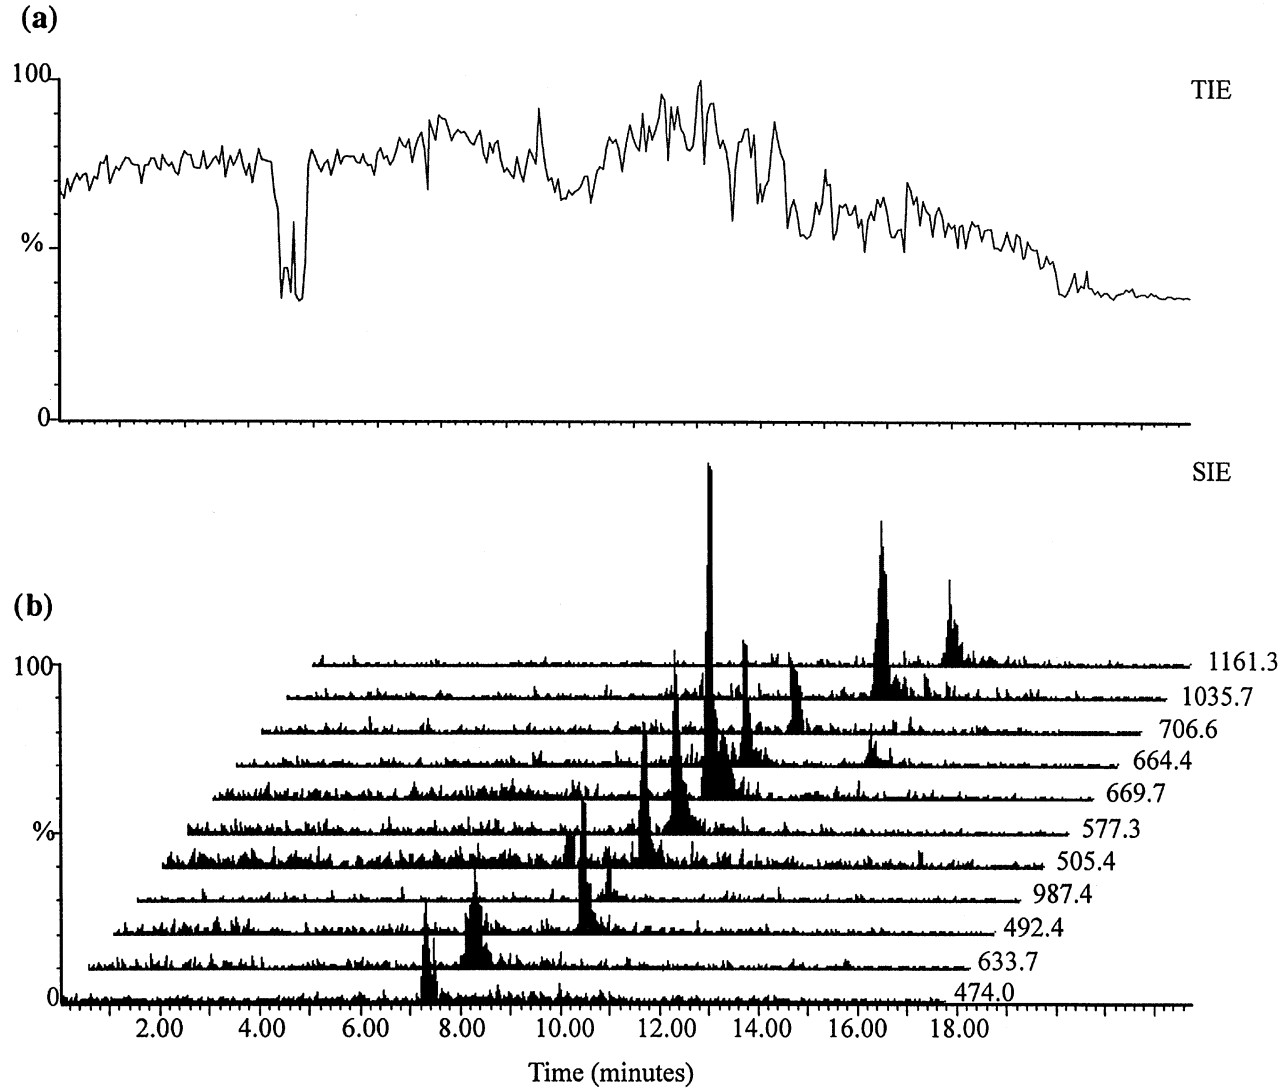
Fig. 2. On-line CE–ESI-MS electrophorograms obtained for the tryptic digestion products of wild-type citrate synthase. (*a*) Total ion electrophorogram (TIE), and (*b*) some selected reconstructed ion electrophorograms (SIE).



higher conductivity than 5% acetic acid, and thus sample stacking (isotachophoresis) will not have occurred. In general, the electrophorograms were reproducible in terms of migration order of the tryptic peptides, and average *N* values on CE peaks. The results presented here in Fig. 2 are representative of the CE–ESI-MS system used.

Some comparisons between the mass spectra (raw data) obtained on the two mass spectrometers are presented in Fig. 3. The mass resolution was superior with the TOF mass spectrometer than with the Quattro-LC instrument, and high resolution facilitated the assignment of multiply charged fragment ions. This performance was typical of the ESI-TOF instrument (19, 20) with mass resolution $\approx 6000(m/\Delta m_{FWHM})$, enabling baseline isotopic resolution. In comparison, the triple quadrupole analyzer was tuned for unit mass resolution. Although lower, the extent of resolution still allowed the identification of the peptides over the mass range investigated, albeit with more difficulty in the case of higher charge states. In general, sensitivity was higher on the TOF instrument than on the triple quadrupole instrument, and comparable CE efficiency was obtained on the two mass spectrometers (18).

Table 1 shows *S*/*N* and theoretical plate count values derived from three SIE traces shown in Fig. 3 (*m*/*z* 577.3, 633.4, and 1035.7). The mass spectra of the three peptides corresponding to these traces are shown in Fig. 3 (*b*, *d*, *f*). These values were typical of the peptides observed on the Quattro-LC. The comparative spectra in Fig. 3 (*a*, *c*, *e*) were obtained by CE–ESI-TOFMS.

A mass spectrum was obtained from each SIE, resulting in the identification of 44 tryptic fragments. These were tentatively identified and matched with literature values as shown in Table 2. It is noted that a few peptides were observed from their SIE, with *S*/*N* values less than 5, and were therefore not included in Table 2. In some cases, molecular ions corresponding to two charge states were observed for a single peptide, and these results were confirmed by similar SIE for each charge state. The charge states of molecular

[a]Peaks indicated may be assigned to more than one peptide.

ions observed on the two instruments varied. This was due, presumably, to different ESI and declustering potentials and different interface designs.

Fewer peptides were readily observed and identified in the TOF mass spectra, because not every possible spectrum could be obtained individually out of 1 min segments. Peptides with low *S*/*N* spectra were likely obscured by other abundant components or baseline noise. Also, the samples run by CE–ESI-MS and CE–ESI-TOFMS were digested separately and at different times, using enzymes from different batches. However, the ESI-TOFMS data obtained complemented the results obtained with the LC-Quattro and enabled complete characterization of the digest. In three cases, the assignments were ambiguous and could not be confirmed due to peptides that had similar *m*/*z* values, i.e., T9 and T32 at *m*/*z* 577.66 and 577.73. It was not possible to differentiate these peptides based on mass alone. Further characterization would require digestion with a different enzyme or the use of sequencing methods, which we are currently investigating. The use of tandem MS on-line with CE is also under investigation.

The *m*/*z* values in Table 2 indicate lower accuracy for CE–ESI-TOFMS measurements than for CE–ESI-MS experiments, due mainly to calibration drift of the TOF instrument, which may be corrected as long as calibrants are run immediately prior to analysis. In our case, the drift occurred during the time required to condition the system. Also, calibration was performed using sample infusion, which could have caused discrepancies vs. the use of CE introduction.

Mapping of the proteolytic fragments is useful for positive identification of the protein by database searching. Figure 4 shows the tryptic peptide map of synthase citrate based on the results shown in Table 2. A complete peptide map was obtained based solely on the CE–ESI-MS results, with the exception of Tryptic Fragment no. 19, which was observed only with the ESI-TOF mass spectrometer. The *m*/*z* values of the most intense singly charged peaks were used to perform an on-line database search, in order to investigate the possibility of identifying the protein using the peptide information alone. The search parameters were as follows: protein name: unknown; M_r range: 40 kDa ± 20%; species: *Escherichia coli*; peptide masses: 492.4, 505.4, 577.3, 613.9, 664.4, 791.5, 795.2, 822.2, 897.6, 1035.7; minimum number of peptides to match: 4; enzyme: trypsin; missed cleavage sites: 2; cysteine: reduced form. The search was performed on Feb. 8, 1999, SWISS-PROT Release 37, and updates up to Feb. 5, 1999: 78 197 entries. The search produced one protein match: score: 0.5; no. peptide matches: 6; accession no.: P00891; ID: CISY-ECOLI; description: CITRATE SYNTHASE (EC 4.1.3.7). The search was performed in less than 1 min on-line and resulted in a correct match for the protein studied. We note that a combination of limited search parameters must be used in order to minimize the number of results from the search. Eliminating the species name and M_r range of the intact protein resulted in over 100 search results, which would make the correct identification of the protein much more difficult.

Conclusions

ESI-MS using sample infusion produces very indicative values for the M_r of two very closely related citrate synthase species, the wild type and a mutant. On-line CE–ESI-MS and CE–ESI-TOFMS produced significant results for the separation and analysis of tryptic peptides of wild-type citrate synthase. It should be emphasized that CE–MS analyses were performed on nonpurified protein samples, which traditionally require extensive buffer exchange via dialysis prior to further characterization. This article is the first to demonstrate the coupling of sheathless CE with the Z-Spray™ ESI interface on the Micromass Quattro LC triple quadrupole mass spectrometer and its use for characterization of a large enzyme. We have confirmed the usefulness of on-line CE–MS, as performed on two different mass spectrometers, in enabling the complete sequence elucidation of wild-type citrate synthase.

Acknowledgments

We thank the members of the Time-of-Flight Laboratory, especially K.G. Standing and W. Ens, for helpful discussions, and for use of the ESI-TOF instrument. We express our thanks to R. Bordoli who obtained the q-TOF spectra by sample infusion at the Micromass factory. We acknowledge the Natural Sciences and Engineering Research Council of

NMR and molecular structure of partially oriented mono and *para* methyl- and chlorobenzenes dissolved in nematic liquid crystals

Raymond T. Syvitski and E. Elliott Burnell

Abstract: Spectral parameters, order parameters, and structural parameters, including the vibrationally corrected r_α structure of the partially oriented solutes *p*-xylene, *p*-chlorotoluene, *p*-dichlorobenzene, toluene, and chlorobenzene dissolved in three liquid crystal mixtures, are reported. For samples containing the three solutes *p*-xylene, *p*-dichlorobenzene, and 1,3,5-trichlorobenzene, multiple quantum (MQ) nuclear magnetic resonance was used to aid in the analysis of the complex high-resolution spectra of the *p*-xylene. The high-resolution spectra of 1,3,5-trichlorobenzene and *p*-dichlorobenzene were easily identified and analyzed once the calculated *p*-xylene spectrum was subtracted from the experimental one. The methyl groups of *p*-xylene, *p*-chlorotoluene, and toluene have similar geometries when the structure is determined from dipolar couplings corrected for harmonic vibrations.

Key words: nematic liquid crystal, NMR, molecular structure, order parameter.

Résumé : On a déterminé les paramètres spectraux, d'ordre et structuraux, y compris la structure r_α vibrationnellement corrigée de solutés partiellement orientés (*p*-xylène, *p*-chlorotoluène, *p*-dichlorobenzène, toluène et chlorobenzène) dissous dans trois mélanges de cristaux liquides. Pour les échantillons contenant le *p*-xylène, le *p*-dichlorobenzène et le 1,3,5-trichlorobenzène comme solutés, on a utilisé la résonance magnétique nucléaire à multiples quantum (MQ) comme aide dans l'analyse du spectre complexe du *p*-xylène à haute résolution. Les spectres à haute résolution du 1,3,5-trichlorobenzène et du *p*-dichlorobenzène sont facilement identifiables et on peut les analyser directement dès que le spectre calculé du *p*-xylène est soustrait du spectre expérimental. Les groupes méthyles du *p*-xylène, du *p*-chorotoluène et du toluène possèdent des géométries semblables quand on détermine la structure à partir des couplages dipolaires corrigés pour les vibrations harmoniques.

Mots clés : cristal liquide nématique, RMN, structure moléculaire, paramètre d'ordre.

[Traduit par la Rédaction]

1. Introduction

The NMR spectra of solute molecules dissolved and orientationally ordered in liquid-crystalline solvents can provide a wealth of valuable information. For example, this is one of the few methods available for obtaining accurate molecular structures in the liquid phase. In addition, directional properties such as anisotropies of chemical shifts and indirect spin–spin coupling constants, as well as dipolar and quadrupolar coupling constants, are measurable (1–3). Moreover, the average second-rank orientational order parameters that can be calculated from the dipolar or quadrupolar couplings provide information about the anisotropic intermolecular forces that are responsible for the orientational ordering (4).

There is general consensus that molecular size- and shape-dependent short-range interactions represent the dominant mechanism that is responsible for orientational ordering in nematic liquid crystals. However, additional interactions are known to be present, and their precise description is a matter of current controversy (4). Because the orientational ordering is dominated by short-range effects, it seems appropriate to choose for study probe solutes that have very similar sizes and shapes; differences in orientational order parameters might then reflect the effects of the additional, weak interactions. Hence, in this paper, we report on proton NMR experiments on a series of similar-shaped solutes in nematic liquid crystals. To compare results among solute molecules in as equivalent a manner as possible, several solutes are dissolved in the same sample tube. The manner in which we deal with the added complexity caused by superimposed spectra of several partially oriented solutes is one primary focus of this paper, and is discussed below in the section on spectral analysis. The other primary focus is the use of the dipolar couplings obtained from the spectra to determine vibrationally corrected molecular structures for the probe

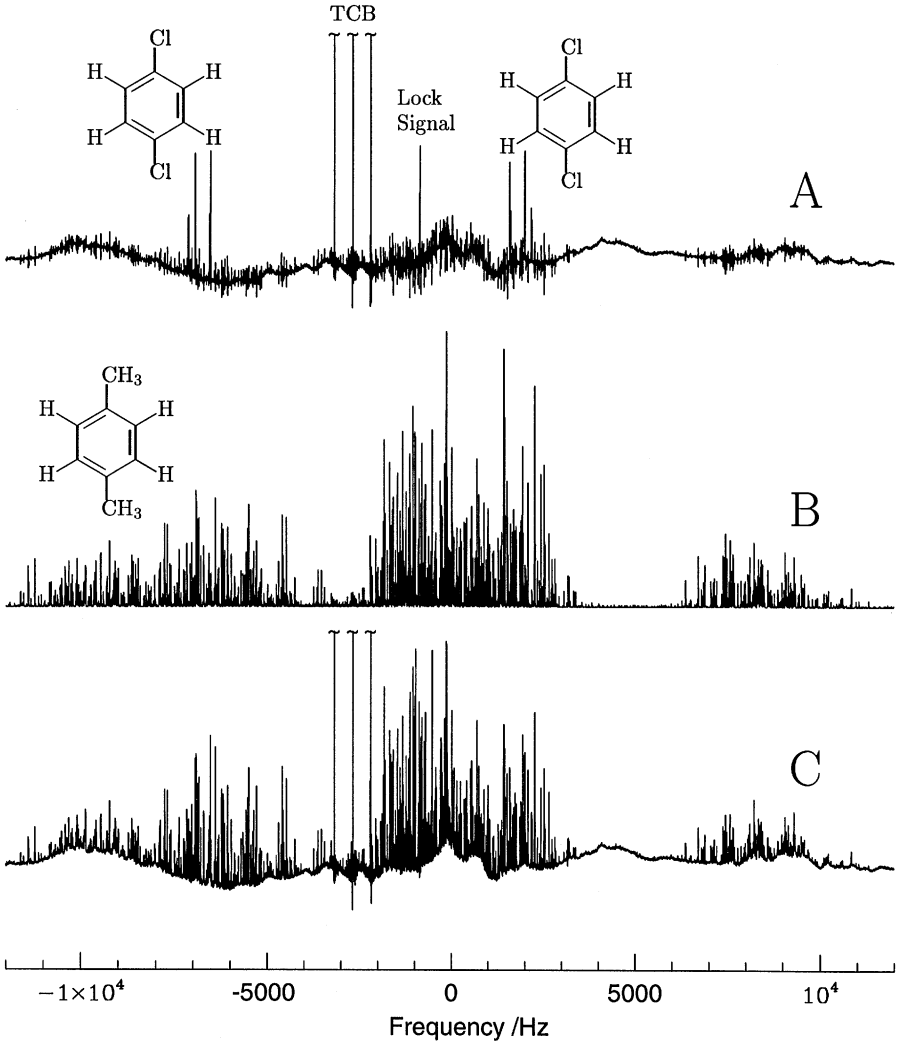
Fig. 1. The experimental high-resolution spectrum *C* is of Sample no. 8, partially oriented *p*-xylene–*p*-dichlorobenzene–TCB in 55 wt.% ZLI 1132–EBBA at 299 K. Spectrum *B* is the calculated spectrum of *p*-xylene from the fit to spectrum *C*. Spectrum *A* is a subtraction of the calculated from the experimental spectrum. Since experimental lines had a broad base, the subtraction was performed using a calculated spectrum in which the line shape is the addition of two Lorentzians with line broadenings of 1 and 4 Hz. Note that resonances corresponding to the external lock signal (acetone-d_6 in a capillary tube), TCB, and *p*-dichlorobenzene are clearly visible in the top spectrum. In the experimental spectrum *C*, the rolling base line, which is approximately 50 kHz wide, is from the liquid crystal. Lines from the TCB triplet have been truncated.



solutes. A detailed discussion of the order parameters that have not been corrected for the effects of molecular vibrations appears elsewhere (5).

The complexity of high-resolution NMR spectra of partially oriented molecules, and thus the ability to determine accurately spectral parameters such as chemical shifts and nuclear coupling constants from such spectra, depends on the flexibility and symmetry of the molecules and on the number and type of nuclear spins. For example, the proton NMR spectrum of complex liquid crystal molecules is typically broad and featureless and therefore impossible to analyze accurately; the rolling base line in the experimental spectrum of Fig. 1*C* is from the liquid crystal. Nuclear quadrupolar couplings from deuterium spectra (6) (and, in favorable cases, nuclear dipolar couplings from proton spectra (7–12)) of randomly or specifically deuterated molecules can be determined easily. However, these compounds are not readily available (the synthesis of a wide variety of such molecules is very time consuming and problematic (13)), and the accuracy of order parameters determined from such spectra is far less than that obtained from high-resolution proton NMR. As a consequence, it is common to utilize small protonated solute molecules for precise NMR studies involving liquid-crystalline solvents. Unfortunately, even with small solutes that contain ≥6 spins, determining spectral parameters from high-resolution spectra can be extremely difficult. In such cases, the use of two-dimensional multiple-quantum (MQ) NMR spectroscopy (14–16) is very helpful, since there are comparatively fewer lines in the spectra (17–22). However, the use of MQ spectra is not entirely straightforward; the intensities depend on both spectral and experimental parameters in such a complicated manner that they are not normally used for the analysis. In addition, care must be taken so that an incorrect and therefore mean-

8	*p*-Xylene–*p*-dichlorobenzene–TCB[a]	55 wt.% ZLI 1132–EBBA
9	*p*-Xylene–*p*-dichlorobenzene–TCB[a]	EBBA

[a]TCB refers to the internal orientational standard 1,3,5-trichlorobenzene that was utilized for the scaling method described in ref. 5. Total solute concentration was <10 mol%.

[b]See ref. 23 for chemical composition.

ingless "fit" is not obtained. Nevertheless, the analysis is far easier than for the normal high-resolution spectra.

An additional problem with MQ NMR is the technical limitation that leads to spectra with broad peaks and therefore poor resolution. Thus, although the relatively few number of lines in the MQ spectrum can be advantageous, spectral parameters are not determined with high accuracy. Therefore, parameters determined from MQ spectra are used only as a starting point when analyzing high-resolution spectra. Despite the poor resolution of the MQ spectra, often only minor adjustments to parameters determined from such spectra are required in order to obtain a fit to the high-resolution spectrum (see refs. 19–22). High-resolution spectra can have many hundreds of lines, and thus, obtaining erroneous spectral parameters from a well fit spectrum is extremely unlikely.

Unlike microwave or electron diffraction data, dipolar couplings can provide accurate relative proton positions; by combining structural data from liquid crystal NMR and from microwave or from electron diffraction studies, it is possible to determine accurate molecular structures. However, since molecular vibrations affect the observed results, data should be vibrationally corrected before determining such structures. In this study, we analyze MQ and high-resolution proton NMR spectra of the partially oriented probe solutes: *p*-xylene, *p*-chlorotoluene, *p*-dichlorobenzene, toluene, and chlorobenzene. We determine spectral parameters, molecular order parameters, and internuclear distances, including the vibrationally corrected r_α structure for these solute molecules. It is interesting that there is variation in the methyl group geometries reported in the literature for this series of methylbenzenes. The technique used here (NMR spectroscopy of the five orientationally ordered solutes in the three nematic liquid crystal mixtures: Merck ZLI 1132 (see ref. 23 for chemical composition), 55 wt.% ZLI 1132–EBBA, and *N*-(*p*-ethoxybenzylidene)-*p*′-*n*-butylaniline (EBBA)) is an ideal tool for the investigation of such an interesting result.

2. Experiment

The nematic liquid crystal Merck ZLI 1132 and all solutes were used without further purification. The liquid crystal EBBA was synthesized (24) and purified by recrystallization from cold methanol. Each of nine samples was prepared by dissolving three solutes in one of the liquid crystal solvents: ZLI 1132, 55 wt.% ZLI 1132–EBBA, or EBBA. The composition of each sample is given in Table 1.

Proton NMR spectra of the nine samples were acquired at 299.6 ± 0.5 K on a Bruker AMX-500 spectrometer. Acetone-d_6 in a coaxial capillary provided the deuterium lock. For high-resolution proton NMR spectra, 32K point FIDs were acquired after a single pulse, zero filled to 64K points and processed using a Lorentzian line broadening of 1.0 Hz. Half-height line widths for these high-resolution spectra were typically 2–3 Hz. The spectrum obtained from Sample no. 8 is presented in Fig. 1, with an expanded region in Fig. 2. For samples containing *p*-xylene (Sample nos. 7–9, Table 1) two-dimensional MQ interferograms were acquired using the pulse sequence (25, 26)

$$[1]\qquad \left(\frac{\pi}{2}\right)_\phi - - - \tau - - - \left(\frac{\pi}{2}\right)_\phi - - - t_1 - - - \left(\frac{\pi}{2}\right) - - - t_2(\text{acquire})$$

with 1000–1500 increments in t_1, and for each t_1 increment 1024 points were collected in t_2; a one-dimensional MQ spectrum was produced by zero filling to 2048 in t_1, 2D magnitude Fourier transforming, and performing a summed projection onto the F1 axis. Selective detection of specific MQ coherences was accomplished by the repeated application of the pulse sequence [1] for each t_1 increment; after each application the phase ϕ of the first and second pulse was incremented relative to the third pulse (and receiver). To selectively detect the 7- or 8-quantum coherences, a 14 or 16 step phase cycle, where ϕ was incremented by 25.7° or 22.5°, was used. Alternate adding and subtracting within the phase cycle eliminates all but the ±7- or 8-quantum coherences (25, 26). While in principal this phase cycle also permits detection of $\pm k \times$ 7-quantum or $\pm k \times$ 8-quantum spectra, where k = 2, 3,..., this was not a problem since, for a n-spin-1/2 system, n is the highest attainable MQ order. For Sample nos. 7– 9, only *p*-xylene will contribute to the 7- and 8-quantum spectra, since the other two solutes have <7 spins. The intensity of MQ lines is highly dependent on the τ value, and therefore, at least two MQ spectra with τ values between 10 and 21 ms were acquired for each *p*-xylene sample in an attempt to detect all 7- or 8-quantum transitions.

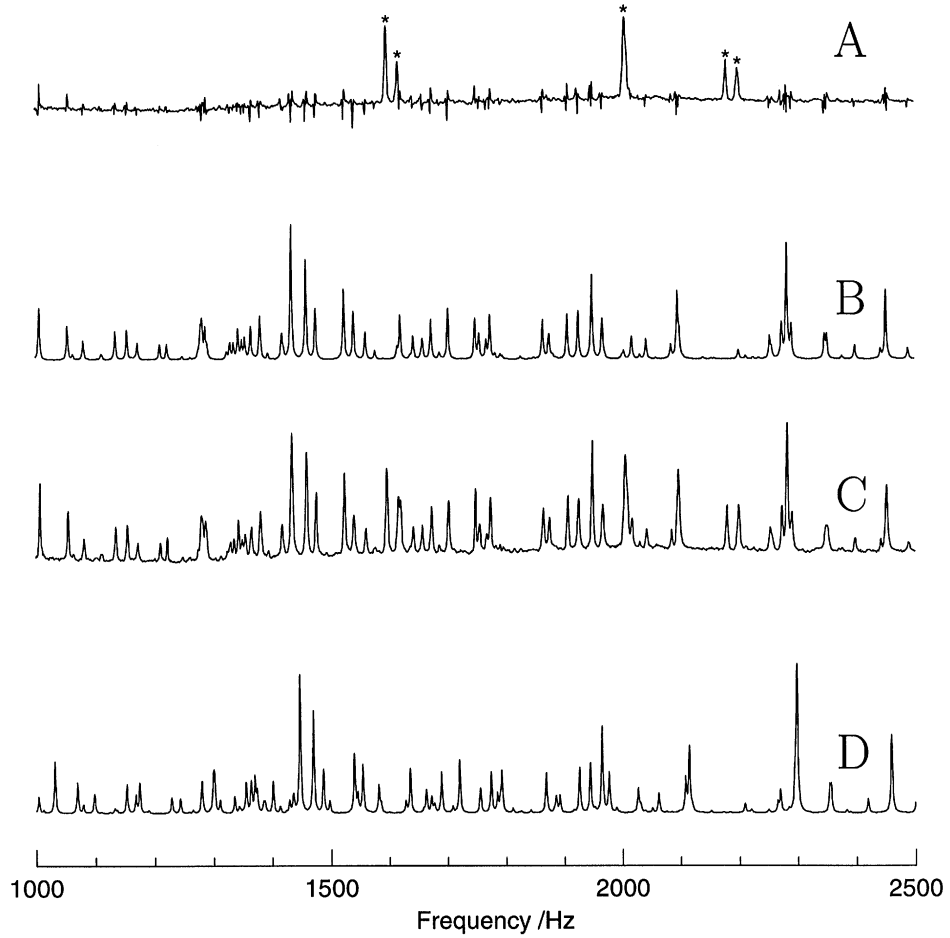
Fig. 2. The top three spectra *A*, *B*, and *C* are an expansion of Fig. 1. Spectrum *D* is an expansion of the spectrum predicted from the fit to the 7-quantum spectrum. Note that the line positions and intensities between the 7-quantum prediction and the experimental spectra are in sufficiently good agreement that only minor adjustments to spectral parameters were required to fit the experimental spectrum. In the experimental spectrum, the average line width at half maximum height is 2–3 Hz. The intensities of the calculated spectrum closely correspond with those of the experimental one. In spectrum *A*, resonances indicated with an asterisk are from *p*-dichlorobenzene.



The recycling time was 4 s. The 7-quantum spectrum obtained from Sample no. 8 is presented in Fig. 3.

3. Spectral analysis

Since the component molecules of liquid crystal phases are undergoing random and rapid translational diffusion, intermolecular dipolar couplings are averaged to zero. However, due to anisotropic molecular reorientation, intramolecular dipolar couplings are averaged to a non-zero value. As a consequence, MQ and high-resolution NMR spectra contain only couplings between nuclei on the same molecule. Spectral parameters can be determined accurately by analyzing the experimental spectrum using the spin Hamiltonian

$$H = -\sum_i \nu_i I_i^Z + \sum_i \sum_{j>i} \left[(J_{ij} + 2D_{ij}) I_i^Z I_j^Z + \frac{1}{2}(J_{ij} - D_{ij})(I_i^+ I_j^- + I_i^- I_j^+) \right] \quad [2]$$

where ν_i is the resonance frequency of nucleus, *i*, J_{ij}, and D_{ij} are the indirect and direct (dipolar) coupling constants between nuclei *i* and *j* on the same molecule, and I^Z, I^+, and I^- are the spin operators.

For analysis of experimental spectra, initial estimates of spectral parameters ν_i, J_{ij}, and D_{ij}, either from previous studies or a "best guess," are required. The best guess may be values of ν_i and J_{ij} obtained from isotropic phase NMR spectra and values of D_{ij} calculated from

$$D_{ij} = -\frac{\mu_0 \hbar \gamma_i \gamma_j}{8\pi^2} \sum_{\beta\xi} S_{\beta\xi} \left\langle \frac{\cos\theta_\beta \cos\theta_\xi}{r_{ij}^3} \right\rangle \quad [3]$$

where the angle brackets indicate a statistical average over all intramolecular motions, β and ξ are the molecular fixed *x*, *y*, *z* axes, r_{ij} is the internuclear distance between nuclei *i* and *j*, θ_β and θ_ξ are the angles between the internuclear vector and the molecular β and ξ axes, and $S_{\beta\xi}$ is an element of the molecular order parameter matrix. Estimates of internuclear distances can be determined from general knowledge of structures or from previous structural studies. The molecular order parameter matrix,

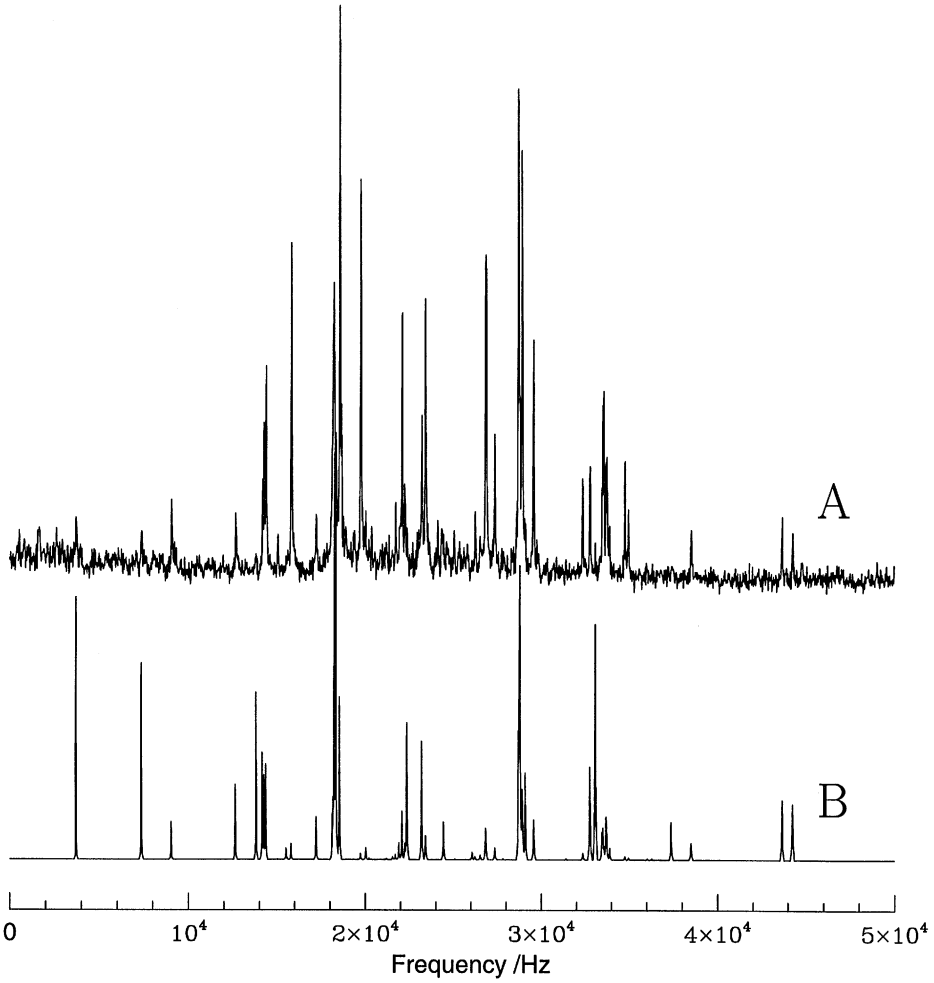
Fig. 3. The experimental +7-quantum spectrum *A* is of Sample no. 8. Only resonances from *p*-xylene are observed; for an *n*-spin-1/2 system, *n* is the highest attainable MQ order. Spectrum *B* is the calculated +7-quantum spectrum of *p*-xylene. Note that the line width in the experimental spectrum is approximately 50 Hz, and the intensities of the calculated spectrum do not correspond with those of the experimental.



$$[4] \qquad S_{\beta\xi} = \frac{1}{2}\left\langle 3\cos\theta_{\beta Z}\cos\theta_{\xi Z} - \delta_{\beta\xi}\right\rangle$$

(where the angle brackets indicate a statistical average over all orientations of the molecules, and $\theta_{\beta Z}$ and $\theta_{\xi Z}$ are the angles between the magnetic field direction Z and molecular β and ξ axes), is inferred from studies of similar molecules or from calculations based on theories or models for the anisotropic intermolecular potential. Since there are no large-amplitude molecular motions which significantly affect the $S_{\beta\xi}$ or structural parameters (21), and orientational–vibrational correlations (27–29) are assumed to be negligible, the averages of the orientational and structural parameters have been separated in eq. [3].

From the estimates of the spectral parameters, a trial spectrum is calculated using eq. [2] and the appropriate selection rules for high-resolution or MQ spectra. Experimental and calculated spectra are compared, and ν_i and (or) D_{ij} are manually adjusted until the overall structure of the calculated spectrum is similar to the experimental. The calculated frequencies are then assigned to the experimental ones, and spectral parameters are adjusted by a least-squares fitting routine. Frequencies are repeatedly assigned and (or) unassigned and parameters adjusted until a reasonable fit to the experimental spectrum is obtained; this is the most time-consuming portion of spectral analysis. Assignment of calculated to experimental frequencies was performed with the aid of a cursor-controlled graphical interface program SM.[2] Care was taken to avoid assignment of overlapping or unresolvable lines. Frequencies were determined from a five-point weighted average about the maximum intensity point. In all cases, the frequencies were no more than 0.2 Hz different from a standard Bruker peak-picking routine for lines with half-height line width ≤3 Hz.

Without accurate estimates of spectral parameters, analysis of high-resolution spectra for molecules with ≥6 spins can be extremely difficult (30); this will be particularly true when there are resonances from other solutes in the spec-

trum. In an attempt to reduce analysis time of the complex high-resolution *p*-xylene spectra, MQ spectra were examined first. For Sample no. 7, the 7- and 8-quantum spectra were examined before good estimates of chemical shifts and D_{ij} could be determined, whereas only 7-quantum spectra were necessary for the other two samples containing *p*-xylene (Sample nos. 8 and 9). The experimental 7-quantum spectrum of Sample no. 8, along with the one calculated using the spectral parameters obtained from the analysis, are shown in Fig. 3. The agreement between experimental and calculated spectral line positions is excellent. It must be remembered that intensities in the calculated MQ spectrum are meaningless. The spectral parameters obtained from the fit to the MQ spectrum are then used to calculate the high-resolution NMR spectrum, and the result for Sample no. 8 is shown in Fig. 2*D*. Most peaks can be assigned immediately to lines in the experimental spectrum (compare Fig. 2*C* and *D*). As has been found for several other complicated spin systems (19, 21, 22), a correct fit to the MQ spectrum can give a prediction of the high-resolution spectrum that is amazingly close to that observed. In the current case, the fit to the high-resolution spectrum is complicated by the presence of lines from the extra two solutes that are present. Once spectral parameters for the MQ spectra were determined, the high-resolution spectra were analyzed within hours, and the spectral parameters obtained are given in Table 2. The spectrum calculated from the parameters in Table 2 for Sample no. 8 is presented in Figs. 1*B* and 2*B*. The excellent quality of the fit for *p*-xylene is demonstrated by subtracting the calculated (Figs. 1*B* and 2*B*) from the experimental (Figs. 1*C* and 2*C*) spectrum, the results being presented as Figs. 1*A* and 2*A*. The experimental *p*-dichlorobenzene and TCB spectra are easily observed and were analyzed without the aid of MQ NMR. For each sample that contained *p*-xylene, the complete determination of spectral parameters obtained by starting from the MQ spectra and then analyzing the high-resolution spectrum only required a month.

Spectra for samples that contained toluene–chlorobenzene–TCB and *p*-chlorotoluene–*p*-dichlorobenzene–TCB were analyzed without the aid of MQ NMR. Spectral parameters for the monomethylbenzenes (toluene and *p*-chlorotoluene) were determined first. A cluster of lines approximately 2000 Hz upfield from the main spectrum contained no frequencies from chlorobenzene or *p*-dichlorobenzene, and thus, many lines in this cluster could be assigned, and some D_{ij}, which are unique to the methylbenzene, could be determined; this allowed for easier assignment of lines within the main portion of the spectrum. Once spectral parameters for the methylbenzenes were determined (Table 2), the calculated spectra were subtracted from the experimental, and the spectra from the chlorobenzenes and 1,3,5-trichlorobenzene were easily identified and analyzed (Table 2).

4. Determination of molecular structure and molecular order parameters

Solute molecular order parameters and proton internuclear distances were calculated from a simultaneous fit to D_{ij} determined for the solute in all three liquid crystal mixtures (Tables 3 and 4); calculations were performed using the least-squares minimization routine NL2SNO (31), eq. [3], and a priori estimates (32) of proton–carbon bond distances and angles. A priori estimates are values that are adjusted in the least-squares routine; thus, the least-squares routine includes equations for both D_{ij} and geometrical parameters. The structure is allowed to deviate from that determined previously; however, large deviations are discouraged by the least-squares criteria. In previous studies (19, 22, 33–35) of solutes in liquid crystals, the structure of the benzene ring did not vary significantly from that determined by electron diffraction. Thus, during the least-squares minimization the benzene ring was fixed to the geometry determined previously. Values of D_{ij} between methyl and ring protons for toluene, *p*-chlorotoluene, and *p*-xylene were calculated for each 15° rotation of the methyl group using a sixfold potential $U = V/2(1 + \cos(6\theta))$ where V was fixed at 60 J/mol (36) and $\theta = 0$ is when one proton is in the plane of the benzene ring. No attempt was made to correlate methyl rotation and reorientational motion. In the approximation that a $P_2(\cos\theta)$ bond additive interaction (37) describes the orientational potential, and that the methyl group retains C_3 symmetry upon rotation, then the orientational potential is invariant to the methyl rotation.

The effects of vibrational motion on the experimental observations (and thus the molecular structure) are different for different experimental techniques. Therefore, in order to compare or combine structural information derived from various experimental methods, the observed data should be "vibrationally corrected." Electron diffraction and microwave techniques study molecules in the gas phase where molecular collisions and interactions are minimized. In comparison, in this study, molecules are in an anisotropic condensed phase, and the anisotropy of the phase affects vibrational motions (orientational–vibrational correlations). For orientational–vibrational correlations, it is assumed that the orienting forces alter the vibrational potential of the molecules, which affects the observed D_{ij}. Corrections have been calculated for certain molecules such as CH_4 (27), acetylene (29), benzene (34), chlorobenzene (34), and CH_3F (38). For molecules with a large $S_{\beta\xi}$, the orientational–vibrational correlations will have a very small effect (≈0.2%) on the observed D_{ij} (34, 39). Normal-mode bond vibrations have a larger effect (≈2.0%) on the observed D_{ij} (39), and thus, we have attempted to correct for these effects only. The average structure determined by subtracting the contributions from harmonic vibrations, the r_α structure, has been established as a suitable physical basis for comparing results (40–43). The average r_α structures determined from different techniques are usually in good agreement with each other.

A second calculation of order parameters and structural parameters was performed using a version of the least-squares routine modified to include the subroutine VICO (33, 44), which corrects for the non-negligible effects of molecular vibrations on D_{ij} (Tables 3 and 4). VICO calculates corrections using the Taylor expansion of D_{ij} about the equilibrium position

$$[5] \qquad D_{ij} = D_{ij}^{e} + \sum_{\delta}\left(\frac{\partial D_{ij}}{\partial \delta}\right)_{e}\langle\Delta\delta\rangle + \frac{1}{2}\sum_{\delta}\left(\frac{\partial^2 D_{ij}}{\partial \delta^2}\right)_{e}\langle\Delta\delta^2\rangle + \ldots$$

where D_{ij}^{e} is the dipolar coupling at equilibrium, δ is the x', y', and z' internuclear axis, $\langle\Delta\delta\rangle$ is the average vibrational

[a]For atom numbering refer to Fig. 4. Numbers in parentheses are errors (68% confidence) in the last two reported digits of varied parameters.
[b]Dipolar couplings, *J* couplings, chemical shifts, and rms errors are in Hz.
[c]Parameters not varied during analysis of spectrum. Values were determined from a separate analysis of chlorobenzene dissolved in the nematic phase of ZLI 1132.
[d]Frequency is referenced to an arbitrary zero and is increasing to high field. In principle, chemical shift anisotropies can be determined from isotropic–nematic frequency shifts; however, proton shifts are small, and the variation in anisotropic local solvent effects among chemically distinct protons makes such measurements impracticable (61).
[e]Parameters not varied during fitting of spectrum. Values taken from ref. 62.
[f]TCB refers to an internal orientational standard 1,3,5-trichlorobenzene.
[g]Parameters not varied during fitting of spectrum. Values taken from ref. 63.
[h]Parameters not varied during fitting of spectrum. Values taken from ref. 64.
[i]Values in square brackets are from analysis of the 7-quantum spectrum. *J* couplings were set to zero for the MQ analysis.

amplitude (anharmonic) in the δ direction, and $\langle\Delta\delta^2\rangle$ is the corresponding mean-square amplitude (harmonic). The r_α structure was determined by subtracting the harmonic contribution from D_{ij} and calculating the molecular order parameters and internuclear distances using these corrected dipolar couplings. Mean-square amplitudes $\langle\Delta\delta^2\rangle$ were calculated[3] from normal-mode vibrational analysis (46) using force constants from refs. 47 and 48).

5. Discussion

5.1. Molecular structure

Accurate molecular structure determination using proton NMR dipolar couplings faces the problem that the dipolar couplings are products of order and geometric parameters. Hence, only accurate relative proton coordinates are available. To determine the complete molecular structure, it is necessary to fit the proton geometry to the carbon skeleton. The error associated with the resulting structure is difficult to determine. Bond angles are probably not accurate to better than 0.2°, and CH bond distances to 0.01 Å. Thus, the statistical uncertainties (68% confidence level) reported in Table 3 are optimistic.

The relative values of the proton coordinates reported in Table 3 are from simultaneous fits to the dipolar couplings obtained in three different liquid crystals for each molecule. The use of more than one liquid crystal provides extra independent equations to the fitting procedure. The complete structure is then obtained by utilizing data from other studies (mainly gas-phase work) for geometric parameters. Some of these parameters are used as a priori estimates. It is noteworthy that most of the values so obtained do not differ significantly from the a priori estimates. For chlorobenzene, toluene, *p*-dichlorobenzene, and *p*-chlorotoluene, the $\angle_\alpha$(C3C2H1) is about 0.4° larger than the a priori estimate. This difference is ascribed to the difficulty associated with fitting the proton structure around the carbon skeleton, as discussed above. In the case of *p*-xylene, $\angle_\alpha$(C3C2H1) differs by 1° and r_α(C2—H1) by 0.013 Å from the a priori estimates, which are taken from gas-phase electron diffraction work. However, it is well known that proton coordinates are difficult to determine by electron diffraction, and the new NMR values are taken to be more reliable.

A glance at the a priori estimates for the methyl group geometry indicates that the methyl group structure appears to vary among the molecules studied. On the contrary, our results indicate that the methyl groups in the series of

[3]Program written by R.L. Hilderbrant utilizing the methods developed by Hilderbrant and Wieser (45).

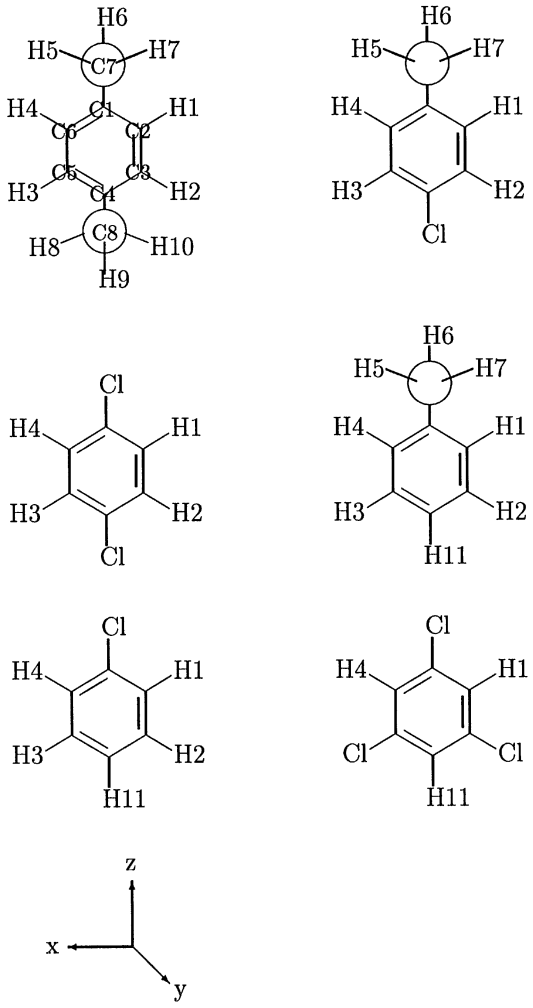
Fig. 4. Coordinate system and atom numbering of solute molecules.



methylbenzenes (toluene, *p*-xylene, and *p*-chlorotoluene) have essentially the same r_α(C—H(Me)) bond length and $\angle_\alpha$(CCH(Me)) angle. The unexpected scatter among a priori estimates is likely a result of the different experimental techniques utilized for the various studies.

It is interesting that one effect of the vibrational corrections is that there is a slight improvement in the rms error over the fit without such corrections (*p*-xylene is an exception). In general, the vibrationally corrected structural parameters lie closer to the a priori estimates than do the noncorrected ones.

5.2. Order parameters

The main motivation behind the choice of solutes in this work is the investigation of the solute order parameters, and a discussion of the scaled order parameters that were not corrected for the minor effects of molecular vibrations is presented elsewhere (5). It is generally accepted that anisotropic short-range repulsive forces are primarily responsible for the orientational ordering of liquid crystals, i.e., forces that can be related to size, shape, and conformation of the molecules (49–52). Controversy has arisen over the importance of anisotropic long-range interactions (5, 53–55). The spectra in this paper have been recorded in such a manner that the order parameters obtained can be used to explore various models for the anisotropic potential. In many previous studies, solutes dissolved in the same liquid crystal were in different sample tubes; thus, to examine the order parameters of the molecules an orientational scaling parameter was required for each solute to account for different sample conditions (53, 56–60). In this study, several solutes are dissolved in the same sample (similar to the sample preparation described in ref. 58); order parameters among these solutes can be directly compared without scaling.

The order parameters calculated both with and without vibrational corrections are reported in Table 4. The vibrationally corrected values are consistently about 2% larger. Hence, the neglect of vibrational effects when utilizing order parameters to investigate intermolecular forces is justified, as it is unlikely that any current theory will be able to predict order parameters to the 2% level.

The solute molecules chosen for investigation represent two groups; solutes in each group are related by their similar size and shape (the mono- and *para*-substituted molecules), but solutes within the groups have different molecular multipole moments. The S_{zz} of the *para* group of molecules in the 55 wt.% liquid-crystal mixture are all similar (Fig. 5). As short-range interactions are expected to be similar for these molecules, the long-range interactions, which involve molecular quadrupoles and dipoles, appear to be negligible in this particular liquid-crystal mixture. In previous studies, the long-range interactions were also determined to be of minimal importance with D_2 and HD dissolved in this liquid-crystal mixture (4).

In previous studies, D_2 and HD were found to have a positive orientational order in the component liquid crystal ZLI 1132 and a negative orientational order in EBBA (4). The ordering was attributed to the molecular electric quadrupole of D_2 and HD interacting with the anisotropic electric field gradient experienced in the liquid-crystal environment. In ZLI 1132, the trend for the scaled values of S_{zz} is S_{zz}(*p*-xylene) > S_{zz}(*p*-chlorotoluene) > S_{zz}(*p*-dichlorobenzene). However, in EBBA this trend is reversed (Fig. 5). This is consistent with the sign and magnitude of the interaction found for D_2 and HD (4, 5). For toluene and chlorobenzene, the quadrupoles of these two molecules are very similar, and thus, the effect is not as prevalent.

Dipoles appear to have little effect on the ordering of the molecules. If dipoles were important, then *p*-chlorotoluene, which has a large dipole along the *z*-axis, should have a vastly different S_{zz} than do the other two *para*-substituted benzenes, which have zero dipole moment. However, S_{zz} of *p*-chlorotoluene lies between the values for *p*-xylene and *p*-dichlorobenzene in both EBBA and 1132 (Fig. 5).

6. Summary

In this paper, we have determined spectral parameters, order parameters, and structural parameters (including the vibrationally corrected structural parameters) of *para*- and mono-substituted benzenes dissolved in various liquid crystals. Spectral parameters for *p*-xylene were estimated by analyzing the MQ spectra first, then accurately determined using the high-resolution spectra. The spectra of TCB and *p*-dichlorobenzene were easily identified and analyzed once

[a]Refer to Fig. 4 for structure and atom numbering of molecules. Bond distances *r* in Å and bond angles ∠ in degrees. In the least-squares fit to experimental dipolar couplings, the weight given to each dipolar coupling is $(1/\text{error})^2$ where the errors are from Table 2. Numbers in parentheses are statistical errors (68% confidence) in the last two reported digits of varied parameters (see text).

[b]Parameters that are indicated with "n" are calculated with no vibrational corrections to dipolar couplings, whereas parameters indicated with "v" are calculated with vibrational corrections and are the r_α structural parameters.

[c]Structural parameters not adjusted. From ref. 65. TCB refers to an internal orientational standard 1,3,5-trichlorobenzene.

[d]Parameters are calculated from ∠(C1C2C3) and ∠(C3C2H1).

[e]The rms error in Hz between calculated and experimental dipolar couplings.

[f]The rms error in Hz between vibrationally corrected and experimental dipolar couplings.

[g]A priori estimates are from refs. 34, 63, 64, 66, 67, and the weight associated with the estimates is $(1/\text{error})^2$ where the errors are reported in parentheses.

[h]r_α structure determined from liquid-crystal NMR data, which has been corrected for normal-mode vibrations and orientational–vibrational correlations (34).

[i]From molecular orbital calculations using Gaussian 92 and HF/6-31G* theory/basis set (66).

[j]r_α structure from a joint analysis of liquid-crystal NMR, electron diffraction, and rotational spectroscopy data (63).

[k]r_α structure from liquid-crystal NMR data, which has been corrected for normal-mode vibrations (64).

[l]r_α structure from electron diffraction data (67).

[m]No error is associated with this parameter. This is adjusted so the C1—C7 (and C4—C8) bond directions are collinear with the *z* axis of the molecule.

the calculated *p*-xylene spectrum was subtracted from the experimental. Spectral parameters for toluene, chlorobenzene, *p*-chlorotoluene, *p*-dichlorobenzene, and TCB were determined without the aid of MQ spectra. This is one of very few studies where many solutes were dissolved in a liquid-crystal mixture and where MQ spectroscopy was utilized in a successful attempt to simplify analysis of high-resolution spectra.

Proton positions were determined from at least three independent sets of dipolar couplings; only after dipolar couplings were corrected for vibrations did bond angles and lengths of the methyl groups on *p*-xylene, *p*-chlorotoluene, and toluene have similar values despite variations in a priori estimates.

Acknowledgments

We thank James M. Polson and Thambirajah Chandrakumar for their useful suggestions when analyzing the NMR spectra, and the Natural Sciences and Engineering Research Council of Canada for financial support. We are grateful to the E. Merck Company of Darmstadt, Germany, for their gift of the nematic liquid crystal Merck ZLI 1132.

Modelling and calculation of dipole moment functions for XH bonds

Christopher D. Daub, Bryan R. Henry, Martin L. Sage, and Henrik G. Kjaergaard

Abstract: Two studies of aspects of modelling dipole moment functions of XH bonds in small molecules for use in calculating overtone intensities have been undertaken. The first study deals with the fitting of ab initio calculations of the dipole moment at discrete points to a functional form. The two methods that are compared are the use of least-squares regression and the use of interpolating polynomials. The interpolating polynomial method is deemed superior due to its greater efficiency in terms of the number of points necessary to obtain reasonable results. The second study attempts to explain the indifference of calculated overtone intensities to the inclusion of electron correlation in the ab initio calculation of the dipole moment function. It is found that in most cases the influence of electron correlation can be modelled as a function with a very small matrix element, which results in a very small contribution to the overtone intensity.

Key words: dipole moment function, vibrational overtone intensities, electron correlation, ab initio calculations.

Résumé : Nous présentons deux études de modèles pour la fonction du moment dipolaire dans les liens XH. La première a pour sujet le raccord à une forme fonctionnelle des calculations ab initio à des points discrets. Deux méthodes sont comparées, la régression des moindres carrées et l'interpolation polynomiale. On trouve que l'interpolation polynomiale est meilleure, parce qu'elle donne des résultats raisonnables plus efficacement. La deuxième étude essaie d'expliquer nos observations que l'intensité des transitions vibrationnelles à haute excitation n'est pas tellement affectée par l'inclusion de la corrélation entre les électrons dans nos calculs du moment dipolaire. On trouve que l'effet de la corrélation peut être modelé comme une fonction avec un élément de matrice minuscule, ayant pour résultat une petite contribution à l'intensité.

Mots clés : fonction du moment dipolaire, intensité des transitions vibrationelles, corrélation entre électrons, calculs ab initio.

Introduction

For the past several years, the HCAO (Harmonically Coupled Anharmonic Oscillators) model has been widely used to understand the observed energy levels in the vibrational spectra of XH_n groups, both qualitatively and quantitatively (1, 2). However, due to several factors, understanding the observed intensities has posed more of a challenge. First, experimental vibrational intensities are difficult to determine accurately, especially in the overtone region, due to the weakness of the highly vibrationally excited transitions. Second, the nature of the vibrational potential surface is uncertain, although a Morse potential seems to fit the energy levels very well for most of the spectroscopically relevant region. Third, an accurate dipole moment function (DMF) is required. It is the third requirement that we address in this paper.

Historically, the modelling of the DMF was done on the basis of ideas such as the bond-dipole approximation, which attempted to fit the DMF to a functional form. The function was chosen so that it displayed the physically correct limiting behaviour for a single XH bond at large bond displacements (3–5). There are two weaknesses in this approach. First, the DMF of a polyatomic molecule, even if it is only calculated along a single bond, is not independent of the rest of the molecular environment. Therefore, there is no reason to think that the limiting behaviour of a single XH bond should be transferable to an XH bond in a molecule (6), although it is possible that a functional form could be devised to suit the limiting behaviour of the remaining molecular

Received January 29, 1999.

fragment. Second, there are external parameters in the functional form, which must be fit to the observed intensities in a post hoc fashion. This approach compromises the predictive power of the intensity calculation. In the last few years, advances in computing power have made the calculation of ab initio DMFs possible, even for quite large molecules (e.g., He @ C_{60} (7)). Despite the fact that the limiting behaviour of these DMFs is often unphysical, especially for Hartree–Fock calculations, their accuracy near the equilibrium bond length is quite good, and the calculated intensities tend to be within a factor of two of the observed values. Another interesting effect that we have noticed is the fact that, although increasing the basis set size almost universally improves our calculated intensities, any improvement on moving beyond the Hartree–Fock theory tends to be limited to the fundamental transition (8, 9).

The purpose of this paper is twofold. First, we wish to examine the various methods of converting discrete, ab initio values of the DMF to a useful functional form via a fitting procedure of some kind. This study is in many ways an extension of a previous paper (6). Second, we want to have a better understanding of why inclusion of electron correlation in the DMF has little effect on our calculations of overtone intensities.

Theory and computational methods

We express the intensity of a vibrational transition in terms of the oscillator strength *f*, given by (10)

$$[1] \qquad f_{e\leftarrow g} = \frac{4\pi m_e}{3e^2 h}\nu_{eg}\left|\vec{\mu}_{eg}\right|^2 = 4.702\times10^{-7}(\text{cm D}^{-2})\tilde{\nu}_{eg}\left|\vec{\mu}_{eg}\right|^2$$

where $\tilde{\nu}_{eg}$ is the transition frequency given in cm^{-1} and $\vec{\mu}_{eg} = \langle e|\vec{\mu}|g\rangle$ is the transition dipole moment matrix element in Debye (= $3.335\,64 \times 10^{-30}$ C m).

Dipole moment functions

The DMF $\vec{\mu}$ for an XH_n group is modelled as a polynomial expansion in the internal bond displacement coordinates q_j

$$[2] \qquad \vec{\mu}(q_1, q_2, \ldots, q_n) = \sum_{i_1 i_2 \ldots i_n} \vec{\mu}_{i_1 i_2 \ldots i_n} q_1^{i_1} q_2^{i_2} \ldots q_n^{i_n}$$

where

$$[3] \qquad \vec{\mu}_{i_1 i_2 \ldots i_n} = \frac{1}{i_1!\, i_2! \ldots i_n!} \frac{\partial \sum_{j=1}^{n} i_j \vec{\mu}}{\partial q_1^{i_1} \partial q_2^{i_2} \ldots \partial q_n^{i_n}}$$

In this paper, we wish to separate the fundamental problem of modelling the DMF from the complications of applying the model to a specific situation. Therefore, we will consider only the single bond one-dimensional DMF. This simplifies eqs. [2] and [3] considerably:

$$[2a] \qquad \vec{\mu}(q) = \sum_i \vec{\mu}_i q^i$$

and

$$[3a] \qquad \vec{\mu}_i = \frac{1}{i!}\frac{\partial^i \vec{\mu}}{\partial q^i}$$

For the same reason, we will ignore the problem of Eckart embedding (8–11).

The coefficients $\vec{\mu}_i$ are determined from ab initio calculations of the dipole moment at various bond displacements using the Gaussian 94 program (12) and numerical calculation of the derivatives.

Morse oscillator wave functions and matrix elements

The wave functions and matrix elements for the Morse oscillator were first derived by Rosen (13). However, they are given in a simpler form by Sage (3). Refer to ref. 3 for the definitions of the various quantities in eqs. [5], [7], and [8].

In the HCAO approach, Morse oscillator wave functions are used in $\vec{\mu}_{eg} \equiv \langle e|\vec{\mu}|g\rangle \equiv \langle v|\vec{\mu}|0\rangle$. The one-dimensional Morse oscillator potential is expressed as

$$[4] \qquad V(q) = D_e(e^{-aq} - 1)^2$$

where D_e is the dissociation energy and *a* is the Morse oscillator parameter with units of inverse length. The derivation of the wave functions is given elsewhere (3). The result is

$$[5] \qquad |v\rangle = N_v e^{-x/2} x^{C-v-1/2} L_v^{2C-2v-1}(x)$$

The energy eigenvalues for the Morse oscillator relative to the bottom of the potential well are given by (5)

$$[6] \qquad E_v/hc = (v+1/2)\tilde{\omega} - (v+1/2)^2\tilde{\omega}x$$

where $\tilde{\omega}$ and $\tilde{\omega}x$ are the Morse oscillator frequency and anharmonicity, respectively.

In most of our previous work, we have generated the various matrix elements of Morse oscillators using numerical integration methods. However, in this paper, an analytical expression for one matrix element in particular is needed, $\langle v|A(1 - e^{\gamma aq})|0\rangle$, where *A* and γ are adjustable parameters. The reasons for this will become clear later. For the present, we will only state the result.

Rewriting the matrix element, we have

$$[7] \qquad \langle v|A|0\rangle - A\langle v|e^{\gamma aq}|0\rangle = -A(2C)^{\gamma}\langle v|x^{-\gamma}|0\rangle$$

$\langle v|x^{-\gamma}|0\rangle$ has been evaluated previously (3). Using this result, we can write

$$[8] \qquad \langle v|A(1-e^{\gamma aq})|0\rangle = -A(2C)^{\gamma} N_v N_0 \binom{\gamma}{v} \Gamma(2C-\gamma-v-1)$$

Modelling of the DMF

The fundamental problem of modelling the DMF is how to obtain the coefficients $\vec{\mu}_i$ defined in eqs. [2*a*] and [3*a*]. There are two obvious choices to consider. The first possibility is a multivariate least-squares regression on the calculated ab initio points. The second is a numerical procedure to obtain an interpolating polynomial from the calculated ab initio points.

Our test system is the CH bond in CHD_2F. We have optimized the geometry at the Hartree–Fock level of theory using the 6-311++G(2d,2p) basis set. The Morse parameters for this bond are taken from experiment ($\tilde{\omega}$ = 3079 ± 6 cm^{-1} and $\tilde{\omega}x$ = 53.9 ± 1.5 cm^{-1} (14, 15)).

Fig. 1. Comparison of different orders in the polynomial expansion for the least-squares regression model of the DMF.

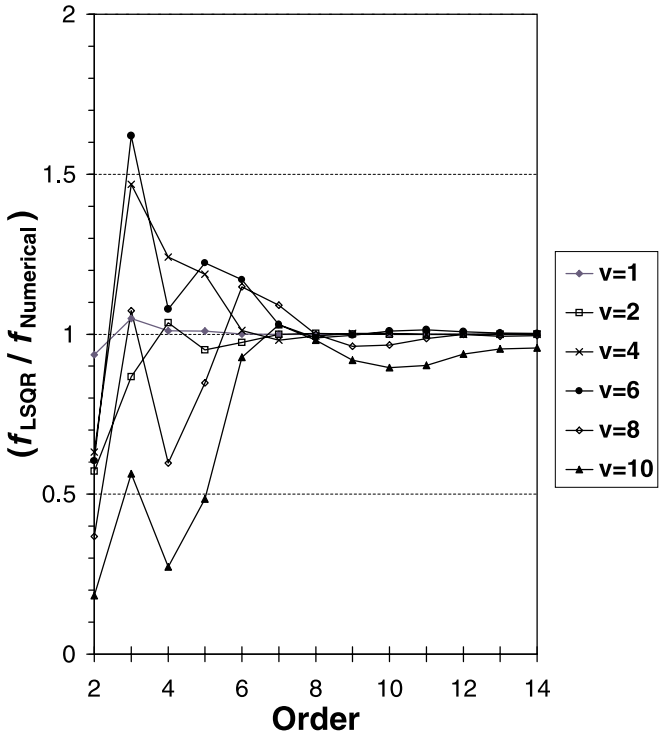

Fig. 2. Comparison of different orders in the polynomial expansion for the interpolating polynomial model of the DMF.

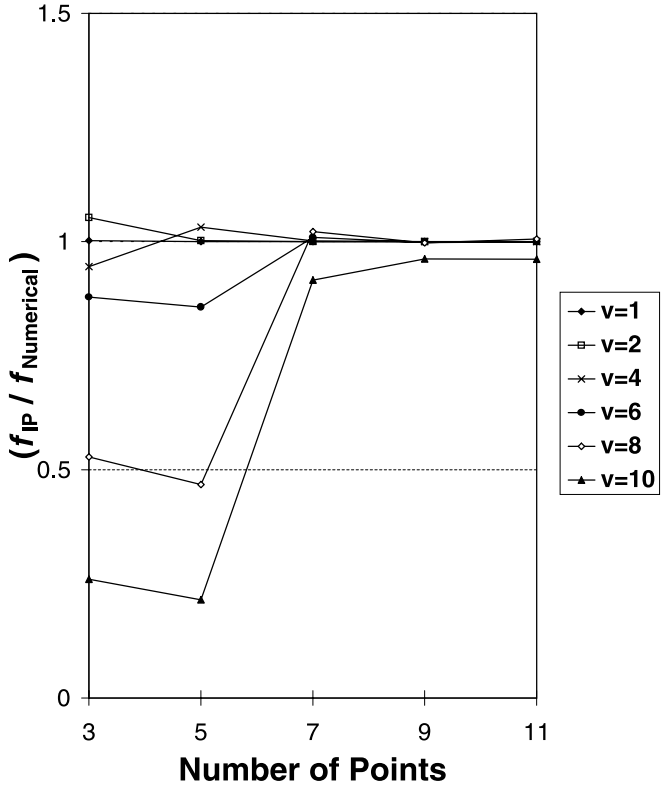


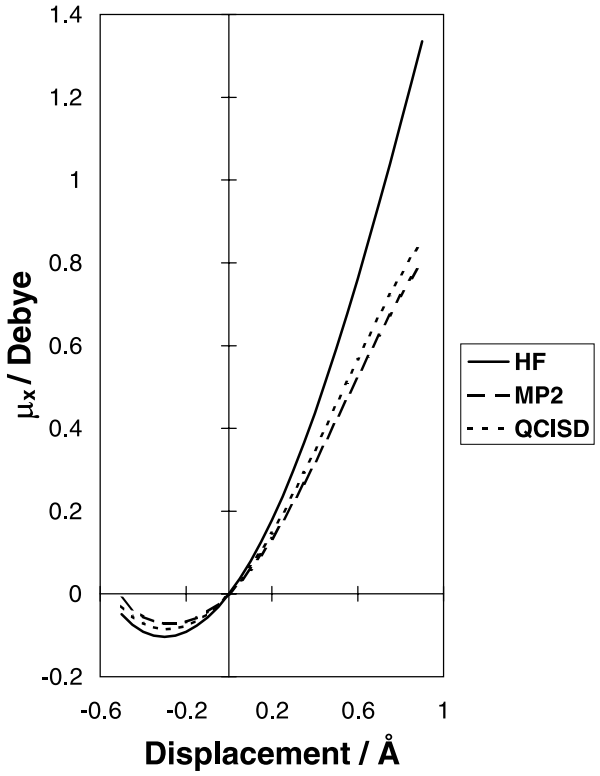
To make meaningful conclusions about the accuracy of the two methods, we need to compare them to an exact answer. An exact numerical result was obtained by numerically calculating $\vec{\mu}_{eg}$ directly from the ab initio results with decreasing step size until the calculation converged (Table 1). The integration converged to within 10% for a step size of 0.05 Å. However, we will compare our results to the smallest step size we considered (0.0125 Å). The numerical calculation was also used to determine the optimal integration range. We found that the range from $q = -0.5$ Å to $q = 0.9$ Å led to a relative error on the order of 10^{-4}, even for the worst case of the $0 \rightarrow 10$ transition.

