs. 1/T, the values of ΔH° and ΔS° were obtained; they are listed in Table 3.

From Tables 1 and 3, we can find that, due to electrostatic repulsive effects, the second protonation constants of the metal complexes are about 12~50 for ligands L^1~L^3, about 3.0×10^3 for ligand L^4 (estimated from the assumption of $1/K_2 << [H^+]$), much smaller than that of the first protonation ($4.0 \times 10^6 \sim 2.7 \times 10^7$). From Table 1, we can find that, due to steric effects of N-substituted alkyl, the coordination ability of amino nitrogens decreases obviously with the increase of alkyl cubage; this can be see from the increase of the first protonation constants of the complexes (log K increase from 6.6 to 7.4). It is apparent that the second protonation K_2 of the complex L^4 is larger than that of L^1~L^3, since the substituted alkyl-tetrabutyl appears obviously to have greater steric effects than in L^1~L^3.

We find that for different *N*-alkyl substituents, the activation enthalpies and entropies appear to have a linear relationship. The plot of $\Delta H^{\neq}$ verus $\Delta S^{\neq}$ for reaction of eq. [11] with four different complexes studied was shown to be clearly linear (R^2 = 0.996) with an apparent isokinetic temperature (24, 25), T_{iso}(app), of 282 ± 10 K (Fig. 5). The Krug–Greiger (26) method confirms the existence of an isokinetic relationship (IKR), but only if the data for the complex of L^4 are omitted, when T_{iso} = 282 ± 2 K and R^2 = 0.990 (Fig. 6). The fact that the complex of L^4 appears abnormal presumably arises due to the effect of steric of *tert*-butyl.

Fig. 6. Modified Krug–Grieger plot of $\Delta H^{\neq}$ vs. $\Delta G^{\neq}$ (at 313 K) for reactions. (Data for the complex of L^4 (△) not included in least-squares analysis).

Mechanisms for the formation of epoxide and chlorine-containing products in the oxidation of ethylene by chromyl chloride: a density functional study

Maricel Torrent, Liqun Deng, Miquel Duran, Miquel Solà, and Tom Ziegler

Abstract: The reaction between CrO_2Cl_2 and ethylene leading to the formation of epoxide and chlorohydrin precursors or directly to 1,2-dichloroethane has been studied by density functional theory. The formation of the epoxide precursor ($Cl_2(O)Cr\text{-}OC_2H_4$) was found to take place via a [3+2] addition of ethylene to two Cr=O bonds followed by rearrangement of the five-membered diol to the epoxide product. The alternative mechanisms involving a direct addition of oxygen to ethylene or the [2+2] addition of the olefin to a Cr=O bond were found to have much higher activation energies. The formation of the chlorohydrin precursor ($Cl(O)Cr\text{-}OCH_2{=}CHCl$) was found to take place via a [3+2] addition to one Cr—Cl and one Cr=O bond. Pathways involving initial [2+2] addition to a Cr—Cl or Cr=O bond had much higher activation barriers. The generation of 1,2-dichloroethane is highly unfavorable with an endothermicity of 44.7 kcal/mol and an even higher activation barrier. It is suggested that the formation of epoxide and chlorohydrin from the respective precursors requires the addition of H_2O.

Key words: reaction mechanisms, epoxide, oxidation of ethylene, chromyl chloride, DFT.

Résumé : Faisant appel à la théorie de la densité fonctionnelle, on a étudié la réaction du CrO_2Cl_2 avec l'éthylène qui conduit à la formation de précurseurs époxyde et chlorohydrine ou directement de 1,2-dichloroéthane. On a trouvé que la formation du précurseur époxyde [$Cl_2(O)Cr\text{-}OC_2H_4$] se produit par le biais d'une addition [3+2] de l'éthylène sur deux liaisons Cr=O, suivie d'un réarrangement du diol à cinq chaînons en produit époxyde. On a trouvé que les autres mécanismes possibles, addition directe d'oxygène à l'éthylène ou l'addition [2+2] de l'oléfine sur une liaison Cr=O, comportent des énergies d'activation beaucoup plus élevées. On a trouvé que la formation du précurseur chlorhydrine [$Cl(O)Cr\text{-}OCH_2{=}CHCl$] se fait par le biais d'une addition [3+2] sur une liaison Cr—Cl et une sur une liaison Cr=O. Les voies réactionnelles impliquant une addition [2+2] initiale à une liaison Cr—Cl ou Cr=O comportent des barrières d'activation beaucoup plus élevées. La formation de 1,2-dichloroéthane est très défavorisée par son grand caractère endothermique (44,7 kcal/mol) et sa barrière d'activation encore plus élevée. Il est suggéré qu'une addition d'eau est nécessaire pour la formation de l'époxyde et de la chlorohydrine à partir de leurs précurseurs respectifs.

Mots clés : mécanismes réactionnels, époxyde, oxydation de l'éthylène, chlorure de chromyle, « DFT ».

I. Introduction

The oxygen-transfer reaction from CrO_2Cl_2 to olefins is an old (1) and now well-established process (2). Unlike other oxo transition metal compounds, CrO_2Cl_2 reacts with alkenes to form predominantly an epoxide product, whereas $KMnO_4$ and OsO_4 form diols without significant epoxide formation (3). Some time ago it was found that, in fact, the three primary products in the oxidation of alkenes with CrO_2Cl_2 are epoxide, chlorohydrin, and, in some cases, vicinal dichloride (4, 5). The full mechanism by which these products are formed still remains unsolved despite having been the subject of extensive studies (6–9).

To explain the formation of the abovementioned products, Sharpless et al. (5) originally proposed a mechanism involving organometallic intermediates with Cr—C σ bonds. In particular, the key feature in the formation of epoxide was claimed to be the involvement of a chromaoxetane, i.e., a four-membered cyclic compound formed via a [2+2] interaction between the olefin and an oxo group on the chromium (5). This mechanism was very much contrary to the previously suggested mechanisms for this reaction in which a di-

rect interaction between the alkene and the oxo groups of CrO_2Cl_2 had been postulated (1, 6).

Although the new idea was suggested as an alternative path based only on the observed products of the reaction (no evidence for a chromaoxetane intermediate was established), it was quickly adapted within a few years in the discussion of many types of oxygen-transfer reactions involving high-valent oxochromium compounds (10) and other oxo transition metal species (11).The advantage of the novel proposal was that experimental observations concerning *cis* addition (5) could now be more easily accommodated. Sharpless et al. (5), however, introduced their hypothesis with reserve because some mechanisms involving direct interaction with the ligands were able to account for experimental facts as well. Particularly, neither a direct addition of the olefin to one oxygen atom nor a [3+2] addition of the olefin to two heteroatom ligands could be excluded at that time as operative routes for the mechanism of epoxidation. Some years later, Samsel et al. (7) argued for a direct interaction between the alkene and the oxygen in OCr(V)–salen complexes in the epoxidation of alkenes, rather than a chromaoxetane. Some interesting results that cast doubt on the metallaoxetane reaction path were also reported by Barrett et al. (12), and later on by Groves and Nemo (13). To date, experimental input has not been sufficient to rule out either of the mechanistic channels.

To obtain further insight into the sequence of this reaction, some theoretical contributions have appeared. The most notable earlier computational study is that of Rappé et al. (8, 9) where a thermodynamic analysis by means of the generalized valence bond method was performed, with attention being devoted to the energies of the intermediates in the oxidation of ethylene with CrO_2Cl_2 and MoO_2Cl_2. Unfortunately, due to limitations in methodology and computational facilities at that time, these authors were not able to fully optimize the geometrical structures of the different species involved. Their results favored a [2+2] cycloaddition path involving a four-centered intermediate, and confirmed the proposal that the metallaoxetane is a likely common precursor for all of the observed oxygen-containing products (8).

Further theoretical support for a chromaoxetane was provided (14) later by an ab initio study of the addition of ethylene to $Cr{=}O^{n+}$ (n = 1–3). Several gas-phase investigations have also supported the chromaoxetane as an intermediate in the reaction of oxochromium species with alkenes (15). In fact, the metallaoxetane intermediate derived from a [2+2] cycloaddition has been proposed in many other studies of oxygen-transfer reactions from oxomanganese and oxoiron porphyrins to alkenes (11), but often without detailed mechanistic investigations or without any direct experimental evidence to support it (16). A few isolated metallaoxetanes are known for Rh (17), Ir (18), Pd (19), and Pt (20). However, none of these species were synthesized by direct addition of olefin to a M=O bond. Also to date no chromaoxetane has been isolated.

It appears that at least three different reaction modes have been used to explain the formation of epoxide (Scheme 1): (1) a direct addition of ethylene to one oxygen atom, (2) a [2+2] addition of ethylene to one Cr=O linkage, and (3) a [3+2] addition to two Cr=O bonds. However, what appears to have been forgotten, at least in some of the proposed mechanisms, is that the reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$ is endothermic with an experimental heat of reaction (21) given by 24.8 kcal/mol. Thus, the intermediates formed in the three mechanisms will not spontaneously decompose to epoxide. In fact, experimentally, epoxide is only isolated after the original reaction mixture in an organic solvent (such as CH_2Cl_2) is extracted into aqueous solution. Thus, it is likely that epoxide is formed from the reaction of water with one or more of the precursors in Scheme 1. Regarding the formation of the chlorine-containing products (Scheme 2), both a [2+2] and (or) a [3+2] cycloaddition pathway can account in principle for the mechanisms leading to a chlorohydrin (left) precursor and dichloride (right). However, again for the chlorohydrin (left) precursor a hydrogen containing agent such as water is needed to release $CH_2(OH)CH_2Cl$.

In the present paper, the pathways outlined in Schemes 1 and 2 are explored in terms of reaction energies and activation barriers. The objective of our study is (*i*) to examine the energetics and kinetics of the mechanism leading to the epoxide precursors of Scheme 1 when ethylene is oxidized by CrO_2Cl_2, (*ii*) to provide an interpretation for the formation of chlorohydrin precursor of Scheme 2 as one of the main products in the reaction of CrO_2Cl_2 with ethylene, and (*iii*) to rationalize why only in some cases dichloride is observed among the products. Finally, we shall briefly discuss the thermochemistry of the reaction between H_2O and the precursors in Schemes 1 and 2. To the best of our knowledge, this is the first time that mechanistic insight is given into the formation of epoxide, chlorohydrin, and dichloride using optimization procedures, and transition state search schemes.

II. Computational details

The reported calculations were carried out using the Amsterdam Density Functional (ADF) package developed by Baerends et al. (22*a*). and vectorized by Ravenek (22*b*). The adopted numerical integration procedure was due to te Velde et al. (23). A set of auxiliary s, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, were introduced in order to fit the molecular density and Coulomb potential accurately in each SCF cycle (24). An uncontracted STO basis set was employed for the valence orbitals of the chromium atom (double-ζ 3*s* and 3*p*, triple-ζ 3*d* and 4*s*, and a single- ζ 4*p* orbital). For carbon (2*s*, 2*p*), oxygen (2*s*, 2*p*), chlorine (3*s*, 3*p*), and hydrogen (1*s*), use was made of a double-ζ basis set augmented by an extra polarization function (25). The fully occupied inner shells of chlorine and chromium (1*s*2*s*2*p*), as well as carbon and oxygen (1*s*) were assigned to the cores and treated by the frozen-core approximation (26). All the geometries and frequencies were calculated at the local density approximation (LDA) level(27) with the parametrization of Vosko et al. (28). The relative energies were evaluated by including Becke's nonlocal exchange (29) and Perdew's nonlocal correlation corrections (30) as perturbations based on the LDA density. This approach is denoted NL-P, and its validity to treat CrO_2X_2 (X = halogen) complexes (31) and similar systems (32) has been demonstrated elsewhere. The

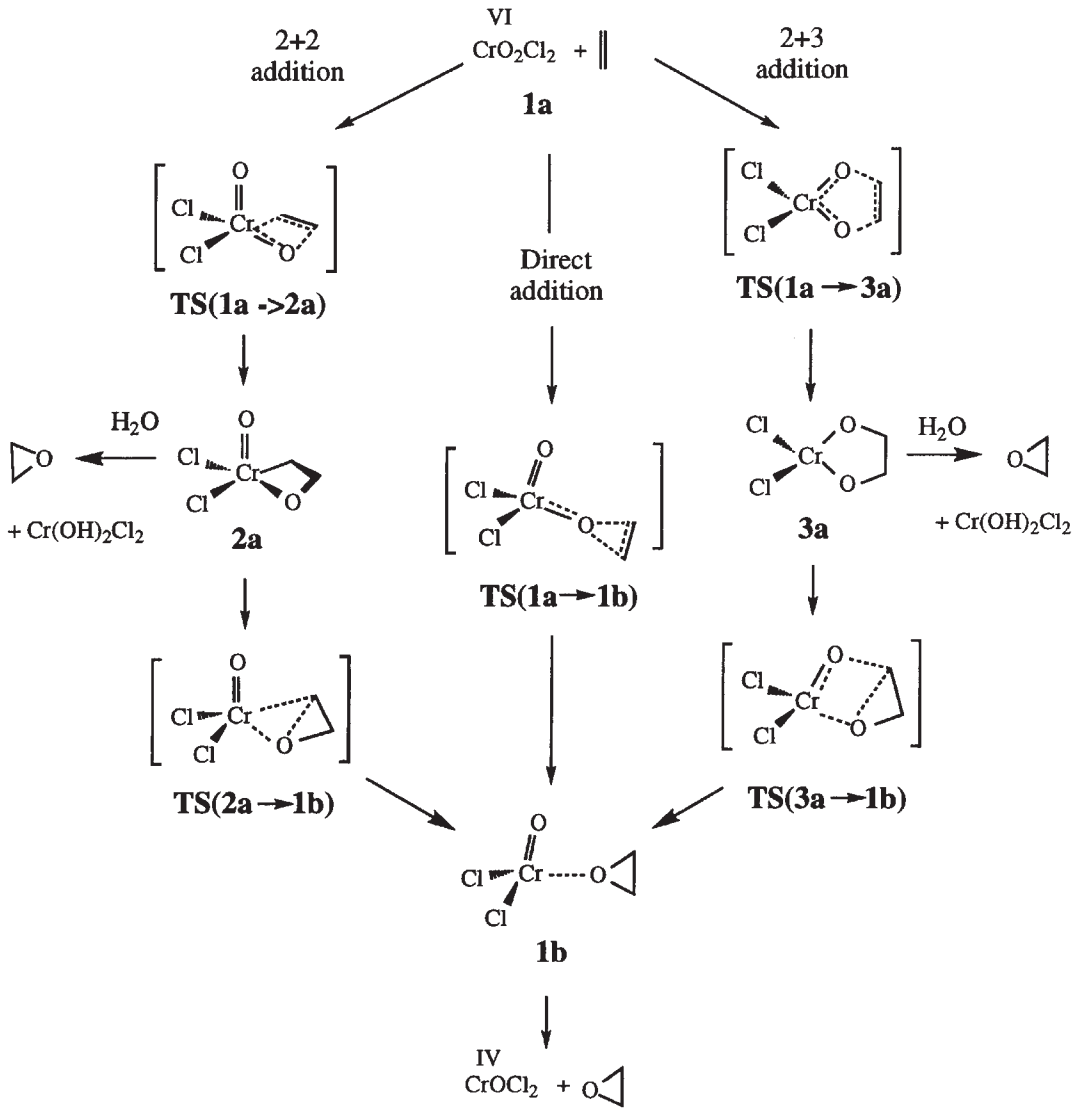
Scheme 1. Mechanisms for the CrO_2Cl_2-mediated formation of epoxide.



geometry optimization procedure was based on an analytical gradient scheme developed by Ziegler and co-workers (33). The harmonic vibrational frequencies were computed from the force constants obtained by numerical differentiation of the energy gradients (34). The transition state (TS) structures were located by a series of constraint geometry optimizations in which the bonds formed and broken were fixed at various lengths while the remaining internal coordinates were optimized. The approximate TSs located from such a procedure were then fully optimized using the standard TS optimization procedure with an algorithm due to Banerjee et al. (35) and Baker (36) in the ADF implementation due to Fan and Ziegler (37). All first-order saddle points were shown to have a Hessian matrix with a single negative eigenvalue. The reaction pathways were traced by the intrinsic reaction coordinate (IRC) method due to Fukui (38) based on a search scheme by González and Schlegel (39), and incorporated into the ADF program by Deng and Ziegler (40). Zero-point energy contributions were not included because energy differences for a related system have been reported not to change significantly when such contributions are taken into account (41*a*).

Previous validations (32*b*, 41*b–d*) have shown that the present DFT method affords metal–ligand bond energies with an accuracy of ±5 kcal/mol. Table 1 affords calculated and experimental heats of reaction for the oxidation of ethylene and norbornene by, respectively, $CrCl_2O_2$, CrF_2O_2, and Cp^*ReO_3. The comparison indicates that a similar accuracy of ±5 kcal/mol can be expected for the type of systems under investigation here. It is further clear from Table 1 that epoxidation of olefin by CrX_2O_2 (X = F, Cl) and Cp^*ReO_3 in all cases is endothermic.

Also shown in Table 1 are the heats of reaction obtained by an extended basis. An increase in the basis changes the heats of reaction by 2–3 kcal/mol. This change is within the error limits of the employed BP86 functional. To further assess the quality of the employed basis, we compare in Table 2 our calculated results with those reported by Rappé

and co-workers (51) in a study that employed an extended basis set and the B3LYP functionals to calculated reaction enthalpies for oxidation of ethylene by a series of Re–oxo complexes. It can be deduced from Table 2 that the root mean square difference between Rappé estimates and our corresponding values is 1.8 kcal/mol with a maximum discrepancy of 2.9 kcal/mol. Again, this comparison indicates that the basis set we used can produce reliable relative energies for the systems under investigation.

III. Results and discussion

The first part of this section is dedicated to thoroughly analyze three different mechanistic proposals for the formation of epoxide precursor in terms of reaction energies and activation barriers. This is, in fact, the main goal of the present paper. The second part is devoted to the elucidation of the reaction steps leading to the formation of chlorohydrin precursor, together with the characterization of the main inter-

$Cp^*ReO_3 + C_2H_4 \rightarrow Cp^*ReO(OCH_2CH_2O)$	–2.8	–4
$CpReO_3 + C_2H_4 \rightarrow CpReO(OCH_2CH_2O)$	–5.7	–8
$ClReO_3 + C_2H_4 \rightarrow ClReO(OCH_2CH_2O)$	17.4	16
$(OH)ReO_3 + C_2H_4 \rightarrow (OH)ReO(OCH_2CH_2O)$	19.5	19
$(OCH_3)ReO_3 + C_2H_4 \rightarrow (OCH_3O)ReO(OCH_2CH_2O)$	19.9	17
$CH_3ReO_3 + C_2H_4 \rightarrow CH_3ReO(OCH_2CH_2O)$	30.6	31
$(O)ReO_3^- + C_2H_4 \rightarrow (O)ReO(OCH_2CH_2O)^-$	30.9	33

[a]The BP86 calculations show that (*i*) all species have singlet ground sate, and (*ii*) the singlet and triplet states of the diolate $ClReO(OCH_2CH_2O)$ are nearly degenerated.

[b]This work, BP86 calculations were carried out with double-ζ plus polarization basis set (ADF standard basis set III/H, C.1*s*, O.1*s*, Cl.2*p*) for nonmetal atoms, and triple-ζ basis set (ADF standard basis set IV/Re.4*f*) for Re atom, geometries were optimized by the quansirelativistic method (ref. 52).

[c]Reference 51, the B3LYP results were based on the geometries optimization with 6-31G* basis set for nonmetals, and the modified LANL2DZ basis with a single *f* function for Re, and the relative energies were determined by single-point calculations at the minima using an extended basis in which the metal *f* function was replaced by two, and the nonmetal basis set expanded to 6-31+G*.

mediates and TS structures involved in the potential energy surface (PES) of the two suggested paths. Finally, the formation of dichloride is also discussed.

III.1. Formation of the epoxide precursor

The CrO_2Cl_2-mediated transformation of ethylene to epoxide can be viewed as a one-oxygen atom transfer reaction. As seen from Scheme 1, it involves formally a reduction of the metal center from Cr(VI) d^0 in the reactants, **1a**, to Cr(IV) d^2 in the products. Regardless of the path leading to epoxide, a common direct precursor in all suggested mechanisms has been species **1b** (Fig. 1).This species was already postulated by Sharpless et al. (5) as the immediate precursor of epoxide, and more recently (21*b*), also as the oxirane adduct intermediate leading to acetaldehyde. The two forming C—O bond distances are certainly close to the ones in the final epoxide (1.416 Å), and the C—C bond is no longer the double bond in ethylene (1.323 Å). We find that **1b** has a d^2 configuration with a triplet ground state. We shall in the following discuss the energetics and kinetics for the suggested mechanisms leading to **1b**.

Figure 2 summarizes the energy profiles for the three mechanisms we are going to describe in the following paragraphs. Energetic aspects will be discussed in connection to the molecular structures obtained for each path (Figs. 3–6) following the sequence: direct addition, [2+2] cycloaddition, and [3+2] cycloaddition.

Starting from **1a**, the possible routes leading to **1b** can be classified according to the number of steps required in the transformation. Either the [2+2] or the [3+2] cycloaddition turns out to be two-step processes. A possible alternative to these routes is the apparently more simple direct addition of ethylene to one of the oxygen atoms in a single step. Since the ground-state structures of **1a** and **1b** lie on different PESs (singlet and triplet, respectively), a crossing point is expected to be found somewhere along the reaction path.

Figure 3 displays the optimized geometries of the two possible transition states connecting **1a** and **1b**:

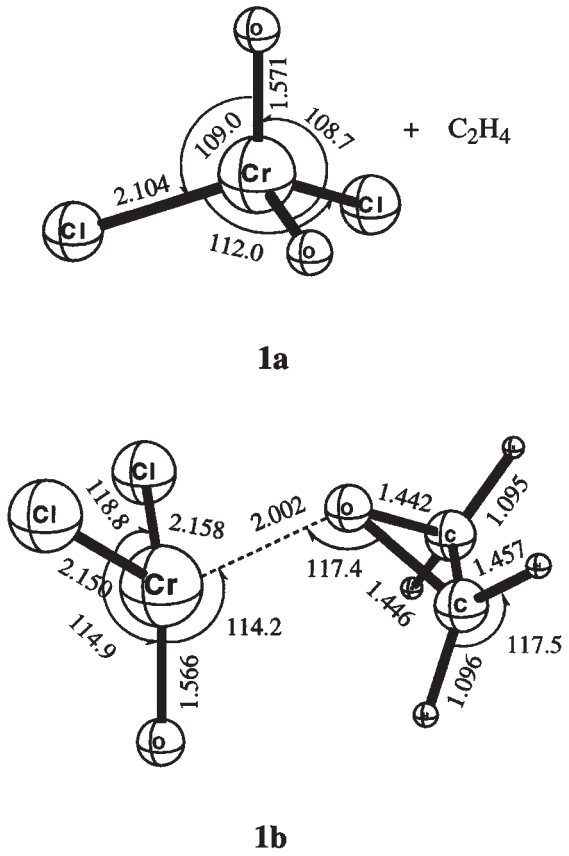
Fig. 1. Optimized geometrical parameters of reactants **1a** and intermediate **1b**. Distances in Å, and angles in degrees.



TS(1a→1b)/s (s = singlet) and **TS(1a→1b)/t** (t = triplet). Geometrical analysis reveals that the former TS resembles species **1b** (elongation of the Cr—O bond and stretching of the C—C bond to similar extents) whereas, in the latter, both the olefin and the metal fragment mainly retain the original character they have in the separated reactant species. Thus, **TS(1a→1b)/s** can be considered a product-like TS and **TS(1a→1b)/t** a reactant-like.

Table 3 gathers the energies of first-order saddle points involved in the three suggested mechanisms for the formation of epoxide. **TS(1a→1b)/t** is found to be only 4.8 kcal/mol less stable than **TS(1a→1b)/s**, and 34.8 kcal/mol above the reactants species. Further exploration of the PES shows that the crossing point might be located on the reactant side of the reaction path. Under these circumstances, the real TS for the reaction **1a→1b** cannot be directly taken as either **TS(1a→1b)/s** or **TS(1a→1b)/t**. Thus, it is only possible to estimate an upper bound to the energy of the actual TS from the crossing point where the two PESs merge. To locate this crossing point, IRC calculations have been performed (*i*) from **TS(1a→1b)/t** to the products, and (*ii*) from **TS(1a→1b)/s** to the reactants, Fig. 4.

The crossing point was located on the singlet PES immediately before **TS(1a→1b)/s** is reached from the reactant side. In the region where the two PESs intersect, the molecular geometries from the two reaction paths are very similar. It means that the activation barrier for the reaction **1a→1b** corresponds closely to the amount of energy required to surmount **TS(1a→1b)/s** (+30.0 kcal/mol, Fig. 2). Since it is the singlet TS that governs the reaction path from the reactant side, the oxygen-transfer process is not concerted: the two

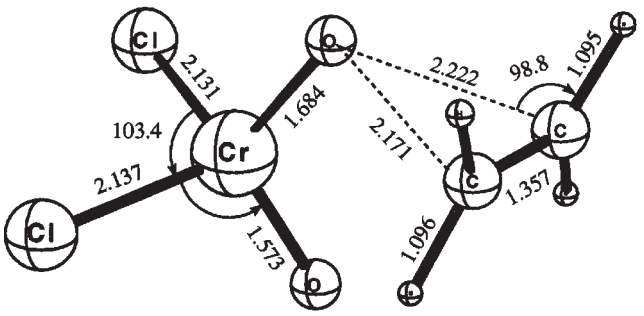
TS(1a→1b)/s



TS(1a→1b)/t

emerging C—O bonds are quite dissimilar (1.422 and 1.768 Å) in **TS(1a→1b)/s** (Fig. 3). Once the maximum has been reached on the singlet PES, the reaction can proceed along the triplet PES while the energy keeps decreasing until species **1b** is formed. The crossing from the singlet to the triplet PESs can be facilitated under the adiabatic assumption (42) by spin-orbit coupling.

Let us turn now our attention to the mechanism by postulated Sharpless et al. (5) involving a [2+2] interaction. The initial step was suggested to be the formation of a chromyl chloride olefin π complex. Despite looking for such a complex, we have not been able to localize any minimum on the PES close to the reactants region. This notwithstanding, its existence cannot be definitively ruled out, keeping in mind the well-known difficulties for DFT methods to describe weak interactions (43).

From that hypothetical complex, a four-centered intermediate **2a** was postulated to be formed via a [2+2] interaction between the olefin and an oxo group on the chromium (5). Indirect support for this process was provided by means of similar reported examples involving block-*p* elements (44).

Table 3. Energies[a] (in kcal/mol) and imaginary frequencies (in cm^{-1}) of all first-order saddle points involved in the three suggested mechanisms for the formation of the epoxide precursor (s = singlet, t = triplet).

TS	$\nu^{\neq}$	Energy
TS(1a→1b)/s	385.6*i*	30.0
TS(1a→1b)/t	229.5*i*	34.8
TS(1a→2a)/s	394.6*i*	27.1
TS(2a→1b)/s	555.0*i*	46.9

TS(3a→1b)/t	27.4*i*	8.9

[a]Energies relative to free CrO_2Cl_2 + C_2H_4.

The optimized geometry of intermediate **2a**, together with the corresponding TSs of the whole [2+2] path are sketched in Fig. 5.

No change of the PES occurs in the reaction step **1a→2a**, since both reactants and product have singlet ground states. In contrast, the crossing takes place in the step **2a→1b**. The first step, **1a→2a**, turns out to be endothermic by 14.5 kcal/mol, and has an activation barrier of 27.1 kcal/mol (Fig. 2). The high energy required to reach **TS(1a→2a)** mainly arises from the Cr—O and C=C bond-breaking processes, which are slightly ahead of the bond-making ones (Fig. 5). This value is close to the 24.6 kcal/mol energy barrier found for the [2σ+2π] attack between CrO_2Cl_2 and CH_3OH (32*c*). Remarkably, the corresponding [2+2] addition involving OsO_4 has been found to have an even higher energy barrier of 39.7 kcal/mol (45*a*).

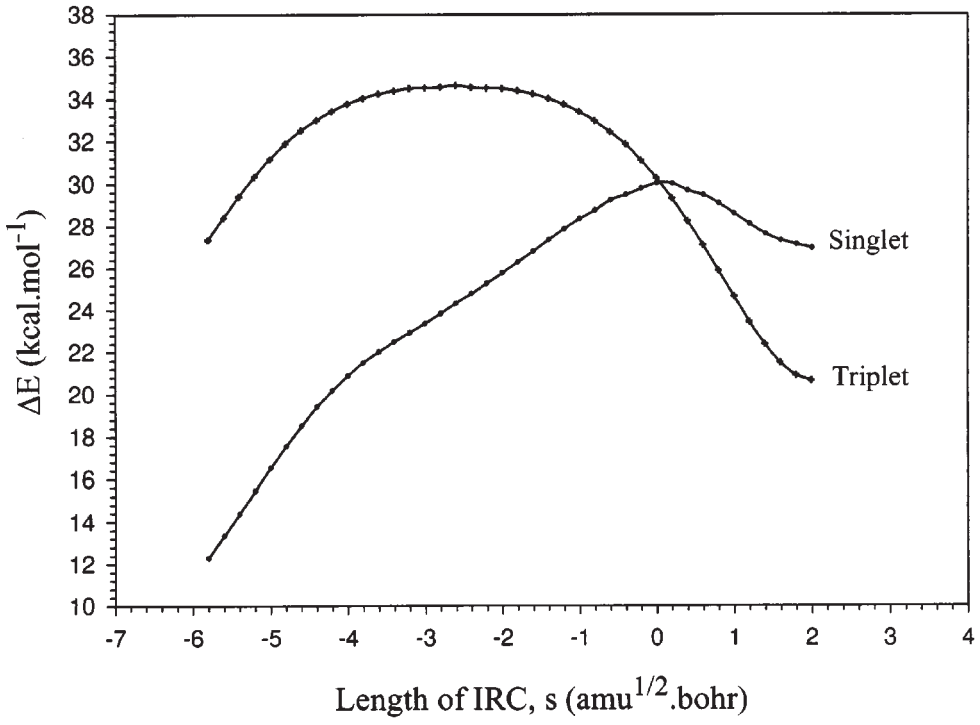
Regarding the second step, it is found to be slightly exothermic (–5.7 kcal/mol), with an activation barrier as high as 46.9 kcal/mol (Fig. 2). By inspection of Fig. 5, such an energy-demanding barrier can be mainly ascribed to the strain around the oxygen atom in the four-center kite-shaped **TS(2a→1b)**. Also the loss of the Cr-C σ interaction is a destabilizing factor.

We have tentatively (Fig. 2) assigned **TS(2a→1b)/t** as the transition state for the second rearrangement step, since it lies 15.5 kcal/mol below **TS(2a→1b)/s**. According to Fig. 5, **TS(2a→1b)/s** is ahead of **TS(2a→1b)/t** along the reaction coordinate from **2a/s** to **1b/t**. It means that there are two different possibilities for the crossover to occur: (*i*) at the early stages of the reaction, prior to any of the two TSs, or (*ii*) still in the reactant-side of the reaction, but between the two TSs. Only in the former case the true TS governing the reaction step is **TS(2a→1b)/t** (as depicted in Fig. 2). If the crossover took place between the two TSs, then the highest point in energy in the step **2a→1b** would not correspond to **TS(2a→1b)/t** but to the crossing point of the two surfaces, and the barrier would be somewhat lower than the reported 46.9 kcal/mol. This second possibility cannot be discarded. However, it is clear from Fig. 2 that the structures of the two TSs are similar enough to ensure that the crossing point would not be far away in energy from **TS(2a→1b)/t**.

Up to this point, none of the two presented mechanisms seems to afford a low-energy path to the epoxide precursor **1b**. A third alternative for the reaction to proceed is via a [3+2] cycloaddition. Figure 6 shows the optimized geome-

© 1999 NRC Canada

Fig. 4. Energy profile for the reaction involving direct addition of CrO_2Cl_2 to ethylene along the IRC path in the region where the crossing between the two PESs occurs. The TS in the singlet surface is at $s = 0.0$, and the TS in the triplet surface at $s = -2.6$. Energies (in kcal/mol) are relative to singlet **1a**.



tries of the main stationary points corresponding to the [3+2] mechanism. The activation barriers for the two-step process involving a [3+2] interaction are +14.0 kcal/mol for the **1a**→**3a** reaction step (for the same OsO_4-catalyzed process (45), the energy barrier is 1.8 kcal/mol), and 21.9 kcal/mol for the **3a**→**1b** reaction step. The former step involves a crossover from the singlet surface in **1a** to the triplet surface in **3a** (Table 2). Such a crossover has been analyzed in detail in a previous study by means of IRC calculations (46). It has been found that the crossing point is located in the product side of the reaction path, the corresponding **TS(1a→3a)** lying on the singlet surface. Should this crossing be made possible by spin-orbit coupling (42), nothing seems to prevent the **1a**→**3a** reaction step from being kinetically feasible. From a thermodynamic viewpoint, this process is found to be exothermic (–13.0 kcal/mol), and therefore also very favorable.

As seen from Fig. 6, the TS for the second reaction step, **3a**→**1b**, resembles very much intermediate **1b**. For instance, the geometry of the $O(CH_2)_2$ skeleton in this product-like TS is very close to the geometrical arrangement found in the precursor of the epoxide (Fig. 1). This is consistent with the fact that **TS(3a→1b)** is only 0.1 kcal/mol above **1b** (Fig. 2). Also notice the low value of the unique imaginary frequency for this TS (Table 2), which is indicative of a flat region.

It follows from the previous discussion that the most suitable path leading to the epoxide precursor **1b** is through [3+2] cycloaddition. The [3+2] addition of ethylene to CrO_2Cl_2 has a relatively low activation barrier of 14.0 kcal/mol, as the occupied π-orbital of ethylene can interact, stabilizing with the CrO_2Cl_2 LUMO throughout the reaction (46). Further, the resulting five-membered ring, **3a**/**t**, is sufficiently flexible to allow for a facile rearrangement route to the epoxide product **1b**/**t** with the transition state being only 8.9 kcal/mol above the separated reactants. We note that the recent photochemical matrix isolation study by Limberg and Köppe (53) found complexed epoxides to be formed by CrO_2Cl_2 whereas they found no evidence for the formation of a dioxylate. This, however, does not contradict our theoretical result that, on the ground-state potential energy surface, complexed epoxide can easily rearrange to the dioxylate with a barrier of 0.1 kcal/mol. As the authors pointed out, "the PES investigated in the matrix experiments under photolytic conditions is probably different from the one the system moves on when the reactions are induced thermally. Light of the wavelength 411 nm is far below the Cr=O dissociation threshold so that CrO_2Cl_2, which shows a visible absorption band nearby, takes up energy via this transition to reach an excited state capable of reacting with olefins under matrix conditions. Consequently the first transition states and intermediate geometries which have to be passed will be different from the thermal ones" (53).

In contrast to the [3+2] path, the [2+2] addition has a sizable barrier of 27.1 kcal/mol due to (46) the poor overlap between the occupied π-orbital of ethylene and the LUMO of CrO_2Cl_2. It is as a consequence not likely to be the first step in the epoxidation process. Also, the further rearrangement of chromaoxetane, **2a**/**s**, leads to a strained transition state, **TS(2a→1b)/t** with a large estimated barrier of 31.4 kcal/mol. Finally, the direct [1+2] addition is also hampered by poor initial interaction between ethylene and CrO_2Cl_2, leading to a prohibitive barrier of 30.0 kcal/mol.

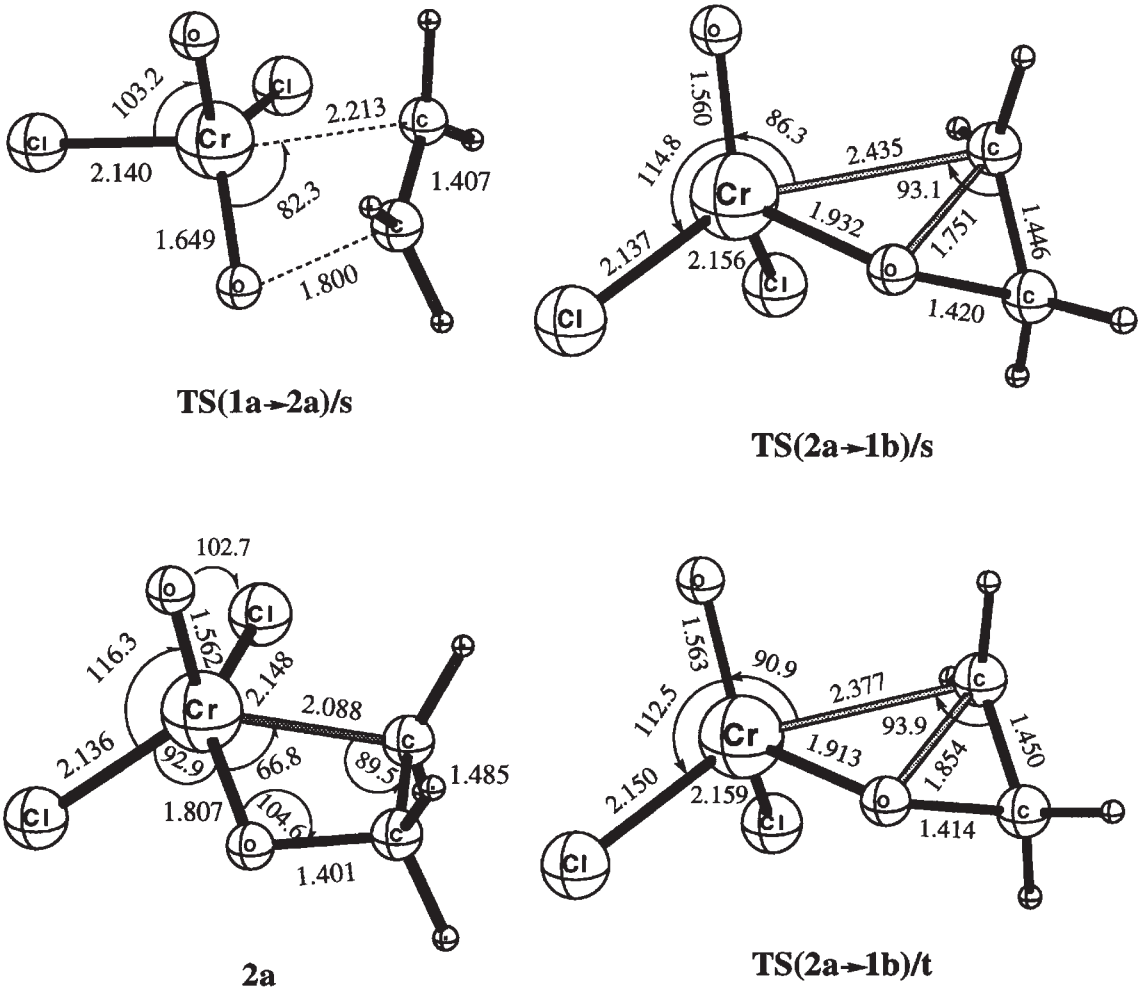
Fig. 5. Optimized geometrical parameters of the main stationary points (minima and first-order saddle points) for the mechanism involving a [2+2] cycloaddition between CrO_2Cl_2 and ethylene for the formation of epoxide precursor. Distances in Å, and angles in degrees.



Similar conclusions have been drawn recently with regard to the relative feasibility of [2+2] and [3+2] addition for the osmium-catalyzed hydroxylation of olefins (41, 45, 47, 48). Our results contradict previous findings by Rappé et al. (8). In that work, the [3+2] path was ruled out because it was found to be strongly endothermic (+56 kcal/mol), whereas the [2+2] path was concluded to be exothermic (–14 kcal/mol) and actually the only one capable of yielding epoxide. However, that work was hampered by the lack of fully optimized structures. Also, Rappé et al. (8) find the reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$ to be exothermic by –35 kcal/mol whereas our DFT method and experiment find it to be endothermic by 26.7 kcal/mol and 24.8 kcal/mol, respectively.

The assumed epoxide precursor **1b/t** does not readily decompose into epoxide. In fact, we calculate the reaction **1b/t** $\rightarrow CrCl_2O + C_2H_4O$ to be endothermic by 16.9 kcal/mol, in keeping with the fact that the overall reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$ is calculated to be endothermic by 26.7 kcal/mol. Thus, the many mechanisms invoking **1b/t** (and an implied exothermicity for the overall reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$) might not be valid. We speculate that H_2O instead is involved in the formation of epoxide as the reaction mixture of Scheme 1 is extracted from an organic solvent (such as CH_2Cl_2) into aqueous solution. This possibility will be the subject of an upcoming investigation (45*a*).

It is worthwhile pointing out that dioxylate complexes of Re and Os are both known and well characterized. Unlike the Cr system, these complexes are known to hydrolyze to *cis* diols rather than epoxides. This can be understood because both the Re and Os system contain only oxygen ligands whereas the Cr system involves both oxygen and chlorine ligands.

III.2. Formation of the chlorohydrin precursor

The conversion of olefins into chlorohydrins was originally suggested to result from highly stereoselective *cis* addition of the elements of HOCl across the olefinic linkage (5). Chlorohydrins resulting from *trans* addition were concluded to be secondary products derived by opening of the epoxide (5). According to Scheme 2, *cis*-oxychlorination can be accounted for by two different mechanistic routes: inter-

mediate **5a** (the immediate precursor of 1,2-chlorohydrin) can be thought to derive from either a [2+2] addition (center) or a [3+2] addition (left).

In the mechanism involving a [2+2] cycloaddition, the formal transfer of O and Cl from CrO_2Cl_2 to ethylene occurs in two separated steps, whereas in the [3+2] mechanism the two heteroatoms are transferred in the same reaction step. As far as the [2+2] route is concerned, there are even two different possibilities for the reaction to proceed, depending on the relative order by which the heteroatoms are inserted: (*i*) insertion of Cl in the first step, then O, or (*ii*) first O, then Cl. Only the former possibility has been depicted in Scheme 2. The latter possibility would mean that, instead of intermediate **4a**, the product obtained after the first reaction step would be the highly energetic chromaoxetane **2a**, whose endothermic formation has been already discussed in the previous section; afterwards, the second step would be a bond migration between **2a** and **5a**. We will come to this point later on.

Tables 4 and 5 gather relevant information concerning all the stationary points involved in the mechanisms for the CrO_2Cl_2-mediated formation of chlorine-containing products from ethylene. Notice that the immediate precursor of 1,2-chlorohydrin, **5a**, lies on the triplet surface in its ground state, whereas **4a** is more stable on the singlet surface. To ensure that these conformations (Fig. 7) are the more stable ones, we also examined three other conformers in which the ligands that do not participate in the ring adopt different orientations. All the isomers were found to be very close in energy to **4a** and **5a** (higher by only 0.1–0.9 kcal/mol). The

TS(4a→5a)/t	121.7*i*	50.5

[a]Energies relative to free CrO_2Cl_2 + C_2H_4.

differences are so small that those species must be thought to coexist and easily interconvert between each other during the reaction.

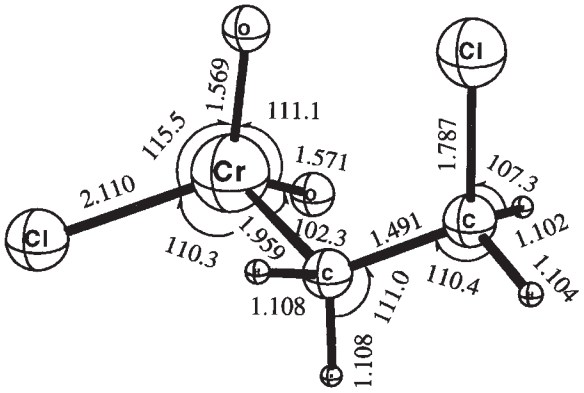
The relative energies and activation barriers for the two pathways leading to chlorohydrin are summarized in Fig. 8. Figures 9 and 10 display the molecular structures of the TSs corresponding to the [2+2] and [3+2] mechanisms, respectively. The [2+2] attack of ethylene on the Cr—Cl bond (Fig. 8) has an energy barrier (9.1 kcal/mol), which is only one third of the barrier corresponding to the same attack on the Cr=O bond (Fig. 2).

However, as can be seen from Fig. 8, the whole [2+2] pathway cannot compete in energy with the [3+2] path. In particular, the main bottleneck for the former route happens to take place in the second step. The conversion of **4a** to **5a**, despite being formally exothermic (ΔE = –3.8 kcal/mol), is kinetically prevented ($\Delta E^{\#}$ = +49.8 kcal/mol). Indeed, the TS connecting **4a** and **5a** (either singlet or triplet) suffers from substantial constraint due to the tight three-membered ring formed during the transfer of the second heteroatom (one O atom in this case) to the organic skeleton. It can be inferred that, if the second heteroatom to be transferred was Cl instead of O (as it would occur in the bond migration **2a→5a**), similar constraints would be also responsible for the strain and, therefore, for the large amount of energy required for this process to take place.

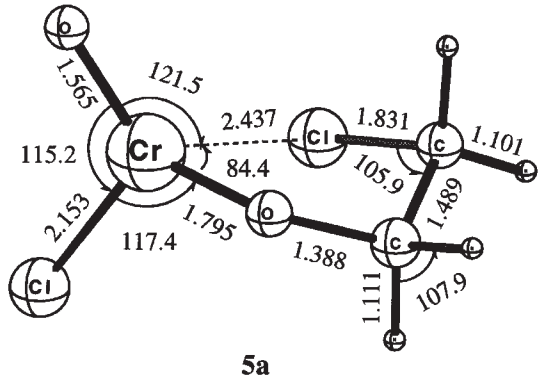
Complex **5a/t** (ground state) is computed to lie 10.2 kcal/mol below **5a/s** (first excited state). According to our calculations, the alternative [3+2] cycloaddition reaction should proceed from **1a** to **5a/t** in a single step involving a change of the PES. Notice from Fig. 10 that **TS(1a→5a)/s** is slightly ahead of **TS(1a→5a)/t**. The crossing point is expected to be found somewhere between the two TSs, and much closer to **TS(1a→5a)/s** than to **TS(1a→5a)/t**, since the latter lies 21.6 kcal/mol above the former. In principle, one could make a rough approximation and assume that the crossover occurs at **TS(1a→5a)/s** (as aforeseen for the **1a→1b** step). In this way, the barrier assigned to the **1a→5a** step (+15.7 kcal/mol) should be better considered as an upper bound to the real activation barrier. Strictly speaking, the crossing point might not coincide with the singlet TS. The closer the two points, the more valid the approximation. However, even in the case that the crossing point happened to occur much earlier than **TS(1a→5a)/s**, the global result would not be significantly affected because the trend is in the direction of making the barrier even smaller.

Taking into account such an assumption, notice from Fig. 10 that **TS(1a→5a)/s** does not suffer from much distortion. The most remarkable point is the closing of the ClCrO bond angle (89.2°) in order to better assist the olefin attack, which proceeds coplanar to the Cl-Cr-O plane (dihedral angle Cl-C-C-O = 2.2°). Once in the product side, the reaction is predicted to proceed smoothly along the triplet PES.

Fig. 7. Optimized geometrical parameters of intermediate **4a** and ester **5a** derived, respectively, from a [2+2] addition of ethylene to one Cr—Cl bond, and from a [3+2] addition of ethylene to one Cr—Cl bond and one Cr=O bond in CrO_2Cl_2. Distances in Å, and angles in degrees.



4a



5a

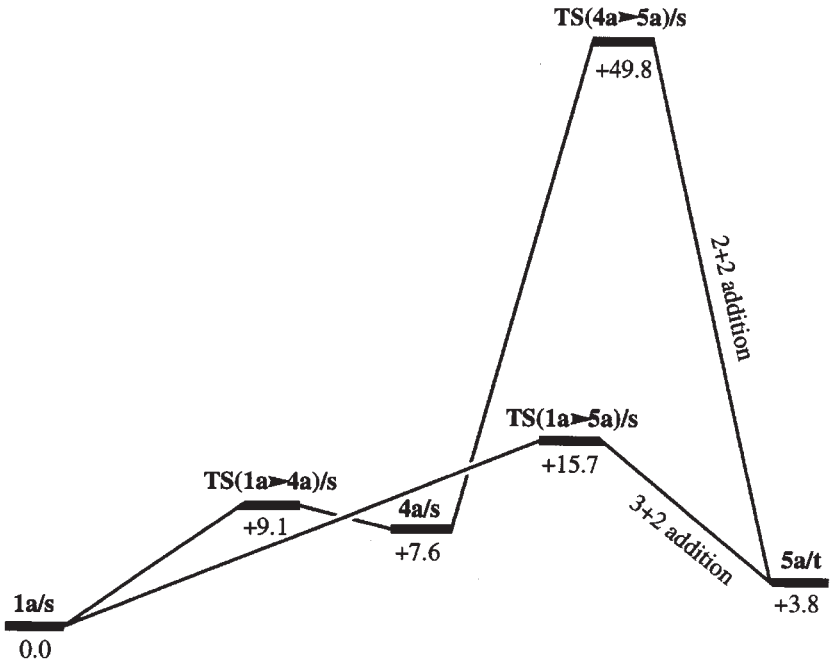
Weighing up both mechanisms, the [2+2] cycloaddition proves less beneficial to the energetics of *cis*-oxychlorination than the [3+2], regardless of the relative order by which the two heteroatoms are inserted. Consequently, it can be concluded that the mechanism that actually operates in the formation of the chlorohydrin precursor (**5a/t**) from the addition of ethylene to CrO_2Cl_2 is the one involving the direct formation of the five-membered intermediate **5a/t** from a [3+2] addition.

We have previously shown (45*a*) that the [3+2] addition of ethylene to two Cr=O bonds has a low barrier due to stabilizing interactions between the LUMO of CrO_2Cl_2 and the occupied ethylene π-orbital. Quite similar interactions are operative for the [3+2] addition of ethylene to, respectively, a Cr=O and Cr—Cl bond. It is thus not surprising that the two types of [3+2] addition have nearly the same activation energies.

The final formation of chlorohydrin from **5a/t** requires a hydrogen agent. We speculate again that H_2O is involved as

© 1999 NRC Canada

Fig. 8. Reaction profile of the two possible mechanisms for the formation of 1,2-chlorohydrin precursor from the addition of CrO_2Cl_2 to ethylene. Energies (in kcal/mol) are relative to **1a**.



the reaction mixture of Scheme 2 is extracted from an organic solvent (such as CH_2Cl_2) into aqueous solution. Thus, the reaction of H_2O with **5a/t** to produce Cr(OH)OCl/t + chlorohydrin is calculated to have a modest endothermicity of 2.4 kcal/mol. We shall examine this step in an upcoming investigation.[2]

III.3. Dichloride formation

Chromyl chloride oxidations of olefins are known to produce complex mixtures of products (1). However, it was found that when these reactions are performed at low temperature the epoxide and the chlorohydrin become the major products. Only in a few cases does *cis*-dichlorination really occur (5). According to Scheme 2, formation of dichloride may proceed through two different reaction pathways. Again, either a [2+2] (center) or a [3+2] addition path (right) seem conceivable modes of reaction. In the former case, ethylene may insert into a chlorine–chromium bond (*cis*-chlorometalation) to produce the alkylchromium intermediate **4a**. Such a process has been already analyzed in the previous section. This species could then lead to the precursor of dichloride, **6a**, by reductive elimination in the second step. The first step, however, has to occur with retention of configuration at the carbon center bound to the chromium in **4a** in order to result in overall *cis* addition. Alternatively, the two chlorine atoms may be transferred in a one-step process.

Figure 11 shows the optimized geometry of the immediate precursor of dichloride, **6a**. This can be considered a five-membered species such as **3a** and **5a**. However, notice that, unlike in **3a** and **5a**, the five atoms of the ring in intermediate **6a** are not coplanar. This conformation ensures the optimal interaction between ethylene π-orbital and the LUMO of CrO_2Cl_2. The energetics of the reaction leading to dichloride is summarized in Fig. 12. The most remarkable point here is the high endothermicity of the net reaction (+44.7 kcal/mol), which prevents dichloride formation from being favored at low temperatures. Since already the thermodynamics makes dichloride formation prohibitive under normal condition, the TSs involved in the path from **1a** to **6a** have not been investigated.

To sum up, comparison of Figs. 2, 8, and 12 allows us to conclude that the formation of dichloride, regardless of the mechanistic path being followed, cannot compete energetically with the formation of either epoxide or chlorohydrin. Our calculations reveal that, thermodynamically, *cis*-dichlorination is more unlikely to occur than any other of the processes leading to the observed products.

III.4. Dependence of the reaction mechanism on the organic substrates

We shall finally briefly discuss changes of relative energies and possibly the reaction mechanism when considering olefins other than ethylene. Table 6 compares the reaction enthalpies for the formation of diolate and epoxide complexes as well as the fully separated epoxides from reaction between $CrCl_2O_2$ and the two olefins cyclohexene and tetramethyl ethylene. It follows from Table 6 that, although the relative energies change to a certain extent when the organic substrates changes, the main conclusions drawn from the discussion for oxidation of ethylene remain the same. That is, (*i*) diolate is the most stable complex in all cases; (*ii*) difference in relative energies between the diolate and epoxide complexes are substantial; and (*iii*) oxidation of olefin to the separated epoxide is highly endothermic. We

[a]The BP86 calculations show that all the reactants have singlet ground state and all the products have triplet ground state.

[b]Unless otherwise specified, the BP86 calculations were carried out with double-ζ basis set plus polarization (the standard ADF basis set III/H, C.1*s*, O.1*s*, Cl.2*p*) for nonmetal atoms, and triple-ζ basis set (the standard ADF basis set IV/Cr.2*p*) for Cr atom.

[c]Energy difference relative to the diolate complexes for each different organic substrates, respectively.

[d]The ADF calculations were performed with triple-ζ plus 3*d* and 4*f* polarization functions for C and Cl atoms, triple-ζ plus 2*p* and 3*d* polarization functions for H, and triple-ζ plus two 4*f* functions for Cr; the basis set for the nonmetals was taken from standard ADF basis set V, and the basis set IVB of ref. 49 was used for Cr atom.

therefore conclude that the mechanistic picture drawn from ethylene is not likely to change qualitatively with other olefins.

IV. Conclusions

We have shown that the formation of the reputed epoxide intermediate **1b/t** from the reaction between CrO_2Cl_2 and ethylene is unlikely to involve a chromaoxetane intermediate derived from a [2+2] cycloaddition as previously assumed (5). Our calculations reveal that the [3+2] addition of ethylene to chromium–oxygen bonds in CrO_2Cl_2 is favored over the [2+2] addition to a Cr=O linkage, and also over the direct addition of ethylene to one oxygen atom. It is concluded that epoxides originate from an ester intermediate, which in turn is formed via a [3+2] cycloaddition.

We also suggest that chlorohydrin, the other major product observed in the oxidation of olefins by CrO_2Cl_2, should arise from a [3+2] cycloaddition as well, in particular from the addition of ethylene to two different heteroatoms in the chromium reagent. Our theoretical results do not support an alternative two-step mechanism involving a [2+2] addition followed by a bond migration. Such a process is found to be too demanding in terms of energy, especially as far as the

© 1999 NRC Canada

activation barrier for the second step is concerned. In addition, the present investigation justifies why only in some cases dichloride is found among the observed products. Dichlorination is computed to be thermodynamically far less favorable than either epoxidation or oxychlorination as a product.

The decomposition of the reputed epoxide precursor **1b/t** into the final product (**1b/t** $\rightarrow CrCl_2O + C_2H_4O$) was found to be endothermic by 16.9 kcal/mol, in keeping with the fact that the overall reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$ is calculated to be endothermic by 26.7 kcal/mol. Thus, the many mechanisms invoking **1b/t** (and an implied exothermicity for the overall reaction $CrCl_2O_2 + C_2H_4 \rightarrow CrCl_2O + C_2H_4O$) might not be valid. We plan in an upcoming investigation[2] to study the role of H_2O (or H^+/OH^-)for the formation of epoxide as the reaction mixture of Scheme 1 is extracted from an organic solvent (such as CH_2Cl_2) into aqueous solution. This investigation should also explain why diols are absent as products in the reaction between $CrCl_2O_2$ and olefins whereas the corresponding reaction between OsO_4 and olefins generates exclusively diols with little epoxide as a product.

3-Deoxy-D-erythro-hexos-2-ulose bis(thiosemicarbazone) copper(II) chelate. Studies in solution and in the solid state

Sandra Signorella, Claudia Palopoli, Alejandro Frutos, Graciela Escandar, Tomoaki Tanase, and Luis F. Sala

Abstract: The 3-deoxy-D-erythro-hexos-2-ulose bis(thiosemicarbazone) (LH_2) acts as a tetradentate ligand with S_2N_2 donor sites to form a copper(II) chelate (Cu(II)L). The Cu K-edge X-ray absorption spectra analysis of a powdered sample revealed a square-planar S_2N_2 local coordination geometry with average Cu—N and Cu—S distances of 1.92 and 2.33 Å. The EXAFS and XANES spectra and the structural parameters of a DMF solution sample indicate the retention of the square-planar local structure of the Cu(II)S_2N_2 chromophore upon dissolution. Semiempirical PM3 calculations indicate that the structure of Cu(II)L with the copper(II) ion bound to the S_2N_2 donor set disposed in a square-planar geometry is the most favorable one (with the highest $|\Delta H_f|$). The formation constant (log K_f = 20.65 ± 0.06) of the neutral [CuL] species was calculated in 30% v/v dioxane–water and the protonation and deprotonation constants determined.

Key words: bis(thiosemicarbazone), copper(II), chelate, structure, stability constant.

Résumé : La bis(thiosemicarbazone) du 3-désoxy-D-érythro-hexos-2-ulose (LH_2) agit comme ligand tétradentate avec les sites donneurs S_2N_2 pour former un chélate du cuivre(II) [Cu(II)L]. Une analyse du spectre d'absorption des rayons X du Cu sur l'arête K d'un échantillon en poudre démontre que la géométrie de la coordination locale du S_2N_2 est de type plan carré avec des distances moyennes Cu—N et Cu—S de 1,92 et 2,33 Å. Les spectres « EXAFS » (de structure fine d'absorption étendue des rayons X) et XANES et les paramètres structuraux d'un échantillon en solution dans le DMF indiquent que le chromophore Cu(II)S_2N_2 conserve sa structure locale plan carré lors de sa dissolution. Des calculs semi-empiriques au niveau PM3 indiquent que la structure la plus favorable (avec la valeur la plus élevée du $|\Delta H_f|$) est celle du Cu(II)L lié au donneur S_2N_2 dans une disposition géométrique plan carré. On a calculé la constante de formation (log K_f = 20,65 ± 0,06) de l'espèce neutre [CuL] dans un mélange dioxane–eau à 30% v/v et on a déterminé les constantes de protonation et de déprotonation.

Mots clés : bis(thiosemicarbazone), cuivre(II), chélate, structure, constante de stabilité.

[Traduit par la Rédaction]

Introduction

We are interested in the coordination chemistry of sugar derivatives with the first row transition metal ions (1–7). The sugar derivative of specific concern here is a bis(thiosemicarbazone) derived from glucose and its copper(II) chelate. Transition metal complexes of thiosemicarbazones have been extensively studied (8, 9). Thiosemicarbazones exhibit a range of types of biological activity, and transition metal complexes of thiosemicarbazones, in some instances, have enhanced or modified activity in comparison to the uncomplexed ligands (8, 10). Compounds such as 3-deoxyaldos-2-uloses themselves may be involved in preparation having

carcinostatic activity (11), and Cu(II)–thiosemicarbazone complexes are among the most potent antiviral, antitumor, and antiinflammatory agents (8, 9).

Preliminary studies performed on the copper(II) chelate of 3-deoxy-D-erythro-hexos-2-ulose bis(thiosemicarbazone) (LH_2) have shown that it possesses in vivo antitumor activity in the murine L-1210 assay (12). The Cu(II)L chelate has been characterized in solution by spectroscopic methods (^{13}C NMR, EPR, UV-vis), but the reported spectroscopic data on the structure of this complex in the solid state are not conclusive (13). Besides, since the biological potential of this kind of complex might be related to the water solubility enhancement due to the presence of the monosaccharide moiety, the behavior of the complex in solution merits to be studied. We report here the structure of this copper(II) chelate in the solid state and the quantitative equilibrium data for the complex in solution.

Experimental section

Physical measurements

X-ray absorption measurements around Cu K-edge (8300–10 300 eV with 800 steps) were carried out at the Photon Factory of the National Laboratory for High Energy Physics on beam line 10B using synchrotron radiation (2.5 GeV, ~350 mA). The experiments were done at room temperature in transmission mode on a BN pellet of the sample by using Si(311) monochromator, details being already reported elsewhere (14).

The extended X-ray absorption spectrum (EXAFS) is derived from the absorption spectrum above the Cu K-edge (E_0 = 8983.39 eV) and is extracted by cubic spline method and Victreen's fit to give the raw EXAFS wave, $k^3\chi(k)$, where k is the photoelectron wave vector defined as $k = [(2m/\hbar^2)(E - E_0)]^{1/2}$. The $k^3\chi(k)$ oscillation (k = 4.50–16.15 Å^{-1}) is Fourier transformed into r-space to clear the contributions of back-scattering atoms, and the r-space ranging from 0.8 to 4.5 Å was back Fourier transformed to produce a Fourier filtered EXAFS oscillation, $k^3\chi(k)_{obsd}$, which was subject to the curve-fitting analysis by a three-terms model, $k^3\chi(k)_{calcd} = k^3\chi_N(k) + k^3\chi_S(k) + k^3\chi_C(k)$, on the basis of a single scattering theory (15). The back-scattering amplitude and the phase shift functions used were the theoretical parameters tabulated by MacKale et al. (16). Parameters, interatomic distance r_i, coordination number N_i, and the Debye–Waller factor σ_i, for each atom were varied in the nonlinear least-squares refined curve fitting. The least-squares fitting was converged at $R = [\Sigma (k^3\chi(k)_{obsd} - k^3\chi(k)_{calcd})^2 / \Sigma (k^3\chi(k)_{obsd})^2]^{1/2}$ = 0.069 (and 0.032 in dimethylformamide (DMF)) to give the structural parameters listed in Table 1. All calculations were performed with the systematic program REX (Rigaku Co. Ltd.) on a IBM PC Master P120.

Geometry optimizations were carried out with HYPERCHEM modeling software using a personal computer.[2] The geometry of the copper(II) complex was obtained from PM3 calculations.

Reagents and solvents used in quantitative determinations

A 0.0100 mol dm^{-3} stock solution of copper(II) ion was prepared from $Cu(NO_3)_2 \cdot 3H_2O$ (Riedel – de Haën) and its exact concentration was determined by titration with ethylenediaminetetraacetic acid using murexide as indicator (17). Solutions of NaOH in 30% dioxane – 70% water (v/v) were standardized with the use of Gran's plots (18). 1,4–Dioxane (p.a.) was obtained from Merck and was purified according standard methods. Deionized water was employed and doubly distilled under potassium permanganate.

Synthesis of the Cu(II)L complex

The complex was synthesized as previously described (12). Anal. calcd. for $CuC_8H_{14}N_6O_3S_2$: Cu 17.18, C 25.98, H 3.82, S 17.33, N 22.72; found: Cu 18.0 (determined by complexiometric titration), C 25.76, H 3.78, S 17.31, N 22.58.

Equilibrium constant determinations

Since the ligand and the cupric complex were not soluble in water, the determinations were carried out in mixtures of water with dioxane. A minimum value of 30% v/v dioxane–water was found to be adequate for those proposes. Both the deprotonation constants of the ligand and the complex deprotonation constants were evaluated through potentiometric techniques. Due to the fact that the complex found in acid media was fully formed below the lower limit at which the pH can be accurately determined in potentiometric titrations (ca. pH 2), its formation constant was spectrophotometrically determined in a separate experiment (19). All measurements were made at 20.0°C, I = 0.10 mol dm^{-3} ($NaNO_3$), and under nitrogen atmosphere.

The pH values were obtained with a Metrohm 713 pH meter fitted with a glass and reference electrodes. The electrode calibration was made with buffer solutions at 0.10 mol dm^{-3} ionic strength. The ligand was dissolved in the solvent medium both in the absence and presence of metal

ion in order to obtain concentrations of 1×10^{-3} mol dm^{-3} in both metal ion and ligand. The potentiometric titrations were carried out by addition of NaOH prepared in 30% v/v dioxane–water, so that 40 or more experimental points were provided for each run. The pH range studied was 2–12. The effect of the solvent composition in the pH measurements was taken into account by correcting each meter reading with a conversion factor (20). This factor was obtained, prior to each experiment, by titration of 30% v/v dioxane–water solutions with standard NaOH solution in the same solvent mixture, at 20°C and I = 0.10 mol dm^{-3}. The water hydrolysis constant was found to be $10^{-14.6}$ for 30% v/v dioxane–water. There was no need of invoking cupric hydrolytic species in the present study. The potentiometric data were converted into equilibrium constant with the use of the program BEST (21*a*). All refinements showed a σ_{fit} <<0.02 (21*b*).

The absorption spectra were read on a Beckman DU640 spectrophotometer in 1.00 cm quartz microcells. Conformity to Beer's law in the concentration range used was verified prior to the determinations. The initial concentrations of LH_2 and Cu(II) ion in the 1:1 metal–ligand experimental solutions were 2×10^{-5} mol dm^{-3}. A typical spectrophotometric titration was previously described in the literature (22). Briefly, profiles of absorbances (at a selected wavelength) vs. pH were obtained according to the following procedure: small increments of a 30% v/v dioxane–water NaOH solution were added to the solution containing LH_2 and Cu(II) ion in the same solvent system. For each pH point (in the range 1.3–4) a known aliquot of solution was extracted, and the absorption spectrum was measured. The data processing for the computation of the equilibrium constants and the species distribution diagram were performed by use the EPSILON program (23).

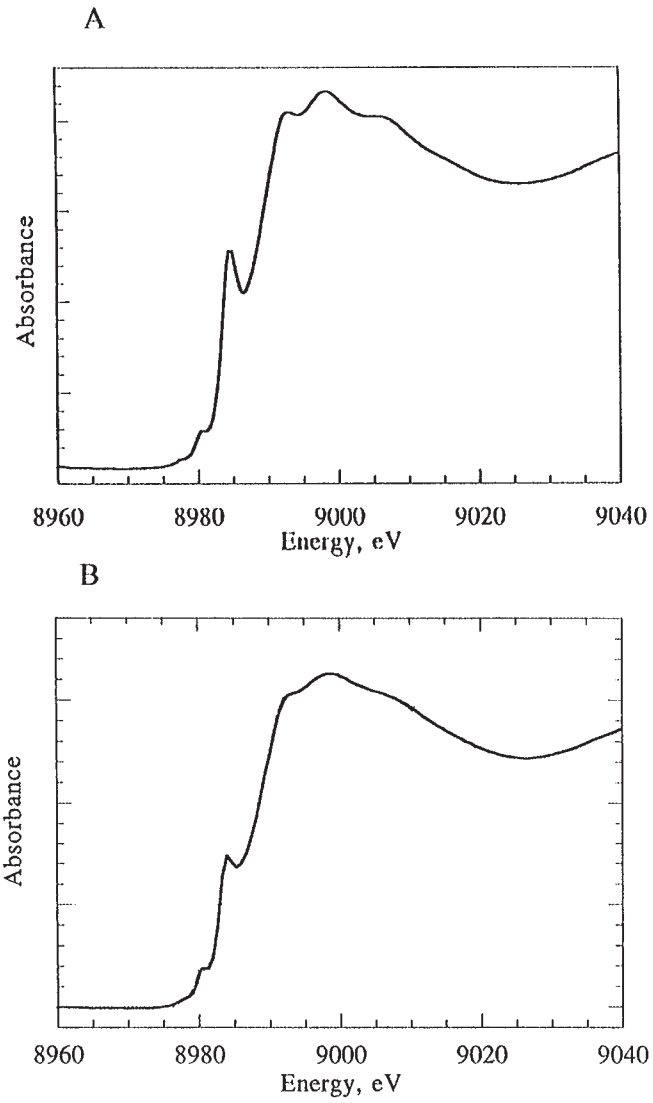
Both potentiometric and spectrophotometric titrations were run in triplicate.

Results and discussion

To obtain direct structural parameters relevant to the copper centre, X-ray absorption spectroscopic analysis was performed on a powdered sample of the Cu(II)L complex. The XANES spectrum of the complex (Fig. 1) shows a characteristic feature of a square-planar coordinated copper(II) ion (24–27). The isotropic K-edge XANES spectra of many copper(II) complexes have a shoulder or partially resolved peak on the rising edge at ~8986 eV in addition to the $3d \leftarrow 1s$ pre-edge transition at ~8979 eV (28). Although it is not easy to assign all the peaks of the present spectrum in detail, the main peak can be assigned to the $4p \leftarrow 1s$ transition, and specially the partially resolved peak on the absorption edge at 8986 eV can be assigned to the $1s \rightarrow 4p_\pi$ transition accompanied by a shakedown process through ligand to metal copper (3*d* hole) charge transfer (l.m.c.t.), which enhances the screening of the core hole, resulting in lower transition energy (26, 29).

The radial structure function describing the local coordination about the copper ion is shown in Fig. 2. The Fourier transform of the raw EXAFS oscillation shows two intense peaks at about 1.6 and 2 Å and a moderate peak around 2.5 Å (before the phase-shift correction), which was back

Fig. 1. X-ray absorption near edge spectrum (XANES) (*A*) powder; (*B*) DMF solution.



Fourier transformed by the use of an appropriate window to produce abstracted EXAFS oscillation subject to curve-fitting analysis (Fig. 3). The structural parameters from the three-terms curve-fitting technique (summarized in Table 1) indicate that the two large peaks attributable to nitrogen and sulfur atoms directly coordinate to the copper, and the third peak to the contribution of the carbon/nitrogen atoms in the chelation rings. These results support that the donor system (first coordination sphere) consists of N_2S_2 with average Cu—N and Cu—S distances of 1.92 and 2.33 Å, respectively, which is consistent with the feature of the XANES spectrum previously discussed and are similar to those observed by X-ray diffraction for S_2N_2 square-planar copper(II) complexes (30–33).

To verify if the square-planar geometry of the Cu(II)-S_2N_2 chromophore is retained upon dissolution, the X-ray absorption spectrum of a 0.1 M Cu(II)L DMF solution was measured (path length 5 mm) and analyzed by using the single scattering theory (Figs. 1–3 and Table 1). The EXAFS and

Fig. 2. Fourier transform of the raw EXAFS oscillation, $k^3\chi(k)$ (*A*) powder; (*B*) DMF solution.

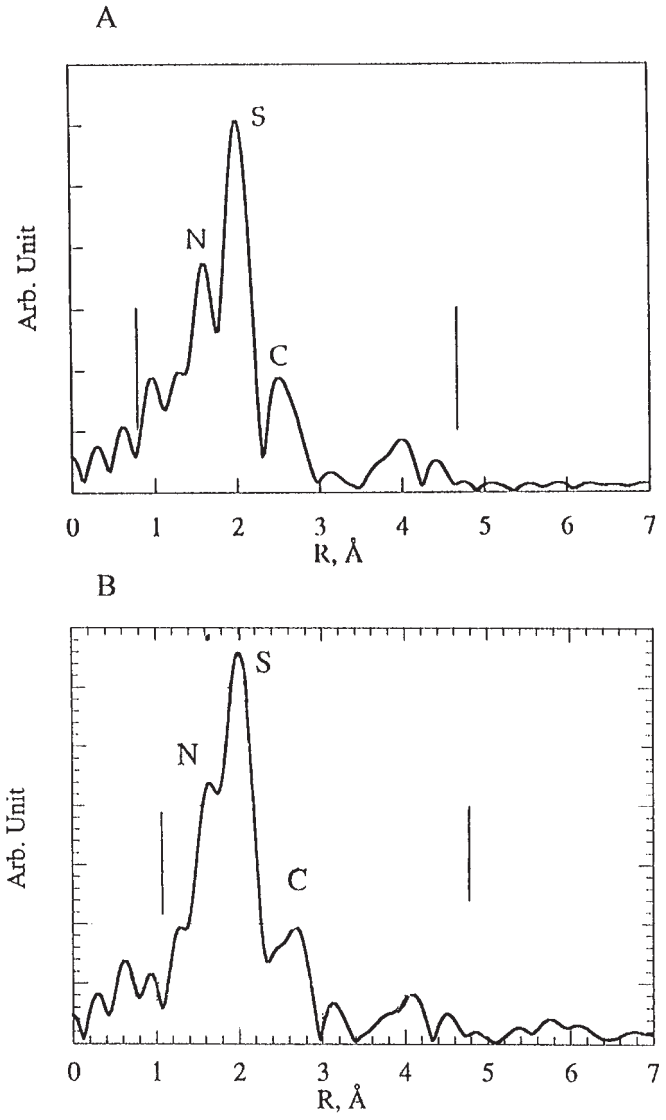

Fig. 3. Curve fitted data, $k^3\chi(k)_{calcd}$ (---), over the range of k = 4.5–16 Å^{-1}, to the Fourier filtered data, $k^3\chi(k)_{obsd}$ (—) (*A*) powder; (*B*) DMF solution.

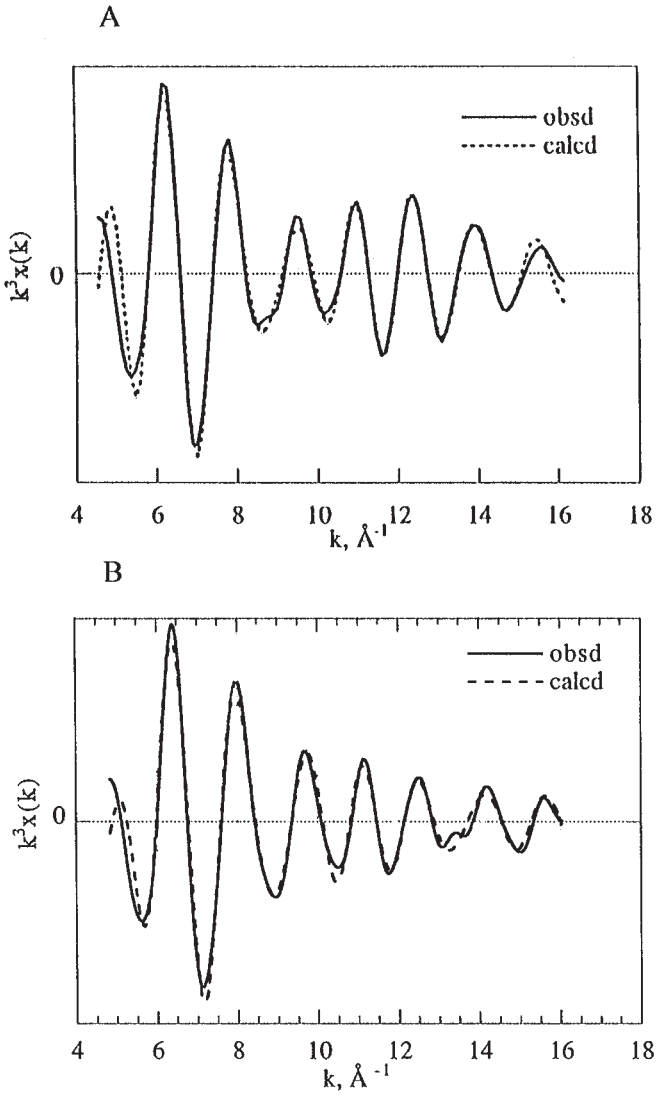

XANES spectra and the structural parameters of the solution sample are closely similar to those of the powdered sample, which strongly indicates that the Cu(II) centre retains the square-planar local structure in solution.

These results are in agreement with the energy minimization calculations for the complex. PM3 calculations were performed for several probable Cu(II)L linkage isomers, and the results indicate that **I** (Fig. 4) is the most favorable structure. The optimized geometry of **I** has a global minimum of –686.51 kJ mol^{-1} on the potential energy surface, and it corresponds to the isomer with the copper(II) ion bound to the S_2N_2 donor set disposed in a square-planar array, a structure stabilized through the formation of the three five-membered chelate rings. The calculated Cu—N and Cu—S distances are 1.88 and 2.12 Å, respectively, and the N^1CuN^2, S^1CuN^1, S^2CuN^2, S^1CuS^2 angles are around 86°, 88º, 88°, and 98°, respectively.

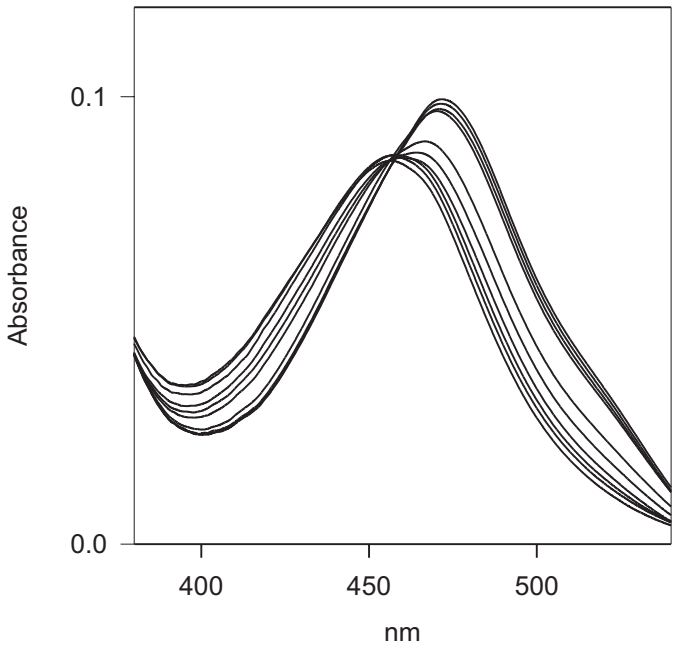
Solution studies

Potentiometric measurements

Figure 5 shows the potentiometric curve of LH_2 in 30% v/v dioxane–water solution. The deprotonation constant values obtained from this curve are shown in Table 2.

Preliminary studies of the potentiometric profile for the Cu(II)– LH_2 system in purely aqueous solution showed the formation of a red precipitate in the pH range 2–11, which dissolved in highly alkaline media. In principle, the solid phase was attributed to a neutral complex formation, which dissolved at high pH to give a more deprotonated species. The potentiometric curve for the Cu(II)–LH_2 system in 30% v/v dioxane–water (Fig. 5) did not show any precipitation and was satisfactorily fitted by considering the species $[CuLH]^+$, [CuL], and $[CuLH_{-1}]^-$, in agreement with the observations in the exploratory experiments in aqueous solution. In the latter formulas, L represents the ligand in its deprotonated form, and H_{-n} indicates the protons released in the complex formation in addition to the two lost ligand protons. Since the free concentrations of the interacting species at the beginning of the titration are very low, only deprotonation complex constants could be determined from this experiment. Table 2 displays these constant values.

Fig. 6. Absorbance at different pH values of Cu(II)–LH_2 system in 30% v/v dioxane–water, initial $C_L = 2 \times 10^{-5}$ mol dm^{-3}, initial $C_M = 2 \times 10^{-5}$ mol dm^{-3}, I = 0.10 mol dm^{-3}, t = 20.0°C.



Spectrophotometric determinations

With the purpose of determining the formation constants for the cupric complexes, a more diluted Cu(II)–LH_2 system was spectrophotometrically evaluated at acid pH. Figure 6 displays the absorption spectra for the Cu(II)–LH_2 system at different pH values. As the pH is increased, the absorption maximum at 456 nm was slightly red-shifted with a concomitant increase in the absorption intensity. An isosbestic point was observed around 456 nm. All these facts were understood as indicative of a complex formation. Figure 7 shows the absorbance profile at λ = 470 nm vs. pH for the system under study. The best fit for this curve involved the formation of only the [CuL] species, and its equilibrium constant value is listed in Table 2.

Concluding remarks

Our X-ray absorption studies reveal that the Cu(II)L complex presents a square-planar S_2N_2 local coordination geometry in the solid state with retention of the metal centre geometry upon dissolution. The high stability of the neutral Cu(II)L complex in solution is revealed by the high formation constant measured spectrophotometrically in a 30% v/v dioxane–water mixture. The hydrophilicity conferred by the sugar moiety is not enough to avoid the precipitation of the complex in water in the 2–11 pH range, at least for the concentrations used in the potentiometric measurements.

Electron self-exchange, oxidation, and reduction reactions of bis(2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline)copper(II/I) and bis(6,6′-dimethyl-2,2′-bipyridine)copper(II/I) couples in acetonitrile: gated ET for the reduction, oxidation, and self-exchange processes

Nobuyoshi Koshino, Yoshio Kuchiyama, Shigenobu Funahashi, and Hideo D. Takagi

Abstract: The electron self-exchange rate constant for the $Cu(dmbp)_2^{2+/+}$ couple (dmbp = 6,6′-dimethyl-2,2′-bipyridine) was measured in acetonitrile by the NMR method (k_{ex} = 5.5 × 10^3 kg mol^{-1} s^{-1}, ΔH^* = 35.0 ± 0.3 kJ mol^{-1} and ΔS^* = –56 ± 1 J mol^{-1} K^{-1}). Reduction reactions of $Cu(bcp)_2^{2+}$ (bcp = 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) and $Cu(dmbp)_2^{2+}$ with $Co(bipy)_3^{2+}$ (bipy = 2,2′-bipyridine) and ferrocene ($Fe(Cp)_2$ = bis(cyclopentadienyl)iron(II)), and oxidation reactions of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$ by $Ni(tacn)_2^{3+}$ (tacn = 1,4,7-triazacyclononane) and $Mn(bipyO_2)_3^{3+}$ ($bipyO_2$ = *N*,*N*′-dioxo-2,2′-bipyridine) were also studied in acetonitrile. The electron self-exchange rate constants, k_{ex}, estimated for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples from the oxidation reactions of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$ by $Ni(tacn)_2^{3+}$ and $Mn(bipyO_2)_3^{3+}$ were consistent with the directly measured values by NMR, while k_{ex} estimated from the reduction reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ by $Co(bipy)_3^{2+}$ ($[Cu(bcp)_2^{2+}]_0$, $[Cu(dmbp)_2^{2+}]_0$ >> $[Co(bipy)_3^{2+}]_0$) were 10^3 times smaller than those directly measured by the NMR method. The pseudo-first-order rate constant for the reduction reaction of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ by $Fe(Cp)_2$ was not linear against the concentration of excess amounts of $Fe(Cp)_2$. Analyses of the reactions revealed that the reductions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ involve slow paths related to the deformation of $Cu(II)N_4$ center from tetragonal to tetrahedral coordination. The energetic preference for the deformation of Cu(II) species rather than that of Cu(I) was discussed on the basis of the ligand field activation energy (LFAE).

Key words: electron transfer, copper(II) and copper(I) complexes, gated behavior.

Résumé : Opérant dans l'acétonitrile et faisant appel à la RMN, on a mesuré la constante de vitesse d'auto-échange électronique du couple $Cu(dmbp)_2^{2+/+}$ (dmbp = 6,6′-diméthyl-2,2′-bipyridine) (k_{ex} = 5,5 × 10^3 kg mol^{-1} s^{-1}, ΔH^* = 35,0 ± 0,3 kJ mol^{-1} et. ΔS^* = –56 ± 1 J mol^{-1} K^{-1}). Opérant dans l'acétonitrile, on a aussi étudié les réactions de réduction du $Cu(bcp)_2^{2+}$ (bcp = 2,9-diméthyl-4,7-diphényl-1,10-phénanthroline) et du $Cu(dmbp)_2^{2+}$ par le $Co(bipy)_3^{2+}$ (bipy = 2,2′-bipyridine) et le ferrocène ($Fe(Cp)_2$ = bis(cyclopentadiényl)fer(II)) et les réactions d'oxydation du $Cu(bpc)_2^{+}$ et du $Cu(dmbp)_2^{+}$ par le $Ni(tacn)_2^{3+}$ (tacn = 1,4,7-triazacyclononane) et le $Mn(bipyO_2)_3^{3+}$ ($bipyO_2$ = *N*,*N*′-dioxo-2,2′-bipyridine). Les constantes de vitesse d'auto-échange électronique, k_{ex}, évaluées pour les couples $Cu(bcp)_2^{2+/+}$ et $Cu(dmbp)_2^{2+/+}$ à partir des réactions d'oxydation du $Cu(bcp)_2^{+}$ et du $Cu(dmbp)_2^{+}$ par $Ni(tacn)_2^{3+}$ et $Mn(bipyO_2)_3^{3+}$, sont en accord avec les valeurs mesurées directement par RMN; par ailleurs, les valeurs de k_{ex} évaluées à partir des réactions de réduction du $Cu(bcp)_2^{2+}$ et du $Cu(dmbp)_2^{2+}$ par le $Co(bipy)_3^{2+}$ ($[Cu(bipy)_2^{2+}]_0$, $[Cu(dmbp)_2^{2+}]_0$ >> $[Co(bipy)_3^{2+}]_0$) sont 10^3 fois plus faibles que celles mesurées directement par la méthode de RMN. La constante de vitesse de pseudo-ordre un pour la réaction de réduction du $Cu(bcp)_2^{2+}$ et du $Cu(dmbp)_2^{2+}$ par le $Fe(Cp)_2$ n'est pas linéaire par rapports à la concentration de quantités excédentaires de $Fe(Cp)_2$. L'analyse des réactions révèle que les réductions du $Cu(bcp)_2^{2+}$ et du $Cu(dmbp)_2^{2+}$ impliquent des voies lentes reliées à la déformation du centre $Cu(II)N_4$ d'une coordination tétragonale à tétraédrique. On fait appel à l'énergie d'activation du champ de ligand pour discuter de la préférence énergétique pour la déformation de l'espèce Cu(II) par rapport à celle de l'espèce Cu(I).

Introduction

For ordinary outer-sphere electron transfer reactions, concerted inner- and outer-sphere reorganizations are assumed (1, 2). Therefore, the electron transfer reaction is slow for the reactions involving a large coordination geometry change during the course of the electron transfer process. Recent theoretical investigations by Hoffman and Ratner (3) and Brunschwig and Sutin (4) indicate that the "gated *intramolecular* process" with high-energy intermediates never competes with the direct outer-sphere process in the *normal* region. This indication, however, does not exclude the "gated electron transfer" phenomena postulated by Rorabacher et al. (5–9) in which large stereochemical changes take place *prior to* the ordinary outer-sphere electron transfer processes. Although such gated reactions cannot be treated as a simple outer-sphere process (i.e., the Ratner type cross relation has the possibility of failing to predict proper electron self-exchange rate constants for such reactions), the outer-sphere electron transfer reactions between the deformed species and the outer-sphere redox reagents may follow the norm of the Ratner type cross relation (10). Therefore, the classical "entatic state view," saying that the rate of the electron transfer is slow for the redox couple with large coordination geometry changes, seems still valid irrespective of the condition whether the reaction is gated or not (11, 12).

Results of the early works on the reactions of $Cu(bpy)_2^{2+/+}$, $Cu(phen)_2^{2+/+}$, and its derivative $Cu(dmp)_2^{2+/+}$ (13–15) indicated the gated ET, as the self-exchange rate constants for these redox couples estimated by the Marcus cross relation from the *forward* and *backward* reactions were inconsistent with each other. In 1983, Lee and Anson (16) pointed out that steric interconversion may have an important role in the electron transfer processes of the $Cu(bpy)_2^{2+/+}$ and $Cu(phen)_2^{2+/+}$ couples. The studies of electron transfer reactions for $Cu(dmp)_2^{2+/+}$ with various reaction partners in aqueous solution were also reported (17–22). However, ambiguities in the coordination structures of these ions as well as the low solubility of these ions in water made it difficult to analyze the reactions more precisely. The studies of the reduction of water-soluble $Cu(dpsmp)_2^{2-}$ (dpsmp = 2,9-dimethyl-4,7-bis((sulfonyloxy)phenyl)-1,10-phenanthroline) by Sykes and co-workers (23, 24) and Lappin and co-workers (25) indicated the involvement of such steric interconversion. There are some cases where electron exchange is extremely slow even for the near tetrahedral Cu(II/I) couples (26–28). Most recently, Stanbury and co-workers (29) reported a very slow electron exchange reaction of $Cu(bib)_2^{2+/+}$ (bib = 2,2′-bis(2-imidazoly)biphenyl). The estimated self-exchange rate constant of $Cu(bib)_2^{2+/+}$ is merely 0.16 kg mol^{-1} s^{-1}. Takagi and Swaddle (30, 31) have been studying Cu(II/I) electron self-exchange reactions by NMR where the coordination geometry of Cu(I) and Cu(II) are constrained to be similar, in which the kinetic behavior *was* expected to follow the context of the moderately fast electron transfer case, and no significant change in coordination number or coordination geometry *had been* expected in the electron transfer processes.

In the case of the gated ET reactions, a *slow* equilibrium corresponding to the deformation of one of the reactants precedes the outer-sphere ET process. For copper(II/I) couples, a tetragonal four or five coordination (D_{2d} symmetry) is expected for Cu(II), while tetrahedral geometry is expected for copper(I). When cyclic polythiaethers were used as ligands, Rorabacher et al. (5–9) showed that the oxidation reaction of Cu(I) is gated, which implies that the deformation of Cu(I) from tetrahedral to tetragonal conformation takes place prior to the ET process. In such a case, the principle of the microscopic reversibility requires that the deformation of Cu(II) is energetically less favored compared to that of Cu(I).

In this article, we examined electron transfer reactions of two $Cu(II/I)(N_2)_2$ couples and found that the electron transfer reactions for $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ are gated. When the normal coordination geometry (slightly twisted structure from the ordinary tetragonal 4 or 5 coordination preferred by the Cu(II) species) is in equilibrium with the deformed tetrahedral state, the electron transfer processes involving the deformed tetrahedral Cu(II) may be much faster than those involving the ground state Cu(II). The energetic origin of the gated ET is discussed on the basis of the ligand field activation energies (LFAE) corresponding to the Cu(II) deformation. A possibility of the mixing of the *gated* and *direct* ET was also examined for the electron self-exchange processes of $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples.[2]

Experimental section

Chemicals

Acetonitrile was obtained from Wako Pure Chemicals Inc. and purified by distillation from phosphorus pentoxide. The content of the residual water in thus purified acetonitrile was examined by a Mitsubishi Kasei CA01 Karl–Fisher apparatus by which the amount of residual water was determined to be less than 5 mmol kg^{-1}. Ferrocene (Wako) was purified by sublimation at ambient pressure. All other chemicals from Wako, Aldrich, and Fluka were used without further purification. Bis(2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline)-copper(II) and -(I) perchlorate were synthesized by the reported method (32, 33). Anal. calcd. for $CuC_{52}H_{40}N_4Cl_2O_8$: C 63.5, N 5.70, H 4.10; found: C 63.8, N 5.62, H 4.18. Anal. calcd. for $CuC_{52}H_{40}N_4ClO_4$: C 70.7, N 6.34, H 4.56; found: C 71.0, N 6.42, H 4.52. Bis(6,6′-dimethyl-2,2′-bipyridine)-copper(II) and -(I) perchlorate were synthesized by the reported method (32, 33). Anal. calcd. for $CuC_{24}H_{24}N_4Cl_2O_8$: C 45.7, N 8.88; found: C 44.7, N 8.72. Anal. calcd. for $CuC_{24}H_{24}N_4ClO_4$: C 54.2, N 10.5, H 4.55; found: C 54.4, N 9.98, H 4.60.

$[Co(bipy)_3](ClO_4)_2$, $[Ni(tacn)_2](ClO_4)_3$, and $[Mn(bipyO_2)_3](ClO_4)_2$ were synthesized by the literature method (34–36). Anal. calcd. for $CoC_{30}H_{24}N_6Cl_2O_8$: C 49.6, H 3.33, N 11.6; found:

General

All manipulations were carried out in an atmosphere of dry nitrogen to avoid any possible contamination by water and oxygen from the environment. Unisoku stopped-flow apparatus was used for the kinetic measurements at various temperatures controlled by a Hetofrig circulation bath. The reservoirs for the reactant solutions were kept under nitrogen atmosphere during the experiments. At least 10 kinetic traces were collected for each run, and the results were analyzed by an NEC personal computer fitted with an interface for the stopped-flow apparatus. Unisoku software was used for the data analyses. Under the conditions of [Cu(II)] << [L] (L = dmbp or bcp), no electroactive species other than $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ was observed within the redox window of acetonitrile (–2 ~ +2 V) by cyclic voltammetry, which indicates that either $Cu(bcp)^{2+}$, $Cu(dmbp)^{2+}$, or Cu^{2+} produced by the decomposition of $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ in solution does not oxidize ferrocene and $Co(bipy)_3^{2+}$ used in this study. The absorbance changes at 470 and 454 nm, corresponding to the absorption maxima of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$, respectively, were monitored for the kinetic measurements.

Electrochemical measurements were carried out by a BAS 100BW electrochemical analyzer with a 1.5 mm ϕ platinum disk or glassy carbon disk as the working electrode, and a 0.5 mm ϕ platinum wire as the counter electrode. A silver/silver nitrate electrode with 0.1 mol kg^{-1} tetrabutylammonium perchlorate (TBAP) in acetonitrile was used as a reference electrode. A solution of $Mn(bipyO_2)_3^{3+}$ was prepared electrochemically in acetonitrile, containing 0.10 mol kg^{-1} TBAP at carbon electrode (Hokuto Denko HX-201). The NMR measurements were carried out by a Bruker AMX-400WB spectrometer.

Results

Electron self-exchange rate constant for $Cu(dmbp)_2^{2+/+}$

$$[1] \quad Cu(dmbp)_2^{2+} + {}^*Cu(dmbp)_2^{+} \xrightarrow{k_{ex}} Cu(dmbp)_2^{+} + {}^*Cu(dmbp)_2^{2+}$$

The electron self-exchange rate constant, k_{ex}, of the $Cu(dmbp)_2^{2+/+}$ couple was measured by monitoring the broadening of the methyl proton signal on diamagnetic $Cu(dmbp)_2^{+}$ by the addition of $Cu(dmbp)_2^{2+}$.

$$[2] \quad k_{obs} = \pi(\nu_{obs} - \nu_0) = k_{ex}[Cu(dmbp)_2^{2+}]$$

where ν_{obs} is the line width of the methyl proton signal at the half signal height in the presence of $Cu(dmbp)_2^{2+}$, while ν_0 is the line width at the half signal height in the absence of $Cu(dmbp)_2^{2+}$. The dependence of k_{obs} on the concentration of added $Cu(dmbp)_2^{2+}$ at constant ionic strength (0.10 mol kg^{-1} by TBAP) is shown in Fig. 1 at various temperatures. The estimated electron self-exchange rate constant at 298 K and the activation parameters are listed in Table 1.

© 1999 NRC Canada

Fig. 2. Dependence of k_{obs} on the concentration of $Ni(tacn)_2^{3+}$ for the oxidation reaction of $Cu(bcp)_2^{+}$. $[Cu(bcp)_2^{+}] = 1.50 \times 10^{-5}$ mol kg^{-1}, $I = 0.1$ mol kg^{-1} (TBAP). The symbols represent the data obtained at 303.0 (◆), 298.0 (○), 293.2 (●), 288.4 (□), and 283.2 (■) K.

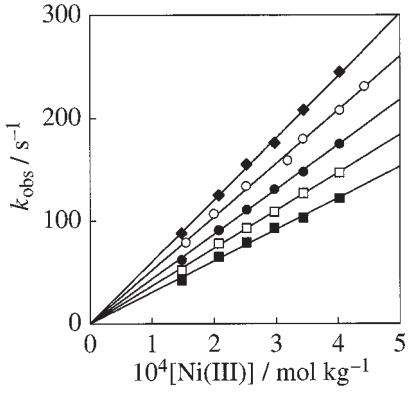

Fig. 3. Dependence of k_{obs} on the concentration of $Fe(Cp)_2$ for the reduction reaction of $Cu(bcp)_2^{2+}$. $[Cu(bcp)_2^{2+}] = 8.47 \times 10^{-6}$ mol kg^{-1}, $[bcp]_{free} = 1.01 \times 10^{-4}$ mol kg^{-1}, $I = 0.1$ mol kg^{-1} (TBAP). The symbols represent the data obtained at 308.2 (◇), 303.2 (◆), 298.2 (○), 293.2 (●), and 288.2 (□) K.

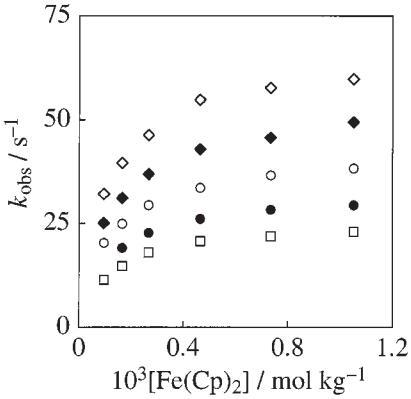

Oxidation reactions of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$ by $Ni(tacn)_2^{3+}$ and $Mn(bipyO)_3^{3+}$

The reaction of $Cu(bcp)_2^{+}$ with $Ni(tacn)_2^{3+}$ in acetonitrile was first order for up to three half-lives and was described by eq. [3] under the pseudo-first-order conditions of $[Cu(bcp)_2^{+}]_0 << [Ni(tacn)_2^{3+}]_0$.

$$[3] \quad Cu(bcp)_2^{+} + Ni(tacn)_2^{3+} \xrightarrow{k_{12}} Cu(bcp)_2^{2+} + Ni(tacn)_2^{2+}$$

$$[4] \quad k_{obs} = k_{12}[Ni(tacn)_2^{3+}]_0$$

The dependence of k_{obs} on the concentration of $Ni(tacn)_2^{3+}$ at various temperatures is shown in Fig. 2 for the reaction of $Cu(bcp)_2^{+}$. The second-order rate constants thus estimated at 298 K, $I = 0.1$ mol kg^{-1} are listed in Table 1 for the reactions of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$, together with the activation parameters of the reactions. The estimated electron self-exchange rate constants for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples by the Marcus cross relation were 2.0×10^3 and 6.7×10^2 kg mol^{-1} s^{-1}, respectively, both of which were in fair agreement with the values (1.4×10^3 and 5.5×10^3 kg mol^{-1} s^{-1}, respectively) obtained from the NMR measurements (33) in view of the uncertainties inherent in the Marcus cross relation (37).

The oxidation reaction of $Cu(dmbp)_2^{+}$ by $Mn(bipyO)_3^{3+}$ was also carried out under the conditions of $[Cu(dmbp)_2^{+}]_0 >> [Mn(bipyO)_3^{3+}]_0$. The second-order rate constants as well as the activation parameters are also listed in Table 1. The electron self-exchange rate constants for $Cu(dmbp)_2^{2+/+}$ was estimated as 1.9×10^3 kg mol^{-1} s^{-1} by the Marcus cross relation.

Reduction reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ by $Co(bipy)_3^{2+}$

The reactions were observed under the conditions of $[Cu(bcp)_2^{2+}]_0$, $[Cu(dmbp)_2^{2+}]_0 >> [Co(bipy)_3^{2+}]_0$. The kinetic traces were first order for up to three half lives. The dependence of the pseudo-first-order rate constant on the concentration of $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ was linear at various temperatures. The second-order rate constants at 298 K and the corresponding activation parameters for these reactions are listed in Table 1. The application of the Marcus cross relation to these reactions yielded 1.2 and 1.4 kg mol^{-1} s^{-1}, respectively, as the electron self-exchange rate constant, which are some 10^3 times smaller than those directly estimated by the NMR method.

Reduction reaction of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ by $Fe(Cp)_2$

The kinetic traces were excellently first-order for Cu(II) up to three half lives.

$$[5] \quad -\frac{d[Cu(II)]}{dt} = k_{obs}[Cu(II)] \qquad [Fe(Cp)_2]_0 >> [Cu(II)]_0$$

However, the dependence of the pseudo-first-order rate constants on the concentration of $Fe(Cp)_2$ was not linear as shown in Fig. 3. The curvature in Fig. 3 may be explained by the following two-step mechanism involving a conformational change of Cu(II) *prior to* the fast electron transfer reaction (Path B in Scheme 1 proposed by Rorabacher et al. (5–9)).

$$[6] \quad Cu(II) \underset{k_{QO}}{\overset{k_{OQ}}{\rightleftharpoons}} Cu(II)^* \qquad Cu(II)^* + A_{Red} \xrightarrow{k_{B2}} Cu(I) + A_{Ox}$$

where Cu(II), Cu(II)*, A_{Red}, and A_{Ox} represent $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ in the ground state, deformed $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$, $Fe(Cp)_2$ and $Fe(Cp)_2^{+}$, respectively. When the conformational change (k_{OQ}) is slower than the electron transfer process (k_{B2}), the pseudo-first-order rate constant is expressed by eq. [7] by using the terms in Scheme 1.

$$[7] \quad Rate = \frac{k_{B2}k_{OQ}}{k_{B2}[A_{Red}] + k_{QO}} [A_{Red}][Cu^{II}L]$$

Scheme 1.

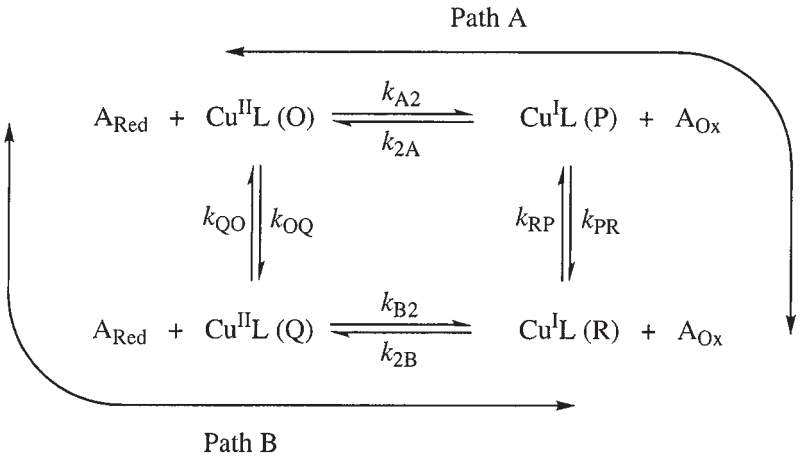

Table 2. Estimated rate constants for the reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ at 298 K.[a]

Reaction			ΔH^{*b}	ΔS^{*c}
$Cu(bcp)_2^{2+}$ + $Fe(Cp)_2$	k_{OQ}	40 s^{-1}	32.0 ± 0.3	–107 ± 1
	k_{QO}	6.5×10^6 s^{-1}		
	$k_{OQ}/k_{QO} = K_{OQ}$	6.2×10^{-6}		
	k_{B2}[d]	6.6×10^{10} kg mol^{-1} s^{-1}		
$Cu(dmbp)_2^{2+}$ + $Fe(Cp)_2$	k_{OQ}	50 s^{-1}	30.5 ± 1.3	–110 ± 4
	k_{QO}	1.7×10^7 s^{-1}		
	$k_{OQ}/k_{QO} = K_{OQ}$	3.0×10^{-6}		
	k_{B2}[d]	9.1×10^{10} kg mol^{-1} s^{-1}		

[a]Ionic strength of the solutions was adjusted to 0.1 mol kg^{-1} by $(n\text{-}Bu_4N)ClO_4$.
[b]kJ mol^{-1}.
[c]J mol^{-1} K^{-1}.
[d]Using the estimated values of the electron self-exchange rate constant for $Cu(bcp)_2^{2+*/+}$ (3.8×10^{10} kg mol^{-1} s^{-1}) or $Cu(dmbp)_2^{2+*/+}$ (1.3×10^{10} kg mol^{-1} s^{-1}) and the self-exchange rate constant for $Fe(Cp)_2^{+/0}$ (9×10^6 dm^3 mol^{-1} s^{-1}). Ionic radii for $Fe(Cp)_2^{+/0}$ = 600 pm.

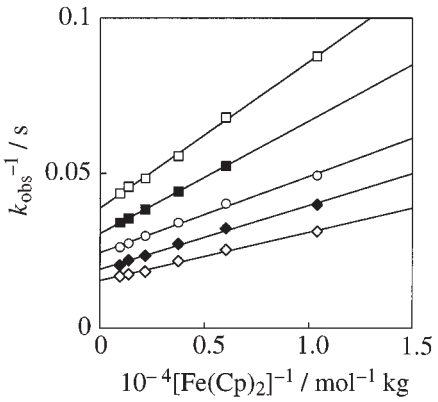
$$[8] \qquad k_{obs} = \frac{k_{OQ}k_{B2}}{k_{B2}[A_{Red}] + k_{QO}} \quad [A_{Red}]\,([A_{Red}] >> [Cu^{II}L])$$

Therefore, the plots of the reciprocal value of k_{obs} against $[A_{Red}]^{-1}$ should be linear with an intercept when $[A_{Red}]_0 >> [Cu^{II}L]_0$. Such plots are shown in Fig. 4.

$$[9] \qquad \frac{1}{k_{obs}} = \frac{k_{QO}}{k_{OQ}k_{B2}[A_{Red}]} + \frac{1}{k_{OQ}}$$

The values of the rate constant, k_{OQ}, and the corresponding activation parameters are also listed in Table 2. It is clear that the estimation of k_{QO} and K_{OQ} is possible once the k_{B2} value is known.

Fig. 4. Plots of k_{obs}^{-1} vs. $[Fe(Cp)_2]^{-1}$ for the reduction reaction of $Cu(bcp)_2^{2+}$ by $Fe(Cp)_2$. The symbols are the same in Fig. 3.



Discussion

General

Rorabacher et al. (5–9) explained the "gated" electron transfer for copper – cyclic thioether ions using the mechanism described by Scheme 1. The reactions proceeded mostly through Path A for the copper–thioether complexes by comparing the electron self-exchange rate constants estimated from both the reduction and oxidation cross reactions.

In this study, the electron self-exchange rate constants for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples were estimated from both the oxidation and reduction reactions by using the Marcus cross relation, which were then compared with the values measured directly by the NMR method. The estimated self-exchange rate constants from the cross reactions were 2.0×10^3 and $(0.67–1.9) \times 10^3$ kg mol^{-1} s^{-1} from the oxidation reactions of $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$, respectively, while the estimated self-exchange rate constants from the reduction cross reactions were merely 1.2 and 1.4 kg mol^{-1} s^{-1}. As the electron self-exchange rate constants mea-

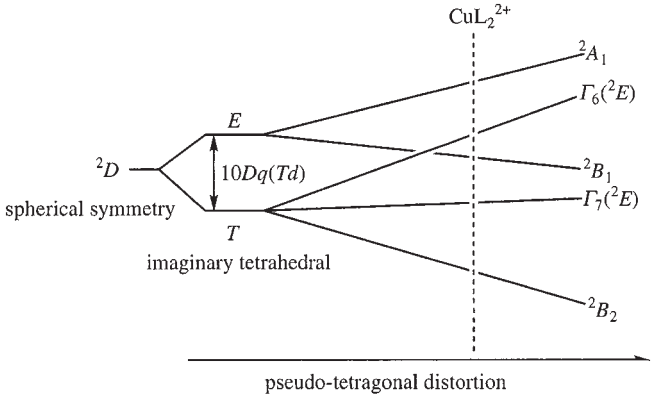
Table 3. Absorption band maxima for $Cu(bcp)_2(ClO_4)_2$ and $Cu(dmbp)_2(ClO_4)_2$ observed by the diffuse reflectance spectrophotometry.[a]



Assignment	$Cu(bcp)_2(ClO_4)_2$[b]	$Cu(dmbp)_2(ClO_4)_2$[b]
Charge transfer	23697	27027
$^2B_2 \rightarrow {}^2A_1$	14064	13698
$^2B_2 \rightarrow \Gamma_6(^2E)$	9891 (broad)	9900 (broad)
$^2B_2 \rightarrow {}^2B_1$	8658 (shoulder)	8620 (shoulder)
$^2B_2 \rightarrow \Gamma_7(^2E)$	5984	6042

[a]The 10*Dq* value for the imaginary tetrahedral field was estimated as 6.4×10^3 cm^{-1} for $Cu(bcp)_2^{2+}$ and 6.2×10^3 cm^{-1} for $Cu(dmbp)_2^{2+}$ from the difference between the average value of the $^2B_2 \rightarrow {}^2B_1$ and $^2B_2 \rightarrow {}^2A_1$ transition and the average value of the energy levels of $^2B_2$, $\Gamma_7(^2E)$, and $\Gamma_6(^2E)$ (see text).

[b]Band maximum/cm^{-1}.

sured by the NMR method are 1.4×10^3 and 5.5×10^3 kg mol^{-1} s^{-1} for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples, respectively, the reactions involving the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples may also be gated, and the preferred pathway for the redox reactions of these couples seems Path B in Scheme 1, rather than Path A observed for the reactions of copper – macrocyclic thioether complexes.

According to Scheme 1, Rorabacher and co-workers (5, 6) derived rate laws for oxidation and reduction reactions corresponding to Path A and Path B as follows, by assuming steady state for the concentrations of the intermediates, $Cu^{II}L(Q)$ and $Cu^{I}L(P)$.

Reduction reaction:

$$[10] \quad -\frac{d[Cu^{II}L]}{dt} = \left(\frac{k_{A2}k_{PR}}{k_{2A}[A_{Ox}] + k_{PR}} + \frac{k_{B2}k_{OQ}}{k_{B2}[A_{Red}] + k_{QO}} \right) [Cu^{II}L(O)][A_{Red}]$$

Oxidation reaction:

$$[11] \quad -\frac{d[Cu^{I}L]}{dt} = \left(\frac{k_{2A}k_{RP}}{k_{2A}[A_{Ox}] + k_{PR}} + \frac{k_{2B}k_{QO}}{k_{B2}[A_{Red}] + k_{QO}} \right) [Cu^{I}L(R)][A_{Ox}]$$

$Cu^{II}L(O)$ and $Cu^{I}L(R)$ represent the Cu(II) and Cu(I) species in the ground state: i.e., $Cu^{II}L(O) = Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ in the D_{2d} symmetry, and $Cu^{I}L(R) = Cu(bcp)_2^{+}$ or $Cu(dmbp)_2^{+}$ in the T_d symmetry. As the reduction reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ take place through Path B, the rate law is expressed by eq. [7]. When $k_{B2}[A_{Red}] << k_{QO}$, eq. [7] is reduced to eq. [12], and the dependence of the pseudo-first-order rate constant on the concentration of $Cu^{II}L$ becomes linear as seen for the reduction reactions of $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ by $Co(bipy)_3^{2+}$.

$$[12] \quad k_{obs} = \frac{k_{OQ}k_{B2}}{k_{QO}}[Cu^{II}L] \qquad ([A_{Red}]_0 << [Cu^{II}L]_0)$$

On the other hand, when $[A_{Red}] >> [Cu^{II}L]$, the dependence of k_{obs} on $[A_{Red}]_0$ deviates from a straight line as seen in Fig. 3. The slopes of the plots in Fig. 4 are given by $k_{QO}/k_{B2}k_{OQ}$ $(= 1/K_{OQ}k_{B2})$.

As the theoretical investigation for intramolecular ET reactions by Brunschwig and Sutin (4) suggests that no reaction path with high-λ intermediate compete with the direct electron transfer in the *normal* region, the kinetic results obtained in this study strongly indicate the *intermolecular* gated electron transfer after a conformational change.

With a d^9 configuration, Cu(II) ion prefers tetragonal structure in general. In the case of $Cu(bcp)_2^{2+}$, it has been reported that the ground state structure is already largely distorted from the normal tetragonal structure, and the dihedral angle between the two phenanthroline planes is close to 60° (33), while the dihedral angle for $Cu(dmbp)_2^{2+}$ is merely 35° from the ESR measurements (33).[3] However, the similar values of the electron self-exchange rate constants for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples indicate that either the coordination geometry or the ligand field in $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ is similar to each other. The similarity of the absorption spectra of these ions (Table 3) also indicates that the ligand fields by the bcp and dmbp ligands are similar to each other. From the crystal structures, these Cu(II) species may be the five coordination in solution (39, 40). However, the water exchange rate constant of five coordinated Cu(II)-2,2′,2″-triaminotriethylamine complex is 2×10^5 s^{-1} (41), which is much larger than the conformational change process, k_{OQ}. Therefore, such a fast solvent exchange for the fifth coordinated solvent molecule on Cu(II) may not affect the very slow conformational change from $Cu^{II}L(O)$ to $Cu^{II}L(Q)$.

The crystal structures of the Cu(I) species have been reported: the dihedral angles between the two ligands for $Cu(bcp)_2^{+}$ and $Cu(dmbp)_2^{+}$ are 87.5° and 80.9°, respectively (32, 42). By considering the flexibility along the C—C bond

[3]ESR parameters, $g_{//}$ and $A_{//}$, were estimated for $Cu(dmbp)_2^{2+}$ as 2.22 and 127 G, respectively, in glassy methanol at 77 K in this study. According to the relation of the dihedral angle and $g_{//}$ postulated by Yokoi and Addison (38), an apparent dihedral angle was estimated as 35°. However, the flexible bipyridine ligands such as dmbp may not follow the norm postulated by Yokoi and Addison.

© 1999 NRC Canada

of the dmbp ligand, the coordination structures of Cu(I) species examined in this study may be considered to be close to T_d in solution, as the strong preference of the tetrahedral structure by Cu(I) is well established (43).

It is possible to estimate the energy difference (LFAE) between the tetragonal $Cu^{II}L(O)$ ground state and the hypothetical tetrahedral $Cu^{II}L(Q)$ state, by calculating the 10*Dq* value corresponding to the hypothetical tetrahedral conformation of $Cu^{II}L(Q)$ ($4\Delta_o/9$) from the diffuse reflectance spectra of $Cu(bcp)_2(ClO_4)_2$ and $Cu(dmbp)_2(ClO_4)_2$ species (44). The absorption band maxima were observed as shown in Table 3. As the distortion from the ordinary tetragonal structure lifts the degeneracy of all *d* orbitals (45, 46), four major absorptions corresponding to $^2B_2 \rightarrow {}^2\Gamma_7(^2E)$, $^2B_2 \rightarrow {}^2B_1$, $^2B_2 \rightarrow {}^2\Gamma_6(^2E)$, $^2B_2 \rightarrow {}^2A_1$ should appear in the visible and near IR regions (the notation for the D_{2d} symmetry is used). The observed band maxima were assigned to these transitions. Following the method of Gouge et al. (45), the 10*Dq* values for the hypothetically tetrahedral $Cu(bcp)_2^{2+*}$ and $Cu(dmbp)_2^{2+*}$ (= $Cu^{II}L(Q)$) were estimated as shown in Table 3. It is assumed that the original energy level for the spherically symmetrical CuN_4 geometry lies close to the difference in the weighted mean energy levels of *T* and *E* terms.[4] By using the 10*Dq* values of hypothetical $Cu^{II}L(Q)$, the ligand field stabilization energies (LFSE) for the imaginary tetrahedral geometry and the ground state geometry of d^9 $Cu(bcp)_2^{2+}$ were calculated as –2560 and –7720 cm^{-1} relative to the energy of the spherically symmetric CuN_4^{2+} (–2500 and –7650 cm^{-1} were calculated for $Cu(dmbp)_2^{2+}$). The largely distorted tetragonal structures of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ in the ground state are, therefore, still ca. 62 kJ mol^{-1} more stabilized compared with perfectly tetrahedral geometry for both of the bcp and dmbp complexes, and this value may be taken as the upper limit of the free energy difference between $Cu(bcp)_2^{2+}$ or $Cu(dmbp)_2^{2+}$ (= $Cu^{II}L(O)$) in the ground state and hypothetical $Cu(bcp)_2^{2+*}$ or $Cu(dmbp)_2^{2+*}$ (= $Cu^{II}L(Q)$) in the tetrahedral configuration. It should be noted that the LFAE calculation above does not include the entropic contribution to the free energy.

As it is clear that the reduction reactions of $Cu^{II}L(O)$ (= $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ complexes) take place through Path B in Scheme 1, microscopic reversibility requires that the oxidation reaction of $Cu^{I}L(R)$ should also take place through Path B. Therefore, $Cu^{I}L(P)$ is necessarily less stable than $Cu^{II}L(Q)$. Cu(I) with d^{10} electronic configuration is well known to be stabilized as its tetrahedral form. The less stability of $Cu^{I}L(P)$ (distorted tetragonal form) may, therefore, be attributed to the nature of Cu(I) with a strong thermodynamic preference to form the tetrahedral geometry. Such tendency is explained by the possible hybridization of the 3*d*, 4*s*, and 4*p* orbitals and by the covalent character of the bonding. The tetrahedral $Cu(I)(N_2)_2$ is some 100 kJ mol^{-1} more stable than the hydrated Cu(I) ions, from the stability constant of Cu(I) species.[5] Therefore, the deformation of Cu(II) species seems preferred compared with the deformation of Cu(I) for the cases of $Cu(N_2)_2^{2+/+}$ couples. The preference of Path A in the case of Cu – macrocyclic thioether complexes (5–9) may be attributed to the less stable structures of $Cu^{I}L(R)$ species in solution: water or solvent coordination to the fourth position of Cu(I) is suggested for the [12]aneS$_4$, [13]aneS$_4$, [14]aneS$_4$ complexes, while corresponding Cu(II) complexes hold relatively planar coordination geometry suitable for the stabilization of $Cu^{II}L(O)$.

Estimation of K_{OQ} and k_{B2}

The value of the k_{B2} process depends on the nature of the reaction partner, as this process includes the effect of the inner-sphere free energy change and the redox potential of the reductant. However, k_{B2} may be very fast: the deformation of $Cu(bcp)_2^{2+}$ to $Cu(bcp)_2^{2+*}$ raises the redox potential of the $Cu(bcp)_2^{2+*}/Cu(bcp)_2^{+}$ couple as much as the structural deformation of $Cu(bcp)_2^{2+}$ to $Cu(bcp)_2^{2+*}$ before the electron transfer process, and the electron transfer (k_{B2}) with minimal internal rearrangement for Cu(II) species must be very fast. The rise of the redox potential, which is equivalent to the LFAE, is estimated by using the Nernst equation.

$$[13] \quad E^\circ_{Cu^{2+*/+}} = E^\circ_{Cu^{2+/+}} - \frac{RT}{F} \ln K_{OQ}$$

where $E^\circ_{Cu^{2+*/+}}$, $E^\circ_{Cu^{2+/+}}$, and *F* are the standard redox potentials of the $Cu(bcp)_2^{2+*/+}$ and $Cu(bcp)_2^{2+/+}$ couples and the Faraday constant, respectively. In this study, we obtained 0.275 V as $E^\circ_{Cu^{2+/+}}$ with reference to ferricinium/ferrocene couple. As the value of K_{OQ} (= k_{OQ}/k_{QO}) is expected to be small (no significant spectral change corresponding to the existence of such intermediate was observed throughout the study), $E^\circ_{Cu^{2+*/+}}$ may be large.

To the outer-sphere electron transfer reaction corresponding to the k_{B2} process, the Marcus cross relation is applicable. Coulombic work terms may be ignored for the reactions of $Cu(bcp)_2^{2+*}$ with ferrocene (29, 37).

$$[14] \quad k_{B2} = \sqrt{k_{Cu^{2+*/+}} k_{Fe^{+/0}} K_{Cu^{2+*}/Fe} f W}$$

$$[15] \quad \ln f = \frac{[\ln K_{Cu^{2+*}/Fe} + (w_{Cu^{2+*}/Fe} - w_{Cu^{+}/Fe^{+}})/RT]^2}{4[\ln (k_{Cu^{2+*/+}} k_{Fe^{+/0}} / Z^2) + (w_{Cu^{2+*/+}} + w_{Fe^{+/0}})/RT]}$$

$$[16] \quad W = \exp\left(\frac{-(w_{Cu^{2+*}/Fe} + w_{Cu^{+}/Fe^{+}} - w_{Cu^{2+*/+}} - w_{Fe^{+/0}})}{2RT}\right)$$

$$[17] \quad w_{ij} = \frac{37.9 z_i z_j}{a(1 + 0.481 a\sqrt{\mu})} \quad (\text{kJ mol}^{-1})$$

where *a*, *z*, and μ are the interatomic distances (Å) between the reacting species, charge on complex ions, and the ionic

[4] The octahedral 10*Dq* value for $Cu(en)_3^{2+}$ was reported as 1.64×10^4 cm^{-1} by Orgel (47). The 4/9 of this value, 7.2×10^3 cm^{-1}, may be taken as the 10*Dq* for the tetrahedral coordination. Therefore, the values of 6.4×10^3 and 6.2×10^3 cm^{-1} obtained here seem reasonable as hypothetical 10*Dq* for the bcp and dmbp complexes.

[5] The stability constant for $Cu(dmp)_2^{+}$ (dmp = 2,9-dimethyl-1,10-phenanthroline) is reported as $10^{19.1}$ in water (48). With a naive assumption that the chemical potential of the distorted tetragonal form of Cu(I) is close to that for solvated Cu(I), the free energy difference between the solvated Cu_{aq}^{+} and $Cu(dmp)_2^{+}$ in water is estimated as 109 kJ mol^{-1} at 298 K. This value may be regarded as the upper limit for the energy difference between $Cu^{I}L(R)$ and $Cu^{I}L(P)$.

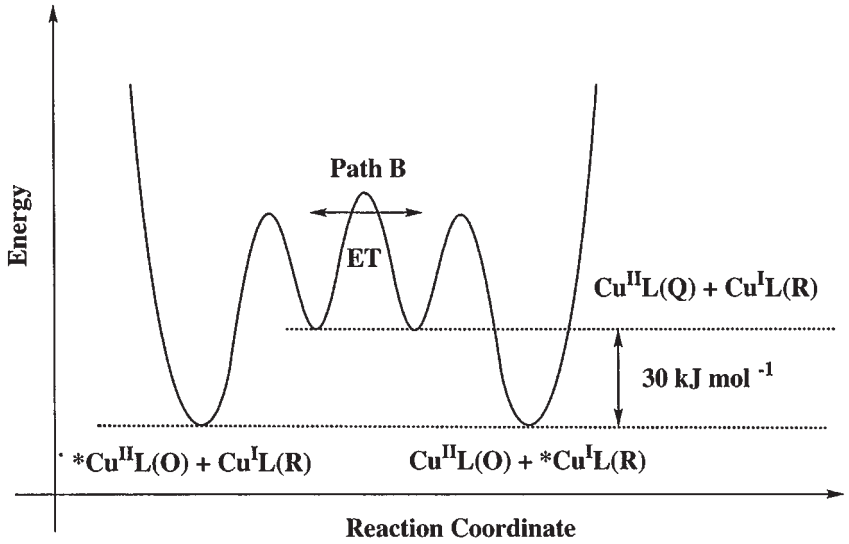
Scheme 2.



strength of the solution, respectively. By using the slope of the plot in Fig. 4, eq. [14] is rearranged to eq. [18].

$$[18] \quad k_{B2} = 4.6\times10^4\, k_{Cu^{2+*/+}} k_{Fe^{+/0}}\, Sf$$

where S denotes the slope obtained from the plot in Fig. 4, and 4.6×10^4 represents the equilibrium constant for the overall reaction of $Cu(bcp)_2^{2+}$ with ferrocene ($\Delta E° = 0.275$ V).

The value of $k_{Cu^{2+*/+}}$ may be estimated as the limiting electron transfer rate constant by using Marcus theory (1), assuming this process is essentially controlled by the outer-sphere reorganization free energy and the electrostatic terms: 12 kJ mol^{-1} for ΔG^*_{os} and 0.5 kJ mol^{-1} for $\Delta G^*_{coul} + \Delta G^*_{DH}$, respectively, by setting the ionic radii of both $Cu(bcp)_2^{2+/+}$ to 760 pm in acetonitrile at 298 K (33). Using the value of ΔG^*_{os}, $k_{Cu^{2+*/+}}$ can be calculated as 3.8×10^{10} kg mol^{-1} s^{-1}. This result was obtained under the assumption that the reactions (each self-exchange reaction and the cross reaction) are adiabatic with the transmission coefficient, κ, is unity. As the driving force of the cross reaction is very large, the f factor in the Marcus cross relation becomes significantly smaller than 1. As a result, the calculated self-exchange rate constant for the $Cu^{2+*/+}$ couple becomes very large. Therefore, the value of 3.8×10^{10} kg mol^{-1} s^{-1} estimated here indicates that the electron self-exchange rate constant for the $Cu^{2+*/+}$ couple is taken to be close to the diffusion limit in acetonitrile. A similar explanation is possible for the value of k_{B2} estimated below. With 3.8×10^{10} kg mol^{-1} s^{-1} thus estimated for $k_{Cu^{2+*/+}}$, a value of 6.6×10^{10} kg mol^{-1} s^{-1} was obtained for k_{B2} by using the reported value of $k_{Fe^{+/0}}$, the electron self-exchange rate constant for the ferricinium/ferrocene couple (49). Therefore, $K_{OQ} = 6.2 \times 10^{-6}$, and $k_{QO} = 6.5 \times 10^6$ s^{-1}. The free energy difference between $Cu(bcp)_2^{2+}$ and $Cu(bcp)_2^{2+*}$ is ca. 31 kJ mol^{-1}, which is rather small compared with the estimated value, 62 kJ mol^{-1} from the LFAE calculation. These results indicate that the structure of $Cu^{II}L(Q)$ is either not perfectly tetrahedral as assumed for the above LFAE calculation, or the contribution of the entropy or the steric repulsion between four methyl groups on the ligands to the free energy is close to 31 kJ mol^{-1}. Similar results were obtained for the reaction of $Cu(dmbp)_2^{2+}$ with ferrocene. The kinetic parameters estimated for the reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ are summarized in Table 2. The large negative activation entropies for the k_{OQ} process may be explained by the similar effect observed for several racemization reactions through the "twist" mechanism (50). The estimated pre-equilibrium constant for Path A (K_{RP}) by Villeneuve et al. (51) is in the order of 1×10^{-3} to 1×10^{-6} for Cu^+ – macrocyclic polythiaether complex. The value for K_{OQ} estimated in this study for CuN_4^{2+} ($\approx 10^{-6}$) is close to the lowest limit of the estimated value for Cu^+ – macrocyclic polythiaether complexes, which indicates that the deformation in the Cu(I)-S species is the more preferable to that in the Cu(II)-S species (intermediate P is the more stable compared with Q).

Apparent electron self-exchange rate constant directly measured by NMR for the gated reactions

It is possible that Path B is also the more preferred for the electron self-exchange reactions of the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples. As the free energy profile for the electron self-exchange reaction is symmetric along the reaction coordinate (Scheme 2), the rate law of the electron self-exchange reaction is described by eq. [19], assuming steady state for $Cu^{II}L(Q)$.

$$Cu^{II}L(O) \underset{k_{QO}}{\overset{k_{OQ}}{\rightleftharpoons}} Cu^{II}L(Q)$$

$$Cu^{II}L(Q) + *Cu^{I}L(R) \xrightarrow{k_{ET}} Cu^{I}L(R) + *Cu^{II}L(Q)$$

$$[19] \quad \text{Rate} = \frac{k_{ET}k_{OQ}/k_{QO}}{1 + k_{OQ}/k_{QO}}\,[Cu(I)]_T[Cu(II)]_T$$

$$[20] \quad \tau_{ex}^{-1} = k_{ex}[Cu(II)]_T$$

$$[21] \quad k_{ex} = \frac{k_{ET}k_{OQ}/k_{QO}}{1 + k_{OQ}/k_{QO}}$$

© 1999 NRC Canada

where $[Cu(I)]_T$ and $[Cu(II)]_T$ denote the total concentrations of Cu(I) and Cu(II) species, respectively. When k_{OQ} is small compared with k_{QO}

$$[22] \quad k_{ex} = k_{ET}k_{OQ}/k_{QO}$$

The values of k_{QO} and k_{OQ} are 6.5×10^6 s^{-1} and 40 s^{-1} for the deformation of $Cu(bcp)_2^{2+}$ while k_{ET} (ET rate constant for the $Cu^{II}L(Q)/Cu^{I}L(R)$ couple without structural change, $k_{Cu^{2+*/+}}$) is 3.8×10^{10} kg mol^{-1} s^{-1} as estimated above. Therefore, k_{ex} for the $Cu(bcp)_2^{2+/+}$ couple is calculated as 2.4×10^5 kg mol^{-1} s^{-1}, which may be compared with the directly measured value by NMR (1.4×10^3 kg mol^{-1} s^{-1}). For the electron self-exchange of $Cu(dmbp)_2^{2+/+}$, a value of 3.9×10^4 kg mol^{-1} s^{-1} was calculated from eq. [22], while k_{ex} estimated by the NMR method was 5.5×10^3 kg mol^{-1} s^{-1}. Such differences may be attributed to the error introduced by the rough nature of the estimation of $k_{Cu^{2+*/+}}$. The activation free energy for the *gated* exchange reaction is, therefore, close to 50 ± 10 kJ mol^{-1}.

Direct (concerted) ET and Gated ET

The activation free energies obtained for the cross reactions examined in this study may be compared with those expected for the *direct* (concerted) electron transfer processes. The reorganization parameter for the cross reaction, λ_{rp}^{cross}, is generally described by eq. [23] (1, 2, 4).

$$[23] \quad \lambda_{rp}^{cross} = \frac{\lambda_{rp}^{Cu} + \lambda_{rp}^{Fe}}{2}$$

where λ_{rp}^{Cu} and λ_{rp}^{Fe} represent the reorganization parameters of the imaginary *direct* self-exchange reactions for $Cu(dmbp)_2^{2+/+}$ and $Fe(Cp)_2^{+/0}$. The experimental results indicate that the reduction reaction of $Cu(dmbp)_2^{2+}$ by ferrocene is gated. As the free energy difference for the reaction of $Cu(dmbp)_2^{2+}$ with ferrocene, $\Delta G°$, is 32 kJ mol^{-1}, the following relation should be satisfied to achieve the observed *gated* ET

$$[24] \quad \frac{(\lambda_{rp}^{cross} - \Delta G°)^2}{4\lambda_{rp}^{cross}} >> \Delta G_{gated}^{*}$$

where ΔG_{gated}^{*} is the activation free energy observed for the cross reaction of $Cu(dmbp)_2^{2+}$ and ferrocene, ca. 50 kJ mol^{-1} ($k_{12} = K_{OQ}k_{B2}$). Therefore, λ_{rp}^{Cu} >> 388 kJ mol^{-1} by solving inequality [24] as $\lambda_{rp}^{Fe}/4$ is 33 kJ mol^{-1} ($k_{Fe^{+/0}} = 9 \times 10^6$ dm^3 mol^{-1} s^{-1}). A similar result was obtained for the reactions of $Cu(bcp)_2^{2+/+}$. The expected activation free energy, ΔG^*, for the direct exchange reaction of the $Cu(L)_2^{2+/+}$ couple (L = bcp or dmbp) should then be larger than 100 kJ mol^{-1}. The reorganization parameter for an electron self-exchange reaction is defined as the sum of the free energy of the products at the equilibrium nuclear configuration of the product's state (1, 4). The estimated very large reorganization parameter, >>400 kJ mol^{-1}, for the direct self-exchange reaction of $Cu(L)_2^{2+/+}$ indicates that the inner-sphere and outer-sphere contribution to the reorganization parameter is significantly larger than the sum of the estimated values: 31 kJ mol^{-1} for the deformation of $Cu^{II}L(O)$ to $Cu^{II}L(Q)$ and 100 kJ mol^{-1} for the deformation of $Cu^{I}L(R)$ to $Cu^{I}L(P)$. Therefore, either (*i*) the free energy change for the deformation of $Cu^{I}L(R)$ to $Cu^{I}L(P)$ may be underestimated; or (*ii*) the relation of eq. [23] is not applicable to the cross reactions with very large reorganization parameters (1, 2), probably through the anharmonic nature of the potential surface; or (*iii*) the direct ET is nonadiabatic. In either case, the self-exchange, oxidation, and reduction cross reactions involving $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ are all *gated*, as the gated process is energetically preferred. It is known that anharmonicity of the potential surface increases the value of transition probability (52), and quantum mechanical correction also increases the ET rate (53). Moreover, it is not probable that the reorganization energy required for the structural change from $Cu^{I}L(R)$ to $Cu^{I}L(P)$ is as large as 350 kJ mol^{-1}. Therefore, it may be concluded that the very slow *direct* (concerted) electron exchange between $Cu^{II}L(O)$ and $Cu^{I}L(R)$ is attributed to the nonadiabaticity of the reaction: a poor electronic coupling between $Cu^{I}L(R)$ and $Cu^{II}L(O)$ may originate from the ion pairing, the extensive solvation of these species in acetonitrile, and (or) the delocalization of the metal *d* electrons on the central Cu(II)/(I) ions because of the weak orbital interactions between Cu(II)/(I) and ligands in the deformed geometry (49, 54, 55). Nonadiabaticity of the direct ET process was also suggested for a certain *directional* (or intramolecular gated) reaction by Brunschwig and Sutin [4].

Conclusions

Reduction and oxidation reactions of the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples were examined in acetonitrile. It was found that the reduction reactions of $Cu(bcp)_2^{2+}$ and $Cu(dmbp)_2^{2+}$ were regulated by the slow conformational change, and the reactions proceeded through Path B in Scheme 1. The conformational change in Cu(II) species was attributed to the large LFAE from tetragonal $Cu^{II}L(O)$ to the pseudo-tetrahedral $Cu^{II}L(Q)$.

The apparent self-electron exchange rate constants for the $Cu(bcp)_2^{2+/+}$ and $Cu(dmbp)_2^{2+/+}$ couples were examined on the basis of the gated mechanism through Path B, and the calculated electron self-exchange rate constants using k_{OQ} and k_{QO} estimated from the results of the cross reactions were in fair agreement with the directly measured k_{ex} by the NMR method. Theoretical calculations of the activation free energies for the *direct* exchange reaction indicate that all the reactions, including the self-exchange reactions, examined in this study are *gated* through Path B in Scheme 1. Nonadiabaticity was suggested for the explanation of the very large free energy barrier of the *direct* exchange between $Cu^{II}L(O)$ and $Cu^{I}L(R)$.

Étude thermodynamique des acides phtalique, isophtalique et téréphtalique

Raphaël Sabbah et Laurence Perez

Résumé : Dans le présent travail a été réalisée l'étude thermodynamique des acides phtalique, isophtalique et téréphtalique de formule générale $C_8H_6O_4$ par calorimétrie de sublimation et par analyse thermique différentielle. En empruntant à la littérature les valeurs des enthalpies de combustion, nous avons pu calculer les enthalpies de formation à l'état gazeux et à 298,15 K de ces acides ainsi que leurs énergies de conjugaison. À partir de ces valeurs, nous avons effectué une étude sur la stabilité relative de ces composés, d'une part, et de divers dérivés du benzène disubstitué, d'autre part. À partir de l'enthalpie de sublimation, nous avons pu déterminer la part énergétique des différentes forces intermoléculaires dans les cristaux de ces trois acides.

Mots clés : thermodynamique, calorimétrie, analyse thermique différentielle, acides phtalique, isophtalique, téréphtalique, enthalpie de fusion, de sublimation, de formation, de liaisons intermoléculaires, énergie de conjugaison, température du point triple.

Abstract: A thermodynamic study of phthalic, isophthalic, and terephthalic acids (general formula: $C_8H_6O_4$) was carried out by sublimation calorimetry and differential thermal analysis. With values of combustion enthalpy taken from the literature, it was possible to determine their enthalpies of formation in the gaseous state and at 298.15 K and their resonance energy. The results enabled us to do a comparative study of the relative stability of the three acids, on the one hand, and of different benzene disubstituted derivatives, on the other hand. From the enthalpy of sublimation, it was possible to determine the energetic contribution of the different intermolecular forces in the crystals of the three acids.

Key words: thermodynamic, calorimetry, differential thermal analysis, phthalic, isophthalic, terephthalic acids, enthalpy of fusion, of sublimation, of formation, of intermolecular bonds, resonance energy, triple point temperature.

1. Introduction

Cette étude s'inscrit dans la continuité de celles qui ont été entreprises au laboratoire depuis quelques années sur les dérivés disubstitués du benzène (1–6). Les résultats obtenus, ajoutés à ceux qui ont été précédemment obtenus au laboratoire, nous ont permis de réaliser, dans ce mémoire, une étude comparative sur la stabilité des isomères d'une même série et sur celle des dérivés de séries différentes. Toutes ces études s'inscrivent dans le cadre de notre thème de recherche « Énergétique des liaisons inter- et intramoléculaires » visant la mise en évidence du lien existant entre grandeurs énergétiques et structure.

Les données thermodynamiques de la littérature relatives à la combustion des acides phtalique, isophtalique et téréphtalique sont très cohérentes (7). Aussi, n'avons-nous pas jugé utile de refaire des mesures de l'enthalpie de combustion. En revanche, on ne trouve que quelques rares résultats divergeants relatifs à l'enthalpie de sublimation des acides isophtalique (8) et téréphtalique (8–10) obtenus par méthodes indirectes à partir de mesure de pression de vapeur en fonction de la température. En conséquence, nous avons étudié ces trois acides par calorimétrie de sublimation. Ce travail a été complété par une analyse thermique différentielle de ces acides qui nous a permis de déterminer leurs enthalpies de fusion et la température de leur point triple. Comme il sera précisé plus loin dans le texte, nous avons rencontré avec cette technique des difficultés expérimentales lors de l'étude de l'acide téréphtalique. Par ailleurs, nous n'avons trouvé aucune donnée dans la littérature concernant les enthalpies de fusion de ces acides.

Notons que les travaux sur leur structure cristalline sont peu nombreux et concernent les trois isomères (11–13).

Du point de vue pratique, signalons, au passage, que l'acide téréphtalique est un important intermédiaire chimique dans la synthèse de polymères.

Reçu le 26 mars 1999.

2. Partie expérimentale

2.1. Produits utilisés

Les acides phtalique et isophtalique sont des produits Aldrich de pureté 99,5 % et 99 %, l'acide téréphtalique est un produit Fluka de pureté >99 %. Ce dernier, se décomposant à la fusion avec bris d'ampoule, n'a pu être étudié par analyse thermique différentielle. Par ailleurs, le degré de pureté du produit commercial nous a paru suffisamment élevé pour l'utiliser tel quel. L'analyse thermique différentielle de

© 1999 CNRC Canada

l'acide isophtalique commercial ayant révélé un degré de pureté jugé suffisant, nous n'avons pas procédé à sa purification. Par contre, nous avons repurifié l'acide phtalique par sublimation à 373 K et sous une pression résiduelle de 1,3 Pa. Les résultats de l'analyse thermique sont consignés dans le tableau 1.

2.2. Appareillages, techniques et modes opératoires

2.2.1. Analyse thermique différentielle

Nous avons utilisé la version moyenne température de l'analyseur thermique différentiel du laboratoire et les cellules en verre décrites dans la référence 14.

Dans toutes nos expériences : (*i*) la vitesse de montée en température du four a été de 0,2 K min^{-1}; (*ii*) la masse de substance utilisée a été d'environ 100 mg, déterminée par double pesée à l'aide d'une balance Mettler, type M5, sensible au μg et dont l'exactitude des pesées est de ±2 μg; (*iii*) la préparation des échantillons et leur mise en container ont été conduites de la façon décrite dans la référence 14.

La mesure des températures a été faite à l'aide de deux thermocouples (thermocoax, type 2ABI 15); l'un est solidaire de l'échantillon, l'autre de la référence (alumine-α). La différence entre les f.e.m délivrées par ces deux thermocouples est amplifiée par un microvoltmètre AOIP, type EVA, sensibilité 100 μV pleine échelle. Le signal ainsi amplifié est envoyé simultanément sur un enregistreur Sefram, type Gépérac, pour le visualiser et sur un multimètre Keithley, modèle 175, pour le numériser. Un autre multimètre Keithley, modèle 196, sensibilité 300 mV (résolution 100 nV) est utilisé pour mesurer la f.e.m. correspondant à la température de l'échantillon. Les données issues de ces deux multimètres sont envoyées vers un ordinateur en vue de leur traitement à l'aide d'un programme écrit et mis au point au laboratoire. En appliquant l'équation de Clausius–Clapeyron et la loi de Raoult, ce programme permet de déterminer la pureté de l'échantillon, son enthalpie de fusion ainsi que la température de son point triple.

Comme indiqué dans la référence 14, l'étalonnage en température de notre analyseur thermique a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque, diphénylacétique et anisique, de carbazole et d'anthraquinone, dont la température de leur point triple est bien connue dans la littérature. Quant à son étalonnage en énergie, il a été fait à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque et diphénylacétique, dont l'enthalpie de fusion est bien connue dans la littérature.

2.2.2. Calorimétrie de sublimation

Nous avons utilisé un calorimètre Tian–Calvet (sensibilité 0,0149 V W^{-1} à 415 K et 0,0628 V W^{-1} à 437,2 K) associé à un montage différentiel doté de cellules d'effusion de Knudsen pour déterminer les enthalpies de sublimation de nos composés. L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après chaque série d'expériences. Le mode opératoire a été décrit dans la référence 15. Précisons que :

(*i*) le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147, sensibilité 30 ou 100 μV pleine échelle suivant le cas, puis numérisé par un multimètre numérique Keithley modèle 175 et enregistré sur un enregistreur potentiométrique Sefram, modèle Servotrace.

(*ii*) L'isomère *ortho* a été étudié à 415,0 K alors que les deux autres isomères l'ont été à 437,2 K en raison de leur faible pression de vapeur saturante P_s (cf. tableau 2). Compte tenu de ces faibles valeurs, nous avons admis l'identité $\Delta_{sub}H_m(T) \equiv \Delta_{sub}H°_m(T)$.

(*iii*) D'après les résultats de la littérature, l'acide téréphtalique existerait sous deux formes cristallines (13, 16) dont la température de transition serait située à 423 K (16). En conséquence, nos expériences ont été vraisemblablement réalisées avec la forme dite « haute température » de cet acide.

(*iv*) Le diamètre des trous d'effusion pratiqués dans des joints métalliques de 0,1 mm d'épaisseur est de 0,7, 0,7 et 3 mm respectivement dans le cas des acides phtalique, isophtalique et téréphtalique.

(*v*) Toutes les pesées ont été effectuées à l'aide d'une balance « Mettler », type UM3 équipée d'un jeu de poids étalonnés par le NIST (sensibilité 0,1 μg, exactitude ±0,2 μg sur une pesée de quelques milligrammes, portée 3 g).

L'acquisition et le traitement des données ont été réalisés à l'aide de l'ordinateur et d'un programme conçu et mis au point au laboratoire. Il permet, entre autres, de déterminer la pression de vapeur saturante, l'aire des thermogrammes et, à partir du coefficient d'étalonnage, l'enthalpie molaire de sublimation de nos composés à la température de l'expérience $\Delta_{sub}H°_m(T)$.

2.2.3. Mesure des capacités calorifiques

Pour calculer $\Delta_{sub}H°_m$ (298,15 K) à partir de $\Delta_{sub}H°_m(T)$, il est nécessaire de connaître :

(*i*) le comportement thermique de nos substances entre 298,15 K et *T*. Nous nous sommes donc assurés qu'elles ne présentaient aucun changement de phase dans cet intervalle;

(*ii*) la capacité calorifique à pression constante des phases condensée et gazeuse des substances étudiées à 298,15 K et *T* de façon à pouvoir appliquer la relation suivante :

$$\Delta_{sub}H°_m(298,\ 15\ K) = \Delta_{sub}H°_m(T) + \int_T^{298,15\,K} [C°_{p,m}(g) - C°_{p,m}(cr)]dT$$

La différence enthalpique $H°_m(T) - H°_m(298,15\ K)$ à l'état solide a été calculée par la méthode de chute à l'aide d'un calorimètre Tian–Calvet et d'un four maintenus respectivement à 298,15 K et *T*. Le calorimètre a été préalablement étalonné en utilisant des échantillons d'alumine-α (6*d*).

Quant aux valeurs des capacités calorifiques à l'état gazeux $C°_{p,m}(g)$ et aux températures 298,15 K et *T*, elles ont été déterminées à partir d'une méthode incrémentale en utilisant, à chacune de ces deux températures, les capacités calorifiques à l'état gazeux des molécules de benzène et d'acide benzoïque (17), ce qui nous a permis, dans un premier temps et à chacune de ces deux températures, de déterminer la part du chaînon COOH puis de calculer une valeur moyenne de $C°_{p,m}$ pour les trois acides étudiés en ajoutant cette quantité au $C°_{p,m}$ de l'acide benzoïque.

Les différents calorimètres et analyseur thermique, leurs périphériques ainsi que les balances, sont placés dans des salles thermorégulées à (19,0 ± 0,2)°C.

3. Résultats

3.1. Analyse thermique différentielle

Les résultats obtenus sont consignés dans le tableau 1. Les isomères *ortho* et *méta* se décomposent à la fusion (8, 18) en prenant une légère coloration brune. Quant à l'isomère *para*, comme signalé dans le paragraphe 2.1, il n'a pu être étudié car sa décomposition à la fusion s'accompagne du bris de la cellule.

Le manque de données de la littérature relatives à l'enthalpie de fusion ne nous a pas permis d'en faire une comparaison avec nos résultats expérimentaux.

Quant aux températures de leur point triple, la référence 18 indique les valeurs suivantes : acide phtalique : 464 K en tube scellé; acide isophtalique : 621 K (614–616 K d'après le catalogue Aldrich); acide téréphtalique : >573 K (698 K en tube scellé d'après la référence 16).

Comme nous pouvons le constater, nos résultats expérimentaux sont tout à fait compatibles avec ces données.

3.2. Calorimétrie de sublimation

L'ensemble des résultats est consigné dans le tableau 2. La littérature mentionne quelques valeurs de l'enthalpie de sublimation des isomères *méta* et *para* obtenues par méthode indirecte à partir de mesures de pression de vapeur en fonction de la température :

Isomère *méta* : 106,7 kJ mol^{-1} à 523 K (8), valeur consignée dans la compilation de Pedley et al. (7).

Isomère *para* : 98,2 kJ mol^{-1} à $392 \leq T/K \leq 425$ (9), valeur consignée dans la compilation de Pedley et al. (7); 131 kJ mol^{-1} à 573 K (8); 139,3 kJ mol^{-1} à $568 \leq T/K \leq 675$ (10).

Signalons que la masse molaire des trois acides phtalique, isophtalique et téréphtalique a été calculée à partir des masses atomiques de 1993 (19); elle est égale à 166,1332 g mol^{-1}.

Dans le présent travail, l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, $\sigma_m = \pm \{\sum (x - x_0)^2 / n(n-1)\}^{1/2}$, x étant chacune des n valeurs entrant dans le calcul de la moyenne x_0. Lorsque la valeur expérimentale est fonction de plusieurs variables, l'incertitude

calculée tient compte de l'erreur sur chacune de ces variables.

4. Discussion

Les principales fonctions thermodynamiques des trois acides étudiés dans ce mémoire sont rassemblées dans le tableau 3.

4.1. Enthalpie de formation à l'état gazeux

Nous avons voulu comparer entre elles les valeurs de l'enthalpie de formation à l'état gazeux et à 298,15 K des trois isomères de divers dérivés du benzène disubstitué se différenciant par la nature du substituant. Ces différentes valeurs sont rassemblées dans le tableau 4. Cette comparaison nous permet de faire les constatations suivantes :

1. Les substances étudiées dans ce travail sont les plus stables. En effet, les valeurs de leur $\Delta_f H°_m$(g, 298,15 K) sont négatives et élevées (en valeur absolue). La stabilité semble décroître dans l'ordre suivant : benzènediacides carboxyliques, dihydroxybenzènes et benzènediamines.

2. Quelle que soit la famille considérée, l'isomère *ortho* paraît être le moins stable. Ceci peut s'expliquer par l'effet stérique provoqué par les deux substituants adjacents.

4.2. Energie de conjugaison

L'énergie de conjugaison est la différence entre l'énergie réelle de la molécule et celle qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Sur le plan pratique, pour la déterminer, il suffit d'utiliser les enthalpies standard de combustion à l'état gazeux de la molécule réelle et de la molécule fictive non conjuguée à 298,15 K. La première de ces grandeurs s'obtient expérimentalement et la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages qui est consignée dans la référence 20.

Les valeurs de l'énergie de conjugaison des acides phtalique, isophtalique et téréphtalique sont consignées dans le tableau 5 avec celles de divers dérivés du benzène disubstitué. Ce tableau nous permet de constater que :

(*i*) Les benzènediacides carboxyliques sont les dérivés les plus conjugués. Ceci est vraisemblablement dû au fait que les groupements (COOH), donneurs d'électrons, consolident la conjugaison du cycle.

(*ii*) Comme dans le cas de l'enthalpie de formation à l'état gazeux et pour la même raison, quelle que soit la famille considérée, l'isomère *ortho* paraît être le moins stable.

4.3. Liaisons intermoléculaires dans les acides phtalique, isophtalique et téréphtalique

4.3.1. Liaisons hydrogène intermoléculaires

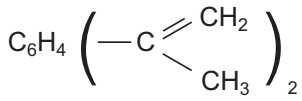
L'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires comprenant la part énergétique due aux forces de van der Waals (de dispersion et dipolaires) et, le cas échéant, celle qui est relative aux liaisons hydrogène.

Un procédé de calcul, plusieurs fois utilisé avec succès au laboratoire (2, 3, 5, 21–25) nous a permis de déterminer la contribution énergétique des liaisons hydrogène intermoléculaires dans les cristaux d'acides phtalique, isophtalique et téréphtalique. Il consiste, dans notre cas, à comparer l'enthalpie de sublimation des molécules de ces acides à celle d'une molécule isoélectronique (ici la molécule de 1,4-dinitrobenzène) possédant les mêmes forces de dispersion et d'interactions dipolaires. Malheureusement, nous n'avons pas trouvé dans la littérature la valeur de l'enthalpie de sublimation de cette molécule.

L'expérience acquise au laboratoire nous ayant montré que la différence entre les valeurs de l'enthalpie de sublimation des isomères *méta* et *para* d'une même série n'est que de quelques kJ mol^{-1}, nous avons utilisé dans nos calculs la valeur de l'enthalpie de sublimation de la molécule de 1,3-dinitrobenzène empruntée à la référence 7 ($\Delta_{sub} H°_m$(298,15 K) = (81,2 ± 1,7) kJ mol^{-1}). Cette dernière valeur correspond, en première approximation, à la part des forces de dis-

© 1999 CNRC Canada

persion et dipolaires dans les cristaux des trois acides étudiés dans ce mémoire. Malheureusement, il ne nous a pas été possible de départager ces deux types d'interaction. En effet, la littérature ne propose aucune valeur de l'enthalpie de sublimation de la molécule d'hydrocarbure isoélectronique



qui nous aurait permis de déterminer la part énergétique due aux forces de dispersion dans les cristaux d'acides phtalique, isophtalique et téréphtalique. Il s'ensuit que la contribution des liaisons hydrogène intermoléculaires dans les isomères *ortho*, *méta* et *para* est respectivement égale à 48,6 kJ mol^{-1}, 60,8 kJ mol^{-1} et 65,4 kJ mol^{-1}.

Si l'on considère la molécule d'isomère *para*, qui est dépourvue de tout effet stérique dû aux substituants et dans laquelle il ne peut y avoir que des liaisons hydrogène intermoléculaires et compte tenu qu'il ne peut se former que deux liaisons de ce type par molécule, il s'ensuit que l'enthalpie d'une liaison hydrogène intermoléculaire est environ égale à 32,7 kJ mol^{-1}. Cette valeur est tout à fait compatible avec celle que donnent Saska et Myerson (26) dans le cas des cristaux de cet acide (26,2 kJ mol^{-1}) et celles qui sont proposées dans celui des acides carboxyliques par Pimentel et Clellan (27).

Quant à la différence observée entre les valeurs de l'enthalpie de sublimation des isomères *ortho* et *para*, on pourrait, à première vue, penser, comme c'est le cas pour d'autres isomères de dérivés disubstitués du benzène (acides hydroxybenzoïques (4) et aminobenzoïques (1)) que cette différence est due à une chélation entre les deux groupements fonctionnels dans l'isomère *ortho* avec formation de liaison hydrogène intramoléculaire. En réalité, il n'en est rien compte tenu de la structure cristalline de l'acide phtalique proposée par Küppers (11) dans laquelle les deux groupements fonctionnels sont perpendiculaires. En conséquence, la valeur la plus basse de l'enthalpie de sublimation observée pour cet isomère est vraisemblablement due à un manque de liaison hydrogène dans ses cristaux en raison de l'effet stérique provoqué par les deux groupements fonctionnels adjacents.

4.3.2. Calcul de l'enthalpie moyenne de sublimation des trois acides par voie incrémentale

La valeur moyenne de l'enthalpie de sublimation des trois acides étudiés dans ce mémoire est égale à 139,46 à 298,15 K kJ mol^{-1}. Nous avons tenté de retrouver cette valeur par voie incrémentale. Pour cela, nous avons déterminé la contribution du chaînon (COOH) en retranchant à la valeur de $\Delta_{sub}H°_m$(298,15 K) de la molécule d'acide benzoïque (89,74 kJ mol^{-1}) (28) celle de la molécule de benzène. Cette dernière est, en première approximation, calculée à partir de la relation :

$$\Delta_{sub}H°_m(298{,}15\ \text{K}) = \Delta_{fus}H_m(298{,}15\ \text{K}) + \Delta_{vap}H°_m(298{,}15\ \text{K})$$

où $\Delta_{fus}H$(298,15 K) est obtenue à l'aide de la règle de Sidgwick (29) :

$$\Delta_{fus}H_m(298{,}15\ \text{K}) = \Delta_{fus}H_m(T_{fus}) - 0{,}055\ (T_{fus} - 298{,}15)$$

Les valeurs relatives à la molécule de benzène sont empruntées aux références 30 et 31. Après calcul, nous trouvons $\Delta_{sub}H°_m$(298,15 K) = 44,88 kJ mol^{-1} pour cette molécule. La part du chaînon (COOH) est donc estimée à 44,88 kJ mol^{-1}.

Il s'ensuit que l'enthalpie moyenne de sublimation des trois acides à 298,15 K, calculée en ajoutant à l'enthalpie de sublimation du benzène deux fois la contribution énergétique du chaînon (COOH) à cette température, est égale à 134,62 kJ mol^{-1}. Elle diffère d'environ 3,5 % de la valeur moyenne expérimentale.

Annotinine revisited. A new pentacyclo[7.3.3.0^{1,13}.0^{2,12}.0^{5,13}]pentadecane ester and other products derived from annotinine

William A. Ayer, Monika Wichlacz, and Latchezar S. Trifonov

Abstract: Several annotinine derivatives were prepared and their conformations were determined on the basis of 1D NMR and 2D NMR spectra (GCOSY, HMQC, HMBC, TROESY). One of these compounds has new unique 5-ring skeleton.

Key words: alkaloids, chemical tranformations, structure elucidation, conformation.

Résumé : On a préparé plusieurs dérivés de l'annotinine et on a déterminé leurs conformations en se basant sur les spectres de RMN 1D et 2D (« GCOSY », « HMQC », « HMBC », « TROESY »). L'un de ces composés comporte un squelette pentacyclique unique.

Mots clés : alcaloïdes, transformations chimiques, élucidation de structure, conformation.

[Traduit par la Rédaction]

Introduction

Annotinine (**1**, Fig. 1) is a major alkaloid of the club mosses *Lycopodium annotinum* and *L. annotinum* var. *acrifolium*, and a minor alkaloid of *L. flabelliforme* and *L. obscurum* (1). The unique structure of this compound was solved in 1957 by Wiesner et al. as a result of extensive degradative studies (2) culminating later with the total synthesis of the optically active enantiomer (3). The structure was verified by X-ray analysis (4).

The large quantities of annotinine available permitted the performance of a variety of reactions. In 1957 Martin-Smith et al. reported that methyl epiannotinate (**2**) was the only product isolated in 75% yield when annotinine was treated with KOMe–MeOH at room temperature (r.t.) (5). In our laboratory in the late 50s the same reaction afforded several minor products (**2**, **3**, **4**) in addition to a major product with interesting properties, designated "ester M," whose structure was suggested to be **5**. However, this was not supported by solid spectroscopic data (6). Even a simple ^{1}H NMR spectrum was not available at that time due to the exceptionally low solubility of **5** in conventional NMR solvents. The routine use of powerful 2D NMR techniques in recent years and a simple solution to the solubility problem prompted us to reinvestigate the above reaction of annotinine. In this study we report the structure determination of ester M and of the minor reaction products, as well as complete assignments of all NMR signals.

Received December 7, 1998.

Results and discussion

The epimeric methyl epiannotinate (**2**) and methyl annotinate (**3**) have molecular formula $C_{17}H_{25}NO_4$ as determined by HRMS spectra. In both compounds the epoxide ring is preserved and a CH(OH) group and a CH-COOCH$_3$ group replace the lactone functionality of annotinine. Although in both isomers H1 appears as a doublet of doublets with one large and one small coupling constant (Table 1), the large coupling in **2** (12.3 Hz) is due to coupling to H2α, while in **3** (14.6 Hz) it is due to coupling to H2β. This pattern of couplings is only attainable if the C1–C6 ring adopts a chair conformation in **2** and a boat conformation in **3**. The TROESY spectra (7) further support this conformational assignment (Fig. 2). Thus, in compound **2** H1 shows a cross peak with H15, while in compound **3** H1 shows a cross peak with H7. In both isomers H15 is correlated to H2β, but not to H2α, and the correlations H15–H13b and H14–H13a, and H2β–H13b as well, allow us to assign the signals for H13a and H13b. The correlation H4–H9α (both axial) is crucial for the assignment of H9α and H9β in **2** and **3**. The correlations H10β–H13a, H12α–H3, H12β–H13b, and 9α–11α as well as H10β–H12β (axial–axial) and H10α–H11α allow us to assign H10, H11, and H12.

Interestingly, H10α is correlated to H9β but not to H9α, and also H12α is correlated to H3 but not to H4, which is in agreement with the proximities shown in molecular model studies.

The complete assignment of all ^{1}H and ^{13}C signals shown in Tables 1–3 is based on ^{1}H–^{1}H COSY, HMQC, HMBC, and TROESY spectra (Figs. 2 and 3).

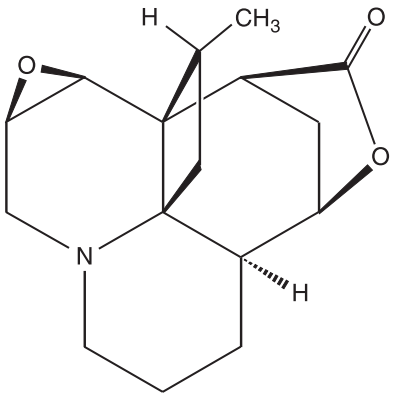
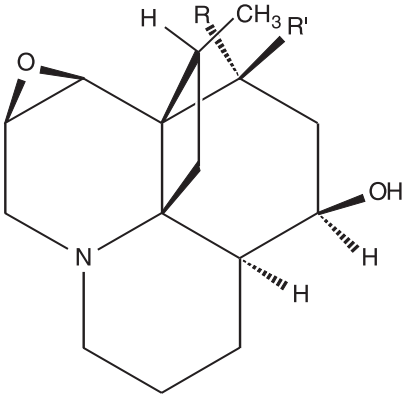
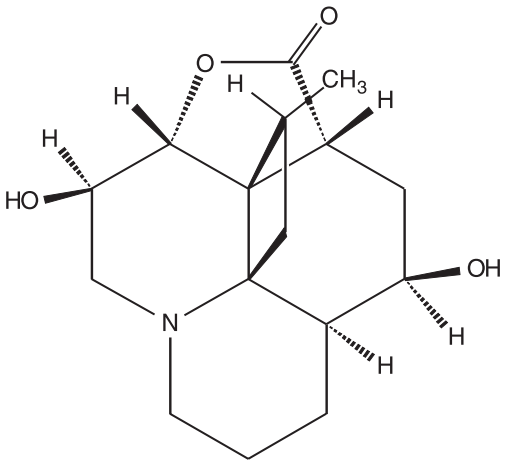
Fig. 1.



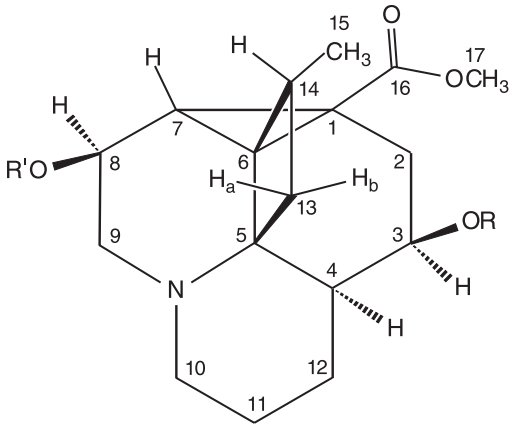
Annotinine (**1**)



2 R = $COOCH_3$, R' = H
3 R = H, R' = $COOCH_3$



Annotinine hydrate (**4**)



5 R = R' = H
6 R = Ac, R' = H
7 R = H, R' = Ac
8 R = R' = Ac

The structure of annotinine hydrate (**4**), proposed in the 50s, was also corroborated by extensive 2D NMR studies. The presence of a lactone ring is reflected in the signals for C7 and a CO-O group (at 80.7 and 180.0 ppm, respectively, Table 3). The two CH-OH groups are at C3 and C8 as indicated by the coupling patterns in the ^{1}H NMR spectrum (Table 1), as well as by the HMBC correlations (Fig. 4).

The stereochemistry at C1 and C7 was deduced from the TROESY spectrum. Thus, H1 showed correlation to H15, while H7 was correlated to H14, a pattern consistent only with α orientation of the lactone ring, which forces the C1–C6 ring to adopt a boat conformation. Consequently, the coupling constants of H1 (6.4 and 2.8 Hz) are significantly different from those of H1 in **3** (14.6 and 3.5 Hz), also having the C1–C6 ring with a boat conformation, but axial H1 (Table 1).

Additional TROESY correlations of annotinine hydrate (**4**) are shown in Fig. 3, and complete ^{1}H and ^{13}C assignments in Tables 1–3.

Ester M was obtained as a colorless solid having very low solubility in the conventional NMR solvents. Its hydrochloride, however, was quite soluble in methanol. Consequently, all NMR studies were conducted with the hydrochloride in CD_3OD.

The molecular formula $C_{17}H_{25}NO_4$ of ester M was obtained from the HREIMS spectrum. Thus ester M is isomeric to methyl epiannotinate (**2**) and methyl annotinate (**3**). The presence of a $COOCH_3$ group in ester M was deduced from the ^{1}H and ^{13}C NMR spectra (Tables 2 and 3, respectively). Since there is no evidence for the presence of double bonds or other carbonyl groups, ester M must be penta-

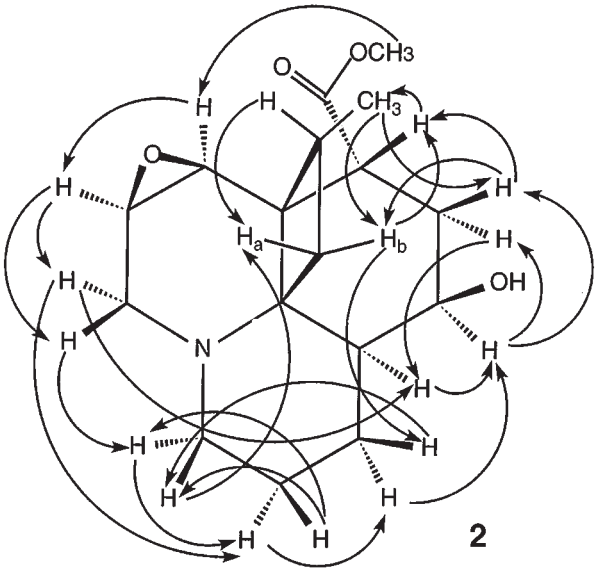
Fig. 2. TROESY correlations of **2** and **3**.



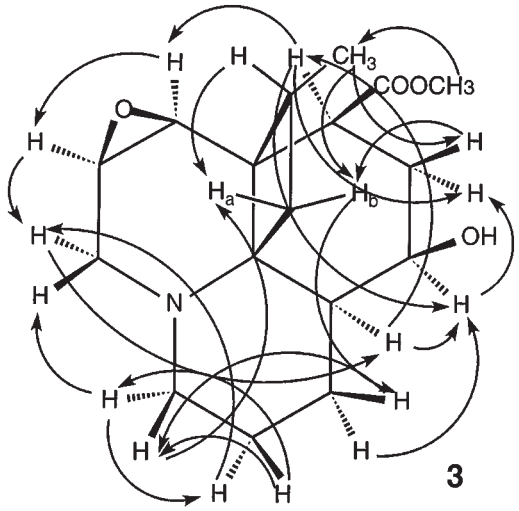


Fig. 3. TROESY correlations of **4** and **8**.

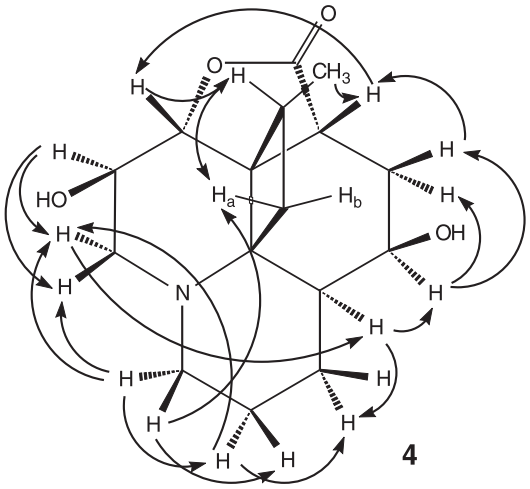

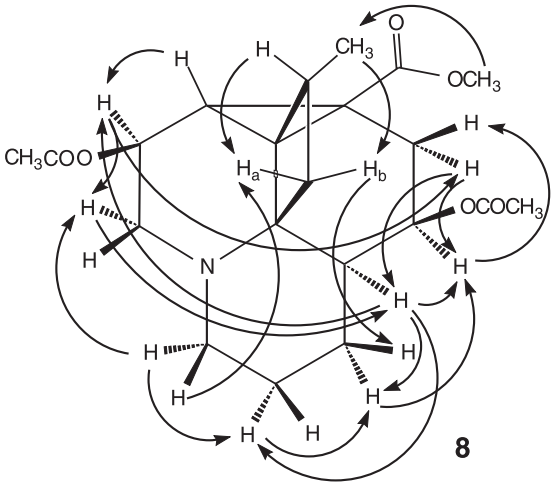

cyclic. The presence of two CH-OH groups is indicated by the ^{1}H NMR (a broad singlet at δ 3.88 and a ddd at δ 3.87) and by the ^{13}C NMR (doublets at δ 68.9 and δ 59.5) spectra. A comparison with the NMR data of annotinine (8) reveals that ester M does not have an epoxide ring. Another difference between annotinine and ester M is the presence of three quaternary carbon atoms in ester M, two of which had to be assigned to C5 (at δ 63.4) and C6 (at δ 38.5), not significantly different from the corresponding signals of annotinine (8). The third signal, at δ 29.2, is attributed to C1 in order to explain the HMBC correlation to H2α, H2β, H3, H8, and H14 (Fig. 4). The correlation C1–H8 necessitates a direct bond between C1 and C7 leading to the formation of a cyclopropane ring. The only proton attached to this ring, at C7, is coupled only to H8 (J = 4.0 Hz). All the above information is in agreement with the unprecedented 9-azapentacyclo[7.3.3.$0^{1,13}$.$0^{2,12}$.$0^{5,13}$]pentadecane structure **5** for ester M.

Complete assignment of all ^{1}H and ^{13}C NMR signals of **5** was further facilitated by the HMQC spectrum and especially by the TROESY spectrum. The cross peaks in the TROESY spectrum between H15 and H13b, and between H14 and H13a, allow us to assign the two signals for the H13 methylene group. The cross peaks H9α-H4, H9α-H8, and H4-H2α allow assignment of the α orientation to all these protons since the α orientation of H4 is known (2, 4). All other correlations shown in Fig. 3 are in agreement with the remaining assignments included in Tables 2 and 3.

The overlapping of the signals of H-3 and H-8 under the above conditions, however, did not allow complete assignment of all HMBC correlations of compound **5**. Consequently, we undertook acetylation with Ac_2O–Py, which afforded a mixture of a monoacetate and a diacetate. Interestingly, a

partial hydrolysis occurred during chromatographic purification of the diacetate, providing a monoacetate different from the monoacetate produced by direct acetylation. A detailed analysis of all spectroscopic data revealed that monoacetylation occurs at the less sterically hindered hydroxyl group at C-8, leading to derivative **7**, while the partial hydrolysis of the diacetate **8** leads to monoacetate **6**, having an acetoxy group at C-3. The complete assignment of all ^{1}H and ^{13}C signals of the acetates **6**, **7**, and **8** are given in Tables 2 and 3 and are based on ^{1}H NMR, ^{1}H–^{1}H COSY, HMQC, HMBC, and TROESY spectra.

Several cases of base-induced cyclization of carbonyl compounds leading to the formation of a cyclopropane ring have been documented in the literature. A close analogy involving a carbanion attack on an epoxide ring is described in ref. 9.

Experimental

General methods

Melting points are uncorrected. The HREIMS spectra were recorded on a AEI-50 mass spectrometer. ^{1}H NMR, ^{1}H–^{1}H COSY, HMQC, HMBC, and TROESY spectra were re-

corded on a Varian Inova 600 spectrometer, and routine ^1H NMR spectra on a Varian Inova 300. ^{13}C NMR and APT spectra were recorded on a Bruker AM-400 spectrometer. Chemical shifts are reported in ppm downfield of TMS, and carbon multiplicities were measured with the APT and HMQC sequence. UV spectra were recorded on a Hewlett–Packard diode array UV–VIS spectrometer (ICP) with a cell path of 1 mm, and IR spectra on a Nicolet 7199 FTIR spectrometer in solution or under a NIC-PLAN microscope (USCOPE). The optical rotation was measured on a Perkin–Elmer 241 polarimeter with a cell path of 10 cm, and CD spectra were measured on a Jasco ORD-CD spectrometer with a cell path of 1 mm.

Preparation of ester M (5)

Potassium (540 mg, 13.8 mmol) was dissolved in 30 mL of anhydrous methanol and, after cooling to room temperature, annotinine (514 mg, 1.87 mmol) was added. After 3 days at r.t. the reaction mixture was evaporated to dryness in vacuo, treated with 20 mL of distilled cold water, filtered, and dried in vacuo to afford ester M (**5**) as colorless crystals (291 mg, 51%). The aqueous residue was extracted with EtOAc (5 × 20 mL). The extract was dried over $MgSO_4$, filtered, evaporated in vacuo to 1 mL, and kept overnight at r.t. to provide annotinine hydrate (**4**, 79 mg, 15% yield). The mother liquor was evaporated to dryness and subjected to flash chromatography on neutral alumina. Elution with hexane:EtOAc 1:1 provided methyl epiannotinate (**2**, 12.7 mg).

Preparation of 2, 3, and 4

Potassium hydroxide (229 mg, 4.08 mmol) was dissolved in anhydrous methanol (20 mL) and annotinine (450 mg, 1.63 mmol) was added. After standing for 3 days at r.t. the reaction mixture was evaporated to dryness in vacuo, treated with 20 mL of distilled water, and extracted with CH_2Cl_2 (5 × 20 mL). The organic extract was dried over $MgSO_4$, filtered, and evaporated in vacuo to dryness. The crude extract (440 mg) was subjected to flash chromatography on silica gel. Elution with CH_2Cl_2:MeOH 95:5 provided annotinine hydrate (**4**, 87.3 mg), methyl epiannotinate (**2**, 286.5 mg), and, with CH_2Cl_2:MeOH 1:1, methyl annotinate (**3**, 59.6 mg). Ester M was not obtained under these conditions.

Preparation of hydrochloride of ester M

To a solution of ester M (3.8 mg) in MeOH (200 μL) was added 5% HCl (15 μL). Toluene (500 μL) was added and the solvent was removed in vacuo. The residue was crystallized from methanol to provide the hydrochloride of ester M (**5**·HCl, 4.1 mg) as colorless prisms.

Acetylation of ester M

Ester M (10 mg) was dissolved in 0.5 mL of hot acetic anhydride. After cooling to room temperature 0.5 mL of pyridine was added. The reaction mixture was evaporated to dryness in vacuo, then dissolved in CH_2Cl_2 and washed with 1% aqueous ammonia. The organic layer was dried with $MgSO_4$, filtered, and evaporated in vacuo. The crude mixture was separated by flash chromatography on neutral alumina using hexane:EtOAc 7:3 to provide the diacetate of ester M (**8**), and hexane:EtOAc 1:1 to elute the monoacetate of ester M (**7**). The reaction was monitored using TLC and ^1H NMR. Immediately after dissolving ester M in hot acetic anhydride a mixture (10 mg) of **7** and **8** in 5:1 ratio was obtained; after 4 h 2:1, 20 h 1:1, after 4 days 1:2, and after 7 days 0:1.

Hydrolysis of the diacetate of ester M (8)

Distilled water (300 μL) and 36% HCl (100 μL) were added to a solution of diacetate **8** (8.5 mg) in MeOH (100 μL). The solution was left at r.t. for 17 h. Methylene chloride (10 mL) was added and the mixture was washed

with 10 mL of 1% aqueous ammonia. The organic layer was dried with $MgSO_4$ and the solvent was reduced in vacuo to 1 mL and kept overnight at r.t. to provide the monoacetate **6** (4.1 mg) as colorless crystals.

New aspects on the reactivity of $MoO_2(S_2CNEt_2)_2$ with Me_3SiX. A peculiar *trans* effect control

H. Teruel and A. Sierraalta

Abstract: The reaction of $MoO_2(S_2CNEt_2)_2$ with Me_3SiI and Me_3SiNCS yielded $MoOI_2(S_2CNEt_2)_2$ and $MoO(NCS)_2(S_2CNEt_2)_2$, respectively, similar to results reported for Me_3SiCl and Me_3SiBr. On the contrary, $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ was the only compound isolated from the reaction of $MoO_2(S_2CNEt_2)_2$ with Me_3SiCN. To study the effects of ligands on the reactivity of siloxy compounds, ab initio calculations were undertaken for $Mo(OSiH_3)L(S_2CNH_2)_2$ molecules, for L = Cl, Br, I, NCS, and CN. The electronic density, $\rho(\boldsymbol{r})$, was analysed by means of the topological theory of Atoms in Molecules (AIM). The analysis of $-\nabla^2\rho(\boldsymbol{r})$ critical points (CPs) at the molybdenum valence shell showed, only in the case of L = CN, a local charge concentration region (N-type CPs) susceptible to electrophilic attacks. However, for L = Cl, Br, I, and NCS, local charge depletion sites (E-type CPs) were found in a bond-free region. The absence of any accessible E-type CPs and the presence of an N-type CP in the same region, opposite to the Mo=O group, justified the stability of $Mo(OSiMe_3)L(S_2CNEt_2)_2$ for L = CN, and the formation of $MoOL_2(S_2CNEt_2)_2$ for L = Cl, Br, I, and NCS by further reaction with the corresponding Me_3SiL.

Key words: ab initio calculation, electronic density, Mo-siloxy compound, reactivity, theoretical.

Résumé : Les réactions du $MoO_2(S_2CNEt_2)_2$ avec le Me_3SiI et le Me_3SiNCS conduisent respectivement au $MoOI_2(S_2CNEt_2)_2$ et $MoO(NCS)_2(S_2CNEt_2)_2$; ces résultats sont semblables à ceux obtenus avec le Me_3SiCl et Me_3SiBr. Par ailleurs, lors de la réaction du $MoO_2(S_2CNEt_2)_2$ avec le Me_3SiCN, le seul produit isolé est le $MoO(OSiMe_3)CN(S_2CNEt_2)_2$. Afin d'étudier les effets des ligands sur la réactivité des composés siloxy, on a effectué des calculs ab initio sur les molécules $Mo(OSiMe_3)L(S_2CNEt_2)_2$ dans lesquelles L = Cl, Br, I, NCS et CN. On a analysé la densité électronique, $\rho(\boldsymbol{r})$, à l'aide de la théorie topologique des atomes dans les molécules. L'analyse des points critiques (PC) du $-\nabla^2\rho(\boldsymbol{r})$ au niveau de la couche de valence du molybdène a montré que le cas où L = CN est le seul à comporter une région de concentration locale de charge (PC de type N) susceptible de subir des attaques électrophiles. Au contraire, dans les cas où L = Cl, Br, I et NCS, on a observé l'existence de sites dépourvus de charge locale (PC de type E) dans une région sans liaison. L'absence de tout PC de type E accessible et la présence d'un PC de type N dans la même région, à l'opposé du groupe Mo=O, explique la stabilité du $Mo(OSiMe_3)L(S_2CNEt_2)_2$ dans le cas où L = CN ainsi que la formation, dans les cas où L = Cl, Br, I et NCS, de $MoOL_2(S_2CNEt_2)_2$ qui résulte d'une réaction additionnelle avec le Me_3SiL correspondant.

Mots clés : calculs ab initio, densité électronique, composé Mo-siloxy, réactivité, théorique.

[Traduit par la Rédaction]

Introduction

Metallosiloxanes have been found to be structurally similar to modified silica surfaces (1). This structural resemblance has proved useful in interpreting reaction mechanisms for different catalytic transformations. In view of the latter, there have been many attempts to develop suitable homogeneous compounds as models for heterogeneous catalysts. The reactions of CrO_3 (2), Me_3ReO_3 (3), $(\eta^5\text{-}C_5Me_5)ReO_3$ (3), $(\eta^5\text{-}C_5Me_5)_2WO$ (4), $AgTcO_4$ (5), $AgReO_4$ (5), and $[(\eta^5\text{-}C_5Me_5)WO_3][NEt_4]$ (6) with R_3SiCl are some examples of these studies. However, in nearly all cases it has been reported that the expected metalsiloxy compound is rarely isolated, a dihalogenated compound being obtained instead.

It has been proposed (7) that the reaction of oxocompounds and halosilanes takes places in two steps, both involving a 1,2-addition (Scheme 1).

The initial adduct containing the silyl fragment is not isolated, as it reacts, very quickly, with a second mole of the R_3SiX compound. Nevertheless, it is not clear what determines the isolation of the siloxy or disubstituted compound. For instance, the preparation of $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ has been reported from the reaction of $MoO_2(S_2CNEt_2)_2$ with Me_3SiCN (8) while $MoOCl_2(S_2CNEt_2)_2$ is the sole product isolated from the analogous reaction with Me_3SiCl (7).

A better understanding of this reactivity can be obtained from an analysis of the quantum electronic properties of the siloxy compounds, as this provides a better insight into the electronic factors that may control the silylation of oxocompounds. In the quantum-mechanical theory "Atoms

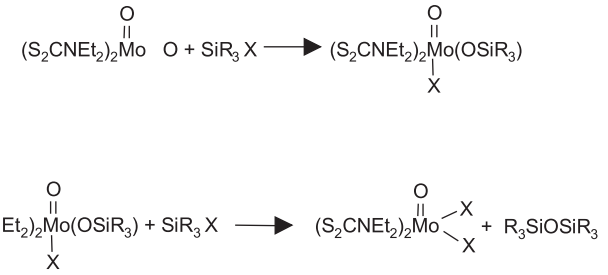
Scheme 1.



in molecules" (AIM) (9–11), the chemical bonds, electronic structure, and molecular reactivity are interpreted in terms of the total molecular electronic density, $\rho(\boldsymbol{r})$, and its corresponding Laplacian, $\nabla^2\rho(\boldsymbol{r})$. The $\rho(\boldsymbol{r})$, which is an observable parameter, allows the categorization of the atomic interactions in a molecule. The atomic and bond properties are settled in terms of well-defined parameters providing a rigorous interpretation of quantum-chemical calculations. Therefore, the AIM theory allows a more precise description of the chemical phenomena than the use of atomic or localized orbitals. A topological analysis of $-\nabla^2\rho(\boldsymbol{r})$, that is, the spatial array and absolute values of $-\nabla^2\rho(\boldsymbol{r})$, maximal and saddle points, provides useful information concerning the localization and characterization of the nucleophilic and electrophilic sites in a molecule.

In this work, a systematic theoretical study based on the quantum-mechanical theory "Atoms in molecules" (AIM) for $MoO(OSiH_3)L(S_2CNH_2)_2$ compounds, L = Cl, Br, I, NCS, and CN, was made. Experimentally, the reactions of $MoO_2(S_2CNEt_2)_2$ with Me_3SiI and with $Me_3Si(NCS)$ were carried out and the new compounds, $MoO(NCS)_2(S_2CNEt_2)_2$ and $MoOI_2(S_2CNEt_2)_2$, were prepared.

Experimental section

Manipulations involving air-sensitive reagents were performed under nitrogen with the aid of Schlenk techniques. Solvents were purified as follows: dichloromethane and acetonitrile were distilled using P_2O_5; diethyl ether was thoroughly degassed prior to use by repeated evacuation followed by admission of dry and oxygen-free nitrogen. $MoO_2(S_2CNEt_2)$ (12) and $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ (8) were prepared by previously reported methods. All other reagents were purchased from commercial sources and used without prior purification. Infrared spectra were recorded on a Brucker IFS 55 FT-IR spectrometer. ^1H and ^{13}C NMR were recorded on a Brucker MX300 spectrometer. Chemical shifts were obtained by residual solvent protons. Elemental analyses were performed on a Perkin–Elmer 2400 microanalyzer.

Reaction of $MoO_2(S_2CNEt_2)_2$ with $(CH_3)_3Si(NCS)$

$(CH_3)_3Si(NCS)$ (0.05 mL; 0.557 mmol) was added at 25°C, while stirring, to a CH_2Cl_2 solution (20 cm^3) containing $MoO_2(S_2CNEt_2)_2$ (0.200 g; 0.472 mmol). An immediate colour change from the original light yellow to red was observed. After 3 h, the volume of the solution was reduced to 5 cm^3 under reduced pressure. Diethyl ether (5 cm^3) was then added. The red microcrystalline solid formed was filtered, washed with cold diethyl ether (3 × 5 cm^3), and dried under vacuum. Yield (based on $MoO_2(S_2CNEt_2)_2$) was 0.215 g, 87%. The main IR bands were (KBr/cm^{-1}) 2050 (s, sh), 2018 (vs) (N-C); 951 m (Mo=O); 2987 w, 2940 w, 176, 1545 s, 1462 m, 1445 m, 1386 w, 1353 m, 1290 s, 1203 m, 1077 w, 1009, 850 w, 577 w (S_2CNEt_2). Anal. calcd. for $MoC_{12}H_{20}N_4S_6O$: C 27.38, H 3.83, N 10.65, S 36.48; found: C 27.78, H 3.76, N 10.13, S 35.88.

Reaction of $MoO_2(S_2CNEt_2)_2$ with $(CH_3)_3SiI$

$(CH_3)_3SiI$ (0.05 mL; 0.354 mmol), was added at 25°C, while stirring, to a CH_2Cl_2 solution (20 cm^3) containing $MoO_2(S_2CNEt_2)_2$ (0.100 g; 0.236 mmol). An immediate darkening from light yellow to red occurred. After 3 h, the volume of the solution was reduced to 5 cm^3 under reduced pressure and diethyl ether (5 cm^3) was added. The red microcrystalline solid formed was filtered, washed with cold diethyl ether (3 × 5 cm^3), and dried under vacuum. Yield (based on $MoO_2(S_2CNEt_2)_2$) was 0.103 g, 66%). ^1H NMR (300 MHz, $CDCl_3$, ppm): 1.46 (12H, t, CH_3), 3.97 (8H, m, CH_2). The main IR bands were (KBr/cm^{-1}) 937 m (Mo=O); 2975 w, 2929 w, 176, 1541 s, 1515 s, 1456 m, 1437 m, 1351 m, 1298 m, 1276 m, 1204 m, 1151 m, 1070 m, 848 m, (S_2CNEt_2). Anal. calcd. for $MoC_{10}H_{20}N_2S_4OI$: C 18.08, H 3.04, N 4.22; found: C 18.45, H 3.22, N 4.06.

Theoretical section

Theoretical background

According to the AIM theory $\nabla^2\rho(\boldsymbol{r})$ provides information concerning electronic charge: $\nabla^2\rho(\boldsymbol{r}) > 0$ (or $-\nabla^2\rho(\boldsymbol{r}) < 0$) implies locally depleted charge while $\nabla^2\rho(\boldsymbol{r}) < 0$ (or $-\nabla^2\rho(\boldsymbol{r}) > 0$) signifies locally concentrated charge (13–16). There are two important types of $-\nabla^2\rho(\boldsymbol{r})$ CPs at the atoms: maximum and saddle points, or electronic holes. The former are classified as (3, –3) CPs or N-type CPs since they possess local concentrations of electronic charge and represent nucleophilic sites susceptible to attack by electrophiles. The saddle points are (3, +1) or E-type CPs and represent local charge depletion, or electronic holes, that are associated with electrophilic sites susceptible to nucleophile attack. Thus, the AIM theory explains the Lewis model for acid–base reactions by the alignment of local charge concentrations, N-type CPs, at the base, with charge depletions, and E-type CPs, at the acid centre. This proposed scheme is quite general and, for instance, it has been shown that in hydrogen abstraction from CH_4, by MgO or LiO, the oxide active sites correspond to the $-\nabla^2\rho(\boldsymbol{r})$ N-type CPs (17).

Computational details

All calculations and geometry optimizations were carried out using the Gaussian 94 program (18) at the HF-SCF level. The basis sets and the ab initio relativistic effective potentials proposed by Christiansen and co-workers (19) were used for Si, S, Cl, Br, and I atoms. The 3*d* and 4*d* electrons were included in the valence space of the Br and I, respectively. The basis sets for these atoms were augmented with diffuse *p* functions ($\xi_p(Cl) = 0.049$, $\xi_p(Br) = 0.044$) and *d* polarization functions ($\xi_d(Cl) = 0.50$, $\xi_d(Br) = 0.36$) (20). For Si and S atoms only *d* polarization functions ($\xi_d(Si) = 0.45$, $\xi_d(S) = 0.65$) were added. These changes result in the following contraction schemes: Si(31/31/1), S(31/31/1), Cl(31/311/1), Br(21/211/311), I(21/211/311). The all-

electron 6-31G* basis sets from the Gaussian library were employed for the H, C, N, and O atoms. The basis set and the relativistic compact effective potentials proposed by Stevens et al. (21) were used, without any modification, for the Mo atom.

The topological properties of $\rho(\boldsymbol{r})$ and $-\nabla^2\rho(\boldsymbol{r})$ were calculated with a locally modified version of the EXTREM program.[2] In the calculations of $\rho(\boldsymbol{r})$ the wfn file was generated using the HF-SCF geometry with the Gaussian 94 program at the MP2 level.

Calculated geometry for $MoO_2(S_2CNH_2)_2$ and $MoOL_2(S_2CNH)_2$

Due to the lack of X-ray structural information available for compounds $MoO(SiMe_3)L(S_2CNEt_2)_2$ where L = Cl, Br, I, or NCS, we performed quantum chemical calculations to determine their optimal geometry. Thus, to test the accuracy of the geometry optimization procedure the structures of $MoOCl_2(S_2CNH_2)_2$ and $MoOBr_2(S_2CNH_2)_2$ were calculated (Fig. 1). These results were compared with those reported by X-ray diffraction for $MoOCl_2(S_2CNEt_2)_2$ and $MoOBr_2(S_2CNEt_2)_2$, respectively (23). Selected calculated and experimental bond lengths and angles are given in Table 1, showing good agreement in all cases.

Fig. 2. Calculated geometry for $MoO_2(S_2CNH_2)_2$.

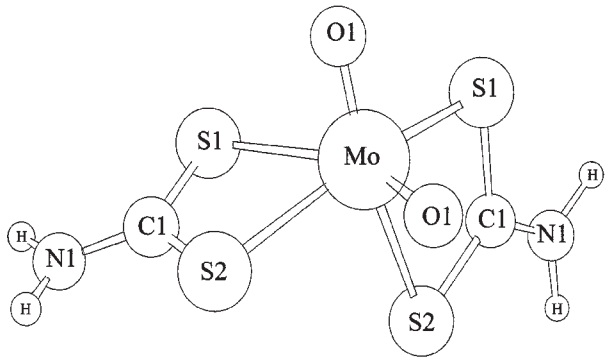

Table 2. Comparison of some important bond distances (Å) and angles (degrees) between $MoO_2(S_2CNEt_2)_2$ (13) and $MoO_2(S_2CNH_2)_2$.

Bond distances and angles	Experimental	Calculated
Mo—O1	1.703	1.661
Mo—S1	2.450	2.512
Mo—S2	2.639	2.793
S1—C1	1.738	1.728
S2—C2	1.700	1.683
C1—N1	1.315	1.315
O1-Mo-O1	105.3	105.3
S1-Mo-S1	148.5	148.6
S1-Mo-S2	68.8	66.7
S1-Mo-S2′	87.0	93.2
S1-Mo-O1	110.3	105.8
S2-Mo-S2′	80.1	80.5
S2-Mo-O1	91.0	90.0
S2-Mo-O1′	155.6	157.7

As an additional test, the optimal geometry of $MoO_2(S_2CNH_2)_2$, **1**, was calculated (Fig. 2). The results were compared with the crystallographic structure reported for $MoO_2(S_2CNEt_2)_2$ (12). Some relevant calculated and experimental bond lengths and angles are compared in Table 2. The deviation observed between both geometries can be attributed mainly to the theoretical level used in this work.

In a similar way, the structures for $MoO(OSiH_3)L(S_2CNH_2)_2$, where L = NCS **2**, Cl **3**, Br **4**, I **5**, and CN **6**, were calculated (Fig. 3). Selected bond lengths (Å) and angles (deg) along with structural data reported for $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ (8) are shown in Table 3. The calculated Mo—O1, Mo—O2, Mo—S1, Mo—S2, and Mo—L bond lengths match rather well the X-ray structure values reported for $MoO(OSiMe_3)CN(S_2CNEt_2)_2$.

Results and discussion

$MoO(NCS)_2(S_2CNEt_2)$ and $MoOI_2(S_2CNEt_2)_2$ preparation

The reaction of $MoO_2(S_2CNEt_2)_2$ with a twofold excess of Me_3SiI or $Me_3Si(NCS)$ produces $MoOI_2(S_2CNEt_2)_2$ and

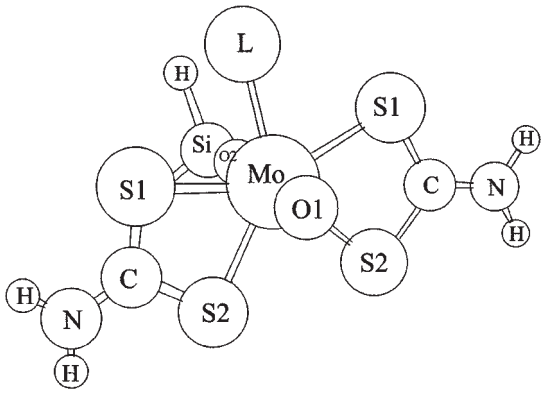
[b]This work.

Fig. 3. Calculated geometry for $MoO(OSiH_3)L(S_2CNH_2)_2$, where L = NCS, Cl, Br, I or CN.



$MoO(NCS)_2(S_2CNEt_2)_2$, respectively. This product distribution is similar to that reported for the same reaction with Me_3SiCl and with Me_3SiBr, where the only products were the dihalogenated compounds $MoOCl_2(S_2CNEt_2)_2$ and $MoOBr_2(S_2CNEt_2)_2$, respectively (7). Under the same experimental conditions $MoO(OSiMe_3)(CN)(S_2CNEt_2)_2$ can be prepared in good yields when M_3SiCN is used (8). The fact that no changes in the stoichiometry were observed when this compound was tested with $(CH_3)_3SiCl$ indicates that the presence of the CN ligand inhibits further reaction with either Me_3SiCN or Me_3SiCl.

Theoretical part

N-type CPs or nucleophilic sites

The values of $-\nabla^2\rho(\boldsymbol{r})$ at the N-type CPs, and the distance from the molybdenum to the CPs $R_{\text{Mo-N,}}$ for compounds **2–6** are reported in Table 4. In all cases, the molybdenum valence shell shows three different local charge concentration groups, N1, N2, and N3. The first of these groups, N1, is composed of an N-type CP positioned opposite the double-bonded oxygen atom, O1, in the Mo—O2 bond direction (Figs. 4 and 5). The $-\nabla^2\rho(\boldsymbol{r}_{N1})$ value for the Mo—O1 bond shows that the O1 atom induces a large charge concentration on the metallic atom at the N1 critical point position. In fact, as a consequence of the electronic repulsion between the

shown that, in oxocompounds, double-bonded oxygen atoms produce charge concentration at the metal valence shell in the direction opposite to the oxygen atom (24–26).

The second group of N-type CPs, or N2, is composed of two components located in the plane comprising the S1-Mo-S1 moiety, in the region of the Mo—L bond (Figs. 4 and 5). For **2**–**5**, two points facing the latter N2 CP, i.e., around the Mo—S2 bonds (Fig. 4), constitute N3, the last of these CP groups. The values of $-\nabla^2\rho(\boldsymbol{r})$ at the N2 and N3 points, $-\nabla^2\rho(\boldsymbol{r}_{N2})$ and $-\nabla^2\rho(\boldsymbol{r}_{N3})$, respectively, are quite similar (Table 4). Similar to double-bond oxygen atoms (vide supra), sulphur atoms induce charge concentrations at the positions opposite to metal–S bonds (26). This charge concentration phenomenon, generated by the sulphur atoms, either S1 or S2, or the double-bonded O atom (O1), can be rationalized in terms of an electronic *trans* effect. That is, the strong σ and π charge donation from S1, S2, or O1 to the Mo atom generates a local charge concentration, or nucleophilic site, at the position *trans* to these atoms. Thus the O1 atom produces the N1 site, while S1 and S2 generate N3 and N2, respectively.

In the case of, **6**, there is only one N3-type CP located in the S2-Mo-S2 angle, facing the CN ligand, instead of the two N3 obtained for **2**–**5** (Fig. 5). Furthermore, considering that the CN group is a stronger *trans* director than sulphur atoms, such as S1, a combined electronic *trans* effect would explain the difference in N-type CPs for compounds **2–5** and **6**. In the latter, the combined electron donation by the S1 and CN ligands produces the coalescence of the two N3 CPs present in **2**–**5**. Thus it is this unique N3 critical point in complex **6** that is responsible for the S2-Mo-S2 angle opening to 77.3°, compared to that in **2**, 74.0°. This geometry modification by charge concentration has been observed and explained before in inorganic compounds (24, 25).

The spatial distribution of the $-\nabla^2\rho(\boldsymbol{r})$ N-type CPs discussed above has clear chemical implications for the reactivity of compounds **2**–**6** towards electrophiles. For complexes **2**–**5**, the proximity of Mo—O2, Mo—S1, and Mo—S2 bonds to N1, N2, and N3 groups, respectively, blocks or sterically hinders any electrophilic attack, unless there is a simultaneous scission of the bond involved. On the contrary, in **6** the nucleophilic site N3 is located in a bond-free region and an electrophilic attack can take place without bond rupture. Therefore, it is expected that **6** would react with electrophiles while **2**–**5** would remain unaltered.

E-type CPs, or electrophilic sites

An analysis of the $-\nabla^2\rho(\boldsymbol{r})$ E-type CPs, or electronic charge holes, obtained for compounds **2**–**5** yielded four different groups or electrophilic sites: E1, E2, E3, and E4 (Table 5). The E1 group is formed by two CPs located at the middle of the S1-Mo-S2 angle, while the E2 and E3 CP groups are situated in the Mo—L and Mo—O1 bonding regions, respectively (Fig. 6). Previous reports have established that this CP distribution is related to certain types of ligands, such as oxo groups, with a preference for face-charge depletion sites (24, 26). The remaining E-type CP, the E4 group, is located at the S2-Mo-S2 angle, while in **6** there are only E1, E2, and E3 groups (Fig. 7).

Thus, due to the spatial distribution of the different electrophilic sites for compounds **2**–**6,** where the E1, E2, and E3 groups are sterically hindered, a nucleophilic attack cannot occur at these points without simultaneous bond breaking. However, for **2**–**5,** because E4 is located in a bond-free

Fig. 6. Distribution of the E-type critical points calculated in $MoO(OSiH_3)L(S_2CNH_2)_2$. The hydrogen atoms are omitted.

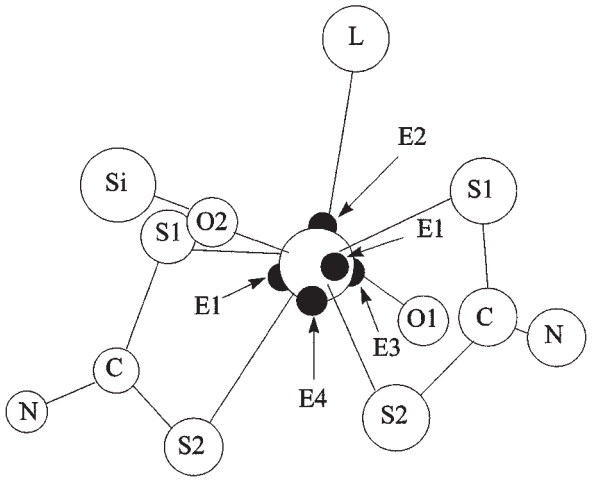

Fig. 7. Distribution of the E-type critical points calculated in $MoO(OSiH_3)CN(S_2CNH_2)_2$. The hydrogen atoms are omitted.

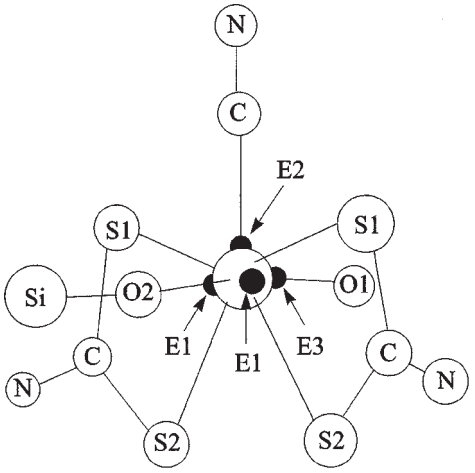

region, an electrophilic attack is possible and energetically favoured at this site. On the contrary, compound **6** will show a lack of reactivity towards nucleophiles due to the absence of any accessible electrophilic site (Fig. 7).

So, for compounds **2**–**5** further reaction with H_3SiL takes place with $MoOL_2(S_2CNH_2)_2$ formation while **6** will never yield $MoO(CN)_2(S_2CNH_2)_2$. In fact, this relation between reactive site accessibility and reactivity is observed experimentally. In the reaction of $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ with a large excess of Me_3SiCl, the starting material was completely recovered after 3 days, while the only product obtained for the reaction of $MoO_2(S_2CNEt_2)_2$ and Me_3SiL was $MoOL_2(S_2CNEt_2)_2$ for L = Cl, Br, I, and NCS. Furthermore, the isolation of an oxosiloxy compound, $MoO(OSiMe_2{}^tBu)Cl(S_2CNEt_2)_2$, from the reaction of $MoO_2(S_2CNEt_2)_2$ and $(Me_2{}^tBu)SiCl$ (7), can also be explained by the accessibility of the E-type CPs. As discussed for $MoOCl(OSiH_3)(S_2CNH_2)_2$, four E-type groups should be present but, in this case, the E4 point, located at the S2-Mo-S2 angle, Fig. 6, should become quite hindered by the bulkiest $(Me_2{}^tBu)Si$ ligand compared to H_3Si.

On the other hand, it has been reported that the magnitude of $-\nabla^2\rho(\boldsymbol{r})$ at the E-type CPs can be related to the site reactivity towards nucleophilic additions, i.e., the higher the $-\nabla^2\rho(\boldsymbol{r})$ value the more reactive the site (13, 15). For the $MoO(OSiH_3)L(S_2CNH_2)_2$ compounds **2**–**5**, the values obtained for $-\nabla^2\rho(\boldsymbol{r})$ at the E4 point, Table 6, indicate the following reactivity order for nucleophilic additions: **2** > **3** > **4** > **5**, or L = NCS > Cl > Br > I. Unfortunately, this reactivity order was difficult to confirm experimentally as the reaction of $MoO_2(S_2CNEt_2)_2$ with Me_3SiL to produce $MoOL_2(S_2CNEt_2)_2$ turned out to be so fast that the formation of $MoO(OSiMe_3)L(S_2CNEt_2)_2$ was never observed even when the reaction was followed by ^{29}Si NMR at low temperature.

In addition, a rather different situation is expected for the reactivity of **2**–**6** towards electrophiles. Despite the fact that reactive nucleophilic sites (N-type CPs) are inaccessible in **2**–**5**, compound **6** exhibits an N4 CP at a sterically unhindered region and this situation should permit an electrophilic attack. The reactivity of $MoO(OSiMe_3)CN(S_2CNEt_2)_2$ with electrophiles has not yet been reported but, according to this study, this reaction could lead to an interesting new family of compounds.

Conclusions

According to this study, if the reaction of $MoO_2(S_2CNEt_2)_2$ with R_3SiX proceeds through a 1,2-addition at the Mo=O bond (7), compounds like $MoO(OSiMe_3)L(S_2CNEt_2)_2$ should be isolated only in those cases where further nucleophilic attacks on the molybdenum atom, by X, are obstructed. Thus, unlike the compound $MoOL_2(S_2CNEt_2)_2$, isolated from the reaction of $MoO_2(S_2CNEt_2)_2$ with R_3SiX, when X = NCS, Cl, Br, and I, $MoO(OSiMe_3)CN(S_2CNEt_2)$ does not react further, due to the absence of any suitable electrophilic site.

In addition, in the case of σ and π donating ligands, stronger than dithiocarbamates, S_2CNEt_2, the only compound obtained should be $MoO(OSiMe_3)X(S_2CNEt_2)$ instead of $MoOX_2(S_2CNEt_2)$.

Carboxylic acid amide enols: keto–enol/enolate interconversion of *N*-methylindoline-2-one and its 2-thione and 2-selone analogs in aqueous solution

A. Jerry Kresge and Qingshui Meng

Abstract: Carbon-acid ionization constants, Q_a^K (concentration quotient at ionic strength = 0.10 M), were determined by spectrophotometric titration in aqueous solution for *N*-methylindoline-2-one, pQ_a^K = 15.70, *N*-methylindoline-2-thione, pQ_a^K = 8.93, and *N*-methylindoline-2-selone, pQ_a^K = 7.25. Rate profiles were also constructed for the thione and selone. These were interpreted, with support from the form of acid–base catalysis as well as solvent and substrate isotope effects, as representing keto – enol/enolate ion interconversion. That led to the enol acidity constant pQ_a^E = 4.05 and the keto–enol equilibrium constant pK_E = 4.88 for the thione and estimates of the limits on these quantities, $pQ_a^E < 3$ and $pK_E > 4$, for the selone.

Key words: lactam, thiolactam, selenolactam, keto–enol equilibria, carbon-acid ionization constants.

Résumé : Opérant en solution aqueuse et faisant appel à des titrages spectrophotométriques, on a mesuré les constantes d'ionisation d'acide carboné, Q_a^K (quotient des concentrations à une force ionique = 0,10 M), de la *N*-méthylindoline-2-one, pQ_a^K = 15,70, de la *N*-méthylindoline-2-thione, pQ_a^K = 8,93 et de la *N*-méthylindoline-2-sélénone, pQ_a^K = 7,25. On a aussi élaboré les profils de vitesse de la thione et de la sélénone. En se basant sur la forme de la catalyse acide–base ainsi que sur les effets isotopiques du solvant et du substrat, on peut interpréter ces résultats sur la base d'une interconversion cétoénolique/ion énolate. Sur cette base, la constante d'acidité énolique, pQ_a^E = 4,05, et la constante d'équilibre cétoénolique, pK_E = 4,88, pour la thione alors que les évaluations des limites de ces grandeurs pour la sélénone sont $pQ_a^E < 3$ et $pK_E > 4$.

Mots clés : lactame, thiolactame, sélénolactame, équilibre cétoénolique, constantes d'ionisation d'acide carboné.

[Traduit par la Rédaction]

Enol isomers of simple carboxyic acids and their functional derivatives, such as esters and amides, are very labile and thermodynamically unstable substances, and their lifetimes in aqueous solution are expected to be exceedingly short. For example, the keto–enol equilibrium constant for acetic acid in aqueous solution, though not yet determined experimentally, has been reliably estimated as pK_E = 20 (1), and the hydronium-ion catalytic coefficient for conversion of acetic acid enol to its keto form, also not yet measured experimentally, is believed to lie in the range $k_{H^+} = 10^8$–10^9 M^{-1} s^{-1} (2). Recent high-level calculations (3) suggest that keto–enol equilibrium constants for esters and amides will be not very different from those for carboxylic acids, and this is borne out by the estimate pK_E = 19 for ethyl acetate (4), similar to pK_E = 20 for acetic acid.

Daunting realities such as this have driven the study of enols of carboxylic acids and their derivatives to systems where the enol is stabilized by some special structural features. Bulky groups in the β-position of enols can accomplish this by blocking access to the enol double bond (5), through whose protonation ketonization must take place (6), and this strategy has recently been used to make stable enols of bis(2,4,6-triisopropylphenyl)acetic acid amides (7).

In the present study of amide enols, we have used a somewhat different approach: we have examined systems in which the enol or enolate ion is stabilized by formation of a new aromatic ring, eq. [1], and also by replacement of the carbonyl oxygen atom with sulfur or selenium. Replacement of oxygen by sulfur has recently been shown to increase enol content by a large factor (8), and it seemed likely that selenium would have a similar effect.

We have found that the enol isomers (**2a**, **b**, and **c**) and enolate ions (**3a**, **b**, and **c**) of *N*-methylindoline-2-one (**1a**), *N*-methylindoline-2-thione (**1b**), and *N*-methylindoline-2-

selone (**1c**) are stable enough to exist in aqueous solution. This has allowed us to determine acidity constants for these substances ionizing as carbon acids in that medium. We have also found that rates of keto–enol/enolate interconversion in the thione and selone systems can be measured by stopped flow methods, and this has enabled us to determine keto–enol and enol acidity constants for the thione system and to set limits on these quantities for the selone system.

Experimental section

Materials

N-*Methylindoline-2-one* was prepared by methylating oxindole (Aldrich) using a published procedure (9).

N-*Methylindoline-2-thione* was prepared by treating *N*-methylindole-2-one (1.00 g) with Lawesson's reagent (10) (1.64 g) in dry toluene at 100°C for 2 h under an argon atmosphere. The solvent was removed, and the residue was purified by flash chromatography on silica gel with 20% ethyl acetate in pentane as the eluent. Recrystallization from ethyl acetate:pentane gave a solid, mp 109–110°C (lit. (9) 106.5–108°C) whose NMR spectra were consistent with literature values (9, 11).

N-*Methylindoline-2-selone* was prepared by adapting a method used to synthesize the parent *N*–methyl-2-pyrroline-2-selone (12). To a solution of 2.0 g *N*-methylindole in 30 mL tetrahydrofuran maintained at 0°C in an argon atmosphere, 8.5 mL of 1.8 M phenyllithium dissolved in 70:30 cyclohexane:ether was added. When the addition was complete, the temperature was raised to 40°C, and the reaction mixture was stirred for 2 h. It was then cooled to 0°C, 1.2 g of selenium was added, and stirring was continued for another hour. The resulting reaction mixture was quenched with cold aqueous acetic acid, was extracted with chloroform, and the extract was washed with water and brine and was dried over magnesium sulfate. The residue obtained upon evaporation of the solvent was purified by flash chromatography on silica gel using 5% ethyl acetate in hexane as the eluent. Repeated recrystallization from chloroform:hexane gave 100 mg (3% yield) of a yellow solid; mp: 131–133°C; ^{1}H NMR ($CDCl_3$), δ/ppm: 7.02–7.36 (m, 4 H), 3.81 (s, 2 H), 3.70 (s, 3 H); ^{13}C NMR ($CDCl_3$), δ/ppm: 203.25, 146.79, 131.17, 128.08, 124.72, 124.03, 110.01, 53.63, 34.03; HRMS, *m*/*e*: 210.9895 (calc.), 210.9900 (obs.). Only part of the starting material had reacted, suggesting that a higher yield would have been obtained if a stronger base, such as butyllithium, had been used.

All other materials were best available commercial grades.

Acidity constants

Carbon-acid ionization constants of *N*-methylindoline-2-one, -thione, and -selone were determined by monitoring the reversible UV spectral changes that these substances undergo upon ionization. Absorbance (*A*) measurements were made at λ = 310 nm for *N*-methylindoline-2-one, at λ = 240 nm for *N*-methylindoline-2-thione, and at λ = 330 nm for *N*-methylindoline-2-selone, using a Cary Model 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. Constant stoichiometric substrate concentrations (2×10^{-5} M) were used, and the data were analyzed by nonlinear least-squares fitting of the titration curve expression shown as eq. [2], where Q_a^K is the carbon-acid ionization constant of the substrate, and A_{HA} and A_B are the limiting absorbances of its acidic and basic forms, respectively.

$$[2] \qquad A = (A_B Q_a^K + A_{HA}[H^+])/(Q_a^K + [H^+])$$

Kinetics

Rates of approach to keto–enol/enolate equilibrium in the *N*-methylindoline-2-thione and -selone systems were determined using a Hi-Tech Scientific Model SF-S1 stopped-flow spectrometer operating at 25.0 ± 0.1°C. For studies on solutions more basic than the carbon-acid dissociation constant of the substrate, Q_a^K, kinetic runs were initiated by mixing a solution of substrate in water contained in one syringe with a solution of sodium hydroxide or buffer contained in the other syringe, and for studies in solutions more acidic than Q_a^K, runs were initiated by mixing a solution of initially deprotonated substrate in 0.0002 M sodium hydroxide solution in one syringe with a solution of perchloric acid or buffer in the other syringe. Reactions were monitored by following changes in enol and enolate absorbance at λ = 240 nm or keto form absorbance at λ = 310 nm for *N*-methylindoline-2-thione and changes in keto form absorbance at λ = 330 nm for *N*-methylindoline-2-selone. Substrate concentrations in the final reaction mixtures were 5×10^{-6} M. The rate data conformed to the first-order rate law well, and observed first-order rate constants were obtained by least-squares fitting of an exponential function.

Results

Carbon-acid ionization constants

For *N*-methylindoline-2-thione and -selone, reversible UV spectral changes characteristic of carbon-acid ionization took place in aqueous solution in the pH range, and measurements could consequently be made in dilute sodium hydroxide and buffer solutions. For *N*-methylindoline-2-one, on the other hand, these spectral changes occurred only in more basic solutions, and measurements for this substrate were therefore made in concentrated aqueous potassium hydroxide solution.

For the thione and selone, HCO_3^-, NH_4^+, $(CH_2OH)_3CNH_3^+$, $H_2PO_4^-$, and CH_3CO_2H buffers were used. Two to four different buffer ratios were employed for each buffer system, and several different sodium hydroxide concentrations were used as well; triplicate absorbance measurements were made with each solution. The ionic strength of all solutions was maintained at 0.10 M using $NaClO_4$ as required. Hydrogen ion concentrations were obtained by calculation using literature pK_a values and activity coefficients recommended by Bates (13). These data are summarized in Table S1.[2]

As Fig. 1 illustrates, the data so obtained conformed to the expected titration curve expression of eq. [2] quite well. Least-squares fitting gave $Q_a^K = (1.18 \pm 0.04) \times 10^{-9}$ M,

[2] Tables of equilibrium and rate data (Tables S1–S8) have been deposited and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

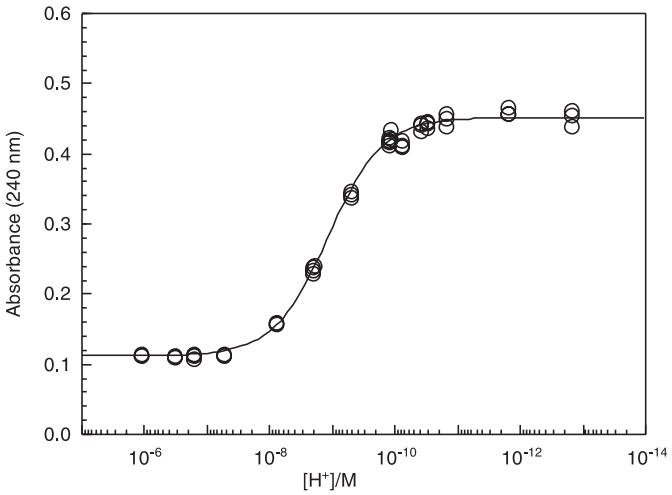
Fig. 1. Spectrophotometric titration curve for *N*-methylindoline-2-thione in aqueous solution at 25°C.



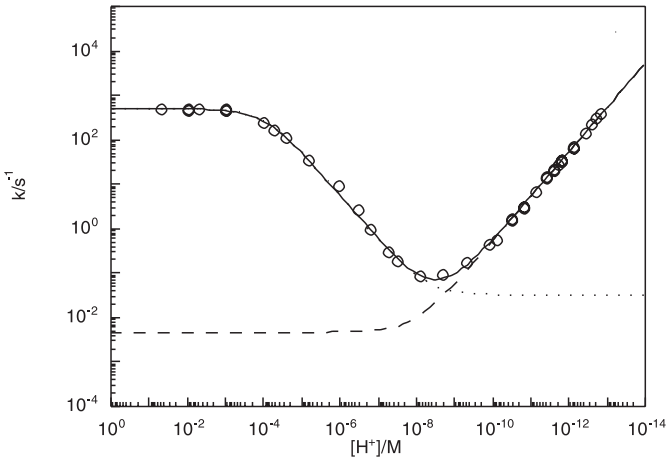
pQ_a^K = 8.93 ± 0.02 (see footnote 3) for *N*-methylindoline-2-thione, and Q_a^K = (5.66 ± 0.29) × 10^{-8} M, pQ_a^K = 7.25 ± 0.02 (see footnote 3) for *N*-methylindoline-2-selone.

Absorbance measurements for *N*-methylindoline-2-one were made in KOH solutions over the concentration range 0.1–11 M. The data so obtained, summarized in Table S2,[2] were transformed into values of log *I* (= [enolate ion]/[keto form]), and the fit of log *I* to different basicity functions was examined. Three functions were tried: an H_- scale based on neutral indole indicators (14), an $H_=$ scale based on indoles bearing carboxylate groups (14), and an $H_=$ scale based on aromatic amines bearing carboxylate and sulfonate groups (15). The H_- scale was found to be the most appropriate: it gave a plot of log *I* vs. H_- whose slope was near unity (0.95 ± 0.02), whereas the other basicity functions produced slopes significantly farther from unity (0.77 ± 0.01 and 0.78 ± 0.01). The data were therefore analyzed using the H_- scale, i.e., were fitted using the titration curve expression of eq. [2] with 10^{-H_-} replacing [H^+]. This gave K_a^K = (1.40 ± 0.08) × 10^{-16} M, pK_a^K = 15.86 ± 0.03.

Since basicity functions are referenced to an infinitely dilute standard state whose ionic strength is zero, this value is a thermodynamic ionization constant, expressed in terms of activities, unlike the concentration constants determined above for *N*-methylindoline-2-thione and -selone. This thermodynamic value may be converted into a concentration ionization constant by applying appropriate activity coefficients. The result for ionic strength = 0.10 M, obtained using the activity coefficient for the hydrogen ion recommended by Bates (13) and that for picrate ion (16) as a surrogate for the unavailable activity coefficient of the present enolate ion, is pQ_a^K = 15.70 ± 0.03.

Carbon-acid ionization constants for two of the substrates studied here, *N*-methylindoline-2-one and *N*-methylindoline-2-thione, have been measured in DMSO solution (9). The results obtained, pK_a = 18.5 and 10.0, respectively, show these substances to be stronger acids in H_2O than in DMSO by relatively small amounts, as expected for acids whose ionization produces highly delocalized anions (17).

Fig. 2. Rate profile for keto–enol/enolate interconversion in the *N*-methylindoline-2-thione system in aqueous solution at 25°C; circles and solid line: rate of approach to equilibrium, dashed line: rate of enolization, dotted line: rate of ketonization.



Kinetics: *N*-methylindoline-2-thione

Rates of approach to keto–enol/enolate ion equilibrium for *N*-methylindoline-2-thione were measured in aqueous perchloric acid solutions over the concentration range 0.001–0.05 M, and in aqueous sodium hydroxide solutions over the concentration range 0.0004–0.1 M. The ionic strength of these solutions was maintained at 0.10 M using $NaClO_4$ as required. These data are summarized in Tables S3 and S4.[2]

Rate measurements for this substrate were also made in aqueous CH_3CO_2H, $H_2PO_4^-$, $(CH_2OH)_3CNH_3^+$, and NH_4^+ buffer solutions, using series of buffer solutions of different total buffer concentration but constant buffer ratio and constant ionic strength (0.10 M). For the $H_2PO_4^-$ and $(CH_2OH)_3CNH_3^+$ buffers, this served to hold [H^+] constant along a given buffer series, but in some of the CH_3CO_2H and NH_4^+ buffers "buffer failure" (18) occurred; i.e., [H^+] changed systematically somewhat as the buffer was made more dilute. In these cases, observed rate constants were adjusted to values they would have had had [H^+] been constant; these adjustments were made using required rate and equilibrium constants obtained from the rate profile (vide infra). Such adjustments were minor — never more than a few percent. The data are summarized in Table S5.[2]

Buffer catalysis was strong, with rate constants increasing with increasing buffer concentration in a linear fashion. The data were therefore analyzed by least-squares fitting of eq. [3] in which k_{exp} represents either observed or adjusted rates of approach to equilibrium.

$$[3] \qquad k_{exp} = k_o + k_{Buff}[\text{Buffer}]$$

Values of k_o obtained in this way, together with the rate constants measured in perchloric acid and sodium hydroxide solutions, were used to construct the rate profile shown in Fig. 2. This profile describes the rate of approach to keto–enol/enolate equilibrium by reaction through solvent-related species. It can be analyzed as the sum of rate constants for enolization occurring through rate-determining proton

[3] This is a concentration ionization constant, applicable at the ionic strength of its determination.

© 1999 NRC Canada

removal from the keto isomer by either hydroxide ion or a water molecule to give an equilibrium mixture of enol and enolate, eq. [4], plus rate constants for ketonization occurring through rate-determining carbon protonation of enolate ion, in equilibrium with enol, by either hydronium ion or a water molecule, eq. [5].

[4] 
[5] 
This interpretation is consistent with the established reaction mechanisms for enolization and ketonization (6), and it is supported in the present instance by isotope effects and the form of acid–base catalysis by buffer species (vide infra).

The rate law for this reaction scheme is given in eq. [6], whose rate constants are defined by eqs. [4] and [5], and Q_a^E

$$[6] \quad k_{exp} = k^E{}_o + k^E{}_{HO^-}[HO^-] + (k^K{}_o + k^K{}_{H^+}[H^+])\{Q_a^E/(Q_a^E + [H^+])\}$$

is the acidity constant of the enol ionizing as an oxygen acid. Least-squares fitting of this expression as it stands could not be effected, because the fraction modifying $k^K{}_o$, $Q_a^E/(Q_a^E + [H^+])$, is essentially unity in the region where this rate constant makes a significant contribution: $[H^+] = 10^{-8}$–10^{-9} M ($Q_a^E \cong 10^{-4}$ M, vide infra). That makes the relationship between this rate constant and solvent acidity effectively the same as that of $k^E{}_o$; these two rates are therefore strongly correlated and cannot be evaluated separately by analysis of the rate profile. They are consequently combined as $k^E{}_o + k^K{}_o = k_{uc}$, giving eq. [7]. Least-squares fitting of this

$$[7] \quad k_{exp} = k^E{}_{HO^-}[HO^-] + k_{uc} + k^K{}_{H^+}[H^+]\{Q_a^E/(Q_a^E + [H^+])\}$$

expression produced $k^E{}_{HO^-} = (3.42 \pm 0.06) \times 10^3$ M^{-1} s^{-1}, $k_{uc} = (3.75 \pm 0.65) \times 10^{-2}$ s^{-1}, $k^K{}_{H^+} = (5.62 \pm 0.27) \times 10^6$ M^{-1} s^{-1}, and $Q_a^E = (8.85 \pm 0.54) \times 10^{-5}$ M, $pQ_a^E = 4.05 \pm 0.03$.[3] Combination of the latter constant with Q_a^K according to the relationship $Q_a^K/Q_a^E = K_E$ then gave the keto–enol equilibrium constant $K_E = (1.33 \pm 0.10) \times 10^{-5}$, $pK_E = 4.88 \pm 0.03$.

Although only the sum of the rate constants $k^E{}_o$ and $k^K{}_o$ can be evaluated from the rate profile, individual values may be obtained by combining this sum with the ratio $k^E{}_o/k^K{}_o$ derived in the following way. The equilibrium constant for the process shown in eq. [8], $Q^K{}_a$, is also equal to the ratio of forward to reverse rate constants for this reaction: $Q_a^K = k^E{}_o/k^K{}_{H^+}$; this leads to the expression $k^E{}_o = Q_a^K k^K{}_{H^+}$. An

[8] 
analogous expression for $k^K{}_o$ may be derived using the process shown in eq. [9] whose equilibrium constant, the

[9] 
ionization constant of water Q_w divided by Q_a^K, is also equal to the rate constant ratio $k^K{}_o/k^E{}_{HO^-}$; this leads to $k^K{}_o = Q_w k^E{}_{HO^-}/Q_a^K$. Combination of these expressions then gives the relationship shown in eq. [10]. Since all the quantities on

$$[10] \quad k^E{}_o/k^K{}_o = k^K{}_{H^+}(Q_a^K)^2/\ k^E{}_{HO^-}Q_w$$

the right side of eq. [10] are known, the ratio $k^E{}_o/k^K{}_o$ can be evaluated, and combination of that with the sum $k^E{}_o + k^K{}_o$ obtained from the rate profile produces the results $k^E{}_o = (4.72 \pm 0.87) \times 10^{-3}$ s^{-1} and $k^K{}_o = (3.27 \pm 0.65) \times 10^{-2}$ s^{-1}.

These results, coupled with values of $k^E{}_{HO^-}$ and $k^K{}_{H^+}$ obtained from the rate profile, provide complete rate laws for the enolization and ketonization reactions effected by solvent-related species over the range of acidity studied. This allows separation of observed rates of equilibration into rates of enolization and rates of ketonization, as illustrated in Fig. 2. Such dissection shows that ketonization dominates observed rates of equilibration in acidic solutions down to about $[H^+] = 10^{-8}$ M and that enolization dominates in basic solutions beginning at about $[H^+] = 10^{-9}$ M.

These dominances are consistent with the nature of buffer catalysis in the buffer solutions examined. The buffer catalytic coefficients of eq. [3] may be separated into general acid, k_{HA}, and general base, k_B, contributions with the aid of eq. [11], in which f_A is the fraction of buffer present in the

$$[11] \quad k_{Buff} = k_B + (k_{HA} - k_B)f_A$$

acid form. The data obtained obeyed this relationship well; an example is shown in Fig. 3. Least-squares analysis gave the results listed in Table 1.[4] This analysis showed that only general acid catalysis was significant in CH_3CO_2H and $H_2PO_4^-$ buffers, which is consistent with the fact that these buffers gave solutions in the region $[H^+] = 1 \times 10^{-4}$ to 6×10^{-8} M where ketonization dominates; ketonization, being a reaction involving rate-determining proton transfer from acid catalyst to substrate, can be expected to show only gen-

[4] Data obtained in acetic acid buffers were adjusted to allow for the fact that the enolate ion exists in equilibrium with significant amounts of enol in these solutions.

NH_4^+	NH_3	0.114	0.247	—	1.38

[a]Ionic strength = 0.10 M.

eral acid catalysis. The data for $(CH_2OH)_3CNH_3^+$ and NH_4^+ buffers, on the other hand, gave significant general base as well as general acid catalysis, which is consistent with the fact that these buffers gave solutions in the region $[H^+] = 3 \times 10^{-8}$ to 1×10^{-10} M where both enolization and ketonization make important contributions to observed rates; enolization, being a reaction that involves rate-determining proton removal from the substrate by a basic catalyst will show general base catalysis.

The numerical values of the general acid and general base catalytic coefficients obtained by this analysis offer further support for the interpretation made. The equilibrium constant for keto–enolate interconversion catalyzed by a general acid–base pair, shown in eq. [12], has the value Q_a^K/Q_a^{HA}, in

[12]

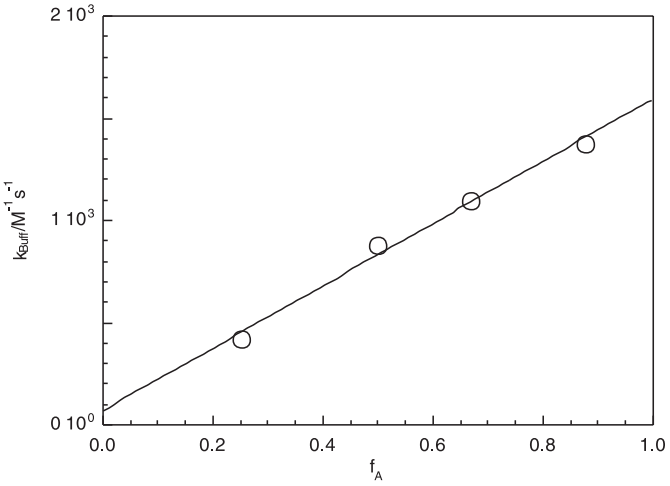
which Q_a^{HA} is the acidity constant of the catalyzing acid. This equilibrium constant is also equal to the rate constant ratio k^E_B/k^K_{HA}, and equating these two values leads to eq. [13], which shows that an estimate of Q_a^K may be obtained from the rate constant pair and Q_a^{HA}. Data for $(CH_2OH)_3CNH_3^+$

[13] $$Q_a^K = Q_a^{HA} k^E_B / k^K_{HA}$$

buffers give $pQ_a^K = 8.91 \pm 0.12$, and data for NH_4^+ buffers give $pQ_a^K = 8.95 \pm 0.04$; both of these results are in very good agreement with $pQ_a^K = 8.93 \pm 0.02$ obtained by spectrophotometric titration of this substrate.

Additional support for the interpretation made may be had from estimates of K_E based on keto–enol interconversion by the two routes of eqs. [14] and [15]. The route of eq. [14] gives $K_E = k^E_o/k^K_{H^+} Q_a^E$, and the route of eq. [15] gives $K_E = k^E_{HO^-} Q_w/k^K_o Q_a^E$. Insertion of the quantities required into the first of these expressions produces $pK_E = 5.02 \pm 0.09$ and into the second, $pK_E = 4.73 \pm 0.09$; both of these results agree well with $pK_E = 4.88 \pm 0.03$ obtained by combining Q_a^K determined by the spectrophtometric titration with Q_a^E based upon the rate profile.

Fig. 3. Relationship between buffer catalytic coefficients and fraction of buffer present in the acid form for keto–enol/enolate interconversion of the *N*-methylindoline-2-thione system in aqueous $H_2PO_4^-/HPO_4^=$ buffer solutions at 25°C.



Further support for the interpretation made comes from isotope effects. These are provided by rate measurements performed in D_2O solutions of $DClO_4$, summarized in Table S3,[2] and in CH_3CO_2D buffers, summarized in Table S5.[2] The measurements in buffers were done in series of solutions of constant buffer ratio and ionic strength, just like the measurements in H_2O solutions of CH_3CO_2H, and the data were treated in an analogous fashion. Only general acid catalysis was found, again just like in H_2O, and combination of the general acid catalytic coefficient determined, $k_{DA} = (3.27 \pm 0.11) \times 10^3$ M^{-1} s^{-1}, with its H_2O counterpart gives the isotope effect $k_{HA}/k_{DA} = 9.98 \pm 0.65$. This is a large kinetic isotope effect, fully consistent with the dominance of ketonization in this region of acidity and the expectation that ketonization occurs by rate-determining hydron transfer from acetic acid to the enolate substrate.

The intercepts of the D_2O buffer dilution plots (k_o, eq. [3]), together with the rate constants measured in $DClO_4$ solutions, are compared with their H_2O counterparts in Fig. 4. It

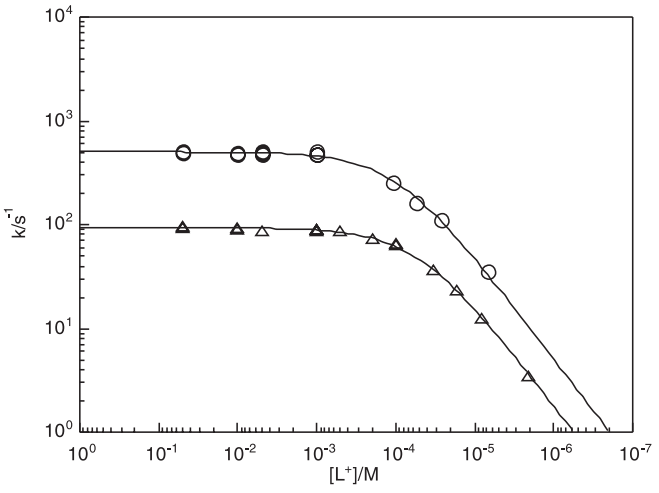

Fig. 5. Rate profile for keto–enol/enolate interconversion in the *N*-methylindoline-2-selone system in aqueous solutions at 25°C; circles and solid line: rate of approach to equilibrium, dashed line: rate of enolization, dotted line: rate of ketonization.

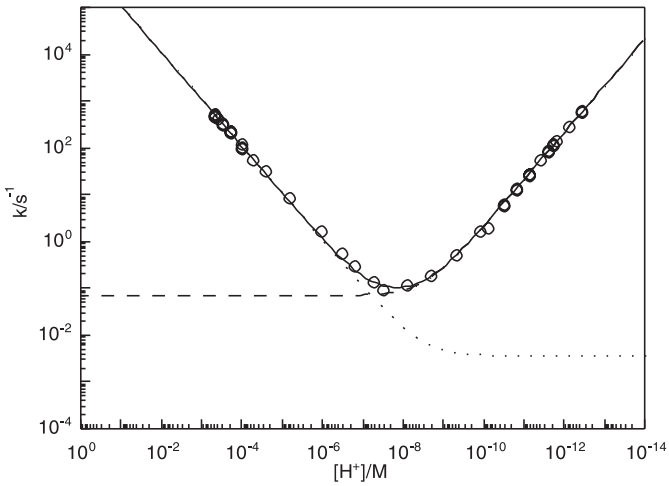
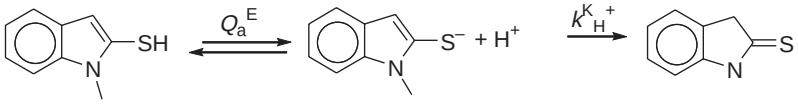


[16]



may be seen that reactions in H_2O are faster than those in D_2O throughout the range of acidity examined, as expected for ketonization occurring by rate-determining hydron transfer to carbon. The difference between rates in H_2O and those in D_2O, however, is greater in the horizontal plateau region at higher acidity than it is in the diagonal region at lower acidity. This again is consistent with the general ketonization mechanism assigned in eq. [5], shown in the specific form that applies here as eq. [16]. Enolate ions are known to be orders of magnitude more reactive to protonation on carbon than are the corresponding unionized enols (19), and ketonization consequently occurs by rate-determining reaction of the enolate ion throughout the region of acidity examined here. In the more acidic solutions, however, the process starts with unionized enol as the initial state, and this species must first undergo equilibrium ionization to provide the more reactive enolate. In this region, therefore, the isotope effect is on the enol equilibrium ionization constant as well as on the rate-determining rate constant. In the region of lower acidity where enolate ion is the initial state, on the other hand, the isotope effect is on the rate constant alone.

Analysis of the D_2O data by least-squares fitting of the acidic portion of the rate law of eq. [7] gave the results $(Q_a^E)_{D_2O} = (5.16 \pm 0.12) \times 10^{-5}$ M, $p(Q_a^E)_{D_2O} = 4.29 \pm 0.01$ (see footnote 3), and $k^K{}_{D^+} = (1.81 \pm 0.03) \times 10^{-6}$ M^{-1} s^{-1}, and combination of these with their H_2O counterparts gives $(Q_a^E)_{H_2O}/(Q_a^E)_{D_2O} = 1.90 \pm 0.09$ and $k^K{}_{H^+}/k^K{}_{D^+} = 2.83 \pm 0.11$. Both of these isotope effects are entirely consistent with expectation. The equilibrium constant Q_a^E refers to the ionization of a thiol acid, and solvent isotope effects on the ionization of a number of thiols have been found to be $K_{H_2O}/K_{D_2O} \cong 2$ (20). The rate constant $k^K{}_{H^+}$ refers to hydron transfer from the hydronium ion to substrate, a process whose solvent isotope effect includes an inverse ($k_H/k_D < 1$) secondary component in addition to a normal ($k_H/k_D > 1$) primary component (21); the result obtained here, in fact, is a near-maximum value (22), consistent with the large isotope effect found for ketonization of this substrate catalyzed by acetic acid (vide supra).

A substrate isotope effect was also determined by allowing *N*-methylindoline-2-thione to undergo deuteration at the 3-position in 0.001 M $DClO_4$–D_2O for 30 min and then adding enough NaOD to give $[OD^-] = 0.01$ M and measuring the rate of the subsequent enolization reaction. The data so obtained are summarized in Table S4[2]; when combined with rates of reaction of the undeuterated substrate in H_2O solutions of NaOH, they give the isotope effect $k_H/k_D = 4.35 \pm 0.07$. This isotope effect contains, in addition to its primary component, an inverse secondary component on the consumption of hydroxide ion (21). It consequently is a strong effect, as expected for enolization effected by rate-determining removal of a hydron from the substrate by hydroxide ion. This reinforces the conclusion that the basic portion of the rate profile corresponds to an enolization process.

Kinetics: *N*-methylindoline-2-selone

Rates of approach to keto–enol/enolate equilibrium for this substrate were measured, as for *N*-methylindoline-2-thione, in aqueous perchloric acid and sodium hydroxide solutions and in CH_3CO_2H, $H_2PO_4^-$, $(CH_2OH)_3CNH_3^+$, and NH_4^+ buffers. These data are summarized in Tables S6–S8.[2]

The results obtained in buffer solution were analyzed in a manner similar to that applied to buffer data for the thione (vide supra). The zero buffer concentration intercepts obtained in this way were then used, together with the rate constants determined in perchloric acid and sodium hydroxide solutions, to construct the rate profile shown in Fig. 5. It may be seen that this rate profile differs from that for the thione system (Fig. 2) in that it lacks a bend in acid solution.

	$Q_a^{K}/10^{-9}$ M:	1.18	56.6
	pQ_a^{K}:	8.93	7.25

[a]Aqueous solution; ionic strength = 0.10 M; acidity constants are concentration quotients applicable at ionic strength = 0.10 M.

Such bends are produced by acid ionization of the enol, and absence of this bend here means that ionization of the selone enol occurs at acidities that produce rates beyond the capability of our stopped-flow method (upper limit: $k \cong 500\ s^{-1}$). We were therefore unable to determine this acidity constant for the selone enol. We could, however, set a lower limit of $Q^{E}_{a} > 5 \times 10^{-4}$ M, $pQ^{E}_{a} < 3.3$, based upon the highest acidity we were able to use, $[H^+] = 5 \times 10^{-4}$ M.

Once again, the rate constants for uncatalyzed enolization, k^{E}_{o}, and ketonization, k^{K}_{o}, could not be separated, and the rate–profile data were analyzed by least-squares fitting of a version, eq. [17], of the general rate law of eq. [6] that combines these rate constants as k_{uc}; this rate law is also without

$$[17] \quad k_{obs} = k^{E}_{HO^-}[HO^-] + k_{uc} + k^{K}_{H^+}[H^+]$$

Q_a^{E} because $Q_a^{E} > [H^+]$ throughout the region examined. The results obtained are $k^{E}_{HO^-} = (1.33 \pm 0.03) \times 10^4\ M^{-1}\ s^{-1}$, $k_{uc} = (7.44 \pm 0.72) \times 10^{-2}\ s^{-1}$, and $k^{K}_{H^+} = (1.08 \pm 0.02) \times 10^6\ M^{-1}\ s^{-1}$.

Resolution of k_{uc} into its components with the aid of eq. [10] gave $k^{E}_{o} = (7.01 \pm 0.68) \times 10^{-2}\ s^{-1}$ and $k^{K}_{o} = (4.28 \pm 0.54) \times 10^{-3}\ s^{-1}$. This result, coupled with values of $k^{E}_{HO^-}$ and $k^{K}_{H^+}$, then provides complete rate laws for enolization and ketonization promoted by solvent-related species, and that in turn allows separation of observed rates of equilibration into rates of enolization and ketonization, as shown in Fig. 5. It may be seen that the two rates become equal at about $[H^+] = 10^{-7}$ M, and that ketonization dominates at acidities greater than this while enolization dominates at acidities lower than this.

The nature of buffer catalysis was once again consistent with these dominances: CH_3CO_2H buffers gave only general acid catalysis, and NH_4^+ buffers gave only general base catalysis, whereas $H_2PO_4^-$ and $(CH_2OH)_3NH_3^+$ buffers showed both general acid and general base catalysis. These catalytic coefficients are summarized in Table 1. Combination of the results with Q_a^{HA} according to eq. [13] gave $pQ_a^{K} = 7.38 \pm 0.06$ for $H_2PO_4^-$ buffers and $pQ_a^{K} = 7.25 \pm 0.04$ for

© 1999 NRC Canada

$(CH_2OH)_3NH_3^+$ buffers, consistent with $pQ_a^K = 7.25 \pm 0.02$ obtained by spectrophotometric titration.

Rate measurements in the *N*-methylindoline-2-selone system were also made in D_2O solutions of $DClO_4$ and of NaOD, the latter using deuterated substrates generated as described above for the thione system. These data are summarized in Tables S6 and S7.[2] When combined with the appropriate H_2O data they give the isotope effect $k^K_{H^+}/k^K_{D^+} = 2.61 \pm 0.10$, as expected for the ketonization reaction that dominates in acid solutions, and $k^E_{HO^-}/k^E_{DO^-} = 4.12 \pm 0.03$, again as expected for the enolization that dominates in basic solution.

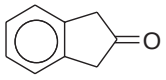
N-Methylindoline-2-one

Measurement of rates of keto–enol/enolate interconversion by the methods used in the present study require the keto form to be a sufficiently strong carbon acid to allow significant amounts of enolate ion to be present at equilibrium in dilute aqueous solution. This is necessary, both for direct observation of enolate formation from the keto form, and also for preparation of enolate in dilute base for quenching into acid to generate greater than equilibrium amounts of enol. Since the carbon-acid ionization of *N*-methylindoline-2-one occurs only in concentrated base solution (pQ^K_a = 15.86), this requirement is not met, and rate measurements could not be made with this substrate. We hope, however, to be able to make these measurements by another technique at some future time.

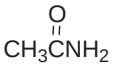
Discussion

Keto–enol equilibria

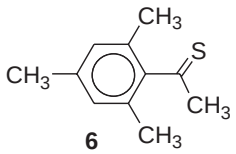
The keto–enol equilibrium constant determined here for *N*-methylindoline-2-thione, $pK_E = 4.88$, is remarkably large for a carboxylic acid amide: it is nearly as great as that for 2-indanone, **4**, ($pK_E = 3.84$) (23), a structurally similar simple ketone. On the assumption that the keto–enol equilibrium constants for carboxylic acid amides are similar to those of carboxylic acid esters (3), and using the value $pK_E = 19$ for ethyl acetate (4), the present result makes the enol content of *N*-methylindoline-2-thione some 14 orders of magnitude greater than that of a simple acyclic carboxylic acid amide such as acetamide, **5**.



4



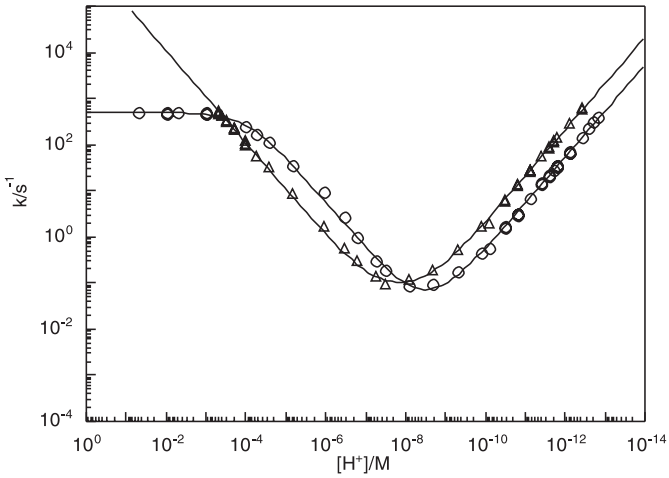
5



6

A good portion of this large difference may be attributed to replacement of carbonyl oxygen by sulfur in going from acetamide to *N*-methylindoline-2-thione. Thioketones are well known to have considerably greater enol contents than oxygen ketones, a phenomenon generally attributed to the relative weakness of the sulfur–carbon π-bond (24), and a recent comparison of keto–enol equilibrium constants for 2,4,6-trimethylthioacetophenone, **6**, with that of its oxygen analog puts this effect at six orders of magnitude (8). That leaves eight orders of magnitude for other effects, the strongest of which is likely to be formation of a new aromatic ring upon enolization of *N*-methylindoline-2-thione, as illustrated in eq. [1]. Formation of such a new aromatic ring has been shown to have a strong influence upon the ionization of indoline-2-ones and related substances in DMSO solution (9). It is likely, however, that reduced conjugation between the carbonyl group and amide nitrogen in *N*-methylindoline-2-thione will play a role as well. It is conjugative stabilization of the keto form that makes enol contents of simple oxygen amides so low, and in thioamides this conjugation will be weaker than in oxygen amides because of mismatch of orbital size. In an aromatic amide such as *N*-methylindoline-2-thione, moreover, conjugation of carbonyl and nitrogen will be reduced further by offsetting conjugation of nitrogen with the aromatic ring.

Fig. 6. Comparison of rate profiles for keto–enol/enolate interconversion in the *N*-methylindoline-2-thione (○) and *N*-methylindoline-2-selone (△) systems in aqueous solution at 25°C.



Determination of a keto–enol equilibrium constant by the method employed here requires knowledge of the acidity constant of the enol, Q_a^E, which in turn is evaluated from a bend in the rate profile for ketonization in acidic solution. Unfortunately, rate constants in the *N*-methylindoline-2-selone system became too fast to measure before this bend could be reached (see Fig. 5), and we consequently could not determine a keto–enol equilibrium constant for this substrate. We were, however, able to set the limit $pQ_a^E < 3.3$, and use of this in the relationship $pK_E = pQ_a^K - pQ_a^E$, coupled with $pQ_a^K = 7.25$, then gives the lower limit $pK_E > 4.0$.

This limit is consistent with an estimate that can be made based on the fact that selenols are generally more acidic than the corresponding thiols by a roughly constant 3p*K* units (25). Application of this difference to $pQ_a^E = 4.05$ for the enol of *N*-methylindoline-2-thione then gives $pQ_a^E = 1$ for the selone, and that leads to $pK_E = 6$ for the selone system.

This result is not very different from $pK_E = 4.88$ for *N*-methylindoline-2-thione, and that suggests that, whereas replacing carbonyl oxygen by sulfur produces a marked increase in enol content, further replacement of sulfur by selenium has little effect.

Reaction rates

The comparison of rate profiles provided by Fig. 6 shows that ketonization of the enol of *N*-methylindoline-2-thione in

© 1999 NRC Canada

acid solution is more rapid than that of *N*-methylindoline-2-selone, whereas for enolization in basic solution this order is reversed. The greater rate of ketonization of the thione enol is consistent with the fact that aryl vinyl sulfides undergo acid-catalyzed hydrolysis faster than the corresponding aryl vinyl selenides (26); both of the hydrolyses are cation-forming reactions that occur by rate-determining hydron transfer to carbon, just like enol ketonization, and the difference in reactivity indicates that sulfur is better able to stabilize an adjacent positive charge than is selenium. Enolization, on the other hand, is an anion-generating reaction, and the superiority of the selone here indicates that selenium is better than sulfur at stabilizing negative charge; this is consistent with the greater C-H acidity of *N*-methylindoline-2-selone (pQ^K_a = 7.25) over *N*-methylindoline-2-thione (pQ^K_a = 8.93) as well as the greater acid strength of selenols over thiols (25).

Solubility of acenaphthene in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon Mobile Order theory

Karina M. De Fina, Tina L. Sharp, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for acenaphthene dissolved in 36 different organic nonelectrolyte solvents containing ether-, carbonyl-, hydroxy-, ester, methyl-, and *tert*-butyl functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 29 solvents for which predictions could be made computations show that Mobile Order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 37.8%. In comparison, the average absolute deviation is 1080% when ideal solution behavior is assumed.

Key words: acenaphthene solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : Opérant à 25.0°C, on a mesuré les solubilités expérimentales de l'acénaphtène dissous dans 36 solvants organiques non électrolytiques différents contenant des groupes fonctionnels éther, carbonyle, hydroxyle, ester, méthyle et *tert*-butyle. Les résultats de ces mesures sont utilisés pour évaluer les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Pour les 29 solvants pour lesquels il était possible de faire de prédictions, les calculs montrent que la théorie de l'ordre fonctionnel conduit à des évaluations assez raisonnables des solubilités exprimées en fraction molaire de saturation. La déviation absolue moyenne entre les valeurs prévues et observées est de 37,8%. En comparaison, la déviation absolue moyenne est de 1080% quand on fait l'hypothèse que le comportement de la solution est idéal.

Mots clés : solubilités de l'acénaphtène, solvants organiques non électrolytiques, prédictions des solubilités.

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and hetero-atom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semi-empirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application, though, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the database contain as many different functional groups as possible, preferably with adequate representation from both mono- and multi-functional solute/solvent molecules to permit evaluation of potential synergistic effects. The database should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham et al. (12, 13) recently developed a general solvation equation that can be used in the correlation and understanding of physico-chemical and biochemical phenomena. Physical properties that have been correlated include gas/solvent partition coefficients (as log L)

$$[1] \qquad \log L = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + d \log L^{16}$$

and water/solvent partition coefficients (as log P)

[2] $$\log P = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + vV_x$$

where R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, and $\sum\alpha_2^H$ and $\sum\beta_2^H$ are measures of the hydrogen-bond acidity and hydrogen-bond basicity of the solute. For any given solvent, numerical values of the seven curve-fit coefficients (*c*, *r*, *s*, *a*, *b*, *d*, and *v*) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported curve-fit coefficients for water (12, 13) and a few select organic solvents (13).

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs) and polycyclic aromatic nitrogen hetero-atoms (PANHs). In the present communication, we report acenaphthene solubilities in 36 different organic solvents at 25°C. Results of the measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory. Subsequent studies will use the experimental acenaphthene solubilities in developing gas/liquid partition and water/organic solvent partition correlations based upon eqs. [1] and [2].

Materials and methods

Acenaphthene (Aldrich, 98%) was recrystallized several times from methanol. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), dibutyl ether (Aldrich, 99 %), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Co., absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros, 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), ethylene glycol (Aldrich, 99.8%, anhydrous), 1,4-dioxane (Aldrich, 99.8%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), 2-butanone (Aldrich HPLC, 99.5+%), ethyl acetate (Aldrich, HPLC, 99.9%), 2-methyl-2-propanol (Arco Chemical Company, 99+%), and butyl acetate (Aldrich HPLC, 99.7%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol% or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated acenaphthene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with 2-propanol for spectrophotometric analysis at 289 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve for nine standard solutions. The concentration of acenaphthene in the standard solutions varied from 5.34×10^{-5} M to 2.67×10^{-4} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\varepsilon \approx 6430$ L mol^{-1} cm^{-1} (5.34×10^{-5} M) to $\varepsilon \approx 6200$ L mol^{-1} cm^{-1} (2.67×10^{-4} M). 2-Butanone did absorb at the analysis wavelength. Acenaphthene was sufficiently soluble in this solvent that by the time the saturated solution was appropriately diluted for the measured absorbance to fall on the Beer–Lambert Law curve the solvent background absorbance was negligible.

Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of acenaphthene, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental acenaphthene solubilities, X_A^{sat}, in 36 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%.

Results and discussion

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (14–21) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume *V* of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

[a]Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%.

[b]Deviations (%) = $100[(X_A^{sat})^{calc} - (X_A^{sat})^{exp}]/(X_A^{sat})^{exp}$.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

$$[3]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\,\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be 2 for water or diols, and to equal 0 for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[4]\quad r_{solvent} = (K_{solvent}\,\phi_{solvent}/V_{solvent})/(1 + K_{solvent}\,\phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent}$ = 5000 cm^3 mol^{-1} assumed for all mono-functional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[5]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ_A' and $\delta_{solvent}'$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[6]\quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T) \ln (T_{mp}/T)$$

the solute's molar enthalpy of fusion, ΔH_A^{fus}, and heat capacity difference, $\Delta C_{p,A}$, at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1}$ term. Ruelle et al. (17–21) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Predictive application of eqs. [3] and [5] is relatively straightforward. First, an average numerical value of $\delta_{acenaph}'$ = 19.60 MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes acenaphthene mole fraction solubility data in *n*-hexane ($\delta_{acenaph}'$ = 19.75 MPa$^{1/2}$), *n*-heptane ($\delta_{acenaph}'$ = 19.54 MPa$^{1/2}$), and *n*-octane ($\delta_{acenaph}'$ = 19.51 MPa$^{1/2}$). The numerical value of a_A^{solid} = 0.1976 is calculated using eq. [6] with ΔH_A^{fus} = 21 540 J mol^{-1} and T_{mp} = 366.56 K (22). The two heat capacity terms in eq. [6] were set equal to zero, as we were unable to find heat capacity data for the subcooled liquid solute. A numerical value of $V_{acenaph}$ = 137.77 cm^3 mol^{-1} was used for the molar volume of the hypothetical

Table 2. Solvent and solute properties used in Mobile Order predictions.

Component (*i*)	V_i/(cm^3 mol^{-1})	δ'_i/(MPa$^{1/2}$)[a]
n-Hexane	131.51	14.56
n-Heptane	147.48	14.66
n-Octane	163.46	14.85
n-Nonane	179.87	15.07
n-Decane	195.88	15.14
n-Hexadecane	294.12	15.61
Cyclohexane	108.76	14.82
Methylcyclohexane	128.32	15.00
2,2,4-Trimethylpentane	166.09	14.30
Cyclooctane	134.9	15.40
tert-Butylcyclohexane	173.9	15.50
Dibutyl ether	170.3	17.45
Tetrahydrofuran	81.4	19.30
1,4-Dioxane	85.8	20.89
Methanol	40.7	19.25
Ethanol	58.7	17.81
1-Propanol	75.10	17.29
2-Propanol	76.90	17.60
1-Butanol	92.00	17.16
2-Butanol	92.4	16.60
2-Methyl-1-propanol	92.8	16.14
1-Pentanol	108.6	16.85
1-Hexanol	125.2	16.40
1-Heptanol	141.9	16.39
1-Octanol	158.3	16.38
Ethylene glycol	56.0	19.90
Butyl acetate	132.5	19.66
Ethyl acetate	98.5	20.79
2-Butanone	90.2	20.90
Acenaphthene[b]	137.77[c]	19.60[d]

[a]Tabulated values are taken from a compilation given in Ruelle et al. (17, 18, 20, 21).

[b]The numerical value of a_A^{solid} = 0.1976 was calculated from eq. [6] using ΔH_A^{fus} = 21 540 J mol^{-1} and T_{mp} = 366.56 K (22).

[c]Numerical value of $V_{acenaph}$ = 137.77 cm^3 mol^{-1} was estimated using the group contribution method of Shahidi et al. (23).

[d]Numerical value was calculated using the measured acenaphthene mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [3] and [5]; with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0.

subcooled liquid solute. The molar volume of the solute was estimated using the group contribution method of Shahidi et al. (23) for partial molar volumes of aromatic hydrocarbons dissolved in carbon tetrachloride.

Table 1 summarizes the predictive ability of Mobile Order theory for the 29 different organic solvents for which both acenaphthene solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (17, 18, 20, 21), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (24) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does provide fairly reasonable estimates of the solubility behavior of acenaphthene in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 37.8%. Expressed on a natural logarithmic mole fraction scale, Mobile Order theory predicts the acenaphthene solubilities to within ±0.281 ln units. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data covers over a 165-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid} = 0.1976$ for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 1080% between predicted and observed values.

La radiolyse de l'eau et des solutions aqueuses : historique et actualité

Christiane Ferradini et Jean-Paul Jay-Gerin

Résumé : Les premières expériences montrant la décomposition de l'eau par action des rayonnements ionisants datent d'un siècle. À l'occasion de cet anniversaire, nous avons tenté de réaliser une synthèse des travaux concernant ce sujet depuis son origine, en insistant plus particulièrement sur les diverses étapes physicochimiques ayant conduit à l'état actuel de cette science. Dans ce but, nous décrivons l'influence sur la radiolyse de l'eau des paramètres intervenant, tels que la concentration du soluté, le pH, le débit de dose, la nature et l'énergie du rayonnement, la présence d'oxygène, la température, la nature de la phase et la pression. Bien qu'elle soit incomplète, une bonne description des phénomènes a pu être obtenue. Elle conduit à diverses perspectives concernant, d'une part, le développement de cette science et, d'autre part, ses possibilités d'applications et de retombées.

Mots clés : chimie radicalaire, courbe de dilution, eau, électron hydraté, radicaux hydroxyle et superoxyde, radicaux libres, radiolyse, réactions en chaîne, rendements radicalaires et moléculaires, survie cellulaire, transfert d'énergie linéique.

Abstract : Experiments showing that water is decomposed by the action of high-energy radiations date back to the first days of the discovery of radioactivity, a century ago. On the occasion of this anniversary, we have attempted to give a comprehensive account of the radiation chemistry of water and its solutions since its origin, with special emphasis on the various physical and chemical stages that led to the present state of this science. To this aim, we describe the effect of different intervening factors on the molecular and radical yields, including dissolved solute concentration, pH, radiation intensity (or dose rate), type and energy of the radiation, presence of oxygen, temperature, phase, and pressure. We also discuss briefly the chemical behavior of the free radicals produced in radiolyzed aqueous solutions. A good, albeit incomplete, description of the phenomena is obtained that leads to various perspectives concerning, on the one hand, the development of this science and, on the other hand, its potential for applications.

Key words : radical chemistry, dilution curve, water, hydrated electron, hydroxyl and superoxide radicals, free radicals, radiolysis, chain reactions, molecular and radical yields, cell survival, linear energy transfer.

I. Introduction

La plus grande partie des premiers travaux de radiolyse a concerné l'irradiation de l'eau. Ceci est dû à différentes raisons. D'une part, les méthodes utilisées dès l'abord consistaient principalement à analyser un faisceau de données expérimentales impliquant des solutés variés : par rapport à d'autres solvants, l'eau offre à ce point de vue une chimie plus riche et mieux établie. D'autre part, les études de radiolyse des solutions aqueuses ne perdaient pas de vue les apports éventuels vers les applications radiobiologiques qui se développaient parallèlement; or l'eau est un constituant majeur de la matière vivante, au moins pondéralement.

Un grand nombre de résultats expérimentaux et théoriques concerne donc la radiolyse de l'eau et de ses solutions et a permis de développer les connaissances à ce sujet. Toutefois, l'évolution de celles-ci se poursuit rapidement et il n'y a pas actuellement de mises au point récentes facilitant l'accès à ce domaine. Cette constatation nous a conduits à envisager et à décrire, sous un jour actuel, le passé et le présent des recherches portant sur l'action des rayonnements ionisants sur l'eau et les solutions aqueuses.

Après un rappel de l'historique de la radiolyse de l'eau, nous décrirons comment ont été identifiés les intermédiaires réactionnels alors impliqués et leurs devenirs. La notion de « rendements radicalaires et moléculaires » a ainsi pu être introduite; elle donne un certain nombre de renseignements sur les événements se produisant pour des temps pouvant aller jusqu'à ~10^{-7} s après l'absorption du rayonnement ionisant. L'influence de divers paramètres sera ensuite développée et justifiée, et finalement un certain nombre d'applications sera évoqué.

II. De la découverte de la radioactivité à celle de l'électron hydraté (e^-_{aq})

A. Premières expériences concernant la radiolyse de l'eau

On sait que, quelques mois seulement après la découverte des rayons X par Wilhelm C. Röntgen, la radioactivité fut à son tour découverte en février–mai 1896 par Henri Becquerel à Paris et que le polonium (1) et le radium (2) furent mis en évidence en 1898 par Pierre et Marie Curie. C'est en 1902 que fut observée pour la première fois, par Giesel (3), la décomposition de l'eau sous l'influence d'un sel de radium dissous. Il constata que de telles solutions donnaient lieu à un dégagement permanent d'hydrogène et d'oxygène, phénomène comparable, d'après Marie Curie (4), à une *« électrolyse sans électrodes »*. Ces résultats furent confirmés l'année suivante par Ramsay et Soddy (5) qui trouvèrent, de plus, que de faibles quantités d'hélium étaient présentes dans ce dégagement. Peu après, Debierne (6) souligne qu'il est admis *« que cet hélium résulte de la désagrégation de l'atome de radium »*. Il étudie quantitativement les dégagements gazeux provenant de solutions de bromure de radium ou de chlorure d'actinium et conclut que *« le gaz hélium résulte bien de la présence des corps radioactifs »*. Rappelons que l'expérience magistrale de Rutherford et Royds (7) montrant directement que les particules α sont des atomes d'hélium ionisés date de 1909. Divers autres travaux concernant les dégagements gazeux provenant de l'action du radon sur l'eau ont été ensuite développés par Ramsay et Cameron (8, 9) et par Usher (10).

La question alors posée concernait l'origine de cette décomposition de l'eau; elle pouvait être attribuée, soit à une action chimique du radioélément mis en solution, de ses dérivés ou de leurs produits de transformation, soit à l'effet des divers rayonnements intervenants. Debierne (11, 12) a établi que l'action sur l'eau pouvait être observée même lorsque la source et la solution n'étaient pas en contact direct, ce qui l'a conduit à écrire : *« l'énergie nécessaire à la décomposition ne peut être empruntée qu'au rayonnement absorbé par l'eau »*. Ces résultats furent confirmés très rapidement par Kernbaum (13). À titre d'exemple, la filiation principale des radioéléments impliqués dans le cas observé est indiquée figure 1, selon les données actuelles. On voit que le passage de ^{226}Ra à ^{206}Pb (stable) met en jeu cinq émissions α successives et quatre émissions β^-. Diverses transitions γ sont également incluses dans ces décroissances, permettant le retour à l'état fondamental des noyaux excités. L'eau est donc généralement soumise à trois types de rayonnements : α, β^- et γ provenant du radium et de ses descendants (voir fig. 1). D'après les différents auteurs, les durées d'irradiation étaient bien supérieures aux temps nécessaires aux radioéléments précédents pour atteindre l'équilibre radioactif. Dans ces expériences, les rayons α sont totalement absorbés dans l'eau, alors que les rayons β^- et γ ne le sont que partiellement ou très partiellement. Toutefois, les doses relatives cédées à l'eau pour les trois types de rayonnements varient dans ces travaux avec les conditions expérimentales (géométrie du récipient, volume mort au-dessus de la solution irradiée, etc.). Les auteurs précédemment cités (8–10) ont montré, de plus, que ce sont les particules α qui sont responsables de la très grande partie des effets chimiques observés. Par ailleurs, Kernbaum (13) a mis en évidence le fait que les rayons X ne donnent pas, dans ces conditions, de dégagement gazeux observable. Des remarques analogues ont été faites ultérieurement par Risse (15) et par Fricke et Brownscombe (16). On sait en effet, maintenant, que les rayons α conduisent à une radiolyse de l'eau en produits stables mesurables, tandis que dans le cas des rayons γ ou X la radiolyse en l'absence d'air

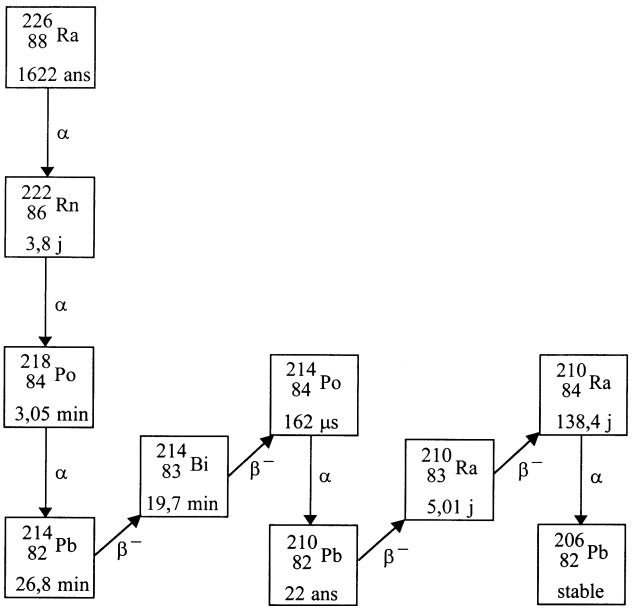
Fig. 1. Famille radioactive du radium 226 : séquence principale (voir, par exemple, réf. 14). Soulignons que diverses transitions γ, traduisant le retour à l'état fondamental des noyaux excités, doivent également être incluses dans ces décroissances. À titre d'exemple, dans la transition de ^{226}Ra à ^{222}Rn, environ 6 % du bilan énergétique emprunte la voie impliquant l'émission d'un rayon α de 4,676 MeV et d'un rayon γ de 0,187 MeV, la fraction restante ne mettant en jeu qu'un seul rayon α (4,863 MeV) par désintégration.



est très faible par suite de réactions inverses importantes et rapides.

En 1911, Usher (10) a conclu de ses résultats qu'un atome d'*« émanation »* (c'est-à-dire de ^{222}Rn) peut décomposer 154 000 molécules d'eau. Pour le rayonnement β^-, la quantité de gaz dégagé est bien inférieure à celle observée dans le cas des rayons α.

Il est apparu, d'après les mesures de gaz, que le bilan en hydrogène et en oxygène n'était pas vérifié (3, 8, 11–13, 17 (cité par F. Giesel, réf. 3), 18). Kernbaum (13), le premier, a montré que le déficit en oxygène est compensé par une formation parallèle d'eau oxygénée (ou peroxyde d'hydrogène) H_2O_2.

Une première tentative d'interprétation de la radiolyse de l'eau pure remonte à 1914, date à laquelle Debierne (12) a émis l'hypothèse de la dissociation de l'eau en atomes H• et en radicaux •OH sous l'influence des rayonnements. Il écrit (12) : *« On peut supposer que chaque molécule d'eau est décomposée en un atome H et un radical hydroxyl OH, deux atomes d'hydrogène se soudant pour faire une molécule d'hydrogène, et deux radicaux hydroxyls donnant lieu à la production d'une molécule d'eau oxygénée »*. Les espèces H• et •OH seraient formées à partir des ions primaires de l'eau. Une telle interprétation, reposant en grande partie sur des bases justes, a été ignorée pendant de nombreuses années jusqu'à ce qu'elle soit énoncée, indépendamment, par Risse (19), par le groupe de Burton et Franck (voir, par exemple, réf. 20) et par Weiss (21).

On voit que des résultats intéressants ont été obtenus avec des moyens simples dès les premières années suivant la découverte de la radioactivité. Toutefois, long a été ensuite le chemin conduisant à la compréhension actuelle de la radiolyse de l'eau. Une étape particulièrement importante dans cette voie a été l'étude de l'influence de l'oxygène dissous. En effet, en irradiant, par des rayons γ ou X, de l'eau contenant de l'oxygène, on observe, dans ce cas, la formation d'eau oxygénée (15, 22, 23), un dégagement d'hydrogène (24, 25) et une consommation d'oxygène.

On le sait, pour l'eau pure, donc désaérée, aucun produit stable ne peut être mesuré dans les conditions précédentes d'irradiation. L'eau aérée contient, à température ambiante, seulement ~4×10^{-6} molécule d'oxygène pour une molécule d'eau, et cela suffit pourtant à modifier profondément sa radiolyse. Ce rôle important joué par un soluté a incité de nombreux chercheurs à étudier la radiolyse de solutions de composés minéraux et organiques. Comme nous allons le voir, l'étude de l'action des rayonnements ionisants sur les solutions aqueuses diluées a contribué grandement à la compréhension des mécanismes intervenant lors de la radiolyse de l'eau. De plus, un intérêt croissant pour l'étude des effets chimiques des rayonnements était suscité, ainsi qu'il a été mentionné, par la nécessité de comprendre les processus mis en jeu en radiobiologie (voir, par exemple, réf. 26).

B. Premières expériences concernant les solutions aqueuses diluées

Dès 1911, Kailan a irradié un certain nombre de solutions aqueuses avec les rayonnements associés au radium.[2] Mais, à partir des années 1930, on a pu disposer de sources de rayons X équivalentes à plusieurs milliers de curies, alors que les expériences utilisant le radium impliquaient des activités inférieures au curie.[3] Mieux encore, à partir de 1950, le développement des réacteurs nucléaires a permis d'obtenir des quantités de plus en plus importantes de radioéléments, et en particulier de cobalt 60 émetteur de rayons γ d'énergies 1,17 et 1,33 MeV, de période 5,27 ans et dont l'activité pouvait dépasser 10^4 curies.

Les irradiations de solutions aqueuses se développèrent rapidement et on peut aujourd'hui évaluer à plusieurs centaines le nombre de systèmes minéraux ou organiques ainsi étudiés. Pour rendre ces études quantitatives, on a défini le rendement G reliant la transformation chimique induite à l'énergie cédée au milieu par le rayonnement.[4] G s'exprime en molécules pour 100 eV absorbés (que nous écrirons, dans

[2] Pour une description d'ensemble des travaux d'Anton Kailan, voir, par exemple, réf. 27.

[3] On sait que l'activité de 1,025 g de radium correspond à 1 curie (Ci), le curie étant l'ancienne unité de radioactivité et représentant la quantité d'un élément radioactif dans lequel le nombre de désintégrations par seconde est égal à $3{,}700 \times 10^{10}$. L'unité SI, on le sait, est le becquerel (Bq) qui correspond à une désintégration par seconde.

[4] Plus précisément, le rendement $G(P)$ est défini comme la dérivée de la concentration [P] de l'espèce « P », formée ou détruite, par rapport à la dose absorbée D : $G(P) = (1/\rho)(d[P]/dD)$, où ρ est la masse volumique du système irradié. Du point de vue pratique, on retient généralement le *rendement initial*, calculé à partir de la pente de la tangente à l'origine de la courbe expérimentale représentant [P] en fonction de D. Puisque $D = It$, où I et t sont respectivement l'intensité ou débit de dose et le temps d'irradiation, on a : $G(P) = (1/\rho I)(d[P]/dt)$.

ce travail, moléc./100 eV) ou, dans le système SI, en mol/J.[5] Nous évoquerons ici seulement le comportement de trois solutés : les ions ferreux, les ions cérium IV et l'acide formique, qui ont été choisis principalement par suite de leur intérêt historique.

Les ions ferreux, en solution acide (H_2SO_4 0,4 M) aérée et irradiée avec les rayons γ de ^{60}Co ou les rayons X de même énergie, sont oxydés en ions ferriques avec un rendement $G(Fe^{3+})$ = 15,6 moléc./100 eV (voir, par exemple, réfs. 28–30).[6] Il a été montré expérimentalement (31, 32) que la quantité d'ions ferreux oxydés croît linéairement en fonction de la dose absorbée et que le facteur de proportionnalité est, dans ce cas, indépendant du débit de dose dans une large gamme,[7] ainsi que de la concentration initiale en ions ferreux entre ~5×10^{-5} et 10^{-1} M. Le choix initial de l'acide sulfurique a été dicté par sa relative inertie vis-à-vis du rayonnement et au fait qu'à la concentration 0,4 M la solution a un pouvoir d'arrêt équivalent à celui de l'air (34). Les caractéristiques précédentes, associées aux facilités de dosage de Fe^{3+} par spectrophotométrie, montrent que ce système, appelé « dosimètre de Fricke »,[8] a toutes les qualités nécessaires pour jouer un tel rôle.

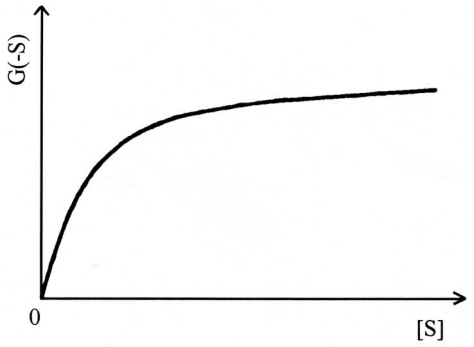
Pour certains solutés, à l'inverse des ions ferreux, on peut parfois observer une réduction. Tel est le cas des ions cérium IV, étudiés tout d'abord par Clark et Coe (36). Le rendement de réduction pour ce système a été trouvé égal à une valeur voisine de 2,45 moléc./100 eV, en milieu H_2SO_4 0,4 M, pour les rayons γ de ^{60}Co (voir, par exemple, réfs. 28, 30, 37 et 38).[6] Cette facilité de réduction de l'ion cérium IV doit être rapprochée de la valeur relativement élevée du potentiel de réduction du couple Ce^{IV}/Ce^{III} (1,44 V), celui du couple Fe^{3+}/Fe^{2+} étant égal à 0,77 V. Le rendement de disparition des ions Ce^{IV} est le même en la présence ou en l'absence d'air. À cela s'ajoutent des dégagements d'hydrogène et d'oxygène avec des rendements respectivement de 0,40 et 0,84 moléc./100 eV (38).

Une des premières études concernant les solutés organiques porte sur l'acide formique (HCOOH) en solution aqueuse diluée (39, 40). Ce système a l'avantage sur les précédents de pouvoir être étudié pour une large gamme de pH. Les principaux produits formés en radiolyse γ ou X et en la présence d'air ou d'oxygène sont l'hydrogène, l'eau oxygénée et le dioxyde de carbone. Lors d'irradiations avec les rayons γ de ^{60}Co, les rendements correspondants, d'après Hart (40), seraient environ respectivement 0,44, 3,42 et 2,62 moléc./100 eV, pour une concentration initiale de 10^{-3} M en acide formique.