Comparison of models

Before the two models could be compared, it was necessary to determine the optimal step size between data points. In the least-squares regression, a step size of 0.05 Å was sufficient. However, as in the numerical integration, we use the smallest step size (0.0125 Å). The range used in the regressions was the same as that used in the numerical integration. In the interpolating polynomial, since the data points must be equally spaced around $q = 0$, a smaller step size places limits on the range of points included in the model. A step size of 0.1 Å balances the need to sample a large enough range with the need for enough data points.

© 1999 NRC Canada

Fig. 3. Comparison of DMFs for CHD_2F, *x* component, for different levels of theory. All calculations used the 6-311++G(2d,2p) basis set.



Once the details of the calculations were decided upon, we could perform the calculations for different polynomial orders and compare them to the exact numerical result. Figures 1 and 2 show the effect of differing polynomial orders in the regression and the interpolating polynomial, respectively.

Conclusions

Both methods produce good results, provided that the order of the polynomial generated is sufficiently high. Results within a few percent of the exact numerical results are obtained for all values of *v* with a DMF polynomial of at least sixth order from the interpolating polynomial method, and at least seventh order for the least-squares regression. This indicates that our usual practice of using a fourth order DMF polynomial may not be sufficient for accurately calculating overtone intensities above $v = 5$ or 6.

The results for the interpolating polynomial method are very good, especially given that useful results can be obtained from only a few data points. Thus, for practical reasons the interpolating polynomial method is better than the least-squares method. However, one should beware of the problems brought about by modelling high-order interpolating polynomials. Nonrealistic, rapid oscillations can occur between data points as the high-order terms attempt to fit between the data points (16). Since the DMF is so smooth, this is for the most part avoided unless the step size is small. The fact that the tenth order results show little improvement over the eighth order results is likely due to the onset of these oscillations combined with the lesser impact of very high-order terms.

The influence of electron correlation

The insensitivity of overtone intensities to the inclusion of electron correlation is now well established, at least for molecules with no unsaturated bonds (8, 9). However, what is still lacking is an understanding of the source of this insensitivity. Figure 3 shows that there are significant differences between a DMF calculated using Hartree–Fock theory and a DMF that accounts for electron correlation in some form. However, this difference in the DMF appears to cancel out in the final intensity calculation.

In our previous work, we attempted to explain this insensitivity using the idea that the inner wall of the potential might be more important for the calculation of overtone intensities, combined with the fact that the DMF over this inner part tends to be much less sensitive to electron correlation effects (8, 17). However, an examination of the value of the transition dipole moment calculated only over the inner wall compared to the value calculated over the outer wall shows that they are very nearly equal. The overtone intensity arises due to minute differences between the inner wall integration and the outer wall integration, and hence, the inner wall cannot be considered to be the only important region.

What we will present is a new method of analysing the insensitivity to electron correlation, based on a different model of the influence of electron correlation on the DMF.

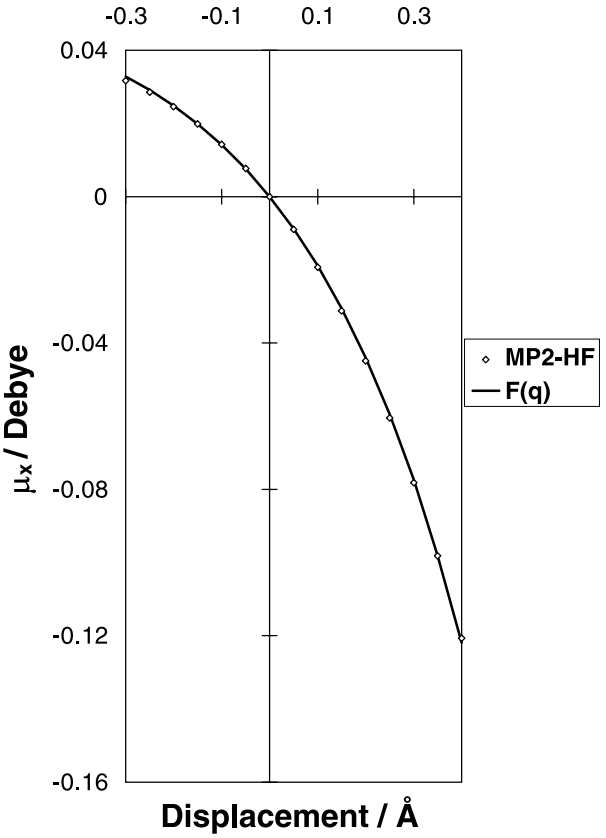
Modelling electron correlation in the DMF

Consider two different dipole moments calculated at the same value of the bond coordinate *q*, one obtained using Hartree–Fock theory and one obtained using a theory including electron correlation. The influence of electron correlation is simply the difference between the two values. We want to fit this difference to a model. The natural choice is a polynomial expansion. However, examination of the difference over the important range of *q* suggests that some form of exponential type function may be more suitable. We have chosen to fit to the function $F(q) = A(1 - e^{\gamma q q})$, but there may be other possibilities. This function is nonlinear in the fitting parameters *A* and γ, and therefore requires an iterative approach to the best-fit parameters. The statistical procedure generates a fit to *A* and γa. A value for γ is obtained with a value for *a* derived from Morse parameters in (8), except for CHF_3 where the Morse parameters are derived from the polyad positions in (18) and for HCl and HF where the Morse parameters are taken from (19). Figure 4 shows the difference between the Hartree–Fock and the electron correlation DMF, as well as the least-squares fit to the function $F(q)$, for CHD_2F. Table 2 shows the values of the parameters *A* and γ for several XH bonds.

The matrix element for $F(q)$ is evaluated in eqs. [7] and [8]. We can gain more insight by considering the ratio of this matrix element for the *v*th overtone to the matrix element for the fundamental transition. We call this ratio $R_{F(q)}(v)$, where the symbol *R* is used to indicate a ratio, with the subscript indicating the function being ratioed. From the

© 1999 NRC Canada

Fig. 4. Comparison of the difference between the HF/6-311++G(2d,2p) and MP2/6-311++G(2d,2p) calculated DMF (x component) of CHD_2F with the model function $F(q)$. The fit is over the range of q = –0.3 Å to q = 0.4 Å with a step size of 0.05 Å.



definitions of the gamma function and the binomial function (20), we can obtain

$$[9] \qquad R_{F(q)}(v) = \frac{\langle v|F(q)|0\rangle}{\langle 1|F(q)|0\rangle} = \sqrt{\left(\frac{4C(C-1)+2v(1-2C)+1}{(4C^2-8C+3)v!}\right)[(2C-2)\ldots(2C-v)]} \times \frac{(\gamma-1)\ldots(\gamma-v+1)}{(2C-\gamma-3)\ldots(2C-\gamma-v-1)}$$

The motivation for calculating this ratio is that we have an indication of how the influence of electron correlation changes with v. Furthermore, $R_{F(q)}(v)$ only depends on two parameters, the dimensionless anharmonicity $C = \omega/2\omega x$ and the fit parameter γ, which makes its general behaviour relatively simple to understand. Qualitatively, it is sufficient to study the factor appearing outside the root in eq. [9]. For all $v > 1$, integer values of $\gamma < v$ will correspond to roots of $R_{F(q)}(v)$. Thus, in the event that γ is close to an integer (which is the case for several of the examples in Table 2), the effects of electron correlation will be negligible for transitions to states with v greater than γ. Note that when $\gamma \approx 2$, the intensity of the first overtone (v = 2) can be affected by electron correlation, while higher overtones are unaffected.

To get more quantitative results, a criterion is needed for deciding how small $R_{F(q)}(v)$ must be in order for it to be considered negligible. An empirical rule is that the oscillator strength for the first overtone $f(2)$ tends to be a factor of 10^2 less than that of the fundamental transition $f(1)$, and falls by another order of magnitude for each subsequent overtone (21). If we call the ratio of oscillator strengths $R_{f_{\text{empirical}}}(v)$, we can write

$$[10] \qquad R_{f_{\text{empirical}}}(v) = \frac{f(v)}{f(1)} = \frac{1}{10^v}$$

We define a new parameter, ϵ, that corresponds to the fraction of oscillator strength due to electron correlation ($R_{f_{\text{EC}}}(v)$) that we are willing to allow. Thus, we write this criterion as

$$[11] \qquad R_{f_{\text{EC}}}(v) < \epsilon R_{f_{\text{empirical}}}(v) = \frac{\epsilon}{10^v}$$

Since the matrix element and the oscillator strength f are related by eq. [1], we can write

$$[12] \qquad R_{F(q)}(v) = \sqrt{\frac{\nu_{10}}{\nu_{v0}}}\sqrt{R_{f_{\text{EC}}}(v)} < \sqrt{\frac{\epsilon}{v}}\frac{1}{10^{v/2}}$$

where we have used as an approximation the fact that for a harmonic potential $\nu_{10}/\nu_{v0} = 1/v$.[2]

Figure 5 shows the area of parameter space where the criterion of eq. [12] is satisfied for several values of ϵ for $R_{F(q)}(3)$, i.e., for transitions to the v = 3 state. It also shows the parameters corresponding to some real XH bonds from Table 2.

Conclusions

Nearly all the XH bonds in Table 2 fit the form of $F(q)$ very closely upon the addition of electron correlation to the dipole moment calculation. There are a few exceptions, for example, the behaviour of the NH bond in NH_3 and the CH bond in CHF_3. In NH_3, the MP2 result in particular is atypical, while the QCISD result, when modelled using an interpolating polynomial, is virtually identical to the HF result except for the linear term. In CHF_3, on the other hand, the influence of electron correlation on the DMF is much less than in the rest of the species studied, which makes the lack of agreement with $F(q)$ that is present in this molecule unimportant.

Another interesting effect is the fact that the particular type of electron correlation has little effect on how well the bond fits the model. Even DFT methods seem to follow the

[2] Equation [12] should not be interpreted as a rigorous comparison of the relative contribution of electron correlation to the oscillator strength. Although we can model the DMF as $\vec{\mu} = \vec{\mu}_{\text{HF}} + F(q)$, and the matrix element as $\langle v|\mu|0\rangle = \langle v|\mu_{\text{HF}}|0\rangle + \langle v|F(q)|0\rangle$, once we calculate ratios, this easy comparison is lost. However, eq. [12] in combination with Fig. 5 still provides a useful estimate of the sensitivity of real XH bonds to the inclusion of electron correlation.

[a]The range of the fit in all cases is from q = –0.3 Å to q = 0.4 Å, with a step size of 0.05 Å.

[b]The 6-311++G(2d,2p) basis set is used in all cases, except for CHF_3 where the 6-311++G(d,p) basis set is used, and for HCl where the 6-311++G(3df,3pd) basis set is used.

[c]Uncertainties are one standard deviation.

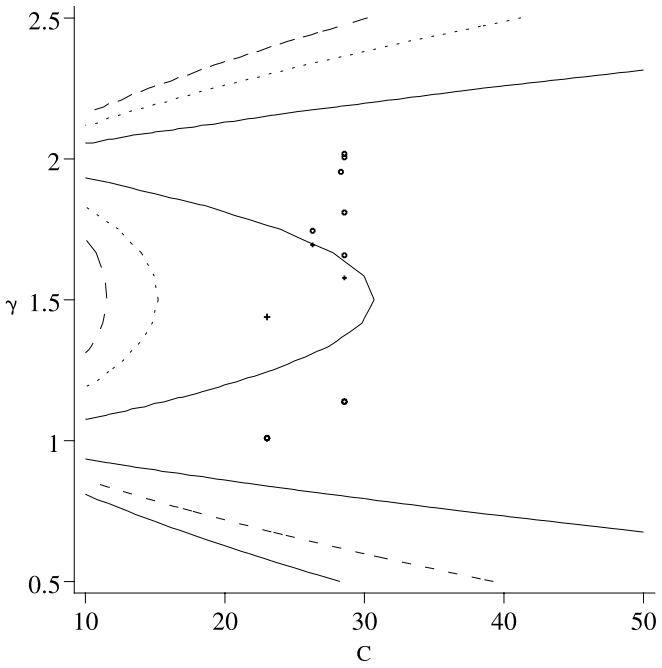
[d]γ is dimensionless.

[e]The coordinate system has the z axis along the CF bond and the CH bond in the xz plane.

[f]The z axis is along the bond being modelled.

[g]The coordinate system has the z axis along the C_3 axis, with the chosen NH bond in the xz plane.

Fig. 5. Contour plot of $R_{F(q)}(3)$ with contours satisfying eq. [12] for values of ϵ = 0.1 (---), 0.05 (····), and 0.01 (—). Points correspond to some of the fit parameters from Table 2, with circles within ϵ = 0.01 and crosses between ϵ = 0.01 and 0.05.



general trend, in agreement with recent results showing that DFT DMF calculations do not significantly alter overtone intensities calculated from a Hartree–Fock DMF. It appears that if one method of electron correlation can be fit to $F(q)$ for a particular bond, then other methods show the same behaviour.

If the bond under investigation does show a good fit to $F(q)$, the actual values of the fit parameters A and γ are relatively unimportant, especially for the higher overtones. A typical CH bond has a value of $\tilde{\omega}$ around 3000 cm^{-1}, and a value of $\tilde{\omega}x$ around 50 cm^{-1}. These values of the Morse parameters will give a value of C around 30, and other XH bonds will have dimensionless anharmonicities in this range as well. Figure 5 shows that a very wide range of values of γ will lead to a small contribution for $R_{F(q)}(3)$ at values of C of around 30. In the specific cases shown in Fig. 5, all points but three satisfy the criterion of ϵ = 0.01. The three remaining points are within the area satisfying ϵ = 0.05. From our calculations with eqs. [9] and [12], we have noted that this range widens even further for higher overtones, as expected.

Thus, a good approach would be to look at several types of XH bonds, and to determine how closely they agree with the model $F(q)$ in a small molecule upon the addition of electron correlation. When a similar type of bond occurs in a larger molecule, the result of the earlier calculation can be used to decide whether computational resources can be saved by ignoring electron correlation in the calculation on the larger molecule.

A further complication arises when considering molecules that contain unsaturated bonds, such as HCN. In our previous study (8), we noted that the influence of electron correlation was greater in HCN than in the other molecules under study. We believe that this difference arises due to the linearity of the DMF calculated at the Hartree–Fock level, which

© 1999 NRC Canada

leads to smaller intensities. Consequently, even though the influence of electron correlation on the DMF may be typical, the criterion of eq. [12] is no longer valid.

Despite the fact that we have obtained a reasonable mathematical framework for understanding the insensitivity of overtone intensities to the inclusion of electron correlation, we are still without a good physical explanation. A possible explanation could involve inspecting the electronic wave functions for the Hartree–Fock and the correlated calculations, and examining how they differ as q is changed. The fact that Hartree–Fock calculations tend to predict an ionic dissociation limit may be a factor.

As a referee has pointed out, it would be interesting to see the effect of extending the DMF calculation to a multiconfiguration approach (MCSCF). Normally, MCSCF becomes important for a reliable determination of the wave function when bond extensions are large. As we have noted above, the truly important region of the DMF for calculating intensities is determined by the overlap with the ground and excited state vibrational wave functions. Since the ground state wave function is centered at $q = 0$, the behaviour of the DMF at higher values of q is relatively unimportant. Nevertheless, it still may be worth investigating multi-reference effects to shed light on a physical picture for the observed insensitivity of the overtone intensities to the effects of electron correlation in the DMF.

Zinc-67 NMR study of tetrahedral and octahedral zinc sites with symmetrical oxygen, nitrogen, and sulfur ligands

Simon Sham and Gang Wu

Abstract: We report a ^{67}Zn nuclear magnetic resonance (NMR) study of compounds containing zinc ions coordinated by oxygen, nitrogen, and sulfur ligands. New information concerning ^{67}Zn nuclear quadrupole coupling constants (NQCC) and chemical shift was obtained from magic-angle spinning (MAS) spectra of solid compounds containing both natural abundance and enriched ^{67}Zn isotopes. Rapid ligand exchange processes of $[Zn(thiourea)_4]^{2+}$ in aqueous solutions were also observed.

Key words: ^{67}Zn NMR, nuclear quadrupolar coupling constant, ligand exchange.

Résumé : On a mesuré les spectres de résonance magnétique nucléaire (RMN) du ^{67}Zn de composés contenant des ions zinc coordinés à des ligands oxygénés, azotés et sulfurés. Grâce aux spectres obtenus par la technique de rotation à l'angle technique (magique) de composés solides contenant du ^{67}Zn en abondance naturelle ou enrichie, on a obtenu de nouvelles informations relatives aux constantes de couplage quadripolaire nucléaire (CCQN) et les déplacements chimiques du ^{67}Zn. On a aussi observé des processus d'échange rapide de ligand pour le $[Zn(thiourée)_4]^{2+}$.

Mots clés : RMN du ^{67}Zn, constante de couplage quadripolaire nucléaire, échange de ligands.

[Traduit par la Rédaction]

Introduction

Zinc is among the most important metal elements in biology and is an integral constituent of a large number of enzymes (1, 2). To study the catalytic or structural role of zinc ions in these enzymes, it is important to have a means of probing the nature of the zinc binding site. In the absence of X-ray crystallographic data, direct detection of diamagnetic d^{10} Zn^{2+} ions in biological systems is difficult because of the lack of a suitable spectroscopic probe. From an NMR perspective, ^{67}Zn (the only NMR-active zinc isotope) is among a number of potentially important but insensitive metal nuclei such as ^{43}Ca and ^{25}Mg. The insensitivity of ^{67}Zn NMR arises from the fact that ^{67}Zn is a quadrupolar nucleus (spin 5/2, $Q = 0.15 \times 10^{-28}$ m^{-2}) with low natural abundance (4.11%) and a small magnetogyric ratio ($\gamma = 1.6768 \times 10^7$ rad T^{-1} s^{-1}). Consequently, ^{67}Zn NMR experiments are remarkably difficult. In addition to the low intrinsic sensitivity, solution state ^{67}Zn NMR is further hampered by the fact that molecular tumbling motion always induces efficient ^{67}Zn quadrupole relaxation, resulting in short life times of Zeeman energy levels, which lead to broad NMR lines. To date, ^{67}Zn NMR of liquid samples has been limited to studies of either highly symmetric species or unsymmetrical complexes undergoing rapid exchange with large excessive $[Zn(H_2O)_6]^{2+}$ (3–6). Despite the biological relevance of zinc ions, the aforementioned practical difficulties have made ^{67}Zn NMR a nearly forgotten area. In the past, NMR studies of the metal binding sites in zinc-containing proteins have essentially relied on the utility of a surrogate nuclear probe, ^{113}Cd (7).

Solid-state NMR represents a useful approach to obtaining high-resolution NMR spectra for quadrupolar nuclei. In many aspects, it is more advantageous to study quadrupolar nuclei in the solid state than in solution. Since molecular motion is largely restricted in solids, quadrupole relaxation is not as efficient as in solution. As a result, the intrinsic resolution of solid-state NMR spectra is not limited by the lifetime of the quadrupole energy levels. However, solid-state ^{67}Zn NMR studies are still rare. Two solid-state ^{67}Zn NMR studies have appeared in the literature (8, 9); but the compounds under study are of cubic symmetry, so the electric field gradient (EFG) at the zinc site vanishes. The ^{67}Zn NMR study of $Zn(CH_3COO)_2 \cdot 2H_2O$ by Oldfield and coworkers (10) is the first report dealing with a noncubic zinc compound in the solid state. Later, Bastow and Stuart (11) obtained ^{67}Zn NMR spectra of both single-crystal and powdered ZnO samples. Recently, we reported some preliminary results of a natural abundance ^{67}Zn NMR study of zinc compounds with both tetrahedrally and octahedrally coordinated

oxygen ligands (12). Here we extend our solid-state ^{67}Zn NMR study to compounds where the zinc center is coordinated by either nitrogen or sulfur ligands. To the best of our knowledge, ^{67}Zn nuclear quadrupole coupling constants (NQCC) have not been determined for any noncubic zinc center coordinated by nitrogen and sulfur ligands.

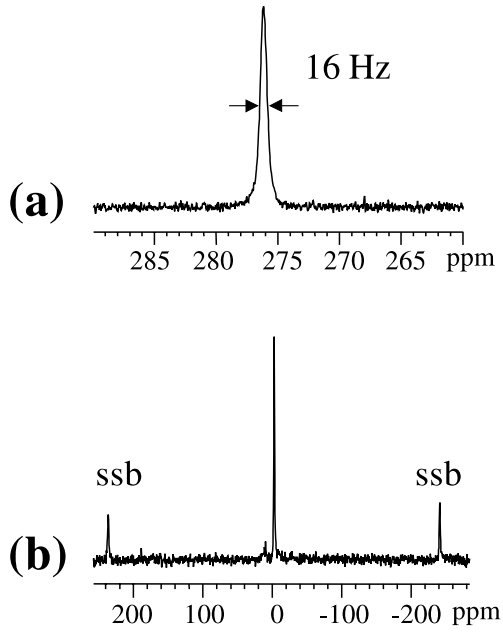
Experimental section

All solid-state NMR spectra were obtained on a Bruker Avance-400 NMR spectrometer operating at 25.036 MHz for ^{67}Zn nuclei. Solution NMR spectra were obtained on Bruker Avance-500 and Avance-400 spectrometers. All ^{67}Zn chemical shifts were referenced to an external sample of 1.0 M $Zn(NO_3)_2$ aqueous solution (δ_{iso} = 0 ppm). Magic-angle spinning (MAS) ^{67}Zn NMR experiments were performed using a probe purchased from Doty Scientific Inc. (Columbia, S.C.). Powder samples were packed into zirconium oxide rotors (5 mm o.d.). Typical sample spinning speeds were between 7 and 9 kHz. A pulse width of 5 μs was used, and the recycle time was between 1 and 10 s. Samples of ZnSe and $Zn(CH_3COO)_2{\cdot}2H_2O$ were obtained from commercial sources and used without further purification. Anhydrous $Zn(CH_3COO)_2$ was obtained by heating the corresponding hydrate sample in oven for 2 days at 80°C. ZnO (88% ^{67}Zn-enriched) was purchased from Trace Science International (Toronto, Ont.). Crystals of $^{67}Zn(ClO_4)_2{\cdot}6H_2O$ were formed by dissolving 25 mg of ^{67}ZnO in 3.6 mL of 0.25 M $HClO_4$. A solid sample of tetrakis(imidazole)zinc(II) perchlorate, $Zn[ImH]_4(ClO_4)_2$ (ImH = imidazole), was then obtained by slow evaporation of a 1:4 molar ratio mixture of $^{67}Zn(ClO_4)_2{\cdot}6H_2O$ and imidazole (81 mg) from 1 mL of 95% ethanol. An aqueous solution of $^{67}Zn(NO_3)_2$ was prepared by dissolving 24 mg of ^{67}ZnO in 1.1 mL of 0.5 M HNO_3. To this solution, 93 mg of thiourea, $SC(NH_2)_2$, in 1 mL of distilled H_2O was added. Crystals of tetrakis(thiourea)zinc(II) nitrate, $^{67}Zn[SC(NH_2)_2]_4(NO_3)_2$, were then formed by slow evaporation of the solvent. For concentration-dependent experiments, the concentration of $[Zn]^{2+}$ was kept constant at 0.65 mM, and an appropriate amount of thiourea was added to the solution to form a specific $[Zn]^{2+}$ to thiourea concentration ratio. Solution ^{67}Zn NMR experiments were carried out at room temperature (298.5 K), using a pulse width of 55.0 μs and a recycle delay of 100 ms. Typically, 2000–3000 scans were collected. Prior to Fourier Transformation (FT), FIDs were left-shifted to remove data points due to probe ring-down, followed by 200–250 Hz exponential line broadening. Simulations of solid-state NMR spectra were performed on a Pentium 200 personal computer using the SOLIDS program package kindly provided by Dr. Klaus Eichele and Professor Rod Wasylishen (Dalhousie University, Halifax, N.S.).

Results and discussion

Figure 1 shows ^{67}Zn MAS spectra of solid ZnSe and $Zn(ClO_4)_2{\cdot}6H_2O$ obtained at 9.4 T. The cubic structure of ZnSe (13) yields a negligible ^{67}Zn NQCC at the zinc center, and therefore, the MAS spectrum of ZnSe shows a sharp isotropic peak centered at 276 ppm with a full width at the half-height (FWHH) of 16 Hz. Interestingly, this value is even smaller than that observed for the standard reference sample, $Zn(NO_3)_2$ (aq), which has a line width of 80 Hz. In an early study, Haller et al. (8) reported a 50 Hz line width for the ^{67}Zn NMR signal from a stationary ZnSe sample. Close inspection of the spectrum presented in Fig. 1(*a*) showed no indication of any indirect spin–spin coupling (J) between ^{67}Zn and ^{77}Se (spin 1/2, natural abundance = 7.58%) nuclei, suggesting that $^1J(^{67}Zn, ^{77}Se)$ must be smaller than the observed line width.

Fig. 1. ^{67}Zn MAS spectra of (*a*) natural abundance ZnSe (number of scans, 360; recycle delay, 1 s; spinning rate, 5.0 kHz) and (*b*) ^{67}Zn-enriched $Zn(ClO_4)_2{\cdot}6H_2O$ (number of scans, 128; recycle delay, 10 s; spinning rate, 6.0 kHz). Spinning sidebands are marked as "ssb."



The isotropic ^{67}Zn chemical shift observed for solid $^{67}Zn(ClO_4)_2{\cdot}6H_2O$ is –3 ppm, which suggests a similar zinc environment in both solid and solution state. The crystal structure of $Zn(ClO_4)_2{\cdot}6H_2O$ at room temperature (space group $P6_3mc$) (14) reveals that the zinc ion is coordinated by six water molecules with a nearly perfect O_h site symmetry. The Zn—O distances are 2.123 and 2.152 Å. The O-Zn-O angles are very close to those expected for a regular octahedron, e.g., 86.3°, 179.0°, 94.4°, and 84.9°. From the line width observed in the ^{67}Zn MAS spectrum, it is estimated that e^2qQ/h is less than 0.2 MHz.

Figure 2(*a*) shows the natural abundance ^{67}Zn MAS spectrum of $Zn(CH_3COO)_2$. The spectrum exhibits a typical line shape arising from the second-order quadrupolar interaction (15). The isotropic ^{67}Zn chemical shift of $Zn(CH_3COO)_2$ is found to be 245 ppm, which is similar to that found for ZnO (11, 12) where the zinc atom is tetrahedrally bonded to four oxygen atoms. No solution ^{67}Zn NMR data are available in the literature for zinc centers coordinated to four oxygen ligands. The crystal structure of $Zn(CH_3COO)_2$ (space group *Fdd*2) indicates that the zinc ion is in a slightly distorted tetrahedral environment (16). The Zn—O bond length varies from 1.914 to 1.955 Å, and the O-Zn-O angle ranges from

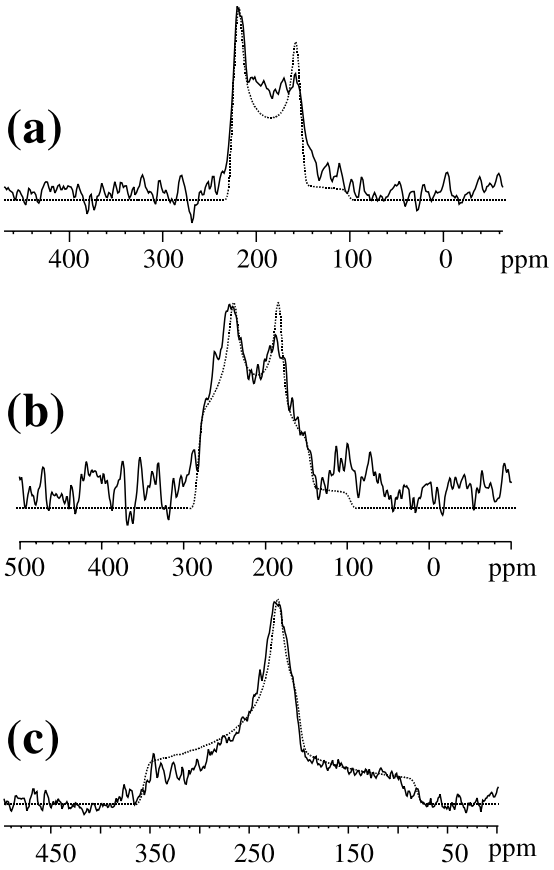
Fig. 2. Experimental (solid lines) and calculated (broken lines) ^{67}Zn MAS spectra of (*a*) natural abundance $Zn(CH_3COO)_2$ (number of scans, 32 225; spinning rate, 8.5 kHz; recycle delay, 1 s), (*b*) ^{67}Zn-enriched $Zn(imidazole)_4(ClO_4)_2$ (number of scans, 16 774; recycle time, 1 s; spinning rate, 8.1 kHz), and (*c*) ^{67}Zn-enriched $Zn(thiourea)_4(NO_3)_2$ (number of scans, 19 188, recycle time, 2 s; spinning rate, 9.1 kHz).



102.2° to 115.9°. Analysis of the MAS line shape shown in Fig. 2(*a*) yields that e^2qQ/h = 2.42 MHz and η = 0.1.

To explore the sensitivity enhancement by isotopic enrichment, we prepared two ^{67}Zn-enriched compounds: $^{67}Zn[ImH]_4(ClO_4)_2$ and $^{67}Zn[SC(NH_2)_2]_4(NO_3)_2$. The enrichment level is about 88% for both compounds. Figures 2(*b*) and (*c*) show the ^{67}Zn MAS spectra of the two ^{67}Zn-labeled compounds. For $^{67}Zn(ImH)_4(ClO_4)_2$, the isotropic ^{67}Zn chemical shift is 291 ppm, which is comparable to the value of 264 ppm observed in acetone solution. The ^{67}Zn chemical-shift value for zinc ions coordinated by four nitrogen ligands is also in agreement with that observed in $[Zn(NH_3)_4]^{2+}$ from solution ^{67}Zn NMR studies (3). However, both the line width and peak position of the solution state ^{67}Zn spectrum of $^{67}Zn(ImH)_4(ClO_4)_2$ were found to be solvent dependent. For example, the ^{67}Zn NMR spectrum of $Zn(ImH)_4(ClO_4)_2$ in methanol exhibits a peak at 280 ppm with a much larger line width, 2500 Hz, than that found in acetone, 500 Hz. Furthermore, we did not observe any ^{67}Zn NMR signal from an aqueous solution of $Zn(ImH)_4(ClO_4)_2$, presumably due to rapid ligand exchange (vide infra). The crystal structure of $Zn(ImH)_4(ClO_4)_2$ (space group *C*2/*c*) shows that the zinc ion lies on a crystallographic C_2 axis and is tetrahedrally coordinated by four nitrogen atoms from the imidazole molecules (17). The two independent Zn—N(imidazole) bond lengths are nearly identical, 1.997 and 2.001 Å. The N-Zn-N angles range from 105.3° to 113.3°. Analysis of the ^{67}Zn MAS line shape shown in Fig. 2(*b*) also yields that e^2qQ/h = 2.80 MHz and η = 0.4. To our knowledge, $Zn(ImH)_4(ClO_4)_2$ represents the only example where the ^{67}Zn NQCC for a ZnN_4 coordination environment is determined.

Figure 2(*c*) shows the ^{67}Zn MAS spectrum of $^{67}Zn[SC(NH_2)_2]_4(NO_3)_2$. The isotropic ^{67}Zn chemical shift is 359 ppm, which is in agreement with those reported for zinc sites coordinated by four sulfur atoms (3). From analysis of the ^{67}Zn MAS spectrum, we obtained that the ^{67}Zn NQCC is 3.15 MHz with η = 1. The crystal structure of $Zn[SC(NH_2)_2]_4(NO_3)_2$ (space group *Pnaa*) indicates that the zinc ions are coordinated by four sulfur atoms from the thiourea ligands (18). The two Zn—S distances are 2.324 and 2.361 Å, which are considerably longer than the Zn—N distances in the zinc–imidazole complex. The S-Zn-S angle between the two longer Zn—S bonds is 100.0°, and the angle between the two shorter Zn—S bonds is 121.5°, both of which deviate considerably from the perfect tetrahedral angle. It is also noted that the ^{67}Zn EFG tensors in $Zn(ImH)_4(ClO_4)_2$ and $Zn[SC(NH_2)_2]_4(NO_3)_2$ exhibit very different asymmetry parameters. This observation is somewhat surprising, since the two compounds have a similar tetrahedral arrangement at the zinc center.

Compared with the ^{67}Zn MAS spectrum of natural abundance $Zn(CH_3COO)_2$, as shown in Fig. 2(*a*), the overall sensitivity enhancement in the ^{67}Zn MAS spectra of the two ^{67}Zn-enriched compounds does not appear as dramatic as expected from the enrichment level, i.e., a factor of 20. Although solution ^{67}Zn NMR did prove that the ^{67}Zn enrichment procedure was successful, several other factors may contribute to the apparent lack of full signal enhancement in the ^{67}Zn spectra of $^{67}Zn(ImH)_4(ClO_4)_2$ and $^{67}Zn[SC(NH_2)_2]_4(NO_3)_2$. First, the molecular size of $Zn(ImH)_4(ClO_4)_2$ (FW = 536) and $Zn[SC(NH_2)_2]_4(NO_3)_2$ (FW = 493) is larger than that of $Zn(CH_3OO)_2$ (FW = 183). Second, in the case of $^{67}Zn(ImH)_4(ClO_4)_2$, a small sample of the enriched compound (ca. 50 mg) was used, which is much less than ca. 150 mg used for the natural abundance $Zn(CH_3COO)_2$ sample. Third, the ^{67}Zn spin-lattice relaxation time (T_1) is much longer in $^{67}Zn(ImH)_4(ClO_4)_2$ and $^{67}Zn[SC(NH_2)_2]_4(NO_3)_2$ than in $Zn(CH_3COO)_2$. By performing ^{67}Zn MAS experiments with different recycle delays, we were able to provide an estimate for ^{67}Zn T_1 in $^{67}Zn[SC(NH_2)_2](NO_3)_2$, $T_1 \approx 2$ s. In $Zn(CH_3COO)_2$, however, the T_1 was estimated to be less than 0.5 s (12). After considering all these factors, the sensitivity enhancement in Figs. 2(*b*) and (*c*) seems reasonable. It is worth pointing out that our attempts to record ^{67}Zn MAS spectra for natural abundance samples of $Zn(ImH)_4(ClO_4)_2$ and $Zn[SC(NH_2)_2]_4(NO_3)_2$ were unsuccessful, presumably due to the long T_1 values.

Similar to the case of the zinc imidazole complex, we also observed rapid ligand exchange in the aqueous solution of $Zn[SC(NH_2)_2]_4(NO_3)_2$. Figure 3 shows the result of the concentration study to examine the rapid ligand exchange process in $Zn[SC(NH_2)_2]_4(NO_3)_2$. When the concentration of thiourea is low, the ^{67}Zn chemical shift is close to 0 ppm, in-

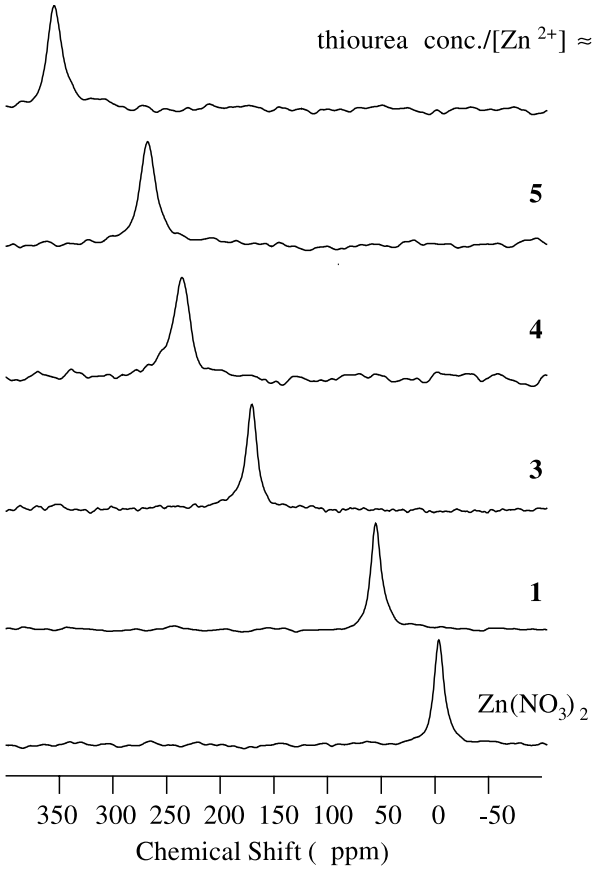
Fig. 3. ^{67}Zn NMR spectra of aqueous solutions of $Zn(NO_3)_2$ and thiourea at different thiourea conc./$[Zn^{2+}]$ ratios. The pH value of the solution varies from 4.20 (1:1) to 3.78 (1:9).



dicating the existence of $[Zn(H_2O)_6]^{2+}$ species. As the concentration of the thiourea ligand is increased, the ^{67}Zn NMR signal is shifted toward higher frequencies. At the highest metal–ligand ratio used in this study, thiourea conc./$[Zn^{2+}] \approx 9$, the ^{67}Zn chemical shift of 355 ppm for the solution sample is practically identical to that observed in the solid state, 359 ppm.

To examine possible trends in solid-state ^{67}Zn NMR parameters, we summarize in Table 1 the presently available data in the literature for zinc compounds. It is noted that the ^{67}Zn NQCC has also been determined in zinc metal, e^2qQ/h = 11.983 MHz (19–21); however, it is reasonable not to compare this value with those obtained for zinc compounds. With this exception, the largest ^{67}Zn NQCC found in zinc compounds is that in $Zn(CH_3COO)_2\cdot 2H_2O$, e^2qQ/h = 5.3 MHz (10). The crystal structure of $Zn(CH_3COO)_2\cdot 2H_2O$ (22) indicates that the zinc ion is coordinated by six oxygen atoms in a very distorted octahedral environment. Four of the six oxygen atoms are from the acetate groups. The other two oxygen atoms are those from the water molecules. Whereas, the Zn—O bond length varies slightly from 2.14 to 2.18 Å, a significant distortion from perfect O_h symmetry exists in the O-Zn-O bond angles. For example, large distortions are found when the two mutually *trans* oxygen atoms are due to the acetate and water, respectively, i.e., O(Ac)-Zn-O(W) = 152°, or when the two *cis* oxygen atoms are from the same acetate group, O(Ac)-Zn-O(Ac) = 61°. The distortion is, however, smaller when the two *cis* oxygen atoms arise from the acetate and water, respectively, i.e., O(Ac)-Zn-O(W) = 108°. To study the possible correlation between ^{67}Zn NQCC and molecular structure, we have used a parameter called the mean deviation of bond angles as a measure of the degree of deviation of the zinc site of interest from a perfect symmetry, T_d or O_h. The mean deviation of bond angles can be defined for a tetrahedral site as

$$[1] \qquad \Delta(T_d) = \frac{1}{4}\sum_i \left| \theta_i - 109.5° \right|$$

where θ_i is the ith bond angle across the zinc center. In a similar fashion, one can define a mean deviation of bond angles for an octahedral site using 90° and 180° as perfect angles. In Fig. 4, ^{67}Zn NQCC is plotted against the mean deviation of bond angles as defined in eq. [1] for presently available ^{67}Zn NMR data. As seen in Fig. 4, the octahedral

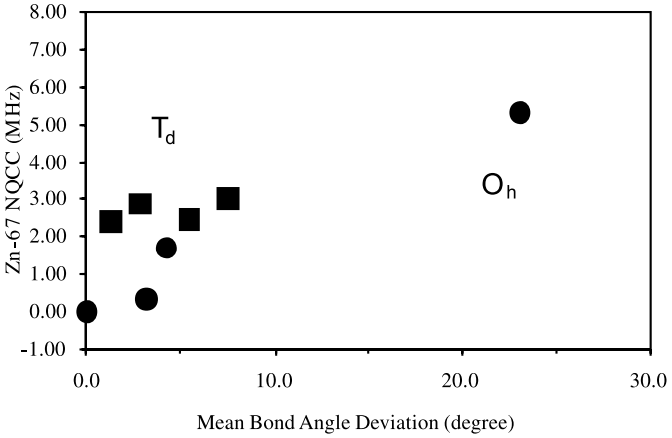
Fig. 4. Plot of ^{67}Zn NQCC versus mean bond angle deviation from perfect T_d (■) and O_h (●) symmetry.



compounds appear to show a correlation between the magnitude of the ^{67}Zn NQCC and the degree of deviation from the O_h symmetry, whereas the tetrahedral compounds are insensitive to the mean deviation of bond angles, at least within the presently available data. It is also somewhat surprising that a very small distortion from the perfect T_d symmetry in ZnO (O-Zn-O: 108.14° and 110.77°) (23) results in a reasonably large ^{67}Zn NQCC, 2.40 MHz. However, $ZnSO_4 \cdot 7H_2O$ exhibits larger distortion (O-Zn-O: 80.6°, 97.5°, 172.3°) than ZnO but has a smaller ^{67}Zn NQCC, 1.7 MHz. It is clear that using the mean deviation of bond angles alone to explain the results may be oversimplified because the model does not consider the nature of the Zn—ligand bond. For the octahedral compounds examined in this study, the zinc ions are coordinated to six oxygen atoms with similar bond lengths, 2.09 ± 0.10 Å. Thus, it is perhaps not surprising that a reasonable correlation is observed among octahedral compounds. However, the Zn—ligand distance for the tetrahedral compounds varies from 1.914 to 2.000 to 2.361 Å for Zn—O (acetate), Zn—S (thiourea), and Zn—N (imidazole), respectively. This discrepancy may be responsible for the lack of correlation between ^{67}Zn NMR parameters and molecular structure among tetrahedral compounds. Nevertheless, more investigations are definitely required before one can draw any conclusion about the correlation between ^{67}Zn NMR parameters and molecular structure.

Based on the presently available solid-state ^{67}Zn NMR data, it seems that the value of 5.3 MHz found in $Zn(CH_3COO)_2 \cdot 2H_2O$ may represent an upper limit of the ^{67}Zn NQCC for zinc ions coordinated octahedrally by *symmetrical* ligands but a lower limit for octahedral compounds with *unsymmetrical* ligands. The zinc binding geometry in the zinc–insulin complex belongs to the latter case, since each of the two zinc sites in the two-zinc insulin hexamer is coordinated by three imidazolyl nitrogen atoms and three water oxygen atoms (24). In light of the new solid-state ^{67}Zn NMR data, it appears that the value of 1.86 MHz suggested for the ^{67}Zn NQCC in insulin by Shimizu and Hatano (25) may be grossly underestimated.

Conclusions

In this study, we have focused on the solid-state ^{67}Zn NMR spectra of tetrahedral and octahedral zinc centers that are symmetrically coordinated by water, acetate, imidazole, and thiourea ligands. It is well known that the active zinc sites in metalloproteins usually contain *unsymmetrical* ligands. Therefore, it would be desirable, although technically challenging, to extend these solid-state ^{67}Zn NMR studies to some model compounds where the zinc center resembles those in zinc-containing proteins. Unfortunately, to this date, our efforts in recording solid-state ^{67}Zn NMR signals for unsymmetrical zinc sites have been unsuccessful, presumably due to the large quadrupole coupling constants associated with those sites. It should be noted that the solid-state ^{67}Zn NMR results reported in this study were obtained at a relatively low magnetic field, 9.4 T. Since the second-order quadrupolar broadening is inversely proportional to the applied magnetic field strength, the availability of very high-field instrument (18.8 T or greater) holds the promise of making unsymmetrical coordination zinc sites accessible.[2]

Solvent dependence of rotational energetics and formyl-proton long-range spin–spin coupling behavior of 2,6-dichloro- and 2,6-dinitrobenzaldehydes using dipolar couplings and temperature dependence of long-range couplings

Juhani Lounila, Yrjö Hiltunen, Kari Tuppurainen, Anja Pulkkinen, and Reino Laatikainen

Abstract: The formyl rotational energetics, solvent effects on the energetics and formyl-proton spin–spin coupling behavior of 2,6-dichlorobenzaldehyde were studied by using dipolar couplings analysis and the temperature dependence of the spin–spin couplings. The general form of the rotational potential was taken from molecular mechanics and the conjugative $\sin^2 \Theta$-type component (where Θ is the formyl-ring dihedral angle) was then optimized using the dipolar couplings obtained by analyzing ^{1}H NMR and ^{13}C proton satellite spectra in a liquid crystal solvent. The optimization based on the dipolar couplings gave the following rotational free energy potential: $V(\Theta) = 4.5 \cos^6 \Theta + 10.7\ (\pm 2.0) \sin^2 \Theta$, in kJ/mol. The analysis based on the temperature dependence of ^6J data allowed estimation of solvent effects on the potential. For example, the potentials in acetone and in acetonitrile differ by a $1.0 \sin^2 2\Theta$ (in kJ/mol). The chloroform solvent effect can be described by term of $-1.0 \cos^6 \Theta$. When the formyl-proton six-bond coupling data was fit, assuming it obeyed the expression $^6J(\Theta) = {}^6J_{90} \sin^2 \Theta + {}^6J_0$ and assuming $^6J_0 = 0.015$ Hz, the analysis yielded $^6J_{90}$ of –0.48 (± 0.03) Hz. The scalar coupling temperature dependence method was applied also to the conformational analysis of 2,6-dinitrobenzaldehyde.

Key words: spin–spin coupling, dipolar coupling, solvent effect, rotational barrier, benzaldehyde.

Résumé : Faisant appel à une analyse du couplage dipolaire et de l'influence de la température sur les constantes de couplage, on a étudié les énergies associées à la rotation du formyle, les effets de solvant sur ces énergies ainsi que le comportement de couplage spin–spin formyle-proton du 2,6-dichlorobenzaldéhyde. La forme générale du potentiel de rotation a été tirée de calculs de mécanique moléculaire et on a ensuite optimisé la composante de conjugaison de type $\sin^2 \Theta$ (dans lequel Θ est l'angle dièdre entre le formyle et le noyau) à l'aide des couplages dipolaires obtenus en analysant les spectres RMN du ^{1}H et les satellites du proton dans les spectres du ^{13}C mesurés dans un solvant cristal liquide. L'optimisation réalisée en se basant sur les couplages dipolaires conduit au potentiel d'énergie libre de rotation suivant: $V(\Theta) = 4{,}5 \cos^6 \Theta + 10{,}7\ (\pm 2{,}0) \sin^2 \Theta$, en kJ/mol. L'analyse résultant de la variation des valeurs de ^6J en fonction de la température permet d'évaluer les effets de solvant sur le potentiel. Par exemple, les potentiels dans l'acétone et dans l'acétonitrile diffèrent par $1{,}0 \sin^2 2\Theta$ (en kJ/mol). L'effet de solvant du chloroforme peut être décrit en termes de $-1{,}0 \cos^6 \Theta$. Quand on a ajusté les données de couplage formyle-proton à travers six liaisons en faisant l'hypothèse que $^6J(\Theta) = {}^6J_{90} \sin^2 \Theta + {}^6J_0$ et $^6J_0 = 0{,}015$ Hz, l'analyse conduit à une valeur de $^6J_{90}$ de –0,48 (± 0,03) Hz. On a aussi appliqué la méthode de la variation du couplage scalaire en fonction de la température à l'analyse conformationnelle du 2,6-dinitrobenzaldéhyde.

Mots clés : couplage spin–spin, couplage dipolaire, effet de solvant, barrière à la rotation, benzaldéhyde.

Introduction

The experimental characterization of rotational energetics in solution, and especially a determination of the solvent dependence of the energetics, are difficult tasks although there are a number of methods available, the most common being the infrared, Raman and dynamic NMR spectroscopies (1, 2). The former methods suffer from experimental problems, DNMR suits only for relatively large rotational barriers, and all of them produce only little information about the shape of the barrier. The DNMR barrier is usually interpreted by using two parameters, $\Delta H^{\#}$ and $\Delta S^{\#}$, although the relationship between them and the shape of barrier is not straightforward (3). The problems of the optical spectroscopies have been reviewed by Jorgensen (2). For these reasons the studies on solvent effects on low rotational barrier are rather scarce, if the studies on systems containing nitrogen or sulphur are ignored. In aromatic systems, also the *J*-method, the conformational dependence of spin–spin couplings of benzylic protons, can also be used for very low barriers (4). The *J*-method has been developed and widely applied by Ted Schaefer for estimation of rotational energetics in aromatics. In this paper we show that significant information about the formyl-ring torsion barrier in 2,6-dichlorobenzaldehyde (26DCBA) and 2,6-dinitrobenzaldehyde (26DNBA) can be derived using dipolar couplings obtained in a liquid crystal solvent and by examining the temperature dependence of the formyl proton long-range couplings in various isotropic solvents. The theory and applications of the dipolar coupling method has been previously discussed by Emsley (5).

It has been found previously, for example, that a change of solvent from CS_2 to DMSO stabilizes the CF-off-planar conformation of benzyl fluoride by 2 kJ/mol (6), a value typically found by other means (2). An opposed change is indicated by the ^6J data for benzyl alcohol (7) while the data for ethylbenzene imply practically no solvents effects (8). Medium effect analyses based on the *J*-method have been carried out also for some other alkoxy benzenes (9), benzal fluoride (10), 3,5-dichlorobenzyl fluoride (11), and fluorobenzyl fluorides (12). The solvent effect on the relatively low barrier of 2,6-fluorobenzaldehydes was studied by DNMR (13). The results suggest that the electrostatic interactions play a role, but not straightforward, in the phenomenon. In general, a polar solvent favors conformations of larger dipole or higher moments although the packing effects may also be significant when the barrier is flat (2), as it is in our case. For 26DCBA, another electrostatic mechanism may also operate: the barrier contains a significant contribution from the chlorine–oxygen Coulombic repulsion. This contribution depends on the medium around the molecules and should be reduced in a medium of higher dielectric constant. We have used the explanation for the behavior of some methylene malonaldehydes (14), and it has also been examined theoretically (15). The solvent may operate also by entropic mechanism (16).

The *J*-method can be used only if the conformational behavior of the coupling is known. This is the case with CH_2-type protons, but not with a formyl proton. The problem can be solved and also more information about the energetics is obtained by using the temperature dependence of the spin–spin couplings, "the temperature dependent *J*-method" (17). In our case, the determination of the conformational behavior of the formyl proton in benzaldehydes offers a challenge, because being usually very small, the couplings are difficult to determine, and on the other hand, the formyl proton spin–spin coupling behavior differs interestingly from that of the methyl, methylene, and vinyl protons (18–20): it is known that $^6J_{90}$ in the well-known expression for benzylic six-bond coupling (4)

$$[1] \qquad {}^6J(\Theta) = {}^6J_{90} \sin^2 \Theta + {}^6J_0$$

is abnormally small, maybe –0.30 to –0.500 Hz (19, 20), whereas it is ca. –1.2 Hz for toluene (21). Θ is the dihedral angle between the ring and the benzylic proton. It has been also shown that the value of $^6J_0$ is, unexpectedly, positive for some *meta*-substituted benzaldehydes (22) and, probably, for 2-chlorobenzaldehyde (19), while for other CH protons it can be assumed to be zero or negative. The estimation of $^6J_{90}$ is difficult because the conjugation holds the formyl group tightly in the ring plane, and the group is not easily twisted out of plane even by large substituents. The largest known values have been reported for 2,6-dinitrobenzaldehyde, –0.230 Hz, and 2,6-dichlorobenzaldehyde, –0.156 Hz (23). Because the potential is a sum of opposing conjugational and steric (including Coulombic) terms and because the Coulombic terms depend also on the solvent, it is also difficult to predict $\langle \sin^2 \Theta \rangle$ (= the expectation value of $\sin^2 \Theta$) with theoretical methods. In 26DNBA there are three rotors and a reliable estimation of $\langle \sin^2 \Theta \rangle$ is theoretically even more difficult.

The low torsion barrier of 26DCBA offers a good probe for study of the solvents effects on the torsion barrier. In this work, the dipolar coupling method and the "temperature dependent *J*-method" were used to study the formyl torsion energetics and the barrier shape of 26DCBA in various isotropic solvents. An estimate of $^6J_{90}$ was also obtained.

Experimental

The samples for isotropic spectra were prepared as ca. 10 wt.%/vol.%, degassed and measured in a routine way (19). The spectra were measured on a Bruker AM 400WB spectrometer. The temperatures were determined by the methanol method (24).

The liquid crystal solvent was a mixture composed of 42 wt.% Phase IV (eutectic mixture of *p*-methoxy-*p*′-*n*-butylazoxybenzenes by Merck) and 58 wt.% ZLI 1167 (eutectic mixture of 4-*trans* cyano, 4′-*trans* alkyl bicyclohexyls (alkyl = propyl, pentyl, and heptyl) by Merck). The liquid crystal sample contained 5 wt.% of 2,6-dichlorobenzaldehyde. The ^1H and ^{13}C NMR spectra were recorded at 399.8 and 100.5 MHz, respectively, on a JNM-GX400 spectrometer (at about 300 K) from a coaxial double tube (outer diameter 5 mm) with $CDCl_3$ as a locking substance in the interwall space. The indirect spin–spin coupling constants, J_{ij}, of 26DCBA were measured in the isotropic phase of the Phase IV – ZLI 1167 mixture (at about 350 K).

A rotation barrier calculation with full geometry optimisations at the HF/6-31G* level was done using the Gaussian98 program (25) running on IBM RISC/6000 320 workstation.

[a]The numbers in parentheses give the 90% confidence limits in the last significant numbers of the spectral parameters, arising from the random errors. The total errors are somewhat larger, as they contain also systematic contributions arising from the uncertainties in the fixed values of the *J*-couplings.

Spectral analysis

The numbering of the nuclei of 26DCBA is shown in Fig. 1.

The spectra measured in the isotropic and nematic phases of the Phase IV – ZLI 1167 mixture were analysed by the computer program LEQUOR (26). The spin–spin coupling constants J_{ij} obtained in the isotropic phase were kept constant in the refinements of the dipolar couplings D_{ij}. The resulting *J* and *D* couplings are shown in Table 1.

The isotropic spectra were analyzed with the current version of the program PERCHit (27). The resulting spectral parameters of 26DCBA are given in Table 2. The analyses yielded also the values of dipolar couplings between the aromatic protons. The phenomenon has been explained previously for some aromatics (28): the larger absolute values of the dipolar couplings in benzene solution arise from parallel stacking of the benzene and 26DCBA. Because the *D* couplings correlate rather strongly with the ^3J coupling, especially for those spectra approaching the AX_2 type, we bound the values of the *D*-couplings to each other by the constraining equation $D_{meta} = 0.192\ D_{ortho}$, arising from the geometry of aromatic ring (28). The constraint reduced the confidence limits of all the couplings by 20–80%. The spectrum of 26DNBA was close to an AX_2 system and did not allow the determination of the dipolar couplings (Table 3).

Results and discussion

The molecular mechanics of 2,6-dichlorobenzaldehyde

A STO-3G calculation has given the rotational potential $V(\Theta) = 2.7 \sin^2 \Theta - 2.8 \sin^2 2\Theta$ (in kJ/mol) (20). In the same way, a fitting to seven energy values calculated at the HF/6-31G* level gave $V(\Theta) = 3.0 \sin^2 \Theta - 3.2 \sin^2 2\Theta$ or $V(\Theta) = 15.8 \sin^2 \Theta + 12.8 \cos^4 \Theta$. The rms value was 0.03 kJ/mol for both of the fittings. The potential in benzaldehyde is markedly higher than the first terms; the $\sin^2 \Theta$ terms do not represent a pure conjugational effect but are sums of a positive conjugational and a negative term arising from formyl-ring steric interactions. In general, also more sophisticated ab initio methods give rather poor results for the formyl rotational energetics in benzaldehydes (29–31), and the uncertainties of less than 1 kcal/mol (proposed recently (31)) are too large for estimation of $\langle \sin^2 \Theta \rangle$ when the barriers are as low as they are in this case. Because molecular mechanics allows a separation of the conjugational and steric terms, it was used in this work to find the shapes of the terms, which were then optimized on the basis of the experimental data.

Because the standard MMP2 parametrisation (32) gives 28.3 kJ/mol for the rotational barrier for benzaldehyde, which is close to the observed values in solution, reviewed in ref. 29, the method is expected to give a rather realistic picture about the barrier. We decomposed the computed rotational energy function of 26DCBA into two parts, first, into the conjugational component:

$$[2] \qquad V_c = 29.27 \sin^2 \Theta - 16.38$$

and, second, into the steric part:

$$[3] \qquad V_{st} = 17.14 \cos^2 \Theta + 4.51 \cos^6 \Theta + 23.34$$

The rms values of the fits were 0.07 and 0.02 kJ/mol, for eqs. [2] and [3], respectively. The first terms of the equations partly cancel each other, explaining thus the lowness of the

barrier. If the $\sin^2\Theta$ and $\cos^2\Theta$ terms are combined and the constant term (having no effect on $\langle\sin^2\Theta\rangle$) is ignored,

$$[4] \qquad V_{MM} = 12.14\ \sin^2\Theta + 4.51\ \cos^6\Theta$$

The first term contains now the conjugational energy and the $\cos^2\Theta$-shaped steric energy, the second one contains the $\cos^6\Theta$-shaped steric interactions. The theoretical barriers are depicted in Fig. 2.

The rotational potential and dipolar couplings

The anisotropy of the potential energy of a molecule in the average field generated by its neighbors distinguishes liquid crystals from ordinary liquids. The resulting anisotropy of the molecular motion leads to large intramolecular magnetic dipole–dipole interactions between nuclei, and to corresponding structure in the NMR spectrum. The resulting dipolar couplings D_{ij} contain detailed information on the geometry and potential energy functions of the molecule (33).

In the mean field approximation the external anisotropic forces acting on a molecule in a uniaxial liquid crystal environment are specified by the single particle potential energy U_{ext}. Its truncated series expansion in terms of the direction cosines of the director in the molecular frame, $\cos\theta_\alpha$, defines the symmetric and traceless *interaction tensor* $A_{\alpha\beta}$ (34):

$$[5] \qquad U_{ext} = -\frac{3}{2}\sum_{\alpha,\beta} A_{\alpha,\beta}\ \cos\theta_\alpha\ \cos\theta_\beta$$

The problem of describing the interaction between a nonrigid molecule and the liquid crystal mean field is essentially that of describing the dependence of $A_{\alpha\beta}$ on the molecular geometry. A straightforward solution is the hypothesis of

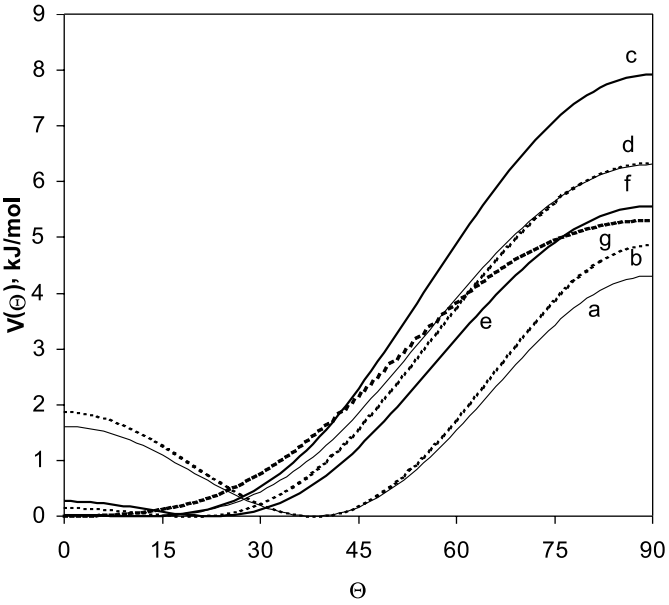
segment additivity of $A_{\alpha\beta}$: the interaction is built up from the contributions associated with the rigid segments of the molecule, considered as isolated entities. If the principal axis systems of the segmental interaction tensors are known, they are completely specified by two independent parameters each. These parameters are $\Delta A = A_3 - (A_1+A_2)/2 = 3A_3/2$, the *anisotropy* of the tensor, and $\eta = (A_1 - A_2)/A_3$, its *asymmetry*, where A_1, A_2, and A_3 are the principal values of the tensor (35). As these parameters are treated as geometry-independent constants, the dependence of the *molecular* $A_{\alpha\beta}$ on the geometry arises entirely from the rotations of the principal axes of the segmental tensors with respect to the molecule fixed frame. Thus, the external potential energy of each segment is separately described by the function [5], which can be written as

$$[6] \qquad U_{ext} = -\frac{\Delta A}{2}(3\cos^2\theta - 1 + \eta\sin^2\theta\cos 2\phi)$$

in which θ and ϕ are the spherical polar angles of the liquid crystal director in the principal axis system of the segmental $A_{\alpha\beta}$.

This so-called "zero-order" segment additivity has been used extensively to describe the anisotropic forces acting on non-rigid molecules in liquid crystals. Originally, Marcelja (36) generalized the Maier–Saupe theory of liquid crystals (37) by assuming an additive dispersive interaction between the mean field and each segment of mesogenic molecules consisting of rigid cores and flexible alkyl chains. Subsequently, Emsley et al. (38) extended this approach to a general second-order mean field interaction using essentially the spherical tensor equivalent of eq. [5]. Photinos et al. (39) proposed a more sophisticated additivity approach for alkyl chains, wherein the elementary rigid segments are the chords joining the midpoints of adjacent CC bonds, together with the terminal segments parallel with the CC bonds at the ends of the chain. The additivity scheme has been reasonably successful in its liquid crystal applications, that is, in studying the interactions associated with large-amplitude conformational changes in various mesogens and solutes (5) as well as with small-amplitude vibrational motions in solute molecules (40).

Fig. 2. The rotational barrier of 2,6-diclorobenzaldehyde predicted by (*a*) STO-3 G method, (*b*) HF/6-31G* method, (*c*) MM2 method, (*d*) the dipolar coupling analysis, (*e*) the *J*-method for acetone-d_6, (*f*) the *J*-method for $CDCl_3$ + benzene (9:1), and (*g*) the *J*-method for CCl_4 + benzene (9:1) solutions.



In 26DCBA, the rigid segments are the aromatic ring and the formyl group. As the isolated aromatic ring has C_{2v} symmetry, the directions of the principal axes of its interaction tensor are known: the axes 1 and 3 are taken to be in the plane of the ring, with the 3 axis along the *para* HC-CC direction. Thus, the interactions of the ring (denoted as R) are specified by the parameters ΔA_R and η_R. The principal axes of the formyl group are not completely determined by its symmetry. However, if the hydrogen is assumed to have a negligible effect on U_{ext}, then the interaction tensor of the formyl group can be taken to be cylindrically symmetric about the CO bond, and hence, its interactions are described by the single parameter ΔA_{CO}. This common approximation should be apt for the present case, because previous investigations (41) have indicated that in the particular liquid crystal solvent used in this study the determined values of ΔA_{CH} of the CH bonds of solute molecules are generally small. Thus, the external forces acting on 26DCBA can be characterized by a total of three independent parameters, ΔA_R, η_R, and ΔA_{CO}.

The total potential energy of the molecule is the sum

$$[7] \qquad U_{tot}(\theta, \phi, \Theta) = U^R_{ext}(\theta, \phi) + U^{CO}_{ext}(\theta, \phi, \Theta) + U_{int}(\Theta)$$

Here, $U_{ext}{}^R$ and $U_{ext}{}^{CO}$ are the external potential energies of the aromatic ring and the formyl group (CO bond), respectively, and U_{int} is the internal conformational energy of the molecule. The variables θ and ϕ are the spherical polar angles of the director in the ring fixed principal axis system 1, 2, 3 defined above, and Θ is the rotational angle between the planes of the ring and the formyl group. According to eq. [6], $U_{ext}{}^{CO}$ is a function of the single variable θ', the angle between the CO bond and the director (as η_{CO} is taken to be zero), which can be expressed as a function of θ, ϕ, and Θ.