C. Avènement de la radiolyse pulsée

En 1952, des essais consistant à irradier la cible de façon discontinue (procédé dit du « secteur tournant »; voir, par exemple, réf. 41) ont été développés pour étudier quantitativement les réactions en chaîne[9] produites lors de la radiolyse γ de solutions aqueuses (42, 43). Par la suite, les progrès de l'électronique rapide ont permis l'avènement de la radiolyse pulsée proprement dite, dont la mise en oeuvre, à l'échelle de la microseconde, date du début des années 1960 (44–47). Cette méthode a ensuite pris rapidement un essor considérable grâce au développement d'accélérateurs d'électrons produisant des impulsions intenses et de plus en plus brèves (voir, par exemple, réfs. 48–51). Le principe de celle-ci est basé sur l'emploi d'un montage optoélectronique approprié permettant de suivre, le plus fréquemment en spectrophotométrie ultra-rapide, l'évolution des radicaux libres formés ou des produits transitoires de leurs réactions, ceci pour des échelles de temps allant jusqu'à quelques nanosecondes (voir, par exemple, réfs. 49 et 50) et même quelques picosecondes (52–54). L'utilisation de la radiolyse pulsée s'est avérée, nous le verrons, des plus utiles et fructueuses au cours des études développées dans le cadre de la radiolyse de l'eau et des solutions aqueuses.

Fig. 2. Allure typique d'une « courbe de dilution » pour un soluté S.



D. Nature des intermédiaires réactionnels

On pouvait se demander, dans le cas des solutions diluées, si les rendements mesurés résultaient de l'absorption du rayonnement par l'eau (« effet indirect ») ou de l'absorption par le soluté (« effet direct »). Il est apparu que, dans la plupart des cas, les courbes donnant le rendement de disparition du soluté en fonction de sa concentration aboutissaient à un palier (fig. 2). Cet *effet de dilution* a été mis en évidence pour la première fois par Dale (55) dans ses travaux sur la désactivation « radiochimique » d'enzymes en solution aqueuse. Ce fait prouvait péremptoirement que c'était la fraction d'énergie absorbée par l'eau, de beaucoup la plus importante, qui entraînait la modification du soluté par « effet indirect » (21, 55, 56). Il fallait donc invoquer l'intervention d'intermédiaires provenant de la radiolyse de l'eau elle-même et agissant sur le soluté. Le palier observé dans l'effet de dilution correspond alors à la capture totale des intermédiaires transitoires. À la lumière des hypothèses de Debierne (12), Risse (19), Burton et Franck (20) et Weiss (21) précédemment citées, ces intermédiaires semblaient devoir être les radicaux $H^{\bullet}$ et $^{\bullet}OH$. Effectivement, les réac-

[5] 1 moléc./100 eV = $1{,}0364 \times 10^{-7}$ mol/J.
[6] Pour une compilation antérieure à 1961 et concernant en particulier les rendements radiolytiques des ions ferreux et cériques, voir réf. 30.
[7] Dans le cas de la radiolyse pulsée (voir sect. II-C), pour lequel le débit de dose est parfois très important, l'influence de celui-ci peut se faire sentir, le rendement de disparition des ions ferreux commençant à baisser à partir d'environ 10^{25} eV L^{-1} s^{-1}, soit ~10^6 Gy/s (réf. 33; voir aussi sect. III-C.3). Le gray (Gy) est l'unité SI de dose absorbée : 1 Gy = 1 J/kg.
[8] Pour le mode d'emploi de ce dosimètre, voir, par exemple, réfs. 33 et 35.
[9] Pour les caractéristiques d'une réaction en chaîne, voir sect. III-C.1.a.

© 1999 CNRC Canada

tions d'oxydation étaient comparables à celles du radical $^{\bullet}OH$. Au contraire, des difficultés se sont présentées pour l'atome $H^{\bullet}$. En effet, on trouvait, pour cette espèce, des résultats différents en milieu acide et en milieu neutre. C'est ainsi, par exemple, que les « atomes H » réagissaient avec des vitesses différentes sur H_2O_2 selon l'acidité du milieu (57). De même, le mécanisme de leur réaction vis-à-vis de l'acide monochloracétique variait avec le pH. Cela a conduit à penser que l'entité réductrice existait sous deux formes distinctes selon l'acidité de la solution, formes qui furent dénommées H et H′ (58). L'identification de ces espèces est restée douteuse pendant un certain temps. Ainsi, on a assimilé H et H′ soit au couple $H^{\bullet}$ et $H_2^{\bullet+}$ (59), soit à $H_2O^{\bullet-}$ et $H^{\bullet}$ ou encore à l'électron hydraté (e^-_{aq}) et $H^{\bullet}$. Cette dernière hypothèse a été suggérée en 1959 par Barr et Allen (60) en étudiant la réaction en chaîne[9] de décomposition de H_2 et H_2O_2 et en comparant le comportement cinétique de H et H′ vis-à-vis de O_2 et H_2O_2. Ce n'est cependant qu'à partir de la fin 1961 qu'il a été montré que l'entité réductrice en milieu neutre avait une charge négative (61, 62). Ce résultat favorisait l'hypothèse de l'existence de l'électron hydraté en milieu neutre. Soulignons que l'intervention d'une telle entité avait déjà été invoquée théoriquement par Stein (63) dès 1952, par Platzman (64) en 1953 et par Weiss (65) en 1953 et 1960.

D'autre part, en 1960 (66), l'avènement de la radiolyse pulsée a permis à Keene (44, 67) d'observer l'existence d'une forte absorption transitoire dans la partie visible du spectre de l'eau irradiée, à l'échelle de la microseconde, avec des électrons de 4 MeV. Matheson (68) a suggéré en ces termes que cette absorption pouvait être due à l'électron hydraté : *« Could the short-lived absorption observed by Keene at about 6000 Å in deaerated water be related to* e^-_{aq}*? »*. Durant l'été 1962 (69), Hart et Boag (45, 70) ont observé une espèce transitoire absorbant dans l'eau irradiée. Ces auteurs ont indiqué que le spectre d'absorption correspondant présentait un maximum vers 700 nm. De plus, ce spectre pouvait être inhibé par l'oxygène et par diverses molécules avides d'électrons, telles que CO_2 et N_2O. Ils ont conclu que l'espèce considérée était l'électron hydraté. De nombreux travaux ont rapidement confirmé cette identification et ont déterminé les propriétés cinétiques et thermodynamiques de cette espèce radicalaire : *« As a matter of fact, the hydrated electron fascinated radiation chemists so much when it was discovered that they diverted attention to measure its reactivity with everything they could think of. The specific reaction rates of* e^-_{aq} *with 3000 substances are known »* (71). Divers modèles théoriques ont parallèlement été proposés dans le but de décrire ces caractéristiques (pour une revue d'ensemble récente, voir, par exemple, réf. 72).

À partir de la mise en évidence de l'électron hydraté, la radiolyse pulsée a donné lieu à de fructueux développements et a conduit en particulier à l'identification de nombreuses espèces transitoires jusqu'alors inconnues.

Il semblerait que, désormais, le mécanisme de radiolyse de l'eau et des solutions aqueuses puisse être principalement décrit en termes de la chimie des radicaux formés, à savoir : e^-_{aq}, $H^{\bullet}$ et $^{\bullet}OH$. En milieu acide, l'entité réductrice est entièrement sous la forme $H^{\bullet}$, tandis qu'en milieu neutre, la plus grande partie de celle-ci se trouve sous forme d'électrons hydratés. Toutefois, pour ce dernier milieu, il a été mesuré en plus un rendement relativement faible en atomes $H^{\bullet}$ (73).

E. Écriture de la réaction fondamentale

Un autre ensemble de résultats a posé de nouveaux problèmes. On s'est en effet aperçu que de l'hydrogène et de l'eau oxygénée pouvaient très souvent être formés lors de l'irradiation de solutions aqueuses diluées, en quantités variant avec la nature du rayonnement. Il a été admis que ces deux espèces proviennent de la combinaison des entités radicalaires : $^{\bullet}OH + {}^{\bullet}OH \rightarrow H_2O_2$, $H^{\bullet} + H^{\bullet} \rightarrow H_2$ ou plutôt $e^-_{aq} + e^-_{aq} \rightarrow H_2 + 2\ OH^-$. Ces rendements se sont avérés être indépendants, dans certaines limites, de la concentration du soluté, de sa nature et du débit de dose. On s'attendait pourtant à ce que les variations de ces paramètres déplacent les compétitions portant sur les réactions précédentes, et par conséquent agissent sur les rendements d'hydrogène et d'eau oxygénée. L'interprétation de ces résultats ne pouvait donc être faite sur des bases de cinétique homogène (74). Allen (75) a décrit qualitativement, dès 1948, un processus hétérogène[10] de la radiolyse des solutions aqueuses : *« ...the source of these products* (H_2 et H_2O_2) *is probably the small regions of high ionization density... which lie at the end of each electron track... Radicals formed in these little regions will react with one another to produce a certain yield of reaction products before they have a chance to get out into the solution and suffer reaction with the* (solutes) *»*.

Ainsi, selon ce modèle, les *« ...produits, soit radicalaires (OH et H), soit moléculaires (*H_2O_2 *et* H_2*), sont formés dans des sites privilégiés autour des grappes d'ionisations primaires et l'approximation d'Allen consiste à dire que ces sites sont suffisamment petits pour qu'en général, le soluté n'intervienne sensiblement pas dans cette formation, du moins pour un domaine de concentration assez large. Les vitesses d'apparition dans le milieu des espèces radicalaires et moléculaires seraient alors indépendantes du soluté... Après cette apparition les réactions secondaires avec le soluté auraient lieu dans l'ensemble de la solution d'une manière homogène et il serait possible de leur appliquer les règles classiques de calcul cinétique, notamment les équations d'état stationnaire pour les produits intermédiaires »* (77). Dans les années qui suivirent, l'interprétation d'Allen, comme nous le verrons, s'affirma quantitativement, tant par l'analyse de nouveaux résultats expérimentaux que par la description analytique de modèles théoriques.

On est donc amené à considérer que la radiolyse de l'eau ne conduit pas seulement à l'électron hydraté et au radical $^{\bullet}OH$, mais implique de plus une formation de H_2 et H_2O_2. Elle pourrait, dans ce cas, être représentée par la *réaction chimique* suivante (78, 79) :

$$[1] \qquad G_{-H_2O}\ H_2O \overset{100\ eV}{\rightsquigarrow} G_{H^{\bullet}}\ H^{\bullet} + G_{e^-_{aq}}\ e^-_{aq} + G_{H^+}\ H^+ + G_{^{\bullet}OH}\ {}^{\bullet}OH + G_{H_2}\ H_2 + G_{H_2O_2}\ H_2O_2$$

dans laquelle la notation G_S représente les rendements, dits *« rendements radicalaires et moléculaires »* (RRM), concernant la disparition ou la formation des espèces S considérées

[10]Mentionnons ici que certains auteurs (voir, par exemple, réf. 76) utilisent parfois, à ce propos, « nonhomogeneous » ou « inhomogeneous » comme traductions anglaises de *hétérogène*. Nous avons employé ici seulement le terme « hétérogène » pour ces deux vocables.

pour 100 eV absorbés dans la solution.[11] Bien entendu, ce n'est qu'à partir de 1962 que l'électron hydraté fut impliqué dans cette écriture. Les coefficients G_S sont reliés par les deux relations stœchiométriques suivantes, traduisant le bilan de charge et de masse de la réaction globale [1] :

$$[2] \qquad G_{e^-_{aq}} = G_{H^+}$$

$$[3] \qquad G_{e^-_{aq}} + G_{H^\bullet} + 2\,G_{H_2} = G_{^\bullet OH} + 2\,G_{H_2O_2} = G_{-H_2O}$$

Ils peuvent être calculés d'après les données expérimentales et apporter ainsi d'utiles indications sur la distribution spatio-temporelle des zones hétérogènes intervenant alors.[12]

L'ensemble des faits expérimentaux et théoriques que nous venons de décrire sont résumés dans le tableau 1.[13]

III. De la découverte de l'électron hydraté jusqu'à la fin du XX^{ème} siècle

La réaction [1] résume les conséquences de la radiolyse de l'eau à un stade considéré alors comme primaire. Dans la mesure où les hypothèses ayant conduit à cette réaction apparaissaient comme valables, les recherches se sont développées selon plusieurs directions que nous allons successivement envisager :

(*a*) Tout d'abord, la détermination des RRM a pu être réalisée vers la fin des années cinquante en utilisant les résultats expérimentaux disponibles à ce moment-là, et en particulier ceux concernant la radiolyse γ ou X de solutions diluées en milieu neutre.

(*b*) Il était évident que l'influence de la concentration du soluté réclamait d'être examinée en détail tant au point de vue théorique qu'expérimental, puisque l'interprétation d'une partie des phénomènes était basée, comme nous l'avons vu précédemment, sur l'intervention de processus cinétiques hétérogènes.

(*c*) La mise au point de modèles quantitatifs fut entreprise parallèlement afin de justifier théoriquement les valeurs précédentes.

(*d*) Les modèles établis pour la radiolyse γ ou X de l'eau et de ses solutions ont été étendus à des conditions expérimentales différentes : grands débits de dose, solutions acides et surtout rayonnements d'autre nature. En effet, nous avons vu que les toutes premières expériences de radiolyse utilisaient les rayons α. Depuis lors, les rayonnements à grande densité d'ionisation n'ont pas cessé d'être étudiés, d'autant plus que la construction d'accélérateurs a permis un grand développement de la gamme utilisable des pouvoirs d'arrêt. Ces recherches ont conduit à diverses ouvertures. En particulier, de tels rayonnements se sont avérés, dans certains cas, intéressants à utiliser en radiothérapie (voir, par exemple, réf. 81).

Nous allons examiner comment le développement des différents points qui viennent d'être évoqués a conduit à de nouveaux aspects de la radiolyse.

A. Détermination expérimentale des rendements radicalaires et moléculaires (RRM) : cas des rayons γ et X et des milieux neutres

Pour rendre quantitative et utilisable la réaction chimique [1], il faut déterminer les valeurs des coefficients impliqués, à savoir, trois rendements radicalaires et quatre moléculaires. Ces valeurs vérifiant les relations [2] et [3], il reste à établir entre elles quatre relations indépendantes.

Pour ce faire, parmi tous les résultats expérimentaux existants, nous pouvons utiliser, à titre d'exemple, les irradiations γ de solutions aqueuses d'ions formiate en milieu neutre et en la présence d'air dont il a déjà été question plus haut (voir sect. II-B). Les produits stables mesurés sont CO_2,

[11] La notation G_S est employée pour représenter le rendement « primaire » de l'espèce S, écrite en indice, c'est-à-dire le rendement qui est normalement mesuré après réactions complètes dans les zones hétérogènes et avant que cette espèce n'ait eu une opportunité de réagir en dehors de ces zones. Rappelons que l'écriture *G*(P) correspond, quant à elle, au rendement final mesuré du produit P (voir note 4 de bas de page). Le symbole ⇝ est utilisé pour signaler les réactions attribuées à l'absorption de radiations ionisantes.

[12] Une zone d'hétérogénéité radiolytique est un site privilégié pour lequel la concentration en diverses espèces (produits radicalaires et moléculaires et éventuellement solutés) est relativement élevée, de sorte que la probabilité que certaines d'entre elles réagissent les unes avec les autres est supérieure à cette même probabilité dans l'ensemble de la solution irradiée (voir, par exemple, réf. 76).

[13] Leur déroulement dans différents pays est raconté de façon détaillée dans la réf. 80.

© 1999 CNRC Canada

H_2O_2 et H_2. Leurs rendements expérimentaux sont représentés sous la forme $G(CO_2)$, $G(H_2O_2)$ et $G(H_2)$, notation évitant toute confusion avec les coefficients de la réaction [1].[11] Pour interpréter les résultats concernant la radiolyse de l'ion formiate en solution aqueuse diluée, le schéma de réaction suivant a été adopté (40) :

Les radicaux $^{\bullet}OH$ sont oxydants et forment le radical formyle $COO^{\bullet-}$:

$$HCOO^- + {}^{\bullet}OH \rightarrow COO^{\bullet-} + H_2O$$

Les atomes $H^{\bullet}$, l'électron hydraté et le radical $COO^{\bullet-}$ sont oxydés par l'oxygène O_2 en donnant le radical anion superoxyde $O_2^{\bullet-}$, forme basique du radical $HO_2^{\bullet}$:

$$H^{\bullet} + O_2 \rightarrow HO_2^{\bullet}$$

$$e^-_{aq} + O_2 \rightarrow O_2^{\bullet-}$$

$$COO^{\bullet-} + O_2 \rightarrow CO_2 + O_2^{\bullet-}$$

$$HO_2^{\bullet} \rightleftarrows H^+ + O_2^{\bullet-},\ pK_a = 4{,}8$$

Le radical $O_2^{\bullet-}$ disparaît par dismutation selon (82) :

$$O_2^{\bullet-} + HO_2^{\bullet} \xrightarrow{H^+} H_2O_2 + O_2$$

On sait que les radicaux libres réagissent en général très rapidement et ne s'accumulent pas. Ils sont à l'état quasi stationnaire, hypothèse émise très tôt puis vérifiée quantitativement lorsque l'aspect cinétique a été maîtrisé.

Le schéma ci-dessus conduit aux équations suivantes si on prend les valeurs expérimentales déterminées en 1954 par Hart (40) et données plus haut (voir sect. II-B), concernant des solutions 10^{-3} M en acide formique :[14]

$$G(H_2O_2) = G_{H_2O_2} + (\tfrac{1}{2})(G_{e^-_{aq}} + G_{{}^{\bullet}OH} + G_{H^{\bullet}}) = 3{,}42$$

$$G(CO_2) = G_{{}^{\bullet}OH} = 2{,}62$$

$$G(H_2) = G_{H_2} = 0{,}44$$

d'où, en tenant compte des relations de bilan [3],

$$G_{e^-_{aq}} + G_{H^{\bullet}} = G(H_2O_2) - G(H_2) = 2{,}98$$

$$G_{H_2O_2} = 0{,}62$$

Les rendements sont exprimés en moléc./100 eV. On a ainsi déterminé les valeurs des deux rendements moléculaires G_{H_2} et $G_{H_2O_2}$, du rendement radicalaire $G_{{}^{\bullet}OH}$ et de la somme $(G_{e^-_{aq}} + G_{H^{\bullet}})$. Dans ce cas, il n'est pas possible de calculer les rendements respectifs de l'électron hydraté et de l'atome $H^{\bullet}$ puisqu'ils jouent ici le même rôle chimique.

Les valeurs de $G_{e^-_{aq}}$ et de $G_{H^{\bullet}}$ peuvent être déduites de la radiolyse γ de solutions aqueuses de méthanol désaérées et saturées de protoxyde d'azote N_2O (voir, par exemple, réf. 83). En effet, N_2O est un capteur spécifique de e^-_{aq} et on a :

$$N_2O + e^-_{aq} \rightarrow N_2 + {}^{\bullet}OH + OH^-$$

$${}^{\bullet}OH + CH_3OH \rightarrow {}^{\bullet}CH_2OH + H_2O$$

$$H^{\bullet} + CH_3OH \rightarrow {}^{\bullet}CH_2OH + H_2$$

Le radical organique disparaît principalement selon les deux réactions :

$$2\ {}^{\bullet}CH_2OH \rightarrow (CH_2OH)_2 \rightarrow H_2CO + CH_3OH$$

pour former des produits stables, l'éthylène glycol et le formaldéhyde (voir, par exemple, réf. 84). Les rendements d'azote et d'hydrogène, mesurés pour des solutions 10^{-3} M en N_2O et 0,1 M en méthanol, sont donnés par les relations (83) :

$$G(N_2) = G_{e^-_{aq}} = 2{,}8$$

$$G(H_2) = G_{H_2} + G_{H^{\bullet}} = 1{,}05$$

ou

$$G_{e^-_{aq}} = 2{,}8 \text{ et } G_{H^{\bullet}} = 0{,}6$$

On a

$$G_{e^-_{aq}} + G_{H^{\bullet}} = 3{,}4$$

en accord approximatif avec la détermination précédente concernant l'acide formique.

Le tableau 2 donne des estimations plus récentes des RRM, obtenues d'après les résultats de la radiolyse par les rayons γ de ^{60}Co ou les rayons X de même énergie,[15] de diverses solutions aqueuses neutres et diluées. En tenant compte de ce tableau, on peut adopter, pour le milieu neutre et l'ensemble des solutés, les valeurs suivantes (exprimées en moléc./100 eV) :[16]

[4] $G_{e^-_{aq}} = 2{,}65$ $G_{H^{\bullet}} = 0{,}60$ $G_{H_2} = 0{,}45$
$G_{{}^{\bullet}OH} = 2{,}80$ $G_{H_2O_2} = 0{,}68$ $G_{-H_2O} = 4{,}15$

Le fait de trouver des valeurs à peu près identiques pour les RRM, quelle que soit la nature du soluté, est en faveur du modèle précédemment évoqué, modèle que nous allons détailler ci-dessous. Nous serons aidés en cela par l'étude expérimentale de l'influence de la concentration du soluté sur la validité de l'équation [1].

En effet, lorsque la concentration d'un bon capteur de e^-_{aq} ou de $^{\bullet}OH$ est augmentée au delà de certaines limites, les valeurs des rendements moléculaires correspondants (c'est-à-dire, G_{H_2} et $G_{H_2O_2}$) ne sont plus constants et diminuent (pour une série de références sur ces expériences, voir réfs. 91–93). Ce fait peut être, par exemple, mis en évidence par le tracé, pour divers solutés S, du rapport $G_{H_2}/(G_{H_2})^0$ en fonc-

[14]Mentionnons le fait que les valeurs de ces rendements augmentent sensiblement avec la concentration d'acide formique utilisée, dans la gamme allant de 10^{-4} à 1 M (réfs. 35 et 40). Un tel effet peut être attribué, en partie, à une capture plus efficace des radicaux libres et également à une modification du mécanisme de formation de H_2 lorsque la concentration en acide formique augmente.

[15]Rappelons que, pour la gamme habituelle d'énergie (typiquement, de l'ordre du MeV), les rayons γ ou X interagissent avec la matière essentiellement par l'intermédiaire des électrons Compton.

[16]Comme nous le verrons plus loin, ces valeurs représentent les rendements des espèces ~10^{-7} s après le dépôt primaire d'énergie, c'est-à-dire à une échelle de temps correspondant à leur homogénéisation par diffusion dans l'ensemble de la solution.

tion du logarithme du produit k_S[S], où $(G_{H_2})^0$ représente le rendement moléculaire d'hydrogène en l'absence de soluté, k_S la constante de vitesse de la réaction du soluté avec le radical réducteur (en M^{-1} s^{-1}) et [S] la concentration du soluté (en M). Ne disposant alors que de peu de données cinétiques expérimentales, Schwarz (91), dès 1955, a tracé en fait $G_{H_2}/(G_{H_2})^0$ en fonction de [X] = p[S], où p est un paramètre de normalisation caractéristique d'un soluté donné (p = 1 est choisi pour le soluté NO_2^-). Il a constaté que tous les points expérimentaux, après normalisation, se trouvaient sensiblement sur la *même* courbe (fig. 3). D'après l'analyse de cet auteur, les constantes de normalisation p doivent être égales aux rapports $k_S/k_{NO_2^-}$. Un tel résultat a amplement été confirmé par la suite et a justifié l'emploi extensif de cette représentation (voir, par exemple, réfs. 92–100).

Cette courbe, dite « courbe de Schwarz, » reflète le devenir du radical e^-_{aq}[17] en fonction de l'efficacité de sa capture par le soluté dans les zones hétérogènes. En résumé, ce destin consiste :

(*a*) soit à réagir avec lui-même ou avec les autres espèces radiolytiques présentes dans les zones hétérogènes;

(*b*) soit à réagir dans ces mêmes zones avec le soluté si la concentration de celui-ci est suffisamment grande;

(*c*) soit à diffuser dans la partie homogène.

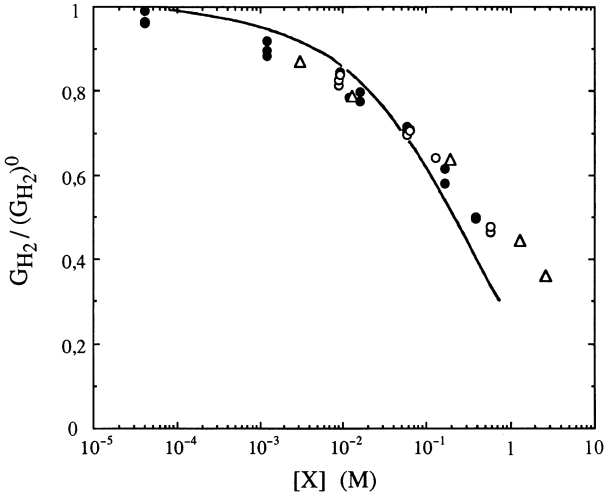
D'après la figure 3, concernant l'hydrogène, il apparaît que l'action des solutés dans les zones hétérogènes est négligeable pour les faibles concentrations de ceux-ci (inférieures à ~10^{-3} M pour les bons capteurs de e^-_{aq}). Mais on voit également que le rendement moléculaire en H_2 ne peut plus être considéré comme constant lorsqu'augmente cette concentration. Le soluté intervient alors à un stade plus primaire. Des résultats analogues ont été établis pour H_2O_2 en tant que produit moléculaire (voir, par exemple, réfs. 91, 92 et 94).

L'étude de l'influence de la concentration du soluté était à l'époque le seul moyen d'obtenir des données sur les stades alors assez méconnus précédant l'homogénéisation.

B. Élaboration de modèles diffusionnels

Les hétérogénéités ainsi mises expérimentalement en évidence proviennent de deux origines : d'une part, de la répartition des ionisations dans la solution et, d'autre part, de la réponse de la matière à ces ionisations. À partir des années cinquante, des modèles ont été développés pour décrire ces phénomènes, modèles d'abord simples, puis de plus en plus élaborés.

Fig. 3. Effet, sous l'influence des rayons γ de ^{60}Co et pour des solutions aqueuses désaérées, de la concentration du soluté S sur le rendement moléculaire en H_2, exprimé sous la forme $G_{H_2}/(G_{H_2})^0$, où $(G_{H_2})^0$ représente le rendement d'hydrogène en l'absence de soluté. [X] = p[S], où $p = k_S/k_{NO_2^-}$, $k_{NO_2^-}$ = 4,1 × 10^9 M^{-1} s^{-1} (réf. 86) et k_S sont respectivement les constantes de vitesse des réactions de e^-_{aq} avec NO_2^- et avec le soluté S, et [S] est la concentration du soluté. La courbe est théorique. D'après réf. 91.



Pour obtenir la distribution énergétique initiale des électrons libérés lors des actes successifs d'ionisation, les calculs ont utilisé le plus souvent la formule de Møller donnant la section efficace différentielle $d\sigma = \sigma(Q)\, dQ$ pour une collision électron–électron où le transfert d'énergie est compris entre Q et $Q + dQ$ (en unités SI) (101) :

$$[5] \qquad d\sigma = \left(\frac{1}{4\pi\varepsilon_0}\right)^2 \frac{2\pi e^4}{m_0 v^2}\; A(Q)\; \frac{dQ}{Q^2} \quad (\text{m}^2/\text{électron})$$

où v est la vitesse de l'électron incident, e sa charge et m_0 la masse de l'électron au repos. $A(Q)$ est une fonction de Q et de l'énergie de l'électron incident, qui varie peu autour de 1 comparativement à $1/Q^2$ pour des énergies inférieures à ~1 MeV. D'après cette formule, $\sigma(Q)$ peut donc être considérée comme inversement proportionnelle au carré de l'énergie échangée. On s'attend, par conséquent, à une grande population d'électrons libérés de faible énergie, ainsi qu'il sera précisé plus loin (voir sect. IV-A).

Afin de traduire l'hétérogénéité spatiale des dépôts d'énergie, Magee et al. (102) ont distingué trois classes selon les valeurs des énergies échangées, classes qu'ils ont intitulées : « *spurs* » (ou grappes) (<100 eV), « *blobs* » (ou gouttes) (~100 à 500 eV) et « *short tracks* » (ou trajectoires

[17]Rappelons toutefois que l'entité réductrice donnant naissance à H_2 était assimilée jusqu'à la découverte de l'électron hydraté en 1962 à l'atome d'hydrogène. Ceci n'enlève rien aux conclusions que l'on peut retirer de la figure 3.

© 1999 CNRC Canada

courtes) (~500 eV à 5 keV).[18] Moyennant certaines hypothèses, ces auteurs ont calculé la distribution de ces trois classes qui serait, dans le cas de l'eau liquide et pour un électron d'énergie initiale de 1 MeV, respectivement 67 %, 11 % et 22 %.[19]

Il a été ensuite nécessaire d'estimer quel était, dans ces conditions, le devenir des espèces radiolytiques sachant que leur répartition initiale est conditionnée par l'hétérogénéité des ionisations.

Signalons que Samuel et Magee (105) avaient envisagé, dès 1953, la diffusion des radicaux dans ces zones hétérogènes qu'ils avaient déjà nommées *« spurs »* et définies comme des entités sphériques évoluant indépendamment les unes des autres. Dans la plupart des modèles, la distribution des radicaux dans les zones hétérogènes était supposée initialement gaussienne et il était le plus souvent admis qu'elle le restait pendant toute la diffusion. Cette hypothèse fut dite de la « diffusion prescrite », ou « approximation de Jaffé » (91, 97–99, 105–110).

On était ainsi amené à un système d'équations aux dérivés partielles, non linéaires, de résolution difficile, qui s'écrivait, par exemple pour les deux radicaux $H^\bullet$ et $^\bullet OH$, sous la forme :

$$[6]\quad \begin{cases} \dfrac{\partial[^\bullet OH]}{\partial t} = D_{^\bullet OH}\nabla^2[^\bullet OH] \\ \qquad\qquad - 2k_{^\bullet OH + ^\bullet OH}[^\bullet OH]^2 - k_{H^\bullet + ^\bullet OH}[H^\bullet][^\bullet OH] \\ \dfrac{\partial[H^\bullet]}{\partial t} = D_{H^\bullet}\nabla^2[H^\bullet] \\ \qquad\qquad - 2k_{H^\bullet + H^\bullet}[H^\bullet]^2 - k_{^\bullet OH + H^\bullet}[^\bullet OH][H^\bullet] \end{cases}$$

équations dans lesquelles les concentrations radicalaires $[^\bullet OH]$ et $[H^\bullet]$ sont fonctions à la fois des coordonnées d'espace *x, y, z* et de temps *t*, ∇^2 est l'opérateur Laplacien, $D_{^\bullet OH}$ et $D_{H^\bullet}$ désignent les coefficients de diffusion des espèces $^\bullet OH$ et $H^\bullet$, et $k_{^\bullet OH + ^\bullet OH}$, $k_{^\bullet OH + H^\bullet}$ et $k_{H^\bullet + H^\bullet}$ représentent respectivement les constantes de vitesse des réactions :

$$^\bullet OH + {}^\bullet OH \rightarrow H_2O_2$$

$$^\bullet OH + H^\bullet \rightarrow H_2O$$

$$H^\bullet + H^\bullet \rightarrow H_2$$

Indépendamment, en 1955, Fricke (108), Magee (109), et plus particulièrement Schwarz (91), considérèrent, dans ce cadre, l'action d'un soluté S dans les zones hétérogènes, ce qui revient à introduire un terme supplémentaire de la forme $k_{H^\bullet + S}[H^\bullet]$ [S] ou $k_{^\bullet OH + S}[^\bullet OH]$ [S] dans les équations [6]. La figure 3 montre la courbe d'inhibition du rendement d'hydrogène moléculaire, ainsi calculée analytiquement par Schwarz (91). Par la suite, divers auteurs ont repris et développé ce modèle diffusionnel en mettant en oeuvre, pour sa résolution, l'emploi de méthodes numériques (97–99, 110–114). C'est ainsi que, par exemple, Flanders et Fricke (111), en 1958, furent les premiers à utiliser un ordinateur (*« high-speed electronic computer »*) pour résoudre une équation cinétique analogue aux équations [6] mais écrite pour un seul radical et un soluté. Leurs résultats sont très voisins de ceux obtenus de façon analytique. Le problème de l'appauvrissement en soluté des zones hétérogènes a également été abordé (112), mais la prise en compte d'un tel effet s'est avérée inutile, sa participation n'entraînant qu'une correction de l'ordre de 1 % sur la fraction des radicaux réagissant avec le soluté. D'autres travaux, de la même époque, et notamment ceux de Kuppermann et Belford (113), Mozumder et Magee (98), Kuppermann (99) et Schwarz (114), ont aussi justifié, par l'emploi de méthodes numériques plus élaborées, la validité des approximations impliquées dans les traitements analytiques utilisés antérieurement pour interpréter l'évolution des radicaux.

L'ensemble de ces travaux a permis d'affiner la comparaison des courbes expérimentales et théoriques, traduisant l'action de solutés dans les zones hétérogènes, et de confirmer ainsi les résultats obtenus initialement par Schwarz (91). L'accord est relativement bon, excepté pour les concentrations importantes du soluté (>0,1 M), concentrations pour lesquelles des mécanismes supplémentaires de formation de l'hydrogène difficile à inhiber ont été invoqués (115). D'autres auteurs, tels que Sowden (116) et Mahlman (117), ainsi que Peled et Czapski (100), ont rapporté des observations identiques. Ces résultats ont conduit à adopter pour l'hydrogène difficile à capter un rendement égal à 0,15–0,2 moléc./100 eV (114, 118, 119). Ce rendement est inclus dans la valeur G_{H_2} = 0,45, préconisée plus haut pour le rendement moléculaire d'hydrogène dans le cas d'irradiations avec les rayons γ de ^{60}Co (voir éq. [4]). L'origine d'un tel rendement n'est toutefois pas encore élucidée (voir, par exemple, réfs. 89 et 120; voir aussi sect. IV-A).

Comme nous allons le voir, de nombreux autres résultats concernant les modèles diffusionnels ont été décrits par la suite tant au point de vue expérimental que théorique, et l'application récente des méthodes de simulation Monte-Carlo a permis en particulier d'obtenir un panorama valable des conséquences de l'irradiation, par des rayonnements à ionisations diffuses, des solutions aqueuses diluées.

C. Influence de divers paramètres sur les RRM

La description donnée précédemment pour la radiolyse γ ou X de l'eau neutre et de ses solutions diluées demande à être étendue à des conditions expérimentales différentes : variation importante de concentrations, solutions acides et alcalines, grands débits de dose, utilisation d'autres types de rayonnements, milieux aérés, et influences de la température, de la nature de la phase et de la pression. C'est ce que nous allons maintenant examiner successivement.

1. Influence de la concentration du soluté

(a) Exceptions aux courbes de dilution : Ainsi que nous l'avons déjà mentionné, pour les solutions diluées, les

[18]Pour des échanges supérieurs à 5 keV, l'électron éjecté donne un embranchement (ou *« branch track »*) dont la trajectoire est traitée théoriquement, comme celle de l'électron primaire, en y comptabilisant les échanges des trois classes précédentes. Ces électrons « secondaires », d'énergie de recul importante, sont parfois appelés « rayons δ ».

[19]Des calculs récents, utilisant les techniques de simulation Monte-Carlo, ont donné, pour la répartition des pertes d'énergie sous forme de grappes, gouttes et trajectoires courtes, des valeurs correspondantes de 75 %, 12 % et 13 % (réf. 103) et de 52 %, 19 % et 29 % (réf. 104), en accord relatif avec les valeurs de Magee et al. (réf. 102).

© 1999 CNRC Canada

courbes donnant le rendement de disparition du soluté en fonction de la concentration de celui-ci aboutissent à un palier traduisant la capture complète des radicaux (voir sect. II-D). La figure 2 schématise cet « effet de dilution ».

Tel n'est pas toujours le cas. Par exemple, le rendement de réduction par les rayons γ de ^{60}Co de l'ion cérium IV en milieu H_2SO_4 0,4 M aéré est donné par (voir sect. II-B et réfs. 28, 30, 37 et 38) :

$$G(-Ce^{IV}) = 2\ G_{H_2O_2} + G_{H^\bullet} - G_{^\bullet OH} = 2{,}45 \text{ moléc./100 eV}^{20}$$

relation traduisant le mécanisme

[7] $H^\bullet + O_2 \rightarrow HO_2^\bullet$

[8] $HO_2^\bullet + Ce^{IV} \rightarrow H^+ + O_2 + Ce^{III}$

[9] $^\bullet OH + Ce^{III} \rightarrow OH^- + Ce^{IV}$

[10] $H_2O_2 + Ce^{IV} \rightarrow Ce^{III} + H^+ + HO_2^\bullet$

Or, en la présence d'air, le rendement de formation de H_2O_2 dans l'eau de même acidité mais en l'absence d'autres solutés, est égal à la moitié du rendement de disparition de Ce^{IV} :

$$G(H_2O_2) = G_{H_2O_2} + (1/2)(G_{H^\bullet} - G_{^\bullet OH}) = 1{,}2 \text{ moléc./100 eV}$$

par suite du mécanisme

[7] $H^\bullet + O_2 \rightarrow HO_2^\bullet$

[11] $^\bullet OH + H_2O_2 \rightarrow HO_2^\bullet + H_2O$

[12] $HO_2^\bullet + HO_2^\bullet \rightarrow H_2O_2 + O_2$

Ainsi que l'a signalé Sworski (37), le rendement de réduction de l'ion cérium IV sera le même, que la réduction se produise par les réactions [7]–[10] ou [7] et [10]–[12]. Cette dernière voie subsiste pour des concentrations très faibles en Ce^{IV} et on n'observe donc pas de courbe de dilution, telle que nous l'avons définie ci-dessus.[21]

Un exemple de nature différente est donné par les réactions en chaîne initiées par le rayonnement. Elles conduisent expérimentalement à des rendements de transformation du soluté souvent bien supérieurs à ceux calculables à partir des RRM. Un seul radical assure alors la transformation d'un nombre important de molécules du soluté. Tel est le cas de la peroxydation (voir, par exemple, réf. 121) de certains produits organiques ou biologiques (représentés par RH), réaction qui peut s'écrire globalement :

$$RH + O_2 \rightsquigarrow ROOH$$

Cette réaction en chaîne peut être déclenchée par des radicaux $^\bullet OH$ provenant de la radiolyse de l'eau. On est alors amené, par exemple, au schéma simplifié suivant :

[13] initiation : $^\bullet OH + RH \rightarrow H_2O + R^\bullet$

[14] propagation : $R^\bullet + O_2 \rightarrow RO_2^\bullet$

[15] $RO_2^\bullet + RH \xrightarrow{k_p} ROOH + R^\bullet$

[16] terminaison : $2\ RO_2^\bullet \xrightarrow{k_t}$ produits non radicalaires

Le calcul basé sur l'état quasi stationnaire en radicaux libres $^\bullet OH$, $R^\bullet$ et $RO_2^\bullet$ conduit à (122) :

$$[17] \quad G(-RH) = G_{^\bullet OH} + \frac{k_p}{\sqrt{2\,k_t}}\sqrt{\frac{G_{^\bullet OH}}{I}}\,[RH]_0$$

où I est le débit de dose (ou intensité d'irradiation), k_p et k_t représentent les constantes de vitesse des réactions [15] et [16], et $[RH]_0$ est la concentration initiale en solutés peroxydables. Un calcul analogue aurait permis d'obtenir le rendement en hydroperoxyde :

$$[18] \quad G(ROOH) = \frac{k_p}{\sqrt{2\,k_t}}\sqrt{\frac{G_{^\bullet OH}}{I}}\,[RH]_0$$

$G(-RH)$ et $G(ROOH)$ sont donc fonctions linéaires de la concentration en solutés, et dans ce cas l'effet de dilution n'est pas observé.

(b) Utilisations des courbes de dilution : Comme il apparaît figure 2, pour les solutions très diluées, la courbe de dilution peut être confondue avec sa tangente à l'origine. Le rendement est alors proportionnel à la concentration. Par conséquent, dans cette zone, pour une dose donnée, il disparaît le même pourcentage de soluté, quelle qu'en soit la concentration (122; voir aussi réf. 123). Ceci est à prendre en considération lors de la radiolyse des solutions extrêmement diluées, en particulier lorsqu'on étudie l'autoradiolyse d'un système en solution aqueuse. En effet, un soluté radioactif ou une molécule marquée à forte activité spécifique peut subir des transformations dues aux produits de la radiolyse de l'eau provoquée par son propre rayonnement.

En général, c'est dans la zone de 10^{-5} à 10^{-3} M que peuvent être utilement étudiés les mécanismes de radiolyse et donc les propriétés des radicaux. Cette zone correspond souvent à un palier expérimental traduisant une capture totale des radicaux dans la zone homogène et une action encore négligeable du soluté dans les zones hétérogènes. Si l'on augmente la concentration (jusqu'à ~1 M) de ce dernier, la quasi-totalité des produits moléculaires peut alors être inhibée. Par ailleurs, une partie de plus en plus importante de l'ionisation se fait directement sur le soluté lui-même. On a ainsi un mélange d'effets direct et indirect (voir sect. II-D). Nous allons maintenant étudier plus précisément les caractéristiques de l'effet direct.

(c) Effet direct : Pour pouvoir étudier l'effet direct sur un soluté, il faut que celui-ci soit en concentration relativement élevée, disons supérieure à ~1 M (voir, par exemple, réf. 124). C'est ainsi qu'ont été examinés à ce point de vue des solutés à haute solubilité dans l'eau, tels que les anions nitrate (125, 126), perchlorate (127), chlorure (128, 129) et iodure (130), ainsi que l'acide sulfurique (131). Certains effets directs peuvent également être étudiés en utilisant comme

[20] La marge d'erreur sur cette valeur est de ±0,1 moléc./100 eV (réf. 30).
[21] Les valeurs des RRM concernant la radiolyse de l'eau en milieu acide sont données plus loin (voir sect. III-C.2).

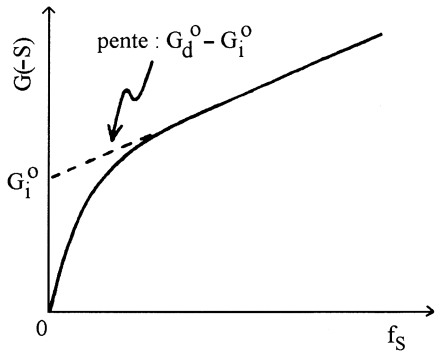
Fig. 4. Représentation schématique des effets direct et indirect. L'exemple présenté ici correspond au cas où $G_i^0 < G_d^0$. D'après réfs. 122 et 129.



soluté un liquide organique miscible à l'eau, tel que l'acide formique (132).

Les difficultés sont les suivantes :

(*i*) Les espèces formées lors de l'irradiation de solutions concentrées résultent tout à la fois de l'effet direct et de l'effet indirect. Ces deux effets peuvent ne pas être additifs par suite de compétitions impliquant des réactions entre les produits de radiolyse de l'eau et du soluté.

(*ii*) L'utilisation de solutés en très grande concentration introduit une modification profonde de la structure des solutions, qui peut se traduire en particulier par une variation de la constante diélectrique et une influence de la force ionique sur les vitesses de réaction.

Ce n'est pourtant que lorsque effet direct et effet indirect sont additifs que le rendement global de transformation du soluté S peut être exprimé par l'équation (122, 129) :

$$G(-S) = f_S\ G_d^0 + (1 - f_S)\ G_i^0\ \varphi([S])$$

f_S est ici le rapport entre l'énergie directement absorbée par le soluté et l'énergie totale absorbée par la solution, rapport sensiblement égal à la fraction électronique de S. G_d^0 est le rendement de l'effet direct exprimé en moléc./100 eV absorbés par le soluté. Ce rendement est supposé indépendant de la concentration de S. G_i^0 est le rendement maximal de l'effet indirect et dépend du mécanisme de réaction des produits primaires de radiolyse de l'eau avec S pour donner la transformation considérée. La fonction de la concentration $\varphi([S])$ varie entre 0 et 1 et exprime la fraction de ces produits primaires effectivement utilisée pour cette transformation.

Pour les plus grandes concentrations de S, $\varphi([S]) = 1$, et l'équation précédente se ramène alors à la relation linéaire :

$$G(-S) = G_i^0 + f_S(G_d^0 - G_i^0)$$

Par conséquent, si l'on trace la courbe donnant la valeur du rendement expérimental en fonction de f_S, on obtiendra une courbe asymptotique à cette droite. D'après l'ordonnée à l'origine et la pente de la droite, on peut obtenir G_i^0 et G_d^0 et estimer donc la part de l'effet direct et celle de l'effet indirect (fig. 4) (122, 125, 130).

(d) Cas des macromolécules biologiques : L'irradiation des macromolécules et tout particulièrement des biopolymères in vivo présente un aspect plus complexe que les cas précédemment décrits, consistant à distinguer effets direct et indirect. Tout d'abord, la matière biologique humaine est formée, pondéralement, de ~70 % d'eau, ce qui entraîne que les deux effets peuvent se produire simultanément et donner lieu à des actions non additives. De plus, dans le cas de l'ADN cellulaire, la radiolyse peut s'effectuer sur des molécules d'eau liées à celui-ci (133, 134) conduisant à un effet dit *« quasi direct »* (135–137), effet qui peut se ramener à l'un ou à l'autre des cas précédents.

Par ailleurs, l'ionisation est parfois suivie d'un phénomène de transfert de charge intramoléculaire qui intervient lors de l'irradiation de certaines protéines (138, 139) et de l'ADN (137, 139–141), et qui peut ainsi modifier profondément les transformations mises en jeu. C'est dès 1965 qu'un tel phénomène a été envisagé (142); il a donné lieu à diverses études dont certaines continuent à se développer activement.

2. Influence du pH

Dès 1950, de nombreuses expériences de radiolyse γ et X ont concerné les milieux aqueux acides. En fait, elles ont été développées avant celles se rapportant aux solutions neutres précédemment décrites. Comme on l'a déjà vu, l'acide le plus souvent utilisé était dans ce cas l'acide sulfurique en solution aqueuse 0,4 M. Pour les RRM, les valeurs déduites de l'étude d'un grand nombre de systèmes minéraux et organiques en milieu acide présentent un accord remarquable, confirmant l'interprétation émise par Allen (75) en 1948 et concernant l'existence des zones d'hétérogénéité. Le tableau 3 indique, à titre d'exemple, cinq séries de valeurs obtenues par différents auteurs. En tenant compte de ce tableau, nous adopterons, pour le milieu H_2SO_4 0,4 M, les rayons γ de ^{60}Co et l'ensemble des solutés, les valeurs suivantes (exprimées en moléc./100 eV) (122) :

$$[19]\quad \begin{aligned} &G_{e^-_{aq}} + G_{H^\bullet} = 3{,}70 \quad G_{H_2} = 0{,}40 \\ &G_{^\bullet OH} = 2{,}90 \quad G_{H_2O_2} = 0{,}80 \quad G_{-H_2O} = 4{,}50 \end{aligned}$$

L'hypothèse le plus souvent avancée pour interpréter l'influence de l'acidité sur les RRM consiste évidemment à supposer que les ions H^+ captent, à ces concentrations, une grande partie, voire la totalité, des électrons hydratés situés dans les zones hétérogènes, en produisant des atomes $H^\bullet$ par la réaction :

$$[20]\quad e^-_{aq} + H^+ \rightarrow H^\bullet$$

[b]Nous avons indiqué les rendements en entités oxydantes par les expressions $(G_{^\bullet OH} + G_{O^{\bullet-}})$ et $(G_{H_2O_2} + G_{HO_2^-})$, afin de tenir compte des formes basiques de $^\bullet OH$ (pK_a = 11,9) et de H_2O_2(pK_a = 11,7), sans toutefois que les rôles de $O^{\bullet-}$ et de HO_2^- soient ici précisés.

[c]Valeur interpolée.

[d]3 < pH < 13.

Le rendement de l'entité réductrice radicalaire est alors représenté, pour chaque pH, par la somme $(G_{e^-_{aq}} + G_{H^\bullet})$. Selon Hayon (146), ces électrons donneraient préférentiellement en milieu neutre une réaction de recombinaison avec $^\bullet OH$, formant de l'eau :

[21] $e^-_{aq} + {}^\bullet OH \rightarrow OH^-$

En milieu acide, ce processus serait défavorisé par le fait que les atomes $H^\bullet$ qui remplacent e^-_{aq} sont moins réactifs vis-à-vis des radicaux $^\bullet OH$. Ces derniers, ainsi « protégés » de l'action des électrons hydratés, entraîneraient une augmentation du rendement de décomposition de l'eau (146, 147), comme le montre l'expérience (79, 90, 92, 143–145; voir aussi réfs. 35, 41 et 148–151). La validité d'un tel mécanisme est confirmée par des calculs récents de simulation Monte-Carlo (152) qui montrent qu'en milieu neutre la réaction [21] se produit effectivement de façon prédominante. Ces processus tendent en milieu acide à augmenter $G_{^\bullet OH}$ et aussi $G_{H_2O_2}$ (voir éqs. [4] et [19]), par suite de la dimérisation des radicaux $^\bullet OH$. Le fait que e^-_{aq} soit ainsi transformé en atome $H^\bullet$ rend par conséquent l'entité réductrice moins réactive, ce qui augmente bien $(G_{e^-_{aq}} + G_{H^\bullet})$ et donc G_{-H_2O} puisque le rendement en H_2 n'est que très faiblement modifié (voir éqs. [4] et [19]).

Ces expériences ont été étendues en milieu alcalin à des pH allant jusqu'à 14 (35, 145, 147, 148, 150, 153–156). Les valeurs des RRM ainsi déterminées restent constantes entre pH 4 et 11. En milieu fortement alcalin, on a trouvé des valeurs assez dispersées (voir, par exemple, réf. 147 et tableau 4). Mentionnons un certain nombre d'auteurs (35, 150, 154) qui suggèrent que les RRM demeurent constants depuis la neutralité jusqu'aux pH les plus élevés étudiés. L'existence de telles dispersions dans les déterminations de ces rendements provient en partie du fait que seul un petit nombre de solutés peut être étudiée commodément en ces milieux (156).

Cette dispersion des résultats expérimentaux pour des pH basiques rend difficile leur interprétation quantitative. On peut toutefois supposer, par analogie avec le milieu acide, que l'ion OH^- intervient dans les zones hétérogènes pour donner probablement la réaction (153) :

$$^\bullet OH + OH^- \rightarrow O^{\bullet-} + H_2O$$

Cette réaction, en milieu suffisamment alcalin, consomme vraisemblablement la quasi-totalité des radicaux $^\bullet OH$. L'eau oxygénée proviendrait alors uniquement de la dismutation de l'anion $O^{\bullet-}$ selon

[22] $$O^{\bullet-} + O^{\bullet-} \xrightarrow{H_2O} HO_2^- + OH^-$$

La réaction [22], moins rapide que son homologue $^\bullet OH + {}^\bullet OH \rightarrow H_2O_2$ (157), conduirait à une diminution de $(G_{H_2O_2} + G_{HO_2^-})$ par rapport au milieu neutre, en accord avec la majorité des auteurs (145, 147, 153, 155). En ce qui concerne la somme des rendements radicalaires réducteurs $(G_{e^-_{aq}} + G_{H^\bullet})$, le fait de remplacer $^\bullet OH$ par $O^{\bullet-}$ défavoriserait probablement la réaction de recombinaison :

$$e^-_{aq} + O^{\bullet-} \xrightarrow{H_2O} 2OH^- \quad (k = 2{,}31\times10^{10}\ M^{-1}\ s^{-1})$$

bien que la différence de sa constante de vitesse avec celle de la réaction [21] (k = 3,02 × 10^{10} M^{-1} s^{-1}) soit relativement faible (158). On s'attendrait ainsi à une augmentation de $(G_{e^-_{aq}} + G_{H^\bullet})$. Quant à la somme $(G_{^\bullet OH} + G_{O^{\bullet-}})$, elle tendrait à croître, de façon concomitante avec la diminution annoncée plus haut de $(G_{H_2O_2} + G_{HO_2^-})$. G_{H_2} étant inchangé, le rendement de décomposition de l'eau augmenterait donc, puisque l'écriture des équations de bilan :

$$G_{-H_2O} = (G_{e^-_{aq}} + G_{H^\bullet}) + 2\,G_{H_2}$$
$$= (G_{^\bullet OH} + G_{O^{\bullet-}}) + 2\,(G_{H_2O_2} + G_{HO_2^-})$$

doit être satisfaite. De tels résultats ne sont pas en contradiction avec les données expérimentales de Hayon (145) et de Haïssinsky (147).

Malheureusement, en milieu alcalin, les radicaux $O^{\bullet-}$ pourraient donner des réactions supplémentaires, notamment avec les solutés présents, soit pour capter les radicaux, soit pour ajuster le pH. Ceci expliquerait les divergences constatées entre certains auteurs, la nature de leurs solutions étant différentes.

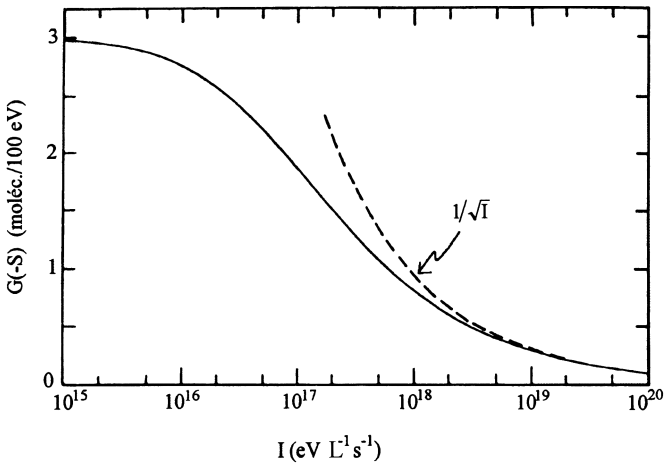
Bien que le problème de l'influence de l'acidité ne soit pas encore totalement résolu, on voit que des interprétations peuvent être envisagées. Toutefois, des données expérimentales supplémentaires apparaissent nécessaires, afin de préciser en particulier, de façon définitive, la valeur des RRM en milieux alcalins et d'estimer quantitativement l'influence des divers paramètres intervenant. Les méthodes de simulation Monte-Carlo pourraient, à ce point de vue, apporter d'utiles renseignements.

3. Influence du débit de dose

Une influence du débit de dose est observée, en particulier, chaque fois qu'une réaction du premier ordre en radical est en compétition avec une réaction du deuxième ordre de

© 1999 CNRC Canada

Fig. 5. Variation de $G(-S)$ en fonction du débit de dose I, calculée à partir de l'équation [23] pour la série de données indiquée dans le texte (courbe en trait continu). La courbe en tirets représente la loi asymptotique en $1/\sqrt{I}$ obtenue d'après l'équation [24] pour des débits de dose suffisamment élevés.



ce même radical (voir, par exemple, réf. 159). Un cas simple peut être traité, si l'on imagine, pour le radical $R^{\bullet}$ et un soluté S, les réactions suivantes :

$$R^{\bullet} + S \xrightarrow{k_1} \text{produit supposé non réagissant dans le système étudié}$$

$$R^{\bullet} + R^{\bullet} \xrightarrow{k_2} R_2$$

En écrivant l'état quasi stationnaire pour les radicaux $R^{\bullet}$, on obtient la relation suivante exprimant le rendement initial de disparition du soluté $G(-S)$:

$$[23] \qquad G(-S) = \left(\frac{k_1^{\,2}\,[S]_0^{\,2}}{4\,k_2\,I}\right)\left[\sqrt{1+\frac{8\,k_2\,I\,G_{R^{\bullet}}}{k_1^{\,2}\,[S]_0^{\,2}}}-1\right]$$

où k_1 et k_2 représentent les constantes de vitesse des deux réactions précédentes, $G_{R^{\bullet}}$ le rendement en radicaux $R^{\bullet}$, $[S]_0$ la concentration initiale du soluté et I le débit de dose (intensité d'irradiation). On voit que, dans ce cas, l'expression de $G(-S)$ est fonction de I.

Un exemple numérique peut être donné en prenant la série de valeurs : $k_1 = 10^6\ M^{-1}\ s^{-1}$, $k_2 = 10^{10}\ M^{-1}\ s^{-1}$, $G_{R^{\bullet}} = 3$ moléc./100 eV et $[S]_0 = 10^{-5}$ M. La figure 5 représente la variation de $G(-S)$ avec I (exprimé en eV $L^{-1}\ s^{-1}$) dans une échelle semi-logarithmique, telle qu'obtenue à partir de la relation [23] et des données précédentes. Il apparaît sur la figure que, pour les faibles valeurs de I, $G(-S)$ tend vers la valeur $G_{R^{\bullet}}$, indépendante de I; ce rendement diminue ensuite jusqu'à zéro en suivant, pour les débits de dose plus élevés, une loi asymptotique en $1/\sqrt{I}$:

$$[24] \qquad G(-S) \approx \sqrt{\frac{k_1^{\,2}\,[S]_0^{\,2}\,G_{R^{\bullet}}}{2\,k_2\,I}}$$

Des mécanismes analogues se retrouvent dans le cas des courbes de dilution. Une courbe de dilution, nous l'avons vu (voir sect. II-D), traduit le plus souvent des compétitions entre des réactions du soluté et des réactions biradicalaires; son allure est donc fonction de I, le palier étant atteint pour des concentrations d'autant plus faibles que I est faible. Ce n'est que quand tous les radicaux sont captés par le soluté que le rendement de transformation de celui-ci devient indépendant, dans de très larges limites, de I.

Un cas analogue se produit lors des réactions en chaîne telles que celles citées précédemment (voir sect. III-C.1-a), et pour lesquelles nous avons établi une dépendance du rendement en hydroperoxyde $G(ROOH)$ en $1/\sqrt{I}$ (voir éq. [18]). La chaîne est d'autant plus longue que le débit de dose est faible, puisque la réaction de terminaison est biradicalaire.

Lorsque le débit de dose atteint de très grandes valeurs (disons supérieures à 10^{25} eV $L^{-1}\ s^{-1}$), les zones d'hétérogénéité se recoupent dans l'ensemble de la solution irradiée, favorisant ainsi la formation de produits moléculaires qui survient alors de façon quasi homogène. Cette formation ne sera inhibée par le soluté que si celui-ci est en grande concentration. Pour les faibles concentrations, seuls réagiront avec le soluté les produits moléculaires formés, c'est-à-dire l'eau oxygénée (H_2 étant peu réactif). Les valeurs des RRM sont donc modifiées et ne doivent pas être confondues avec celles de la radiolyse γ classique (160).

À titre d'exemple, avec des débits de dose exceptionnellement élevés, Muller et al. (160) ont utilisé successivement comme capteurs de H_2O_2 les ions ferreux et le cérium IV. Le débit de dose était de 5×10^{30} eV $L^{-1}\ s^{-1}$ ($\sim 10^{12}$ Gy s^{-1}) pour une impulsion d'électrons de 2 MeV d'une durée de 50 ns. Pour de faibles concentrations en capteurs (10^{-3} M) et en milieu H_2SO_4 0,4 M désaéré, ces auteurs trouvent que :

$$G(Fe^{3+}) = G(Ce^{III}) = 2\,G(H_2O_2) = 1{,}4 \text{ moléc./100 eV}$$

L'égalité de ces trois rendements prouve que l'eau oxygénée est le seul produit réagissant. Pour des concentrations plus élevées, le calcul montre que $G(Fe^{3+})$ tend vers 4,6 moléc./100 eV, valeur résultant de la capture des radicaux $^{\bullet}OH$ par les ions ferreux dans les zones hétérogènes (160). Entre ces deux extrêmes, l'influence de la concentration en Fe^{2+} s'effectue selon les lois de compétition homogène.

Le fait de produire par radiolyse pulsée à haute intensité des concentrations homogènes d'eau oxygénée ($\sim 10^{-4}$ M) en quelques microsecondes permet d'étudier la physionomie cinétique de cette molécule dans des délais très brefs, ce qui constitue une application originale de cette méthode. C'est ainsi qu'on a pu mesurer directement la constante de vitesse de la réaction $H_2O_2 + VO_2^{+} \rightarrow VO_3^{+} + H_2O$, égale à $5{,}7 \times 10^3\ M^{-1}\ s^{-1}$ en milieu H_2SO_4 0,4 M (161).

Un problème important doit attirer l'attention : lorsqu'on réalise des simulations expérimentales d'irradiation, comme par exemple, le stockage de déchets radioactifs, le débit de dose est un paramètre dont les influences doivent être étudiées à la lumière des deux possibilités d'intervention précédentes.

Un travail réalisé par Fanning et al. (162), dans une perspective différente, a consisté à étudier, par radiolyse pulsée, l'influence de l'intensité d'irradiation sur l'évolution dans l'eau pure de l'électron hydraté. La gamme des doses étudiée allait jusqu'à 80 Gy pour des impulsions d'électrons de 20 ns. Il est apparu que la fraction de e^{-}_{aq} disparaissant à un temps donné dépend, à partir d'un certain seuil, de la dose délivrée par impulsion. Un tel seuil a été interprété

[c]Voir aussi réf. 168.

comme résultant d'un recoupement des zones hétérogènes. À partir des données ci-dessus, les auteurs (118, 162) ont pu obtenir certaines informations concernant la dimension des zones d'hétérogénéité et la distribution spatiale des électrons hydratés à l'intérieur de celles-ci.

4. Influence de la nature et de l'énergie du rayonnement

Nous avons vu que les premières expériences concernant la radiolyse de l'eau pure (1902–1914) ont été effectuées en employant comme sources surtout des émetteurs α, principalement le polonium 210 (voir sect. II-A et tableau 1). De tels émetteurs ont continué à être utilisés dans les travaux qui suivirent l'interruption due à la première guerre mondiale, développant ainsi l'aspect quantitatif de cette radiolyse (voir, par exemple, réfs. 27, 77 et 163–169). On s'est alors aperçu que les effets chimiques des rayons α étaient différents de ceux des rayons β^-, γ ou X, puisque, en l'absence d'air, ces derniers ne conduisaient pas, pour les doses habituelles, à une production mesurable de H_2O_2 et de H_2, tandis que ces deux produits s'accumulaient dans le cas des rayons α (170; voir aussi sect. II-A).

Ce résultat, ainsi que ceux concernant des irradiations utilisant d'autres types de rayonnements à ionisations denses, ont été considérés au début comme traduisant une différence de mécanismes, alors qu'ils provenaient en fait d'une différence dans les vitesses initiales de formation de H_2O_2 et de H_2. De même, les rendements de divers solutés irradiés en solutions aqueuses dans les mêmes conditions se sont avérés profondément distincts de ceux obtenus avec les rayons γ ou X. Le tableau 5 indique, à titre d'exemple et pour les rayons α, les rendements pour deux systèmes oxydo-réducteurs bien étudiés : Fe^{3+}/Fe^{2+} et Ce^{IV}/Ce^{III}. Soulignons néanmoins que, pour certains solutés, la dispersion des résultats expérimentaux, et donc des déterminations des valeurs des RRM à transfert d'énergie linéique élevé, est importante (30, 168; voir aussi réf. 171).

Cette influence de la nature du rayonnement provient en général du fait que, pour les rayonnements à ionisations denses, les rendements des produits moléculaires H_2O_2 et H_2 sont supérieurs à ceux mesurés pour les rayons γ, tandis que le contraire est constaté pour les produits radicalaires. C'est ainsi qu'en milieu aéré, le rapport $G(Fe^{3+})/G(Ce^{III})$ décroît, passant de 6,5 pour les rayons γ à environ 2 pour les rayons α émis par ^{210}Po (122). En effet, d'après leur schéma réactionnel, le rendement des ions ferriques en milieu H_2SO_4 0,4 M aéré soumis à l'action des rayons γ de ^{60}Co, $G(Fe^{3+}) = 2\,G_{H_2O_2} + G_{\bullet OH} + 3\,G_{H\bullet} = 15{,}6$ moléc./100 eV (voir sect. II-B et réf. 122), est très sensible à la valeur des rendements radicalaires. Au contraire, le rendement en cérium III, $G(Ce^{III}) = 2\,G_{H_2O_2} + G_{H\bullet} - G_{\bullet OH} = 2{,}45$ moléc./100 eV (voir sect. II-B et réf. 122), dépend, dans les mêmes conditions, principalement du rendement moléculaire en H_2O_2. Ces caractéristiques ont été attribuées à une hétérogénéité particulière intervenant au niveau des phénomènes primaires et due au recoupement des zones d'hétérogénéité déjà décrites (voir plus haut). Le paramètre choisi pour refléter cette hétérogénéité est le TEL, « transfert d'énergie linéique » ou « pouvoir d'arrêt » ($-dE/dx$) (172), traduisant la densité des actes primaires, ionisations et excitations, le long de chaque trajectoire. Le tableau 6 donne, à titre d'exemple, quelques valeurs de TEL dans l'eau pour diverses particules énergétiques.

Tableau 6. TEL,[a] pour l'eau, de différents types de rayonnement.

Rayonnement	TEL	Références
Rayons γ[b] de ^{60}Co	0,2–0,3	172, 173
Protons ($^1H^+$) de 100 MeV	0,65	173
Rayons β^- de 5,7 keV (^{3}H)	0,65	173
Rayons X[b] de 220 kV	0,7	173
Protons de 10 MeV	4,7	159
Deutons ($^2H^+$) de 18 MeV	5,2	92, 143
Hélions ($^4He^{2+}$) de 32 MeV	22,5	92, 143
Protons de 1 MeV	28	159
Ions $^{12}C^{6+}$ de 900 MeV	30	174
Protons de 100 keV	75	175
Rayons α de 5,3 MeV (^{210}Po)	92	176, 177
Rayons α de 1,5 MeV ($^{10}B(n,\alpha)^7Li$)	220	177

Ions $^{12}C^{6+}$ de 25 MeV	520	179
Ions $^{58}Ni^c$ de 40 MeV	5200	180, 181
Ions $^{238}U^c$ de 1250 MeV	17 000	181

[a]Valeurs « initiales », exprimées en keV/μm (voir, par exemple, réf. 168).

[b]Soulignons qu'il s'agit en fait du TEL des électrons éjectés lors de l'absorption du rayonnement γ ou X.

[c]Partiellement « épluchés ».

Les études précédentes ont été ainsi étendues, au fur et à mesure, à différents types de rayonnements. Citons les rayons α et les noyaux de lithium de recul de la réaction $^{10}B(n,\alpha)^7Li$ (voir, par exemple, réf. 182), les rayons β^- du tritium[22] en utilisant l'eau tritiée (40, 183, 184) et surtout les faisceaux d'ions accélérés. Il peut s'agir, par exemple, de protons d'énergie pouvant être inférieure à 600 keV (185), ou encore d'ions lourds énergétiques (179–181, 186, 187) ayant perdu (entièrement ou partiellement) leurs électrons et caractérisés alors par des valeurs de TEL élevées (voir tableau 6). Ainsi, pour les ions d'uranium 238, « épluchés » à un état de charge de +35 et accélérés à une énergie de 1250 MeV, le TEL obtenu est de 17 000 keV/μm (181). Par ailleurs, le rendement en radicaux $^{\bullet}OH$ a pu être mesuré en fonction du TEL à l'aide de divers capteurs (fig. 6) (187). Quant à l'électron hydraté (fig. 7), son rendement a été obtenu grâce à l'emploi de faisceaux pulsés de protons, de deutons et d'hélions (188–190).

[22]Rappelons que l'énergie maximale du spectre des rayons β^- du tritium (^{3}H ou T) est de 18,6 keV, avec une énergie moyenne de 5,7 keV.

© 1999 CNRC Canada

Fig. 6. Rendement en radicaux •OH (exprimé en moléc./100 eV) en fonction du TEL lors de la radiolyse de l'eau. D'après réf. 187.

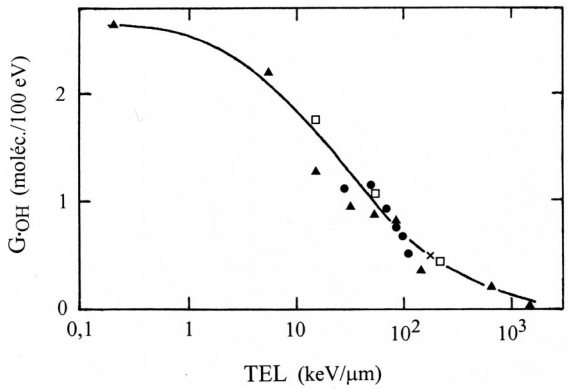

Fig. 7. Rendement en électrons hydratés (exprimé en moléc./100 eV) en fonction du TEL lors de la radiolyse pulsée (~10 μs) de l'eau à pH 7 par hélions (●) et par deutons (○). Les courbes sont théoriques. D'après réfs. 188 et 190.

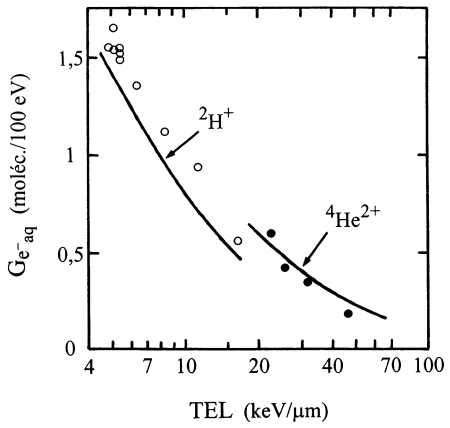


L'expérience a montré qu'il ne fallait pas se contenter de décalquer le modèle appliqué au cas des rayons γ, mais qu'on devait prendre en considération un rendement radicalaire G_{HO_2}•, même en l'absence d'oxygène. Ce rendement peut être révélé par le dégagement d'oxygène associé à la radiolyse de solutions acides Fe^{2+}/Cu^{2+}, dont le mécanisme est le suivant (191, 192) :

$$Fe^{2+} + {}^{\bullet}OH \rightarrow Fe^{3+} + OH^-$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$$

$$Cu^{2+} + H^{\bullet} \rightarrow Cu^{+} + H^{+}$$

$$Cu^{2+} + HO_2^{\bullet} \rightarrow Cu^{+} + H^{+} + O_2$$

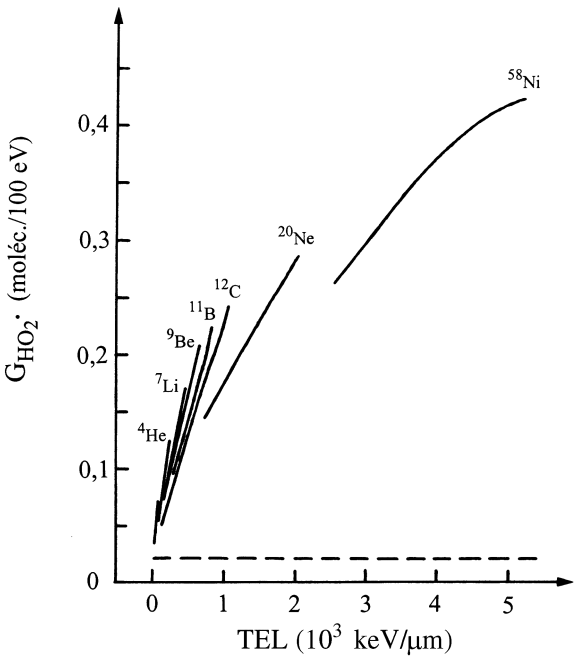
$$Cu^{+} + Fe^{3+} \rightarrow Cu^{2+} + Fe^{2+}$$

Par conséquent,

$$G(O_2) = G_{HO_2}\bullet$$

On avait ainsi observé, dès 1955, pour les faibles TEL (~0,2 keV/μm), un très petit rendement G_{HO_2}• = 0,02 moléc./100 eV (191). Il a été constaté que ce rendement augmentait avec le TEL (178–180, 187, 188, 192–195), atteignant une valeur de 0,43 moléc./100 eV pour des ions

Fig. 8. Rendements différentiels en $HO_2^{\bullet}$ en fonction du TEL pour différents ions accélérés. La ligne en tirets donne le rendement limite (0,02 moléc./100 eV) obtenu avec des électrons rapides. D'après réf. 180.



^{58}Ni de TEL égal à 5200 keV/μm (180). Ces résultats sont résumés figure 8, d'après LaVerne et Schuler (180).

Le premier modèle appliqué pour interpréter l'ensemble des résultats concernant l'influence du TEL fut celui, simpliste, du « collier de perles » (*« string of beads »*) (105, 110, 196) proposé dès 1953 pour décrire la distribution des zones hétérogènes le long des trajectoires des particules ionisantes. Bien que conduisant à des estimations géométriques vraisemblables, il fut vite abandonné.

On fut ensuite amené à supposer (40, 77, 167, 168, 191, 192, 197) que la grande densité des produits radiolytiques dans les trajectoires entraînait dans une zone périphérique les réactions suivantes entre radicaux et produits moléculaires :

[*a*] $${}^{\bullet}OH + H_2O_2 \rightarrow HO_2^{\bullet} + H_2O$$

[*b*] $${}^{\bullet}OH + H_2 \rightarrow H_2O + H^{\bullet}$$

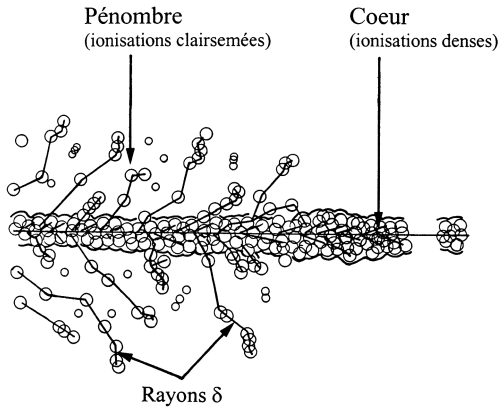
[*c*] $$H^{\bullet} + H_2O_2 \rightarrow H_2O + {}^{\bullet}OH$$

ce qui explique tout à la fois la possibilité de formation de $HO_2^{\bullet}$ en l'absence d'air, la complexité de l'action des solutés qui, selon leur comportement cinétique, peuvent ou non interférer avec ces réactions à l'intérieur de la trajectoire, et enfin le fait que le TEL ne suffit pas à appréhender l'ensemble des phénomènes.

La description spatiale impliquée dans le mécanisme précédent a conduit à envisager au sein d'une même trajectoire deux zones coaxiales (196) (fig. 9) : (*i*) l'une, le « coeur », de forte densité en événements, où s'élaborent les produits moléculaires H_2 et H_2O_2; (*ii*) l'autre est une zone annulaire, dite « pénombre », où s'absorbent les électrons secondaires qui y forment majoritairement des produits radicalaires.

© 1999 CNRC Canada

Fig. 9. Représentation de la trajectoire d'une particule lourde chargée. D'après réf. 198.



C'est donc le spectre de TEL qui définira mieux la radiolyse, spectre prenant en compte non seulement la trajectoire de la particule incidente, mais aussi celle des électrons éjectés avec suffisamment d'énergie.

Au cours de la diffusion, les réactions [*a*], [*b*] et [*c*] ont lieu dans la pénombre sauf si le soluté est trop concentré ou trop réactif avec les espèces intervenant. Pour les TEL pas trop élevés, la réaction [*a*] serait responsable de la formation de $HO_2^{\bullet}$, ou d'une partie de celle-ci, ainsi qu'il a été déjà proposé (191, 192). Pour les TEL élevés, il semble que la participation de la réaction [*a*] soit insuffisante pour expliquer, à elle seule, le rendement de $HO_2^{\bullet}$. Il est donc apparu nécessaire de faire intervenir d'autres mécanismes de formation de ce radical, tels que, par exemple, la production d'un atome d'oxygène susceptible de réagir avec $^{\bullet}OH$ (99, 194; voir aussi réf. 179), ou encore l'intervention d'ions de l'eau multichargés (199–202). Des calculs de simulation Monte-Carlo, développés récemment à partir des considérations précédentes, donnent des résultats encourageants (203).

Le problème de la radiolyse à haut TEL n'est toutefois pas encore pleinement résolu, mais l'intérêt de ses applications radiobiologiques incitent à en développer une meilleure compréhension.

5. Influence de la présence d'oxygène

(a) Introduction : Nous avons vu l'intérêt que présente l'étude de la radiolyse de solutions diluées. Elle permet en effet de caractériser, non seulement les espèces, radicalaires ou non, formées par radiolyse du solvant, mais aussi celles provenant de l'action de ces intermédiaires sur le soluté. La radiolyse de solutions d'oxygène est particulièrement riche en renseignements utiles et originaux. En effet, l'oxygène joue des rôles fondamentaux en biologie et en radiobiologie. Sa chimie concerne principalement les échanges d'électrons, et l'étude de la radiolyse des solutions aérées a développé considérablement nos connaissances concernant la chimie radicalaire de cet élément.

(b) Actions de l'oxygène sur la radiolyse de solutions diluées : Ce gaz est soluble dans de nombreux milieux et en particulier dans l'eau, c'est donc un vecteur d'oxydoréduction quasi universel. Si on ne prend pas de précautions particulières, la cible irradiée contient de l'oxygène. Par exemple, la concentration de celui-ci dans l'eau équilibrée avec l'air à pression atmosphérique et température ambiante est ~2,5 × 10^{-4} M.[23] Ceci indique qu'un soluté, bon capteur de O_2 ($k \sim 10^{10}$ M^{-1} s^{-1}, par exemple), en concentration suffisante, réagit dans ce milieu avec un temps de réaction de quelques microsecondes, permettant de développer certaines compétitions dans cette échelle de temps (205).

Tableau 7. Influence de l'oxygène sur les rendements[a] de radiolyse de divers solutés en solutions aqueuses irradiées par les rayons γ de ^{60}Co.

	G(–S)		
Soluté (S)	O_2 absent	O_2 présent	Références
Fe^{2+}	8,15[b]	15,6[b]	30
As^{III}	1,8[c]	3,5[c]	30
Ce^{IV}	2,45[b]	2,45[b]	28, 30, 37
Acide formique	3,2	2,6	40, 206
Éthanol	5,1	2,3	206

[a]Exprimés en moléc./100 eV.
[b]En solution aqueuse H_2SO_4 0,4 M.
[c]pH 2,5.

L'influence de l'oxygène, en radiolyse, a été rapidement mise en évidence. Ainsi, comme nous l'avons vu, le rendement d'oxydation des ions ferreux en solution aqueuse H_2SO_4 0,4 M, pour les rayons γ de ^{60}Co, est 15,6 moléc./100 eV en présence d'air et 8,15 en son absence (voir sects. II-B et III-C.4 et tableau 5) (30, 122). Le tableau 7 donne quelques exemples concernant les effets de O_2 en radiolyse. Le plus souvent, celui-ci augmente les rendements d'oxydation du soluté, mais il peut parfois les diminuer en jouant un rôle protecteur comme dans le cas de l'acide formique (40, 206) et de l'éthanol (206). Dans certains cas, les rendements (par exemple, pour Ce^{IV}) ne sont pas modifiés par la présence d'oxygène (28, 30, 37).

(c) Réactions gouvernant la radiolyse des solutions aérées :

La chimie de l'oxygène se caractérise par le fait qu'il peut échanger quatre électrons. La réaction globale :

[25] $O_2 + 4\ e^- + 4\ H^+ \rightarrow 2\ H_2O$

s'effectue souvent avec formation des intermédiaires suivants, dont deux sont radicalaires :

[26] $O_2 \rightarrow O_2^{\bullet -} \rightarrow H_2O_2 \rightarrow {}^{\bullet}OH \rightarrow H_2O$

Les potentiels de réduction des couples mis en jeu ont les valeurs suivantes, exprimées en volts, à pH 7 et 25°C, par rapport au potentiel standard d'électrode à hydrogène (207; voir aussi sect. IV-C.2) :

$O_2/O_2^{\bullet -}$ $E^{\circ\prime} = -0{,}33$ V

$O_2^{\bullet -}/H_2O_2$ $E^{\circ\prime} = 0{,}94$ V

$H_2O_2/{}^{\bullet}OH$ $E^{\circ\prime} = 0{,}46$ V

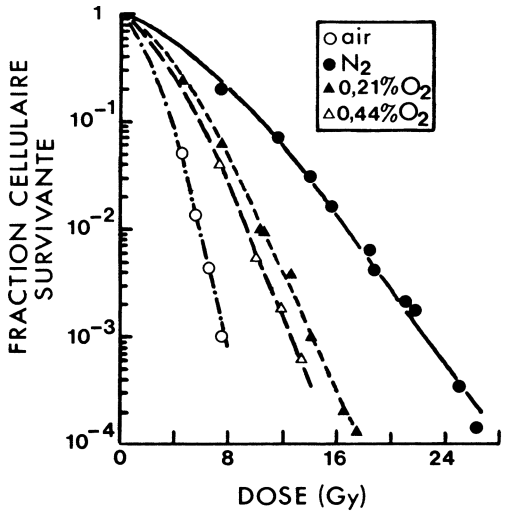
${}^{\bullet}OH/H_2O$ $E^{\circ\prime} = 2{,}18$ V

tandis qu'à pH 0, ils ont les valeurs (207) :

[23]La concentration d'une solution aqueuse saturée en oxygène, à température ambiante, est donc de $[O_2] \sim 1{,}25 \times 10^{-3}$ M (voir, par exemple, réf. 204).

© 1999 CNRC Canada

Fig. 10. Exemple de courbes de survie. D'après réf. 214.



$O_2/HO_2^{\bullet}$	$E° = -0{,}05$ V
$HO_2^{\bullet}/H_2O_2$	$E° = 1{,}48$ V
$H_2O_2/^{\bullet}OH$	$E° = 0{,}87$ V
$^{\bullet}OH/H_2O$	$E° = 2{,}59$ V

Voyons, à titre d'exemple, le mécanisme mis en jeu dans le cas de la radiooxydation des ions ferreux en solution diluée aqueuse acide en l'absence ou en la présence d'air. En l'absence d'air, le rôle oxydant est joué par l'atome H. La séquence, impliquant une telle radiooxydation,

$$H^+ + H^{\bullet} + Fe^{2+} \rightarrow H_2 + Fe^{3+}$$

$$^{\bullet}OH + Fe^{2+} \rightarrow OH^- + Fe^{3+}$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + {}^{\bullet}OH + OH^-$$

conduit à la réaction endergonique globale :

$$2\ H^+ + 2\ Fe^{2+} \rightarrow H_2 + 2\ Fe^{3+}$$

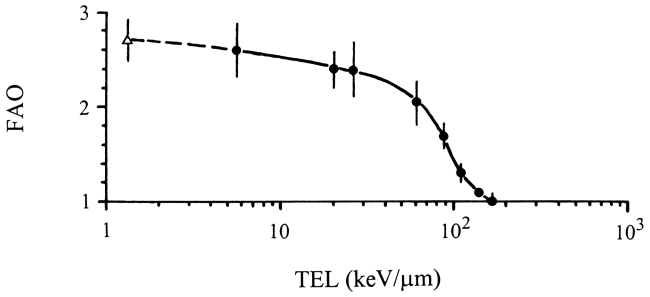
Cette réaction n'est pas thermodynamiquement possible de manière spontanée car le potentiel du couple mettant en jeu l'oxydant (H^+/H_2, $E° = 0$) est inférieur à celui du couple contenant le réducteur (Fe^{3+}/Fe^{2+}, $E° = 0{,}77$ V). Elle demande, dans les conditions standard, 1,54 eV (~148,6 kJ/mol), énergie qui est fournie dans ce cas par les espèces réactives formées par la radiolyse de l'eau (208).

En la présence d'air, les atomes $H^{\bullet}$ oxydants sont transformés en $HO_2^{\bullet}$ qui oxydent trois ions ferreux, ce qui conduit à la réaction globale (208) :

$$O_2 + 4\ H^+ + 4\ Fe^{2+} \rightarrow 2\ H_2O + 4\ Fe^{3+}$$

Cette réaction est responsable de ~71 % de la radiooxydation des ions Fe^{2+} en milieu aéré, le complément étant dû à l'action des radicaux $^{\bullet}OH$ et de H_2O_2. Elle diffère profondément de la précédente car elle dégage de l'énergie (1,84 eV en valeur absolue, soit ~177,5 kilojoules par mole d'oxygène consommée). Néanmoins, par suite de l'obstacle présenté par la faible valeur du potentiel $O_2/HO_2^{\bullet}$, elle ne se produit pas spontanément. Le pouvoir oxydant de l'oxygène est, en revanche, libéré par l'intervention des espèces transitoires produites par le rayonnement, celui-ci jouant ainsi le rôle de catalyseur de la réaction. Tel est souvent le cas lors de l'irradiation de milieux organiques ou biologiques (208). En particulier, les chaînes de peroxydation (121) représentent la catalyse par le rayonnement de la réaction exergonique (voir sect. III-C.1.a) :

Fig. 11. Variation du facteur d'amplification de l'oxygène (FAO) en fonction du TEL, pour un tissu de densité unité. D'après réf. 219.



$$RH + O_2 \rightsquigarrow ROOH$$

où RH représente la molécule subissant la peroxydation.

(d) Action à l'échelle cellulaire : La première étude connue concernant l'intervention de l'oxygène en radiobiologie date de 1921 (209), bien que l'on doive rappeler ici les travaux de Gottwald Schwarz (210), qui avaient montré, dès 1909, un effet radioprotecteur de l'ischémie.[24] Cet *effet oxygène* fut depuis lors l'objet de nombreuses études (voir, par exemple, réfs. 26, 81, 211 et 212). Son rôle est d'importance primordiale lors de la plupart des actions biologiques des rayonnements ionisants.

C'est ainsi que, pour l'eau, O_2 peut réagir soit sur des radicaux primaires en transformant le couple $H^{\bullet}/e^-_{aq}$ en $HO_2^{\bullet}/O_2^{\bullet -}$, soit sur des radicaux ($R^{\bullet}$) provenant du soluté en donnant en particulier un peroxyradical $RO_2^{\bullet}$. Il peut aussi réagir sur un site radicalaire créé au sein d'une macromolécule. Pour l'ADN, il peut ainsi bloquer les processus de réparation (voir, par exemple, réf. 213).

À l'échelle cellulaire, les effets de l'oxygène sur la radiolyse sont souvent complexes. Ils se traduisent toujours par une radiosensibilisation que l'on caractérise par la mesure de l'influence de l'oxygène sur la survie cellulaire. Celle-ci est explicitée par les *courbes de survie* obtenues en portant le logarithme de la fraction cellulaire survivante (S/S_0) en fonction de la dose absorbée D (fig. 10) (voir, par exemple, réfs. 26, 81 et 212–217). Elles sont souvent paramétrées sous la forme :

$$[27] \quad S = S_0\, e^{-\alpha D - \beta D^2}$$

dite « forme linéaire-quadratique » (217). Ces courbes permettent d'estimer la valeur du « facteur d'amplification de

[24]L'ischémie caractérise l'état d'une cellule ou d'un tissu peu ou non oxygéné.

© 1999 CNRC Canada

l'oxygène » (FAO) (en anglais : *« oxygen enhancement ratio »* ou OER) (26, 81, 208, 212), qui est donné par :

$$\text{FAO} = \frac{\text{dose en l'absence d'air}}{\text{dose en la présence d'air}}$$

pour obtenir le même effet biologique (la même survie cellulaire) (218).

Pour les faibles TEL (électrons accélérés), le FAO reste voisin de 3 pour des doses comprises entre 2 et 20 Gy, et diminue quand augmentent le TEL (fig. 11) et le débit de dose. D'autre part, l'effet de l'oxygène croît pour des pressions partielles (pO_2) allant de 0 à ~30 Torr[25] (208). Pour des pO_2 plus élevées, le gain en radiosensibilité est très faible, même en utilisant des pressions hyperbares[25] (208; voir aussi réfs. 26 et 220).

Divers mécanismes ont été invoqués pour expliquer les effets biologiques de l'oxygène sous irradiation. Il a été montré par étude des mélanges O_2/N_2O que, au niveau cellulaire, ces effets sensibilisateurs n'étaient pas dus au simple remplacement de e^-_{aq} par $O_2^{\bullet-}$ et que le radical anion superoxyde $O_2^{\bullet-}$ ne semble pas indispensable à la radiosensibilisation (221). Il est apparu qu'au moins une partie de cet effet pourrait être attribuée à la réaction déjà évoquée du type

$$R^\bullet + O_2 \rightarrow RO_2^\bullet$$

conduisant à une inhibition par O_2 de la réparation de certains défauts radioinduits (213; voir aussi réf. 51). Le problème est toutefois loin d'être complètement résolu.

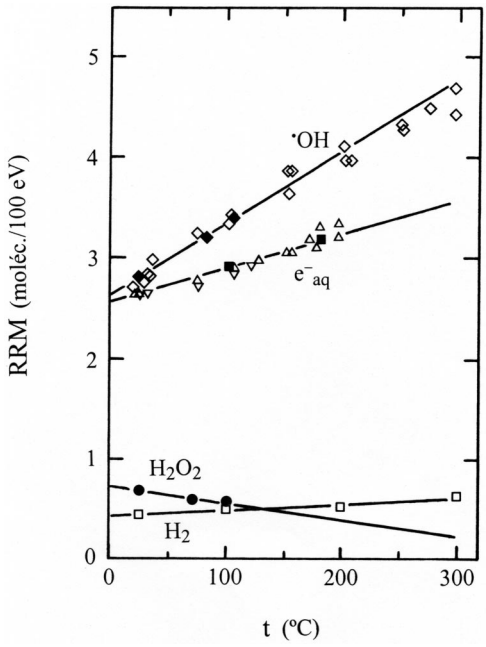
6. Influence de la température

Des études systématiques concernant les influences de la température sur les phénomènes de radiolyse n'ont été entreprises qu'assez tardivement. Elles ont été souvent impulsées par la nécessité de connaître les mécanismes de la radiolyse de l'eau se déroulant au sein de certains réacteurs nucléaires (voir, par exemple, réf. 222). Ces travaux se sont développés selon plusieurs directions : l'une d'elles s'intéresse à la variation, en fonction de la température, des rendements radicalaires et moléculaires, une autre concerne la modification du spectre de l'électron hydraté, la troisième enfin correspond à l'influence de la température sur les vitesses ou les équilibres des réactions mises en jeu.

(a) Variation des RRM en fonction de la température :
Depuis 1962 (223), un certain nombre de déterminations des RRM en fonction de la température a été publié; elles utilisent le plus souvent la méthode des solutés. Pour une bonne part, ces déterminations concernent les rayons γ ou les électrons accélérés et les milieux neutres (85, 224–229) ou parfois acides (H_2SO_4 0,4 M) (223, 230, 231), les températures étant situées dans la gamme 2–410°C. En comparant les résultats des divers auteurs, des dispersions expérimentales relativement importantes ont été constatées. Un intérêt particulier doit toutefois être accordé aux travaux récents d'Elliot et al. (89) aboutissant aux résultats suivants pour les RRM en milieu neutre entre 20 et 300°C (fig. 12) :

$$G_{e^-_{aq}} = 2{,}56 + (3{,}40 \times 10^{-3})\ t$$

Fig. 12. Variation des RRM (exprimés en moléc./100 eV), pour l'eau neutre irradiée avec les rayons γ de ^{60}Co ou des électrons accélérés, en fonction de la température t (exprimée en degrés Celsius). D'après réf. 89.



$$G_{\cdot OH} = 2{,}64 + (7{,}17 \times 10^{-3})\ t$$

$$G_{H_2} = 0{,}43 + (0{,}69 \times 10^{-3})\ t$$

$$G_{H\cdot} = 0{,}54 + (1{,}28 \times 10^{-3})\ t$$

$$G_{H_2O_2} = 0{,}72 - (1{,}49 \times 10^{-3})\ t$$

où t est la température, exprimée en degrés Celsius, et où les valeurs de G sont données en moléc./100 eV. On voit, d'après les relations précédentes, que les rendements radicalaires augmentent avec la température tandis que le rendement en H_2O_2 diminue, ce qui semble montrer que la distribution des espèces primaires est plus étalée quand croît la température (et donc la vitesse de diffusion) dans l'intervalle considéré. Une variation analogue a été trouvée par Kent et Sims (227). Elliot et al. (232) ont établi de même que, pour les deutons de 23 MeV et les ions $^7Li^{3+}$ de 157 MeV irradiant des solutions neutres, les rendements en radicaux $^\bullet OH$ et en e^-_{aq} croissent et celui de H_2O_2 diminue, dans la gamme 25–180°C.

Le rendement en H_2 dans la plupart des cas précédents pose problème puisqu'il semble varier en sens inverse de H_2O_2. Il a été suggéré que H_2 est formé unimoléculairement (85), par exemple à partir de la décomposition d'une molécule d'eau excitée électroniquement (89, 201, 233) :

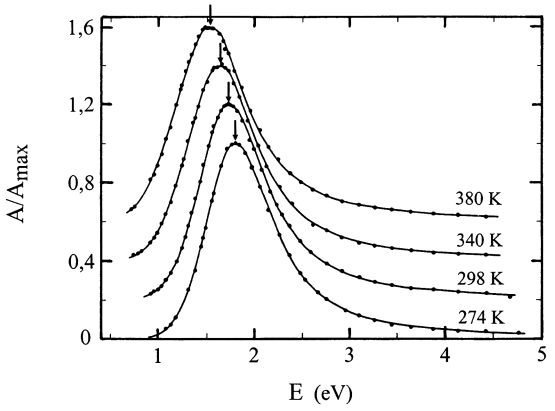
$$H_2O^* \rightarrow H_2 + O$$

Cette suggestion a néanmoins été discutée par LaVerne et Pimblott (234). L'influence de la température sur les RRM

[25]1 bar = 10^5 Pa = 0,986 92 atm (1 atm = 760 Torr = 101 325 Pa), l'unité SI de pression étant le pascal (Pa) ou N/m^2. Les pressions dites hyperbares, parfois utilisées en radiothérapie, sont de l'ordre de 3 à 4 atm.

© 1999 CNRC Canada

Fig. 13. Spectres d'absorption de e^-_{aq} pour différentes valeurs de la température (exprimée en kelvins). Les valeurs donnent, en fonction de l'énergie *E* (exprimée en électron-volts), l'absorbance *A* normalisée par rapport au maximum d'absorption (A_{max}). Les fléches indiquent les positions (E_{max}) des maxima de A/A_{max} pour les différents spectres. Les spectres successifs ont été décalés de 0,2 unité vers le haut pour éviter les recouvrements. D'après réf. 242.



n'est donc pas clairement expliquée. En fait, plusieurs propriétés de l'eau, telles que la densité, la viscosité, la constante diélectrique et le produit ionique, doivent intervenir (85, 235). L'étude des effets de température sur la radiolyse de l'eau a été développée théoriquement par Swiatla-Wojcik et Buxton (233, 236), LaVerne et Pimblott (234) et Kabakchi et Bugaenko (237), à l'aide de modèles déterministes, et par Frongillo et al. (238) en utilisant les techniques de simulation Monte-Carlo. L'influence du TEL a, de plus, été estimée par différents auteurs (229, 236, 238), dans la gamme 25–300°C.

(b) Spectre d'absorption de e^-_{aq} en fonction de la température : Le spectre de l'électron hydraté se déplace vers le rouge (c'est-à-dire vers les énergies plus faibles) lorsque la température augmente (239–243; voir aussi réf. 72), comme on peut le constater sur la figure 13, d'après les résultats de Jou et Freeman (242). Ces derniers auteurs ont étudié les modifications du spectre entre 274 et 380 K et ont constaté que celui-ci demeure de forme gaussienne pour les énergies inférieures à E_{max} (énergie associée au maximum d'absorption) et de forme lorentzienne pour les énergies supérieures à E_{max}.[26] Comme le montre la figure 13, les déplacements spectraux sont différents pour les deux zones considérées, ce qui laisse à penser que l'on a affaire à des transitions de nature différente pour chacune d'elles (72). De plus, le produit $G_{e^-_{aq}}\varepsilon_{max}$ (où ε_{max} est le coefficient d'extinction molaire de e^-_{aq} au maximum du spectre, exprimé en M^{-1} cm^{-1}) varie très peu, de $50{,}4 \times 10^3$ moléc./(100 eV M cm) à 274 K à $51{,}8 \times 10^3$ moléc./(100 eV M cm) à 380 K (242). Comme $G_{e^-_{aq}}$ augmente avec la température (voir fig. 12), $\varepsilon_{max}(e^-_{aq})$ décroît avec celle-ci. Elliot et Ouellette (244) ont ainsi rapporté, pour des températures allant jusqu'à 200°C, une décroissance sensiblement linéaire de $\varepsilon_{max}(e^-_{aq})$ en fonction de la température, suivant la loi $\varepsilon_{max} = 20\,364 - 20{,}4\,t$ (où *t* est en degrés Celsius).

Au-dessus de 175°C, le maximum d'absorption continue à se déplacer vers les énergies plus faibles, mais avec un coefficient de température moindre; cette variation se poursuit jusqu'à la température critique de l'eau (~371°C pour D_2O[27]), et même au-delà (240, 241, 243). Ce déplacement peut être attribué à la modification des pièges électroniques due au changement progressif avec la température de la structure associative de l'eau.

Notons enfin que la simulation numérique du spectre d'absorption de e^-_{aq} pour diverses valeurs de la température (298, 340 et 373 K) (245) n'est pas pleinement en accord avec les résultats expérimentaux.

(c) Influence de la température sur diverses constantes de vitesse de réaction : La méthode de radiolyse a permis de mesurer en fonction de la température la constante de vitesse de certaines réactions rapides concernant entre autres : e^-_{aq} (158, 224, 239, 243, 244, 246–250), $O^{\bullet-}$ (251), $H^\bullet$ (158, 247, 252–256), ainsi que des radicaux produits secondairement par le rayonnement, tels que $N_3^\bullet$, $NO_2^\bullet$, $Br_2^{\bullet-}$, $I_2^{\bullet-}$ et $(SCN)_2^{\bullet-}$ (257). Pour cette dernière série, donnée ici à titre d'exemple, les énergies d'activation pour les réactions avec divers phénols et l'ion ascorbate sont comprises entre 7 et 41 kJ/mol, dans la gamme de températures 5–75°C. Les variations correspondantes de la constante de vitesse semblent dépendre, pour cette même série, à la fois de l'énergie d'activation et du facteur préexponentiel, cette dernière influence apparaissant jouer un rôle prédominant (257).

Des mesures récentes jusqu'à 300°C ont montré que, pour un certain nombre de réactions, l'énergie d'activation ne demeurait pas constante dans l'intervalle de température considéré (158, 224, 243, 247, 248, 256). Tel est le cas, entre autres, des réactions (158) :

$$^\bullet OH + {}^\bullet OH \rightarrow H_2O_2$$

$$e^-_{aq} + H_3O^+ \rightarrow H^\bullet$$

$$e^-_{aq} + {}^\bullet OH \rightarrow OH^-$$

$$H^\bullet + O_2 \rightarrow HO_2^\bullet$$

$$e^-_{aq} + O_2 \rightarrow O_2^{\bullet-}$$

Des valeurs négatives peuvent même être obtenues, par exemple dans le cas des réactions de e^-_{aq} avec NO_2^-, NO_3^-, SeO_4^{2-} (224, 248) et éventuellement avec lui-même (158, 243). Il a été montré que l'ensemble de ces situations pouvait être décrite adéquatement par l'équation de Noyes (258; voir aussi réfs. 158, 247 et 248) :

[28] $$1/k = 1/k_{diff} + 1/k_{réact}$$

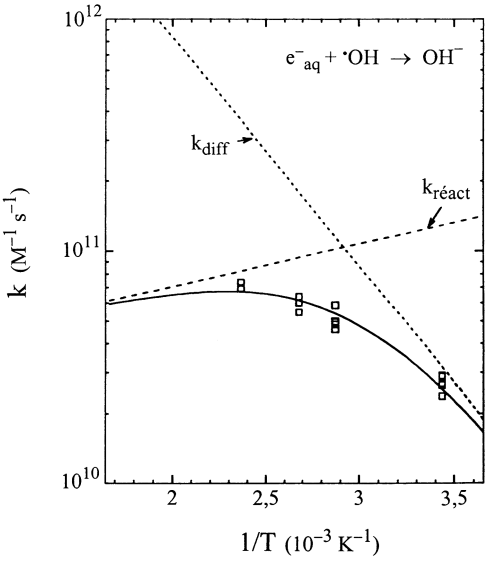
où k_{diff} est la constante de vitesse de la réaction limitée par la diffusion et $k_{réact}$ est celle de la réaction chimique ultérieure (fig. 14). Lorsque $k_{diff} << k_{réact}$, l'étape limitante est la

[26]On sait que E_{max} est reliée à la longueur d'onde λ_{max} correspondant au maximum d'un spectre de e^-_{aq} par $E_{max} = 1240/\lambda_{max}$, où E_{max} est exprimée en eV et λ_{max} en nm. $T(K) = t(°C) + 273{,}15$.

[27]Notons que, afin de minimiser les pertes de lumière dues à l'absorption infrarouge, de l'eau lourde est le plus souvent employée pour l'étude des spectres d'absorption de e^-_{aq} au-dessus de 100°C (voir, par exemple, réf. 240).

© 1999 CNRC Canada

Fig. 14. Variation de k en fonction de $1/T$, dans une échelle semi-logarithmique, pour le cas de la réaction $e^-_{aq} + {}^\bullet OH \rightarrow OH^-$. D'après réfs. 158 et 244.



diffusion des espèces réagissantes et lorsque $k_{diff} >> k_{réact}$, c'est la réaction chimique qui impose sa vitesse (235).

7. Influence de la nature de la phase

Nous avons, jusqu'à présent, considéré la radiolyse de l'eau à l'état liquide. En effet, l'ensemble des données concernant la phase vapeur (voir, par exemple, réfs. 41 et 259–262) ou solide (voir, par exemple, réfs. 41 et 263–267) est relativement moins développé. Le fait que le stade de condensation ou d'agrégation du solvant joue sur les résultats expérimentaux doit cependant être envisagé. Par exemple, il semble logique d'admettre que la part des réactions biradicalaires, tout particulièrement la réaction $H^\bullet + {}^\bullet OH \rightarrow H_2O$, soit favorisée par la densité du milieu, produisant un effet de « cage » (268). Les rendements qui traduisent la radiolyse de l'eau seraient donc d'autant plus faibles que la phase est condensée, les mécanismes restant *grosso modo* qualitativement semblables.

La comparaison quantitative des rendements primaires entre les deux phases, vapeur et liquide, est toutefois difficile à établir. Les méthodes de simulation Monte-Carlo ont néanmoins permis de calculer le rendement initial de radiolyse de l'eau, dans l'une et l'autre phase, par des électrons d'énergie 10 keV. Pour la phase vapeur, les valeurs calculées du rendement de décomposition de l'eau ainsi obtenues : 7,87 (269), 6,33 (270), 7,21 (271) et 7 (272) moléc./100 eV, sont comparables aux résultats expérimentaux (7,5 ± 1 moléc./100 eV) (260–262; voir aussi tableau 8). Quant à l'eau liquide, par simulations Monte-Carlo, il a été obtenu des données : 7,67 (270), 7,47 (271), 7,2 (272) et 6,6 (273, 274) moléc./100 eV, qui supportent, elles aussi, la comparaison avec l'expérience (~5–7 moléc./100 eV) (118, 119, 130, 275–277). Ces résultats ont été discutés par Bednář (278), Sukhonosov (279) et Pimblott et Mozumder (280).

La comparaison des rendements vapeur/liquide de H_2 et H_2O_2 est également difficile à établir car les rendements mesurés de ces deux produits lors de la radiolyse de la vapeur d'eau sont peu élevés et correspondent probablement à des états quasi stationnaires relativement bas pour les débits de dose habituels (41, 261, 281, 282). Ceci présenterait une analogie qualitative avec l'eau liquide irradiée avec des rayonnements de faibles TEL (voir sect. II-A).

Tableau 8. Rendements[a] des processus primaires de la radiolyse de l'eau en phase vapeur, estimés par Willis et Boyd (réf. 261).

Processus primaires d'ionisation	Rendements
$H_2O \rightarrow H_2O^{\bullet+} + e^-$	1,99
$H_2O \rightarrow H^+ + {}^\bullet OH + e^-$	0,67
$H_2O \rightarrow OH^+ + H^\bullet + e^-$	0,57
$H_2O \rightarrow H_2 + O^{\bullet+}(^2D) + e^-$	0,06
$H_2O \rightarrow H_2^{\bullet+} + O + e^-$	0,01
	$G_{ionisation}$ = 3,30
Processus primaires d'excitation électronique	Rendements
$H_2O \rightarrow H^\bullet + {}^\bullet OH$	3,58
$H_2O \rightarrow H_2 + O$	0,45
	$G_{excitation}$ = 4,03

[a]Exprimés en moléc./100 eV.

En la présence de capteurs d'atomes $H^\bullet$ et d'électrons, on a toutefois mesuré, à ~120°C, un rendement G_{H_2} = 0,45 ± 0,1 (260, 282–285). Ce rendement « non captable » en H_2 a été attribué (voir, par exemple, réfs. 260 et 278) à une contribution des molécules d'eau excitées électroniquement, selon le processus : $H_2O^* \rightarrow H_2 + O$, ou à un mécanisme de capture électronique résonante dissociative : $H_2O + e^- \rightarrow H_2O^- \rightarrow H^- + {}^\bullet OH$, suivi de $H^- + H_2O \rightarrow H_2 + OH^-$, ou bien encore à la formation d'atomes d'hydrogène excités électroniquement ou « chauds », c'est-à-dire possédant suffisamment d'énergie cinétique, et pouvant participer à la réaction : $H^{\bullet *}$ (ou $H^\bullet_{\text{« chaud »}}$) + $H_2O \rightarrow H_2 + {}^\bullet OH$.

Les rendements ci-dessus évoqués s'appliquent particulièrement aux irradiations par électrons rapides et rayons γ ou X, mais ils sont à peu près indépendants du TEL au moins jusqu'aux irradiations par des produits de fission de ^{235}U (286). Ils ne sont, de plus, modifiés par la température qu'au delà de ~150°C (281, 287; voir aussi réf. 260).

Par ailleurs, pour des pressions suffisantes, l'électron peut former avec l'eau des agrégats gazeux négatifs (voir, par exemple, réf. 72; voir aussi réf. 288) :

$$e^- + (H_2O)_n \rightarrow (H_2O)_n^-$$

qui se comportent, vis-à-vis des différents solutés, de manière analogue à l'électron hydraté en phase liquide.

Pour la glace, le rendement de décomposition de l'eau diminue lorsque la température décroît : ainsi, il a été proposé (41) les valeurs (en moléc./100 eV) de 3,4 à –10°C, 1 à –78°C et 0,5 à –200°C. Selon les conditions d'irradiation, quatre espèces radiolytiques principales peuvent être piégées : les atomes $H^\bullet$, les radicaux ${}^\bullet OH$ et $HO_2^\bullet$ (ce dernier étant formé en petite quantité, probablement par la rencontre de ${}^\bullet OH$ et de H_2O_2), et les électrons (263, 264, 289–294). Ces espèces ont généralement été identifiées, et suivies cinétiquement en fonction de la température, par résonance paramagnétique électronique (RPE) ou par spectrophotométrie d'absorption optique. À 4,2 K, les rendements de $H^\bullet$ et de ${}^\bullet OH$ sont égaux à ~0,9 moléc./100 eV (264). À partir de 20 K, les atomes $H^\bullet$ deviennent mobiles et disparaissent rapidement au-dessus de 50 K (295). Quant aux radicaux ${}^\bullet OH$, ils

© 1999 CNRC Canada

commencent à migrer à compter de ~100 K (291). Les expériences de conductivité ont montré, d'autre part, que les électrons « en excès » quasi libres (ou « secs ») sont, dans la glace cristalline irradiée, formés avec une mobilité relativement grande (25 ± 10 cm^2 V^{-1} s^{-1}) et sensiblement constante entre –65 et –120°C (296–299). Le temps de vie (ou de piégeage) de ces électrons dépend fortement de la température : 250 ns à –80°C, 1 ns à –30°C et 100 ps à –5°C (297, 299, 300). Kevan (264) a souligné, par ailleurs, la possibilité d'une corrélation entre les températures de déclin des diverses espèces radicalaires formées et celles des réorganisations moléculaires de la glace cristalline.

Les électrons piégés (e^-_{vis}) ont été observés dans la glace neutre ou alcaline (264, 265) et sont caractérisés par une bande d'absorption dans le visible (avec un maximum situé autour de ~630–650 nm) (290, 293, 300–303), très similaire à celle de l'électron hydraté (72, 83; voir aussi réf. 293). On a ainsi été conduit à conclure que e^-_{vis} dans la glace a une structure analogue à celle de e^-_{aq} dans l'eau liquide (299, 304) et que les pièges correspondants pourraient être des lacunes du réseau, produites lors de l'irradiation (305, 306). De plus, le rendement de e^-_{vis} (en moléc./100 eV) est faible : 0,95 à –5°C (303), 0,05 à –50°C (303) et 10^{-4}–10^{-3} à –196°C (302). À très basse température, une bande d'absorption a également été observée dans l'infrarouge (~3600 nm) et attribuée à un autre type d'électrons piégés (e^-_{ir}) (306–308). Certains auteurs (306, 307) ont suggéré que les pièges associés à e^-_{ir} sont constitués par les cavités naturelles de la structure cristalline de la glace.

Les glaces alcalines irradiées pourraient conduire à la formation du « diélectron » (264), c'est-à-dire une espèce composée de deux électrons piégés dans le même site selon une structure qui serait analogue à celle des centres F′ rencontrés, par exemple, dans les halogénures alcalins.[28] L'existence transitoire d'une telle espèce a également été avancée, dans certains cas, lors de la radiolyse de l'eau liquide (255, 310–313).

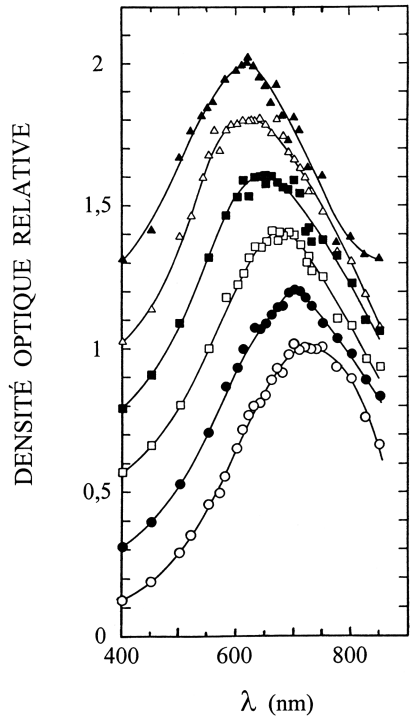
Soulignons enfin divers travaux de désorption stimulée par impact d'électrons de faible énergie (3–150 eV) sur des couches minces solides d'eau (H_2O/D_2O), amorphes ou cristallines, déposées sur un substrat métallique, qui montrent la production de H_2/D_2 (314), $D^\bullet$ et O (315), H^-/D^- (316, 317), H^+/D^+ (318) et O_2 (319). L'interprétation de ces résultats s'appuie principalement sur les mécanismes (voir, par exemple, réf. 320) d'attachement dissociatif électronique (formation résonante d'ions négatifs transitoires), de dissociation dipolaire, ou encore d'excitation électronique (« excitons de Frenkel ») dissociative de H_2O. Ces travaux pourraient apporter d'utiles renseignements sur les interactions et le devenir des électrons secondaires, en fin de parcours dans les traces des rayonnements ionisants. Une large proportion de ces électrons possèdent, on le sait, des énergies inférieures à une centaine d'électron-volts (voir sect. III-B).

8. Influence de la pression

À 20°C, l'eau liquide subit, pour des pressions supérieures à ~1,5 kbar,[25] d'importants changements structuraux, l'eau semblant alors se comporter comme un fluide « simple » non associé (321). Un certain nombre d'expériences portent sur l'influence de la pression sur la radiolyse γ de l'eau et de solutions aqueuses, allant de 1 atm jusqu'à 8,7 kbar (pression pour laquelle le point de fusion de la glace est de 25°C). Hentz et al. (322–324) ont ainsi montré que, pour des solutions neutres ou acides et dans l'intervalle de pression considéré, les rendements primaires (RRM) de e^-_{aq}, $^\bullet OH$, $H^\bullet$, H_2 et H_2O_2 sont indépendants de la pression. Selon ces auteurs (323), ceci entraîne comme conséquence qu'une variation, en fonction de la pression, du rendement d'un produit de la radiolyse de ces solutions, ne pourrait provenir que de l'effet de la pression sur les constantes de vitesse relatives de certaines réactions secondaires. Une telle interprétation a permis la détermination des volumes molaires d'activation pour certaines réactions de l'électron hydraté et de l'atome $H^\bullet$, en particulier pour $H^\bullet + OH^- \rightarrow e^-_{aq} + H_2O$. À partir de ces données et moyennant certaines hypothèses concernant le complexe activé dans chaque cas, les volumes molaires partiels de e^-_{aq} et de $H^\bullet$ ont pu être estimés (324–326).

Citons également, parmi les résultats obtenus, l'influence de la pression sur le spectre de l'électron hydraté qui montre un déplacement du maximum vers le bleu (327–329; voir aussi réf. 72) (fig. 15).

Fig. 15. Spectres de e^-_{aq} à 29°C, pour diverses valeurs de la pression : ○, 1 atm, ●, 1,10 kbar, □, 2,13 kbar, ■, 3,53 kbar, △, 4,88 kbar et ▲, 6,26 kbar. Les spectres successifs ont été décalés de 0,2 unité vers le haut pour éviter les recouvrements. D'après réf. 328.



[28]Le centre F′ (ou F^-) est généralement considéré comme formé par un site anionique vacant ayant capté deux électrons (voir, par exemple, réf. 309).

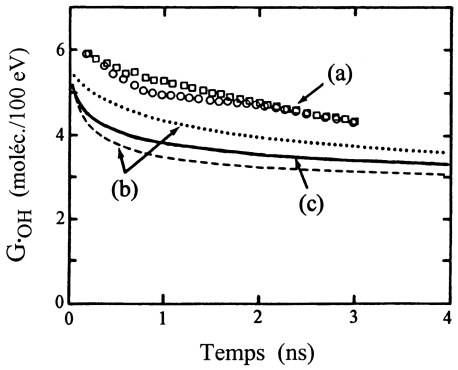
Fig. 16. Variation du rendement en radicaux •OH en fonction du temps lors de la radiolyse de l'eau par des électrons accélérés (voir texte). À noter que la courbe simulée (*c*) a été obtenue pour des répartitions spatiales initiales d'électrons hydratés et de radicaux •OH de formes gaussiennes, d'écarts-types respectivement égaux à $\sigma(e^-_{aq})$ = 40 Å et $\sigma(^\bullet OH)$ = 7,5 Å. D'après réf. 273.



IV. Conclusion : la radiolyse de l'eau à l'orée du XXI^{ème} siècle

A. État actuel des connaissances

Nous avons vu comment, à partir des premières expériences concernant la radiolyse de l'eau et datant de 1902 (voir sect. II-A), nos connaissances ont pu s'élargir et se clarifier. Il est toutefois apparu que certains aspects quantitatifs de cette radiolyse ne sont pas encore pleinement résolus. Il serait intéressant que, dès les premières années du XXI^{ème} siècle, des progrès soient réalisés dans cette direction, progrès qui favoriseraient dans l'avenir les applications et les retombées de la radiolyse. C'est ainsi qu'un certain nombre de problèmes nous semblent appelés à de proches développements.

Un des plus importants parmi ceux-ci est sans doute le rôle joué par la distribution hétérogène de l'énergie, représentée schématiquement par le paramètre TEL (voir sect. III-C.4). En effet, s'il est apparu dès 1948 (75) que la répartition initiale des ionisations conditionnait une part importante des phénomènes ultérieurs, l'accord quantitatif n'est cependant pas toujours établi entre les mesures expérimentales, les calculs analytiques et l'application des méthodes Monte-Carlo. La figure 16 montre une telle comparaison en ce qui concerne les valeurs de $G_{\bullet OH}$ en fonction du temps, obtenues (*a*) par spectrophotométrie rapide à 280 nm d'après Jonah et al. (275), (*b*) par calculs semi-analytiques utilisant l'action sur le rendement radicalaire de divers solutés bons capteurs de •OH et la transformation de Laplace inverse (119, 273; voir aussi réf. 330), et (*c*) par calculs de simulation mettant en oeuvre la méthode des temps de réactions indépendants d'après Pimblott et LaVerne (273). On voit que l'accord est bon entre les courbes (*b*) et (*c*), mais que la courbe (*a*) donne des résultats différents. Ce même désaccord est retrouvé par d'autres auteurs (voir, par exemple, réfs. 152 et 331–334). Selon LaVerne et Pimblott (119, 273), le rendement en radicaux •OH à 200 ps ne serait d'ailleurs pas 5,9 moléc./100 eV comme rapporté par Jonah et Miller (275), mais plutôt ~4,4–4,6 moléc./100 eV tel qu'obtenu à partir des études avec des capteurs. D'autres expériences seraient nécessaires.

De plus, il semble que, lorsque le TEL augmente, de nouvelles réactions soient susceptibles d'entrer en jeu. C'est ainsi que, comme nous l'avons vu (voir sect. III-C.4), a été invoquée la production d'atomes d'oxygène pouvant réagir avec •OH (99, 178, 194), ou encore l'intervention d'ions de l'eau multichargés (200–202), réactions conduisant toutes deux à l'espèce radicalaire $HO_2^\bullet$. Des calculs préliminaires de simulation Monte-Carlo de la radiolyse de l'eau à haut TEL (203) ont été abordés récemment à ces points de vue.

Même pour les faibles TEL dont les effets ont été largement étudiés, certaines questions demeurent posées. Ainsi, les résultats concernant l'action de capteurs dans les zones hétérogènes indiqueraient que la contribution des réactions suivantes :

[29] $H^\bullet + e^-_{aq} \rightarrow H_2 + OH^-$

[30] $e^-_{aq} + e^-_{aq} \rightarrow H_2 + 2\ OH^-$

[31] $H^\bullet + H^\bullet \rightarrow H_2$

ne soit pas suffisante pour expliquer l'origine du rendement d'hydrogène « moléculaire » égal, on le sait, à G_{H_2} = 0,45 moléc./100 eV (89, 120; voir aussi réf. 35). En fait, il existerait un rendement *non captable* en H_2 de 0,15–0,2 moléc./100 eV (114, 118–120; voir aussi sect. III-B) qui pourrait provenir d'une contribution des molécules d'eau excitées électroniquement, soit directement, soit après recombinaison géminée d'un électron avec son cation parent H_2O^+ (voir, par exemple, réfs. 87, 152 et 335) :

$$H_2O^* \rightarrow H_2 + O$$

$$H_2O^+ + e^- \rightarrow H_2O^* \rightarrow H_2 + O$$

ou encore d'un mécanisme d'attachement électronique dissociatif (120, 320, 336–338), mis en évidence en phase condensée par Rowntree et al. (316) et étudié ensuite par plusieurs auteurs (314, 317), pour des électrons d'énergie comprise dans les deux gammes ~5,5–11 eV et ~18–32 eV :

$$H_2O + e^- \rightarrow H_2O^- \rightarrow H^- + {}^\bullet OH$$

suivi de la réaction

$$H^- + H_2O \rightarrow H_2 + OH^-$$ [29]

Par ailleurs, nous l'avons vu (voir sect. III-C.2), le problème de la radiolyse de l'eau aux grands pH n'est pas complètement résolu, les valeurs des RRM étant souvent, en milieu alcalin, en désaccord apparent, selon les auteurs.

Nous avons vu également que l'influence de la température est en cours d'étude (voir sect. III-C.6). Soulignons ici que des points d'interrogation peuvent demeurer, comme par exemple l'anomalie cinétique de la disparition de e^-_{aq} qui se manifeste par une valeur négative de l'énergie d'activation à partir de 150°C (158, 243). Une telle anomalie devrait se

[29]Peled et Czapski (réf. 100) ont de plus émis l'hypothèse que l'origine du rendement « non captable » en H_2 proviendrait des zones d'hétérogénéité contenant des concentrations initiales élevées en radicaux.

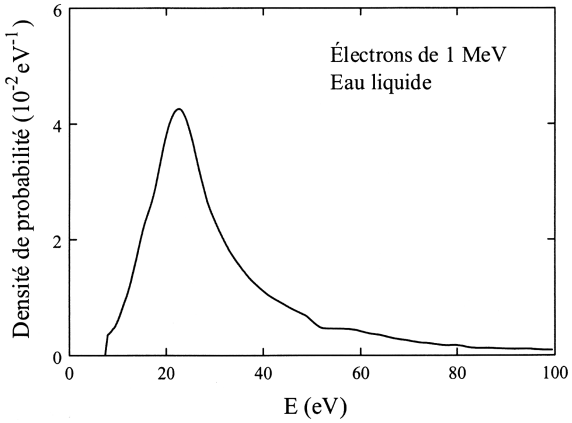
Fig. 17. Distribution des pertes d'énergie pour des électrons incidents de 1 MeV dans l'eau liquide, d'après les calculs de simulation Monte-Carlo de LaVerne et Pimblott (réf. 104). La perte d'énergie la plus probable est égale à 22–23 eV, alors que la perte d'énergie moyenne est de ~57 eV. Le seuil à ~7,3 eV correspond au seuil d'excitation électronique de l'eau en phase condensée (voir réf. 344). D'après réf. 104.



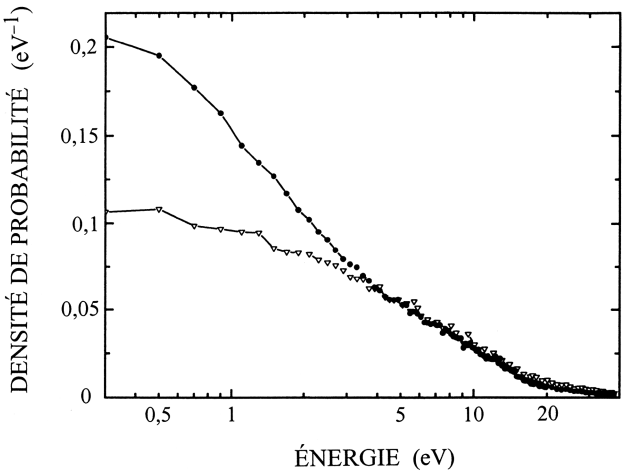
traduire par une modification concomitante du rendement en H_2 (233, 234, 236), ce qui ne paraît pas être observé (158). Le biélectron a été suggéré en tant qu'espèce transitoire intervenant au cours de ce processus, mais son existence n'a pas été établie (243, 255, 311–313). Une confirmation expérimentale de la valeur de la constante de vitesse de la réaction [30] en fonction de la température serait utile.

D'autres données expérimentales et (ou) théoriques auraient, elles aussi, besoin d'être déterminées. Citons un certain nombre d'entre elles.

Les sections efficaces d'interaction des électrons d'énergie inférieure à ~100 eV restent mal connues (152, 273, 280, 320, 333, 339–343). C'est pourtant dans cette zone que se fait une part importante des échanges d'énergie entre l'eau et les électrons incidents, comme on peut le voir figures 17 et 18. Cette dernière figure montre le spectre d'énergie des électrons secondaires, au moment de leur éjection, calculé par simulation Monte-Carlo pour des électrons incidents de 20 keV dans l'eau liquide (152) : une large proportion des électrons éjectés (88 %) a une énergie inférieure à 20 eV. La détermination de ces sections efficaces est indispensable pour assurer en particulier une bonne description des phénomènes par les méthodes de simulation Monte-Carlo. Les seuls résultats expérimentaux actuellement disponibles dans la littérature à ce sujet, pour l'eau en phase condensée, sont ceux de Michaud et Sanche (346; voir aussi réfs. 320, 338 et 343) pour des énergies de l'électron comprises entre 1 et 18 eV.

Un autre problème concerne la caractérisation de la distribution spatiale initiale (à ~10^{-12} s) des espèces créées par l'absorption du rayonnement. Cette distribution constitue, en effet, le point de départ de l'étape de chimie hétérogène au cours de laquelle les espèces qui résultent de la dissociation des molécules d'eau ionisées et (ou) excitées diffusent dans le milieu et réagissent entre elles. Si la position initiale des espèces telles que $^{\bullet}OH$, H_3O^+, $H^{\bullet}$ et H_2 découle directement du déploiement de la trajectoire des particules incidentes dans le milieu, les électrons éjectés lors des ionisations parcourent, quant à eux, une distance au cours de laquelle ils

Fig. 18. Spectre énergétique des électrons secondaires, au moment où ils sont éjectés par des électrons incidents de 20 keV dans l'eau liquide, d'après les calculs de simulation Monte-Carlo de Cobut et al. (réf. 152) : ▽, éjectés par les électrons primaires seulement; ●, éjectés à la fois par les électrons primaires et par toutes les générations d'électrons secondaires successives. Dans ce dernier cas, 64 % des électrons éjectés ont une énergie inférieure à 7,3 eV (seuil d'excitation électronique de l'eau en phase condensée; voir réf. 344), 70 % ont une énergie inférieure à ~8,8 eV (potentiel d'ionisation de l'eau liquide; voir réf. 345) et 88 % ont une énergie inférieure à 20 eV. Ces proportions demeurent approximativement les mêmes lorsque l'énergie des électrons primaires varie entre 5 et 150 keV. D'après réf. 152.



perdent progressivement leur énergie cinétique pour finalement se thermaliser, se localiser et s'hydrater. La distance radiale qui sépare les positions initiale et finale de l'électron est appelée « distance de thermalisation » (r_{th}), car on considère généralement que les électrons se localisent très rapidement à partir du moment où leur énergie cinétique devient comparable à l'énergie thermique. La connaissance de r_{th} conditionne ainsi grandement la distribution spatiale initiale de e^-_{aq} (347).

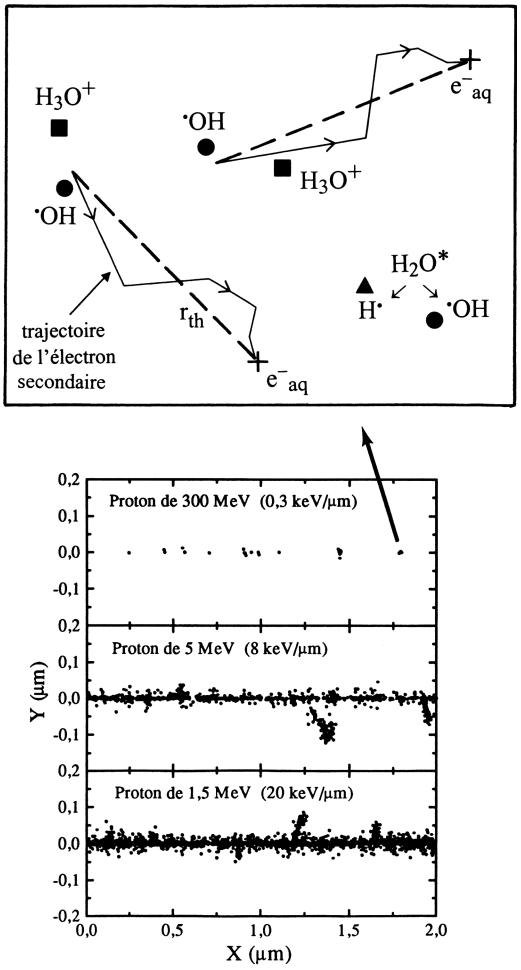
De nombreuses études ont porté sur la détermination de r_{th} pour l'eau liquide et ont conduit à une large gamme de valeurs, s'étendant de ~15 Å à plus de 100 Å (99, 105, 114, 118, 119, 152, 272, 273, 277, 331, 333, 334, 338, 347–359). Des calculs récents de simulation Monte-Carlo ont indiqué cependant qu'une bonne description du déclin mesuré des rendements en e^-_{aq} pour les trajectoires de rayonnement de faible TEL pouvait être obtenue avec des valeurs de r_{th} se situant entre ~69 Å (273) et ~90–100 Å (152, 333, 347).

À titre d'illustration, la géométrie de trois trajectoires de protons est représentée figure 19 pour trois valeurs de TEL initial différentes (152, 333). Un agrandissement du schéma indique la distribution spatiale, à ~10^{-12} s, des entités primaires.

Il a été montré que, non seulement pour l'eau mais aussi pour un grand nombre d'autres liquides, une corrélation existe entre r_{th} et la mobilité de l'électron thermique (352; voir aussi réf. 360), ce qui semble indiquer que la plus grande partie de la distance de thermalisation s'effectue alors que l'électron est suffisamment ralenti, proche de l'état thermalisé. Une meilleure caractérisation des propriétés des « électrons de subexcitation » (361), pour lesquels l'énergie

© 1999 CNRC Canada

Fig. 19. Géométries de trois trajectoires de protons, dans l'eau liquide, pour trois valeurs de TEL initial différentes (0,3, 8 et 20 keV/μm), d'après les calculs de simulation Monte-Carlo de Frongillo et al. (réf. 333; voir aussi réf. 152). La figure montre les projections, sur le plan *XY*, des positions des entités primaires produites à ~10^{-12} s. L'encadré du haut donne, à cette échelle de temps, un schéma agrandi d'une zone hétérogène (impliquant ici, à titre d'exemple, deux ionisations et une excitation électronique; voir, à ce sujet, réfs. 103, 280 et 340). r_{th} est la distance de thermalisation de l'électron secondaire éjecté lors d'une ionisation.



est inférieure au seuil d'excitation électronique de l'eau (~7,3 eV; voir réf. 344), apparaît ainsi souhaitable au niveau de la détermination de leurs paramètres de transport. De tels électrons, comme il a déjà été vu (120, 152, 314, 316, 317, 336–338), peuvent intervenir, en compétition avec la thermalisation, dans des réactions de capture résonante dissociative.

Les avancées récentes réalisées dans la production d'impulsions laser ultracourtes et dans les calculs de simulation utilisant les méthodes de dynamique moléculaire et (ou) Monte-Carlo associées aux intégrales de chemin de Feynman, ont permis de mieux cerner le mécanisme séquentiel et la dynamique du processus d'hydratation de l'électron (voir, par exemple, réf. 72; voir aussi réfs. 362 et 363). On a pu ainsi déterminer les cinétiques d'apparition (temps caractéristique : T_1 ~ 110–180 fs) et de relaxation (temps caractéristique : T_2 ~ 240–620 fs) du précurseur (e^-_{ir}) de e^-_{aq} (72), précurseur absorbant dans l'infrarouge. Si la plupart des auteurs privilégient un modèle d'hydratation, simple ou élaboré, mettant essentiellement en jeu les deux états électroniques e^-_{ir} et e^-_{aq}, la nature et le(s) mode(s) de déclin de e^-_{ir} restent l'objet de controverses (72, 362, 363). Il a aussi été suggéré que e^-_{ir} pourrait réagir avec H_2O selon la réaction (364, 365) :

$$e^-_{ir} + H_2O \rightarrow H^\bullet + OH^-$$

en compétition avec l'hydratation.

Nous venons d'attirer l'attention sur certains points qui semblent actuellement mériter de plus amples développements. Malgré le manque relatif de données, un panorama de la radiolyse de l'eau pure ou contenant divers solutés peut néanmoins être obtenu dans la plupart des cas, à condition de développer une analyse critique des paramètres intervenant. Cette analyse est facilitée par le fait que les valeurs des RRM sont bien établies pour les milieux neutre et acide, ainsi que nous l'avons vu précédemment (voir équations [4] et [19]).

B. Applications

La plupart des applications des radiations ionisantes sortent du cadre de cet article, car elles n'impliquent pas nécessairement la radiolyse de l'eau. Nous allons cependant en citer quelques-unes (impliquant ou non cette radiolyse), afin de souligner l'importance pratique du développement des travaux généraux portant sur l'effet chimique des radiations. On trouvera, dans un article récent de Draganić (366), un plus large aperçu sur ces problèmes.

Par exemple, 80 % des réacteurs nucléaires générateurs d'électricité sont refroidis à l'eau. Il faut donc connaître le comportement de celle-ci lorsqu'elle est soumise, à environ 300°C, à de grands flux de rayonnements. Des travaux sont en cours (voir, par exemple, réfs. 158, 222, 227, 229, 235 et 367).

Par ailleurs, les rayonnements ionisants, et tout particulièrement les électrons accélérés, sont utilisés comme méthode complémentaire des traitements classiques de recyclage des eaux usées et des boues résiduaires (voir, par exemple, réfs. 90 et 368). Les produits chlorés sont dégradés, les microorganismes tués et la germination des graines inhibée.

Le stockage des déchets radioactifs pose évidemment de très gros problèmes concernant d'une part, l'action des rayonnements sur les containers et le milieu environnant et d'autre part, la nature des dégagements gazeux associés (voir, par exemple, réfs. 369–371). Une des difficultés provient du fait qu'il n'est pas possible expérimentalement de comparer les résultats pour les mêmes débits de dose, étant donnée la durée importante des temps de stockage.

Un autre problème, lui aussi difficile à résoudre, consiste à évaluer les doses auxquelles sont soumis les astronautes. Ils reçoivent des électrons, des protons et des ions lourds de grande énergie et de diverses origines. Les mécanismes alors mis en jeu sont différents de ceux se produisant sur Terre (voir, par exemple, réfs. 198 et 372–375).

Disons pour terminer que les rayonnements sont utilisés pour la conservation des aliments (viandes en morceaux, graines, etc.) (voir, par exemple, réfs. 90 et 376) et la stérili-

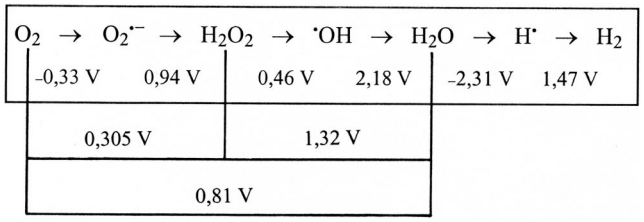
Fig. 20. Données thermodynamiques correspondant à la réduction de l'oxygène, par captures successives d'un électron, pour les systèmes O_2–H_2O et H_2O–H_2 (réfs. 51, 122, 207, 208 et 382–384). Les potentiels standard de réduction sont exprimés en volts, à pH 7 et 25°C, par rapport au potentiel normal d'électrode à hydrogène.



sation du matériel médical et des médicaments (voir, par exemple, réfs. 90 et 377).

Enfin, l'emploi des rayonnements se fait au stade industriel pour produire, dans de très bonnes conditions, des réactions de polymérisation ou de greffe (voir, par exemple, réfs. 90 et 378–381).

C. Retombées

Nous allons évoquer rapidement quelles sont actuellement les principales retombées de la radiolyse de l'eau.

1. Apport à l'étude des interactions matière – rayonnements ionisants

La radiolyse fournit des données concernant une interaction particulière entre l'énergie et la matière et complète ainsi celles apportées par la photolyse, la sonolyse, la thermolyse, l'électrolyse et même la voltolyse, qui constituent une partie importante de la chimie-physique tant théorique qu'expérimentale. Il est donc utile de connaître les mécanismes réactionnels, la nature des intermédiaires, les rendements des transferts d'énergie, etc., intervenant lors de la radiolyse de l'eau afin de les comparer à ceux gouvernés par d'autres échanges d'énergie impliquant eux aussi la décomposition de l'eau. Le développement de cette comparaison pourrait se révéler fructueux.