© 1999 NRC Canada

The parameters specifying U_{tot}, i.e., ΔA_R, η_R, and ΔA_{CO}, and the coefficients of the rotational potential energy U_{int} can be determined from the experimental dipolar couplings D_{ij} between the magnetic nuclei i and j. The observable D_{ij} is the average value of the function

$$[8] \qquad d_{ij}\ (\theta, \phi, \Theta) = -P_2\ (\cos\ \alpha)\ K_{ij}\ \frac{P_2\ (\cos\ \Theta_{ij})}{r_{ij}^3}$$

over the reorientational and internal motions of the molecule (42). In eq. [8], $P_2(x) = (3x^2 - 1)/2$ is the second-order Legendre polynomial, α is the angle between the director and the applied magnetic field direction, Θ_{ij} is the angle between the director and the internuclear vector $\boldsymbol{r}_{ij}$ (of length r_{ij}), and $K_{ij} = \mu_0\, h\gamma_i\, \gamma_j/(16\pi^3)$. where μ_0 is the permeability in vacuo and γ_i is the magnetogyric ratio of the nucleus i. The angle Θ_{ij} is a function of θ and ϕ; in addition, Θ_{ij} and generally also r_{ij} depend on the rotational angle Θ, if one of the nuclei i, j is the formyl proton. Thus, if the motions of the molecule are treated by the classical Boltzmann statistics (as in the approaches of Marcelja (36), Emsley et al. (38), and Photinos et al. (39)), then the dipolar couplings can be computed by equations

$$[9] \qquad D_{ij} = \frac{1}{Z}\int_0^{\pi} d\theta \sin\theta \int_0^{2\pi} d\phi \int_0^{2\pi} d\Theta\, d_{ij}(\theta, \phi, \Theta) e^{-U_{tot}(\theta,\phi,\Theta)/kT}$$

where Z is the partition function:

$$[10] \qquad Z = \int_0^{\pi} d\theta \sin\theta \int_0^{2\pi} d\phi \int_0^{2\pi} d\Theta\ e^{-U_{tot}(\theta,\phi,\Theta)/kT}$$

If the molecular geometry is fixed, the theoretical expressions, eq. [9], are fitted to the experimental values of the dipolar couplings by the least squares adjustment of the parameters specifying U_{tot}.

The rotational potential from the dipolar couplings

Despite the number of the dipolar couplings (Table 1), it was necessary to apply severe constraints in the least-squares refinement of the parameters. The molecular geometry was kept fixed to the values given in Fig. 1, obtained by structural studies on similar compounds. The structure of the aromatic ring was taken to be identical with that of 1,3-dichlorobenzene as determined by a combined analysis of electron diffraction, rotation constant, and liquid crystal NMR data (43). The bond lengths and angles of the formyl group were taken from an electron diffraction study of terephthalaldehyde (44). The latter study indicates also that the formyl group leaves the geometry of the aromatic ring almost unchanged, thus lending support to the reliability of the present combined geometry.

As a matter of fact, the structure of the formyl group reported in ref. 44 is based on the set of average internuclear distances (r_g structure), while the ring geometry reported in ref. 43 is based on the average nuclear positions (r_α structure). In the present work the vibrational averaging effects were ignored (except for the one-bond couplings D_{CH}, see below), and thus the small differences between the r_g and r_α structures can be disregarded. However, it is well known (45) that the dipolar couplings between directly bonded nuclei involving a proton are significantly influenced by the vibrational motions. In particular, in various substituted benzene derivatives the harmonic vibrational corrections for the one-bond D_{CH} couplings in the ring are normally of the order of 9%. In fact, the values of these corrections are remarkably insensitive to the type of the substitution and liquid crystal solvent (except in anomalous cases where D_{CH} is very small due to an opportune orientation of the nuclear pair). For these reasons the one-bond D_{CH} couplings of 26DCBA were in the present work multiplied by a correction factor of 1.09. All the other vibrational corrections are much smaller, normally significantly less than 3%, corresponding to errors of less than 1% in the internuclear distances. As the relative errors in the fixed molecular geometry are probably larger than 1%, such small vibrational corrections are irrelevant. In any case, incorporation of accurate vibrational corrections in the analysis would necessitate also the incorporation of the so-called deformational corrections, which are due to the orientation-dependent distortions of the solute molecule in the liquid crystal environment (34, 35, 46). This in turn would increase the number of adjustable parameters (because the intermolecular interactions are then built up from the contributions associated with the individual *bonds* of the molecule), and the least-squares fit of the couplings would not result in well determined values for the parameters. Because the rotational effects on the formyl-ring geometry are similar in magnitude with the other vibrational corrections, no rotational corrections were done on the geometry. For example, our HF/6-31G* calculations indicate that the rotational effects on the formyl-ring CC bond are small; the bond-length grows from 1.501 to 1.511 Å when Θ grows from 0° to 90°. The corresponding effects on the C1′-C7-H7 and C2′-C1′-C7′ angles were +1.1° and +1.4°, respectively.

Only one coefficient in the rotational potential energy function U_{int} was sufficiently well determined to allow its refinement. Hence, the results of the molecular mechanics calculations described in the preceding section were used to write the dependence of U_{int} on the rotational angle Θ as

$$[11] \qquad U_{int}(\Theta) = V_2\ \sin^2\ \Theta + V_6\ \cos^6\ \Theta$$

where V_2 was an adjustable parameter, and V_6 was constrained to the calculated value of 4.51 kJ/mol (see eq. [4]).

The constrained fits of the 21 dipolar couplings resulted in well determined values for the four remaining parameters: $\Delta A_R = (29.1 \pm 1.2) \times 10^{-22}$ J, $\eta_R = 3.27 \pm 0.06$, $\Delta A_{CO} = (8.0 \pm 0.7) \times 10^{-22}$ J, and $V_2 = 10.7 \pm 0.9$ kJ/mol. With these values, the couplings are reproduced within 3.7% (the average deviation between the calculated and experimental couplings being 1.7%) except for the small long-range couplings $D_{37'}$ and $D_{47'}$ which have deviations of 6.1 and 4.6% (1.8 and 0.8 Hz), respectively. Hence, the level of agreement between the calculated and experimental data is within the uncertainty resulting from the fixed molecular geometry, together with the vibrational and deformational contributions. To allow for the effects of these systematic uncertainties on the error limits of the resulting parameters, standard deviations of 2% were assigned to the experimental couplings in the error analysis of the fitting procedure. Thus, the uncertainties

of the parameters quoted above are the standard deviations propagating from these enlarged errors of the couplings.

The resulting $V_2 = 10.7 \pm 0.9$ kJ/mol is in good agreement with the values of 12.1 and 9.8 ± 1.0 kJ/mol obtained by the molecular mechanics calculation and the temperature dependence of the ^6J (see below), respectively. The result, together with the theoretical barriers and that based on the *J*-method, is presented in Fig. 2.

Estimation of rotational energetics and $^6J_{90}$ using temperature and solvent dependence of ^6J

Although all the spectral parameters of 26DCBA (Table 2) appeared solvent and temperature dependent, the relative variation (totally 14%) in ^6J is far larger than in the others (0.6% in ^3J and 1.7% in ^5J) and can be thus accounted for mostly by the solvent dependence of the conformational freedom of the formyl group. Our data offers thus an opportunity for estimation of solvent effects on low rotational potentials in solution.

For the data fitting we assumed that the rotational potential follows the function described above with

$$[12] \quad V = V_c \sin^2\Theta + V_{st} \cos^6\Theta + V_s$$

where the last term V_s arises from solvent and, that ^6J behaves as given by eq. [1]. $^6J_0$ is of ca. +0.01 Hz in 2-chlorobenzaldehyde, in benzaldehyde it is probably closer to zero (19), and thus if the substituent effects are additive, $^6J_0$ of 26DCBA should fall well into the range from 0 to 0.03 Hz. Although $^6J_0$ is sensitive to *meta* substitution (22), the equality of the coupling in benzaldehyde and salicylaldehyde (47) indicates no strong *ortho* substituent effect.

If we assume that potential terms are intrinsically solvent and temperature independent, we have five parameters (V_c, V_s, V_{st}, $^6J_{90}$, and $^6J_0$) to be fitted into the data. Because $^6J_0$ and $^6J_{90}$ correlate strongly, one of them must be fixed. Because $^6J_0$ is obviously rather close to zero or slightly positive (19), we fitted the data keeping $^6J_0$ fixed and just tested the sensitivity of the result to its value. Also V_{st} and V_c values correlate strongly. Therefore, V_{st} was fixed to 4.51 kJ/mol, as obtained by molecular mechanics. The fitting was done with program FUNNY using "classical averaging" in computing the ensemble of the $\sin^2\Theta$ term for eq. [1], as has been described before (17).

If the solvent potential is kept the same (i.e., $V_s = 0.0$) for all of the solvents, the rms error of the fit is 0.0048 Hz. The goodness of the fit depends also on the form of V_s: if it has the $\sin^2\Theta$ shape, the rms error is 0.00046 Hz, while 0.00041 or 0.00040 Hz are obtained by using $\cos^6\Theta$ or $\sin^2 2\Theta$ shaped V_s, respectively. The parameters obtained using the last one are given by the model A in Table 4. An inspection of the fits reveals some systematic trends in the calculated–observed differences. These are removed and the rms error is reduced to 0.0003 Hz by using different forms of V_s for each solvent. Admitting $^6J_{90}$ to be different in the polar (acetone and acetonitrile) and non-polar solvents does not improve the fit and the $^6J_{90}$ values do not differ significantly. The result of the last model, varying also V_{st} and $^6J_0$ are also given in Table 4. In the final fitting 27 observations were used, and the number of optimized parameters was seven.

We may conclude now, *first*, that the value of $^6J_{90}$ is not sensitive to the value V_{st} (an uncertainty of ca. 25% in latter causes 0.025 Hz uncertainty in $^6J_{90}$), and because $^6J_0$ is rather well defined, its uncertainty does not affect $^6J_{90}$ too much, *second*, that the solvent effects are insensitive of the approximations and are well described by 1–2 kJ/mol high terms, *third*, that the shape of V is not sensitive to the value of $^6J_0$ and V_{st} and is similar to that obtained with the other methods used in this work. If we assume that $V_6 = 4.51$ kJ/mol, the resulting V_2 term of 9.8 kJ/mol is in agreement with the above value of 10.7 kJ mol, obtained from the dipolar couplings. *Fourth*, the solvent effects do not follow the dielectricity of the solvent: the solvents effects of CD_3CN and CCl_4 are similar and different from that of acetone. This is in accordance with the predictions of Jorgensen (2): for flat barriers also the solvent-packing effects can be significant. The barrier is lowered in $CDCl_3$ suggesting that chloroform forms a hydrogen bond simultaneously to the formyl oxygen and the aromatic chlorine.

© 1999 NRC Canada

Conformational dependence of ^3J and ^5J

Although the variation of ^6J is far larger than that of ^3J and. ^5J, a part of the variation of the latter may arise from the formyl torsion. When ^3J is plotted vs. T or ^6J, the rms error is as large as 0.016 Hz. When a solvent effect J_s is included, the rms error is reduced to 0.0011 Hz with

[13] $$^3J = 8.1909(14) + 0.359(50)\ ^6J + J_s$$

J_s (zero for acetone) varies between 0.001 and –0.045 Hz, which is ca. 0.5% of the total value. The numbers in parentheses give the standard deviations of the coefficients. The result indicates that the conformational variation contribution is ca. 30% of that of ^6J. The corresponding plot for ^5J gives rms error of 0.0004 Hz with

[14] $$^5J = 0.3810(30) - 0.156(21)\ ^6J + J_s$$

where J_s varies between –0.003 and 0.002 Hz, which is ca. 1% of the total value. The rather small coefficient of the ^6J term reflects the so-called π-contribution to the ^5J (48, 49). Assuming $^6J_{90}$ of 0.48 Hz the contribution can be described with a term of 0.06 $\sin^2\Theta$, which is clearly smaller than the terms of 0.34 $\sin^2\Theta$ and 0.24 $\sin^2\Theta$ proposed for toluoic (49) and styrenoic systems (50), respectively.

Conformational analysis of 2,6-dinitrobenzaldehyde

The solvent and temperature behavior of the long-range couplings of 26DNBA are somewhat perplexing (Table 3). Anyhow, ^6J varies much more than ^5J suggesting that a great deal of the ca. 5% variation of the former (at 303 K) arises from conformational flexibility. The corresponding ca. 1% variation of ^5J does not correlate with that of ^6J and must thus be explained with an intrinsic solvent effect, which is not unexpected with the nitro groups. Because the equilibrium position of the formyl group, indicated by ^6J, and even the direction of the temperature dependence of ^6J depends on such a weak perturbation as solvent, we conclude that the rotational free energy potential at the equilibrium position is rather flat.

To estimate the formyl torsion barrier we parameterized MMP2 molecular mechanics to give a torsion barrier of 28.5 kJ/mol for benzaldehyde and barriers of 11 and 14 kJ/mol for nitrobenzene (the average value of the three literature values given in ref. 51 is 12.5 kJ/mol). All the four combinations of the parameters gave very flat potentials with $\langle\sin^2\Theta\rangle$ between 0.35 and 0.80; the average of 0.55 gave $^6J_{90}$ of –0.42 Hz. The result is sensitive to the force field parameters, and we may only conclude that $^6J_{90}$ is somewhere between –0.300 and –0.500 Hz.

Conclusions

All the methods used here agree that the rotational barrier of 2,6-dichlorobenzaldehyde is rather low, see Fig. 2. The solvent effect can be described with terms of 1–2 kJ/mol in size as presumed on the basis of Monte Carlo calculations (2) for flat potentials or as found experimentally (6–12). The changes in the shapes and values of the solvent effects cannot be explained by the polarity alone; also, packing effects seem to have some contribution to the solvent effects. Together with previous studies (17), we believe that there is enough evidence that the solvent and temperature dependence of long-range spin–spin couplings offers a sensitive tool also for study of weak solvent–solute interaction.

The above analysis indicates that $^6J_{90}$ of 2,6-dichlorobenzaldehyde is ca. –0.48 ± 0.03 Hz. The data of ^5J(CHO, H_m) suggest also that the expression for the coupling contains a 0.06 $\sin^2\Theta$ term, which is relatively smaller than for the toluoic (49) and styrenoic systems (50).

Controlled molecular design of ether- and ester-bridged norbornenes and their ring-opening metathesis polymerizations

Alaa S. Abd-El-Aziz, Andrea L. Edel, Leslie J. May, Karen M. Epp, and Harold M. Hutton

Abstract: A series of functionalized polynorbornenes containing pendent ether- or ester-bridged poly(aromatic ether) chains were prepared. The ether-bridged norbornene complex was synthesized via cyclopentadienyliron-mediated nucleophilic aromatic substitution reactions. This methodology, combined with that of dicyclohexylcarbodiimide-mediated coupling, allowed for the formation of novel oligomeric aryl ether and ester substituted norbornene complexes. Photolytic demetallation gave the monomers in good yields. Structural identification of the *exo* and *endo* isomers of both the metallated and demetallated norbornene derivatives was accomplished using HH and CH COSY NMR techniques. Ring-opening metathesis polymerization (ROMP) of these monomers using $RuCl_3$(hydrate) and $(Cy_3P)_2Cl_2Ru$=CHPh allowed for the preparation of the functionalized polynorbornenes. Thermal analysis of the resulting polymeric materials demonstrated greater thermal stability as the number of aryl ether groups increased.

Key words: aromatic ethers, cyclopentadienyliron, polynorbornene, ROMP, ruthenium catalysts.

Résumé : On a préparé une série de polynorbornènes fonctionnalisés comportant des chaînes pendantes (latérales) poly(éthers aromatiques) à pont éther ou ester. On a synthétisé le complexe du norbornène à pont éther par le biais de réactions de substitutions aromatiques nucléophiliques catalysées par le cyclopendiénylfer. Cette méthodologie, combinée à celle du couplage catalysé par le dicyclohexylcarbodiimide, permet de former de nouveaux complexes oligomères du norbornène substitué par des esters ou des éthers aromatiques. La démétallation photolytique conduit aux monomères avec des bons rendements. On a déterminé la structure des isomères tant *exo* qu'*endo* des dérivés norbornènes métallés et démétallés en faisant appel aux techniques RMN « COSY » HH et CH. En soumettant ces monomères à une réaction de polymérisation par ouverture de cycle accompagnée d'une métathèse à l'aide de $RuCl_3$(hydrate) et de $(Cy_3P)_2Cl_2Ru$=CHPh, permet de préparer des polynorborbènes fonctionnalisés. Une analyse thermique des matériaux polymériques qui en résultent a permis de démontrer que la stabilité thermique augmente avec une augmentation du nombre de groupes éthers aromatiques.

Mots clés : éthers aromatiques, cyclopentadiénylfer, polynorbornène, « ROMP », catalyseurs de ruthénium.

[Traduit par la Rédaction]

Introduction

Polynorbornene, first prepared in the early 1960's by Truett et al. (1), has seen numerous applications in industry due its high tear strength and dynamic-damping properties (2–5). As the demand for higher temperature applications has increased, there have been attempts to modify polynorbornene via functionalization of the polymer backbone (6–9). Poly(aromatic ethers) are of particular importance due to their high thermal stability (10–14). In addition, ester derivatives of polynorbornene warrant investigation due to their potential as thermoplastic resins (2, 3). It has therefore been of interest to functionalize polynorbornene with pendent aryl ether chains bridged to the norbornene unit either through an ether or ester linkage.

Ring-opening metathesis polymerization (ROMP) of highly strained bicyclo[2.2.1]heptenes using classical initiators has been well established in the literature (1–5). A drawback of these initiators is their low tolerance for monomers containing polar functional groups, which results in appreciable catalyst deactivation during polymerization (5). However, recent developments in ROMP catalysts have allowed for the incorporation of polar functionalities such as chloro, fluoro, hydroxyl, nitrile, ester, and imide groups into the norbornene unit (15–24). Two classes of catalytic systems have been developed and adopted as the primary cata-

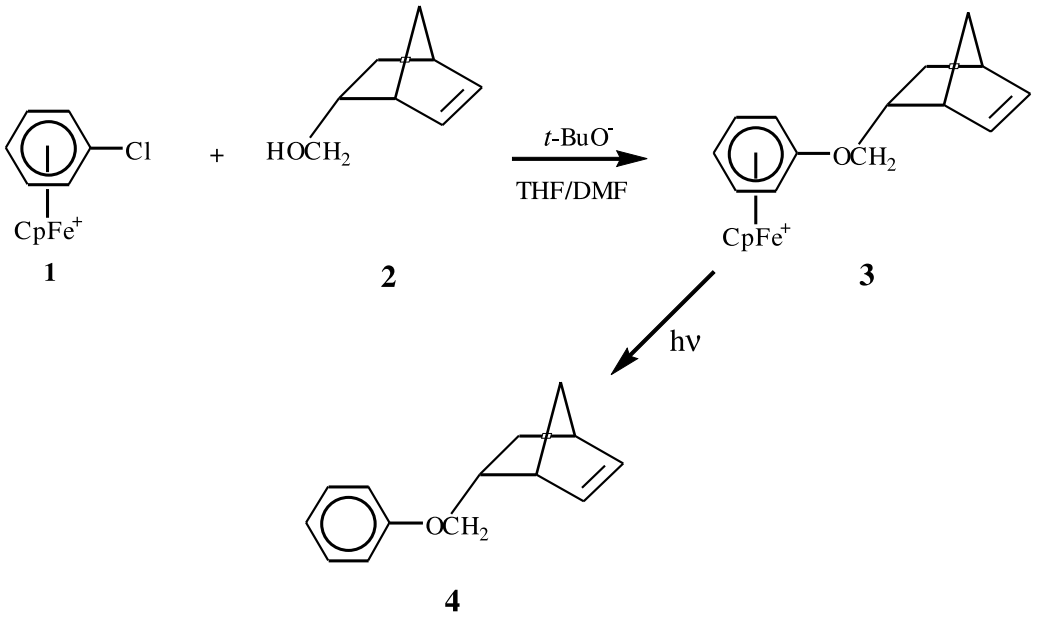
Scheme 1.



lysts used in the ROMP of polar norbornene monomers. These include ruthenium carbene complexes (9, 25–39) as well as molybdenum and tungsten alkylidene complexes (6–8, 17, 18, 21, 23, 40–50). Ruthenium-based systems have found greater industrial application due to their ability to facilitate ROMP in the presence of oxygen and protic environments, as well as their increased tolerance towards a large variety of polar functional groups. Recently, Grubbs and coworkers (29) developed a highly reactive ruthenium-based benzylidene catalyst, which allows for the living ring-opening metathesis polymerization of a variety of functionalized norbornene monomers in both organic and aqueous solvents. This catalyst, known as bis(tricyclohexylphosphine)benzylidene ruthenium(IV) dichloride or "Grubbs' catalyst," has proven to be extremely effective in the ROMP of highly strained bicyclic olefins (29, 30, 32, 39).

Our success in the preparation of poly(aromatic ethers) via cyclopentadienyliron ($CpFe^+$)-mediated nucleophilic aromatic substitution reactions (51–58) has prompted our investigation into the controlled molecular design of norbornene monomers containing pendent aryl ether and (or) ester chains. Recently, we communicated our initial results of the cyclopentadienyliron-complexed norbornenes and their subsequent polymerizations (59). Here, we report the full synthesis and characterization of these substituted norbornene monomers, as well as their ROMP using either $RuCl_3$(hydrate) or $(Cy_3P)_2Cl_2Ru$=CHPh catalysts.

Results and discussion

Monomer syntheses

Norbornene monomers containing ether and (or) ester bridges were synthesized using metal-mediated nucleophilic aromatic substitution (S_NAr). This methodology was used to prepare poly(aromatic ether) chains pendent to norbornene monomers, which would otherwise be difficult to prepare using traditional organic methods (60). This report details the synthesis of two new classes of norbornene monomers, the first containing an ether bridge between the norbornene unit and the aromatic ether side chain, and the second containing an ester bridge.

Preparation of the etheric linked monomer was readily performed via S_NAr of the chloroarene complex (**1**) with an excess of *exo*,*endo*-5-norbornene-2-methanol (**2**), as shown in Scheme 1. Generation of the nucleophile under an inert nitrogen atmosphere for 1 h, followed by the addition of η^6-chlorobenzene-η^5-cyclopentadienyliron hexafluorophosphate (**1**) dissolved in a mixture of *N*,*N*-dimethylformamide (DMF) and THF yielded the product (**3**) in 85% yield after reacting for 16 h at room temperature.

Preparation of the ester-bridged complexes was accomplished via the condensation reaction of 5-norbornene-2-methanol (**2**) with the benzoic acid complexes as described in Scheme 2. (Benzoic acid)$CpFe^+$ (**5**) and (*p*-chlorobenzoic acid)$CpFe^+$ (**6**) were prepared using the methodology established by Nesmeyanov et al. (61). Condensation of these acid complexes with **2** in the presence of dicyclohexylcarbodiimide (DCC) and pyridine in dichloromethane afforded the ester-functionalized norbornene complexes **7** and **8**, in 62 and 70% yields, respectively.

This methodology was further extended towards the preparation of norbornene complexes containing two or three pendent metal moieties within the aryl ether chain. The synthesis of these aryl ether derivatives involved the initial preparation of the terminal phenoxy complexes (**14, 15**), as detailed in Scheme 3. This was accomplished by reacting the bimetallic arene complex (**12**), for example, with an excess of hydroquinone (**13**) in a THF–DMF solvent mixture for 16 h. The resulting yellow precipitate was isolated in 90% yield for complex **15**. Characterization of the bimetallic complex (**15**) was readily accomplished using ^{1}H NMR spectroscopy. The two Cp resonances, appearing as distinct singlets at 5.31 and 5.25 ppm, indicated successful preparation of the desired product. Further verification resulted from the analysis of the ^{13}C NMR spectrum, which also showed two Cp resonances at 78.80 and 78.13 ppm.

Nucleophilic aromatic substitution was used to prepare the bi- (**16**) and tri-metallic (**17**) norbornene complexes. This was done by reacting a 1:1 molar ratio of complex **14** or **15** with **8** in the presence of excess base in DMF, as described in Scheme 4. The resulting yellow precipitates were consistently isolated in high yields ranging from 81–86%. Confirmation of the structure of the trimetallic complex (**17**) was obtained using one-dimensional NMR techniques. Three Cp resonances in the ^{1}H NMR spectrum appearing at 5.34, 5.32, and 5.26 ppm and in the ^{13}C NMR at 79.60, 78.97, and 78.08 ppm were consistent with the proposed structure.

Isolation of the organic monomers from their cyclopentadienyliron moieties was achieved via photolytic demetallation (62). Complexes **3**, **7**, **8**, **16**, and **17** were each

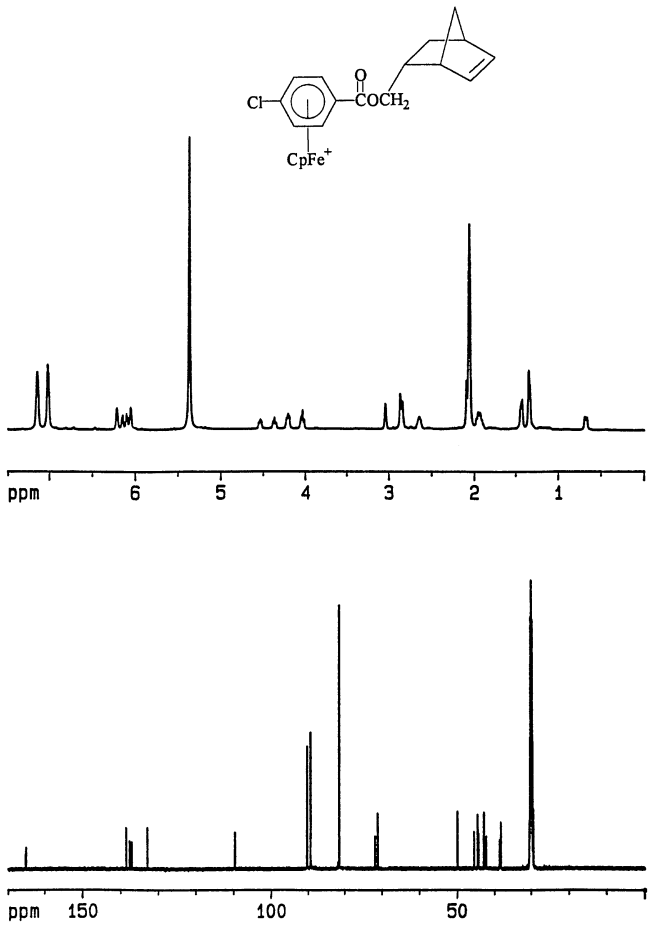
dissolved in a 1:4 ratio of acetonitrile to dichloromethane, followed by irradiation under a xenon lamp for 4–8 h, the length of time increasing as the number of $CpFe^+$ moieties increased. The organic monomers **4**, **9**, **10**, **18**, and **19**, were isolated by this process in good yields.

Monomer characterization

Structural analysis of the functionalized norbornene molecules (**3**, **4**, **7**–**10**, **16**–**19**) was accomplished using NMR, IR, C-H analysis and MS. One- and two-dimensional NMR spectroscopic techniques were extremely valuable in the characterization process due to the complicated *exo*, *endo* isomeric mixture of the products. As the 1-D NMR spectra were quite complex, homonuclear correlation spectroscopy (HH COSY) was employed as a means to identify proton–proton connectivities and chemical shifts. Once all of the protons were assigned to the *exo* or *endo* isomers, hetero-

Fig. 1. ^1H and ^{13}C NMR spectra of complex **8**.

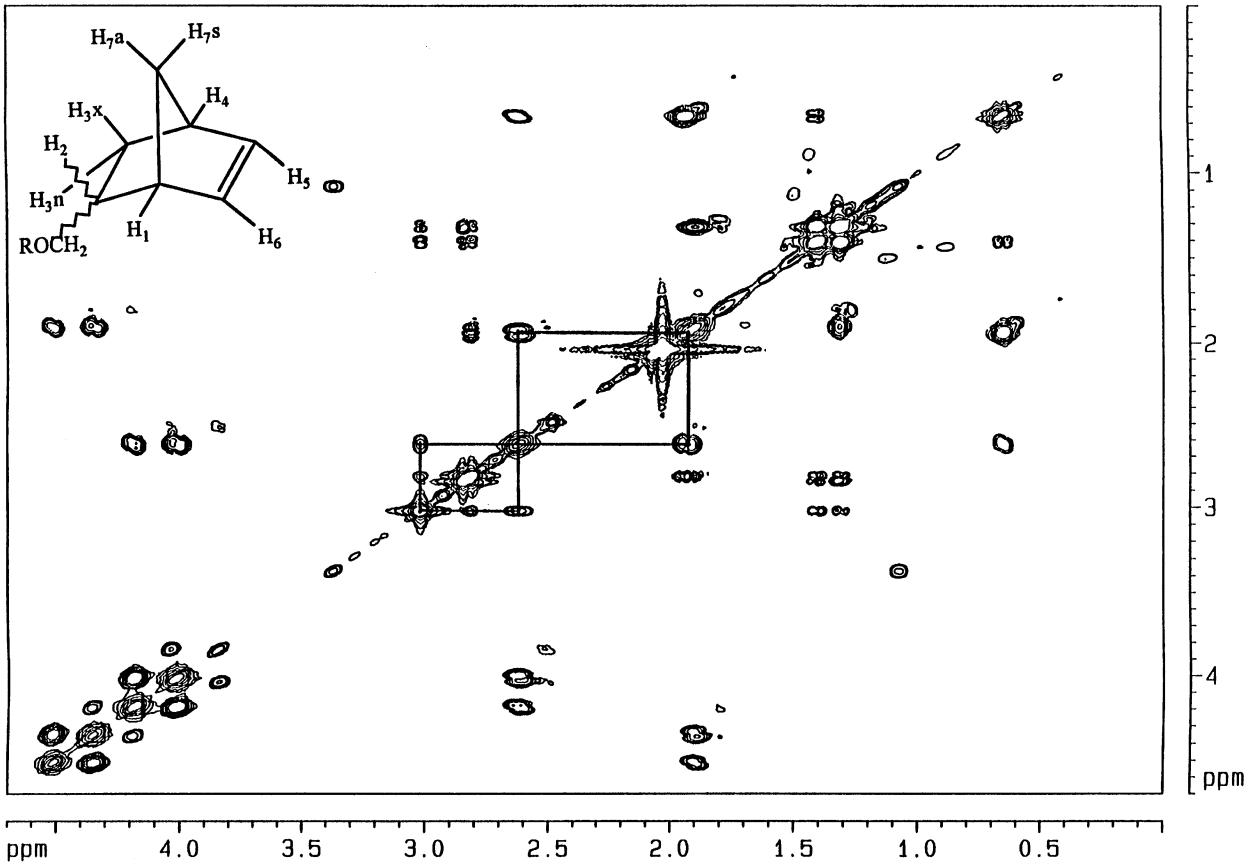


nuclear correlation spectroscopy (CH COSY) was used to locate the ^{13}C NMR chemical shifts.

Cyclopentadienyl resonances, which appear from 5.4 to 5.0 ppm in the ^1H NMR spectra and from 82 to 78 ppm in the ^{13}C NMR spectra, were instrumental in confirming the structure of the complexed norbornenes **3**, **7**, **8**, **16**, and **17**. Complex **3** showed a strong singlet at 5.14 ppm and at 77.06 ppm in the ^1H NMR and ^{13}C NMR spectra, respectively, representative of the cyclopentadienyl resonance. In the ester-bridged derivatives, the Cp resonance was identified further downfield than in the ether-bridged complex due to the stronger electron-withdrawing capability of the carbonyl group. Therefore, the Cp resonance in complex **8** appeared as a single peak at 5.36 ppm and at 81.47 ppm in the ^1H and ^{13}C NMR spectra, respectively (Fig. 1). The appearance of only one Cp signal for the two isomers in both of these complexes was attributed to the large separation between the norbornene unit and the Cp ring. This distance provided sufficient spacing between the two groups such that the electronic effects of the *exo*, *endo* isomerism at C-2 did not influence the Cp protons. Although only one Cp was present for these complexes, evidence for the presence of two isomers was observed with respect to the number of methylene protons (norbornene–CH_2O) and vinyl protons. With respect to the methylene protons, four resonances at 4.20 and 4.03 ppm and at 4.53 and 4.36 ppm in **8** for the

© 1999 NRC Canada

Fig. 2. HH COSY NMR of complex **8** showing relevant connectivities for *exo* and *endo* isomer determination.



endo and *exo* isomers, respectively, were observed. The vinyl protons at 6.21 and 6.05 ppm for the *endo* H_5 and H_6 protons and at 6.14 and 6.10 ppm for the *exo* H_5 and H_6 protons, as described in Fig. 1.

Previous NMR studies involving substituted bicyclo[2.2.1]heptenes have detailed the identification of the *exo* and *endo* isomers relative to several key couplings located for certain proton resonances (63–70). These correspond to the H-1, H-2, H-3x, and H-3n protons, as identified in Fig. 2. Location of the *endo* isomer was assigned based upon the coupling between the *exo* H-2 and the bridgehead H-1 protons and (or) for the *exo* H-3x proton to the bridgehead H-4 proton, showing moderate intensity in their contours. Although these couplings could not be measured due to peak broadness, their connectivities were observed in the HH COSY NMR spectrum, as shown in Fig. 2 for complex **8**. Literature values for this particular coupling report *J* values in the range of 3.2–3.9 Hz, which verifies the modest coupling for these protons (67). As for the *exo* isomer, no coupling or connectivity was observed for the *endo* H-2 proton to H-1, or for the *endo* H-3n proton to H-4. This observation is in agreement with previous investigations of the *endo* H-2 and H-3n resonances in *exo* substituted norbornene derivatives (67). Strong coupling between the two *exo* protons H-2 and H-3x was identified in the HH COSY, indicating the presence of the *endo* isomer. Complex **8** had a calculated *J* value of 8.9 Hz for this coupling, which is also shown in the HH COSY spectrum. Musher (65) has reported more intense coupling between two *exo* protons (H-2 and H-3x) than between two *endo* protons (H-2 and H-3n) despite identical dihedral angles. This allowed for further distinction between the *exo* and *endo* isomers. Once these well-defined couplings were located, the rest of the protons could be identified based upon their connectivities as determined by the HH COSY spectrum.

Photolytic demetallation of complexes **3**, **7**, **8**, **16**, and **17** led to the isolation of the substituted norbornene monomers **4**, **9**, **10**, **18**, and **19** in good yields. NMR, IR, C-H analysis, and MS techniques were used to confirm the structures of the demetallated products. In the ^{1}H NMR spectrum of compound **4**, as an example, the absence of the Cp resonance at 5.14 ppm observed in complex **3** indicated the loss of the metallic moiety. Further evidence for the liberation of the organic monomer was observed in the upfield shift of the methylene resonances (norbornene–CH_2O) from 4.38 to 3.87 ppm in **3** to 4.05–3.57 ppm in **4**. A downfield shift of the aromatic protons from their original positions at 6.40–6.30 and 6.20–6.16 ppm in the starting material, to 7.50–6.70 ppm in the spectrum of the photolyzed product, was also observed. Similar chemical shift trends were identified for the ester-containing norbornene derivatives. Further spectral identification of all the products is listed in the experimental section.

Polymer syntheses

Ring-opening metathesis polymerizations were performed using ruthenium-based catalysts, namely $RuCl_3$(hydrate) and $(Cy_3P)_2Cl_2Ru$=CHPh. Polymerization of monomer **4** was ex-

[d]Molecular weights are representative of the soluble portions of the polymer.

amined using a monomer to initiator ratio ([M]:[I]) of 100:1 with $RuCl_3$(hydrate) as the catalyst. The catalyst was prepared by stirring ruthenium trichloride hydrate in ethanol for 2 h; this solution was then added to monomer **4** and heated at 60°C for 24 h yielding an off-white, fibrous solid (**20**) following precipitation into methanol. Previous investigations using ruthenium chloride(hydrate) as a catalyst detail the advantages of using ethanol–water solvent mixtures, as it has been noted that an increased amount of water yields higher molecular weight polymers with lower polydispersities (PDI) (71, 72). In keeping with this methodology, polymerizations were carried out using varying ratios of ethanol to water as observed in Table 1. Molecular weight determination of the resulting polymeric materials was accomplished using gel permeation chromatography (GPC). A weight-average molecular weight (Mw) of 298 000 was observed when using 100% EtOH, which increased up to 535 000 with a 50:50 EtOH/H_2O mixture. Polymerization was also successful when using 100% water, yielding a molecular weight of 397 000.

Ring-opening metathesis polymerization of the ester-containing monomers with both ruthenium catalysts was also attempted. Under analogous conditions to those employed for monomer **4**, monomer **9** was subjected to ROMP using $RuCl_3$(hydrate). Numerous attempts to polymerize this monomer using this catalyst were unsuccessful. The recent development of ruthenium benzylidene catalysts, namely $(Cy_3P)_2Cl_2Ru{=}CHPh$, by Grubbs and co-workers (29), has led to the availability of a highly active metathesis catalyst. This ruthenium-based system is of significant interest as it offers mild reaction conditions and affords high conversion rates of the monomer to the polymer. These catalysts also show a marked improvement in their functional group tolerance, prompting our investigation into the polymerization of the ester-bridged norbornene monomers.

The general methodology used in the preparation of these polymeric materials involved the initial transfer of the catalyst to the round-bottomed flask in a glove box. Initially, the catalyst was dissolved in CH_2Cl_2, which was then added to a CH_2Cl_2 solution of the monomer (**9**, **10**, **18**, **19**). The resulting mixture was stirred at room temperature under a nitrogen atmosphere until a gelatinous material formed, generally within 1 h. An excess of ethyl vinyl ether was then added to cleave the catalyst from the polymer chain. Subsequent precipitation from methanol gave off-white, fibrous polymeric materials (**21**–**24**), as described in Scheme 5, in yields ranging from 66 to 74%. GPC analyses of the polymers are described in Table 2, showing Mw's ranging from 74 000 to 462 000 for the variously functionalized polynorbornenes, with PDIs from 1.5 to 2.4.

[b]Number-average molecular weight.

[c]Polydispersity index.

In an attempt to obtain higher molecular weight polymers with narrow polydispersities, the reaction conditions were altered by varying the [M]:[I] ratios to 25-, 50-, 100-, and 150:1 using monomer **9** as a model for these experiments (Table 3). Ratios of 25:1 and 50:1 yielded fairly low molecular weight polymers with Mw's of 8400 and 16 000 with PDIs of 2.2 and 2.5, respectively. Polymerizations performed using ratios of 100:1 yielded higher molecular weight polynorbornenes (108 000) with polydispersities of 1.9. When a ratio of 150:1 was used, a significant increase in the molecular weight was obtained (511 000), although the PDI was 3.0. As a result of these observations, polymerizations were consistently performed using [M]:[I] ratios of 100:1 with the purpose of maintaining high molecular weight polymers with low polydispersities.

To obtain a living polymer, complete consumption of the monomer must be accomplished in such a way that initiation proceeds faster than propagation (73). In an attempt to determine whether or not the ruthenium benzylidene polymerizations were living, a ROMP reaction was conducted with the intention of forming a homopolymer using monomer **9**. This proceeded with the withdrawal of a small portion of polymer solution 1 h after the initial ROMP reaction commenced. A second aliquot of monomer **9** was then added to the stirring polymer solution as a means to facilitate chain growth by the continued propagation of the monomer. GPC analysis of the polymer removed from solution after 1 h was compared to the final polymer. Based upon the trace provided from the GPC plot, two significantly different peaks were present for each of the polymers. The initial aliquot of polymer removed from the reaction flask had a much lower weight-average molecular weight (Mw = 22 600 g/mol, PDI = 2.8) than the final polymer (Mw = 108 000 g/mol, PDI = 1.9). This increase in molecular weight provided definitive evidence that the polymerization was living.

Polymer characterization

Solubility studies of the ether- and ester-bridged polymers were performed as a means to assess their processability. Chloroform ($CHCl_3$), dimethylacetamide (DMAc), dimethylformamide (DMF), and dimethylsulfoxide (DMSO) were all examined to determine their suitability as solvents for dissolving the functionalized polynorbornenes. Polymers **20**–**22**, containing single aromatic groups pendent to the polynorbornene backbone, demonstrated good solubility in $CHCl_3$ and DMAc at room temperature. However, DMF and DMSO only partially solubilized the polymeric materials. With respect to the longer pendent aromatic ether chains, it was found that as the length of the chain increased, the solubility of the polymeric materials decreased. Polymers **23** and **24** demonstrated minimal solubility in $CHCl_3$ at room temperature and only partial solubility when refluxed for 1 h. Low solubility of the polymers was observed in both DMAc and DMF; however, in DMSO, they remained completely insoluble.

Structural characterization of the polymers was most effectively carried out using ^1H and HH COSY NMR spectroscopy. As the monoarene-substituted polymers **20**–**22** demonstrated greater solubility in organic solvents in comparison to the oligoether polynorbornenes, higher resolution NMR spectra could be obtained. The broadness of the aromatic peaks located between 8.05 and 7.95 ppm and between 7.60 and 7.30 ppm in **21** is characteristic of the broadening effects associated with polymerization. More importantly, successful polymerization was readily identifiable by the shifting of the olefinic resonances from 6.20 to 6.01 ppm in the monomer (**9**) to 5.40–5.20 ppm in the polymer (**21**). As this resonance appeared as a single broad band and knowing that $(Cy_3P)_2Cl_2Ru{=}CHPh$ yields the *trans* microstructure, it can be said with confidence that the vinylene units exist in the *trans* configuration (32, 47).

FT-IR spectroscopy was useful in estimating the microstructure of the polymeric materials by looking at the respective *cis* and *trans* absorptions. Previous studies involving the geometry of polynorbornene and its derivatives have found that *cis* in-plane = C-H bending occurs at 1404 and 740 cm^{-1}, with the *trans* appearing at 960 cm^{-1} (22, 74, 75). Comparison of monomer **9** with its respective polymer (**21**), allowed for the peak at 969 cm^{-1} to be assigned to the *trans* = C-H bending absorption. In addition, the absence of absorption in the regions of 1404 and 740 cm^{-1} confirmed the lack of the *cis* configuration within the polymer.

Thermal analysis of the polymeric materials was performed using differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA). In comparison to polynorbornene, which has a glass transition temperature (Tg) of 35°C (74), it was found that as the length of the aryl ether chain increased, a noticeable increase in the Tg's was obtained. The results showed that the polymers containing single arene units pendent to the polynorbornene backbone (**20**, **21**) displayed a well-defined Tg at 55°C. Examination of the penta-arene functionalized polymer (**24**) showed that the Tg increased to 73°C, as shown in Table 4. The DSC thermogram further verified the amorphous nature of the *trans*-rich polynorbornene derivative, as no crystalline melting peaks were observed, which is consistent with previous studies of *trans* polynorbornenes (73).

Polymer degradation was also investigated using TGA. It was determined that as the number of aryl ether linkages in the monomer increased, the polymeric material exhibited higher thermal stability. This is in agreement with previous findings for industrially prepared engineering thermoplastics such as PEEK or PEKK, which demonstrate increased thermal stability resulting from the high number of aromatic ethers in the polymer backbone (10–12). Our results revealed that this increase in aryl ether groups pendent to the polynorbornene backbone allowed for greater thermal stability, as defined by the increase in polymer degradation from 417°C for polymer **21** to 460°C for polymer **24**. Further thermal decomposition data is given in Table 4.

24	73.3	408.5	460.2	509.6

[a]Glass transition temperatures (Tg's) are reported as the midpoint.

Experimental section

General

^1H and ^{13}C NMR spectra were recorded at 200 and 50 MHz on a Gemini 200 NMR spectrometer and at 500 and 125 MHz on a Bruker 500 spectrometer, respectively. Chemical shifts were calculated from the solvent that was used as the internal reference and coupling constants were calculated in Hz. IR spectra were recorded on a Bomem FT-IR spectrophotometer. Mass spectra were obtained on a Hewlett–Packard 5890 Series II mass spectrometer as well as on a Hewlett–Packard 5989A mass spectrometer. Molecular weight analyses by GPC were performed using a BL-gel mixed D column (Phenomenex) equipped with a CH-30 column heater (Eppendorf) and a PL-DCU (Polymer Laboratories) detection system, with $CHCl_3$ as the eluent at a flow rate of 0.7 mL per min. Calibration of the instrument was accomplished using polystyrene standards. Glass transition temperatures were determined using differential scanning calorimetry (DSC) performed on a Mettler DSC 25 at a heating rate of 10°C/min, taking the midpoint of the transition from the second heating. Thermogravimetric analysis (TGA) was recorded on a Mettler Toledo TGA/SDTA851 with a heating rate of 10°C/min under a steady stream of nitrogen (20 mL/min).

Materials

Preparation of the starting complex **1** was performed via the previously reported ligand exchange reaction (76, 77). Complexes **5** and **6** were prepared by the ligand exchange of toluene and *p*-chlorotoluene, respectively, and their subsequent oxidation was previously described by Nesmeyanov et al. (61). Complexes **12** and **14** were synthesized using previously reported methodologies (51). Anhydrous aluminum chloride, aluminum powder, ferrocene, chloroarenes, ammonium hexafluorophosphate, hydroquinone, 98%-*exo*,*endo*-5-norbornene-2-methanol, dicyclohexylcarbodiimide, ruthenium(III) chloride hydrate, and bis(tricyclohexylphosphine)benzylidene ruthenium(IV) dichloride are all commercially available and were used without further purification. Pyridine was vacuum distilled over calcium chloride and dried over 4 Å molecular sieves. All solvents (reagent grade) were used without further purification, with the exception of tetrahydrofuran, which was distilled over sodium metal under nitrogen gas. Silica gel 60–100 mesh, was used in the column chromatographic purification of the liberated arenes. Prior to polymerization, dichloromethane was dried over calcium chloride, distilled, and then degassed by several freeze–pump–thaw repetitions.

Monomer syntheses

*Nucleophilic substitution reaction. Preparation of complex **3***

Into a 50 mL round-bottom flask, 2.1 mmol (0.25 mL) of **2**, 2.5 mmol (0.281 g) of potassium *tert*-butoxide, and 3 mL of THF were stirred at room temperature for 1 h under a nitrogen atmosphere. Subsequently, 1.0 mmol (0.378 g) of **1** dissolved in 3 mL of THF and 1 mL of DMF was added to the reaction flask and stirred for 16 h at room temperature under nitrogen. The resulting solution was then filtered through a sintered glass crucible into a 10% (v/v) HCl solution, resulting in the generation of a yellow solution. After rinsing the reaction flask and crucible with a small amount of CH_2Cl_2, a concentrated aqueous solution of NH_4PF_6 was added. This solution was then extracted with CH_2Cl_2 (4 × 50 mL) and the organic layer dried over $MgSO_4$, filtered, and the solvent removed by rotary evaporation. The resulting dark orange oil (**3**) was rinsed with several aliquots of diethyl ether and dried under vacuum: 0.396 g (85%). ^1H NMR (500 MHz, CD_3COCD_3): (*endo*) δ (ppm): 6.40–6.30 (br m, 3H, ArH), 6.22 (m, 1H, J = 3.0 Hz and J = 5.3 Hz, H_5), 6.20–6.16 ppm (br d, 2H, ArH), 6.02 (m, 1H, J = 2.6 and 5.3 Hz, H_6), 5.14 (br s, 5H, Cp), 4.02 (t, 1H, J = 9.1 Hz, nor-CH_2O), 3.87 (t, 1H, J = 7.1 Hz, nor-CH_2O), 3.02 (br s, 1H, H_1), 2.85 (br s, 1H, H_4), 2.62–2.63 (br s, 1H, H_2) 1.92–1.94 (br m, 1H, H_{3x}), 1.45 (br d, 1H, J = 7.8 Hz, H_{7s}), 1.34 (br d, 1H, J = 7.8 Hz, H_{7a}), 0.70 (m, 1H, J = 11.6 and 2.6 Hz, H_{3n}); (*exo*) δ (ppm): 6.40–6.30 (br m, 3H, ArH), 6.20–6.16 (br d, 2H, ArH), 6.15 (m, 1H, H_5), 6.13 (m, 1H, H_6), 5.14 (br s, 5H, Cp), 4.38 (t, 1H, J = 9.2 Hz, nor-CH_2O), 4.19 (t, 1H, J = 6.5 Hz, nor-CH_2O), 2.88 (br s, 2H, H_1 and H_4), 2.06–2.04 (br m, 1H, H_{3x}), 1.90–1.92 (br, 1H, H_2), 1.49 (br d, 1H, H_{7s}), 1.35 (br d, 1H, H_{7a}), 1.31 (m, 1H, H_{3n}). ^{13}C NMR (125 MHz, CD_3COCD_3): (*endo*) δ (ppm): 138.49 (1C, C_5), 135.04 (1C, quat ArC), 132.53 (1C, C_6), 87.34 (2C, ArC), 84.65 (1C, ArC), 77.06 (5C, Cp), 75.31 (2C, ArC), 73.87 (1C, nor-CH_2O), 49.73 (1C, C_7), 44.36 (1C, C_1), 42.78 (1C, C_4), 38.58 (1C, C_2), 28.95 (1C, C_3); (*exo*) δ (ppm): 137.64 (1C, C_6), 136.70 (1C, C_5), 135.13 (1C, quat ArC), 87.34 (2C, ArC), 84.65 (1C, ArC), 77.06 (5C, Cp), 75.31 (2C, ArC), 74.41 (1C, nor-CH_2O), 45.30 (1C, C_7), 44.17 (1C, C_1), 42.22 (1C, C_4), 38.91 (1C, C_2), 29.51 (1C, C_3). Anal. calcd. for $C_{19}H_{21}F_6FeOP$: C 48.95, H 4.54; found: C 48.75, H 4.61.

*Condensation reaction. Preparation of complexes **7** and **8***

Into a 25 mL round-bottom flask was placed 1.00 mmol (0.422 g) of **5** or **6**, 1.00 mmol (0.206 g) of DCC, and 1.654 mmol (0.20 mL) of **2**. To this was added 10 mL of CH_2Cl_2 followed by four drops of pyridine. The reaction mixture was gently stirred at room temperature for 7 h (**7**) or 3 h (**8**), resulting in the formation of a heterogeneous yellow solution. Due to the precipitation of dicyclohexylurea (DCU) from the reaction mixture, the solution was gravity filtered, rinsed with 2 × 10 mL portions of CH_2Cl_2, and then rotovaped to dryness. The resulting yellow viscous material was dissolved in a minimal amount of acetone and filtered once again to remove the remaining DCU. Precipitation of the crude product into diethyl ether and subsequent cooling in the freezer overnight yielded the pure complex as a yellow semi-crystalline material.

*Nucleophilic substitution reactions. Preparation of complex **15***

Into a 50 mL round-bottom flask, 1.00 mmol of **12** was combined with 8.00 mmol (0.881 g) of hydroquinone (**13**) and 2.00 mmol (0.276 g) of potassium carbonate. These reagents were stirred and refluxed for 16 h at 65°C in 16 mL of THF and 4 mL of DMF under an inert N_2 atmosphere. After cooling to room temperature, the reaction mixture was poured into 10% (v/v) HCl, and to this was added a concentrated solution of NH_4PF_6. Immediate precipitation of the product as a yellow solid allowed for isolation of the complex in very high yield.

*Nucleophilic substitution reactions. Preparation of complexes **16** and **17***

Typically, 1.00 mmol of the phenolic complex (**14** or **15**) was added to 1.00 mmol of **8** along with 2.50 mmol of potassium carbonate. To this was added 10 mL of DMF, and the reaction mixture was allowed to stir at room temperature under a N_2 atmosphere for 16 h. The resulting solution was then poured into 10% (v/v) HCl and formed a yellow precipitate upon addition of a concentrated solution of NH_4PF_6.

Photolytic demetallation. Preparation of compounds ***4***, ***9***, ***10***, ***18***, *and* ***19***

Each of the complexes, **3**, **7**, **8**, **16**, and **17**, were dissolved in a 4:1 mixture of CH_2Cl_2:CH_3CN, and transferred to a Pyrex photolytic tube. The reaction tube was then fitted into a photochemical apparatus equipped with a xenon lamp and irradiated at room temperature for 4–8 h, the time increasing as the number of metal moieties increased. After this time, the solvent was removed by rotary evaporation, and the contents were dissolved in $CHCl_3$ and washed with several aliquots of water (3 × 50 mL). The resulting solution was dried over $MgSO_4$, gravity filtered, and then evaporated under reduced pressure. Using a minimal amount of CH_2Cl_2 (1–2 mL), the crude product was transferred to a silica gel column, which was eluted first with hexane and then $CHCl_3$. Once again, the solvent was removed by rotary evaporation, liberating the arene–norbornene derivatives in good yields.

Polymer syntheses

$RuCl_3$(hydrate) polymerization. Preparation of polymer ***20***

In a 10 mL round-bottom flask, 1 mol % of $RuCl_3$(hydrate) was stirred in the previously described ethanol or water solvent system (71, 72). Generation of the catalyst proceeded under a nitrogen atmosphere for 2–3 h, after which it was added to the monomer (**4**). The resulting solution was heated at 60°C for a 24 h period, yielding a viscous material. After dissolution in $CHCl_3$, the polymer was precipitated into methanol with vigorous stirring. A fibrous, off-white solid was obtained following this purification process. IR (cm^{-1}): 1714 (CO), 969 (*trans* olefin). ^1H NMR (200 MHz, $CDCl_3$): δ (ppm): 7.30–7.10 (br s, 2H, ArH), 6.90–6.70 (br s, 3H, ArH), 5.40–5.25 (br s, 2H, olefinic H), 3.90–3.60 (br d, 2H, poly-CH_2O), 2.90–1.10 (br peaks, 7H, aliphatic ring protons).

$(Cy_3P)_2Cl_2Ru{=}CHPh$ polymerizations. Preparation of polymers ***21–24***

Using [M]:[I] ratios of 100:1, the catalyst was weighed out in a glove box and transferred to a 10 mL RBF. To this flask was added 0.5 mL of CH_2Cl_2 for every 100 mg of monomer used. Outside of the glovebox, another equivalent of CH_2Cl_2 (0.5 mL/100 mg) was added to a second 10 mL round-bottom flask containing the monomer under a N_2 atmosphere. Using an airtight syringe, the catalyst solution was then transferred under N_2 to the vigorously stirring monomer. The polymerization reaction proceeded for approximately 1 h, giving a gelatinous material. To this, a small volume of ethyl vinyl ether was added. The polymer

© 1999 NRC Canada

was then dissolved in either CH_2Cl_2 or $CHCl_3$ and precipitated into methanol yielding a fibrous, off-white material.

On combination lines in the NMR spectra of strongly coupled spin systems

Alex. D. Bain

Abstract: Strongly coupled spin systems provide many curious and interesting effects in NMR spectra, one of which is the presence of unexpected (from a first-order viewpoint) lines. A physical reason is given for the presence of these combination lines. The X part of the spectrum of an ABX spin system is analysed as an example. For an ABX system, it is well known that the AB nuclei give a spectrum consisting of two AB-type spectra, corresponding to the two orientations of the X nucleus. It can also be shown that the X part of the spectrum corresponds to the X nucleus undergoing a transition in the presence of an AB-like spin system. For weakly coupled systems, the four observed lines correspond to the four different orientations of the A and B nuclei. For a strongly coupled system, two additional lines may appear, the combination lines. The resulting six lines correspond to the four spin orientations, plus the two zero-quantum transitions. It is shown that these six lines are such that there is no net excitation of the AB-like spin system associated with the X transitions. There is no AB coherence created directly by a pulse applied to X. AB coherence is created as the system evolves, and this is responsible for many of the curious effects. This is shown to be true for all spin sub-systems, which are weakly coupled to a strongly coupled sub-system.

Key words: NMR, strong coupling, second-order spectra, ABX spin system, combination lines, spectral analysis.

Résumé : Les spectres RMN des systèmes de spin fortement couplés fournissent des effets intéressants et curieux; l'un d'eux est la présence de raies inattendues d'un point de vue du premier ordre. On présente une raison physique pour la présence de ces raies de combinaison. À cette fin, on analyse la partie X du spectre d'un système de spin ABX. Pour un système ABX, il est bien connu que les noyaux AB donnent un spectre correspondant à deux spectres de type AB qui correspondent aux deux orientations du noyau X. On peut aussi montrer que la partie X du spectre correspond au noyau X subissant une transition en présence d'un système de spin de type AB. Pour les systèmes faiblement couplés, les quatre raies observées correspondent aux quatre orientations différentes des noyaux A et B. Pour un système fortement couplé, deux raies supplémentaires apparaissent; les raies de combinaison. Les six raies qui en résultent correspondent aux quatre orientations de spin, en plus des deux transitions de quantum nul. On montre que ces six raies sont telles qu'il n'y a pas d'excitation nette du système de spin de type AB associé aux transitions X. Aucune cohérence AB n'est créée directement par une pulsation appliquée à X. La cohérence AB est créée lorsque le système évolue et elle est responsable de plusieurs effets curieux. On montre que ceci est vrai pour tous les sous systèmes de spin faiblement couplés à un sous système fortement couplé.

Mots clés : RMN, couplement fort, spectre du seconde ordre, système de spin ABX, raies de combinaison, analyse spectral.

Introduction

The ABX spin system is a classic part of NMR (1–4). It is a spin system that can be solved analytically, yet it illustrates many important features of NMR spectra. These range from simple first-order, weakly coupled, spectra (AMX), through to magnetic equivalence (A_2X). When the system is strongly coupled, the phenomena of combination lines, deceptively simple spectra (5), and virtual coupling (6) can be seen. The ABX system is the simplest example in which the relative signs of couplings become visible and important. The pedagogical value of the ABX system has long been recognised (7–9). It is tempting to think, in the days of high-field magnets, that strong coupling is no longer important, but we will always have AA′X systems. For all these reasons, the ABX spin system is still an important one to understand.

Further phenomena can be seen in pulse experiments. If the X part of a weakly coupled heteronuclear AMX system undergoes a spin echo, the signal simply decays as T_2. However, if the A and B are strongly coupled, the signal can undergo substantial modulations as a function of echo time (10, 11). Phase and intensity distortions may also be expected in other experiments (12, 13). In a deceptively simple case, it has been shown that although the observed splittings

are small (due to opposite signs of couplings), the DEPT experiment responds to the true couplings (14).

Since there is an analytical solution (1, 15, 16), all of these effects can be readily calculated and simulated. In this paper, we seek to give some less mathematical rationalizations, in order to gain some more insight.

The ABX spin system

It is useful to start with the AB spin system. The wave functions are well known (1). They are mixtures of the basic wave functions, governed by the angle θ defined by eq. [1]:

$$[1] \qquad \tan(2\theta) = J/(\nu_A - \nu_B)$$

In this equation, J is the coupling, and ν_A and ν_B are the resonance frequencies of the two nuclei. The density matrix for the AB spin system is made from all possible combinations (as kets and bras) of these four wave functions. This leads to 16 density matrix elements: four level populations, one pair of zero-quantum transitions, four pairs of single-quantum transitions, and one pair of double-quantum transitions. The pairs arise because all the transitions have a non-zero frequency, so they can precess in either the positive or negative sense.

The ABX spin system is a combination of the AB and the X spin system. This is obvious in the AB part, which consists of two AB patterns, each with a different value of θ, denoted by θ_+ and θ_-. If J_{AX} is not equal to J_{BX}, then the difference in magnetic field experienced by A and B depends on the orientation of the X nucleus. The AB part of the spectrum has two AB patterns, depending on the *z* component of the X spin.

Although it is not obvious, a similar statement holds for the X part of the spectrum. In the case of equivalent spins, or weak coupling, the four lines in the X part of the spectrum represent the four orientations of the A and B nuclei. For strong coupling, we need to expand the idea of orientations to the more general concept of coherence level zero. There are four level populations for AB, but six coherence-level-zero density matrix elements, since the zero-quantum transitions must be included. The six lines in the X part of a general ABX spectrum map onto the six coherence level zero density matrix elements.

How is this mapping done? Some heroic algebra shows that the density matrix for an ABX system can be factored into an X part and an AB part (15). However, the AB part depends on the state of the X nucleus. A single spin, X, has four density matrix elements, corresponding to the unit operator, *1*, and the operators I_z, I_+, I_-, as in eq. [2]:

$$[2] \qquad 1 = |0) = \frac{1}{\sqrt{2}}\{|\alpha><\alpha| + |\beta><\beta|\}$$

$$I_+ = |1_{+1}) = |\alpha><\beta|$$

$$\sqrt{2I_z} = |1_0) = \frac{1}{\sqrt{2}}\{|\alpha><\alpha| - |\beta><\beta|\}$$

$$I_- = |1_{-1}) = |\beta><\alpha|$$

In superspin terms, these correspond to $|1_0)$, $|1_{+1})$, $|1_{-1})$, and $|0)$, where the subscript is the coherence level of each density matrix element. Note that if the kets and bras are identical, there is no coherence. If the coherence level of the X nucleus is zero, then the AB part of this part of the factored density matrix is just an AB density matrix with the appropriate value of θ. This is the mathematical description of the two AB patterns in that region of the spectrum. However, when the X spin has coherence,. i.e., we are looking in the X part of the spectrum, life gets more interesting.

Just as the AB part of an ABX spectrum is factored according to the orientation of the X spin, so also the X part of the spectrum can be factored according to a rather special AB-type spin system. An AB density matrix can always be constructed from a ket–bra combination of the AB wave functions. When the X spin has coherence, the AB part of an ABX is slightly different: the ket has one of the values of θ, say θ_+, and the bra has the *other* angle, θ_-. In other words, during an X transition, the AB part of the density matrix "jumps" from one value of θ to the other (6). In this unusual AB-type density matrix, what used to be a level population now has coherence, since the two θ values are different. The role of the zero-quantum transitions, the combination lines, is to cancel out this coherence.

There is a fundamental principle that physics should be local. That is, a ^{13}C transition should not create coherence in the spectrum of two ^{31}P nuclei making up the AB part of an ABX. This is rigorously true for all spin systems — a non-selective pulse applied to one region of the spectrum will not excite any of the other regions. In terms of the density matrix, the element that corresponds to the total X spectrum has no coherence associated with the AB part. Although strongly coupled spin systems must obey this principle before any evolution, they find it difficult to adhere to it as a function of time.

The density matrix element representing the total X spectrum is the sum of the elements that represent the individual transitions. In a weakly coupled AMX system, there is no AM coherence associated with any of the individual X transitions. Therefore, the total X spectrum will have no AM coherence. However, for an ABX system, the density matrix elements for the individual transitions *have* AB coherence (17). The X transition is represented by the operator I_+, or superspin $|1_{+1})$, combined with a ket–bra density matrix element for the AB system. In weak coupling, the ket and bra are identical, so there is no coherence associated. In strong coupling, the ket and bra are different, so there must be AB coherence. This difference in wave function creates the AB coherence associated with that X transition. This cancels out only in the sum of all the transitions.

The pattern of combination lines in a strongly coupled spin system is therefore the one that gives no *net* coherence to the AB part of the spectrum. In weak coupling each of the individual X transitions has no AM coherence. This is no longer possible for strong coupling, since the X spin affects the AB part of the spectrum. The physical principle of no AB coherence only applies to the sum. The interesting effects, such as echo modulation, show up as the spin system evolves in time. As time progresses, the density matrix elements oscillate at different frequencies, so the coherence cancellation in the AB part of the spectrum no longer occurs. The various consequences are predictable, but may be counter-intuitive.

For the ABX spin system, the coherences can be calculated explicitly. This makes it easy to see the creation of AB

© 1999 NRC Canada

coherence following the excitation of the X spin alone. However, there is nothing in this discussion that restricts the phenomenon to the ABX spin system. Any time there is a strongly coupled spin subsystem, M, which is weakly coupled to another subsystem, N, similar results will occur. Excitation of the N subsystem will not create M coherence immediately, but such coherence will arise during the evolution. As with the ABX system, curious and unexpected results may occur.

Conclusions

The ABX spin system can be factored into an AB part and an X part. The AB part of the spectrum depends on the orientation of the X spin, as is well-known. Similarly, the X part of the spectrum depends on the AB part, provided that the nature of the AB part is generalized. The six transitions in the X part of the spectrum map onto the six coherence-level-zero density matrix elements of the generalized AB part. These coherence-level-zero elements can be regarded as combinations of four level populations and two zero-quantum transitions. Their intensities are governed by the principle that there should be no net excitation of the AB spins when X is excited. However, the cancellation is true only at time zero. If an ABX system is subjected to a sequence of pulses and evolutions, the coherences no longer cancel as time progresses. This is responsible for all the peculiar effects. The phenomenon is not restricted to the ABX spin system, but will arise any time a subsystem of the total system is strongly coupled.

A solid state NMR and molecular orbital study of hydroxylammonium chloride

Glenn H. Penner, Y.C. Phillis Chang, and H. Michelle Grandin

Abstract: Deuterium and nitrogen-15 NMR spectroscopy has been used to measure the ^{2}H quadrupolar coupling and ^{15}N chemical shift tensors in solid hydroxylammonium chloride, $NH_3OH^+Cl^-$, (HAC). In addition, the NH_3 and OH dynamics have been investigated by variable temperature ^{2}H line shapes and T_1 measurements. The Arrhenius activation energy for NH_3 rotation is 22.5 ± 1.8 kJ/mol with a pre-exponential factor of $8 \pm 3 \times 10^{12}$ s^{-1} from line shapes and 21.3 ± 2 kJ/mol with an infinite temperature correlation time, τ_∞, of $5.0 \pm 0.4 \times 10^{-14}$ s from the T_1 analysis. The latter value corresponds to a pre-exponential factor of $6.7 \pm 0.5 \times 10^{12}$ s^{-1}, if a three-site exchange is assumed. There was no evidence for OH reorientation up to 405 K, indicating a rather strong OH···Cl hydrogen bond. Previously reported inconsistencies between crystal structure and molecular orbital derived N—O bond lengths are cleared up by performing geometry optimizations with large basis sets and taking electron correlation into account. The internal rotational potential for the isolated HA cation is calculated to be 5.8 kJ/mol at the MP2/6-31G** level, with the *trans* geometry preferred. Calculations that employ the neutron diffraction geometry and include the Cl^- anions that surround the HA^+ cation yield an upper limit for the activation energy for NH_3 group rotation of 62 kJ/mol. Analysis of the deuterium spectrum and T_1 data yield nuclear quadrupolar coupling constants of 160 ± 5 kHz and 194 ± 5 kHz (η = 0.50 ± 0.05) for the ND_3 and OD deuterons, respectively. Density functional calculations of the deuterium and nitrogen-14 nuclear quadrupolar coupling constants at the B3LYP level show that it is necessary to include the influence of the surrounding chloride anions. We have also shown that it is possible to obtain accurate proton chemical shifts from the deuterium MAS spectrum of solid HAC-d_4.

Key words: solid state NMR, molecular dynamics, nitrogen 15 chemical shift anisotropy.

Résumé : On a utilisé la spectroscopie RMN du ^{2}H et du ^{15}N pour mesurer le couplage quadripolaire du ^{2}H et les tenseurs des déplacements chimiques du ^{15}N dans le chlorure d'hydroxylammonium solide, $NH_3OH^+Cl^-$ (CHA). De plus, on a étudié la dynamique du NH_3 et du OH à l'aide de mesures de T_1 et des formes des raies du ^{2}H à température variable. En se basant sur les formes des raies, l'énergie d'activation d'Arrhenius pour la rotation du NH_3 est de 22,5 ± 1,8 kJ/mol avec un facteur préexponentiel de $8 \pm 3 \times 10^{12}$ s^{-1}; l'analyse des valeurs de T_1 conduit à une valeur de 21,3 ± 2 kJ/mol avec une température infinie de temps de corrélation de, τ_{inf}, de $5{,}0 \pm 0{,}4 \times 10^{-14}$. Cette dernière valeur correspond à un facteur préexponentiel de $6{,}7 \pm 0{,}5 \times 10^{12}$ s^{-1} si l'on fait l'hypothèse que l'échange se fait sur trois sites. Aucune donnée ne permet de laisser croire qu'il se produit une réorientation du OH jusqu'à 405K; ceci suggère l'existence d'une forte liaison hydrogène OH···Cl. En procédant à des optimisations de la géométrie à l'aide d'ensembles de bases élargies et en tenant compte de la corrélation électronique, on a pu corriger les incohérences qui avaient été rapportées antérieurement relativement aux longueurs des liaisons N—O observées dans la structure cristalline et les valeurs obtenues par calculs d'orbitales moléculaires. On a calculé que le potentiel de rotation interne du cation HA isolé est égal à 5,8 kcal/mol au niveau MP2/6-31G** et que la géométrie *trans* est privilégiée. Des calculs qui font appel à la géométrie déterminée par diffraction de neutrons et qui incluent les anions Cl^- qui entourent le cation HA^+ permettent d'établir que la limite supérieure pour l'énergie d'activation pour la rotation du NH_3 est de 62 kcal/mol. L'analyse du spectre du deutérium et les données de T_1 permettent de déterminer que les constantes de couplage quadripolaire nucléaire des deutérons du ND_3 et du OD sont respectivement de 160 ± 5 kHz et 194 ± 5 kHz (η = 0,50 ± 0,05). Des calculs de densité fonctionnelle des constantes de couplage quadripolaire nucléaire du ^{2}H et du ^{14}N au niveau B3LYP montrent qu'il est nécessaire d'inclure l'influence des anions chlorures avoisinants. On a aussi montré qu'il est possible d'obtenir des valeurs exactes pour les déplacements chimiques du spectre d'après la technique de rotation à l'angle technique (magique) du CHA-d_4.

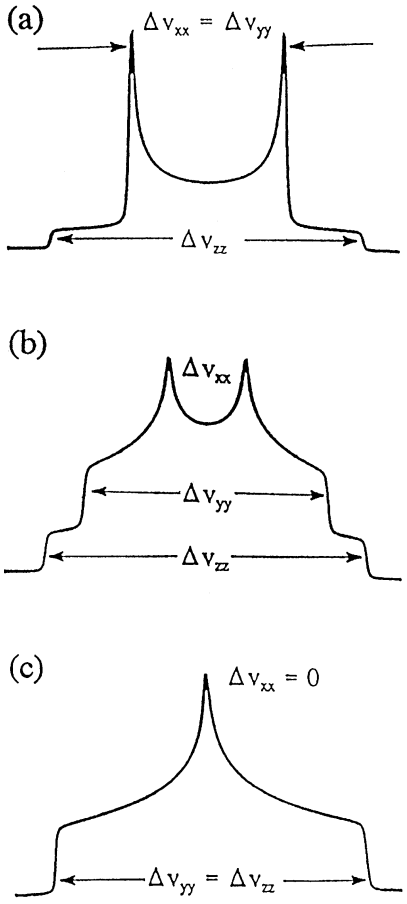
Fig. 1. Simulated deuterium NMR powder spectra for η values of (*a*) 0.0, (*b*) 0.5, and (*c*) 1.0.



Introduction

The purpose of this study is twofold. We are primarily interested in the measurement of the ^{15}N chemical shift and ^{2}H nuclear quadrupole interactions in HAC, comparison of these with the values obtained from ab initio molecular orbital calculations and the uses of the temperature dependent ^{2}H line shapes and T_1 to investigate the dynamics of the HA cation in solid HAC. Our second goal is to obtain reliable molecular orbital calculations of the optimum geometry of HA^+. There has been considerable disagreement in the past as to the length of the N—O bond in HA^+. Neutron diffraction (1) and X-ray studies (2–4) give very different results and previous MO calculations at the HF level yield results that are rather dependent on basis set (3). No calculations of the optimized geometry have been reported in the last decade nor have any calculations employed computational methods that included electron correlation.

Theoretical background

Deuterium line shapes

The solid state deuterium NMR spectral line shape is dominated by the quadrupolar interaction. This is the interaction between the nuclear quadrupole moment, *eQ*, and the electric field gradient (efg) tensor at the nucleus. The quadrupolar coupling constant, χ, which is a measure of the strength of the quadrupolar interaction is given as

$$[1] \qquad \chi = \frac{e^2 q_{zz} Q}{h}$$

The line shape is also influenced by the asymmetry parameter of the efg tensor, η, which is defined as the difference between the two smaller principal components of the diagonalized electric field gradient tensor, eq_{xx} and eq_{yy}, with respect to the largest component, eq_{zz}.

$$[2] \qquad \eta = \frac{eq_{zz} - eq_{xx}}{eq_{zz}} = \frac{\Delta\nu_{yy}\Delta\nu_{xx}}{\Delta x_{zz}}$$

where $|eq_{xx}| < |eq_{yy}| < |eq_{zz}|$ and $eq_{xx} + eq_{yy} + eq_{zz} = 0$.

The quadrupolar coupling constant and asymmetry parameter are related to the three separations, or splittings, in the powder spectrum, $\Delta\nu_{xx}$, $\Delta\nu_{yy}$, and $\Delta\nu_{zz}$, which are shown in Fig. 1. The splitting are related to the quadrupolar coupling constant, χ.

$$[3] \qquad \begin{aligned} \Delta\nu_{xx} &= 3/4\chi(1-\eta) \\ \Delta\nu_{yy} &= 3/4\chi(1+\eta) \\ \Delta\nu_{zz} &= 3/2\chi \end{aligned}$$

In many cases the efg tensor is nearly axially symmetric about along the X—D bond, and the value of η is rather small (<0.1). Then the powder spectrum is a typical Pake doublet with a characteristic splitting between peaks of 3χ/4 and shoulders separated by 3χ/2. The effects of motion on the deuterium powder spectrum are twofold. First the width of the spectral line is narrowed by the motion. In the case of a jumping motion of the X—D bond between three or more equally populated sites, as is expected for ND_3 groups, η is averaged to zero, and if the motion is fast compared to the quadrupolar interaction (i.e., $>10^6$ s^{-1}), the quadrupolar splitting, Δν, is reduced to

$$[4] \qquad \Delta\upsilon_{\text{eff}} = \frac{3\chi}{8}(3\cos^2\theta - 1)$$

where θ is the angle between the X—D bond and the rotational axis. Secondly, if the motional rate, *k*, is of the order of χ (~10^4 –10^6 s^{-1}) the spectral line shape is severely distorted due to the large T_2 anisotropy associated with the dynamic process. The distorted line shapes can readily be simulated for a given combination of χ, θ, and *k*.

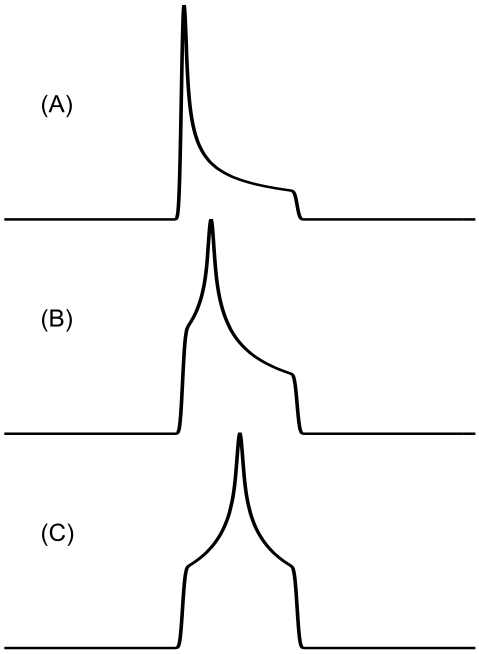
Deuterium spin-lattice relaxation

The spin-lattice relaxation time, T_1, characterizes the return of the bulk magnetization to its equilibrium state after a perturbing pulse. Relaxation is stimulated by time dependent nuclear spin interactions, and is most efficient when these fluctuations occur at the resonance frequency of the nucleus. For deuterons, the primary source of these fluctuating fields is the time dependent part of the quadrupolar interaction.

When the reorientational motion can be described by an exponential correlation function, and the temperature dependence of the correlation time follows Arrhenius behaviour, the rate of relaxation may be fit to the following equations (5):

© 1999 NRC Canada

Fig. 2. Simulated ^{15}N NMR powder spectra for η values of (*a*) 0.0, (*b*) 0.5, and (*c*) 1.0.



$$[5] \qquad \frac{1}{T_1} = K\left(\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right)$$

$$[6] \qquad \tau_c = \tau_\infty \exp\left(\frac{E_a}{RT}\right)$$

where τ_c is the correlation time for the motion ($\tau_c \therefore \beta 5\ k^{-1}$), τ_∞ is its value at infinite temperature, and ω_0 is the Larmor precession frequency. In addition, E_a is the activation energy for the motion influencing T_1, and K depends on the strength of the dominant nuclear spin interaction (in this case χ^2) and the exact nature of the reorientational motion. For jumps of the X—D bond between three or more equivalent positions oriented at an angle θ about the rotational axis, K is given by

$$[7] \qquad K = \frac{9\pi^2\chi^2}{20}(3\cos^2\theta - 1)^2$$

In this case, if a plot of ln (T_1) vs. inverse temperature is made, one often sees a V-shaped curve, with a T_1 minimum at $\omega_0\tau_c = 0.62$. There is, in general, much information to be extracted from this T_1 plot. The slope of the curve on either side of the T_1 minimum is characteristic of the activation energy for the motion influencing T_1. The intercept at $1/T = 0$ yields a value for τ_∞, while the depth of the minimum can be used to determine a value for the effective quadrupolar coupling constant. Note that knowledge of τ_∞ and E_a allows calculation of the motional rate at any temperature, through eq. [6]. The relaxation rate was not the same across the powder spectrum indicating an orientational dependence of the T_1. This T_1 anisotropy is consistent with our assumption of a three-site jump rotational model (6).

Nitrogen-15 powder line shapes

In an applied magnetic field, B_0, a magnetic nucleus in a molecule experiences an effective magnetic field, B_{eff}, due to the shielding effect of the surrounding electrons. This shielding is anisotropic and thus depends on the orientation of the molecule in the applied magnetic field. The dependence of the observed spectral frequency is given by

$$[8] \qquad \nu(\theta,\phi) = \nu_0 - \nu_0(\sigma_{11}\sin^2\theta\cos^2\phi + \sigma_{22}\sin^2\theta\cos^2\phi + \sigma_{33}\cos^2\theta)$$

where the two angles, θ and φ, describe the orientation of the shielding tensor with respect to B_0 and σ_{ii} is the *i*th principal component of the shielding tensor. The principal components of the shielding tensor are usually reported as chemical shifts, δ_{ii}, with respect to a reference. The commonly accepted convention is that $\delta_{11} > \delta_{22} > \delta_{33}$.

Powder samples contain many small crystallites that are randomly oriented with respect to B_0. As a result the powder spectrum consists of a broad line shape spanning the range of chemical shifts for every possible orientation. Three typical powder spectra are shown in Fig. 2. The powder spectrum is usually characterized by the chemical shift anisotropy, Δδ, and the asymmetry parameter, η.

If

$$[9] \qquad \left|\delta_{11} - \delta_{isotropic}\right| > \left|\delta_{33} - \delta_{isotropic}\right|$$

then

$$[10] \qquad \Delta\delta = \delta_{11} - (\delta_{22} + \delta_{33})/2$$

and

$$[11] \qquad \eta = \frac{\delta_{22} - \delta_{33}}{\delta_{11} - \delta_{isotropic}}$$

If

$$[12] \qquad \left|\delta_{11} - \delta_{isotropic}\right| < \left|\delta_{33} - \delta_{isotropic}\right|$$

δ_{11} and δ_{33} in eqs. [10] and [11] are exchanged.

The isotropic shift, observed in solution or in the magic angle spinning spectra of solids, is

$$[13] \qquad \delta_{isotropic} = (\delta_{11} + \delta_{22} + \delta_{33})/3$$

Experimental

Samples of $^{15}NH_3OHCl$ (99% ^{15}N) and ND_3ODCl (98% D) were purchased from MSD isotopes and Aldrich, respectively.

The deuterium spectra were recorded on a Bruker ASX-200 NMR spectrometer operating at 30.7 MHz, using the quadrupolar echo pulse sequence: $(\pi/2)_x - \tau_Q - (\pi/2)_y - \tau_Q -$ acquire (7). The length of the π/2 pulse was approximately 2.5 μs. At each temperature, the echo signals were collected for a τ_Q value of 40 μs. The echo signals were Fourier transformed to obtain the deuterium NMR spectra. The temperature of the sample chamber was electronically regulated by a Eurotherm B-VT 2000 temperature controller to within ±0.2°C over the course of a measurement. The true temperature of the sample was recorded just prior to each measurement by lowering a copper-constantan thermocouple down

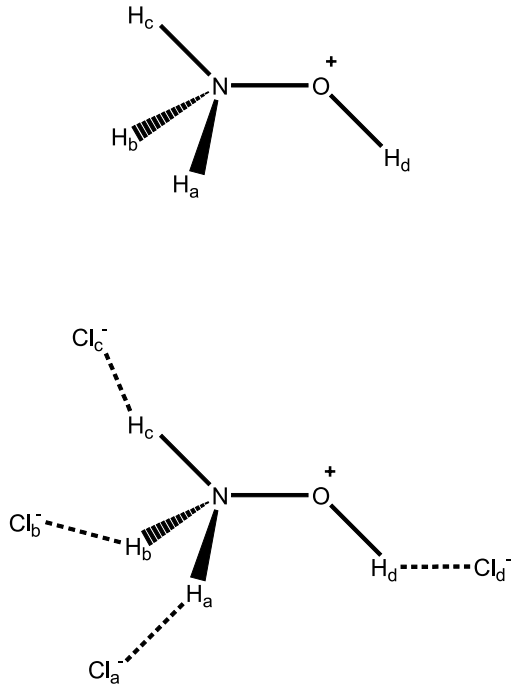
[c]All calculated geometries gave a plane of symmetry passing through H_c-N-O-H_d.

[d]X-ray structures of the NO_3^- and ClO_4^- salts gave r(NO) values of 1.40 and 1.41 Å, respectively (4, 2).

Fig. 3. The structure of the NH_3OH^+ cation.



the gas venting tube until it came into contact with the sample coil. The estimated uncertainty of the recorded sample temperature was about ±0.5°C.

The deuterium T_1 data were acquired using an inversion recovery pulse sequence modified for quadrupolar nuclei: $(\pi)_x - \tau - (\pi/2)_{\pm x} - \tau_Q - (\pi/2)_y - \tau_Q$ – acquire (8). Typically, 12 values of τ were used to determine T_1 at each temperature. The pulse spacing, τ_Q, for the T_1 determination was 40 μs. The time between repetitions of the pulse sequence was always greater than $5T_1$. The data were fit using a nonlinear least-squares algorithm employing an exponential fitting function to obtain the relevant relaxation time parameters.

Deuterium MAS spectra were obtained with a sample spinning speed of 5 kHz using single pulse excitation and a pulse width of 3.0 μs. The chemical shifts were referenced to $[(CD_3)_3Si]_4C$, which has a chemical shift of 0.23 ppm with respect to liquid TMS.

Magic angle and static ^{15}N cross polarization (9) experiments were performed with a contact time of 10 ms and a 90° pulse of 5.5 μs. Chemical shifts were referenced to the nitrate peak of $^{15}NH_4{}^{15}NO_3$, which has a chemical shift of –4.0 ppm with respect to liquid nitromethane (10).

Quadrupolar echo spectra were simulated by standard methods using the program MXQET (11). Simulated spectra were visually matched to experimental line shapes. The T_1 data were least-squares fit to the BPP spectral density function, to obtain the activation energy, E_a, the correlation time at infinite temperature, τ_∞, and the effective quadrupolar coupling constant, χ_{eff}.

Molecular orbital calculations were performed using GAUSSIAN 98W (12) on a 300MHz Pentium II personal computer. Computed ^{15}N chemical shielding values, σ, were converted to the chemical shift, δ, scale using the equation (14):

$$[14] \quad \delta = -135.8 - \sigma$$

Deuterium and ^{14}N nuclear quadrupolar coupling constants were obtained from the computed electric field gradient values using the equation (15):

$$[15] \quad \chi(\text{MHz}) = -237 Q q_{zz}$$

were Q is the nuclear quadrupolar moment in units of barns (1 barn = 10^{-28} m^2) and q_{zz} is the largest component of the efg tensor at the nucleus and is given in atomic units. The values of $Q(^{14}N)$ = 20.1 and $Q(^2H)$ = 2.86 were taken from the compilation of Pyykkö (15).

Results and discussion

The structure of NH_3OH^+

The structure of HA^+ is depicted in Fig. 3. Table 1 shows the structural parameters of the HA cation in HAC as obtained from diffraction experiments together with geometry optimized structures of HA^+ at various levels of molecular

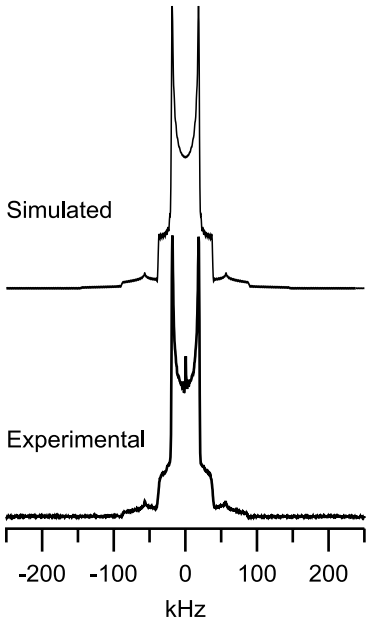
Fig. 4. Experimental and simulated deuterium powder spectra for HAC-d_4.



orbital theory. As can be seen, the computed NO bond lengths are in good agreement with the X-ray values for solid HAC and the nitrate and perchlorate salts. Since X-rays are diffracted by electron density, hydrogen positions can not be reliably determined. On the other hand, if a deuterated sample can be obtained, neutron diffraction structures can yield accurate deuteron positions. A comparison of the optimized and neutron diffraction structures show reasonable agreement with the exception of r(NO) and a(ONH_c). The neutron diffraction NO bond length is significantly shorter than the X-ray or optimized values. The optimized O-N-H bond angle for the N—H bond *trans* to the O—H bond, a(ONH_c), is consistently and significantly smaller than the expected tetrahedral angle at all levels of theory employed in this study.

Deuterium line shapes

The ^2H spectrum of a fully deuterated sample of HAC is shown in Fig. 4. This spectrum is clearly a composite of two Pake doublets, one with a small effective χ and one with a large χ value. The narrower line shape is due to the ND_3 group, and the broader component is due to the OD deuteron. Figure 4 also shows a simulation of the ^2H spectrum and yields values of χ_{eff} = 53 ± 1.5 kHz and η_{eff} = 0.0 for the narrow component and χ_{eff} = 194 ± 5 kHz and η_{eff} = 0.50 ± 0.05 for the broad component.These χ values are consistent with rapid rotation of the ND_3 group and a static OD deuteron at room temperature. Figure 5 shows the ^2H line shape as a function of temperature. The ND_3 line shape changes below 200 K but the OD part of the spectrum is unchanged. The ND_3 part of the spectrum can be simulated, and these are also shown in Fig. 5 for different rates of the three-site jumping motion of the ND_3 deuterons. A fit of the temperature dependent rates to the Arrhenius equation yields an activation energy of 22.5 ± 1.8 kJ/mol and a pre-exponential factor of 8 ± 3 × 10^{12} s^{-1} and an unaveraged χ value of 160 ± 5 kHz. The OD part of the line shape does not change up to 405 K.

Fig. 5. The deuterium powder spectra for HAC-d_4, together with simulations, as a function of temperature.

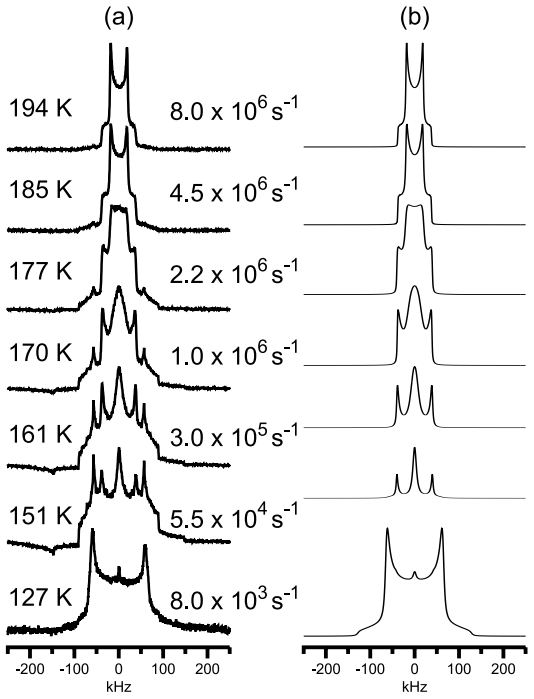


Fig. 6. The deuterium T_1 curve for solid HAC-d_4 as a function of inverse temperature. The solid curve is a least-squares fit of the points to eqs. [5] and [6].

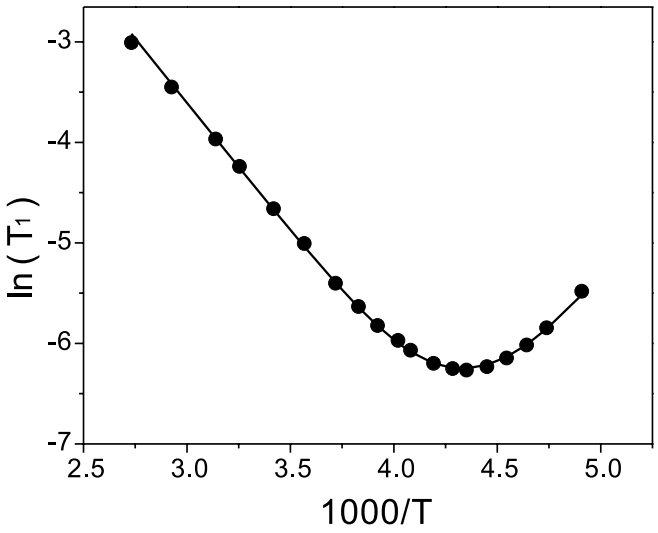

Deuterium spin-lattice relaxation

The ^2H T_1 as a function of temperature is presented in Fig. 6. As the OD deuteron is static throughout the temperature range studied, the curvature in the ln (T_1) vs. 1/T plot is entirely due to the change in the reorientational rate of the ND_3 group. A fit of the experimental data to eqs. [5] and [6] yields E_a = 21.3 ± 2 kJ/mol, τ_∞ = 5.0 ± 0.4 × 10^{-14} s, and χ = 155 ± 5 kHz. An earlier proton T_1 study gave E_a = 18.0

kJ/mol and $\tau_\infty = 2.3 \times 10^{-14}$ s (16). The value of χ also agrees with that obtained from the line shape analysis. For a three-site jumping motion the rotational correlation time and jumping rate are related by $\tau = 1/(3k)$. Using the infinite temperature rate constant from the line shape analysis a τ_∞ value of $(3.0 - 6.7) \times 10^{-14}$ s is obtained, in good agreement with the deuterium and proton T_1 results. Our E_a values are about 20–25% higher than that of the proton study. This effect has been previously reported (17), and it has been attributed to a shifting of the torsional energy levels towards the bottom of the potential well due to an increase in the moment of inertia upon deuteration. The predicted result is an increase in the energy difference between the zero-point energy and the energy maximum for NH_3 rotation.

Internal rotation

The calculated value of E_a for internal rotation in isolated NH_3OH^+ is 5.8 kJ/mol. At the MP2/6-31G** level with geometry optimization. The value changes to 6.6 kJ/mol if the neutron diffraction structure is used. Both of these values are significantly smaller than the activation energy for NH_3 rotation measured in solid HAC. Evidently there are important intermolecular interactions affecting the rotational barrier. The neutron diffraction structure shows relatively short N-H···Cl distances, indicative of hydrogen bonding. If the NH_3 end of the HA^+ cation is surrounded by three Cl^- anions, arranged according to the neutron diffraction structure, E_a goes up to 62 kJ/mol. Although this is now significantly higher than the measured values, it does represent an upper limit, since the geometry of the $[NH_3OH^+\ Cl_3^-]^{-2}$ complex was not allowed to relax during these calculations.

The ^{15}N chemical shift tensor

The experimental and simulated ^{15}N spectra for a non-spinning sample of ^{15}N enriched HAC are shown in Fig. 7. The chemical shift tensor components are $\delta_{11} = \delta_{22} = -267 \pm 1$ ppm and $\delta_{33} = -330 \pm 1$ ppm with respect to pure CH_3NO_2. The observed chemical shift anisotropy, $\Delta\delta$, is 63 ppm with an asymmetry parameter, η, of 0.0. Rapid rotation of the NH_3 group insures that η is negligible. A small (less than 1% of the total intensity) featureless peak appears at –341 ppm and is due to a small amount of NH_4Cl in the sample. Table 2 gives the ^{15}N tensor components calculated at various levels and with different basis sets for several structures of the isolated NA^+ cation and the neutron diffraction structure of the $[NH_3OH^+Cl_3^-]^{-2}$ cluster. The tabulated results show clearly that the calculated chemical shift components are rather insensitive to a change of NO or NH bond length. The set of calculated tensor components for isolated HA^+ that are closest to the experimental values are those calculated at the B3LYP level of density functional theory using the D95** basis set. DFT calculations at the B3LYP/D95** level employing solid state diffraction structures have been in good agreement with measured values for a series of nitrogen heterocycles (18) and for nitrobenzene derivatives.[2] A further calculation on $[NH_3OH^+Cl_3^-]^{-2}$ yields values of δ_{11}

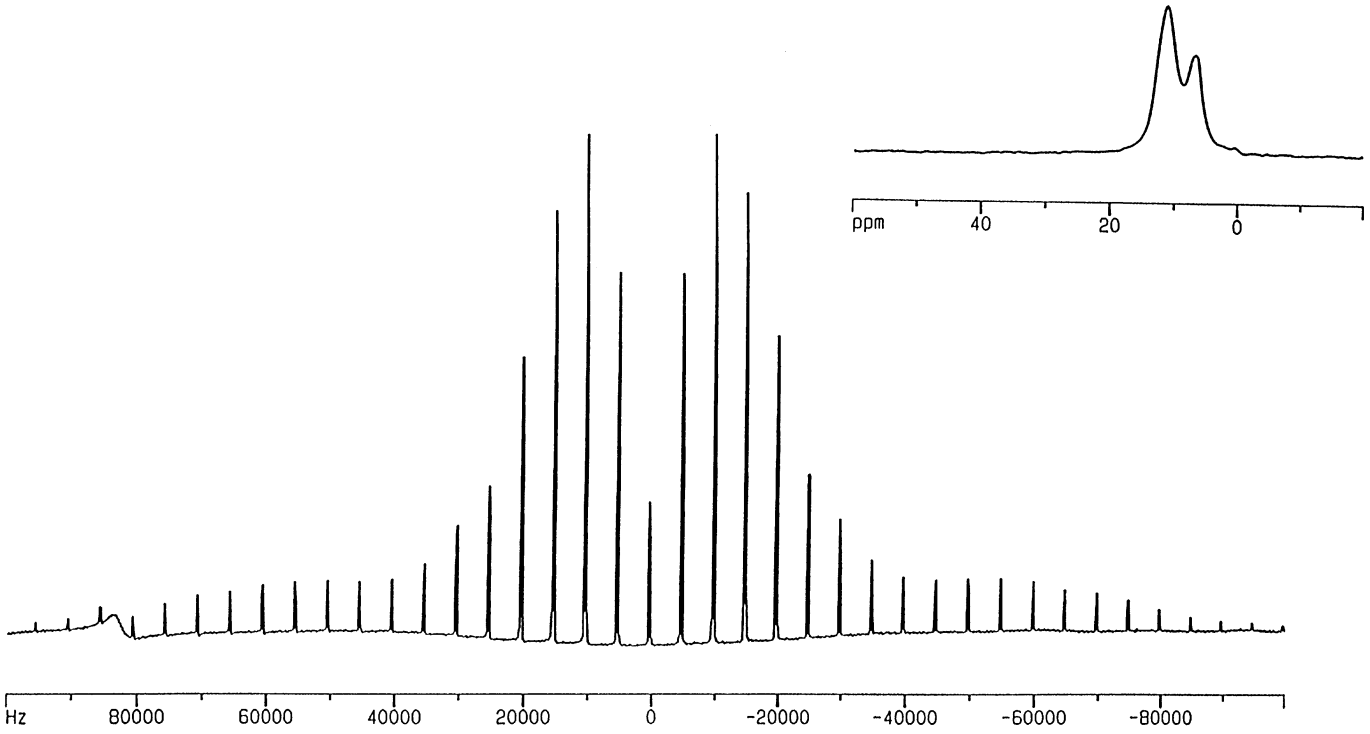
Fig. 8. The deuterium MAS spectrum of HAC-d_4. The inset shows the central set of peaks.



= –280 ppm, δ_{22} = –285 ppm, and δ_{33} = –340 ppm. This calculation yields a δ_{33} value that is much closer to experiment and the best calculated value of $\Delta\delta$ but slightly poorer agreement for δ_{11} and δ_{22}. The NH_3OH^+ cation is unique among ammonium cations in that is has by far the largest chemical shift anisotropy reported to date.

Calculation of nuclear quadrupolar coupling constants

Our experimental values for the deuterium nuclear quadrupolar coupling constants, χ(OD) and $\chi(ND_3)$, are 194 ± 5 kHz and 155–160 kHz, respectively, the latter value being a motional average over all three ND deuterons. The corresponding, calculated values for free HA^+, using the neutron diffraction geometry are 251 kHz (η = 0.26) and 221 kHz. These values were obtained from B3LYP/6-31G** calculations, which have been shown to give χ(D) values in excellent agreement with gas phase experimental values (19). These values are strongly dependent on X—D bond lengths, the χ values decreasing with elongation of the bond. Calculations for the $[NH_3OH^+Cl_4^-]^{-3}$ cluster give values of 233 (η = 0.27) and 217 kHz, in slightly better agreement with experiment. If one then corrects for thermal motion (1) (r_{OD} = 0.996 and r_{ND} = 1.045) a significantly better agreement is achieved with χ(OD) = 205 (η = 0.29) and χ(ND) = 179 kHz.

The ^{14}N quadrupolar coupling constant has been measured in solid HAC by nuclear quadrupole resonance spectroscopy (20). A $\chi(^{14}N)$ value of 4.0 MHz and an asymmetry value of 0.04 were obtained. Calculations on free HA^+, using all of the geometries and basis sets of Table 2 gave values in the rather narrow range of 2.8 ± 0.2 MHz with η values of less than 0.05. The value of χ as in poor agreement with the NQR experiment. On the other hand MP2/6-31G** calculations on $[NH_3OH^+Cl_3^-]^{-2}$ gave $\chi(^{14}N)$ = 4.3 MHz and η = 0.04. A B3LYP/D95** calculation on $[NH_3OH^+Cl_4^-]^{-3}$ gave $\chi(^{14}N)$ = 4.0 MHz and η = 0.10 in very good agreement with the experimental values. Obviously, the inclusion of the chloride ions around the HA^+ cation strongly affects the efg at the nitrogen nucleus.

Isotropic deuterium chemical shifts

The accurate determination of proton chemical shifts in solids has been notoriously difficult. Two techniques have contributed significantly to overcoming these difficulties. The CRAMPS experiment removes the strong homonuclear dipolar coupling while maintaining chemical shift information (21). Very fast magic angle spinning will remove the homonuclear couplings and anisotropic chemical shift interaction. The combination of these two can yield high-resolution ^{1}H spectra for solid samples. Unfortunately, CRAMPS is a fairly demanding experiment, and ultrafast MAS requires special equipment. Alternatively, one can obtain comparable resolution by performing a simple ^{2}H MAS experiment at typical spinning speeds. Isotropic chemical shifts can be obtained from an MAS spectrum of a uniformly deuterated polycrystalline sample provided that the deuterons are not involved in an exchange process with rates on the order of the quadrupolar coupling constant (10^3–10^5 s^{-1}). A deuterium MAS spectrum is shown in Fig. 8. There are two isotropic peaks with chemical shifts of 11.4 ± 0.1 ppm and 6.9 ± 0.1 ppm with respect to TMS. The assignment, while not agreeing with the expected intensities, is based on the fact that the peak at 11.4 ppm is associated with a much broader manfold of spinning sidebands. We as-

© 1999 NRC Canada

sign the more intense peak at 11.4 ppm to the OD deuteron. Unfortunately, our calculations (B3LYP/D95**) on $[NH_3OH^+Cl_4^-]^{-3}$ yield isotropic NH_3 and OH chemical shifts that differ by less than 1 ppm.

Summary

We have determined the deuterium quadrupolar coupling constant, χ, for the ND_3 and OD deuterons in solid HAC-d_4. In addition, the temperature dependent rates and activation energy for ND_3 group rotation have been determined. These are in good agreement with an earlier proton NMR study. Analysis of the ^{15}N powder spectrum of HAC-^{15}N provides the ^{15}N chemical shift tensor components. Calculation of the ^{15}N shift tensor gave the best agreement with experiment for B3LYP calculations using the neutron diffraction structure. Molecular orbital calculations of $\chi(^2H)$ and $\chi(^{14}N)$ in isolated HA^+ are in poor agreement with the experimental numbers. Including the effects of the surrounding Cl^- anions results in a significant improvement. Similarly, calculations on the E_a for NH_3 rotation are more realistic if the N-H···Cl hydrogen bonding interactions are included. Finally, we show that a deuterium MAS experiment can distinguish the ND_3 and OD deuterons providing solid state proton chemical shifts for *solid* HAC.

Acknowledgments

We wish to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support. Dr. Nick Taylor of the University of Waterloo is also thanked for help with interpreting the neutron diffraction structure.

Synthesis and X-ray structural characterization of the ruthenium β-diketonato complexes: $Ru(hfac)_3$, *cis*-$Ru(hfac)_2(MeCN)_2$, and *cis*-$Ru(hfac)(acac)(MeCN)_2$

Ian R. Baird, Steven J. Rettig, Brian R. James, and Kirsten A. Skov

Abstract: $Ru(hfac)_3$ (**2**) was synthesized via peroxide oxidation of the Ru(II) species $[Na][Ru(hfac)_3]$ (**1**) (hfac = 1,1,1,5,5,5-hexafluoroacetylacetonate). Treatment of either **1** or **2** with CF_3SO_3H in MeCN generated *cis*-$Ru(hfac)_2(MeCN)_2$ (**3**). $Ru(acac)_2(hfac)$ (**4**) (acac = acetylacetonate) was generated by addition of hfac to an EtOH solution of *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$. Subsequent treatment of **4** with CF_3SO_3H in MeCN yielded *cis*-$Ru(acac)(hfac)(MeCN)_2$ (**7**). Syntheses of $[Na][Ru(hfac)_2(acac)]$ (**5**) and $Ru(hfac)_2(acac)$ (**6**) are also reported. The complexes were characterized generally by elemental analysis, cyclic voltammetry, UV-vis, NMR, and IR spectroscopies. The structures of **2**, **3**, and **7** were established by X-ray crystallographic analyses. Crystals of **2** are monoclinic with a = 8.7781(4), b = 13.0760(11), c = 19.1857(5) Å, β = 92.2275(5)°, Z = 4, and space group $P2_1/n$; those of **3** are monoclinic with a = 25.731(4), b = 8.8332(13), c = 18.1955(4) Å, β = 93.3395(6)°, Z = 8, and space group $C2/c$; and those of **7** are triclinic with a = 7.6812(9), b = 10.680(2), c = 12.578(2) Å, α = 88.062(6)°, β = 83.874(3)°, γ = 69.5898(15)°, Z = 2, and space group $P\bar{1}$. The structures were solved by Patterson methods and refined by full-matrix least-squares procedures to $R(F)$ = 0.036, 0.035, and 0.068 ($R_w(F^2)$ = 0.061, $R_w(F)$ = 0.052, and $R_w(F)$ = 0.089), respectively.

Key words: ruthenium, β-diketonato complexes, acetylacetonate, 1,1,1,5,5,5-hexafluoroacetylacetonate, acetonitrile complexes.

Résumé : On a synthétisé le $Ru(hfac)_3$ (**2**) par le biais d'une oxydation au peroxyde de l'espèce Ru(II) suivante: $[Na][Ru(hfac)_3]$ (**1**) (hfac = 1,1,1,5,5,5-hexafluoroacétonylacétonate). Le traitement des composés **1** ou **2** avec du CF_3SO_3H dans du MeCN conduit au *cis*-$Ru(hfac)_2(MeCN)_2$ (**3**). On a généré du $Ru(acac)_2(hfac)$ (**4**) (acac = acétylacétonate) par addition de hfac à du *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$ en solution dans EtOH. Un traitement subséquent du produit **4** avec du CF_3SO_3H dans du MeCN conduit au *cis*-$Ru(acac)(hfac)(MeCN)_2$. On rapporte aussi les synthèses de $[Na][Ru(hfac)_2(acac)]$ (**5**) et $Ru(hfac)_2(acac)$ (**6**). Les complexes ont généralement été caractérisés par analyse élémentaire, voltampérométrie cyclique et par spectroscopies UV-vis, RMN et IR. Les structures **2**, **3** et **7** ont été confirmées par diffraction des rayons X. Les cristaux du composé **2** sont monocliniques, groupe d'espace $P2_1/n$, avec a = 8,7781(4), b = 13,0760(11) et c = 19,1857(5) Å, β = 92,2275(5)° et Z = 4; ceux du composé **3** sont monocliniques, groupe d'espace $C2/c$, avec a = 25,731(4), b = 8,8332(13) et c = 18,1955(4) Å, β = 93,3395(6)° et Z = 8 et ceux du composé **7** sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 7,6812(9), b = 10,680(2) et c = 12,578(2) Å, α = 88,062(6)°, β = 83,874(3)° et γ = 69,5898(15)° et Z = 2. Les structures ont été résolues par les méthodes de Patterson et affinées par les méthodes des moindres carrés (matrice complète) jusqu'à des valeurs de $R(F)$ = 0,036, 0,035 et 0,068 ($R_w(F^2)$ = 0,061, $R_w(F)$ = 0,052 et $R_w(F)$ = 0,089) respectivement.

Introduction

1,1,1,5,5,5-Hexafluoroacetylacetonate (hfac) and other β-diketonates constitute a class of chelating ligands that has been widely employed; their coordination chemistry with Ru(II) and Ru(III) has been widely studied (1–7), with stable, six-membered chelate rings being formed. Variation of the substituents at the 1 and 5 positions of hfac leads to numerous ligand possibilities (8–11). Many research groups, especially Shimizu's, have studied the electrochemical and chemical properties of tris(β-diketonato) ruthenate(II) and ruthenium(III) complexes, including the effects of such substituents (6, 8, 9–16). Patterson and Holm (15) reported that the half-wave reduction potentials span a large range from +0.726 V for $Ru(hfac)_3$ to –0.728 V for $Ru(acac)_3$ (vs. SCE).

Typically, the synthesis of Ru(III) tris(β-diketonato) complexes is performed by reacting the β-diketone with $RuCl_3 \cdot 3H_2O$ in H_2O:EtOH (1:2) (i.e., via a "Ru blue" intermediate) (3) or in 10% aqueous HCl and Na_2CO_3 (1). However, for isolation of mixed-ligand β-diketonato complexes, such syntheses are limited, and yield only a small amount of a mixture of the tris and the mixed-ligand species, which must be isolated chromatographically (7). The synthesis of tris(β-diketonato) complexes with asymmetric ligands (where R ≠ R′ for R(CO)CH(CO)R′) has also been reported, but a mixture of optical isomers with *mer*- and *fac*- configurations resulted, making subsequent purification difficult (17).

In one instance, the mixed-ligand complexes $Ru(hfac)_2(acac)$ and $Ru(acac)_2(hfac)$ were prepared by refluxing $Ru(hfac)_3$ and $Ru(acac)_3$ in toluene for days, but neither complex was isolated pure (15); however, $Ru(acac)_2(hfac)$ has been isolated via a Ru blue route (10) and from *cis*-$Ru(acac)_2(MeCN)_2$ (18). Substitution of a β-diketonate ligand by two MeCN ligands in the presence of a strong acid, such as CF_3SO_3H, yields [Ru(β-diketonato)$_2$(MeCN)$_2$][CF_3SO_3] species which are useful precursors for the synthesis of other mixed-ligand, β-diketonato complexes (18–20).

Here we report the synthesis and structural characterization of $Ru(hfac)_3$ (**2**), the new complex *cis*-$Ru(hfac)_2(MeCN)_2$ (**3**) and *cis*-Ru(hfac)(acac)$(MeCN)_2$ (**7**). The NMR, IR, UV-vis, and CV data are reported for all the complexes. Only elemental analysis data for **7** were previously reported. The syntheses and characterizations of [Na][$Ru(hfac)_2(acac)$] (**5**) and pure $Ru(acac)_2(hfac)$ (**4**) and $Ru(hfac)_2(acac)$ (**6**) are also reported. These complexes have been used as precursors for syntheses of various Ru-imidazole species that are of interest biologically (21–23).

Experimental

Hacac, Hhfac, and $NaHCO_3$ (Aldrich products) were used as received, as were anhydrous MeCN (Aldrich) and benzene (Fisher). Other solvents were dried using the appropriate drying agent: MeOH (Mg), EtOH (Mg), acetone (K_2CO_3), and CH_2Cl_2 (CaH_2). d_6-Acetone and $CDCl_3$ were obtained from CIL, Inc.

UV-vis absorption spectra were recorded in MeOH on an HP 8452A diode array spectrophotometer and are given as λ_{max} (nm) ($\varepsilon_{max} \times 10^{-3}$ (M^{-1} cm^{-1})), sh = shoulder. IR spectra (as KBr pellets) were recorded as cm^{-1} on an ATI Mattson Genesis FTIR instrument (only the relatively intense bands are reported), and ^1H and $^{19}F\{^1H\}$ NMR spectra were recorded on Bruker AC200F or Varian XL300 spectrometers. ^1H shifts are referenced to the residual proton shift of the internal deuterated solvent, and ^{19}F shifts are referenced to trifluoroacetic acid. Electrochemistry was performed on 10^{-3} M solutions (MeCN) in 0.1 M TBAP (tetrabutylammonium perchlorate) on a Pine biopotentiostat model AFCBP1; the working and counter electrodes were Pt plates (6 mm^2) and the reference electrode was Pt wire. Reduction potentials are reported vs. SCE, the values being determined by reference to a measured ferrocene/ferrocenium couple. TLC was run on precoated (0.2 mm) silica gel 60 F_{254} plates (E.M. Laboratories, Inc). LR–MS (+ LSIMS) data were obtained in this department on a KRATOS Concept IIHQ instrument. All the spectra, CV data, and procedures were done at room temperature (r.t.). Elemental analyses were performed here by Mr. P. Borda.

cis-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3]

This precursor was synthesized using a modification of a procedure reported for the synthesis of the analogous perchlorate salt (19). This same synthesis for the triflate, starting from the $Ru(acac)_3$ precursor, appeared in the literature during the course of our work on such systems (20). Data for *cis*-[$Ru(acac)_2(MeCN)_2$][CF_3SO_3]: yield 96% (cf. lit. yield of 70% (20)). Anal. calcd. for $C_{15}H_{20}N_2O_7SF_3Ru$: C 33.96, H 3.80, N 5.28; found: C 34.18, H 3.87, N 4.97. LR–MS (+ LSIMS): 382 (M^+), 341 (M^+ – MeCN), 300 (M^+ – 2MeCN). IR: 3469 (O-H); 3098, 2990, 2931 (C-H); 2326 ($C{\equiv}N_{asym.}$); 2296 ($C{\equiv}N_{sym.}$); 1524 (C=O); 1428, 1329, 1265, 1157, 1030, 939, 639. UV-vis: 214 (11.6), 282 (9.67), 318 (5.12), 552 (1.40). ^1H NMR (300 MHz, $CDCl_3$) δ: 37.53 (br s, 6H, *Me*CN), –23.46 (s, 6H, acac-*Me*), –27.22 (s, 6H, acac-*Me*). $^{19}F\{^1H\}$ NMR (188 MHz, $CDCl_3$) δ: –1.89 (s, $CF_3SO_3^-$). The IR and ^1H NMR data are similar to those reported for the analogous perchlorate salt (19). $E_{1/2}$ = –77 ± 3 mV.

[Na][Ru(hfac)$_3$] (1)

The synthesis of [K][$Ru(hfac)_3$] was previously reported (9). Here, we report a new route to the analogous sodium salt. In a Schlenk tube, a solution of $RuCl_3 \cdot 3H_2O$ (4.015 g, 0.0162 mol) in 30 mL EtOH was stirred at 75°C for 4 h under a steady stream of H_2. $NaHCO_3$ (4.615 g, 0.0549 mol) was added slowly to the resulting Ru blue solution, followed by addition of Hhfac (7.76 mL, 0.0549 mol). The reaction vessel was sealed under 1 atm N_2 and the mixture then stirred for 16 h at r.t. The final solution was purple–pink, and TLC analysis revealed the major product as a pink band (**1**), which was separated by column chromatography (silica gel; CH_2Cl_2:MeOH, 20:1) to yield a purple–black solid (~8 g), which was further purified via vacuum sublimation at 100°C (7.576 g, 65%). Anal. calcd. for $C_{15}H_3O_6F_{18}RuNa$: C 24.18, H 0.41; found: C 24.07, H 0.50. IR: 1555 (C=O); 1526, 1447, 1333, 1265, 1221, 1150, 820, 698, 606. UV-vis: 210 (8.01), 236 (8.89), 290 (17.4), 490 (11.6), 528 (13.9). ^1H NMR (200 MHz, d_6-acetone) δ: 6.19 (s, hfac-*H*). $^{19}F\{^1H\}$ NMR (188 MHz, d_6-acetone) δ: 2.18 (s, -CF_3), not previously reported. The other spectroscopic data are in good agreement with those previously reported for the K salt (9). $E_{1/2}$ = 718 ± 3 mV.

© 1999 NRC Canada

$Ru(hfac)_3$ (2)

The compound **2** was synthesized according to a modified literature procedure (9). Compound **1** (1.05 g, 1.41 mmol) was suspended in H_2O:benzene (200 mL, 1:1) to give a red–brown biphasic system. H_2O_2 (1% aqueous, 5 mL) was added dropwise and the mixture stirred at r.t. for 2 h; the resulting aqueous phase was opaque, yellow–brown, while the organic layer was deep red. The aqueous phase was separated and washed with benzene (2 × 40 mL). The organic washings were taken to dryness at r.t., and the crude **2** was purified by sublimation at 60°C to yield red crystals (0.776 g, 76%). Anal. calcd. for $C_{15}H_3O_6F_{18}Ru$: C 24.95, H 0.42; found: C 25.07, H 0.60. IR: 1582 (C=O); 1539, 1421, 1348, 1266, 1210, 1149, 822, 698, 601. UV-vis: 216 (12.5), 274 (14.5), 376 (6.65), 524 (1.87). ^{1}H NMR (300 MHz, $CDCl_3$) δ: –41.67 (s, hfac-*H*). $^{19}F\{^1H\}$ NMR (188 MHz, $CDCl_3$) δ: –11.49 (s, -CF_3), not previously reported. The other spectroscopic data agree well with those previously reported (9). $E_{1/2}$ = 721 ± 3 mV.

***cis*-$Ru(hfac)_2(MeCN)_2$ (3)**

Compound **1** (4.00 g, 5.54 mmol) was dissolved in 150 mL MeCN to give a purple–pink solution. The mixture, heated slowly during dropwise addition of CF_3SO_3H (0.865 mL, 6.09 mmol), quickly turned red–brown, this being accompanied by much fuming. The solution was refluxed for 1 h in air during which the colour turned dark brown. TLC analysis revealed a number of side-products and a brown band (R_f = 0.90; CH_2Cl_2:MeOH, 50:1), which was separated by column chromatography (silica gel; CH_2Cl_2) to give pure **3** as a brown solid (2.709 g, 95%). Suitable crystals for X-ray analysis were obtained from slow evaporation of a concentrated MeOH solution of **3**. Anal. calcd. for $C_{14}H_8N_2O_4F_{12}Ru$: C 28.15, H 1.35, N 4.69; found: C 28.35, H 1.33, N 4.62. LR–MS (+ LSIMS): 598 (M^+), 516 (M^+ – 2MeCN). IR: 2357 ($C{\equiv}N_{asym.}$); 2285 ($C{\equiv}N_{sym.}$); 1576, 1546 (C=O); 1482, 1475, 1335, 1262, 1212, 1195, 1153, 1095, 798, 696. UV-vis: 218 (17.1), 286 (16.8), 418 (6.10), 470 (8.43). ^{1}H NMR (200 MHz, d_6-acetone) δ: 6.20 (s, 2H, hfac-*H*), 2.87 (s, 6H, *Me*CN). $^{19}F\{^1H\}$ NMR (188 MHz, d_6-acetone) δ: 0.98 (s, -CF_3), 0.38 (s, -CF_3). $E_{1/2}$ = 1143 ± 3 mV. Of note, **3** could also be synthesized from **2** in relatively high yield (75%) using conditions identical to those reported above for the synthesis from **1**.

$Ru(acac)_2(hfac)$ (4)

In a Schlenk tube, *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$ (2.45 g, 4.61 mmol) was dissolved in 30 mL EtOH. $NaHCO_3$ (0.433 g, 5.16 mmol) and Hhfac (725 μL, 5.12 mmol) were then added, and the reaction mixture was heated to reflux under air (~80°C). After 1.5 h, the mixture, originally navy blue, became dark red. The solvent was removed and the residue was loaded onto a silica gel column and eluted quickly (CH_2Cl_2:MeOH, 25:1) by flash chromatography to remove any low R_f side-products. The first band (dark red) yielded a solid, which was dissolved in acetone, and the solution was then transferred to a sublimation flask equipped with a cold finger and heated to 100°C under vacuum; the dark red product, which sublimed onto the cold finger, was transferred to a sample vial and dried in vacuo at r.t. (1.75 g, 75%). (**4** is hygroscopic and must be transferred quickly when handling in air. Because **4** sublimes at ~60°C under vacuum, the removal of acetone solvate, prior to elemental analysis, was not possible.) Anal. calcd. for $C_{15}H_{15}O_6F_6Ru{\cdot}0.5C_3H_6O$: C 37.02, H 3.39; found: C 37.02, H 3.26. IR: 1543, 1521 (C=O); 1420, 1340, 1259, 1201, 1146, 1099, 1025, 934, 808, 693. UV-vis: 210 (13.4), 284 (13.6), 332 (6.43), 502 (2.38). ^{1}H NMR (300 MHz, d_6-acetone) δ: –8.82 (s, 6H, acac-*Me*), –9.01 (s, 6H, acac-*Me*), –28.45 (s, 1H, hfac-*H*), –38.95 (s, 2H, acac-*H*). $^{19}F\{^1H\}$ NMR (188 MHz, d_6-acetone) δ: –9.71 (s, -CF_3), not previously reported. The spectroscopic data generally agree well with those previously reported (10), but δ for hfac-*H* in $CDCl_3$ is reported at –35.10. $E_{1/2}$ = –232 ± 3 mV.

[Na][$Ru(hfac)_2(acac)$] (5)

In a Schlenk tube, **3** (0.300 g, 0.502 mmol) was dissolved in 10 mL EtOH to give a dark brown solution. $NaHCO_3$ (0.0534 g, 0.636 mmol) and Hacac (60 μL, 0.584 mmol) were added, and the mixture was heated to reflux (~80°C) in air. The reaction was monitored using TLC as no colour change was observed; the concentration of **3** decreased while a new pink band appeared after ~2 h. After 7 h the solvent was removed under reduced pressure, and then CH_2Cl_2 (20 mL) was added. The mixture was sonicated for 5 min, yielding a dark purple solid, which was collected and washed with CH_2Cl_2 (3 × 10 mL). The crude solid was purified by column chromatography (silica gel; CH_2Cl_2:acetone, 20:1) to yield a pink–purple solid (0.0986 g, 32%). Anal. calcd. for $C_{15}H_9O_6F_{12}RuNa$: C 28.27, H 1.42; found: C 28.06, H 1.38. IR: 1550, 1521 (C=O); 1466, 1391, 1323, 1264, 1198, 1146, 940, 808, 695. UV-vis: 210 (8.06), 248sh (11.1), 278 (18.2), 380 (2.01), 478 (7.59). ^{1}H NMR (200 MHz, d_6-acetone) δ: 5.77 (s, 2H, hfac-*H*), 5.00 (s, 1H, acac-*H*), 1.86 (s, 6H, acac *Me*). $^{19}F\{^1H\}$ NMR (188 MHz, d_6-acetone) δ: 2.50 (s, -CF_3), 2.48 (s, -CF_3). $E_{1/2}$ = 284 ± 3 mV.

$Ru(hfac)_2(acac)$ (6)

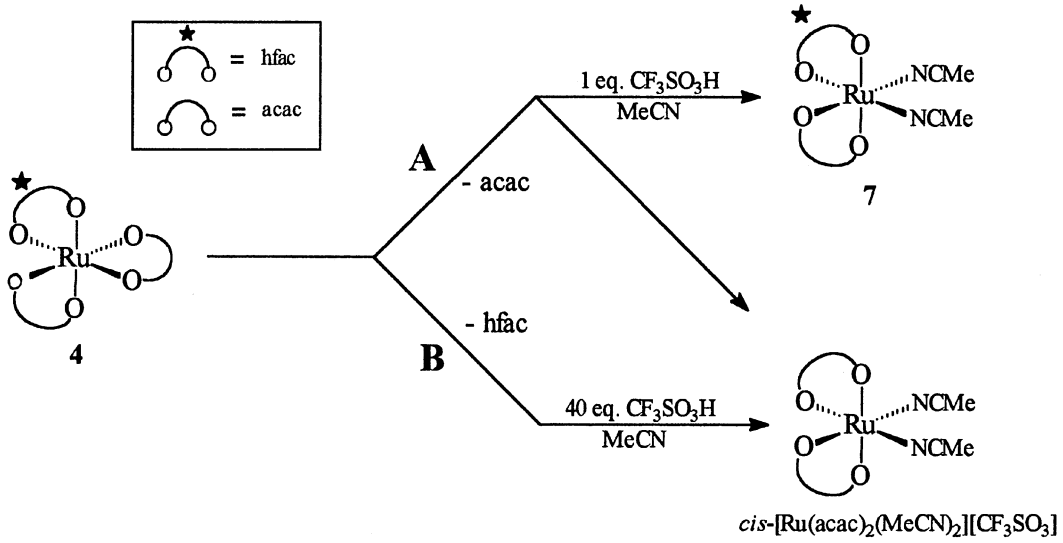
Compound **5** (0.0550 g, 0.0863 mmol) was suspended in an H_2O (20 mL):benzene (20 mL) mixture to give a dark purple, biphasic system. This was stirred at r.t. in air, and H_2O_2 (1% aqueous, 5 mL) was added dropwise, the mixture becoming green. The aqueous phase was pale yellow while the organic layer was dark green. After 1 h, the organic phase was separated and the benzene removed via rotary evaporation at 20°C. The crude **6** was purified by sublimation at 60°C to give a green–black solid (0.0423 g, 80%). Anal. calcd. for $C_{15}H_9O_6F_{12}Ru$: C 29.33, H 1.48; found: C 28.99, H 1.49. IR: 1583, 1579 (C=O); 1553, 1520, 1436, 1344, 1264, 1207, 1152, 807, 699, 598. UV-vis: 248sh (11.1), 286 (19.2), 376 (8.25), 556 (1.67). ^{1}H NMR (300 MHz, $CDCl_3$) δ: –14.34 (s, 6H, acac *Me*), –31.82 (s, 1H, acac-*H*), –56.72 (s, 2H, hfac-*H*). $^{19}F\{^1H\}$ NMR (188 MHz, $CDCl_3$) δ: –6.71 (s, -CF_3), –8.06 (s, -CF_3). $E_{1/2}$ = 289 ± 3 mV.

***cis*-$Ru(acac)(hfac)(MeCN)_2$ (7)**

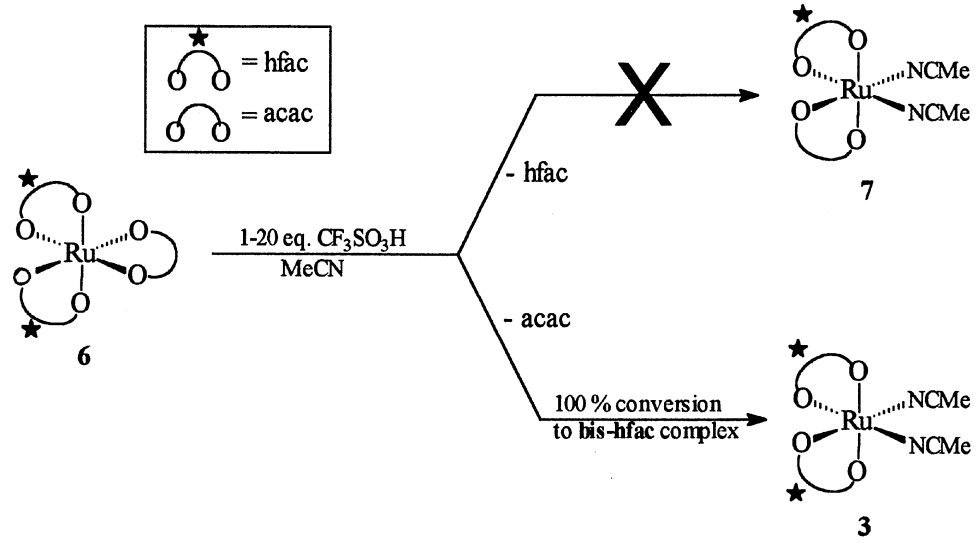
Compound **7** was synthesized according to a modified literature procedure (18). Compound **4** (0.159 g, 0.313 mmol) was dissolved in 10 mL MeCN and the mixture heated in air to 70°C yielding a red solution to which CF_3SO_3H (44 μL,

© 1999 NRC Canada

Scheme 1. Synthesis of *cis*-Ru(acac)(hfac)$(MeCN)_2$ from $Ru(acac)_2(hfac)$ (**4**); **7**: *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$ = 1.0 (path *A*) and 0.1 (path *B*).



Scheme 2. Attempted synthesis of *cis*-Ru(acac)(hfac)$(MeCN)_2$ (**7**) from $Ru(hfac)_2(acac)$ (**6**).



0.313 mmol) was then added. TLC analysis after 2 h revealed that $acac^-$ and $hfac^-$ displaced products ((**7**) and *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$, respectively) were formed in equal amounts. The mixture was purified using preparative TLC (CH_2Cl_2:MeOH, 20:1); the band corresponding to **7** yielded a red–brown solid (0.0746 g, 49%). Crystals suitable for X-ray analysis were obtained via slow evaporation of a concentrated MeOH solution of **7**. Anal. calcd. for $C_{14}H_{14}N_2O_4F_6Ru$: C 34.46, H 2.88, N 5.72; found: C 34.38, H 2.88, N 5.42. IR: 2993, 2930 (C-H); 2346 ($C{\equiv}N_{asym.}$); 2270 ($C{\equiv}N_{sym.}$); 1567, 1547 (C=O); 1406, 1261, 1200, 1147. UV-vis: 228 (15.8), 276 (14.1), 352 (4.07), 482 (4.67). ^1H NMR (200 MHz, d_6-acetone) δ: 6.04 (s, 1H, hfac-*H*), 5.37 (s, 1H, acac-*H*), 2.76 (s, 3H, *Me*CN), 2.69 (s, 3H, *Me*CN), 1.94 (s, 3H, acac *Me*), 1.93 (s, 3H, acac *Me*). $^{19}F\{^1H\}$ NMR (188 MHz, d_6-acetone) δ: 2.29 (s, -C*F*$_3$), 2.09 (s, -C*F*$_3$). $E_{1/2}$ = 544 ± 3 mV. Only the elemental analysis data were previously reported (18).

This reaction was repeated using a ratio of 1:40 for **4**:CF_3SO_3H, which yielded results different from those described above. The major product here was *cis*-$[Ru(acac)_2(MeCN)_2][CF_3SO_3]$ as determined by TLC and ^1H NMR, while only ~10% of **7** was present, showing that the stoichiometry of the reactants is important in determining the reaction path (see Scheme 1). The synthesis of **7** was also attempted starting from either **5** or **6**, following the same reaction conditions as described above; however, only **3** was produced (see Scheme 2).

X-ray crystallographic analyses of 2, 3, and 7

Crystallographic data for **2**, **3**, and **7** appear in Table 1, and the respective structures are shown in Figs. 1–3. The final unit-cell parameters were obtained by least squares on the setting angles for 13 128 reflections with 2θ = 4.0°–61.0° for **2**, 14 188 reflections with 2θ = 4.0°–60.1° for **3**, and 9023 reflections with 2θ = 4.0°–60.1° for **7**. [g]Includes crystal decay, absorption, and scaling corrections.

data processed,[2] corrected for Lorentz and polarization effects, and absorption.

The structures were solved by Patterson methods and expanded using Fourier techniques. Complex **2** crystallized in the monoclinic space group $P2_1/n$. The Λ enantiomer is seen here, but both stereoisomers must be present in the unit cell; the Δ isomer was illustrated for the previously reported X-ray structure of $Ru(acac)_3$ (3), which crystallized in the $P2_1/c$ space group. Complex **3** crystallized in the monoclinic space group $C2/c$. Complex **7** crystallized in the triclinic space group $P\bar{1}$. The CF_3 groups at C(6) and C(10) for **2** and **3**, respectively, were modelled as 1:1 two-fold disordered. Population parameters for the disordered atoms were adjusted to give roughly equivalent isotropic thermal parameters. For **2** and **3** the non-hydrogen atoms were refined anisotropically while for **7** some of the atoms were refined isotropically. Hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2B_{bonded\ atom}$. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from Standard Tables (24). Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths and bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters,

Results and discussion

Series of Ru(III) tris(β-diketonato) complexes have been synthesized previously (14, 15), and such species have been used as catalysts, e.g., $Ru(acac)_3$ effects the hydrogenation of nitroarenes to amines (25). Our interest was more in their use as precursors for synthesizing nitroimidazole derivatives (see Introduction). Because of the substitution – inert nature of the Ru tris(β-diketonato) complexes, more useful precursors for introduction of further mono- and bidentate ligands via ligand substitution were needed. Kobayashi et al. (18) initially reported that bis(MeCN)bis(β-diketonato)ruthenium(II) complexes could be prepared by reducing the corresponding tris(β-diketonato)ruthenium(III) with zinc amalgam in an MeCN–EtOH–H_2O mixture, and that these bis-MeCN complexes were useful intermediates for the synthesis of mixed-ligand β-diketonato ruthenium(III) complexes. Kasahara et al. (19) then reported the preparation of bis(MeCN)bis(β-diketonato)ruthenium(III) species through a ligand displacement reaction of tris(β-diketonato)ruthenium(III) complexes, induced by strong acid. $Ru(acac)_3$ has been shown to be stable under basic and neutral conditions, while introduction of acid leads to protonation of an acac ligand (26).