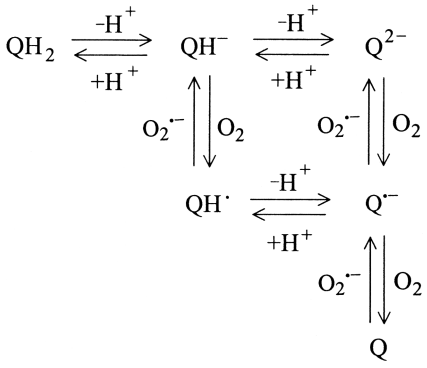
2. Chimie radicalaire

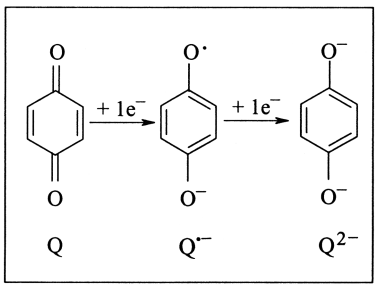
On sait que, dès 1914, Debierne (12) avait suggéré que le rayonnement décompose l'eau en atomes $H^\bullet$ et en radicaux $^\bullet OH$, hypothèse qui fut reprise plus tard (19–21; voir aussi sect. II-A). C'est ainsi qu'il a été admis que l'irradiation de l'eau liquide formait des intermédiaires radicalaires. Ces espèces furent ensuite identifiées et caractérisées, cinétiquement et thermodynamiquement.

La radiolyse est actuellement la méthode la plus utilisée pour l'étude des radicaux libres dérivés de l'oxygène. Ces différentes espèces sont les intermédiaires de la séquence conduisant de l'oxygène à l'hydrogène par captures successives d'un électron (fig. 20) (51, 122, 207, 208, 382–384; voir sect. III-C.5-c) et peuvent être formées par radiolyse de l'eau aérée ou désaérée.

En milieu acide, $O_2^{\bullet-}$ est remplacé par $HO_2^\bullet$, son acide conjugué, tandis que, en solution alcaline, $^\bullet OH$ et $H^\bullet$ sont transformés en leur base conjuguée, respectivement $O^{\bullet-}$ et e^-_{aq}. Les valeurs de pK_a correspondantes sont (82, 86, 122, 207) :

Fig. 21. Réduction des structures quinoniques. L'anion radicalaire semiquinone ($Q^{\bullet-}$) est obtenu à partir de la *p*-benzoquinone (Q) par addition d'un électron. La fonction quinonique peut interférer avec l'oxygène (O_2) et l'anion superoxyde ($O_2^{\bullet-}$) en donnant des réactions redox dont les caractéristiques sont fonctions de l'acidité du milieu et de la nature des substituants. D'après réf. 388.





$$HO_2^\bullet \rightleftarrows O_2^{\bullet-} + H^+ \qquad pK_a = 4{,}8$$

$$H_2O_2 \rightleftarrows HO_2^- + H^+ \qquad pK_a = 11{,}7$$

$$^\bullet OH \rightleftarrows O^{\bullet-} + H^+ \qquad pK_a = 11{,}9$$

$$H^\bullet \rightleftarrows e^-_{aq} + H^+ \qquad pK_a = 9{,}6$$

On voit figure 20 que $O_2^{\bullet-}$ peut être oxydant ou réducteur, tandis que $^\bullet OH$ est très oxydant, son potentiel redox étant élevé.

Ces radicaux peuvent donner lieu, à leur tour, à des radicaux de 2ème génération (voir, par exemple, réfs. 51, 90 et 385–387). Ainsi, $^\bullet OH$ peut facilement arracher un atome d'hydrogène à une molécule organique RH et conduire au radical $R^\bullet$:

$$^\bullet OH + RH \rightarrow R^\bullet + H_2O$$

tandis que $O_2^{\bullet-}$ peut, entre autres, réduire les formes quinoniques et donner un radical semiquinone (fig. 21) (51, 387–390). Les structures quinoniques se rencontrent fréquemment dans des molécules présentant un intérêt biologique, telles que la vitamine K, certains transporteurs biologiques d'électrons, divers médicaments, etc. (389).

De nombreux autres radicaux peuvent également être obtenus par radiolyse pulsée ou continue. Parmi ceux les plus fréquemment rencontrés, citons $N_3^\bullet$ (radical azide), $Cl_2^{\bullet-}$, $Br_2^{\bullet-}$, $SO_4^{\bullet-}$, $(SCN)_2^{\bullet-}$, $RS^\bullet$ (radical thiyle), $COO^{\bullet-}$, $NO_2^\bullet$, $NH_2^\bullet$, etc.

3. Chimie bioradicalaire

À la suite des travaux de McCord et Fridovich (391), il est apparu que, au cours de diverses oxydations biologiques, des radicaux libres, principalement $O_2^{\bullet-}$, pouvaient être formés in vivo. Ces espèces sont capables de conduire à d'autres radicaux qui, à leur tour, peuvent jouer un rôle soit bénéfique, soit délétère (voir, par exemple, réfs. 51, 122, 204, 387 et 392–394). Une enzyme, la *superoxyde dismutase* (391), est dédiée à la régulation de l'ion-radical $O_2^{\bullet-}$ dont la dismutation est très lente ($k < 0{,}3\ M^{-1}\ s^{-1}$) quand elle n'est pas catalysée (82).

C'est ainsi qu'il est nécessaire de tenir compte des mécanismes radicalaires intervenant, par exemple, au niveau mitochondrial (voir, par exemple, réf. 395) ou lors de l'ischémie-reperfusion, de la phagocytose, de l'inflammation (voir, par exemple, réfs. 392–394), du métabolisme de médicaments (389), ou encore lors de divers processus biologiques complexes tels que la mort cellulaire programmée (ou apoptose) (voir, par exemple, réf. 396). De plus, il faut souligner que l'organisme humain contient, pondéralement, ~70 % d'eau et que la radiolyse de l'eau joue probablement un rôle important en radiobiologie, en introduisant une part d'effet indirect et (ou) quasi direct (voir, par exemple, réfs. 134–137).

L'étude in vitro de la radiolyse de solutions aqueuses diluées apporte, à certains points de vue, des éléments originaux permettant de mieux comprendre la nature et l'évolution de tels processus.

Remerciements

J.-P. J.-G. a bénéficié du Programme d'échanges franco-canadien INSERM-CRM en recherche médicale, qui lui a permis d'effectuer un stage au Laboratoire de Chimie-Physique de l'Université Paris V. Il est reconnaissant des facilités qui lui ont ainsi été accordées. Il remercie également le Conseil de Recherches Médicales (CRM) du Canada pour son support financier (Subvention n° MT-14617).

Long chain β-aminoethanols as micellar catalysts for the hydrolysis of diphenyl-*p*-nitrophenyl phosphate. The observation of an unusual enhancement of catalysis in the presence of added polyols

H. Oumar-Mahamat, H. Ślebocka-Tilk, and R.S. Brown

Abstract: The hydrolysis of *p*-nitrophenyldiphenyl phosphate (PNPDPP, **7**) catalyzed by *N*-dodecylaminoethanol (**6a**), *N*-tetradecylaminoethanol (**6b**), *N*-methyl-*N*-tetradecylaminoethanol (**6c**), and *N*-hexadecylaminoethanol (**6d**) was investigated at 25°C at various pH values in aqueous media containing additives. Added ethanol or dimethoxyethane produces very little activity of **6a**, **b**, **c** toward **7**. The highest activities of **6a**, **b** were found at pH 8.0 and 8.5 in solvents containing 20% glycerol or ethylene glycol. Under no conditions was *N*-hexadecylaminoethanol (**6d**) found to be active. The kinetics of the reaction of **6b** with **7** were also investigated in a medium containing various amounts of glycerol, polyethylene glycol 400 (PEG 400), and water at pH 7.6–8.5. The best catalytic system comprised 3 mM **6b** in 20% aqueous ethylene glycol, pH 8.5, which accelerated the hydrolysis of **7** by ~1700-fold over the blank rate. Kinetic experiments conducted using [**7**]/[**6b**] = 1 and 2 demonstrate that **6b** exhibits true turnover catalysis. A mechanism for the catalyzed reaction is proposed.

Key words: β-aminoethanols, hydrolysis, *p*-nitrophenyldiphenyl phosphate, micelles, polyhydroxy alcohols.

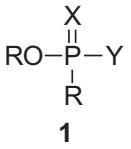
Résumé : Opérant à 25°C, à divers pH, dans des milieux aqueux contenant des additifs, on a étudié l'hydrolyse du phosphate de diphényle et de *p*-nitrophényle (**7**) catalysée par *N*-dodécylaminoéthanol (**6a**), *N*-tétradécylaminoéthanol (**6b**), *N*-méthyl-*N*-tétradécylaminoéthanol (**6c**) et *N*-hexadécylaminoéthanol (**6d**). L'addition d'éthanol ou de diméthoxyéthane ne produise que de faibles activités des catalyseurs **6a**, **b**, **c** vis-à-vis de **7**. Les activités les plus élevées de **6a**, **b** ont été observées à des pH de 8,0 et 8,5, dans des solvants contenant 20% de glycérol ou d'éthylèneglycol. On n'a pas trouvé de conditions dans lesquelles le *N*-hexadécylaminoéthanol (**6d**) est actif. On a aussi examiné la cinétique de la réaction de **6b** avec **7** dans un milieu contenant diverses quantités de glycérol, de polyéthylèneglycol 400 (PEG 400) et d'eau, à des pH allant de 7,6 à 8,5. Le meilleur système catalytique est formé de 3 mM de **6b** dans de l'éthylèneglycol aqueux à 20%, à un pH de 8,5; dans ces conditions, l'hydrolyse de **7** se produit 1700 fois plus rapidement que dans l'essai à blanc. Des expériences cinétiques effectuées en utilisant un rapport [**7**]/[**6b**] = 1 et 2 démontre que le composé **6b** donne lieu à une réelle catalyse. On propose un mécanisme pour la réaction catalysée.

Mots clés : β-aminoéthanols, hydrolyse, phosphate de diphényle et de *p*-nitrophényle, micelles, alcools polyhydroxylés.

[Traduit par la Rédaction]

Introduction

Activated phosphate, phosphinate, and phosphonate esters of the general form **1** are potent acetylcholinesterase inhibitors (1). These include such substances as the insecticides parathion (RO = R = OEt; X = S; Y = $OC_6H_4NO_2$) and paraoxon (RO = R = OEt; X = O; Y = $OC_6H_4NO_2$), as well as the alkylphosphonofluoridate esters soman (RO = $(CH_3)_3CCH(CH_3)O$; R = CH_3; X = O; Y = F) and sarin (RO = $(CH_3)_2CHO$; R = CH_3; X = O; Y = F), the latter gaining their notoriety as organophosphorus nerve agents. Due to their potential toxicity, considerable attention has been directed toward methods of facilitating the hydrolysis or decomposition of organophosphates.



1

In some cases, metal chelates have been successfully shown to catalyze the hydrolysis of neutral phosphate and (or) phosphonate esters (2). More work has been directed to-

Received March 29, 1999.

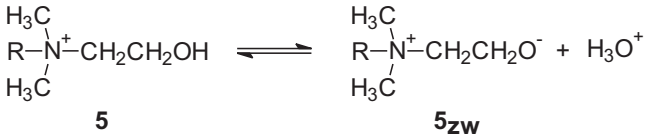
ward micelles (3) (which may (3*b–e*, *g–i*, *k*, *m*, *n*) or may not (3*a*, *f*) contain nucleophilic or general-base additives), functionalized micelles (4), and vesicular (5) means of decomposing organophosphate esters. Of the above surfactant systems, only a few exhibit true catalytic properties (2*e*, *f*, 3*e*, *k*, *m*, *o*, 4*g*, *o*, *q*). Perhaps the most efficacious are the systems initially discovered by Menger et al. (2*e*, *f*, 4*o*) (**2**, **3**), and Moss et al. (3*e*, *j–l*) (**4**), various derivatives of the latter being further investigated (6) due to the high reactivity attributable to the iodosobenzoates.

In general, functionalized quaternary ammonium materials containing a hydroxyethyl group (**5**) possess several important features that have been exploited for the reaction with phosphate esters. First, above the critical micelle concentration (CMC), hydrophobic substrates are attracted to the micellar pseudophase, which increases the local concentration and the likelihood of reaction with the polar head group. Second, the presence of the positively charged quaternary ammonium group electrostatically reduces the pK_a of the attached hydroxyethyl group, thereby creating appreciable quantities of $\mathbf{5_{ZW}}$ at reduced pH. For example, while the pK_a values for alcohols normally range from 15 to 19, those of choline and 2-(*N*,*N*,*N*-triethylammonium)ethanol are 12.8 (7) and 12.9 ± 0.3 (8), while those of micellar **5** (R = $C_{12}H_{25}$ and R = $C_{16}H_{33}$) are 12.9 and 12.4 (4*b*). Furthermore, zwitterionic $\mathbf{5_{ZW}}$ has been shown in several instances (4*b*, 8, 9) to be sufficiently nucleophilic to attack activated C and P esters.



5 $\mathbf{5_{ZW}}$

Unfortunately, these hydroxyethyl quaternary ammonium species are not true catalysts in that they possess no internal means to subsequently regenerate **5** or $\mathbf{5_{ZW}}$ other than through attack of external OH^-. It appeared to us that one might expand the catalytic utility of such micelles by utilizing secondary or tertiary hydroxyethyl amines related to **5**. In principle, derivatives of **6** containing a long chain alkyl moiety should impart micellar characteristics. As shown in Scheme 1, such species can exist in aqueous media as a pH-dependent mixture of four species ($\mathbf{6^+}$, **6**°, $\mathbf{6_{ZW}}$, $\mathbf{6^-}$), the relative amounts of which are controlled by the four microscopic ionization constants K_1–K_4. Forms $\mathbf{6^+}$ and $\mathbf{6_{ZW}}$, in which the amine is protonated, formally resemble the charge types inherent in the more traditional quaternary ammonium micellar species **5**, $\mathbf{5_{ZW}}$. Following nucleophilic attack of the O^- of $\mathbf{6^-}$ or $\mathbf{6_{ZW}}$ on the activated phosphate, a possibility exists that the β-amino group, when deprotonated, might act as an internal nucleophile to displace phosphate to yield an aziridine, which, under the reaction conditions, could suffer nucleophilic ring opening to regenerate the catalyst.

Herein we describe our preliminary findings with surfactants in which four long chain alkyl substituted derivatives

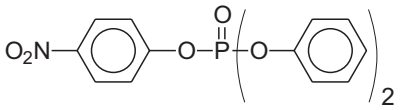
of **6** are reacted with *p*-nitrophenyldiphenyl phosphate (**7**, PNPDPP) under various conditions of solvent composition and pH. Importantly, we have observed that the amino alcohols themselves are rather ineffective in promoting the hydrolysis of **7** unless added polyhydroxy cosolvents are present. In the presence of polyols such as glycerol, ethylene glycol, and even sorbitol, two of these derivatives, **6a**, **b**, probably as their zwitterionic forms, $\mathbf{6_{ZW}}$, appear to be effective nucleophiles toward PNPDPP, producing an *O*-phosphorylated intermediate. Furthermore, under the optimum conditions, **6b** is shown to be catalytically active due to its built-in turnover capabilities.



7

Experimental

a. Materials

p-Nitrophenyldiphenyl phosphate (**7**) was prepared as previously described (10). The amino alcohols **6a**–**d** were made by a generalized procedure (11) modified as follows. A 1130 mL acetone solution containing 300 mmol of 2-aminoethanol (or 2(*N*-methyl)aminoethanol) and 20 mmol of the C_{12}, C_{14}, or C_{16} primary alkyl bromide was heated at reflux for 15–18 h. After cooling, the acetone was removed at reduced pressure, and ether was added to the residue. The ether solution was twice washed with saturated $NaHCO_3$, and then H_2O. Following drying (Na_2SO_4) of the organic solution, the volatiles were removed to yield a semi-crystalline mass that was recrystallized from ether/pet. ether (1:1). The following physical properties were observed.

*2-(*N-*Dodecylamino)ethanol (**6a**)*: Yield 46.5%; mp 41–42°C; IR ($CHCl_3$ cast): 3282, 3120 cm^{-1}; ^1H NMR ($CDCl_3$) 80 MHz, δ: 3.64 (t, 2 H, CH_2OH), 2.78 + 2.62 (2 t, 4 H, CH_2NHCH_2), 1.97 (s, 2 H, NH + OH), 1.28 (bs, 20 H, $(CH_2)_{10}$), 0.88 (t, 3 H, CH_3). Anal. calcd. for $C_{14}H_{31}NO$: C 73.30, H 13.62, N 6.11; found: C 73.35, H 13.41, N 6.08.

*2-(*N-*Tetradecylamino)ethanol (**6b**)*: Yield 93% in methanol as solvent; mp 50–51°C; IR (KBr): 3492, 3272 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.6 (t, 2 H, $NH_2CH_2CH_2OH$), 3.06 (bs, 2 H, NH + OH), 2.72 + 2.63 (2 t, 4 H, CH_2NHCH_2), 1.51 (m, 2 H, $-CH_2CH_2NHCH_2CH_2OH$), 1.28 (bs, 22 H, $(CH_2)_{11}$, 0.89 (t, 3 H, CH_3). Anal. calcd. for $C_{16}H_{35}NO$: C 74.64, H 13.70, N 5.44; found: C 74.82, H 13.79, N 5.26.

*2-(*N-*Methyl*-N-*tetradecylamino)ethanol (**6c**)*: Yield 19.2%; mp <25°C (crystallized from ether/pet. ether at low temperature and quickly filtered); IR ($CHCl_3$ cast): 3410 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.54 (t, 2 H, CH_2OH), 2.99 (bs, 1 H, CH_2OH), 2.48 (t, 2 H, $N(CH_3)CH_2CH_2OH$), 2.37 (t, 2 H, $CH_2N(CH_3)CH_2CH_2OH$), 2.20 (s, 3 H, $N(CH_3)$), 1.43 (m, 2 H, $(CH_2)_{11}CH_2CH_2N$), 1.26 (s, 22 H, $(CH_2)_{11}$), 0.87 (t, 3 H, CH_3). Anal. calcd. for $C_{17}H_{37}NO$: C 75.21, H 13.74, N 5.16; found: C 74.61, H 13.74, N 4.94.

*2-(*N-*Hexadecylamino)ethanol (**6d**)*: Yield 54.5%; mp 49–50°C; IR ($CHCl_3$ cast): 3110, 3290 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.62 (t, 2 H, $NHCH_2CH_2OH$), 2.75 (t, 2 H, $NHCH_2CH_2OH$), 2.60 (t, 2 H, $CH_2NHCH_2CH_2OH$), 2.36 (bs, 2 H, NH + OH), 1.48 (m, 2 H, $(CH_2)_{13}CH_2CH_2N$), 1.27 (bs, 26 H, $(CH_2)_{13}$), 0.88 (t, 3 H, CH_3). Anal. calcd. for $C_{18}H_{39}NO$: C 75.72, H 13.77, N 4.91; found: C 75.70, H 13.46, N 4.77.

b. Kinetics

Kinetics were monitored by observing the rate of formation of *p*-nitrophenoxide at 400 nm (T = 25°C) using a Hewlett–Packard 8451A diode array spectrophotometer or a Cary 210 UV-vis. spectrophotometer. Buffers employed were HEPPS (*N*-[2-hydroxyethyl]piperazine-*N*′-3-propanesulfonic acid), pH 7.5–8.5; CHES (cyclohexylaminoethanesulfonic acid), pH 8.5–10; and CAPS (cyclohexylaminopropanesulfonic acid), pH 10.5–11.5. Final buffer concentrations were 0.01 M, μ = 0.3 (KCl). pH values were measured using a Radiometer TTT2 titration unit with a Radiometer GK-2321C combination electrode, which was standardized using Fisher certified pH 7.00 and 10.00 buffers. pH values were simply measured from solutions that contained the organic cosolvents and amino alcohols and were not corrected. pH values measured before and after the reactions showed no significant deviations. Organic cosolvents were commercially available and used without further purification. Buffer solutions containing the amino alcohols at various concentrations and cosolvents were sonicated for 5 min, and then placed in 3 mL quartz cuvettes in the spectrophotometer cell holder for 20 min to allow thermal equilibration. Reactions were initiated by injecting 5 μL of a 3×10^{-2} M solution of PNPNPP (**7**) in ethanol or DME into the contents of the quartz cuvettes (final concentration of **7**, 5×10^{-5} M). Pseudo-first-order rate constants (k_{obs}) were evaluated by fitting the absorbance (Abs.) vs. time data to a standard exponential model via nonlinear least-squares treatment. Reactions were monitored in triplicate and followed to at least $3t_{1/2}$; in most cases the reactions displayed excellent first-order kinetics, and when they failed to do so, the reactions were repeated. Kinetic data for **6a**, **b**, **c** are presented in Tables 1–3, and the error limits presented are standard deviations.

c. Reactions in the presence of polyethylene glycols

One litre of polyethylene glycol (PEG) 400, having an average molecular weight of 400, was purified by mixing with 15 g of Celite followed by filtration through a medium pore sintered glass funnel. The material was then filtered through about 50 g of neutral alumina (~2 cm thick on sintered glass filtration funnel). The so-purified PEG was kept in a sealed bottle under Ar and thoroughly mixed before any use to ensure homogeneity. For kinetic runs, the solvent–PEG system requires the following protocol for ensuring clear solutions. (*i*) A 5×10^{-3} M mixture of **6b** was prepared in a solvent consisting of 20% v/v glycerol and 80% water containing 0.3 M KCl and 0.01 M HEPPS buffer, by shaking or sonication for 30 min at 50°C. (*ii*) To this solution was added, with agitation, the same volume of PEG 400 as the volume of glycerol added in part (*i*), resulting in a final composition of 16.5% PEG 400, 16.5% glycerol, and 67.5%

water (v/v). The pH of the resulting solution was adjusted to the desired value by addition of NaOH or HCl. Kinetic runs were undertaken using these mixtures as described above, and the results are presented in Table 4.

d. Turnover reactions

(*i*) To determine the catalytic ability of these amino alcohols a standard protocol of conducting the reaction in 20% (v/v) glycerol/H_2O media containing HEPPS (0.01 M, μ = 0.1 (KCl)), pH = 8.0, T = 25°C was investigated. The appearance of *p*-nitrophenoxide was monitored at 460 or 465 nm, and to maintain the final absorbance <1, the respective initial concentrations of DPPNPP (**7**) were 5×10^{-4} and 1×10^{-3} M. Two sets of experiments were conducted, one with sonication, and another without, but in each case the [**6b**] was 5×10^{-4} M. With sonication, the Abs. vs. time plots displayed an irregular and nonreproducible behavior, which is attributable to problems of turbidity. Without sonication, at [**6b**] = [**7**] = 5×10^{-4} M, the kinetics displayed an approximate first-order behavior, but with a small apparent burst of *p*-nitrophenoxide at the beginning of the reaction. Importantly, at the completion of the Abs. vs. time profile, the amount of *p*-nitrophenoxide liberated was (within experimental uncertainty) equal to the initial [PNPDPP]. When the [**7**] = 2[**6b**] ([**6b**] = 5×10^{-4} M), a burst in the production of *p*-nitrophenoxide (amounting to about 40% of the initial [PNPDPP] occurring within 160 min) was observed followed by a slower further release of *p*-nitrophenoxide, the final concentration of which was equivalent to the total initial [PNPDPP] (approximate time for completion of reaction 2000 min).

(*ii*) A series of turnover experiments was also conducted in a solvent system comprising 16.5% glycerol, 67% water, 16.5% PEG 400 (all v/v), 0.25 M KCl, and 0.01 M HEPPS, pH 8, T = 25°C containing three concentrations of **6b**, 1.1×10^{-3}, 2.8×10^{-3}, and 4.16×10^{-3} M. Three mL of the above solutions were inserted into a quartz cuvette in the spectrophotometer cell holder, which was then thermally equilibrated for 15 min. The reaction was initiated by sequential injection of $4 \times 25\mu$L of 3×10^{-2} M of DPPNPP in DME (final conc. of PNPDPP after four additions = 2×10^{-3} M). For the first injection, the Abs. vs. time profile was followed at 420 nm for $10t_{1/2}$ of reaction. The second to fourth portions were added to the same cell, and the Abs. vs. time profiles followed similarly but at 450, 460, and 470 nm, respectively, to keep the final absorbance less than 2.0. The pseudo-first-order rate constants for the individual runs were calculated as above and are presented in Table 5.

Results

a. Kinetics

Amino alcohols **6a**–**d** are not soluble in purely aqueous media and thus require organic cosolvents to attain sufficient solubility to conduct kinetic experiments with PNPDPP (**7**). The hexadecyl derivative (**6d**) is the least soluble of the series and requires at least 50% added ethanol or DME to attain a [**6d**] of 2×10^{-3} M. Even so, at pH 9 virtually no enhancement of the decomposition of **7** is observed in the presence of **6d** relative to the blank rate. Further studies with **6d** were abandoned.

Given in Tables 1–3 are the pseudo-first-order rate constants for the decomposition of **7** under a variety of conditions in the presence of **6a**, **b**, and **c**. In 33.3% EtOH or DME, **6b** is generally a better catalyst than is **6a**, but neither provides a dramatic enhancement of the decomposition of **7** at any pH between 8 and 11. However, as shown from the data in Tables 1 and 2, the presence of the polyhydroxy cosolvents ethylene glycol and glycerol leads to marked enhancement in the reactivity of both **6a** and **6b**. A comparison of these amino alcohols is given by the pseudo-first-order rate constants for decomposition of **7** in 33.3% ethylene glycol in Table 1. There is no linear pH dependent trend in the rate constants observed in the presence of either of **6a** or **6b**.

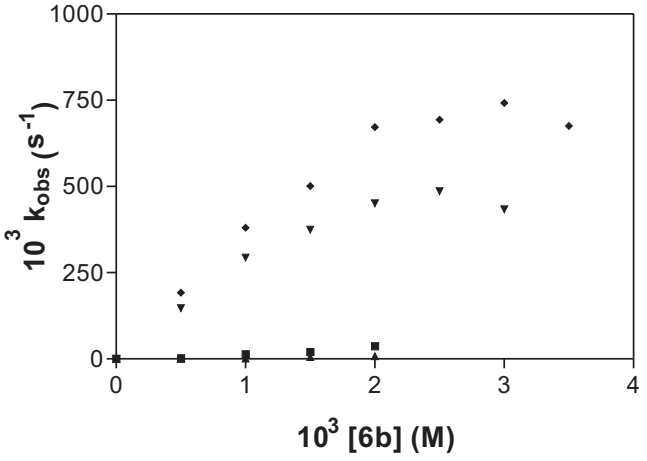
[c]pH 8.

Fig. 1. A plot of k_{obs} for the hydrolysis of **7** vs. [**6b**] in various media at 25°C, μ = 0.3 (KCl), [buffer] = 0.01 M. (▲, 33% ethanol, pH 9; ■, 33% DME, pH 9; ▼, 20% glycerol, pH 8; ◆, 20% ethylene glycol, pH 8.5.)



Shown in Fig. 1 are graphical representations of the pseudo-first-order rate constants for the decomposition of **7** as a function of [**6b**] at the optimum pH in various media. While we have not determined the critical micelle concentration (CMC) of any of these alcohols under the reaction conditions, the appearance of the k_{obs} vs. catalyst conc. plots with maxima at 2.5–3 mM strongly suggests micelle formation. For **6b**, ethylene glycol gives maximum activity at pH 8.5 when at 20% v/v, while 20% glycerol gives maximum activity at pH 8.0. Increasing or decreasing the amounts of these cosolvents leads to reduced activity, as do changes in the respective media pH. Given in Table 4 are rate constants for the reaction of **6b** with **7** in media containing polyethylene glycol (PEG 400) as a cosolvent. Up to half of the glycerol can be replaced by PEG 400 without noticeable drop in activity (relative to 33% glycerol), and the data show that when mixed with glycerol in a 1:1 ratio (16.5% v/v each), the k_{obs} for decomposition of **7** is about the same as with 33% glycerol at pH 8. In the absence of glycerol, 33% PEG 400 accelerates the reaction with 3.12×10^{-3} M **6b** by about 200-fold relative to the blank rate, while 16.5% each of added glycerol and PEG 400 accelerates the reaction with 3.33×10^{-3} M **6b** by about 400-fold. Methylated PEG 350, with the terminal OH groups replaced by CH_3O, seems to be as effective as PEG 400 in promoting the reactions of **6b** in glycerol media, pH 7.6–8.5 (see data in Table 4).

b. Control experiments

Under no conditions is the rate of decomposition of **7** accelerated markedly by simple medium effects in the absence of **6a**–**c**. The *N*-methyl derivative, **6c**, was investigated at the pH optima found for **6b** in solvents of different composition. The data for **6c** in Table 3 show similar overall trends to the reactions with **6b**, but in 20% ethylene glycol the maximum activity of **6c** is 2–4 times lower than that of **6b**, indicating that both secondary and tertiary amine are active. To investigate whether a simple N-substituted β-amino alcohol would exhibit a similar marked activity for the decomposition of **7** in 20% glycerol, the effects of 2×10^{-3} M added 2(*N*-methylamino)ethanol and 2(*N*,*N*-dimethylamino)ethanol were investigated at pH 8.0, T = 25°C, μ = 0.3 (KCl), [**7**] = 5×10^{-5} M. Under these conditions **7** was only slowly hydrolyzed, and the kinetic traces were clearly not first order. Although it is difficult to compare kinetics of dissimilar order, an approximate measure of the reactivity is the $t_{1/2}$ for appearance of the *p*-nitrophenoxide anion. In the presence of **6b**, **6c**, and 2(*N*-methylamino)ethanol, the respective halftimes (pH 8, 20% glycerol) were 2.55, 10.6, and 1667 min.

c. Turnover experiments

The reactions of equimolar and 1:2 stoichiometry of **6b**:**7** were investigated in 20% glycerol, pH 8, μ = 0.1 (KCl), 10^{-2} M HEPPS at 25°C where [**6b**] = 5×10^{-4} M. These conditions are not optimal, since the [**6b**] is roughly fourfold lower than for maximal activity. Nevertheless, they were chosen because the rate of appearance of *p*-nitrophenoxide could be monitored at 460 or 465 nm where the final absorbance was not greater than 1, (460 nm for [**7**] = 5×10^{-4} M; 465 nm for [**7**] = 1×10^{-3} M). Concentrations of **7** in excess of $1 \times l0^{-3}$ M could not be obtained for reasons of solubility.

Shown in Fig. 2 are the Abs. vs. time plots for the above experiments: for Fig. 2*a*, [**7**] = [**6b**] = 5×10^{-4} M, while for Fig. 2*b*, [**7**] = $1 \times l0^{-3}$ M = 2[**6b**]. The appearance of the plots, with the initial burst followed by nearly first-order production of *p*-nitrophenoxide, is consistent with a process involving phosphorylation of the amino alcohol to form an intermediate that decomposes on a similar time scale to regenerate the active amino alcohol.

[a]Determined after allowing catalyst system to stand 24 h.

[b]Precipitates.

[c]Methyl PEG, average MW = 350, terminal groups methylated.

A second set of turnover experiments was conducted in the PEG containing solvents under more optimal conditions. Given in Table 5 are the pseudo-first-order rate constants for appearance of *p*-nitrophenoxide in the presence of **6b** in a solvent comprising 16.5% each of glycerol and PEG 400 and 67% water. To ensure that the reactions were done under homogeneous conditions, aliquots of 2.5×10^{-4} M **7** in DME were injected into the solutions and the absorbance vs. time profiles monitored for $10t_{1/2}$. After this time, another aliquot was added, and the process repeated. To ensure that the total absorbance of the solution did not exceed 2.0, progressively longer wavelengths (420–470 nm) for monitoring the reaction were used. The so-obtained Abs. vs. time data were analyzed to obtain the pseudo-first-order rate constants, which are seen to be the same for a given [**6b**], indicating that the catalyst must turn over during the time taken for the analysis.

Discussion

The choice of these long chain secondary and tertiary aminoethanols as potential micellar turnover catalysts for the decomposition of phosphate esters was dictated by several considerations including simplicity of preparation, ability to form micelles, possession of a nucleophilic pendant, and the requirement for turnover capabilities. From the observations and data given in the results section, **6b** possesses all of the above properties. The most surprising aspect, to our knowledge, is the marked enhancement in reactivity of **6b** in media containing 20–33% ethylene glycol or glycerol. Many

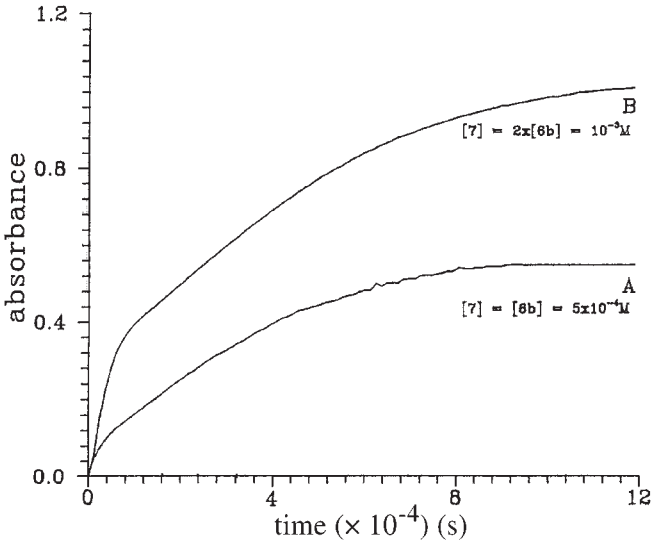
reactions, including carboxyl (12), phosphoryl (13), and surfuryl (14) -group transfers are accelerated in going to less protic and less polar mixed solvent systems (15). The solvent effect generally results from either transition state (TS) stabilization or destabilization of the ground state consisting of nucleophile plus substrate. Poor solvation of anions in dipolar aprotic solvents leads to very marked acceleration of nucleophilic attack if charge is dispersed in the TS (15). Recently Bunton et al. (16) have investigated the attack of HO^- and the oximate of 2,3-butanedione on PNPDPP in water–CH_3CN and water–*t*-BuOH solvent mixtures. They found that the rates initially drop as the percentage of water decreases, but that further reductions in the water conc. led to increases in rate. This is rationalized by an initial stabilization of the nonionic PNPDPP followed by increasing destabilization of the anionic nucleophile resulting from its loss of hydration. Nevertheless, the total effects are far less than what is observed in the present study. Some work has been done on the effects of added DMSO on the hydrolysis of PNPDPP in media containing co-micelles of cetyltrimethylammonium bromide and diethylheptadecylimmidazolium ethylsulphate (4*r*), the net effect being that as the [DMSO] was increased to 90%, substantial increases in rates could be achieved.

Far less work appears to have been done on the effect of polyhydroxy additives on hydrolytic reactions (17). Nusselder and Engberts (17*a*) investigated the hydrolysis of three activated amides (1-acyl-1,2,4-triazoles) in aqueous media containing up to 4 mol% of carbohydrates such as maltose, glucose, and ribose. Although the effect of the additive was to slightly decrease the overall rate of reaction, there were substantial medium effects on the $\Delta S^{\ddagger}$ of reaction attributable to alterations in the three-dimensional H-bonded network in water. Cleve (17*b*) has looked at the hydrolysis of methyl trifluoromethylacetate in water containing alcohols such as butanol and found only modest effects on the reaction rates. Notably, in neither of these studies was there observed the sort of strong rate enhancements such as seen in the present study using the polyol additives, but the concentrations studied were far lower than is the case here.

The effect of the polyhydroxy solvents on the activity of **6b** toward **7** is probably not simple and likely results from a complex mixture of phenomena including changes in the micellar pseudophase, alteration of the pK_a values and K_{eq} associated with **6b** (Scheme 1), and hydrogen bonding by the cosolvent in a way that may lower the TS energy for phosphoryl group transfer from **7** to the O(H) of **6b**. Alternatively, it is possible that the polyhydroxy alcohols or PEGs provide the right environment to promote micellization of **6a**, **b**, and in their absence, no micelles are formed, but more work would be required to sort this out. It has been suggested that strong H bonds due to the hydroxy functions at the polar head groups of micelles are likely to be responsible for the binding of surfactants (4*b*, 8). The polyols in our case could provide such intermolecular H bonds, which transiently bind both the DPPNPP and **6b** thereby increasing the likelihood of productive encounters. However, since PEG 400 without glycerol and Methyl PEG 350 with 16.5% glycerol seem to promote the reactions, albeit somewhat less than with only glycerol or ethylene glycol, the additive cannot primarily be a H bond donor.

Fig. 2. Plots of the absorbance vs. time profiles for hydrolysis of **7** by **6b** in 20% glycerol (v/v), pH 8, μ = 0.1 (KC1), [buffer] = 0.01 M at 25°C. (*A*) [**6b**] = [**7**] = 5×10^{-4} M; (*B*) [**7**] = 2[**6b**] = 10^{-3} M.



The enhancement of reactivity is not limited to the polyols ethylene glycol or glycerol, since 0.5 M sorbitol ($(HOCH_2CH(OH)CH(OH))_2$), pH 7.5, *T* = 25°C, and 2.5 mM **6b** gives a pseudo-first-order rate constant for reaction with **7** of 3.4×10^{-3} s^{-1}. By way of comparison, the system containing 20% ethylene glycol at pH 8.5 gives the highest k_{obs} of 7.42×10^{-3} s^{-1}. Thus, under the optimized conditions given in Table 2, at 3 mM added [**6b**], the ratio of the catalyzed to uncatalyzed process in 20% glycerol or 20% ethylene glycol ranges from 1000- to 1700-fold, pH 8–8.5.

Turnover

The additional point of interest in decomposition of **7** mediated by the micelles of **6b** relates to the turnover. Shown in Fig. 2 are absorbance vs. time plots for the reaction of **6b** with **7** under at relative concentration of 1:1 and 1:2, with [**6b**] = 5×10^{-4} M in 20% glycerol (v/v), pH 8, μ = 0.1 (KC1), buffer conc. = 0.01 M at 25°C. The plots are notable for an initial burst in the production of *p*-nitrophenoxide fol-

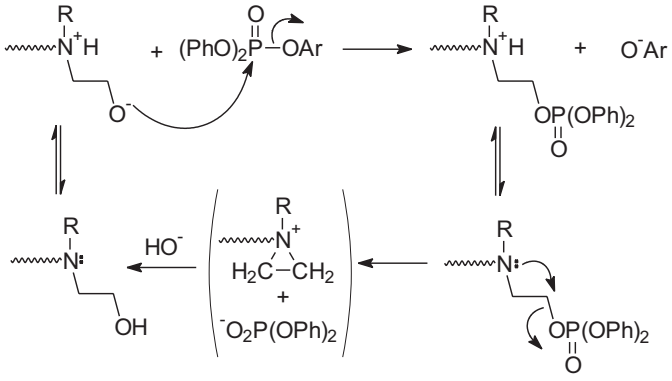
Scheme 2.



lowed by a slower process indicative of turnover. In that set of experiments, the [**6b**] was less than required for optimal activity due to the requirement of solubility and maintaining the final absorbance <1. In a second set of experiments using 1×10^{-3} to 4.2×10^{-3} M **6b** under more solubilizing conditions (16.5% glycerol, 67% water, 16.5% PEG 400, μ = 0.25 (KCl), T = 25°C, EPPS buffer conc. = 0.01 M, pH = 8.0) aliquots of 2.5×10^{-4} M **7** were added, and the successive pseudo-first-order rate constants for generation of *p*-nitrophenoxide were determined. From the data presented in Table 5 it is apparent that the rates of the reactions are the same up to the point of precipitate formation, indicating that the catalyst must be regenerating during the time of the individual rate experiments.

Since hydroxyethyl substituted quaternary ammonium micellar species (5) have not been demonstrated to have turnover capabilities other than through direct OH^--mediated hydrolysis (4*b*), the action of the free β-amino group in **6b** is implicated. Our belief in the free β-amino group as a potential mediator of turnover was guided by work reported by Heath (18), Baer (19), and Mannineu (20) detailing the reaction course for the decomposition of **8** (eq. [2] (18)) and **9** (eq. [3] (20)) as well as the known inability to produce a phosphorylethanolamine from base hydrolysis of **10** (eq. [4] (19)), the hydrolysis of which undoubtedly leads to aminoethanol. In the latter study (19*a*) the behavior of **10** toward base can be contrasted with that of diphenylphosphorylcholine, **13**, the hydrolysis of which yields phosphorylcholine, **14** (eq. [5] (19*b*)).

In an analogous process, the ability of a 2-amino group to act as a neighboring group in displacing $OSO_3^=$ from β-(aminoethyl)hydrogensulfate in NaOH solution forms the basis of the synthesis of aziridine (21). Finally, Lazarus and Benkovic (22) have reported a detailed analysis of the mechanism of hydrolysis of phosphorylethanolamine triesters, which reveals multiple catalytic effects of the intramolecular amino group, one of these being analogous to the process shown in eq. [3].

In view of the above, we envision the catalyzed decomposition of **7** by **6b** to follow the mechanism depicted in Scheme 2 where the zwitterionic form ($\mathbf{6_{ZW}}$) captures **7** to yield *p*-nitrophenoxide and the *O*-phosphorylated **6b**. Loss of the ammonium proton generates a free β-amino group, which is capable of an internal displacement of diphenyl phosphate to generate the aziridine/aziridinium, which subsequently reacts with OH^- to regenerate **6b**.

Finally, it is instructive to compare the reactivity of **6b** and other catalytic entities that have been reported to hydrolyze **7**. Given in Table 6 are the reported maximal observed pseudo-first-order rate constants, conditions, and $t_{1/2}$ values for hydrolysis of **7** mediated by various systems. It is clear that the best catalysts presently available are those related to the Moss' iodosobenzoates in cetyltrimethylammonium micelles (entries 5 (3*j*), 6 (3*d*), and 7 (6*e*) in Table 6) which are about two orders of magnitude better than the functionalized micelles. Of the remainder of the series, where a comparison can be made, the pseudo-first-order rate constants for the formulations reported to give maximal activity all lie within the same order of magnitude. Also, some of the better catalysts exhibit maximal activity at lower catalyst conc. than are required for our system. The Bunton surfactant

 (5×10^{-4})	pH 9 5×10^{-4} M CTABr	~8.5×10^{-3}	~81	4*q*
 (4.5×10^{-4})	pH 8.5, 1 mM CTACl	2.4×10^{-2}	28.8	3*m*
$C_{16}H_{33}N^{+}Me_2(CH_2)_2OH$ (2.5×10^{-5})	0.01 M NaOH (pH 12)	~1.5	~0.5	4*b*

($C_{16}H_{33}N^{+}(CH_3)_2CH_2CH_2OH$) (entry 13 (4*b*)) is the most closely related to **6b** structurally and seems to be very reactive at pH 12, but the reactivity drops linearly with pH, so that at pH 8 it is the least effective of all the species in the table.

Conclusions

The above study indicates that formulations of the easily obtained **6b** in 20% ethylene glycol–H_2O or glycerol–H_2O at pH 8.5 or 8, respectively, provide a micellar catalyst system that reacts with **7**, giving a rate enhancement of ~1500-fold relative to spontaneous hydrolysis. The advantages of the present formulations with **6b** include ease of preparation, cost of the formulation, long-term stability, and low toxicity of the components. The activity of **6b** is critically dependent on the presence of polyols and (or) PEGs in the solution. The reasons for the marked enhancement in activity in the presence of these additives is not clear at present but could arise from medium effects, which favour the formation of micelles, or from a stabilization of the transition state for reaction brought about by transient H bonding with nucleophile and PNPDPP substrate. In addition, it has been shown that **6b** is catalytic in its reaction with PNPDPP, a phenomenon that we suggest arises from neighboring group assistance by the N in facilitating cleavage of the phosphorylated intermediate. It has been stated that

© 1999 NRC Canada

DPPNPP (**7**) is an attractive model for study because its spontaneous hydrolysis is slower than that of the more noxious phosphorus materials such as the nerve agents (2*e*, *f*). One expects that any catalyst capable of facilitating the hydrolysis of **7** should be effective for hydrolysis of the nerve agents. However, where direct comparison can be made, although certain catalysts (e.g., **4**) exhibit spectacular rate enhancements with **7**, their reactions with sarin and soman are somewhat less spectacular, being ~20–80-fold over the spontaneous hydrolysis (3*d*). Presumably this relates to differences in partitioning of **7** and sarin or soman between the aqueous and micellar pseudophase in which the catalytic entity resides, and TS energy differences for that reaction relative to cleavage of PNPDPP. In a given case the true test for a decontaminant is, of course, its reaction with the more noxious agent, and it remains to be determined how efficacious the **6b**–polyol systems are in this respect.

Solubility of biphenyl in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon Mobile Order theory

Karina M. De Fina, Tina L. Sharp, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for biphenyl dissolved in 26 different alkane, dialkyl ether, and alcohol solvents. Results of these measurements, combined with previously published biphenyl solubility data, are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 40 solvents for which predictions could be made computations show that Mobile Order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 13.0%.

Key words: biphenyl solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : Opérant à 25,0°C, on a déterminé les solubilités expérimentales du biphényl dissous dans 26 solvants différents comprenant des alcanes, des éthers et des alcools aliphatiques. Les résultats de ces mesures, combinées aux données de solubilité du biphényl publiées antérieurement, sont utilisés pour évaluer les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Pour les 40 solvants pour lesquels il était possible de faire de prédictions, les calculs montrent que la théorie de l'ordre fonctionnel conduit à des évaluations assez raisonnables des solubilités exprimées en fraction molaire de saturation. La déviation absolue moyenne entre les valeurs prévues et observées est de 13,0 %.

Mots clés : solubilités du biphényl, solvants organiques non électrolytiques, prédictions de la solubilité.

[Traduit par la Rédaction]

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and heteroatom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of refs. see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–14). Group contribution methods typically predict solid–liquid equilibria and phase diagrams to within a root-mean-square deviation of 2 K. Practical application though, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the database contain as many different functional groups as possible, preferably with adequate representation from both mono- and multifunctional solute/solvent molecules to permit evaluation of potential synergistic effects. The database should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham et al. (15, 16) recently developed a general solvation equation that can be used in the correlation and understanding of physico-chemical and biochemical phenomena. Physical properties that have been correlated include gas/solvent partition coefficients (as log L)

$$[1] \qquad \log L = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + \mathrm{d} \log L^{16}$$

and water/solvent partition coefficients (as log P)

$$[2] \qquad \log P = c + rR_2 + s\pi_2^H + a\sum \alpha_2^H + b\sum \beta_2^H + vV_x$$

Received March 22, 1999.

where R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, and $\sum \alpha_2^H$ and $\sum \beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity. For any given solvent, numerical values of the seven curve-fit coefficients (*c*, *r*, s, *a*, *b*, *d*, and *v*) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported regression coefficients for water (15, 16) and a few select organic solvents (16).

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs) and polycyclic aromatic nitrogen heteroatoms (PANHs). In the present communication, we report biphenyl solubilities in 26 different alkanes, dialkyl ether, and alcohol solvents. Results of these measurements, combined with previously published biphenyl solubility data (17), are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory. Subsequent studies will use the experimental biphenyl solubilities in developing gas/liquid partition and water/organic solvent partition correlations based upon eqs. [1] and [2].

Materials and methods

Biphenyl (Aldrich, 99%) was recrystallized several times from methanol. *n*-Nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), dibutyl ether (Aldrich, 99%), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Co., absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 2-methyl-2-propanol (Arco Chemicals, 99+%), and ethylene glycol (Aldrich, 99.8%, anhydrous) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mol% or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated biphenyl solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with 2-propanol for spectrophotometric analysis at 250 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve for nine standard solutions. The concentration of biphenyl in the standard solutions varied from 2.38×10^{-5} M to 1.19×10^{-4} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\epsilon \approx 16\,500$ L mol^{-1} cm^{-1} (2.38×10^{-5} M) to $\epsilon \approx 16\,000$ L mol^{-1} cm^{-1} (1.19×10^{-4} M). Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of biphenyl, volume(s) of volumetric flask(s) used and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance versus concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental biphenyl solubilities, X_A^{sat}, in 26 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%.

Results and discussion

Solubility data is available in the pharmaceutical literature for biphenyl dissolved in binary aqueous-methanol solvent mixtures. Khossravi and Connors (18) reported a molar solubility of $C_A^{sat} = 0.4245$ for biphenyl in neat methanol at 298.15 K. Molar solubilities can be converted to mole fractions using $V_{methanol} = 40.7$ cm^3 mol^{-1} and $V_{biph} = 149.4$ cm^3 mol^{-1} (16), and by assuming that the excess volume is negligible. Performing this computation, we calculate a mole fraction solubility of $X_A^{sat} = 0.018\,11$. Our experimental value of $X_A^{sat} = 0.018\,51$ differs from the published value by approximately 2%. Differences in chemical purities and experimental methodologies can lead to differences of a few percent between values determined by two different research groups.

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (20–27) assumes that all molecular groups perpetually move, and that neighbours of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume *V* of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen-bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

[a]Deviations (%) = $100[(X_A^{sat})^{calc} - (X_A^{sat})^{exp}]/(X_A^{sat})^{exp}$.

$$[3]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hy-

© 1999 NRC Canada

drocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[4] \quad r_{solvent} = (K_{solvent}\phi_{solvent}/V_{solvent})/(1 + K_{solvent}\phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent}$ = 5000 cm^3 mol^{-1} assumed for all mono-functional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[5] \quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ'_A and $\delta'_{solvent}$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[6] \quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp})$$

the solute's molar enthalpy of fusion, ΔH_A^{fus} at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1}$ term. Ruelle et al. (23–27) and Acree and co-workers (28–34) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, 12-tricosanone, *trans*-stilbene, thioxanthen-9-one, and phenanthrene solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Predictive application of eqs. [3] and [5] is relatively straightforward. First, an average numerical value of δ'_{biph} = 19.51 MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes biphenyl mole fraction solubility data in *n*-hexane (δ'_{biph} = 19.60 MPa$^{1/2}$), *n*-heptane (δ'_{biph} = 19.45 MPa$^{1/2}$), and *n*-octane (δ'_{biph} = 19.48 MPa$^{1/2}$). The numerical value of a_A^{solid} = 0.3844 is calculated using eq. [11] with ΔH_A^{fus} = 18 410 J mol^{-1} (35). A numerical value of V_{biph} = 149.4 cm^3 mol^{-1} (19) was used for the molar volume of the hypothetical subcooled liquid solute.

Table 1 summarizes the predictive ability of Mobile Order theory for the 40 different organic solvents for which both biphenyl solubility data and modified solubility parameters could be found. We could not find modified solubility parameters for all of the branched and secondary alcohol solvents. Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (23, 24, 26, 27), and were either deduced by regressing actual solubility data

of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (36) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does provide fairly reasonable estimates of the solubility behavior of biphenyl in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 13.0%. The solvents hexane, heptane, and octane were excluded from the average deviation computation, since δ'_{biph} was based upon the measured biphenyl solubilities in these three alkane solvents. Expressed on a natural logarithmic mole fraction scale Mobile Order theory predicts the biphenyl solubilities to within ±0.12 ln units. It should be noted that Ruelle et al. (25) previously presented a similar comparison involving Mobile Order theory; however, the authors' solvent set included primarily saturated alkane hydrocarbons, benzene derivatives, and halogenated alkanes. Our comparison is more complete in that 19 additional solvents are considered. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data covers over a 150-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid} = 0.3844$ for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 613% between predicted and observed values.

Étude de l'adsorption des hydrocarbures aromatiques polycycliques sur l'hydroxyde d'aluminium par chromatographie liquide à haute pression

Chakib Ameziane Hassani et Hugues Ménard

Résumé : L'étude par HPLC de l'adsorption des HAP dans le toluène sur l'hydroxyde d'aluminium calciné à des températures allant de 25 jusqu'à 700°C montre que le taux d'adsorption est maximal sur l'hydroxyde chauffé à 300°C. Les mesures du potentiel électrocinétique et de la surface spécifique sont en accord avec ces résultats. Les enthalpies d'adsorption des différents HAP sur l'hydroxyde chauffé à 300°C sont calculées, ceci nous a permis de mettre en évidence le phénomène de physisorption. Cette étude compare le pouvoir adsorbant élevé de l'hydroxyde d'aluminium vis-à-vis les HAP par rapport à celui d'autres matériaux réputés être potentiellement cancérigènes.

Mots clés : adsorption des HAP, hydroxyde d'aluminium.

Abstract: A study by high performance liquid chromatography of adsorption isotherm of HAP in toluene on $Al(OH)_3$ heated between 25 and 700°C shows that the rate of adsorption is maximal on the $Al(OH)_3$ heated at 300°C. The measurement of electrokinetic potential and the surface area of adsorbants approve this result. The determination of adsorption enthalpies of different HAP on the aluminium hydroxide has shown the existence of physical adsorption. The adsorbing power of $Al(OH)_3$ heated at 300°C is compared with that of other materials known or suspected very carcinogens.

Key words: adsorption isotherm of HAP, aluminium hydroxide.

Introduction

Il est généralement admis que l'inhalation des particules de dimension respirable dont les sources d'émission sont naturelles ou industrielles (Fonderie d'aluminium,[2] Fonderie de Fer (1)) peut avoir un effet sur la santé et le bien être des travailleurs. Ces particules interagissent avec les Hydrocarbures Aromatiques Polycycliques (HAP) au niveau pulmonaire et entraînent des maladies respiratoires en général et le cancer des poumons en particulier (2–5).

L'influence de la pollution de l'air sur l'apparition du cancer des poumons est encore un problème très discuté. Les HAP qui sont des produits potentiellement cancérigènes et mutagènes (6–8) constituent une importante catégorie des polluants chimiques rejetés dans l'atmosphère. À peu près tous les processus thermiques faisant intervenir des carburants organiques peuvent produire ces HAP. Une autre importante source de ces polluants est la fumée des cigarettes (9, 10).

En dehors des HAP d'autre corps sont suspect d'être initiateurs des tumeurs malignes, on citera l'amiante (11, 12), le noir de charbon et la silice (12).

Dans cette étude nous avons utilisé la chromatographie liquide à haute pression pour mesurer l'adsorption des différents HAP dans le toluène sur l'hydroxyde d'aluminium ayant subit des traitements thermiques allant de 25°C jusqu'à 700°C.

La mesure du potentiel électrocinétique et de la surface spécifique a permis d'expliquer la variation du taux d'adsorption des différents HAP sur les échantillons de l'hydroxyde d'aluminium.

Nous avons comparé les isothermes d'adsorption obtenues de l'hydroxyde d'aluminium avec les isothermes de l'amiante et des fibres de carbone.

Reçu 6 janvier 1999.

Partie expérimentale

Appareillage

Le système à chromatographie liquide à haute pression est constitué de plusieurs instruments. Nous avons utilisé une pompe Beckman modèle 100-A couplée à un détecteur ultraviolet (U.V.) de la compagnie Altex Hitachi, modèle 100–40 muni d'une cellule de détection de 10 μL. L'acquisition et le traitement des données sont faits à l'aide d'un microordinateur RX-8800 tel qu'utilisé par Noël (13).

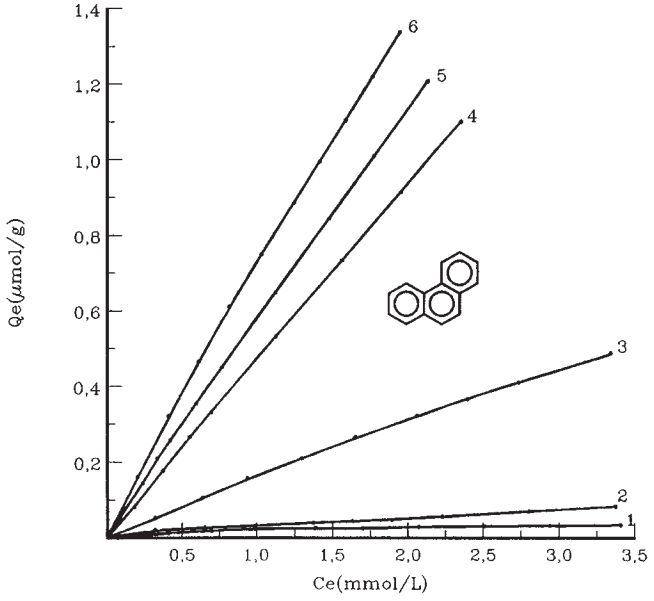
Fig. 1. Isothermes d'adsorption sur les différents échantillons de l'hydroxyde d'aluminium calciné du phénanthrène–toluène à débit constant 0,2 mL/min et température 20°C. Les températures de calcination sont (1) 100, (2) 150, (3) 700, (4) 400, (5) 250 et (6) 300°C.



Deux systèmes d'injection sont utilisés, le premier est un système Rhéodyne, modèle 7125, le deuxième est un système Valco-valves, modèle C6W. Les boucles d'injection sont respectivement 20 et 50 μL.

Pour éviter les changements brusques de la température, nous avons utilisé un bain thermostable de la compagnie Haake, modèle FE-2 d'une précision de 0,01°C.

Les colonnes utilisées sont des tubes en acier inoxydable de la compagnie Swagelock ayant un diamètre interne de 4,6 mm et une longueur de 3,5 cm seulement.

Les tracés chromatographiques sont enregistrés simultanément par un intégrateur Hewlett Packard modèle 3390 A et un enregistreur Varian modèle 9176.

La mesure du potentiel électrocinétique est réalisée à l'aide d'un appareil de la compagnie Komlime-Sanderson modèle ZR-11. Les analyses sont effectuées dans une solution de KCl à pH neutre. Ce dernier est ajusté soit par HCl soit par KOH à une concentration de 10^{-3} M.

Les mesures de la surface spécifique sont effectuées par un appareil quantasorb-sorption de la compagnie Quantachrome Corp. modèle QS-10.

Réactifs

Les HAP utilisés sont l'anthracène (≥ 99,9 %), le pyrène (≥ 99 %), le benzo(e)pyrène (≥ 99 %) de la compagnie Aldrich Chemical Inc. et le phénanthrène (≥ 95 %) de la compagnie BDH.

L'hydroxyde d'aluminium utilisé comme support chromatographique est obtenu de la compagnie J.J. Baker Chemical Co. Il a subi des traitements thermiques allant de 25°C jusqu'à 700°C.

Nous avons utilisé comme éluant le toluène et l'hexane de qualité accuslov de la compagnie Anachemia, pour les sécher on ajoute dans une bouteille de 4 L, 40 g de tamis moléculaire (type 3A, grade 546) de la compagnie Fisher Scientific.

Tableau 1. Température de calcination, surface spécifique, potentiel électrocinétique, perte en poids et formule des différents échantillons de l'hydroxyde d'aluminium après calcination.

T (°C)	Σ (m^2/g)	ς (mV)	Perte en poids (%)	Formule
25	0,34	–32	0	Al_2O_3, 3 H_2O
100	0,40	–5	—	—
150	0,40	+19	0,03	Al_2O_3, 2,997 H_2O
250	282	+19	20,21	Al_2O_3, 1,2 H_2O
300	223	+15	27,85	Al_2O_3, 0,6 H_2O
400	188	+16	29,85	Al_2O_3, 0,4 H_2O
700	93	+13	34,37	Al_2O_3, 0,02 H_2O

Procédure

Tous les solvants utilisés pour le HPLC sont désoxygénés sous vide pendant une période de 15 min et une légère surpression d'azote sec circule au-dessus du solvant pendant la durée de l'expérience.

La colonne et la buse sont remplies et compactées à sec avec les supports utilisés et par la suite, de l'hexane est pompé sous pression à travers la colonne et la buse par une pompe Haskel. La colonne est placée dans un cylindre thermostable et reliée au HPLC. Le débit de l'éluant est de 0,2 mL/min.

Les échantillons calcinés de l'hydroxyde d'aluminium sont chauffés dans un four pendant 24 h à la pression atmosphérique.

Les différentes solutions des HAP sont préparées à partir d'une solution mère de 5×10^{-2} M et les quantités injectées varient entre 10 et 1000 nmol.

Les isothermes d'adsorption sont déterminées par la méthode de Chuduk et al. (14) et les énergies d'adsorption des HAP sur les différents supports sont calculées en appliquant l'équation de Takeuchi et al. (15) pour une série des isothermes obtenues à des températures variables. À partir des pics chromatographiques on peut obtenir Qe (concentration de la molécule sur l'absorbant) en fonction de la concentration en solution Ce (11).

Résolution et discussion

La figure 1 présente les isothermes d'adsorption du phénanthrène dans le toluène sur les différents échantillons de l'hydroxyde d'aluminium calcinés. Cette figure montre que le taux d'adsorption est pratiquement nul sur l'hydroxyde commercial (calciné à 25°C), il augmente à un maximum pour une température de traitement de 300°C puis diminue au-delà de cette température.

Le tableau 1 donne, en fonction de la température de calcination, les variations de la surface spécifique (Σ), le potentiel électrocinétique (ς), la perte en poids et les formules du solide après calcination.

Le tableau 1 montre que la surface spécifique (Σ) augmente de 0,34 m^2/g pour l'hydroxyde d'aluminium commercial à 282 m^2/g pour $Al(OH)_3$ chauffé à 250°C, et pour

Fig. 2. Isothermes d'adsorption sur l'hydroxyde d'aluminium chauffé à 300°C du (1) anthracène–toluène; (2) phénanthrène–toluène; (3) pyrène–toluène; (4) pyrène–toluène à débit constant 0,2 mL/min et température de 20°C.

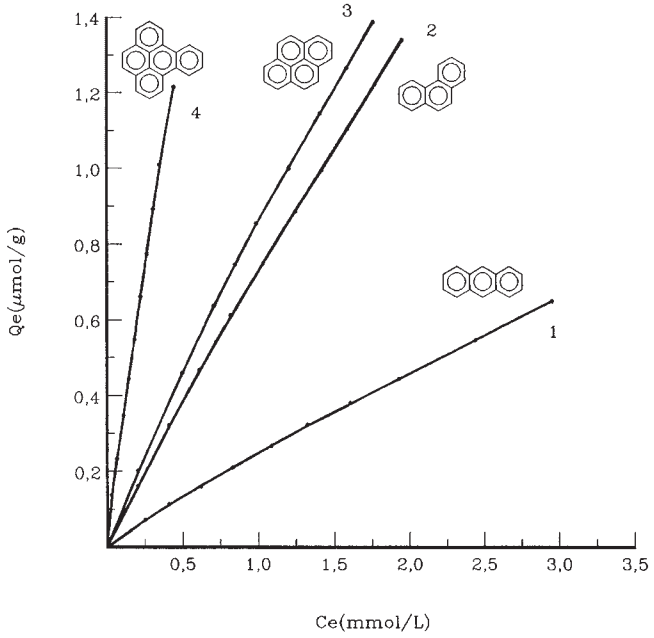

Fig. 3. Isothermes d'adsorption sur l'hydroxyde d'aluminium chauffé à 300°C du (1) phénanthrène–toluène; (2) phénanthrène–hexane à débit constant 0,2 mL/min et température de 20°C.

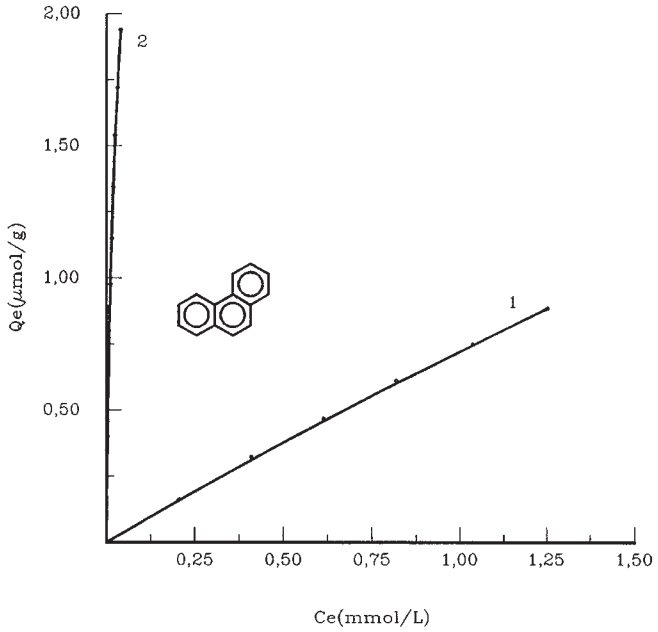

l'échantillon chauffé à 700°C cette valeur diminue à 93 m^2/g.

La variation du potentiel électrocinétique (ς) montre que sa valeur change de signe et devient positive à partir d'une température de 100°C. Ce changement de signe peut entraîner une augmentation du taux d'adsorption à cause de l'attraction des électrons Π des HAP par la surface de support chargée positivement.

Le tableau 1 montre aussi que la majeure partie de la perte en poids a lieu entre 250 et 300°C et correspond respectivement à 20,21 et 27,65 % ce qui donne les formules Al_2O_3, 1,2 H_2O pour l'hydroxyde chauffé à 250°C et Al_2O_3, 0,6 H_2O pour celui chauffé à 300°C.

Tous ces résultats montrent que l'hydroxyde d'aluminium atteint son activité maximale à une température comprise entre 250 et 300°C. Ceci justifie le grand taux d'adsorption des HAP sur l'échantillon calciné à 300°C.

La variation de la surface spécifique avec la température de traitement a déjà été trouvée par Sing (16) en faisant un traitement thermique sur la bayerite (forme cristalline de l'hydroxyde d'aluminium).

Rouquerol et al. (17), en faisant une étude sur la décomposition de l'hydrargillitte, a remarqué que la décomposition de celle-ci commence à une température de 183°C et se termine à 300°C avec des surfaces spécifiques respectives de 15,8 et 300 m^2/g. Sing (16) explique cette augmentation de la surface spécifique par la création des pores et la génération de la surface interne du solide à la suite du départ des groupements hydroxyles sous forme d'eau. La majeure partie de cette perte se produit entre 250 et 300°C. Dépassant cette température, le système subit le réarrangement spatial du réseau qui entraîne la fermeture des pores, et par conséquent la diminution de la surface spécifique (16, 18).

Cette phase active de l'hydroxyde d'aluminium que nous avons trouvée est mal connue jusqu'à présent. Trambouze et Courtial (19) l'ont préparé en chauffant le trihydrate à 236°C pendant 24 jours à la pression atmosphérique. Ils obtiennent un solide de formule Al_2O_3, 0,69 H_2O. Utilisant un dosage sélectif de bochmite, ils ont conclu que le solide est formé de bochmite et d'une phase amorphe répondant à la formule Al_2O_3, 0,48 H_2O, très voisine de celle trouvée par Papée et Tertian (20).

Ayant trouvé que le taux d'adsorption du phénanthrène dans le toluène est maximal sur l'hydroxyde $Al(OH)_3$ chauffé à 300°C, nous avons injecté sur ce support les différents HAP utilisés : l'anthracène, le pyrène et le benzo(e)pyrène. Les différentes injections ont donné les isothermes présentés à la figure 2. De cette figure on remarque que le taux d'adsorption augmente avec le nombre de cycles aromatiques de l'hydrocarbure, le benzo(e)pyrène soupçonné être le plus cancérigène est le plus fortement adsorbé.

La figure 3 illustre l'effet de la phase éluante sur l'adsorption des HAP sur $Al(OH)_3$ chauffé à 300°C. On remarque que l'utilisation de l'hexane au lieu du toluène comme éluant augmente le taux d'adsorption. Ce résultat s'explique par le fait que le toluène est un solvant plus polaire ayant une force d'élution nettement supérieure à celle de l'hexane.

Dans le but de savoir l'ordre d'énergie impliquée lors de l'adsorption des différents HAP sur $Al(OH)_3$ chauffé à 300°C nous avons appliqué la formule de Takeuchi et al. (15) pour une série d'isothermes obtenus à des températures variables. Selon Takeuchi et al. le facteur de capacité est relié à la température par la relation suivante:

$$\ln\ (K') = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} + \ln\left(\frac{V_s}{V_M}\right)$$

© 1999 CNRC Canada

Tableau 2. Les enthalpies d'adsorption des différents HAP sur l'hydroxyde d'aluminium chauffé à 300°C.

Soluté	ΔH (kJ/mol)
Benzo(e)pyrène	–15,70 + 0,12
Pyrène	–11,66 + 0,31
Phénanthrène	–10,87 + 0,02
Anthracène	–2,22 + 0.03

$\Delta H°$ et $\Delta S°$ sont respectivement l'enthalpie et l'entropie lors du transfert du soluté de la phase mobile à la phase stationnaire, R la constante des gaz parfaits, T la température de la colonne, V_s le volume total de la phase stationnaire et V_m le volume du solvant dans la colonne. L'enthalpie d'adsorption est liée à la pente de la courbe donnant ln (K') en fonction de $1/T$.

Le tableau 2 présente les enthalpies d'adsorption des différents HAP sur $Al(OH)_3$ chauffé à 300°C. Ces résultats montrent que l'interaction des HAP avec la surface de support augmente avec le nombre de cycles que contient l'hydrocarbure. En plus nous remarquons que les énergies mises en jeu ne dépassent pas les 20 kJ/mol, ce qui permet de classer l'adsorption des HAP sur l'hydroxyde d'aluminium chauffé à 300°C dans la classe de physisorption.

La figure 4 permet de faire la comparaison de l'adsorption des HAP sur $Al(OH)_3$ chauffé à 300°C, l'amiante chrysotile et les fibres de carbone chauffées à 100°C. Elle présente les isothermes d'adsorption du phénanthrène dans le toluène sur les trois supports. Nous remarquons ici que $Al(OH)_3$ chauffé à 300°C adsorbe beaucoup plus que l'amiante soupçonné être très cancérigène.

Conclusions

Les tracés des isothermes par HPLC du phénanthrène sur les différents échantillons de $Al(OH)_3$ calcinés montrent que le taux d'adsorption est maximal sur l'hydroxyde chauffé à 300°C.

Les mesures du potentiel électrocinétique et de la surface spécifique effectuées sur les différents échantillons montrent que $Al(OH)_3$ atteint son activité maximale entre 250°C et 300°C; la surface devient chargée positivement et la surface spécifique atteint le maximum de 282 m^2/g.

La comparaison des isothermes d'adsorption des différents HAP sur $Al(OH)_3$ chauffé à 300°C révèle que le taux d'adsorption augmente avec le nombre de cycles aromatiques que contient l'hydrocarbure.

Le calcul des énergies d'adsorption des différents HAP sur $Al(OH)_3$ chauffé à 300°C a permis de classer l'adsorption dans la catégorie de physisorption.

La comparaison du pouvoir adsorbant de $Al(OH)_3$ chauffé à 300°C, l'amiante chrysotyle et les fibres de carbone montre que l'hydroxyde d'aluminium adsorbe les HAP beaucoup plus que l'amiante soupçonnée être très cancérigène.

Fig. 4. Isothermes d'adsorption sur (1) hydroxyde d'aluminium chauffé à 300°C; (2) amiante chrysotile; (3) fibres de carbone chauffés à 100°C à débit constant de 0,2 mL/min et température de 20°C.

Thermodynamic calculations for reactions involving hydrogen halide polymers, ions, and Lewis acid adducts. 4. The temperature dependence of some reactions of HF and HCl

Kathryn N. Rankin, W. David Chandler, and Keith E. Johnson

Abstract: Ab initio MP2/6-311++G(d,p) structure optimizations and frequency calculations have been carried out on 10 polymers, $(HX)_n$; on eight polyhalohydrogenate(1-) anions, $H_nX_{n+1}^-$, and on four polyhalohydrogen(I) cations, $H_{n+1}X_n^+$, (X = F and Cl) at a number of temperatures from 188 to 673 K, and at various total pressures. From the results, $\Delta G°$ and K values have been calculated for some reactions involving these species, and the relative amounts determined under a variety of conditions:

$$n\text{HX} \rightarrow (\text{HX})_n \qquad (n = 2\text{–}6)$$

$$\text{HX} + \text{H}_n\text{X}_{n+1}^- \rightarrow \text{H}_{n+1}\text{X}_{n+2}^- \qquad (n = 0\text{–}3)$$

$$\text{HX} + \text{H}_{n+1}\text{X}_n^+ \rightarrow \text{H}_{n+2}\text{X}_{n+1}^+ \qquad (n = 0, 1)$$

There are some marked differences between the fluorine and chlorine series, but generally, the relative amounts of the large molecules and ions decrease as the temperature increases. For all reactions, ln K can be expressed as function to the fourth power in $1/T$ indicating that $\Delta H°$ is more or less temperature dependent over a range of 400–500°.

Key words: ab initio, thermodynamics, HCl, HF.

Résumé : Opérant au niveau MP2/6-311++G(d,p), on a effectué une optimisation ab initio de structure et des calculs de fréquence pour dix polymères, $(HX)_n$; sur huit anions polyhalogénohydrogénate(–1), $H_nX_{n+1}^-$, et sur quatre cations polyhalogénohydrogène(I), $H_{n+1}X_n^+$, (X = F et Cl), à diverses températures entre 188 et 673 K et à diverses pressions totales. À partir des résultats de ces calculs, on a évalué les $\Delta G°$ et K de quelques réactions impliquant ces trois espèces et les valeurs relatives déterminées pour diverses conditions sont les suivantes

$$n\text{HX} \rightarrow (\text{HX})_n \qquad (n = 2\text{–}6)$$

$$\text{HX} + \text{H}_n\text{X}_{n+1}^- \rightarrow \text{H}_{n+1}\text{X}_{n+2}^- \qquad (n = 0\text{–}3)$$

$$\text{HX} + \text{H}_{n+1}\text{X}_n^+ \rightarrow \text{H}_{n+2}\text{X}_{n+1}^+ \qquad (n = 0, 1)$$

On observe des différences marquées entre les séries du fluor et du chlore, mais les quantités relatives des molécules et des ions plus importants diminuent généralement avec une augmentation de la température. Pour chacune des réactions, la valeur de ln K peut être exprimée en fonction de la quatrième puissance de $1/T$; ceci indique que, sur la plage de température allant de 400 à 500°, le $\Delta H°$ est plus ou moins dépendant de la température.

Mots clés : calculs ab initio, thermodynamique, HCl, HF.

Introduction

The formation and reactions of hydrogen halide polymers, $(HX)_n$, polyhalohydrogenate(1-) anions, $H_nX_{n+1}^-$, and polyhalohydrogen(I) cations, $H_{n+1}X_n^+$, (X = F, Cl) can proceed in the pure hydrogen halide or in mixtures of HX with $AlCl_3$ and ZCl, where ZCl is an alkali chloride or an organic chloride such as 1-ethyl-3-methyl-1*H*-imidazolium chloride (ImCl) (1). The optimized gas-phase structures and three general classes of reactions (reactions [1]–[3]) have been studied using data at 298 K obtained from MP2/6-311+G(d,p) calculations (1*d*–*f*). In those papers we have shown that, at 298 K, the gas phase formation of the polymers $(HF)_n$ (reaction [1]), has small and positive $\Delta G°$ values for n = 2–6; of

these clusters, only $(HF)_2$ does not exist in a cyclic structure. The standard reaction Gibbs energies for the corresponding HCl polymers (n = 2–4) are somewhat larger. By contrast, reaction series [2] and [3] are exergonic for all values of n studied and for both HF and HCl.

[1] $n\mathrm{HX} \rightarrow (\mathrm{HX})_n$

[2] $\mathrm{HX} + \mathrm{H}_n\mathrm{X}_{n+1}^- \rightarrow \mathrm{H}_{n+1}\mathrm{X}_{n+2}^-$

[3] $\mathrm{HX} + \mathrm{H}_{n+1}\mathrm{X}_n^+ \rightarrow \mathrm{H}_{n+2}\mathrm{X}_{n+1}^+$

Although the relevant literature relating to these complexes, anions, and cations was reviewed up to that time in our earlier work, there has been a fair amount of more recent interest in at least some of these species. There have been a variety of theoretical and (or) experimental assessments of the structures, energy surfaces, and bond energies (D_o and D_e), of IR and NMR spectra, and of solution equilibria for $(HF)_2$ (2), $(HF)_3$ (2*v*, 3), $(HF)_4$ (2*v*, 3), $(HF)_5$ (2*v*), $(HCl)_2$ (2*w*, *x*, 4), $(HCl)_3$ (4*c*), $(HCl)_4$ (4*c*), HF_2^- (5), $H_2F_3^-$ (5*d*–*f*, h), $H_3F_4^-$ (5*d*–*f*), and $H_4F_5^-$ (5*d*–*f*).

In this paper we discuss the results of ab initio MP2/6-311++G(d,p) structure optimizations and frequency calculations on 10 complexes, $(HX)_n$ (n = 2–6); on eight polyhalohydrogenate(1-) anions, $H_nX_{n+1}^-$ (n = 0–3), and on four polyhalohydrogen(I) cations, $H_{n+1}X_n^+$ (n = 0, 1), where X = F and Cl. The structures and thermodynamic data of $(HCl)_5$ and $(HCl)_6$ are reported for the first time. The frequency calculations were carried out at a number of temperatures from 188, the normal boiling point of HCl, to 673 K, and, in some cases, at various total pressures.

Most previous theoretical studies, with the exception of our earlier papers (1*d*–*f*), have tended to provide relative energies for some of these reactions at 0 K, (D_e), sometimes corrected for zero-point energies (D_o or the reaction internal energy, ΔU). However, if calculations are to be helpful in predicting the outcomes of reactions at equilibrium, they should provide standard reaction Gibb's energies, $\Delta G°$, or standard reaction enthalpies, $\Delta H°$, at useful temperatures. The difference between ΔH at 298 K and ΔU at 0 K, even with zero-point-energy differences taken into account, involves thermal energy (usually small) as well as the term ΔnRT, where Δn is the change in the total number of moles of gas during the reaction (eq. [4]). This PV work term, even at room temperature, can be as much as 12 kJ/mol for reactions we are interested in, although it more frequently is less than a quarter of that. At the same time, while $T\Delta S$, the energy change due to reactant/product entropy differences, can be as large as 80 kJ/mol in cluster formations, it is usually found to be less than 30 kJ/mol. Clearly the ΔE (D_e) or ΔU (D_o) values at 0 K, usually reported by theoreticians, while informative, simply do not provide the most reliable picture of how a chemical change should be viewed under equilibrium conditions. For example, the dimerization of HF has been well studied (eq. [1], X = F, n = 2, vide infra). The "best computed estimate" for D_e at 0 K is –19.1 ± 0.2 kJ/mol (2*aa*). Including the zero-point correction provides D_o or $\Delta U(0)$ of about –13 kJ/mol (2*x*, *z*). However, we will show that at 298 K $\Delta H°$ is –15.9 kJ/mol while $\Delta G°$ is +8.7 kJ/mol. For this reason, $\Delta G°$ and K values have been calculated for reactions [1]–[3], and the relative amounts of all species at equilibrium have been determined for the gas-phase reactions under a wide range of conditions of temperature and pressure.

The effect of temperature on the products and yields of inorganic and organic reactions can be dramatic. An excellent example of temperature dependence occurs in metal reductions as shown in Ellingham diagrams (9). It is our intention to illustrate how the temperature dependence of some relatively simple equilibria can be estimated from routine and readily available computational methods.

Calculations

Ab initio calculations were performed using GAUSSIAN 94 (6). Geometries of all species were optimized using the 6-311++G(d,p) basis set at the MP2 level. Vibrational frequencies were also obtained using the same computational model and basis set. From these latter calculations, it was possible (*a*) to determine that a structure represented a true minimum and not a saddle point in the energy surface, and (*b*) to obtain entropies (S), as well as zero-point energies and thermal corrections at the required temperature and pressure. All ab initio energies were corrected for thermal energies, including zero-point vibrations (Hartree–Fock zero-point energy values were scaled by 0.90 (7) and MP2 values by 0.95 (8), to give U values. Reaction internal energies (ΔU) were converted to reaction enthalpies (ΔH) by means of eq. [4], which assumes ideal gas behavior for all species (9). In Gaussian 94 the conversion of U to H, with thermal corrections, is carried out automatically. The ΔS values were computed using the S values resulting from frequency calculations.

[4] $\Delta H = \Delta U + \Delta nRT$

Results

The MP2/6-311++G(d,p) optimized structures of all species, except $(HCl)_5$ and $(HCl)_6$, which are new to this paper, are virtually the same as those given in the earlier papers (and references quoted therein) (1*e*, *f*) as well as in some of the more recent literature (2–5). While these are the structures or conformations with lowest energy in the gas phase and at 0 K, there are others, particularly for larger species, which are not much more energetic and which could be significantly populated in solution and at higher temperatures. One recent report suggests that the calculated structure of $(HF)_2$ is somewhat different when a counterpoise correction is included (2*y*). In particular, the FF distance becomes longer than that found experimentally or with computations that do not consider basis set superposition errors (BSSE). Table 1 provides the structural parameters calculated for all these molecules and ions along with experimental values where the latter are available. The agreement with experimental data is exceptionally good in most cases. The ions are essentially structures involving H^+ or X^- solvated by up to four molecules of the hydrogen halide. As a result, HF_2^- and HCl_2^- are linear. H_2F^+, H_2Cl^+, $H_2F_3^-$, and $H_2Cl_3^-$ are bent with C_{2v} symmetry. $H_3F_4^-$ and $H_3Cl_4^-$ have D_{3h} symmetry (trigonal planar). $H_4F_5^-$ has T_d symmetry while $H_4Cl_5^-$ is a distorted tetrahedron. Both $H_3F_2^+$ and $H_3Cl_2^+$ are structures

of H^+ sandwiched between two hydrogen halide molecules; however, the former is planar while the latter, with an H-Cl-Cl-H dihedral angle of 103.6°, is not. All the HF polymers as well as $(HCl)_n$, n = 2–4, are planar, and all except the dimers adopt a cyclic arrangement. The structures of $(HCl)_5$ and $(HCl)_6$, determined for the first time, are shown in Fig. 1. $(HCl)_5$ assumes a "half-chair" conformation in which the average H—Cl bond length is 1.279 Å, and the average HClH bond angle is 100.9°, although the angles vary between 97.4° and 104.3°. The optimized structure of $(HCl)_6$ is a symmetrical "chair" with H—Cl bond lengths of 1.280 Å. The HClH bond angles are identical at 100.7°. Unlike the fluorine analogues the "short" HCl bond in the series $(HCl)_n$ does not change significantly with n.

Table 2 is a list of the standard thermodynamic data ($\Delta H°$ and $\Delta G°$), calculated at 298 K, for the 24 reactions.

In all the reactions one side of the equilibrium is represented by an ion or molecule that is compounded from the species on the other side. As a result, energy calculations of the reactants and products involve differing numbers of basis functions so that energy differences will contain a basis set truncation error (BSTE). This BSTE can be split into two terms: (*i*) a basis set superposition error (BSSE), which can be approximated using a counterpoise (CP) correction, and (*ii*) a basis set incompleteness error (BSIE) that arises because the basis set used is never "complete." For the dimerization of HF (eq. [1], X = F, n = 2) Klopper and Lüthi (2*aa*) have estimated the BSSE and BSIE corrections using CCSD(T) calculations with a variety of basis sets. Their best estimate of D_e for the reaction, correcting for both the BSIE

[a]All data were obtained using MP2/6-311++G(d,p) optimizations and frequency calculations and are quoted in kJ/mol.

and the BSSE, is –19.1 ± 0.2 kJ/mol. At the CCSD(T)/6-311++G(d,p) computational level, the CP correction is +4.6 kJ/mol, and the estimate of the BSIE correction is –3.5 kJ/mol. As the size of the basis set increases, both the CP and BSIE corrections get smaller, and their sum, the estimated BSTE error, becomes less consequential. For example, with the aug-cc-pVQz basis set these corrections are 1.0 and –0.3 kJ/mol, respectively. We have carried out counterpoise corrections on all the reactions studied. While some of these are significant, they become much less so when a larger basis set is used. For reactions [5] and [6] (X = F), MP2/6-311++G(d,p) CP corrections are +18.8 and +13.4 kJ/mol, respectively. However, MP2/aug-cc-pVQZ CP corrections are +4.6 and +2.8 kJ/mol, between 20 and 25% as large. We have assumed that, while the CP corrections can be large with the 6-311++G(d,p) basis set used in this work, the BSIE correction will also be large and of opposite sign. As a result, the BSTE error will be relatively inconsequential, particularly when compared with large values of the energies, and the data quoted do not include it. In those reactions for which we have used both the 6-311++G(d,p) and aug-cc-pVQZ basis sets in calculating thermodynamic parameters, the largest difference in $\Delta G°$ is 7.5%.

From the data of Table 2 it is possible to make some general conclusions:

(*i*) The formation of the polychlorohydrogenate(1-) anions, polychlorohydrogen(I) cations, and the HCl polymers is much less exothermic than the formation of the corresponding fluorine species with one notable exception; H_2Cl^+ is more stable than H_2F^+ relative to the hydrogen halide and proton.

(*ii*) Once the halide ion becomes available, the formation of the polyhalohydrogenate(1-) anions can proceed according to reaction [2]. Since $\Delta G°$ becomes less negative as *n* increases, any one or several of the four anions could occur depending on the relative amounts (pressures) of HX and X^-.

(*iii*) Once H^+ becomes available, the formation of the polyhalohydrogen(I) cations can proceed according to reaction [3]. Either or both the cations (*n* = 0 and 1) can exist depending on the conditions.

(*iv*) As *n* increases, the formation of the hydrogen halide polymers, according to reaction [1], becomes more exothermic. However, because of the unfavorable entropy term, at 298 K, these reactions are all endergonic. Interestingly, whereas the formation of the HCl clusters becomes increasingly unfavorable as the size increases, there is no comparable progression in $(HF)_n$ production; in fact, the preferred HF polymers are those with *n* = 5 and 6.

Our data agree extremely well with the recent ab initio and other calculations found in the literature (1–5), although, as noted earlier, some of the work does not involve zero-point energy corrections and most is reported at 0 K. In some cases experimental data are available. Our $\Delta H°$ of –189.3 kJ/mol at 298 K for reaction [5] (X = F) compares extremely well with the gas-phase fluoride ion affinity determinations of –162 ± 8 kJ/mol (19) and more recently of –192 ± 7 kJ/mol (at 298 K) (20). The calculated value of –104.0 kJ/mol for the corresponding chloride affinity of HCl (X = Cl, reaction [5]) is remarkably close to experimental values of –99.2 (21) and –96.7 kJ/mol (22).

[5] $\quad HX + X^- \rightarrow HX_2^-$

Proton affinities of HF (reaction [6], X = F) have been experimentally determined as –469 ± 8 (23) and 490 kJ/mol (24), in excellent agreement with the calculated $\Delta H°$ of –485.7 kJ/mol (Table 2). The corresponding proton affinities for HCl (reaction [6], X = Cl) are –538.1 (24) and –556.5 kJ/mol (25) as compared to our calculated $\Delta H°$ of –543.8 kJ/mol.

[6] $\quad HX + H^+ \rightarrow H_2X^+$

The formation of hydrogen fluoride polymers, particularly $(HF)_2$, has been the subject of a great deal of interest; recently, Quack and Suhm (2*e*) have published an excellent review of much of this work. Experimental estimates of the association energy of $(HF)_2$ (eq. [1], X = F, *n* = 2), such as –12.73 (17*b*), –12.41 (26), and the most recent –12.70 ± 0.01 kJ/mol (2*a*), correspond to computed D_o (ΔU at 0 K) values such as –12.8 (2*z*) and –12.6 kJ/mol (2*x*), and are in reasonable agreement with our calculated –15.9 kJ/mol at 298 K for $\Delta H°$. Reddington (27) estimated $\Delta H°$ to be –17.9 kJ/mol at 299 K by using a multi-parameter model to fit known properties of HF at that temperature. The same model

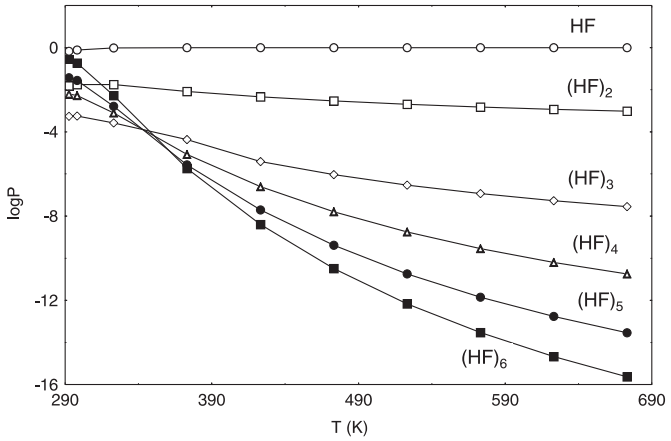
[a]Calculated using thermodynamic data obtained from MP2/6-311++G(d,p) optimizations and frequency determinations.

[b]Data obtained using equilibrium constants available from ref. 27.

Fig. 2. Temperature dependence of the partial pressures of $(HF)_n$, n = 1–6, in pure HF at a total pressure of 1 atm. (○) HF; (□) $(HF)_2$; (◇) $(HF)_3$; (△) $(HF)_4$; (●) $(HF)_5$; (■) $(HF)_6$.



predicted $\Delta H°$ at 299 K to be –47.2, –97.1, –132.1, and –164.8 kJ/mol for the formation of the HF trimer, tetramer, pentamer, and hexamer, respectively. Our calculated values for the same set of complex formations, viz. –48.7, –92.6, –130.3, and –162.0 kJ/mol, are remarkably close.

Polymer formation in HCl is much less well studied. Our value of –5.96 kJ/mol for the standard formation enthalpy at 298 K of $(HCl)_2$ (eq. [1], X = Cl, n = 2) compares well with experimental association energy values of –5.15 ± 0.26 (17*b*) and –5.23 ± 0.01 kJ/mol (4*a*) and computed D_o value of –4.98 kJ/mol (2*x*).

Using equilibrium constant values, calculated at a particular temperature and pressure, it is possible to compute the relative pressures (amounts) of HX and the various polymers $(HX)_n$ present in an equilibrium mixture. These data are shown in Table 3 for the HF system at 292 K (the normal boiling point of pure HF) and 298 K, as well as for HCl at 188 K (its normal boiling point). The table also presents the corresponding data calculated using the equilibrium constants obtained by Reddington (27) from his experimentally based model. The percentages of the various species present in HF obtained from our ab initio calculations are surprisingly close to those estimated from Reddington's model. HF is the major species present at liquid HF temperature or at 298 K, but the hexamer, pentamer, and dimer are predicted to appear in significant amounts as well (20, 3, and 2%, respectively). For HCl, even at liquid temperature, 98% is monomeric HCl with less than 2% dimer. There is virtually nothing of the larger polymers. Figures 2 and 3 show the relative amounts of the species present in pure HF or HCl at various temperatures at 1 atm, calculated from our data. As the temperature rises, the amounts of the higher polymers, including the HF hexamer, which is so evident in liquid HF, decrease dramatically primarily as the result of the $T\Delta S°$ term in $\Delta G°$. Calculations of the percentage of each species present in HF at 292 K as a function of the total pressure show that the relative amount of the hexamer increases with pressure up to 5 atm. The amounts of the pentamer and tetramer increase up to a certain pressure and then decrease. The others species, including HF, decrease as the pressure increases above 1 atm. For example, at 5 atm, there is 5.5% HF, 0.3% dimer, 0.5% tetramer, 5.7% pentamer, and 88.0% hexamer.

Fig. 3. Temperature dependence of the partial pressures of $(HCl)_n$, n = 1–6, in pure HCl at a total pressure of 1 atm. (○) HCl; (□) $(HCl)_2$; (◇) $(HCl)_3$; (△) $(HCl)_4$; (●) $(HCl)_5$; (■) $(HCl)_6$.

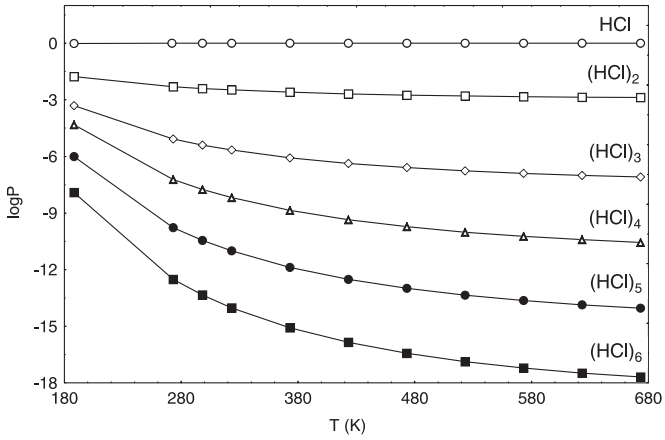


Fig. 4. Partial pressures of $H_nF_{n+1}^-$ species in a basic mixture (containing excess F^-) at 292 K. (○) HF; (□) HF_2^-; (◇) $H_2F_3^-$; (△) $H_3F_4^-$; (●) $H_4F_5^-$.

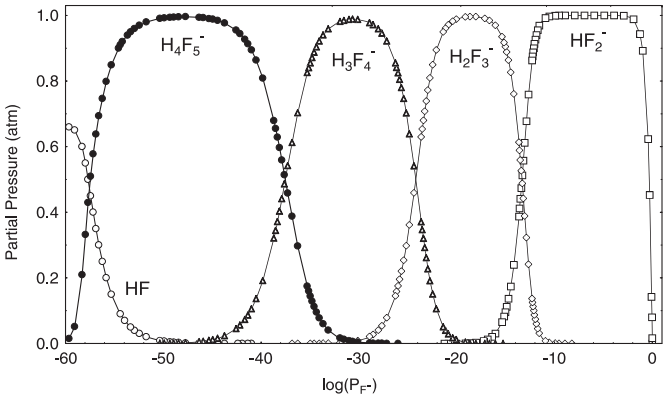

Using the equilibrium constants computed for reactions [1] and [2] at a number of temperatures between 188 and 673 K, it is also possible to calculate the relative amounts of the various species present in a basic mixture, one containing excess X^-. To illustrate, Figs. 4 and 5 are plots of partial pressures of

Fig. 5. Partial pressures of $H_nF_{n+1}^-$ species in a basic mixture (containing excess F^-) at 673 K. (○) HF; (□) HF_2^-; (◇) $H_2F_3^-$; (△) $H_3F_4^-$; (●) $H_4F_5^-$.

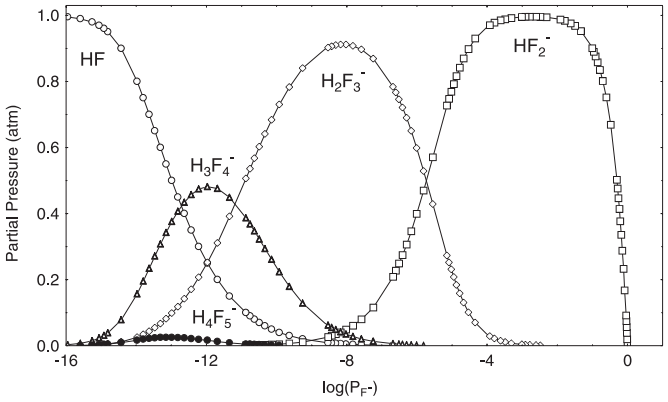

Fig. 6. Partial pressures of $H_nCl_{n+1}^-$ species in a basic mixture (containing excess Cl^-) at 188 K. (○) HCl; (□) HCl_2^-; (◇) $H_2Cl_3^-$; (△) $H_3Cl_4^-$; (●) $H_4Cl_5^-$.

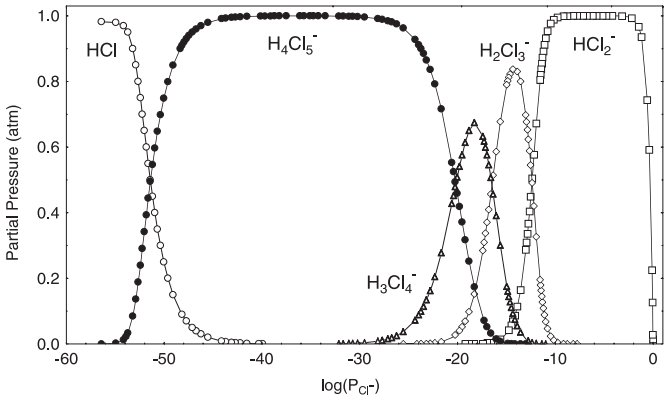

the species against the pressure of F^- at 292 and 673 K, respectively. At a F^- partial pressure approaching zero, HF and the polymers noted above predominate. As the pressure of F^- increases, the anion $H_4F_5^-$ begins to form, becoming the only species, and then disappearing as $H_3F_4^-$ forms. The process continues with the disappearance of $H_3F_4^-$, the consequent formation of $H_2F_3^-$ and then the formation of HF_2^- as the only species at higher fluoride ion pressures. Although these calculations are for gas phase reactions, they are entirely in accordance with solution experiments. For example, the NMR evidence, from mixtures of tetrabutylammonium fluoride with HF dissolved in a 1:2 mixture of CDF_3 and CDF_2Cl, indicates that at low HF concentration, HF_2^- is observed (5*f*). At higher HF concentrations the larger ions are formed. Ràfols et al. (5*d*) have studied the equilibria of HF in an ethanol–water mixture using conductiometric and potentiometric techniques. Their data give equilibrium constants quantitatively different from ours for reaction [2] (X = F, n = 0–3) but qualitatively in the same relative order. The authors also demonstrate that HF_2^- predominates in dilute HF solutions whereas HF and the larger anions predominate in solutions more concentrated in HF. A comparison of Figs. 4 and 5 also shows how the larger anions become less stable at higher temperature. For example, whereas at 292 K all ions could form depending on the conditions, at 673 K there should be almost no detectable $H_4F_5^-$

Fig. 7. Partial pressures of $H_{n+1}F_n^+$ species in an acidic mixture (containing excess H^+) at 292 K. (△) HF; (□) H_2F^+; (○) $H_3F_2^+$.

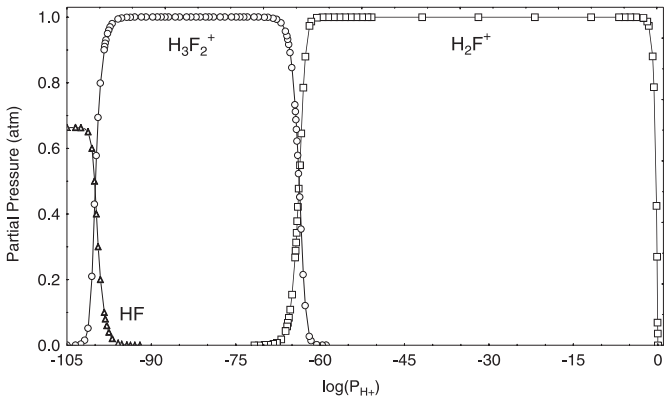

Fig. 8. Partial pressures of $H_{n+1}F_n^+$ species in an acidic mixture (containing excess H^+) at 673 K. (△) HF; (□) H_2F^+; (○) $H_3F_2^+$.

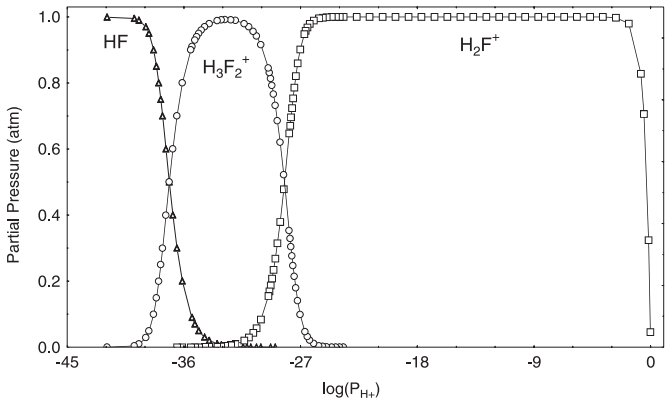

and little $H_3F_4^-$. As well, in going from 292 to 673 K, the range of F^- partial pressures needed to observe all the species present in solution decreases by many orders of magnitude.

Figure 6 is a partial pressure plot at 188 K for the comparable polychlorohydrogenate(1-) ions in solutions with an excess of Cl^-. Qualitatively, the figure is similar to those for the HF/F^- mixtures. However, at 188 K, the normal HCl boiling point, HCl, $H_4Cl_5^-$, and HCl_2^- are the predominant species. As the temperature rises, all of the larger anions become less stable so that at 673 K only HCl and (or) HCl_2^- should exist regardless of the amount of chloride ion present.

Plots of the partial pressures of HX and the two polyhalohydrogen(I) cations, $H_{n+1}X_n^+$, in acidic mixtures (excess H^+) at different temperatures are illustrated in Figs. 7–9. At very low H^+ pressures HX predominates. With increasing acidity the larger cations form, first $H_3X_2^+$, then H_2X^+. At higher temperatures the larger cation is less stable and less in evidence. In fact, at 673 K, only HCl and (or) H_2Cl^+ would be expected to exist regardless of the pressure of H^+.

The van't Hoff equation represents the temperature dependence of an equilibrium constant (9). Specifically, the derivative of ln K with respect to $1/T$ is $-\Delta H°/R$. For all the reactions represented by eqs. [1]–[3] a plot of ln K vs. $1/T$ is a concave curve that can be fitted to the expression [7] with high correlation coefficient (for example, Fig. 10) indicating that $\Delta H°$ is not temperature independent over the temperature range of 400–500°. The plots with the greatest curvature

(the greatest temperature dependence of $\Delta H°$) are those obtained for the polymer formation reactions of HCl. Table 4 lists the coefficients for [7] found by nonlinear regression for all the equilibria studied.

$$[7] \qquad \ln K = a + bT^{-1} + cT^{-2} + dT^{-3}$$

Summary

Complete ab initio MP2/6-311++G(d,p) structure optimizations and frequency calculations have been carried out on 10 hydrogen halide polymers, $(HX)_n$; on eight polyhalohydrogenate(1-) anions, $H_nX_{n+1}^-$, and on four polyhalohydrogen(I) cations, $H_{n+1}X_n^+$, (X = F and Cl) at a number of temperatures ranging from 188 to 673 K, and at various total pressures. The structures predicted for these species agree with experimental results, where they are available, and with previously obtained calculations done at comparable or better computational levels. The structures of two of the polymers, $(HCl)_5$ and $(HCl)_6$, are reported for the first time. The former adopts a half-chair conformation, the latter a chair.

From the computational results, $\Delta H°$, $\Delta G°$, and K values have been calculated for 24 reactions involving these species. Our calculated values of $\Delta H°$ agree extremely well with the available experimental proton and halide affinities of HF and HCl. The formation of the polychlorohydrogenate(1-) anions, polychlorohydrogen(I) cations, and the HCl polymers is much less exothermic than the formation of the corresponding fluorine species with one notable exception; H_2Cl^+ is more stable than H_2F^+ relative to the hydrogen

halide and proton. Once halide ion or H^+ is available, the formation of the polyhalohydrogenate(1-) anions or polyhalohydrogen(I) cations can proceed. Since $\Delta G°$ becomes less negative as n increases, any one or several of the four anions or two cations in each series could occur depending on the relative amounts (pressures) of HX and ion. The percentages of the various species present in pure HF obtained from our ab initio calculations are surprisingly close to those estimated from a model proposed by Reddington (27). At low temperatures the HF and its hexamer predominate. However, as the temperature increases at constant pressure the hexamer partial pressure decreases until only HF is observed. With increasing H^+ or X^- partial pressure, HX disappears to be replaced by the largest cation or anion. Continued increase in ion pressure sees subsequent formation of the possible smaller anions or cations. There are some marked differences between the fluorine and chlorine series, but generally, the relative amounts of the large molecules, anions, and cations, and the range of partial pressures over which they are stable decrease as the temperature increases. For all reactions, ln K is not quite a linear function of $1/T$, indicating that $\Delta H°$ is temperature dependent over a range of 400–500°.

Excess molar volumes of methanol or ethanol + *n*-polyethers at 298.15 K

F.J. Carmona, F.J. Arroyo, I. García de la Fuente, J.A. González, and J.C. Cobos

Abstract: Excess molar volumes V_m^E at 298.15 K and atmospheric pressure for methanol and ethanol + 2,5-dioxahexane, + 3,6-dioxaoctane, + 2,5,8-trioxanonane, + 3,6,9-trioxaundecane, + 5,8,11-trioxapentadecane, + 2,5,8,11-tetraoxadodecane, and + 2,5,8,11,14-pentaoxapentadecane have been obtained from densities measured with an Anton–Paar DMA 602 vibrating-tube densimeter. All the excess volumes are negative over the whole mole fraction range. The V_m^E curves are shifted to the region rich in the alkanol, increasing their asymmetry with the number of oxygen groups in the polyethers. Results seem to remark the predominant contribution of free volume effects on interactional effects, particularly when the ethers are of the type CH_3-(O-$CH_2CH_2)_m$-CH_3. In the case of polyethers with longer *n*-alkyl chain ends, self-association of methanol and ethanol is more relevant. A short comparative study with results for mixtures with higher 1-alkanols and polyethers is also presented.

Key words: experimental, excess volumes, 1-alkanols, polyethers, self-association, free volume effects.

Résumé : Utilisant un densimètre à tube vibrant Anton–Paar DMS 602 et opérant à 298,15 K et à la pression ambiante, on a mesuré les densités du méthanol ainsi que de l'éthanol additionnés de 2,5-dioxahexane, 3,6-dioxaoctane, 2,5,8-trioxanonane, 3,6,9-trioxaundécane, 5,8,11-trioxapentadécane, 2,5,8,11-tétraoxadodécane et 2,5,8,11,14-pentaoxapentadécane et on en a déduit les volumes molaires en excès, V_m^E. Tous les volumes en excès sont négatifs pour l'ensemble des plages des fractions molaires. Les courbes des V_m^E sont déplacées vers les régions riches en alcanol et leur asymétrie augmente avec le nombre d'atomes d'oxygène dans les polyéthers. Les résultats semblent mettre en évidence la contribution prédominante des effets de volume libre sur les effets d'interaction, en particulier avec les éthers du type CH_3-(O-$CH_2CH_2)_m$-CH_3. Dans les cas de polyéthers dans lesquels les chaînes alkyles aux extrémités sont plus longues, l'autoassociation du méthanol et de l'éthanol est plus importante. On présente aussi une courte étude comparative avec les résultats obtenus avec des mélanges d'alcan-1-ols et de polyéthers de masses moléculaires plus élevées.

Mots clés : expérimental, volumes en excès, alcan-1-ols, polyéthers, autoassociation, effets des volumes libres.

[Traduit par la Rédaction]

1. Introduction

Mixtures containing oxygenated compounds, such as ethers (-O- group) and alkanols (-OH group), are of great importance from a practical point of view due to they are increasingly used as additives to gasoline owing to their octane-enhancing and pollution-reducing properties.

From a theoretical point of view, solutions involving oxaalkanes are of high interest because make possible the study of a number of effects (e.g., steric or proximity effects, cyclization) on the interactions present in the mixture considered. Binary systems of oxaalkanes and 1-alkanols are particularly interesting due to their complexity, consequence of the self-association of the alkanols partially destroyed by the active molecules of ethers, and of the new *intermolecular* OH---O bonds created. So, the treatment of this class of mixtures is a severe test for any theoretical model. Moreover, the analysis of the present systems is a previous step to study mixtures containing hydroxyethers, where the *intramolecular* effects between the -OH and -O- groups of cellosolves become of great importance (1, 2).

DISQUAC (3, 4), a purely physical model, has been successfully applied to the mixtures under study by considering structure-dependent interaction parameters (5). In this way, properties as excess molar enthalpies, H_m^E, or excess molar heat capacities at constant pressure, $C_{p,m}^E$, which are very sensitive to molecular structure are properly represented by DISQUAC. The Dortmund version of UNIFAC (6), which ignores proximity or steric effects fails to describe the mentioned properties (5). Unfortunately, both the DISQUAC and the UNIFAC models are based on rigid lattice theories and hence $V_m^E = 0$, a useful property to evaluate, e.g., changes in free volume or interstitial accommodation. The model more widely applied to represent simultaneously H_m^E and V_m^E is the so-called ERAS model (7), which combines the chemical, physical, and equation of state contributions, the two latter being expressed by the Flory equation of state (8). However,

as far as we know, the ERAS model has been merely applied to mixtures of 1-propanol with 2,5,8-trioxanonane, or with 2,5,8,11-tetraoxadodecane (9). The lack of a systematic treatment of the present mixtures in the framework of the ERAS model underlines the difficulty in studying such mixtures.

As a continuation of our previous experimental studies on binary mixtures containing oxaalkanes and (or) 1-alkanols (10–21), and in order to extend the available database for 1-alkanols + polyethers mixtures, we report here V_m^E of systems formed by methanol or ethanol and 2,5-dioxahexane, 3,6-dioxaoctane, 2,5,8-trioxanonane, 3,6,9-trioxaundecane, 5,8,11-trioxapentadecane, 2,5,8,11-tetraoxadodecane, and 2,5,8,11,14-pentaoxapentadecane over the whole mole fraction range at atmospheric pressure and at 298.15 K. They will be useful to develop a further complete treatment of the present mixtures.

2. Experimental

An Anton–Paar DMA 602 vibrating-tube densimeter (22–24), operating under static conditions, was used to determine the densities, ρ, of the pure liquids and of their binary mixtures. The oscillation period τ (of about 3.6 ms) was measured with a Philips PM 6669 frequency meter. This was counted with eight digits, which were integrated and renewed every 10 s. Each value of τ was obtained from an average of 80 measurements, and for each pure liquid or mixture, three runs were developed. Protection against the generation of static electricity around the instrument and temperature stability were effective in maintaining an overall stable indication of $\Delta\tau = \pm 5$ ns, and hence $|\Delta\tau/\tau| = 1.4 \times 10^{-6}$. This gives a resolution in density of $|\Delta\rho/\rho| = 6 \times 10^{-6}$, where the errors due to calibration and the density of the references liquid are not taken into account. All the measuring operation and calculations were computer controlled.

Before each series of measurements the instrument was calibrated with doubly distilled and degassed water and "vacuum." The accuracy in the determination of ρ is believed to be less than $\pm 2 \times 10^{-2}$ kg m^{-3}. Hexane and acetone or ethanol were used for rinsing the cell tube between measurements. More details are given elsewhere (25). Temperature was evaluated by resistance measurement of an Anton–Paar thermistor (using a PM2534 Philips multimeter) previously tested against a HP-2804A quartz thermometer calibrated on the basis of the ITS-90 scale of temperature using the triple point of water. The densimeter was thermostated to ±0.003 K and measurements were carried out at 298.15 K and atmospheric pressure.

The source, purity, and experimental densities at 298.15 K of the pure compounds used are listed in Table 1. They are in good agreement with published values (Table 1). All liquids were carefully dried with molecular sieve (Union Carbide 4 Å, from Fluka) added to the chemicals, which were not degassed.

Binary mixtures were prepared by mass in small vessels of about 10 cm^3. Caution was taken to prevent evaporation, and the error in the final mole fraction is estimated to be less than ±0.0001. Conversion to molar quantities was based on the relative atomic mass table of 1985 issued by IUPAC (26).

The excess molar volumes were calculated from the densities of the pure liquids and their mixtures. As in order to obtain reliable results for V_m^E the absolute value of ρ are less important compared to the relative certainty in ρ (25), the accuracy in V_m^E is believed to be less than $\pm (0.01|V_{m,min}^E| + 0.005$ cm^{3}mol^{-1}), where $V_{m,min}^E$ denotes the minimum experimental value of the excess molar volume with respect to x_1.

3. Results

The results of V_m^E as a function of mole fraction of the alkanol, x_1, are collected in Table 2. The data were fitted by

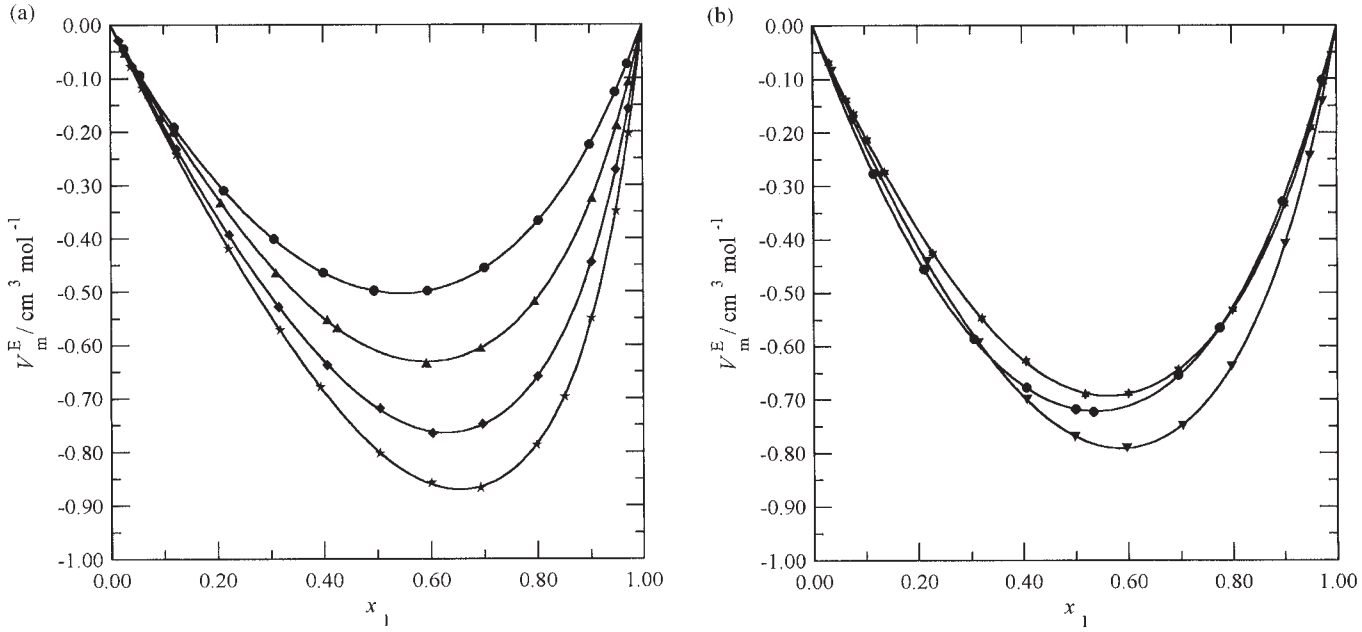
Fig. 1. V_m^E at 298.15 K and atmospheric pressure for methanol (1) + *n*-polyethers (2) mixtures. Solid lines, results from the smoothing eq. [1] with the coefficients listed in Table 3. Points, experimental data. (*a*) ● 2,5-dioxahexane; ▲ 2,5,8-trioxanonane; ◆ 2,5,8,11-tetraoxadodecane; ★ 2,5,8,11,14-pentaoxapentadecane. (*b*) ● 3,6-dioxaoctane; ▼ 3,6,9-trioxaundecane; ★ 5,8,11-trioxapentadecane.



unweighted least-squares polynomial regression to the equation:

$$[1] \qquad V_m^E/\text{cm}^3\ \text{mol}^{-1} = x_1(1-x_1)\sum_{i=0}^{k} A_i(2x_1-1)^i$$

The number of coefficients k used in eq. [1] for each mixture was determined by applying an F test (27) at the 95% confidence level. Table 3 lists the parameters A_i obtained in the regression, together with the standard deviations σ, defined by

$$[2] \qquad \sigma(V_m^E)/\text{cm}^3\ \text{mol}^{-1} = [\sum (V_{m,\text{cal.}}^E - V_{m,\text{exp.}}^E)^2/(N-k)]^{1/2}$$

where N stands for the number of direct experimental values. For all the mixtures $\sigma(V_m^E)/|V_{m,\text{min}}^E| < 0.01$, in accord with the precision attainable with the instrument used. A graphical representation of the experimental results together with the smoothing curves are shown in Figs. 1 and 2.

For all the mixtures investigated, $V_m^E < 0$ over the whole mole fraction range. Systems with methanol show $|V_m^E|$ larger than those with ethanol. We note that the V_m^E curves are shifted to the region rich in alkanol, increasing their asymmetry with the number of oxygen groups in the polyether (see next section). V_m^E for methanol + 2,5-dioxahexane, + 3,6-dioxaoctane, + 2,5,8-trioxanonane, and + 5,8,11-trioxapentadecane and for ethanol + 3,6-dioxaoctane

and + 2,5,8-trioxanonane have been measured previously (28, 29). At x_1 = 0.5, data from Pal and Sharma (29) are about 3.5% larger than ours and are more scattered at low dilution of the alkanol, as the comparison of the respective V_m^E/x_1x_2 curves shows. Results at equimolar composition from Villamañán et al. (28) are also larger than those presented in this work (~5% for ethanol + 2,5,8-trioxanonane) except for the methanol + 2,5,8-trioxanonane system, which is lower (~3%).

4. Discussion

It is well known that V_m^E in 1-alkanols + *n*-alkanes mixtures is the result of several opposing effects: changes in self-association and physical interactions (dipole–dipole) between alkanol multimers and monomers lead to an increasing of volume; a decreasing of volume is obtained by changes of free volume and interstitial accomodation (30). So, for a given *n*-alkane, say *n*-heptane, V_m^E is positive over

the whole range of concentration for lower 1-alkanols, and becomes sigmoid for longer alkanols (31). The magnitudes of these contributions are sensitive to the lengths of component molecules (31). For example, as the length of the 1-alkanol is increased, the negative effect accompanying the fitting of the *n*-alkane molecules into the alkanol multimer structure becomes progresively more important, and predominates for sufficient long alkanol molecules.

In systems of linear oxaalkanes and *n*-alkanes, the dipole–dipole interactions between ether molecules are weaken by the addition of the alkane. The sign of V_m^E depends on the relative size of the mixture components (32, 33). For di-*n*-propylether + *n*-heptane, where the molecular size of both components are similar, $V_m^E > 0$ over the whole range of concentration (32). In exchange, for systems comprising longer ether and shorter alkane molecules, e.g., di-*n*-butylether + *n*-hexane, free volumes contributions are relatively more important and $V_m^E < 0$ (33). The V_m^E of linear polyethers + *n*-alkanes are usually higher than those of linear ethers + *n*-alkanes, indicating larger differences between positive and

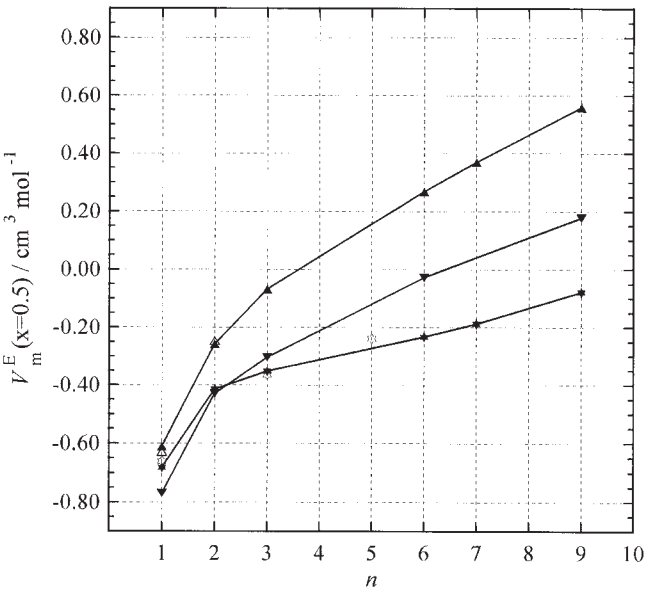
Source of data: methanol and ethanol (this work); 1-propanol (15); 1-hexanol (21); 1-heptanol and 1-nonanol (20). Hollow symbols are corresponding data from literature: △ 1-alkanol + 2,5,8-trioxanonane (28); ☆ 1-alkanol + 5,8,11-trioxapentadecane (29).



negative contributions (34). It is remarkable that in mixtures of CH_3-O-(CH_2-CH_2-O-)$_m$-CH_3 with *n*-pentane, V_m^E becomes S-shaped for m = 3, 4 (35).

For the mixtures under study, one must also take into account interactions between unlike molecules; i.e., the new OH---O bonds created, which contribute negatively to V_m^E.

From a purely interactional point of view, we note that H_m^E of solutions of methanol with polyethers are much lower than those of the remainder alkanols (Table 4), which actually show larger H_m^E than when are mixed with *n*-alkanes. So, polyethers are enough active to break the self-association of the alkanols (from ethanol) in such way that the number of broken H-bonds is not compensated by the new OH---O bonds formed. In the case of methanol, inmiscible with alkanes at room temperature, H_m^E is much lower, indicating stronger interactions between unlike molecules. Systems of 1-alkanols and *n*-alkanones behave similarly (36).

Now we'll examine qualitatively some of the main features found along our investigations on V_m^E of 1-alkanol + linear polyether mixtures.

4.1. Equimolar V_m^E values

4.1.1. *The effect of increasing the alkanol size for a given polyether*

In this case, V_m^E increases (Figs. 3–6), what may be due to (*i*) interactional effects as H_m^E also increases (Table 4); i.e., the number of broken hydrogen bonds is larger for longer alkanols and is not compensated by the OH---O bonds created; (*ii*) free volume effects, which are more important in mixtures containing short alcohol molecules. When both compounds are lengthened, the contribution from the interstitial accomodation might be enough negative and then V_m^E < 0. It occurs, e.g., in the 1-nonanol + 5,8,11-trioxapentadecane system (Fig. 4).

Systems of 1-alkanols and linear monoethers behave quite differently. For each monoether, V_m^E increases from methanol to ethanol or 1-propanol, and then decreases. H_m^E varies as in 1-alkanol + *n*-alkane mixtures when the *n*-alkane is fixed: increases from methanol to 1-propanol and then decreases rather slowly (14). It suggests that for longer alcohols the interactional contribution is practically the same, while the structural effects increase. Such different behaviour may be attributed to H_m^E is higher for the actual mixtures than for systems with monoethers, i.e., to a more important interactional contribution to V_m^E, in part due to the strong dipole–dipole interactions between polyether molecules.

4.1.2. The effect of increasing the n*-alkyl chain end length of the ether when the number of oxygen atoms and their relative position is fixed*

For a given alcohol, V_m^E is lower for the oxaalkane with the longer alkyl chain (except in some cases for methanol and ethanol; Figs. 3–4). This may be due to (*i*) H_m^E also decreases with the size of the ether (Table 4); i.e., ethers with larger *n*-alkyl chain ends are less active to break the self-association of the alcohol as the -O- groups are more hindered; (*ii*) free volume effects for shorter alcohols or interstitial accomodation for longer alkanols. The anomalous behaviour found for some mixtures with methanol or ethanol (Figs. 1*b*, 2*b*, 4, and 6) remarks the stronger self-association of these alcohols.

4.1.3. The effect of adding OCH_2CH_2 groups at the middle of the ether molecule when the n*-alkyl chain end is fixed*

We note that for short alkanol molecules, V_m^E decreases with the size of the ether (and $V_m^E < 0$; Figs. 5, 6). Longer 1-alkanols behave in opposite way, and the sign of V_m^E depends on the methyl or ethyl character of the polyether ends (Figs. 5, 6). As H_m^E (triether, e.g., CH_3CH_2-(O-$CH_2CH_2)_2$-O-CH_2CH_3) > H_m^E (diether; e.g., CH_3CH_2-O-CH_2CH_2-O-CH_2CH_3; see Table 4), this means that more H-bonds are disrupted, producing a positive contribution to V_m^E. As for the shorter alcohols V_m^E decreases, it must be due to free volume effects are predominant, particularly when the polyether ends are of ethyl character. In exchange, for longer 1-alkanols, when a less difference in size of the compounds exists, interactional effects become more important; e.g., at equimolar composition and 298.15 K, for the 1-heptanol + 2,5,8,11,14-pentaoxapentadecane system H_m^E/J mol^{-1} = 2056 (A. Roux, personal communication). Then the order of V_m^E is inverted (Figs. 5, 6).

We remark that, for CH_3-O-(CH_2-CH_2-O-)$_m$-CH_3 + alkane mixtures, $V_m^E(x = 0.5)$ behaves similarly with the size of the alkane (35).

4.2. The concentration dependence

The V_m^E curves are usually asymmetrical and shifted to higher concentration of alcohol. This may be attributed to free volume effects, as in this case the curves are shifted to the region rich in the compound of smaller molar volume. In exchange, the H_m^E curves are nearly symmetrical (11). For 1-alkanols + monoethers systems, the latter are skewed to low mole fractions of the alcohol and are also lower than for the systems treated here. It suggests that the self-association of alcohols is more important in solutions with monoethers than in those with polyethers.

We have also analysed the partial molar excess volume curves, V_i^E (i = 1, alcohol; i = 2, polyether) calculated from eq. [1] (and not shown in this work). The main difference between V_1^E and V_2^E is the changes in curvature found for V_1^E of methanol, ethanol, and 1-propanol, which can be related to their stronger self-association. For the longer alcohols, V_1^E results in more smoothed curves, in agreement with the fact that self-association is less important. The V_2^E curves show a very regular shape as polyethers are not self-associated. A similar behaviour is found for 1-alkanols + *n*-alkanes (30).

5. Conclusions

Data on V_m^E at 298.15 K and atmospheric pressure for methanol or ethanol + *n*-polyethers are reported. Results underline the predominant contribution of free volume effects on interactional effects, particularly for mixtures including polyethers of the type CH_3-(O-CH_2-$CH_2)_m$-CH_3. In systems with ethers of longer *n*-alkyl chain ends, self-association of methanol and ethanol is more relevant.

The effect of preparation and aging conditions on the internal environment of sol-gel derived materials as probed by 7-azaindole and pyranine fluorescence

Kulwinder K. Flora, Monika A. Dabrowski, Sean P. Musson, and John D. Brennan

Abstract: Sol-gel derived silicate materials were prepared by a two-stage processing method similar that commonly used for entrapment of biomolecules. In the first step, tetraethylorthosilicate (TEOS) was hydrolyzed by sonicating in the presence of water (molar ratio of H_2O:Si = 4:1) and 0.044 M HCl with no added alcohol. The hydrolyzed TEOS was then mixed with varying amounts of a buffer solution (1:1 up to 4:1 vol:vol of silane:buffer) to induce gelation, and the monoliths were aged at room temperature either in air or in buffer for several days, followed by prolonged drying in air over several months. The emission spectra of the entrapped probes 7-azaindole (7AI) and 8-hydroxy-1,3,6-trisulfonated pyrene (pyranine) were examined at various times during the aging process to monitor the effects of the H_2O:Si ratio on the evolution of the internal environment of the silicate materials. The results showed that (*i*) the internal environment of the silicate materials continued to evolve long after the drying of the matrix (as determined by mass changes) was complete; (*ii*) the internal structure of the silicate materials, as monitored by both 7AI fluorescence and infrared spectroscopy, was affected by the proportion of water used for gelation of dry-aged materials, but was similar for all wet-aged samples, and (*iii*) both wet-aged and dry-aged monoliths had a distribution of final environments present both during and after drying. The implications of these findings for protein entrapment are discussed.

Key words: fluorescence, sol-gel, silicate materials, aging conditions, biosensor.

Résumé : On a préparé des matériaux sol-gels dérivés de silicates en faisant appel à une méthode en deux étapes similaires à celle utilisée couramment pour l'encapsulation de biomolécules. Dans la première étape, on hydrolyse l'orthosilicate de tétraéthyle (OSTE) par sonification en présence d'eau (rapport molaire de H_2O:Si = 4:1) et 0,044 M HCl, sans addition d'alcool. On mélange ensuite l'OSTE hydrolysé à diverses quantités d'une solution tampon (de 1:1 à 4:1, vol:vol, de silane:tampon) afin d'induire la formation d'un gel, puis on fait vieillir les monolithes à la température ambiante, à l'air ou dans un tampon, pour plusieurs jours et finalement on fait sécher à l'air pendant plusieurs mois. Afin d'évaluer les effets du rapport H_2O:Si sur l'évolution de l'environnement interne des matériaux à base de silicate, on a ensuite examiné les spectres d'émission des sondes encapsulées (7-azaindole (7AI) et 8-hydroxy-pyrène-1,3,6-sulfoné (pyranine)) à divers moments du processus de vieillissement. Les résultats montrent que (*i*) l'environnement interne des matériaux à base de silicate continue d'évoluer même lorsque le séchage de la matrice est terminé (tel que déterminé par les changements de masses); (*ii*) la structure interne des matériaux à base de silicate, telle que déterminée par les spectroscopie de fluorescence et infrarouge du 7AI, est déterminée par la proportion d'eau utilisée lors de la formation du gel des matériaux vieillis et séchés, mais elle est la même pour tous les matériaux vieillis et humides et (*iii*) les monolithes vieillis, secs ou humides, comportent une distribution des environnements finals tant durant le séchage qu'après. On discute des implications de ces observations pour l'encapsulation des protéines.

Mots clés : fluorescence, sol-gel, matériaux à base de silicate, conditions de vieillissement, biosenseur.

Introduction

In the past few years several reports have appeared describing a modified sol-gel processing method that is suitable for the encapsulation of biomolecules into materials derived from tetraethylorthosilicate (TEOS) or tetramethylorthosilicate (TMOS) (1–14). One modification involved the promotion of hydrolysis by sonication of TEOS or TMOS in the presence of water and acid, thereby removing the need for an alcohol co-solvent. A second modification was the ad-

© 1999 NRC Canada

dition of a buffered aqueous solution to the hydrolyzed silane to promote gelation. The buffer raised the pH to a value that was close to the physiological range and diluted the alcohol produced during hydrolysis of the alkoxysilane, resulting in an environment that was suitable for entrapped proteins (3–14). These modifications, combined with aging at low temperatures over a period of several days or weeks, have resulted in a large number of successful protein encapsulation protocols, as outlined in the review by Avnir et al. (11).

Efficient encapsulation of active biomolecules represents a major advance in the area of sol-gel science. However, little is known about the initial pore-liquid composition of materials processed in this manner, and how the internal environment evolves over time. Such information is critically important, since the pore-liquid will contain both alcohol and water, and the level of alcohol is important in determining the stability of entrapped biomolecules (1). Furthermore, the continued evolution of the matrix over periods of months can result in significant changes in the behaviour of entrapped proteins, making it difficult to develop analytical devices, such as biosensors, which rely on long-term stability of the entrapped protein. A detailed study of the changes in the chemical properties of sol-gel derived materials, prepared according to the standard procedures adopted for protein entrapment, is therefore required to optimize entrapment protocols.

In the present study, the fluorescent probes pyranine (8-hydroxy-1,3,6-trisulfonated pyrene) and 7-azaindole (7AI) were used to examine the internal environment of the sol-gel derived matrixes. Pyranine undergoes excited-state proton transfer reactions that depend on the pK_a of the solvent (15), and the emission of the probe is sensitive to trace amounts of water (16). Hence, pyranine provides quantitative information on ethanol:water ratios, giving useful information on pore-liquid composition (16, 17). The emission of 7AI is affected by pH (18, 19) and local dipolarity (20). The probe also undergoes specific hydrogen-bond mediated interactions in the presence of protonated species that result in the formation of an excited state tautomer with a unique emission wavelength of ca. 520 nm (21–23). Thus, 7AI can be used to obtain information regarding the presence of protonated species in the local microenvironment within the monolith. In the case of sol-gel derived silica, we show that 7AI also reports on the presence of silanol groups within the silicate matrix, causing the emission peak to shift to a characteristic wavelength between 410 and 415 nm, in agreement with a previous report of 7AI emission in silicate materials (24). Hence, 7AI can monitor changes in the relative amount of silanol groups within the matrix as a function of preparation and aging conditions. Based on the changes in the fluorescence emission of 7AI and pyranine as a function of the amount of water used for gelation and aging, an optimal set of processing conditions for the encapsulation of biomolecules is proposed.

Experimental

Chemicals

Tetraethylorthosilicate (TEOS, 99.999+%) was obtained from Aldrich Chemicals (Milwaukee, Wisconsin). 7-Azaindole and polymethacrylate fluorimeter cuvettes (1 cm^2) were obtained from Sigma Chemicals (St. Louis, Missouri). Pyranine (8-hydroxy-1,3,6-trisulfonated pyrene) and seminaphtharhodafluor-1 (SNARF-1) were obtained from Molecular Probes (Eugene, Oregon). Water used for preparation of buffers was distilled and deionized using a Milli-Q five-stage water purification system. All other chemicals were of analytical grade and were used without further purification.

Preparation of sol-gel derived monoliths

TEOS was hydrolyzed by mixing 9.0 mL of the silane, 2.8 mL of deionized water, and 0.2 mL of 0.1 N hydrochloric acid (molar ratio of H_2O:Si (R value) = 4.1) and sonicating the solution until a clear, single-phase solution was formed (approximately 2 h). The hydrolyzed solution was stored for 7 days at minus 20°C before use to ensure complete hydrolysis of the TEOS (25). Following hydrolysis, the silane solution was mixed with a phosphate buffer solution (10 mM, pH 8.20, 100 mM KCl) containing 20 μM of the appropriate fluorophore in a disposable polymethacrylate cuvette. The ratio of hydrolyzed TEOS to buffer was varied from 1:1 to 4:1 (by volume) while maintaining the total volume of the mixture at 1.5 mL. These ratios provided R values of 21, 13, 10, and 8 for the 1:1, 2:1, 3:1, and 4:1 mixtures, respectively. The TEOS:buffer mixture was vortexed at low speed to ensure proper mixing and was then allowed to gel with the cuvette in an upright position. Cuvettes containing dry-aged monoliths were capped with Parafilm and several small holes (ca. 1 mm diameter) were punched in the film. The monoliths were then allowed to dry at room temperature for a period of four months (125 days).

Wet-aged monoliths were prepared as outlined above, but had 2.0 mL of the phosphate buffer solution added approximately 10 min after gelation, resulting in R values of 64, 45, 39, and 28 for the 1:1, 2:1, 3:1, and 4:1 mixtures, respectively. The cuvettes containing these monoliths were then capped with Parafilm, and the samples were aged for 10 days in the buffer with an exchange of buffer each day. The buffer solutions used for the exchanges contained 20 μM of the appropriate probe to avoid leaching of the entrapped probe from the monoliths. After 10 days the buffer was removed, and the monoliths were allowed to dry for several months in a manner identical to that used for the dry-aged monoliths.

Fluorescence spectroscopy of sol-gel monoliths

Fluorescence spectra were collected using instrumentation that is described in detail elsewhere (25). Samples containing 7AI were excited at 290 nm with emission collected from 310 to 570 nm, those containing pyranine were excited at 351 nm with emission collected from 400 to 650 nm, while those containing SNARF-1 were excited at 514 nm with emission collected from 550 to 700 nm. All spectra were collected in 1 nm increments with 4 nm excitation and emission bandpasses. Appropriate blanks were subtracted from each sample, and the spectra were corrected for deviations in the emission monochromator throughput and photomultiplier tube response.

For dry-aged monoliths, spectra were collected on a daily basis at approximately 24 h intervals, starting 30 min after

© 1999 NRC Canada

gelation and continuing until there were no further changes in the mass of the samples (as determined daily using an analytical balance) or in the spectra (usually 25 days). Generally, fresh 1:1 TEOS:water samples weighed 2.04 ± 0.05 g, while the terminal mass was 0.39 ± 0.04 g, consistent with the expected 80% reduction in mass during drying (25). For wet-aged monoliths, spectra were collected daily from samples that had the surrounding phosphate buffer solution removed just prior to collection of spectra to minimize contributions from fluorophores that were present in solution. While it is possible that a residue of the probe may have remained adsorbed to the external surface of the monoliths, the strength of the fluorescence signal, which increased as the samples shrank and concentrated the entrapped probe, was sufficient to ensure that the spectra reflected the internal environment of the matrix. After collection of the spectra, 2 mL of a fresh phosphate buffer solution (containing 20 μM of the appropriate probe) was added to dilute any residual alcohol while avoiding leaching of the probes from the monoliths during aging. After 10 days (at which point no further changes in spectra were observed), the buffer was removed and the monoliths were capped with Parafilm (with a 1 mm hole punched in the film) and dried in air, with spectra collected every 2 or 3 days until no further changes in the size or mass of the monoliths occurred (ca. 30 days). Both wet-aged and dry-aged samples were left to age until a total of 125 days had elapsed since gelation, with spectra being collected at various times over this period.