To synthesize mixed β-diketonato Ru(III) complexes, the appropriate homoleptic β-diketonato complexes were first required. $Ru(hfac)_3$ (**2**) could not be directly synthesized from an EtOH Ru blue solution in the presence of $NaHCO_3$, as previously described (3) for $Ru(acac)_3$, because of in situ re-

[3] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a] In **2**, **3**, and **7**, the "external" C—C bond distances (i.e., outside of the chelate rings) of the hfac and acac ligands are in the range 1.502–1.551 Å, while those within the delocalized ring systems are 1.365–1.415 Å. The C—F bond lengths, excluding data for the disordered F-atoms, are 1.269–1.346 Å.

duction to the air-stable, Ru(II) species [Na][Ru(hfac)$_3$] (**1**). The H_2O_2 oxidation of **1** to **2** followed that reported previously by Endo et al. (9) who reported **2** to be unstable, even under N_2 in the absence of light. In the present work, **2** was, however, found to be stable for long periods in air. Its X-ray structure (Fig. 1, Table 3) reveals average O-Ru-O intra- and inter-ring bond angles of 92.58°and 88.26°, respectively, and the average Ru—O bond length (1.999 Å) is the same as that of the acac structure (3), implying that the electron-withdrawing CF_3 groups have surprisingly little effect on the interaction of these β-diketonate ligands with Ru(III). There are strong intramolecular interactions between the methyne CH atoms and adjacent F-atoms of both CF_3 groups: the H···F distances are ~2.35 Å, while the C···F distances are ~2.71 Å and the C···H···F angles are close to 100°.

The mixed-ligand complexes containing both acac and hfac were isolated, but not without some difficulty. Patterson and Holm (15) reported the synthesis of Ru(acac)$_2$(hfac) (**4**) and Ru(hfac)$_2$(acac) (**6**), by refluxing Ru(acac)$_3$ and Ru(hfac)$_3$ (1:1) in toluene for 7 days (15), but the products were not isolated and purified. Compound **4** has been isolated, albeit in only 7% yield, from a Ru blue route (10). The bis-MeCN complexes, *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3], and *cis*-Ru(hfac)$_2$(MeCN)$_2$ (**3**), were thus developed as synthetic precursors as they gave less complicated product mixtures in much higher yields.

Complex **4** was synthesized by treating *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3] with about one equiv. each of Hhfac and $NaHCO_3$; the reaction proceeded rapidly giving a high yield (75%), presumably because of the relatively labile nitrile ligands and the entropically favoured chelate formation. Kobayashi et al. (18) have synthesized **4** from the Ru(II) precursor *cis*-Ru(acac)$_2$(MeCN)$_2$ in 32% yield.

Synthesis of **6** required a two-step procedure: ligand substitution in **3** to form [Na][Ru(hfac)$_2$(acac)] (**5**) followed by a Ru(II) → Ru(III) oxidation step using H_2O_2. The reaction to generate **5** required longer times and gave only 32% yield in comparison to the synthesis of **4**; i.e., the displacement of two MeCN ligands by acac$^-$ at Ru(II) is more difficult than the corresponding displacement by hfac$^-$ at Ru(III). Using the same reaction conditions for the transformation of **1** to **2**, H_2O_2 oxidation of **5** proceeded quickly. This corresponding oxidation is more efficient than for the synthesis of **2** as the final aqueous phase was pale yellow, suggesting all of **5** had been oxidized and transferred to the organic phase. The final green product (**6**), not previously isolated (10), was purified via sublimation and obtained in 80% yield.

The IR spectra of metal acetylacetonato complexes show a strong, characteristic $\nu_{C=O}$ stretching mode near 1570 cm^{-1} (27, 28). The $\nu_{C=O}$ and $\nu_{C=C}$ bands of Ru(III) β-diketonato complexes typically appear in the 1510–1620 and the 1420–1580 cm^{-1} regions, respectively, and are substituent-dependent, the hfac complexes displaying higher values than the acac complexes. These shifts can be explained in terms of the electron-withdrawing CF_3 group, and the consequent strengthening of the C=O and C=C bonds. For example, for Ru(hfac)$_2$(acac) (**6**), the $\nu_{C=O}$ bands appear at 1583 and 1579 cm^{-1}, corresponding to the hfac and acac ligands, respectively. Correspondingly, the Ru(II) complex [Na][Ru(hfac)$_2$(acac)] (**5**) has C=O bands at 1550 and 1521 cm^{-1}, the shift of the bands to lower energy being due to the lower oxidation state of the metal. The higher $\nu_{C=O}$ (1582 cm^{-1}) for Ru(hfac)$_3$ (**2**) (vs. the value of 1555 cm^{-1} for the Ru(II) analogue, [Na][Ru(hfac)$_3$] (**1**)) coincides with the value previously reported (9).

Ru(III) complexes often give very broad, poorly resolved ^{1}H NMR signals as a result of rapid nuclear spin relaxation induced by the paramagnetism (2), but examples of interpretable ^{1}H NMR data for Ru(III) species have appeared (29–31), and these studies on the β-diketonate complexes provide further examples. Table 5 summarizes the chemical

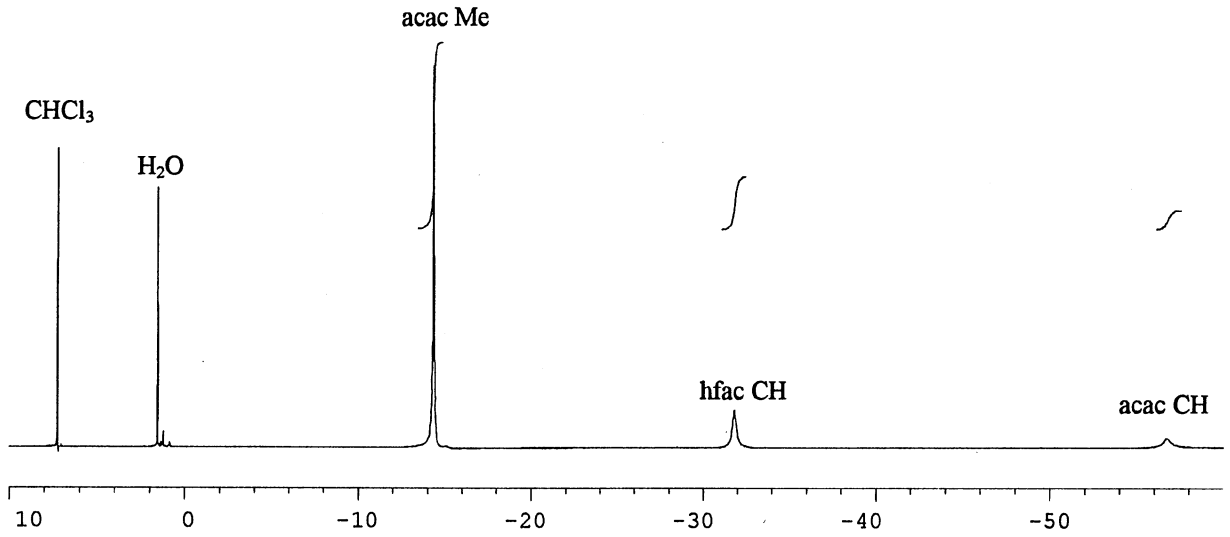
[a]Excluding data for disordered F-atoms, the F-C-F angles are in the range 104.1–109.0°, while the F-C-C angles are 108.8–115.6°.

Table 5. ^{1}H and $^{19}F\{^{1}H\}$ NMR data for the Ru(III) tris(β-diketonato) complexes.[a]

Complex	δ_H Me (acac)	δ_H CH (acac)	δ_H CH (hfac)	δ_F
$Ru(acac)_3$	–7.11	–30.25	—	—
$Ru(acac)_2(hfac)$, **4**	–8.82, –9.01	–38.95	–28.45	–9.71
$Ru(hfac)_2(acac)$, **6**	–14.34	–56.72	–31.82	–6.71, –8.06
$Ru(hfac)_3$, **2**	—	—	–41.67	–11.49

[a]At r.t.; in $CDCl_3$ for **2**, **6**, and $Ru(acac)_3$, and in d_6-acetone for **4**.

Fig. 4. ^{1}H NMR spectrum of $Ru(hfac)_2(acac)$ (**6**) in $CDCl_3$ at r.t.



shifts for the three tris(β-diketonato) complexes. The δ values for the Me signals of the coordinated acac ligands reveal an upfield shift (compared to a "diamagnetic value") due to interaction with the paramagnetic Ru(III) centre. The "stronger electron-withdrawing hfac ligand" shifts the Me signals further upfield. Complex **4** has two Me group signals, one from a moiety *trans* to the hfac ligand and one from a moeity *trans* to an acac ligand. Complex **6** has only one signal for the Me groups due to its increased symmetry with regard to the methyls. The signals for the methyne protons of acac and hfac exhibit even more significant upfield shifts. This is consistent with electronic delocalization on the chelated ligand across the methyne proton, that produces an even greater electron spin imbalance between the ligand and the metal and hence a greater isotropic shift (2). Again, the more hfac ligands, the greater the upfield shift. This effect is more pronounced for the acac methyne signal as substitution of two acac ligands of $Ru(acac)_3$ by hfac (to give **6**) renders a chemical shift change of ~26 ppm, while the reverse process (from **2** to **4**) produces a chemical shift change of ~13 ppm. A representative ^{1}H NMR spectrum illustrating the upfield shifts is shown in Fig. 4 for complex **6**; δ assignments were made according to integration ratios. The signals of the methyne protons that are bonded directly to the chelate ring are always relatively broad in Ru(III) species, and indeed, in some acac/nitroimidazole derivatives, the signals are not observed.

The $^{19}F\{^{1}H\}$ NMR spectra (Table 5) show that $Ru(hfac)_3$, with magnetically equivalent CF_3 groups, has the highest upfield signal (δ –11.49). Substitution of one hfac by acac results in a downfield shift for **6**, with two signals at δ –6.71 and –8.06, comparable to the Me proton signals of acac in **4**. The non-regular trend in δ_F with number of hfac ligands may result from a solvent effect ($CDCl_3$ vs. d_6-acetone).

The Ru(III) → Ru(II) $E_{1/2}$ values for **2**, **6**, and **4** (721, 289, and –232 mV vs. SCE in MeCN, respectively) compare reasonably well with those previously reported by Patterson and Holm (15) (726 in MeCN, 332 and –184 mV in DMF, respectively), noting that data for **6** and **4** had been determined using a mixture of the species. $E_{1/2}$ data reported by Hoshino et al. (10) appear to be in error, but in all cases, relative stabilization of Ru(II) increases markedly with increasing number of hfac ligands.

The reaction of $Ru(hfac)_3$ with CF_3SO_3H in MeCN, in an attempt to generate *cis*-$[Ru(hfac)_2(MeCN)_2][CF_3SO_3]$ analogous to the acac species (19), formed *cis*-$Ru(hfac)_2(MeCN)_2$

© 1999 NRC Canada

(**3**), implying an in situ reduction of Ru(III) to diamagnetic Ru(II). The electron-accepting CF_3 substituents clearly stabilize the Ru(II) oxidation state, thus promoting reduction of Ru(III), presumably by residual H_2O introduced by either the MeCN solvent or the hygroscopic CF_3SO_3H. Compound **3** was also readily synthesized from [Na][Ru(hfac)$_3$] (**1**). The geometry of **3** is *cis*, according to the IR, NMR, and X-ray crystallographic data. The two ν_{CN} bands for **3** (at 2357 and 2285 cm^{-1}) and for the corresponding bis-acac complex (at 2326 and 2296 cm^{-1}) (cf. 2254 cm^{-1} for free MeCN) are consistent with the absence of $d\pi \rightarrow p\pi$ backbonding from Ru. The ^1H NMR data (singlets at δ 6.20 and 2.87 corresponding to the hfac methyne proton and Me of MeCN, respectively) do not distinguish the geometry of the complex, but the $^{19}F\{^1H\}$ NMR spectrum (singlets at δ 0.98 and 0.38 for two inequivalent CF_3 groups) supports the *cis* formulation in solution, as the *trans* isomer would have revealed only one singlet. The X-ray structure (Fig. 2) reveals the *cis* geometry. The Ru—O distances average 2.038(2) Å, and the two Ru—N distances average 2.011(2) Å (Table 3). The nitriles exhibit a lengthening of the Ru—N bonds compared to those, for example, in [Ru(MeCN)(PPh$_3$)]$_2$(μ-$O_2CC_6H_4$-*p*-NO_2)$_4$(μ-H_2O) (Ru—N 1.98 Å) (32), suggesting a stronger *trans* influence for hfac versus carboxylate. Both Ru—N bonds are longer than 2.0 Å, the sum of the estimated single covalent radii (33), implying little Ru(II)$\rightarrow$N, $d\pi \rightarrow p\pi$ backbonding. The C—N bond lengths average 1.137(2) Å, slightly shorter than the 1.157 Å calculated for MeCN in the gas phase (34). Shortening of the C—N bond is commonly observed in both transition metal (35) and main group (36) nitrile complexes and is evidence against any π-backbonding in the metal–ligand interaction; this correlates well with the positive infrared shift of ν_{CN} for **3**. Intramolecular methyne CH$\cdots$F interactions are again evident, as noted for **2**.

The synthesis of *cis*-Ru(acac)(hfac)(MeCN)$_2$ (**7**) was attempted from the two mixed-ligand Ru(III) precursors **4** and **6**; however, only one of the reactions was moderately successful (involving in situ reduction of Ru(III)). Addition of 1 equiv. of triflic acid to an MeCN solution of **4** revealed rapid formation of *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3] and **7** in approximately equal amounts (Scheme 1). Use of 40 equiv. of triflic acid resulted in a lower yield of **7**, thus displaying the acid dependence of the reaction: at higher acid concentration, the hfac ligand is preferentially displaced. This observation is opposite to that reported by Kobayashi et al. (18) where for a number of mixed Ru(III) β-diketonato complexes (not involving hfac) the more basic acac ligand was preferentially displaced. These workers also reported the synthesis of **7** by treatment of **4** with a refluxing mixture of EtOH, MeCN, and H_2O (10:1:1) in the presence of zinc amalgam for 2 h; the yield was 39% versus the 49% reported here. Attempts to form **7** from **6** via triflic acid treatment in MeCN gave complete conversion to **3** whatever concentration of acid was used (Scheme 2); i.e., the acac is now preferentially displaced. There is clearly a delicate balance between factors affecting acid cleavage of the Ru—O bonds. Structural data for **7** (Table 3) show Ru—O_{hfac} bond lengths of 2.053 and 2.030 Å, and Ru—O_{acac} lengths of 2.036 and 2.023 Å, with the shorter bond in each set being *trans* to MeCN. The factors involved include: the relative basicities of acac and hfac, the relative strengths of the Ru—O bonds as reflected in ratios of kinetic labilities, and the stage at which reduction to Ru(II) occurs. Of note, attempts to synthesize **7** from the Ru(II) starting material [Na][Ru(hfac)$_2$(acac)] (**5**) were also unsuccessful.

X-ray analysis of **7** (Fig. 3) revealed essentially octahedral bonding at the metal within the *cis* geometry. The Ru—N(1) bond distance is 2.006(4) Å for MeCN *trans* to hfac while that of Ru—N(2) for MeCN *trans* to acac is 2.030(3) Å, any *trans* influencing effects being small. As in **3**, the C—N bond lengths (average 1.133(5) Å) are shorter than that of free MeCN and indicate zero π-backbonding in the ligand–metal interaction. Of note, the average Ru^{II}—O_{hfac} bond lengths in **7** (2.041 Å) and **3** (2.038 Å) are significantly longer than the average Ru^{III}—O_{hfac} bond length in **2** (1.999 Å), and the difference is typical of that usually found between corresponding bond lengths in Ru^{II} and Ru^{III} complexes (37).

The ^1H NMR spectrum of **7** supports a *cis* geometry in solution. Thus, two signals for the coordinated MeCN ligands are observed (δ 2.76 and 2.69), and the methyne ^1H signal for hfac is further downfield than the corresponding signal for acac (δ 6.04 and 5.37, respectively) due to the electron-withdrawing property of the CF_3 substituents. The IR spectrum correspondingly shows two ν_{CN} bands at 2346 and 2270 cm^{-1}, in the range observed for *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3] and **3**.

A comparison of UV-vis spectra of the Ru(II) complexes **3** and **7** shows the effect of replacement of hfac by acac on the MLCT band of these complexes; the energy for this electronic transition increases, λ_{max} shifting from 418 to 352 nm for **3** and **7**, respectively. The LMCT band for the Ru(III) species, *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3], was observed at 318 nm.

The Ru(III)$\rightarrow$Ru(II), $E_{1/2}$ reduction potentials for *cis*-[Ru(acac)$_2$(MeCN)$_2$][CF_3SO_3], *cis*-Ru(acac)(hfac)(MeCN)$_2$ (**7**), and *cis*-Ru(hfac)$_2$(MeCN)$_2$ (**3**) are –77, +544, and +1143 mV (vs. SCE), respectively, again demonstrating relative stabilization of Ru(II) with increasing number of hfac ligands. The stepwise increase in $E_{1/2}$ for the bis-MeCN complexes is ~610 mV, greater than that observed for the series of tris(β-diketonato) Ru(III) species (see above). The data also show that replacement of an hfac ligand by two MeCN ligands increases $E_{1/2}$ by up to ~420 mV, while corresponding replacement of an acac increases $E_{1/2}$ by up to ~775 mV. Such increases in $E_{1/2}$ on coordination of MeCN to Ru are well documented (20, 32, 38, 39); one of these reports states that a single MeCN ligand stabilizes the +2 oxidation state by ~0.4 V (39). The in situ reduction that occurs during the synthesis of **7** from a Ru(III) precursor resembles that seen in formation of **3** from Ru(hfac)$_3$ (**2**) or Ru(hfac)$_2$(acac) (**6**) and is considered to be due to the presence of residual H_2O.

Symmetry in double-diffusive convection

Brian Pettitt and Werner Danchura

Abstract: A theoretical treatment of the double-diffusive convection instability is presented, with a focus on the isothermal case of two solutes in a common solvent, initially forming a distinct interface. Linear stability analysis is used to determine the wave number of the marginal mode and symmetry properties of the corresponding fluid flow for realistic values of two control parameters: (*i*) the ratio of the diffusion coefficient of the solute in the lower solution to that in the upper solution (τ_d), and (*ii*) the ratio of the excess densities (relative to the solvent) of the upper to the lower solutions (τ_ρ). It is shown that the instability has two regimes: (*i*) $\tau_d^{-3/2} < \tau_\rho < \tau_d^{-1}$ in which diffusion precedes convection, and (*ii*) $\tau_d^{-1} < \tau_\rho < 1$ in which convection is immediate. The two regimes are separated by a point ($\tau_\rho = \tau_d^{-1}$) through which the wavelength diverges and the fluid velocity undergoes a continuous symmetry change. Above this point, columns of alternating up-and-down flow fade continuously into the solutions above and below the original interface. Below it, the flow within a column undergoes at least one reversal. The horizontal nodal plane associated with such a reversal should be observable.

Key words: double-diffusive convection, fluid instability, pattern formation, solutions.

Résumé : On présente un traitement théorique à l'instabilité de convection à double diffusion en mettant l'accent sur le cas isothermique de deux solutés dans un solvant commun qui forment initialement une interface distincte. On a utilisé l'analyse de stabilité linéaire pour déterminer le nombre d'onde du mode marginal et les propriétés de symétrie de l'écoulement du fluide correspondant pour des valeurs réalistes de deux paramètres de contrôle: (*i*) le rapport du coefficient de diffusion du soluté dans la solution inférieure par rapport à celui dans la solution supérieure (τ_d) et (*ii*) le rapport des excès de densités (par rapport au solvant) de la solution supérieure par rapport à la solution inférieure (τ_ρ). On a démontré que l'instabilité a deux régimes: (*i*) $\tau_d^{-3/2} < \tau_\rho < \tau_d^{-1}$ dans lequel la diffusion précède la convection et (*ii*) $\tau_d^{-1} < \tau_\rho < 1$ dans lequel la convection est immédiate. Les deux régimes sont séparés par un point ($\tau_\rho = \tau_d^{-1}$) à travers lequel la longueur d'onde diverge et la vitesse du fluide subit un changement continu de symétrie. Au-dessus de ce point, il se produit un déplacement vertical continu et alternant des colonnes au-dessus et en-dessous de l'interface originale. En-dessous de ce point, l'écoulement dans une colonne subit au moins une inversion. On devrait pouvoir observer le plan nodal horizontal associé avec cette inversion.

Mots clés : convection à double diffusion, instabilité fluide, patron de formation, solutions.

[Traduit par la Rédaction]

Introduction

An inhomogeneous solution containing two solutes, which is initially stable in the sense that its density decreases upward, can develop a convective flow pattern in regions where small vertical velocity disturbances are amplified by lateral diffusive fluxes. If an element of the fluid, suddenly displaced upward by such a disturbance, contains an excess of the solute with the larger diffusion constant, buoyancy is created in it by a net transport of molecules out. The neighboring element, displaced downward by the initial disturbance, is driven further by the net transport of molecules into it. Along with the analogous case of heat and one solute, this isothermal fluid instability is referred to as double-diffusive convection (1–3). Most work on this class of problems has involved heat transport, with model applications in oceanography (3, 4), geology and minerology (3, 5), and fluid mechanics (6). Diffusion/convection effects are important in the pattern formation produced by autocatalytic reactions (7) and some electrochemical reactions (8, 9), but there is little in the way of detailed theories coupling the hydrodynamics and chemical kinetics of processes as complicated as these.

In this paper we present a thorough linear stability analysis of double-diffusive hydrodynamics for two solutes evolving out of an initially discrete horizontal interface, which goes beyond the usual assumptions of linear concentration gradients, prescribed instability heights, and rigid boundary conditions. The presentation includes enough basic fluid mechanics to reveal the main features of the model and the approximations needed to make it tractable, in a way that emphasizes its general properties and leads to some new results. Part of this analysis is similar to that of Sartory (10), but it differs extensively in basic descriptive features (such as dimensionless groups), numerical methods, results, and interpretation. One of our objectives is to show that geometric features of this instability are suggestive of a rich variety

of patterns (11, 12), even within the linearized hydrodynamic regime.

Double-diffusive hydrodynamics

The initial system is a solution with concentration c_l^0 of a solute (diffusion constant D_l) overlaid by a solution of a second solute with concentration c_u^0 (diffusion constant $D_u < D_l$) (10). The pure solvent (with density ρ_0 and kinematic viscosity ν_0) is the same in both layers, and the density of this system is assumed to be described by an equation-of-state that is linear in the solute concentrations:

$$[1] \qquad \rho(\vec{r},t) = \rho_0(1 + \beta_l c_l(\vec{r},t) + \beta_u c_u(\vec{r},t))$$

with constant coefficients $\beta_i = \rho_0^{-1}\partial\rho/\partial c_i$. Static stability of this state requires that the density of the lower layer be greater than that of the upper layer ($\rho_0\beta_l c_l^0 = \delta\rho_l^0 > \delta\rho_u^0 = \rho_0\beta_u c_u^0$). It is well known that aqueous solutions with distinctly different densities can be layered with sharp interfaces if care is taken to avoid turbulent mixing. The idealized initial state is a model for such systems. It is perhaps best visualized in terms of removal of a thin, horizontal membrane initially separating the two layers. For mathematical simplicity, the layers are regarded as infinitely thick and wide. In practical terms, this means that they must be thick enough to exceed the vertical range of an instability at its onset and extend horizontally on a scale much larger than the wavelength. For aqueous solutions, this is typically a few centimeters. Evolution out of this state is described by the concentrations

$$[2] \qquad c_i(\vec{r},t) = c_i^{\mathrm{d}}(\vec{r},t) + \delta c_i(\vec{r},t)$$

and the velocity field $\vec{v}(\vec{r},\, t)$, where c_i^{d} and δc_i are diffusive and convective contributions, respectively. The pressure in the fluid is similarly partitioned as

$$[3] \qquad p(\vec{r},t) = p^{\mathrm{d}}(\vec{r},t) + \delta p(\vec{r},t)$$

It is assumed that the reference state is described by simple independent diffusion of the solute molecules, such that a perturbation analysis of the δc_i's, $\vec{v}$, and δp is capable of revealing the simplest features of the instability.

If the initially sharp interface is the horizontal plane $z = 0$ (in a lab-fixed frame to which all subsequent equations apply), the diffusive parts are

$$[4] \qquad \begin{aligned} c_l^{\mathrm{d}}(\vec{r},t) &= \frac{1}{2}c_l^0 \ \ \mathrm{erfc}(z/\sqrt{4D_l t}) \\ c_u^{\mathrm{d}}(\vec{r},t) &= \frac{1}{2}c_u^0 \ \ \mathrm{erfc}(-z/\sqrt{4D_u t}) \end{aligned}$$

for this constant-volume process, well away from any vertical walls and assuming that there are always regions of the original solutions above and below the active region. The corresponding vertical gradients are

$$[5] \qquad \begin{aligned} \gamma_l(z,t) &= \frac{\partial c_l^{\mathrm{d}}}{\partial z} = -\frac{c_l^0}{h_l} \ \ \exp(-\pi z^2/h_l^2) \\ \gamma_u(z,t) &= \frac{\partial c_u^{\mathrm{d}}}{\partial z} = \frac{c_u^0}{h_u} \ \ \exp(-\pi z^2/h_u^2) \end{aligned}$$

The quantities $h_i = \sqrt{4\pi D_i t}$ are distances that represent the diffusive broadening of the concentration profiles of the two species during the time t.

Convection is assumed to arise out of this diffusive state with the appearance of a zone in the mixing layer within which the fluid becomes dynamically unstable by the mechanism described in the introduction. The relevant hydrodynamical equations (13) are the equation of continuity

$$[6] \qquad \frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\vec{v}) = 0$$

the Navier–Stokes equation (for a spatially uniform shear viscosity, $\eta = \rho\nu$)

$$[7] \qquad \rho\left(\frac{\partial}{\partial t} + \vec{v}\cdot\nabla - \nu\nabla^2\right)\vec{v} = -\nabla p - g\rho\hat{z}$$

and the diffusion equations for solutes undergoing independent diffusion (14)

$$[8] \qquad \left(\frac{\partial}{\partial t} + \vec{v}\cdot\nabla - D_i\nabla^2\right)c_i = 0$$

g is the acceleration of gravity and $\hat{z}$ is a unit vector upward. A tractable model of double-diffusive convection is obtained using the incompressibility condition, $\nabla\cdot\vec{v} = 0$, rather than the full continuity equation, and by adopting the Boussinesq approximations (13) for the Navier–Stokes equation (i.e., using the solvent values for the density and the viscosity everywhere except in the gravitational force-density, $-g\rho\hat{z}$). The Navier–Stokes and diffusion equations then reduce to the following forms for the convective parts:

$$[9] \qquad \begin{aligned} &\left(\frac{\partial}{\partial t} + \vec{v}\cdot\nabla - \nu_0\nabla^2\right)\vec{v} = -\frac{1}{\rho_0}\nabla\delta p - g\hat{z}\sum_i \beta_i\delta c_i \\ &\left(\frac{\partial}{\partial t} + \vec{v}\cdot\nabla - D_i\nabla^2\right)\delta c_i = -\gamma_i v_z \end{aligned}$$

where v_z is the vertical component of the local velocity. These approximate equations are valid for more than two solutes and for other initial states if the concentration gradients are adapted accordingly.

Linear stability analysis

For cases where the velocity field grows from an infinitesimal disturbance, there is a linear regime in which the operator $(\vec{v}\cdot\nabla)$ can be ignored in the description of the onset of an instability. With this assumption, and some lengthy but standard vector analysis to remove the pressure (13), the previous equations reduce to

$$[10] \qquad \begin{aligned} &\left(\frac{\partial}{\partial t} - \nu_0\nabla^2\right)\nabla^2\vec{v} = -g\sum_i \beta_i\left(\hat{z}\nabla^2\delta c_i - \frac{\partial}{\partial z}\nabla\delta c_i\right) \\ &\left(\frac{\partial}{\partial t} - D_i\nabla^2\right)\delta c_i = -\gamma_i v_z \end{aligned}$$

with the form

© 1999 NRC Canada

$$[11]\quad \left(\frac{\partial}{\partial t}-\nu_0\nabla^2\right)\nabla^2 v_z = -g\sum_i \beta_i\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)\delta c_i$$

for the vertical component being of particular importance. These equations are fairly general, in that they apply to cases with physical boundaries (free or rigid for the velocity and no flux for the solutes) as well as the infinitely extended model, provided the amplitudes are small enough to be described by linearized perturbation analysis.

Diffusion is assumed to progress in the time interval $0 \le t \le t_d$, during which $\vec{v} = 0$ and $\delta c_i = 0$ and after which growth of a mode in the disturbance

$$[12]\quad \begin{aligned} v_z &= W(z)\,\sin(k_x x)\,\sin(k_y y)\,e^{\zeta(t-t_d)} \\ v_x &= \frac{1}{k^2}\frac{\partial^2 v_z}{\partial x \partial z} \\ v_y &= \frac{1}{k^2}\frac{\partial^2 v_z}{\partial y \partial z} \\ \delta c_i &= \Theta_i(z)\,\sin(k_x x)\,\sin(k_y y)\,e^{\zeta(t-t_d)} \end{aligned}$$

with $k_x^2 + k_y^2 = k^2$, occurs at a rate ζ for an interval during which the concentration gradients are frozen at $\gamma_i(z) \equiv \gamma_i(z, t_d)$. With the definition

$$[13]\quad d_k^2 = \frac{d^2}{dz^2} - k^2$$

the equations reduce to the forms

$$[14]\quad \begin{aligned} (d_k^2 - \zeta/\nu_0)d_k^2 W(z) &= -\frac{gk^2}{\nu_0}\sum_i \beta_i \Theta_i(z) \\ (d_k^2 - \zeta/D_i)\Theta_i(z) &= \frac{\gamma_i(z)}{D_i}W(z) \end{aligned}$$

After additional manipulations, this set can be summarized in the single form (written for the velocity, but common to all three quantities)

$$[15]\quad \begin{aligned} &(d_k^2 - \zeta/D_l)(d_k^2 - \zeta/D_u)(d_k^2 - \zeta/\nu_0)d_k^2 W(z) \\ &= -k^2 R(z)(d_k^2 - \zeta/D(z))W(z) - 2k^2 R'(z)W'(z) - k^2 R''(z)W(z) \end{aligned}$$

where the primes denote derivatives in z, and the new quantities are

$$[16]\quad R(z) = \frac{g}{\nu_0}\left(\frac{\beta_l \gamma_l(z)}{D_l} + \frac{\beta_u \gamma_u(z)}{D_u}\right)$$

and

$$[17]\quad D(z) = \frac{\beta_l D_u \gamma_l(z) + \beta_u D_l \gamma_u(z)}{\beta_l \gamma_l(z) + \beta_u \gamma_u(z)}$$

$D(z)$ is undefined where the concentration gradients vanish (notably for $z >> h_l$), but no difficulty results from this property because $R(z)$ and $R(z)/D(z)$ vanish in this limit, as do $R'(z)$ and $R''(z)$. Thus, $W(z)$ and $\Theta_i(z)$ have asymptotic forms that are, in general, linear combinations of $\exp(\pm kz)$, $\exp\left(\pm\sqrt{k^2 + \zeta/\nu_0 z}\right)$ $\exp\left(\pm\sqrt{k^2 + \zeta/D_u z}\right)$, and $\exp\left(\pm\sqrt{k^2 + \zeta/D_l z}\right)$.

A convective mode grows out of a disturbance if $\zeta > 0$, and it is damped out if $\zeta < 0$. The stationary states with $\zeta = 0$ thus represent the margin between stability and instability, where this linear model of the process is most reasonable. For these marginal states, eqs. [14] simplify to

$$[18]\quad \begin{aligned} \left(\frac{d^2}{dz^2} - k^2\right)^2 W(z) &= -\frac{gk^2}{\nu_0}\sum_i \beta_i \Theta_i(z) \\ \left(\frac{d^2}{dz^2} - k^2\right)\Theta_i(z) &= \frac{\gamma_i(z)}{D_i}W(z) \end{aligned}$$

with the solutions behaving as $\exp(-k|z|)$ as $z \to \pm\infty$. These equations and boundary conditions are the foundation of the analysis and calculations on the characteristic properties of double-diffusive convection presented in the rest of this work. Most of the literature on this problem is concerned with the analogous process in water layers driven by *linear* thermal and salt gradients, with prescribed boundary conditions at the top and bottom of a distinct layer.

Dimensional analysis and interpretation

It is appropriate to use $h_l = \sqrt{4\pi D_l t_d}$ as a unit of distance, this being a measure of the extent of diffusion by the more mobile species up to time t_d, and leading to dimensionless distances $s = z/h_l$ and wave numbers $\kappa = kh_l$. It is convenient to define the ratio of the diffusion constants $\tau_d = D_l/D_u > 1$ and the ratio of the initial excess densities $\tau_\rho = \delta\rho_u^0/\delta\rho_l^0 < 1$ (two parameters open to experimental control), and the dimensionless number

$$[19]\quad R = \frac{g\delta\rho_l^0 h_l^3}{\nu_0 \rho_0 D_l} \propto t_d^{3/2}$$

The last quantity is analogous to the Rayleigh number, with the crucial difference that, unlike the case of a fluid layer with a given height (heated from below), there are no distinct horizontal boundaries. In terms of these quantities, eqs. [18] for the marginal states become

$$[20]\quad \begin{aligned} \left\{\frac{d^2}{ds^2} - \kappa^2\right\}^2 w(s) &= -R\kappa^2[\theta_l(s) + \tau_\rho \theta_u(s)] \\ \left\{\frac{d^2}{ds^2} - \kappa^2\right\}\theta_l(s) &= -\exp(-\pi s^2)\,w(s) \\ \left\{\frac{d^2}{ds^2} - \kappa^2\right\}\theta_u(s) &= \tau_d^{3/2}\exp(-\pi\tau_d s^2)\,w(s) \end{aligned}$$

where $w = W \cdot h_l/D_l$, $\theta_l = \Theta_l/c_l^0$, and $\theta_u = \Theta_u/c_u^0$ are dimensionless velocity and convective concentration profiles behaving as $\exp(-\kappa|s|)$ as $s \to \pm\infty$.

© 1999 NRC Canada

The distance $h_0 = (\nu_0 \rho_0 D_l / g \delta \rho_l^0)^{1/3}$ is characteristic of the initial state of the lower solution, and it is related to h_l by $R = (h_l/h_0)^3$. Thus, $z_s = R^{1/3}s$ and $k_s = R^{-1/3}\kappa$ are positions and wave numbers in units of h_0 and h_0^{-1}, respectively. These are natural units for comparing the marginal states of systems with the same lower solution, especially those with different concentrations of the solute in the upper layer.

These considerations indicate that the (s, κ) form of the equations is suitable for solving the problem, but interpretation of the results (especially those to do with the geometry of the flow) is more appropriate in terms of the (z_s, k_s) variables. The equations, with the appropriate boundary conditions, represent a transcendental relationship between κ and R. That is, the equations can be solved for R with varying values of κ, the lowest positive value of R permitting such a solution corresponding to the time at which this mode becomes unstable. The minimum such value of R (corresponding to the shortest evolution under pure diffusion) identifies the mode of convection that first grows out of the diffusive state. The initial state is inherently unstable with respect to convection if the limit $\kappa \to 0$ gives $R \to 0$ but a well-defined value of $k_s = \kappa/R^{1/3}$. In this manner, the behavior of the marginal states can be mapped for varying values of the excess-density ratio (τ_ρ) and the diffusion-constant ratio (τ_d).

Symmetry and boundary conditions

Only the relative amplitudes of $w(s)$, $\theta_l(s)$, and $\theta_u(s)$ are determined by their equations (eq. [20]), which constitute a linear, non-autonomous set of (4 + 2 + 2)th = 8th-order differential equations with an eigenvalue (R). The lowest eigenvalue is not necessarily positive, but the lowest positive eigenvalue necessarily corresponds to the marginal state (because of the relationship between R and h_l). Because these linearized equations do not determine the amplitudes or the growth rates, they only describe the shape and the range of the vertical flow initiated by passage through a marginal state. The corresponding wave vector, through the relation $k^2 = k_x^2 + k_y^2$ and the associated rotational symmetry around the vertical axis, gives an infinitely degenerate set of flow patterns in the horizontal plane (13).

That s appears in the operators of these equations as s^2 indicates that the solutions divide into even and odd classes (i.e., $w(-s) = \pm w(s)$ and similarly for the concentrations). It is convenient to scale the amplitudes for the even class with $w(0) = 1$. Other symmetry properties of the system are revealed by combining eqs. [20] into the single equation

$$[21] \quad \left\{\frac{d^2}{ds^2} - \kappa^2\right\}^3 w(s) = R\kappa^2 \{\exp(-\pi s^2) - \tau_\rho \tau_d^{3/2} \exp(-\pi \tau_d s^2)\} w(s)$$

For even $w(s)$ the left-hand-side is negative at $s = 0$, and $R > 0$ therefore requires $1 - \tau_\rho \tau_d^{3/2} < 0$ for the right-hand-side to be negative. The resulting condition, $\tau_\rho > \tau_d^{-3/2}$, for convection to be possible was derived heuristically by Huppert and Manins (15), who gave experimental evidence for its validity. It was shown to be obeyed in a variety of aqueous solutions by Huppert and Hallworth (16), who also noted an equivalent form in the work of Sartory (10). If both solutes are strong electrolytes, the effects of off-diagonal terms in the diffusion matrix are important (17).

Multiplication of eq. [21] by $w(s)$, and integration by parts gives the relation

$$[22] \quad -\int_0^\infty \{[w'''(s)]^2 + 3\kappa^2[w''(s)]^2 + 3\kappa^4[w'(s)]^2 + \kappa^6[w(s)]^2\} ds = -R\kappa^2 \int_0^\infty \{\mathrm{erf}(\sqrt{\pi} s) - \tau_\rho \tau_d \, \mathrm{erf}(\sqrt{\pi \tau_d} s)\} w(s) w'(s) ds$$

thus imposing the symmetry condition (for positive R)

$$[23] \quad \int_0^\infty \{\mathrm{erf}(\sqrt{\pi} s) - \tau_\rho \tau_d \, \mathrm{erf}(\sqrt{\pi \tau_d} s)\} \, w(s) w'(s) ds > 0$$

on the solutions to this problem. For a function with the symmetry properties $0 \le w(z) \le 1$ and $w'(z) \le 0$, and no other restrictions, this condition is satisfied if the factor within the brackets of the integrand is negative on the entire range. This being true only if $\tau_\rho > \tau_d^{-1}$, the point $\tau_\rho = \tau_d^{-1}$ is associated with a change in the basic symmetry of the vertical velocity profile.

There is an alternative to imposing the boundary conditions in the asymptotic region, where all three functions decay exponentially. Where s is large enough for the right-hand sides of eqs. [20] to be negligible, the functions have the forms (for $s >> 0$)

$$[24] \quad \begin{aligned} \theta_l(s) &= A_l \exp(-\kappa s) \\ \theta_u(s) &= A_u \exp(-\kappa s) \\ w(s) &= (w_0 + w_1 s + w_2 s^2) \exp(-\kappa s) \\ &= -\frac{R}{4\kappa}[\theta_l(s) + \tau_\rho \theta_u(s)] - \frac{2}{\kappa} w'(s) - \frac{1}{\kappa^2} w''(s) \end{aligned}$$

With these conditions, it must be decided where s is large enough for them to be applicable. With the purely exponential forms, it must be decided where s is effectively infinite. The results must be the same for these two approaches, a feature that can be used for checking calculations.

Computational method

The set of eqs. [20] was converted to the equivalent set of eight first-order equations and the supplementary condition $dR/ds = 0$ on the eigenvalue. The solutions were divided into even ($w(-s) = w(s)$) and odd ($w(-s) = -w(s)$) classes and solved for $s \ge 0$, subject to the following sets of nine conditions within each class.

Even (at $s = 0$)	Odd (at $s = 0$)	Even and odd (as $s \to \infty$)
$w = 1$	$w = 0$	$w' + \kappa w = 0$
$w' = 0$	$w' = 1$	$w'' - \kappa^2 w = 0$
$w''' = 0$	$w'' = 0$	$\theta_l' + \kappa \theta_l = 0$
$\theta_l' = 0$	$\theta_l = 0$	$\theta_u' + \kappa \theta_u = 0$
$\theta_u' = 0$	$\theta_u = 0$	

The last two conditions for $s \to \infty$ also apply to the alternate set for s large, but the first two are replaced with

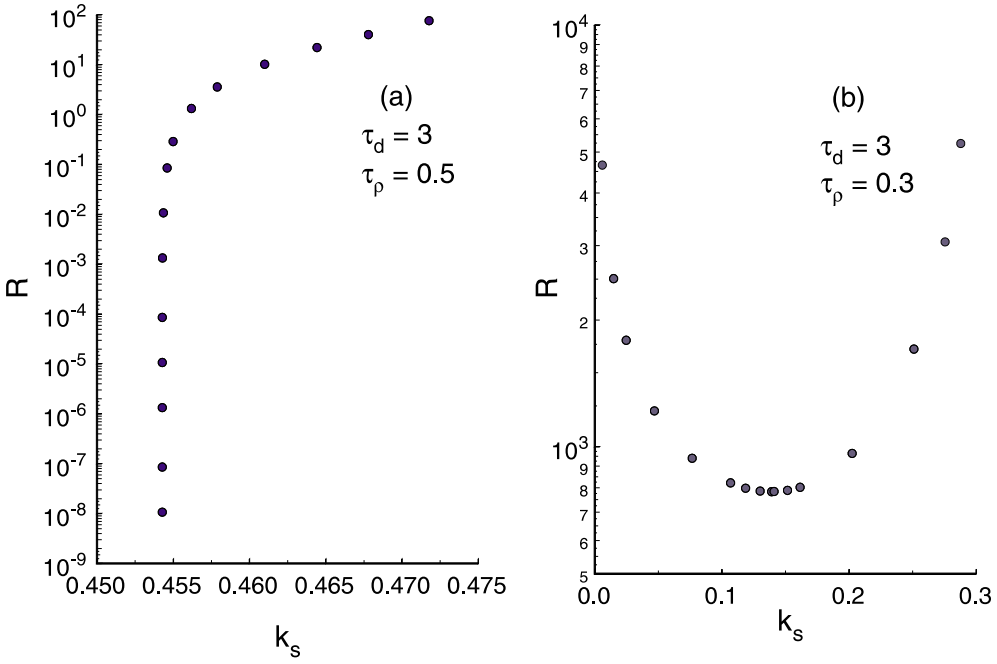
Fig. 1. Characteristic dependence of the eigenvalue (R) on the wave number (k_s) above (*a*) and below (*b*) the divergence for $\tau_d = 3.0$. The mode of marginal stability has the limiting wave number $k_m = 0.4543$ for $\tau_\rho = 0.5$ in (*a*) and the value at the minimum, $k_m = 0.1390$, for $\tau_\rho = 0.3$ in (*b*). The units are explained in the text.



$$w + \frac{R}{4\kappa}[\theta_l + \tau_\rho \theta_u] + \frac{2}{\kappa} w' + \frac{1}{\kappa^2} w'' = 0$$

$$w' - \frac{R}{4}[\theta_l + \tau_\rho \theta_u] + \frac{2}{\kappa} w'' + \frac{1}{\kappa^2} w''' = 0$$

The equations were solved with a shooting method (18), programmed in such a way as to allow extensive control of the input and inspection of the results. Fourth-order Runge–Kutta integration with adaptive grid-spacing projected the initial values and guesses at $s = 0$ (for either symmetry class) to the long-range region (where both types of boundary conditions were applied). A Newton–Raphson procedure refined the initial guesses, and iterative solutions were sought (in double precision) such that the error in the eigenvalue, R, was insensitive to the initial guesses and the limit of the integration to within 1 ppm. The corresponding velocity profile, $w(s)$, was inspected graphically. Extensive calculations showed that the same results were obtained with both types of boundary conditions, but the exponential forms were slightly easier to implement. In all cases studied, the lowest non-negative eigenvalue appeared in the class of even functions.

Results and discussion

We treated the excess-density ratio, τ_ρ, as a control parameter for a given value of the ratio of the diffusion constants, τ_d, and looked for the lowest positive eigenvalue (R) as a function of k_s. Two characteristic behaviors were exhibited, as illustrated in Fig. 1 for $\tau_d = 3$, which corresponds approximately to aqueous solutions of sucrose over NaCl (19). For $\tau_\rho = 0.5$ (Fig. 1*a*), k_s has the limiting value $k_m = 0.4543$ for $R \rightarrow 0$. As the figure shows, for $R << 1$ the disturbance with this wave number is a well-defined state, which we have interpreted to mean that the initial interface is inherently unstable at k_m. The corresponding vertical velocity profile, illustrated in Fig. 2, is symmetric and nodeless. For $\tau_\rho = 0.3$, states with this symmetry or a single node at $z_s = 0$ exist only for $R < 0$. The dependence of R on k_s for the next state is shown in Fig. 1*b*, and the corresponding vertical velocity profile is included in Fig. 2. The minimum in Fig. 1*b* is at $R_m = 783.103$ for the corresponding wave number $k_m = 0.1390$. The initially stable interface evolves by diffusion for the corresponding minimum time before the onset of convection through marginal Fourier components with this wave number.

The spatial symmetries of these two representative marginal states are further illustrated in Fig. 3 so as to show the relationships of their vertical ranges to their lateral periodicities. For this figure, the cellular fluid flow was assumed to have a square planform ($k_x = k_y = k/\sqrt{2}$), which is the simplest approximation to the irregular forms observed for sucrose–NaCl solutions (21). The contours connect points with equal values of the vertical velocity, $w(z)\ \sin(k_x x)\ \sin(k_y y)$, across the middle of a cell ($k_x x = \pi/2$). Whereas the disturbance for $\tau_\rho = 0.5$ fades monotonically into the solutions above and below the interfacial zone of cellular up and down flow, that for $\tau_\rho = 0.3$ has a prominent central zone with distinct counter-rotating zones above and below it that fade into the solutions.

The unit of distance in these figures is h_0. For example, in dilute aqueous NaCl ($D_l \approx 1.5 \times 10^{-9}$ m^2 s^{-1} and $\nu_0 \approx 1 \times 10^{-6}$ m^2 s^{-1}) with $\delta\rho_l^0/\rho_0 = 0.02$ (i.e., 0.48 M), this has the value $h_0 = 20\ \mu$m. The wavelengths exhibited in Fig. 3 correspond to 0.4 mm ($\tau_\rho = 0.5$) and 1.3 mm ($\tau_\rho = 0.3$) for 0.065 and 0.045 M sucrose in the upper layer, respectively (20). The former case is expected to be immediately unstable with respect to regular columns of alternating up-and-down flow,

Fig. 2. Vertical velocity profiles above ($\tau_\rho = 0.5$) and below ($\tau_\rho = 0.3$) the divergence for $\tau_d = 3$, corresponding to the marginal modes defined in Fig. 1. The curves represent the relative speed of the fluid along a vertical line at the center of the upward-flowing half of a cell.

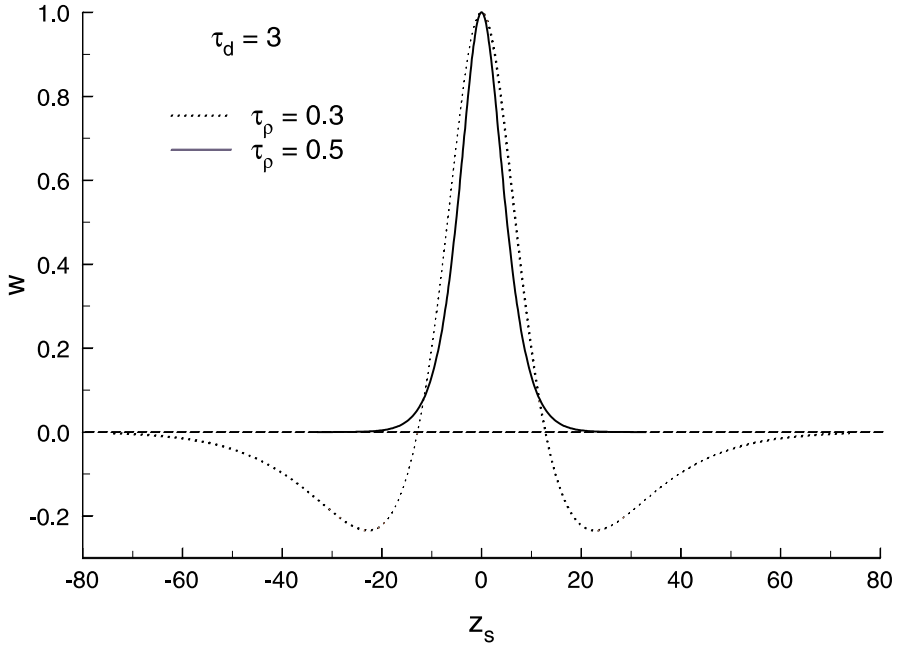

Fig. 3. Contour plots of the vertical component of the fluid velocity in vertical cross-sections of square-planform cells for the modes shown in Figs. 1 and 2. The horizontal and vertical distance scales are the same in each figure. The arrows indicate the relative magnitude and the direction of the flow, and the contours illustrate the symmetry difference above (*a*) and below (*b*) the divergence.

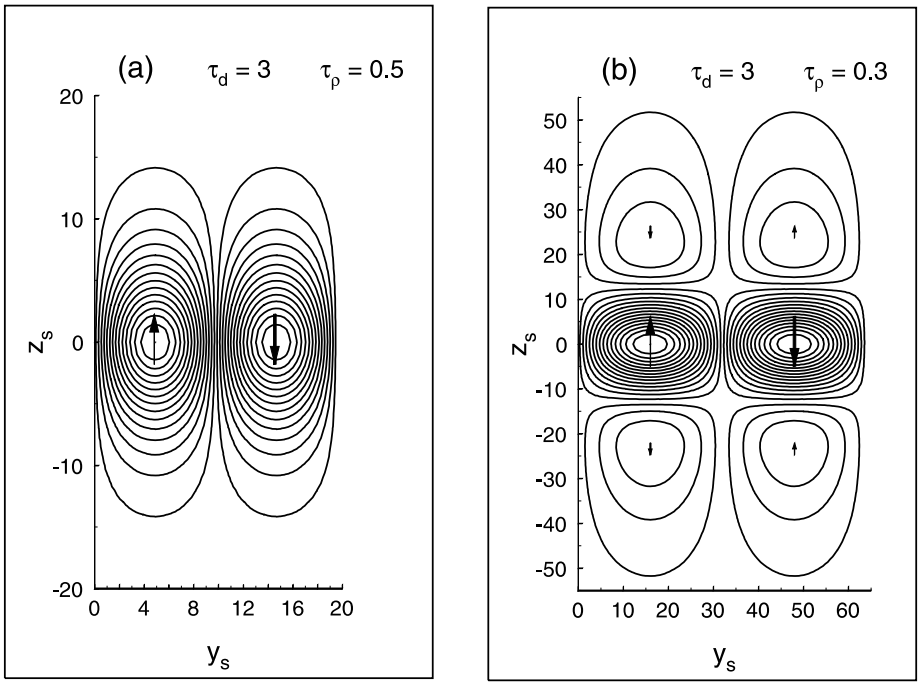

and the latter to evolve under diffusion for 2 s before an instability appears with weaker counter-rotating components capping and underlying such columns.

These examples also serve to illustrate that the layers do not have to be very deep for the neglect of upper and lower surfaces to be valid. While the length and time scales are only approximate, the distinctly different symmetry signatures of these two cases are definite predictions of the linear analysis. We are not aware of any clear experimental evidence for this symmetry difference, but the dominant milli-

Fig. 4. The wave number of the marginal mode (k_m) as a function of excess-density ratio (τ_ρ) for diffusion-constant ratios $\tau_d = 3.0$ and 1.25. The circles are results of numerical calculations, the lines represent the 1/3 power law of eq. [26], and the squares are the threshold values $\tau_\rho = \tau_d^{-3/2}$. The divergent points appear at $\tau_\rho = \tau_d^{-1}$.

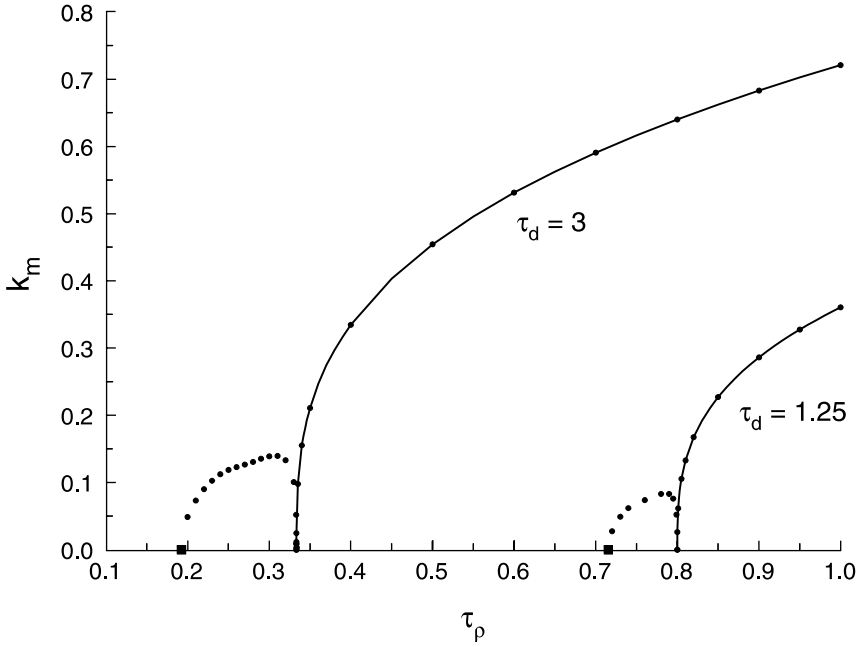

Fig. 5. Wave numbers (k_m) and eigenvalues (R_m) of marginal states as functions of excess-density ratio (τ_ρ) for diffusion-constant ratio $\tau_d = 3.0$. The wave number graph is expanded from Fig. 4.

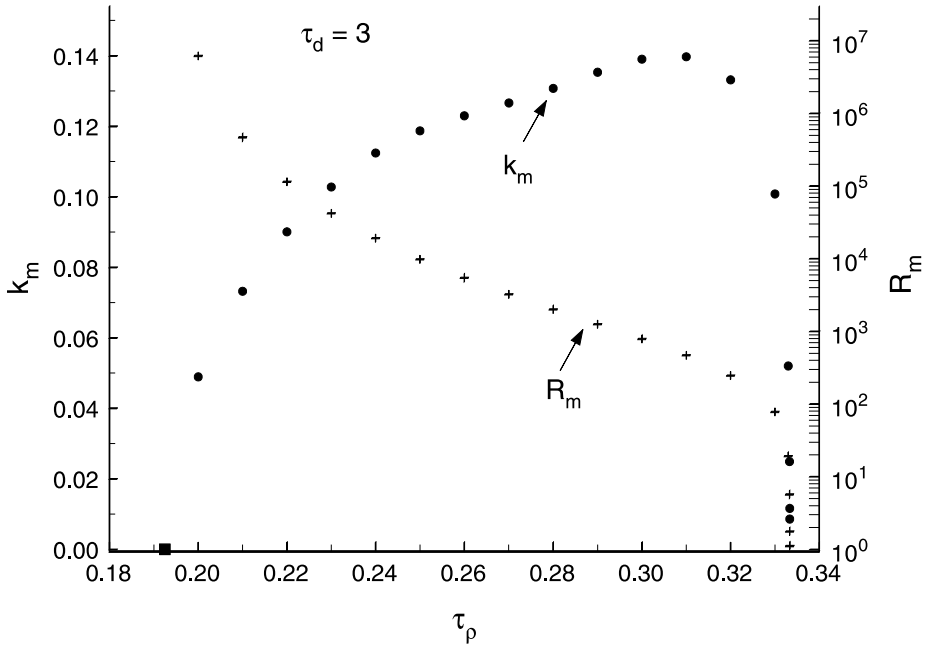

meter wavelength scale for this system is exhibited in the work of Shirtcliffe and Turner (21) on solutions with large τ_ρ (immediate convection).

Figure 4 shows the behavior of k_m as a function of τ_ρ for $\tau_d = 3$ and $\tau_d = 1.25$, and Fig. 5 expands part of the $\tau_d = 3$ data so as to observe the corresponding behavior of R_m. These graphs illustrate the main properties of the marginal states, and they are best interpreted by considering a sequence of sucrose solutions with increasing concentrations over samples from a stock solution of NaCl. For very low sucrose concentrations, such that $\tau_\rho < \tau_d^{-3/2} \approx 0.19$, diffusion alone drives the system to equilibrium. For sucrose concentrations such that the excess density is in the range $\tau_d^{-3/2} < \tau_\rho < \tau_d^{-1}$, a decreasing interval of diffusion precedes the onset of marginal states of convection with wave numbers approaching zero at the two ends of the range. As τ_ρ increases in the range $\tau_d^{-1} < \tau_\rho < 1$, convection is immediate in a marginal mode with increasing wave number (decreasing wave-

length and vertical range) and the symmetry of Fig. 3(*a*). Velocity profiles for $\tau_\rho \to \tau_d^{-1}$ (from below) exhibit a continuous change of symmetry from that of Fig. 3(*b*) to that of Fig. 3(*a*).

If τ_ρ is regarded as a control parameter for these two-layer initial states, then our calculations indicate that $\tau_\rho = \tau_d^{-1}$ is a unique point in their stability, through which the wavelength of the lateral periodicity ($2\pi/k_m$) diverges. Analyzed with the equation

$$[25] \qquad k_m = A_\pm \left| \tau_\rho - \tau_d^{-1} \right|^{a_\pm}$$

near the two sides of this point, our data for both values of τ_d in Fig. 4 gave an exponent $a_+ = 1/3$ to within 2 ppm. The fit is described by

$$[26] \qquad k_m^3 = \frac{3}{16}(\tau_d \tau_\rho - 1)$$

with the error in the amplitude also within 2 ppm, over the entire range $\tau_d^{-1} < \tau_\rho < 1$. The behavior on the other side of this point is much more complicated, giving a limiting value of $a_- \approx 0.332$ from the $\tau_d = 3$ data.

The range of excess densities within which diffusion precedes convection, $\tau_d^{-1} - \tau_d^{-3/2}$, has a maximum value of 4/27, which occurs for $\tau_d = 2.25$. For very large values of τ_d, this range is very small and the initial state is inherently unstable for nearly all values of τ_ρ. As $\tau_\rho \to \tau_d^{-3/2}$ (from above), the eigenvalue (R_m) increases rapidly (Fig. 5), and more nodes appear in $w(z)$ (not shown). For example, $R_m = 6.1875 \times 10^6$ for $\tau_d = 3$ and $\tau_\rho = 0.2$, corresponding to a diffusion time of 12 min for the system ($\delta\rho_1^0/\rho_0 = 0.02$) that takes only 2 s at $\tau_\rho = 0.3$. The wavelength of the corresponding square flow field is 3.6 mm, and the vertical profile exhibits a dominant central zone with a sequence of progressively weaker oscillations (with four nodes) above and below it before decaying exponentially. The height of the central zone, defined as the distance between the first nodes above and below $z = 0$ is 1. 7 mm, and the fluid velocity outside this zone is everywhere less than 3% of its maximum at $z = 0$. These small amplitude oscillations and the associated large eigenvalues make it difficult to calculate the marginal states in this region, just above the threshold for double-diffusive convection.

The position of this threshold ($\tau_\rho = \tau_d^{-3/2}$) was shown to arise from a symmetry condition, and the detailed calculations (illustrated in Figs. 4 and 5) indicate that the wavelength of the instability and the diffusion time decrease rapidly on passing through it. The point $\tau_\rho = \tau_d^{-1}$ was shown to be associated with a symmetry change in the vertical velocity profile and the detailed calculations reveal this to be a point around which the system is inherently unstable with respect to long-wavelength disturbances. Although the initial state of a perfectly sharp interface is artificial, the limiting behavior of k_m (Fig. 1*a*) shows that this feature is not responsible for the divergence. The diffusive concentration profiles for any $t_d > 0$ (however small) evolving out of this initially sharp state are the same as if the initial state was any one in the earlier time-course of this evolution. The absence of any containing boundaries for the fluid is implicated in the divergence only to the extent that they must be well beyond the wavelength and vertical range of the marginal disturbance. Within the approximations of linear stability analysis, this behavior is an inherent feature of this system of two solutes in a common solvent. There must be a critical matching of the initial diffusive fluxes, which tend to overturn the stable density gradient, for long-wavelength disturbances to be released by the viscous damping of the solution.

The most interesting result of this work is the prediction of a distinct symmetry change in the pattern of fluid flow across the point at $\tau_\rho = \tau_d^{-1}$. Above this point, alternating columns of up-and-down flow fade montonically away from the original interface. Below it, the columns contain more complex patterns, the simplest being a single reversal in the sense of the flow above and below a prominant central zone. These counter-rotating components of the columns are strongest for the short-wavelength instabilities of this type. The horizontal nodal planes of these reversals should be observable in the refractive index gradients of aqueous layers of sugar over salt, and other systems.

The theory outlined above provides a coherent, approximate scheme for calculating the effects of viscosity, densities, and diffusion coefficients on pattern formation by double-diffusive convection. It is reasonable to expect that patterns set by passage through marginal states will be preserved to some extent in growing modes (11). Dynamical nonlinearities, nonlinear equations-of-state, concentration-dependence of viscosity and diffusion coefficients, more general initial states, and finite boundaries are expected to complicate the observable features of such patterns, perhaps leading to secondary instabilities similar to those of Rayleigh–Bénard convection (13, 22–24). The general problem of pattern formation by multicomponent chemical and thermal fluxes coupled by diffusion and chemical reactions, a central one in several sciences (12), is usefully approached through simplified models in which precise calculations can be made.

Collagen remodeling in the extracellular matrix of the cardiomyopathic Syrian hamster heart as assessed by FTIR attenuated total reflectance spectroscopy

Pamela S. Bromberg, Kathleen M. Gough, and Ian M.C. Dixon

Abstract: Collagen type I and III deposition in the cardiac extracellular matrix contributes significantly to myocardial dysfunction. Diffuse and focal fibrosis is believed to accompany human congestive cardiomyopathy (CCM) associated with congestive heart failure (CHF). The left ventricle collagen remodeling that occurs in the hamster model of CCM is marked by left ventricle fibrosis, hypertrophy and dilation, proceeded by CHF post 150 days of age. The objectives of our study were to (*i*) evaluate changes in collagen deposition in the right (RV) and left (LV) ventricular tissue of cardiomyopathic (CMP) and control (CON) myocardium using FTIR ATR spectroscopy, (*ii*) classify the normal and diseased heart tissue using linear discriminant analysis (LDA) aided by a genetic algorithm (GA) selection of spectroscopically diagnostic regions in the mid-IR region, (*iii*) rationalize the spectroscopic differences between left/right ventricle tissue as well as CON/CMP tissue according to the pathophysiology documented for the UM-X7.1 strain of CMP hamsters. The presence of collagen in the tissue was confirmed spectroscopically by observation of the collagen IR fingerprint in the 1000–1800 cm^{-1} region. Difference spectroscopy was utilized to substantiate which tissue under comparison exhibited pronounced collagen content. Multivariate analysis (LDA) was carried out on user-selected spectral subregions and compared to class separation based on spectral subregions chosen nonsubjectively by a GA. Our study confirmed that the animals experienced LV collagen remodeling denoted by focal rather than diffuse fibrosis. In addition, RV collagen remodeling, denoted by decreased RV collagen content, appeared to accompany the increased LV collagen deposition found for the CMP animals.

Key words: FTIR spectroscopy, collagen, cardiomyopathy, genetic algorithm, linear discriminant analysis.

Résumé : Les dépôts de collagènes de type I et III dans la matrice cardiaque extracellulaire apporte une contribution importante au dysfonctionnement du myocarde. On croit généralement que la fibrose diffuse et focale accompagne la cardiomyopathie humaine congestive (CMC) associée à l'insuffisance cardiaque globale (ICG). Le remodelage du collagène du ventricule gauche qui se produit lors d'une CMC dans un hamster servant de modèle est caractérisé par une fibrose, une hypertrophie et une dilatation du ventricule gauche qui est suivi d'une ICG pour les sujets de plus de 150 jours. Les objectifs de notre étude étaient (*i*) d'évaluer les changements dans les dépôts de collagène dans les tissus des ventricules gauche (VG) et droit (VD) de myocardes cardiomyophatique (CMP) et de contrôle (CON) à l'aide de la spectroscopie « ATR FTIR », (*ii*) de classifier les tissus cardiaques normaux et malades en faisant appel à une analyse discriminante linéaire (ADL) s'appuyant sur une sélection à algorithme génétique (AG) de régions de l'IR moyen pouvant servir de diagnostique spectroscopique, (*iii*) de rationaliser les différences spectroscopiques entre les tissus des ventricules gauche et droit ainsi que entre les tissus CON et CMP suivant les pathophysiologies reconnues pour la souche UM-X7.1 de hamsters CMP. On a pu confirmer spectroscopiquement la présence de collagène dans les tissus par l'observation des empreintes digitales du collagène dans la région 1000–1800 cm^{-1} de l'IR. On a utilisé la spectroscopie différentielle pour établir quel tissu comportait la quantité la plus élevée de collagène. On a effectué une analyse discriminante linéaire à plusieurs variables sur des sous régions spectrales choisies par l'utilisateur et on l'a comparée à une séparation de classe effectuée sur la base de sous régions spectrales choisies de façon non subjective par un AG. Notre étude confirme que les animaux subissent un remodelage du collagène du VG caractérisé par une fibrose focale plutôt que diffuse. De plus, il semble que le remodelage du collagène du VD, caractérisé par une diminution dans la teneur en collagène dans le VD, accompagne l'augmentation du dépôt de collagène dans le VG qui a été observée avec les animaux CMP.

Introduction

Cardiomyopathy has an ill-defined etiology and a clinical treatment strategy has yet to be clearly defined. Several cardiomyopathies are inheritable or induced by alcohol toxicity, malnutrition or viral infection, however, idiopathic congestive cardiomyopathy (CCM), classified as either hypertrophic or dilated cardiomyopathy, is of unknown etiology in humans (1). The incidence of CCM has been reported to be 5–8 cases/100 000 population annually with a 5 year mortality of nearly half of those afflicted (2). CCM is typically diagnosed by the presence of dilation and systolic dysfunction in the left ventricle when congenital, coronary, valvular, hypertensive or pericardial heart disease is not a predisposing factor (1). Essentially, CCM leads to left ventricle dysfunction and decreases the heart's efficiency to eject oxygenated blood into the arterial circulation, causing progressive accumulation of fluid in the lungs (congestion) and subsequent congestive heart failure. Histopathologically, CCM reveals myocyte hypertrophy and atrophy, myofilament loss, lymphocyte infiltration, intracellular changes such as large irregularly shaped nuclei and lipid droplet deposition as well as diffuse and focal fibrosis (predominantly collagen type I and III) (1). Remodeling of the major components of the cardiac extracellular matrix (ECM), such as collagen, is believed to play a pivotal role in myocardial dysfunction, such that the change in the collagen content of a ventricle may compromise the stiffness, contractility and electrical properties of the heart muscle (3).

Over the last three decades, Fourier transform infrared (FTIR) spectroscopy has been successfully implemented in studies concerning the interaction, structure and dynamics of isolated tissue components such as proteins, (4) lipids, (5) carbohydrates, (6) and nucleic acids (7). The wealth of information accumulated on isolated tissue components, and combinations thereof, has facilitated the spectroscopic examination of select tissue components in their native environments, namely in cells and tissues (8). Furthermore, the spectral comparison of normal and diseased tissue provides a method by which the pathology may be objectively addressed in concordance with the disease state itself (8).

Since the early sixties, attenuated total reflectance (ATR) spectroscopy in the mid-IR region has been applied to the structural analysis of a variety of materials (bulk, thin films, liquids, solids, gases) (9). The attraction that lies in the use of ATR spectroscopy on bulk materials, such as tissues, is that in comparison to conventional transmission mid-IR spectroscopy, sample preparation is easy and nondestructive and spectral contrast is typically better. The former benefit is due to the sampling of the material in its natural state, while the latter improvement in spectral quality is due to the absence of the interference fringes and atmospheric bands commonly observed in traditional transmission spectroscopy (9). In the mid sixties, the biological and medical application of ATR spectroscopy was explored, and the possibility of creating an ATR accessory in the form of a hypodermic needle using fibre optic technology for in vivo blood and tissue analysis was under contention (10, 11). Recent advances in the area of in vivo analysis of blood components (glucose, haemoglobin, O_2, CO_2) using fibre optics have mainly concerned the near IR region, but have included measurements acquired by both transmission and reflection spectroscopy (12–14). Therefore, FTIR spectroscopy utilizing an ATR accessory offers a valuable alternative to conventional transmission spectroscopy for the examination of tissues and disease at the macromolecular level.

When one takes the traditional histological findings into account, an IR spectrum of CCM heart tissue may in turn show appreciable alterations in protein, carbohydrate, lipid, and nucleic acid content and (or) structure when compared to that of normal heart tissue. Recently, the absorption band assignment of collagen type I in the mid-IR spectra of human breast tissue (15) and infarcted rat heart tissue (16) has been documented. The latter investigators demonstrated that differences in the spectra of infarcted rat left ventricle, in comparison to that of control rats, were attributable to an increased deposition of collagen type I in the cardiac ECM as well to subtle differences in the lipid and nucleic acid content of the respective tissues (16). Characteristic IR absorption bands between 1000 and 1400 cm^{-1} were assigned to the C–O stretching vibrations of the carbohydrate residues attached to collagen (1032 and 1082 cm^{-1}) and the amide III and CH_2 wagging vibrations of collagen (1202, 1240, 1283, 1315, and 1338 cm^{-1}) (16). It has also been established that the amide I band profile (1610–1690 cm^{-1}) of collagen type I triple helix is distinct and can be characterized by predominant absorptions near 1662 and 1628 cm^{-1}, where absorptions from the 3_1 helices and intermolecular hydrogen bonding interactions of collagen chains, respectively, are thought to occur (15, 16). Normal cardiac tissue can therefore be differentiated from diseased cardiac tissue with elevated collagen deposition simply by the simultaneous evaluation of the deviation of the amide band profile from a maximum near 1655 cm^{-1}, due to predominant contributions from α-helical proteins, to that expected for the collagen triple helix and inspection of the 1000–1400 cm^{-1} region of the spectrum.

In the present study, ATR–FTIR spectroscopy was utilized to monitor collagen-related changes/pathology in the cardiac extracellular matrix of a strain of cardiomyopathic hamsters. Substantial documentation is available denoting the predictable pathological course of progressive cardiomyopathy in the line of hamsters used in this study, such as dilation, left ventricle hypertrophy, left ventricle collagen deposition, and congestive heart failure (17–20). To facilitate objective classification of the cardiac tissue as cardiomyopathic (CMP) or as normal (CON) the spectra were subjected to multivariate analysis using a linear discriminant algorithm (8, 21). LDA is a complex statistical analysis that takes into account within-group and between-group variance to discriminate between assigned classes, resulting in an overall (%) separation of classes. Moreover, two methods were used to discriminate the most spectroscopically diagnostic subregions,

© 1999 NRC Canada

namely user-selected subregions and genetic algorithm-selected subregions for subjective and nonsubjective classification, respectively. In this manner, the spectral subregions that yielded the highest linear discriminant analysis (LDA) separation between left and right ventricular tissue and between CMP and CON tissue could be evaluated in terms of collagen remodeling in this animal model.

Materials and methods

Materials and IR spectroscopy

The UM-X7.1 strain of Syrian hamsters, supplied by the laboratory of Dr. Ian Dixon (Division of Cardiovascular Science, St. Boniface General Hospital and Research Centre, Winnipeg, Manitoba), was used in this study as a paradigm of human congestive cardiomyopathy. The excised hearts of male hamsters (controls, four animals, 200 days old. Cardiomyopathic, four animals, 200 days old) were stored on dry ice prior to dissection. The left and right ventricular tissue was cut free of atria and spectra were collected from left and right ventricles (LV and RV, respectively) of cardiomyopathic (CMP, N_{LV} = 30, N_{RV} = 27 spectra) and control (CON, N_{LV} = 20, N_{RV} = 15 spectra) hearts. Mid-IR spectra (1000–4000 cm^{-1}) were acquired from randomly sampled tissue (sample size ca. 2 × 2 × 2 mm^3) using a Bio-Rad FTS-40A infrared spectrometer equipped with a "Split Pea" single reflection ATR accessory (Harrick Scientific). For each sample 256 interferograms were acquired, signal-averaged and Fourier transformed to generate spectra with a nominal resolution of 2 cm^{-1}. Spectra were then truncated between 1000–1800 cm^{-1} and the area under the curve normalized to an arbitrary numerical value of 10 to compensate for inconsistencies in tissue volume sampled. Second derivative spectra of the normalized raw data were then calculated prior to their use in multivariate analysis (LDA).

Data analysis

In the preliminary analysis, class average spectra were calculated as the arithmetic mean of all spectra in each of the following designated classes: LV(CON), LV(CMP), RV(CON), and RV(CMP). Difference spectra[2] between ventricles of the same tissue class (CON or CMP) and between tissue classes of the same ventricle (LV or RV) were calculated to ascertain the most diagnostic regions of the mid-IR. The difference spectra were utilized only as a guide to user-selection of diagnostic subregions for multivariate analysis. It was established that the 1000–1800 cm^{-1} region, particularly subregions within this range, illustrated the most prominent differences between the class average spectra. Further data reduction methodologies were then investigated to prepare the normalized, second derivatives of the raw spectra for LDA.

Two data reduction methodologies were used: manual splicing of the derivative spectra and the use of a genetic algorithm. Data reduction was necessary due to the restriction of the LDA program, which required that the number of attributes (data points) be less than the number of spectra under comparison. In the first approach, spectral subregions within the 1000–1800 cm^{-1} fingerprint region were manually chosen on the basis of spectroscopic assignments. Spectral regions with observable differences of diagnostic significance were identified in the class average spectra (Figs. 1–4). The corresponding regions in the second derivative spectra of the normalized raw data were selected as input for the LDA to discriminate between the following two-class problems:

LV(CON) vs. RV(CON)

LV(CMP) vs. RV(CMP)

RV(CMP) vs. RV(CON)

LV(CMP) vs. LV(CON)

This manual splicing (data reduction) was continued on each of the four two-class problems until a high LDA separation (>80%) was achieved. In the second data reduction approach, the normalized, derivative spectra were subjected to a genetic algorithm (22) to determine spectral subregions that were most diagnostic as inputs for LDA. Genetic algorithm (GA) selected subregions for LDA served in the nonsubjective classification of the cardiac tissue in the four two-class problems defined previously. The GA was programmed to choose less than 10 spectral subregions within 50 iterations of the program until the LDA separation between the chosen classes was optimized. For each spectral subregion chosen by the GA, the program automatically averaged the data points to one value (attribute) prior to feed into the LDA algorithm.[3]

Results and discussion

The class average spectra for LV(CON), RV(CON), LV(CMP), and RV(CMP) along with the relevant difference spectra are shown in Figs. 1–4. The visual inspection of the 1000–1800 cm^{-1} portion of the spectra revealed subtle differences in several spectral subregions, mainly those concerning absorptions due to collagen, carbohydrate, and lipid. Although differences were evident in the amide I (~1650 cm^{-1}) and amide II (~1545 cm^{-1}) band profiles of the groups under comparison, these spectral subregions exhibited a high within-group standard deviation especially in the LV(CMP) group (data not shown). Therefore, the amide I and amide II spectral subregions were left out of the user-selected subregion data reduction methodology. Sharp peaks in difference spectra are most likely due to variance in the signal-to-noise quality of the spectra rather than poor water vapor compensation, since the ATR technique does not typically suffer from the atmospheric bands seen in traditional transmission spectroscopy. The user-selected subregions utilized in the LDA of the four defined two-class problems and the LDA results are summarized in Table 1. The spectral subregions chosen nonsubjectively by the genetic algorithm and utilized as input for LDA are summarized in Table 2.

[2] *A* minus *kB* where *k* is a constant near unity chosen so that the baseline is flat and near zero.

[3] The GA and LDA programs were both developed "in house" by the Informatics Division of the Institute for Biodiagnostics (IBD), National Research Council of Canada (NRCC) in Winnipeg, Manitoba.

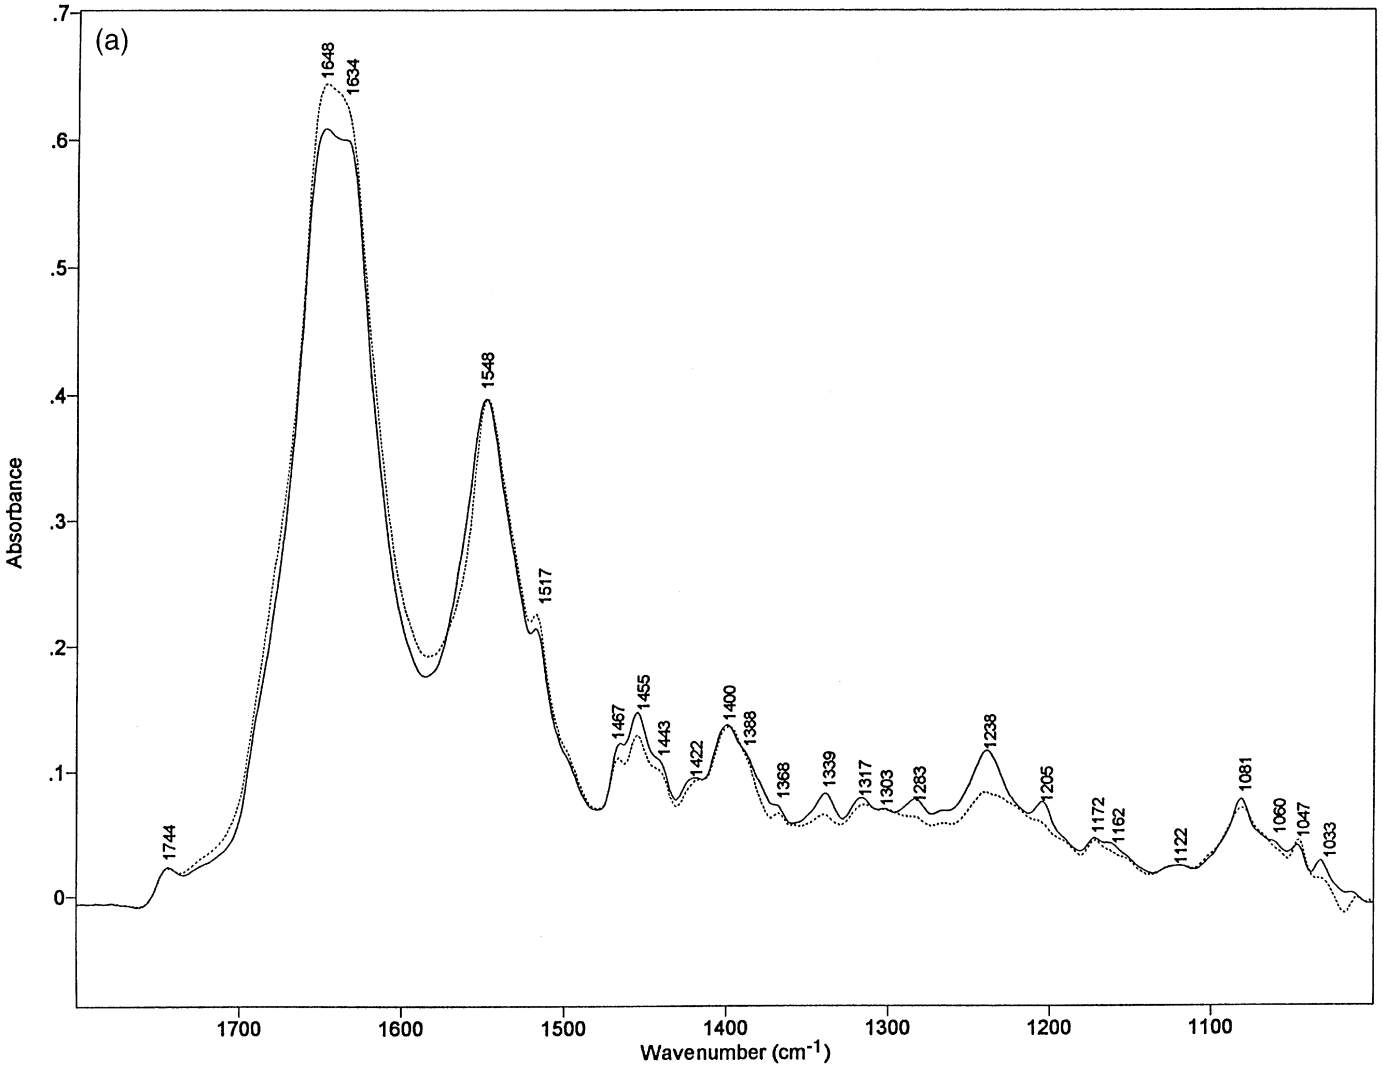
Fig. 1. Differences between the class average spectra from the left and right ventricles of the control animals illustrate between-group variances. Difference spectra were not used in the statistical analyses (LDA). (*a*) Class average spectra; RV(CON), solid line; LV(CON), broken line.



Visual comparison of the class average spectra for the left and right ventricles of control hamster hearts (Fig. 1*a*) suggested that compositional differences, especially in terms of collagen content, existed between the two ventricles of the normal heart. The difference spectrum, shown in Fig. 1*b*, illustrated that the collagen type I content of control right ventricles was greater than that of the control left ventricles. Absorption bands that may be assigned to the C–O stretching vibrations of the carbohydrate residues attached to collagen (1031 and 1081 cm^{-1}) and the amide III and CH_2 wagging vibrations of collagen (1204, 1239, 1280, 1318, 1338, and 1380 cm^{-1}) were greater in RV(CON) than in LV(CON). Secondly, the relative intensity of the CH_2 scissoring vibration (~1466 cm^{-1}) to the COO^- symmetric stretch (~1400 cm^{-1}), upon visual inspection of the two class average spectra, was found to be greater in RV(CON) than in LV(CON). The high proline/hydroxyproline and glycine content of collagen (nearly 60% of the amino acid composition of collagen) in comparison to the lower aspartate/glutamate content may serve as an explanation for the enhancement of the CH_2 bending vibration over that of the COO^- symmetric stretching absorption (15). The difference spectrum (Fig. 1*b*) also revealed that a lower frequency amide I component near 1631 cm^{-1} was more prevalent in RV(CON) than in LV(CON), which may be tentatively assigned to an amide I feature representative of the influence of strong intermolecular H-bonding between collagen chains (16). The hydroxyl groups of the hydroxyproline residues stabilize the collagen triple helix by the formation of interchain hydrogen bonds (23).

Confirmation for the distinction of RV(CON) from the LV(CON) class in terms of collagen content was provided by the LDA separation (92.5%) between the classes when regions of the second derivative spectra, representative of the amide III/CH_2 wagging subregion (1200–1285 cm^{-1}), were manually spliced together and used in the analysis (Table 1). Therefore, variations existed in the ventricular collagen content of control hearts in which the right ventricle contained a greater quantity of collagen in its ECM. The right ventricle, a smaller chamber with thinner walls than that of the left,

may require greater collagen in its ECM perhaps as a means to increase the ventricular tensile strength and thus enhance the contraction and relaxation phases of the ventricle. Greater collagen content in the right ventricle as opposed to the left ventricle of control rat hearts, detected by biochemical assay of the 4-hydroxyproline concentration of the myocardium, has been noted in other studies (19, 24, 25).

The nonsubjective classification of the control heart tissue as either left or right ventricle, using spectral subregions selected by a genetic algorithm, yielded a 100% LDA separation based on attributes derived from spectral regions where the collagen signature in RV(CON) was found. The GA had a tendency to pick subregions that were found to lie upon the side of an absorption or between absorptions rather than centred upon a peak (Table 2). For instance, the subregions 1431–1432, 1112–1114, and 1001–1013 cm^{-1} may be considered as subregions between the CH_2 scissoring and the COO^- symmetric stretching vibrations and subregions within or along the sides of the various C–O stretching vibrations of carbohydrates, respectively. However, the GA did select a spectral subregion (1276–1289 cm^{-1}) centred about an absorption of the amide III mixing with the proline side chain and glycine backbone CH_2 wagging vibrations (15). Furthermore, the GA also chose spectral subregions, which did not correspond to those chosen subjectively for the LDA above. For example, the GA selected the subregion 1507–1513 cm^{-1}, which lies upon the side of the absorption that one would see for the residue tyrosine (1517 cm^{-1}) as well as that assigned to the side of the nucleoside base C=O stretch of nucleic acids (1708–1720 cm^{-1}). The absorption for tyrosine ring vibration would normally be expected to be of higher relative intensity in tissue containing a lower proportion of collagen (i.e., LV(CON) as opposed to RV(CON) in this instance), since tyrosine is not a recurrent residue found in the collagen protein (15). The weak C=O absorption due to nucleic acids has been reported to appear at 1721 cm^{-1}, and in infarcted tissue this absorption is expected to be attenuated because extensive collagen type I deposition occurs after phagocytosis of cellular debris (8). However, the difference spectrum between LV(CON) and RV(CON) in Fig. 1*a* does

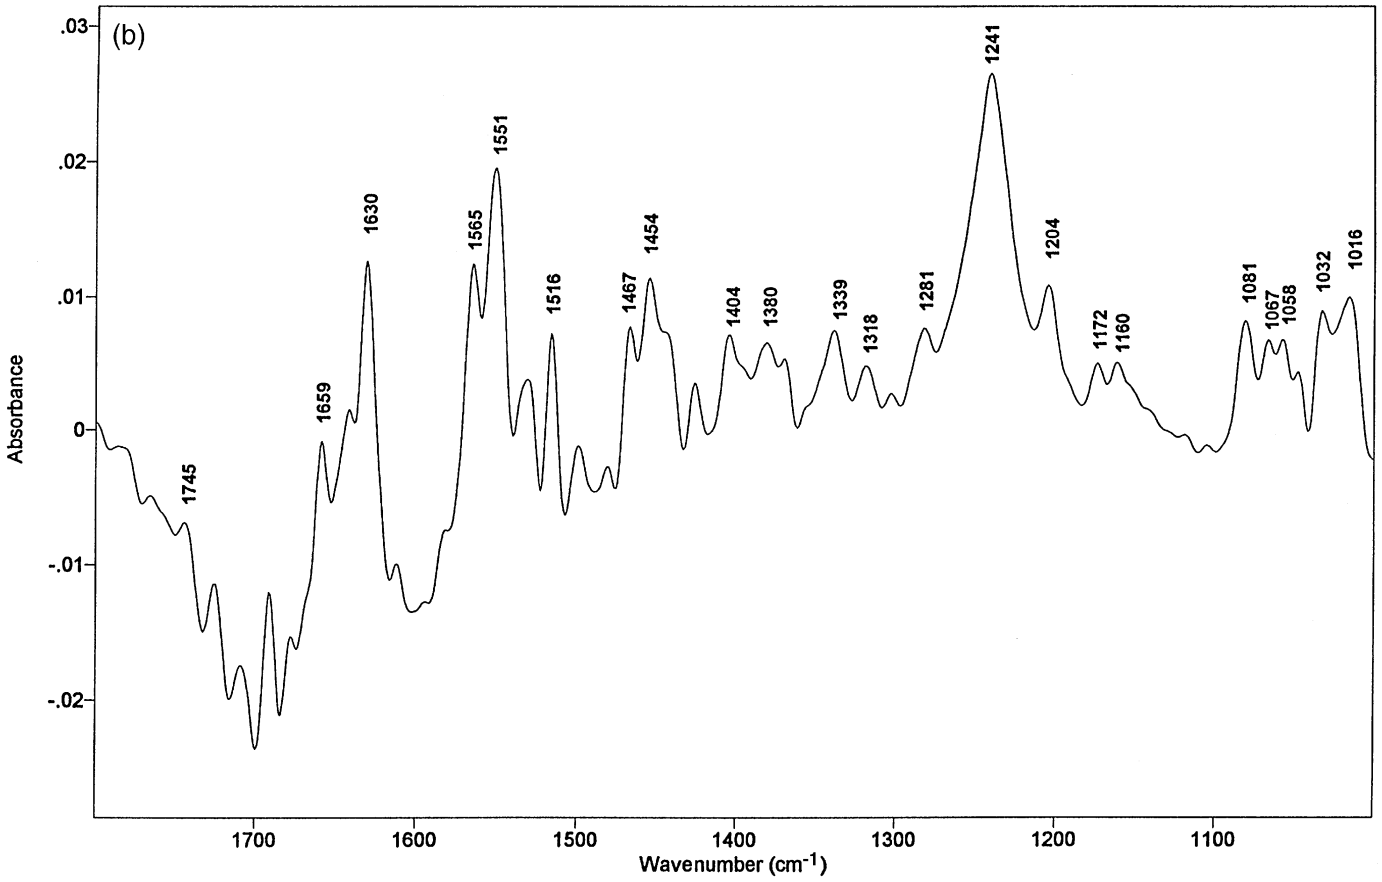
Fig. 2 (*concluded*). (*b*) Difference spectrum LV(CMP) minus RV(CMP).



not provide any significant information about whether the left or right ventricle contains more tyrosine or nucleic acids. The GA also selected the subregion corresponding to the C–OH stretching vibration (1155–1164 cm^{-1}). Absorptions in this subregion are commonly seen in the spectra of carbohydrates or of proteins high in hydroxyproline content, such as collagen, or proteins that contain a number of serine or threonine residues (16). Furthermore, Liu et al. (16) found that the ratio of the 1159:1172 cm^{-1} absorptions was greatly increased in infarcted rat heart as opposed to that of control, suggesting that the 1159 cm^{-1} feature was due specifically to the C–OH stretching of hydroxyproline. Although this C–OH stretching subregion did not enhance the LDA separation when significant spectroscopically diagnostic subregion were user-selected, comparison of RV(CON) and LV(CON) revealed that the 1162:1172 cm^{-1} ratio was slightly greater in RV(CON) (Fig. 1*a*). Therefore, the GA not only provided a nonsubjective classification of control ventricular tissue, but it also utilized subregions for LDA classification that were more subtly distinct than those chosen manually.

In contrast to the differences observed in the class average spectra of the control ventricular tissue, the cardiomyopathic ventricular tissue spectra were not as distinct upon visual comparison (Fig. 2*a*). The difference spectrum between the class average spectra for the groups LV(CMP) and RV(CMP), shown in Fig. 2*b*, illustrated the minute difference in collagen content of the two ventricles. Both class average spectra, LV(CMP) and RV(CMP), displayed the collagen fingerprint (i.e., absorption bands at 1032, 1082, 1202, 1240, 1283, 1315, and 1338 cm^{-1}). However, the difference spectrum (Fig. 2*b*) indicated a slight difference between these spectral subregions of the two class average spectra, whereby the collagen fingerprint was found to be slightly more pronounced in the LV(CMP) class average spectrum. Upon subtraction of RV(CMP) from LV(CMP), a collagen-like fingerprint remained just above a zero difference. Furthermore, the difference spectrum illustrated a less prominent phospholipid ester C=O stretching vibration (~1745 cm^{-1}) in LV(CMP). The phospholipid content of a tissue typically decreases when the content of another component (i.e., collagen) increases. The LDA separation using the user-selected subregions to classify the groups LV(CMP) and RV(CMP) was satisfactory (85.8%) when subregions such as those representing the phospholipid ester C=O (1720–1735 cm^{-1}), amide III/CH_2 wagging (1310–1315 and 1330–1335 cm^{-1}) and C–O stretching of carbohydrates (1020–1030 cm^{-1}) were used in (Table 1). The collagen content in the ECM of the left and right ventricles of the CMP hearts does not differ to the extent observed with the control ventricles. This is perhaps due to collagen remodeling in both ventricles wherein the left ventricular collagen increased and the right ventricular collagen remained similar to control levels or decreased.

The nonsubjective classification of the CMP tissue yielded a 100% separation of subregions that were GA-selected.

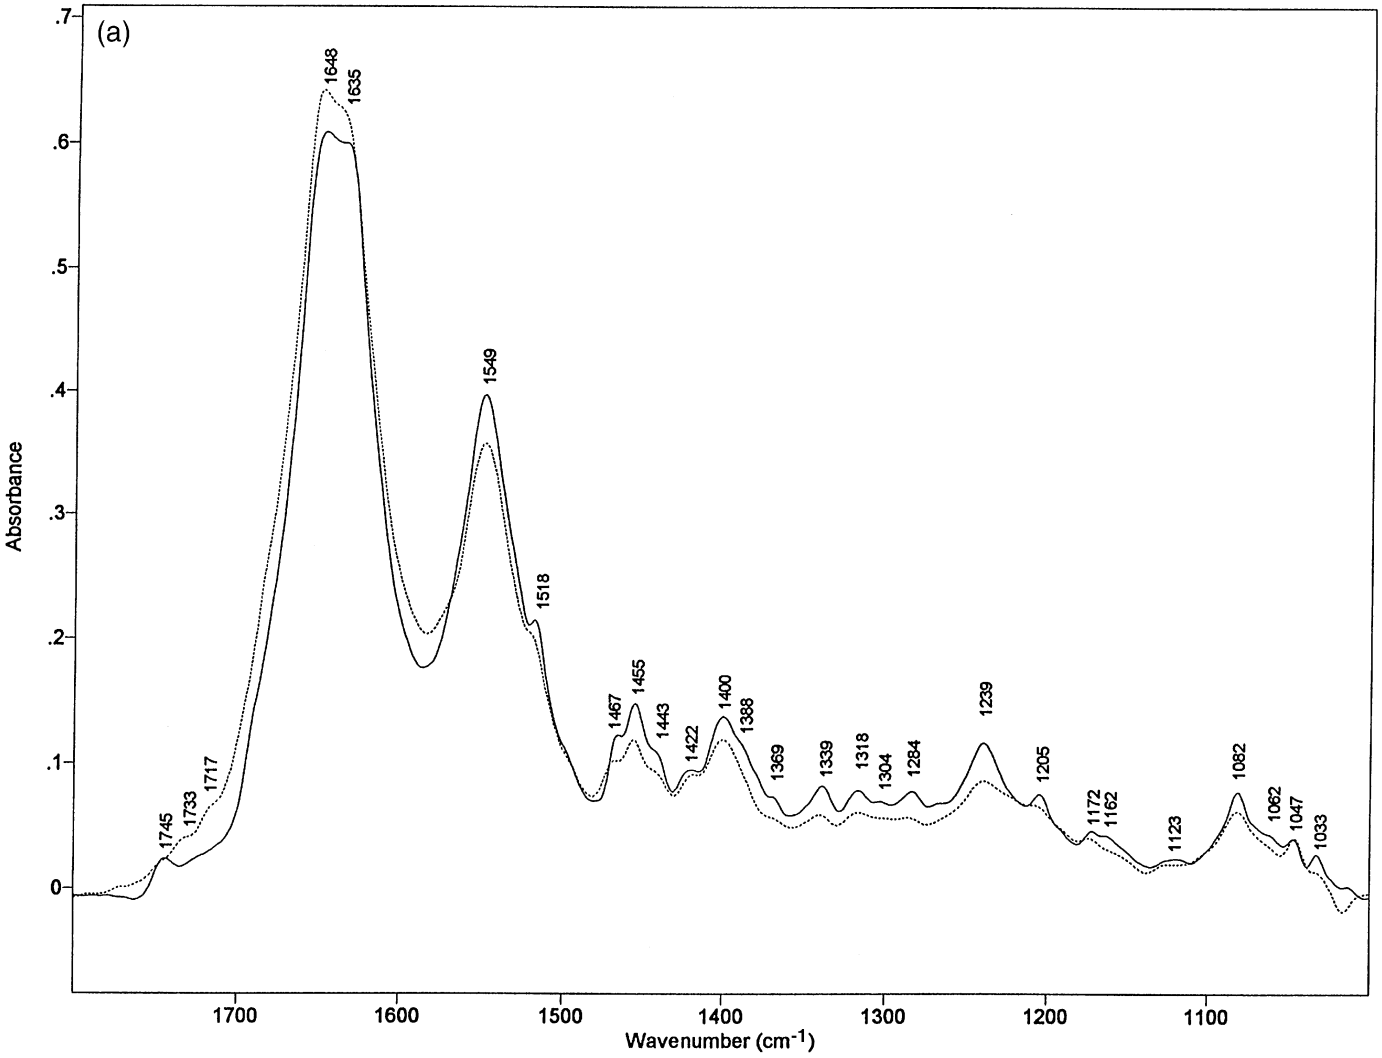
Fig. 3. Differences between the class average spectra from the right ventricles of the cardiomyopathic and control myocardium are indicative of decreased collagen deposition in the right ventricles of the CMP hearts. Difference spectra were not used in the statistical analyses (LDA). (*a*) Class average spectra; RV(CON), solid line; RV(CMY), broken line.



However, in contrast to the subregions chosen by the GA for the control spectra, the CMP spectral subregions were of rather a broad range (>30 cm^{-1}) such that classification was based on nearly the entire fingerprint region (Table 2). Since the GA program "averaged" each spectral range to a single point (attribute), the GA/LDA 100% separation of the LV(CMP) group from the RV(CMP) group may have been an artifact. The rather large subregions selected by the GA that generated a 100% separation between the left and right CMP ventricles included the lipid/nucleic acid C=O stretching subregion (1713–1743 cm^{-1}), the amide I and II band profiles (1511–1712 cm^{-1}), the subregion between the CH_2 scissoring and the amide II (1474–1500 cm^{-1}), the subregion containing the COO^- symmetric stretching vibration (1364–1436 cm^{-1}), the amide III/proline CH_2 wagging subregion (1316–1350 and 1205–1238 cm^{-1}) and the C–O stretching subregion of carbohydrates or carbohydrate residues of collagen (1000–1032 and 1070–1112 cm^{-1}). Therefore, although the GA was a useful method for reduction of the number of spectral attributes and for selection of less obvious distinctions between spectra for LDA input, manual selection of spectral subregions that exhibited observable differences between the class average spectra was necessary to avoid possible artifactual distinctions between groups under comparison.

Verification of collagen remodeling in the right ventricle of cardiomyopathic hamster hearts involved the direct comparison of the groups RV(CMP) and RV(CON). Visually, the most apparent differences between the class average spectra RV(CMP) and RV(CON) concern the IR subregions where absorptions due to phospholipid and collagen occur (Fig. 3). The subregions chosen and manually spliced for LDA input that generated an LDA separation between classes of 98.1% are shown in Table 1. Absorptions in the subregions 1735–1740 cm^{-1} (side of lipid C=O), 1205–1208 cm^{-1} (amide III/CH_2 wagging) and the ratio of the 1162:1172 cm^{-1} (contribution from the C–OH stretching of hydroxyproline) were greater in RV(CON) than in RV(CMP). Further differences between the groups RV(CMP) and RV(CON) were noted upon visual inspection of Fig. 3; the C–O stretching of car-

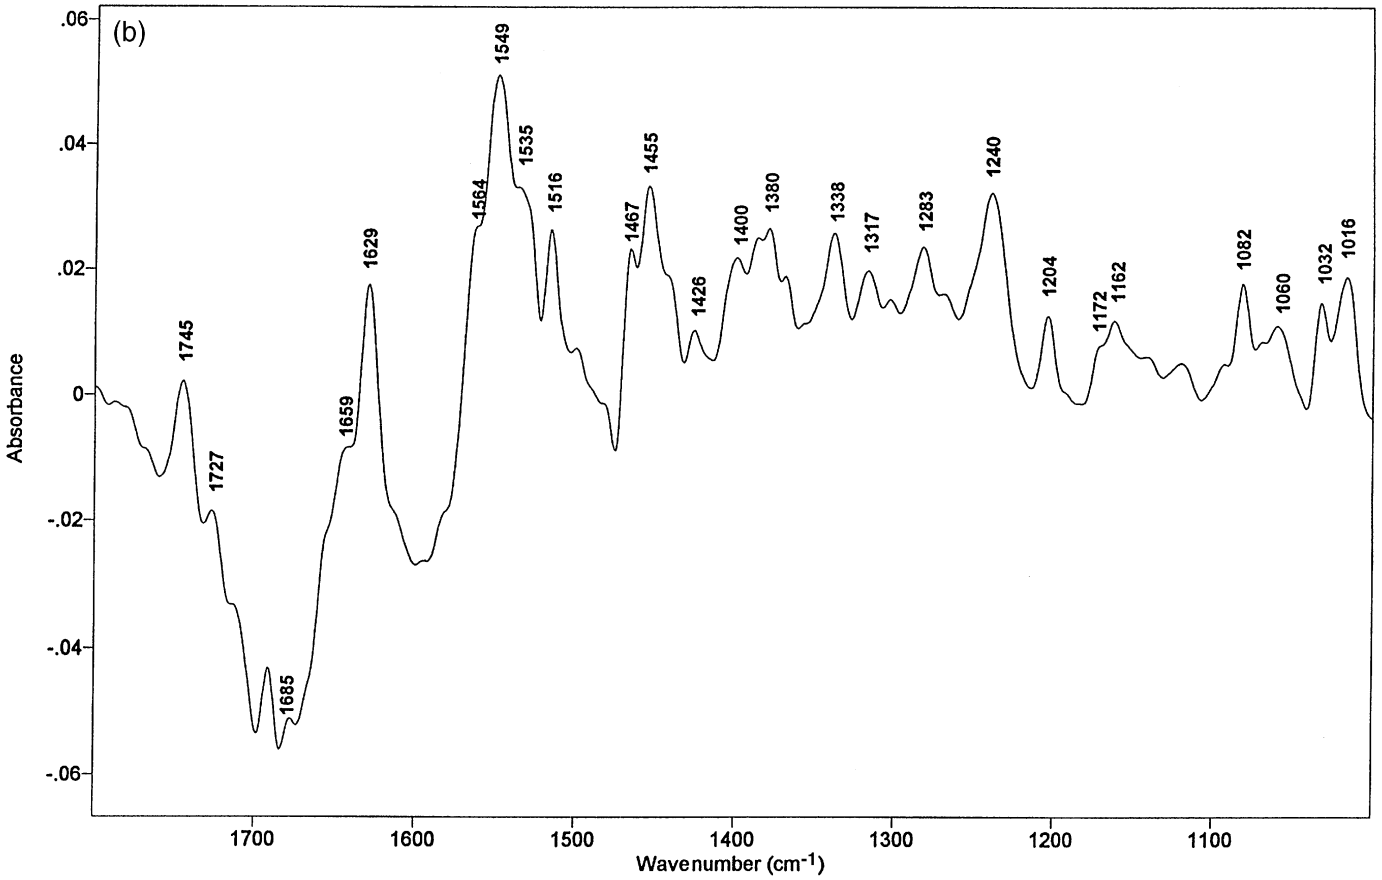
Fig. 3 (*concluded*). (*b*) Difference spectrum RV(CON) minus RV(CMP).



bohydrates or carbohydrate residues attached to collagen (1031 and 1081 cm^{-1}) was more prevalent in RV(CON); the CH_2 scissoring (1466 cm^{-1}) was greater than the COO^- symmetric stretch (1398 cm^{-1}) in RV(CON); and the amide I maximum had shifted to lower frequency in RV(CON) in comparison to RV(CMP). Thus, although the model used in this study was expected to be a paradigm of LV cardiomyopathy in which collagen remodeling of the ECM occurs primarily in the left ventricle, the greater phospholipid and collagen type I content in the right ventricle of control rather than in right ventricle of the CMP hearts, supported the likelihood of collagen remodeling of the ECM of the right ventricle as well. However, while RV(CMP) was found to have decreased collagen deposition in comparison to RV(CON), little difference was found in the collagen deposition of RV(CMP) and LV(CMP) in comparison to the noticable difference between RV(CON) and LV(CON). Therefore, the decrease in RV collagen deposition in the CMP hearts was not great enough to augment the difference in collagen deposition between the two ventricles of the CMP hearts beyond that found for the two ventricles of the control hearts.

The nonsubjective classification of the right ventricles as either CON or CMP, using GA-selected subregions, yielded a 100% LDA separation based on attributes derived from spectral subregions that mainly involved absorptions due to collagen (Table 2). In contrast to the subregions chosen manually, the GA did not select the lipid C=O absorption. The GA, however, did choose the C–OH stretching subregion due to carbohydrates and (or) hydroxyproline (1156–1188 cm^{-1}) and the amide III/proline CH_2 wagging subregion (1294–1335 and 1201–1238 cm^{-1}), similar to those subregions selected by the manual splicing methodology. In addition, the GA selected subregions in the C–O stretching region due to carbohydrates or carbohydrate residues on collagen (1084–1127 and 1022–1071 cm^{-1}), the side of the COO^- symmetric stretch (1360–1404 cm^{-1}), and the amide I and amide II band profiles (1592–1670 and 1497–1578 cm^{-1}, respectively), all of which were found to differ between RV(CMP) and RV(CON) as illustrated in the difference spectrum in Fig. 3*b*.

Finally, evidence for collagen remodeling in the left ventricle of the cardiomyopathic hamster hearts was derived initially from the direct comparison of the groups LV(CON) and LV(CMP). Visual comparison of the fingerprint region of the class average spectra for LV(CON) and LV(CMP) revealed that the groups differed predominantly in spectral subregions where absorptions due to collagen and phospholipid occur (Fig. 4*a*). For instance, deposition of a greater amount of collagen in the group LV(CMP) was inferred from the presence of more prevalent absorptions in the amide III/proline CH_2 wagging region (1339, 1283, 1240, 1204 cm^{-1}) and by attenuation of the phospholipid C=O (1745 cm^{-1}) stretching absorption in LV(CMP). In addition, the enhanced relative intensity of the CH_2 scissoring absorption (1467 cm^{-1}) to the COO^- symmetric stretching

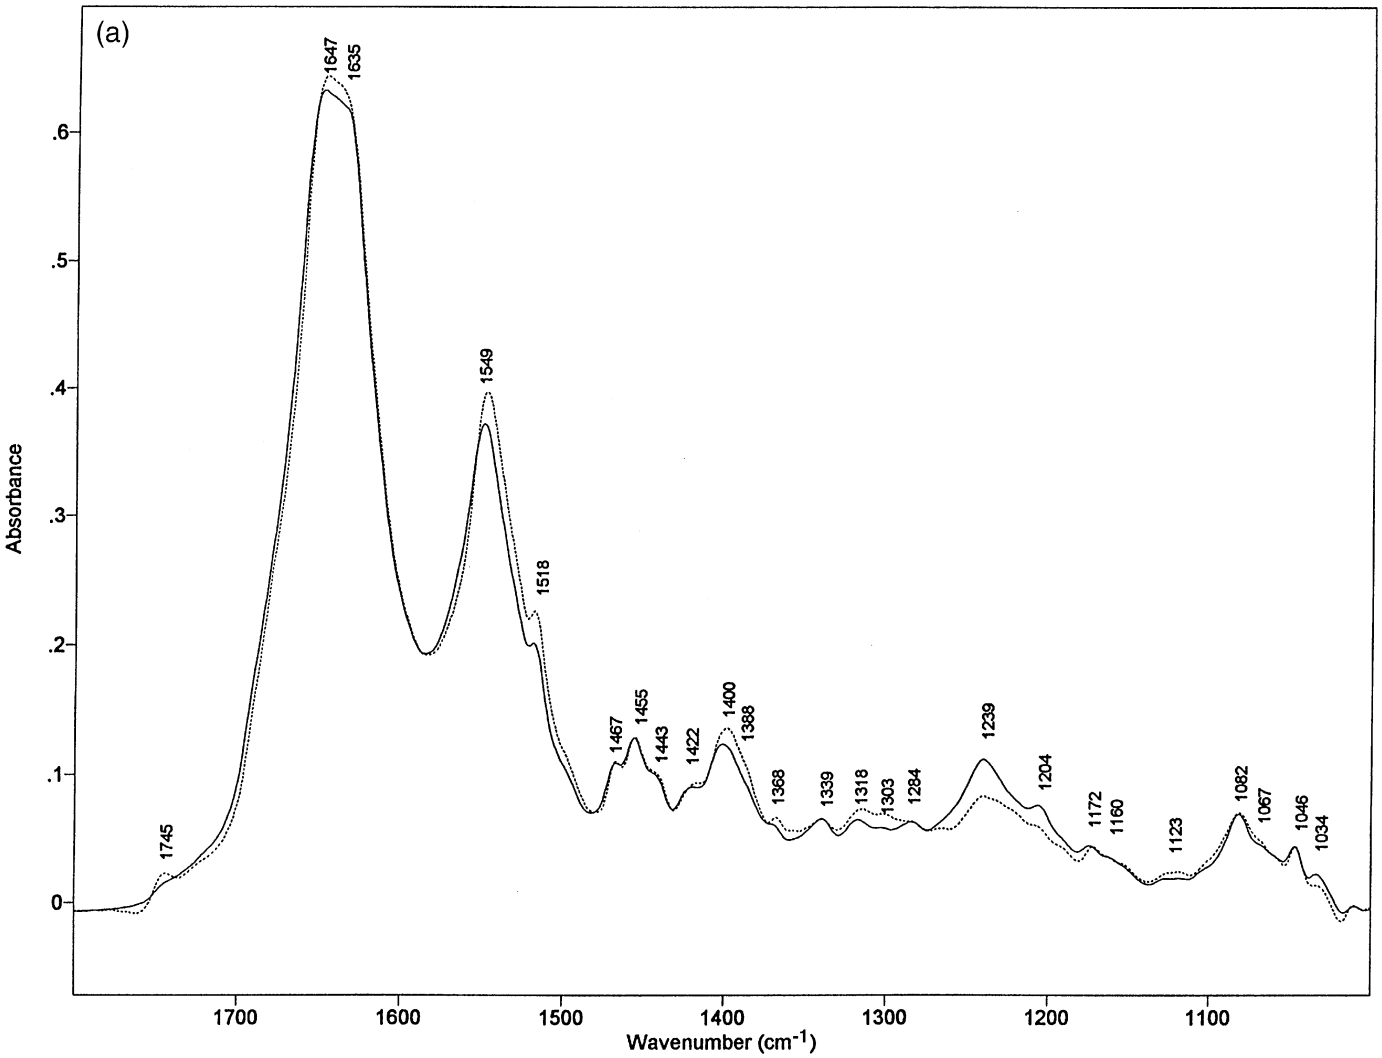
Fig. 4. Differences between the class average spectra from the left ventricles of the cardiomyopathic and control myocardium are indicative of increased collagen deposition in the left ventricles of the CMP hearts. Difference spectra were not used in the statistical analyses (LDA). (*a*) Class average spectra; LV(CMP), solid line; LV(CON), broken line.



absorption (1400 cm^{-1}) in LV(CMP), visually detected upon comparison of the group-mean spectra further supported elevated collagen deposition in LV(CMP). The CH_3 bending/CH_2 scissoring subregion (1455–1465 cm^1), sides of bands within the amide III/proline CH_2 wagging subregion (1320–1325 and 1203–1205 cm^{-1}) and the C=O stretching subregion (1735–1745 cm^{-1}) were found to augment the separation between classes in the LDA resulting in a LDA class separation of 98.3% (Table 1). Differences in the C–O and C–OH stretching regions (1030–1175 cm^{-1}) and in the absorption due to tyrosine (1515 cm^{-1}), wherein the former was found to be greater in LV(CMP), and the latter was found to be greater in LV(CON), could be detected visually (difference spectrum, Fig. 4*b*) but were not found to further enhance the LDA separation between the classes beyond that reported.

Nonsubjective classification of the left ventricles as either CON or CMP, using GA-selected subregions, generated a 100% LDA separation based on attributes derived from spectral subregions that contained collagen absorptions (Table 2). Analogously to the manual-splicing methodology for data reduction, the GA selected the CH_3 bending/CH_2 scissoring region (1455–1468 cm^{-1}). Although it was not detected visually, the relative intensity of the CH_2:CH_3 absorptions has been found to increase in infarcted tissue where increased collagen deposition may be found (16). Moreover, the GA selected a subregion containing the procession of CH_2 scissoring vibrations (1429–1440 cm^{-1}), as well as a region centred about the COO^- symmetric stretching vibration (1397–1413 cm^{-1}). Therefore, the LDA that utilized the GA-selected subregions may have also classified upon differences in the relative intensity of CH_2 scissoring (proline/glycine) to the COO^- symmetric stretching (aspartate/glutamate) in tissue with elevated collagen deposition due to the high glycine and proline residue count in the collagen sequence. Contrary to the subregions chosen manually, the GA did select the subregions due to the C–O stretching of carbohydrates and carbohydrate residues on collagen and the C–OH stretching of carbohydrates and (or) hydroxyproline (1088–1177 cm^{-1}) to distinguish between the

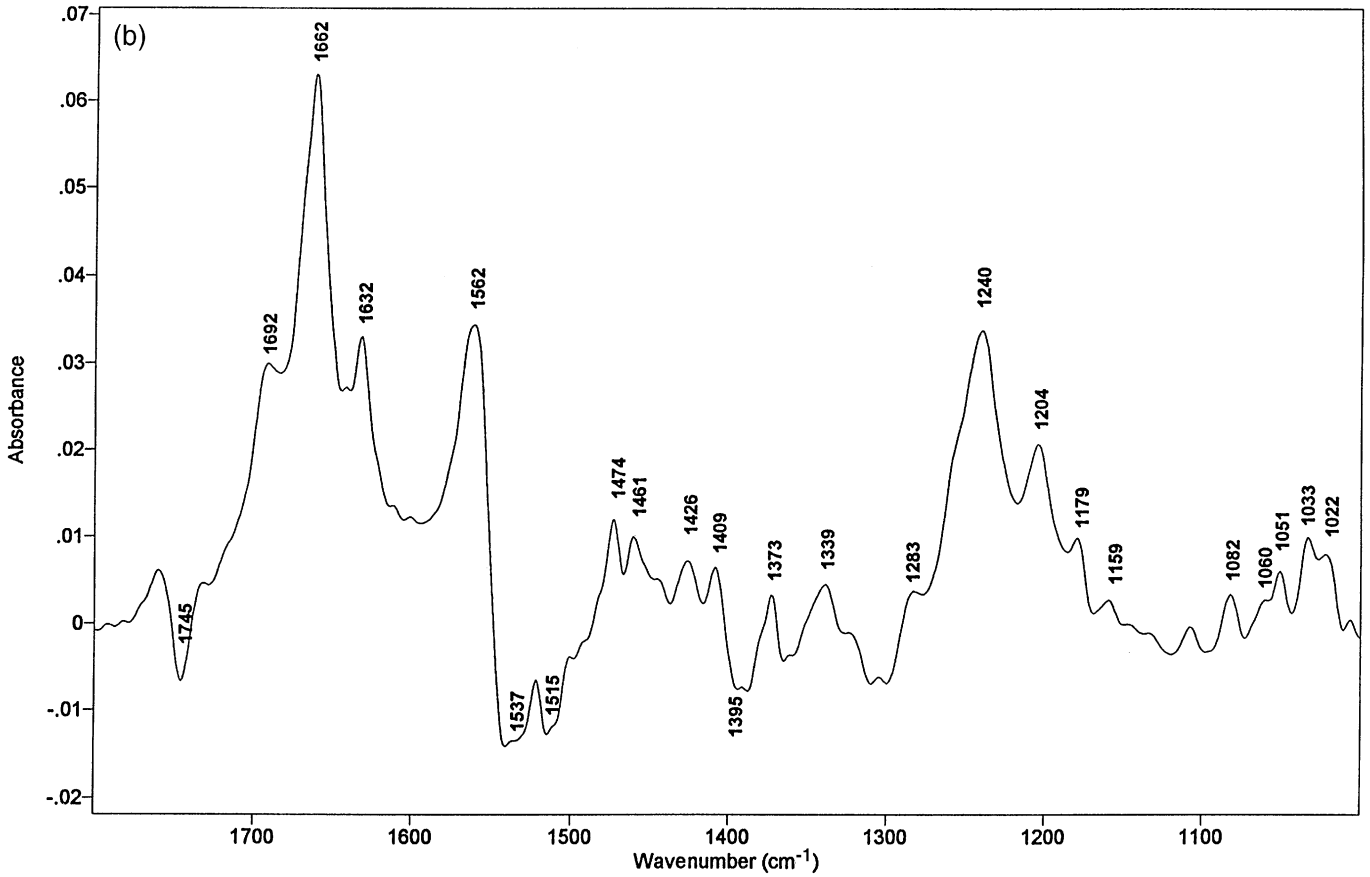
Fig. 4 (*concluded*). (*b*) Difference spectrum LV(CMP) minus LV(CON).



classes, while it did not select the lipid C=O subregion nor the amide III/proline CH_2 wagging subregion (Table 2). Although the latter regions were not chosen by the GA, both the difference spectrum (Fig. 4) and the LDA performed upon the user-selected subregions (Table 1) validated that class distinction could be augmented by use of these regions. Instead of subregions containing absorptions reflective of phospholipid content or absorptions containing the slew of overlapping bands due to the amide III/proline CH_2 wagging vibrations, the GA chose subregions that contained the amide I absorption (1597–1633 and 1634–1711 cm^{-1}), which were not utilized in the LDA performed on the manually-spliced spectral subregions. The LV(CMP) group exhibited a high standard deviation in the amide I subregion (data not shown), thus this subregion was not considered as reliable in class distinction strategies as some of the other spectral subregions already mentioned. However, the difference spectrum in Fig. 4*b* supported the GA selection of subregions within the amide I absorption for LDA separation of the LV(CMP) and LV(CON) classes, since the greatest difference was found to lie within the amide I band profile. In Fig. 4*b* the amide I region of LV(CMP) contained significant contributions from components that may be attributed to structure of the collagen triple helix. For instance, the enhanced absorptions near 1632 and 1662 cm^{-1} in LV(CMP) as opposed to LV(CON) were representative of the amide I absorptions due to the cross-linking intermolecular hydrogen bonding network between collagen chains and the 3_1-helix structural motif of collagen, respectively (16). Therefore, implementation of difference spectroscopy in combination with the utilization of a genetic algorithm to select spectroscopically diagnostic subregions of spectra for comparative purposes such as LDA allowed for distinction of the two classes LV(CMP) and LV(CON) based upon collagen deposition. The cardiomyopathic left ventricular tissue exhibited elevated collagen content in the extracellular matrix, which would progressively worsen until the contractility of the left ventricle was so compromised that congestive heart failure would ensue.

Conclusions

The results of the current study illustrated that the use of a genetic algorithm to select diagnostic spectral subregions of tissues with varied composition coupled to multivariate analysis (LDA) was a successful approach for 100% objective classification of the cardiac tissue. The reliability of the GA–LDA results was tested through the manual splicing of spectra to generate spectral subregions to classify by LDA in the user-selected methodology. The analysis of cardiac collagen deposition by IR spectroscopy confirmed those found by other studies of the hamster paradigm of congestive cardiomyopathy that utilized biochemical assays, while in some instances further information was acquired. Specifically, left ventricular collagen remodeling in the cardiomyopathic ECM was denoted by localized elevated collagen deposition rather than by diffuse fibrosis. Furthermore, the decreased collagen deposition observed in the

right ventricles of cardiomyopathic hearts in comparison to control samples indicated that right ventricular collagen remodeling accompanied left ventricular collagen remodeling in this animal model. This observation of decreased collagen deposition in the CMP right ventricle was opposite to that found in a recent FTIR microspectroscopic study of hearts of the same hamster line. That is, Liu et al. (26), found increased focal fibrosis in the RV of the CMP hamster heart tissue examined at a spatial resolution of $50 \times 50\ \mu m^2$ by IR microspectroscopy. It would be of particular interest to further investigate the localized deposition of collagen deposition in this hamster model by IR microscopy of thin sections of the heart myocardium (epicardium to the endocardium) at a greater spatial resolution (i.e., $10 \times 10\ \mu m^2$) by utilizing a synchrotron-generated source in the IR microspectroscopy.

Chelated fluoroboron cations. I. Synthesis and NMR studies involving the tertiary-amine ligands *N*,*N*,*N*′,*N*′-tetramethylethylenediamine and *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine

James A.W. Shoemaker and J. Stephen Hartman

Abstract: Several possible methods of synthesis of chelated fluoroboron cations are explored, using the *tert*-amines *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (Me_4en) and *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (Me_5dien) as model chelating ligands. Both ligands displace pyridine from $(pyr)_2BF_2^+$ (as its PF_6^- salt) to form the bidentate $(Me_4en)BF_2^+$ and $(Me_5dien)BF_2^+$ cations. The same cations, as well as the corresponding $BFCl^+$ and $BFBr^+$ cations, can also be prepared by displacement of the donor molecule (D = pyridine or isoxazole) and the heavy halide ion (Cl^- or Br^-) from the neutral $D{\cdot}BF_2X$ and $D{\cdot}BFX_2$ adducts. The central nitrogen of Me_5dien becomes chiral when it and one terminal nitrogen are coordinated, and the prochiral and magnetically nonequivalent fluorines of $(Me_5dien)BF_2^+$ give ^{19}F NMR signals separated by 1.2 ppm. In $(Me_5dien)BFCl^+$ the boron is a second chiral centre and the two diastereomers, distinguishable by NMR with ^{19}F chemical shifts differing by 3.0 ppm, form in a 3:1 ratio. The bidentate $BFBr^+$ cations of Me_4en and Me_5dien are insoluble in non-coordinating solvents but have been detected by positive ion FAB mass spectrometry and ^{11}B MAS NMR. The tridentate complex $(Me_5dien)BF^{+2}$ does not form under our conditions.

Key words: *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, *N*,*N*,*N*′,*N*″,*N*″- pentamethyldiethylenetriamine, chelated fluoroboron cations, fluorine-19 NMR, boron-11 NMR, pyridine, isoxazole, chiral, magnetically nonequivalent.

Résumé : Utilisant les amines tertiaires *N*,*N*,*N*′,*N*′-tétraméthyléthylènediamine (Me_4en) et *N*,*N*,*N*′,*N*″,*N*″-pentaméthyldiéthylènetriamine (Me_5dien) comme ligands chélatants modèles, on a exploré plusieurs méthodes de synthèse de cations fluorobores chélatés. Les deux ligands déplacent la pyridine du $(pyr)_2BF_2^+$ (sous forme de sel PF_6^-) pour conduire aux cations bidentates $(Me_4en)BF_2^+$ et $(Me_5dien)BF_2^+$. On peut préparer ces mêmes cations, ainsi que les cations correspondants $BFCl^+$ et $BFBr^+$, en déplaçant la molécule donneur (D = pyridine ou isoxazole) et l'ion halogénure lourd (Cl^- ou Br^-) des adduits neutres $D{\cdot}BF_2X$ et $D{\cdot}BFX_2$. Quand un azote terminal et l'azote central du Me_5dien sont coordinés simultanément, ce dernier devient chiral et, en RMN du ^{19}F, les atomes de fluor prochiraux et magnétiquement inéquivalents du $(Me_5dien)BF_2^+$ donnent des signaux séparés par 1,2 ppm. Dans le $(Me_5dien)BFCl^+$, le bore est un deuxième centre chiral et les deux diastéréoisomères, que l'on peut distinguer par RMN avec des déplacements chimiques du ^{19}F de 3,0 ppm, sont présents dans un rapport de 3:1. Les cations bidentates $BFBr^+$ du Me_4en et Me_5dien sont insolubles dans les solvants qui ne peuvent donner lieu à de la coordination; on peut toutefois les détecter par spectrométrie de masse par bombardement avec des atomes rapides et la RMN du ^{11}B par la technique « MAS ». Dans nos conditions réactionnelles, le complexe tridentate $(Me_5dien)BF^{+2}$ ne se forme pas.

Mots clés : *N*,*N*,*N*′,*N*′-tétraméthyléthylènediamine, *N*,*N*,*N*′,*N*″,*N*″-pentaméthyldiéthylènetriamine, cations fluorobores chélatés, RMN du fluor-19, RMN du bore-11, pyridine, isoxazole, chiral, magnétiquement inéquivalent.

[Traduit par la Rédaction]

Introduction

Boron trifluoride adducts of Lewis bases (electron pair donors D) normally have the covalent structure $D{\cdot}BF_3$, which forms very rapidly, usually with no activation barrier, from D and BF_3. However ionic coordination isomers $D_2BF_2^+{\cdot}BF_4^-$, as well as $D_3BF^{+2}{\cdot}(BF_4^-)_2$ and $D_4B^{+3}{\cdot}(BF_4^-)_3$, are also possible; indeed we have prepared $(quinuclidine)_2BF_2^+{\cdot}BF_4^-$ (1). Occasionally the $D_2BF_2^+{\cdot}BF_4^-$ coordination isomer forms spontaneously, when both donor sites are part of the same chelating ligand. The prototype case was reported by Wiberg and Buchler (2) in 1963, and included an early use of ^{11}B

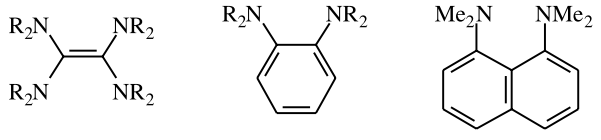
and ^{19}F as well as ^{1}H NMR to prove the structure. However it is still true that only a few chelated BF_2^+ cations are known (2–6), although there are many neutral BF_2 chelated species, for example, dipyrromethene boron difluoride derivatives with interesting fluorescence properties (7). Attempts at forming chelated BF_2^+ cations with bidentate N-donor ligands have been reported sporadically over the past 30 years (2–6, 8, 9). Typically the reaction with *tert*-amine chelating donors has been carried out in dry ether (2, 8, 9) or $CHCl_2F$ (4), with 1–4 equiv. of $Et_2O{\cdot}BF_3$ at room temperature (2, 8, 9), or with BF_3 at –196°C followed by slow warming (2, 4, 9). During the reaction, fluorine must be transferred between boron atoms in order to form a BF_2^+ cation and BF_4^- anion from two BF_3 units (reaction [1]). In general,

[1] 
R = H or Me

these methods have been successful if the amine chelating ligands are rigid (compounds **1**–**5**) (2, 4). However, with more flexible ligands, even "textbook" chelating ligands such as ethylenediamine (en) and *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (Me_4en), only non-chelated products



R = H or Me

1,2 **3,4** **5**

are formed: the mono and bis BF_3 adducts of the ligands (8, 9). Although the chelate effect should stabilize the ionic coordination isomer, the activation barrier to transfer of a fluoride ion apparently interferes, and the simpler process of covalent BF_3 adduct formation occurs instead. It seems that only when the two donor sites are held in close proximity is there a good chance of forming the ionic isomer. To further study these systems, alternative approaches to the synthesis of chelated $D_2BF_2^+$ ions are needed.

Our recent studies of the formation of four-coordinate fluoroboron cations (1, 10–12) are based on reactions of the mixed boron trihalide adducts (13). These precursors form fluoroboron cations via heavy halogen displacement:

[2] $D.BF_2X + D' \longrightarrow DD'BF_2^+ + X^-$

$D.BFX_2 + D' \longrightarrow DD'BFX^+ + X^-$

[3] $DD'_2BF^{2+} + X^-$

B—Cl, B—Br, and B—I bonds are much weaker than B—F bonds (444, 368, and 267 kJ/mol, respectively, compared to 646 kJ/mol for B—F in the boron trihalides (14), and the same trend occurs in four-coordinate boron), so the heavy halides are much more easily displaced than fluoride, and this is the basis of our systematic formation of $D_2BF_2^+$, $DD'BF_2^+$, and D_2BFX^+ ions (1, 10–12). We now report the first application of these methods to the synthesis of chelated fluoroboron cations, and the first systematic synthesis of the previously elusive chelated-ethylenediamine class of fluoroboron cations.

Experimental section

Materials

Materials were handled with standard inert-atmosphere Schlenk line and glove bag techniques. Boron trifluoride etherate (Aldrich), ethylenediamine (en) (J.T. Baker Chemical Co., 100.4%), isoxazole (Aldrich, 99%), Me_4en (Aldrich, 99%), and Me_5dien (Aldrich, 99%), and crude *N*,*N*,*N*″,*N*″-tetraethyldiethylenetriamine (Et_4dien) (Aldrich, 90%) were used without further purification. Boron trifluoride etherate was stored at –20°C until use. The bases were dried over 3 Å Molecular Sieves that had been heated in a muffle furnace at 400°C for more than 3 h and cooled over a period of 0.5 h in a vacuum desiccator. Boron trifluoride (Aldrich, 99.5%), boron trichloride (Matheson, 99.5%), boron tribromide (Aldrich, 99.9%), ammonium hexafluorophosphate (Aldrich, 95+%), and pyridine (Aldrich, 99.5%) were all handled as described previously (10, 11). Acetone (Caledon, HPLC grade), chloroform (Caledon, hydrocarbon stabilized, 99.8%), chloroform-d_1 (Cambridge Isotope Laboratories, 99.8%), nitromethane (Fisher Scientific Co.), and sulpholane (BDH) were dried over 3 Å Molecular Sieves. Hexane (Caledon, HPLC grade) was dried over sodium wire. All solvents were used without further purification.

Mixed boron halide adducts and salts

The pyr·BF_nCl_{3-n} (n = 0–3) adduct system was prepared by the method used previously (10), and the same method was used to prepare the ISOX·BF_nX_{3-n} systems (ISOX is isoxazole, **6**). ^{11}B and ^{19}F NMR parameters for the ISOX·BF_nX_{3-n} adducts in chloroform are as follows: ISOX·BF_3: ^{11}B, –0.6 ppm,

6

^{19}F, –149.0 ppm, $^1J_{BF}$ not resolved; ISOX·BF_2Cl: ^{11}B, 2.6 ppm, ^{19}F, –130.9 ppm, $^1J_{BF}$ = 32.9 Hz; ISOX·$BFCl_2$: ^{11}B, 4.9 ppm, ^{19}F, –123.4 ppm, $^1J_{BF}$ = 61.0 Hz; ISOX·BCl_3: ^{11}B, 4.9 ppm; ISOX·BF_2Br: ^{11}B, 0.4 ppm, ^{19}F, –124.3 ppm, $^1J_{BF}$ = 45.1 Hz; ISOX·$BFBr_2$: ^{11}B, –3.1 ppm, ^{19}F, –117.3 ppm, $^1J_{BF}$ = 81.4 Hz; ISOX·BBr_3: ^{11}B, –13.4 ppm.

$(pyr)_2BF_2^+{\cdot}PF_6^-$ was prepared by a modification of the method used previously (10), involving precipitation from a 1:1 chloroform:ethanol solution. $(pyr)_2BF_2^+{\cdot}PF_6^-$ decomposes at 95°C. Its NMR parameters in acetone-d_6 are as follows: ^1H: 9.16 ppm (s), 8.70 ppm, $^3J_{HH}$ = 7.2 Hz (t), and 8.20 ppm, $^3J_{HH}$ = 7.0 Hz (t); ^{11}B: 3.0 ppm, $^1J_{BF}$ = 23.2 Hz;

[a]Coupling constants ($^1J_{BF}$) obtained from the ^{11}B spectra are somewhat larger than those determined from the ^{19}F spectra: 33.5 Hz in $CDCl_3$, 34.5 Hz in acetone.