Infrared spectroscopy

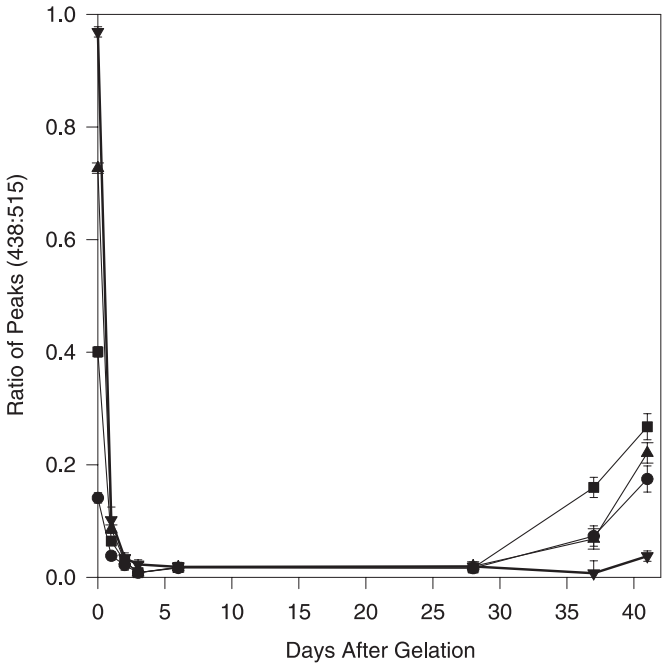
Representative infrared spectra were collected from wet-aged and dry-aged monoliths using a FTIR spectrometer (ATI-Mattson Research Series) with a diffuse reflectance accessory. The samples were prepared with 1:1 to 4:1 TEOS:buffer ratios and aged 125 days using the conditions described above. The samples were crushed and were degassed by heating at 120°C for 60 min before spectra were collected. A total of 1024 scans were collected in absorbance mode from 4000 to 400 cm^{-1} with a resolution of 4 cm^{-1} for each sample.

Results and discussion

Pyranine fluorescence

Pyranine has two emission peaks, one at 438 nm (protonated form, indicative of ethanol) and another at 518 nm (deprotonated form, indicative of water), which change in proportion as a function of the ratio of ethanol-to-water (16). The peak ratio was calibrated using standard ethanol:water mixtures, and was used to ascertain the volumetric ratio of ethanol:water in the freshly formed monoliths, and to monitor the evolution of the pore-liquid composition during aging and drying. The initial percentages of ethanol (by volume) were 36 ± 3, 46 ± 2, 54 ± 3, and 62 ± 3% for the dry-aged 1:1, 2:1, 3:1, and 4:1 TEOS:water systems, respectively. For the wet-aged samples, 2.0 mL of buffer was added to each sample after gelation. In this case, the percentages of ethanol were 10 ± 2% (1:1 ratio), 15 ± 2% (2:1 ratio), 21 ± 2% (3:1 ratio), and 28 ± 3% (4:1 ratio). Hence, a substantial dilution of the ethanol occurs immediately, as expected. Knowledge of the exact volumetric ratio of ethanol:water is important since many proteins remain stable at low ethanol concentrations (usually below ~20%), but become unstable at higher levels (1). The removal and replacement of the surrounding buffer at 24 h intervals resulted in further dilution of ethanol, with the percentage of ethanol being between 0% (1:1) and 10% (4:1) after the second buffer rinse, and zero for all samples after the third rinse. Thus, three rinses with buffer after gelation should remove all of the ethanol (provided equilibrium is reached) so that it would have no influence on the behaviour of entrapped proteins.

Fig. 1. Effect of aging conditions on pyranine emission ratio (438:514) during wet-aging for TEOS derived monoliths prepared with different TEOS:buffer ratios for gelation. (●) 1:1 TEOS:buffer, (■) 2:1 TEOS:buffer, (▲) 3:1 TEOS:buffer, (▼) 4:1 TEOS:buffer.



Continued aging of the wet-aged monoliths resulted in a long period during which there were no changes in pyranine fluorescence (about 28 days), followed by a slow increase in the ratio of protonated to deprotonated forms of the probe, as shown in Fig. 1. This spectral change indicates the slow loss of water from the interior of the monoliths, resulting in a re-emergence of the protonated form of the probe. The increase continued slowly until about day 125 (data not shown), even though the mass of the samples became constant by day 40. By day 125, the emission ratios of the different samples were all similar (values were between 0.89 and 0.93). The similarity in the emission ratios indicated that the final environment of all samples was similar, regardless of the initial amount of water used for gelation.

In the case of dry-aged monoliths, the loss of ethanol was much slower. Figure 2 shows the ratio of emission peaks corresponding to the protonated and deprotonated forms over the first 40 days of aging. As the monoliths aged, this ratio decreased for all samples, consistent with the preferential loss of ethanol from the interior of the matrix. This decrease continued for approximately 15 days for most

samples (about 20 days for the 1:1 ratio), showing that the loss of ethanol takes between 2 and 3 weeks, even when higher levels of water are initially present. Beyond about 15 days, the ratio began to increase slowly, in keeping with the trend observed from wet-aged samples. The increase in the spectral ratio continued for all samples up to and beyond day 40, indicative of a loss of internal water. Beyond day 40, trends became erratic. Each sample showed a large increase in the emission ratio, peaking at about day 90, indicative of a loss of water and a shift to a less polar environment. At day 90, the emission ratios were between 1.60 (1:1) and 2.25 (4:1), with the ratios increasing as water content decreased. Between days 90 and 125, the emission ratio of each sample first decreased and then increased again, likely signifying aggregation of the probe and (or) adsorption of the probe onto the surface of the silica. The only apparent trend during this period was that the samples prepared with less water (i.e., 4:1 sample) showed higher emission ratios than those made with more water (1:1 sample). Overall, the continuing changes in the ratio of the protonated and deprotonated forms of the probe indicates that changes in the internal environment of the matrix continue over periods of at least 12 weeks. Given that all of the dry-aged samples attained constant mass by day 28 (data not shown), the changes in the internal environment indicate that the internal structure of the silicate matrix, including condensation reactions which would reduce the number of SiOH groups and increase the number of water molecules, continue long after the mass of the sample becomes constant.

7-Azaindole fluorescence

7AI fluorescence emission spectra were monitored during aging of the sol-gel derived glasses to further examine how the internal environment of the glasses was affected by the preparation and aging conditions. Representative spectra of 7AI as a function of aging time for wet-aged monoliths formed with a silane:buffer ratio of 1:1 are shown in Fig. 3. The spectral properties (emission maximum and spectral full-width-at-half-maximum (FWHM)) measured at different times up to day 125 are listed in Table 1 for all wet-aged samples, and in Table 2 for dry-aged samples. In all cases, the initial fluorescence emission maxima were between 367 and 372 nm, while the FWHM values were between 71 and 75 nm. Comparison of these emission wavelength and FWHM values with those obtained from standard ethanol:water mixtures suggested an internal environment similar to that of a solution containing between 30% ethanol and 60% ethanol by volume, in agreement with the pyranine results. However, the emission maximum did not follow the trend expected based on the pyranine results (i.e., a blue-shift in the emission wavelength maximum as the TEOS:water ratio increased), suggesting that the 7AI emission was not reporting solely on the ethanol content of the pore liquid.

Figure 4 shows the evolution of the fluorescence emission maximum for 7AI during aging of each wet-aged system. For all TEOS:buffer ratios the fluorescence emission maximum red-shifted in a similar manner over the first seven days, evolving from ca. 370 nm to between 394 and 399 nm, after which the emission maximum remained constant. During this time, the FWHM value increased to ~101 nm for all systems, showing that a distribution of environments exists during the drying of the matrix, in agreement with previous reports (26). The wavelength shift and the increase in the FWHM value are consistent with the internal environment shifting toward higher polarity as ethanol is removed. How-

ever, two points merit further attention. Firstly, the 7AI wavelength shift requires 6 days to reach completion, even though the results obtained using pyranine clearly show that the ethanol is removed by day 3. Secondly, the final values for both the emission maximum and the FWHM are *larger* than the values obtained for 7AI in water. These results support the suggestion that 7AI does not report solely on the pore-liquid composition. This point is discussed in more detail later.

At day 10 the buffer was removed from the wet-aged monoliths and the monoliths were aged and dried in air. Table 1 shows that the emission maximum for all samples continues to shift over time, reaching values as high as 403 nm, with minimal changes in the FWHM over the first 55 days. Beyond day 55 the FWHM values increased for most samples while the emission maximum slowly blue-shifted, consistent with the slow loss of internal water, as indicated by pyranine. Given that this emission shift occurred only after the mass of the samples became constant, it is likely to be the result of both the continuing chemical evolution of the silica matrix (i.e., condensation of silanol groups to siloxanes) and the loss of entrapped water, in agreement with the results obtained from pyranine.

Figure 5 shows the changes in the emission wavelength for 7AI in dry-aged monoliths. In all cases the spectra red-shifted slightly over the first 6 days, with the emission maxima shifting by ~5 nm for each system and ending up between 375 and 380 nm. These spectral shifts are consistent with the preferential loss of ethanol from the matrix as determined using pyranine. Between days 6 and 10, the emission of 7AI in each system showed a broadening of the spectral contour and a large red-shift in the emission wavelength maximum, even though the pyranine spectra showed a steady loss of ethanol from all samples. It is likely that the loss of ethanol lowered the solubility of 7AI, causing the probe to either aggregate or adsorb to the surface of the evolving silica matrix, resulting in the broadening in the spectral contour.

Careful inspection of the changes in 7AI emission between days 6 and 10 reveal three points that warrant special attention. First, the emission wavelength of 7AI in all samples shifts to a value greater than 400 nm by day 10 and then

Similar error values are obtained for all other ratios.

become constant. Given that the pyranine results show large changes in pore-liquid composition long after day 10, it is clear that 7AI is not sensitive only to pore-liquid composition. It is also clear that 7AI must undergo specific interactions with its surroundings, since the emission is substantially red-shifted compared to the values in water. The earlier time for the large spectra shift of 7AI as compared to pyranine is likely the result of poorer solubility of 7AI in water, resulting in adsorption of 7AI to the silicate at a higher water content than would occur for pyranine. Second, the FWHM values increase significantly to values that are ca. 25–30 nm broader than those obtained in water. Hence, the probe experiences a distribution of environments as the matrix evolves, as was the case with wet-aged materials. Third, the emission wavelength of 7AI at the completion of the wavelength shift (i.e., beyond day 10) is longer for systems that had a lower initial water content. For example, 7AI in the 4:1 TEOS:buffer system had an emission wavelength at 418 nm while the emission maximum of 7AI in the 1:1 system was 408 nm. These results indicated that the internal environment probed by 7AI changed as the amount of water used for gelation increased. Between days 10 and 125, the emission maximum of 7AI slowly shifted to shorter wavelengths and in most cases the spectra became more narrow, but the trend of shorter emission wavelength with higher R value remained, even up to day 125.

In comparing the wet-aged and dry-aged samples, three key observations can be made. First, it is noted that the final emission maxima of 7AI in dry-aged monoliths blue-shifted as the proportion of water used for gelation increased, while for wet-aged samples, the final emission maximum was the same regardless of the initial amount of water used for gelation. These results are in qualitative agreement with those obtained from pyranine, where wet-aged samples showed similar emission spectra while the spectra of dry-aged samples were dependent on the amount of water used for gelation. These results indicate that the final environment of wet-aged samples, which had R values of 28 or higher due to the presence of an excess amount of buffer during the first 10 days or aging, is not affected by the initial gelation conditions, while samples with $R < 28$ do depend on initial gelation conditions. Second, it is noted that the emission wavelength of 7AI in both wet-aged and dry-aged materials shifted to values beyond that obtained for the probe in water, but was always longer for dry-aged samples as compared to wet-aged samples. Hence, the proportion of water present during gelation affects the internal environment, but only when water levels are below an R value of 28. Finally, the final spectral widths after 125 days of drying were in all cases between 25 and 40 nm greater than the initial values, indicating that there was a distribution of final environments for the entrapped probe. However, the FWHM of 7AI in wet-aged monoliths was usually broader than in dry-aged samples, indicating a more uniform distribution of probe environments in dry-aged samples.

Both pyranine and 7AI indicate that the internal environment of both wet-aged and dry-aged sol-gel derived materials continues to evolve long after the samples have attained constant mass. The evolution of the internal environment continues for right up to 125 days for both wet-aged and

© 1999 NRC Canada

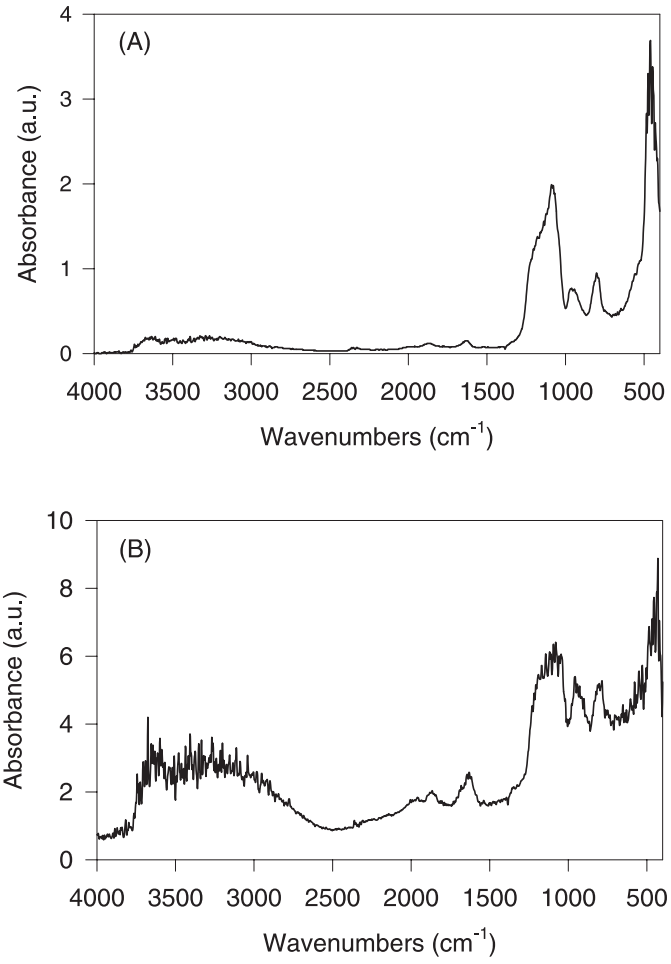
dry-aged samples. The length of time over which the samples change may cause some proteins to become inaccessible (25), or may alter protein binding constants (27, 28). It is also likely that the loss of water during the final stages of drying may result in dehydration and (or) denaturation of the entrapped proteins, causing loss of sensor function. The 7AI results also indicated the presence of a distribution of internal environments, even as early as 10 days into the aging step. The distribution of internal environments, and the change in this parameter over time, can lead to changes in sensor response times and sensitivity as the matrix ages, causing difficulties in sensor calibration (29). Hence, aging should be done only for 15 days for dry-aged samples, or 25 days for wet-aged samples, which correspond to the time at which constant mass is attained for the two types of samples. The samples should then be stored in a buffer solution to avoid the loss of entrapped water.

Origin of the 7AI spectral shift

A question that arises is the origin of the large red-shift for entrapped 7AI. The emission maximum is in all cases larger that that obtained for 7AI in water, therefore the spectral shift must be based on specific rather than general solvent effects (30). The red-shift for entrapped 7AI could in principle be due to a number of factors, including shifts in internal pH to values lower than ~5 (21), interaction of 7AI with buffer salts, which become more concentrated as the matrix dries, pressure-induced spectral shifts arising from the large capillary pressures, which would be between 19 and 36 MPa based on the typical pore sizes measured for such systems (25, 27), aggregation of the probe, or adsorption of the probe onto sites on the silica surface. To further examine these possibilities, several experiments were done. First, the internal pH of both wet-aged and dry-aged samples was measured by entrapping the pH sensitive fluorophore SNARF-1. The emission spectra indicated an internal pH of 6.5 ± 0.2, ruling out pH shifts as the basis of the 7AI red shift. Second, we measured the emission maximum of 7AI adsorbed onto the surface of phosphate or PIPES buffer salts. The emission maximum was 377 ± 2 nm regardless of the level of probe loading (1–20 μM), thus ruling out both interactions with buffer salts as the basis of the wavelength shifts. Third, emission spectra were collected from 7AI that was adsorbed onto quartz slides to eliminate pressure effects. 7AI was adsorbed onto either clean quartz slides, which had been soaked in hydrofluoric acid to provide a high surface silanol content, or onto quartz that was treated with trimethylchlorosilane (TMS) to cap the silanol groups. The emission maximum was between 408 and 415 nm on the HF treated slide, and was 392 nm on the TMS coated quartz slide. Hence, the large spectral shift for entrapped 7AI must be due to aggregation and (or) adsorption of the 7AI. It should be noted that red-shifts in both absorbance (31) and emission (32, 33) maxima are commonly observed for probes that are formed as Langmuir–Blodgett films or self-assembled monolayers, owing to specific interactions between the probe and the surface (33).

Matsui et al. (24) have also reported an emission maximum of between 415 and 420 nm for 7AI entrapped into TEOS derived materials. In this study, the absorbance, excitation, and emission spectra of the probe was investigated at several concentrations of entrapped 7AI to examine the question of whether 7AI was aggregated or adsorbed onto the silanol groups of the matrix. Their results clearly indicated that the red-shift in the 7AI emission spectra was due to adsorption of the probe onto silanol sites on the surface of the silica. To confirm this assertion, we collected infrared absorbance spectra for both the wet-aged and dry-aged samples that were prepared with a 1:1 to 4:1 TEOS:buffer ratio to determine if the silanol content was reflected by the 7AI emission data. Representative spectra collected for wet-aged and dry-aged materials prepared with a 3:1 TEOS:buffer ratio are shown in Fig. 6. The ratio of intensities in the SiOH stretching regions between 3000 and 3700 cm^{-1} and at 950 cm^{-1}, and the Si-O-Si stretching region at ~490 cm^{-1} (34) clearly show that the wet-aged sample had a lower proportion of SiOH groups (i.e., higher degree of crosslinking) as compared to the dry-aged sample. IR spectra collected for dry-aged samples prepared with different amount of water also indicated that the ratio of silanol groups to siloxane groups increased as the amount of water used for gelation decreased, suggesting that the use of larger amounts of water

Fig. 6. Diffuse reflectance infrared spectra of TEOS derived monoliths prepared with a 3:1 TEOS:buffer ratio for gelation. The samples were crushed to powder form and dried at 120°C for 60 min before spectra were collected. (*A*) wet-aged monolith, (*B*) dry-aged monolith.



© 1999 NRC Canada

for gelation led to an increase in crosslinking. These results confirm that the 7AI emission spectral shifts reflect silanol content, and can therefore be used to qualitatively monitor the extent of cross-linking within sol-gel derived materials.

The sensitivity of 7AI emission to specific interactions involving silanol groups explains the emission red-shifts to values beyond those obtained in water, and is also in keeping with the shift of 7AI emission in the dry materials to shorter wavelengths as the level of water during aging increased. Increased levels of water during aging promote the dissolution and reprecipitation of silica, providing an increase in crosslinking through the process of coarsening and a corresponding decrease in silanol content (35–38). Hence, the 7AI emission spectra correspond well with the expected structure of the different silica matrixes. The finding that 7AI responds to silanol content is significant in that it shows 7AI to be a new and useful probe for examining the internal environment, the internal and external surface chemistry (assuming that some probes are likely adsorbed to the external surface of the matrix), and potentially the internal structure (i.e., silanol content) of sol-gel derived silicate materials.

Conclusions

The fluorescence of pyranine and 7AI were used to provide detailed information on the evolution of the internal environment of sol-gel derived silicate materials during aging and drying. Based on our studies, several useful conclusions can be drawn which have ramifications for the entrapment of biomolecules. First, it is advisable to use as high an *R* value as possible for gelation to reduce the initial level of ethanol, reducing the impact on the stability of entrapped proteins. Second, the buffer should be exchanged after gelation at least three times (i.e., samples should initially be wet-aged for at least three days, with daily buffer exchanges) to completely remove entrapped ethanol. Third, aging should be done only until there is an observable decrease in the amount of entrapped water. At this point there are shifts in both the FWHM value and emission wavelength maximum, and hence the distribution of environments, and the internal polarity. Based on emission data, these changes continue well beyond the point where the samples attain constant mass, indicating that the internal environment and structure continue to evolve for several months. Based on our observations, dry-aged samples should be aged for no more that 15 days, while wet-aged samples should be aged in air for no more than 25 days. After the initial period of aging the samples should be stored in a fully hydrated environment to avoid further losses of entrapped water. Such storage conditions should minimize further changes in the matrix, and thus maximize protein stability, in agreement with recent results from our laboratory (27, 28).

Estimation of particle size distribution in Athabasca oil sands by indirect instrumental neutron activation analysis

Robert Schutte, Gordon R. Thompson, Kingsley K. Donkor, M. John M. Duke, Roger Cowles, Xiu Ping Li, and Byron Kratochvil

Abstract: Instrumental neutron activation analysis (INAA) was used to predict the relative amounts of various sizes of fine particles in Athabasca oil sands. The method is based on regression analysis of element concentration data for 529 oil sand test portions, determined by INAA, against particle size distributions determined by three currently used methods. The most important elements for the estimation of particle sizes below 44 μm were found to be aluminum, sodium, and manganese. The INAA estimation method works because variation in elemental composition within particle size fractions in oil sands up to at least 44 μm is relatively small, whereas the variation between size fractions is significant. The new method does not involve the use of organic solvents, is faster and simpler to perform than the methods currently in use, and is comparable in precision. It has the added advantages that it can be readily automated, and concentrations of elements of special interest in oil sand processing, such as chlorine, are obtained simultaneously.

Key words: instrumental neutron activation analysis, oil sand, particle size distribution.

Résumé : On a utilisé l'analyse instrumentale par activation neutronique (AIAN) pour faire des prédictions concernant les quantités relatives des diverses tailles des particules fines des sables bitumineux de l'Athabasca. La méthode repose sur une analyse de régression des données relatives à la concentrations des éléments dans 529 portions analytiques de sables bitumineux, déterminées par AIAN, en fonction des distributions de tailles des particules déterminées par trois méthodes couramment utilisées. On a trouvé que les éléments les plus importants pour l'évaluation des tailles des particules en-dessous de 44 μm sont l'aluminium, le sodium et le manganèse. La méthode d'évaluation par AIAN est appropriée en raison de la faible variation de la composition élémentale dans des fractions dont la taille des particules dans les sables bitumineux est inférieure à 44 μm; par ailleurs, on note une variation importante entre des fractions de tailles différentes. La nouvelle méthode n'implique pas d'utilisation de solvants organiques et sa précision est comparable. De plus, on peut la rendre automatique et on peut obtenir de façon simultanée les concentrations d'éléments de sables bitumineux qui présentent un intérêt particulier, tel le chlore.

Mots clés : analyse instrumentale par activation neutronique, sable bitumineux, distribution de la taille des particules.

[Traduit par la Rédaction]

Introduction

In a previous study (1) on the variability of oil sands, it was shown that the fines concentration in the solids fraction of oil sands can be calculated from the concentrations of selected elements in the oil sand. This work follows that study, extending the method to other particle size ranges, addressing the basis for, and validation of, the method, and assessing the errors associated with it.

Information about the particle size distribution (PSD) of oil sand is essential to optimal extraction of bitumen from oil sands (2). It indicates ore quality, provides a measure of process performance during bitumen extraction, and provides information useful in the management of tailings (3). Oil sands with predominantly coarse particulates are usually rich in bitumen and easy to process in the conventional hot water extraction process. These ores do not require the addition of sodium hydroxide as a process aid, and tailings vol-

umes are minimal. In contrast, high fines oil sands contain less bitumen, are difficult to process, require more water and sodium hydroxide, and longer residence times for extraction, yet still yield lower bitumen recoveries.

Process performance measures, such as froth quality and bitumen losses, are correlated with specific size fractions of the mineral components of oil sands. Particle size distribution also affects parameters such as wear on mining equipment, pressure drop in hydrotransport, flow rate in tailings disposal, and chloride content of produced bitumen. Furthermore, optimum tumbler residence time and middlings density during extraction depend on the fines (specifically clay) content of the ore. In light of the above there are incentives on the operations side to have particle size distribution information. On the laboratory side the incentives are to reduce the time and cost of PSD determinations, and to increase the reliability of the results.

The methods currently used in the oil sand industry for determining PSD are either a combination of screen/hydrometer separations (4), or laser scattering techniques with commercial Microtrac (model no. 7995, Leeds and Northrup, Florida, U.S.A.) or Coulter (model LS130, Coulter Corp., Florida, U.S.A.) instrumentation (4). These methods are time-consuming and laborious because they require removal of bitumen with organic solvents and wet screening prior to measurement. In addition, they are only applicable over a limited particle size range, and their sensitivity to particle shape leads to a bias in the estimation of the PSD. The method described here is rapid, simple to carry out, and does not involve use of organic solvents with attendant disposal problems.

The principle behind the method is the development of a set of correlations by applying regression analysis to a large set of PSD and elemental analysis data. To be useful the model must be significant and applicable to a wide variety of oil sand compositions. Therefore in this study an equal representation of all available oil sand facies (5) was employed to ensure wide applicability. The term facies is defined here as the sum total of features such as sedimentary rock type, mineral content, sedimentary structures, bedding characteristics, fossil content, etc., which characterizes a sediment as being deposited in a given environment (5).

Part 1. Basis for the method

Theory of the INAA method for PSD

To establish a basis for the INAA method, equations that express the amount of a component present in a sample as a function of the concentration of an element were derived. Later this result was modified to give the amount of a particle size fraction. The derivations use as key variables the concentrations of the elements in the total sample, as this is what is measured in the INAA method.

A two-component system can conveniently be used to arrive at the desired equations. Consider that one component is clay (weight fraction, x_1) and the other is pure quartz (SiO_2) (weight fraction, $1 - x_1$). The Al content of the clay is Al_c, and for a typical clay $Al_c = 0.159$ weight fraction. Initially, the aluminum content of the quartz is set at zero. The weight fraction of Al in the mixture is then

$$[1] \qquad Al = Al_c x_1$$

The amount of clay in the mixture as a function of the Al content is

$$[2] \qquad x_1 = \frac{Al}{Al_c}$$

To arrive at a more general case the aluminum content in quartz is introduced (weight fraction, Al_s). When irradiated in the SLOWPOKE reactor, silicon produces an aluminum signal due to the fast neutron induced transmutation reaction $^{28}Si(n, p)^{28}Al$. For the inner SLOWPOKE irradiation sites, the Si/Al interference factor is 207 ± 14 (6). That is, when analyzed under identical conditions, 207 μg Si produces the equivalent ^{28}Al activity as 1 μg Al. Thus, for the SLOWPOKE reactor, irradiation of pure quartz (SiO_2) produces an Al signal equivalent to 0.23% Al. The aluminum content of a mixture of SiO_2 and minerals containing Al is therefore the weighted sum of the Al in the two components. Equation [1] thus becomes

$$[3] \qquad Al = Al_c x_1 + Al_s(1 - x_1)$$

from which, through rearrangement, a new expression is obtained for the weight fraction of clay in the mixture as a function of the Al content:

$$[4] \qquad x_1 = \frac{Al - Al_s}{Al_c - Al_s} = \frac{-Al_s}{Al_c - Al_s} + \frac{Al}{Al_c - Al_s}$$

A plot of x_1 against Al yields a straight line with a non-zero intercept and a greater slope than in eq. [2]. The ratio (intercept/slope) = $-Al_s$.

Equation [4] implies that for the INAA method to work the concentrations of the elements must vary with component (as will be seen later, what is valid for components is equally valid for particle sizes). If element concentrations are equal, the weight fraction of each component becomes indeterminate. That elemental concentrations do vary with particle size fractions for oil sands is documented later.

Let us now introduce particle size distribution to the first example of clay in pure quartz. If a weight fraction p of the clay is $<q$ (size), and all the quartz is present in particles larger than q, then the weight fraction z of the sample $<q$ (size) as function of the Al content is given by

$$[5] \qquad z(<q) = px_1 = \frac{pAl}{Al_c}$$

When the quartz contains a fraction r of the $<q$ size class the equation becomes

$$[6] \qquad \begin{aligned} z(<q) &= px_1 + r(1 - x_1) \\ &= (p - r)x_1 + r \\ &= \frac{(p - r)Al}{Al_c} + r \end{aligned}$$

There is then a positive intercept for $Al = 0$ in the wt.% $<q$ vs. Al graph since $r \geq 0$.

When $p = r$ the coefficient of Al equals zero, and the element aluminum cannot be used to measure or calculate particle size $<q$ because under these conditions $<q$ is independent of sample composition. In the more general case where the quartz also contains, or appears to contain, aluminum, the

© 1999 NRC Canada

expression for the weight fraction of clay given by eq. [4] is substituted in eq. [6], giving as final result:

$$[7] \qquad z(<q) = \frac{(p-r)(Al - Al_s)}{Al_c - Al_s} + r$$

In general, the constants Al_s, Al_c, and the variables p and r in eq. [7] will not be known a priori for each geological deposit of interest. They are instead determined by regression analysis from an empirical set of data, a set large enough to provide acceptable confidence limits.

An improvement in the accuracy and precision of the determination of particle size can be achieved by incorporating additional elements. The derivation given above for the dependence of particle size $<q$ on the Al content can be applied to any element, so long as its concentration varies between the size fraction of interest and the remainder of the sample. In the ideal case the weight fraction of particles $<q$ may be determined independently n times from n elements. The multiple regression equation is a linear combination of the equations for the individual elements. Each element contributes a term of the form of eq. [7] multiplied by a weight factor that takes account of the covariance of the concentrations of the elements. In the simplest case of linear covariance between two size-determining elements, the weighting will be 0.5 for each of those elements.

Experimental

Samples and sample preparation

Two sets of samples representing a range of facies and oil content were provided by the Edmonton Research Laboratory of Syncrude Canada Ltd. These samples were obtained from the Athabasca oil sand deposit mined by Syncrude near Fort McMurray, Alberta. The first set consisted of 529 test portions of bulk oil sand and were analyzed as received. A second set of 10 samples, labelled X-5 through X-14, were sampled, the bitumen removed, and the solids separated into nine size fractions by sedimentation and sieving before analysis.

Prior to sizing, the second set was first homogenized with a Comil (Quadro Engineering, Waterloo, Ont.) at Syncrude's Edmonton Research Laboratory. Upon receipt, each sample was spread out in a layer about 2 cm thick and 1 g portions scooped from random locations to produce 100 g subsamples. Four subsamples were taken from each of the 10 bulk oil sands and Soxhlet-extracted to remove the bitumen and yield the solids (4). The solids were separated into size fractions and the particle size distribution and element concentrations determined as described in the next sections.

Separation by sieving/sedimentation and PSD analysis

Elutriation and sedimentation were explored for quantitative separations. Elutriation was found unsuitable because the excessive volume of liquid product streams obtained for each size fraction (about 6 L) required long run times, large glassware, and several days to evaporate the water. Sedimentation was therefore used for particle sizes below 44 μm (the fines fraction). Screening was employed for sizes >44 μm. Although screens are available for smaller sizes, sedimentation in water using a Stokes equivalent radius was considered more appropriate for oil sand samples because the important dimension for oil sand processing is the equivalent dimension in the water streams used for commercial extraction and tailings disposal.

A subsample of 84–86 g bitumen-free solids was first separated by sedimentation into fractions smaller and larger than 31 μm. To carry out the sedimentation, the sample was suspended in water in a glass beaker and stirred for 2–5 min. The solids were then allowed to settle for a predetermined time as estimated from Stokes equation. Times ranged from 2 min for the coarsest fraction to 15 min for the <3.9 μm fraction. A set volume of supernate was then transferred to a filter flask by suction. Since the slurry remaining in the beaker still contained particles of less than 31 μm, an amount of water equivalent to that removed was added to the beaker and the process repeated until the supernate appeared clear. About 10 repetitions were typically required. The sediment, of approximately 25 mL total volume and containing particles >31 μm, was air-dried and sieved, using a shaker (model RX-24 Tyler) and standard screens, into the size ranges >250, 180–250, 150–180, 90–150, 45–90, and 31–45 μm. A result of this procedure is that water soluble salts from the sample of oil sand solids end up in the <3.9 μm fraction. This may explain the very high Na and Cl levels in the <3.9 μm fraction from samples X-6 and X-8. Ultra pure water was used for samples X-11 to X-14 to avoid possible contamination from the distilled water but no difference was observed. In all, nine size fractions from each of the 10 oil sands were obtained by this method. The separated size fractions from all 10 oil sands were subsampled and their elemental composition determined by INAA.

All particle size distribution measurements were carried out at the Edmonton Research Laboratory of Syncrude using their screen/hydrometer and laser scattering equipment (Microtrac Model 7995 and Coulter Model LS130) and procedures (4, 7, 8). Statistical analysis of the data was carried out using the software program SIMSTAT (9) on an IBM Pentium computer.

INAA of elements that produce short-lived radionuclides

All irradiation and counting operations were performed at the University of Alberta SLOWPOKE-II Nuclear Reactor Facility. For the sized mineral fractions of the 10 oil sand solids, representative portions of 300–600 mg were accurately weighed into individual nitric acid washed 0.75 mL polyethylene irradiation vials. Standard reference materials from NIST, CANMET, and NRC were prepared in the same manner. The sized mineral fractions and standards were irradiated at a nominal thermal neutron flux of 1×10^{11} n cm^{-2} s^{-1} for 240 s in the inner site of the reactor. Following irradiation each sample was counted twice, initially for 300 s live-time after a decay time of ca. 15 min and a second time following a decay time of 30–60 min. The first count was performed at a sample-to-detector distance of 6 cm using a 19% hyperpure Ge detector with an automatic sample changer and PC-based multichannel analyzer (MCA) card. The second count was also performed at a sample-to-detector distance of 6 cm. However, for this count a 34% hyperpure Ge detector with automatic sample changer and PC-based MCA card was used.

© 1999 NRC Canada

Utilizing a dual counting scheme permits some optimization for those radionuclides with $T_{1/2} \leq 12$ min and for those with $T_{1/2} \geq 12$ min. From the initial count the elements Al, Ti, V, Ca, and Mn were quantified (Na and Dy may also be readily determined from the first count). The second count gives data on Dy, Sm, Eu, Ba, Na, K, Cl, and Mn. Element concentrations were determined by the semi-absolute method of INAA (10).

For the 529 bulk oil sand samples, portions of 10–12 g were packed in clean 7 mL polyethylene irradiation vials and individually irradiated for 4 min at a nominal thermal neutron flux of 2×10^{10} n cm^{-2} s^{-1} in an inner site of the reactor. Following a decay period of ca. 15 min each sample was counted for 5 min live-time at a sample-to-detector distance of 6 cm using a 19% hyperpure Ge detector. Following a decay period of not less than 30 min, each sample was recounted for 6 min live-time at a sample-to-detector distance of 6 cm, with a 34% hyperpure Ge detector. Again both γ-ray spectrometers were equipped with automatic sample changers and PC-based MCA cards. As for the mineral fractions, element concentrations were determined via the comparator semi-absolute method of INAA (10) using CANMET and NRC reference standards for comparison and quality control purposes. Utilizing the described analysis protocol the elements Ti, V, Al, Ca, Mn, K, Ba, Dy, Sm, Eu, and Cl were determined.

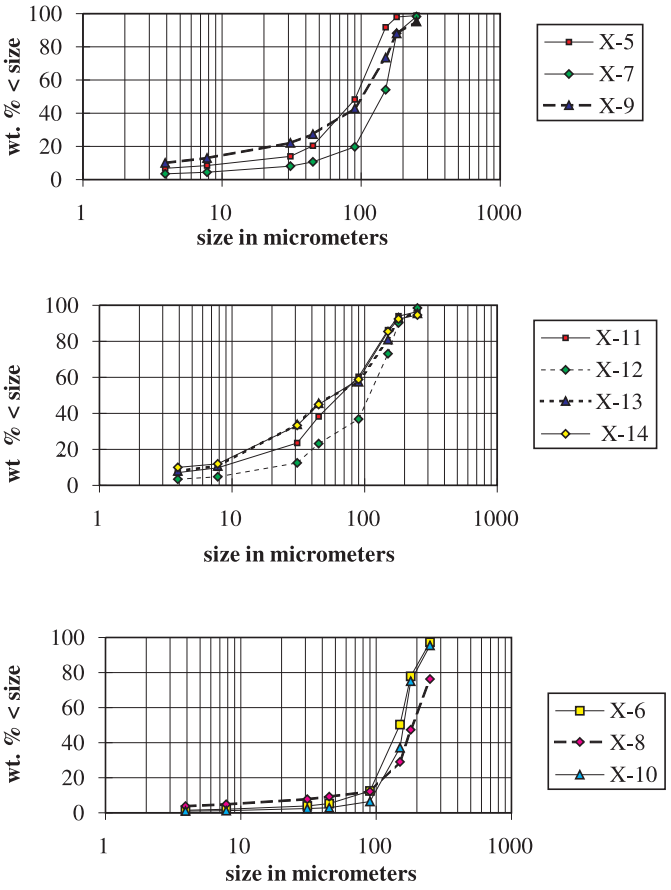
A stable, reproducible neutron flux is important in NAA, particularly when measuring short-lived radionuclides for quantitative elemental analysis. For SLOWPOKE II reactors operating at typical neutron flux levels of 1 to 10×10^{11} n cm^{-2} s^{-1}, the flux characteristics are reported to vary by $<\pm 2\%$ (2σ) over a period of several months (11). Data are not available, however, on flux stability at 2×10^{10} n cm^{-2} s^{-1}, the level used in this study. Therefore an Al standard was analyzed 15 times over a period of 5 weeks at a nominal flux of 2×10^{10} n cm^{-2} s^{-1}. Owing to the short half-life of ^{28}Al, multiple measurements could be made on the Al standard during extended runs on the same day as well as on separate days. The standard was also irradiated simultaneously with and without an oil sand sample in a second inner site to assess flux differences between sites; none were found. The variation in neutron flux at 2×10^{10} n cm^{-2} s^{-1} was found to be $\pm 1.35\%$ (1σ, $n = 15$), which was acceptable for this work.

Results and discussion

The model equations consider a mixture of particles as a two-component system, the components being those less than and those larger than a certain size. If all the particles contain an element of interest, for instance, clay contains silicon and so does quartz sand, then it is possible to separate the particles into two piles based on silicon concentration. Thus, a mixture, regardless of its complexity, is reducible to a two-component system. For another cutoff size, another system, with an associated regression analysis, is required.

The cumulative particle size distribution (PSD) by sedimentation and screening of the 10 oil sands is shown in Fig. 1 for the individual size fractions.[2] The data show that a range of particle sizes were obtained. The clay fraction (<3.9 μm) varied from 1% for X-10 to 10% for X-9 and X-14. The silt to fine sand fraction (45–90 μm) also varied considerably, ranging from 2.9 wt.% for X-8 to 27.9 wt.% for X-5. Sample X-8 contained 23 wt.% >250 μm sand, whereas all other samples contained less than 5.3% of this size fraction.

Fig. 1. Cumulative particle size distributions by sedimentation and screens.



The cumulative data showed that total fines content (<45 μm) varied from 2.9% for X-10 to 45.6% for X-13 with a good distribution of values between. Total material <180 μm ranged from a low of 47% (X-8) to a high of 98% (X-5). It was important that the test oil sands covered a wide range of PSD so that the validity of the new method could be established over expected values.

Elemental analysis of size fractions by INAA

Twelve elements could be determined with reasonable precision by INAA using a short irradiation/count scheme. The average, standard deviation, and relative standard deviation (RSD) of the concentration of each element in the size fractions for the 10 oil sands are given in Table 1. The re-

[2] Complete data may be obtained from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

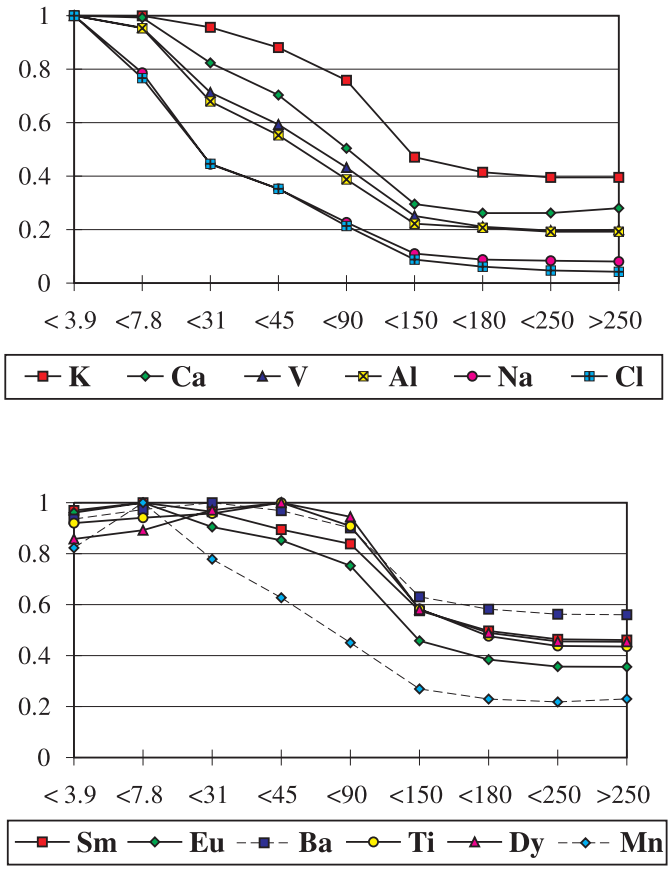
sults of Table 1 show that for the <3.9 μm fraction the concentration of Ti, V, Al, and Ba vary little, with relative standard deviations of between 0.17 and 0.24, while the largest variation is shown by Cl(1.58), followed by Na(0.74). For the 31–45 μm (silt-size) fraction, the concentrations of the elements hardly vary. The RSDs for most of the elements are comparable to those for aluminum in the <3.9 μm fraction. Similarly, for the 150–180 μm (fine sand) fraction RSDs ranged from 0.17 for Ba to 0.78 for Sm. For the 180–250 and >250 μm fractions, the RSDs ranged from 0.30 to 2.01. In general, Al, V, and Ti had small RSDs for all size fractions; those for Dy, Sm, and Eu were somewhat larger, and those for Na and Cl the largest of all. With the exception of Na and Cl in the <3.9 μm fraction, none of the elements varied over wide ranges within a given size range.

For an element to be useful as a predictor of particle size, it is not sufficient for its concentration to be constant within a particle size fraction; it is also necessary that the concentration vary from one size fraction to another. This property is illustrated in Table 1, which summarizes the average concentrations for different size fractions. Titanium, barium, and dysprosium concentrations stay fairly constant up to 45 μm particle size. These elements therefore cannot discriminate between particle sizes below 45 μm, though they may provide some general differentiation between fine and coarse particles. In contrast, V, Al, Na, and K showed a steady decrease in concentration with increase in particle size and are therefore useful in discriminating among the size ranges of the finer particles. Such trends form the basis for the use of INAA for PSD measurements.

The other measurable elements — Ca, Sm, Eu, Mn, and Cl — displayed more irregular concentration/particle-size profiles, although the overall trend for all was towards lower concentrations in the larger particles. Standard deviations and RSDs for these elements (Table 1) show reasonable precision, confirming that the trends are real. These findings are

© 1999 NRC Canada

Fig. 2. Normalized element concentrations as a function of cumulative particle size for 10 oil sands.



consistent with the role that these elements play in the model equations.

Evaluation of the soundness of the INAA prediction method should also include consideration of the composition of the cumulative particle size fractions. These compositions have been calculated, and the averages, standard deviations, and relative standard deviations of the concentrations are available.[2] Figure 2 illustrates the trends in the concentrations with cumulative particle size. To accommodate the wide range of absolute values of the averages, the averages were normalized by dividing them by the maximum average observed for each element. For six elements (K, Ca, V, Al, Na, and Cl), concentrations were greatest in the <3.9 μm fraction (Fig. 2). It is of note that Na and Cl normalized concentrations track together closely, as do V and Al. These elements appear closely associated with the clay size fraction. Because vanadium is present in oil sand in both the bitumen and the minerals, the V/Al ratios found here will not be the same as in bulk oil sand. Calcium and potassium showed the least variation with particle size. Manganese was at highest concentration in the <7.8 μm fraction. From that point on it showed considerable variation with particle size (Fig. 2, lower plot). The trend for K, Sm, Eu, Ba, Ti, and Dy was for little variation in concentrations in the finer particles, with significant decreases in concentrations in the >90 μm fraction. These elements appear to be predominantly associated with silt-size particles. All cumulative concentrations were essentially constant over the larger size ranges, therefore, the INAA method could not be applied to the prediction of PSD values for particles larger than about 150 μm. Particle sizes above 90 μm, do not, however, have a significant effect on the processibility of oil sands, and so their measurement is of lesser importance.

It should be noted that some fine particulates may be lost during the bitumen extraction step used to prepare the solids for screening. Previously, it was found that Soxhlet-extracted bitumen contained traces of the rare earth elements and aluminum, indicative of the presence of clay minerals (12). The extracted bitumen was not tested for these elements in this study.

Part 2. Application of the method

Development of regression equations for PSD from INAA

The method used to develop the model equations involved the following steps: finding the best fit equation, using multiple regression (least-squares) mathematical techniques, and relating element concentration to a given particle size range. Those terms in the equation that were redundant were deleted, and only those terms that improve the agreement between calculated and observed particle size measurements were retained.

Samples used to define and test the equations were obtained from two Syncrude mines (Base and Aurora), located about 35 km apart in the Athabasca deposit. Three data sets were used:

INAA, Microtrac, and Coulter data on 196 samples from the Base mine.

INAA, screen/hydrometer, and Coulter data on 129 samples from the Aurora mine.

INAA and Microtrac data on 214 samples from the Base mine. Of these, 112 samples included only <44, <22, and <11 μm size fraction data.

All of the INAA measurements were carried out under the same conditions as described earlier in this paper.

A preliminary cluster analysis was performed to provide insight into which of the particle sizes contained independent information about the sample. An analysis of the 214 Microtrac data set showed that particle sizes <3.9 μm correlated closely with each other, as do particle sizes in the 5.5–31 μm range. Based on these findings it was decided to study only four fines fractions, <3.9, 3.9–7.8, 7.8–31, and 31–44 μm in 10 samples (Part 1). Subsequently, because of a long Syncrude history of using <22, <11, <5.5, and <2.8 μm size ranges, these ranges were adopted for the INAA models. Cluster analysis for the Coulter data showed similarity in sizes to the Microtrac data; some differences appeared between 3.9 and 5.5 μm and between 22 and 31 μm. A break between 88 and 125 μm was found in the Microtrac but not in the Coulter data. This may be a result of a difference in the maximum particle size measurable by the two methods. The screen/hydrometer data showed little discrimination between fine size material, but breaks appeared between 44 and 75 μm, and between 75 and 125 μm.

Element correlation matrices provided insight into the number of independent variables available from the INAA data. For the Aurora mine, 32 of the 72 correlation coeffi-

cients (*r*-values) calculated for 12 elements were <0.5. For the Base mine, 36 out of 72 were <0.5.

Model equations: testing and accuracy of the models

The principle behind the new INAA based method for particle size distribution is to use multiple linear regression analysis wherein the weight fraction smaller than a given size is the dependent variable, and the concentrations of elements, as measured by INAA on a sample of whole oil sand, are the independent variables. The statistically significant independent variables are kept, and the marginal and insignificant variables are omitted. The regression analysis is then rerun with only the significant variables. This fine tunes the values of the coefficients of the independent variables.

Each of the methods compared in this study (Coulter, Microtrac, and screen/hydrometer) has strengths and weaknesses for oil sands PSD determinations and yield differing results. Consequently, INAA equations must be derived from data obtained by each method. The constants and coefficients in the derived linear equations are given in Table 2. It is encouraging to see that the elements present in almost all equations (Al, Mn, and Na) are also amongst the elements that in the 10 oil sands tested show good variation of concentration with particle size, as required for successful size discrimination. The coefficients for Al in the Microtrac regression equations show an increase with cumulative particle size, as per eq. [7]. The coefficient for Al is 0.253 for <1.4 μm, 0.655 for <1.9 μm, 1.20 for <2.8 μm, 5.99 for <11 μm, and 6.87 for <22 μm. Only for the <44 μm fraction does the calculated value of 4.89 disagree with the trend. This may be due to an increase in the factor *r,* which may be appreciable for the non-Al containing fraction. In other words, the silica (quartz) sand in these solids has a sizable fraction of >22 and <44 μm particles. Another reason for the lower Al coefficient is that Ti was found to be a size discriminating element in the <44 μm fraction. Inclusion of Ti in the equations changed the coefficient for Al. Since the Al content of the non-clay component in most oil sands is expected to be smaller than that of the clay component, the intercept of a graph of wt.% particle size versus Al concentration will be <0, and the slope >0. The coefficient for Ba in the Coulter model for particles in the size ranges of <11, <22, and <44 μm was <0, which suggests Ba is more abundant in particles >11 μm than in those <11 μm. Observations on the 10 oil sands indicated that Ba, on a cumulative basis, peaks in the 7.8–32 μm fraction, providing support for this interpretation of the sign of the coefficient of individual elements.

As mentioned earlier, silicon produces an Al signal in INAA. If the Al/Si ratio of a sample is small, the correction to the Al result becomes important. Both slope and intercept of the model equations are affected. No correction for this interference was made in this work.

Table 3 gives values for correlation coefficients of the model equations of Table 2, along with the standard error of the estimate for the regression lines for each of the methods and particle sizes. A comparison of Table 3 with Table 4 shows that the standard error of the INAA method (0.090–6.69) is generally less than the standard error between the Microtrac and Coulter methods currently in use (4.85–8.08). From these data we conclude that overall the proposed INAA method is at least as good as, and in many ways better than, the PSD methods on which it is based.

Agreement of the models for the particle size ranges studied was good, as illustrated for the <44 μm fraction using equations derived from the coefficients in Table 2 for the Microtrac model (Fig. 3) and for the Coulter model (Fig. 4).

Microtrac–Microtrac	<44		5.6	89
	<22		5.5	89
	<11		3.1	89

The Coulter method was the only one used on both Base and Aurora mine samples. Prediction models based on the Coulter data were found to be equally applicable to both mines.

Results for the screen/hydrometer model, given in Fig. 5 for the <44 and <22 μm fraction, also show satisfactory reproducibility. Hydrometers are "blind" below certain concentrations, depending on particle size (see Table 5). By selecting hydrometer data above the minimum values in Table 5, the models improve but the results become less useful. Anytime the hydrometer-based INAA method predicts a particle size concentration below the limits shown in Table 5, the results should be treated with caution.

Precision of model equations, INAA, and oil sand sampling

A study was done on the precision of the proposed and existing methods to provide a basis for statistical comparison.

A set of equations was applied to the INAA data to determine particle size values for six size fractions for each method. Each equation was applied to three subsamples from each of six samples (X-5, X-6, X-7, X-8, X-9, X-10). Each of the three subsamples was then analyzed four times by INAA. This yielded a (3 × 4) matrix of particle size values for each size fraction and each oil sand. The standard deviation, average, and overall relative standard deviation

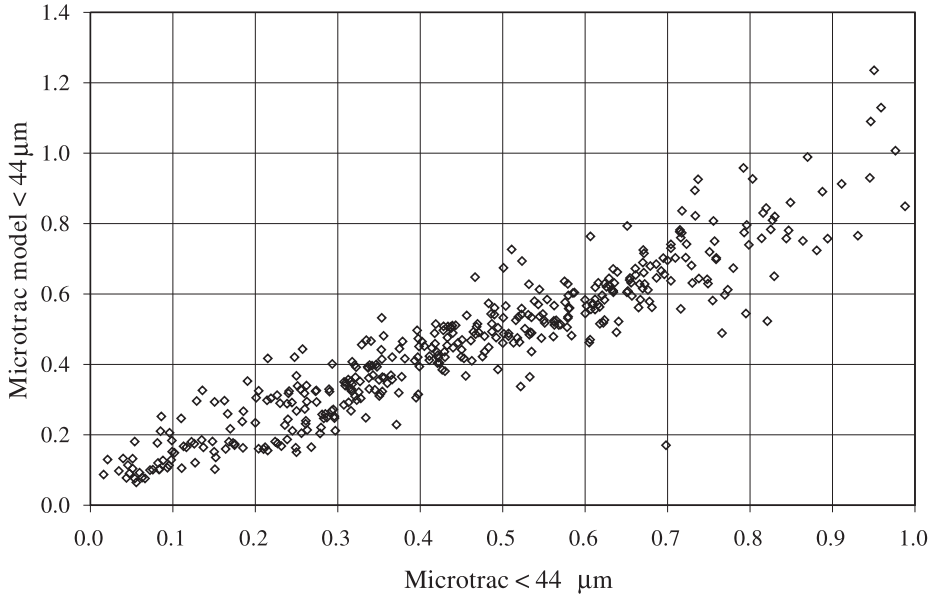

Fig. 4. Degree of fit. Coulter model equivalent versus observed Coulter PSD <44 μm, expressed as volume fraction (r = 0.96).

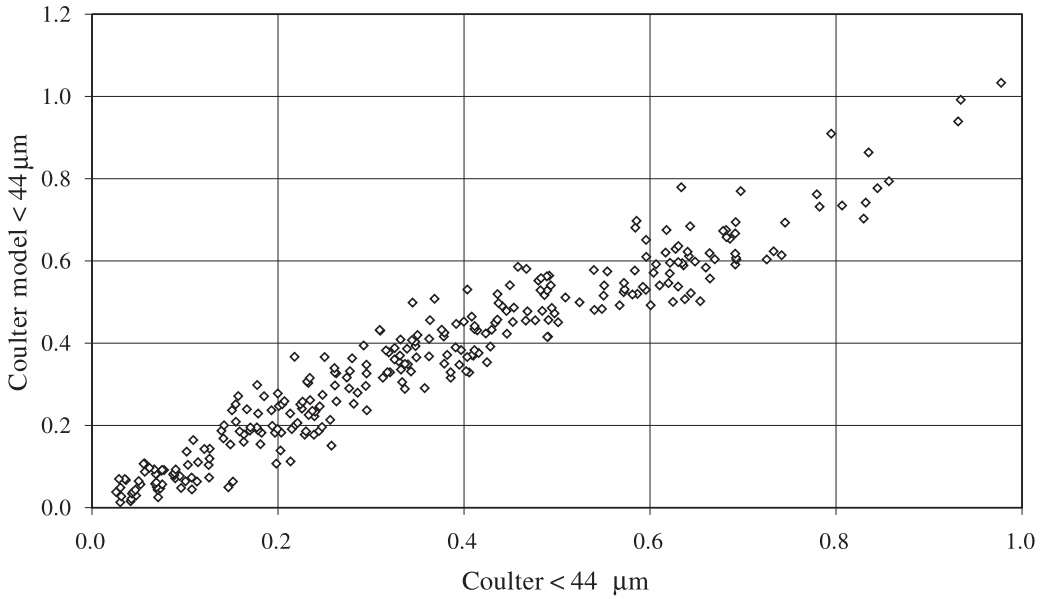


(RSD) were determined for each oil sand sample for the Microtrac and Coulter models. The four INAA measurements on each sample provided a measure of the repeatability (RSD*rep*) of the INAA technique for PSD measurement. The equations were later refined by inclusion of an additional 196 data sets; recommended coefficients for the terms are given in Table 2.

Three subsamples of each of six samples (X-5, X-6, X-7, X-8, X-9, X-10) were analyzed by INAA for elements via their short-lived radionuclides, then sent to the Syncrude Edmonton Research Laboratory for PSD measurement using Microtrac and Coulter instruments. At Syncrude the three approximately 12 g bulk oil sand subsamples from each sample were combined and the bitumen extracted. The cleaned solids were subdivided again into three portions and returned for INAA. After radioactive decay to essentially background levels the samples were returned to Syncrude for Microtrac and Coulter instrumental PSD determination. For each of the six oil sand samples, the standard deviation, mean, and relative standard deviation values were determined for both the Microtrac and Coulter data from the observations on the three subsamples to give overall RSD values.

A contributing factor to the overall uncertainty in the INAA prediction method is statistical counting variability in the INAA measurements. Conditions were adjusted to minimize this uncertainty. Uncertainties in the irradiation, decay, and counting times were estimated to be less than 1 in 2400, and that for counting geometry to be ≤1.5%. Uncertainty values for counting (1 SD) were determined at the time of measurement and are shown in Table 6 as RSD(c). It was

© 1999 NRC Canada

Table 5. Lower limits to which the hydrometer method measures particle concentrations.

Procedure	Cumulative size, μm	wt.%
Screen	<44	1.8
Hydrometer	<22	6.0
	<11	5.0
	<5.5	3.9
	<2.8	3.0

found that the uncertainty due to counting statistics amounts to only 1.5–2% of the overall uncertainty for PSD prediction by INAA.

Uncertainty values for measurements using the Microtrac and Coulter instruments and for the corresponding INAA procedure are summarized in Table 6. The results show that for all six particle sizes the INAA model has lower overall uncertainty than either of the Microtrac or Coulter methods. The repeatability of the INAA method falls between that of the Microtrac and Coulter methods, with the Coulter instrument having better repeatability and, with the exception of the <44 μm fraction, a lower overall uncertainty than the Microtrac instrument. It can be expected that for oil sands an INAA-based method for PSD determination at and below 44 μm will give results that are in all aspects comparable to either historic or current Microtrac and Coulter methods. It should be noted that in this study a recent model Coulter instrument (Model LS130) was being compared with an earlier Microtrac instrument (Model 7995).

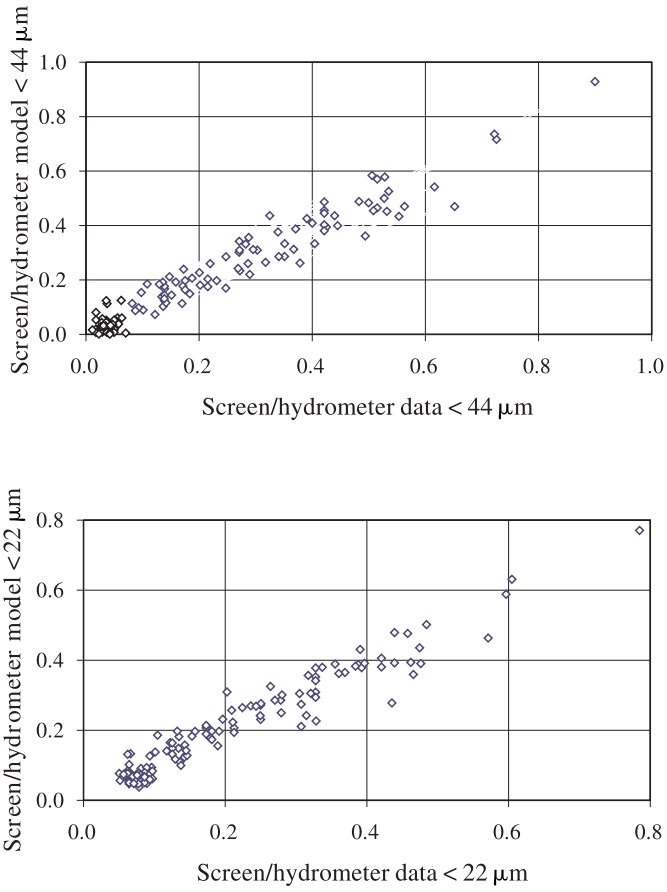
The subsampling uncertainty for oil sand could be determined from the variability in concentration of the elements used in the model equations, Al, Eu, Mn, Na, Ti, V, Ba, Ca, and Dy. From the concentration data overall uncertainties, RSD(*o*), which include subsampling uncertainty and the uncertainty of the INAA measurement (repeatability) RSD(*m*), were calculated. From the values of RSD(*o*) and RSD(*m*) the uncertainty in the sampling operations, RSD(*s*), was obtained as the difference of the variances, where variance is the square of RSD. The results, summarized in Table 7, show that the sampling uncertainty for all the elements fell below 12% relative at the sample weights of approximately 12 g used for the INAA work. The last two columns in the table give the fraction of the overall uncertainty contributed by the measurement and sampling steps. The values indicate that for Al, Mn, Na, Ti, and Dy, sampling contributes more than 0.6 of the overall uncertainty. On the other hand, for Eu, V, Ba, and Ca, sampling contributes less than 0.4, indicating that sampling is not a major contributor to the overall uncertainty for these elements.

The overall uncertainty for the elements in cleaned solids was also determined by INAA in the same way as for the bulk oil sand and compared with the bulk oil sand results to provide insight into the relative uncertainty in subsampling whole oil sand as compared to clean solids. It was found that the latter operation had an uncertainty of about half that of subsampling whole oil sand.

Variability in elemental concentrations within and between facies

It was also of interest to determine the level of variability among samples of oil sand from the same facies. Samples

Fig. 5. Degree of fit. Screen/hydrometer model versus observed screen/hydrometer data: (*a*) <44 μm (r = 0.97) (*b*) <22 μm (r = 0.96).



X-6, X-8, and X-10, all from facies 11, were used for this study. For a given oil sand facies, vanadium showed the least sampling uncertainty of the elements studied. The values for RSD(*s*) in Table 8 showed that for a particular facies the sampling contribution to the overall uncertainty varied widely from element to element, ranging from 2.0% for V to 49.2% for Mn. These results tend to parallel an earlier study of elemental variability across a transverse section of a single oil sand core (1, 12).

A single-factor analysis of variance (ANOVA) was performed on the original elemental concentrations of three selected samples of bulk oil sand, X-5, X-7, and X-10, from facies 10, 8, and 11, respectively. Table 9 summarizes the findings on the significance of the *F*-value for elements and samples. No consistent trend among elements was observed. For five of the elements, in two oil sands out of three, the between-sample heterogeneity did not differ from the within-sample heterogeneity. For Na, however, in two out of three oil sands, the between-sample heterogeneity differed from the within-sample heterogeneity, while for Ba and Eu, the three oil sand samples showed no difference. The most significant conclusions were that barium was constant in concentration from subsample to subsample within the uncertainty of the measurement, while Mn was variable. The conclusions reached from an analysis of variance were similar to the conclusions obtained from the uncertainty study on

Ca	N	N	Y
Dy	N	N	Y

[a]N, no significant difference between the *within*-sample heterogeneity (four repeats) and *between*-sample heterogeneity. 95% confidence limit. Y, significant difference.

elements, as expected. The uncertainty study identified Ca and Ba as elements for which the measurement uncertainty was large compared to the sampling uncertainty, and Na with Mn as elements for which the sampling uncertainty exceeded the measurement uncertainty.

Conclusions

A method has been developed for estimating particle size distribution (PSD) in bulk oil sand. Model equations were derived and tested for the prediction of PSD from the concentration of nine elements measured by INAA. Predicted particle size distributions compared favorably with results obtained by existing methods. Each of the three PSD methods currently in use could be simulated by the INAA method. The INAA-based model that predicts hydrometer equivalent data was only applicable above certain lower limits for the amount of the fine size fractions present because of the limited sensitivity of the hydrometer method for PSD determination of fine fractions. For all six particle sizes studied, the INAA model had lower overall uncertainty than the corresponding Microtrac and Coulter instrument methods; the instrument repeatability of INAA fell between those of Microtrac and Coulter, with the Coulter instrument having the best repeatability. For Athabasca oil sands, the INAA-based method outlined here for PSD determination at and below 44 μm gave results comparable to current Microtrac and Coulter methods.

Analysis of variance indicated that Ba and Eu tended to be constant in concentration in subsamples from a given oil sand, while Mn showed the greatest variability. The sampling uncertainty for cleaned solids was half that for bulk oil sand; the greatest contributor to uncertainty in the determination of element concentrations was the sampling of the oil sand itself.

The approach outlined in this paper may have application to particle size distribution estimation in other environmental systems such as soils, airborne particulates, or stream sediments.

Acknowledgements

The authors thank Syncrude Canada Ltd. for providing the oil sand samples used in this study, for performing the bitumen extractions, for the Microtrac and Coulter particle size measurements, and for permission to publish this work. Financial assistance was provided by Syncrude Canada Ltd., the University of Alberta Department of Chemistry, and the Natural Sciences and Engineering Research Council of Canada.

Electron transfer reactions of bis(1,4,7-trithiacyclononane)palladium(III/II), -platinum(III/II), and -gold(III/II) complexes in aqueous solution and in acetonitrile

Mitsuru Matsumoto, Makoto Itoh, Shigenobu Funahashi, and Hideo D. Takagi

Abstract: The oxidation reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$, and $Au(ttcn)_2^{2+}$ (ttcn = 1,4,7-trithiacyclononane) complexes by a typical outer-sphere oxidizing reagent, $Ni(tacn)_2^{3+}$ (tacn = 1,4,7-triazacyclononane), were studied in aqueous acidic solution and in acetonitrile. The rate constants corresponding to the oxidation and reduction reactions were isolated for $Pd(ttcn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$ couples in both media. The electron exchange rate constants (k_{ex}) for $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples at 25°C were estimated as 1.7×10^3, 59, 3.9×10^4 mol^{-1} dm^3 s^{-1} in aqueous solution and 6.7×10^3, 1.3×10^2, and 2.7×10^5 mol^{-1} kg s^{-1} in acetonitrile, respectively. An attempt to observe the reduction reaction of $Pt(ttcn)_2^{3+}$ was not successful because of the instability of $Pt(ttcn)_2^{3+}$ in aqueous solution. A comparison of the electron exchange rate constants of $Pd(tacn)_2^{3+/2+}$, $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples in aqueous solution and in acetonitrile revealed that the inner-sphere contribution to the activation free energy for each reaction is identical in both solvents and that the self-exchange rate constants of these complexes directly reflect the structural differences of these complexes.

Key words: electron transfer, kinetics, Marcus theory, inner-sphere contribution.

Résumé : Opérant en solutions aqueuses acides et dans l'acétonitrile, on a étudié les réactions d'oxydation des $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$ et $Au(ttcn)_2^{2+}$ (ttcn = 1,4,7-trithiacyclononane) par un réactif oxydant typique de la couche externe, $Ni(tacn)_2^{3+}$. Pour chacun des milieux, on a pu isoler les constantes de vitesse correspondant aux réactions d'oxydation et de réduction des couples $Pt(ttcn)_2^{3+/2+}$ et $Au(ttcn)_2^{3+/2+}$. On a évalué que, à 25°C, les constantes de vitesse d'échange d'électron, ($k_{éch}$), pour les couples $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$ et $Au(ttcn)_2^{3+/2+}$ sont respectivement de $1,7 \times 10^3$, 59 et $3,9 \times 10^4$ mol^{-1} dm^3 s^{-1} en solution aqueuse et de $6,7 \times 10^3$, $1,3 \times 10^2$ et $2,7 \times 10^5$ mol^{-1} dm^3 s^{-1} en solution dans l'acétonitrile. Il n'a pas été possible d'observer la réaction de réduction du $Pt(ttcn)_2^{3+}$ en raison de l'instabilité du $Pt(ttcn)_2^{3+}$ en solution aqueuse. Une comparaison des constantes de vitesse d'échange d'électron des couples $Pd(tacn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$ et $Au(ttcn)_2^{3+/2+}$ en solutions dans l'eau ou dans l'acétonitrile indique que la contribution de la sphère interne à l'énergie libre d'activation de chaque réaction est identique pour chacun des solvants et que les constantes de vitesse d'autoéchange de ces complexes sont un reflet direct des différences de structure de ces complexes.

Mots clés : transfert d'électron, cinétiques, théorie de Marcus, contribution de la sphère interne.

[Traduit par la Rédaction]

Introduction

It is well known that 1,4,7-triazacyclononane (tacn) and 1,4,7-trithiacyclononane (ttcn) stabilize unusual oxidation states of metal ions, such as Ni(III), Pd(III), Au(II), and Pt(III) (1–6). However, the kinetic measurements of the electron transfer (ET) reactions involving these complexes have been limited to the $Ni(tacn)_2^{3+/2+}$ (7–9) and $Pd(tacn)_2^{3+/2+}$ couples (10) partly because of the stability of these compounds in solution and the lack of suitable oxidizing and reducing reagents. However, it seems essential to understand the precise reaction mechanism of the redox reactions involving these complexes for understanding the structure–reactivity relation in the outer-sphere electron transfer reactions.

Current interest in electron transfer chemistry is the quantitative examination of the magnitude of the activation barrier (11–13). The authors have been investigating the electron exchange reactions of Cu(I)/Cu(II) couples with various bidentate ligands for the better understanding of the structure–reactivity relation (14, 15). Marcus theory (16–19) pre-

dicts that the outer-sphere reorganization energy is not very different for the ET reactions in the same solvent, especially when the ionic charges and sizes of the reactants are similar to each reaction couple. Therefore, the difference in the reactivity (i.e., the rates of ET) of metal complexes may be governed essentially by the internal reorganization barrier originating from the changes in nuclear coordinates that accompany the changes in the oxidation states, when the inner- and outer-sphere reorganizations take place concertedly (10, 20).

The $Pt(tacn)_2^{2+}$ and $Pd(tacn)_2^{2+}$ complexes are four-coordinate (3, 21, 22) with the square planar geometry typical of low-spin d^8 centers, while the corresponding tervalent d^7 complexes have six-coordinate distorted octahedral structure (23). The d^8 and d^7 palladium complexes with 1,4,7-trithiacyclononane were synthesized and characterized by Wieghardt et al. (24) and Schröder and co-workers (25, 26), and the structure of these complexes are similar to those of tacn complexes: $Pd(ttcn)_2^{2+}$ is square planar with a much shorter bond length between Pd and axial sulfur atoms than that between Pd and the axial nitrogen atoms in $Pd(tacn)_2^{2+}$, while $Pd(ttcn)_2^{3+}$ is tetragonally distorted octahedral with elongated bonds between Pd and the axially coordinated sulfur atoms. The gold(II) and -(III) complexes of ttcn were synthesized and characterized by Schröder and co-workers (27, 28) the d^9 gold(II) exhibits a tetragonally distorted octahedral structure, while the d^8 gold(III) has a structure similar to the corresponding Pd(II) complex. In case of Pt(II) complex, the structure is reported to be square pyramidal with elongated axial coordination of sulfur, while a distorted octahedral structure is suggested for Pt(III) complex from the ESR measurements (29). Therefore, structural changes in $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples during the course of the electron exchange process are expected to be smaller than those observed for the $Pd(tacn)_2^{3+/2+}$ couple, when the reactions proceed through the outer-sphere process (10).

In this study, self-exchange rate constants were estimated for $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples in aqueous acidic solution and in acetonitrile by using $Ni(tacn)_2^{3+}$ as the oxidizing reagent. $Ni(tacn)_2^{3+/2+}$ couple has been used in many studies as the typical outer-sphere electron transfer reagent because of the high oxidation potential and stability in aqueous acidic solutions and in organic solvents (7–9). Whether the solvent molecules play an important role in the activation process or not may be examined by comparing the activation barriers for the electron exchange reactions in aqueous solution and in acetonitrile. The structure–reactivity relation for $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples is discussed in terms of the free energy required for the inner-sphere rearrangement.

Experimental

Materials

Triazacyclononane trihydrochloride and trithiacyclononane, obtained from Aldrich, were used without further purification. $[Ni(tacn)_2](ClO_4)_2$ and $[Ni(tacn)_2](ClO_4)_3$ were synthesized by the literature method (7, 8). Anal. calcd. for $NiC_{12}H_{30}N_6Cl_2O_8$: C 27.9, H 5.9, N 16.3; found: C 27.9, H 5.8, N 16.1. Anal. calcd. for $NiC_{12}H_{30}N_6Cl_3O_{12}$: C 23.4, H 4.9, N 13.7; found: C 23.4, H 5.0, N 13.6. (*Caution: Perchlorate salts of metal complexes with organic ligands are potentially explosive.*) $[Pd(ttcn)_2](PF_6)_2$ was prepared from potassium tetrachloropalladate (Wako Pure Chemicals Inc.) following the literature method (26). Anal. calcd. for $PdC_{12}H_{24}S_6P_2F_{12}$: C 19.0, H 3.2; found: C 19.0, H 3.0. $[Pt(ttcn)_2](PF_6)_2$ was synthesized from potassium tetrachloroplatinate (Wako) by the literature method (29). Anal. calcd. for $PtC_{12}H_{24}S_6P_2F_{12}$: C 17.0, H 2.9; found: C 16.9, H 2.7. $[Au(ttcn)_2](BF_4)_2$ was synthesized from potassium tetrachloroaurate (Fluka) using Schröder's method (27). Anal. calcd. for $AuC_{12}H_{24}S_6B_2F_8$: C 19.7, H 3.3; found: C 20.1, H 3.3. Tetra-*n*-butylammonium perchlorate (TBAP) was recrystallized twice from ethyl acetate – hexane mixture and dried under vacuum for 2 days. Acetonitrile (Wako) was twice distilled over P_2O_5 before use. The amount of water in thus purified acetonitrile was examined by a Mitsubishi Kasei Karl Fisher moisturemeter (<1 mmol kg^{-1}). Other chemicals were obtained from Wako (analytical grade) and used without further purification. Doubly distilled water was used for the preparation of aqueous solutions, and the ionic strength of the sample solutions was adjusted to 0.11 mol dm^{-3} by Na–$HClO_4$. The ionic strength of the acetonitrile solutions was adjusted to 0.10 mol kg^{-1} by TBAP.

Instruments

A Shimadzu UV-1600 spectrophotometer was used for the measurements of absorption spectra. Cyclic voltammograms were recorded by using a BAS-100B/W electrochemical analyzer. The temperature of the electrochemical cell was controlled at 25.0 ± 0.1°C. Kinetic measurements were carried out by a Unisoku RA401 stopped-flow spectrophotometer connected to a NEC PC computer via a Unisoku A/D converter. More than 10 traces were stored and analyzed for each run. The electron transfer reactions were observed under pseudo-first-order conditions at various temperatures (±0.1°C). The sample solutions were deaerated with N_2 or Ar before the measurements, and all measurements were carried out under N_2 or Ar atmosphere. The kinetic traces were analyzed by a nonlinear least-squares method using over 300 points for the 10 half-lives of the reactions. However, for some reactions, only three half-lives portion was used, because of the decomposition of the product through the succeeding reactions. Because of the instability of the M(III) states, the reactions of $Pt(ttcn)_2^{2+}$ and $Au(ttcn)_2^{2+}$ at higher temperatures were not so reliable as those obtained at relatively low temperatures. In such cases, the traces up to three half-lives were analyzed by the nonlinear least-squares method. However, the fits were excellent even in such cases. The second-order rate constants and the activation parameters were calculated from the linear least-squares analyses, and the errors were calculated by the standard procedure.

Results

Electrochemical measurements

To estimate the equilibrium constants for the redox reactions between $M(ttcn)_2^{2+}$ (M = Pd, Pt, Au) and $Ni(tacn)_2^{3+}$, the redox potentials of these couples were measured by cyclic voltammetry. $Ni(tacn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$ exhibited

[b]The potentials were corrected by use of $Fc^{+/0}$ (+400 mV vs. NHE).

quasi-reversible signals in aqueous acidic solution and in acetonitrile. The redox potential of $Pd(ttcn)_2^{3+/2+}$ in aqueous solution reported in Table 1 may be erroneous as the gradual decomposition of this complex was observed in water. The large peak to peak separation (100 mV) observed for the $Pt(ttcn)_2^{3+/2+}$ couple indicates that the electrode process is rather slow for this couple. These results and the equilibrium constants for the oxidation reactions of $M(ttcn)_2^{2+}$ with $Ni(tacn)_2^{3+}$ are summarized in Table 1.

Kinetic measurements in aqueous acidic solution

The oxidation reaction of $Pd(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ was studied by observing the increase in the absorbance at 475 nm, which corresponds to the absorption maximum of the $Pd(ttcn)_2^{3+}$ species. The redox potentials reported in Table 1 indicate that the following reaction is not thermodynamically favored even with excess $Ni(tacn)_2^{3+}$ (K = 0.05).

$$[1] \quad [Pd(ttcn)_2]^{2+} + [Ni(tacn)_2]^{3+} \xrightarrow{k_f} [Pd(ttcn)_2]^{3+} + [Ni(tacn)_2]^{2+}$$

The rate law is complicated because of the reverse reaction even with excess $Ni(tacn)_2^{3+}$, and the forward rate constant, k_f, can be obtained only from the initial rate of the reaction. However, in the presence of an excess amount of one of the product, $Ni(tacn)_2^{2+}$, the rate law of reaction [1] becomes simple, and a pseudo-first-order kinetic trace is expected[2]:

$$[2] \quad \frac{d[Pd(ttcn)_2^{3+}]}{dt} = k_{obs}[Pd(ttcn)_2^{2+}] - k_b[Ni(tacn)_2^{2+}]_0[Pd(ttcn)_2^{2+}]_0$$

$$k_{obs} = k_f[Ni(tacn)_2^{3+}]_0 + k_b[Ni(tacn)_2^{2+}]_0$$

The reactions with excess amounts of $Ni(tacn)_2^{3+}$ and $Ni(tacn)_2^{2+}$ were excellently first order with respect to $Pd(ttcn)_2^{2+}$ for more than three half-lives. Plots of the pseudo-first-order rate constant, k_{obs}, against $[Ni(tacn)_2^{3+}]_0$ at various temperatures are shown in Fig. 1*a*. Second-order rate constants, k_f (forward) and k_b (backward), estimated from the slopes and intercepts of the plots, are summarized in Table 2. The k_b value obtained from the dependence of k_{obs} on $[Ni(tacn)_2^{2+}]_0$ (Fig. 2*a*) was (8.3 ± 0.2) × 10^3 mol^{-1} dm^3 s^{-1} at 25°C, which was in satisfactory agreement with the value obtained from the intercept of the plots shown in Fig. 1*a*, considering the fact that results obtained from the intercepts of plots are subject to large errors (Table SI).[3] The validity of eq. [2] was also confirmed by varying $[Ni(tacn)_2^{3+}]_0$ when $[Ni(tacn)_2^{2+}]_0 >> [Pd(ttcn)_2^{2+}]_0$, and by varying $[Pd(ttcn)_2^{2+}]_0$ when $[Ni(tacn)_2^{2+}]_0 >> [Ni(tacn)_2^{3+}]_0$. (Table SIX).

The oxidation reaction of $Pt(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ was observed by the increase in the absorbance at λ = 400 nm, the absorption maximum of $Pt(ttcn)_2^{3+}$, under the conditions of $[Pt(ttcn)_2^{2+}]_0 >> [Ni(tacn)_2^{3+}]_0$. The reaction was first order for more than three half-lives. The plots of the conditional rate constants against the concentration of $Pt(ttcn)_2^{2+}$ were linear as shown in Fig. 1*b* at various temperatures. Therefore, the observed rate constant, k_{obs}, of the reaction was expressed by the following equation.

$$[3] \quad k_{obs} = k_f[Pt(ttcn)_2^{2+}]_0$$

The estimated second-order rate constants as well as the activation enthalpy and entropy are also listed in Table 2.

The oxidation reaction of $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ was monitored following the decrease of the absorbance at 404 nm, corresponding to the absorption maximum of $Au(ttcn)_2^{2+}$ species. Though the equilibrium constant of the reaction calculated from the redox potentials is 7.9 at 25°C, no meaningful intercept corresponding to the k_b process was observed under the experimental conditions, $[Ni(tacn)_2^{3+}]_0 >> [Au(ttcn)_2^{2+}]_0$. Therefore, the observed rate constant, k_{obs}, of the reaction was expressed by the following equation.

$$[4] \quad k_{obs} = k_f[Ni(tacn)_2^{3+}]_0$$

Although the slow decomposition of $Au(ttcn)_2^{2+}$ was observed in aqueous acidic solutions, the product of the decomposition reaction did not affect the kinetic data. As the

[2] When $[Ni^{3+}]_0$ and $[Ni^{2+}]_0 >> [Pd^{2+}]_0$, the rate of the oxidation reaction is expressed as below,
($[Pd^{3+}] = [Pd^{2+}]_0 - [Pd^{2+}]$)

$$\text{Rate} = k_f[Ni^{3+}]_0[Pd^{2+}] - k_b[Ni^{2+}]_0[Pd^{3+}]$$
$$= k_f[Ni^{3+}]_0[Pd^{2+}] - k_b[Ni^{2+}]_0\{[Pd^{2+}]_0 - [Pd^{2+}]\}$$
$$= \{k_f[Ni^{3+}]_0 + k_b[Ni^{2+}]_0\}[Pd^{2+}] - k_b[Ni^{2+}]_0[Pd^{2+}]_0$$

[3] The following have been deposited as supplementary material: observed rate constants for the oxidation reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$, and $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$, listed in Tables SI–SXIV (10 pp.); Fig. SI: Dependence of the observed rate constants on the concentrations of the excess reagent; Fig. SII: The observed rate constants for the reverse reactions of (*a*) $Ni(tacn)_2^{3+}$ + $Pd(ttcn)_2^{2+}$ and (*b*) $Ni(tacn)_2^{3+}$ + $Au(ttcn)_2^{2+}$ in acetonitrile, I = 0.10 mol kg^{-1} (TBAP). Depository material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

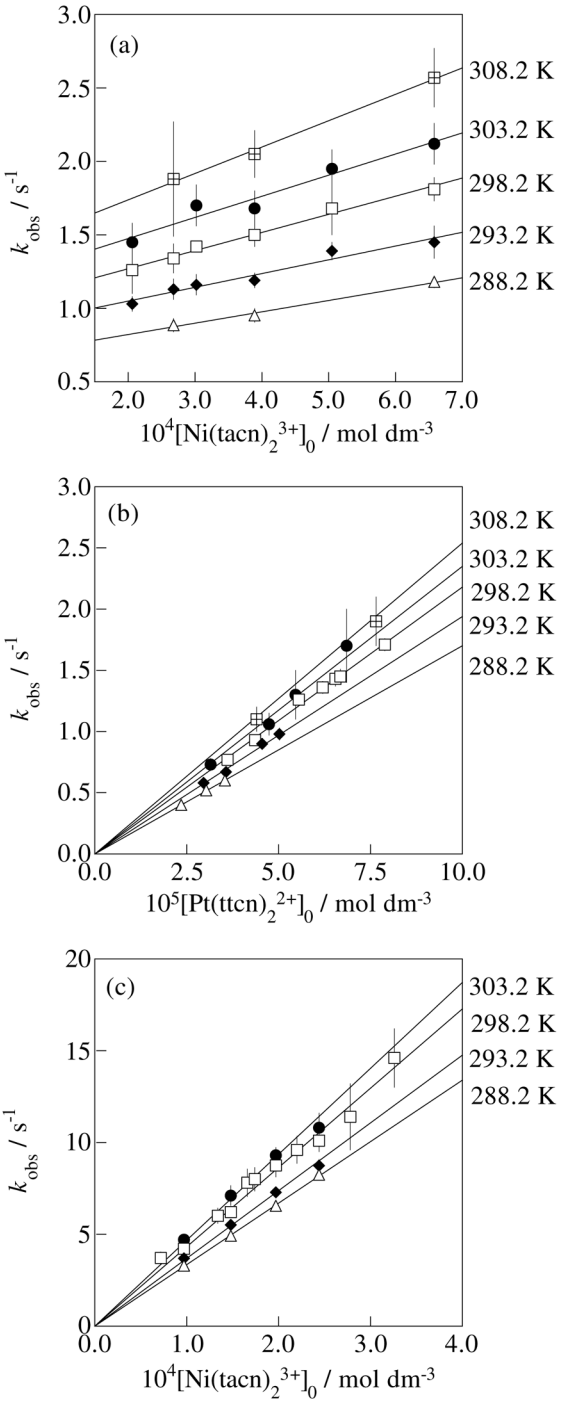
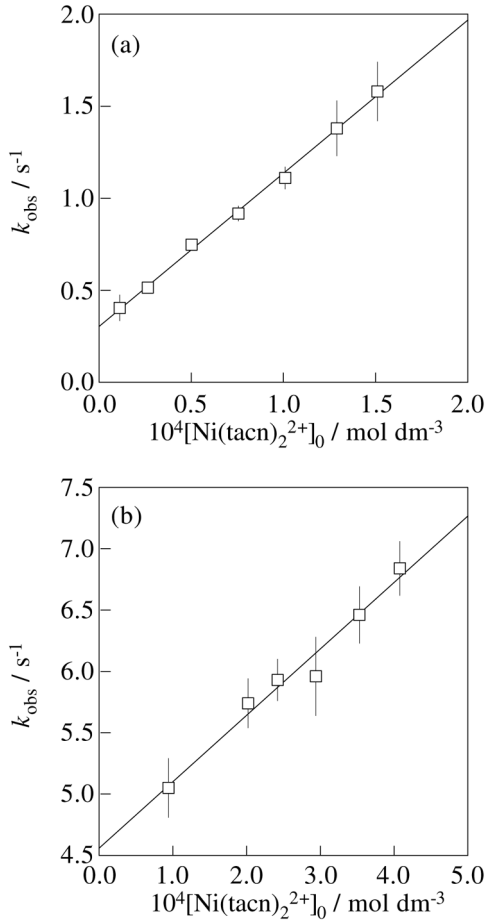
Fig. 1. The observed rate constants for the oxidation reactions of (*a*) $Pd(ttcn)_2^{2+}$, (*b*) $Pt(ttcn)_2^{2+}$, and (*c*) $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ in aqueous solution under the pseudo-first-order conditions at various temperatures. $[H^+] = 1.0 \times 10^{-2}$ mol dm^{-3}, I = 0.11 mol dm^{-3} ($NaClO_4$). In (*a*), $[Ni(tacn)_2^{2+}]_0 = 1.0 \times 10^{-4}$ mol dm^{-3}.



specific rate constant for the decomposition reaction lies between 3×10^{-4} and 8×10^{-4} s^{-1} under the experimental conditions, the sample solutions were freshly prepared prior to each run. Because of the auto-decomposition of the $Au(ttcn)_2^{3+}$ species, deviation from the typical first-order behavior was observed at the end of each reaction. The initial

Fig. 2. The observed rate constants for the reverse reactions of (*a*) $Ni(tacn)_2^{3+}$ + $Pd(ttcn)_2^{2+}$ and (*b*) $Ni(tacn)_2^{3+}$ + $Au(ttcn)_2^{2+}$ in aqueous solution, $[H^+] = 1.0 \times 10^{-2}$ mol dm^{-3}, I = 0.11 mol dm^{-3} ($NaClO_4$).



three half-life portions of each kinetic trace were therefore analyzed to determine the rate constants. The dependence of the pseudo-first-order rate constant, k_{obs}, on the initial concentration of $[Ni(tacn)_2^{3+}]_0$ is shown in Fig. 1*c*. An attempt was made to estimate the rate constant for the reverse reaction, by adding excess $Ni(tacn)_2^{2+}$ (eq. [2], Table SV[3]). The forward (k_f) and backward (k_b) rate constants so estimated are also listed in Table 2.

The dependence of the observed rate constants on pH was also examined (Tables SVI–SVIII)[3]. Though the pH range was limited because of the instability of $Ni(tacn)_2^{3+}$ at high pH, it was shown that the oxidation reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$, and $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ were independent of pH over the range of $2 < pH < 3$, indicating that there is no specific reaction pathway involving proton-dissociated species, such as $[Ni^{III}(tacn)(H_{-1}tacn)]^{2+}$, for the reactions examined in this study under the experimental conditions (30).

Kinetic measurements in acetonitrile

The absorption spectra of the reactants and products of the oxidation reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$, and $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ were examined in water and in acetonitrile. No significant shift of the absorption maxima of each species in the UV, visible, and near IR region in

acetonitrile and aqueous solutions indicates that the structures of these species in water are retained in acetonitrile, and that there is no specific solute–solvent interactions for these species in these two media.

All the oxidation reactions in acetonitrile were examined under pseudo-first-order conditions: $[Pd(ttcn)_2^{2+}]_0$, $[Ni(tacn)_2^{2+}]_0$ >> $[Ni(tacn)_2^{3+}]_0$, $[Pt(ttcn)_2^{2+}]_0$ >> $[Ni(tacn)_2^{3+}]_0$, $[Ni(tacn)_2^{3+}]_0$ >> $[Au(ttcn)_2^{2+}]_0$, for the oxidation reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$, and $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$, respectively. For the reactions of $Au(ttcn)_2^{3+/2+}$, the reverse reaction was also investigated under the conditions of $[Ni(tacn)_2^{3+}]_0$, $[Ni(tacn)_2^{2+}]_0$ >> $[Au(ttcn)_2^{2+}]_0$. The dependence of the pseudo-first-order rate constant, k_{obs}, on the initial concentration of excess reagents is shown in Fig. 3. The estimated second-order rate constants as well as the activation enthalpy and entropy are summarized in Table 3.

Discussion

For the electron transfer reactions involving very large conformational change of one or both of the reactants, sluggish behaviors originating from the non-concerted inner- and outer-sphere reorganization processes may take place (31, 32). Examples of such cases have been reported as the "gated behavior" in some copper(II)/(I) couples for which a large structural inter-conversion of one of the reactants takes place prior to the ET process (33). The authors discussed the

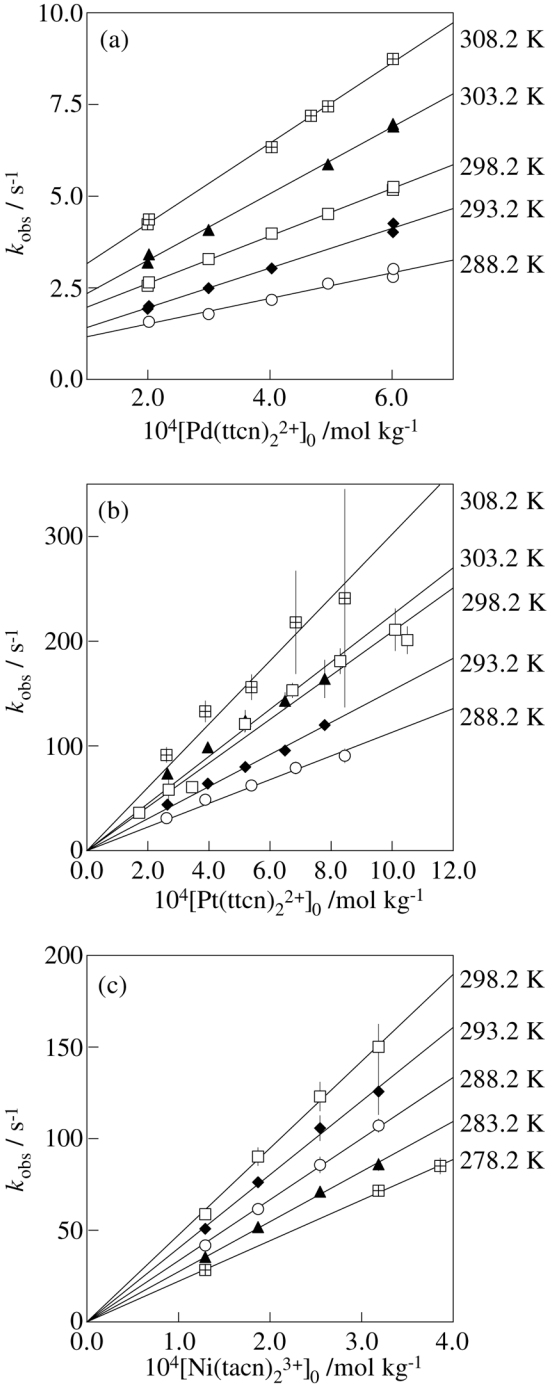
Fig. 3. The observed rate constants for the oxidation of (*a*) $Pd(ttcn)_2^{2+}$, (*b*) $Pt(ttcn)_2^{2+}$, and (*c*) $Au(ttcn)_2^{2+}$ by $Ni(tacn)_2^{3+}$ in acetonitrile under the pseudo-first-order conditions at various temperatures. I = 0.10 mol kg^{-1} (TBAP). In (*a*), $[Ni(tacn)_2^{2+}]_0$ = 1.5 × 10^{-4} mol kg^{-1}.



energetic origin of such a gated behavior (34) and concluded that the non-adiabaticity plays an important role in the hypothetical concerted electron transfer process of such redox couples and that the gated pathway opens up a lower-energy pathway than the direct concerted pathway.

Non-adiabaticity of a reaction originates from the poor electronic coupling between the reactants because of the effective shielding of the electronic orbitals, which are involved in the ET reactions, either by the outer shell electrons (35), by rather thick solvation sheaths (30), or by the very large energy gap between the donor and acceptor orbitals caused by the largely different coordination structures of the reactants as seen in the gated reactions (36).

Although a large negative activation entropy is expected for non-adiabatic electron exchange reactions (36), it seems that there are few experimental results that support this expectation (37). Several investigations of the outer-sphere self-exchange reactions in various solvents have not lead to simple relation between the activation entropy and the effect of solvents (38, 39). Tabulated results for the outer-sphere self-exchange reactions in water indicate that the activation entropies lie in the range of –50 to –130 J mol^{-1} K^{-1} (36). The activation volumes for such adiabatic outer-sphere self-exchange reactions are ca. –5 cm^3 mol^{-1} for most cases, and the exceptionally large activation volumes for $Co(ethylenediamine)_3^{3+/2+}$ and $Fe(CN)_6^{3-/4-}$ couples were attributed to the non-adiabaticity or to the cation effect, respectively (40, 41). Very few kinetic results concerning the outer-sphere self-exchange reactions in both water and non-aqueous solvents have been reported because of the instability of one of the species in certain solvents (42, 43). Results reported for $Fe(1,10\text{-penanthroline})_3^{3+/2+}$ in water and in acetonitrile (44) show that the activation enthalpy as well as the activation entropy varies in different solvents. Such a tendency has been observed for many outer-sphere ET reactions (45). However, it is now regarded that the linear isokinetic relation for such reaction systems may not lead to any fruitful conclusion (46). All these previously reported results indicate that the Marcus theory predicts the reliable activation free energies. However, the activation entropy certainly includes the information related to the numbers of the electronic states in the ground and activated levels related to the ET reaction. The discussion given below are, therefore, made on the basis of the activation free energies for each self-exchange reaction examined in this study.

ET reactions in aqueous acidic solution

The cross reaction rate constant, k_{et}, is related to the individual electron self-exchange rate constants, k_{11} and k_{22}, and the overall equilibrium constant, K_{12}, by the following Marcus cross relation (11, 47):

[5] $$k_{et} = \sqrt{k_{11}k_{22}K_{12}f}\,W_{12}$$

$$\ln f = \frac{[\ln K_{12} + (w_{12} - w_{21})/RT]^2}{4[\ln(k_{11}k_{22}/Z_{11}Z_{22}) + (w_{11} + w_{22})/RT]}$$

$$W_{12} = \exp\,[-(w_{12} + w_{21} - w_{11} - w_{22})/2RT]$$

$$w_{ij} = (Z_{11}Z_{22}e^2)/(D_s\sigma(1 + \beta\sigma I^{1/2}))$$

$$\beta = ((8\pi Ne^2)/(1000D_sk_BT))^{1/2}$$

where w_{ij}, Z_{ii} are the coulombic work required to bring the two species to a distance σ at which ET occurs with maximum probability, the diffusion rate of the species *ii*. N, k_B, and D_s are Avogadro's number, Boltzmann constant, and the static dielectric constant, respectively. From the rate constants, k_f, for the cross reactions of $Pd(ttcn)_2^{2+}$, $Pt(ttcn)_2^{2+}$,

and $Au(ttcn)_2^{2+}$ with $Ni(tacn)_2^{3+}$, the electron self-exchange rate constants for the $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples were estimated as 5.2×10^3, 59, and 3.9×10^4 mol^{-1} dm^3 s^{-1} by using 6.0×10^3 mol^{-1} dm^3 s^{-1} as the self-exchange rate constant for the $Ni(tacn)_2^{3+/2+}$ couple (7, 9). The electron exchange rate constants for the $Pd(ttcn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$ couples were also estimated from the reverse reaction rate constants, k_b: $k_{Pd} = 620$ and $k_{Au} = 3.8 \times 10^4$ mol^{-1} dm^3 s^{-1}. The consistency of the calculated self-exchange rate constants from the forward and backward reactions is excellent for the $Au(ttcn)_2^{3+/2+}$ couple, while a rather poor agreement between the self-exchange rate constants from both directions was exhibited for the $Pd(ttcn)_2^{3+/2+}$ couple. Such an inconsistency may be attributed to the rather poor voltammogram for the latter couple, and the kinetically estimated equilibrium constant of reaction [1] ($k_f/k_b = 0.15$) seems more reliable. As a result, the value of 1.7×10^3 mol^{-1} dm^3 s^{-1} was taken as the electron exchange rate constant of the $Pd(ttcn)_2^{3+/2+}$ couple (Table 4).

The self-exchange rate constant for the $Pd(tacn)_2^{3+/2+}$ couple is reported by McAuley and Whitcombe (10) as 2×10^{-6} mol^{-1} dm^3 s^{-1}, which implies a substantial structural rearrangement in the course of the electron transfer process.

The semi-classical Marcus–Sutin model enables the theoretical calculation of electron exchange rate constants in solution (47). The adiabatic self-exchange rate constant, k_{ii}, is given by the product of the pre-equilibrium constant, K_0, the effective frequency of the nuclear vibrations, ν_n, and the nuclear factor, κ_n.

$$[6] \qquad k_{ii} = K_0 \nu_n \kappa_n$$

The pre-equilibrium constant may be expressed by the conventional Fuoss type equation, on the basis of the extended Debye–Hückel theory (48, 49). The effective frequency of nuclear vibration and the nuclear factor are given by the following equations (47):

$$[7] \qquad \nu_n^2 = \frac{\nu_{out}^2 \Delta G^*_{out} + \nu_{in}^2 \Delta G^*_{in}}{\Delta G^*_{out} + \Delta G^*_{in}}$$

$$[8] \qquad \kappa_n = \Gamma \exp\left[-(\Delta G^*_{out} + \Delta G^*_{in})/RT\right]$$

where ΔG^*_{in} and ΔG^*_{out} are the inner-sphere and outer-sphere contributions to the activation free energy, and ν_{in} and ν_{out} are the inner- and outer-sphere frequency terms representing the reduced metal-ligand stretching and solvent dipole orientation (typically 10^{11}–10^{12} s^{-1} for most liquids), respectively. ΔG^*_{in} and ΔG^*_{out} are given by eqs. [9] and [10] using the reduced force constant, f_i, the difference in the metal-ligand distance between reduced and oxidized forms of the ex-

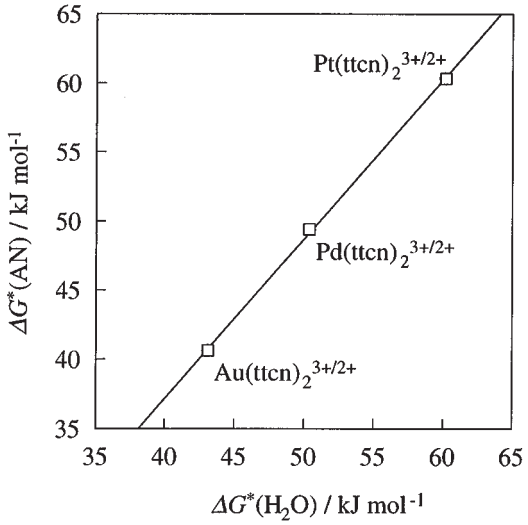
Fig. 4. A comparison of the activation free energies in water and in acetonitrile, ΔG^* (H_2O).vs. ΔG^* (AN), for the self-exchange reactions of a series of $M(ttcn)_2^{3+/2+}$ (M = Pd, Pt, and Au) couples.



change couple, Δd_0, and the high- and low-frequency dielectric constants, D_{op} and D_s.

$$[9] \qquad \Delta G^*_{in} = \frac{1}{2} N \sum f_i \left(\frac{\Delta d_i}{2} \right)^2$$

$$[10] \qquad \Delta G^*_{out} = \frac{Ne^2}{16\pi\varepsilon_0} \left(\frac{1}{2a_1} + \frac{1}{2a_2} - \frac{1}{\sigma} \right) \left(\frac{1}{D_{op}} - \frac{1}{D_s} \right)$$

The nuclear tunneling factor, Γ, is usually expressed by the following Holstein's equation, and the value of Γ approaches unity at high temperature limit (47, 50). The value of ν_{in} is taken as being 1.5×10^{13} s^{-1} (47). Γ is close to unity when ΔG^*_{in} is less than ca. 30 kJ mol^{-1}.

$$[11] \qquad \Gamma = \exp \left[-\frac{\Delta G^*_{in}}{4h\nu_{in}} \right] \left(\tanh \frac{h\nu_{in}}{4kT} - \frac{h\nu_{in}}{4kT} \right)$$

When the solvent barrier is large, which is the case in most reactions in solution, ν_n can be replaced by the classical limit of the outer-sphere orientational frequency ν_{out}.

The effective radii a_i of the $M(ttcn)_2^{2+}$ and $M(ttcn)_2^{3+}$ complexes were estimated from the crystallographic data as 450/470 pm for Pd(III/II), 530/480 pm for Pt(III/II), and 480/470 pm for Au(III/II), respectively (24–29). By using these values, the application of the Marcus–Sutin model to the electron exchange reactions of $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples, calculates the pre-equilibrium and outer-sphere contribution to the activation free energy, by the subtraction of which from the experimentally obtained total activation free energies the inner-sphere contributions to the activation free energies were roughly calculated as 30, 42, and 23 kJ mol^{-1} for $Pd(ttcn)_2^{3+/2+}$, $Pt(ttcn)_2^{3+/2+}$, and $Au(ttcn)_2^{3+/2+}$ couples, respectively (Table 4). These values are much smaller than that reported for the $Pd(tacn)_2^{3+/2+}$ couple (85 kJ mol^{-1}) (10).

For the electron exchange reaction between $Pd(tacn)_2^{2+}$ and $Pd(tacn)_2^{3+}$, ca. 135 pm was estimated for Δd_0, which involves the inversion process of two tacn rings around the axially positioned nitrogen atoms (22). However, Δd_0 values for the $Pd(ttcn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$ couples are merely 41–46 and 10 pm, respectively, even at the elongated axial positions. The oxidation of $Pt(ttcn)_2^{2+}$ involves an inversion of the ttcn ring around a non-coordinated sulfur atom, while another axial S atom is kept bound to the Pt center.

By using the reduced force constant for the M—S bond, ca. 100 Nm^{-1} (51), the free energy difference in internal rearrangements of the $Pd(ttcn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$ couples is estimated to be merely 2 kJ mol^{-1}, which may be compared with the calculated difference of 7 kJ mol^{-1} (ΔG^*_{in} values are 30 and 23 kJ mol^{-1} for $Pd(ttcn)_2^{3+/2+}$ and $Au(ttcn)_2^{3+/2+}$, respectively). It was suggested that the axially positioned nitrogen atoms in the square planar $Pd(tacn)_2^{2+}$ complex are also interacting with the Pd center so as to significantly influence the geometry in the equatorial plane, although the force constant for such interaction is fairly small (10 Nm^{-1}) (10). Similar situation may be expected for $Pt(ttcn)_2^{2+}$. The very large value of ΔG^*_{in} for the $Pd(tacn)_2^{3+/2+}$ may be partly attributed to the relatively large force constants between Pd and N atoms (51). A rapid fluxional behavior in $Pd(tacn)_2^{2+}$ ($>1 \times 10^5$ s^{-1}) was also reported by McAuley and co-workers (22). This fluxionality is obviously caused by the local concentration effect of the nearby uncoordinated nitrogen atoms with relatively low activation energy corresponding to the tacn ring inversion (32 kJ mol^{-1}) (52). Therefore, the very small electron exchange rate constant for the $Pd(tacn)_2^{3+/2+}$ couple is attributed largely to the inner-sphere contribution originates from the double inversion of the tacn rings in the activation process ($>2 \times 32$ kJ mol^{-1}). On the other hand, the electron exchange reactions are relatively fast for $Au(ttcn)_2^{3+/2+}$ and $Pd(ttcn)_2^{3+/2+}$ couples as the conformational changes required for the ET process are small, while an inversion (ca. 32 kJ mol^{-1}) around the uncoordinated S atom is involved in the $Pt(ttcn)_2^{3+/2+}$ electron exchange reaction. A larger interaction between Pt center and S atom than that for Pd center and S atom may also contribute to the larger inner-sphere activation free energy for the reaction of the $Pt(ttcn)_2^{3+/2+}$ couple.

ET reactions in acetonitrile

Because of the low dielectric constant of acetonitrile and the charge on the complex ions used in this study (3+/2+), the effect of the ion pair formation has to be taken into account. It is known that the metal(II) and -(III) complexes almost quantitatively form 1:1 ion pairs with ClO_4^- in acetonitrile. Applying the Marcus cross relation to the reactions in acetonitrile, we obtained k_{ex} for $M(ttcn)_2^{3+/2+}$ couples as $k_{Pd} = 6.7 \times 10^3$, $k_{Pt} = 1.3 \times 10^2$, $k_{Au} = 2.7 \times 10^5$ mol^{-1} kg s^{-1} from the oxidation reactions (the effect of the ion-pair formation was accounted for). By using the reverse reaction rate constant, k_b, the k_{Pd} and k_{Au} were calculated as 4.4×10^3 and 2.6×10^6, respectively. The larger k_{ex} in acetonitrile than in aqueous acidic solution is attributed to the difference of ΔG^*_{out} and K_0 in water and in acetonitrile. The activation free energies corresponding to the estimated self-exchange rate constants of each couple in acetonitrile at

© 1999 NRC Canada

25°C, ΔG^* (AN), are plotted against those in water, ΔG^* (H_2O), in Fig. 4. The plot is linear with unit slope (1.2 ± 0.1) as seen in Fig. 4. Such a linear relation implies that the difference in ΔG^*_{in} for various $M(ttcn)_2^{3+/2+}$ complexes is identical in water and acetonitrile. The intercept of the plot in Fig. 4 corresponds to the difference of the ΔG^*_{out} in H_2O and in acetonitrile. Therefore, specific solute–solvent interactions, such as the solvent intrusion to the vacant site of $M(ttcn)_2^{3+/2+}$ species, may not be significant in these reactions, which is also supported by the fact that no significant shift of the absorption maxima was observed for these species in water and in acetonitrile. As a result, the ET reaction rates for the species studied in this article are governed by the structural change of each species.

Conclusions

In this study, the electron exchange rate constants (k_{ex}) for $M(ttcn)_2^{3+/2+}$ couples (M = Pd, Pt, and Au) in H_2O and in acetonitrile were estimated. The difference between these k_{ex} values were explained by the difference in the inner-sphere contributions to the activation free energy (ΔG^*_{in}) of each redox couple. The relation between $\Delta G^*(H_2O)$ and $\Delta G^*(AN)$ indicates that there is no specific solute–solvent interactions involved these reactions. Unfortunately, the present study could not shed a light on the solution structures of the species involved in the ET reactions.

The free energy analysis of an ET reaction cannot tell if the reaction takes place in a concerted manner or not. However, a large structural change accompanying the ET process sometimes leads to sluggish electron transfer processes, such as gated or directional reactions (31–33, 53). It is a rather difficult task to distinguish gated and directional reactions from the concerted processes by means of the ordinary kinetic methods, as the activation free energies for gated and directional reactions also reflect the free energy barrier corresponding to the conformational change prior to the ET process (33). We anticipate that the mode of the inner-sphere activation process is the key to the understanding of the gated ET: the vibrationally coupled inner-sphere process (time scale is ca. 10^{13} s^{-1}) may lead the ordinary outer-sphere ET reactions in which the structural change takes place within the encounter complex, while the slower activation mode such as twisting or inversion cannot take place within the encounter complex and an intermolecular gated ET may become important. Studies at elevated pressures on the basis of the Stranks–Hush–Marcus–Swaddle theory (54, 55) are currently in progress, to clarify the involvement of non-adiabaticity and (or) the involvement of the gated process in these reaction systems.

Addition of cyclopentadiene derivatives on aromatic aldehydes or nitrosobenzene initiated by electrochemical reduction

F. Williot, M. Bernard, D. Lucas, Y. Mugnier, and J. Lessard

Abstract: The electrochemical reduction of nitrosobenzene (PhNO) in the presence of cyclopentadiene derivatives containing the indenyl group represented as In′H_2 (**10a**, **10b**, and **12b**) gives the imine derivatives PhN=In′. The process requires only a catalytic amount of electricity. When the electrolysis of aromatic aldehydes (ArCHO), 2,6-dichlorobenzaldehyde (**1a**), benzaldehyde (**1b**) and terephthalaldehyde (**2**), is performed in the presence of the In′H_2 derivatives, compounds ArCH=In′ are obtained in low yields. These compounds have been characterized by mass spectrometry and microanalysis. The overall process involves two consecutive chain reactions with regeneration of the anion In′H^-.

Key words: electrochemical reduction, nitrosobenzene, aromatic aldehydes, base catalysis, chain reaction.

Résumé : La réduction électrochimique du nitrosobenzène (PhNO) en présence de dérivés du cyclopentadiène contenant le groupe indényle symbolisé par In′H_2 (**10a**, **10b**, and **12b**) conduit à des dérivés de type imine, ArN=In′. Le processus ne requiert qu'une quantité catalytique d'électricité. Lorsque l'électrolyse d'aldéhydes aromatiques (ArCHO) comme le 2,6-dichlorobenzaldéhyde (**1a**), le benzaldéhyde (**1b**) et le téréphtalaldéhyde (**2**) est réalisée en présence des dérivés In′H_2, les composés ArCH=In′ sont obtenus en faible rendement. Ces derniers composés ont été caractérisés par spectrométrie de masse et microanalyse. Le processus global implique deux réactions en chaîne avec régénération de l'anion InH^-.

Mots clés : réduction électrochimique, nitrosobenzène, aldéhydes aromatiques, catalyse basique, réaction en chaîne.

Introduction

We have reported previously that the reaction between aromatic aldehydes (ArCHO), 2,6-dichlorobenzaldehyde (**1a**), benzaldehyde (**1b**), and terephtalaldehyde (**2**)[2], in the presence of indene (InH_2) gave the derivatives ($ArCH(InH)_2$), **10a**, **10b**, and **12b**, respectively, in a process involving three consecutive chain reactions (1): addition of electrochemically generated InH^- to ArCHO to form a carbinol, ArCH(OH)InH, with regeneration of InH^- (2, 3), base catalysed dehydration of the carbinol to the hydrocarbon ArCH=In, and finally, addition of InH^- to ArCH=In to give $ArCH(InH)_2$ with regeneration of InH^-. The latter chain reaction was a slow process requiring several hours (1). The ^{1}H-NMR spectra of **10a**, **10b**, and **12b** indicated that all the indenyl moieties exist in the γ form (a trisubstituted double bond and a methylene group) (1). This was confirmed by the X-ray structure of **12b** showing the four indenyl moieties in the γ form (1) (Scheme 1).

Results and discussion

Chain reactions initiated by electrochemical reduction of nitrosobenzene

The cyclic voltammogram of nitrosobenzene (ArNO) on a vitreous carbon electrode in DMF 0.2 M Bu_4NPF_6 at –20°C shows a reversible system A/A′ (Fig. 1). Peak A corresponds to the reduction of ArNO to its radical anion $ArNO^{\cdot-}$ and peak A′ to the oxidation of the anion (4). In the presence of 5 equiv. of **10a**, the voltammogram is changed: peak A decreases and peak A′ disappears (Fig. 1). The rapid drop of the current after the peak potential, resulting in a sharp, narrow, and symmetric peak A, is characteristic of a catalytic reaction occurring outside the diffusion layer (5). We have

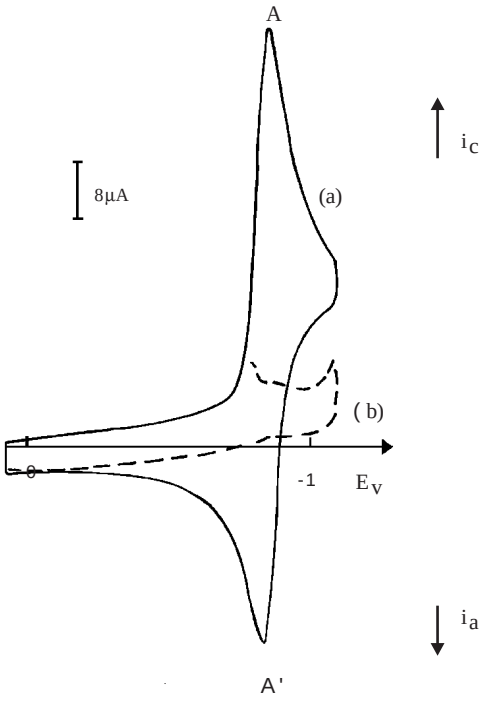
Fig. 1. Cyclic voltammogram of nitrosobenzene in DMF/Bu$_4$NPF$_6$ solution at –20°C. Sweep rate: 0.1 V/s. Starting potential: +0.1 V. (*a*) ArNO alone; (*b*) in the presence of 5 equiv. of **10a**.



verified that **10a** does not react with ArNO when no potential was applied under the same experimental conditions.

When an electrolysis of ArNO was performed in the presence of 4 equiv. of **10a** at the potential of peak A and at –20°C, the current dropped to zero after the consumption of a catalytic amount of electricity (see Table 1). After the addition of water and extraction with methylene chloride, the crude product was purified by chromatography on silica gel (see Table 4) to give imine **13a** (see Table 1 and Scheme 2). Similar results were obtained from the electroreduction of ArNO in the presence of **10b** or **12b**, giving **13b** and **14b**, respectively. In all cases, azoxybenzene was also formed.

The voltammetric behaviour and the results of controlled potential electrolyses (Table 1) show that the electrochemical reduction of PhNO in the presence of **10a**, **10b**, or **12b** as proton donor induces a chain reaction giving an imine, ArN=In′ (**13a**, **13b**, or **14b**, respectively), and azoxybenzene. The mechanism of formation of these compounds is the same as that described previously for the electrochemically initiated reaction of PhNO with fluorene or indene (5, 6). No nitrone was isolated or detected in the reaction with **10a**, **10b**, or **12b**, whereas the formation of a nitrone was reported in the reaction with fluorene or indene (5). In all reactions of Table 1, only one of the indene rings (out of two in **10a** and **10b**, out of four in **12b**) did react with PhNO due to the fact that an excess of proton donors (**10a**, **10b**, or **12b**) has been used.

The reaction of nitrosoaromatic compounds with active methylene compounds in the presence of a basic catalyst to give anils (Erlich–Sachs reaction (7)) and nitrones has been known for a long time. The reaction gives either the anil or the nitrone or a mixture of both, depending on the active methylene compound, the basic catalyst, and the reaction conditions (8, 9).

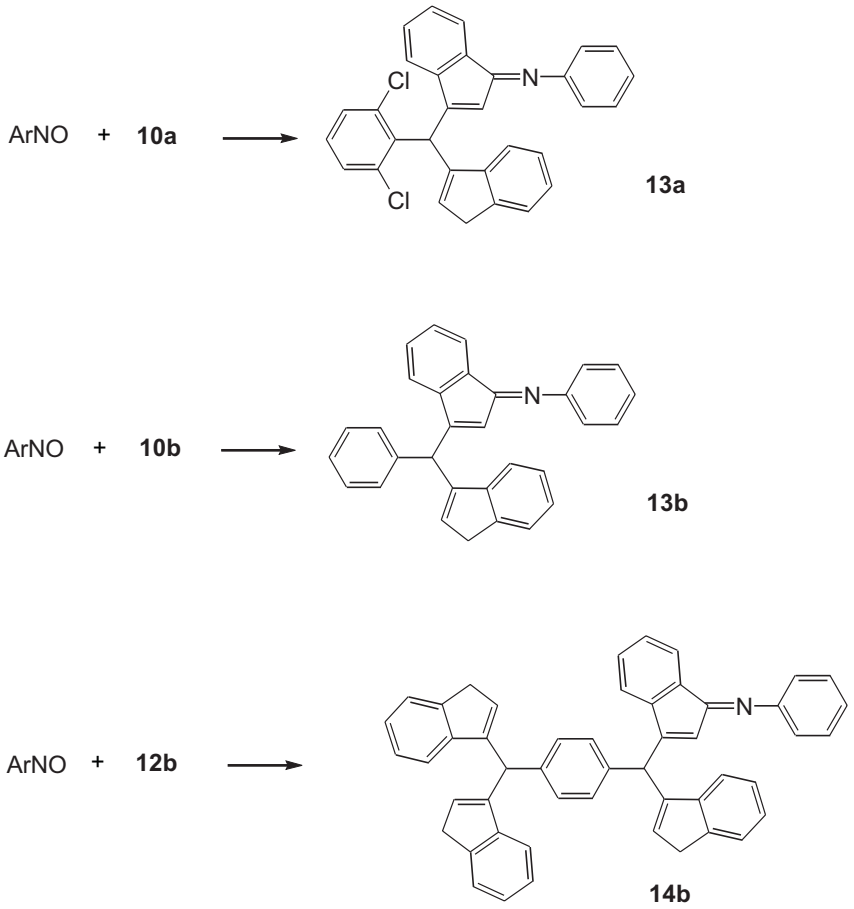
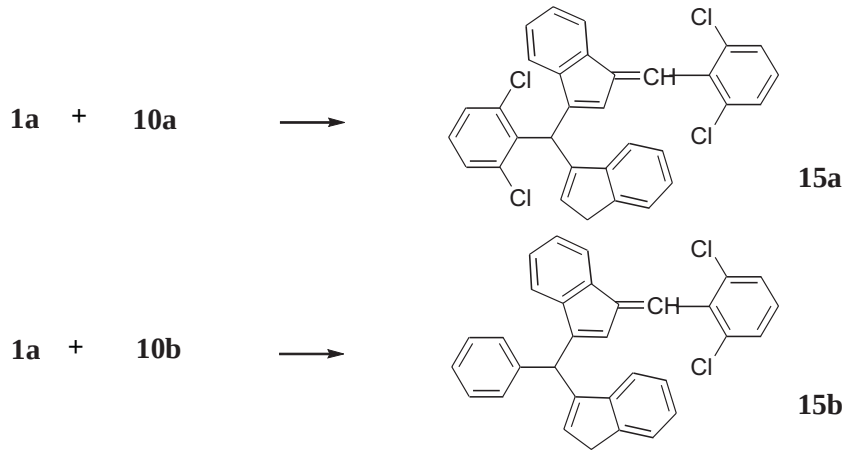


Scheme 3.



Chain reactions initiated by electrochemical reduction of aromatic aldehydes

It has long been known that indene or fluorene can be added to aldehydes, mainly aromatic aldehydes in the presence of a basic catalyst like potassium hydroxide (10, 11), sodium hydroxide (12, 13), KF-Al_2O_6 (14), or benzyltrimethylammonium hydroxide (triton B) (11).

As mentioned in the introduction, the reaction between InH_2 and aromatic aldehydes (ArCHO), initiated by electroreduction of the aldehyde, can give ArCH=In and (or) $ArCH(InH)_2$ through chain reactions. The latter was obtained after keeping the electrolysis solution at room temperature for several hours (1). The longer the standing time, the higher the yield of $ArCH(InH)_2$ (1).

We have examined the electrochemical behavior of aromatic aldehydes **1a**, **1b**, and **2** in the presence of proton donors **10a**, **10b,**or **12b** ($In'H_2$) in DMF 0.2 M Bu_4NPF_6 as supporting electrolyte with the aim of synthesizing the cor-

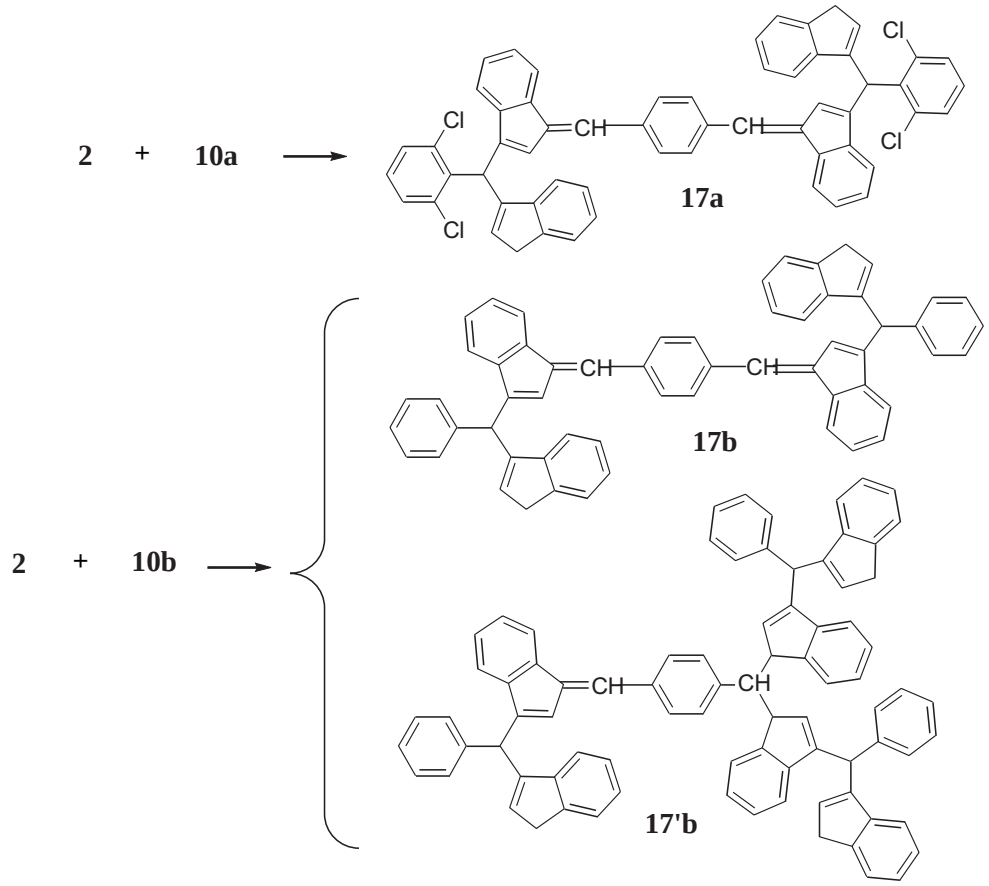
[a]The electrolyses were carried out under argon and the electrolysis solution was kept under argon after the current dropped to zero.
[b]Working potential vs. SCE.

responding hydrocarbons ArCH=In′H (see for instance **15a**, **15b**, **16a**, **16b**, **17a**, and **17b** in Schemes 3–5). The controlled potential reduction of these aromatic aldehydes at –30°C consumed a catalytic amount of electricity varying from 0.11 to 0.04 equiv. of electron (see Table 2), indicating that a chain reaction occurred as with FlH_2 and InH_2. The electrolyzed solutions were then kept under argon at room temperature for 19–72 h before extraction to ensure a complete dehydration of the carbinols formed initially. After appropriate work-up and chromatographic separation, the hydrocarbons **15a** and **15b** (see Scheme 3) were obtained in low yields (29 and 14%, respectively) from reduction of **1a** in the presence of an excess of **10a** or **10b**, respectively (entries 1 and 2). Compounds **15a** and **15b** were characterized by mass spectrometry (see Table 3) and microanalysis (see Table 4). Only one isomer of **15a** and **15b** was isolated but its configuration (*E* or *Z*) could not be assigned.

The two other aldehydes **1b** and **2** behave similarly as aldehyde **1a**, giving products of addition involving the methylene groups of **10a** and **10b** (see Schemes 4 and 5) in the yields indicated in Table 2 (entries 3–6).

© 1999 NRC Canada

Scheme 5.



Interestingly, the reaction between **1b** and **10a** (Scheme 4) and between **2** and **10b** (Scheme 5) led to derivatives **16′a** (12% yield, entry 3) and **17′b** (10% yield, entry 6), respectively, after very long standing times (60 and 72 h). The formation of **16′a** can be explained by addition of **10a** onto **16a** and that of **17′b** by addition of **10b** onto **17b**.

The mechanism of formation of all compounds in Tables 1 and 2 involves base catalysed additions (chain reactions) of the type previously described for the formation of ArCH=In and $ArCH(InH)_2$ by electrochemical reduction of ArCHO in the presence of excess InH_2 (1).

Structure of products

To our knowledge all compounds are new. Imine derivatives ArN=In′ and hydrocarbon derivatives were characterized by mass spectrometry (see Table 3) and microanalytical data (see Table 4). In mass spectrometry, the molecular ion peak was observed for all derivatives (see Table 3).

Experimental part

The apparatus and techniques have been described previously (1). The reference electrode was an aqueous saturated calomel electrode (SCE) separated from the solution by a sintered glass disk. 2,6-Dichlorobenzaldehyde (**1a**), benzaldehyde (**1b**), terephtalaldehyde (**2**), and nitrosobenzene were commercially available products.

Typical electrolysis procedure

Formation of imine ArN=In′

Nitrosobenzene (75 mg, 0.6425 mmol) was electrolyzed on a mercury electrode at –0.95 V vs. SCE with **10a** (1 g, 2.57 mmol) in DMF (25 mL) containing $(n\text{-Bu})_4NPF_6$ (0.2 M) under argon atmosphere. The electrolysis was stopped when the current dropped to zero (0.06 electron per molecule of ArNO). The electrolyzed solution was stirred at room temperature under argon during 67 h (the color turned from brown to red) then poured into water and extracted with dichloromethane. Chromatography on silica gel with hexane–dichloromethane (1.85:1) as eluent gave compound **13b** in 21% yield.

Formation of derivative ArCH=In′

Benzaldehyde **1b** (95 μL, 0.90 mmol) was electrolyzed on a mercury electrode at –2 V vs. SCE with **10b** (1.01 g, 3.15 mmol) in DMF (25 mL) containing $(n\text{-Bu})_4NPF_6$ (0.2 M) under argon atmosphere. The electrolysis was stopped when the current dropped to zero (0.1 electron per molecule of ArCHO). The electrolyzed solution was stirred at room temperature under argon during 19 h (the color turned from green–brown to blue) then poured into water and extracted with dichloromethane. Chromatography on silica gel with pentane–acetone (9:1) as eluent gave compound **16b** in 10% yield.

The photochemistry of 4-halobenzonitriles and 4-haloanisoles with 1,1-diphenylethene in methanol. Homolytic cleavage versus electron-transfer pathways[1]

Dino Mangion and Donald R. Arnold

Abstract: The photochemical reactivity of a series of 4-halobenzonitriles and 4-haloanisoles with 1,1-diphenylethene in a nucleophilic solvent (methanol) has been investigated. Analysis of the photochemical reactions involving the 4-halobenzonitriles revealed formation of alkene–methanol adducts, such as 1-methoxy-2,2-diphenylethane, 1-methoxy-2,2-diphenylethene, and 1,1-dimethoxy-2,2-diphenylethane, indicative of a photochemical electron-transfer mechanism. These products were not significant in the photochemical reactions involving the 4-haloanisoles. Both the 4-halobenzonitriles and the 4-haloanisoles produced an arene–alkene–methanol Markovnikov adduct, 1-aryl-2-methoxy-2,2-diphenylethane (aryl = 4-cyanophenyl or 4-methoxyphenyl). This compound was shown to undergo an acid-catalysed elimination to 1-aryl-2,2-diphenylethene under the reaction conditions, which subsequently underwent a 6π-electrocyclization to the 3-substituted(cyano or methoxy)-9-phenylphenanthrene. Possible mechanisms for the observed reactivity are discussed and evaluated.

Key words: photochemistry, photoinduced electron transfer, bond homolysis, radical ions, radicals, exciplexes.

Résumé : On a étudié la réactivité photochimique d'une série de 4-halogénobenzonitriles et de 4-halogénoanisoles avec le 1,1-diphényléthène, dans un solvant nucléophile (méthanol). L'analyse des réactions photochimiques impliquant les 4-halogénobenzonitriles a mis en évidence la formation d'adduits alcène–méthanol, tels que les 1-méthoxy-2,2-diphényléthane, 1-méthoxy-2,2-diphényléthène et 1,1-diméthoxy-2,2-diphényléthane; ces résultats suggèrent que le mécanisme de la réaction implique un transfert photochimique d'électron. Dans les réactions impliquant les 4-halogénoanisoles, la formation de ces produits n'est pas importante. Les 4-halogénobenzonitriles ainsi que les 4-halogénoanisoles conduisent tous à la formation d'un produit d'addition arène–alcène–méthanol selon la règle de Markovnikov, soit le 1-aryl-2-méthoxy-2,2-diphényléthane (aryl = 4-cyanophényl ou 4-méthoxyphényl). Il a été démontré que, dans les conditions de la réaction, ce produit subit une élimination acidocatalysée qui conduit au 1-aryl-2,2-diphényléthène et que ce dernier subit ensuite une électrocyclisation-6π avec formation d'un 9-phénylphénanthrène portant un substituant (cyano ou méthoxy) en position 3. On discute et on évalue divers mécanismes possibles pour la réactivité observée.

Mots clés : photochimie, transfert d'électron photoinduit, homolyse d'une liaison, ions radicaux, radicaux, exciplexes.

[Traduit par la Rédaction]

Introduction

A considerable portion of our recent research effort has been directed towards the elucidation of the electron-transfer photochemistry involving cyanoarene electron acceptors, olefinic electron donors, and nucleophiles (1, 2). Our most notable contribution in this area has been the development of the photoinduced nucleophile addition to aryl olefins (1) and the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction (2). The mechanisms for these reactions are well understood, as illustrated in Scheme 1. Both the photoinduced nucleophile addition to olefins and the photo-NOCAS reaction start off along a common mechanistic route and diverge along their specific pathways at a later stage, depending on the nature of the olefin.

Irradiation of the mixture of reactants leads initially to electronic excitation of the cyanoarene, here exemplified by 1,4-dicyanobenzene, to its first excited singlet state. Electron transfer with a ground state olefin gives a pair of radical ions. The olefinic radical cation may be trapped by the nucleophile, typically methanol, to give the more stable β-alkoxy radical. It is at this stage that the two reaction pathways diverge. If the olefin is aromatic, the β-alkoxy radical will have a reduction potential, which is low enough to al-

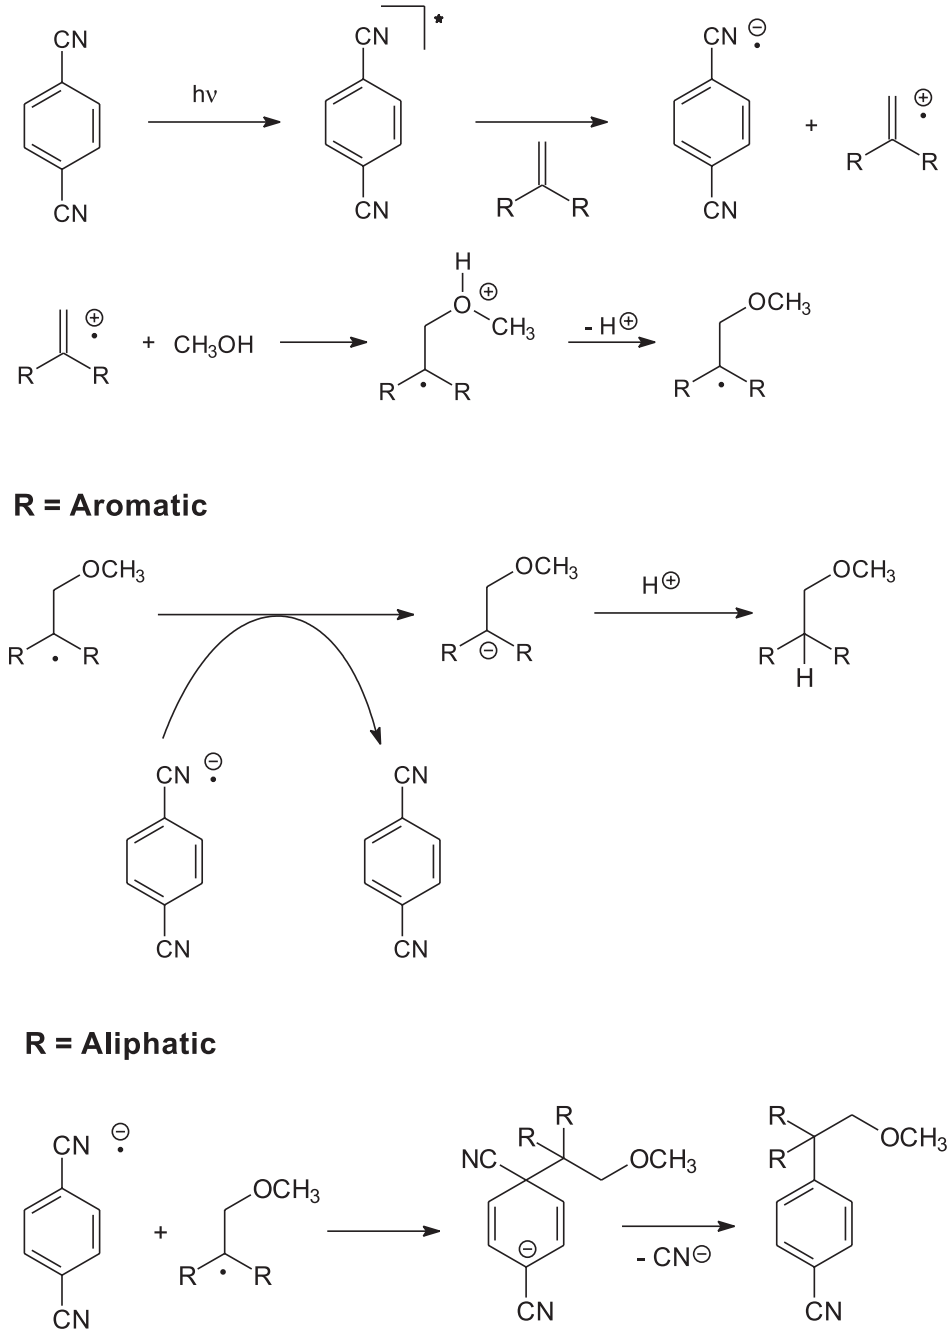
Scheme 1. Mechanism for the photoinduced nucleophile addition (R = aromatic) and photo-NOCAS reaction (R = aliphatic).



low reduction to the corresponding anion by the cyanoarene radical anion. The resulting β-alkoxy anion is subsequently protonated to give the ether product. On the other hand, if the olefin is aliphatic, then the intermediate β-alkoxy radical cannot be reduced to the corresponding anion; instead, the radical will add to the *ipso* position of the cyanoarene, expelling cyanide anion in order to rearomatize, and thus furnish the photo-NOCAS product. In both cases, the overall regioselectivity of the methanol addition is *anti*-Markovnikov; this is a direct consequence of the involvement of the olefin radical cation.

The scope and limitations of these reactions have been thoroughly investigated and documented, particularly with respect to the olefin and the nucleophile. Not much is known, however, about varying the electron acceptor, which in the past has invariably been a cyanoarene, commonly 1,4-dicyanobenzene, 1,4-dicyanonaphthalene, or 9,10-dicyanoanthracene.

The reasons for selecting these cyanoaromatics are manifold. The cyano function is strongly electron-withdrawing, imparting low reduction potentials to these compounds and thus making them good electron acceptors for the photoinduced electron transfer (PET) process. Unlike most other electron-withdrawing groups (such as carbonyl and nitro functions), the cyano group has no low-lying excited state of its own, and therefore, it does not exhibit its own

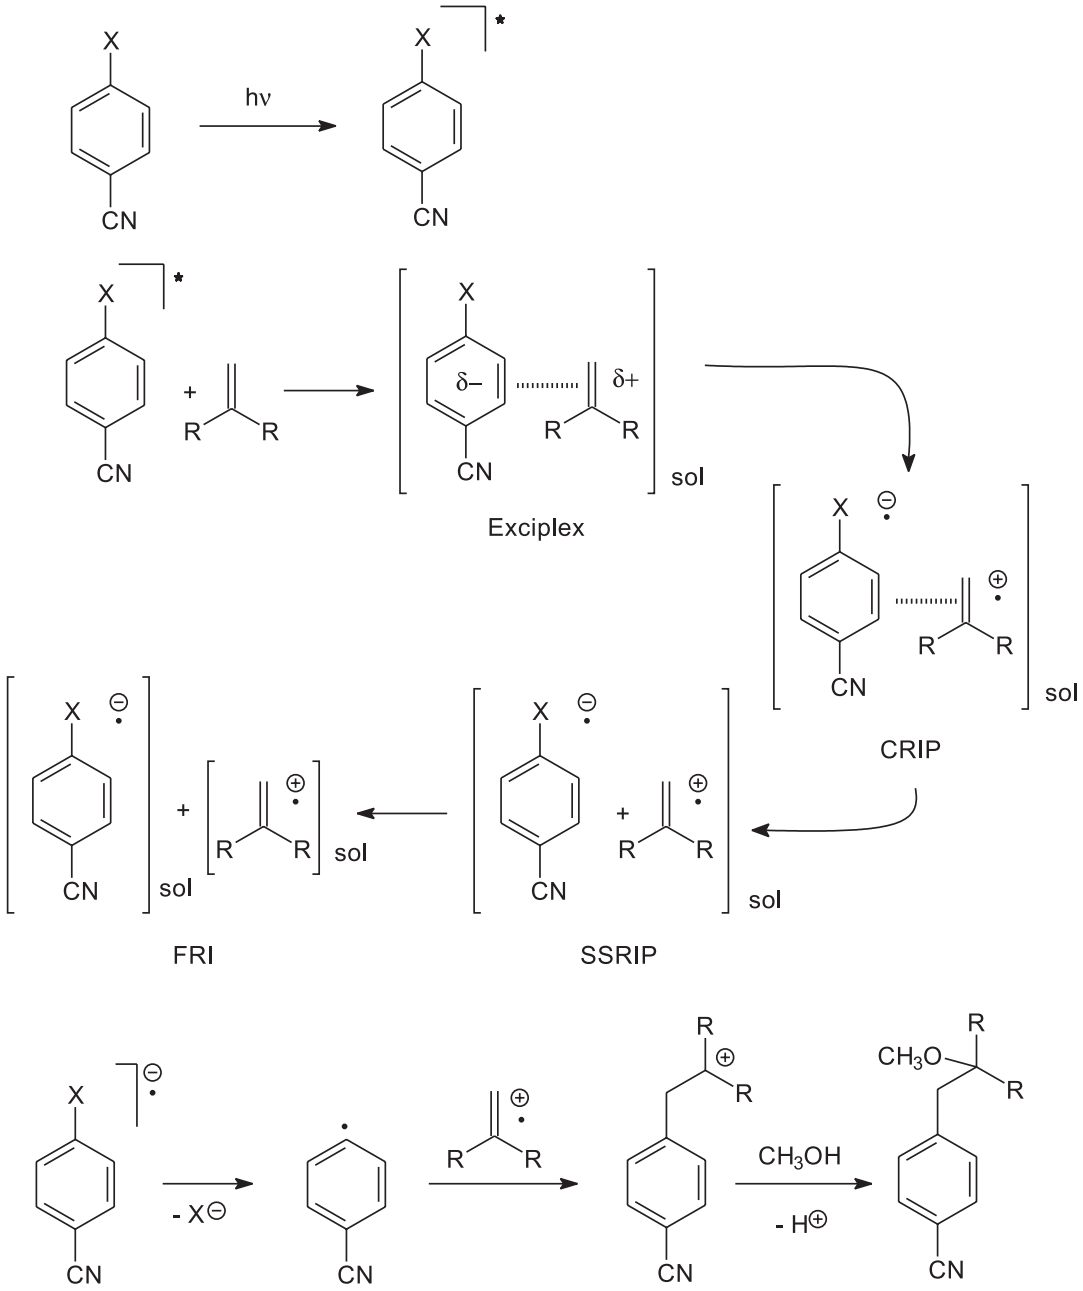
Scheme 2. Envisaged mechanism for the photochemical reaction between a cyanoarene bearing a cleavable group (X), an olefin, and methanol (CRIP, contact radical ion pair; SSRIP, solvent separated radical ion pair; FRI, free radical ions).



photochemistry. Furthermore, the cyanoarene radical anions resulting from the PET process are relatively stable and long-lived (as is evidenced by their fully reversible cyclic voltammetric scans), making the cyanoarenes particularly suitable as photosensitizers. In addition, when incorporated in the product (example, the photo-NOCAS reaction) the cyano substituent is a versatile function that can be readily converted into various other useful groups.

The aim of our current research is to investigate the effect of different electron acceptors on the outcome of these photochemical reactions. In particular, we are interested in altering the sequence of events in the mechanistic scheme by utilizing an electron acceptor that possesses an unstable, readily cleavable, radical anion. Rapid cleavage of the radical anion within the solvent cage would lead to the formation of an aryl radical in the vicinity of the olefinic radical cation. These highly reactive intermediates are expected to combine to give the more stable adduct cation, which will subsequently be trapped by a nucleophile, such as methanol, to give the final adduct. The proposed mechanism is illustrated in Scheme 2, utilizing a benzonitrile with a cleavable group (X) as the model compound.

The compounds selected for this investigation are a series of 4-halobenzonitriles (**1a**–**4a**), ranging from 4-fluoro- (**1a**) to 4-iodobenzonitrile (**4a**) (Fig. 1). There is considerable evidence in the literature that the radical anions of these species are unstable, due to cleavage of the aryl–halogen bond, giving the aryl radical and the corresponding halide anion

(3). Cleavage of haloarene radical anions has been extensively studied, primarily in connection with the photochemical (4) and electrochemical (5) unimolecular nucleophilic substitution reaction (via a radical intermediate; $S_{RN}1$). The olefin chosen as the model electron donor was 1,1-diphenylethene (**5**). A series of 4-haloanisoles (**2b**–**4b**), which are not expected to function as electron acceptors in the PET process, have also been investigated under similar conditions to provide additional insight into the mechanism.

Results

Irradiation of a methanol solution of 4-fluorobenzonitrile (**1a**) and 1,1-diphenylethene (**5**) leads solely to photoproducts (**8**–**10**) derived from the olefin without incorporation of the benzonitrile (Table 1, Reaction 1). The lack of photoreactivity of the fluoroarene **1a** was also observed upon irradiating **1a** in the absence of **5** in methanol using Pyrex ($\lambda > 280$ nm) or Quartz ($\lambda > 190$ nm) filters — no consumption of **1a** was observed in either case (Table 1, Reaction 2). In an attempt to explain the photoproducts observed in Reaction 1 and to define any alternative photochemical reactions of **5**, the olefin was irradiated in methanol in the absence of any cyanoarene (Table 1, Reaction 12). This led to a sluggish reaction, which delivered 1-methoxy-1,1-diphenylethane (**9**, 33%), 1,1-diphenylethane (**8**, 11%), and 1-methoxy-2,2-diphenylethane (**10**, 3%), as well as substantial polymerization after prolonged irradiation. This observation is in accord with results from a similar study reported in the literature (6). Furthermore,

[a]Reactions contained biphenyl (**7**) as co-donor.

irradiation in the presence of the bona fide PET sensitization pair, 1,4-dicyanobenzene (**6**) and biphenyl (**7**), delivered ether **10** (83%), together with **9** (7%) and 1-methoxy-2,2-diphenylethene (**11**, 2%) (Table 1, Reaction 13). This reaction provides an enhanced yield as a result of the added co-donor **7** (1*a*).

Similar irradiation of a mixture of 4-chlorobenzonitrile (**2a**) and alkene **5** in methanol (Table 1, Reaction 3) afforded a series of olefin–methanol adducts — **9** (2%), **10** (26%), **11** (7%), and the diethers **12** (6%) and **13** (2%). In addition, products incorporating the 4-cyanophenyl moiety were now formed. The major adduct was 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethene (**17a**, 17%), with lesser amounts of 1-(4-cyanophenyl)-2,2-diphenylethane (**16a**, 12%) and 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**, 3%). Adducts **16a** and **17a** are, to the best of our knowledge, new compounds.

To determine the mechanism for the formation of the diethers **12** and **13**, the methoxyalkene **11** was independently synthesized and subsequently subjected to irradiation in methanol (Table 1, Reaction 14). Under these conditions, **11** yielded 40% of the 1,1-diether **12** and 23% of the 1,2-isomer **13**. Furthermore, irradiation of **11** in the presence of the 1,4-dicyanobenzene (**7**) – biphenyl (**8**) PET-sensitization pair yielded 85% of **12** and 2% of **13** (Table 1, Reaction 15).

Irradiation of 4-bromobenzonitrile (**3a**) together with the olefin **5** gave a series of photoproducts similar to that obtained with the chloro derivative **2a** (Table 1, Reaction 5). In addition to the products observed previously, a considerable amount of benzonitrile (**14a**, 13%) was obtained as well as an additional product, identified as 3-cyano-9-phenylphenanthrene (**18a**, 4%). The structure of this new compound was firmly established by single-crystal X-ray crystallographic analysis (Fig. 2).[3]

Irradiation of 4-iodobenzonitrile (**4a**) in the presence of **5** resulted in a similar series of photoproducts. In this case, the major products were **15a** (38%) and **18a** (21%) (Table 1, Reaction 7).

Irradiation of the halobenzonitriles **2a**–**4a** in the absence of olefin **5** did not lead to any consumption of the starting material in the case of **2a** (Table 1, Reaction 4) but resulted in essentially quantitative conversions of **3a** and **4a** to benzonitrile (**14a**) (Table 1, Reactions 6 and 8).

The formation of **18a** was investigated by subjecting a pure sample of **15a** to irradiation in methanol. Alkene **15a** remained unconsumed when irradiated on its own (Table 1, Reaction 9) or in the presence of chlorobenzonitrile **2a** (Table 1, Reaction 10). However, **15a** was quantitatively converted (98%) to **18a** upon irradiation in the presence of **4a** (Table 1, Reaction 11). The 4-iodobenzonitrile (**4a**) was largely converted to benzonitrile (**14a**, 80%) under these conditions.

The 4-haloanisoles (**2b**–**4b**) were subjected to similar photochemical reaction conditions. Irradiation of 4-chloroanisole (**2b**) and olefin **5** in methanol led to a small amount of alkene:methanol adducts **9** (5%) and **10** (5%), together with a series of products incorporating the 4-methoxyphenyl moiety. 1-(4-Methoxyphenyl)-2,2-diphenylethene (**15b**) was the major product (40%), but considerable amounts of anisole (**14b**, 14%), 1-(4-methoxyphenyl)-2-methoxy-2,2-diphenylethane (**17b**, 4%), and 3-methoxy-9-phenylphenanthrene (**18b**, 8%) were also formed (Table 2, Reaction 16). Only a trace of 1-(4-methoxyphenyl)-2,2-diphenylethane (**15b**) was observed and its identification rests solely, though convincingly, on

mass spectral data. 4-Bromoanisole (**3b**) and 4-iodoanisole (**4b**) reacted similarly (Table 2, Reactions 18 and 20).

Irradiation of the haloanisoles **2b**–**4b** in the absence of olefin **5** led to rapid consumption of the starting materials, coupled with the formation of **14b** (Table 2, Reactions 17, 19, and 21). In the case of 4-chloroanisole (**2b**), 1,4-dimethoxybenzene (**19**, 12%) was also formed.

Alkene **15b** was synthesized independently and subjected to irradiation in the presence of **4b** in methanol. Under these conditions, **15b** was quantitatively converted to **18b**. This was accompanied by considerable consumption of **4b** and the formation of **14b** (80%).

The ratio of **17**:**15** was observed to decrease in all the haloarene reaction mixtures as the irradiations progressed. This was shown to be due to an acid-catalysed thermal decomposition of **17** to **15**, implying that both **15** and **18** are secondary products, derived from **17**.

Discussion

Even though some of these photoinduced reactions deliver photoproduct **17**, consistent with the envisaged mechanism (Scheme 2), there are indications that in some cases the reaction may be more complex; in fact, an alternative mechanism might be operative. Rapid photoinduced homolytic cleavage of the haloarene carbon–halogen bond might preempt the PET process. Homolytic dissociation would furnish an aryl radical but would not produce the olefin radical cation. The direct photolysis of haloarenes has been extensively investigated, and reactions involving this process have found widespread application as reductive dehalogenation (7) and arylation (8) methods (Scheme 3).

Past studies involving the generation of haloarene radical anions, generally in connection with the $S_{RN}1$ mechanism, have circumvented the problem of competing homolytic

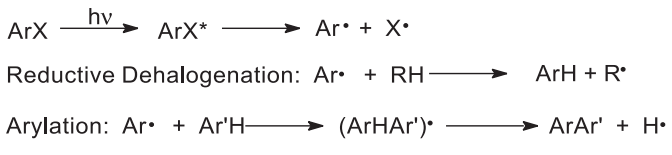
Scheme 3. Reductive dehalogenation and arylation reactions initiated by homolytic dissociation of a haloarene ArX (X = halogen).



cleavage by avoiding the haloarene excited state. This was achieved by utilizing electrochemical techniques to generate the radical anion (5) or, in photochemical methods, by ensuring selective electronic excitation of the electron donor (commonly an enolate) or of a charge-transfer complex (4). Although PET involving an excited state haloarene has sometimes been proposed as the initiation step for the photochemical reactions, little is known about the exact nature of the photoinitiation mechanism (4*c*).

The primary requirement for an effective PET process involves the energetics. The electron-transfer process, as predicted by the Weller equation (9), must be exergonic. There is, however, a kinetic aspect that has to be considered as well. The lifetime of the excited state, the rate of electron transfer, and the concentration of the other constituent of the electron-transfer pair (i.e., the quencher) are all important in determining whether an excited state can partake in the electron-transfer process. The rate of PET depends on the energetics of the process, with a free energy for the PET process, ΔG_{PET}, more negative than –13 kJ mol^{-1} usually resulting in a diffusion-controlled rate (1.1×10^{10} M^{-1} s^{-1} in methanol) (9).

Examination of the electronic absorption spectra of the haloarenes (**1**–**4**) and 1,1-diphenylethene (**5**) indicates that these species will absorb competitively under the experimental conditions. Hence, it is not readily established which component is the light absorber and which excited state species is thus involved in the PET process (if such a process is occurring). Table 3 lists the calculated free energies, ΔG_{PET}, for the various possibilities. These values suggest that PET should occur at a diffusion-controlled rate with the halobenzonitriles **2a**–**4a** as well as with **6**, but should occur slowly, or not at all, with the fluorobenzonitrile **1a** or with the haloanisoles **2b**–**4b**, irrespective of whether it is the elec-

© 1999 NRC Canada

tron acceptor or the electron donor that is acting from its excited state.

The nature of the excited state is also an important factor. The haloarene singlets are expected to exhibit rapid intersystem crossing rates, i.e., short singlet excited state lifetimes. Chlorobenzene, for example, is reported to have a quantum yield of intersystem crossing of 0.7 (10) and a singlet lifetime of 0.74 ns (11). If we assume these values, we can conclude that, at a quencher concentration of 0.1 mol dm^{-3}, about 50% of the singlet excited states may live long enough to undergo electron transfer; 70% of the unquenched singlets will intersystem cross to the longer lived triplet state, but the loss in excitation energy on crossing to the triplet renders the electron-transfer process prohibitively endergonic (Table 3).

Deciding whether PET or photochemical homolytic dissociation is the predominant mechanism also depends upon the relative rates of the homolytic cleavage and the electron-transfer processes. Here we must recognize that PET is disadvantaged by the fact that this process is bimolecular and is thus restricted by the rate of diffusion through the medium and by the concentration of the electron-transfer partner. The efficiency of this process is also severely hindered by rapid back electron transfer. Homolytic cleavage, in its simplest form, is a unimolecular process, independent of the alkene, its concentration, and its rate of diffusion. One simple method that has been used to predict the likelihood of the homolytic dissociation is comparison of the energy of the reacting exciting state with the bond dissociation energy of the bond to be cleaved. Although the bond dissociation energies of the haloarenes involved in this study are not available, these energies can be approximated to the corresponding values for the halobenzenes (15), as displayed in Table 3. If we assume that the reacting excited state is the triplet then the values indicate that homolytic cleavage will probably be viable for the bromo (**3**) and iodo (**4**) derivatives, but is unlikely for the fluoro (**1**) and chloro (**2**) compounds. In the less probable situation that cleavage is rapid enough to occur from the singlet in competition with intersystem crossing, the chloro (**2**), bromo (**3**), and iodo (**4**) compounds are expected to undergo homolytic dissociation. These postulates were tested by a series of experiments involving irradiation of the haloarenes in pure methanol (Table 1, Reactions 2, 4, 6, and 8; Table 2, Reactions 17, 19, and 21). Whereas the bromo- (**3**) and iodoarenes (**4**) underwent extensive homolysis to give the corresponding dehaloarene (i.e., benzonitrile or anisole), the fluoro- (**1a**) and chlorobenzonitriles (**2a**) were stable under these conditions. These observations suggest that the observed homolysis, in these cases, occurs from the excited triplet state. 4-Chloroanisole (**2b**) exhibited appreciable cleavage despite the unfavourable energetics for the postulated pathway. Such apparently anomalous behaviour has been observed before with compounds such as 4-bromobiphenyl and 1-chloronaphthalene, where cleavage was attributed to the involvement of excimers, which facilitate the homolysis (19). The inefficacy of **2b** to undergo direct homolytic dissociation is highlighted by the formation of 1,4-dimethoxybenzene (**19**) via a photoinduced nucleophilic aromatic substitution (S_NAr) reaction. This reaction has been observed previously (20) and is an indication of the stability of the carbon–chlorine bond towards homolytic cleavage.

One of the strongest pieces of evidence for the PET mechanism is the observed formation, in all the halobenzonitrile reactions (Table 1, Reactions 1, 3, 5, and 7), of the alkene:methanol adduct, 1-methoxy-2,2-diphenylethane (**10**). The *anti*-Markovnikov regiochemistry of this adduct provides strong support for the involvement of the alkene radical cation. The high deuterium incorporation (47–86%) at the bisbenzylic position, when utilizing methanol-*O*-*d* as solvent, is a confirmation that the PET nucleophile addition outlined previously in Scheme 1 is operative. This mechanism requires a secondary electron transfer between the intermediate alkene:methanol adduct radical and the sensitizer radical anion in order to furnish the adduct anion, which is subsequently protonated to give the ether **10** as product. If we approximate the half-wave reduction potential $E_{1/2}^{red}$ of the 2-methoxy-1,1-diphenylethyl radical ($Ph_2C^{\cdot}CH_2OCH_3$) to that of the 1,1-diphenylethyl radical ($Ph_2C^{\cdot}CH_3$), which has been reported by Wayner et al. (21) as –1.34 V vs. SCE, we find that the reduction of the intermediate adduct radical by the sensitizer radical anion is highly exergonic with all the haloarene radical anions.

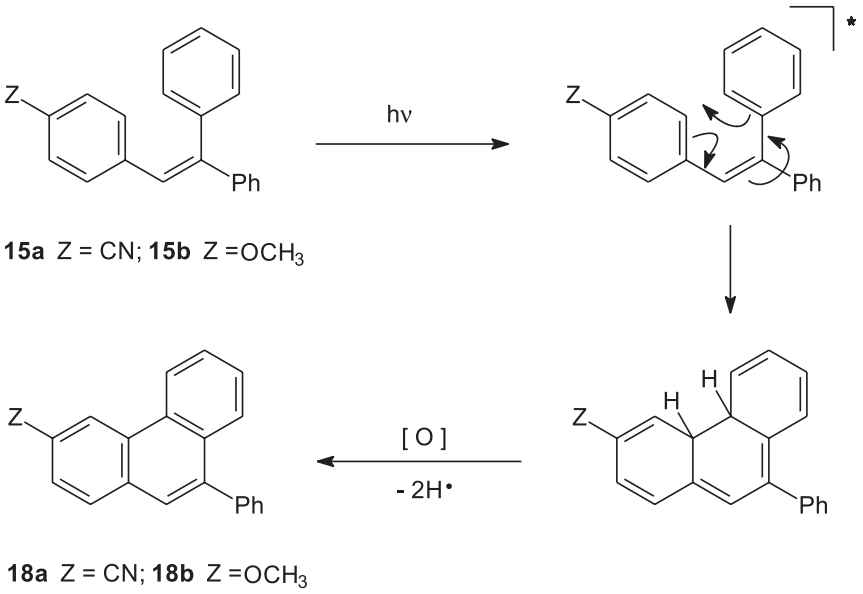
This process, however, requires the halobenzonitrile radical anion to survive long enough for this secondary electron transfer to occur, which is surprising, particularly since the rates of cleavage of the halobenzonitrile radical anion are extremely rapid in all cases except for the fluoro derivative, which is thought to be stable towards cleavage (although this is still the subject of debate) (22). The rates of cleavage of these radical anions have been determined by Saveant and co-workers (5*c*): 9×10^8 s^{-1} for $\mathbf{2a}^{\cdot-}$, 2×10^9 s^{-1} for $\mathbf{3a}^{\cdot-}$, and 2×10^{10} s^{-1} for $\mathbf{4a}^{\cdot-}$.

There is, however, evidence in the photochemical reactions for these species cleaving prior to the second electron transfer. In the photoreaction involving 1,4-dicyanobenzene (**6**) in methanol-*O*-*d*, the bisbenzylic position of the ether **10** exhibited 96% deuterium incorporation, indicating that reduction of the adduct radical to the corresponding anion and its subsequent protonation is essentially the sole pathway leading to the ether product (Scheme 1). However, in the case of the halobenzonitriles **1a**–**4a**, the deuterium incorporation percentage, albeit high, is appreciably lower (47–86%). This might reflect the unavailability of a proper reducing agent to complete the process. In such a situation, the 2-methoxy-1,1-diphenylethyl radicals have the option to undergo a disproportionation reaction to yield 1-methoxy-2,2-diphenylethane (**10**) (with no deuterium incorporation) and 1-methoxy-2,2-diphenylethene (**11**). In fact, considerable amounts of **11** have been observed in the chloro- (**2a**), bromo- (**3a**), and iodobenzonitrile (**4a**) reactions. This compound was shown to be photochemically active, reacting similarly to **5**. In a control experiment, **11** was observed to undergo an efficient PET methanol addition in the presence of the 1,4-dicyanobenzene (**6**) – biphenyl (**7**) pair, to give 1,1-dimethoxy-2,2-diphenylethane (**12**) in high yield (85%). Furthermore, **11** was shown to undergo methanol addition in the absence of a sensitizer to give the two isomeric diethers **12** and 1,2-dimethoxy-1,1-diphenylethane (**13**). Both of these products are found in the photochemical reactions involving the cleavable halobenzonitriles **2a**–**4a**.

As highlighted in the introduction, the major interest of this study is in those pathways that involve the co-reactivity

© 1999 NRC Canada

Scheme 4. 6π-Electrocyclization of **15** to **18**.



of the haloarene and the incorporation of the aryl moiety in the final products. Such products are absent in the 1,4-dicyanobenzene (**6**) reactions due to the stability of the 1,4-dicyanobenzene radical anion. For similar reasons, or possibly because PET is energetically unfavourable and does not occur, no such products were observed in the 4-fluorobenzonitrile (**1a**) reactions.

Analysis of the other haloarene photoreactions reveals the presence of four products resulting from the co-reaction of the alkene with the aryl fragment (**15**–**18**). In a series of separate experiments using **15a** and **15b** as starting materials, it was established that the phenanthrene derivatives **18a** and **18b** were secondary photoproducts arising from the photoinduced cyclization of **15a** and **15b**, respectively (Scheme 4). This 6π-electrocyclization reaction is well documented (23). Interestingly, this cyclization did not occur if **15a** or **15b** were irradiated in the absence of a haloarene. Addition of 4-chlorobenzonitrile (**2a**) to the solution also failed to affect the photocyclization, and in fact, none of this product was observed in the 4-chlorobenzonitrile (**2a**) photoreactions. However, irradiation of the solution upon addition of the iodoarenes **4a** or **4b** led to a quantitative conversion of **15a**–**b** to the phenanthrene derivatives **18a**–**b**. An explanation for this may be that the 6π-electrocyclization initially yields a 4*a*,4*b*-dihydrophenanthrene derivative that has to be oxidized to the final product. In the absence of a suitable oxidizing agent, this intermediate may undergo a photoinduced electrocyclic ring opening back to the starting material (23*a*). The introduction of **4a**–**b** provides a suitable oxidizing agent in the form of an iodine atom (or molecule) derived from the homolytic cleavage of the parent haloarene. No reactivity is observed in the presence of **2a**; this particular haloarene is resistant to homolytic cleavage and thus fails to provide a suitable oxidizing agent.

Control experiments have established that 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**) and its methoxy analogue **15b** are secondary photoproducts arising from the acid-catalysed elimination of methanol from the corresponding ethers **17a** and **17b**, respectively. This provides a rational explanation for the fact that the ratios **15a**:**17a** and **15b**:**17b** increase in all reactions as the photoreaction proceeds. The photochemical reaction generates a hydrogen halide, and hence, the acidity of the medium increases as the reaction occurs. The larger ratios of **15**:**17** observed on going from chloro- to iodoarene might be due to the relative acidity of these halo acids.

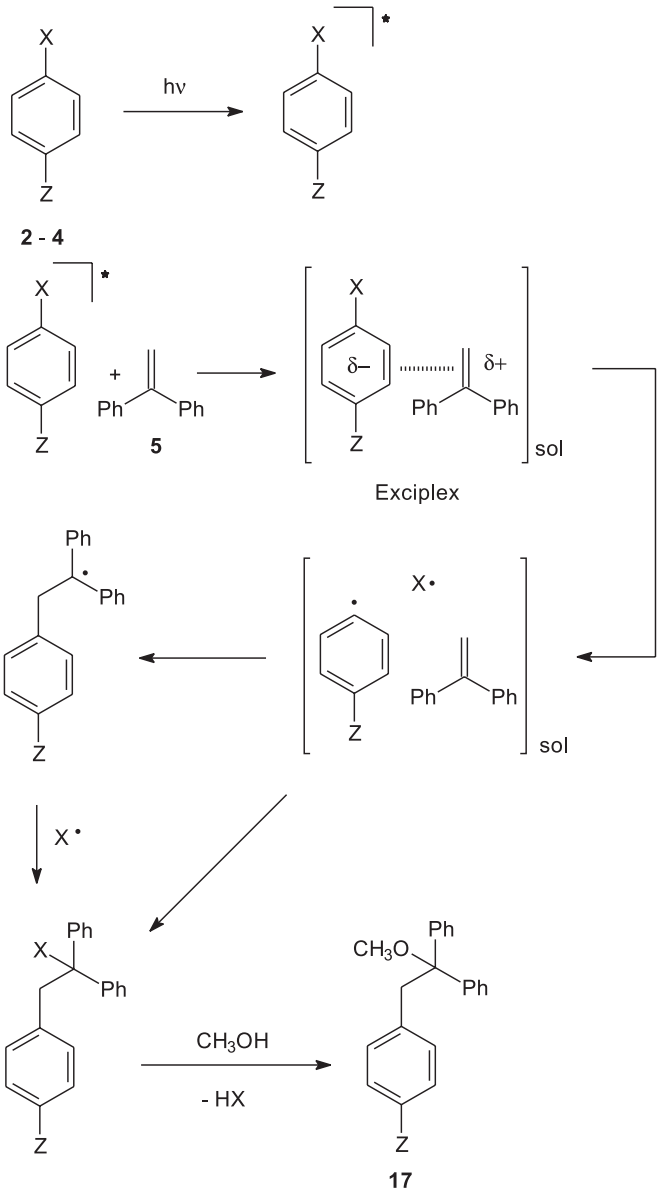
The reactions of the halobenzonitriles are consistent with the previously proposed mechanism involving photoinduced electron transfer (Scheme 2). However, the fact that the 4-haloanisoles (**2b**–**4b**) also undergo an efficient reaction with 1,1-diphenylethene (**5**) to give a similar series of products (Table 2, Reactions 16, 18, and 20), despite unfavourable PET energetics (Table 3), is inconsistent with this mechanism. Therefore, we propose a modified, more general, mechanism in which the haloarene and the alkene initially form an exciplex of varying degree of charge separation, depending upon the constituents. If charge separation is considerable, then this initial exciplex might lead to a PET mechanism as suggested initially (Scheme 2). This will account for the formation of products, such as the alkene:methanol adducts **10**, **11**, and **12**, which are attributed to a PET mechanism. These products are only formed in the halobenzonitrile reactions in which appreciable charge separation is expected.

Alternatively, if charge separation in the exciplex is less favourable, the haloarene may undergo a homolytic dissociation, generating a halogen atom and an aryl radical, which will add to the neutral alkene to give the more stable radical (Scheme 5). This intermediate radical would then be trapped by the halogen atom, to give the 1-aryl-2-halo-2,2-diphenylethane, which may subsequently undergo an S_N1 reaction with methanol to furnish the observed products, ethers **17a**–**b**. This key halogen-containing intermediate compound has not been observed, however, its absence is consistent with its expected high S_N1 reactivity under these reaction conditions.

This exciplex-mediated pathway finds support upon consideration of the photochemistry of 4-chlorobenzonitrile (**2a**). This compound is stable to irradiation, on its own, in

© 1999 NRC Canada

Scheme 5. Proposed mechanism for the formation of products **17a** and **17b**.



methanol (Table 1, Reaction 4), but does undergo a photoreaction in the presence of **5** (Table 1, Reaction 3), clearly indicating that the latter is necessary for reaction to occur. This rules out the possibility that a straightforward, unassisted homolytic cleavage of the carbon–chlorine bond is taking place in this case. The hypothesis that an exciplex, which activates the otherwise unreactive carbon–halogen bond towards homolysis, is a likely explanation for the observed reactivity. The role of exciplexes in similar situations involving haloarenes has been documented (24). In particular, the enhanced homolysis of the carbon–chlorine bond as a consequence of exciplex formation between chloroarenes and dienes has been firmly established (24*a*, *c*). However, no co-reaction between the two constituents was reported in these studies — the haloarenes were only observed to undergo a reductive dehalogenation.

Other photoproducts that we have observed in small quantities in all the reactions involving cleavable haloarenes are the 1-aryl-2,2-diphenylethanes **16a** and **16b**. Deuterium incorporation studies involving **16a** in methanol-*O*-*d* indicate deuterium incorporation (41–64%) at the bisbenzylic (C-2) position (Table 1, Reactions 3, 5, and 7), suggesting a 2-aryl-1,1-diphenylethyl anion as precursor. The plausible route to this species is via reduction of the corresponding radical (Scheme 6). Calculations suggest that this electron-transfer step is energetically viable when a halobenzonitrile radical anion acts as reducing agent. However, such a situation requires the halobenzonitrile radical anion to survive long enough for the electron transfer to occur. As previously mentioned, this is surprising in view of the short lifetimes of these species. Nevertheless, the variation in the yield of **16** in relation to the different haloarenes investigated does support this hypothesis. The 4-chlorobenzonitrile (**2a**) radical anion, which is the longest lived anion radical among all the cleavable haloarenes studied, does afford the greatest yield of **16a** (12%). This decreases in the case of the bromobenzonitrile **3a** (8%) and further in the case of the iodo derivative **4a** (5%). The haloanisoles **2b**–**4b** furnish only trace amounts (<2%) of the corresponding product **16b**, although in these cases, it is dubious whether the haloanisole radical anions are actually formed. This last point, as well as the incomplete deuterium incorporation in **16a** in the methanol-*O*-*d* reactions, requires a second reaction pathway that does not involve protonation of an anionic precursor. We suggest that this alternative route involves hydrogen atom abstraction by the 2-aryl-1,1-diphenylethyl radical (Scheme 6).

Conclusions

The involvement of a cyanoarene bearing a cleavable group has a drastic effect on the outcome of the photochemical reaction between cyanoarenes, olefins, and nucleophiles. The main photoproduct incorporating the cyanoaromatic moiety, i.e., 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (**17a**), possesses a Markovnikov regioselectivity, in contrast to the *anti*-Markovnikov regioselectivity characteristic of the otherwise similar photo-NOCAS product (2). This is a direct consequence of a different sequence of mechanistic events — cyanoarene moiety reacting with the olefin prior to trapping by the nucleophile, in contrast to the photo-NOCAS reaction where nucleophile and olefin combine before substituting on the cyanoarene.

The observed photoreactions are mechanistically quite complex. There is convincing evidence pointing towards both PET as well as direct photolytic carbon–halogen bond dissociation pathways. Both processes may be occurring competitively. Alternatively, an exciplex-mediated pathway, with varying degrees of charge separation, may be invoked to reconcile the observations, which might appear contradictory when considered from exclusively either the PET or the homolytic cleavage pathway.

Experimental section

General information

Photochemical reactions were monitored and analysed by gas chromatography – mass spectrometry (GC–MS) using an

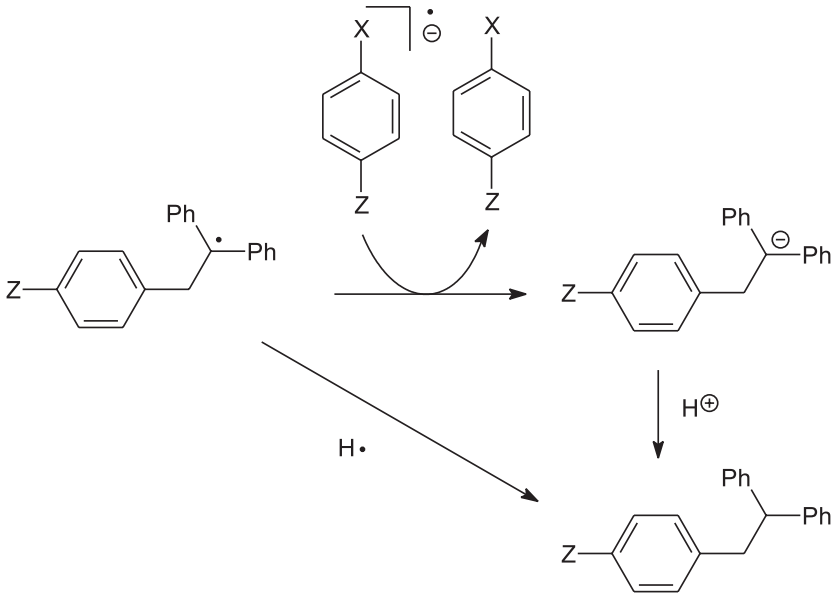
Scheme 6. Proposed mechanism for the formation of products **16a** and **16b**.



16a Z = CN, **16b** Z = OCH_3

HP 5890 gas chromatograph with a 5% phenylmethylsilicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness) and an HP 5970 mass selective detector. Deuterium incorporation studies were performed using single-ion monitoring mass spectrometry (sim-MS). Quantitative gas chromatographic analysis was performed on a Perkin Elmer AutoSystem gas chromatograph equipped with an autosampler, flame ionization detector (fid), and a DB-5 fused silica WCOT column (15 m × 0.25 mm, 1.5 μm film thickness).

Preparative separation of product mixtures was performed using flash chromatography (25) on a 15 × 5 cm silica gel (Aldrich, 230–400 mesh, 60 Å) column. This was generally followed by preparative, centrifugally accelerated, radial, thin-layer chromatography of the partially purified mixtures using a Chromatotron (Harrison Research) on 4, 2, or 1 mm silica gel (Aldrich, TLC grade 7749 with gypsum binder and fluorescent indicator) plates. The mobile phase was typically hexanes with increasing amounts of ethyl acetate. Collected fractions were analyzed by thin-layer chromatography using silica gel plates (Aldrich, 250 μm plate thickness, 5–17 μm, 60 Å, with fluorescent indicator) and (or) GC–MS.

All ^{1}H and ^{13}C NMR spectra were acquired on a Bruker AC 250F spectrometer at 250.13 MHz for ^{1}H and 62.90 MHz for ^{13}C. Chemical shifts are reported in ppm relative to tetramethylsilane (δ = 0 ppm) in ^{1}H NMR spectra and chloroform-*d* (δ = 77.0 ppm) in ^{13}C NMR spectra. Infrared spectra were recorded as films on sodium chloride plates on a Nicolet 205 FT-IR spectrophotometer and are reported in wave numbers (cm^{-1}) calibrated against the 1602 cm^{-1} polystyrene absorption. Ultraviolet-visible absorption spectra were recorded on a Hewlett–Packard (HP) 8452A diode-array spectrophotometer within a resolution of ±1 nm.

Melting points were determined using a Cybron Corporation Thermolyne apparatus equipped with a digital thermocouple (± 0.1°C) and are corrected. Elemental analysis was carried out by Canadian Microanalytical Service Ltd., Delta, B.C. High-resolution mass spectrometry (HRMS) for exact mass determination was performed on a CEC 21-110 mass spectrometer using an electron-impact energy of 70 eV. X-ray crystallographic analysis was performed on a Rigaku AFC5R diffractometer with graphite monochromated Cu-Kα radiation and a 12 kW rotating anode generator.

The cyclic voltammetry was performed on an EG&G PARC Potentiostat Model 173 and an EG&G PARC Universal Programmer Model 175. The measurements were done in a three-electrode electrochemical cell (5 mL volume) equipped with a spherical platinum working electrode, a platinum coil counter electrode, and a saturated calomel reference electrode (SCE). The acetonitrile solutions were deoxygenated by bubbling argon (presaturated with solvent) for 15 min prior to measurement. Tetraethylammonium perchlorate (0.1 mol dm^{-3}) was used as supporting electrolyte. The voltammograms were scanned at 100 mV s^{-1} and calibrated against the 1,4-dicyanobenzene reduction wave at –1.66 V (2*f*). In all cases, the electron transfer was irreversible and the half-wave potential was taken at 0.03 V before the peak potential (12).

Materials

1,4-Dicyanobenzene (98%, Aldrich) was purified by treatment with Norite in methylene chloride, followed by sublimation and recrystallization from 95% ethanol. 4-Iodobenzonitrile (Acros) and 4-bromobenzonitrile (98%, Aldrich) were recrystallized from hexanes while 4-chlorobenzonitrile (99%, Aldrich) was recrystallized from an ethanol–water mixture. Biphenyl (99%, Aldrich) was recrystallized from methanol. 4-Fluorobenzonitrile (99%, Aldrich), 4-chloroanisole (99%, Aldrich), 4-bromoanisole (99%, Aldrich), 4-iodoanisole (99%, Aldrich), and 1,1-diphenylethene (97%, Aldrich) were used as received.

Methanol was purified by reflux and fractional distillation over magnesium and stored over 3 Å molecular sieves (Aldrich). Hexanes for preparative chromatography were

© 1999 NRC Canada

fractionally distilled prior to use while ethyl acetate was used without further purification. Acetonitrile (anhydrous, Aldrich) for electrochemistry was used as received and transferred under nitrogen by cannula.

Irradiations

Investigative irradiations were performed in 2 mL sample volumes in 20 × 0.5 cm tubes using a 1 kW medium-pressure mercury-arc lamp (CGE) fitted with a Quartz water-cooled jacket immersed in a bath at 5°C. Reactions used for quantitative analyses were performed in 10 mL sample volumes in 20 × 1 cm tubes while large-scale preparative photochemical reactions were carried out in 20 × 2 cm tubes. All large-scale and quantitative-analysis reactions were deoxygenated by nitrogen ebullition for 15 min prior to irradiation. Tube distance from lamp axis was ca. 6 cm. Unless otherwise stated, all irradiations were carried out behind Pyrex ($\lambda > 280$ nm).

Dark control experiments were prepared for all major photochemical reaction mixtures. These consisted of solutions identical in composition to the ones being irradiated but stored in the dark. These controls were monitored after a time interval equal to that of the irradiated solutions and in no case was any reactivity observed, except where specifically mentioned.

Reaction details reported below are for the 10 mL quantitative-analysis samples unless otherwise stated. All yields were calibrated with respect to consumed starting material, i.e., the haloarene or 1,1-diphenylethene, depending on whether the product incorporates the 4-cyanophenyl/4-methoxyphenyl group or not. All quantitative-analysis GC runs were done in triplicate. Wherever relevant, isolated yields are also reported.

Irradiation of 1,1-diphenylethene (5) in methanol

A solution of 1,1-diphenylethene (**5**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 300 h. Calibrated GC-fid analysis indicated that 81% of **5** was consumed, yielding 1,1-diphenylethane (**8**, 11%), 1-methoxy-1,1-diphenylethane (**9**, 33%), and 1-methoxy-2,2-diphenylethane (**10**, 3%). Appreciable polymerization was also noticed.

Pure samples of **8** and **9** were isolated from a large-scale photoreaction (100 mL) identical in composition to the above, while **10** was obtained from an alternative photoreaction (vide infra).

*1,1-Diphenylethane (**8**)*: Isolated yield: 10%, colourless oil. IR (film, NaCl) υ (cm^{-1}): 3061, 3026, 2967, 1600, 1493, 1450, 1026, 699; ^{1}H NMR spectrum in accordance with published data (26): ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 1.64 (d, 3H, J = 7.3 Hz), 4.15 (q, 1H, J = 7.3 Hz), 7.13–7.31 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 21.8 (q), 44.7 (d), 126.0 (d), 127.6 (d), 128.3 (d), 146.3 (s); MS *m/z* (rel. int.): 182(35), 167(100), 165(31), 103(5), 82(6).

*1-Methoxy-1,1-diphenylethane (**9**)*: Isolated yield: 22%, colourless oil. IR (film, NaCl) υ (cm^{-1}): 3089, 3059, 3025, 2981, 2935, 2825, 1492, 1446, 1104, 755, 699; ^{1}H NMR spectrum in accordance with published data (6): ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 1.56 (s, 3H), 3.16 (s, 3H), 7.22–7.38 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 25.1 (q), 50.6 (q), 80.8 (s), 126.77 (d), 126.74 (d), 127.9 (d), 146.4 (s); MS *m/z* (rel. int.): 212 (3), 197 (100), 180 (19), 165 (32), 135 (53), 105(31), 91(6), 77(53).

Irradiation of 1,4-dicyanobenzene (6), biphenyl (7), and 1,1-diphenylethene (5) in methanol

A solution of 1,4-dicyanobenzene (**6**, 0.02 mol dm^{-3}), biphenyl (**7**, 0.05 mol dm^{-3}), and 1,1-diphenylethene (**5**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 6 h. Calibrated GC-fid analysis indicated 100% alkene consumption together with a 92% **6** recovery and an 84% **7** recovery. Products resulting from the photoreaction include 1-methoxy-1,1-diphenylethane (**9**, 7%), 1-methoxy-2,2-diphenylethane (**10**, 83%), and 1-methoxy-2,2-diphenylethene (**11**, 2%). A pure sample of **10** was obtained from a large-scale photoreaction (30 mL) identical in composition to the above.

The sim-MS of an identical photoreaction in methanol-*O-d* indicated 96% deuterium incorporation at the bisbenzylic position (C-2) of **10**.

*1-Methoxy-2,2-diphenylethane (**10**)*: Isolated yield: 81%, colourless oil. IR (film, NaCl) υ (cm^{-1}): 3087, 3061, 3027, 2982, 2922, 2874, 1601, 1495, 1451, 1121, 699; ^{1}H NMR spectrum in accordance with published data (27): ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 3.36 (s, 3H), 3.92 (d, 2H, J = 7.3 Hz), 4.29 (t, 1H, J = 7.3 Hz), 7.16–7.29 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 51.0 (d), 58.9 (q), 76.0 (t), 126.5 (d), 128.2 (d), 128.4 (d), 142.1 (s); MS *m/z* (rel. int.): 212 (4), 167 (100), 165 (36), 152 (19), 77(7).

Compound **11** was positively identified and characterized by alternative synthesis via a Wittig reaction from benzophenone and methoxymethyltriphenylphosphonium bromide, utilizing a literature procedure with minor modifications (28).

*1-Methoxy-2,2-diphenylethene (**11**)*: Colourless oil. IR (film, NaCl) υ (cm^{-1}): 3055, 3029, 2932, 2836, 1634, 1496, 1447, 1231, 1108, 764, 698; ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 3.76 (s, 3H), 6.45 (s, 1H), 7.18–7.40 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 60.6 (q), 120.5 (s), 126.4 (d), 126.6 (d), 127.6 (d), 128.0 (d), 128.2 (d), 128.3 (d), 129.8 (d), 137.6 (s), 140.4 (s), 146.4 (d); MS *m/z* (rel. int.): 210 (100), 167(98), 165(78), 139(7), 115(8), 89(7), 79(4).

Irradiation of 1-methoxy-2,2-diphenylethene (11) in methanol

A solution of 1-methoxy-2,2-diphenylethene (**11**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 300 h. Calibrated GC-fid analysis of the photolysate indicated that 86% of the starting material (**11**) was consumed, yielding 1,1-dimethoxy-2,2-diphenylethene (**12**, 40%), and 1,2-dimethoxy-1,1-diphenylethane (**13**, 23%).

A pure sample of **13** was obtained from a large-scale photoreaction (60 mL) of identical composition to the above, while a pure sample of **12** was obtained from an alternative photoreaction (vide infra).

*1,2-Dimethoxy-1,1-diphenylethane (**13**)*: Isolated yield: 7%, colourless oil. IR (film, NaCl) υ (cm^{-1}): 3059, 3027, 2981, 2931, 2891, 1493, 1448, 1191, 1130, 1102, 1078, 756, 700; ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 3.23 (s, 3H), 3.33 (s, 3H), 4.11 (s, 2H), 7.23–7.38 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 51.6 (q), 59.6 (q), 76.3 (t), 82.2 (s),

127.1 (d), 127.3 (d), 128.0 (d), 143.1 (s); MS *m*/*z* (rel. int.): 210(6), 197(100), 105(71), 77(69).

Irradiation of 1,4-dicyanobenzene (6), biphenyl (7), and 1-methoxy-2,2-diphenylethene (11) in methanol

A solution of 1,4-dicyanobenzene (**6**, 0.02 mol dm^{-3}), biphenyl (**7**, 0.05 mol dm^{-3}), and 1-methoxy-2,2-diphenylethene (**11**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 10 h. Calibrated GC-fid analysis of the final photolysate revealed that 92% of the starting alkene (**11**) was consumed while 100% of **6** and 79% of **7** remained unreacted. Products observed included 1,1-dimethoxy-2,2-diphenylethane (**12**, 85%) and 1,2-dimethoxy-1,1-diphenylethane (**13**, 2%).

A pure sample of **13** was isolated from a large-scale photoreaction (30 mL) identical in composition to the above.

*1,1-Dimethoxy-2,2-diphenylethane (**12**)*: Isolated yield: 56%, colourless oil. Spectral data in accordance with literature report (29): ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ: 3.31 (s, 6H), 4.23 (d, 1H, *J* = 7.6 Hz), 5.00 (d, 1H, *J* = 7.6 Hz), 7.18–7.33 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ: 54.0 (q), 54.5 (d), 106.4 (d), 126.4 (d), 128.3 (d), 128.7 (d), 141.1 (s); IR (film, NaCl) υ (cm^{-1}): 3030, 2930, 1601, 1495, 1450, 1120, 1062, 750, 700; MS *m*/*z* (rel. int.): 210(8), 167(12), 165(14), 152(6), 105(6), 77(6), 75(100).

Irradiation of 4-fluorobenzonitrile (1a) and 1,1-diphenylethene (5) in methanol

A solution of 4-fluorobenzonitrile (**1a**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**, 0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis of the final photolysate revealed that 67% of **5** had been consumed while **1a** showed a 100% recovery. The products observed included 1,1-diphenylethane (**8**, 2%), 1-methoxy-1,1-diphenylethane (**9**, 10%), and 1-methoxy-2,2-diphenylethane (**10**, 21%).

The sim-MS of an identical photoreaction in methanol-*O-d* indicated 47% deuterium incorporation at the bisbenzylic position (C-2) of **10**.

Irradiation of 4-fluorobenzonitrile (1a) in methanol

A solution of 4-fluorobenzonitrile (**1a**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 50 h. Calibrated GC-fid analysis of the final photolysate revealed no product formation together with 100% recovery of **1a**. Similar irradiation behind Quartz (λ > 190 nm) furnished identical results.

Irradiation of 4-chlorobenzonitrile (2a) and 1,1-diphenylethene (5) in methanol

A solution of 4-chlorobenzonitrile (**2a**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**, 0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis of the final photolysate revealed that 78% of **5** and 46% of **2a** had been consumed. The products observed included 1-methoxy-1,1-diphenylethane (**9**, 2%), 1-methoxy-2,2-diphenylethane (**10**, 26%), 1-methoxy-2,2-diphenylethene (**11**, 7%), 1,1-dimethoxy-2,2-diphenylethane (**12**, 6%), 1,2-dimethoxy-1,1-diphenylethane (**13**, 2%), 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**, 3%), 1-(4-cyanophenyl)-2,2-diphenylethane (**16a**, 12%), and 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (**17a**, 17%).

Pure samples of **16a** and **17a** were obtained from a large-scale photoreaction (60 mL) having an identical composition to the above. A pure sample of **15a** was obtained from an alternative photoreaction (vide infra).

The sim-MS of an identical photoreaction in methanol-*O-d* indicated 75% deuterium incorporation at the bisbenzylic position (C-2) of **10** and 64% deuterium incorporation at the bisbenzylic position (C-2) of **16a**.

Irradiation of 4-chlorobenzonitrile (2a) in methanol

A solution of 4-chlorobenzonitrile (**2a**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 50 h. Calibrated GC-fid analysis of the final photolysate revealed no product formation together with 100% recovery of **2a**.

Irradiation of 4-bromobenzonitrile (3a) and 1,1-diphenylethene (5) in methanol

A solution of 4-bromobenzonitrile (**3a**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**, 0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis of the final photolysate revealed that 90% of **5** and 54% of **3a** had been consumed. The products observed included 1-methoxy-1,1-diphenylethane (**9**, 2%), 1-methoxy-2,2-diphenylethane (**10**, 17%), 1-methoxy-2,2-diphenylethene (**11**, 4%), 1,1-dimethoxy-2,2-diphenylethane (**12**, 5%), 1,2-dimethoxy-1,1-diphenylethane (**13**, <2%), benzonitrile (**14a**, 13%), 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**, 5%), 1-(4-cyanophenyl)-2,2-diphenylethane (**16a**, 8%), 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (**17a**, 11%), and 3-cyano-9-phenylphenanthrene (**18a**, 4%).

Benzonitrile (**14a**) was identified by comparison with a commercial sample. A pure sample of **18a** was obtained from an alternative photoreaction (vide infra). The sim-MS of an identical photoreaction in methanol-*O-d* indicated 77% deuterium incorporation at the bisbenzylic position (C-2) of

© 1999 NRC Canada

10 and 50% deuterium incorporation at the bisbenzylic position (C-2) of **16a**.

Irradiation of 4-bromobenzonitrile (3a) in methanol

A solution of 4-bromobenzonitrile (**3a**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 50 h. Calibrated GC-fid analysis of the final photolysate revealed 100% **3a** consumption and the formation of benzonitrile (**14a**) in 71% yield.

Irradiation of 4-iodobenzonitrile (4a) and 1,1-diphenylethene (5) in methanol

A solution of 4-iodobenzonitrile (**4a**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**, 0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis of the final photolysate revealed that 88% of **5** and 100% of **4a** had been consumed. The products observed included 1-methoxy-1,1-diphenylethane (**9**, 2%), 1-methoxy-2,2-diphenylethane (**10**, 12%), 1-methoxy-2,2-diphenylethene (**11**, 11%), 1,1-dimethoxy-2,2-diphenylethane (**12**, 19%), 1,2-dimethoxy-1,1-diphenylethane (**13**, <2%), benzonitrile (**14a**, 23%), 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**, 38%), 1-(4-cyanophenyl)-2,2-diphenylethane (**16a**, 5%), 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (**17a**, 5%), and 3-cyano-9-phenylphenanthrene (**18a**, 21%).

Pure samples of **15a** and **18a** were obtained from a large-scale photoreaction (60 mL) identical in composition to the above.

The sim-MS of an identical photoreaction in methanol-*O-d* indicated 86% deuterium incorporation at the bisbenzylic position (C-2) of **10** and 41% deuterium incorporation at the bisbenzylic position (C-2) of **16a**.

*1-(4-Cyanophenyl)-2,2-diphenylethene (**15a**)*: Isolated yield: 36%, white crystals, mp 116.5–117.1°C (corrected), lit. (30) mp 107–109°C. Colourless needle with dimensions 0.06 × 0.17 × 0.30 mm, μ(M_O-Kα) = 0.73 cm^{-1}. Data were collected using a Rigaku AFC5R diffractometer in the range 8.56 < 2θ < 23.94°. Refinement was by full-matrix least-squares on F for 512 observed reflections and 117 variable parameters using teXsan crystallographic software package.[4] Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically; the phenyl group was refined as a rigid body. Conventional R (for $I > 3\sigma(I)$) = 0.059 and R_w = 0.068. Largest difference peak and hole 0.21 and –0.22 e $Å^{-3}$.

Irradiation of 4-iodobenzonitrile (4a) in methanol

A solution of 4-iodobenzonitrile (**4a**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 50 h. Calibrated GC-fid analysis of the final photolysate revealed 89% **4a** consumption and the formation of benzonitrile (**14a**) in 85% yield.

Irradiation of 1-(4-cyanophenyl)-2,2-diphenylethene (15a) in methanol

A solution of 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**, 0.025 mol dm^{-3}) in methanol (2 mL) was irradiated for 6 h. No consumption of the starting material was observed. Similarly, a solution of **15a** (0.025 mol dm^{-3}) and 4-chlorobenzonitrile (**2a**, 0.025 mol dm^{-3}) in methanol (2 mL) did not result in any consumption of starting materials after 6 h of irradiation. Conversely, a solution of **15a** (0.025 mol dm^{-3}) and 4-iodobenzonitrile (**4a**, 0.025 mol dm^{-3}) in methanol (2 mL) resulted in 98% **15a** and 72% **4a** consumption after 6 h irradiation. Also observed was the formation of benzonitrile (**14a**, 80%) and 3-cyano-9-phenylphenanthrene (**18a**, 98%).

Irradiation of 4-chloroanisole (2b) and 1,1-diphenylethene (5) in methanol

A solution of 4-chloroanisole (**2b**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**) (0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis revealed 78% consumption of **5** and 79% consumption of **2b** together with the formation of 1,1-diphenylethane (**8**, 2%), 1-methoxy-1,1-diphenylethane (**9**, 5%), 1-methoxy-2,2-diphenylethane (**10**, 5%), anisole (**14b**, 14%), 1-(4-methoxyphenyl)-2,2-diphenylethene (**15b**, 40%), 1-(4-methoxyphenyl)-2,2-diphenylethane (**16b**, <2%), 1-methoxy-2-(4-methoxyphenyl)-1,1-diphenylethane (**17b**, 4%), and 3-methoxy-9-phenylphenanthrene (**18b**, 8%).

Anisole (**14b**) was identified by comparison with a commercial sample. A pure sample of **15b** was obtained by an alternative synthesis method involving the dehydration of 2-(4-methoxyphenyl)-1,1-diphenylethanol (**20**), which was synthesized via a Grignard reaction between 4-methoxybenzylmagnesium chloride and benzophenone. The Grignard reagent was prepared according to a reported procedure (31). The intermediate alcohol **20** was subsequently dehydrated by refluxing with toluenesulphonic acid in benzene.

A pure sample of (**17b**) was obtained by methylation of the alcohol **20** according to a published procedure (33).

*1-Methoxy-2-(4-methoxyphenyl)-1,1-diphenylethane (**17b**)*: White crystals, mp 102.8–103.7°C (corrected), lit. (34) mp 94–95°C. Spectroscopic data in agreement with published results (34): IR (film, NaCl) υ (cm^{-1}): 3057, 3024, 2936, 2831, 1611, 1513, 1245, 1179, 1077, 1036, 828, 755, 701; ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ 3.17 (s, 3H), 3.55 (s, 2H), 3.72 (s, 3H), 6.59–6.67 (4H, AA′BB′), 7.17–7.27 (m, 10H); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ 40.5 (t), 50.8 (q), 55.0 (q), 83.4 (s), 112.8 (d), 126.7 (d), 127.6 (d), 127.7 (d), 128.7 (d), 131.3 (d), 144.8 (s), 157.8 (s); MS *m*/*z* (rel. int.): 77(31), 105(39), 197(100), 286(1).

Compound **16b** was present in too small amounts to be isolated and was identified by GC–MS only.

*1-(4-Methoxyphenyl)-2,2-diphenylethane (**16b**)*: MS *m*/*z* (rel. int.): 77(5), 121(100), 152(7), 165(13), 167 (25), 288(3).

A pure sample of **18b** was obtained from an alternative photoreaction (vide infra).

Irradiation of 4-chloroanisole (2b) in methanol

A solution of 4-chloroanisole (**2b**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis revealed 88% **2b** consumption together with the formation of anisole (**14b**, 56%) and 1,4-dimethoxybenzene (**19**, 12%).

Irradiation of 4-bromoanisole (3b) and 1,1-diphenylethene (5) in methanol

A solution of 4-bromoanisole (**3b**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**, 0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis revealed 69% consumption of **5** and 100% consumption of **3b**, together with the formation of 1-methoxy-1,1-diphenylethane (**9**, 2%), anisole (**14b**, 29%), 1-(4-methoxyphenyl)-2,2-diphenylethene (**15b**, 30%), 1-(4-methoxyphenyl)-2,2-diphenylethane (**16b**, <2%), and 3-methoxy-9-phenylphenanthrene (**18b**, 13%).

Irradiation of 4-bromoanisole (3b) in methanol

A solution of 4-bromoanisole (**3b**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 25 h. Calibrated GC-fid analysis revealed complete consumption of **3b** and the formation of 84% anisole (**14b**).

Irradiation of 4-iodoanisole (4b) and 1,1-diphenylethene (5) in methanol

A solution of 4-iodoanisole (**4b**, 0.05 mol dm^{-3}) and 1,1-diphenylethene (**5**,.0.10 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis indicated that 49% of **5** and 100% of **4b** had been consumed. Products observed included anisole (**14b**, 22%), 1-(4-methoxyphenyl)-2,2-diphenylethene (**15b**, 40%), 1-(4-methoxyphenyl)-2,2-diphenylethane (**16b**, <2%), and 3-methoxy-9-phenylphenanthrene (**18b**, 16%).

Irradiation of 4-iodoanisole (4b) in methanol

A solution of 4-iodoanisole (**4b**, 0.05 mol dm^{-3}) in methanol (10 mL) was irradiated for 75 h. Calibrated GC-fid analysis revealed 64% **4b** consumption together with the formation of 87% anisole (**14b**). The reaction turned dark red upon photolysis.

Irradiation of 1-(4-methoxyphenyl)-2,2-diphenylethene (15b)

A solution of 1-(4-methoxyphenyl)-2,2-diphenylethene (**15b**, 0.025 mol dm^{-3}) and 4-iodoanisole (**4b**, 0.025 mol dm^{-3}) in methanol (2 mL) resulted in 96% **15b** and 79% **4b** consumption after 6 h irradiation. Also observed was the formation of anisole (**14b**, 80%) and 3-methoxy-9-phenylphenanthrene (**18b**, 94%).

A pure sample of **18b** was isolated from a large-scale photoreaction (30 mL) of identical composition to the above.

*3-Methoxy-9-phenylphenanthrene (**18b**)*: Isolated yield: 60%, colourless oil. Spectroscopic data in agreement with published results (35): IR (film, NaCl) υ (cm^{-1}): 3057, 3022, 2932, 2833, 1621, 1598, 1503, 1439, 1429, 1253, 1221, 1177, 1036, 771, 701; ^{1}H NMR (250.13 MHz, $CDCl_3$, TMS) δ 4.02 (3H, s), 7.25 (dd, 1H, J = 8.5, 2.4 Hz), 7.43–7.63 (m, 8H), 7.80 (d, 1H, J = 8.5 Hz), 7.91 (d, 1H, J = 8.2 Hz), 8.07 (d, 1H, J = 2.4 Hz), 8.68 (d, 1H, J = 7.6 Hz); ^{13}C NMR (62.90 MHz, $CDCl_3$) δ 55.5 (q), 103.8 (d), 113.4 (d), 117.0 (d), 126.0 (d), 126.2 (s), 126.5 (d), 126.9 (d), 127.2 (d), 128.3 (d), 130.0 (s), 130.09 (d), 130.13 (d), 131.2 (s), 131.4 (s), 136.4 (s), 140.9 (s), 158.5 (s); MS *m*/*z* (rel. int.): 239 (42), 269 (30), 284 (100); HRMS: calcd.: 284.1201, found: 284.1196.

Thermal decomposition of 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (17a) and 1-methoxy-2-(4-methoxyphenyl)-1,1-diphenylethane (17b)

A solution of 1-(4-cyanophenyl)-2-methoxy-2,2-diphenylethane (**17a**, 0.025 mol dm^{-3}) in methanol (2 mL) was left to stand in the dark for 5 days. GC–MS analysis indicated partial conversion to 1-(4-cyanophenyl)-2,2-diphenylethene (**15a**). Upon addition of a drop of hydrochloric acid, GC–MS indicated almost complete conversion of **17a** to **15a**. 1-Methoxy-2-(4-methoxyphenyl)-1,1-diphenylethane (**17b**) underwent conversion to 1-(4-methoxyphenyl)-2,2-diphenylethene (**15b**) under similar conditions.

Improved hydrophobic zeolites to fill silicone membranes for ethyl acetate extraction from water by pervaporation[1]

Hu Yang, Zhenghua Ping, Yingcai Long, and Quang Trong Nguyen

Abstract: Two types of hydrophobic zeolites Y were prepared by treating the NaY-type zeolite with $SiCl_4$, with or without subsequent hydrothermal treatment. X-ray diffraction analysis showed that the framework of the two modified zeolites Y are more perfect than that of the NaY one, and the Si/Al ratio is greatly enhanced by hydrothermal treatment. The determined sorption isotherms indicate an improvement of the ester-to-water sorption ratio with the increase in Si/Al ratio. When the zeolite-filled silicone membranes are used in separation of ethyl acetate – water mixture by pervaporation, both the total permeation flux and the selectivity to the ester are improved by the use of the hydrophobic zeolite Y as the filler in the membrane. The stronger the hydrophobicity of the zeolite Y, the higher the filled membrane selectivity.

Key words: hydrophobic zeolites Y, silicone-filled membranes, ethyl acetate – water mixture, sorption, pervaporation.

Résumé : On a préparé deux types de zéolithes Y hydrophobes par traitement du zéolithe de type NaY avec le $SiCl_4$, avec ou sans traitement hydrothermique subséquent. La diffraction des rayons X a montré que l'armature des zéolithes ainsi modifiés est plus parfaite que la structure du zéolithe NaY, et que le rapport Si/Al est fortement amélioré par traitement hydrothermique. Les isothermes de sorption déterminées indiquent une amélioration du rapport de la quantité d'ester sorbée à celle de l'eau avec l'augmentation du rapport Si/Al. Quand les membranes en silicone chargées de zéolithes sont utilisées en séparation du mélange eau – acétate d'éthyle par pervaporation, le flux total de perméation et la sélectivité à l'ester sont tous les deux améliorés par l'utilisation des zéolithes Y hydrophobes comme charge. Plus l'hydrophobie du zéolithe Y est élevée, plus la sélectivité de la membrane chargée de zéolithe est élevée.

Mots clés : zéolithes Y hydrophobes, membranes en silicone chargées, mélange eau – acétate d'éthyle, sorption, pervaporation.

Introduction

Since 1986, zeolite-filled polymer membranes have gained increasing attention in the separation of mixtures of water – volatile organic compounds (VOCs) by the pervaporation process (1–8). The separation by this membrane process is based on the difference in the permeation rates of the components, which are selectively sorbed at the membrane upstream face. The process is industrially used for alcohol dehydration and is attractive for the extraction of hydrophobic VOCs from water. It uses polymers with strong affinity to the compound to be preferentially permeated as membrane materials. For VOCs extraction from water, poly(dimethylsiloxane), or silicone rubber, is generally chosen as the membrane material. To improve its selectivity to VOCs, the latter can be filled with a zeolite. Zeolites are used for their high selectivity in catalysis or in separation as sorbent with fixed pore size. By mixing it with a polymer, improvements in membrane performances were observed.

According to its composition, zeolites exhibit different surface properties. For separation by pervaporation, membranologists focused on their hydrophobic and hydrophilic properties. Gao et al. (2) showed that PVC membranes filled with different hydrophilic zeolites to separate water–ethanol mixture improved the removal of water in pervaporation.

For the extraction of VOCs from water by pervaporation, hydrophobic zeolites (such as ZSM-5 or silicalite-1) as fillers impart good selectivity and permeation flux to silicone membranes (3–5). Smolders and co-workers (3) brought out a transport model to explain the function of silicalite in silicone membranes. According to this model, the hydrophobic silicalite-1 sorbs preferentially the organic solvent and prevents water molecules from entering the zeolite pores. The organic molecules can travel through zeolite pores and reach the downstream side of the membrane by less tortuous paths than water molecules.

The membrane performances depend strongly on the zeolite properties. In our previous works (9–11), we systemati-

cally investigated the relationship between the properties of the silicalite-1 filler and the resulting filled silicone membranes. The results showed that the membrane selectivity to ethanol increases with the silicon/aluminum (Si/Al) ratio of the ZSM-5 zeolite. Silicalite-1, an aluminum-free analogue of the ZSM-5 zeolite, which has the strongest affinity towards organic solvent, gave rise to a better membrane selectivity than ZSM-5. However, impurities coming from the raw materials are generally present in synthesized silicalite-1, and cause a loss in the zeolite affinity to the organic compounds. When such residual impurities are eliminated through acid and hydrothermal treatments (12), the silicalite hydrophobicity, and consequently the membrane selectivity, increase.

Besides the hydrophobicity, the zeolite pore size must be the other main factor that governs the membrane performances. However, no other types of hydrophobic zeolite were studied so far (except the ZSM-5). An interesting zeolite is the hydrophilic zeolite NaY; it belongs to faujasite (FAU) type framework. With a 12-oxygen ring and a pore size of ca. 0.8 nm, this zeolite has much larger pore than the common silicalite with 0.6 nm pore and 10-oxygen ring. Used as a filler in its hydrophobic form, one can expect to separate larger molecules or to have larger flux, compared with conventional silicalite-filled membranes. In general, the Si/Al ratio of the zeolite has a strong influence on the capacity of polar molecule sorption (13, 14). In the present work, hydrophobic zeolites Y were prepared by increasing the Si/Al ratio. To obtain the highest Si/Al ratio, we chose to combine two conventional chemical treatments, the $SiCl_4$ treatment (15, 16) and the hydrothermal treatment (17, 18). The structure of the obtained silicalites Y was studied with different techniques, and their characteristics in sorption and desorption of water and ethyl acetate were determined. In a last part, the separation performances of silicone membranes filled with different silicalites Y in the removal of ethyl acetate from water are compared together.

Experimental

Zeolite materials

The NaY zeolite powder was supplied by Wenzhou Corp. (China) with a Si/Al ratio of 2.5. The conversion of the hydrophilic NaY to a hydrophobic one was carried out according to a previously described procedure (16). It was first dehydrated at 502°C under nitrogen atmosphere, then contacted with a $SiCl_4$ saturated nitrogen stream at a flow ratio of 150 mL/min for 4 h at increasing temperatures (from 127 to 520°C). The chemically treated zeolite was flushed with dry nitrogen at 327°C for many hours to eliminate all residual reactant and gaseous reaction product, then cooled down to room temperature and washed with distilled water until pH = 7. Such a Si-enriched zeolite Y is called SY-1 in this work. When the SY-1 sample is hydrothermally treated at 802°C for 12 h, a second sample, SY-2, is obtained.

Characterization of zeolite structure

The powder X-ray diffraction patterns were acquired at room temperature on a Rigaku D-MAX/II A diffractometer at the frequency of the Cu-Kα radiation. The samples were dried at 300°C and then equilibrated in a desiccator containing saturated NaCl aqueous solution for 5 days. The Si was used as internal standard to correct the 2θ angles. The peaks at 2θ range of 50°–60°, such as (11,11,1), (15,3,3) reflection, were used to calculate the unit cell parameters of zeolites, and the least-squares method was used to adjust it. The starting materials were assumed to be 100% crystalline.

The ^{27}Al and ^{29}Si MAS NMR spectra were recorded using a Bruker MSL-300 spectrometer, whose ^{27}Al resonance frequency was 78.20 MHz. The rotor was spun at 3.5 kHz. The radio-frequency field was 45.5 kHz (corresponding to a $\pi/2$ pulse width of 5.5 μs); the recycle time is set at 100 ms. $AlCl_3(H_2O)_6$ (solid) was used as a reference. To make the structure analysis easier, the sample was presaturated with *acetylacetone* in a 50% ethanol solution in a reactor for a few days, then dried again. In the ^{29}Si MAS NMR measurement, the ^{29}Si resonance frequency used was 59.595 MHz. The rotor was spun at 3.0 kHz. The radio frequency field was 37.0 kHz (corresponding to a $\pi/3$ pulse width of 4.5 μs); the recycle time was set at 2 s; Q_8M_8 was used as a second reference for the ^{29}Si chemical shift.

The specific surface area and the pore volume were determined from N_2 adsorption isotherms at 77.35 K, using a Micrometric ASAP 2000 instrument.

Sorption and desorption measurements

The sorption isotherms of pure ethyl acetate and pure water vapors were measured in a Sartorius-7012 super-micro electrobalance at 25°C. The sample was activated in situ at 350°C under vacuum (<2.7 Pa) until complete desorption before the measurement. The vapor sorption capacity is expressed as the weight gain *per* 100 g of dry material.

Desorption was performed by thermogravimetric analysis (TGA) (with a NETZSCH TG-209 apparatus) on samples pre-equilibrated with a saturated solvent vapor at room temperature.

Preparation of zeolite Y – silicone membrane

The size of our FAU zeolite is about 1 μ, it is very hard to disperse, especially in high loading amount. So only 5% (w/w) filled PDMS was prepared. The membrane is prepared as the following. The zeolites were dehydrated at 500°C for 5 h before use. Ninety-five parts of a two- component silicone rubber (room temperature vulcanizable silicone rubber), 5 parts of zeolite, and 150 parts of solvent (cyclohexane) were mixed in a poly(ethylene) beaker until a homogeneous suspension was obtained. The suspension was then cast on a polyester film with a knife, and was left at room temperature for 48 h for vulcanization. The obtained composite membrane of ca. 200 μm thick was used in pervaporation without further treatment, and the SEM was used to characterize the structure of filled membrane.

Sorption and pervaporation measurements

The procedure for sorption in the membranes is the same as that for zeolites, except that the sample was activated at 50°C under vacuum (<2.7 Pa) before sorption. The pervaporation separation of a 1.23% ethyl acetate aqueous solution was measured at 30°C under 100 Pa pressure on the downstream side, using a stainless steel cell with an effective membrane area of 28 cm^2. The permeate collected in a trap cooled in liquid nitrogen for given time intervals was

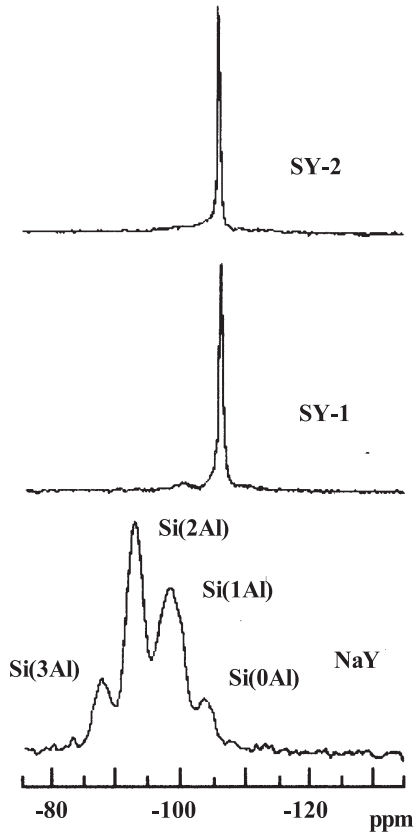
analyzed by gas chromatography. The permeation flux J and selectivity α were calculated as follows:

$$J = W_p/At$$

$$\alpha = (C_{ester}/C_w)^p/(C_{ester}/C_w)^f$$

where W_p is the weight of the permeate, A is the membrane area, t is the pervaporation time, C_{ester} and C_w are, respectively, the ester and the water weight fractions, and p, f superscripts refer to the permeate and the feed liquids, respectively.

Fig. 2. ^{29}Si MAS NMR spectra of FAU zeolite.



Results and discussion

Structure characterization of modified Y zeolites

The XRD (Fig. 1) shows that both samples maintain high crystallinity. Compared with the characteristic peaks in NaY, there are peak shifts toward higher angles; the peak shifts are larger for SY-2 than for SY-1, indicating a higher Si/Al ratio of SY-2.

In the ^{29}Si MAS NMR (Fig. 2), there still remains a Si(1Al) peak, –100 ppm for SY-1. The full width at half maximum of Si(0Al), –106.8 ppm, for SY-1 and SY-2 is 0.64 and 0.52 ppm, respectively. This indicates that the SY-2 framework has higher crystallinity. The ^{27}Al NMR was listed in Fig. 3. For SY-1, it contains mainly framework Al, 58.8 ppm, but for SY-2, there are mainly the octahedrally and tetrahedrally coordinated nonframework Al, 0.16 and 51.4 ppm (19–20). Such nonframework Al can be removed by acid treatment, its influence on the sorption property of zeolite is very limited (21).

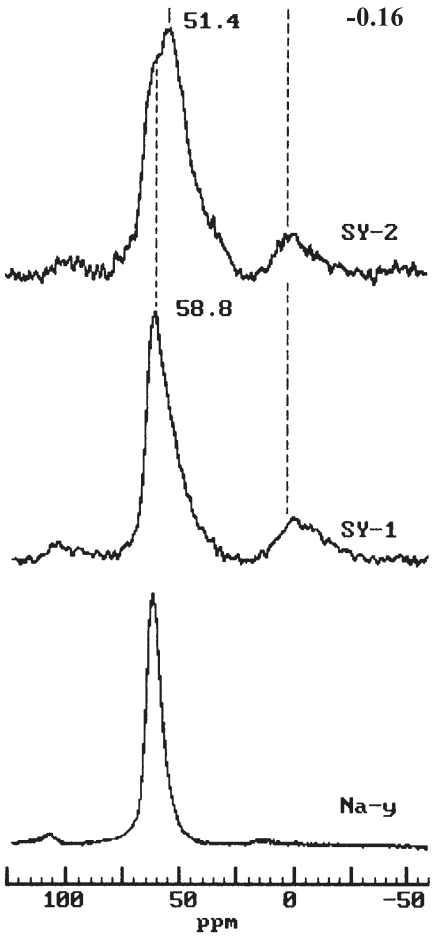
The N_2 sorption curve is shown in Fig. 4. Almost no hysteresis is found in N_2 sorption–desorption cycles, indicating negligible second pore.

Sorption and desorption characteristics

The ethyl acetate sorption isotherms of in the SY-1 and SY-2 zeolites are illustrated in Fig. 5. The sorption amounts at saturation for the SY-1 and SY-2 zeolites (ca. 19 and 15 wt.%, respectively) are consistent with their specific surface area calculated from nitrogen sorption (Table 1): their ratio,

© 1999 NRC Canada

Fig. 3. ^{27}Al MAS NMR spectra of FAU zeolite.



1.2, is practically the same as that of the BET surface areas obtained with nitrogen sorption. The decrease in the sorption amounts at saturation following the hydrothermal treatment corresponds to the pore volume reduction with the decrease in the Al content in the framework. The hydrophilic NaY sample also has strong ester sorption capacity, in spite of its hydrophilicity; this is due to the strong electrostatic interactions between the Na^+ cations and the polar ester molecules.

In the case of water sorption (Fig. 6), the hydrophilic zeolite NaY achieves sorption saturation at very low partial pressure, and reaches high sorption amounts. On the contrary, the dealuminated samples have much lower water sorption amounts compared with that of the zeolite NaY, and with the ester amounts sorbed in the SY samples. The SY-2 sample, which sorbs much less water than the SY-1, appears to have much more hydrophobic pores than SY-1, as the ratio of sorbed amounts is far below that of the BET surface areas. In other words, the pore surface of the SY-2 zeolite strongly repels water vapor, although the pores are fully accessible to the small water molecules. Such equilibrium behavior would favor a sorption-based separation of water – hydrophobic component mixtures. If we use the ratio of the sorption amount of ester to that of water at 0.05 relative vapor pressure to express the selectivity, the SY-2 sorption selectivity would be higher than 70.

Table 1. Some characteristics of studied zeolites Y: Si/Al ratio, BET surface area.

Zeolite type	NaY	SY-1	SY-2
Si/Al (XRD)	2.5	29.8	>100
BET surface area (m^2/g)	—	651	543

The desorption property of zeolite is another key factor for separation. It reflects the interaction energy between zeolite and the sorbed solvent. The higher the desorption temperature, the stronger the affinity of zeolite to the sorbed species. If the interaction is too strong, the sorbed solvent cannot be easily desorbed out of the membrane downstream side. The permeation flux of the species will decrease due to an extra resistance induced by the zeolite, and a smaller effect of the zeolite on the selectivity will result (22). The apparent endothermic effect can be observed in the DTA curves of NaY sorbed water and ester (see Fig. 7), which shows a very strong interaction existed between NaY and ester and water (electrostatic type). The strong interaction also reflects in the highest desorption T in NaY. The desorption temperature of ester on SY-2 zeolites lies in the medium, presenting both the character of a stronger affinity to ester and the easiness to desorb. SY-2 is the best sorbent for ester or organic VOCs among the studied zeolites.

Sorption and pervaporation characteristics of membrane

STM micrograph of the cross-section of the filled membrane is shown in Fig. 8. There are no apparent aggregates of the zeolite particles, and the adhesion between silicone and zeolite particles seem to be good, as there is no visible void space around the particles.

The sorption isotherms of ethyl acetate in pure silicone and zeolite-filled membranes are shown in Fig. 8. Zeolite particles, due to its high ester sorption capacity, increase the ester sorption extent of the membranes. However, the zeolite particles also act as physical crosslinks of the silicone polymer, thus reinforcing its elastic forces and its resistance to the swelling by solvent sorption. The final sorption capacity of filled membranes is the result of the balance of these trends. The data (Fig. 9) show that the filled membranes sorb more ester than the pure silicone membrane, with the highest sorption extents for the NaY-zeolite-filled membrane. Figure 10 shows the water absorption isotherms for different membranes. The NaY-filled membrane has by far the highest sorption extent. The membranes filled with the SY-1 and SY-2 zeolites absorb less water than the pure silicone membrane. Thus, the incorporation of hydrophobic zeolites into silicone rubber enhances the materials sorption selectivity, by improving the ester sorption while reducing water sorption. The sorption extent of ester in the composite membrane depends not only on the pore volume of the used zeolite, but also on its hydrophobicity. The latter property is probably the main factor for the selectivity change, as the water sorption is drastically reduced when the Si/Al ratio increases.

The pervaporation results of a 1.23 wt.% ester solution through the pure silicone membrane and the membranes filled with 5 wt.% of zeolite Y (Table 2) show that both the water and ethyl acetate fluxes through the filled membranes

are higher than those through the pure silicone membrane. This can be explained by the increase in both the sorption and the overall diffusion coefficients of the ester molecules. Indeed, the diffusion of a molecule in a polymer is connected with the ability of the polymer to physically accommodate the permeate, and to continually provide opportunity, in the form of randomly generated void, for the permeants to progress (23). The ester molecules which are sorbed in the zeolite pores can be rapidly exchanged with the coming ester molecules. Although the free volume in the polymer phase would not change, this results in a faster migration down the chemical potential gradient, through the inter-particle polymer phase. As the sorption is selective in the SY-type zeolite, water molecules do not preferentially take the same paths through the zeolite particles due to the sorption selectivity and have to go around them in the polymer phase. Thus, the water flux decreases, and the ester flux increases, leading to an increase in the selectivity of the SY-zeolite-filled membranes. The increase in the total flux means that the gain in the ester flux is larger than the loss in water flux. Due to its higher hydrophobicity, the SY-2 gives rise to the most selective membrane. The situation is reversed for the membrane filled with the NaY zeolite. The latter zeolite is hydrophilic, thus favors water migration in its pores. However, the selectivity is only reduced from that

© 1999 NRC Canada

Table 2. Pervaporation characteristics of zeolite Y-filled silicone membranes.

		Membrane filled with		
	Unfilled	NaY	SY-1	SY-2
Total flux (g/m^2 h 100 μm)	279	288	296	293
Water flux (g/m^2 h 100 μm)	61	74	53	44
Selectivity	284	228	365	455

of the pure silicone membrane, but not reversed, due to the overall hydrophobicity of the filled membranes. It also appears that the sorption capacity of the zeolite is not the major factor in the selectivity improvement of the zeolite-filled membranes.

In conclusion, it appears that (*i*) the hydrophobic zeolites Y as fillers have a significant effect on the silicone membrane properties, even at a filler content level as low as 5 wt.%, and (*ii*) the ester sorption, permeation selectivity, and flux of the filled membranes increase with the filler Si/Al ratio.

Thiol functionalization of surfaces for biosensor development

Mark E. McGovern and Michael Thompson

Abstract: The immobilization of biomolecules on substrate surfaces for biosensor development requires linking molecules that must meet a specific set of criteria. Two such agents based on bifunctional alkyltrichlorosilane structures, 1-bromo-11-(trichlorosilyl)-undecane and 1-(thiotrifluoroacetato)-11-(trichlorosilyl)-undecane, are employed to generate thiol-functionalized surfaces either by nucleophilic substitution followed by reduction (bromine-containing derivative) or deprotection (fluorine-containing compound). Both molecules have been attached to the surfaces of silicon wafers in conjunction with the diluent silane, octyltrichlorosilane. X-ray photoelectron spectroscopic analysis in the conventional and angle-resolved modes confirms that both silanization reactions were successful. The alkyl-bromine surfaces were subjected to treatment with a set of nucleophilic reactants followed by reduction and derivatization with trifluoroacetic anhydride. The latter in conjunction with surface analysis was used to estimate the level of thiol functionalization achieved. The fluorine-containing undecane surface has been studied by surface analysis both before and after deprotection of the thiol group by hydroxylamine solution. The results indicate that a high coverage of the surface was found for the protected moiety, with approximately 10% of the trifluoro acetate groups remaining after the deprotection procedure.

Key words: bifunctional silanes, thiol surface functionalization, biomolecule immobilization, X-ray photoelectron spectroscopy.

Résumé : Lors du développement de biosenseurs, l'immobilisation de biomolécules sur les surfaces de substrats requière la présence de molécules liantes qui répondent à un ensemble de critères bien définis. Pour générer des surfaces avec thiols fonctionnalisés, on a utilisé deux de ces agents comportant des structures alkyltrichlorosilanes bifonctionnelles, les 1-bromo-11-(trichlorosilyl)-undécane et 1-(trifluoroacétato)-11-(trichlorosilyl)-undécane, en faisant appel à une réaction de substitution nucléophile suivie d'une réduction (dérivé contenant du brome) ou une réaction de déprotection (composé contenant du fluor). Les deux molécules ont été liées aux surfaces de tranches silicium en même temps que le silane utilisé pour diluer, l'octyltrichlorosilane. Des analyses par spectroscopie photoélectronique de rayons X, dans les modes tant conventionnels que résolus en fonction de l'angle, confirment que les deux réactions de silanisation ont réussi. Les surfaces du bromure d'alkyle ont été soumises à un traitement par un ensemble de réactifs nucléophiles, suivi d'une réduction et d'une transformation en dérivé à l'aide de l'anhydride trifluoroacétique. Pour évaluer le degré de fonctionnalisation du thiol, on a fait appel à ce traitement combiné avec une analyse de surface. On a étudié la surface undécane contenant du fluor par une analyse de surface avant ainsi qu'après la déprotection du groupe thiol par une solution d'hydroxylamine. Les résultats indiquent que la portion protégée de la surface est bien recouverte; on a trouvé qu'environ 10 % des groupes trifluoroacétates sont encore présents après la déprotection.

Mots clés : silanes bifonctionnels, fonctionnalisation d'une surface de thiol, immobilisation de biomolécules, spectroscopie photoélectronique des rayons X.

[Traduit par la Rédaction]

Introduction

A key feature of the construction of biosensors is the immobilization of protein molecules or single strands of oligonucleotide to the surface of the device (1). Many strategies have been evolved for the immobilization of biomolecules in general to surfaces (2–11). One route to such a structure is that provided by bifunctional silanes, especially if the underlying device surface is amenable to silane chemistry. Such a moiety must contain a hydrocarbon chain of 8–18 carbons in length for the self-assembly process to function and be capable of synthesis and purification by relatively facile procedures (!12). An additional factor is the possibility for ease of surface characterization by X-ray photoelectron spectroscopic (XPS) analysis (13). The bifunctional trichlorosilanes constitute an attractive route for the immobilization of biomolecules on sensor surfaces.

Several reviews have been published recently regarding silane technology and self-assembled monolayers, and their many potential applications in science and industry (14–17).

Trichlorosilanes can be synthesized by controlled reaction of a Grignard or alkyl lithium reagent with tetrachlorosilane or by hydrosilylation using trichlorosilane and a terminal alkene (13, 14). The latter is the preferred route because it produces a monoalkyltrichlorosilane in high yield, and is tolerant of many types of multifunctional molecules. Silanes with 11-, 16-, or 17-carbon chain lengths are most commonly used, both because they can undergo the self-assembly process, and the fact that intermediates are readily accessible. ω-Undecenyl alcohol or the carboxylic acid are both readily available at low cost and can be transformed into virtually any desired functionality. ω-Hexa- and ω-heptadecenyl intermediates are unavailable, but can be made by cross-coupling ω-undecenyl bromide with 1,5-bromopentane or 1,6-bromohexane to yield the long-chain bromides, which require extensive purification to be useable for hydrosilylation (13, 15). With respect to reaction with a biochemical species, the terminal group of a trichlorosilane can be employed as a nucleophile or act as a leaving group in an S_N2 environment. An example of a compound that can act in both capacities is 1-bromo-11-(trichlorosilyl)-undecane (BTU). (18–21). This molecule can be used to produce an alkylbromide functional surface, which reacts directly with nucleophile-bearing probes, or it can be transformed after the silanization reaction into a nucleophilic group such as a thiol. Other leaving groups such as the more reactive chloro and iodo acetates as well as benzylic bromides have been developed (22), but the main disadvantage with these molecules is their complex synthesis. An alternative pathway to the generation of thiol-functionalized silanes is the direct incorporation of a protected sulfur-containing functionality. Such an acetyl-protected thiol has been described in the literature (13), but appears to suffer from several drawbacks. Deprotection requires strongly basic conditions, which are detrimental to silane adhesion, and the deprotection step itself may be difficult to effect completely. Accordingly, we chose to synthesize a new silane 1-(thiotrifluoroacetato)-11-(trichlorosilyl)-undecane (TTU), which incorporates the trifluoroacetyl group (TFA). The trifluoroacetyl thiol esters are compounds known to be stable in the absence of moisture (23), and the TFA functionality is hydrolyzed in a facile manner, under mild conditions, resulting in greater yields in terms of deprotection. An added bonus with respect to surface immobilization with TTU is that XPS analysis of fluorine in the TFA moiety provides a highly sensitive method for surface characterization, especially if high dilution of the thiol-containing surface is envisaged.

In the present paper, we describe a comparison of the generation of thiol-functionalized surfaces using both BTU and TTU. After silanization with the former compound, the alkyl bromide group is converted to a thiol, whereas the analogous reaction with TTU followed by deprotection yields the same entity. To effect a direct comparison of surface population with these molecules, we have labelled the surface-bound thiol from the BTU procedure with trifluoroacetic anhydride (TFAA) (13). This protocol allows the facile XPS analysis of both surfaces, if the determination for TTU is conducted before the deprotection stage. The reason for the choice of XPS analysis of fluorine lies in the insensitivity of this technique for sulfur and, secondly, the coincidence of the S2*p* binding energy with a surface plasmon peak of substrate silicon. Finally, we note that the surface immobilizations for both TTU and BTU involve silanizing mixtures incorporating monofunctional silane.

Experimental

Materials

ω-Undecenyl alcohol 98%, potassium thioacetate 98%, trifluoroacetic anhydride 99+% (TFAA), hydrogen hexachloroplatinate (IV) hydrate 99.995%, trichlorosilane 99%, 97%, neutral alumina (standard grade, 150 mesh, 58 Å), silica gel (Merck, grade 9385, 230–400 mesh 60 Å), octadecyltrichlorosilane (OTS), octyltrichlorosilane (C8), potassium thiocyanate, tetrabutylammonium thiocyanate, hydroxylamine HCl, methanol, chloroform, dimethylformamide (DMF), 1 M lithium aluminum hydride in tetrahydrofuran (THF) were all obtained from Aldrich and used without further purification. Triphenylphosphine 98%, *N*-bromosuccinimide (NBS) 98%, anhydrous magnesium sulfate, phosphorus pentoxide, potassium hydroxide, hexanes, diethyl ether, tetrahydrofuran, isopropanol, methanol, and hydrochloric acid were purchased from BDH and were used without further purification. Dichloromethane and acetonitrile were purchased from BDH and were distilled over phosphorus pentoxide before use. Pyridine was obtained from BDH and was distilled over KOH before use. Toluene was distilled over Na under N_2 immediately before use. Hydrogen peroxide (30%) was obtained from Anachemia and was used as received. Magnesium nitrate hexahydrate was obtained from Sigma. Orvus soap was obtained from Stepan Canada Inc. under the product name "Stepanol WAC." Silicon wafers obtained from International Wafer Service were supplied approximately 0.4 mm thick and were polished on one side to a mirror finish. They were cut to a size of approximately 1 × 1 cm using a diamond-tipped pencil.

Instrumentation

NMR spectra are reported in units of δ and were recorded on either a Varian Gemini 200 spectrometer using a ^1H–^{13}C switchable probe, or on a Varian VXR400S spectrometer (^1H, ^{13}C, ^{19}F, ^{29}Si) using a 5 mm switchable probe. In the case of ^{29}Si, either inverse-gated decoupling or DEPT were used. The samples were dissolved in $CDCl_3$, which contained 0.03% tetramethylsilane (TMS). Both ^1H and ^{29}Si NMR spectra were referenced to TMS at 0.00 ppm, while ^{13}C NMR spectra were referenced to the center of the $CDCl_3$ triplet at 77.00 ppm. ^{19}F NMR spectra were calibrated using an external $CFCl_3$ standard (0.00 ppm).

Elemental analysis was performed by Canadian Microanalytical Service Ltd. (Delta, B.C.). The trichlorosilanes were handled in an inert atmosphere during various procedures. All elements except oxygen were determined for the TTU sample.

Fourier-transform infrared spectroscopy was performed on Nicolet 5DXB spectrophotometer using the manufacturer's software. Ten scans were collected and averaged at a resolution of 2 cm^{-1} and were referenced to polystyrene. The liquid samples were run neat on NaCl disks.

X-ray photoelectron spectra were recorded on a Leybold MAX-200 X-ray photoelectron spectrometer using an

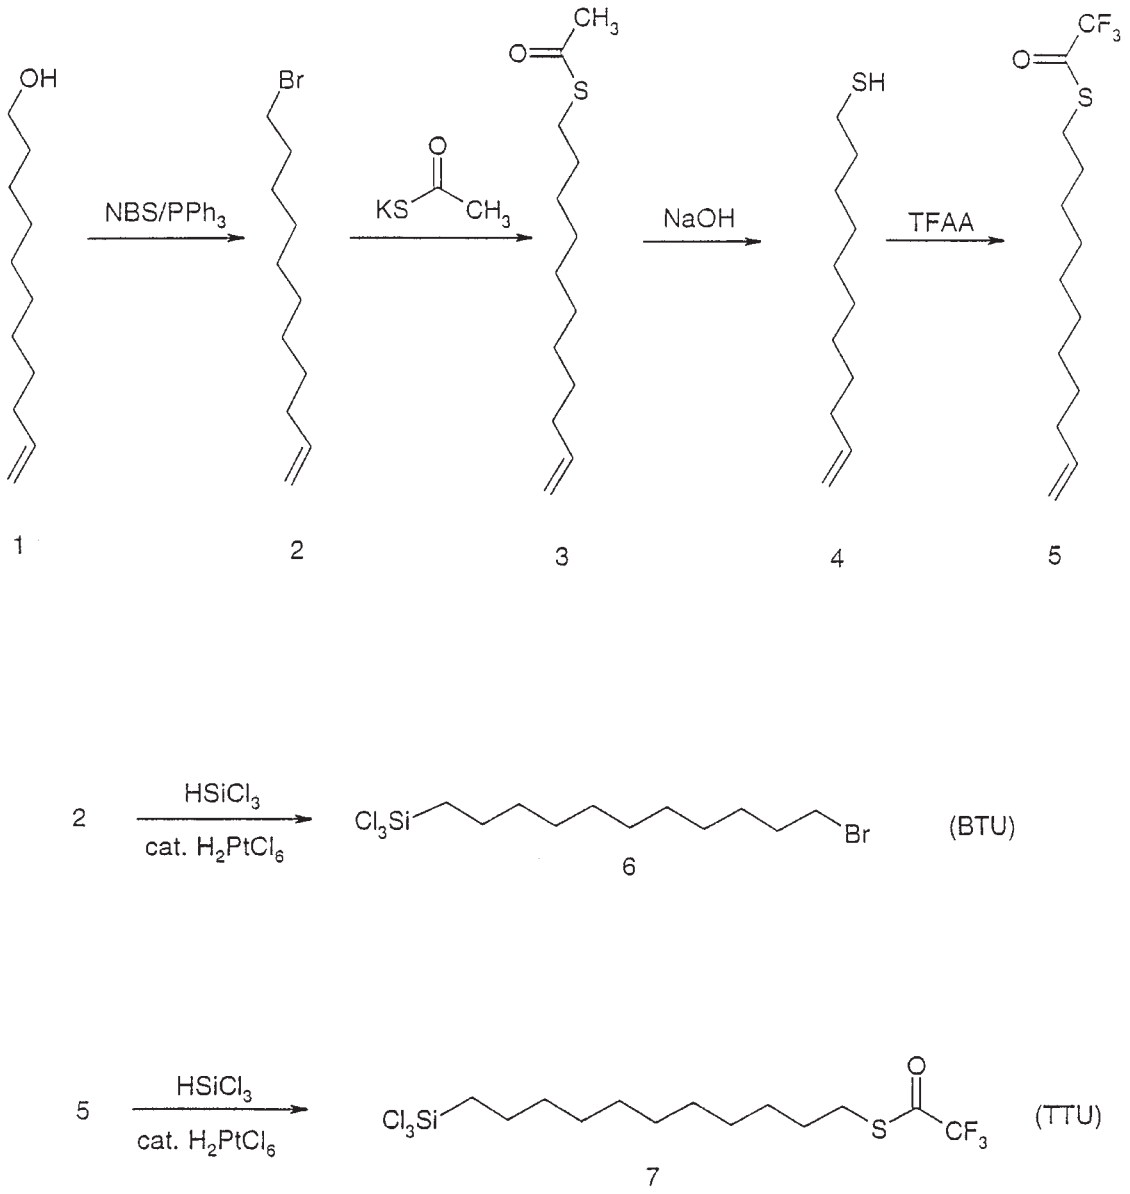
Fig. 1. Synthetic pathways to BTU and TTU.



unmonochromatized Mg K_α source run at 15 kV and 20 mA. The energy scale of the spectrometer was calibrated to the Ag $3d_{5/2}$ and Cu $2p_{3/2}$ peaks at 368.3 and 932.7 eV, respectively. The binding energy scale was calibrated to 285 eV for the main C(1*s*) feature. For all samples, a survey run (pass energy = 192 eV, 0–1000 eV on the binding energy scale was recorded. X-ray analysis area was 4 × 7 mm, for determinations performed at a 90° angle relative to the electron detector). Angle-resolved XPS spectra were obtained using a 2 × 4 mm analysis area at various angles relative to the surface normal. Satellite subtraction and normalization were performed with software obtained from the manufacturer. Quantitation of spectra was performed using empirically derived sensitivity factors (obtained from the manufacturer), and for the Mg anode, the sensitivity factors were; C(1*s*) = 0.34, F(1*s*) = 1.00, O(1*s*) = 0.78, and Si(2*p*) = 0.4. Peak fitting and data analysis was performed using ESCA Tools software, which requires MATLAB (MS-windows version).

Optical microscopy was performed with a Sony CCD color video camera module XC-999/999P using a 10X Nikon lens with a separate fiber optic illumination from side angles. The images were displayed on a 13 in. (1 in. = 25.4 mm) Sony Trinitron monitor and were captured from the screen on standard black and white 400 ASA 35 mm film using a standard 35 mm camera. The magnification achieved was 260X.

Procedures

The various intermediates and silanes described in this work together with a summary of synthetic pathways are summarized in Fig. 1.

(1) Synthesis of intermediates

ω-*Undecenyl bromide (compound 2)*

In a flame-dried dual-necked 200 mL round-bottom flask with teflon coated magnetic stir bar, equipped with a con-

© 1999 NRC Canada

denser and N_2 inlet were placed 8.5 g (50 mmol) of ω-undecenyl alcohol **1** and 100 mL of dry dichloromethane. The flask was covered with aluminum foil and mixture stirred and cooled in a CCl_4 – dry ice bath (–23°C). Triphenylphosphine, 15.7 g (60 mmol), was added to the mixture and stirred until it dissolved. NBS, 9.8 g (55 mmol), was added to the mixture and stirred at –23°C for 1 h. The flask was removed from the cold bath and the mixture allowed to stir at room temperature for 30 min. The solution was transferred to a separatory funnel and washed with water saturated with sodium carbonate. The organic layer was dried with $MgSO_4$, filtered, and concentrated on a rotary evaporator. The purple precipitate was extracted with 3 × 50 mL aliquots of hexanes using a combination of mechanical stirring, heat, and sonification. The resulting suspension was filtered, and the hexanes removed on a rotary evaporator. The material was filtered through a short column of neutral alumina (5 cm ht., 3 cm diam.) using hexanes under vacuum and the product concentrated on a rotary evaporator to yield a clear liquid. Yield 10.64 g (91%); IR (neat): 3074, 2926, 1639, 1458, 999, 909 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 5.79 (^1H, dddd, J = 17.2, 10.2, 7.0, 7.0 Hz), 4.93 (2H, m), 3.38 (2H, t), 2.02 (2H, dd, J = 6.2, 1.1. Hz), 1.83 (2H, m), 1.24–1.44 (12H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 139.03, 114.05, 33.93, 33.79, 32.86, 29.38, 29.08, 28.92, 28.76, 28.18.

*ω-Undecenyl thioacetate (compound **3**)*

In a 50 mL round-bottomed flask with teflon-coated magnetic stir bar, equipped with a condenser and N_2 inlet, were placed 3.50 g (15 mmol) of ω-undecenyl bromide (**2**), 1.71 g (15 mmol) of potassium thioacetate and 25 mL of 95% ethanol. The mixture was refluxed overnight after which the solution was transferred to a separatory funnel, 50 mL of water added and followed by extraction with 3 × 50 mL aliquots of hexanes. The organic layer was dried with $MgSO_4$, filtered, and concentrated on a rotary evaporator. Yield 3.32 g (97%); IR (neat): 3074, 2926, 1696, 1639, 1458, 1360, 1138, 999, 909 cm^{-1}, ^1H NMR (400 MHz, $CDCl_3$) δ: 5.79 (1H, ddd, J = 17.2, 10.2, 7.0, 7.0 Hz), 4.93 (2H, m), 2.85 (2H, t), 2.35 (3H, s), 2.02 (2H, dd, J = 6.2, 1.1 Hz), 1.55 (2H, m), 1.24–1.44 (12H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 195.91, 139.12, 114.07, 33.79, 30.62, 29.49, 29.39, 29.38, 29.14, 28.90, 28.79.

*ω-Undecenyl thiol (compound **4**)*

In a 50 mL round-bottomed flask with teflon-coated magnetic stir bar, equipped with condenser and N_2 inlet, were placed 2.0 g (8.76 mmol) of ω-undecenyl thioacetate (**3**), 20 mL of 95% ethanol, and 5 mL of 1 M NaOH. The mixture was refluxed for 1 h after which the solution was transferred to a separatory funnel, 50 mL of water added followed by extraction with 3 × 50 mL aliquots of hexanes. The organic layer was dried with $MgSO_4$, filtered, and concentrated on a rotary evaporator. Note: this material should be used immediately or stored in a frozen state. Yield 1.49 g (91%); IR (neat): 3074, 2926, 2550, 1639, 1458, 999, 909 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 5.79 (1H, dddd, J = 17.2, 10.2, 7.0, 7.0 Hz), 4.93 (2H, m), 2.52 (2H, dd, 8.0, 4.0), 2.02 (2H, dd, J = 6.2, 1.1 Hz), 1.57 (1H,t), 1.24–1.44 (12H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 138.09, 114.07, 34.04, 33.78, 29.44, 29.39, 29.08, 29.04, 28.90, 28.36, 24.63.

*ω-Undecenyl thiotrifluoroacetate (compound **5**)*

In a 25 mL round-bottomed flask with teflon-coated magnetic stir bar were placed 0.939 g (3.33 mmol) of ω-undecenyl thiol (**4**) and 5 mL of dry pyridine. Trifluoroacetic anhydride, 0.699 g (0.33 mmol), was added, and the mixture stirred at room temperature for 30 min while stoppered. The pyridine was removed under vacuum and the solid material extracted with 3 × 20 mL aliquots of hexanes. The hexanes were removed with a rotary evaporator to yield an oil. The oil was distilled via Kugelrohr distillation apparatus, and a fraction was collected at 90°C at 0.1 mmHg (1 mmHg = 133.3 Pa). Yield 0.556 g (59%); IR (neat): 3074, 2926, 1704, 1639, 1458, 1285, 1203, 1162, 999, 909 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 5.79 (1H, dddd, J = 17.2, 10.2, 7.0, 7.0 Hz), 4.93 (2H,m), 3.05 (2H, t), 2.02 (2H, dd, J = 6.2, 1.1 Hz), 1.55 (2H, m), 1.24–1.44 (12H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 184.81, 139.03, 114.11, 33.79, 29.43, 29.35, 29.32, 29.29, 28.95, 28.90, 28.67, 28.60, 24.66.

(2) Synthesis of silanes

*1-Bromo-(trichlorosilyl)-undecane (BTU, compound **6**)*

In a flame-dried heavy-walled ampoule were placed 2.03 g (8.7 mmol) of ω-undecenyl bromide (**2**), 1 mL of a 0.01 M H_2PtCl_6 sol in THF, and 1.35 g (10 mmol) of $HSiCl_3$. The ampoule was sealed at –195°C, and after thawing at room temperature, it was heated at 90°C overnight. The ampoule was opened at –195°C, and the remaining $HSiCl_3$ and THF removed under low vacuum. The main contents of the ampoule were distilled using a Kugelrohr distillation apparatus. The product distilled at 120–130°C at 0.4 mmHg. Yield 1.40g (69%); ^1H NMR (400 MHz, $CDCl_3$) δ 3.38 (2H, t), 1.84 (2H, m), 1.55 (2H, m), 1.24–1.44 (16H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ 34.05, 23.88, 31.84, 29.51, 29.43, 29.25, 29.04, 28.81, 28.23, 24.38, 22.31; ^{29}Si NMR (400 MHz, $CDCl_3$) δ 13.31.

*1-(Thiotrifluoroacetato)-11-(trichlorosilyl)-undecane (TTU, compound **7**)*

In a flame dried heavy-walled ampoule were placed 0.99g (3.5 mmol) of ω-undecenyl thiotrifluoroacetate (5), 0.47 g (3.5 mmol) of $HSiCl_3$, and 1 drop of a 4% sol of H_2PtCl_6 in isopropanol. The ampoule was sealed at –195°C and after thawing at room temperature, it was heated at 60°C overnight. The vial was then opened at –195°C and the remaining $HSiCl_3$ removed under low vacuum. The main contents of the ampoule were distilled using a Kugelrohr distillation apparatus. The product distilled at 140°C at 0.1 mmHg. Yield 1.17 g (80%); ^1H NMR (400 MHz, $CDCl_3$) δ: 3.05 (2H,t), 1.20–1.80 (20H, m); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 184.90, 115.53, 31.82, 29.45, 29.35, 29.30, 29.00, 28.97, 28.68, 28.63, 24.32, 22.28; ^{29}Si NMR (400 MHz, $CDCl_3$) δ: 13.32; Elem. anal. calcd. (%): C 37.47, H 5.32, F 13.68, S 7.69, Cl 25.52, Si 6.74; found: C 38.91, H 5.58, F 8.32, S 9.05, Cl 21.92, Si 1.20.

(3) Silanization of silicon wafers

The wafers were first gently washed with Orvus soap solution by hand to gently remove large dust particles, then

© 1999 NRC Canada

rinsed copiously with distilled water and dried in air. The wafers were then washed with chloroform, blown dry with nitrogen, and then sonicated in 30% hydrogen peroxide for 30 min. They were rinsed five times with deionized water, and then were placed in an oven at 120°C for 30 min. The wafers were stored in a humidity chamber, which contained water saturated with $Mg(NO_2)_2$ overnight. The hydrated wafers were then quickly removed from the humidity chamber and placed into test tubes (previously silanized with OTS) and stoppered. A dry box filled with air (dried through a Drierite/molecular sieve train) was used to provide a low-moisture environment for the silanization reactions. The substrates were silanized for 2 h using 2 mL of a 1×10^{-3} M solution in dry toluene of one of the following mixtures: 50% BTU – 50% C8, or 50% TTU – 50% C8. The samples were then rinsed with dry toluene, then with chloroform before being dried under nitrogen.

(4) Thiol-functionalized surfaces and derivatization (BTU)

The 50% BTU – 50% C8 surfaces were placed individually into test tubes to be followed by treatment with 2 mL of a 1 M solution of either potassium thioacetate, potassium thiocyanate, or tetrabutylammonium thiocyanate in DMF for 1 h, and 4 h at room temperature, and for 1 h and 4 h at 60°C. After the reaction, the samples were rinsed five times with 2 mL of DMF, then three times with 2 mL of methanol.

To reduce the products obtained above, the samples were soaked in 2 mL of 1 M lithium aluminum hydride in THF under nitrogen for 1 h, rinsed with THF, soaked in 1 M HCl for 1 h, rinsed with deionized water, and then washed with methanol. The samples were then treated with 2 mL of 0.1 M TFAA in pyridine for 30 min, followed by a brief rinse with dry chloroform.

(5) Deprotection of thiol-functionalized surfaces (TTU)

Wafers with TTU immobilized on their surfaces were treated with 2 mL of 0.5 M NH_2OH in water (pH 8.5) for 2 h at room temperature. This was followed by rinsing with copious amounts of water before final washing with methanol and drying by a stream of N_2 gas.

Results and discussion

Strategy for silanization

Two aspects of the present work with regard to the overall protocols used for silanization deserve comment. Previous work in our laboratory has confirmed that the density of silane films deposited on glass is determined by the solvent extraction of surface moisture followed by silane hydrolysis prior to deposition. (Accordingly, geometric comparisons between the solvent molecule and silane hydrocarbon moiety should not be invoked to explain the formation of surface-bound silane films.) This observation leads to an optimum protocol for generating close-packed monolayers of silanes on hydroxylated substrates such as silicon, and this was employed in the present work. To achieve the formation of such layers, the silicon wafers were subjected to an atmosphere of controlled humidity prior to silanization involving anhydrous toluene as the reaction medium (24).

The second point concerns the dilution of the reacting bifunctional silanes, BTU and TTU, with octyltrichlorosilane to a level of 50% mol/mol total silane. This value represents a compromise deduced from observations made with respect to low XPS sensitivity at high levels of BTU dilution, and unwanted surface reactions at dilution values higher than 50%. With regard to the latter, increased proximity appears to result in cross-linking of thiol groups present in the monolayer by surface oxidation. Clearly, this is disadvantageous in terms of the subsequent reaction of surface functional groups with derivatized biological macromolecules. Finally, for surface analysis we required to maximize the detection of surface functional groups by XPS. This led us to the choice of 50% bifunctional silane, but this value can be adjusted with facility to allow control of the final population of thiol groups on the silanized surface.

Thiol-functionalized surfaces via BTU

X-ray photoelectron spectra of a silicon wafer recorded immediately after the substrate had been treated with a 50% mol/mol mixture of BTU and octyltrichlorosilane is shown in Fig. 2. Corresponding XPS high-resolution data together with peak identifications are presented in Table 1. The presence of covalently bound bromine confirms the successful silanization of the silicon surface.

X-ray photoelectron spectroscopy alone cannot provide an absolute value for the amount of BTU deposited on the surface per unit area. However, it is possible to compare the ratio of the bromine-to-carbon signal intensities (adjusted for sensitivity using Scofield parameters) obtained by experiment with those calculated on a theoretical basis for a self-assembled monolayer (of bifunctional silane and C8). Such a comparison can lead to an approximate measure of the yield with respect to attachment of covalently bound bromine groups to the wafer. This theoretical calculation, which is based on the premise that the silane mixture creates an "ideal" close-packed structure, can be presented in the following general format:

$$[1] \qquad \frac{E_{XPS}}{C_{XPS}} = \frac{(E \times f_1 \times f_2)}{(f_1 \times C_1 + (1 - f_1) \times C_2)}$$

where E_{XPS}/C_{XPS} is the theoretical ratio for a particular element to carbon, C_1 and C_2 are the numbers of carbon atoms in the active and diluent silanes, respectively, f_1 represents the weight fraction of active silane in the mixture and f_2 the purity of the active silane (usually assumed to be 1.0). Several assumptions are implicit in this model:

(*i*) Competition for film growth between active and diluent silanes is considered to be negligible, i.e., the surface ratio of the two silanes simply reflects their bulk solution conditions.

(*ii*) Other bromine or carbon-containing materials are absent in the system.

(*iii*) The film is a monolayer.

Experimentally, an XPS Br3*d*/Si2*p* average of 0.017 was obtained for two BTU and silane diluent controls, which should be compared with the theoretical value of 0.053 (E = 1, C_1 = 11, C_2 = 8, f_1 = 0.5, f_2 = 1.00). Therefore, the level of silanization with respect to the bromine moiety represents a yield of about 31%. Given that previous work has

shown that carbon-based contamination on octadecyltrichlorosilane surfaces constitutes no more than approximately 5% of the total carbon analysis, it appears that an explanation based on this source of impurity does not explain the low yield for the BTU film (25). Competition between the two silanes is unlikely to be a significant factor, since the solubility of the two silanes in the reaction solvent is similar. A much more likely explanation for this result lies in the occurrence of a photochemical effect, which is responsible for a reduction in the level of bromine present on the substrate surface. Experiments involving exposure of BTU surfaces to light have confirmed that photochemical cleavage of bromine occurs. Furthermore, it is entirely possible that the XPS X-ray source can instigate similar photochemical processes during the actual surface analysis, since the unmonochromated magnesium X-ray source is also a source of ultraviolet light.

We now turn to a study of the conversion of the alkyl bromine moiety to thiolated surfaces through an initial reaction involving nucleophilic substitution reactions. The mixed silane surfaces were treated with two thiocyanates in addition to potassium thioacetate in dimethylformanide under various conditions of time and temperature. The results presented in Table 2 include the experimental Br to Si intensity ratios corrected for sensitivity factors for the different reactions. The experimental yield is calculated on the basis of the new Br/Si ratio compared to that for the silicon wafer with an intact mixed silane layer in place. In overall terms the results indicate that time of exposure to the three reagents employed is an important factor and that greater removal of Br occurs with the thioacetate anion. This observation likely reflects the enhanced nucleophilic activity of the thioacetate anion over thiocyanate, at least under the conditions employed here.

An additional observation made during these experiments was that a hazy film remained on the silicon wafers subsequent to nucleophile reagent treatment even after considerable solvent washing. These films, under the optical microscope, appeared to be composed of salt-like deposits of reagent, which adhered strongly to the substrate surface. In this regard, it is known that functionalized silane surfaces with medium to high polarity groups can serve as a nucleation site for crystal growth (20). The quantity of salt contaminant increases with reaction time and temperature. Since treatment with thioacetate for a shorter time at room temperature results in a high level of Br removal and minimal fouling, this protocol was employed for subsequent experiments leading to thiol functionalization and derivatization.

Two samples of silicon wafers with 50% BTU attached to their surfaces were exposed to 1 M potassium thioacetate for 2 h at room temperature in DMF. This was followed immediately by reduction with $LiAlH_4$, and after work-up, the thiol surface was derivatized with TFAA in pyridine. The introduction of the TFA group is confirmed by an XPS spectrum (not shown). Since, as mentioned above, the sensitivity of XPS for sulfur is too low to effect a quantitative analysis, the TFA functionality provides a convenient route to determine the thickness and degree of coverage of the BTU-derived thiol on the substrate surface. In the present work, the two samples were analyzed by angle-resolved XPS at four different take-off angles (20°, 30°, 45°, and 90°) with 90° being defined as the position at which the detector is normal to the plane of the sample surface. Fluorine, carbon, and silicon were the main elements of interest, and predictably, the percentage of fluorine was highest at 20°, while carbon and silicon were highest at 90°. To estimate the thickness and coverage of the films, the experimental ratios (F1*s*/C1*s*, C1*s*/Si2*p*, and F1*s*/Si2*p*) are compared to values calculated by a three-layer theoretical model. The following set of equations (eqs. [2]–[4]) (26) describes the relative attenuations experienced by photoelectrons ejected from three surface layers (A, B, and C):

$$[2]\qquad A(\theta) = [(1 - f_c) \times \lambda_a \times [1 - e^{(K_b(\theta))}]] + [f_c \times \lambda_a \times e^{(K_b(\theta))} \times e^{(K_c(\theta))}]$$

$$[3]\qquad B(\theta) = [(1 - f_c) \times \lambda_b \times [1 - e^{(K_b(\theta))}]] + [f_c \times \lambda_b \times [1 - e^{(K_b(\theta))}] \times e^{(K_c(\theta))}]$$

$$[4]\qquad C(\theta) = f_c \times \lambda_c \times [1 - e^{(K_c(\theta))}]$$

where the constants K_b and K_c are related to the particular take-off angle:

$$[5]\qquad K_b(\theta) = \frac{-t_b}{\lambda_b \times \sin\theta}$$

$$[6]\qquad K_c(\theta) = \frac{-t_c}{\lambda_c \times \sin\theta}$$

Where *A* represents the bottom layer, *B* the middle layer, and *C* the top layer. Theta (θ) is the photoelectron take-off angle, *f*(b or c) is the layer fraction coefficient, *t*(b or c) is the layer thickness, and lambda (λ) (a, b, or c) is each respective layer's mean free photoelectron path coefficient. To invoke this model, it was necessary to estimate the various mean free path values, since these are unavailable at the present time. However, for most films of an organic molecular type on an oxidized silicon surface, the mean free paths follow a particular trend. Electrons originating from the substate are

[a]Variables: λ_a = 28 Å, λ_b= 35 Å, λ_c = 44 Å; t_b = 2.5 Å, t_c = 1Å, f_c = 0.68.

[b]Variables: λ_a = 28 Å, λ_b= 35 Å, λ_c = 44 Å; t_b = 23 Å, t_c = 1Å, f_c = 0.78.

attenuated the most, and a value of 28 Å is typical, while electrons derived from the carbon layer have an intermediate level of attenuation, and so it was assigned a value of 35 Å. Fluorine is the least attenuated, since it is on top of the film, and was given a value of 44 Å. By varying these values 20%, it was discovered that even large errors in the estimates do not affect the modelled results significantly. Finally, three sets of ratios are generated, which correspond to the three possible combinations of observed values of element signals:

$$[7] \qquad F_{cb}(\theta) = \frac{C(\theta)}{B(\theta)}$$

$$[8] \qquad F_{ba}(\theta) = \frac{B(\theta)}{A(\theta)}$$

$$[9] \qquad F_{ca}(\theta) = \frac{C(\theta)}{A(\theta)}$$

For the work described here, the calculated ratios mentioned above (eqs. [7]–[9]) correspond to the experimental values for F1*s*/C1*s*, C1*s*/Si2*p*, and F1*s*/Si2*p*, respectively.

The fluorine layer was found to be 1 Å thick, and a coverage value of 0.73 was generated on average. The carbon layer was 25 Å thick, therefore, the total film thickness was determined to be 26 Å using the three-layer model. A summary of the experimental and theoretical values is presented in Table 3 (two samples).

The thickness values discussed above can also be evaluated in terms of molecular modelling for a two-component mixture. Since the active silane and the diluent silane are of different chain lengths, a weighted average length must be incorporated into such a model. Assuming that the surface is composed of an ideal, close-packed monolayer, then

$$[10] \qquad T_{avg} = \sin\theta[(t_1 \times f_1) + (t_2 \times (1 - f_1))]$$

In this expression, T_{avg} = the average film thickness in Angstroms, t_1 = the length of the active silane, f_1 = the percentage of active silane in mixture, t_2 = the length of the diluent silane, and theta (θ) = the angle at which the carbon chains may be tilted relative to the surface. The length of each silane was calculated by constructing a computer model and measuring the distance between two atoms, each at a distal end of the molecule. It has been demonstrated that the alkyl chains of an OTS film can be tilted at an angle as low as 75° relative to the normal (12). However, the orientations for these new films are not known, so theta (θ) was assumed to be 90°, and there is little difference between the numerical values for sin 75° (0.96) and sin 90° (1), in any case. Using t_1 = 17.15 Å, t_2 = 8.85 Å, and f_1 = 0.5, the average thickness was calculated to be 13 Å. Given the assumptions made in the three-layer and molecular model calculations, the comparison of values found from XPS data (26 Å) and from geometrical considerations (13 Å) is reasonable. The higher value for the former indicates, possibly, a tendency for several layer formation for the 50% BTU, 50% C8 silanization.

Thiol-functionalized surfaces via TTU

A survey XPS spectrum of a wafer treated with a 50% mixture of TTU and C8, in a similar fashion to that described above for BTU, is depicted in Fig. 3(*A*). Corresponding high-resolution data and peak identifications are given in Table 4. The trifluoromethyl group is found at 689.0 eV in the fluorine spectrum, but it is difficult to observe this group in the carbon spectrum, although it is partially resolved at 292.4 eV (Fig. 3(*B*)). The carbonyl group is observed at 289.0 eV, the carbon attached to sulfur is found at 286.9 eV, and the alkane carbons are found at 285.0 eV, which is also the peak used to calibrate the XPS spectra. The angle-dependent XPS silicon 2*s* spectrum (Fig. 4) shows well-resolved elemental and oxidized silicon peaks and two surface plasmons, which are produced by an energy-loss mechanism caused by silicon photoelectrons releasing a quantized amount of energy to the bulk silicon to produce mechanical motion. Unfortunately, "plasmon 1," occurring at 168.6 eV, obscures any sulfur 2*p* photoelectrons, which should be observed at 165 eV. Changing the angle to 20° improves the situation slightly, as shown in Fig. 4, and a small peak ascribed to sulfur at 164.1 eV can be seen, but is of insufficient magnitude to allow quantitative analysis.

Using a similar approach to that discussed for the BTU silanization, the F1*s*/C1*s* ratio from experimental work can be compared with a theoretical calculation based on eq. [1]. Two measurements made in this manner resulted in a mean

value of 0.12 (theoretical 0.14) corresponding to a yield of 86%. This result confirms the successful binding of the active silanizing agent to the wafer at a high surface density.

Turning to angle-resolved XPS, TTU provides an ideal benchmark for other thiol surfaces such as BTU that are derivatized with TFAA. Exponential and three-layer model results for TTU are given in Table 5 (two samples). For both samples, the thickness of the fluorine layer was 1 Å, and the degree of coverage was 0.91. The carbon layer was 15 Å thick, therefore the total film thickness was 16 Å. Given that

the error involved in both the XPS measurement and the modelling procedure is about ±2 Å, the experimental results are very close to the theoretical value of 13 Å. Good reproducibility was achieved, largely due to the efforts taken to control moisture in the silanization solvent, the use of a controlled humidity chamber to treat the silicon wafer, and the use of a low-moisture dry-box during the silanization process. Optical microscopy shows that no salt-like deposits are fouling an otherwise featureless surface.

Finally, we deal with the deprotection of TTU, that is, removal of the TFA functionality. Fortunately, assessment of the success of this type of reaction is a simple matter because the TFA group is easily observed in the XPS spectrum. Several deprotection schemes were tested, with the most advantageous being aqueous 0.5 M hydroxylamine (pH 8.5) for 2 h at room temperature. The experimental yield using this protocol (using an analogous calculation to that described for BTU above) was 9.8% (mean of several experiments). It is interesting to note that about 10% of the protecting groups are still attached to the surface after deprotection. Even if stronger nucleophiles or more basic conditions are employed, it is difficult to lower the yield, that is, remove all the TFA groups. We believe that the reason for this behaviour lies in the inaccessiblity of TTU species because they are embedded in pits on the silicon surface.

Conclusions

A number of the methods available for the attachment of biomolecules to substrate surfaces, such as chemisorption, cross-linking and encapsulation, complexation, and direct covalent binding, all suffer from several disadvantages. These are poor density of population of the surface, inadvertent wash-off, multi-point attachment leading to inaccessibility of tertiary structure, and the detrimental introduction of nonspecific binding sites for interfering materials. A goal of our work, in addition to work on proteins, is to produce linkers capable of the covalent, monolayer attachment of oligonucleotides to surfaces in the situation where low concentrations of nucleic acid are produced by synthesis, the immobilization is performed in water at pH 7 and at room temperature, there are no adverse efforts on the nucleic acid, and that the oligos can be attached in both permanent and reversible modes. These requirements are met by the new linking agent, TTU, which forms thiol-functionalized surfaces where the advantages of the thiol group lie in its ability to

form two types of linkage, viz. disulfide and thioether. The disulfide bond can be created using the highly specific thiol–disulfide exchange process. The S_N2 reaction proceeds rapidly in water at neutral pH. Furthermore, asymmetrical disulfides can be prepared, which lead to the prevention of reverse reactions, and the disulfide moiety can be cleaved specifically under extremely mild conditions. A thioether bond can be formed easily via reagents that contain reactive-leaving functionalities. The resulting bond is very resistant to cleavage and is essentially permanent under physiological conditions. Accordingly, TTU offers a spectrum of possibilities for the attachment of nucleic acid through the special derivatization of oligonucleotides, DNA and RNA.

Acknowledgments

We are greatly indebted to the Natural Sciences and Engineering Research Council of Canada, and Materials and Manufacturing Ontario for support of this work. Also, we wish to thank Dr. R. Sodhi of the Centre for Biomaterials, University of Toronto, for assistance with the acquisiton of XPS data.

New "molecular metals" based on symmetrically tetrasubstituted copper phthalocyanine complexes

B.N. Achar and P.K. Jayasree

Abstract: Pure copper(II) tetrasubstituted phthalocyanine complexes, CuPTX (where X = -NO_2, -NH_2, -SO_3H, and -OH) were synthesized. The electrical conductivity properties of these complexes were investigated both before and after iodine doping for the first time. Elemental, electronic, IR, magnetic susceptibility measurements, ESR, X-ray diffraction, and TGA analytical techniques were used to characterize and study the effect of substituents as well as iodine doping. Variation in the electrical conductivity of the copper phthalocyanine derivatives depends on the nature of the substituents and were found to show ~10^5 times improved electrical conductivity in comparison to parent unsubstituted copper phthalocyanine. Interestingly, these substituted complexes after iodine doping showed remarkably increased electrical conductivity nearly 10^{12} times that of unsubstituted copper phthalocyanine. This may be accounted for by the decrease in the metal–metal bond distance, increase in the approach of the ideal eclipsed system, or due to the combined effects of the above factors.

Key words: copper phthalocyanine, iodine doping, electrical conductivity.

Résumé : On a synthétisé des complexes purs de Cu(II) avec des phtalocyanines tétrasubstituées, CuPTX (dans lesquels X = NO_2, NH_2, SO_3H et OH). On a étudié les propriétés de conductivité électrique de ces complexes avant et après dopage par de l'iode. On a fait appel aux analyses élémentaires, aux spectres électroniques et IR, à des mesures de susceptibilité magnétique, à la résonance paramagnétique électronique, à la diffraction des rayons X et aux techniques analytiques thermogravimétriques pour les caractériser et pour étudier l'effet des substituants ainsi que le dopage par l'iode. La variation de la conductivité électrique des dérivés cuivrés de la phtalocyanine dépend de la nature des substituants et on a trouvé que la conductivité électrique est améliorée par un facteur de 10^5 par rapport à celle du complexe par du cuivre avec la phtalocyanine non substituée. Il est intéressant de noter que les complexes substitués, dopés à l'iode, présentent une conductivité électrique qui est pratiquement 10^{12} fois celle du complexe du cuivre avec la phtalocyanine non substituée. Cette observation pourrait être expliquée par la diminution de la longueur de la liaison métal–métal, une augmentation dans l'approche du système éclipsé idéal ou à une combinaison de ces facteurs.

Mots clés : complexe du cuivre et de la phtalocyanine, dopage à l'iode, conductivité électrique.

[Traduit par la Rédaction]

1. Introduction

Phthalocyanines have undergone world-wide intensive investigation because of their attractive properties like high tinctorial power, chemical inertness, thermal stability, electrical and catalytic properties (1–3). Electrical conductivity is one of the properties that attracted a great deal of interest since 1948 (4, 5). Enhancement of electrical conductivity of phthalocyanines by partial oxidation is now a well known phenomenon. Among the many oxidants used to study the effect on the electrical property of the phthalocyanine complexes, iodine has been used more frequently, and its effect on the electrical conductivity has been most extensively studied (6–8). Currently intensive research work is going on to produce useful electrically conducting phthalocyanine compounds, and phthalocyanines are now commercially used in many electronic devices (9–13). However, the electrical properties of the substituted metal phthalocyanines have been relatively little studied (14–17). The present work describes the synthesis of pure copper(II) tetrasubstituted complexes, CuPTX (where X = -NO_2, -NH_2, -SO_3H, and -OH), and their characterization both before and after iodine doping for the first time. The results are used to investigate the effects of substituents as well as iodine doping on the electrical properties of the complexes.

2. Experimental

Methods

Elemental analyses for C, H, and N were made by the Regional Sophisticated Instrumentation Centre, C.D.R.I., Lucknow. The copper contents of the tetrasubstituted copper phthalocyanine complexes were determined by decomposing

© 1999 NRC Canada

a known amount of the complex using H_2SO_4–HNO_3 mixture followed by careful evaporation and calcination (18). The purity of the complexes was further checked by ceremetric titrations (19). Electronic absorption spectra were recorded on a JASCO model UVIDEC-610 UV-vis spectrophotometer in 15 M sulphuric acid. IR spectra were recorded using Shimadzu 8201 PC FT-IR spectrophotometer by KBr disc technique. The magnetic susceptibility measurements were done using a Gouy magnetic balance consisting of the type NP-53 electromagnets with dc power supply type MP-1053 and a Keroy semimicrobalance supplied by Universal Scientific Company, Bombay, India. Pure $HgCo(SCN)_4$ was synthesized and used as a calibration standard (20). A JEOL-JDX-8P X-ray diffractometer was used to study the powder X-ray diffraction pattern of the samples. TGA studies were carried out using a Dupont model 990 thermal analyzer with the following conditions: sample size 5–10 mg, temperature range ambient to 800°C, heating rate 10°C/min. Perkin Elmer KBr die, carver laboratory press model C-12 ton capacity was used to prepare the pellets. The diameter and thickness of the pellets were determined by using a screw gauge readable up to 0.005 cm. Conducting silver paint (ELTECKS conductive silver preparation no. 1228/C) was coated on both surfaces of the pellets, and the electrical contacts of the samples were made using the same silver paint to the electrodes. The electrical contacts were checked to verify the ohmic connection, and the electrical measurements were done at ambient temperature using the Philips model PM 6303 RCL meter.

Materials

Pure copper(II) 2,9,16,23-tetrasubstituted phthalocyanines (CuPTX, where X = $-NO_2$, $-NH_2$, $-SO_3H$, and -OH) were prepared by using procedures as described elsewhere (21–24). A brief outline of the procedures are given below. All chemicals used were of analytical grade.

Preparation of tetrasodium salt of copper(II) 2,9,16,23-tetrasulphophthalocyanine 2-hydrate, CuPTS

Finely ground mixture of copper sulphate pentahydrate (5.2 g), monosodium salt of 4-sulphophthalic acid (23.36 g), ammonium chloride (2 g), ammonium molybdate (0.3 g), and urea (30 g) was taken in a 250 mL three-necked flask containing nitrobenzene (20 mL) fitted with a thermometer, a condenser, and a mechanical stirrer. The mixture was heated slowly with stirring to 180°C and maintained at this temperature for 6 h. The product was washed with methanol to remove nitrobenzene and was then purified using hydrochloric acid (1.0 N) and sodium hydroxide (1.0 N). The filtered product was dried in vacuum desiccator. Yield 80%. IR absorption bands (cm^{-1}): 745m, 920w, 1022s, 1185m, 1316m, 1386m, 1555 (broad), 3000–3625 (broad). Anal. calcd. for CuPTS, $C_{32}H_{16}N_8O_{14}S_4Na_4Cu$: C 37.67, H 1.58, N 10.98, Cu 6.22; found: C 38.01, H 2.01, N 11.02, Cu 6.25.

Preparation of copper(II) 2,9,16,23-tetranitrophthalocyanine, CuPTN

This was prepared by using the procedure as explained above except for using 4-nitrophthalic acid (16.9 g) in place of 4-sulphophthalic acid. The temperature of the reaction was slowly increased to 185°C and maintained at 185 ± 5°C for 4–5 h. The complex was purified by using 1.0 N sodium hydroxide and hydrochloric acid, and finally washing with distilled water. The blue-coloured product was dried at 125°C for 1 h. Yield 68%. IR absorption bands (cm^{-1}): 760m, 855w, 935ws, 1058w, 1090m, 1120w, 1338s, 1512s, 1595w. Anal. calcd. for CuPTN, $C_{32}H_{12}N_{12}O_8Cu$: C 50.83, H 1.59, N 22.23, Cu 8.40; found: C 51.88, H 1.72, N 22.54, Cu 8.50.

Preparation of copper(II) 2,9,16,23-tetraaminophthalocyanine 2-hydrate, CuPTA

Copper(II) 2,9,16,23-tetranitrophthalocyanine (5 g) was placed in a three-necked flask containing water (150 mL). The flask was fitted with a mechanical stirrer, a thermometer, and a stopper. Sodium sulphide nonahydrate (25 g) was added to the flask, stirred at 50°C for 5 h. The product was separated and treated with 250 mL sodium hydroxide (1.0 N), stirred for 1 h, and centrifuged. The product was purified by repeated treatment with water until it was free from sodium hydroxide. The pure CuPTA was dried in a vacuum desiccator. Yield 60%. IR absorption bands (cm^{-1}): 730m, 745m, 830w, 865w, 950m, 1055m, 1095m, 1136m, 1250w, 1302w, 1345w, 1410m, 1605m, 1790w, 3280w. Anal. calcd. for CuPTA, $C_{32}H_{24}N_{12}O_2Cu$: C 57.20, H 3.60, N 25.00, Cu 9.60; found: C 57.80, H 4.00, N 25.20, Cu 9.75.

Preparation of copper(II) 2,9,16,23-tetrahydroxyphthalocyanine, CuPTOH

Finely ground copper(II) 2,9,16,23-tetraaminophthalocyanine was added to 25 mL of 1.0 N hydrochloric acid solution. The mixture was kept in a bath of crushed ice until the temperature of the solution fell below 5°C. To this cold solution, chilled aqueous solution of sodium nitrite (1.55 g/4 mL) was added in small portions (0.5–1.0 mL at a time) with constant stirring. Heat was evolved by the reaction. Temperature should not be allowed to raise above 10°C. The chilled copper(II) tetradiazonium hydrogen sulphate prepared as above with suitable modification was added slowly to 20.0 N sulphuric acid solution (8 mL), boiled further for 5 min, and then poured into ice-cold water (150 mL). The solution was stirred vigorously. The product was decanted and then purified by washing with 1.0 N sodium hydroxide, 1.0 N hydrochloric acid, and finally with water. It was dried at 75°C for 1 h. Yield 85%. IR absorption bands (cm^{-1}): 725m, 885w, 926w, 1040w, 1075m, 1106w, 2700–3600 (broad). Anal. calcd. for CuPTOH, $C_{32}H_{16}N_8O_4Cu$: C 60.04, H 2.52, N 17.51, Cu 9.23; found: C 59.98, H 2.66, N 17.65, Cu 9.31.

Doping procedure

The iodine doping procedure for unsubstituted nickel phthalocyanine as explained elsewhere (25) has been adapted to dope the substituted copper phthalocyanine complexes. A brief summary of the procedure is given below.

Finely ground (0.5 g) tetrasubstituted copper phthalocyanine complex (CuPTX, where X = -OH, $-NO_2$, $-NH_2$, or $-SO_3Na$) was taken in a closed container containing 100 mL iodine saturated chlorobenzene solution and stirred for 48 h. The iodinated copper tetrasubstituted complex was collected by centrifugation, washed with several portions of hexane, and dried in a vacuum desiccator.

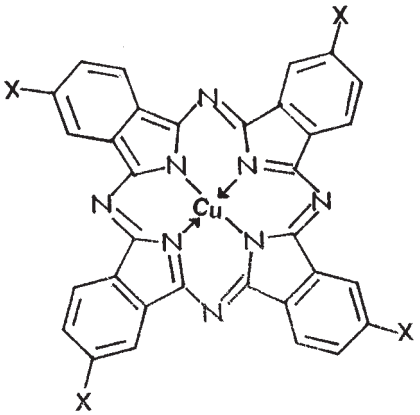
Fig. 1. Structure of copper(II) 2,9,16,23-tetrasubstituted phthalocyanine, CuPTX (where X = -NO_2, -NH_2, -SO_3H, and -OH).