[b]Insoluble in acetone; obtained in 3:1 acetone:sulpholane.

^{13}C: 147.5, 144.8, and 128.9 ppm; ^{19}F: –70.6 ppm, $^1J_{PF}$ = 707.2 Hz, and –153.4 ppm, $^1J_{BF}$ = 23.2 Hz; and ^{31}P: –140.8 ppm, $^1J_{PF}$ = 707.2 Hz.

Instrumentation

Most ^{19}F, ^{11}B, and all ^{31}P NMR spectra were obtained on a Bruker AC-200 4.7 T multinuclear Fourier Transform NMR spectrometer operating at 188.31 MHz (^{19}F), 64.20 MHz (^{11}B), and 81.01 MHz (^{31}P), using 5 mm NMR tubes. ^{19}F spectra were obtained with 16K FIDs, 16K zero-filling, and spectral windows of up to 35 000 Hz, with between 256 and 4096 30° pulses and a relaxation delay of 1.0 s. The 90° pulse length was 6.6 μs. ^{19}F chemical shifts are accurate to ±0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (–162.7 ppm from $CFC1_3$), and are reported in ppm from $CFC1_3$. $^1J_{BF}$ coupling constants are accurate to ±1 Hz. ^{11}B spectra were obtained with 16K FIDs, 16K zero-filling, and spectral windows of up to 6400 Hz, with between 256 and 4096 30° pulses and a relaxation delay of between 0.5 and 10 s. The 90° pulse length was 17.1 μs. ^{11}B chemical shifts are accurate to ±0.1 ppm and were externally referenced to $Et_2O{\cdot}BF_3$. ^{31}P spectra were obtained with 16K FIDs, 16K zero-filling, and spectral windows of up to 36 000 Hz, with between 4096 and 64K 30° pulses and a relaxation delay of 0.5 s. The 90° pulse length was 17.1 μs. ^{31}P chemical shifts are accurate to ±0.1 ppm and were externally referenced to 85% H_3PO_4.

Some ^{19}F, ^{11}B, $^{11}B\{^{19}F\}$, ^{19}F–^{19}F COSY, and ^{11}B–^{19}F HETCOR NMR spectra were obtained at 30°C on a Bruker DRX-500 11.7 T multinuclear Fourier Transform NMR spectrometer (McMaster University) operating at 470.53 MHz (^{19}F) and 160.46 MHz (^{11}B) using between 40 and 128 30° pulses with 32K FIDs. The 90° pulse durations were 7.5 μs (^{19}F) and 15.0 μs (^{11}B). Spectral windows of 42 016 Hz (^{19}F) and 40 000 Hz (^{11}B) were used. $^{11}B\{^{19}F\}$ decoupling experiments used selective and broad band decoupling pulse power between 25 and 35 dB. ^{19}F–^{19}F COSY experiments were performed using the Bruker cosy45 pulse program, with a 2.0 s relaxation delay. ^{11}B–^{19}F HETCOR experiments used the Bruker hxcocp pulse program, with the BIRD sequence removed. The BIRD sequence was removed because there was no $^3J_{HB}$ or $^4J_{HF}$ coupling visible, and the sequence induced T_1 artifacts in our spectra. The relaxation delay was 1.0 s.

^{11}B solid-state magic angle spinning (MAS) NMR spectra of the samples were obtained on a Bruker DPX-300 7.4 T multinuclear Fourier Transform NMR spectrometer operating at 96.29 MHz, using a Bruker MAS probe with 4 mm spinners (capacity ~100 mg) and spin rates of 5–12.5 kHz. From 256 to 2048 scans were obtained, with relaxation delays of between 0.5 to 5.0 s between scans. 32K data points were obtained, and Fourier transformed with 5–15 Hz of line broadening. Trimethyl borate was used as the external standard, with its chemical shift being set to 18.3 ppm from $Et_2O{\cdot}BF_3$.

Routine ^1H, ^1H–^1H COSY, and ^{13}C spectra were obtained on the Bruker DPX-300 7.4 T multinuclear Fourier Transform NMR spectrometer operating at 300.13 and 75.45 MHz, respectively, and referenced to internal TMS.

Positive and negative ion FAB spectra were obtained on a Concept 1S double beam mass spectrometer with 8 kV accelerating voltage, using Xe collision gas at 7.5 W power. 3-nitrobenzyl alcohol (NBA) was used as the liquid matrix. Data were collected on a Kratos DART data system with SUN Spectrostation 10, using XMACH3 software.

Semi-empirical calculations at the PM3 level were performed via MacSpartan 1.7.1 software on an Apple 7600 Power PC with a 233 MHz processor.

Results

(a) The pyr·BF_nCl_{3-n} system: reactions with Me_4en

Addition of 2.5 mol equiv. of Me_4en to a pyr·BF_nCl_{3-n} (BF_3:BCl_3 = 1:1.5) solution in chloroform gives initially $(pyr)(Me_4en)BF_2^+$ from pyr·BF_2Cl. Its NMR parameters are given in Table 1. The singly coordinated Me_4en then readily displaces the remaining pyridine, giving chelated $(Me_4en)BF_2^+$ (**7**) (eq [4]). The cation **7** precipitates from chloroform as the white chloride salt, identified by its positive ion FAB mass spectrum: $(Me_4en)BF_2^+$ (165 *m/z* (100%)) and ion clusters $((Me_4en)BF_2^+)_2(Cl^-)$ (365 *m/z* (5.6%)), $((Me_4en)BF_2^+)_3(Cl^-)_2$ (565 *m/z*), and $((Me_4en)BF_2^+)_4(Cl^-)_3$ (767 *m/z*) (Fig. 1) and elemental analysis: C calcd. = 35.97%, found = 36.13%; N calcd. = 13.98%, found = 14.09%; H calcd. = 8.05%, found = 8.30%.

A side reaction occurs: displacement of pyr from pyr·BF_3 to form the monodentate $Me_4en{\cdot}BF_3$ adduct (Table 2). This reaction is selective and attacks only the BF_3 adduct, as we

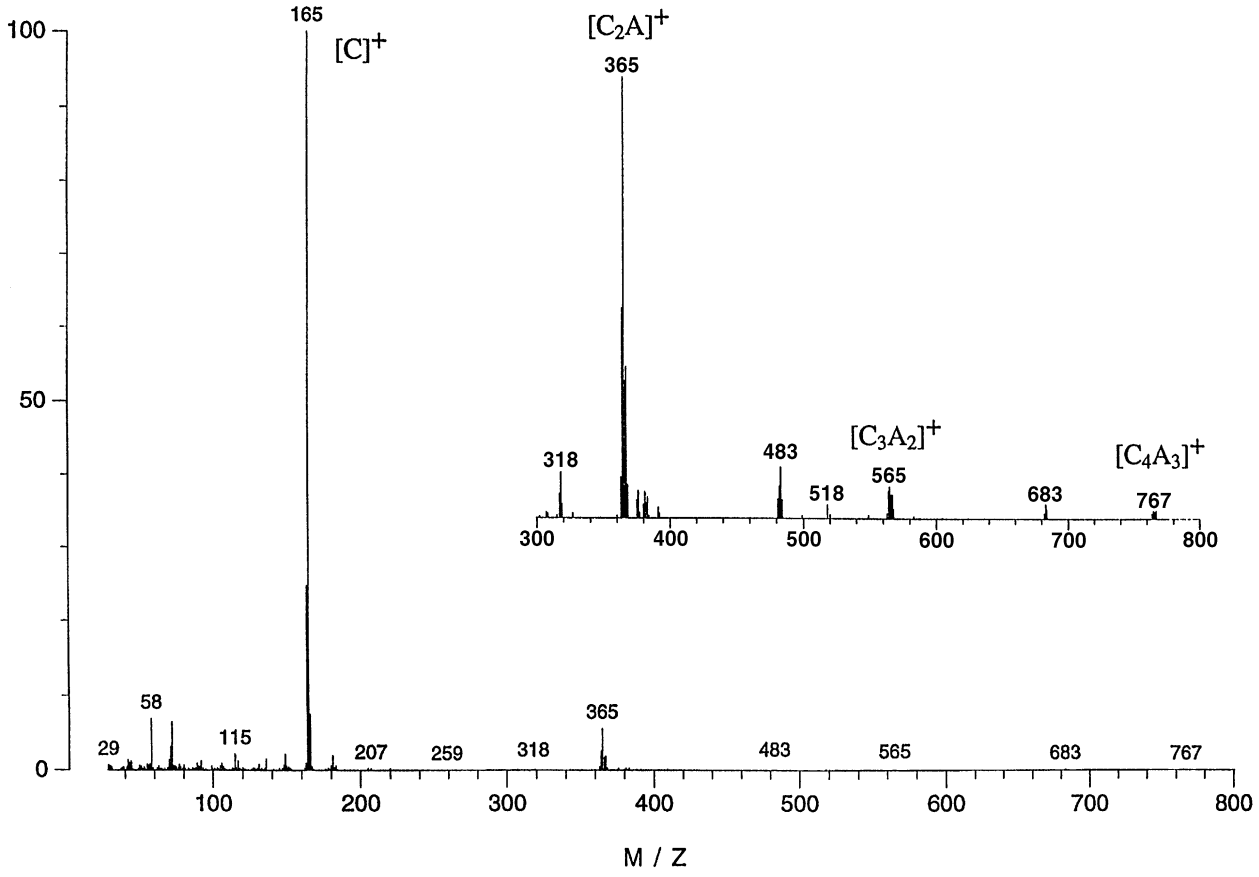
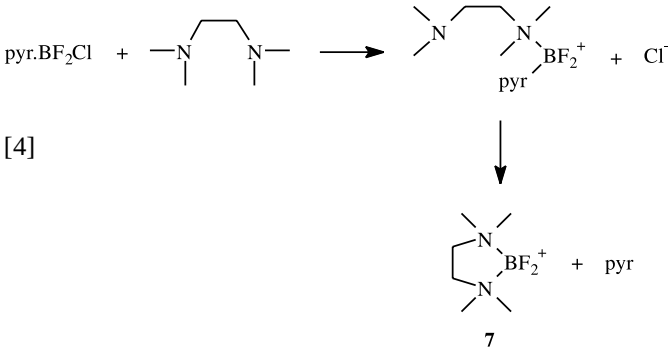
Fig. 1. Positive ion fast atom bombardment mass spectrum of $(Me_4en)BF_2^+ \cdot Cl^-$ in a 3-nitrobenzyl alcohol (NBA) matrix, showing the ion cluster signals C_nA_{n-1} (C = cation, A = anion).





[4]

7

have observed in similar adduct systems (12). Although both nitrogen atoms of Me_4en are available to coordinate to BF_3 (8, 9) (see $Et_2O \cdot BF_3$ section below) only the mono-BF_3 adduct forms in detectable amounts by displacement of pyr from $pyr \cdot BF_3$. This reaction is troublesome because it occurs faster than the formation of our desired $(Me_4en)BF_2^+$ cation, and gives a large amount of uncomplexed pyridine in solution, which then reacts with $pyr \cdot BF_2Cl$ to form $(pyr)_2BF_2^+$ (10). To compensate, a large excess of Me_4en must be added to compete effectively with the displaced pyr. Even so, the best yield of $(Me_4en)BF_2^+$ obtainable is about 60%.

On standing for several days at room temperature this problem rights itself, for the $(pyr)_2BF_2^+$ so formed is used up by reaction with Me_4en, and $(Me_4en)BF_2^+$ continues to precipitate as the chloride salt. A positive ion FAB mass spectrum of the mother liquor after a week confirms this, for only the $(Me_4en)BF_2^+$ and $(Me_4en)BFCl^+$ (see below) cations are detected. Thus, there are rapid initial reactions followed by much slower reactions, as we have noted before in other haloboron adduct–cation systems (12).

As well as the slow formation of more $(Me_4en)BF_2^+$ from $(pyr)_2BF_2^+$, there is also the slow formation of $(Me_4en)BFCl^+$ from $pyr \cdot BFCl_2$ (eq. [3]), and again there is competition from free pyr, which generates $(pyr)_2BFCl^+$ from $pyr \cdot BFCl_2$: confirmed by its NMR data (10) and by a low-intensity peak at 223 *m/z* in the FAB mass spectrum of the solution after standing for 1 week.

(b) The $pyr \cdot BF_nCl_{3-n}$ system: reactions with Me_5dien

Addition of 2.5 mol equiv. of Me_5dien to a $pyr \cdot BF_nCl_{3-n}$ (BF_3:BCl_3 = 1:1.5) solution in chloroform leads to results similar to those described above for Me_4en except that none of the products precipitate from solution, which allows monitoring by solution NMR (Fig. 2). Initial formation of $(pyr)(Me_5dien)BF_2^+$ from $pyr \cdot BF_2Cl$ occurs readily. The coordinated Me_5dien then displaces pyr from the mixed-donor cation, giving the desired chelated $(Me_5dien)BF_2^+$ cation **8**

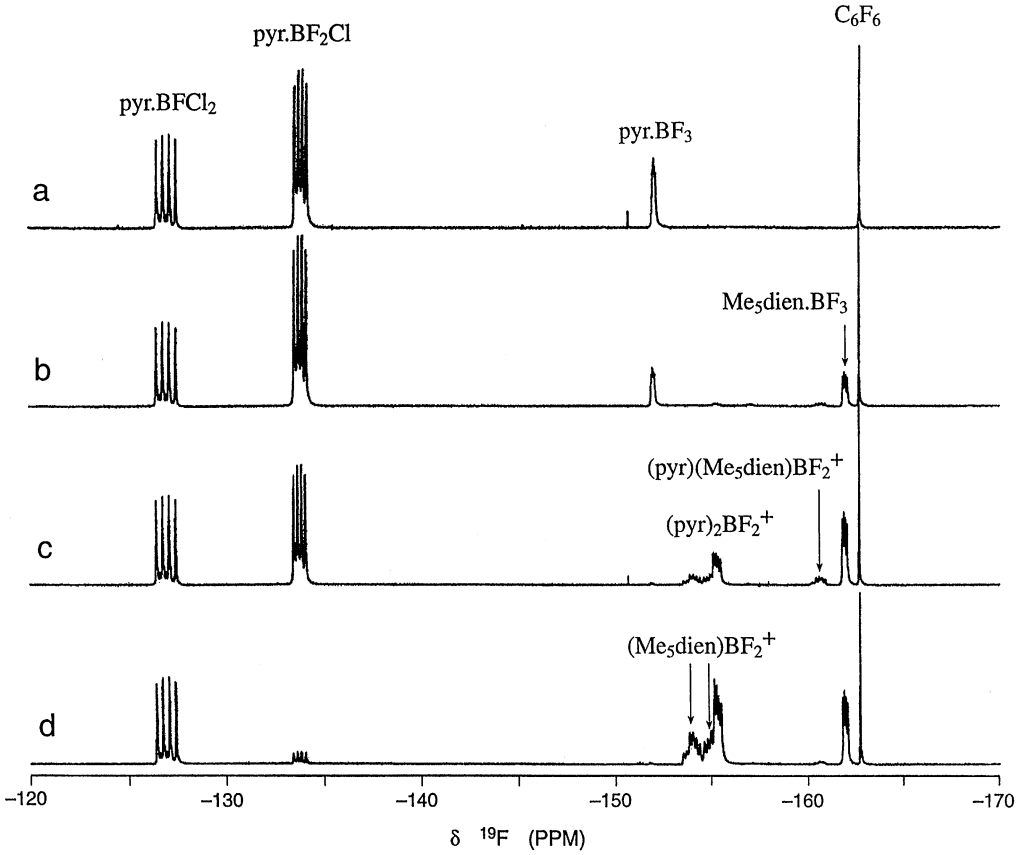
[a]Coordination at an end nitrogen.

[b]Coordination at middle nitrogen.

[c]Dicoordination at both end nitrogen atoms.

[d]Dicoordination at the middle and one end nitrogen. ^{19}F chemical shifts of the centre and end coordinated BF_3 overlap with a separation of only 0.05 ppm at 188.31 MHz.

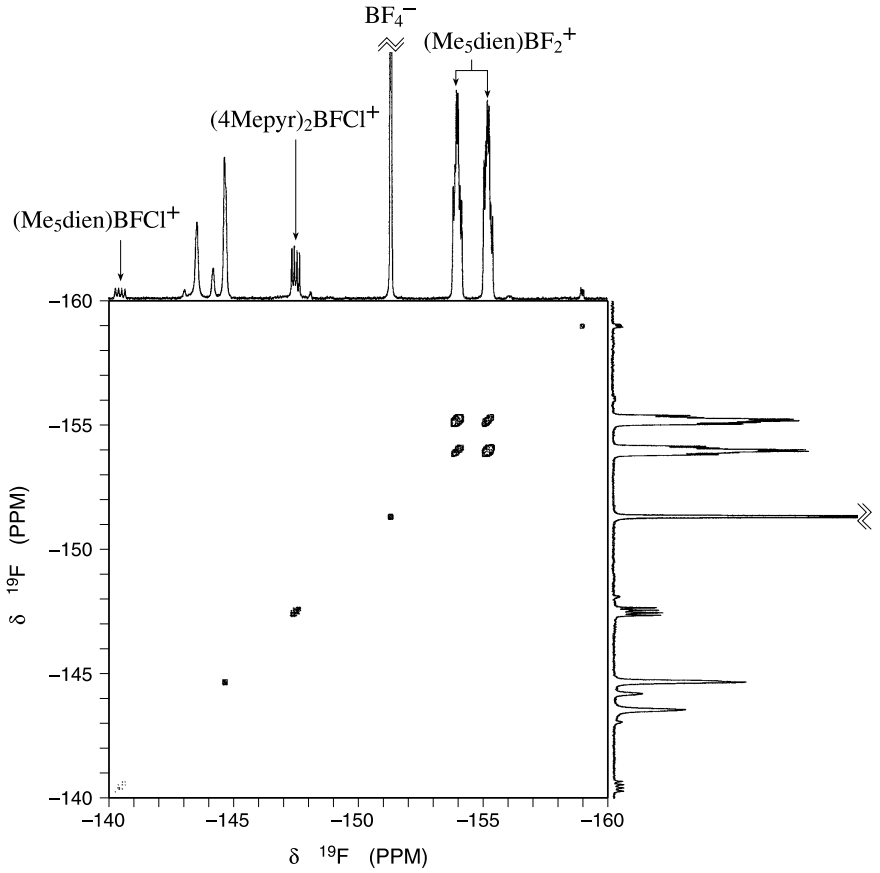
Fig. 2. 188.31 MHz ^{19}F NMR spectra of a $CDCl_3$ solution of $pyr{\cdot}BF_nCl_{3-n}$ (mole ratio pyr:BF_3:BCl_3 = 2.5:1:1.5). (*a*) Initial solution; (*b*) after Me_5dien addition (same number of moles as moles pyr present); (*c*) after standing for 2.3 h; (*d*) after standing for 13.8 h.



(Table 1 and Fig. 2). The centre nitrogen of Me_5dien becomes chiral upon formation of the +1 cation, making the BF_2 fluorines prochiral and magnetically nonequivalent. These fluorines are distinctive in a ^{19}F–^{19}F COSY NMR spectrum (Fig. 3) as the only fluorine signals that give cross peaks, since this is the only compound in the complex mixture with two nonequivalent fluorines. The $^{2}J_{FF}$ value of 61.2 Hz is comparable to the few available literature values for geminal FBF coupling (15, 16). The presence of $(Me_5dien)BF_2^+$ was confirmed by a positive ion FAB mass spectrum obtained di-

© 1999 NRC Canada

Fig. 3. 470.53 MHz partial ^{19}F–^{19}F COSY NMR spectrum of $(Me_5dien)BF_2^+$ and other species present in a solution of 4-Mepyr·BF_nCl_{3-n} following reaction with Me_5dien and standing for 3 months. Some fluorine-containing impurity species do not give rise to signals on the diagonal, apparently because of their longer spin-lattice relaxation times.



rectly from the chloroform solution introduced into an NBA matrix: parent ion at 221 (12.5%) and 222 (49.7%) *m/z*; $Me_5dien·H^+$ was the ion of greatest intensity.

Like Me_4en, Me_5dien readily displaces pyr from pyr·BF_3, forming a monodentate $Me_5dien·BF_3$ adduct (Fig. 2 and Table 2). Either an end nitrogen or the centre nitrogen of Me_5dien can be the donor site, and we detect both isomers of the mono-BF_3 adduct by reaction of Me_5dien with $Et_2O·BF_3$ (see below), but the ^{19}F chemical shift indicates that only the end nitrogen displaces pyr from pyr·BF_3, consistent with the greater steric hindrance of the centre nitrogen. As with the Me_4en system described above, this side reaction is troublesome because the liberated pyridine competes with Me_5dien in forming fluoroboron cations. The initial reactions occurring on the scale of hours, illustrated in Fig. 2, are followed by slower reactions requiring several days. This is a characteristic of many of our mixed boron trihalide – fluoroboron cation systems: many different reactions can occur, some fast and others extremely slow (11, 12). Figure 4 shows ^{19}F NMR monitoring of the later stages of this reaction. As in the Me_4en system, several things happen. Me_5dien slowly displaces pyridine from $(pyr)_2BF_2^+$ so that eventually the only remaining BF_2^+ cation is $(Me_5dien)BF_2^+$. Also $(Me_5dien)BFCl^+$ forms very slowly, over many days, from pyr·$BFCl_2$. Both boron and the central nitrogen of bidentate Me_5dien are chiral, and the well-separated ^{19}F 1:1:1:1 quartets at –137.5 and –140.5 ppm, are assigned to the two diastereomers of $(Me_5dien)BFCl^+$, which form at a ratio of about 1:3 in chloroform. The presence of $(Me_5dien)BFCl^+$ is confirmed by a positive ion FAB mass spectrum taken directly from the same chloroform solution: parent ion at 237 (2.4%) and 238 (8.2%) *m/z*.

Not only $(Me_5dien)BFCl^+$ but also $(pyr)_2BFCl^+$ forms from pyr·$BFCl_2$. The presence of these two cations, after the complete loss of $(pyr)_2BF_2^+$, complicates the system. $(pyr)_2BFCl^+$, unlike $(pyr)_2BF_2^+$, does not undergo appreciable pyridine displacement by Me_5dien, and the presence of this second $BFCl^+$ cation has prevented isolation of $(Me_5dien)BFCl^+$. These two species, along with $(Me_5dien)BF_2^+$, persist in solution for many months. A ^{11}B–^{19}F HETCOR NMR spectrum (Fig. 5), of a solution that had been standing at room temperature for 3 months (and involved the 4-Mepyr rather than the pyr adduct system; the behavior is essentially identical), displays the magnetically nonequivalent fluorine atoms of the $(Me_5dien)BF_2^+$ cation, both correlating to the same ^{11}B 1:2:1 triplet. (Only one diasteoremer of $(Me_5dien)BFCl^+$ is visible in this spectrum.)

We have not found any evidence for tridentate coordination of Me_5dien, i.e., $(Me_5dien)BF^{2+}·Cl^-_2$, which would form by displacement of a further Cl^- from $(Me_5dien)BFCl^+$. This species would have distinctive ^{19}F NMR parameters (10, 11), but FAB mass spectrometry would not distinguish the $(Me_5dien)BFCl^+$ cation from an ion pair containing a tridentate $(Me_5dien)BF^{+2}$ cation and a Cl^- counterion. One of

the objectives of the studies described below, involving mixed boron trihalide adducts of isoxazole, which is a much weaker donor than pyridine, and Br as well as Cl as the heavy halogen since Br^- is a better leaving group than Cl^-, was to obtain the fully chelated (tridentate) species.

(c) The ISOX·BF_nX_{3-n} (X = Cl, Br) systems: reactions with Me_4en

Addition of 2.0 and 4.0 mol equiv. Me_4en to chloroform solutions of ISOX·BF_nCl_{3-n} (ISOX:BF_3:BCl_3 = 2:1:1 and 4:1:3 mol, respectively) caused the colourless solutions to immediately turn yellow, and an orange solid to form at the top. ^{19}F and ^{11}B NMR spectra of the solutions, after standing for 24 h, contained signals of Me_4en·BF_3, Me_4en·$BFCl_2$, (Me_4en)$BFCl^+$, and Me_4en·BCl_3, and for the solution richer in BCl_3, a small amount of (Me_4en)BF_2^+ (Tables 1 and 2). The orange solid, after drying, gave positive ion FAB mass spectra showing the presence of (Me_4en)BF_2^+ (165 *m/z* (100%)) and (Me_4en)$BFCl^+$ (181 *m/z* (16 and 43% in the two samples)). The orange solid, dissolved in 1:1 acetone:sulpholane or nitromethane, gave ^{11}B and ^{19}F NMR signals of the same four species as the yellow solution, plus (Me_4en)BF_2^+ and (or) Me_4en·BF_2Cl. (The former, as its chloride salt, is very insoluble in chloroform; the latter is detected only rarely because chloride is displaced very readily by the uncoordinated nitrogen of Me_4en, giving chelated (Me_4en)BF_2^+.)

The ISOX·BF_nCl_{3-n} system's behavior with Me_4en differs greatly from that of the pyr·BF_nCl_{3-n} system described above, apparently due to the much weaker basicity of ISOX (pK_b = 12.7) than pyridine (pK_b = 8.8). Me_4en (pK_b^1 = 5.0) (17) readily displaces ISOX from all of the ISOX·BF_nCl_{3-n} adducts, giving the full series of Me_4en·BF_nCl_{3-n} adducts (in which Me_4en is monodentate), followed by chelate ring closure with expulsion of Cl^- to give the BF_2^+ (reaction [5]) and $BFCl^+$ cations, which occurs especially readily for Me_4en·BF_2Cl. In contrast, in the pyr·BF_nCl_{3-n} system described above, Me_4en preferentially displaces Cl^- rather than pyr. Furthermore, the displaced ISOX, unlike pyr, is inert and does not cause undesirable side reactions. These differences have important implications for synthesis.

Br^- is a much better leaving group than Cl^- in mixed boron trihalide adducts, so fluoroboron cations form much more rapidly from BF_2Br adducts than from the corresponding BF_2Cl adducts (1). Thus we have explored the ISOX·BF_nBr_{3-n} system, with its two very easily displaceable groups ISOX and Br^-, as a possible starting material for preparing chelated fluoroboron cations. However, in the ISOX system the crucial BF_2Br and $BFBr_2$ adducts form in far less than their statistical proportions at equilibrium compared to the unmixed-halogen adducts, as is commonly observed in mixed boron trihalide adduct systems involving "soft" donors (13).

Addition of 5.0 and 4.0 mol equiv. Me_4en to chloroform solutions of ISOX·BF_nBr_{3-n} (ISOX:BF_3:BBr_3 = 5:2:3 and 4:1:3 mol equiv., respectively) caused the colourless solution to immediately turn yellow, and a brown solid to form at the top. ^{19}F and ^{11}B NMR of the solutions detected only a very small amount of Me_4en·$BFBr_2$ and (Me_4en)BF_2^+ in addition to some unreacted ISOX·BF_3 and an unidentified ^{19}F singlet at –151.3 ppm. The brown solid, after drying, gave FAB mass spectra showing the presence of Me_4en·H^+ (117 *m/z* (100%)), (Me_4en)BF_2^+ (165 *m/z* (22 and 27%)), Me_4en·H·HBr^+ (197 *m/z* (5 and 7%)), and (Me_4en)$BFBr^+$ (225 *m/z* (Br-rich sample only; 5%)). Most of the solid was insoluble in nitromethane, acetone, acetone–sulpholane, and acetonitrile, and the small amount that did dissolve gave only the NMR signals seen in the chloroform mother liquor. ^{11}B MAS NMR spectra of a similar solid are described below.

(d) The ISOX·BF_nX_{3-n} (X = Cl, Br) systems: reaction with Me_5dien

Addition of 2.0 and 4.0 mol equiv. Me_5dien to chloroform solutions of ISOX·BF_nCl_{3-n} (ISOX:BF_3:BCl_3 = 2:1:1 and 4:1:3 mol, respectively) caused the colourless solutions to immediately turn orange, and a red solid to form at the top. ^{19}F and ^{11}B NMR spectra of the solutions, after standing for 24 h, contained signals of the (Me_5dien)BF_2^+ and (Me_5dien)$BFCl^+$ cations (both diastereomers of the latter, in a 1:3 ratio), as well as Me_5dien·BF_3, Me_5dien·$BFCl_2$, and Me_5dien·BCl_3 (Tables 1 and 2). The ^{19}F spectrum also included five singlets in the –150 to –160 ppm range, arising from unknown species, without any corresponding ^{11}B signals. Positive ion FAB mass spectra of the solution included peaks consistent with (Me_5dien)BF_2^+ (222 *m/z* (42.3%)), (Me_5dien)$BFCl^+$ (238 *m/z* (13.3%)), and Me_5dien·H^+ (174 *m/z* (100%)). Positive ion FAB mass spectra of the red solid, after drying, showed the presence of (Me_5dien)BF_2^+ (222 *m/z* (62 and 52%)) and (Me_5dien)$BFCl^+$ (238 *m/z* (24 and 31%)), and Me_5dien·H^+ (174 *m/z* (100%)). The red solid partially dissolved in 1:1 acetone:sulpholane and nitromethane, and ^{11}B and ^{19}F NMR spectra of the solution showed the same species as were present in the mother liquor.

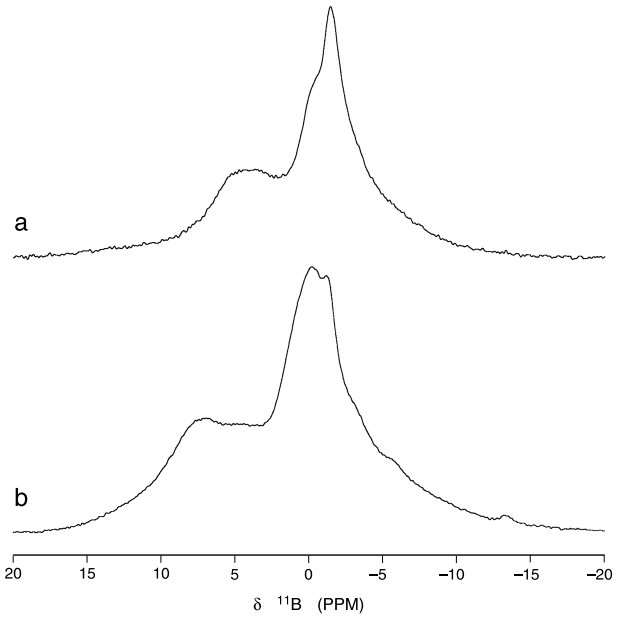
Fig. 6. 96.29 MHz ^{11}B MAS NMR spectra of the insoluble material formed from the reaction of Me_5dien with $ISOX{\cdot}BF_nBr_{3-n}$ solutions of initial proportions of $ISOX:BF_3:BBr_3$ of (*a*) 5:2:3, (*b*) 4:1:3.



Addition of 5.0 and 4.0 mol equiv. Me_5dien to chloroform solutions of $ISOX{\cdot}BF_nBr_{3-n}$ ($ISOX:BF_3:BBr_3$ = 5:2:3 and 4:1:3 mol, respectively) caused the colourless solutions to immediately turn yellow, and a brown solid to form at the top. ^{19}F and ^{11}B NMR of the chloroform solutions gave a small signal of $Me_5dien{\cdot}BF_3$, and other ^{19}F peaks in the –150 to –160 ppm region arising from unknown species. The brown solid, after drying, gave positive ion FAB mass spectra showing the presence of $Me_5dien{\cdot}H^+$ (174 *m*/*z* (100%)), $(Me_5dien)BF_2^+$ (222 *m*/*z* (9 and 6%)), $Me_5dien{\cdot}H{\cdot}HBr^+$ (254 *m*/*z* (18 and 25%)), and $(Me_5dien)BFBr^+$ (282 *m*/*z* (2%)). No new NMR signals were obtained on attempts to dissolve the solid in nitromethane, acetone, 1:1 acetone:sulpholane, or acetonitrile.

^{11}B MAS NMR of the solid gives further information, despite broadening by dipolar coupling to ^{19}F and quadrupolar broadening (Fig. 6). The solids from the Me_4en and the Me_5dien systems give similar spectra. We have shown (unpublished work) that there is a good correlation between solution and solid-state ^{11}B chemical shifts of fluoroboron adduct and cation species, with the solid NMR signal being a few ppm to lower frequency (higher field) than the solution signal. Despite the poor resolution, Fig. 6 clearly shows differences in relative peak intensities with increased Br enrichment. $D{\cdot}BF_nBr_{3-n}$ adducts absorb in the 2 to –10 ppm range while $D_2BF_nBr_{2-n}^+$ cations absorb in the 10–2 ppm range, and there are strong signals in both regions, with the sample prepared from the more bromine-rich mixture (Fig. 6*b*) having much more intensity at lower field corresponding to the presence of a larger proportion of $BF_nBr_{2-n}^+$ cations. This is consistent with the positive ion FAB spectra in which relative peak intensities suggest greater cation intensity, especially the $BFBr^+$ cation, when the starting materials are more bromine-rich.

(e) Stepwise displacement of pyr from $(pyr)_2BF_2^+{\cdot}PF_6^-$

Excess Me_4en (from 2 to 64 mol equiv.), added to acetone solutions containing 20 mg/mL of $(pyr)_2BF_2^+{\cdot}PF_6^-$, reacts over several hours to give first the nonchelated $(pyr)(Me_4en)BF_2^+$, detectable by NMR but never present in high concentrations, and finally chelated $(Me_4en)BF_2^+$. The higher the excess of Me_4en, the greater the yield of the $(Me_4en)BF_2^+$, up to about a 16 mol equivalent excess, beyond which the overall yield stayed constant at about 50–60%, with or without heating to 50°C to accelerate the reaction. Positive ion FAB mass spectra confirmed the existence of $(Me_4en)BF_2^+$ in the acetone solution. However impurities form as well.

Excess Me_5dien (from 2 to 16 mol equiv.), added to acetone solutions containing 20 mg/mL of $(pyr)_2BF_2^+{\cdot}PF_6^-$, reacts over several hours to give first the nonchelated $(pyr)(Me_5dien)BF_2^+$, which never builds up to high concentrations but reacts to give bidentate $(Me_5dien)BF_2^+$. ^{19}F NMR monitoring of the reaction is shown in Fig. 7. The greater the excess of Me_5dien, the greater the yield of $(Me_5dien)BF_2^+$, up to 35–40% when the molar excess is 10 or greater. Positive ion FAB mass spectra of the acetone solution confirm the existence of $(Me_5dien)BF_2^+$.

However in both systems, ^{19}F spectra show that the formation of fluorine-containing impurities competes with the formation of the chelated cations (Fig. 7). There are four significant ^{19}F impurity signals: δ –138.4 ppm (unknown, though likely $BF_2OH_2^-$ (18)), –144.7 ppm, $^1J_{BF}$ = 13.5 Hz (BF_3OH^- (18)), $pyr{\cdot}BF_3$ and BF_4^-. Work on minimizing the formation of these species is in progress. The BF_3OH^- and (tentative) $BF_2OH_2^-$ ^{19}F signals vary in chemical shift by a few ppm in different samples.

Ethylenediamine (en) and *N*,*N*,*N*″,*N*″-tetraethyldiethylenetriamine (Et_4dien) were also reacted with the $(pyr)_2BF_2^+{\cdot}PF_6^-$ salt at 2 and 10 mol excess concentrations, with and without heating to 50°C. Ethylenediamine, when present in a twofold molar excess, forms the desired $(en)BF_2^+$ (Table 1) in very small quantity at room temperature. Its NMR parameters match those previously obtained, in preliminary experiments at the University of Manitoba, from a minor (less than 1%) product that formed, in addition to the major product $en{\cdot}(BF_3)_2$, from the reaction of BF_3 with a mixture of en and $(en{\cdot}2H)^{2+}{\cdot}(BF_4^-)_2$ (19). Et_4dien gave no NMR evidence of coordination. Both of these bases give much more rapid formation of the same impurity species described above, than are obtained when reacting Me_4en and Me_5dien, and this indicates that N—H bonds, not present in the latter bases, favour the formation of the impurities.

(f) Reaction of chelating donors with $Et_2O{\cdot}BF_3$

In a 1:1 ($Me_4en:Et_2O{\cdot}BF_3$) solution in chloroform, both $Me_4en{\cdot}BF_3$ and $Me_4en{\cdot}(BF_3)_2$ (Table 2) were visible by ^{19}F NMR after 24 h at room temperature. A white precipitate formed over this period of time. It was dried and dissolved in nitromethane, and gave ^{19}F signals of both the mono and bis BF_3 adducts. In $Et_2O{\cdot}BF_3$-rich solutions ($Me_4en:Et_2O{\cdot}BF_3$ = 1:2 and 1:3), only a very small amount of the bis BF_3 adduct was detectable after 24 h. Again the

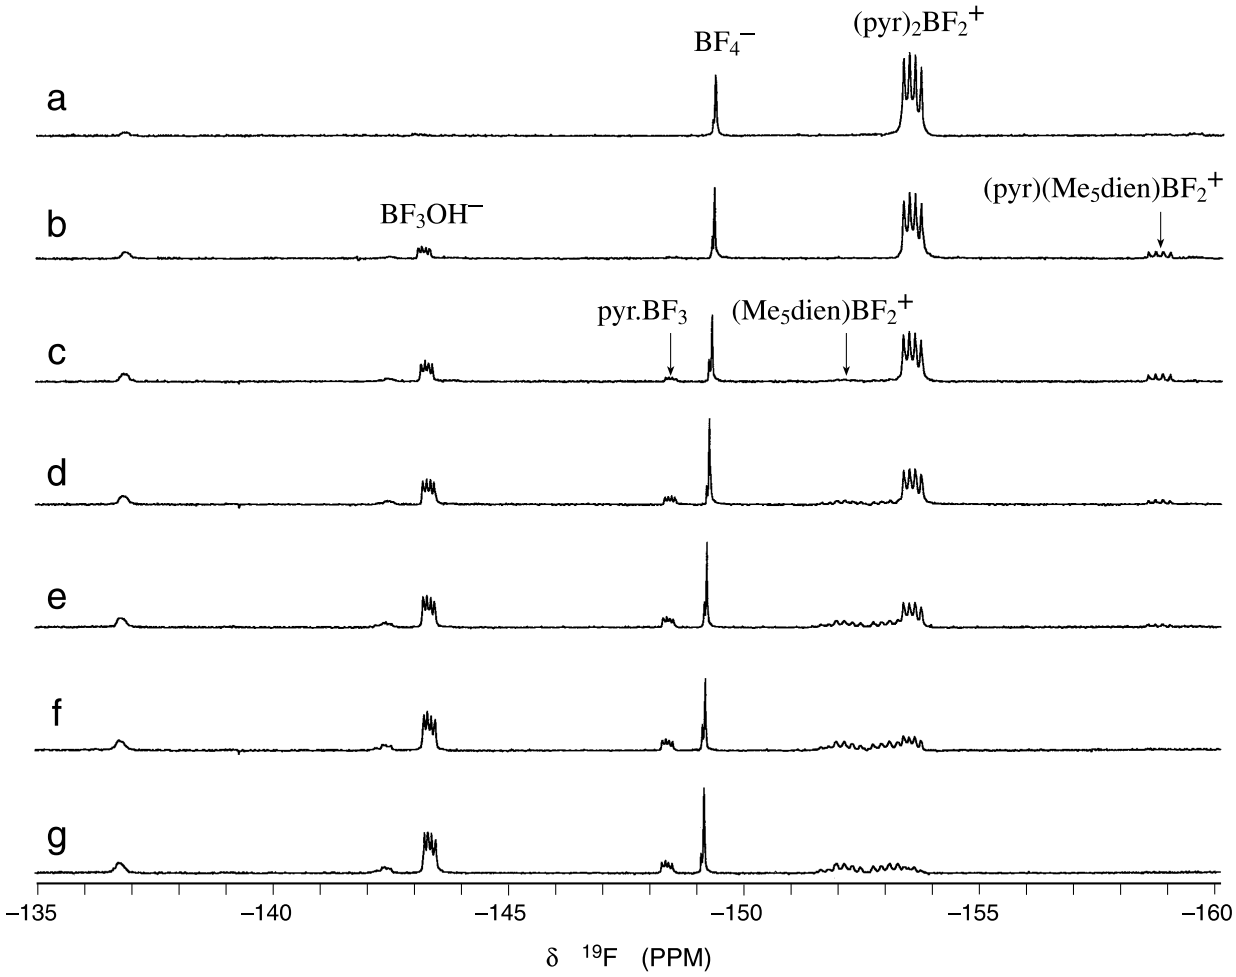
Fig. 7. 188.31 MHz ^{19}F NMR spectra of an acetone solution of $(pyr)BF_2^+ \cdot PF_6^-$ (10 mg in 500 μL) to which a 16-fold excess of Me_5dien had been added. The PF_6^- fluorine signals (doublet at δ –70.6 ppm; $^1J_{PF}$ = 707 Hz) are not shown. (*a*) Initial spectrum, and following reaction at room temperature for (*b*) 0.8, (*c*) 3.2, (*d*) 6.3, (*e*) 12.6, (*f*) 25.3, (*g*) 50.5 h.



white precipitates, dried and dissolved in nitromethane, gave ^{19}F signals of only the mono and bis BF_3 adducts. There was no indication of $(Me_4en)BF_2^+$, consistent with the work of Brown et al. (8) and Singaram and Pai (9).

In a 1:1 (Me_5dien:$Et_2O \cdot BF_3$) solution in chloroform, both isomers of $Me_5dien \cdot BF_3$ (bonded through the end nitrogen and through the centre nitrogen) were detected by ^{19}F NMR after 24 h. A small signal at –147.4 ppm ($^1J_{BF}$ = 14.2 Hz), consistent with BF_3OH^-, and a few unidentified singlets in the –140 to –150 ppm region, were also visible. The dried white precipitate, dissolved in nitromethane, gave ^{19}F signals for both mono-BF_3 adducts. In a 1:2 Me_5dien:$Et_2O \cdot BF_3$ solution, only the mono-BF_3 adduct bonded through the centre nitrogen was detectable by ^{19}F NMR in solution after 24 h. The white precipitate, dissolved in nitromethane, gave ^{19}F signals that we assign to the bis BF_3 adduct of Me_5dien, with BF_3 coordinated to the two terminal nitrogen atoms (i.e., only one ^{19}F signal); and to the tris BF_3 adduct (two ^{19}F signals, in a 2:1 ratio). In a 1:3 Me_5dien:$Et_2O \cdot BF_3$ solution in chloroform, no adducts could be detected by ^{19}F NMR of the solution after 24 h. The precipitate, dissolved in nitromethane, gave ^{19}F signals corresponding to the tris BF_3 adduct and the bis BF_3 adduct with one terminal nitrogen and the central nitrogen coordinated (two ^{19}F signals, in a 1:1 ratio). A 1:6 Me_5dien:$Et_2O \cdot BF_3$ solution gave the same results as the 1:3 solution: no adduct ^{19}F signals detectable in the solution, and the same species detected in the precipitate. As with the Me_4en:$Et_2O \cdot BF_3$ system, no fluoroboron cations could be detected. The NMR signals of these species were assigned by using chemical shift trends based on steric hindrance of tertiary-amine donors (16), as well as relative peak intensities.

Discussion

(a) Reactivity trends and implications for synthesis

Heavy halide ion and donor molecule displacement from $D \cdot BF_2X$ (D = pyridine or isoxazole) gives the chelated BF_2^+ cations of Me_4en and Me_5dien that are not accessible from $Et_2O \cdot BF_3$. Pyridine displacement from $(pyr)_2BF_2^+$ provides an alternative but less efficient route. The $BFCl^+$ and $BFBr^+$ cations form similarly, but much less readily, by displacement from $D \cdot BFX_2$, which reacts much less readily than the corresponding $D \cdot BF_2X$ when it reacts at all (1, 10–12). Me_5dien behaves like monodentate *tert*-amines, but unlike pyridines and amidines (10, 11), in being unable to displace

© 1999 NRC Canada

the second heavy halogen of $D{\cdot}BFX_2$, so the tridentate $(Me_5dien)BF^{2+}$ does not form. Me_5dien is a versatile tridentate chelating ligand and coordinates to many elements (20), but there is only one report of tridentate chelation to boron: Kelly and co-workers (21) prepared $[(Me_5dien)BH]^{2+}$ by displacement of Me_3N and two iodide ions from $Me_3N{\cdot}BHI_2$. Iodide is by far the best halide leaving group, and displacement from a $D{\cdot}BFI_2$ adduct would have the greatest likelihood of giving tridentate $(Me_5dien)BF^{+2}$. However, $D{\cdot}BFI_2$ adducts are not readily accessible. The formation of mixed F, I boron trihalide adducts is very unfavourable, with only traces forming from the reaction of $D{\cdot}BF_3$ with BI_3, a consequence of Pearson's "symbiotic principle" that we have discussed previously (16).

The much slower displacement of pyridine compared to isoxazole from $D{\cdot}BF_nX_{3-n}$ is consistent with the much higher basicity of pyridine. Pyridine's basicity also complicates the system because the displaced pyridine competes with the chelating donor. Isoxazole's ease of displacement and its inability to participate in further displacement reactions makes the $ISOX{\cdot}BF_nX_{3-n}$ adducts particularly useful in fluoroboron cation synthesis, and further studies are under way. Isoxazole displacement from the $ISOX{\cdot}BF_nX_{3-n}$ adducts also allows the formation of monodentate BF_2X and BFX_2 adducts of the chelating ligands, inaccessible by our usual method of BF_nX_{3-n} adduct formation, which requires an excess boron trihalide stage for halogen redistribution. The monodentate BCl_3 and BBr_3 adducts of Me_4en and Me_5dien adducts also form readily by isoxazole displacement from the corresponding ISOX adducts, but do not form chelated BCl_2^+ or BBr_2^+ cations under our conditions that readily displace heavy halide from the mixed fluorine, heavy halogen adducts.

Chelated $(Me_4en)BF_2^+$ and $(Me_5dien)BF_2^+$ can also be formed by stepwise displacement of pyridine from $(pyr)_2BF_2^+{\cdot}PF_6^-$, but the reaction requires weeks at room temperature. Raising the temperature is not an option, since this increases the proportion of undesirable side products. Displacement of isoxazole from $(ISOX)_2BF_2^+{\cdot}PF_6^-$ would be much faster, but isoxazole is too weak a base to displace heavy halide ion from $ISOX{\cdot}BF_2X$, so we cannot prepare $(ISOX)_2BF_2^+$. The ideal base, still being sought, would be sufficiently strong to form $D_2BF_2^+$ but sufficiently weak and low in steric hindrance to be more easily displaced than pyridine.

(b) Reaction pathways

Our work confirms the reports of Brown et al. (8) and Singaram and Pai (9) that chelated BF_2^+ species are not formed by reaction of Me_4en or similar bases with $Et_2O{\cdot}BF_3$. We could not detect even trace amounts by ^{19}F NMR, but only the mono- and bis-BF_3 adducts and for Me_5dien the tris-BF_3 adduct. This can be explained by considering the reaction paths available.

While heavy halide ion is a favourable leaving group, it is well established that fluoride ion must be transferred among other species and does not exist independently in solvents such as $CHCl_3$ (22). Thus, the second nitrogen donor site cannot close the chelate ring by simply driving off fluoride ion, analogous to the loss of chloride or bromide ion. Following formation of the mono-BF_3 adduct, a second BF_3 can either coordinate to the second nitrogen or to a fluorine of the already coordinated BF_3 to give an intermediate B---F---BF_3 bridge, a requirement for fluoride transfer between boron atoms and formation of the chelated BF_2^+ cation as its BF_4^- salt. The bond enthalpy of the nitrogen–boron bond is so much greater than that of the B---F bridge bond (129.3 kJ/mol for $Me_3N{\cdot}BF_3$ vs. 15.25 kJ/mol for bridging B---F (23)) that the second possibility cannot compete, so chelated BF_2^+ cations of the ethylenediamine class of donors do not form from $Et_2O{\cdot}BF_3$. Extreme crowding, such as in an initial BF_3 adduct with the rigid bidentate ligand 1,10-phenanthroline, could change the situation however, and 1,10-phenanthroline apparently interacts directly with BF_3 to form $(1,10\text{-phen})BF_2^+{\cdot}BF_4^-$ (5, 6, 24).

Although fluoride is not a leaving group in the $D{\cdot}BF_nX_{3-n}$ adducts, the presence of fluoride greatly accelerates the loss of the heavy halide ion, rates of halide loss always varying in the order $D{\cdot}BF_2X >> D{\cdot}BFX_2 >> D{\cdot}BX_3$ (1, 10–12). We have previously discussed the mechanistic implications of this in terms of π bonding in the transition state (10). We rarely detect loss of heavy halide from $D{\cdot}BX_3$ under our conditions but Ryschkewitsch and co-workers (25), using stronger conditions, have studied a wide range of such reactions.

Reaction trends involving the chelating ligands are similar to the trends we have observed earlier for substitution of monodentate ligands in $D{\cdot}BF_nX_{3-n}$ adducts, i.e., there seems to be a complex interplay of steric effects, ligand basicity effects, and differential stabilization of the transition state by π bonding to boron from ligands that remain attached throughout the reaction. A similar pattern applies to ligand displacement from $(pyr)_2BF_2^+$ and related $D_2BF_2^+$ ions by monodentate ligands (12) and now by Me_4en and Me_5dien. Me_4en and Me_5dien (pK_b[1] values: 5.0 and 4.6, respectively (17)) are more basic than pyridine but displacement of pyridine is slow, consistent with *tert*-amine steric hindrance as observed previously (1). The intermediate non-chelated $(pyr)(DD)BF_2^+$ species is detected so the reaction must be stepwise, but the intermediate never builds up to high concentrations. Chelate ring closure is evidently favoured, since even a very large excess of chelating donor does not give detectable amounts of the bis(monodentate) species $(Me_4en)_2BF_2^+$ or $(Me_5dien)_2BF_2^+$.

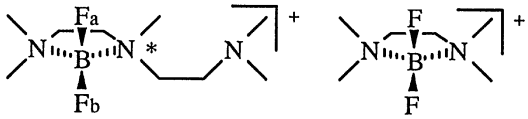
(c) NMR parameters

The wide range of ^{19}F chemical shifts and ^{11}B–^{19}F coupling constants, and their systematic variation with ligand steric hindrance, make NMR the most useful empirical tool in monitoring and interpreting these complex systems. Aside from ^{19}F and ^{11}B chelation shifts of several ppm to high frequency and $^1J_{BF}$ values several Hz smaller than those of corresponding non-chelated systems (Table 1), trends in systems involving Me_4en and Me_5dien are much the same as in previously reported systems. Thus the ^{19}F NMR parameters of the monodentate (pyr)(chelating ligand)BF_2^+ cations (Table 1) are consistent with those of our previously reported $(pyr)(R_3N)BF_2^+$ species (–160.4 to –162.5 ppm; $^1J_{BF}$ = 28.5–29.7 Hz) (1). $(Me_4en)BF_2^+$ and $(Me_5dien)BF_2^+$ ^{19}F chemical shifts and $^1J_{BF}$ values (Table 1) can be compared to the nonchelated $(R_3N)_2BF_2^+$ values (–158.9 to –165.4 ppm; $^1J_{BF}$ = 36.2–39.5 Hz) (1). The NMR parameters of $(en)BF_2^+$,

© 1999 NRC Canada

$(Me_4en)BF_2^+$, and $(Me_5dien)BF_2^+$ (Table 1) are typical of a series of increasing steric hindrance, the ^{19}F signal shifting to higher frequency as steric hindrance increases. The NMR parameters of the mono-adducts of Me_4en and Me_5dien with BF_nCl_{3-n} are consistent with those of simple trialkylamines (16) and match those of the Me_2NEt adducts the most closely, supporting our conclusion that Me_5dien coordinates preferentially through an end nitrogen.

These trends allow us to assign the ^{19}F NMR signals of the nonequivalent BF_2 fluorines of $(Me_5dien)BF_2^+$ and of the major and minor (3:1 ratio) diastereomers of $(Me_5dien)BFCl^+$ (Fig. 4). Fluorine F_a of $(Me_5dien)BF_2^+$, *cis* to two methyl groups, is in an environment very similar in steric hindrance to the $(Me_4en)BF_2^+$ fluorines, while F_b, *cis*



to a methyl group and the more bulky $CH_2CH_2NMe_2$ group, is deshielded. We can therefore assign the –153.9 ppm signal to F_b and the –155.1 ppm signal, very similar in chemical shift to $(Me_4en)BF_2^+$, to F_a. Similarly, the fluorine of one diastereomer of $(Me_4en)BFCl^+$ (**9**) has an environment similar to the fluorine of $(Me_4en)BFCl^+$, whereas the fluo-

9 **10**

rine of the other diastereomer (**10**) is more hindered and should appear at higher frequency. Since the major isomer and $(Me_4en)BFCl^+$ have very similar ^{19}F chemical shifts, while the minor isomer is shifted approximately 2 ppm to higher frequency, the major isomer is **9** and the minor isomer is **10**. In contrast the ^{11}B chemical shifts of fluoroboron cations are not very sensitive to the nitrogen substituents, so **9** and **10** have ^{11}B chemical shifts differing by only 0.1 ppm.

Formation of **9** and **10** in a 3:1 ratio probably reflects differences in steric hindrance in the transition state, since steric hindrance greatly affects rates of substitution at tetrahedral boron in fluoroboron systems (10). However, we cannot dismiss the possibility that their relative thermodynamic stabilities might determine the ratio. Semi-empirical calculations at the PM3 level give a negligible energy difference between **9** and **10**, only 0.18 kJ/mol with **9** lower in energy whereas the experimental error in the calculation of conformational energy differences at the PM3 level is typically about 4 kJ/mol (26). The observed 3:1 ratio of diastereomers would correspond to an energy difference (2.7 kJ/mol, neglecting entropy effects), which is less than the experimental error. Higher level calculations would be instructive.

Solid-state NMR has great potential in these systems because some key species, especially bromine-containing ones, are insoluble in any non-coordinating solvent. ^{11}B and ^{19}F MAS NMR spectra of fluoroboron cations including $(pyr)_2BF_2^+$, as their PF_6^- salts, are poorly resolved but give chemical shifts similar to solution values.[2] Despite the poor resolution, apparently arising from strong dipolar coupling to ^{19}F (27), ^{11}B MAS NMR spectra of the insoluble material formed in the reaction of Me_5dien with $ISOX{\cdot}BF_nBr_{3-n}$ (Fig. 6) confirm that the expected $BF_nBr_{2-n}^+$ cations (10–2 ppm (10, 24)) and BF_nBr_{3-n} adducts (2 to –10 ppm (16)), are present, and that their relative intensities vary in the expected manner with changes in the proportions of F to Br. High-power proton decoupling has little effect on the resolution. High-power ^{19}F decoupling will be required to obtain high-resolution spectra. ^{19}F MAS NMR can be informative, despite serious broadening due to ^{19}F–^{19}F dipolar interactions, and would be much more useful with sample spinning at sufficiently high speeds to eliminate the dipolar interactions (28), or with use of the CRAMPS (combined rotation and multiple pulse spectroscopy) sequence (29). We are exploring these possibilities as we study the formation of a variety of chelated fluoroboron systems, including those involving chiral chelating ligands with possible applications in stereoselective catalysis.

Conclusions

Chelated fluoroboron cations of Me_4en and Me_5dien are accessible by displacement reactions from mixed boron trihalide adducts and by displacement of pyridine from $(pyr)_2BF_2^+$, but not by reaction of the chelating ligands with $Et_2O{\cdot}BF_3$ or $ISOX{\cdot}BF_3$. Mixed boron trihalide adducts of isoxazole are a particularly convenient starting material for the preparation of chelated fluoroboron cations.

Acknowledgments

We thank Tim Jones and Dr. Jhansi Lakshmi for assistance with the instrumentation, W.R. (Rick) Szerminski and Paul Ragogna for synthesis of $(pyr)_2BF_2^+{\cdot}PF_6^-$, Prof. Alex F. Janzen (University of Manitoba) for helpful discussions, Dr. Ayaaz Pirani and Prof. Gary J. Schrobilgen (McMaster University) for technical advice, Dr. Don Hughes and Brian Sayer (McMaster University) for assistance with the 11.7 T NMR instrument, and the Natural Sciences and Engineering Research Council of Canada for financial support.

A ^{19}F nuclear magnetic resonance study of the conjugate Brönsted–Lewis superacid HSO_3F–SbF_5. Part 1

Dingliang Zhang, Markus Heubes, Gerhard Hägele, and Friedhelm Aubke

Abstract: The Brönsted–Lewis superacid HSO_3F–SbF_5 or "magic acid" is re-investigated by modern ^{19}F NMR methods over a wide concentration range. The system is found to be considerably more complex than had been assumed previously. A total of 13 different anions are identified of which only five have previously been identified in magic acid. With increasing SbF_5 contents the concentration of monomeric anions like $[SbF_6]^-$, $[SbF_5(SO_3F)]^-$, *cis*- and *trans*-$[SbF_4(SO_3F)_2]^-$, and *mer*-$[SbF_3(SO_3F)_3]^-$ gradually decreases. Except for $[Sb_2F_{11}]^-$, which is present in very small concentrations only, the formation of oligomers involves exclusively μ-fluorosulfato bridges. In addition to donor $(SO_3F)^-$ and acceptor (SbF_5) complex formation to give $[SbF_5(SO_3F)]^-$ and possibly ligand redistribution, the solvolysis of SbF_5 or $SbF_4(SO_3F)$ in HSO_3F appears to be the principal formation reaction for polyfluorosulfatofluoroantimonate(V) anions. In glass (NMR tubes) the solvolysis product HF is converted to the oxonium ion $[H_3O]^+$, which has previously been identified by ^1H NMR and structurally characterized as $[H_3O][Sb_2F_{11}]$ by us.

Key words: magic acid, conjugate superacid, fluorosulfuric acid, ^{19}F NMR spectra.

Résumé : On a réétudié l' « acide magique » (superacide de Brönsted–Lewis), HSO_3F–SbF_3 en faisant appel à la RMN du ^{19}F et en opérant sur une grande plage de concentrations. On a trouvé que le système est beaucoup plus complexe que ce qui avait été envisagé auparavant. On a identifié un total de 13 anions différents, dont seulement cinq avaient été identifiés antérieurement dans l'acide magique. Avec une augmentation de la concentration de SbF_5, il y a diminution de la concentration des anions monomères, du type $[SbF_6]^-$, $[SbF_5(SO_3F)]^-$, *cis*- et *trans*-$[SbF_4(SO_3F)_2]^-$ et *mer*-$[SbF_3(SO_3F)_3]^-$. À l'exception du $[Sb_2F_{11}]^-$ dont la concentration est très faible, la formation d'oligomères implique exclusivement des ponts μ-fluorosulfato. En plus de la formation de complexes provenant du donneur $(SO_3F)^-$ et de l'accepteur (SbF_5) conduisant au $[SbF_5(SO_3F)]^-$ ou de la possibilité d'une redistribution de ligands, il semble que la solvolyse du SbF_5 ou du $SbF_4(SO_3F)$ dans le HSO_3F soit la réaction principale de formation des anions polyfluorosulfatofluoroantimonantes(V). En présence de verre (tubes de RMN), le HF produit par solvolyse se transforme en ion oxonium $[H_3O]^+$ qui a été identifié antérieurement par RMN du ^1H et pour lequel on a caractérisé la structure, $[H_3O][Sb_2F_{11}]$.

Mots clés : acide magique, superacide conjugué, acide fluorosulfurique, spectre RMN du ^{19}F.

[Traduit par la Rédaction]

Introduction

The conjugate Brönsted–Lewis superacid HSO_3F–SbF_5 or "magic acid" (1) has found in the past extensive use as reaction medium for the generation and stabilization of a wide range of highly electrophilic, long-lived cations. Well documented examples extend from inorganic main group cations (1–3) to a large number of carbocations (1, 4). The reasons for the enormous versatility of magic acid are its outstanding solvent characteristics, in particular its ionizing and protonating abilities, which allow the dissolution of a large number of substrates (1–4). The proton acidity of magic acid is only exceeded by that of the related conjugate superacid HF–SbF_5 (1, 2). This is altogether not surprising because the constituent Brönsted acids fluorosulfuric acid (5) and anhydrous hydrogen fluoride (6) are the strongest simple protonic acids with identical Hammett (7) acidity function values of $-H_0 = 15.1$ (1, 2, 8), while the Lewis superacid SbF_5 is ranked as the strongest molecular Lewis acid (9).

For magic acid Hammett acidity function studies (7) are reported (10–13) for concentrations up to 80 mol% SbF_5. A comparison between HF–SbF_5 and HSO_3F–SbF_5 (14, 15)

Received March 8, 1999.

This paper is dedicated to Professor Ted Schaefer in recognition of his outstanding contributions to Canadian chemistry.

suggests that at 0.5 mol % SbF_5, the former is more acidic by a factor of approximately 10^4 (15). It is not immediately obvious why this should be, since the constituent Brönsted acids have identical -H_0 values (1, 2, 9) and SbF_5 is common to both superacid systems.

To probe the composition of HSO_3F–SbF_5, several ^{19}F NMR studies (16–19) have been reported between 1965 and 1978. Because of the limited resolution and sensitivity of NMR spectra at that time, accurate assignments of the signals have been difficult and some disagreement is found among the reported studies (16–19). There is however general agreement that very complex equilibria are encountered, which will be discussed subsequently. The situation is much simpler in the HF–SbF_5 system, where in addition to $[SbF_6]^-$ oligomeric *cis*-fluorine bridged anions like $[Sb_2F_{11}]^-$, $[Sb_3F_{16}]^-$, etc. are present at high SbF_5 concentrations and detected by ^{19}F NMR (20). Since these early studies the resolution, sensitivity, and evaluation of NMR spectra have all significantly improved by the introduction of pulse spectroscopy and Fourier transformation in one- and two-dimensional techniques (21). We have applied state of the art NMR methods to reinvestigate the HSO_3F–SbF_5 system with two objectives:

(*i*) to obtain more precise structural information on the anionic species present and

(*ii*) to suggest plausible pathways of formation of these anions from the interaction of HSO_3F with SbF_5.

We present here a ^{19}F NMR study of the HSO_3F–SF_5 superacid system over a wide concentration range with SbF_5 molar fractions *x* between 0.001 and 0.795. The techniques employed include high resolution ^{19}F 1D- and 2D NMR methods of the type ^{19}F–^{19}F COSY and ^{19}F *J* resolved spectra at 181 MHz.

Experimental

Preparation of NMR samples

The purity of freshly distilled fluorosulfuric acid was checked by conductometry and by NMR. Purified antimony pentafluoride was transferred in vacuo into a 50 mL vial fitted with a Teflon stopcock. The amount of the antimony pentafluoride transferred was determined by difference weighing. Inside a dry box, freshly distilled fluorosulfuric acid was pipetted into the reactor. The amount of fluorosulfuric acid was also determined by difference weighing. The mixture was then stirred magnetically for ca. 15 min. About 0.4 mL of the solution was pipetted into an NMR tube. A sealed capillary tube containing a solution of 5% (w/w) $CFCl_3$ in CD_3COCD_3 was inserted into the NMR tube in order to provide chemical shift references and a field lock. The NMR tube was attached to a B10–B10 adapter fitted with a Kontes Teflon stem stopcock and then taken out of the dry box. The NMR tube was evacuated after it was cooled to –95 ~ –100°C in an ethanol – dry ice slurry bath. The sample was degassed by three freeze–pump–thaw cycles. The NMR tube was then flame-sealed under vacuum. Samples were checked immediately after preparation by ^1H-NMR in Vancouver and then shipped to Düsseldorf for ^{19}F-NMR studies. All samples were kept at room temperature. Repeated NMR measurements spanning a period of several months showed the stable, equilibrated state of NMR samples discussed in this paper.

^{19}F NMR spectroscopy

Both 1D and 2D ^{19}F NMR spectra were acquired at low temperatures (see text) using a Bruker AM 200 NMR spectrometer equipped with a Bruker variable temperature unit B-VT 1000. For each 1D ^{19}F NMR spectrum, 64K memory size was used for data storage (TD = 64K) and 1024 scans were acquired (NS = 1024) for each Free Induction Decay (FID). No zero-filling was applied to the FIDs before Fourier transformation. For ^{19}F–^{19}F COSY NMR, a standard program, COSY.AUR, was used with the following pulse sequence:

[1] Relaxation time t_1 – 90° pulse – evolution time τ – 45° pulse – FID

TD = 2 K and NS = 32 were used and 512 experiments were measured for every 2D spectrum. For 2D *J*-resolved NMR, a standard program, JRES.AUR, was used and the following pulse sequence was implemented:

[2] Relaxation time t_1 – 90° pulse – evolution time τ – 180° pulse – evolution time *t* – FID

TD = 4 K along the F_1 axis and TD = 128 along the F_2 axis were used, and 64 experiments were measured for each 2D spectrum. The FIDs for 1D NMR were processed using the Bruker Win-NMR software on an IBM-compatible PC and the FIDs for 2D NMR were processed with the program UXNMR running on a UNIX workstation (ASPECT).