3. Results and discussion

The structure of copper(II) symmetrically tetrasubstituted phthalocyanine complex is shown in Fig. 1. Purity of the complexes are checked by elemental analysis, IR spectral data, and titrimetric analysis (19). The elemental analyses of C, H, N, and Cu agreed fairly well with the calculated values.

Electronic absorption spectra

The electronic transitions characteristics of phthalocyanine ring are assigned Q, B, N, L, and C bands (26). These characteristic absorption bands are also observed in the electronic absorption spectra of the tetrasubstituted copper phthalocyanine complexes (CuPTX, where X = -SO_3H, -NO_2, -NH_2, or OH) recorded in 15 M H_2SO_4 medium, Table 1. The Q band due to $a_{1u} \rightarrow e_g$ transition around 750 nm was found to show bathochromic shifts with hyperchromic effect in the case of all the three copper complexes, except in the case of CuPTS wherein the band showed hypsochro-

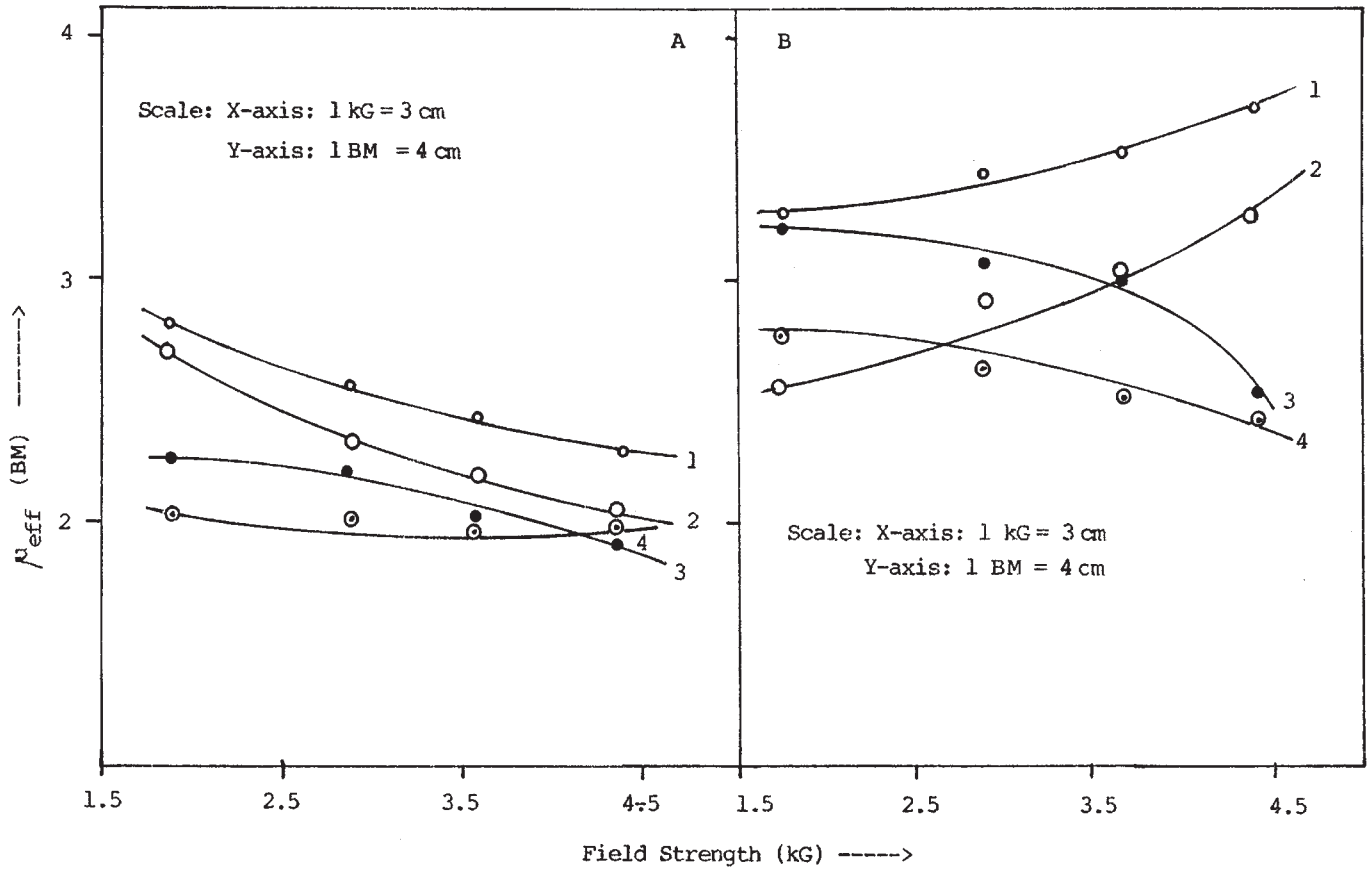
Fig. 2. Variations of magnetic moments with field strength: 1, CuPTS; 2, CuPTN; 3, CuPTA; and 4, CuPTOH. (*A*) Before I_2 doping and (*B*) after I_2 doping.



mic effect with respect to intensity after iodine doping. This band is due to monomeric species and found to be affected by the nature of the substituents. The multiplicity of this band towards the higher energy side in the region 665–704 nm observed for the complexes are due to the configurational interaction between the phthalocyanine molecules leading to the formation of dimeric species in solution. The intensity of this band depends upon the concentration of the dimer formed (27–29). All the complexes both before and after iodine doping showed absorptions around 376–435 nm of comparable intensity with Q band. This absorption is not observed in the vapour absorption spectrum of copper phthalocyanine (30). This is due to the change of the molecular symmetry from D_{4h} to C_{4v} in the strong acidic medium (31). The B (Soret) band around 305 nm, which can be assigned to the $a_{2u} \rightarrow e_g$ transition, was found to have not much affected with respect to positions but appeared broad due to the underlying $Np_\sigma \rightarrow e_g$ (π^*) transitions (32). The electronic absorption spectra of the complexes CuPTOH ad CuPTS showed the absence of L and C bands before iodine doping. But after iodine doping absorption due to C band appeared in CuPTOH but poorly resolved. This C band absorption is observed for the complex CuPTA before iodine doping found to disappear after iodine doping. The bands N and L are expected to observe between B and C, which are not well resolved in the solution spectra of the complexes both before and after iodine doping.

IR spectra

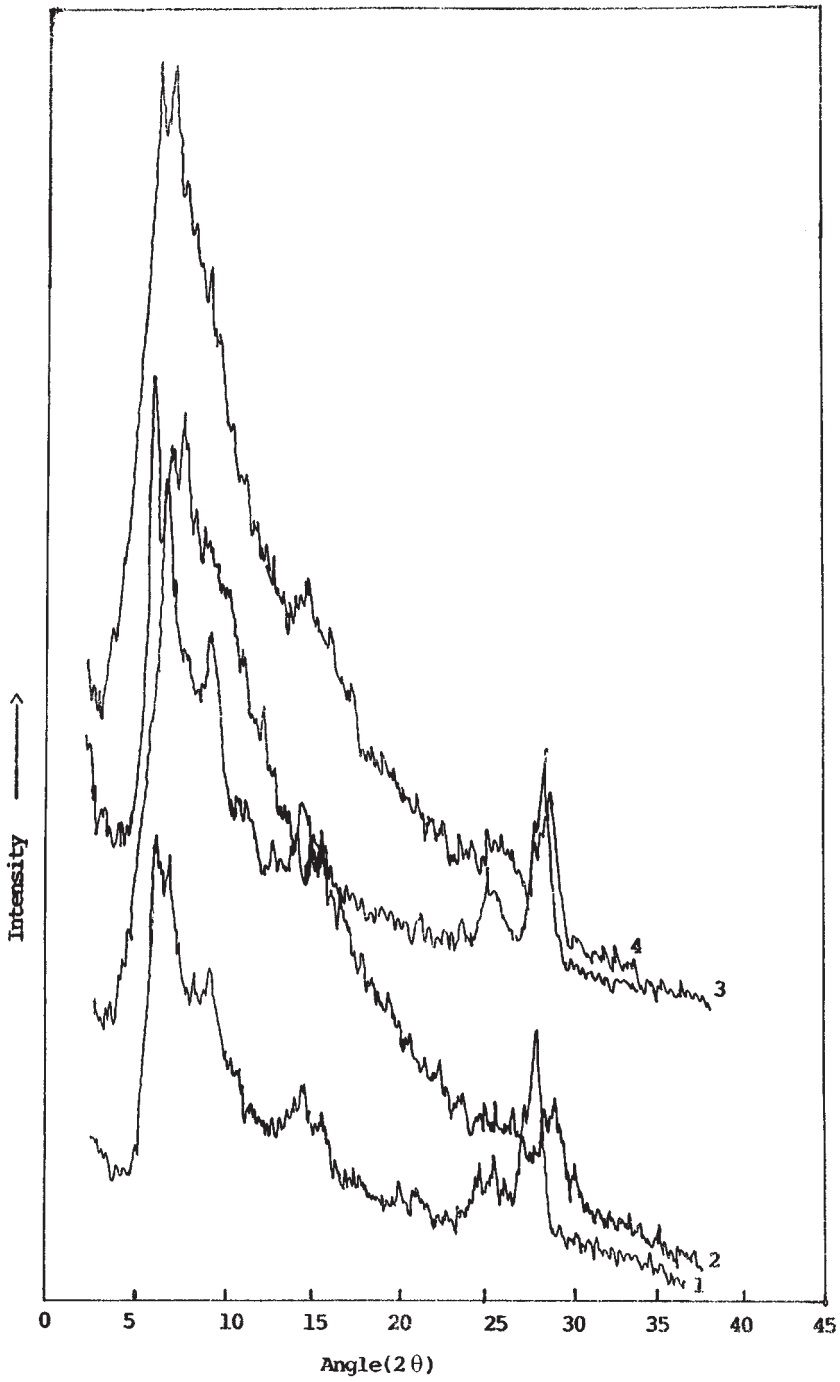
IR spectra of all the four complexes showed absorptions at 725–760, 748–891, 920–966, 1020–1060, 1075–1095, and 1106–1185 cm^{-1} assignable to phthalocyanine skeleton both before and after iodine doping (33). These absorptions are found to be unaffected with respect to their positions. But with respect to their intensity, they appeared broad with hypochromic effect.

Magnetic susceptibility measurements

The investigation on magnetic susceptibility properties of the tetrasubstituted copper(II) phthalocyanine complexes has been carried out in solid state at ambient temperature and varying magnetic field strengths from 1.92 to 4.35 kG (1 G = 0.1 mT), to know the effect of iodine doping. The magnetic moment, μ_{eff} values are calculated using the corrected susceptibility data for diamagnetism (34–35). Each value of magnetic moment calculated from the corrected susceptibility is an average of three independent determinations. The values are reproducible to ±0.1 BM. The plots of magnetic moment (μ_{eff}) values versus field strength are presented both before and after iodine doping, in Fig. 2. These complexes are paramagnetic in nature, which showed magnetic field dependent magnetic moment values both before and after iodine doping. The μ_{eff} values are found to decrease with increase in magnetic field strength before iodine doping, whereas these values are found to increase with increase in

© 1999 NRC Canada

Fig. 3. X-ray diffraction spectra: 1, CuPTA; 2, CuPTA (I_2 doped); 3, CuPTOH; and 4, CuPTOH (I_2 doped).



field strength after iodine doping except in the case of CuPTOH and CuPTA, which contain reactive hydroxy and amino substituted functional groups. These values and their variations with the magnetic field can be due to the combined effects of orbital contribution and intermolecular cooperative effects (21). The results presented in Table 1 indicate that there are two types of cooperative effects — positive and negative. The positive intermolecular cooperative effect leads to the increase in the magnetic moment values, and negative intermolecular cooperative effect leads to decrease in the magnetic moment values with increase in magnetic field strength. The difference in the magnetic moment field values of the copper complexes after iodine doping is due to the partial oxidation of phthalocyanine complexes as well as simultaneous adoption of a face-to-face stacking of the phthalocyanine structure (36). The most likely mechanisms for spin–spin coupling between adjacent copper atoms or superexchange through nitrogen atoms of the copper phthalocyanine macrocycle or direct exchange between the adjacent copper atoms. The former is the most feasible mechanism before iodine doping. The later mechanism seems to explain the magnetic susceptibility values af-

© 1999 NRC Canada

ter iodine doping. In conclusion, the variation of the susceptibility value with magnetic field strength and differences in them before and after iodine doping seem to be affected by the type of substituents at the peripheral benzene structures of the phthalocyanine molecule, ligand-based or metal-based partial oxidation, interplanar distance of the molecular stacks, and the types of intermolecular effects.

ESR studies

The calculated "*g*" values from the ESR spectra of all the complexes both before and after iodine doping are presented in Table 1. ESR spectral data of the complexes are in agreement with the magnetic susceptibility measurements with respect to the paramagnetic nature of the complexes. The nature of the spectra, both before and after iodine doping, indicates tetragonal site in all these complexes. All the complexes both before and after iodine doping showed a single relatively broad ESR signal, which can be explained as the sum of the contributions from all orientations of the molecule, wherein the hyperfine structures are obscured by electron–electron dipole interaction and exchange mechanism.

X-ray diffraction studies

The data of the powder X-ray diffraction study both before and after iodine doping are presented in Table 1. Typical X-ray diffraction spectra are given in Fig. 3. The interplanar spacings are calculated by using the Bragg's equation, $2d \sin \theta = n\lambda$. The nature of the powder X-ray diffraction spectra showed not much difference with respect to the appearance after iodine doping except with respect to the broadening of the Bragg's scattering. This indicates that the crystal lattice is not changed after iodine doping, and the broadening effect may be due to the partial transformation of the polycrystalline phase to the amorphous state.

Thermogravimetric Analytical (TGA) studies

The TGA analytical curves indicated the iodine contents in the doped tetrasubstituted copper phthalocyanine complexes are in the range 28–38%. This corresponds to the doping of iodine in these complexes to the extent of three iodine atoms per molecule. As per the TGA curve, the weight loss due to iodine is in between the temperature range 130–200°C. Iodine is found to be volatilizing slowly with time from the doped material. Because of this volatilization problem, iodine contents from TGA analytical data must be obtained soon after the synthesis of the doped complexes for getting reasonably accurate doped iodine contents.

Electrical conductivity studies

The measured electrical conductivity values both before and after doping with iodine of the complexes studied are reported in Table 1. Electrical conductivity of copper phthalocyanine is reported to be of the order 10^{-12}–10^{-13} $(\Omega\ \text{cm})^{-1}$ (37). These complexes showed 10^4–10^7 times improved electrical conductivity in comparison to the parent copper phthalocyanine. This may be due to the decrease in the metal–metal bond distance, increase in the overlap of the π electron system between the molecules or increase in the approach of the ideal eclipsed stacking systems or due to combined effects of the above factors. The substitution and the iodine doping found to increase the electrical conductivities remarkably ~10^{12} times in comparison to the parent copper phthalocyanine. The high electrical conductivity observed for the iodine doped phthalocyanine complexes shows the conductive path in these complexes does not depend on metal–metal overlap only but also on π–π and *d*–π overlaps. The "holes" for the charge carriers produced by the partial oxidation by iodine may either be at metal or ligand centered. The ESR data before and after iodine doping support the holes produced are ligand centered as the *g* values nearly equal to 2. When these complexes are partially oxidized with iodine, they become conducting while simultaneously adopting a face-to-face stacking of the phthalocyanine structure (36). Based on the observations and conclusions on the improved electrical conductivites of the doped unsubstituted metal phthalocyanine complexes by the other workers (37–39), similar conclusions can be drawn on the increased electrical conductivites observed after iodine doping in these complexes. That is, the improved electrical conductivites, firstly, must be due to the arrangement of the planar molecules in close facial proximity with sufficient intermolecular overlap and, secondly, due to the existence of fractional oxidation states in the arranged molecular stacking.

Acknowledgments

The authors thank Prof. A.S. Aravinda Murthy, Electrical and Electronics Department, National Institute of Engineering, Mysore, for the help in providing the necessary facility to carry out the electrical conductivity measurements.

Preferred conformation and barriers to internal rotation of *ortho*-disubstituted cyclopropylbenzenes

Ludger Ernst, Thomas Rieck, and Mark Soliven

Abstract: Schaefer's "*J* method" was employed to show that 2-cyclopropyl-1,3-dimethylbenzene (**5**) in solution prefers the perpendicular conformation in which the torsional angle Θ between the C(1)—H bond of the cyclopropyl group and the plane of the benzene ring is 90°. This is opposed to the situation in cyclopropylbenzene (**3**) where the bisected conformer (Θ = 0°) prevails. From the value of –0.85 ± 0.01 Hz for ^6J(H-α,H-*para*) in **5** (for solutions in CS_2 and in acetone) a barrier to rotation about the cyclopropyl–aryl bond of 6.4 kJ/mol can be derived if a predominantly two-fold potential and a vanishing ^6J(H,H) for Θ = 0° are assumed. The introduction of the two *ortho*-methyl groups into **3** thus effectively interchanges the ground and transition state conformations of the internal rotation. This effect is well reproduced by ab initio (STO-3G and 6-31G*) and semiempirical (AM1) molecular orbital computations. The preference for the perpendicular conformation of an *ortho*-disubstituted cyclopropyl substituent was also demonstrated by a dynamic NMR study of 2-cyclopropyl-4-isopropyl-1,3,5-trimethylbenzene (**10**). Exchange-broadened ^{1}H spectra due to slow rotation of the cyclopropyl group were only obtained near the low-temperature limit of the spectrometer (–140°C), and the barrier to rotation is estimated to lie near 28 kJ/mol ($\Delta G^{\ddagger}$). MM3 molecular mechanics computations suggest that the rather large increase of the rotational barrier in **10** relative to **5** is caused by the combined buttressing effect of the isopropyl and the 5-methyl groups. The present findings explain why an earlier attempt (in 1970) to determine the rotational barrier in 2-cyclopropyl-1,3,5-trimethylbenzene by dynamic NMR was bound to fail.

Key words: conformation, cyclopropylbenzenes, *ortho*-disubstituted, NMR spectroscopy, rotational barrier.

Résumé : On a utilisé la méthode *J* de Schaefer pour montrer que, en solution, le 2-cyclopropyl-1,3-diméthylbenzène (**5**) adopte préférentiellement la conformation perpendiculaire dans laquelle l'angle de torsion Θ, entre la liaison C(1)—H du groupe cyclopropyle et le plan du noyau benzénique, est égal à 90°. Ce résultat est opposé à la situation qui prévaut dans le cyclopropylbenzène (**3**) dans lequel le conformère bissecté (Θ = 0°) prédomine. Pour la valeur de –0,85 ± 0,01 Hz pour ^6J(H-α,H-*para*) dans le composé **5** (pour des solutions dans le CS_2 et dans l'acétone), on évalue que la barrière à la rotation autour de la liaison cyclopropyle–aryle est égale à 6,4 kJ/mol si l'on fait l'hypothèse que la barrière de potentiel est principalement binaire et que ^6J(H,H) disparaît pour Θ = 0°. L'introduction des deux groupes méthyles en *ortho* du composé **3** provoque donc un échange effectif des conformations des états fondamental et de transition de la rotation interne. On peut très bien reproduire cet effet par des calculs d'orbitales moléculaires ab initio (STO-3G et 6-31G*) et semi-empiriques (AM1). Une étude de RMN dynamique du 2-cyclopropyl-4-isopropyl-1,3,5-triméthylbenzène (**10**) a aussi permis de mettre en évidence la préférence d'un substituant cyclopropyle *ortho*-disubstitué pour la conformation perpendiculaire. Ce n'est que près de la limite inférieure de température du spectromètre (–140°C) qu'on a pu obtenir des spectres RMN du ^{1}H élargis en raison d'une rotation lente du groupe cyclopropyle et on a évalué que la barrière à la rotation se situe près de 28 kJ/mol ($\Delta G^{\ddagger}$). Des calculs de mécanique moléculaire au niveau MM3 suggèrent que la forte augmentation de la barrière rotationnelle dans **10** par rapport à **5** est provoquée par l'effet combiné de compression des groupes isopropyle et 5-méthyle. Les résultats obtenus ici expliquent pourquoi, lors d'un essai antérieur (1970), il n'a pas été possible de déterminer la barrière rotationnelle dans le 2-cyclopropyl-1,3,5-trimétylbenzène par RMN dynamique.

Mots clés : conformation, cyclopropylbenzènes, *ortho*-disubstitution, spectroscopie RMN, barrière rotationnelle.

Introduction

The preferred conformation of simple *sec*-alkylbenzenes, Ph-$C^{\alpha}HR^1R^2$, with respect to internal rotation about the C(sp^2)—C(sp^3) bond, has the C^{α}—H bond in the plane of the benzene ring (1). For the simplest and most prominent example, isopropylbenzene (**1**), this has been shown by numerous experimental techniques, among them ^{1}H NMR on **1** itself (2) and on the 3,5-dibromo derivative (3), or supersonic molecular jet spectroscopy (4). The energy minimum of the rotational potential is hence depicted by conformer **1a** in which the torsional angle Θ of the C^{α}—H bond out of the aromatic plane is 0°. The maximum of the rotation potential is computed to lie at Θ = 90° (**1b**) both by ab initio MO (2) and by MOMM (combined MO/molecular mechanics) calculations (5). The rotational barrier, i.e., the energy difference between **1b** and **1a**, has been determined by NMR to be 6.5–8.4 kJ/mol (2, 3) and has been computed by ab initio MO methods (2) to be 14.1 kJ/mol (geometry-optimized STO-3G) or 13.4 kJ/mol (6-31G), while the MOMM procedure gives 9.6 kJ/mol (5), in better agreement with the experimental finding. The shape of the rotational potential is predominantly twofold with a possible smaller contribution by a fourfold component (2). When the isopropyl group is flanked by two simple *ortho*-substituents such as methyl in 2-isopropyl-1,3,5-trimethylbenzene (**2**) (6) or when a dichloromethyl group is flanked by two *ortho*-chlorines as in 2,6-dichlorobenzal chloride (7), the minimum and maximum energy conformations still have Θ = 0° and 90°, respectively, but the rotational barrier is increased so much that slow rotation about the C(sp^2)—C(sp^3) bond can easily be observed in moderately low-temperature ^{1}H- (6) and ^{13}C-NMR (8) spectra. In **2**, for example, the rotational barrier, $\Delta G^{\ddagger}$, was determined to be 53.6 kJ/mol (6).

1a **1b**

3a **3b**

With respect to its preferred conformation and its barrier to internal rotation, cyclopropylbenzene (**3**) behaves very similarly to **1**. By applying the *J* method (9), Parr and Schaefer (10) determined the barrier in **3** to be 8.4 ± 1.3 kJ/mol and the preferred conformation to be the "bisected" one, **3a**. According to an X-ray crystallographic study (11), the molecule also assumes this conformation in the solid state. Earlier, presupposing the similar conformational behaviour of **1** and **3**, one of us had studied (6) an *ortho*-disubstituted derivative of **3**, viz. 2-cyclopropyl-1,3,5-trimethylbenzene (**4**), expecting that it would show hindered rotation in its ^{1}H NMR spectrum at moderately low temperatures as had been the case with **2**. However, within the limits of the available instrumentation at that time (spectrometer frequency: 90 MHz; lowest attainable temperature: –120°C), no decoalescence of the *ortho*-methyl signal could be observed, and it was concluded that the $\Delta G^{\ddagger}$ value of the rotational barrier was smaller than 31.4 kJ/mol. Our interest in the problem was stirred again when Drumright et al. (12) reported that, in the solid state, 9-chloro-10-cyclopropylanthracene prefers the "perpendicular" conformation corresponding to **3b** and that this was also borne out by MMX molecular mechanics computations on 9-cyclopropylanthracene. Also, Mislow and co-workers (13) had reported barriers to cyclopropyl rotation, determined by dynamic NMR spectroscopy, of 45.6 ± 2.1 and 41.4 ± 2.1 kJ/mol for 1,2-dicyclopropyl-3,4,5,6-tetraisopropylbenzene and 1,2,3,4-tetracyclopropyl-5,6-diisopropylbenzene, respectively. In these compounds, the cyclopropyl groups also assume the perpendicular conformation. We wondered whether there is generality to the finding that the addition of two *ortho*-substituents to the cyclopropyl group in cyclopropylarenes switches the favoured conformation from **3a** to **3b**. If so, our fruitless low-temperature ^{1}H NMR experiments on **4** could be explained not only (*i*) by too low a rotational barrier but also (*ii*) by the preference of **4** for the "wrong" (perpendicular) conformation. In the perpendicular conformation of **4**, the *ortho*-methyl groups are in symmetrical environments, and decoalescence of their signal cannot be expected on lowering the temperature. We therefore devised experiments, using more straightforward compounds than Mislow's, to find out whether explanation (*i*) or (*ii*) is appropriate or whether, possibly, (*i*) and (*ii*) hold simultaneously.

Results and discussion

Application of the *J* method to 2-cyclopropyl-1,3-dimethylbenzene (5)

Schaefer's *J* method (9) provides a way to determine the preferred conformation and the twofold barrier, V_2, to internal rotation (if it is small enough) in benzylic and benzalic compounds. It makes use of the $\sin^2 \Theta$ dependence of the six-bond spin–spin coupling, ^6J, between the nucleus in the *para* ring position and a nucleus bonded to the α position of the side chain:

$$[1] \qquad {}^6J = {}^6J_0 + {}^6J_{90} \langle \sin^2 \Theta \rangle$$

$^6J_0$ and $^6J_{90}$ are the values at Θ = 0° and 90°, and $\langle \sin^2 \Theta \rangle$ represents the value of $\sin^2 \Theta$ averaged over the hindered rotor states. If ^6J is accurately determined and $^6J_0$ and $^6J_{90}$ are known, $\langle \sin^2 \Theta \rangle$ can be calculated and, for a given tempera-

[a]For labelling of the protons, see the formula. Standard deviations of the parameters are given in parentheses after the values and refer to the last decimal quoted. Root mean square errors of the analyses were as follows. Cyclopropyl part: 0.040 Hz (CS_2 solution), 0.026 Hz (acetone-d_6 solution); aromatic part: 0.014 Hz (CS_2 solution), 0.012 Hz (acetone-d_6 solution).

[b]The "CS_2" solution consisted of **5**/CS_2/cyclohexane-d_{12}/hexafluorobenzene/tetramethylsilane in a molar ratio of 5/84.5/10/0.25/0.25. In the "acetone" solution, 84.5 mol% acetone-d_6 were used instead of CS_2.

[c]The values of these coupling constants are very strongly correlated ($r > 0.96$). Their individual values are determined by transitions of extremely small intensities that cannot be observed in the experimental spectrum. No values are therefore given.

[a]For labelling of the protons, see the formula. The solution consisted of **6**/acetone-d_6/cyclohexane-d_{12}/hexafluorobenzene/tetramethylsilane in a molar ratio of 5/84.5/10/0.25/0.25. Standard deviations of the parameters are given in parentheses after the values and refer to the last decimal quoted. The root mean square error of the analysis was 0.013 Hz. Only the cyclopropyl proton transitions were assigned. The chemical shifts of the aromatic protons and their mutual coupling constant were determined "by hand" and kept constant during the iterative analysis. The methyl protons were decoupled.

ture and reduced moment of inertia, leads to the value of V_2 and discloses the nature of the rotational ground state (9). For benzalic compounds, the ground state conformation is bisected (**1a**, **3a**) if $\langle\sin^2\Theta\rangle$ is between 0 and 0.5, and it is perpendicular (**1b**, **3b**) if $\langle\sin^2\Theta\rangle$ is between 0.5 and 1. Good estimates are available for $^6J_0$ (0.0 Hz) and $^6J_{90}$ (–1.11 Hz) in cyclopropylbenzene from the earlier work by Parr and Schaefer (10), who have justified their choice in detail. These values are believed not be affected by methyl substitution on the benzene ring. A careful analysis of the ^{1}H NMR spectrum of 2-cyclopropyl-1,3-dimethylbenzene (**5**) was therefore undertaken in order to obtain the experimental value of ^6J(H,H). Both CS_2 and acetone solutions of **5** were studied, and the results of the iterative analysis are given in Table 1. Figure 1 shows the aromatic region of the experimental and the calculated ^{1}H NMR spectrum of **5** (CS_2 solution) to demonstrate the quality of the fit. For comparison, the spectrum of the unhindered 3,5-dimethyl derivative **6** was also recorded and analysed (Table 2) but only of an acetone solution because material was scarce.

The important coupling constant in **5**, ^6J(H-α,H-*para*), has virtually identical values in the two solutions, viz. –0.848(2) Hz (CS_2) and –0.854(2) Hz (acetone) so that it may be safely regarded as –0.85 ± 0.01 Hz. If we follow the earlier arguments (10) and accept the mentioned values for $^6J_0$ and $^6J_{90}$, the experimental coupling constant leads to $\langle\sin^2\Theta\rangle = -0.85/(-1.11) = 0.77$. A quantum mechanical solution to the hindered rotor problem (14) gives values of $\langle\sin^2\Theta\rangle$ as a function of temperatures, twofold barriers, and reduced moments of inertia, which have been tabulated (15) for easy use.[2] For $\langle\sin^2\Theta\rangle = 0.77$, a temperature of 300 K, and reduced moments of inertia between 1.0 and 4.0 × 10^{-38} g cm^2, these tables give a twofold barrier of 6.4 kJ/mol to rotation about the cyclopropyl–aryl bond in **5**. As $\langle\sin^2\Theta\rangle$ is

[2]We are grateful to Prof. T. Schaefer for a copy of this table.

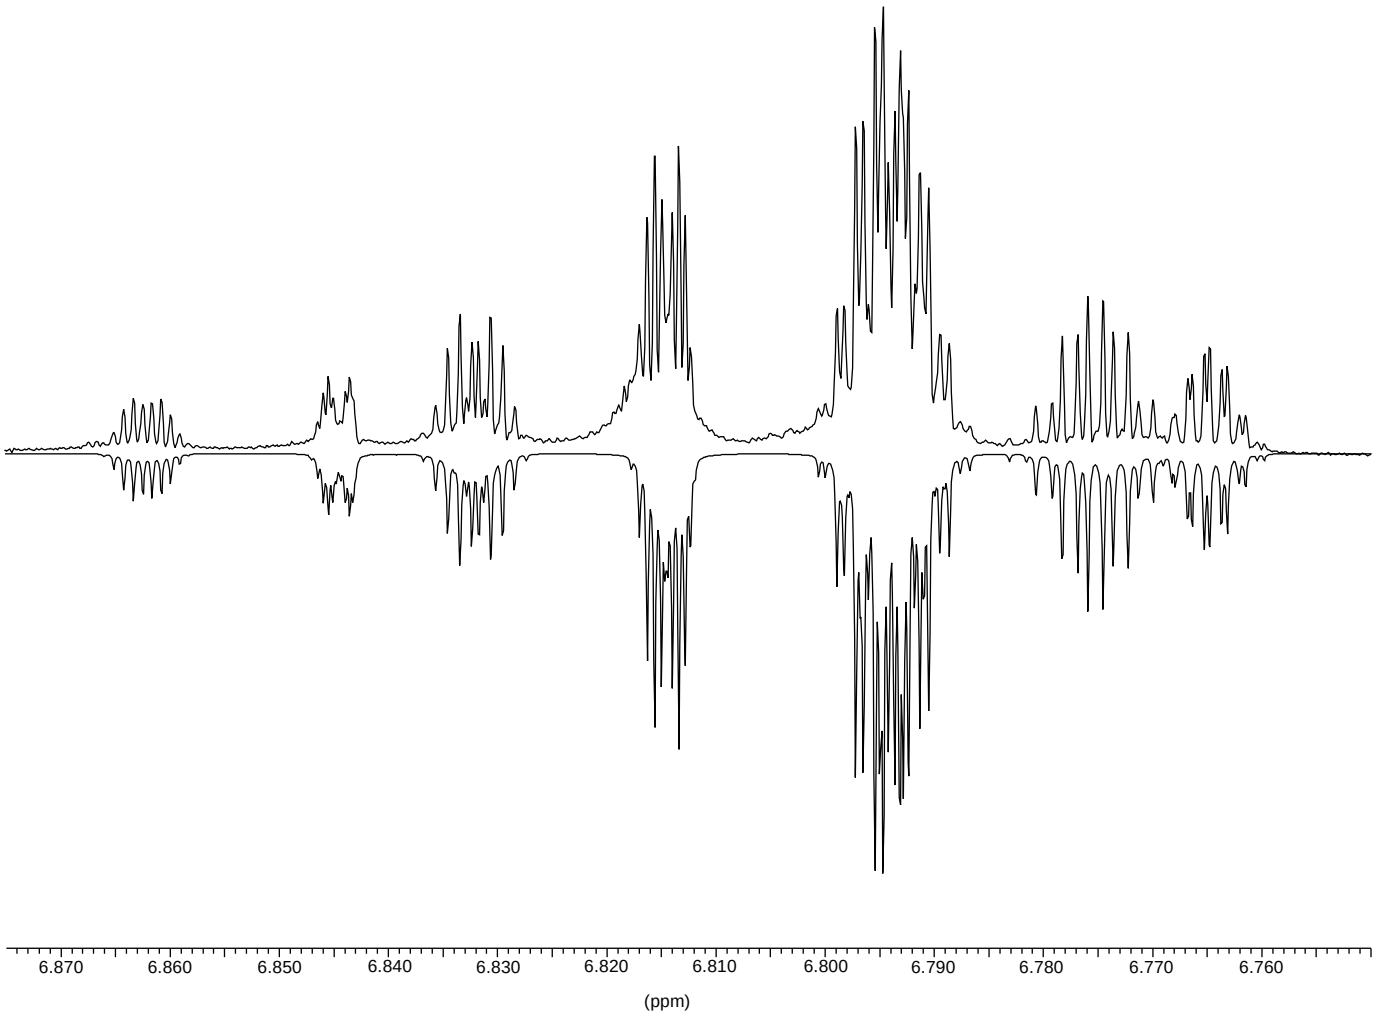
Fig. 1. Aromatic region of the experimental (top) and calculated (bottom) 300 MHz ^{1}H NMR spectrum of a 5 mol% solution of **5** in CS_2.



between 0.5 and 1.0, it also follows that the perpendicular conformation represents the ground state of the rotational potential. For the 3,5-dimethyl derivative **6**, the experimental coupling constant ^6J(H-α,H-*para*) of –0.18 Hz leads to $\langle \sin^2 \Theta \rangle = 0.16$, which proves the preference for the bisected conformation of this molecule and yields an estimate of 9.6 kJ/mol for the rotational barrier, of the same order of magnitude as the value for cyclopropylbenzene (**3**) itself which is 8.4 kJ/mol. Thus, the two important findings are: the rotational barrier in **5** is too small for dynamic NMR experiments on this compound to be successful, and the symmetry of the perpendicular ground state would preclude the observation of signal decoalescence even in case of a sufficiently high barrier. A referee has pointed out that the relative ^{1}H chemical shifts of the cyclopropyl protons H(a) ($\delta = 1.666$ in **5**, $\delta = 1.804$ in **6**) and of H(c) ($\delta = 0.451$ in **5**, $\delta = 0.614$ in **6**) are also consistent with the proposed conformational differences between **5** and **6**, as they are in line with the expected relative ring current effects of the phenyl group in the preferred conformations.

The conformational behaviour of **5** and **3** was qualitatively reproduced by molecular orbital computations. Ab initio computations of the rotational potential of **5** carried out for $\Theta = 0°$ to 90° in steps of 15° predict the energy maximum for $\Theta = 0°$ and a relatively flat energy minimum area extending from 60° to 90°, the 90° conformation lying slightly higher than the 60° conformation and the lowest energy occurring at $\Theta = 75°$ (Fig. 2*a*). The STO-3G and 6-31G* basis sets yield rotational barriers of 6.8 and 7.3 kJ/mol, respectively, in rather good agreement with the experimental result of 6.4 kJ/mol obtained by the *J* method. The semiempirical AM1 procedure predicts a similar shape of the barrier, although with $E(90°) < E(60°)$ and the minimum still at $\Theta = 75°$, but the barrier is overestimated almost exactly by a factor of two. The goodness of the agreement between experiment and ab initio computations is expressed by the $\langle \sin^2 \Theta \rangle$ values calculated for a temperature of 300 K and the shapes of the theoretical potentials, which contain a small fourfold and a negligible sixfold component. The calculated $\langle \sin^2 \Theta \rangle$ values are 0.74 for both the STO-3G and 6-31G* potentials, while the experimental finding was 0.77. The AM1 curve gives 0.85.

The reversal of the relative energies of the bisected and perpendicular conformations that follows from our present and from Parr's and Schaefer's (10) experiments is also reproduced by molecular orbital computations on cyclopropylbenzene (**3**), see Fig. 2*b*. Here, the bisected and perpendicular conformations correspond to an energy minimum and maximum, respectively, and the barrier is estimated to be 7.8 (6-31G*), 1.6 (STO-3G), or 10.0 kJ/mol

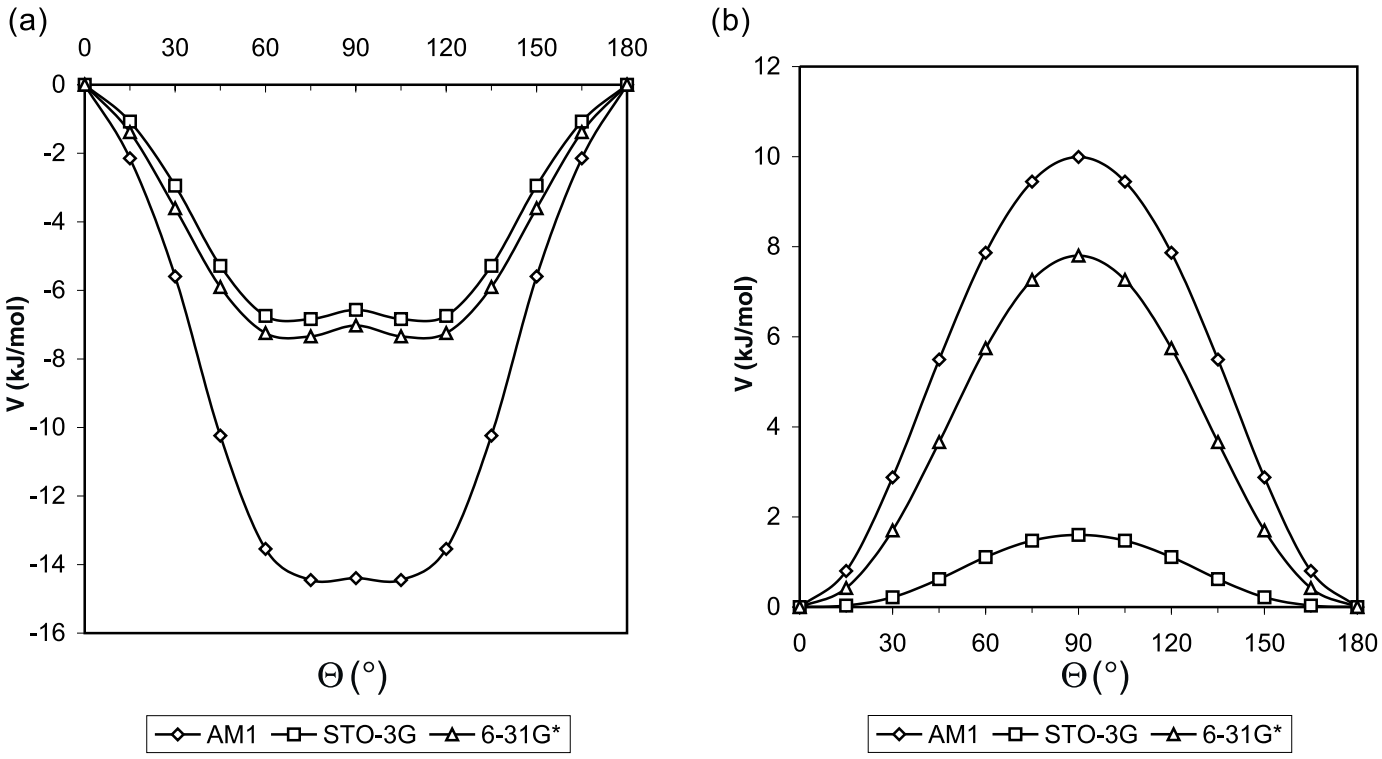
Fig. 2. Results of the molecular orbital computations of the internal rotation potential in 2-cyclopropyl-1,3-dimethylbenzene (**5**) (*a*) and in cyclopropylbenzene (**3**) (*b*). Θ is the torsional angle by which the cyclopropyl C(1)—H bond is twisted out of the plane of the benzene ring.



(AM1). The STO-3G result is clearly at variance with Parr's and Schaefer's (10) experimental finding (8.4 kJ/mol), but the 6-31G* value is similar to the experimental one, and the AM1 value also comes relatively close. To summarize the molecular orbital results, the three computational schemes agree (amongst themselves and with experiment) in the nature of the rotational ground and transition states for **3** and **5** and in the reversal of the stability of these states when two *ortho*-substituents are introduced into cyclopropylbenzene.

A comparison of the coupling constants in the cyclopropane ring of compounds **3** and **5** reveals one unexpected difference. While most of the *J*(H,H) values are very similar in the two compounds, i.e., they are unaffected by the substitution pattern of the phenyl group, the vicinal *trans* coupling constant involving H-1 [^3J(a,c) in Table 1] is distinctly affected, being 5.82 Hz (CS_2) or 5.86 Hz (acetone) in the 2,6-dimethyl derivative **5** and only 5.03 Hz (CS_2) in cyclopropylbenzene (**3**) itself (10), a difference of 14%. In the 3,5-dimethyl derivative **6** the coupling is 5.09 Hz (acetone, Table 2), similar to the value in **3**. As both **3** and **6** prefer the bisected conformation, which allows maximum cyclopropyl–aryl conjugation, while **5** favours the perpendicular conformation in which conjugation is minimal, these findings suggest that the coupling constant $^3J_{1,2}{}^{trans}$ in 1-substituted cyclopropanes is sensitive to conjugative effects exerted by the substituent. This coupling can possibly serve as an indicator of the preferred conformation in cyclopropanes carrying other conjugating substituents. The smaller values of $^3J_{1,2}{}^{trans}$ would point to a preference of the bisected conformation. This idea is supported by the small value of 4.89 Hz for $^3J_{1,2}{}^{trans}$ in vinylcyclopropane (16), in which the s-*trans* (= bisected) conformer predominates.

Application of dynamic NMR spectroscopy to 2-cyclopropyl-4-isopropyl-1,3,5-trimethylbenzene (10)

In a variable-temperature NMR experiment, a prochiral indicator group -CX_2Y in the *meta*-position of an *ortho*-dimethylated cyclopropylbenzene should, in principle, indicate by nonequivalence of the geminal X groups when cyclopropyl rotation becomes slow on the NMR timescale at low temperature if the preferred cyclopropyl conformation is perpendicular. We chose an isopropyl group as the prochiral indicator. As mentioned in the introduction, the rotation of an isopropyl group that is flanked by two *ortho*-substituents can be easily stopped, and in its preferred conformation the two methyl groups reside above and below the aromatic plane, respectively. They should therefore become nonequivalent when cyclopropyl rotation itself is slow and the three-membered ring favours the perpendicular conformation. We studied 2-cyclopropyl-4-isopropyl-1,3,5-trimethylbenzene (**10**), which was prepared as follows. In a Grignard reaction with acetaldehyde, bromo compound **7**, prepared from **2**, gave the secondary alcohol **8**, which was dehydrated with Al_2O_3 in vacuo at 100–150°C to give styrene **9**. This was converted into **10** by methylenation with $CH_2I_2/Al(CH_3)_3$ (17) (Scheme 1).

Low-temperature ^{1}H NMR spectra (Fig. 3*a*–*d*) were recorded of a solution of **10** in CBr_2F_2 containing 10% by volume of CD_2Cl_2 to provide a deuterium lock signal. On cooling the sample to temperatures below 0°C the signals

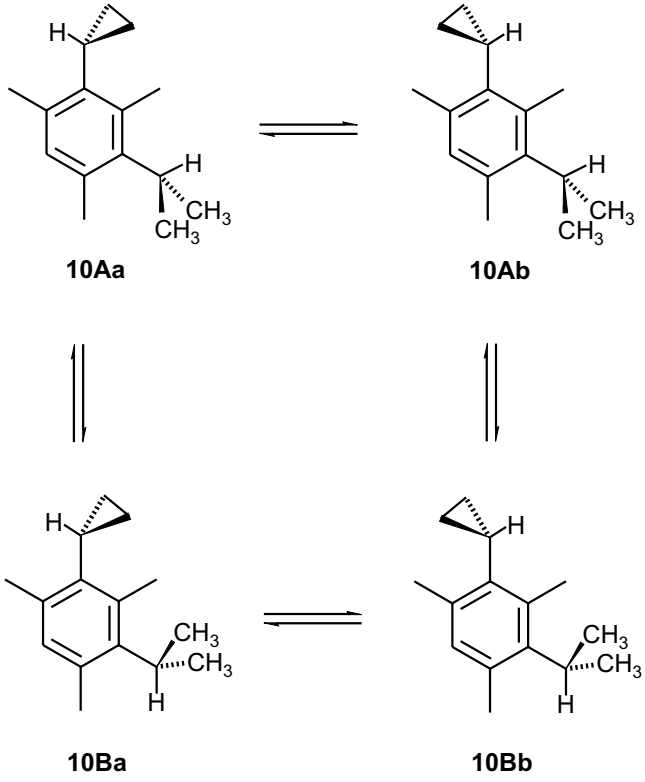
Scheme 3.



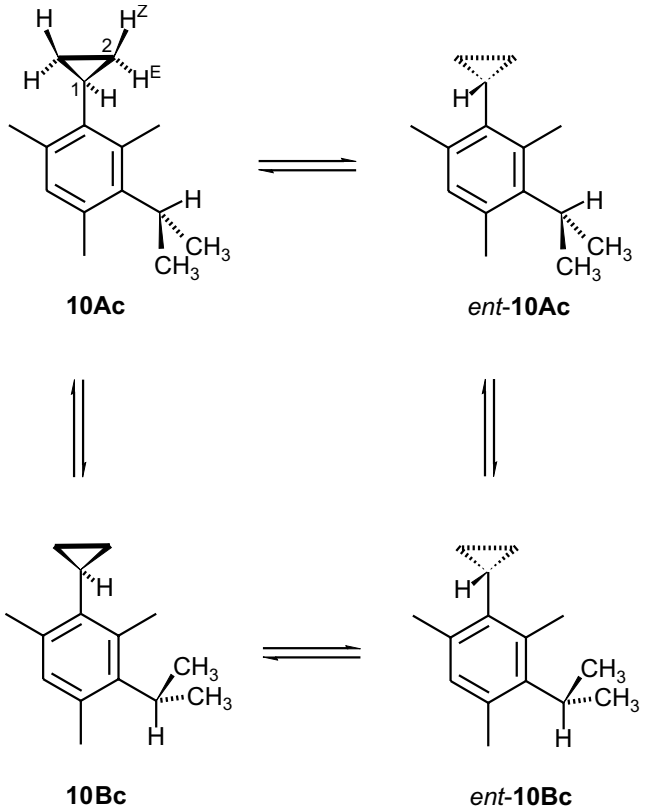
10Aa **10Ab**

10Ba **10Bb**

broadened (Fig. 3*b*; –29°C). Below –30°C the signals of the aromatic proton, of the three ring methyl groups, and the doublet of the isopropyl-CH_3 groups were doubled with a 1:1 ratio of the components (Fig. 3*c*; –80°C). The reason for this doubling of signals is slow rotation of the isopropyl group about the bond by which it is attached to the aromatic ring. Two rotamers are present which both have the C^{α}—H^{α} bond in the plane of the aromatic ring, pointing towards the 3-methyl group in one rotamer (**10A**) and to the 5-methyl group in the other (**10B**). Cyclopropyl rotation is still fast on the NMR timescale at this temperature (Scheme 2).

Apart from general signal broadening due to increasing sample viscosity and decreasing magnetic field homogeneity, an additional instance of line broadening was observed below –120°C, which can only be explained by cyclopropyl rotation also becoming slow. Eventually two broad signals (ratio ca. 3:1) emerged from both the isopropyl-CH_3 and the cyclopropyl-H-2^Z,3^Z (*cis* with respect to aryl) absorptions (Fig. 3*d*). These signals were neither well separated nor reasonably sharp at the low-temperature limit of the spectrometer (–140°C). The slow-exchange chemical shift differences could therefore not be determined. The ring-CH_3 and aryl-H resonances remained as six and two relatively sharp signals, respectively, apart from the accidental coincidence of two methyl lines. This shows that the cyclopropyl group does not adopt the two possible bisected conformations because in that case there should have been four sets of signals for each constitutionally different group in the molecule, i.e., 12 ring-CH_3 and 4 aryl-H singlets, and 4 isopropyl-CH_3 doublets. These four sets of signals would arise from the four possible combinations of bisected isopropyl (**A**, **B**) and bisected cyclopropyl (**a**, **b**) conformations as shown in formulae **10Aa**, **10Ab**, **10Ba**, and **10Bb** (Scheme 3).

Scheme 4.



10Ac *ent*-**10Ac**

10Bc *ent*-**10Bc**

The case of only one pair of bisected cyclopropyl rotamers being populated (e.g., **10Aa**/**10Ba**) may be dismissed, as no exchange broadening would then have occurred below –120°C. The remaining possibility, viz. the perpendicular cyclopropyl conformation (**c**) combined with the two bisected isopropyl conformations (**A**, **B**) to give rotamers **10Ac** and **10Bc** is in full agreement with the number of observed ring-CH_3 and aryl-H signals. Cyclopropyl rotation by 180° in **10Ac** or **10Bc** exchanges the sites of the isopropyl-CH_3 and of the cyclopropyl-CH_2 groups yet transforms these rotamers only into their enantiomers, which explains the smaller number of signals relative to the situation involving **10Aa**, **10Ab**, **10Ba**, and **10Bb** (Scheme 4). The intensity ratio of ca. 3:1 for the partly separated isopropyl-CH_3 and cyclopropyl-H-2^Z signals in the exchange-broadened spectrum at –140°C must be interpreted by one of the four expected chemical shifts being separated from the other three that are close to each other. As the low-temperature

© 1999 NRC Canada

measurements could not be extended to a temperature beyond exchange broadening, only a rough estimate of the barrier to cyclopropyl rotation in **10** is possible. Taking a coalescence temperature of –135°C and a chemical shift difference between the cyclopropyl-H-2^Z signals of ca. 27 Hz leads to an approximate barrier $\Delta G^{\ddagger}$ at that temperature of 28 kJ/mol. Figure 3*e* is intended only to demonstrate that the lowest temperature spectrum can be simulated by selecting a small rate constant and a reasonable set of chemical shifts. However, other combinations of parameters will produce similar spectra, so not too much significance should be attributed to the rate constant of 18 s^{-1} employed.

The estimate, if rough, of 28 kJ/mol for cyclopropyl rotation in **10** contrasts with the value of 6.4 kJ/mol determined for **5**. MM3 molecular mechanics computations were carried out to explain this large difference. For **5**, the dihedral driver option was used to vary the angle of cyclopropyl rotation in 5° steps, and the rest of the molecular geometry was allowed to be minimized. Additionally, for **10**, the torsion of the isopropyl group was fixed in both of the possible bisected conformations. The computations did not provide quantitative agreement with the experimental results but gave the proper geometries of the minimum and maximum energy conformations. They predicted a lower rotational barrier (22 kJ/mol) for **5** than for **10** (30–34 kJ/mol depending on the orientation of the isopropyl group). The barrier increase in **10** relative to **5** is caused by the combined buttressing effects of the isopropyl and 5-methyl groups upon the 3-methyl group, increasing the interaction of the latter with the cyclopropyl group. A referee has kindly performed STO-3G calculations on **10** and obtained a barrier of ca. 30 kJ/mol, in good agreement with our experimental and MM3 results.

Conclusions

Using rather simple model compounds and applying two independent NMR methods, we have shown that the "bisected" conformation, which represents the favoured rotamer of cyclopropylbenzene, becomes the rotational transition state when two *ortho*-substituents of the size of methyl groups are added to the molecule. The symmetrical "perpendicular" conformation becomes the rotational ground state. This reversal of ground and transition states is reproduced by ab initio and semiempirical molecular orbital computations. Larger substituents or additional buttressing groups plus an unsymmetrical substitution pattern are required to make the rotational barrier accessible to dynamic NMR measurements.

Experimental

The melting point of **8** was determined on a Laboratory Devices Mel-Temp II apparatus. Infrared spectra were recorded on a Nicolet 320 FT-IR spectrometer, of substance films or of KBr disks as indicated. EI mass spectra (70 eV) were recorded on a MAT 8430 spectrometer. The ^{1}H NMR spectra for the iterative analyses of **5** and **6** were obtained on a Bruker AM300 spectrometer at 300 MHz and ambient temperature under the solution conditions given in Tables 1 and 2. These samples were degassed five times by the freeze–pump–thaw technique and then flame-sealed. Digital resolutions were better than 0.01 Hz per data point in the Fourier transformed spectra. The iterative analyses were carried out with the computer program NUMARIT (18), as modified by Marat and Sebastian (19). All other NMR spectra were obtained on a Bruker AM400 spectrometer at 400 MHz (^{1}H) or 101 MHz (^{13}C). Chemical shifts in the ^{1}H spectra were referenced to tetramethylsilane (δ = 0.000) or the residual proton signal of 1,1,2,2-tetrachloroethane-d_2 (δ = 5.98). Chemical shifts in the ^{13}C spectra were referenced to the solvent signal, $\delta(CDCl_3)$ = 77.05 or $\delta(C_2D_2Cl_4)$ = 73.79. The low-temperature ^{1}H NMR spectra of **10** were obtained from a dilute solution in CBr_2F_2/CD_2Cl_2 (9:1, by volume). The residual proton signal of CD_2Cl_2 was used as the chemical shift reference, δ = 5.32. The temperature display of the spectrometer was calibrated against the standard methanol sample (4% in methanol-d_4) (20). Elemental analyses were performed at the Institute of Inorganic and Analytical Chemistry of the Technical University of Braunschweig. Flash column chromatography was carried out using silica gel 60 for flash chromatography (Fluka).

Ab initio (STO-3G and 6-31G*) molecular orbital computations employed the program system Gaussian 94 (21). Internal rotational potentials were found by fixing the torsional angle Θ at values between 0° and 90° in steps of 15°, and optimizing the values of other angles and bond lengths, with the constraint, however, that the phenyl moiety remain planar. The semiempirical AM1 algorithm (22) was also used.

2-Cyclopropyl-1,3-dimethylbenzene (5)

This compound was prepared from 2-ethenyl-1,3-dimethylbenzene according to Brown and Cleveland (23). The ^{1}H NMR chemical shifts are similar to those given in ref. 23. For more detailed ^{1}H NMR data, see text, Table 1. ^{13}C NMR (101 MHz, $CDCl_3$, δ = 77.05) δ: 139.1 (s, C-2), 139.0 (s, C-1,3), 127.9 (d, C-4,6), 126.1 (d, C-5), 20.6 (q, 1,3-CH_3), 12.2 (d, *c*-Pr-C-1), 8.1 (t, *c*-Pr-C-2,3).

1-Cyclopropyl-3,5-dimethylbenzene (6)

To lithium granulates (0.96 g, 138.3 mmol) in dry ether (25 mL) under N_2 a solution of 1-iodo-3,5-dimethylbenzene (24) (14.39 g, 62.0 mmol) in dry ether (75 mL) was added dropwise with stirring during 45 min. Stirring was continued for another 30 min. To remove the excess lithium, the reaction mixture was transferred to a second flask by pouring it through a transfer piece filled with cotton wool. A solution of bromocyclopropane (1.50 g, 12.4 mmol) in dry ether (10 mL) was added dropwise and the mixture warmed to reflux for 15 h. The reaction mixture was poured onto ice water (100 mL), the organic phase separated, the aqueous phase extracted with ether, and the combined organic phases washed twice with water and dried over $MgSO_4$. The solvent was distilled off and the residue subjected to flash column chromatography (silica gel, *n*-pentane; R_f: 0.33) to give 178 mg (10%) of **6** as a colourless oil. The ^{1}H NMR chemical shifts are similar to those reported previously (25). For more detailed ^{1}H NMR data, see text, Table 2. ^{13}C NMR (101 MHz, $CDCl_3$, δ = 77.05) δ: 143.9 (s, C-1), 137.8 (s, C-3,5), 127.1 (d, C-4), 123.5 (d, C-2,6), 21.3 (q, 3,5-CH_3), 15.1 (d, *c*-Pr-C-1), 9.0 (t, *c*-Pr-C-2,3).

2-Bromo-4-isopropyl-1,3,5-trimethylbenzene (7)

To 2-isopropyl-1,3,5-trimethylbenzene (**2**) (26) (2.20 g, 13.6 mmol) and iron powder (30 mg) in dry CCl_4 (10 mL) was added bromine (1.72 g, 10.8 mmol) in dry CCl_4 (3 mL) at room temperature. Ten drops were added first and the remainder only when the formation of HBr gas was visible after the induction period. Stirring was continued overnight. The reaction mixture was diluted with CH_2Cl_2 (30 mL) and washed with 10% aqueous $NaHSO_3$ solution (20 mL), 10% aqueous NaOH solution (20 mL), and twice with water (20 mL). Drying over $MgSO_4$ and distilling off the solvent left a yellow oil. Flash column chromatography (silica gel, *n*-pentane; R_f 0.47) gave 2.6 g (99%) of **7** as a colourless oil. The NMR spectra of **7** and of the compounds described below were measured at elevated temperatures because coalescence phenomena led to broad lines in the room temperature spectra. IR (film) cm^{-1}: 2959 vs, 2931 s, 2876 m, 1463 s, 1460 s, 1452 s, 1388 m, 1365 m, 1189 m, 1073 m, 974 vs, 862 m, 722 w. ^1H NMR (400 MHz, 100°C, $C_2D_2Cl_4$, residual solvent signal, δ: 5.98) δ: 6.90 (s, 1H; H-6), 3.50 (sept, J = 7.3 Hz, 1H; i-Pr-CH), 2.54 (s, 3H; 3-CH_3), 2.39 (s, 3H; 1-CH_3), 2.34 (s, 3H; 5-CH_3), 1.37 (d, J = 7.3 Hz, 6H; i-Pr-CH_3). ^{13}C NMR (101 MHz, 100°C, $C_2D_2Cl_4$, δ: 73.79) δ: 143.5 (s, C-4), 135.6 (s, C-3), 135.0 (s, C-1), 134.4 (s, C-5), 131.0 (d, C-6), 127.1 (s, C-2), 30.0 (d, i-Pr-CH), 23.6 (q, 1-CH_3), 21.2 (q, 3-CH_3), 20.9 (q, 2C, i-Pr-CH_3), 20.7 (q, 5-CH_3); assignments by C,H-HETCOR, C,H-COLOC, and H,H-NOE. MS(EI) *m/z* (%): 242/240 (M^+, 38), 227 (96), 225 (100), 147 (18), 146 (52), 145 (16), 131 (17), 119 (14), 115 (10). Anal. calcd. for $C_{12}H_{17}Br$: C 59.76, H 7.10; found: C 59.36, H 7.09.

1-(3-Isopropyl-2,4,6-trimethylphenyl)-ethan-1-ol (8)

To a 30% lithium – mineral oil dispersion (506 mg) in dry ether (3 mL) was added dropwise a solution of **7** (2.40 g, 10.0 mmol) in dry ether (3 mL) under N_2 at room temperature. After addition of the first few drops, the reaction was started by gentle warming. When the addition of **7** was complete stirring was continued for 2.5 h at 30°C. The mixture was cooled to 0°C, and a solution of acetaldehyde (541 mg, 12.3 mmol) in dry ether (8 mL) was added dropwise. After stirring the reaction mixture for 30 min at 0°C and for 1h at room temperature it was poured onto ice water (30 mL), and the organic layer was separated. The aqueous phase was extracted twice with ether (30 mL), and the combined organic phases were washed with a saturated aqueous $NaHSO_3$ solution (25 mL) and thrice with water (10 mL). Drying over $MgSO_4$ and distilling off the solvent furnished a yellow oil (2.6 g) from which white crystals separated on standing in the refrigerator overnight. The crystals were collected and recrystallized from *n*-pentane to yield 1.12 g (55%) of **8**, mp 78°C. IR (KBr) cm^{-1}: 3315 vs, 2958 vs, 2933 vs, 2873 s, 1456 s, 1366 m, 1301 m, 1075 s, 1049 s, 895 m, 865 m, 706 w. ^1H NMR (400 MHz, 90°C, $C_2D_2Cl_4$, residual solvent signal, δ: 5.98) δ: 6.81 (s, 1H; H-5), 5.44 (q, J = 6.8 Hz, 1H; CH-O), 3.54 (sept, J = 7.3 Hz, 1H; i-Pr-CH), 2.48 (s, 3H; 2-CH_3), 2.42 (s, 3H; 6-CH_3), 2.38 (s, 3H; 4-CH_3), 1.75 (s, 1H; OH), 1.60 (d, J = 6.8 Hz, 3H; CH_3-CHO-), 1.404 (d, J = 7.3 Hz, 3H; i-Pr-CH_3), 1.402 (d, J = 7.3 Hz, 3H; i-Pr-CH_3). ^{13}C NMR (101 MHz, 90°C, $C_2D_2Cl_4$, δ: 73.79) δ: 142.9 (s, C-3), 139.0 (s, C-1), 134.8 (s, C-4), 134.0 (s, C-2), 132.5 (d, C-5), 132.4 (s, C-6), 67.7 (d, CHO), 28.9 (d, i-Pr-CH), 21.8 (q, -OCH-CH_3), 21.1 (q, 4-CH_3), 21.0 (q, 2C, i-Pr-CH_3), 20.2 (q, 6-CH_3), 16.8 (q, 2-CH_3); assignments by C,H-HETCOR and -COLOC. MS(EI) *m/z* (%): 206 (M^+, 58), 191 (100), 188 (50), 173 (60), 149 (24), 145 (22), 121 (40). Anal. calcd. for $C_{14}H_{22}O$: C 81.50, H 10.75; found: C 81.36, H 10.77.

2-Isopropyl-1,3,5-trimethyl-4-vinylbenzene (9)

To neutral Al_2O_3 (10 g, ICN, activity: "super I") **8** was added (900 mg, 4.4 mmol) and, at a pressure of 0.8 mbar (1 bar = 100 kPa), the mixture was heated to 100°C for 2.5 h and then to 150°C for 30 min. The product was collected in a cooling trap (liq. N_2) as a colourless liquid and purified by flash column chromatography (silica gel, *n*-pentane; R_f 0.27), yield 703 mg (86%). IR (film) cm^{-1}: 2960 vs, 2933 s, 2874 m, 1632 w, 1459 m, 1363 w, 995 m, 919 s, 865 m. ^1H NMR (400 MHz, 100°C, $C_2D_2Cl_4$, residual solvent signal, δ: 5.98) δ: 6.86 (s, 1H; H-6), 6.72 (dd, J = 17.9 and 11.4 Hz, 1H; -CH=), 5.54 (dd, J = 11.4 and 2.3 Hz, 1H; H_E of =CH_2), 5.20 (dd, J = 17.9 and 2.3 Hz, 1H; H_Z of =CH_2), 3.52 (sept, J = 7.3 Hz, 1H; i-Pr-CH), 2.38 (s, 3H; 1-CH_3), 2.36 (s, 3H; 3-CH_3), 2.27 (s, 3H; 5-CH_3), 1.40 (d, J = 7.3 Hz, 6H; i-Pr-CH_3). ^{13}C NMR (101 MHz, 100°C, $C_2D_2Cl_4$, δ: 73.79) δ: 141.7 (s, C-2), 137.0 (s, C-4), 136.6 (d, -CH=), 134.0 (s, C-1), 133.6 (s, C-3), 132.2 (s, C-5), 130.7 (d, C-6), 118.5 (t, =CH_2), 29.2 (d, i-Pr-CH), 21.0 (q, 3C, i-Pr-CH_3 and 1-CH_3), 20.3 (q, 5-CH_3), 17.8 (q, 3-CH_3); assignments by C,H-HETCOR and -COLOC. MS(EI) *m/z* (%): 118 (M^+, 58), 174 (14), 173 (100), 159 (14), 145 (43). Anal. calcd. for $C_{14}H_{20}$: C 89.30, H 10.70; found: C 89.47, H 10.91.

2-Cyclopropyl-4-isopropyl-1,3,5-trimethylbenzene (10)

To a solution of **9** (0.50 g, 2.7 mmol) and CH_2I_2 (2.1 g, 7.9 mmol) in dry *n*-hexane (5 mL) under N_2 a 2 M solution (6.64 mL) of $Al(CH_3)_3$ in toluene was added dropwise at room temperature. The progress of the reaction was monitored by GC. After 17 h, when the ratio of **9**/**10** was ca. 3:2, more CH_2I_2 (2.1 g, 7.9 mmol) was added followed by more (6.64 mL) of the $Al(CH_3)_3$ solution. After a reaction time of 90 h the ratio of **9**/**10** was ca. 1:22. The reaction mixture was then cooled to 0°C, and 10% aqueous NaOH (6 mL) was added cautiously with stirring. After stirring for another 20 min ether (20 mL) was added and the organic phase separated. The aqueous phase was extracted twice with ether (20 mL). The combined organic phases were washed with water (20 mL) and dried over $MgSO_4$. The solvent was distilled off, and a yellow oil (540 mg) remained. To remove the starting material, the raw product was dissolved in dry CCl_4 (7 mL) in a test tube, and a solution of one drop of bromine in CCl_4 (2 mL) was added at 0°C. After shaking for a short time CH_2Cl_2 (20 mL) was added and the solution washed twice with a saturated aqueous $Na_2S_2O_3$ solution (12 mL) and once with water (20 mL). Drying over $MgSO_4$ and distilling off the solvent left a black oil. Flash column chromatography (silica gel, *n*-pentane; R_f 0.27) yielded 188 mg (46%) of **10** as a colourless oil. IR (film) cm^{-1}: 3079 w, 3001 s, 2962 vs, 2928 s, 2872 m, 1459 m, 1033 m, 1016 m, 902 w, 864 w, 816 w. ^1H NMR (400 MHz, 100°C, $C_2D_2Cl_4$, residual solvent signal, δ: 5.98) δ: 6.80 (s, 1H; H-6), 3.52 (sept, J = 7.2 Hz, 1H; i-Pr-CH), 2.52 (s, 3H;

Stereochemical rearrangements in tricarbonylrhenium(I) halide complexes of the nonracemic chiral ligand 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine (L): a dynamic NMR study

Peter J. Heard, Alex D. Bain, and Paul Hazendonk

Abstract: Tricarbonylrhenium(I) halide complexes of the nonracemic chiral ligand 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine (L), namely *fac*-[ReX(CO)$_3$L] (X = Cl, Br, or I), have been prepared and their latent fluxionality studied by dynamic NMR techniques in the slow and intermediate exchange regimes. In solution, these complexes give rise to four diastereoisomers, depending on the configuration at the metal and at the acetal-carbon atom, respectively; the relative populations are in the order *SR* > *RR* >> *RS* > *SS*. At moderate temperatures, a reversible "acetal ring flip" leads to *formal* inversion of configuration at the acetal-carbon atom; the free energies of activation are in the range 84–88 kJ mol^{-1} at 298 K. Above ca. 370 K, reversible ligand dissociation also occurs, leading to an exchange of all four diastereoisomers on the NMR chemical shift time-scale.

Key words: dynamic NMR, fluxionality, tricarbonylrhenium(I) complexes, chiral acetal ligands.

Résumé : On a préparé les complexes d'halogénures du tricarbonylrhénium(I) avec le ligand chiral non racémique 2-[(4*R*,5*R*)-diméthyl-1,3-dioxan-2-yl]pyridine (L), soit les *fac*-[ReX(CO)$_3$L] (X = Cl, Br, ou I), et on a étudié leurs propriétés fluxionnelles latentes par des techniques de RMN dans des régimes d'échange lents et intermédiaires. En solution, ces complexes présentent quatre diastéréoisomères suivant, respectivement, la configuration au niveau du métal ou de l'atome de carbone de l'acétal; les populations relatives sont dans l'ordre *SR* > *RR* >> *RS* > *SS*. À des températures modérées, une inversion réversible du cycle de l'acétal conduit à une inversion *formelle* de configuration au niveau du carbone de l'acétal; les énergies libres d'activation sont de l'ordre de 84 à 88 kJ mol^{-1} à 298 K. Au-dessus d'environ 370 K, il se produit aussi une dissociation réversible du ligand qui, à l'échelle de temps des déplacements chimiques en RMN, conduit à un échange des quatre diastéréoisomères.

Mots clés : RMN dynamique, propriétés fluxionnelles, complexes du tricarbonylrhénium(I), ligands acétal chiraux.

[Traduit par la Rédaction]

Introduction

Nonracemic chiral ligands play an important role in organometallic chemistry, particularly in homogeneous catalysis (1); understanding the bonding in these complexes is therefore of importance. The systematic study of fluxional processes provides a sensitive method for probing bonding interactions, particularly where multiple mechanistic pathways are competing. We have demonstrated recently that nonracemic chiral ligands can be used to elucidate dynamic processes that are otherwise unobservable (2, 3), providing detailed information on the bonding between the metal and the fluxional ligand. This paper illustrates the power of such an approach for the study of complex fluxional organometallic systems.

The latent fluxionality of transition metal complexes of potentially *mer*-terdentate ligands in which the ligand is restricted to a bidentate bonding mode is of current interest (4, 5). The possible mechanisms of the dynamics are the subject of controversy (6, 7). Our approach has been to employ a nonracemic chiral oxazoline ligand (8); the spectroscopic handle provided by the asymmetric centres enables the mechanism to be determined unambiguously. We reported recently on the use of the C_2-symmetric bis(oxazolines), 2,6-

R = Me or ^{i}Pr

bis[(4*S*)-alkyloxazolin-2-yl]pyridine (alkyl = methyl or isopropyl), as a mechanistic probe for the dynamic stereochemical rearrangements in complexes of the type shown in Fig. 1 (2, 3). This paper describes the results of a detailed dynamic NMR study on the tricarbonylrhenium(I) halide complexes of the closely related acetal ligand, 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine (L), namely *fac*-$[ReX(CO)_3L]$ (X = Cl, Br, or I).

Experimental

Syntheses

All manipulations were performed using standard Schlenk techniques (9) under an atmosphere of dry, oxygen-free nitrogen. Solvents were dried (10) and degassed before use. The pentacarbonylrhenium(I) halides were prepared according to previously published procedures (11). (2*R*,3*R*)-Butanediol, 2-pyridinecarboxaldehyde, and 2,2-dimethoxypropane were purchased from Aldrich Chemical Company and were used without further purification. The compounds were prepared as described below. Analytical and ^{1}H NMR data are reported in Tables 1 and 2, respectively.

2-[(4*R*,5*R*)-Dimethyl-1,3-dioxan-2-yl]pyridine (L)

(See ref. 12.) 2-Pyridinecarboxaldehyde (1.0 cm^3, 10.5 mmol), (2*R*,3*R*)-butanediol (1.5 cm^3, 16.43 mmol), 2,2-dimethyoxypropane (1.5 cm^3, 16 mmol), and ca. 40 mg of *p*-toluenesulfonoic acid were refluxed for 48 h in toluene (30 cm^3). The toluene was then extracted with (*i*) aqueous Na_2CO_3 solution and (*ii*) water. After drying ($MgSO_4$), the toluene was concentrated in vacuo to yield an oil. The ligand, 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine, was purified from hot hexane and characterized by ^{1}H NMR spectroscopy. Yield: 1.40 g, 75%.

The three complexes, $[ReX(CO)_3L]$ (X = Cl, Br, or I), were prepared similarly, as illustrated by the procedure for the complex X = Br.

{2-[(4*R*,5*R*)-Dimethyl-1,3-dioxan-2-yl]pyridine}bromotricarbonylrhenium(I)

$[ReBr(CO)_5]$, 100 mg (0.246 mmol), and 50 mg (0.279 mmol) of 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine were refluxed for ca. 18 h in 20 cm^3 of benzene. The solvent was then removed in vacuo to yield an oil that was purified by precipitation from a CH_2Cl_2–hexane solvent mixture at –20°C. Yield: 72 mg, 60%.

Physical methods

Infrared spectra were recorded as CH_2Cl_2 solutions on a Nicolet 205 FT-IR spectrometer, operating in the region 4000–400 cm^{-1}. Elemental analyses were carried out at University College London. Mass spectra (LSIMS) were obtained at the London School of Pharmacy on a VG Analytical ZAB-SE instrument, using Xe^+ ion bombardment at 8 kV energy.

^{1}H NMR spectra were recorded in $[D]_2$-tetrachloroethane at McMaster University on a Bruker AM300 NMR spectrometer, operating at 300.13 MHz. Chemical shifts are quoted in ppm relative to tetramethylsilane as an internal standard. Probe temperatures were controlled by a standard

[d]Recorded in $CDCl_3$ solution.

[e]Overlaps with the solvent signal.

B-VT 2000 unit and are considered accurate to within ±1°C. Standard one-dimensional variable temperature experiments were carried out in the temperature range 303–393 K; probe temperatures was allowed to equilibrate for ca. 20 min before each spectrum was recorded. Acquisition times were typically ca. 5 s, and a relaxation delay of 5 s was allowed between scans. Band shapes were analysed using the non-iterative simulation program MEX (13). Inversion-recovery experiments were carried out using the automation program INVREC2P (modified from the Bruker program INVREC), which generates the pulse sequence D1–90-τ-90-VD-90-free induction decay. For nonselective inversions the delay, τ, was 10 μs. For the selective experiments, the signal to be inverted was placed on resonance and τ was set at $1/(2\Delta\nu)$; $\Delta\nu$ is the frequency difference between the inverted and observed signals. The relaxation delay, D1, was 30 s. For the selective and nonselective inversions, respectively, 24–30 and 12–16 experiments (i.e., the number of delay times in the VD list) were carried out. Exchange rates were extracted from the longitudinal magnetizations using the program CIFIT (14). Two-dimensional exchange (EXSY) spectra, recorded using the Bruker automation program NOESYPH, were acquired prior to the selective inversions, to ascertain which signals were undergoing chemical exchange. Typical acquisition parameters for the EXSY experiment are described elsewhere (3). The rate constants obtained from the dynamic NMR experiments were used to calculate the Eyring activation parameters; the errors quoted are those defined by Binsch and Kessler (15).

Results

The three complexes, [ReX(CO)$_3$L] {X = Cl, Br, or I; L = 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine}, were isolated as air-stable brown oils as described above. The mass spectra (LSIMS) of the complexes displayed strong peaks due to the species $[M - H]^+$, due to the loss of the acetal carbon – H, and $[M - X]^+$ (X = Cl, Br, or I); the observed and calculated isotope patterns are consistent. The infrared spectra (CH_2Cl_2 solution) displayed three carbonyl stretching bands in the region 1850–2050 cm^{-1}, as expected for a *fac*-octahedral tricarbonylrhenium(I) complex (16). Analytically pure samples could not be obtained; consequently, elemental analyses (C, H, and N) gave poor data. Data are reported in Table 1.

NMR studies

The ambient temperature (303 K) ^{1}H NMR spectra of the complexes, [ReX(CO)$_3$L] (X = Cl, Br, or I; L = 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine), in [*D*]$_2$-tetrachloroethane displayed well-resolved signals due to the presence of four non-exchanging diastereoisomers (Fig. 2). The spectra of the three complexes were similar, and the results obtained for [ReBr(CO)$_3$L] will serve to illustrate the analysis of the problem.

The ^{1}H NMR spectrum of [ReBr(CO)$_3$L] at 303 K displayed signals in two regions of principal interest (Fig. 3): (*i*) acetal-methyl region (ca. δ = 1.1–1.7) and (*ii*) acetal-CH region (ca. δ = 6.0–7.0). The acetal-methyl region displayed

Fig. 2. The four diastereoisomers of the complexes $[ReX(CO)_3L]$, showing the interconversion pathways resulting from the acetal "ring flip" process. The letters *R* and *S* refer to the configuration at the metal and at the acetal carbon atom, respectively. The acetal-carbon atom is labelled C_1, and the acetal carbon-H is labelled H_A.

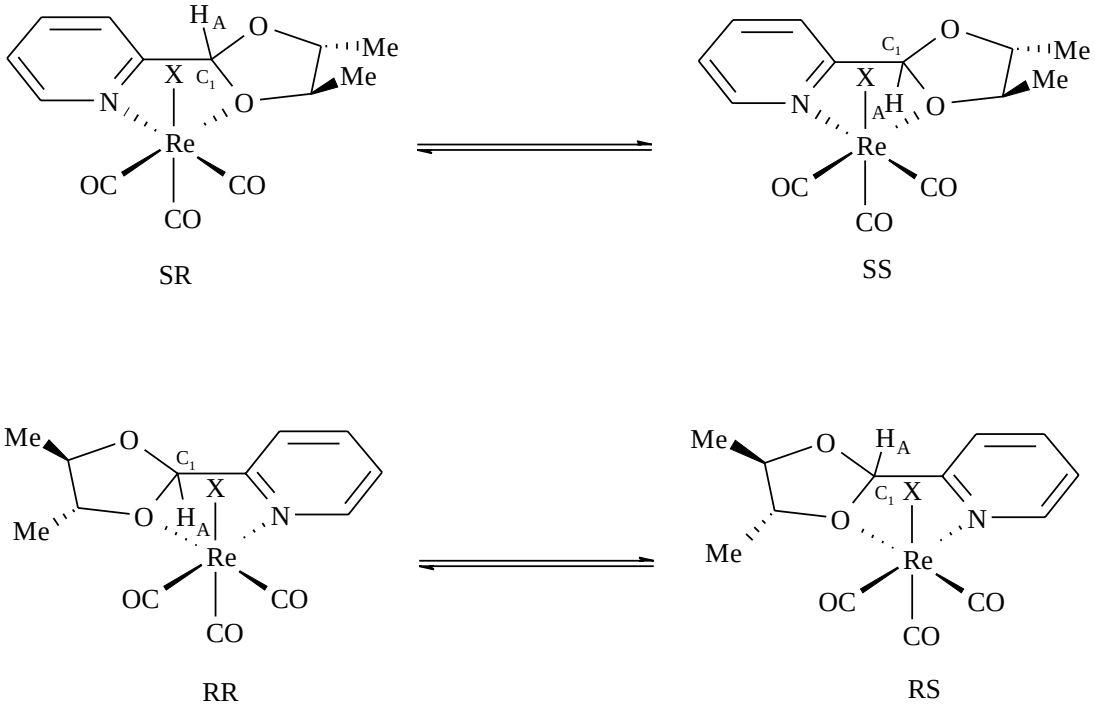

Fig. 3. ^1H NMR (300 MHz) spectrum of $[ReBr(CO)_3L]$ in $(CDCl_2)_2$, showing the acetal ring methyl and acetal carbon-H regions. See Fig. 2 for labelling. The broad signal denoted * is probably due to water.

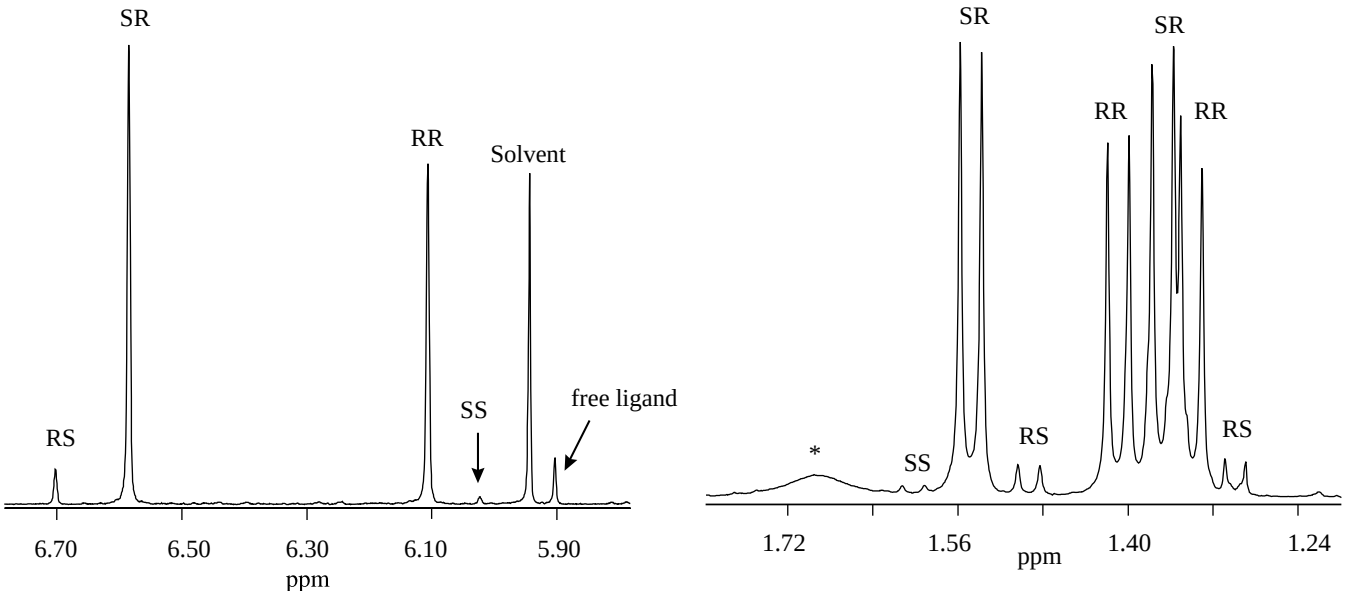

four pairs of doublets ($^3J_{HH} \approx 6$ Hz) of differing intensity. If it is assumed that inversion of configuration at the coordinated oxygen atom is rapid on the NMR chemical shift timescale (17, 18), the four pairs of doublets can be assigned to the four (non-exchanging) diastereoisomers shown in Fig. 2. These are labelled *SR*, *RR*, *RS*, and *SS* (depending on the configuration at the metal and at the acetal-carbon atom (C_1, see Fig. 2), respectively). The configuration at the metal (19) (*R* or *S*) was determined by viewing the molecule down the pseudo C_3 axis of symmetry (with the three CO ligands down) and assigning priorities to the three remaining ligands (halogen, oxygen, and nitrogen), according to the Cahn–Ingold–Prelog system (20).

The acetal-CH region displayed four broad singlets, assignable to the four diastereoisomers. The line broadening of these signals results from unresolved long-range couplings

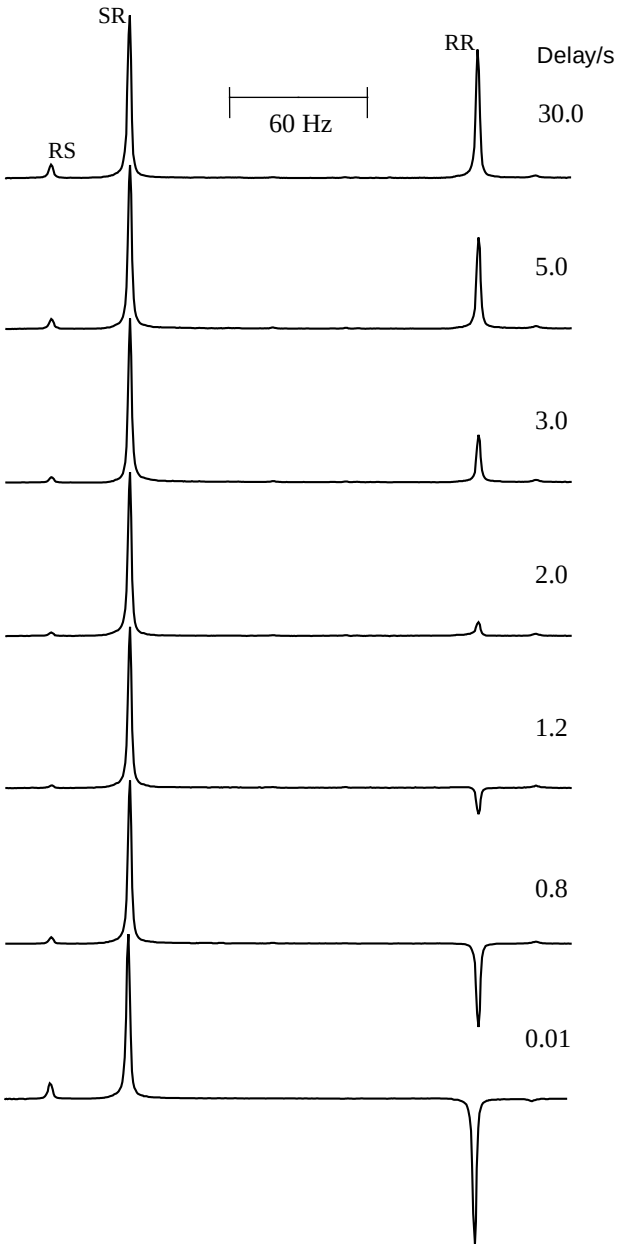
Fig. 4. Spectra show the selective inversion of the signal of the acetal H of the *RR* diastereoisomer of the complex $[ReBr(CO)_3L]$ at 323 K. Delay times are shown alongside. See Fig. 2 for labelling of the diastereoisomers.



to the pyridine-H nuclides. The assignment of the major solution-state diastereoisomer was based on our results on the closely related complex, $[ReBr(CO)_3L^2]$ (L^2 = 2,6-bis[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine), which has four directly analogous diastereoisomers in solution. In the solid state $[ReBr(CO)_3L^2]$ exists exclusively as the *SR* diastereoisomer,[2] and (solid state and solution) ^{13}C NMR data indicate that it predominates in solution. The major solution-state species of the complex $[ReBr(CO)_3L]$ (L = 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine) was therefore assigned as the *SR* diastereoisomer. The assignments of the remaining signals are based on the variable temperature ^1H NMR spectra (see below) and the relative chemical shifts of the acetal-CH signals. Exchange can occur between diastereoisomers (*SR* ⇆ *SS* and *RS* ⇆ *RR*) as a result of an "acetal ring flip" process, which leads to *formal* inversion of configuration at the acetal carbon atom, C_1 (see below). There is no exchange between these pairs because, at moderate temperatures (see below), there is no mechanism for *formal* inversion of configuration at the metal centre. The signal due to the *SS* diastereoisomer is thus readily identified because it exchanges with the signal due to the *SR* diastereoisomer (see above). The acetal-CH of the *SR* diastereoisomer is oriented on the same side as the halogen (Br) and resonates at higher frequency than the acetal-CH of the *SS* diastereoisomer. The acetal-CH of the *RS* diastereoisomer is also oriented on the same side as the halogen, so might be expected to resonate at higher frequency than the acetal-CH of the *RR* diastereoisomer. Thus, the high frequency acetal-CH signal of the *RR*/*RS* pair was assigned to the *RS* diastereoisomer. This is not unambiguous, but the *absolute* assignments do not affect the analysis of the dynamic exchange problem. The populations (Table 2), determined from the relative intensities of the acetal-CH signals, are in the order *SR* > *RR* >> *RS* > *SS*, and follow the trends expected on consideration of the different metal···ligand steric interactions.

The ^1H NMR spectrum of $[ReBr(CO)_3L]$ also displayed signals in the regions ca. δ = 3.6–4.6 and 7.2–9.0, due to the hydrogen nuclides of the acetal and pyridine rings, respectively. The signals of the four diastereoisomers are not well separated in these regions, frustrating complete assignment and accurate measurement of all chemical shifts and scalar couplings. ^1H NMR data for the ligand (L), 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine, and the three complexes, $[ReX(CO)_3L]$ (X = Cl, Br, or I), are given in Table 2.

Variable-temperature dynamic ^1H NMR experiments were carried out on all three complexes in the temperature range 303–393 K. The signals of the acetal-CH nuclides (H_A, see Fig. 2) provide the most suitable spectroscopic handle on the kinetics. Above ca. 330 K, the acetal-CH signals due to the minor species (*RS* and *SS*) broaden quickly, as a consequence of exchange between pairs of diastereoisomers,. i.e., *SR* ⇆ *SS* and *RR* ⇆ *RS*. Rates were measured in the slow exchange regime by selective inversion experiments (21–24) and in the intermediate exchange regime by standard band shape analysis (25). The acetal-CH signals of the two major diastereoisomers, *SR* and *RR*, were selectively inverted at 323 and 328 K. At these temperatures, magnetization transfers were only observed between pairs of diastereoisomers (*SR* ⇆ *SS* and *RR* ⇆ *RS*), as a consequence of *formal* inversion of configuration at the acetal-carbon atom. This presumably arises from an "acetal ring flip" that leads to exchange of the coordinated and pendant oxygen atoms. No magnetization transfers were observed between the *SR*/*SS* pair and the *RR*/*RS* pair, showing clearly that there is no *formal* inversion of configuration at the metal centre (*R* ⇆ *S*) at these temperatures. Spectra for the selective inversion of the *RR* diastereoisomer at 323 K are shown in Fig. 4. Kinetic data are reported in Table 3.

(I)

Analysis of the variable temperature ^{1}H NMR line shapes of the acetal-CH signals was carried out according to the dynamic spin system (**I**).

The six possible rate constants were treated as independent variables in the analysis. Below ca. 370 K, band shapes could be simulated accurately with only two nonzero rate constants, namely k_1 and k_6, corresponding to the *formal* inversion of configuration at C_1 (Fig. 2). At temperatures in excess of 370 K, the band shape analysis indicated the onset of a second dynamic process on the NMR chemical shift time scale. Accurate simulation of the high temperature spectra required the use of equal, non-zero rate constants for k_2, k_3, k_4, and k_5, in addition to the non-zero rates for k_1 and k_6. This second process is presumed to involve ligand dissociation; the process is fully reversible, and there was no evidence of decomposition. Twelve reliable fits were obtained, seven of which are shown in Fig. 5. Kinetic data are reported in Table 3, and the Eyring activation parameters are reported in Table 4. Band shape changes, consistent with the above analysis, were also observed in the other regions of the variable temperature ^{1}H NMR spectra (see above).

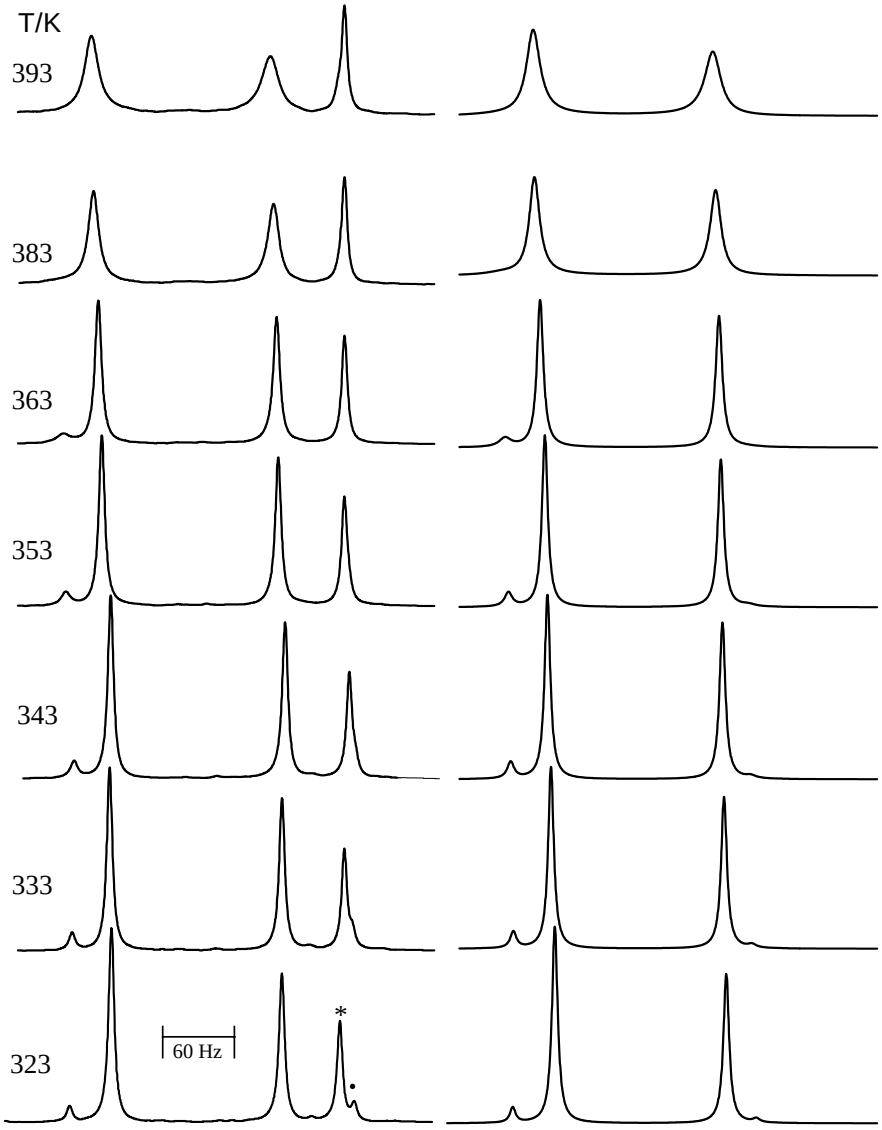
The compounds $[ReX(CO)_3L]$ (X = Cl or I; L = 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine) behaved analogously to the bromo complex, and the dynamic NMR spectra were analysed on the same basis (see above). However, the signal due to the *SS* diastereoisomer of the iodide complex was obscured by the residual solvent signal (δ = 5.96), frustrating a full analysis of the *RS* ⇆ *SS* kinetics; acceptable fits of the experimental spectra were obtained using equal rates for the two independent acetal ring flip processes.

Discussion

Variable temperature ^{1}H NMR data show clearly that, at moderate temperatures, a (reversible) *formal* inversion of

© 1999 NRC Canada

Fig. 5. Experimental and computer simulated variable temperature ^{1}H NMR spectra of the complex [ReBr(CO)$_3$L]. Rate constants are reported in Table 4. The bands denoted * and ● are due to solvent and free ligand, respectively.



configuration occurs at the acetal-carbon atom, C_1, causing an interconversion between pairs of diastereoisomers (*SR* ⇆ *SS* and *RR* ⇆ *RS*). This formal inversion of configuration presumably results from an acetal ring flip process that exchanges the coordinated and pendant oxygen donor atoms. Two possible mechanisms, shown in Fig. 6, can be envisaged for the acetal ring flip. Mechanism (*i*) (Fig. 6) involves cleavage of the Re—O bond, yielding a five coordinate transition state, followed by the formation of a new Re—O bond. Mechanism (*ii*) involves a loosening of the Re—O bond, concomitant with the formation of a pseudo seven coordinate transition state. The small magnitudes for the entropy of activation, $\Delta S^{\ddagger}$, (Table 4) point towards an associated transition state of the type involved in mechanism (*ii*). Conversely, the free energies of activation ($\Delta G^{\ddagger}$(298 K) ≈ 84–88 kJ mol^{-1}) indicate that Re—O bond cleavage is involved; data are comparable to the activation energies for the cleavage of the Re—N bond in the closely related complexes [ReX(CO)$_3$L^3] (X = Cl, Br or I; L^3 = 2,6-bis[(4*S*)-methyloxazolin-2-yl]pyridine) (2). This suggests that mechanism (*i*) (Fig. 6) is preferred. Although entropy of activation data provide information about the structure of the transition state, they are a less reliable indicator than energy of activation data. For this reason we consider mechanism (*i*) (Fig. 6) most likely, but more work is clearly necessary to establish this. We are currently investigating complexes of the analogous ligand 2-[(4*R*,6*R*)-dimethyl-1,3-dioxan-2-yl]pyridine to gain further insight.

The magnitudes of the free energies of activation for the *SR* → *SS* processes are ca. 2–4 kJ mol^{-1} greater than for the *RR* → *RS* process. This may, in part, arise from a weakening of the Re—O bonding interaction, because of increased steric interactions between one of the ligand methyls and the metal moiety in the *RR* diastereoisomer. This would lead to a small increase in the ground state energy of the *RR* diastereoisomer and hence a lowering of the free energy of activation. However, the differences in $\Delta G^{\ddagger}$ are higher than expected from the relative ground-state energies of the two

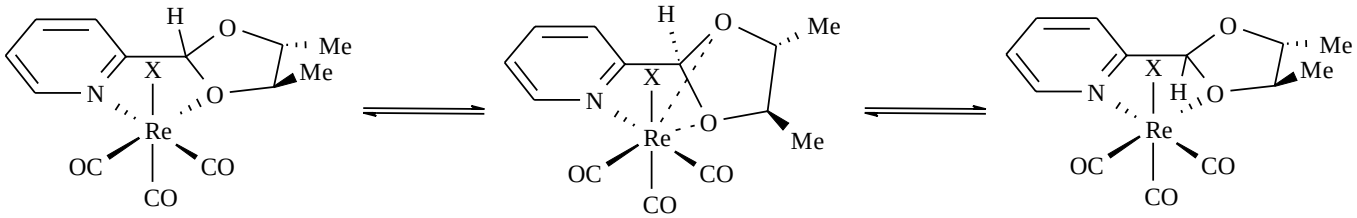
Mechanism (i)



Mechanism (ii)

diastereoisomers. This tends to suggest that the transition-state species of the two processes are subtly different, which is difficult to rationalize, particularly in terms of mechanism (*i*). The effect of the halogen on the dynamics appears to be minimal; this is expected because the halide is *cis* to the fluxional ligand.

Ring flip processes of this type are novel in tricarbonylrhenium(I) halide complexes, but a similar behaviour has been observed previously in palladium(II) complexes of bipyrimidine (bipym) (26). The tricarbonylrhenium(I) halide complexes of bipym, *fac*-$[ReX(CO)_3(bipym)]$ (X = Cl, Br, or I), do not shown analogous fluxional behaviour at a measurable rate on the NMR time-scale.[3]

Above ca. 370 K, the band shape changes indicate that the ligand is undergoing a reversible dissociation from the metal centre (see above), leading to an averaging of all four diastereoisomers. Only two or three reliable rate constants were obtained for this process, and the energy data obtained must therefore be treated with some caution. The principle contribution to $\Delta G^{\ddagger}$ probably comes from the energy required to break the Re—N(pyridine) bond. The higher magnitudes for the ligand dissociation, compared to the acetal ring flip fluxion (see above), presumably reflect the differences in the Re—O and Re—N bond strengths. The considerably higher magnitude of $\Delta G^{\ddagger}$ obtained for the chloro complex is not thought significant; experimental errors, consequential of the narrow temperature range, are the most likely explanation.

Conclusions

The complexes $[ReX(CO)_3L]$ (X = Cl, Br, or I; L = 2-[(4*R*,5*R*)-dimethyl-1,3-dioxan-2-yl]pyridine) give rise to four diastereoisomers in solution. At moderate temperatures an acetal ring flip process leads to exchange of the pendant and coordinate oxygen atoms, causing formal inversion of configuration at the acetal carbon atom. The kinetics of the acetal ring flip were measured in the slow and intermediate exchange regimes, and the results indicate that the mechanism involves initial cleavage of the Re—O(acetal) bond, concomitant with the formation of a five coordinate transition state.

Qualitative analysis of complex mixtures of VOCs using the inside needle capillary adsorption trap

S. Shojania, M.E. McComb, R.D. Oleschuk, H. Perreault, H.D. Gesser, and A. Chow

Abstract: An alternative sampling technique for fingerprint analysis of complex mixtures of petroleum-based products is presented. Fingerprint chromatograms of the volatile organic compounds (VOCs) for class 0–5 accelerants can be readily obtained using the recently developed *inside needle capillary adsorption trap* (INCAT) device. The concentration of VOCs from the static headspace of these complex mixtures, onto the adsorbing carbon coating of the INCAT device, avoids some problems associated with conventional headspace gas chromatography (HS-GC). The INCAT sampling method is a solventless extraction technique in which the analytes adsorbed inside the device are thermally desorbed inside the heated injection port of a gas chromatograph (GC), or a gas chromatograph coupled with a mass spectrometer (GC–MS). The presented method of active sampling with the INCAT device was used to obtain fingerprint chromatograms of the headspace of various gasolines, paint thinners, and lighter fluids. The static headspace chromatograms, from active sampling with the INCAT device, were compared with direct liquid injection of the samples. The INCAT chromatograms showed preferential adsorption of aromatic compounds over lighter, more volatile, but less polar compounds. Each class of the accelerant can be positively identified from the fingerprint chromatogram using only a few characteristic peaks. In addition, the ability to detect these volatile components of gasoline in aqueous samples at environmentally significant levels was also investigated.

Key words: VOC, fingerprinting, INCAT, petroleum, headspace GC.

Résumé : On présente une technique d'échantillonnage alternative pour l'analyse des empreintes digitales de mélanges complexes de produits à base de pétrole. Utilisant le dispositif dénommé *piège d'adsorption capillaire inséré dans l'aiguille* (« INCAT ») développé récemment, on peut facilement obtenir des chromatogrammes d'empreintes digitales des composés organiques volatils (COV) des accélérants des classes 0 à 5. La concentration des COV contenus dans les gaz de confinement (l'espace de tête) statique de ces mélanges complexes sur la couche de carbone adsorbant du dispositif INCAT permet d'éviter certains problèmes associés à la chromatographie gazeuse des gaz de confinement conventionnelle (CG-ET). La méthode d'échantillonnage à l'aide de l'INCAT est une technique d'extraction sans solvant dans laquelle les produits à analyser adsorbés dans le dispositif sont désorbés thermiquement dans l'injecteur de l'échantillon d'un chromatographe en phase gazeuse (CG) ou d'un chromatographe en phase gazeuse couplé à spectromètre de masse (CG–SM). On a utilisé la méthode préposée d'échantillonnage actif à l'aide du dispositif INCAT pour obtenir des chromatogrammes d'empreintes digitales des gaz de confinement de diverses essences, diluants de peinture et d'essences à briquet. Les chromatogrammes des gaz de confinement statiques obtenus par échantillonnage actif à l'aide du dispositif INCAT ont été comparés à ceux obtenus par injection directe du liquide des échantillons. Les chromatogrammes INCAT mettent en évidence une adsorption préférentielle des composés aromatiques par rapport à celle des composés plus légers, plus volatiles, mais moins polaires. Chaque classe d'accélérant peut être identifiée de façon positive à partir du chromatogramme d'empreintes digitales en n'utilisant que quelques pics caractéristiques. De plus, on a aussi étudié la possibilité de détecter ces composants volatiles de l'essence dans des échantillons aqueux, à des niveaux significatifs d'un point de vue environnemental.

Mots clés : composés organiques volatiles (COV), empreintes digitales, piège d'adsorption capillaire inséré dans l'aiguille (INCAT), pétrole, CG des gaz de confinement (d'espace de tête).

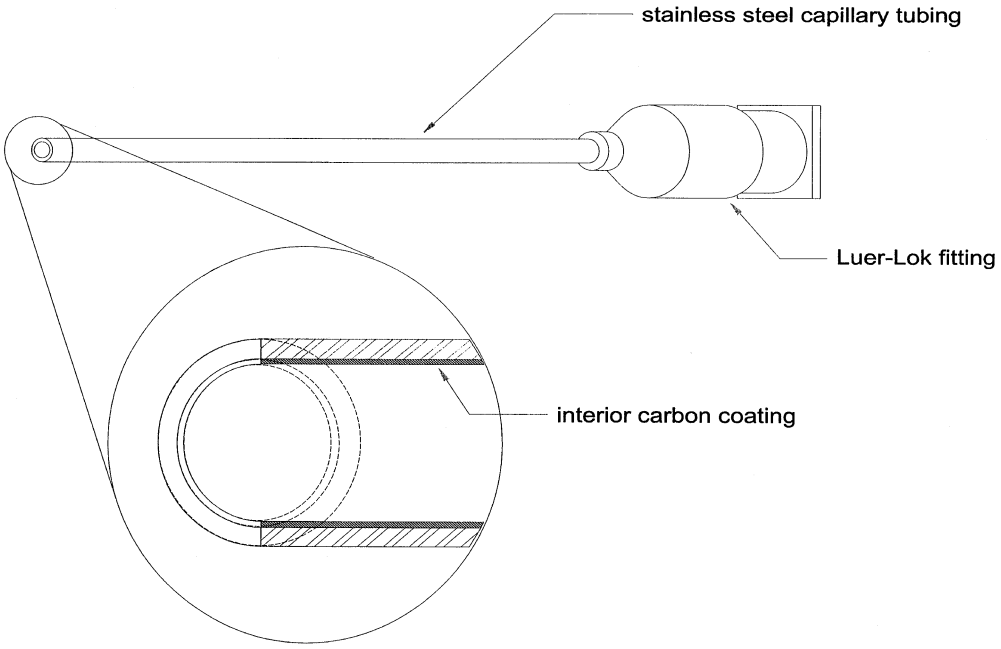
Fig. 1. Schematic of the INCAT device.



Introduction

Pattern recognition, or *fingerprint* analysis, is employed in the qualitative analysis of complex mixtures. Source identification of a sample can be determined by comparing a characteristic chromatogram of the sample to libraries of complex mixture chromatograms (1). In such analysis, the identification of the individual components is not necessary. The characteristic profile or *fingerprint* of the chromatogram allows for positive identification of the material. Fingerprint analysis by gas chromatography has been by itself sufficient for source identification of complex petroleum distillates in both forensic and environmental applications (1). For example, identification of arson accelerants can be achieved by comparing the chromatograms of the static headspace above fire debris with those of similarly obtained commercial reference accelerants (e.g., kerosene, gasoline, etc.). Environmental investigations of point source pollution may also be achieved by fingerprint analysis (2). Identification of the source of a spill may be possible by chromatographic comparison of a sample from the contaminated site with waste or products from suspected source points.

In the analysis of complex mixtures, such as petroleum distillates, the use of headspace gas chromatography (HS-GC) may often simplify the analysis by reducing the number of peaks in the chromatogram and showing distinctive differences between samples based on the levels of volatile organic compounds (VOCs) (2, 3). The VOCs in some liquid samples may be present in relatively low concentrations and thus be obscured by the more abundant nonvolatile components in the chromatogram. The VOCs that are part of these complex mixtures will partition between the liquid and vapor phases. If the sample is placed in a gas-tight container, an equilibrium between the liquid and vapor phases will be established. Most petroleum distillates contain many VOCs in characteristic quantities. Thus, a profile of the peaks from the static headspace of the sample will also serve as fingerprint of the sample.

Headspace sampling (static or dynamic) is advantageous over direct liquid sampling of complex mixtures of VOCs in cases when a liquid sample is not always available, or when the analytes are in a liquid matrix that would complicate GC analysis. The sampling of headspace is then advantageous for samples that would require solvent extraction (i.e., contaminated soil, water, foods, packaging materials, arson debris, etc.). Conventional methods for HS-GC usually involve cryogenic focusing of large volumes of the static headspace onto the GC column (2). Samples often require heating to increase the amount of analyte mass in the static headspace (3). However, depending on the nature of the mixture, thermal degradation of the sample may result upon heating of the sample, thereby producing compounds that may obscure the analysis.

Solid phase extraction (SPE) methods have been used to concentrate headspace components, which are then solvent desorbed from the solid phase (2, 4). A sample of the headspace is actively drawn through small packed columns or cartridges containing the solid phase adsorbent. The adsorbed analytes are then solvent desorbed, and a fraction of the solvent extract is introduced into the GC for analysis. Extraction of the analytes from the static headspace onto the solid phase avoids the necessity of cryogenic focusing of large headspace volumes, but usually requires a solvent extraction step. In some cases, there may be additional sample preparation steps required for the cartridges themselves.

The method of solid-phase microextraction (SPME) has been applied to the analysis of a variety of complex mixtures of VOCs (5–9). The SPME method uses a small fused silica fibre coated with a liquid phase sorbent. The coated fibre is introduced into the static headspace and allowed to reach equilibrium with the VOCs that are present. The headspace analytes are then concentrated onto the fibre coating. The

Table 1. Classification scheme for accelerants and the samples studied.

Class no.	Class	Samples studied
0	Unclassified	Escort camp fuel (Imperial Oil Ltd., Toronto, Ont.)
1	Light Petroleum Distillates (LPD)	Ronsonol pocket lighter fluid (Ronsonol Corporation of Canada, Mississauga, Ont.)
2	Gasoline	Shell octane rated gasolines: Bronze 87, Silver 89 and Gold 91 (Shell Canada Ltd., Calgary, Alta.)
3	Medium Petroleum Distillates (MPD)	Varsol® (Imperial Oil Ltd., Toronto, Ont.), generic paint thinner (Canadian Tire Corporation Ltd., Toronto, Ont.)
4	Kerosene	Kerosene (Reochem Inc., Toronto, Ont.)
5	Heavy Petroleum Distillates (HPD)	Shell diesel fuel (Shell Canada Ltd., Calgary, Alta.)

SPME device is then inserted into a GC or GC coupled to a mass spectrometer (GC–MS) system to thermally desorb the analytes directly onto the column. Thus, the SPME method is a solventless extraction technique.

A new method of solventless extraction of VOCs has been achieved using the *inside needle capillary adsorption trap* (INCAT) (10, 11). The INCAT device (Fig. 1) has an adsorbing carbon coating on the interior surface of a hollow stainless steel needle. This device is able to sample the static headspace of a sample both actively and passively (10). In the active sampling procedure, an aliquot of the static headspace volume is drawn through the device via a syringe. The volatile analytes are then adsorbed and concentrated inside the device. The INCAT device can then be inserted into a heated injection port of a GC to thermally desorb the analytes directly onto the GC column for separation. The concentration of analytes inside the INCAT device avoids the necessity for cryogenic focusing of large sample volumes onto the GC column, a method employed in most HS-GC analyses (3).

Other methods designed to increase headspace sensitivity, such as closed loop stripping (CLS) and purge-and-trap (P&T) methods, require larger headspace sample volumes for cryogenic focusing onto the GC column. The use of extraction devices such as SPE cartridges or SPME fibres increases the sensitivity of headspace sampling. The INCAT device can be used in a similar manner, without a solvent extraction step, and with no time required by the headspace analytes to reach equilibrium. To demonstrate these features, a simple application to qualitative analysis of samples of the six classes of accelerants (1) has been performed. The chromatograms of the static headspace of the six classes of accelerants, according to the ASTM forensic classification scheme (12), were obtained from active sampling with the INCAT device and compared to the chromatograms obtained from direct liquid injection of the samples. Samples included the following: light petroleum distillates (pocket lighter fluid), gasolines, medium petroleum distillates (paint thinner), kerosene, heavy petroleum distillates (diesel fuel), and unclassified accelerants (camp fuel). The BTEX compounds (benzene, toluene, ethyl benzene, and xylenes) present were used as target analytes to compare the different classes. In addition, aqueous samples with low levels of gasoline components were examined to determine the sensitivity of the technique and simulate environmentally significant levels.

Experimental

The INCAT devices used in this study were prepared from 50.8 mm long, 26 gauge (0.46 mm nominal o.d.; 0.25 mm nominal i.d.) hypodermic needles with metal Luer-Lok hub (Hamilton Co., Reno, Nev.). The needles were coated with one of three types of activated carbon blacks: Raven-15 (Columbian Carbon Co., New York, N.Y.), Super Sorb (Amoco Research Corp., Chicago, Ill.), and Saran from poly(vinylidene chloride) (RMC, Kingston, Ont.). The carbon blacks were suspended in 1% w/w solution of Silwet surfactant (Union Carbide, Danbury, Conn.) in isopropanol (Fisher Scientific Co., Fair Lawn, N.J.). The needles were coated using a syringe to draw a 1 mL volume of the carbon black suspension through the length of the needle, which was then pushed out. The coated devices were baked for 1 h at 300°C while passing helium gas through the length of the needle to ensure that no clogging occurred and to remove the suspension solvent. Once ready, the INCAT device was plugged with a small piece of septum at the Luer-Lok end, and inserted into the injection port of a GC to determine if any off-gassing occurred.

Direct liquid sampling and static headspace sampling (via the INCAT device) was performed on the samples listed in Table 1. For each sample, 2 mL of the liquid were placed in a 40 mL GC vial sealed with a screw-top septum containing cap for headspace sampling. A separate sample, with 2 mL in a 4 mL GC vial sealed with screw-top septum containing cap, was prepared for direct liquid sampling. Active sampling of the headspace with the INCAT device was performed by drawing 0.10 mL of the headspace through the device at an approximate rate of 0.35 mL/min, with a 0.50 mL gas-tight syringe (Hamilton Co., Reno, Nev.). The withdrawn headspace volume was then pushed out the device at the same rate. Thus, the 0.10 mL sample was allowed to pass over the coating twice. The Luer-Lok end of the INCAT device was then plugged with a small piece of septum. Subsequently, the INCAT device was immediately inserted into the injection port of the GC for thermal desorption.

Gas chromatography was performed using a Varian Star 3400 CX series GC (Varian Instrument Group, Walnut Creek, Calif.) with a flame ionization detector (FID). The samples were separated on a 15 m DB-1 megabore column (J&W Scientific Inc., Folsom, Calif.) of 100% dimethylpolysiloxane

Table 2. Means, standard deviations, and percent relative standard deviations of the response factors (R_f) and the retention times (R_t) from n = 4 liquid injections of the BTEX standard.

Compound	Mean R_f	Std. dev. R_f	% RSD R_f	Mean R_t	Std. dev. R_t	% RSD R_t
Benzene	1.109	0.014	1.28	6.264	0.013	0.204
Toluene	1.02	0.003	0.282	8.972	0.004	0.05
Ethyl benzene	1.048	0.011	1.086	11.29	0.004	0.035
m,p-Xylene	0.954	0.002	0.201	11.58	0.005	0.043
o-Xylene	0.948	0.004	0.393	12.07	0.008	0.064

(0.53 mm i.d., 5.00 μm film thickness). Analytes were thermally desorbed from the INCAT device in the heated injection port (210°C) of the GC for 2 min. The initial column temperature was held at 30°C for the 2 min injection time. The temperature of the column was ramped to 195°C at a rate of 8°C/min and held for 5 min. The column was then heated to a final temperature of 200°C at a rate of 20°C/min, and held at this temperature for 2 min. The detector temperature was 200°C. The entire run time for the separation was 30 min. A second thermal desorption injection of the device was performed to ensure that all of the sample had been desorbed in the first 2 min injection, and indicated that no carry-over occurred.

To estimate the sensitivity of the INCAT sampling method, and to demonstrate its usefulness in characterizing environmentally significant concentrations of VOCs, an aqueous solution saturated with Shell Bronze gasoline was prepared and an aliquot of this solution was diluted by a factor of 1000 with water. Initially, samples prepared with 2 mL of the aqueous solution in 40 mL vials were used, and 0.10 mL of the static headspace was actively sampled by the INCAT device. However, the chromatogram obtained for the saturated solution showed poor peak intensity. A second set of samples was prepared with 5 mL of the aqueous solution in 40 mL GC vials, and 10.0 mL of the headspace was actively sampled using a gas-tight syringe (Hamilton Co., Reno, Nev.). The rate of sampling with this 10.0 mL syringe was approximately 2.5 mL/min. The withdrawn volume was pushed out of the INCAT device at the same rate at which it was actively removed from the headspace, allowing the headspace sample volume to pass over the coating twice. The larger headspace volume for the aqueous gasoline solutions improved the sensitivity of the sampling method.

The retention times and response factors were determined for the BTEX compounds by repeated (n = 4) 0.10 μL liquid injections of the BTEX standard. The mean, standard deviation, and percent relative standard deviation (RSD) from the mean of the retention times and response factors for each of the BTEX compounds are listed in Table 2. The *meta* and *para* xylenes were not resolved as two distinct peaks with the DB-1 column.

Results and discussion

These experiments were designed to determine if the adsorptive coating of the INCAT device would improve the headspace sensitivity in direct gas sampling. Previously reported INCAT devices (10, 11) were made with a colloidal graphite coating as the carbon adsorbent. However, graphite has a very low surface area, and hence, a low capacity, which gave a variation in the relative amounts of adsorbed compounds as the device reached capacity (10). To improve the capacity of the devices, activated carbon coatings have been incorporated. Other methods designed to increase headspace sensitivity, such as closed loop stripping (CLS) and purge and trap (P&T) methods, require larger headspace sample volumes for cryogenic focusing onto the GC column (3). The use of extraction devices, like SPE cartridges or SPME fibres, increases the sensitivity of the headspace sampling. The INCAT device can be used in a similar manner, without a solvent extraction step, and with no time required to reach equilibrium with the headspace. To demonstrate these features, a simple application to qualitative analysis of the six classes of accelerants (1) has been performed.

The static headspace of the BTEX standard was actively sampled using INCAT devices with three different coatings. The chromatograms obtained for the liquid injection and the injection of INCAT sampled headspace of the standard are shown in Fig. 2. The Raven-15 coated INCAT (Fig. 2*b*) showed the best adsorption of the compounds. Using the change in mass from the uncoated needle and the internal surface area of the capillary, the coating contained 1.01 ± 0.03 mg/cm^2. The Saran and Super Sorb (Figs. 2*c* and *d*) coatings contained 0.28 ± 0.03 mg/cm^2 and 0.60 ± 0.03 mg/cm^2, respectively. The differences in the amount of carbon resulting from the coating process are likely due to the differences in the grain sizes among the three carbon blacks. To reduce the variation in the amount of carbon in each needle, it is necessary to have a uniform grain size for the different carbon blacks. The Raven-15 INCAT device was chosen for the remaining headspace samples due to the larger amount of carbon on the interior surface of the needle. It should also be noted that the tailing in the benzene peaks in Figs. 2*b–d* are the result of benzene diffusing onto the column during the 2 min injection. The initial column temperature during the injection was held at 30°C, but lower temperatures would be required to focus benzene at the top of the column for the entire injection time. Shorter injection times for the INCAT device at higher desorption temperatures would reduce the tailing of benzene. In addition, a lower initial column temperature would prevent benzene from moving through the column until the entire sample had been desorbed from the device. Thus, all of the analytes would be focussed at the top of the column until the temperature program begins upon completion of the injection. The lowering of the initial column temperature, coupled with an increase in the injection port temperature (reducing the desorption time), would then improve the chromatographic resolution. The entire sample would be desorbed before any of the analytes begin to diffuse onto the column — then all

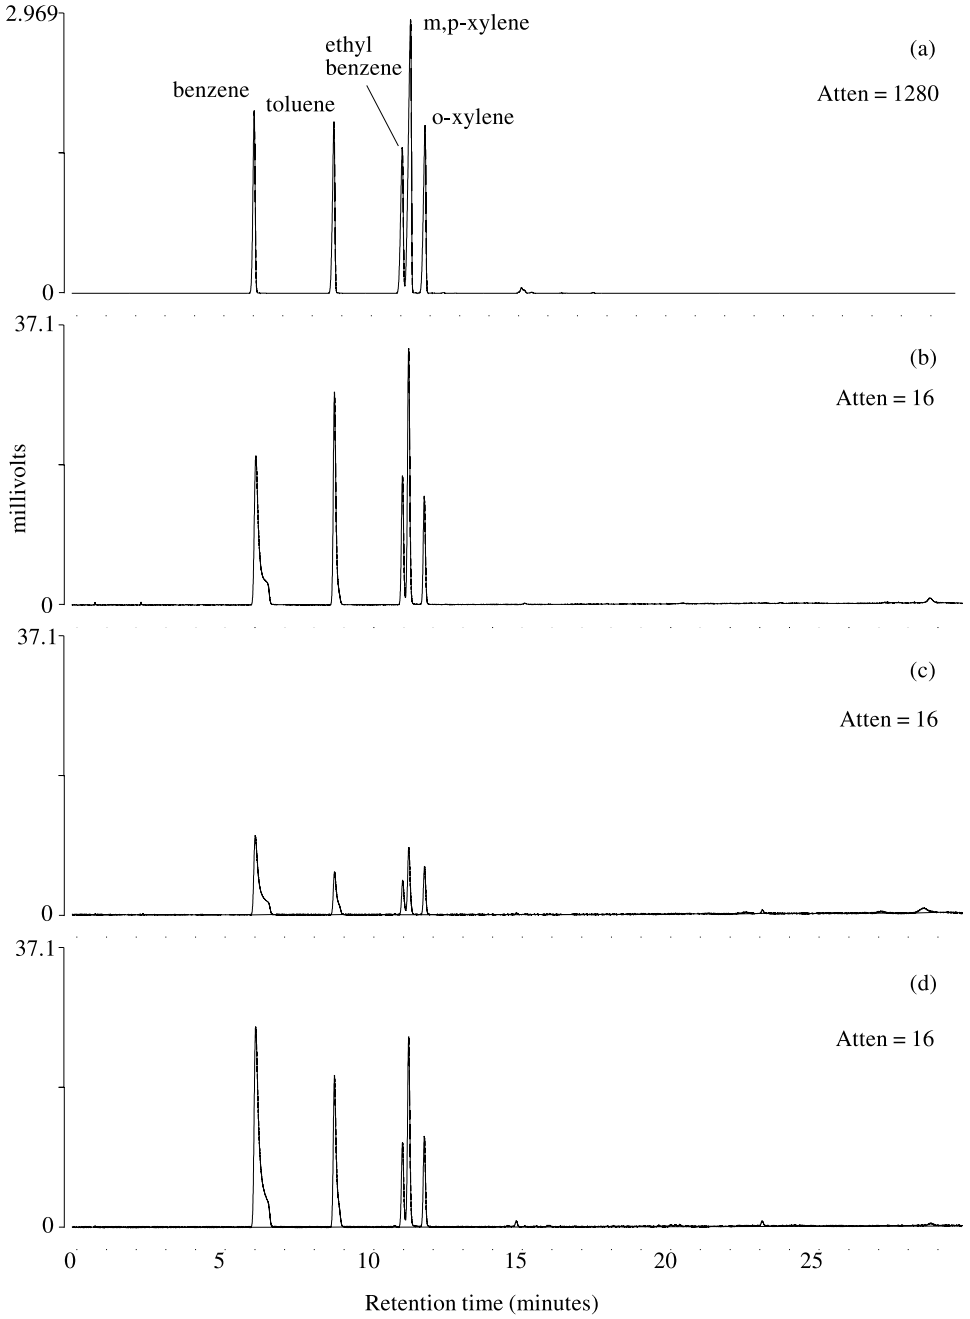
Fig. 2. Comparison of the gas chromatograms obtained from sampling a mixture of BTEX compounds (16.7% v/v of each) by (*a*) direct liquid sampling (0.10 μL), attenuation 1280; (*b*) a Raven-15 coated INCAT (0.10 mL of headspace), attenuation 16; (*c*) a Saran coated INCAT (0.10 mL of headspace), attenuation 16; and (*d*) a Super Sorb coated INCAT (0.10 mL of headspace), attenuation 16.



analytes would enter the column as a small "sample plug," as in liquid sample introduction.

To show that the INCAT device can be used to yield a reproducible fingerprint of a complex mixture, the Shell Bronze gasoline was sampled four times. The chromatograms shown in Fig. 3 were obtained from a 0.10 mL active sampled volume of the static headspace above 2 mL of gasoline in 40 mL containers, for four separate Shell Bronze gasoline samples. The BTEX peaks in the four chromatograms were used to measure the consistency of the sampling method. Table 3 lists the mean retention times and peak areas of the BTEX compounds for the four trials of the Shell Bronze gasoline using active sampling of the headspace with the Raven-15 INCAT device. The RSD for the BTEX peak areas ranged from 6.6 to 11.6%. There is a strong indication of preferential adsorption of aromatic compounds found in the headspace over lighter and more volatile compounds that are in high concentrations in gasoline. Although the presence of these lighter gasoline components is noticeable in the headspace chromatograms, the peak areas are not as high as expected.

Figures 4–9 show direct comparisons between chromatograms obtained using the INCAT to actively sample the headspace and direct liquid sampling for the samples

Fig. 4. Comparison between the gas chromatograms of (*a*) the class 0 accelerant camp fuel, obtained from a direct liquid sample (0.10 μL), attenuation 559, and (*b*) a headspace sample using a Raven-15 coated INCAT device (0.10 mL), attenuation 4.

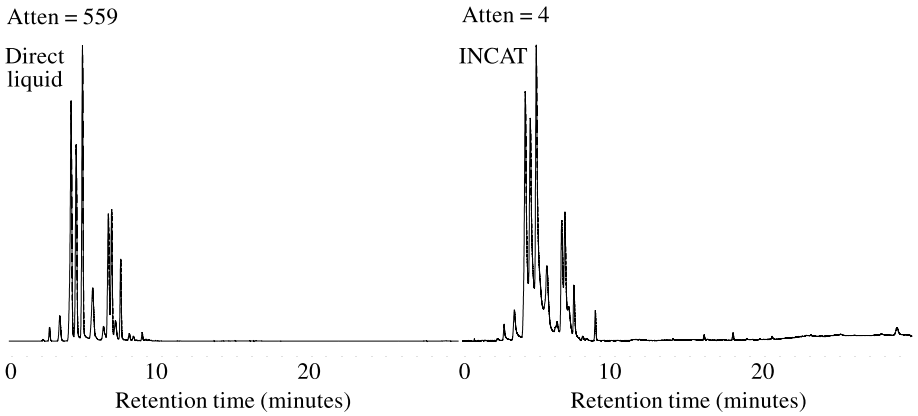

Fig. 5. Comparison between the gas chromatograms of (*a*) the class 1 accelerant Ronsonol pocket lighter fluid, obtained from a direct liquid sample (0.10 μL), attenuation 534, and (*b*) a headspace sample using a Raven-15 coated INCAT device (0.10 mL), attenuation 4.

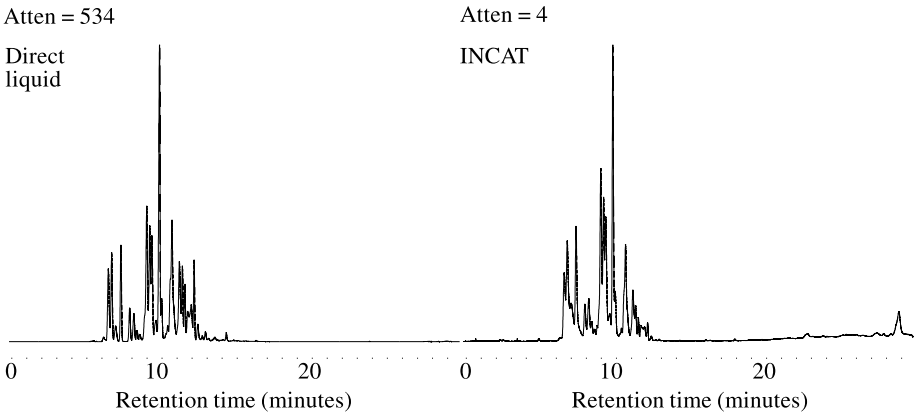

from each class of arson accelerants. The chromatograms have been normalized to percentage of the full scale for qualitative comparison of the fingerprints. The chromatograms obtained for classes 0 and 1 (camp fuel and pocket lighter fluid, Figs. 4 and 5) show only subtle differences between their respective liquid and headspace peak profiles. There are not many components in the mixtures (relative to gasoline) according to the liquid sample chromatograms (Figs. 4*a* and 5*a*), and very little BTEX compounds are present. The similarity between the profiles obtained for the liquid and INCAT headspace sampling suggest that in cases where a liquid sample is not available, the INCAT headspace sampling method can produce a characteristic peak profile of the sample for fingerprint identification.

The liquid and headspace sample chromatograms for the different grades of gasoline, shown in Fig. 6, again indicates the preferential adsorption for aromatic compounds on the coating inside the device. From these chromatograms, it is clear that the lighter components, appearing at shorter retention times, are not as abundant as expected in the headspace sample. BTEX compounds are more abundant than lighter and more volatile compounds when the INCAT device is used. This indicates that the Raven-15 coating has a greater affinity for the aromatic species in the headspace. The presence of BTEX compounds in headspace samples at different levels allows for differentiation of gasolines rated with specific octane numbers, from other classes of accelerants and from each other. However, it is likely that the differences in the relative amounts of BTEX compounds may be too subtle to positively identify a particular brand of gasoline among samples with the same octane rating. In such situations, the monitoring of a few more characteristic peaks would be required to positively identify the manufacturer of the gasoline.

The chromatograms obtained for the two paint thinner samples — the class 3 accelerants (Fig. 7) — show very similar amounts of BTEX components. The presence of BTEX components in this case is sufficient to positively identify the two samples as class 3 accelerants. However, Varsol® and the generic brand of paint thinner could not be differentiated on the basis of BTEX compounds alone. There are a few characteristic peaks in both the initial and final regions of the headspace chromatograms that do allow distinction between the samples.

Figure 8 shows the chromatograms obtained from direct liquid and headspace sampling of the class 4 accelerant, kerosene. As with the class 0 and class 1 accelerants, the chromatograms obtained for the liquid and headspace samples are very similar. The chromatograms can be distinguished based only on the differences in the relative amounts of a few peaks, one of which is the obvious benzene peak. The relative amounts of BTEX compounds in the headspace

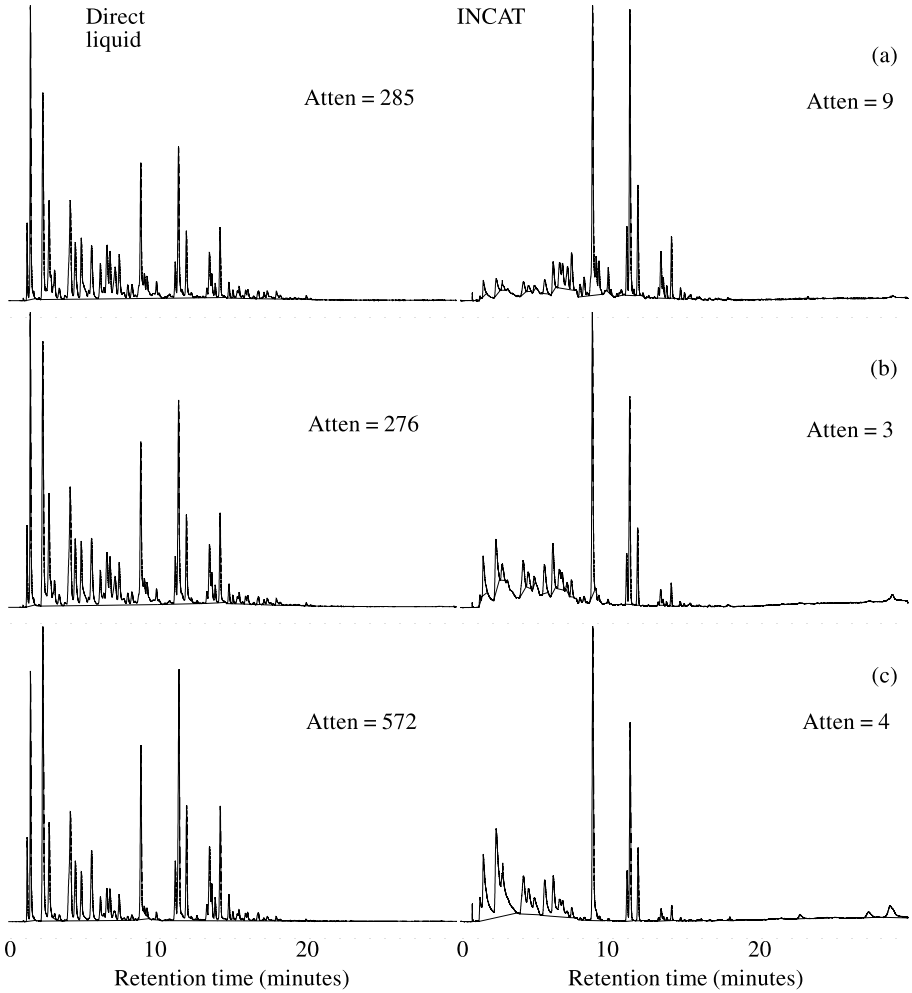
Fig. 6. Comparison between the gas chromatograms of the class 2 accelerant gasoline, obtained from a direct liquid sample (0.10 μL) and a headspace sample using a Raven-15 coated INCAT device (0.10 mL), for (*a*) Shell Bronze (octane rating 87), attenuation 285 (liquid sample), attenuation 9 (INCAT sample); (*b*) Shell Silver (octane rating 89), attenuation 276 (liquid sample), attenuation 3 (INCAT sample); and (*c*) Shell Gold (octane rating 91), attenuation 572 (liquid sample), attenuation 4 (INCAT sample).



are present at characteristic levels relative to the other classes of accelerants. Therefore, the BTEX compounds can be used to distinguish kerosene from the other classes. In addition, the similarity between the two chromatograms of Fig. 8 once again illustrates how the INCAT device would be useful for sampling the headspace when a liquid sample is not available.

The chromatograms obtained from the liquid versus INCAT headspace sampling of diesel fuel (Fig. 9), a class 5 accelerant, show the most noticeable difference in the peak profiles. All of the BTEX compounds are present, and most are in greater amounts relative to their levels in gasoline samples. Only benzene is less abundant in diesel fuel than in the Bronze grade of gasoline, which contained the highest levels of BTEX compounds relative to accelerants from classes 0 to 4.

The bar chart shown in Fig. 10, represents the data for the absolute peak areas of BTEX compounds observed in the six classes of accelerants. From the relative amounts of BTEX compounds in representative samples for each class, it is possible to discriminate between the classes of accelerants. To distinguish between different brands of a sample within a specific class (e.g., Varsol® and the generic paint thinner), it would be necessary to monitor additional peaks. Since the aromatic components in these samples tend to be preferentially adsorbed by the Raven-15 adsorbent, it would be useful to identify a few more characteristic aromatic compounds by GC–MS.

The chromatograms in Fig. 11 were obtained with the INCAT device by active sampling of the static headspace of the aqueous solution saturated with Shell Bronze gasoline (Fig. 11*a*), the 1:1000 diluted solution of the latter (Figs. 11*b* and *c*), and a blank (Fig. 11*d*). The aqueous solution, saturated with gasoline (Fig. 11*a*), shows all of the BTEX compounds, as well as some of the other VOCs. This profile is not comparable to that of the Bronze gasoline, shown in Figs. 3 and 6, due to the different solubilities of the various components in water. The diluted aqueous gasoline solution chromatograms (Figs. 11*b* and *c*) are also shown to contain all of the BTEX compounds. The remaining peaks ($R_t \geq 20$) are likely to be the result of irreversible adsorption of some of the adsorbates, which may gradually lead to the formation of a tar on the adsorbing surface (13) — which is slowly decomposing upon repeated use of the

Fig. 7. Comparison between the gas chromatograms of the class 3 accelerant paint thinner, obtained from a direct liquid sample (0.10 μL) and a headspace sample using a Raven-15 coated INCAT device (0.10 mL), for (*a*) Varsol®, attenuation 430 (liquid sample), attenuation 1 (INCAT sample); and (*b*) a generic brand of paint thinner, attenuation 442 (liquid sample), attenuation 1 (INCAT sample).

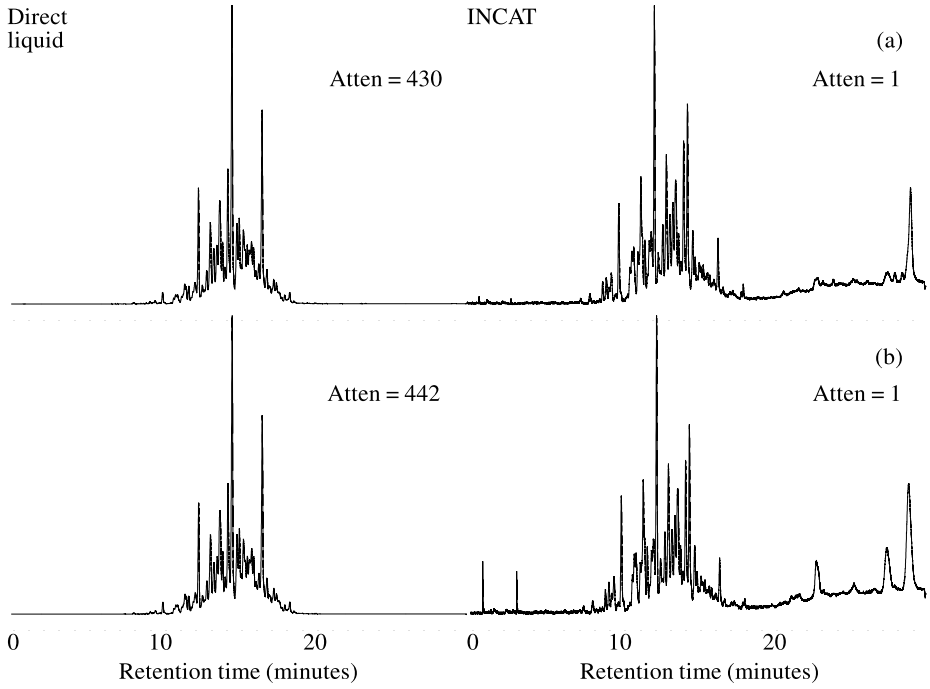

Fig. 8. Comparison between the gas chromatograms of the class 4 accelerant kerosene, obtained from a direct liquid sample (0.10 μL), attenuation 389, and a headspace sample using a Raven-15 coated INCAT device (0.10 mL), attenuation 1.

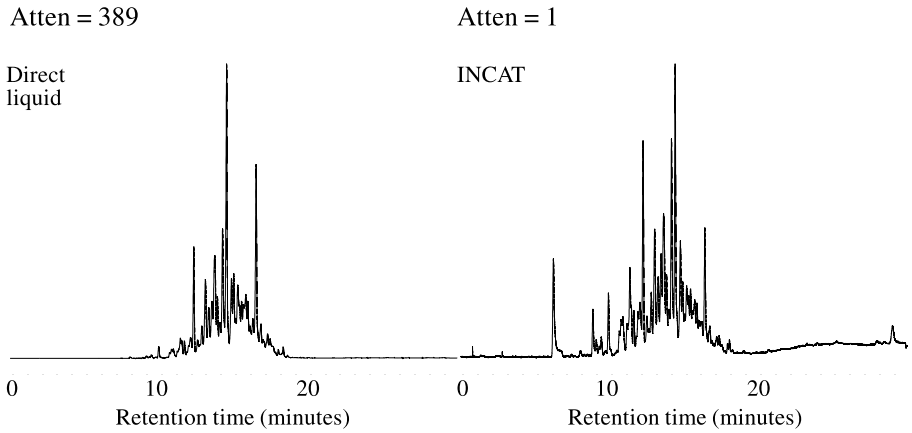

INCAT sampler. A more thorough cleaning step may be required to reduce the amount of tar buildup, such as passing a reactive gas through the device during the cleaning run, or a periodic longer baking period. It should be noted that during the course of these experiments, the Raven-15 INCAT device was used for more than 60 manual injections, and is still being used. It is not surprising then that there may be a gradual buildup of these irreversibly adsorbed compounds — the effects of which became more prevalent in the background with increased use of the device.

To estimate the amounts of the BTEX compounds present (an upper bound estimate), the solubilities of each of pure BTEX compounds in water can be used. Thus, the 1:1000 diluted solution is estimated to contain (w/v): 1.78 ppm of benzene, 0.515 ppm of toluene, 0.152 ppm of ethyl benzene, 0.198 ppm of *p*-xylene, 0.200 ppm of *m*-xylene, and 0.175 ppm of *o*-xylene. The other species present in gasoline will, however, affect the solubilities of the individual components. Pure benzene has a water solubility in the pure phase of 1780 ppm, but in the presence of the other components of gasoline, its solubility is reduced to 65 ppm (14). Thus, the upper bound estimate of the BTEX levels in the 1:1000 diluted solution of saturated aqueous gasoline is very generous. The INCAT device, when sampling at room temperature and sampling less than a third of the headspace volume (10.0 mL out of 35.0 mL of headspace), enabled detection of 65 ppb of benzene in the 1:1000 diluted solution. The limit of detection could still be reduced further by

increasing the volume of the headspace that is actively sampled, or by heating the sample to increase the headspace concentration of the VOCs prior to sampling.

Conclusions

Static headspace sampling of complex mixtures is extremely useful for fingerprint identification of mixtures when liquid samples are not available. Sampling of the headspace above samples can be achieved without solvent extraction. The INCAT device can be used to sample the headspace of a sample and concentrate the analytes inside the device. Thermal desorption of the analytes from the INCAT directly into the GC simplifies the extraction and analysis procedure.

The INCAT device has been shown to enable reproducible GC fingerprints of complex mixtures of VOCs, with an average RSD of 9.8%. Using the INCAT device, the distinction between different classes of accelerants has been achieved using only five target peaks corresponding to BTEX compounds. The INCAT device provides a novel approach to the characterization of complex mixtures for fingerprint analysis. Concentration of the headspace analytes inside the device allows for larger volumes of the headspace to be sampled without requiring cryogenic focusing. The INCAT

© 1999 NRC Canada

sampling technique thus provides a sensitive alternative to the conventional methods of direct headspace sampling, like CLS and P&T methods. Moreover, the solventless extraction aspect of active sampling with the INCAT device simplifies the sampling method without requiring time to reach an equilibrium with the headspace analytes.

Determination of proton exchange rates in aqueous solution using TOCSY

R.E.D. McClung, T.T. Nakashima, H. Yamamoto, and G. Kotovych

Abstract: A product operator description of the nuclei in an ensemble of molecules undergoing intermolecular exchange during the spin-lock period of TOCSY is presented. Experimental measurements of the transfer of magnetization from the CH_2 protons in *N*-acetylglycine to the solvent water protons, via exchange of the NH proton with water protons during the spin-lock period in TOCSY, are shown to be in agreement with theoretical predictions at lower pH values (7.85–9.54) where the rate constants for NH–water exchange are known. Measurements at higher pH (up to 11.03) indicate that the highest rate constant for exchange that can be determined by this technique is $\tau_A^{-1} \sim 4000\ s^{-1}$.

Key words: product operator, density matrix, intermolecular exchange, TOCSY, NMR.

Résumé : On présente une description d'un opérateur de produit du noyau dans un ensemble de molécules subissant un échange intermoléculaire au cours d'une période de spin bloqué de « TOCSY ». On démontre que, à des valeurs faibles de pH (7,85–9,54) pour lesquelles on connaît les constantes de vitesse d'échange NH–eau, il existe une bonne correspondance entre prédictions théoriques et les résultats expérimentaux relatifs du transfert de magnétisation de protons CH_2 de la *N*-acétylglycine aux protons de l'eau qui agit comme solvant, par le biais d'un échange du proton NH avec les protons de l'eau au cours d'une période de spin bloqué de « TOCSY ». Les mesures à des valeurs de pH plus élevées (allant jusqu'à 11,03) indiquent que la valeur la plus élevée pour une constante de vitesse qui puisse être déterminée par cette technique est $\tau_A^{-1} \approx 4000\ s^{-1}$.

Mots clés : opérateur de produit, matrice de densité, échange intermoléculaire, « TOCSY », RMN.

[Traduit par la Rédaction]

Introduction

In a recent communication (1) we reported the observation that the water "stripe" in TOCSY maps of aqueous solutions of compounds containing exchangeable protons (OH, NH, or SH) contained correlations at the resonance frequencies of the protons that were scalar coupled to the exchangeable protons. We suggested at that time that these correlations were attributable to TOCSY transfer of magnetization from nonexchanging protons to the exchangeable protons via scalar coupling, and exchange of magnetization between the exchangeable protons and the bulk water. One would therefore observe a correlation between a nonexchanging proton and water in the water stripe. The intensities of the correlations in the water stripe at the resonance frequencies of the scalar-coupled protons depends, not surprisingly, upon the magnitudes of the scalar couplings and the rate at which protons are transferred from OH, NH, or SH to water. These correlations may be observed even at higher exchange rates where the resonance lines of the exchangeable proton and the water proton have coalesced.

In biological systems, water plays an important role in the determination of the structure and function of biomolecules and the study of the water–biomolecule interaction is very important in understanding their three-dimensional structure in solution. One aspect of such investigations is the exchange processes involving exchangeable protons in the biological molecule and bulk water in order to probe solvent accessibility and solvent "hidden" sites. This gives some insight into the conformation of the biomolecules in solution. Previously, measurements of the rate constant for exchange of NH protons in proteins and peptides were limited to very slow exchange, which can be studied by deuterium substitution (2–5), and to slow exchange, which can be studied by water proton magnetization transfer experiments. In the latter category several methods are available (6–13). The water magnetization is perturbed by some presaturation or inversion sequence and the exchange rate is determined by monitoring the buildup of the resonance from the exchangeable proton as in Forsen–Hoffman type experiments (6). These experiments are limited to slow rates of exchange because the OH, NH, or SH lines must be distinct from the H_2O res-

onance. In other studies (7–11), 1D and 2D techniques have been used to selectively excite the water magnetization, followed by selective detection of the resonances of only those protons arising from exchange with water. For the proton exchange reaction

$$[1] \qquad H^{*}_{(solute)} + H_{(solvent)} \underset{k}{\overset{k}{\rightleftarrows}} H_{(solute)} + H^{*}_{(solvent)}$$

where the asterisk is used only to distinguish the two protons, the rates of forward and reverse reactions are equal to $k\,[H_{(solute)}][H_{(solvent)}]$. It is conventional to report the reciprocal of the lifetime of the solute proton, τ_A^{-1}, which is equal to the pseudo-first-order rate constant for exchange of a proton from the solute to the solvent, $k[H_{(solvent)}]$, rather than the rate constant k. In previous studies (2–13), measurements of the rate constants for exchange were limited to $\tau_A^{-1} \lesssim 100\ s^{-1}$. While, in principle, exchange rate constants of 10^3–$10^4\ s^{-1}$ can be determined by NMR using lineshape analysis, this is only practical for systems where the exchanging sites have comparable populations. In the case of biomolecules, the exchangeable protons are present at mM concentrations in 90% H_2O – 10% D_2O solutions where the solvent proton concentration is ~100 M. This enormous population difference between the exchanging protons renders lineshape analysis impossible because of the predominance of the large water signal.

In the present report, we show that exchange rate constants greater than 1000 s^{-1} may be obtained using the information contained in the water "stripe" from TOCSY experiments even though the exchanging proton resonances have coalesced with that from water. As a model system we chose *N*-acetylglycine in which the rate constant for NH proton–water exchange has been measured over a broad pH range (14).

Experimental

pH measurements

All pH measurements were carried out at 298 K with a Fisher Scientific Accumet model 15 pH meter equipped with a standard glass electrode and a fiber-tip saturated calomel reference electrode. Standard buffers, pH 4.00, 7.00, and 10.00, were used to standardize the pH meter at ambient temperature.

NMR measurements

The samples for NMR spectroscopy contained 0.1 M *N*-acetylglycine (Aldrich Chemical Co.) in 0.6 M KNO_3 – H_2O solution. KOH was added to bring the solutions to the desired pH values. NMR spectra were obtained on a Varian Unity 500 NMR spectrometer at 298 K. All the TOCSY experiments (15) used a B_1 field for which γB_1 = 12.5 kHz and were recorded with 1024 complex points and 64 t_1 increments using the States–Haberkorn–Ruben (16) method. The water signal was attenuated using transmitter presaturation during the relaxation delay for 1.5 s using a saturation field B_1 for which γB_1 = 110 Hz. An external capillary of DMSO-d_6 was used to provide the deuterium lock signal. Accurate spin-locking times were calculated from the number of MLEV loops that were performed for the specified mixing times.

Spectral data were processed using standard Varian software. Zero-filling, exponential apodization, and Fourier transformation of the data were followed by integration of each peak from the f_2 slice through the TOCSY map at the intensity maximum of the CH_2 peak in f_1. No significant differences in the relative intensities of the peaks were obtained when peak volumes rather than peak areas from the f_2 slices were used to measure the peak intensities. Attempts to develop a 1D TOCSY experiment with selective excitation of the CH_2 resonance were unsuccessful.

Theory

In this section, a product operator description (17) of the behaviour of the magnetizations of the nuclei in molecules that are undergoing intermolecular exchange during a spin-lock period is presented. It is convenient to represent the density operator, $\rho(t)$, for the ensemble of spin systems as

$$[2] \qquad \rho(t) = \sum_M \sum_j b_{Mj}(t)\mathbf{B}_{Mj}$$

where the sum over M includes all types of molecules in the ensemble, $\{\mathbf{B}_{Mj}\}$ is the set of spherical-tensor basis product operators (18) for the spin system present in molecules of type M, and $\{b_{Mj}(t)\}$ is a set of complex time-dependent coefficients whose values indicate the types of coherences present at time t. During the spin-lock period, the spin Hamiltonian $H^{(M)}$ for each type of molecule M present in the sample is assumed to be of the form (19)

$$[3] \qquad H^{(M)} = 2\pi \sum_{p,m\neq p} J^{(M)}_{mp}\mathbf{I}^{(Mm)}\cdot\mathbf{I}^{(Mp)}$$

where $J^{(M)}_{mp}$ is the spin–spin coupling constant for the scalar coupling between spins m and p within a molecule of type M, since the spin-locking field effectively eliminates the Zeeman interactions. In the absence of chemical exchange, the equation of motion for the coefficient $b_{Mr}(t)$ is (20)

$$[4] \qquad \frac{db_{Mr}}{dt} = i2^{2-N_M}\sum_j Tr\ \{\mathbf{B}^{*}_{Mr}[\mathbf{B}_{Mj}, H^{(M)}]\}b_{Mj}$$

where N_M is the number of spin-1/2 nuclei in molecules of type M. This free precession results in the transfer of in-phase magnetization among the complete network(s) of mutually coupled spins in molecules of type M.

Intermolecular chemical exchange of nuclei between molecules of type M and molecules of type M' causes the transfer of coherence between the spin systems in the two types of molecules. In the exchange process, there will be $n_{MM'}$ nuclei in molecule M, which interchange with $n_{MM'}$ nuclei in molecule M'. In the interchange, the spin operators $\mathbf{I}^{(M1)}$, $\mathbf{I}^{(M2)}$, $\mathbf{I}^{(M3)}$, $\cdots$,$\mathbf{I}^{(Mn_{MM'})}$ for the exchanging nuclei in molecule M are interchanged with the respective spin operators $\mathbf{I}^{(M'1)}$, $\mathbf{I}^{(M'2)}$, $\mathbf{I}^{(M'3)}$, $\cdots$, $\mathbf{I}^{(M'n_{MM'})}$ for the exchanging nuclei in molecule M'. The rate of exchanges between M and M' is $k\,[M][M']$, where k is the rate constant for the exchange reaction, and the reciprocals of the average lifetimes of molecules of types M and M' are given by

© 1999 NRC Canada

$$[5]\qquad \tau_M^{-1} = \frac{\text{exchange rate}}{[M]} = k[M']$$

and

$$[6]\qquad \tau_{M'}^{-1} = \frac{\text{exchange rate}}{[M']} = k[M']$$

respectively (21). The coefficients of those product operators $\mathbf{B}_{Mq}$ for molecule M that contain any of the operators $\mathbf{I}^{(M1)}$, $\mathbf{I}^{(M2)}$, $\mathbf{I}^{(M3)}$, $\cdots$,$\mathbf{I}^{(Mn_{MM'})}$ and the coefficients of those product operators $\mathbf{B}_{M'q}$ for molecule M' which contain any of the operators $\mathbf{I}^{(M'1)}$, $\mathbf{I}^{(M'2)}$, $\mathbf{I}^{(M'3)}$, $\cdots$,$\mathbf{I}^{(M'n_{MM'})}$ will be affected by the interchange of the $n_{MM'}$ nuclei between M and M'. The rate at which the coefficient b_{Mq} changes is given by

$$[7]\qquad \left(\frac{db_{Mq}}{dt}\right)_{\text{exchange}} = -\tau_M^{-1} b_{Mq}\, \chi_{Mq\in\text{ exchanging}} + \sum_{M'} \tau_{M'}^{-1} \sum_{q'} b_{M'q'} \chi_{Mq\leftrightarrow M'q'} \chi_{Mq\in\text{ exchanging}}$$

where $\chi_{Mq\leftrightarrow M'q'} = 1$ if the product operator $\mathbf{B}_{M'q'}$ becomes product operator $\mathbf{B}_{Mq}$ when the $n_{MM'}$ nuclei on molecules M and M' are interchanged, and is zero otherwise; and $\chi_{Mq\in\text{ exchanging}} = 1$ if the operator $\mathbf{B}_{Mq}$ contains a spin operator for any of the exchanging nuclei and is zero otherwise.

For the solute–solvent proton exchange reaction [1], which is of primary interest in this article, the solvent (water) molecules have a single type of proton with spin operator $\mathbf{I}_{-1}^{\text{W}}$, and the *N*-acetylglycine solute molecules have 6 protons with spin operators $\mathbf{I}_{-1}^{\text{A NH}}$, $\mathbf{I}_{-1}^{\text{A CH}_2(1)}$, $\mathbf{I}_{-1}^{\text{A CH}_2(2)}$, $\mathbf{I}_{-1}^{\text{A CH}_3(1)}$, $\mathbf{I}_{-1}^{\text{A CH}_3(2)}$and $\mathbf{I}_{-1}^{\text{A CH}_3(3)}$. The rate equations that describe the effects of exchange on the coefficients b_{W}, $b_{\text{A NH}}$, $b_{\text{A CH}_2(1)}$, $b_{\text{A CH}_2(2)}$, $b_{\text{A CH}_3(1)}$, $b_{\text{A CH}_3(2)}$, and $b_{\text{A CH}_3(3)}$ associated with the transverse components of the proton magnetizations are

$$[8]\qquad \begin{aligned}
\left(\frac{db_{\text{W}}}{dt}\right)_{\text{exchange}} &= -\tau_{\text{W}}^{-1} b_{\text{W}} + \tau_{\text{A}}^{-1} b_{\text{A NH}}\\
\left(\frac{db_{\text{A NH}}}{dt}\right)_{\text{exchange}} &= -\tau_{\text{A}}^{-1} b_{\text{A NH}} + \tau_{\text{W}}^{-1} b_{\text{W}}\\
\left(\frac{db_{\text{A CH}_2(1)}}{dt}\right)_{\text{exchange}} &= 0\\
\left(\frac{db_{\text{A CH}_2(2)}}{dt}\right)_{\text{exchange}} &= 0\\
&\vdots\ \ \vdots\ \ \vdots\\
\left(\frac{db_{\text{A CH}_3(3)}}{dt}\right)_{\text{exchange}} &= 0
\end{aligned}$$

where $\tau_{\text{A}}^{-1} = 2k[\text{water}]$ and $\tau_{\text{W}}^{-1} = k[\text{acetylglycine}]$. When spin–spin coupling in acetylglycine is included, a large number of product operators are required, and the exchange effects on the corresponding coefficients fall into two categories:

$$[9]\qquad \left(\frac{db_{\text{A}\ell}}{dt}\right)_{\text{exchange}} = -\tau_{\text{A}}^{-1} b_{\text{A}\ell}$$

for product operators $\mathbf{B}_{\text{A}\ell}$ that contain $\mathbf{I}_{-1}^{\text{A NH}}$, and

$$[10]\qquad \left(\frac{db_{\text{A}\ell}}{dt}\right)_{\text{exchange}} = 0$$

for product operators $\mathbf{B}_{\text{A}\ell}$ that do not contain $\mathbf{I}_{-1}^{\text{A NH}}$. Since the product operator $\mathbf{B}_{\text{A}\ell}$ associated with coefficient $b_{\text{A}\ell}$ in eq. [9] contains $\mathbf{I}_{-1}^{\text{A NH}}$ and spin operators for other protons in the acetylglycine molecule, no transfer of coherence from the water proton to this coherence is possible. Therefore, exchange simply causes the coefficients associated with antiphase magnetizations and multiple quantum coherences involving the NH proton to decay.

The equation of motion, including spin–spin coupling and chemical exchange, for the coefficient b_{Mr} during the spin-lock period is

$$[11]\qquad \frac{db_{Mr}}{dt} = i2^{2-N_M} \sum_j Tr\,\{\mathbf{B}_{Mr}^*[\mathbf{B}_{Mj}, H^{(M)}]\} b_{Mj} - \tau_M^{-1} b_{Mq} \chi_{Mq\in\text{ exchanging}} + \sum_{M'} \tau_{M'}^{-1} \sum_{q'} b_{M'q'} \chi_{Mq\leftrightarrow M'q'} \chi_{Mq\in\text{ exchanging}}$$

In matrix form, this equation is

$$[12]\qquad \frac{d\mathbf{b}}{dt} = \mathbf{K}\cdot\mathbf{b}$$

where $\mathbf{b}$ is a vector containing the values of the coefficients $b_{11}(t)$, $b_{12}(t)$, $\cdots$, $b_{21}(t)$, $b_{22}(t)$, $\cdots$, $b_{31}(t)$, $b_{32}(t)$, $\cdots$, with the first index indicating the type of molecule, and the second index the product operator index for molecules of that type. The elements of the $\mathbf{K}$ matrix are

$$[13]\qquad K_{Mr;M's} = i2^{2-N_M} Tr\{\mathbf{B}_{Mr}^*[\mathbf{B}_{Ms}, H^{(M)}]\}\,\delta_{MM'} - \tau_M^{-1}\,\chi_{Mq\in\text{ exchanging}}\,\delta_{MM'}\delta_{rs} + \tau_{M'}^{-1}\chi_{Mq\leftrightarrow M'q'}\chi_{Mq\in\text{ exchanging}}$$

The solution to eq. [12] is

$$[14]\qquad \mathbf{b}(t) = \mathbf{U}\cdot\exp\,[\mathbf{\Lambda}t]\cdot\mathbf{U}^{-1}\cdot\mathbf{b}(0)$$

where $\mathbf{U}$ and $\mathbf{\Lambda}$ are the eigenvectors and eigenvalues of $\mathbf{K}$, and $\mathbf{U}^{-1}$ is the inverse of $\mathbf{U}$. $\mathbf{b}(0)$ describes the state of the ensemble of spin systems at the beginning of the spin-lock period, and $\mathbf{b}(t)$ describes the ensemble at the end of this period. The results of our product operator description of the intermolecular exchange problem (eqs. [12]–[14]) are consistent with the results of the more complicated density matrix description (21, 22). In the present development the transverse magnetization for a particular proton is equal to the coefficient associated with the spin operator $\mathbf{I}_{-1}$ for that proton. In the conventional density matrix description, which uses normalized density matrices (21) or operators (23), the transverse magnetization for that proton would be equal to the product of the concentration of molecules containing that spin and the coefficient associated with spin operator $\mathbf{I}_{-1}$ for that proton. If one sets the exchange rates to zero, the results of the product operator description of isotropic mixing dur-

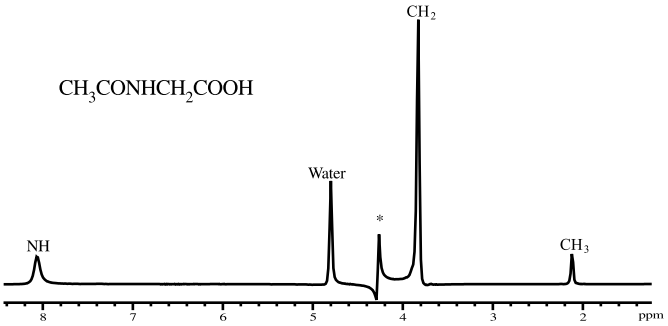
ing a spin-lock period can be used to reproduce the calculated coherence transfer amplitudes given by Cavanagh et al. (24).

In the TOCSY pulse sequence, the magnetizations are labelled by their chemical shifts during the t_1 evolution period at the beginning of the spin-lock period, and we are interested in the detected signals, which result from nuclei that had a particular chemical shift during t_1. Hence we focus our attention on those terms in the density operator at the beginning of the spin-lock period that represent the transverse magnetizations of a particular group of nuclei in one type of molecule, and determine the amplitudes of the transverse magnetizations present at the end of the spin-lock period. Since the coherence levels of all coherences in the ensemble are unchanged during a spin-lock period, only the –1 coherence level operators need be considered. In *N*-acetylglycine, 793 basis product operators (1 for each of the 792 possible single quantum transitions in the *N*-acetylglycine system with 6 coupled protons, plus 1 for the water proton) are required. To determine the fate of the C$\mathbf{H}_2$ magnetization as it evolves through the spin-lock period, one defines the initial conditions by setting the two elements of $\mathbf{b}(0)$ that correspond to the spin operators for the transverse magnetizations of the CH_2 protons of *N*-acetylglycine to 1, and all other elements to zero. The intensities of the various peaks in the slice through the 2D TOCSY contour map at the value of f_1 for the CH_2 protons of *N*-acetylglycine are proportional to the elements of $\mathbf{b}(t)$ for the spin operators for the corresponding transverse magnetizations. The sum of the elements that correspond to the operators for the CH_2 protons gives the intensity of the *N*-acetylglycine CH_2 peak, the element corresponding to the spin operator for the NH proton gives the intensity of the *N*-acetylglycine NH peak, the sum of the elements corresponding to the spin operators for the methyl protons gives the intensity of the *N*-acetylglycine CH_3 peak, and the element associated with the spin operator for the water proton gives the intensity of the water peak.

Results and discussion

To test the applicability of the theory presented above, we have studied the rate of exchange between the NH proton in *N*-acetylglycine with water. Rates from 5 to 95 s^{-1} have been determined as a function of pH by lineshape analysis (14). In that study, the collapse of the doublet of quartets arising from the resonance of the glycine methylene group to a single quartet as the pH increased was simulated using the Bloch equations modified for chemical exchange to extract the rate of exchange of the amide proton. The methylene resonance is split into a doublet from coupling to the amide proton (5.9 Hz) and is further split into a quartet by a 0.3Hz long-range coupling from the methyl protons of the acetate group. The relevant results of this study are summarized in Table 1.

Fig. 1. The f_2 trace of the TOCSY contour map at the f_1 position of the CH_2 resonance of *N*-acetylglycine for an aqueous solution of *N*-acetylglycine at pH 8.75. Mixing time 0.093 s. The dispersive signal at 4.3 ppm is due to the signal of external water in the capillary of DMSO-d_6 used for the lock signal.



In the present investigation, we studied *N*-acetylglycine solutions at pH values that overlap the previous study so that the exchange theory could be tested. Measurements at higher pH values were also performed in order to determine the upper limit of exchange rates measurable with the current technique. TOCSY experiments were performed on each solution at a number of different mixing times and the transfer of the glycine CH_2 magnetization present at the end of the t_1 interval to other nuclei during spin-locking was determined from the f_2 slice of the 2D contour map at the f_1 frequency of the CH_2 resonance. A typical slice is shown in Fig. 1 for the pH 8.75 solution and a mixing time of 0.093 s. The integrals of the CH_2, NH, CH_3, and water resonances were determined at each mixing time for each pH value. The observed magnetization transfer data are compared in Fig. 2 with the intensities calculated using the theory in the previous section, with the value of the exchange rate constant, τ_A^{-1}, chosen to obtain reasonable agreement between observed and calculated peak intensities. The observed intensities were adjusted so that their sum remained equal to the sum for the shortest mixing time in order to minimize relaxation effects, which are not included in the theoretical description. The agreement between theory and experiment is quite good in all cases. At the slowest exchange rate studied here (pH 7.85), the experimental intensity of the CH_2 group is slightly higher than that predicted by the theory and that for the amide resonance is slightly lower than predicted. The experimental intensity of the NH resonance may be low because of T_2 effects. The exchange rate constants determined here are tabulated in Table 1 and these values agree, within experimental uncertainty, with those from Rabenstein's study (14). However, the present method allowed us to study exchange with rate constants as large as 2000 s^{-1}, while lineshape analysis was limited to rate constants of 100 s^{-1} or less.

It is apparent from Fig. 2 that the scalar coupling between the glycine CH_2 and NH protons gives rise to periodic transfer of magnetization between them during the spin-lock pe-

Integrated intensities of peaks in the f_2 trace of the TOCSY contour maps at the f_1 position of the CH_2 resonance of *N*-acetylglycine at various spin-lock periods. □: CH_3 of *N*-acetylglycine; ■: water; O: NH of *N*-acetylglycine; ●: CH_2 of *N*-acetylglycine. (*a*) pH 7.85, τ_A^{-1} = 6 s^{-1}; (*b*) pH 8.75, τ_A^{-1} = 15 s^{-1}; (*c*) pH 9.54, τ_A^{-1} = 160 s^{-1}; (*d*) pH 10.40, τ_A^{-1} = 800 s^{-1}; solid lines show intensities calculated with J_{NH-CH_2} = 5.9 Hz and $J_{CH_3-CH_2}$ = 0.3 Hz and the values of τ_A^{-1} given.

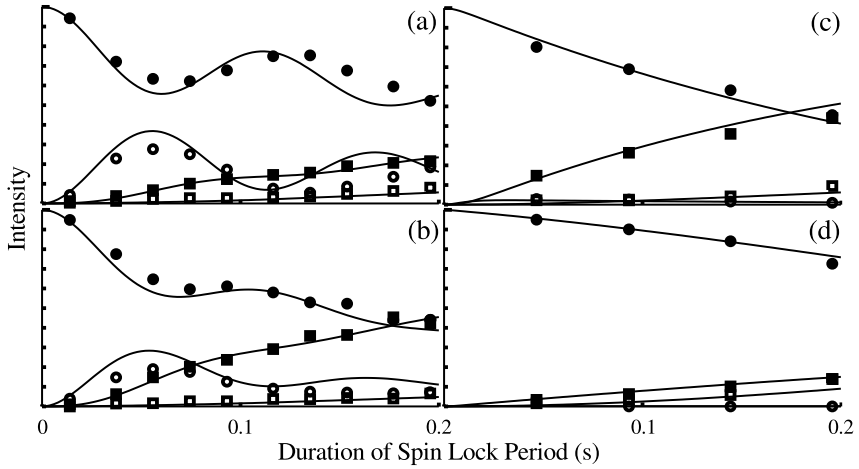

Fig. 3. Calculated TOCSY peak intensities as a function of exchange rate for the water peak and the NH, CH_2, and CH_3 peaks of *N*-acetylglycine for a spin-lock time of 0.150 s.

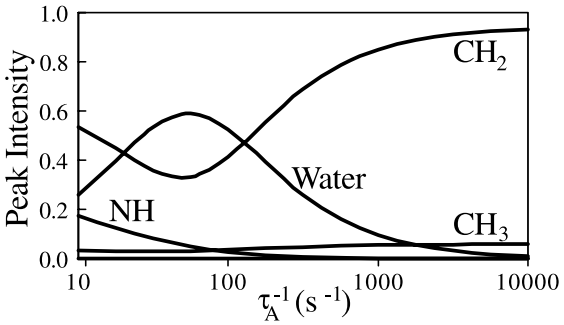

riod at slow exchange rates (Figs. 2*a* and 2*b*). As the exchange rate increases, magnetization transferred from CH_2 to NH via scalar coupling is transferred more rapidly to the water protons so that little of it remains for the scalar coupling to transfer back to the CH_2 protons at later times. In Fig. 2*c*, where τ_A^{-1} = 160 s^{-1}, there is essentially a monotonic decay of the CH_2 magnetization, with a concomitant growth in the magnetization transferred to the water protons by exchange, and the NH proton line has low intensity throughout the spin-lock period. At even faster exchange rates ($\tau_A^{-1} \gtrsim$ 600 s^{-1}), the NH resonance has coalesced with the water resonance and the rate of transfer of magnetization from the *N*-acetylglycine protons to water is much slower than at smaller values of τ_A^{-1}. This is to be expected since the scalar coupling between the NH and CH_2 protons is interrupted so frequently — exchange effectively decouples the NH and CH_2 protons — that little coherent magnetization transfer from CH_2 to NH can occur.

To delineate the variations in the magnitudes of the transferred magnetizations with τ_A^{-1}, the intensities of the spectral peaks at the end of a spin-lock period of 0.15 s were computed for 10 $s^{-1} \leq \tau_A^{-1} \leq$ 10 000 s^{-1}. The results are shown in Fig. 3. The NH intensity is reasonably large when τ_A^{-1} is small, but is very small for $\tau_A^{-1} \geq$ 100 s^{-1} as indicated above. The most striking feature shown in Fig. 3 is the variation of the magnitude of the magnetization transferred from the *N*-acetylglycine CH_2 protons to water with τ_A^{-1}. The intensity of the water peak goes through a maximum at $\tau_A^{-1} \cong$ 80 s^{-1}, and decreases slowly as τ_A^{-1} increases. The CH_2 peak goes through a minimum at $\tau_A^{-1} \cong$ 80 s^{-1}. It is unlikely that reliable measurements of the rate constants for NH–water exchange can be made for $\tau_A^{-1} \gtrsim$ 4000 s^{-1} since the water peak intensity will be too small for accurate measurement. The CH_3 peak intensity increases slowly with τ_A^{-1} above τ_A^{-1} = 80 s^{-1} because the small 0.3 Hz CH_2–CH_3 scalar coupling becomes more effective in transferring magnetization away from the CH_2 protons as the NH and CH_2 protons are increasingly decoupled by exchange. It should be pointed out that the intensity of the water peak is approximately proportional to the length of the spin-lock period in TOCSY for $\tau_A^{-1} >$ 80 s^{-1}. Furthermore, the results reported here are specific to the *N*-acetylglycine spin system, so only qualitative extensions of the conclusions reached here to other spin systems can be made. Calculations of the behaviour expected of other spin systems with exchangeable protons are straightforward.

In earlier work on proton magnetization transfer from nonexchangeable protons in amino acids and peptides to water during the spin-lock period in TOCSY (1), attention was focussed on the water stripe of the TOCSY map, i.e., the f_1 trace of the TOCSY map at the f_2 position of the water resonance. The results reported here have some implications for such studies. The water peak in the f_2 traces of the TOCSY contour maps at the f_1 position of the CH_2 used here is, in fact, the CH_2 peak in the water stripe used in the previous work. Hence the calculated intensities of the water peak shown in Fig. 3 are applicable to studies of the f_2 water stripe. The CH_2 peak of *N*-acetylglycine in the water stripe of the TOCSY map for a spin-lock time of 0.15 s will have maximum intensity when $\tau_A^{-1} \sim$ 80 s^{-1}, and one would expect to observe a CH_2 peak with significant intensity only if $\tau_A^{-1} \lesssim$ 4000 s^{-1}. When the CH_2 peak intensity in the water stripe is smaller than its maximum value, τ_A^{-1} is either greater than or

less than ~80 s^{-1}. If the exchange rate is slow ($\tau_A^{-1} \lesssim 80\ s^{-1}$), the NH resonance should be resolved; but when the exchange rate is fast ($\tau_A^{-1} \gtrsim 80\ s^{-1}$), the NH resonance will have coalesced with the water resonance.

Geometrical isomerism and ^{19}F NMR spectroscopy of octahedral perfluoroethyl- and perfluoropropyl-substituted β-diketonates and monothio-β-diketonates of rhodium(III)

Gary A. Stern and John B. Westmore

Abstract: In solution in acetone at room temperature, tris(perfluoropropanoyl and perfluorobutanoyl)benzoylmethanate complexes of rhodium(III) are shown by ^{19}F NMR spectroscopy to exist as nearly statistical 1:3 mixtures of their respective *fac* and *mer* octahedral isomers, whereas the analogous perfluoroalkanoylthiobenzoylmethanate complexes have a *fac*-octahedral structure. For all four complexes studied, vicinal F–F coupling constants are too small (0–3 Hz) to lead to resolved multiplet peaks, so that perfluoroethyl groups show singlet resonances for their CF_3 groups. Since four-bond coupling constants are significantly larger, ~9 Hz, perfluoropropyl groups show the expected multiplet resonances for their CF_3 groups. In acetone, AB patterns, with geminal coupling constants equal to ~270 Hz, are observed for the CF_2 groups next to the chelate ring (except for the perfluoropropanoylthiobenzoylmethanate complex). (These observations are modified by solvent. In toluene, one of the AB patterns of a *mer*-octahedral complex collapses to a single peak.) The AB spectra, which are subject to substituent and solvent effects, can be interpreted in terms of perfluoroalkyl groups rotating rapidly about the C_{ring}—C_{alkyl} bond, with an unsymmetric double potential well, giving unequal rotamer populations. Changes in the spectra were not noticeable over the temperature range accessible in the acetone and toluene solvents used.

Key words: rotation, perfluoroalkyl groups, fluorine NMR spectra, fluorine–fluorine coupling constants, fluorinated β-diketonate complexes, monothio-β-diketonates, rhodium complexes.

Résumé : Faisant appel à la spectroscopie RMN du ^{19}F, on montre que, en solution dans l'acétone, à la température ambiante, les complexes tris(perfluoropropanoyl et perfluorobutanoyl)benzoylméthanate de rhodium(III) existent sous la forme de mélanges 1:3 pratiquement statistiques de leurs isomères octaédriques *fac* et *mer* respectifs alors que les complexes perfluoroalcanoylthiobenzoylméthanates analogues existent sous la forme d'une structure octaédrique-*fac*. Pour chacun des quatre complexes étudiés, les constantes de couplage F–F vicinales sont trop faibles (0–3 Hz) conduire à des pics multiplets résolus; les groupes CF_3 des groupes perfluoroéthyles apparaissent donc comme singulets. Les constantes de couplage à travers quatre liaisons étant beaucoup plus importantes, ≈9 Hz, les groupes CF_3 des groupes perfluoropropyles se présentent sous la forme de multiplets attendue. Dans l'acétone, on observe des diagrammes AB, avec des constantes de couplage geminales d'environ 270 Hz, pour les groupes CF_2 adjacents du cycle du chélate (à l'exception du complexe perfluoropropanoylthiobenzoylméthanate). (Ces observations varient avec le solvant. Dans le toluène, l'un des diagrammes AB d'un complexe octaédrique-*mer* ne donne qu'un seul pic). Les spectres AB, qui sont soumis à des effets de substituant et de solvants, peuvent être interprétés en fonction de groupes perfluoroalkyles en rotation rapide autour de la liaison C_{cycle}—C_{alkyle} avec un puits de potentiel double et asymétrique conduisant à des populations inégales de rotamères. Dans le domaine de température accessible avec des solutions dans l'acétone ou le toluène, il n'a pas été possible de noter de différences dans les spectres.

Mots clés : rotation, groupes perfluoroalkyles, spectres RMN du fluor, constantes de couplage fluor–fluor, complexes β-dicétonates fluorés, monothio-β-dicétonates, complexes du rhodium.

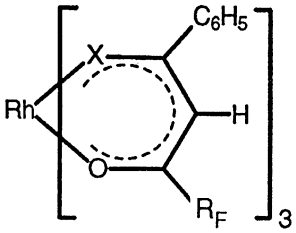
Introduction

Octahedral metal complexes having three unsymmetric bidentate ligands can adopt facial (*fac*) or meridional (*mer*) structures. While the *mer* isomer is statistically three times more likely to form than the *fac* isomer, the ratio is strongly influenced by thermodynamic parameters or by kinetics of the formation reactions. Under appropriate conditions, isomerism of such complexes can be studied by nuclear magnetic resonance spectroscopy. Our initial interest in this topic was prompted by our syntheses of fluorinated β-diketonate complexes of rhodium(III), which are sufficiently volatile for study by electron ionization mass spectrometry. We found, by single crystal X-ray diffraction (XRD), that tris(thioacetyltrifluoroacetonato)rhodium(III) adopts the *fac*-octahedral geometry (1). However, for the rhodium(III) complexes **1**–**4** to be described in this paper, XRD was not an option because we were unable to prepare single crystals of suitable quality. For these complexes, ^{19}F NMR spectroscopy shows that not only does the X substituent (O or S) influence geometrical isomerism but also, as a bonus, has led to some interesting conclusions regarding the rotational behavior of the perfluoroalkyl substituents.



1. X = S, $R_F = C_2F_5$

2. X = S, $R_F = n\text{-}C_3F_7$

3. X = O, $R_F = C_2F_5$

4. X = O, $R_F = n\text{-}C_3F_7$

Because our description of the NMR spectra presented in this paper requires an interpretation of F–F coupling constants, we first present a brief summary of this topic, along with some key references. The coupling constant depends upon the number and nature of the bonds intervening between the coupled fluorine atoms, dihedral angles between bonds, substituent effects, and "through space" interactions. In particular, the near-zero values (<~1 Hz) observed for vicinal coupling constants (2–18) may be a consequence of the averaging effects of internal rotation about the C—C bond, and, in part, to cancellation of the orbital, spin-dipolar, and Fermi contact terms of nonuniform sign (19, 20). All three of these terms make significant contributions to geminal coupling constants (19, 20), which, experimentally, have wide variations (150–400 Hz), that have been attributed partly to the sensitivity of the Fermi contact term to changes in the FCF bond angles, and also partly to the sensitivity of the orbital and Fermi contact terms to substituent effects (21–24). In contrast to the near-zero coupling constants between vicinal fluorines, substantially larger values for coupling over four and five bonds have been observed (25–30).

The ^{19}F NMR spectra of many metal complexes containing perfluoroalkyl groups have been reported (31–37). The compounds include metal-alkyl bonded complexes of Mn, Re, Fe, and Co (31); Co and Rh (32); β-diketonate and (or) monothio-β-diketonate complexes of Ni, Pd, and Co (33); Be (34); Ru, Rh, Pd, and Pt (35); Ni, Pd, and Co (36); and Zn and Pd (37). In most cases the spectra were simply used for characterization purposes. In this paper, we report a more detailed analysis of the spectra of rhodium(III) β-diketonate and monothio-β-diketonate complexes containing perfluoroalkyl substituents. Not only do the spectra reveal the geometry of the complexes, but they also lead to some interesting conclusions about the rotational behavior of the perfluoroalkyl groups.

Experimental section

Syntheses

The four ligands needed to prepare complexes **1**–**4** were synthesized by published methods (38).

To prepare β-diketonate complexes **3** and **4**, $RhCl_3 \cdot H_2O$ (0.32 mmol), in 10 mL of ethanol, was added to a solution of the appropriate ligand (0.96 mmol) in 10 mL of ethanol. The solution was refluxed for 1 h, then cooled, and a small amount of water was added. This solution was then shaken with methylene chloride; the methylene chloride extract was dried over sodium sulfate. After evaporation of methylene chloride, the resulting oily red residue was added to a silica gel column (60–200 mesh) through which methylene chloride was passed. For each complex, two bands separated, while a portion of the sample still remained at the top of the column. The first band (red) eluted quite readily but did not contain the desired complex. The second band (yellow), which contained the desired product, eluted slowly, so that the silica from this part of the column was removed and the product was extracted from it with acetone. After evaporation of acetone, the residue was subjected to fractional sublimation, under roughing pump vacuum, to yield the desired rhodium chelate as a yellow sublimate. The molecular masses and fragmentation patterns determined by mass spectrometry (VG 7070E-HF mass spectrometer) supported assignment of the yellow products as monomeric tris-chelate complexes. Complex **3** *m*/*z*: 898 (100%), RhL_3^+ (898, calcd.); 848 (36%), $[RhL_3 - CF_2]^+$; 633 (57%), RhL_2^+; 181 (81%), $HRhC_6H_5^+$. Complex **4** *m*/*z*: 1048 (100%), RhL_3^+ (1048, calcd.); 733 (51%), RhL_2^+; 181 (65%), $HRhC_6H_5^+$.

The monothio-β-diketonate complexes **1** and **2** were prepared by the same procedure. The desired products were again found in the second band (red) on the silica gel column and were subjected to fractional sublimation, in vacuo, to yield the desired complexes as red sublimates. The assignments of the red products as monomeric tris-chelate complexes were supported by mass spectrometry. Complex **1** *m*/*z*: 946 (100%), RhL_3^+ (946, calcd.); 896 (17%), $[RhL_3 - CF_2]^+$; 665 (32%), RhL_2^+; 383 (49%), $[Rh(L - H)]^+$. Complex **2** *m*/*z*: 1096 (100%), RhL_3^+ (1096, calcd.); 765 (49%), RhL_2^+; 433 (55%), $[Rh(L - H)]^+$.

[a]Values of δ_X, J_{AX}, and J_{AB} are experimentally determined. The other NMR parameters emerge from the computer simulations for which a line width of 1.5 Hz was used. The uncertainties are estimated to be 0.002 ppm for δ_A and δ_B, 0.01 ppm for δ_X, and 0.3 Hz for J_{AB}. $\Delta\upsilon_{AB}$ (Hz) is the frequency difference between the A and B resonances.

[b]For complex **3**, sub-spectra 1–4 and a–d, respectively, are presented from low to high field. No match between a particular resonance occurring in the AB region with another in the CF_3 (X_3) region is implied.

was added to act as an internal chemical shift reference. In these solvents, $\delta_F(C_6F_6)$ was taken as –162.90 ppm with respect to $\delta_F(CFCl_3)$. Thus, the variations in δ_F that are reported for samples in the two solvents will be a combination of solvent effects for both the reference and the sample. The chlorinated solvents, chloroform and methylene chloride, were unsuitable because the complexes appeared to decompose slowly in them. The solutions were transferred to 5 mm o.d. NMR tubes, then degassed by the freeze–pump–thaw procedure; the sample tubes were then flame sealed. All ^{19}F NMR spectra were recorded with a Bruker AM300 spectrometer, at a frequency of 282.4 MHz, with fluorines decoupled from protons by broad-band irradiation. For detailed examinations of selected spectral regions, the spectral window was reduced, and the spectrum was accumulated with up to 500 free induction decays; Fourier transformation yielded spectra with a digital resolution of 0.076 Hz/point. The probe was at room temperature (~27°C) for the results described (we noticed no significant changes in the spectra over the high- or low-temperature range accessible with the acetone and toluene solvents).

The NMR spectra were analyzed with the assistance of the NUMARIT spectral simulation computer program (39)[3], which was extensively modified by R. Sebastian, formerly of this department.

Results and discussion

The ^{19}F NMR spectra of the monothio-β-diketonate complexes are simpler than those of the β-diketonates, so we shall discuss them first.

Monothio-β-diketonate complexes

The spectrum of complex **1** ($R_F = CF_2CF_3$), recorded in acetone at room temperature, consists of only two resonances, both appearing as singlets. The deceptive simplicity of this spectrum must be explained, for the CF_2 group could be an AB system because the plane of the chelate ring is not a molecular plane of symmetry. In addition, in separate experiments, we have observed that the ^{103}Rh–F coupling constant in the analogous complex when $R_F = CF_3$ is ~0.5 Hz, about the same as J_{HF} when not proton decoupled. However, in the spectra discussed in this paper, peak structure resulting from ^{103}Rh–F coupling was not resolved. The low-field resonance, at –81.38 ± 0.01 ppm (relative intensity = 3), and the high-field resonance, at –119.41 ± 0.01 ppm (relative intensity = 2), must be assigned to the fluorine atoms of the CF_3 and CF_2 groups, respectively. The full width at half maximum (FWHM) of each signal was ~2 Hz, i.e., not measurably greater than that of the C_6F_6 reference peak; combined with the lack of peak structure, and assuming that the CF_3 peak is no more than 0.5 Hz broader than the reference peak. This implies that the F–F vicinal coupling constant is no greater than 1 Hz, as anticipated from the introduction. The single-peak CF_2 resonance, unlike the AB patterns shown by complexes **2**–**4** (later), indicates that the chemical shifts of these two fluorines are identical, or nearly so, because geminal coupling constants are expected to be high (see Introduction). To permit easy comparison of NMR parameters of all complexes, the chemical shifts for complex **1** are included in Table 1.

The spectrum of complex **2** ($R_F = CF_2CF_2CF_3$), a potential seven-spin $ABMNX_3$ system, contains three major resonances, namely a triplet (centred on $\delta \approx -79.5$ ppm), a quintet (centred on $\delta \approx -117.7$ ppm), and a singlet ($\delta \approx -125.5$ ppm), with relative intensities of 3:2:2, respectively (Fig. 1). However, this spectrum is much simpler than its full analysis as an $ABMNX_3$ spectrum would require. The triplet must be assigned to the fluorine atoms of the CF_3 group. Assignment of the remaining resonances is consistent with both coupling constant and chemical shift evidence. We assign the singlet to the fluorines of the β-CF_2 group, since vicinal coupling constants between these fluorines and those of the adjacent CF_3 and α-CF_2 groups are expected, on the basis of the earlier discussion, to be very small. Furthermore, there is no evidence of any MN structure for this peak thus indicating that these fluorines have identical, or nearly identical, chemical shifts. *Consequently, we can interpret the other*

parts of the spectrum in terms of coupling between the α-CF_2 and CF_3 groups only. The remaining assignment of the quintet to the α-CF_2 group is also consistent with its chemical shift, which is similar to that of the CF_2 group of complex **1**. This is as expected because the electronic environment of the α-CF_2 group in complex **2** is similar to that of the CF_2 group in complex **1**, i.e., both are located between the ring carbon atom and a perfluoroalkyl group (the inductive effects of the CF_3 and CF_2CF_3 groups bound to the CF_2 group next to the ring should be very similar). On the other hand, the β-CF_2 group in complex **2** has a substantially different environment from the α-CF_2 group, and therefore a different chemical shift. Similar assignments have been made for the fluorine atoms in a metal complex containing the Mn-CO-$CF_2CF_2CF_3$ group (31). The quintet, with peak intensity ratios of 1.01:4.02:6.02:4.01:1.00, is associated with two outer sets, each of four low intensity peaks. The quintet and triplet splitting patterns exhibited by the α-CF_2 and CF_3 groups, respectively, are consistent with a special case of an ABX_3 spin system that we analyze as follows. In the general case (40), for an ABX_3 spin system, the AB part of the spectrum consists of 16 peaks, comprised of four AB sub-spectra of relative intensities 1:3:3:1, each with the same value of J_{AB}, but with effective chemical shift differences given by $\Delta^*\delta_{AB} = \Delta\delta_{AB} + m_s(J_{AX} - J_{BX})/f$, where $\Delta\delta_{AB}$ is the chemical shift difference between A and B; m_s is the resultant spin of the X_3 nuclei, with the values ±1/2, ±3/2; and f is the operating frequency of the spectrometer. The repeated spacings between the AB sub-spectra are equal to $1/2(J_{AX} + J_{BX})$. The X_3 part consists of 14 resolved peaks of which two together, containing half the total intensity of the X_3 region, are always separated by $(J_{AX} + J_{BX})$ (40). When $J_{AX} = J_{BX}$, as expected here for a $CF_2CF_2CF_3$ group with free rotation about the C—C bonds, the X_3 part collapses to a symmetrical 1:2:1 triplet with spacings equal to J_{AX}. The repeated spacings between the AB sub-spectra now equal J_{AX}, and the effective chemical shift differences all equal $\Delta\delta_{AB}$. The eight strong central peaks of the four AB sub-spectra can only collapse to the observed 1:4:6:4:1 quintet if $\Delta\upsilon = J_{AX}$, where $\Delta\upsilon$ is the common separation between the central peaks of the AB sub-spectra. The remaining eight weak peaks of the four AB sub-spectra are assigned to the two sets of four low-intensity outer peaks, with spacings equal to J_{AX}. Figure 2 shows a comparison between the AB portion of the experimental spectrum and a simulated spectrum (39) for which the input parameters δ_A, δ_B, δ_X, J_{AB}, J_{AX}, J_{BX} and line width were adjusted until the best match between the X_3 and AB regions of the experimental and simulated spectra was obtained. The resulting NMR parameters are presented in Table 2. The $^4J_{AX}$ and $^4J_{BX}$ values are 8.9 ± 0.3 Hz, i.e., significantly larger than the vicinal coupling constants. The J_{AB} value, 270.0 ± 0.3 Hz, is within the wide range of values (150–400 Hz), noted in the introduction, that have been observed for geminal coupling constants.

For either monothio-β-diketonate complex only one type of perfluoroalkyl group can be recognized from the NMR spectrum, and consequently, the three groups are equivalent. Therefore, both complexes have a *fac*-octahedral structure for which the perfluoroalkyl groups are necessarily equivalent, owing to the presence of a C_3 symmetry axis. (In contrast, for a *mer*-octahedral structure, which lacks a C_3 axis, the three perfluoroalkyl groups are non-equivalent, i.e., one of the three perfluoroacyl residues is *trans* to a benzoyl residue, while the other two are *trans* to each other but not equivalent by symmetry. Thus, each perfluoroalkyl group of the *mer* isomer has a distinct spectrum.) A *fac*-octahedral structure for the monothio-β-diketonate complexes agrees with our XRD structure determination (1) of tris(thioacetyltrifluoroacetonato)rhodium(III), and is consistent with structures of

[a]Values of δ_X, δ(β-CF_2), and J(vic) are experimentally measured. The other NMR parameters emerge from the computer simulations for which a line width of 1.5 Hz was used. The uncertainties are estimated to be 0.002 ppm for δ_A and δ_B, 0.01 ppm for δ_X, and 0.3 Hz for J_{AB}, $^4J_{AX}$, and $^4J_{BX}$. υ_{AB} (Hz) is the frequency difference between the A and B chemical shifts.

[b]For complex **4**, sub-spectra 1–4, a–b, and w–z, respectively, are listed from low to high field. No matches among particular absorptions occurring in the the three spectral regions are implied.

various other tris(monothio-β-diketonato)rhodium(III) complexes (35, 41).

β-Diketonate complex 3 ($R_F = C_2F_5$)

Spectra of this complex, shown in Fig. 3, were recorded in both toluene and acetone, in order to reinforce the correctness of the assignments given below. In both solvents, the spectra contain two groupings of peaks. One grouping (relative intensity = 3) occurs between –81.65 and –82.10 ppm (in acetone) or between –82.20 and –82.60 ppm (in toluene), and the other grouping (relative intensity = 2) occurs between –117.20 and –119.80 ppm (in acetone) or between –118.20 and –120.60 ppm (in toluene). These must be assigned to the fluorines of the CF_3 and CF_2 groups, respectively. In both solvents, the first set contains four major resonance peaks and a number of minor peaks, while the second set contains at least six major resonance peaks in acetone, seven in toluene, and a number of minor peaks. The minor peaks in the CF_3 region of the spectra are assigned to impurities that, despite several attempts, we failed to remove completely by column chromatography followed by fractional sublimation of the complex under roughing pump vacuum.

The observation of four major peaks in the CF_3 region indicates that both *fac* and *mer* isomers are present in solution. Three of these peaks, which are necessarily of equal intensity, can be assigned to the *mer* isomer and the fourth to the *fac* isomer. The relative areas of the shaded parts of the peaks (Fig. 4), starting from low field, are 1.05:1.01:0.85:1.00 (in acetone) and 1.05:1.00:0.85:1.01 (in toluene). These results suggest that the third peak, starting from low field, can be assigned to the *fac* isomer, even though the intensities of the three remaining peaks are not exactly equal (owing probably to contributions from impurities). The *fac*:*mer* ratio is close to the statistical 1:3 ratio, in contrast to the monothio-β-diketonate complexes **1** and **3** for which the *fac* isomer is formed exclusively.

Although no splitting of the four resonances in the CF_3 region is apparent, the peak widths differ. Thus, for the spectrum recorded in acetone solution, the approximate FWHM values are 4.0, 4.7, 2.0, and 5.0 Hz, from low to high field, respectively. If we interpret these peaks as the X_3 parts of four ABX_3 sub-spectra then, according to the analysis described above for complex **2**, each of these peaks corresponds to a symmetrical 1:2:1 triplet with spacings equal to $1/2(J_{AX} + J_{BX}) = J_{AX}$, since $J_{AX} = J_{BX}$. By noting that the FWHM value for the C_6F_6 resonance used for calibration is ~2 Hz, then we find upper limits for the respective values of J_{AX} to be ~2.0, 2.7, ≤1, and 3.0 Hz. Similarly, the FWHM values in toluene, i.e., 2.7, 4.3, 1.3, and 4.3 Hz, lead to the J_{AX} upper limit values 1.7, 2.3, ≤1, and 2.3 Hz, respectively. Based on the earlier discussion, these small coupling constants are as expected for coupling between vicinal fluorines. The NMR parameters for these resonance peaks (referred to as sub-spectra a–d) are summarized in Table 1.

Fig. 4. CF_3 $^{19}F\{^1H\}$ spectral region (X_3 part) of.complex **3** in (*a*) acetone and (*b*) toluene. Not all impurities could be successfully be removed. Relative areas of the peaks are determined from the shaded portions.

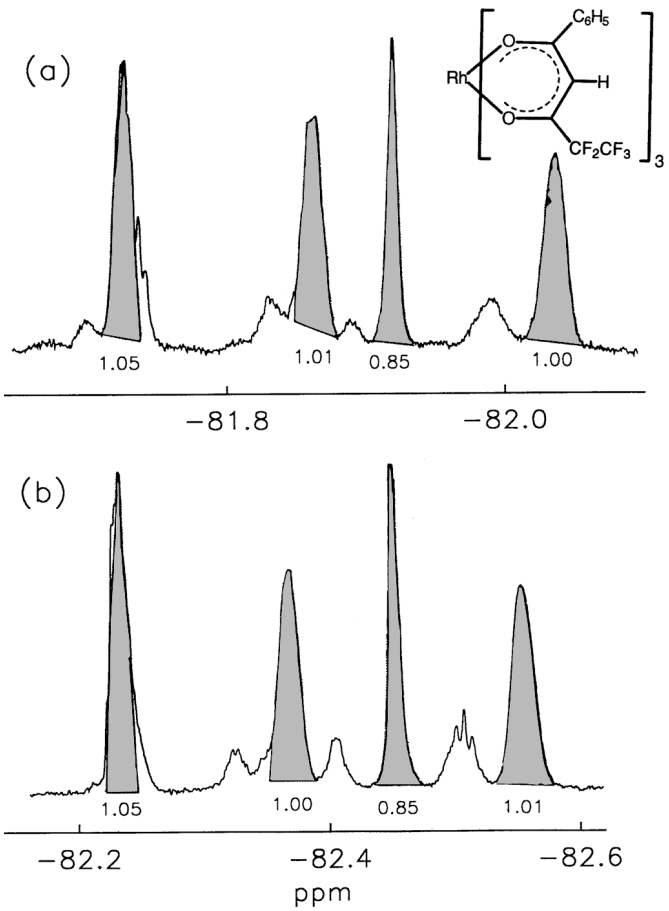

Fig. 5. CF_2 $^{19}F\{^1H\}$ NMR spectral region (AB part) of complex **3**: (*a*) experimental spectrum in acetone, (*b*) simulated spectrum. Not all impurities could be successfully be removed.

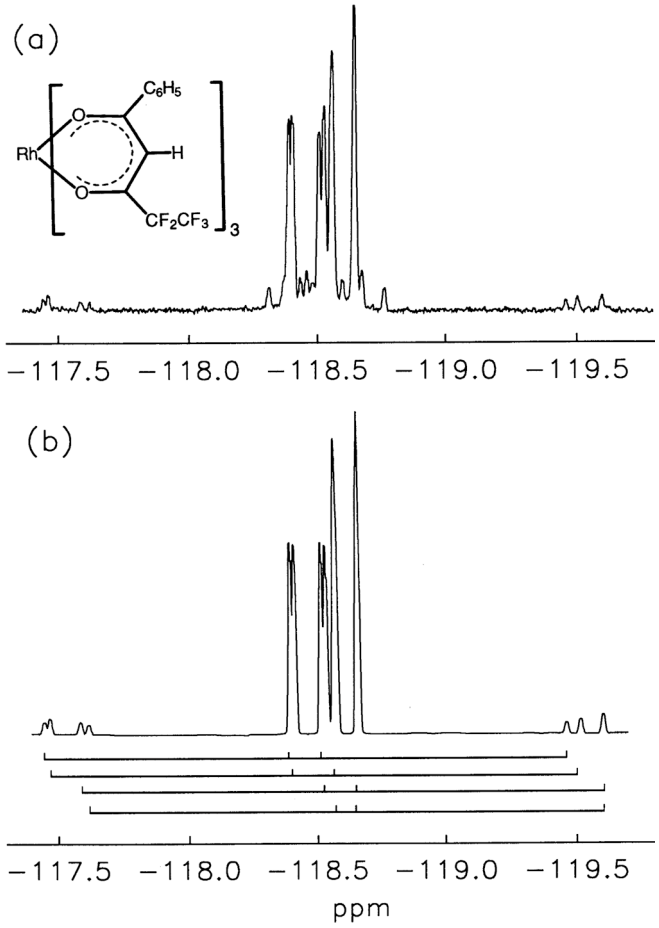
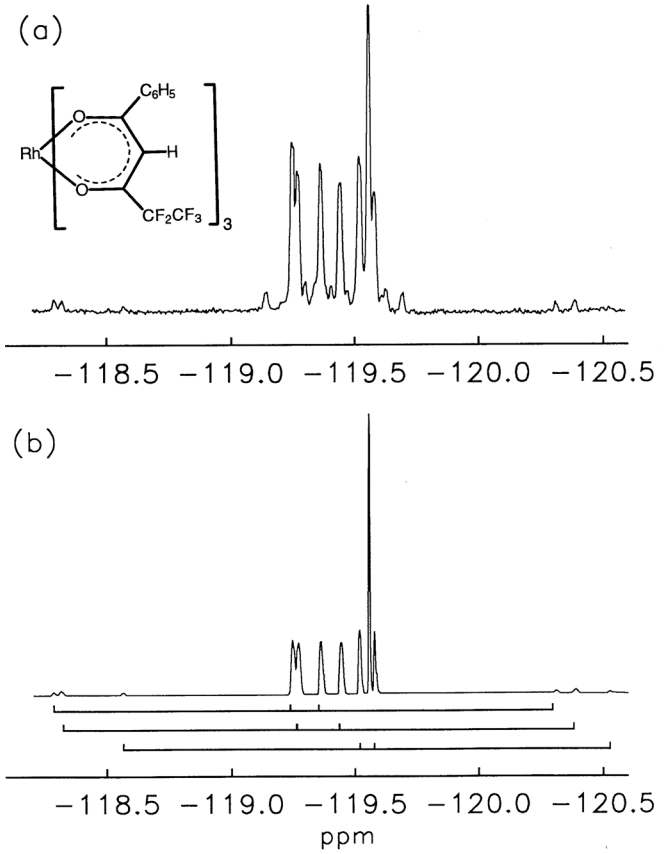


Strictly speaking, the CF_2 region of the spectrum should be interpreted as the AB parts of four ABX_3 spectra. However, in view of the small J_{AX} and J_{BX} coupling constants observed, it is more practical to regard this region as four overlapping AB sub-spectra, with the peaks broadened by the small vicinal couplings. Thus, we expect to observe eight strong peaks in this region, unless some of them are superimposed. The presence of small amounts of impurities as well as partial overlap of some peaks made it impossible to measure the relative intensities of peaks accurately and to associate them with a particular isomer. (As noted above, the intensities of the three resonances for the *mer* isomer should always be equal, and therefore, if one of the four signals is smaller or larger than the other three, it must be assigned to the *fac* isomer. In the present case, the intensities of the peaks in the X_3 region show that the intensities in the AB region will not be sufficiently different to allow us to assign signals in the AB region to a particular isomer.) These AB sub-spectra are therefore simply referred to as sub-spectra 1–4 (counting from low to high field). We have not matched these sub-spectra to any particular peak in the X_3 (CF_3) region of the spectrum. Figures 5 and 6 show expanded views of the AB (CF_2) spectral region, recorded in acetone and toluene, respectively. As before, these sub-spectra were analyzed, by simulation as four ABX_3 spectra, with the Numarit program (39) by using the NMR parameters and line width as input parameters that could be adjusted until a good match to the experimental spectrum was obtained. (In the form used, this program can simulate four ABX_3 spectra, but the four intensities must be equal, and the line widths in all spectra must be the same. This presents little difficulty in the present case because the four experimental spectra for the C_2F_5 groups are of approximately equal intensity, and the line width variations will not significantly influence the appearance of the spectrum. Because we could not match the peaks in the AB (CF_2) region to specific peaks in the X_3 (CF_3) region, we used as input the average δ_X value of the peaks in the CF_3 region, and also $J_{AX} = J_{BX} = 1.6$ Hz. The effect of this approximation on the accuracy of the simulations is, of course, minimal.) The experimental spectra, recorded in acetone and toluene, are compared to the simulated spectra in Figs. 5 and 6. The NMR parameters for the sub-spectra, labeled 1–4, recorded in both solvents, are given in Table 1.

The experimental spectra can now be explained. In acetone (Fig. 5), the two incompletely resolved peaks close to –118.40 ppm arise from the A parts of sub-spectra 1 and 2, while the two incompletely resolved peaks between –118.50 and –118.54 ppm are due to the B part of sub-spectrum 1

© 1999 NRC Canada

Fig. 6. CF_2 $^{19}F\{^1H\}$ NMR spectral region (AB part) of complex **3**: (*a*) experimental spectrum in toluene, (*b*) simulated spectrum. Not all impurities could be successfully be removed.



and the A part of sub-spectrum 3. The single peak at –118.56 ppm is the result of the B part of sub-spectrum 2 lying almost directly over the A part of sub-spectrum 4, while the remaining single peak at –118.65 ppm results from the superimposition of the B parts of sub-spectra 3 and 4. In toluene (Fig. 6), we observed only three small peaks on each side of the central region, implying that one of the potential AB sub-spectra has collapsed to a single peak. The two incompletely resolved peaks near –119.23 ppm correspond to the A parts of sub-spectra 1 and 2, while their B parts occur at –119.36 and –119.44 ppm, respectively. The peaks at –119.52 and –119.58 ppm correspond to the A and B parts, respectively, of sub-spectrum 3. Finally, the peak at –119.56 ppm corresponds to a CF_2 group, where geminal coupling is not observed (i.e., for spectrum 4, $\delta_A = \delta_B$).

β-Diketonate complex 4 (R_F = *n*-C_3F_7)

The spectrum of this complex, recorded in acetone (Fig. 7), consists of three groups of resonances falling in the spectral regions centered on $\delta \approx -79.54$ ppm (relative intensity = 3), $\delta \approx -115.80$ ppm (relative intensity = 2), and $\delta \approx -125.30$ ppm (relative intensity = 2). Thus, the resonances near $\delta \approx -79.54$ ppm, which show 12 resolved or nearly resolved peaks, must be assigned to the fluorine atoms of the CF_3 group. The resonances near $\delta \approx -115.80$ ppm show evidence of 16 peaks in the central part and 16, or more, small peaks in the outer parts. These are assigned to the α-CF_2 group and will be discussed later. The resonances near $\delta \approx$

Fig. 7. $^{19}F\{^1H\}$ NMR spectrum of complex **4** in acetone.

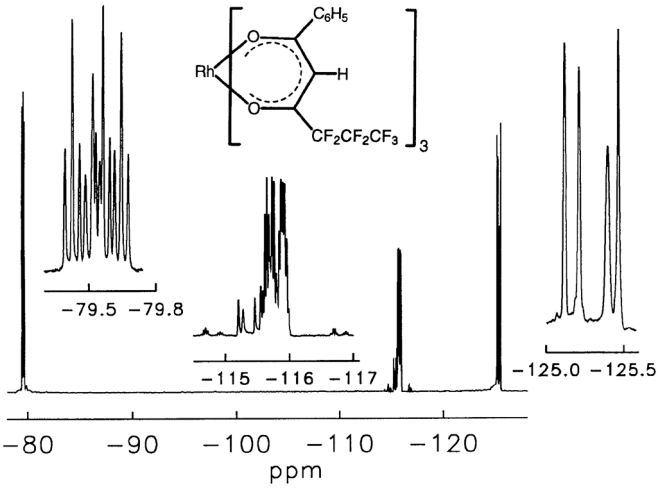


Fig. 8. β-CF_2 $^{19}F\{^1H\}$ NMR spectral region of complex **4** in acetone.

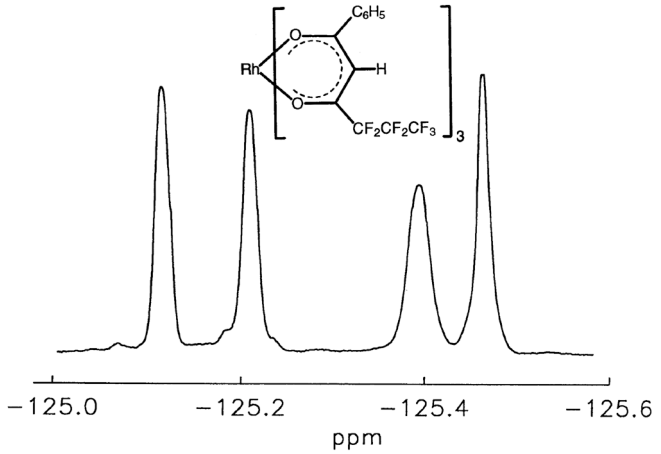

–125.30 ppm must therefore be assigned to the fluorines of the β-CF_2 groups and, because they are simplest, will be discussed first.

When the spectral region around $\delta \approx -125.3$ is expanded (Fig. 8), four peaks, none of which show evidence of splitting, become apparent. These peaks are assigned to the β-CF_2 group, in a mixture of *fac* and *mer* isomers. As noted above, such fluorine atoms are expected to have small, or zero, coupling to vicinal fluorines of the CF_3 and α-CF_2 groups. From low to high field, the FWHM values are 4.6, 4.6, 7.7, and 6.3 Hz, respectively. If we take the FWHM value of the C_6F_6 calibration peak as 2 Hz, then the upper limits for the vicinal coupling constants are 0.9, 0.9, 1.9, and 1.6 Hz, respectively. (This is based on the assumption that these peaks are unresolved 1:5:10:10:5:1 sextets formed by coupling of the β-CF_2 fluorines to the CF_3 and α-CF_2 fluorines, with both sets of vicinal coupling constants equal, and that the FWHM of the sextet equals $3J_{vic}$.) The relative areas of the four peaks (0.96:1.02:1.01:1.00 from low to high field) indicate that the *fac* and *mer* isomers are formed as a nearly statistical 1:3 mixture. These results are summarized as spectra w–z in Table 2.

© 1999 NRC Canada

Fig. 9. CF_3 $^{19}F\{^1H\}$ NMR spectral region (X_3 part) of complex **4** in acetone.

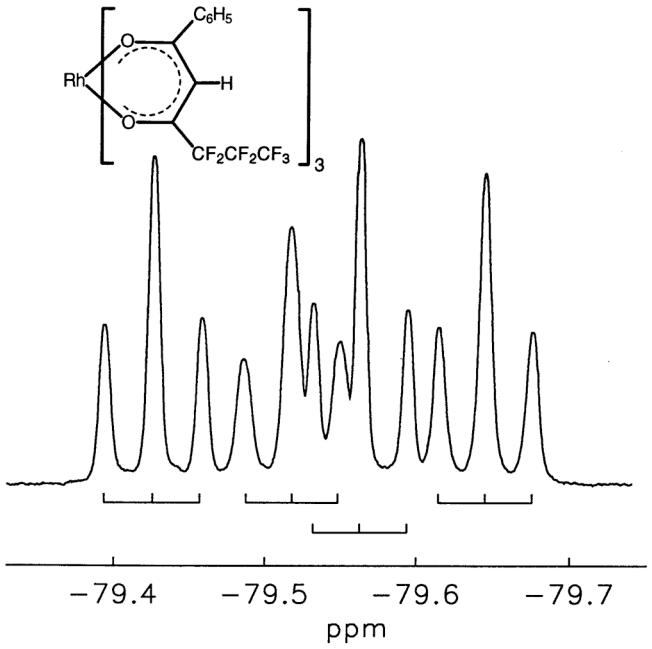

Figure 9 shows an expansion of the CF_3 region of the spectrum. The 12 peaks are easily analyzed as four symmetrical 1:2:1 triplets of nearly equal intensity. No further splitting of any of the peaks is apparent, but there are slight variations in peak width, which can be assigned to non-zero, but small, vicinal couplings, in agreement with the magnitude of the coupling constants deduced above from the β-CF_2 spectral region. To simplify the rest of the analysis, we have assumed that the only effect of the vicinal couplings is to broaden the peaks observed in the α-CF_2 and CF_3 spectral regions. As for complex **2**, a four-bond coupling between the CF_3 fluorines and α-CF_A and α-CF_B fluorines results in an ABX_3 spin system. When $J_{AX} = J_{BX}$, the X_3 spectrum collapses to the observed symmetrical 1:2:1 triplet. The NMR parameters for the CF_3 region of the spectrum, labeled as spectra a–d, are given in Table 2. Because the J_{AX} values are the same within experimental error for each of spectra a–d and w–z, it will not be possible to match the peaks in this region to those in the α-CF_2 region.

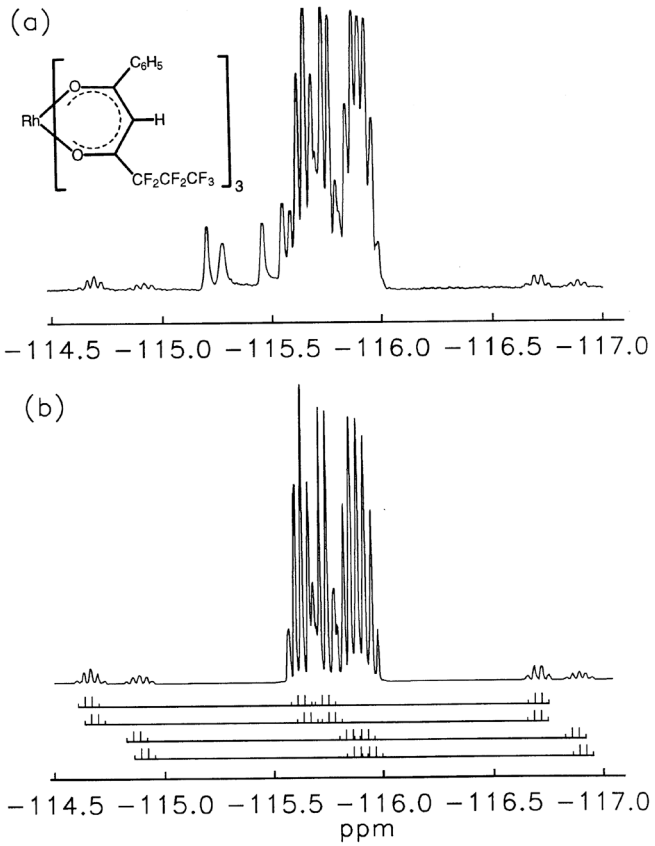
Based on the foregoing, the α-CF_2 region of the spectrum (Fig. 10) corresponds to the AB portions of four ABX_3 spectra of approximately equal intensity. Recalling the analysis given above for complex **2**, we see that, in the general case, each AB region would contain 16 peaks, corresponding to four AB sub-spectra with spacings equal to $1/2(J_{AX} + J_{BX})$, and of relative intensities 1:3:3:1, of which 8 strong peaks would be in the central region, and 4 small satellite peaks would be on either side. Thus, if the chemical shifts of the four AB sub-spectra are not very different, we expect 32 peaks in the central region, and 16 smaller peaks on each side. The number of peaks actually observed is much lower than the maximum. This can be attributed to accidental superimposition of some of the peaks and (or) to the equality of $\Delta\upsilon$ with $n\{1/2(J_{AX} + J_{BX})\}$ (n = 1, 2, 3, etc), within an AB sub-spectrum, where $\Delta\upsilon$ is the common separation between the central peaks of the AB sub-spectra, as before. This was

Fig. 10. α-CF_2 $^{19}F\{^1H\}$ NMR spectral region (AB part) of complex **4**: (*a*) experimental spectrum in acetone, (*b*) simulated spectrum.



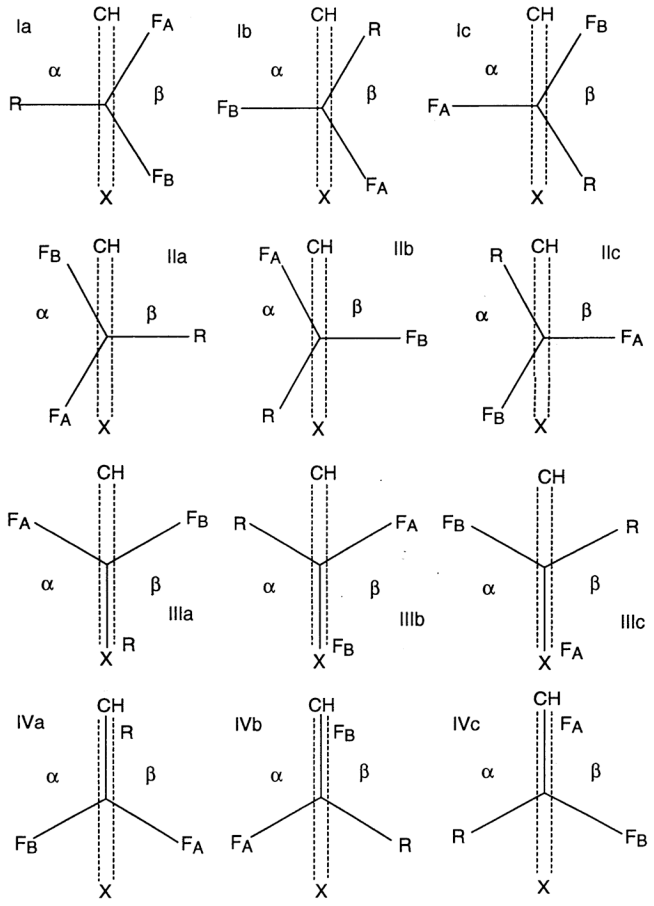
the case above for complex **2** (n = 1). Depending upon the value of $\Delta\upsilon_{AB}$, the two central quartets may overlap with one another. Thus, the complicated pattern of overlapping peaks observed in the central part of the experimental spectrum can be regarded as eight partially overlapping 1:3:3:1 quartets. Similarly, the outer peaks on each side correspond to four overlapping 1:3:3:1 quartets. From the recognizable patterns produced, it was possible to simulate the spectrum, and to obtain the various chemical shifts and coupling constants given in Table 2. Figure 10 shows the close correspondence between the experimental and the simulated (39) AB region of the spectrum, and also shows how the peaks in the experimental spectrum arise. The peaks between –115.61 and –115.74 ppm result from the partial overlap of the central A parts of sub-spectra 1 and 2, while those lying between –115.74 and –115.84 ppm arise from the overlap of the central B parts of sub-spectra 1 and 2, with coincidence of several of the peaks. Finally, the peaks between –115.84 and –116.10 ppm result from the closely overlapping central A and B parts of sub-spectra 3 and 4, again with coincidence of many peaks.

The spectrum (single peak or AB) of the CF_2 group adjacent to the chelate ring

The foregoing discussion has answered the question of the basic structures (i.e., *fac* or *mer* octahedral) of the complexes. However, the part of the spectrum exhibited by the CF_2 group next to the quasi-aromatic planar chelate ring de-

© 1999 NRC Canada

Fig. 11. Conformations considered as rotameric minima for the CF_2R group bound to the planar chelate ring.



serves further analysis. The CF_2CF_3-substituted monothio-β-diketonate complex **1** yields a single-peak resonance for the CF_2 group, whereas the $CF_2CF_2CF_3$-substituted complex **2** exhibits an AB pattern for the α-CF_2 group. For the β-diketonate complex **3** in acetone, all four symmetrically non-equivalent CF_2CF_3 groups of the *fac* and *mer* isomers show AB patterns for the CF_2 group, but one of these AB patterns collapses to a single peak in toluene. Again, for the β-diketonate complex **4**, four AB sub-spectra are exhibited by the α-CF_2 parts of the four non-equivalent $CF_2CF_2CF_3$ substituents.

Without, for now, weighing their relative probabilities or rejecting unlikely conformations, we consider orientations of the CF_2R group with respect to the plane of the chelate ring that would reasonably correspond to energy minima; in Fig. 11 the view is along the C_{ring}—CF_2R bond, and the plane of the chelate ring is represented edgewise by the broken double line. The neighboring CH and X parts of the chelate ring are also shown. As depicted, conformations I(a–c) and II(a–c) have the projection of one of the bonds of the CF_2R group perpendicular to the plane of the chelate ring; conformations III(a–c) have one bond of the CF_2R group eclipsing the C—X bond of the chelate ring, while conformations IV(a–c) have one bond eclipsing the C—CH bond of the chelate ring. The planes of the chelate rings are not molecular planes of symmetry, either for chemically equivalent chelate rings of the *fac*-octahedral isomer or for any of the non-equivalent chelate rings of the *mer*-octahedral isomer. Thus, the two faces of the chelate ring, denoted as α and β, are not symmetrically equivalent, and in none of the 12 conformations are F_A and F_B equivalent.

We are now able to predict the type of spectrum exhibited by the α-CF_2 group for different limiting conditions of interconversion rates and probabilities of the conformations, and of the relative electronic environment of the two faces of the chelate ring. In the case of slow rotation (as set by the NMR experiment), each conformation present in significant amounts will contribute to the observed spectrum. If one conformation dominates, then an AB spectrum appropriate to that conformation will be observed; if several conformations have a significant presence, then a complex spectrum containing several overlapping AB contributions will be observed. A single-peak spectrum can result only if the chemical shifts of F_A and F_B are the same, as would be the case in conformations IIIa and IVa, if the two faces of the chelate ring should be insubstantially different. In fact, we shall show later that these conformations are unlikely.

In the case of rapid interconversion among conformations, the time-averaged chemical shifts of the two α-CF_2 fluorines will depend upon the chemical shifts in the conformations and upon their relative probabilities. Consequently, a single AB spectrum will normally result, although a single-peak resonance occurs under certain conditions. It is with the rapid interconversion scenario that the NMR spectra are consistent.

Preferred conformations and rotation of the perfluoroalkyl group

For simplicity, we confine the following discussion to the conditions most likely to prevail. We have found (1) for tris(thioacetyltrifluoroacetonato)rhodium(III) in the solid state that the orientation of the CF_3 group (i.e., R = F and X = S) corresponds to identical conformations IV(a, b, or c) (Fig. 11) in which a C—F bond eclipses the C–H part of the ring plane. The observed H···F separation of 226 pm is considerably less than the sum (270–305 pm) of the hydrogen and fluorine van der Waals radii, but also much larger than the sum (108 pm) of their covalent radii (42) and is within experimental error of their estimated[4] minimum separation (221 pm) for a rotating CF_3 group. If this result represents a genuine preference for this conformation, possibly as a result of hydrogen bonding, rather than an artifact of crystal packing, then it is reasonable to suppose that IVb and IVc represent low-energy conformations of the CF_2R group of the present molecules.

To assess the energy changes developed on rotation of the CF_2R group, we can note that in benzyl fluoride the conformer of greatest stability in the gas phase is an eclipsed form analogous to one of the equivalent forms IVa–c (R = F, Fig. 11) with a barrier to internal rotation of 1.17 kJ mol^{-1} (43); however, in acetonitrile and cyclohexane solvents a perpendicular conformer, analogous to one of the equivalent forms I/II (R = F), is more stable, with respective barriers to internal rotation of 3.22 and 0.72 kJ mol^{-1} in the two sol-

[4] Molecular Modeling Pro program. WindowChem Software Inc., Fairfield, Calif.

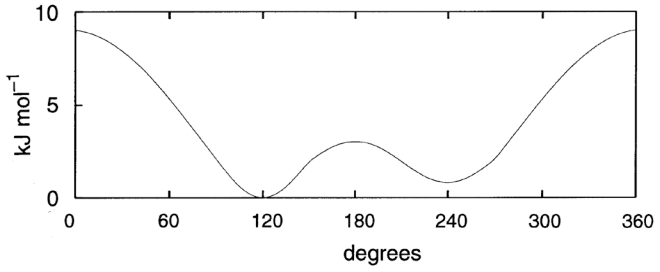
Fig. 12. Energy changes on rotation of the CF_2R group. 0° corresponds to conformation IVa in Fig. 11. The principal barrier is taken as 9 kJ mol^{-1} and the 180° barrier as 3 kJ mol^{-1} (see text).



vents. In the case of 1,1,1-trifluoro-2-phenylethane, the stable conformer is a perpendicular form analogous to Ia/IIa (R = CF_3) with a solvent independent barrier to internal rotation of 9.02 kJ mol^{-1} (44).

It is clear from the foregoing discussion that conformer IVa represents the highest energy form (by ~9 kJ mol^{-1} with respect to the potential energy minimum), while all the remaining 11 conformers differ in energy by no more than ~3 kJ mol^{-1}. Less certain is the choice of low-energy conformations, though the crystal structure evidence favoring an eclipsed C—F bond, coupled with the preference noted above for a perpendicular orientation for the C—R bond, suggests that IVb and IVc are indeed favored choices. If so, the energy changes for rotation of the CF_2R group are of the form depicted in Fig. 12, where the minima (corresponding to the R group being on the α or β sides of the chelate ring) are shown with unequal depths. Interactions of a rotating CF_2R group, in most conformations of the R group with the X substituent, or with another chelate ring or its substituents, appear minimal, but interactions with solvent molecules (themselves influenced by their proximity to different parts of the complexes) could differ on either side of the chelate ring (the results do show that the spectra are, indeed, influenced by the solvent) and give the rationale for the unequal minima in Fig. 12.

This model can be used to explain the spectra generated by the CF_2R groups. When the minima are of unequal depth, the probability of the two low-energy conformers IVb and IVc are unequal, and consequently, the time-averaged chemical shifts of F_A and F_B will differ, and an AB spectrum will result. As the energies of the minima equalize, the probabilities of the conformers also equalize, the time-averaged chemical shifts equalize, and a single-peak spectrum results.

The scenario of rapid interconversion among conformations is consistent with observed chemical shifts. The values of $\Delta\upsilon_{AB}$ shown in Tables 1 and 2 range up to nearly 300 Hz. If these values represent the differences between time-averaged values of the A and B chemical shifts, weighted for different populations of conformations, it is reasonable to propose that the extreme chemical shift difference between A and B resonances in different conformations is not more than ~1000 Hz. Thus, interconversion among various conformations must occur faster than this, as is certainly the case. Even considering an unreasonably high rotational energy barrier of 15 kJ mol^{-1}, a very fast interconversion rate of ~1.5 × 10^{10} s^{-1} is predicted from rate = (kT/h) exp (–Ea/RT) where kT/h = 6.25 × 10^{12} at room temperature (45). Furthermore, the rate would still be very fast even at the lowest temperatures possible with the solvents used, in agreement with our variable temperature experiments.

Substituent and solvent effects

Chemical shift differences are smaller for the monothio-β-diketonate than for the β-diketonate complexes — compare **1** with **3**, Table 1, and **2** with **4**, Table 2 (the difference actually becomes zero for complex **1**). The ring substituent X could influence the results by producing intrinsic changes in the F_A and F_B chemical shifts and (or) by changes in the rotational relative energy minima (i.e., changes in relative rotamer probabilities. The chemical shift differences are also solvent dependent — compare the results for complex **2** in acetone and toluene (Table 1). In toluene, one potential AB spectrum for a perfluoropropyl group has collapsed to a single-peak resonance, thus implying that $\Delta\upsilon_{AB}$ for F_A and F_B is near zero in this solvent. It is more reasonable to attribute this result to a near equalization of conformation probabilities in toluene than to intrinsic changes in chemical shifts producing an accidental near-coincidence of F_A and F_B chemical shifts. These proposals are reminiscent of results obtained for substituted benzenes, as, for example, for benzyl alkyl ethers (29) where the conformations adopted are sensitive to substituent and solvent effects.

Comparisons with reported structures

In agreement with the observations in this paper, the structures of tris(monothio-β-diketonate) complexes of vanadium(III) (46), iron(III) (41, 47), cobalt(III) (46, 48), technetium(III) (49), ruthenium(III) (41), rhodium(III) (35, 41), and indium(III) (50) have all been reported as *fac*-octahedral. Similarly, bis(monothio-β-diketonates) of nickel(II) (41, 51–53), copper(II) (41), palladium(II) (41, 54), and platinum(II) (41, 54) have all been reported as *cis* square planar. On the other hand, tris complexes formed from unsymmetric β-diketones and cobalt(III) (46) or ruthenium(II) (55) adopt *mer*-octahedral, as well as *fac*-octahedral structures, with a preference for the *mer*-octahedral form of the cobalt(III) complex (46). Square planar complexes of copper(II) (56), palladium(II) (57–59), and platinum(II) (59) can adopt the *trans* as well as the *cis* form.

The preferred formation of *fac*-octahedral and *cis* square planar metal complexes from monothio-β-diketones has prompted the suggestion of weak nonbonding interactions between the sulfur atoms (46, 51). This proposal is consistent with the relatively short S···S distance (less than twice the van der Waals radius of sulfur) in a tris(monothio-β-diketonate) rhodium complex (1). In some complexes, the adoption of the *fac*-octahedral structure can also be assisted by better metal $d_\pi(t_{2g}) \rightarrow$ ligand π^* bonding between the metal and sulfur atoms when the three metal–sulfur bonds are mutually perpendicular. This is consistent with the observed shortening of the Rh—S bonds in a monothio-β-diketonate rhodium complex (1).

Conclusions

In acetone and toluene, tris(monothio-β-diketonates) of rhodium(III) exist as *fac*-octahedral complexes whereas

© 1999 NRC Canada

tris(β-diketonates) exist as nearly statistical mixtures of *fac*- and *mer*-octahedral complexes. The ^{19}F NMR spectra are consistent with rapid rotation of the pendant perfluoroalkyl groups.

Acknowledgements

We thank Dr. M. Das for gifts of the perfluorinated β-diketones, T. Wolowiec and M. Jang for recording the NMR spectra, C. Beaulieu for preparation of sample tubes, and the Natural Sciences and Engineering Research Council of Canada for financial support.

Time-reversal in NMR of solids[1]

Serge Lacelle

Abstract: The behavior of multiple spin dynamics under time-reversal excitation is investigated in strongly dipolar coupled spin networks. It is demonstrated that the typical physical intuition that NMR spectroscopists have of time-reversal in such systems is erroneous. By studying the equation of motion of the spin system in an infinite one-dimensional quantum spin chain with nearest-neighbor dipolar interactions and evolving under time-reversal excitation, a more appropriate physical picture emerges. Implications of these new findings are briefly discussed in the context of error propagation and teleportation in NMR quantum information processing.

Key words: time-reversal, NMR, nuclear spin dynamic, quantum information processing.

Résumé : On a étudié le comportement de la dynamique de spins multiples dans des conditions d'excitation à inversion de temps, dans des réseaux de spins couplés fortement dipolaires. On a démontré que l'intuition physique typique des spectroscopistes de la RMN, relative à l'inversion de temps dans de tels systèmes, est erronée. En étudiant l'équation de mouvement du système de spins, dans une chaîne de spins quantiques unidimensionnelle et infinie, comportant des interactions dipolaires avec le voisin le plus près et en évolution sous l'influence d'une excitation à inversion de temps, on observe une représentation physique plus appropriée. On discute brièvement des implications de ces nouvelles observations dans le contexte de la propagation et de la télécinétique des erreurs dans le traitement de l'information quantique en RMN.

Mots clés : inversion de temps, RMN, dynamique des spins nucléaires, traitement de l'information quantique.

[Traduit par la Rédaction]

1. Background

The second law of thermodynamics states that processes in isolated systems are possible only if the entropy increases or remains constant (1, 2). As a consequence, for real (i.e., irreversible) processes, entropy has been construed as "an arrow of time." Cosmological connotations and interpretations of this slogan abound in the popular and scientific literatures (3). In physical chemistry, the elimination of composition gradients by mutual diffusion and temperature gradients by thermal diffusion, as a function of increasing time, represent typical irreversible macroscopic behavior. However, reversibility is nevertheless possible on macroscopic scales; the "mixing-unmixing" experiment of E.L. Hahn (4) with glycerol and dye undergoing Couette flow in the annulus of two concentric cylinders is a case in point.

At the microscopic level, in classical mechanics Newton's equation of motion, $\boldsymbol{F} = m\mathrm{d}^2\boldsymbol{r}/\mathrm{d}t^2$, is invariant under the time-reversal operation, $t \rightarrow -t$. This symmetry implies that the inverse of a dynamical process is also a solution to Newton's equation (5). Likewise, in quantum mechanics (3, 6), time-reversal invariance is a property of the solutions to Schrödinger's time dependent equation, $i\hbar\partial\Psi(\boldsymbol{r}, t)/\partial t = H\Psi(\boldsymbol{r}, t)$. Thus, the reversible behavior of the equations of motion at the microscopic level appear superficially incompatible with the irreversible behavior observed on macroscopic scales.

This dichomotomy of macroscopic and microscopic behavior has occupied different generations of scientists over the last 130 years or so (7, 8). Numerous suggestions to resolve this apparent paradox have been proposed over time. Appeals to statistical mechanics have led the way to rationalize this problem. The dynamical equations of motion apply to individual microscopic states, while macroscopic behavior correspond to conditions of numerous microscopic states. Thus, in phase space, if an initial macroscopic condition is chosen to correspond to an "ordered state," with time the system will evolve in the direction of the more numerous "disordered states," which are compatible with the macroscopic constraints. Each of the microscopic trajectories that relate the macroscopic "ordered and disordered" states are dynamically reversible. However, since the final macroscopic state correponds to many more microscopic states than those found in the initial macroscopic state, the probability of observing a recurrence at the macroscopic level without external intervention, is prohibitively small indeed. For example, an estimate of Poincaré's recurrence time in dilute but macroscopic samples of gas with a number density

of 10^{24} molecules/m^3 yields 10^{18} times the age of the universe (2). Hence, irreversibility observed on the macroscopic realm and reversibility of the microscopic dynamics are indeed compatible.

It is interesting to view NMR spin echoes in this context. In liquids of single or uncoupled spin systems, evolution in static inhomogeneous magnetic fields under the Hahn sequence, $90 - \tau - 180 - \tau$, produces an echo at 2τ for a system that was initially at thermal equilibrium. This behavior is understandable in terms of the deterministic dynamics of the spin isochromats if dissipation is lacking. Following the initial $\pi/2$ rf pulse, a free induction decay (FID) arises from the dephasing of the magnetization due to the differential precession in the spatially inhomogeneous magnetic field. A rewinding of the magnetization in the τ period subsequent to the π rf pulse, which reverses the sense of precession of the different isochromats, results in a spin echo at 2τ. In absence of dissipation, the entropy of the spin system remains constant, and the spin system recovers its initial nonequilibrium macroscopic state (i.e., the one following the initial $\pi/2$ rf pulse). The dynamical trajectories of the spin isochromats in the first and second τ periods are related by time-reversal symmetry; see for example the runners on a racetrack analogy of Brewer and Hahn (4).

Now consider rigid solids consisting of homonuclear dipolar coupled spin systems. In such instances, the Hahn sequence does not refocus the magnetization due to the bilinear character of the dipolar interactions among the spins. To obtain spin echoes, rf pulse sequences with propagators related by changes of signs in the Hamiltonians are needed.Thus, if in the first τ period, the spin density operator evolves under a dipolar Hamiltonian H, then at τ one finds,

$$[1] \qquad \rho(\tau) = U(\tau)\, \rho(0)\, U^{+}(\tau)$$

where $\rho(0)$ is the initial spin density operator, with

$$[2] \qquad U(\tau) = \exp\,(-iH\tau)$$

and $U^{+}(\tau)$ is the Hermitian conjugate of eq. [2]. In the second τ period, if the spin system evolves under a propagator $V(\tau)$ with a Hamiltonian $-H$, i.e., related by Hermitian conjugation to $U(\tau)$, then

$$[3] \qquad V(\tau) = \exp\,[-i(-H\tau)] = U^{+}(\tau)$$

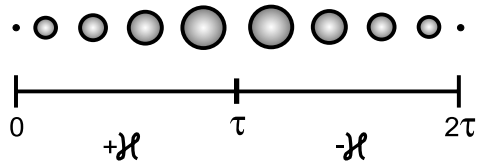
As a consequence, the spin density operator at 2τ becomes

$$\begin{aligned}[4] \qquad \rho(2\tau) &= V(2\tau - \tau)\, \rho(\tau)\, V^{+}(2\tau - \tau) \\ &= V(\tau)\, U(\tau)\, \rho(0)\, U^{+}(\tau)\, V^{+}(\tau) \\ &= U^{+}(\tau)\, U(\tau)\, \rho(0)\, U^{+}(\tau)\, U(\tau) \\ &= \rho(0)\end{aligned}$$

since $U^{+}(\tau) = U^{-1}(\tau)$. Hence, the Hermitian conjugation relationship between the propagators in the first and second τ periods produces a spin echo in a dipolar coupled spin system. A change in the sign of the Hamiltonian would thus appear to be equivalent to time-reversal in the scheme of eq. [4].

Time-reversal excitation in NMR of solids was first suggested by Schneider and Schmiedel (9) as a possibility to observe FIDs of strongly dipolar coupled solids unencumbered by receiver dead-time limitations. It is noteworthy that this proposal originated from the curiosity of determining if it was possible to create an average dipolar Hamiltonian with a negative scaling factor.[3] Following this initial work, Rhim and Kesselmeier (10, 11), examined the consequences of such method with CW irradiation at the magic angle. Rhim et al. (12, 13) were the first to systematically implement and further elaborate pulse sequences with time-reversal excitation properties in solids. Initially, these experiments served to demonstrate the limitations of the spin thermodynamics approach, e.g., the FID of a strongly dipolar coupled spin system was viewed as an irreversible process during which the spin system achieved a quasi-equilibrium state. There was also initial hope that multiple pulse sequences, which exploited time-reversal excitation, could be tailored to achieve high-resolution in NMR of solids.

Fig. 1. Behavior of multiple-spin correlations or multiple quantum coherences (circles with radial filling) as a function of evolution time under $+H$ and $-H$, according to our typical preconceived notion of time-reversal with symmetric evolution and reversal.



Further developments of time-reversal excitation procedures were proposed by Yen and Pines (14) in order to limit dipolar dephasing, which occurred during multiple quantum NMR experiments of solids. By using propagators for the preparation and mixing periods that were Hermitian conjugate to one another, the resulting multiple quantum coherences were generated and converted in such a way that in the corresponding spectra there was no cancellation of phases. Consequently, higher order multiple quantum coherences could be detected (indirectly) with greater ease in solids (15).

More recently, time-reversal excitation procedures have been devised to study a variety of polarization echoes (as opposed to coherence echoes) and transfers in homonuclear and heteronuclear spin systems in static and rotating solids (16–19). In these investigations, transfers of polarization through spin diffusion processes, multiple-spin order growth, and cross-polarization were all reversed, thereby showing the deterministic character of the many-body evolution in strongly dipolar coupled spin systems in absence of dissipation.

In view of this cultural background, the intuition of virtually every NMR spectroscopist of time-reversal excitation in dipolar coupled spin systems, corresponds to the cartoon depicted in Fig. 1. There, one observes the growth of multiple-spin correlations or multiple quantum coherences as a function of τ under $+H$ evolution. In the second τ period, evolution under $-H$ would produce a regression of growth to bring the system back to its initial state. Note the striking similarity of the behavior in Fig. 1 with the runners on a

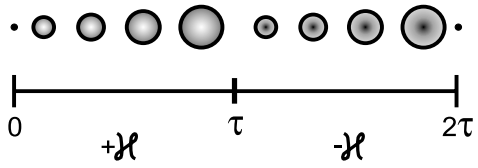
Fig. 2. Behavior of multiple-spin correlations or multiple quantum coherences (circles with radial filling for $0 < t < \tau$, and inverse radial filling for $\tau < t < 2\tau$) as a function of evolution time under $+H$ and $-H$, according to the time series expansion of the Liouville – von Neumann equation of motion for the spin density operator. The reciprocal relationship of the radial filling of the circles among the two evolution periods is to symbolize and emphasize the sign differences between the spin operators during these two time periods, and the ensuing time-reversal asymmetry.



racetrack analogy of the spin echo in single or uncoupled spin systems (4). In the next section, I demonstrate that such physical intuition is wrong, and show the appropriate way to physically view the behavior of strongly dipolar coupled systems under time-reversal excitation. Two applications of this result in the context of quantum information processing in molecular systems are briefly discussed in Sect. 3. Finally, the last section summarizes our findings.

2. Results

A caricature of the physical intuition based on the result of the growth processes derived in this section for time-reversal excitation is shown in Fig. 2. One immediately notices the lack of the mirror image behavior, which is characteristic of the time-reversal interpretation in Fig. 1. Some consequences are obtained in this section, while some implications of Fig. 2 are discussed in the next section.

Our derivations are obtained from a model of an infinite one-dimensional (1-D) quantum spin chain with spins $I = 1/2$ and nearest-neighbor (nn) dipolar interactions. Initially at thermal equilibrium in a strong Zeeman field, the spin system is then driven by a propagator with a nonsecular average dipolar Hamiltonian, $H = H^{+2} + H^{-2}$, between 0 and τ, and $-H$ from τ to 2 τ; $H^{\pm 2}$ is a pure double quantum Hamiltonian given by

$$[5] \qquad H^{\pm 2} = -\frac{1}{2}\sum_{j<k} D_{jk}\, I_j^{\pm}\, I_k^{\pm}$$

with $I_j^{\pm}$ the raising and lowering spin angular momentum operators of spin j. The dipolar coupling constant, D_{jk}, between nearest-neighbor spins j and k is

$$[6] \qquad D_{jk} = D = \frac{\gamma^2 \hbar}{2 r_{jk}^3}(1 - 3\cos^2\theta_{jk})$$

with γ the magnetogyric ratio, r_{jk} the distance between spins j and k, and θ_{jk} the angle between the internuclear vector $\boldsymbol{r}_{jk}$ and the Zeeman field. The spin dynamics of this model were solved exactly for multiple quantum NMR experiments, and the theoretical results compared favorably to corresponding experiments on materials with quasi-1-D distributions of spins (20).

Instead of using the fermion field operator methodologies as in ref. 20, a Taylor series expansion of $\rho(\tau)$ about 0 and with $\rho(0) = I_Z$, and propagation under H will be performed for the first τ period. For the second evolution period, between τ and 2τ, the initial condition corresponds to $\rho(\tau)$, and the system is propagated under $-H$. The characteristics of the solutions of the Liouville – von Neumann equation (see eq. [1]) will become evident by examining just the first few orders of the expansion. The correspondence between the series expansion and the exact solution for this model has been verified in details in the limits when $\tau \to 0$, and when $\tau \to \infty$ in the context of multiple quantum NMR of 1-D quantum spin chains (20).

The series expansion of $\rho(\tau)$ in eq. [1] yields the nested commutator expansion,

$$[7] \qquad \rho(\tau) = \rho(0) - i\tau[H,\rho(0)] - \frac{\tau^2}{2}[H,[H,\rho(0)]] - i\frac{\tau^3}{6}[H,[H,[H,\rho(0)]]] + \ldots$$

Thus, for $\rho(0) = I_Z$, and $H = H^{+2} + H^{-2}$, one finds the evolution between 0 and τ with eq. [7],

$$[8] \qquad \rho(\tau) = I_z + iD\tau(I_j^+ I_{j+1}^+ - I_j^- I_{j+1}^-) - (D\tau)^2(I_j^+ I_{j+1}^z I_{j+2}^- - I_j^- I_{j+1}^z I_{j+2}^+) - i(D\tau)^3\frac{2}{3}(I_j^+ I_{j+1}^z I_{j+2}^z I_{j+3}^+ - I_j^- I_{j+1}^z I_{j+2}^z I_{j+3}^-) + \ldots$$

Implicit in this way of representing the solution $\rho(\tau)$ are sums over the lattice positions j, which are not shown explicitly. Furthermore, the growth of the multiple-spin coherences is symmetric in the lattice label (identified by subscripts on the spin operators) or direction, i.e., only the solutions in the direction of increasing j are shown explicitly in eq. [8], the corresponding solutions growing in the direction of decreasing j are not shown. This amounts to looking at the growth only along one direction of the chain. We also assume that $D\tau < 1$. As τ increases beyond the limit $D\tau = 1$, the violation of the inequality implies a breakdown of the successive approximation concept. In this limit, the question of convergence of the series expansion becomes questionable, and one needs to revert to the exact solution at the expense of simplicity in the mathematical treatment and in the physical reasoning, in order to verify the validity of the expansion in eq. [8] as was done in ref. 20. These simplifications change nothing of the spin dynamics and the results, but should help to lighten up the equations and the reasoning, so that only the essential physical characteristics of the solution remain.

Hence, with increasing time, one finds contributions from single-spin terms, two-spin terms, three-spin terms, ..., n-spin terms, ... which appear *sequentially* in eq. [8] with respective time dependence τ^0, τ^1, τ^2, ..., τ^{n-1}, ... This aspect of the solution is indicated graphically in Figs. 1 and 2 for the evolution between 0 and τ. Furthermore, each n-spin correlation is weighted by a product of $n - 1$ dipolar coupling constants; since only nn dipolar interactions are considered in the model, this product is D^{n-1}. Only zero- and two-quantum coherences are produced. There is also an obvious alterna-

© 1999 NRC Canada

tion between the zero- and two-quantum coherences, which leads to alternating and periodic oscillations of the intensities in the corresponding multiple quantum NMR spectra (20). Interestingly, the growth processes, induced by the average Hamiltonian H, occur by correlating a "new" spin at the (spatial) ends of the previous n-spin coherences, thereby producing $(n + 1)$-spin correlations.

The evolution of the spin system under $-H$ for the period from τ to 2τ proceeds from the initial condition given by eq. [8]. Introducing eq. [8] as initial condition into eq. [7] with $-H$ produces the solution for the second τ period; the time in this period is symbolized by t. To see how this solution comes about, we systematically calculate the different orders in an ascending fashion, starting with t^0. This corresponds to the same manner in which the different spin terms contribute to the solution as t increases between τ and 2τ. When $t = \tau$, a dipolar spin echo is produced.

The zeroth order contribution (t^0) is the initial condition given by the entire eq. [8]. Thus, the sum of all spin terms, which have been produced during the first τ period, is also present at the beginning of the second τ period, i.e., at $t = 0$.

The first-order contribution (t^1) is obtained by inserting I_Z from the initial condition (i.e., eq. [8]) into the first commutator in eq. [7]. This yields $it[H, \rho(0)]$. The sign of this contribution is the opposite of the corresponding two-spin term, which occurred during the first τ evolution period. Hence, for short time periods in both the first (τ) and second (t) period of evolution, these two-spin terms cancel, as it should be, since these are both the first multiple-spin terms to appear in each of these periods. Note that if the duration of the first period is τ, then to cancel exactly, the first-order contribution in the second period under $-H$ must also have a duration equal to τ. On the other hand, for a first evolution period of duration τ and for times $t < \tau$ during the second evolution period, a substantial cancellation will be produced initially only for the two-spin terms, as these are the ones that contribute the most at small t. To cancel higher order multiple-spin terms will require a longer evolution period, i.e., should occur on a time scale $t < t < \tau$, as these processes require higher orders of time to become observable.

The second-order contributions (t^2) come from two different sources. The first-order contribution $iD\tau(I_j^+I_{j+1}^+ - I_j^-I_{j+1}^-)$ from the initial condition (see eq. [8]), when inserted into the first-order commutator of eq. [7] with $-H$ yields $2D^2\tau t(I_j^+I_{j+1}^zI_{j+2}^- - I_j^-I_{j+1}^zI_{j+2}^+)$. The zeroth order contribution, I_Z from the initial condition (see eq. [8]), when inserted into the second-order commutator of eq. [7] with $-H$ produces $-(Dt)^2(I_j^+I_{j+1}^zI_{j+2}^- - I_j^-I_{j+1}^zI_{j+2}^+)$. Hence, the sum of the second-order contributions from the initial condition in eq. [8], i.e., $-(D\tau)^2(I_j^+I_{j+1}^zI_{j+2}^- - I_j^-I_{j+1}^zI_{j+2}^+)$, and the above terms generated under the $-H$ evolution, i.e., $2D^2\tau t(I_j^+I_{j+1}^zI_{j+2}^- - I_j^-I_{j+1}^zI_{j+2}^+)$, and $-(Dt)^2(I_j^+I_{j+1}^zI_{j+2}^- - I_j^-I_{j+1}^zI_{j+2}^+)$, will vanish identically only when the duration of the first and second evolution periods are identical, i.e., when $t = \tau$. However, when $t < \tau$, there is less cancellation of the three-spin terms due to the t^2-dependence, than the two-spin terms that have only a t-dependence.

Higher successive orders can be examined in a similar fashion, and taken to infinite order, the expansion would lead to the conclusion that $\rho(2\tau) = \rho(0) = I_Z$ as already noted from eq. [4]. However, we can already extract useful information and consequences from the behavior of the first few orders of the series expansion for time-reversal excitation.

As observed above, following an evolution period initially under a propagator with $+H$ and then $-H$, it is the lowest order terms that are the first ones to "disappear" to a very good approximation by mutual cancellation from both evolution periods. Consequently, the picture proposed in Fig. 2 is more appropriate to describe the behavior of a dipolar coupled spin systems evolving under time-reversal excitation.

Another important realization is the following: to cancel the contribution of a term of nth order (τ^n) produced during the $+H$ evolution period requires the contributions from all previous orders between τ^0 and τ^{n-1} during the $-H$ evolution. Furthermore, for times $\tau < \tau$ during the second evolution period, the different orders have the following time dependence, where the τ^r dependence arises from the second evolution period, while the τ^s dependence is inherited from the first evolution period: for the zeroth order terms, τ^0t^0; for the first-order terms, $t^0\tau^1$, $t^1\tau^0$; for the second-order terms, $t^0\tau^2$, $t^1\tau^1$, and $t^2\tau^0$; for the third-order terms, $t^0\tau^3$, $t^1\tau^2$, $t^2\tau^1$, and $t^3\tau^0$; and so on for higher order terms. When $t = \tau$, then each contribution to the nth order terms has the required τ^n dependence, and the sum of the different contributions to the nth order is identically zero, with the exception of the zeroth order $t^0\tau^0$, which is the sole survivor, thus yielding $\rho(2\tau) = \rho(0)$.

3. Discussion

The behavior of multiple-spin systems under time-reversal excitation as presented in the previous section imposes limitations on how one could possibly control such systems for quantum information processing purposes. In recent years, the field of quantum information processing has made major theoretical and experimental strides (21).[4] Through the manipulation of coherent superpositions of quantum states, there is the hope of exploiting quantum entanglements (nonseparable states), quantum interference, and parallelism in order to achieve potentially massive speedups in some computational tasks. Tremendous benefits, from skilful utilizations of quantum information in molecular systems, are also expected for technological issues related to miniaturization. Furthermore, in addition to the these features, the quantum computing paradigm offers the possibility to better understand quantum theory. Some excitement has been generated by these prospectives in NMR (22, 23). In this section, two applications, related to the behavior of quantum errors and quantum teleportation from the field of quantum information processing, are examined with the perspectives of taking advantage of time-reversal excitation in multiple-spin systems in these problems. Limitations imposed by the nature of the time-reversal behavior are discussed in light of the results from the preceeding section.

For a quantum computer to function successfully, some error correction and error prevention methodologies will be required due to the interactions of the quantum computer with the environment, and the inherent interactions among quantum bits (qubits) (21).[4] In a quantum computer's pro-

[4] J. Preskill. Unpublished lecture notes for a course on quantum computation, available from http://www.theory.caltech.edu/people/preskill/ph229/.

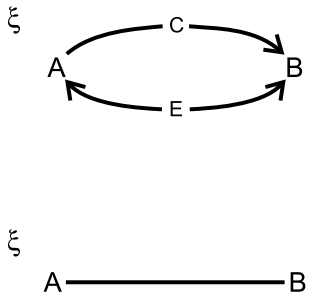
Fig. 3. The upper portion corresponds to the conventional scheme for quantum teleportation of an unknown quantum state ξ from Alice (A) to Bob (B) with channel resources for entanglement sharing (E) and classical communication (C). In the lower portion, both channels are replaced by a single channel, in this case, a 1-D quantum spin chain with nn dipolar interactions.



cessing and memory units, errors correspond to unwanted modifications in the amplitudes and the relative phases of coherent superpositions. Quite some efforts have already been dedicated toward such enterprise, and promising results have appeared (21)[4].

To control errors based on dipolar interactions among qubits in a quantum register of nuclear spins, we have strived at developing error correction and prevention strategies based on multiple pulse line narrowing sequences and time-reversal excitation.[5] As an illustration, imagine an ensemble quantum computer (22) consisting of an ensemble of 1-D infinite and rigid quantum spin chains with only nn dipolar interactions among spins on the same chain. If a computation, composed of quantum gates (combinations of rf pulses and evolution periods) is executed on such a system, with the simultaneous application of a multiple pulse line narrowing sequence in the background to eliminate dipolar interactions, after a period τ, one finds the quantum computer in the state QC(τ; ε_d). To remove determinisitic errors, ε_d, which might have accumulated due to residual dipolar interactions among qubits, one could imagine reversing only the part of the evolution due these interactions by using a time-reversal sequence (12, 13), thus producing QC(2τ). Hence, by alternating periods of computation with periods of error corrections, one could proceed to the final output of the computation.

Now suppose a nondeterministic error occurs, due to the interaction of a spin with the environment (i.e., a T_1 process) halfway ($\tau/2$) during a first evolution period under H in this system; moreover, assume that multiple-spin correlations involving from 2 to k spins have been excited at that point, and that the error appeared in the k-spin coherences. On further evolution, all higher order terms of n-spin coherences with $n \geq k$ become contaminated with the error. Thus, error propagation continues until τ, resulting in QC(τ, ε_k, ε_{k+1}, ε_{k+2},...), where the subscripts on the errors correspond to the size of the multiple-spin coherences in which they occur.

If a time-reversal sequence is applied for a second τ evolution period, it is interesting to calculate the effect of error propagation with both scenarios presented in Figs. 1 and 2. Halfway during the time-reversed period (i.e., at $3\tau/2$), one would find QC($3\tau/2$, ε_k) for the behavior dictated by the physical intuition based on Fig. 1. Due to the nondeterminisitic nature of the error, the time-reversal excitation sequence will not be able to correct the error ε_k. Further evolution would produce at 2τ, QC(2τ, ε_k, ε_{k-1}, ε_{k-2},...), i.e., the error would have propagated to n-multiple-spin coherences with $n \leq k$. Hence, refocusing is possible only for n-spin coherences with $n > k$. On the other hand, with the results obtained in the last section and depicted in Fig. 2, time-reversal excitation during the second evolution period would yield QC($3\tau/2$, ε_k) and QC(2τ, ε_k, ε_{k+1}, ε_{k+2},...) respectively at $3\tau/2$ and 2τ. Refocusing of the $n < k$ spin coherences would be possible, however, due to the error propagation, higher order ($n \geq k$) multiple-spin coherences could not be refocused.

Hence, in 1-D spin systems with nn dipolar interactions, error propagation to higher order multiple-spin correlations is a generic feature of multiple-spin dynamics. Current quantum error correcting strategies cannot deal with such detrimental behavior.[4] It would be interesting to determine the nature of error propagation in spin systems with $d = 1$ and dipolar interactions beyond nn, and for systems with $d > 1$. For systems with $d = 3$ and with full dipolar interactions, physical intuition would lead one to believe that sensitivity to initial conditions in the multiple-spin dynamics would produce error propagation from a single spin to many spins during evolution. A cellular automata model of this idea has been described for $d = 2$ spin systems with nn interactions (24).

Another potential application, where one could envision using time-reversal excitation in a spin system, is quantum teleportation (21)[4]. In this phenomenon, an unknown quantum state ξ is transported from one site A (Alice) to another B (Bob) by only exchanging information. The quantum teleportation protocol (see upper portion of Fig. 3) involves dual channels to allow information exchanges between Alice and Bob. In one channel, one spin each of an entangled pair of spins, such as $1/\sqrt{2}$ ($\alpha\alpha + \beta\beta$), is distributed to Alice and Bob. With the computational basis $0 = \alpha$, and $1 = \beta$, one can write the total state of the system (without the normalization constant) as $\xi_A(0_A0_B + 1_A1_B)$. This state can be expressed as $\phi^+_A\xi_B + \phi^-_A(\sigma_z\xi)_B + \psi^+_A(\sigma_x\xi)_B + \psi^-_A(-i\sigma_y\xi)_B$, where $\phi^\pm = (00 \pm 11)$ and $\psi^\pm = (01 \pm 10)$ correspond to the so-called Bell basis set, and σ_x, σ_y, and σ_z are the Pauli spin matrices. Alice makes a Bell measurement on her two particles (ξ and her spin of the entangled pair). Due to the orthogonality of the Bell basis set, the total state is collapsed by multiplying it with the conjugtate of the Bell state that Alice used, thus leaving Bob with its corresponding state $(\sigma\xi)_B$, where σ is either one of the Pauli matrices or the unit matrix. Alice then sends two bits of classical information to Bob through the classical channel (see upper portion of Fig. 3), telling him which Bell basis state she used, and then Bob obtains the state ξ by performing the appropriate conditional measurement, σ, on his particle. Thus, the quantum state ξ has been teleported from site A to site B. A NMR version of this protocol has been realized experimentally with three contiguous atoms using an ensemble quantum computer (i.e., with

[5] A. Blais and S. Lacelle. Unpublished work.

mixed states or a density matrix as opposed to pure states) (25).

In an effort to improve this teleportation scheme, one could imagine replacing both channels with a single channel (see lower portion of Fig. 3), along which entangled states and classical information would be transmitted. This would reduce the necessary transmission resources. Here, the single channel would be a 1-D quantum spin chain with nn dipolar interactions. Hence, teleportation could potentially be achieved over much longer distances than across three atoms.

The sharing of entangled states would be produced by driving the chain with $H = H^{+2} + H^{-2}$. By examining eq. [8], one finds that indeed, the growth of zero and double quantum coherences occurs only at the "ends" of the chain, so that in principle, it would be possible to bring to Alice and Bob each a spin from an entangled pair, i.e., a state of the form $(I_A^+ I_2^Z I_3^Z \ldots I_{n-1}^z I_B^+ - I_A^- I_2^Z I_3^Z \ldots I_{n-1}^z I_B^-)$ would connect Alice and Bob. Note that other double quantum/*k*-multiple-spin coherences, with $k < n$ would also be produced. To be more efficient, one could presumably devise a selective propagator for exciting only double quantum/*n*-multiple-spin coherences.[6]

Following the Bell measurement with mixed states, transmission of the classical information would be achieved by preparing a mixed state $(I_A I_{A'}, I_2^z I_3^z \ldots I_{n-1}^z I_B^z)$. In such a state, I_A and $I_{A'}$, spin states encoding one bit of information each, and I_B^z are produced by Alice and Bob who both use Stern–Gerlach type preparations to replace the end-atoms used in the entangled spin pair, which they received and retrieved from the *n*-multiple-spin coherence. Thus, by adding the prepared atoms $I_A I_A$ and I_B^z at their respective ends of the remaining $I_2^z I_3^z \ldots I_{n-1}^z$ chain state, and then time-reversing the evolution of this new state with some $-H$, according to the scenario of Fig. 1, a recession of growth in the opposite direction of the chain would be expected. In the end, Bob could receive Alice's bits of information. However, as shown in the previous section, time-reversal excitation proceeds according to the scenario displayed in Fig. 2, so that motion-reversal as proposed in Fig. 1 is not a valid method to transmit information.

At this point, some skeptical readers might be wondering "Where's the chemistry in these applications?" The chemical physics aspects consist of controlling and processing quantum information at the microscopic level, and its measurements and observation at the macroscopic level, with NMR methodologies in chemical systems.

4. Concluding remarks

As NMR spectroscopists, our interpretation of time-reversal excitation in strongly dipolar coupled spin systems is initially based on our previous experiences with spin echoes of single spin systems, reversibility, and irreversibility in macroscopic systems. Due to this cultural foundation, our physical intuition normally leads our preconceived notions to a mental picture like the one depicted in Fig. 1 in order to imagine and interpret the time-reversal of multiple-spin excitations. However, as shown in this work, in order to be consistent with the Liouville – von Neumann equation of motion, the manner in which time-reversal excitation proceeds in strongly dipolar coupled spin systems is more appropriately described by Fig. 2. As a result, attempts to exploit time-reversal excitation procedures, such as demonstrated with quantum error propagation and quantum teleportation in quantum information processing, should be based on the physically correct results associated and represented by Fig. 2. Finally, as an example of another potential avenue, our work suggests the possibility of devising a method in order to discriminate between multiple-spin correlations of different sizes, and thereby achieving a certain degree of selectivity towards higher multiple-spin correlations by using periods of time-reversal excitation with unequal durations[7] when relying on the behavior shown in Fig. 2 as a physical basis.

Acknowledgments

This paper is dedicated to Prof. T. Schaefer, one of the pioneers of NMR in chemistry in Canada. His work helped to open the way for other generations of NMR spectroscopists with different perspectives (as exemplified by the work presented here) and who collectively produce a rich and vibrant tapestry of NMR contributions to Canadian sciences. I would like to thank Prof. A. Pines and A. Blais for their suggestions, and Dr. L. Tremblay for his help with the figures. This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

Electrospray ionization mass spectrometry and on-line capillary zone electrophoresis – mass spectrometry for the characterization of citrate synthase

Mark E. McComb, Lynda J. Donald, and Hélène Perreault

Abstract: The enzyme citrate synthase from *E. coli* is a protein with a molecular weight (M_r) of 47 885 Da (wild type). This enzyme has been studied extensively, and its amino acid sequence has been characterized. This model protein has been used in this work for development and validation of methods involving capillary electrophoresis (CE) and electrospray ionization mass spectrometry (ESI-MS). The M_r determinations were conducted using sample infusion ESI-MS, and the tryptic digestion products of wild-type citrate synthase were characterized by on-line CE–ESI-MS coupled with a sheathless interface. On-line experiments were conducted on two different mass spectrometers, a Quattro-LC triple quadrupole instrument equipped with a Z-Spray™ source (Micromass), and a reflecting time-of-flight (TOF) mass spectrometer built in-house in the Time-of-Flight Laboratory, Department of Physics, University of Manitoba. This is the first article to be written on the interfacing of a Z-Spray™ source with CE. Unmodified fused silica capillaries gold-coated sheathless interfaces were used. The on-line CE separations yielded theoretical plate numbers greater than 10^4 on average. Selected ion electrophorograms (SIE) of the tryptic peptides recorded on the Quattro-LC displayed *S*/*N* ratios ranging from ca. 14 to 120 on raw data. These SIE enabled identification of each peptide. The use of reflecting time-of-flight mass spectrometry (TOFMS) afforded mass resolution values of ca. 6000 ($m/\Delta m_{FWHM}$), which enabled isotopic resolution of the peptide components. CE–ESI-MS and CE–ESI-TOFMS experiments enabled the generation of a complete tryptic map of citrate synthase.

Key words: capillary electrophoresis, electrospray ionization, mass spectrometry, citrate synthase, tryptic digestion, triple quadrupole analyzer, time-of-flight analyzer.

Résumé : L'enzyme synthase du citrate, extraite d'*E. coli*, est une protéine de poids moléculaire (M_γ) de 47 885 Da. On a étudié cet enzyme de façon exhaustive et on a caractérisé sa séquence d'acides aminés. Cette protéine modèle a été utilisée dans ce travail réalisé pour développer et valider des méthodes impliquant l'électrophorèse capillaire (EC) et la spectrométrie de masse avec ionisation par électrovaporisation (« SM-IES »). Les déterminations de M_γ ont été effectuées en faisant appel à SM-IES par une infusion de l'échantillon et on a caractérisé les produits obtenus par digestion enzymatique de la synthase de citrate à l'aide de la trypsine en faisant appel à la SM-IES couplée à l'EC en ligne à l'aide d'une interface sans liquide de support. Les expériences en ligne ont été réalisées sur deux spectromètres de masse différents, un spectromètre de masse Quattro-LC muni d'un analyseur à triple quadripôle équipé d'une source Z-Spray™ et un spectromètre de masse à temps d'envol (« TOF ») muni d'un réflecteur construit dans le Time-of-Flight Laboratory du département de physique, de l'Université du Manitoba. Il s'agit du premier article publié sur le couplage d'une source Z-Spray™ avec un appareil d'EC. Des capillaires de silice fondue non modifiés et des interfaces sans liquide de support, plaquées or, ont été utilisées. En moyenne, les séparations EC en ligne donnent lieu à un nombre de plateaux théoriques supérieur à 10^4. Dans les électrophorogrammes d'ions présélectionnés (EIP) des peptides obtenus par hydrolyse à la trypsine, enregistrés sur le spectromètre de masse Quattro-LC, les rapports *S*/*B* s'étalent d'environ 14 à 120 sur les données brutes. Ces EIP ont permis d'identifier chacun des peptides. L'utilisation du spectrométrie de masse à temps d'envol (SM-TOF) muni d'un réflecteur permet d'obtenir des valeurs de résolution de masse d'environ 6000 ($m/\Delta m_{FWHM}$), ce qui rend possible la résolution isotopique des composants peptidiques. Les expériences de EC–SM-IES et de EC–SM-TOF-IES ont permis de générer une carte tryptique complète de la synthase du citrate.

Introduction

Mass spectrometry (MS) has been described as one of three key technologies available to probe cell proteins and to correlate the latter to their genes (1). Direct identification of proteins may be accomplished using a combination of enzymatic proteolysis, liquid chromatographic or capillary electrophoretic (CE) separations, and MS. Sample infusion electrospray ionization mass spectrometry (ESI-MS) and on-line CE–ESI-MS are now well implemented techniques in several laboratories specializing in protein and peptide analysis, and have been used in this work to confirm the molecular weight (M_r) and amino acid sequence of a biologically important enzyme, citrate synthase.

On-line CE–ESI-MS is a powerful method for the analysis of biological molecules, particularly proteins (2, 3). CE offers high-resolution separations, typically with theoretical plate counts ranging from 10^5 to 10^6, while ESI-MS allows for the characterization of a wide M_r range of peptides and proteins. On-line CE–ESI-MS allows for the analysis of exceedingly small volumes of solution, i.e., on the order of a few tens of nanoliters, which is advantageous, considering that sample sizes may be limited when dealing with biological materials.

Development of on-line methods and validation of their performance both require that these methods be tested with known compounds. A substance of choice for validation of the on-line CE–ESI-MS described in this article is citrate synthase, a protein of medium molecular weight (M_r = 47 885 Da, wild type). This protein was chosen as a model based on prior characterization by electrospray ionization time-of-flight mass spectrometry (ESI-TOFMS) (4) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOFMS) (5).

The use of different types of CE–MS interfaces has been discussed previously. Several groups have used a sheathless ESI design, which affords a stable electrospray and is relatively easy to manufacture (6–12). In this approach, electrical contact at the capillary terminus is provided through a conductive coating, typically gold. The same gold surface is used for production of the electrosprayed ions. Enhanced sensitivity, as well as the elimination of mixing problems associated with a sheath liquid, make the sheathless design favourable, and justify the use of this type of interface in the work presented here.

In the general analytical approach described in this article, mass spectra of intact citrate synthase were acquired first to obtain M_r information, and more complete mass spectral characterization was performed on tryptic peptides by on-line CE–ESI-MS. For these on-line experiments, a Quattro-LC triple quadrupole mass spectrometer (Micromass) and a home-built reflecting time-of-flight mass spectrometer were used.

It should be noted that this article is the first to describe the implementation of CE–MS using the Micromass Z-Spray™ source. Although Major and Ashcroft (13) reported on the use of a coaxial sheathflow CE–MS interface to analyze a standard peptide mixture on a Micromass Quattro-II instrument, this article constitutes the first report on sheathless CE–MS involving a Quattro-LC instrument. The detailed description of the interfacing process will be given in a publication that is currently in preparation.[2]

Experimental

Chemicals

Acetic acid (99.9985%) was used to make up solutions of the running electrolyte and was obtained from Alfa Aesar (Wordhill, Mass.). Hydrofluoric acid (HF), used to prepare the capillaries, was obtained from Fisher (Nepean, Ont.). Trypsin (TCPK treated), used for the digestion, was obtained from Sigma.

Citrate synthase

The protein was prepared from *E. coli* as described (14). Both the wild type and a mutant, L164A, were made available by Ayed and Duckworth (15). Samples for direct infusion ESI-MS measurements were dialyzed into 5 mM ammonium bicarbonate at pH 7.5 as described in an earlier publication (4). It should be noted that the calculated M_r value for wild-type citrate synthase derived from the SWISS-PROT sequence[3] is misleading, due to the following modifications: loss of N-terminal M, post-translational modification N11D (16), and sequencing error F289V (17). With these modifications, the M_r calculated for the wild-type protein is 47 885 Da. Thus, the calculated M_r value for the L164A mutant is 47 843 Da.

Tryptic digest of wild-type citrate synthase

The protein (1.0 mg/mL in 20 mM Tris–HCl and 1 mM EDTA, pH = 7.8) was incubated with 0.01 mg/mL TPCK-treated trypsin for 3 h at 37°C. It should be noted that dialysis (4) was omitted for citrate synthase samples subjected to enzymatic digestion.

Capillary zone electrophoresis

Fused silica capillaries with 50 μm i.d. and 350 μm o.d. were supplied by Polymicro Technologies (Phoenix, Ariz.). The total length of the capillaries used in this study was 40 cm. Capillary electrophoresis was performed using a Spellman CZE 1000R 30 kV power supply (Plainview, N.Y.) operated in the positive polarity mode. The electrospray potential at the cathodic end of the capillary was generated us-

© 1999 NRC Canada

ing an EG&G Ortec no. 459 5 kV bias supply (Oak Ridge, Tenn.) operated in the positive polarity mode. Acetic acid (1–10% in water) was used as the running electrolyte.

Preparation of gold-coated capillaries

Preparation of the capillaries is described in detail elsewhere (18). In brief, the capillaries used for on-line CE–ESI-MS were prepared based on the sheathless ESI approach. Approximately 1 cm of the capillary terminus was etched in 40% HF to make a conical end. The capillary end was then cleaned with methanol and coated with gold by vapour deposition.

Sample-infusion ESI-MS

Direct sample infusion ESI-MS of citrate synthase was performed on a q-TOF instrument located at the Micromass factory (Micromass Inc., Manchester, U.K.). Spectra were acquired using a cone (declustering) voltage of 60 V.

CE–ESI-MS

These experiments were performed on a Quattro LC (Micromass, U.K.) mass spectrometer equipped with a Z-Spray™ interface. Spectral analysis was carried out using Mass-Lynx 3.0 software. Spectra were obtained using 8 points/Da with a scan rate of 500 Da/s over a 1000 Da range. This resulted in acquisition rate of 0.5 spectrum/s and yielded monoisotopic (unit mass) resolution within the mass range scanned. Electrospray was performed using an interface built in-house, complete details of which will be presented in a separate publication.[2] A 60 s hydrodynamic injection was used to load the sample onto the capillary, resulting in approximately 800 fmol of sample being introduced into the capillary.

CE–ESI-TOFMS

These experiments were performed on a reflecting TOF mass spectrometer, an instrument built in-house in the Time-of-Flight Laboratory, Physics Department, University of Manitoba. Spectral analysis was carried out using TOFMA software written in-house. Spectra were recorded in 2 ns channels. The instrument (19, 20) and interface (18) have been described in greater detail elsewhere. For these measurements, it was possible to acquire a complete mass spectrum at each time interval, but not to record it. The total ion electrophorogram (TIE) was thus recorded in one run, separately from the mass spectra. The latter were recorded in a subsequent run, over the duration of the whole CE separation, and summed over 1 min segments, to produce a total of ca. 20 spectra. The technology necessary to realize simultaneous acquisition of TIE and mass spectral data for large data sets associated with CE–MS (12, 21) is currently being installed. Implementations will include software design and storage capabilities.

Results and discussion

CE–ESI-MS and CE–ESI-TOFMS

The M_r measurements on different types of citrate synthase can be effected very efficiently by sample infusion ESI-MS, as shown in Fig. 1. The nominal M_r difference of 42 between the two types, wild type (*a*) and the L164A mutant (*b*), reflects the substitution of a leucine residue by alanine. The M_r measurements yielded 47 887.9 Da for wild-type citrate synthase, and 47 845.5 Da for the mutant. The corresponding calculated values (average mass) are 47 884.95 and 47 842.87, respectively. The error on these measurements is thus of the order of 40–60 ppm.

To characterize wild-type citrate synthase further, a 3 h tryptic digest was performed and the resulting peptides analysed by on-line CE–ESI-MS and CE–ESI-TOFMS. For both analyses, the injection volume was ca. 40 nL (by gravity), and the protein concentration was ca. 2×10^{-5} M resulting in ca. 800 fmol of each peptide being injected. The background electrolyte, 5% acetic acid, was chosen to minimize interaction of the peptides with the negatively charged silanol groups on the inner walls of the fused-silica capillary and to favour protonation of the analytes.

The TIE obtained by analyzing the tryptic digest on the Micromass triple quadrupole mass spectrometer is shown in Fig. 2*a*. Because of the large number of peptides present and the abundant chemical background associated with the separation buffer used, very little information could be obtained from the TIE, which exhibits a S/N value ≤5. Moreover, the S/N of this TIE trace was compromised by the presence of contaminants in the CE electrolyte. A reconstructed TIE excluding signals from impurities would feature a considerably higher S/N value. It should be noted that these results are the first to be published on the use of on-line CE–ESI-MS with a Z-Spray™ source for the characterization of a "real life" sample, and that the interface has not been fully optimized. We have used this interface to analyze standard peptide mixtures (22), and S/N values obtained were between 5 and 40 (TIE), with 400 fmol of the peptides being injected. Other reports on the use of sheathless interfaces give the following values: $S/N = 4$ on 4 fmol of myoglobin (23), $S/N = 5$ on 300 amol of leucine-enkephalin (24), and $S/N > 20$ on 30 fmol of digested cytochrome c (9). It is expected that our interface will allow for similar sensitivity levels once fully optimized.[2] The TIE obtained by CE–ESI-TOFMS of another citrate synthase digest was similar to that of Fig. 2*a*. The performance of the CE–ESI-TOFMS setup has been characterized (18) as yielding S/N values ≥30 in the TIE on 230 fmol of standard peptides.

Citrate synthase has a total of 44 possible tryptic cleavage sites. A large number of peptides may thus be obtained from a single digestion, which in turn provides for a difficult separation. However, it is possible to gain useful information on the peptide through selected reconstructed ion electrophorograms (SIE) as shown in Fig. 2*b*. The SIE traces thus obtained allow detection of single peptides among other components, thus facilitating their mass spectral identification. In total, 44 SIE were obtained with S/N varying from ca. 14 to 120 on raw data (not all shown). Additional peptides were identified from the digest, but due to poor signal intensity, they were not included here. The most intense signals were obtained for $[M + H]^+$ and $[M + 2H]^{2+}$ ions of peptides. The electrophoretic efficiency was relatively high, with theoretical plate counts (N) from ca. 8000 (m/z 633.4) to ca. 88 000 (m/z 540.9). The N values of less than 50 000 are attributed to peptide adsorption on bare fused silica, and to the use of an acidic separation buffer (5% acetic acid). Moreover, the Tris buffer used to perform the digestion has a