Results and discussion

An already published (22) observation, made at the outset of this study, will be briefly summarized. All samples prepared as described in the experimental section are found to exhibit in the ^{19}F NMR spectrum a resonance line at ~–162 ppm, which is attributed to dissolved SiF_4. The ^1H NMR spectrum, in addition to the main resonance due to exchange between HSO_3F and the acidium ion $H_2SO_3F^+$, a second single resonance between ~9.5 and ~8.0 ppm, which is assigned to the oxonium ion H_3O^+. The intensity of both resonances increases with increasing SbF_5 contents. From NMR tubes with a SbF_5 content of 20 mol% or higher a white crystalline solid is obtained, which is identified by vibrational spectroscopy as $[H_3O][Sb_2F_{11}]$ and structurally characterized by single crystal X-ray diffraction. It is concluded, that magic acid contains variable amounts of HF, which will react with glass to give H_3O^+. Evidence for this view is obtained in a recently completed ^{19}F NMR study[2] of magic acid in tubes made from fluoroplastics, where the SiF_4 resonance is absent in the ^{19}F NMR spectrum and the H_3O^+ resonance is of exceedingly low intensity. The commonly held view (1), that HSO_3F–SbF_5, just like pure HSO_3F and SbF_5 will not attack glass must be seriously questioned.

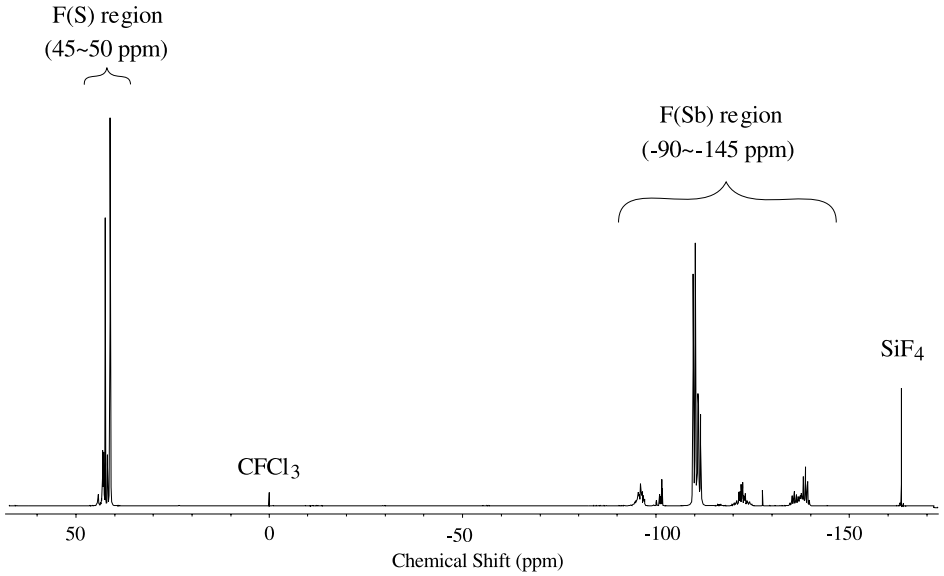
Fig. 1. ^{19}F NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.342 at 213 K.



1D and 2D ^{19}F–^{19}F COSY spectroscopy

The first ^{19}F NMR study of the HSO_3F–SbF_5 system is reported by Thompson et al. (16). Due to the limited sensitivity and resolution, only two partially overlapped AX_4 spin systems are observed from the spectrum of a 1.7 mol kg^{-1} solution of SbF_5 in HSO_3F (x_{SbF_5} = 0.15). They are assigned to monomeric $[SbF_5(SO_3F)]^-$ and the SO_3F-bridged dimer $[Sb_2F_{10}(SO_3F)]^-$, and the following mechanism for their formation is proposed:

[3] $SbF_5 + HSO_3F \rightleftarrows H[SbF_5(SO_3F)]$

[4] $H[SbF_5(SO_3F)] + HSO_3F \rightleftarrows H_2SO_3F^+ + [SbF_5(SO_3F)]^-$

[5] $2H[SbF_5(SO_3F)] \rightleftarrows H_2SO_3F^+ + [Sb_2F_{10}(SO_3F)]^-$

Commeyras and Olah (17) extend the ^{19}F NMR investigation of the HSO_3F–SbF_5 system to a wider SbF_5/HSO_3F ratio range of 0~1.4 (x_{SbF_5} = 0~0.58) and support the earlier assignments (16). In addition, they observe signals due to the monomer $[SbF_6]^-$ (–120 ppm) and F-bridged dimer $[Sb_2F_{11}]$- (–115 ppm) as well as two unassigned signals at –122 and –124 ppm. To explain the formation of the perfluoroantimonate(V) species, the existence of polysulfuric acids is proposed according to

[6] $2SbF_5 + 2HSO_3F \rightleftarrows H_2SO_3F^+ + [Sb_2F_{11}]^- + SO_3$

[7] $SO_3 + HSO_3F \rightleftarrows HS_2O_6F$

[8] $SO_3 + HS_2O_6F \rightleftarrows HS_3O_9F$

This proposal is subsequently disputed by Dean and Gillespie (18). To decrease the viscosity of the system in order to improve the resolution of the spectrum, these authors use sulfuryl chlorofluoride (SO_2ClF) as a diluent for the HSO_3F–SbF_5 system with the SbF_5:HSO_3F ratio at 0.92:1.00 (x_{SbF_5} = 0.48). Besides the signals observed previously, two A_2X_2 spin systems due to *cis*-$[SbF_4(SO_3F)_2]^-$ units and two singlets due to *trans*-$[SbF_4(SO_3F)_2]^-$ units are also observed. Therefore, they argue that $[SbF_6]^-$ and $[Sb_2F_{11}]$- are formed more likely through ligand redistribution such as

[9] $2[SbF_5(SO_3F)]^- \rightleftarrows [SbF_4(SO_3F)_2]^- + [SbF_6]^-$

rather than by decomposition of HSO_3F as suggested in reactions [6]–[8]. More recently, Brunel et al. (19) have carried out ^{19}F NMR studies of the HSO_3F–SbF_5 and HSO_3CF_3–SbF_5 systems, using sulfuryl difluoride (SO_2F_2) as an internal reference. They conclude that the *cis*-F-bridged $H[Sb_nF_{5n}(SO_3F)]$ (n = 0–5) species are the main species in high SbF_5 concentration ranges and that the SO_3F-bridged dimer $[Sb_2F_{10}(\mu\text{-}SO_3F)]^-$ is present in low concentration only in systems with low x_{SbF_5}. This conclusion is contradictory to previous studies (16, 18), which indicate the 1:1 and 2:1 complexes $H[SbF_5(SO_3F)]$ and $H[Sb_2F_{10}(\mu\text{-}SO_3F)]$ are the principal species.

In summary, previous ^{19}F NMR studies of the HSO_3F–SbF_5 system differ in many aspects: the SbF_5 concentrations chosen, the use of diluents, the spectra observed, and the spectral interpretations. The approach in the present study is to start with the HSO_3F–SbF_5 system with x_{SbF_5} as low as possible, provided that reasonable spectra can be acquired. The monomeric antimony(V) species are most likely present at low x_{SbF_5}. The mole fraction of SbF_5 is gradually increased to observe oligomerization and the changes in relative concentrations of species. To avoid any possible interference, no diluent was added into the HSO_3F–SbF_5 system in this study.

General features of 1D ^{19}F NMR spectra of the HSO_3F–SbF_5 system

As an example, the ^{19}F NMR spectrum of an HSO_3F–SbF_5 system with x_{SbF_5} = 0.35 is shown in Fig. 1.

The spectrum may be divided into two regions: the F(S) region (δ C*F*Cl_3 = 40~45 ppm), where the signals due to fluorines of SO_3F groups are observed, and the F(*Sb*).region (δ C*F*Cl_3 = –80~–150 ppm) where signals due to fluorines

© 1999 NRC Canada

bonded to Sb(V) are observed. In addition, there is a sharp singlet at ca. –162 ppm, which is attributed to $SiF_{4(solv)}$.

Apparently, there is a trace amount of HF that reacts with SiO_2, the main component of glass, to produce SiF_4 according to

[10] $4HF + SiO_2 \rightarrow 2H_2O + SiF_4$

The other product, H_2O, is a strong base in the system and is protonated to form the oxonium ion H_3O^+, which is observable using ^1H NMR spectroscopy. Its salt with weakly nucleophilic $[Sb_2F_{11}]^-$ as the counter anion has been isolated as discussed (22). The other possible route for the production of H_2O, dehydration of HSO_3F according to

[11] $2HSO_3F \rightleftarrows H_2O + S_2O_5F_2$

is unlikely because the signal due to $S_2O_5F_2$ at 47~48.5 ppm (23, 24) is not observed in the ^{19}F NMR spectra of all samples studied by us here. Evidence for reaction [10] also comes from the visual observation of etching of NMR tubes and capillary tubes after several weeks.

The mechanism for the generation of HF in magic acid is not obvious. The observation of progressively increasing amounts of SiF_4 with increasing x_{SbF_5} in the system suggests that the trace amounts of HF may be introduced as an impurity in SbF_5. However, as discussed in the following sections, partial solvolysis of SbF_5 in HSO_3F according to

[12] $SbF_5 + HSO_3F \rightleftarrows SbF_4(SO_3F) + HF$

[13] $SbF_4(SO_3F) + HSO_3F \rightleftarrows SbF_3(SO_3F)_2 + HF$

is a much more likely source for HF.

This proposal is based on the assumption that SbF_5 or $SbF_4(SO_3F)$ are more readily solvolyzed by HSO_3F than coordinatively saturated anions like $[SbF_6]^-$ and $[SbF_5(SO_3F)]^-$. Since SiF_4 is also observed by ^{19}F NMR spectroscopy for the neat solvent HSO_3F, it is also possible that some HF may be formed by the self dissociation of HSO_3F ($K < 3 \times 10^{-7}$):

[14] $HSO_3F \rightleftarrows SO_3 + HF$

(see ref. 25) or may be present as an impurity in HSO_3F. It is not at all uncommon to observe SiF_4 as well as BF_3 in the gas phase of freshly distilled HSO_3F or introduced with HSO_3F as an impurity.

Figure 2 illustrates the ^{19}F NMR spectra of pure HSO_3F and HSO_3F–SbF_5 systems with various x_{SbF_5} values in the F(S) region (δ C*F*Cl_3 = 40~45 ppm).

In this region, all signals are singlets. For the solvent and solutions with low SbF_5 content, intense signals due to HSO_3F dominate the region. A main peak due to F-$^{32}SO_3H$ and a weak satellite peak due to F-$^{34}SO_3H$ can be observed (26, 27). For example, in the 1D ^{19}F NMR spectrum of fluorosulfuric acid (see Fig. 2), the very intense peak at 41.98 ppm and a weak satellite peak at 41.94 ppm are observed. The isotope shift is 0.044 ppm, in agreement with the previous studies (26, 27). For less intense F(S) signals, the satellite peak (*F*-$^{34}SO_3$) is not observed. Long-range couplings of the types ^{19}F-S-O-Sb-^{19}F and ^{19}F-S-O-Sb-O-S-^{19}F are not observed for any samples in this study. Consequently, little information about the structures of the fluorosulfato-antimonate(V) species can be extracted from the signals in the F(S) region, and no assignment of resonances in this region will be made.

In contrast, the F(Sb) region (δ C*F*Cl_3 = –80~–150 ppm) (see Fig. 3) provides a great deal of structural information. The observed splitting of the signals results from the coupling between non-equivalent fluorines bonded to the same antimony atom. The complex spectral feature of this region indicates complicated equilibria of various chemical species in the system. The overlap of signals is sometimes so severe that an analysis based solely on traditional 1D ^{19}F NMR spectra remains ambiguous. Even with the assistance of 2D NMR methods, the spectral analysis is occasionally inconclusive.

Significant signal broadening begins to be observed in the spectra of the HSO_3F–SbF_5 system with $x_{SbF_5} \geq 0.500$. The spectra in the F(Sb) region of the systems with x_{SbF_5} = 0.649 and 0.795 are dominated by broad peaks. Such signal broadening precludes any detailed analysis in terms of individual species. Therefore, the assignment of signals discussed in the following sections will focus on the F(Sb) region in the spectra of solutions with low SbF_5 content ($0.000\,999 \leq x_{SbF_5} \geq 0.342$). For the convenience, the following notation system for the assignable signals in the F(Sb) region is used. The signals in the F(Sb) region are labeled according to their multiplicity: S for singlet, D for doublet, T for triplet, Q for quartet, q for quintet, s for sextet, etc. For signals of the same multiplicity, a number is attached in the order of their appearance from low field to high field.

The increasing viscosity of the system, as the SbF_5 content increases, may not be the only factor responsible for the broadness of signals, because a number of relatively sharp lines are also observed as well in the F(Sb) region. The oligomeric structures of $(SbF_5)_m$ and possibly $H[Sb_mF_{5m}(SO_3F)]$ or $H[Sb_mF_{5m+1}]$, as well as ligand exchange, may contribute to the broadness of the signals. The sharp lines are probably from some relatively small complex anions. Among these sharp lines, the most intense signals labeled T3 and T6 can be assigned to *cis*-$[SbF_4(SO_3F)_2]^-$, S8 to $[SbF_6]^-$, and Q1 to $[Sb_2F_{11}]^-$.

As reported previously (16–19), the proton exchange between the Sb(V) species and HSO_3F appears to be rapid and only averaged signals of both complex acids and their conjugate anions are observed in the ^{19}F NMR spectra. For convenience, the anionic formulation is used to represent both forms in the discussion. The assignment of segments (monomeric Sb(V) moieties), $SbF_n(SO_3F)_{5-n}$ μ-(SO_3F), and μ-$(SO_3F)SbF_n(SO_3F)_{4-n}$ μ-(SO_3F), in the oligomeric species will be discussed below. To distinguish the segments from monomeric species (both complex acids and conjugate anions), the segments are formulated as neutral fragments.

Assignment of monomeric species

In the ^{19}F NMR spectra (F(Sb) region) of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.000 999 (see Fig. 3*a*), there are a number of multiplets in addition to two singlets. Apparently, several chemical species are present in the system. The possible monomers of the type $[SbF_n(SO_3F)_{6-n}]^-$ are illustrated in Fig. 4.

In these species, antimony(V) is assumed to be octahedrally coordinated by fluoro and fluorosulfato ligands.

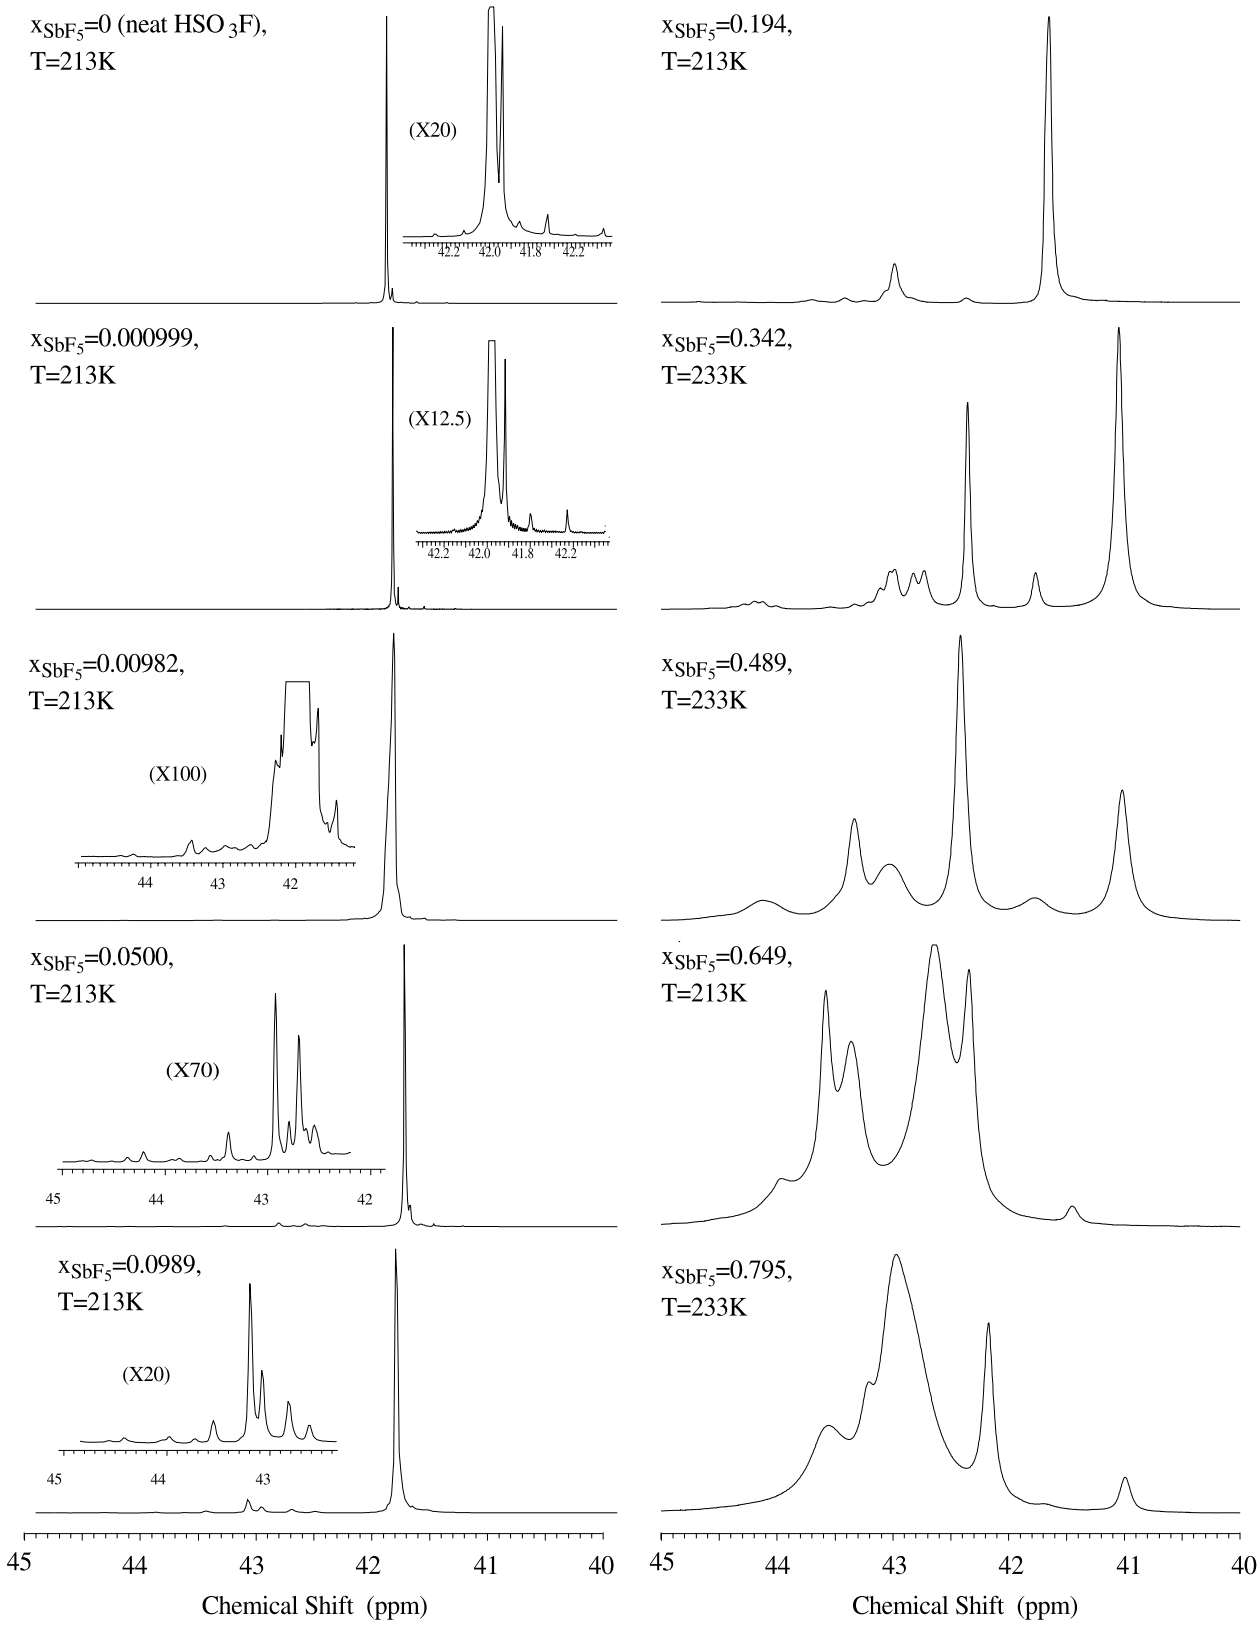
Fig. 2. Low temperature ^{19}F NMR spectra from the F(S) region of the HSO_3F–SbF_5 system.



From the coupling patterns and relative intensities of the signals, they can be readily assigned to some of the monomeric species expected to be present. With the assistance of 2D ^{19}F–^{19}F COSY NMR, the analysis becomes more straightforward and definitive. In the 2D ^{19}F–^{19}F COSY spectrum (F(Sb) region) of the HSO_3F–SbF_5 system

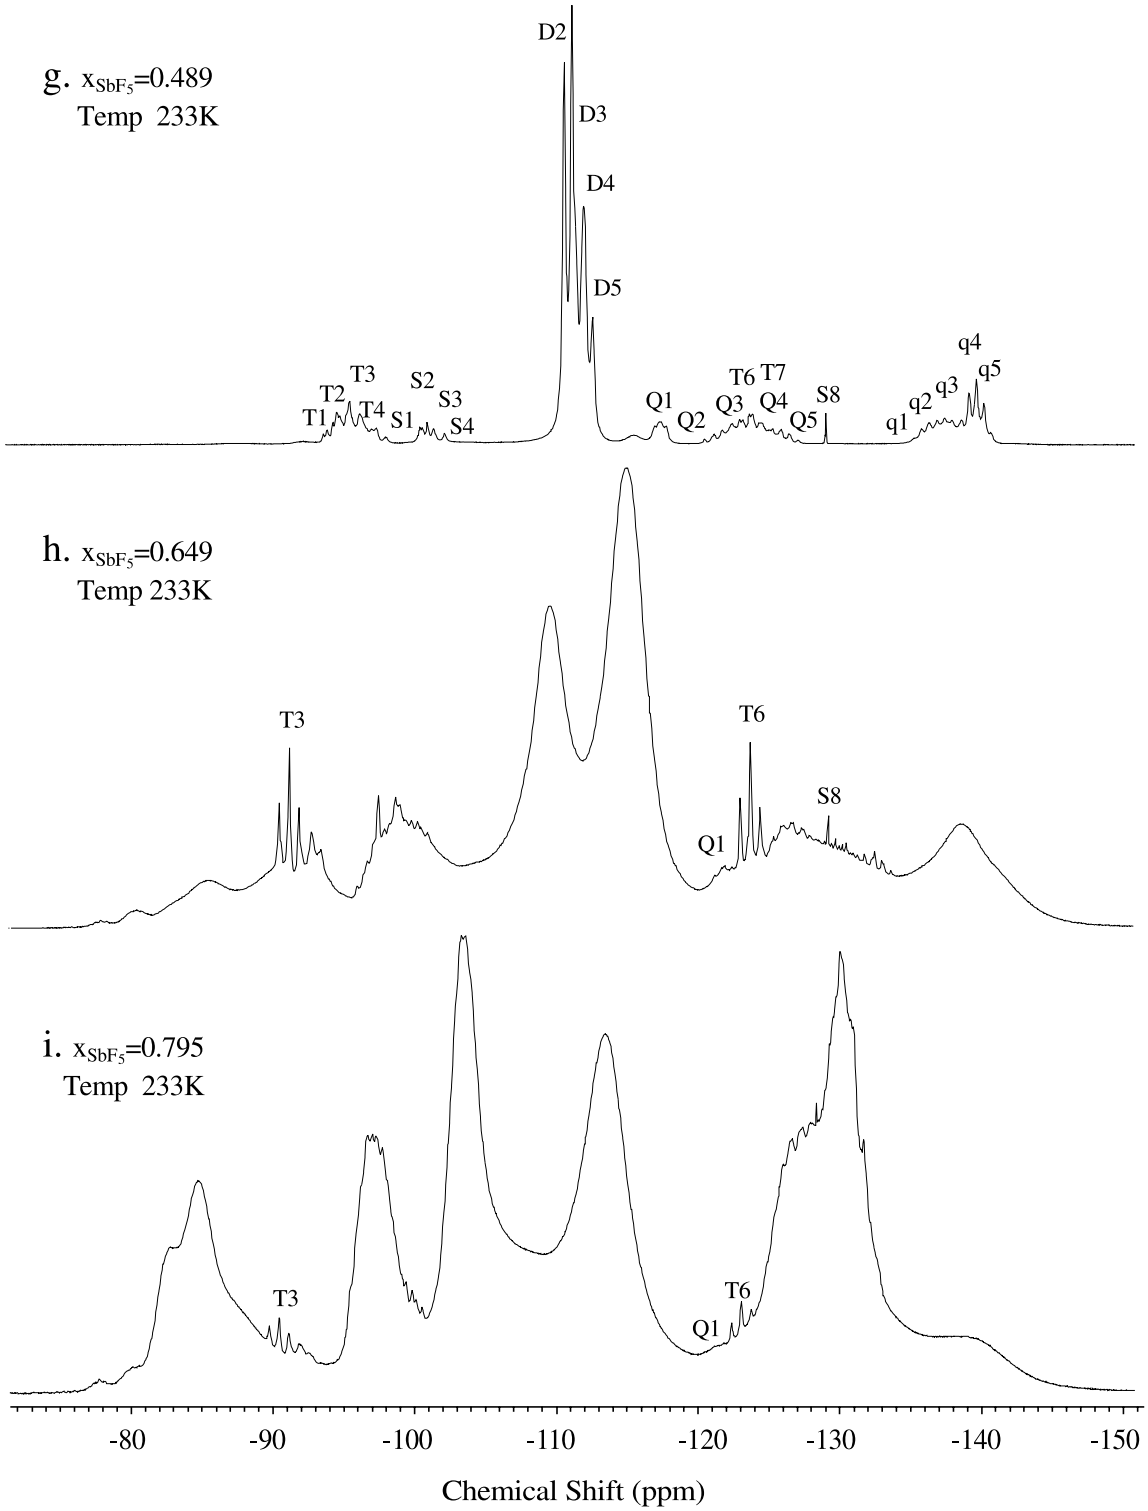
Fig. 3. (*concluded*).



with x_{SbF_5} = 0.000 999 (see Fig. 5), the cross-peaks D1T5 and T3T6 clearly indicate the correlation between doublet D1 and triplet T5, and between triplet T3 and triplet T6.

Thus, we can unequivocally assign D1 and T5 (AX_2 spin system) to *mer*-$[SbF_3(SO_3F)_3]^-$ and T3 and T6 (A_2X_2 spin system) to *cis*-$[SbF_4(SO_3F)_2]^-$.

The singlets in the F(Sb) region may be assigned to species containing chemically equivalent fluorines, namely $[SbF_6]^-$, *trans*-$[SbF_4(SO_3F)_2]^-$, *fac*-$[SbF_3(SO_3F)_3]^-$, *trans*- and *cis*-$[SbF_2(SO_3F)_4]^-$, and $[SbF(SO_3F)_5]^-$ (see Fig. 4). In previous ^{19}F NMR studies of HSO_3F–SbF_5 systems with high SbF_5:HSO_3F ratios, Commeyras and Olah (17) assign the signal at $CFCl_3$ = –120 ppm to $[SbF_6]^-$. In the present study, however, no singlet at –120 ppm is observed. Dean and Gillespie (18) observe two singlets at –102~–104 ppm in the spectrum of a sulfuryl chlorofluoride solution of

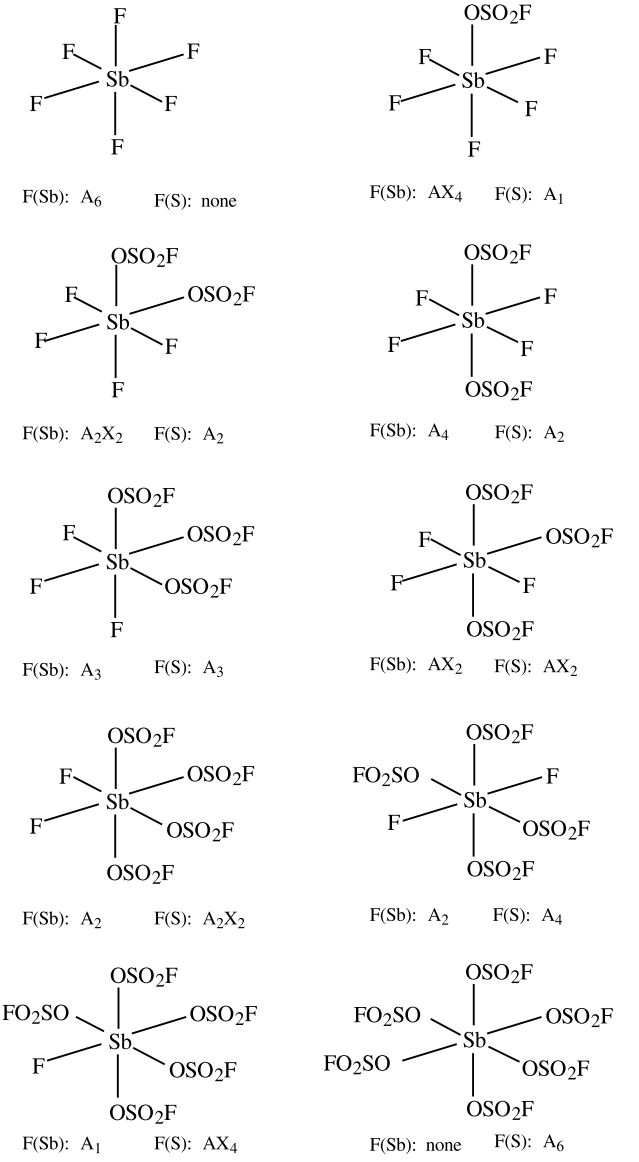
Fig. 4. Monomeric species of the type $[SbF_n(SO_3F)_{6-n}]^-$ (n = 0–6) and corresponding spin systems in the F(Sb) region.

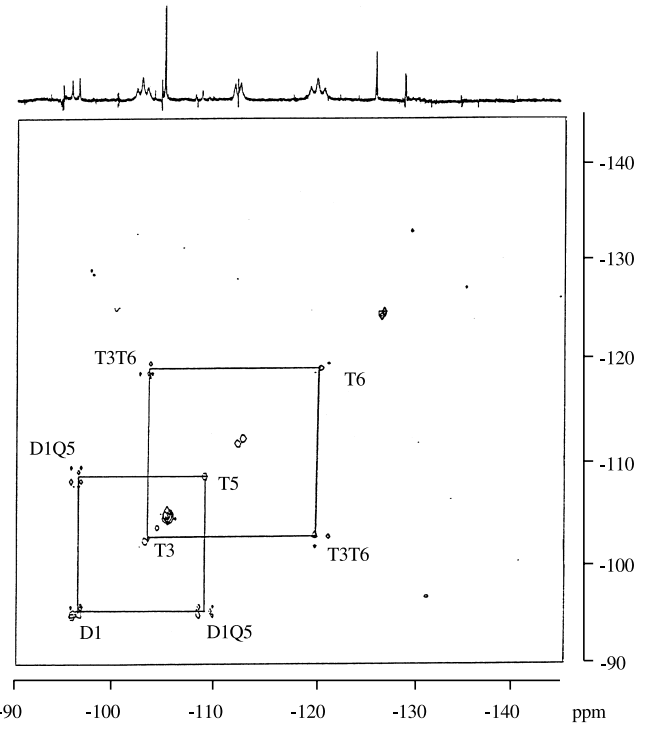


SbF_5:HSO_3F (0.92:1.00) recorded at –100°C and assign both of them to *trans*-$[SbF_4(SO_3F)_2]$ units. Brunel et al. (19) assign a high-field singlet at δ C*F*Cl_3 = –115.8 ppm to $[SbF_6]^-$ and the low-field singlet at δ C*F*Cl_3 = –91.9 ppm to *trans*-$[SbF_4(SO_3F)_2]^-$. Following these previous assignments, the high-field sharp line S8 at –125.6 ppm is assigned to $[SbF_6]^-$ and the other singlet S7 at –105.0 ppm is assigned to *trans*-$[SbF_4(SO_3F)_2]^-$.

As x_{SbF_5} increases from 0.000 999 to 0.009 82 (see Fig. 3*b*), D2 and q4 become considerably more intense in the spectrum. The relative intensities and distinct splitting patterns in the 1D ^{19}F NMR spectrum and the cross-peak D2q4 in the ^{19}F–^{19}F COSY spectrum (see Fig. 6) clearly indicate that the two signals represent an AX_4 spin system.

This AX_4 spin system can be assigned to monomeric $[SbF_5(SO_3F)]^-$, which is in agreement with the previous studies (16–19).

Fig. 5. ^{19}F–^{19}F COSY NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.000 999.



All signals assigned to monomeric species are observable in the HSO_3F–SbF_5 system at least up to x_{SbF_5} = 0.489 except D1 and T5, which is only barely observable for x_{SbF_5} = 0.0500 and is absent in the systems with higher x_{SbF_5}. This observation suggests that the monomeric *mer*-$[SbF_3(SO_3F)_3]^-$, which has the highest SO_3F content among all species observed in this study, exists only at very low SbF_5 concentration. It has not been observed in the previous NMR studies of HSO_3F–SbF_5 systems with high HSO_3F:SbF_5 ratios. However, it has been reported by Thompson et al. (16) for the HSO_3F–$SbF_4(SO_3F)$ and HSO_3F–SbF_5–SO_3 systems. It was reported that, based on cryoscopic measurements, the freshly distilled HSO_3F contains ~0.0006 mol kg^{-1} of SO_3 (25), which is comparable with the concentration of SbF_5 in the x_{SbF_5} = 0.000 999 system. Therefore, the insertion reaction of SO_3 with SbF_5 in HSO_3F (16) may have contributed to the formation of species with high SO_3F/F ratios.

The chemical shifts and coupling constants of signals assigned to monomeric species in the HSO_3F–SbF_5 system with x_{SbF_5} = 0.009 84 are summarized in Table 1.

In spite of some variations in chemical shifts for the signals with increasing x_{SbF_5}, the following general correlation between the ^{19}F chemical shifts and their chemical environment is observed:

(*i*) For the fluorine *trans* to a fluorosulfato group, the signal shifts to low field as *cis* fluorines are sequentially replaced by fluorosulfato groups in fluoro-fluorosulfatoantimonate(V).

(*ii*) Similarly, the signal of the fluorine *cis* to another fluorine shifts to low field as *cis* fluorines are sequentially replaced by fluorosulfato groups in fluoro-fluorosulfatoantimonate(V).

© 1999 NRC Canada

Fig. 6. ^{19}F–^{19}F COSY NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.009 84.

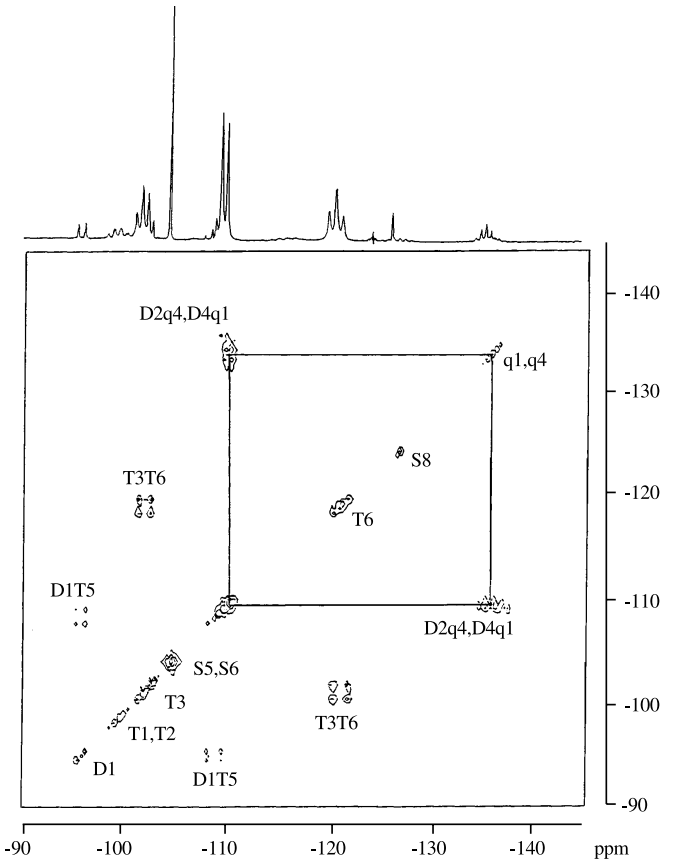


Fig. 7. (*a*) *J*-resolved ^{19}F NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.0500. (*b*) ^{19}F–^{19}F COSY NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.0500.

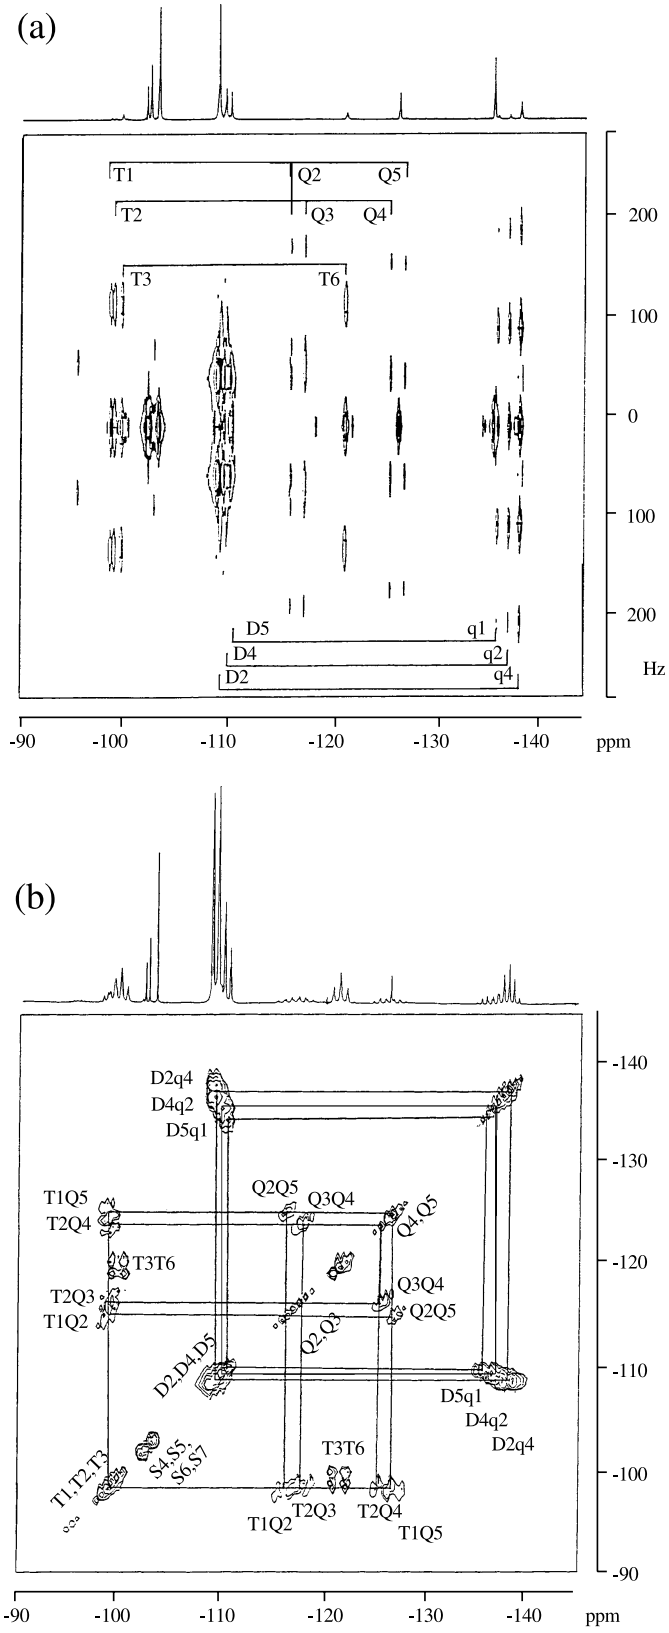

(*iii*) In the same fluoro-fluorosulfato-antimonate(V), signals due to fluorines *trans* to fluorine appear at lower fields than those *trans* to fluorosulfate.

These trends agree in general with the empirical equation established for substituted perfluoro complex anions of the type $[EF_nL_{6-n}]^{m-}$ (E = Ti, W, Sn; m = 2 and E = P; m = 1) (28)

$$[15] \quad \Delta_F = pC + qT$$

In this equation, Δ_F is the difference in chemical shift of a signal between the fully fluorinated and partly substituted species. *C* and *T* are constants for the particular substituent and central atom. The quantities *p* and *q* are the number of substituents *cis* and *trans*, respectively, to the fluorines whose shifts are calculated. However, attempts to quantitatively fit the data with the equation were not successful. A possible explanation is, that the data collected from this system are the averaged chemical shifts of the complex acids and their conjugate anions.

Based on integration of the signals, about 27% of the Sb(V) species is estimated to be present as $[SbF_5(SO_3F)]^-$, 52% as $[SbF_4(SO_3F)_2]^-$, 4% as $[SbF_3(SO_3F)_3]^-$, and less than 1% as $[SbF_6]^-$ in the system with x_{SbF_5} = 0.009 82. This result is not consistent with initial formation of $[SbF_5(SO_3F)]^-$, by direct combination of SbF_5 with HSO_3F (eqs. [3] and [4]) and subsequent ligand redistribution reactions according to

[17] $2[SbF_4(SO_3F)_2]^- \rightleftarrows [SbF_3(SO_3F)_3]^- + [SbF_5(SO_3F)]^-$

The insertion reaction of residual SO_3 and SbF_5 in HSO_3F may contribute partly to the formation of species with a high SO_3F contents in the system with x_{SbF_5} = 0.000 999. For the systems with $x_{SbF_5} \geq 0.009\ 82$, such a contribution seems too small, when the extremely low concentration of SO_3 is considered. Solvolysis of SbF_5 in HSO_3F as shown in eqs. [12] and [13] appears to have occurred. Otherwise, a higher concentration of $[SbF_6]^-$ would have been anticipated.

Assignment of segments in the oligomeric species

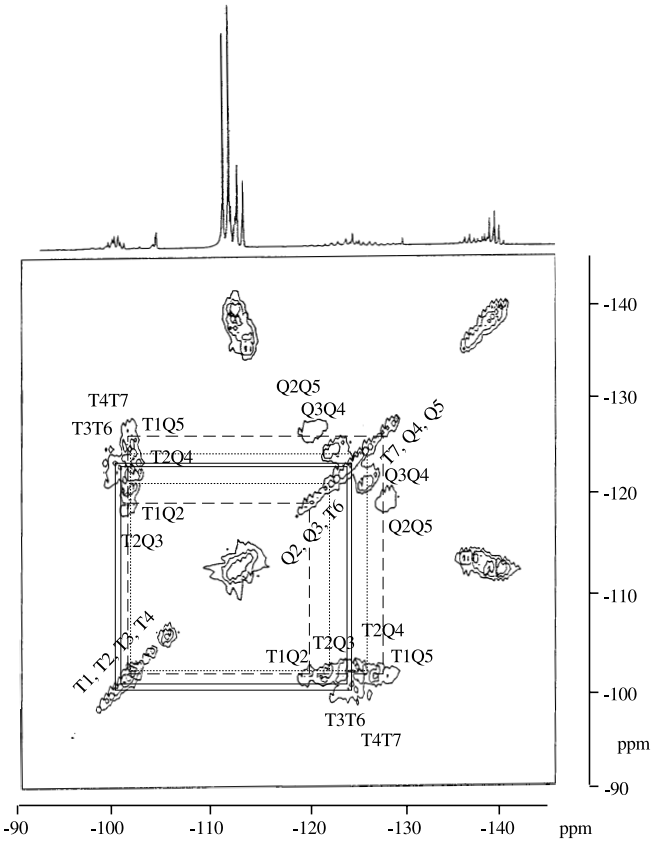
Although oligomerization is expected as the SbF_5 content increases, it is still surprising that it occurs in the system with an SbF_5 concentration as low as x_{SbF_5} = 0.009 82. It is noted from the spectrum of the system with x_{SbF_5} = 0.009 82 (see Fig. 3*b*) that three small peaks just downfield of D2 do not belong to the same multiplet. The separation from the central peak is 100 and 50 Hz for the lower field and higher field peaks, respectively. Moreover, the intensity of the peak at higher field to the central peak is approximately twice the intensity expected for a triplet. As illustrated in Inset 2 in Fig. 3*b*, where the expected but unobserved peaks are indicated by broken lines, it is likely that the first two peaks on the left belong to a triplet T5 with one peak of the multiplet buried in the intense D2, and the high-field peak is one half of a doublet D4, again, with the other half buried in D2. From the corresponding ^{19}F–^{19}F COSY spectrum (see Fig. 6), D4 is correlated with a quintet q1, which is partially overlapped with the intense q4, to form another AX_4 spin system. It can be assigned to a segment of the type $[SbF_5\text{-}(\mu\text{-}SO_3F)^-]$.

In the 1D NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.009 82 (see Fig. 3*b*), the signals at –97.5~–101 ppm are apparently two triplets, T1 and T2, with close chemical shifts and slightly different coupling constants. This is much clearer in the 1D ^{19}F NMR spectrum (see Fig. 3*c*) and ^{19}F *J*-resolved spectrum (F(Sb) region) of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.0500 (see Fig. 7*a*).

In the 1D spectrum (see Fig. 3*c*), the signals in the region –97~–101 ppm are resolved into three triplets T1, T2, and T3. The ^{19}F–^{19}F COSY spectrum (F(Sb) region) (see Fig. 7*b*) indicates T1 and T2 are correlated with Q2 and Q5, Q3, and Q4, respectively. In the 1D ^{19}F NMR spectrum, the quartets Q2 and Q3 are partially overlapped to form a "sextet" with the area ratio of 1:3:4:4:3:1 in the region –115~–118.5 ppm (see Inset 1, Fig. 3*c*). The other two quartets, Q4 and Q5, form another "sextet" at –123.5~–127.5 ppm (see Inset 2, Fig. 3*c*), which is overlapped with the readily recognizable singlet S8 at –125.8 ppm assigned to $[SbF_6]^-$. Careful inspection of the frequencies and area ratios of the peaks sug-

© 1999 NRC Canada

Fig. 8. ^{19}F–^{19}F COSY NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.194.



gests that each of them results from A or M of two AMX_2 spin systems T1Q2Q5 and T2Q3Q4, respectively. These two AMX_2 systems can be assigned to the segments of the type *cis*-[$(SO_3F)SbF_4$-(μ-SO_3F)-], or of the type *cis*-[-(μ-SO_3F)-SbF_4-(μ′-SO_3F)-]with two different terminal segments on each side.

It is also evident from the *J*-resolved spectrum of the x_{SbF_5} = 0.0500 system (see Fig. 7*a*) that the signals at –134~–139 ppm are three overlapped quintets, q1, q2, and q4. In the ^{19}F–^{19}F COSY spectrum, the cross peaks D2q4, D4q2, and D5q1 indicate that q4, q2, and q1 are coupled with three partially overlapped doublets D2, D4, and D5, respectively, to form three AX_4 systems. One of the AX_4 systems, D2q4, has been assigned to monomeric $[SbF_5(SO_3F)]^-$. The other two may be assigned to a segment of the type $[SbF_5$(-SO_3F)-] with different segments on the other side of the bridging fluorosulfato group.

In the ^{19}F NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.009 82 (see Fig. 3*b*), the weak signals at –103.50 ppm are recognized as three singlets, and based on similarities in chemical shifts, are possibly the same singlets as S4, S5, and S6 observed for the x_{SbF_5} = 0.0500 system (see Fig. 3*c*). They can be assigned to segments of the type *trans*-[(SO_3F)-SbF_4-(μ-SO_3F)-]. At high x_{SbF_5}, there are additional three singlets (S1, S2, and S3) at lower field (see Inset 1, Figs. 3*e* and 3*f*), which may be better assigned to segments of the type *trans*-[-(μ-SO_3F)-SbF_4-(μ′-SO_3F)-] in trimers or higher oligomeric species. The assignment of these singlets to monomers with high SO_3F/F ratios, such as *fac*-$[SbF_3(SO_3F)_3]$, $[SbF_2(SO_3F)_4]$, and $[SbF(SO_3F)_5]$, is less likely because:

(*i*) the relative intensity of S4, S5, and S6 increase as the SbF_5 concentration increases, which is contrary to what is expected for the monomers with a high SO_3F/F ratio. As the x_{SbF_5} increases from 0.000 999 to 0.009 82, in fact, the signals D1 and T5 due to *mer*-$[SbF_3(SO_3F)_3]^-$ are barely observable, and the relative intensities of S7 due to *trans*-$[SbF_4(SO_3F)_2]^-$ and T3T6 due to *cis*-$[SbF_4(SO_3F)_2]^-$ are reduced significantly; and

(*ii*) singlets S4, S5, and S6 cannot be observed even in the spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.000 999, which has a high HSO_3F–SbF_5 mole ratio. Singlets S1, S2, and S3 are observed only in the HSO_3F–SbF_5 system with low HSO_3F–SbF_5 mole ratios ($x_{SbF_5} \geq 0.194$).

For the same reasons, assignment of these singlets to segments with a high SO_3F content, such as *trans*-$[(SO_3F)_3SbF_2$-(μ-SO_3F)-] and $[(SO_3F)_4SbF$-(μ-SO_3F)-], seems implausible.

Two triplets, T4 and T7, emerge in the ^{19}F NMR spectrum of the system with x_{SbF_5} = 0.0989 (the inset in Fig. 3*d*) and higher. Parallel to triplets T3 and T6, which are attributed to the monomeric species *cis*-$[SbF_4(SO_3F)_2]^-$, T4 and T7 are also correlated to each other as seen from the ^{19}F–^{19}F COSY spectrum (see Fig. 8).

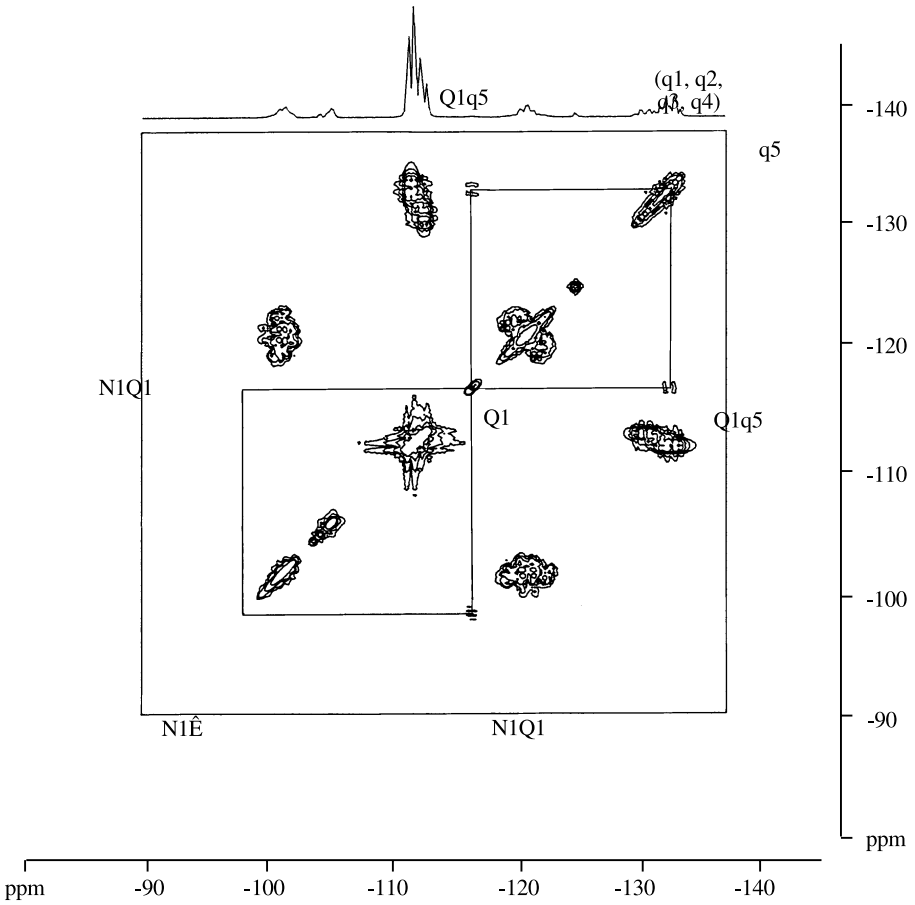
They compose another A_2X_2 spin system, which is better attributed to a segment, *cis*-[-(μ-SO_3F)-SbF_4-(μ-SO_3F)-], linking two identical moieties.

A glimpse at the signals at –109~–111 ppm in spectra of the systems with x_{SbF_5} = 0.0989 and 0.194 may give the impression that they are three overlapped doublets. However, the separation between the two peaks of lowest intensity varies from 55 Hz for x_{SbF_5} = 0.0989–72 Hz for x_{SbF_5} = 0.194. Both these separations are lower than all the coupling constants found for terminal fluorines in this particular system. Analysis of the intensities of the signals suggests that they may be composed of four doublets. In the spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.194, for example, these signals were analyzed by deconvolution into the following four doublets: D2 (109.6 ppm, $^2J_{FF}$ = 99 Hz), D3 (110.1 ppm, $^2J_{FF}$ = 100 Hz), D4 (110.3 ppm, $^2J_{FF}$ = 100 Hz), and D5 (110.9 ppm, $^2J_{FF}$ = 100 Hz) (see Inset 2, Fig. 3*e*). From the ^{19}F–^{19}F COSY spectrum (see Figs. 7 and 9), these doublets are correlated to the quintets q1, q2, q3, and q4 at –134~–140 ppm, respectively. Signal q3, which is correlated to the weakest of the doublets, D3, is so weak that it cannot be clearly observed in the spectrum of the x_{SbF_5} = 0.0989 system. As shown in Inset 3 of Fig. 3*e*, only one peak remains unassignable to either q1, q2, or q4 and therefore is assigned to q3 while the rest of q3 is buried in the intense signal due to q4. Among four AX_4 spin systems, D2q4 has been assigned to the monomer $[SbF_5(SO_3F)]^-$. The other three AX_4 systems can be attributed to fragments of the type $[SbF_5$-(*m*-SO_3F)-].

A quartet, Q1, with the area ratio of 1:1:1:1 appears at ~–116.4 ppm in the spectra of the systems with $x_{SbF_5} \geq 0.342$. It can be assigned to the eight fluorines *cis* to the bridging fluorine in $[Sb_2F_{11}]^-$. As sketched in Inset 2 of Fig. 3*f*, the signal is split into two lines with a 1:1 ratio by a terminal fluorine ($^2J_{FF}$ = 102 Hz) and then further split by the bridging fluorine ($^2J_{FF}$ = 60 Hz). Only the most intense portion of the nonet N1, due to the bridging fluorine, is barely observ-

© 1999 NRC Canada

Fig. 9. ^{19}F–^{19}F COSY NMR spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.342.



able at –91.0 ppm (see Inset 1, Fig. 3*f*). The quintet q5, due to the two terminal fluorines, falls into the q1q2q3q4 region. The correlation between N1, Q1, and q5, however, is very clear from the corresponding ^{19}F–^{19}F COSY spectrum (see Fig. 9).

The assignments discussed above are summarized in Table 2. Some variations in chemical shifts are observed for the signals as x_{SbF_5} changes. The data listed in Table 2 are measured from the spectrum of the HSO_3F–SbF_5 system with x_{SbF_5} = 0.0989 except signals due to *trans*-[-(μ-SO_3F)-SbF_4-(μ′-SO_3F)-] and the dimer $[Sb_2F_{11}]^-$, which can only be clearly observed for HSO_3F–SbF_5 systems with $x_{SbF_5} \geq 0.194$ and for systems with $x_{SbF_5} \geq 0.342$, respectively.

With the assignments proposed above, it is possible to estimate the relative concentrations of different segments in the HSO_3F–SbF_5 system with $x \leq 0.342$. The results are presented in Table 3. Due to the signal overlap and possible inaccurate baseline settings over the wide frequency range, integration errors inevitably occur to some extent. The errors are small for intense, narrow peaks and large for weak, broad peaks. The estimation of concentration of segments is not feasible for the systems with $x_{SbF_5} \geq 0.489$, since integration of the individual signals from overlapped, broadened peaks is not reliable.

Possible oligomeric species in the HSO_3F–SbF_5 system

As the concentration of the Lewis acid SbF_5 increases, it is expected that oligomeric antimony(V) species should begin to appear. The relative concentration of oligomeric species is expected to increase while the relative concentration of monomeric antimony(V) species decreases accordingly. Among the monomeric species observed, $[SbF_3(SO_3F)_3]^-$ has the highest SO_3F content. Therefore, the dimeric species would likely be limited to the types $[Sb_2F_{11-n}(SO_3F)_n]$ (n = 0–3), formed by the following dimerizations by addition of SbF_5 to the monomeric species:

[18] $[SbF_6]^- + SbF_5 \rightleftarrows [Sb_2F_{11}]^-$

[19] $[SbF_5(SO_3F)]^- + SbF_5 \rightleftarrows [Sb_2F_{10}(SO_3F)]^-$

[20] $[SbF_4(SO_3F)_2]^- + SbF_5 \rightleftarrows [Sb_2F_9(SO_3F)_2]^-$

[21] $[SbF_3(SO_3F)_3]^- + SbF_5 \rightleftarrows [Sb_2F_8(SO_3F)_3]^-$

Dimeric SO_3F-containing species are unlikely to be linked by F-bridges. Studies of ternary fluoride fluorosulfates based on vibrational spectra indicate that fluorosulfate always takes precedence over fluoride as a bridging ligand (29–33). Moreover, F-bridged dimers would have spin systems of three or more different types of fluorines, which should result in more complicated ^{19}F NMR spectra. In this study, simple splitting patterns are observed, which can be interpreted either in terms of monomeric species or in terms of segments linked by SO_3F-bridges. Most spin systems observed consist of one or two different types of fluorines. Two AMX_2 spin systems are satisfactorily assigned to seg-

ments of the types *cis*-$[SbF_4(SO_3F)\text{-}(\mu\text{-}SO_3F)\text{-}]$ or *cis*-$[\text{-}(\mu\text{-}SO_3F)\text{-}SbF_4\text{-}(\mu'\text{-}SO_3F)\text{-}]$. Coupling constants observed for most multiplets (98~120 Hz) point to terminal rather than bridging fluorines. The only exceptions are N1 and Q1 for which smaller coupling constants (60 Hz) are observed. Indeed, N1 and Q1 are due to the F-bridged perfluoro anion $[Sb_2F_{11}]^-$, where no SO_3F^- competes with F^- as the bridging ligand. The small coupling constant (60 Hz) results from the coupling between the bridging fluorine and *cis*-terminal-fluorines (equatorial fluorines).

Illustrated in Fig. 10 are all possible dimeric isomers of the types $[Sb_2F_{11-n}(SO_3F)_n]$ (n = 0–3).

The last three isomers of the type $[Sb_2F_8(SO_3F)_3]^-$ have two terminal fluorosulfates on the same antimony. Each of the three isomers has an AX_2 spin system. According to eq. [20], these isomers should have formed from the direct combination of *mer*-$[SbF_3(SO_3F)_3]^-$ and SbF_5. However, signals due to AX_2 spin systems other than those assigned to the monomer *mer*-$[SbF_3(SO_3F)_3]^-$, are not observed in the F(Sb) region. This suggests they may have rearranged to other isomers. Thus, the possible dimeric Sb(V) species are limited to $[Sb_2F_{11}]^-$, $[Sb_2F_{10}(\mu\text{-}SO_3F)]^-$, *cis*- and *trans*-$[Sb_2F_9(SO_3F)_2]^-$, and *cis*,*cis*-, *cis*,*trans*-, and *trans*,*trans*-$[SbF_4(SO_3F)\text{-}(\mu\text{-}SO_3F)\text{-}SbF_4(SO_3F)]^-$.

Since the fluorine on the bridging SO_3F^- does not couple with other fluorines, information about connectivity between different segments of SO_3F-bridged oligomers is unavailable. Only for the F-bridged dimer $[Sb_2F_{11}]^-$ is the connectivity manifested in a unique nonet due to the coupling of the bridging fluorine to eight equivalent terminal *cis*-fluorines. In the spectrum of the system with x_{SbF_5} = 0.342 (see Fig. 3*f*), only a portion of the characteristic nonet N1 centered at δ C*F*Cl_3 = –91.0 ppm can be observed because of its low intensity, but the correlated Q1 at δ C*F*Cl_3 = –116.4 ppm due to eight *cis*-fluorines is clearly observed.

Among the four AX_4 spin systems, D2q4 has been assigned to the monomer $[SbF_5(SO_3F)]^-$. D5q1 is tentatively assigned to the dimer $[Sb_2F_{10}(\mu\text{-}SO_3F)]^-$ and D4q2 to the segment $[SbF_5\text{-}(\mu\text{-}SO_3F)\text{-}]$ in both *cis*- and *trans*-$[SbF_5\text{-}(\mu\text{-}SO_3F)\text{-}SbF_4(SO_3F)]^-$. It is noted that the appearance of the AX_4 spin system D3q3 is accompanied by the emergence of the A_2X_2 spin system T4T7 and three singlets S1, S2, and S3. T4T7 can be assigned to a segment *cis*-$[(\text{-}(\mu\text{-}SO_3F)\text{-}SbF_4\text{-}(\mu\text{-}SO_3F)\text{-}]$ linking two identical moieties at each end. S1, S2, and S3 are assigned to segments of the type *trans*-$[\text{-}(\mu\text{-}SO_3F)\text{-}SbF_4\text{-}(\mu\text{-}SO_3F)\text{-}]$, which link either identical or different moieties at each end. The coincident appearance of these spin systems suggests the formation of various trimeric

fluoro-fluorosulfato-antimonate(V) species, e.g., *cis*- and *trans*-$[SbF_5$-(μ-SO_3F)-SbF_4-(μ-SO_3F)-$SbF_5]^-$. However, it must be pointed out that the possibility of the existence of higher oligomeric species cannot be excluded, particularly in the systems with high SbF_5/HSO_3F ratios.

The most intense signal of the four singlets at low field (–100~–105 ppm), S7, has been assigned to the monomeric $[SbF_4(SO_3F)_2]^-$. The remaining three singlets are assigned to the fragments of the type *trans*-$[SbF_4(SO_3F)$-(μ-SO_3F)-]. S4 is tentatively assigned to *trans*-$[SbF_5$-(μ-SO_3F)-SbF_4-$(SO_3F)]^-$, S5 to *cis, trans*-$[SbF_4(SO_3F)$-(μ-SO_3F)-$SbF_4(SO_3F)]$, and S6 to *trans, trans*-$[SbF_4(SO_3F)$-(μ-SO_3F)-$SbF_4(SO_3F)]$.

Of the two AMX_2 spin systems, T2Q3Q4 and T1Q2Q5, either can be assigned to the segment *cis*-$[SbF_4(SO_3F)$-(μ-SO_3F)-] in the dimer *cis*-$[SbF_5$-(μ-SO_3F)-$SbF_4(SO_3F)]^-$ and the other to the segment *cis*-$[SbF_4(SO_3F)$-(μ-SO_3F)-] in the dimers *cis,cis*- and *cis,trans*-$[SbF_4(SO_3F)$-(μ-SO_3F)-$SbF_4(SO_3F)]^-$ or vice versa. The analysis of relative concentrations of segments favors the assignment of T2Q3Q4 to the dimer *cis*-$[SbF_5$-(μ-SO_3F)-$SbF_4(SO_3F)]^-$ and T1Q2Q5 to the dimers *cis,cis*- and *cis,trans*-$[SbF_4(SO_3F)$-(μ-SO_3F)-$SbF_4(SO_3F)]^-$. It is entirely possible that, at high x_{SbF_5}, terminal fluorosulfato groups in the fragments of the type *cis*-$[SbF_4(SO_3F)$-(μ-SO_3F)-] may transform into bridging fluorosulfato groups to form fragments of the type *cis*-[-(μ-SO_3F)-SbF_4-(μ'-SO_3F)-], which then link two non-equivalent terminal segments to form trimers or even higher oligomers. However, there is no definitive evidence for such transformations in the ^{19}F NMR spectra. The variation in chemical shifts of the signals may also be attributed to the shifts of the equilibria between complex acids and their conjugate anions and to the change of the medium.

[a]From T2Q3Q4 + S4 = 7, it is expected that ca. 7% Sb(V) species may exist as the fragment $[SbF_5$-(μ-$SO_3F)$-] in *cis*- and *trans*-$[Sb_2F_{10}(SO_3F)]^-$. The signals D4q2 due to the -SbF_5 moiety (an AX_4 spin system) is overlapped with D2q4 due to another AX_4 spin system by coincidence.

Based on these assignments, it is possible to estimate the relative concentrations of the proposed oligomeric species by analysis of the relative concentration of segments. The results for HSO_3F–SbF_5 systems with $x_{SbF_5} \leq 0.342$ are listed in Table 4.

Such an estimation is not feasible for HSO_3F–SbF_5 systems with $x_{SbF_5} \geq 0.342$ because it is impossible to obtain integral values for each of the overlapped, broad signals. However, it can be roughly estimated that about 67% of Sb(V) species exist as $[SbF_5]$- moieties, 25% as *cis*-$[SbF_4]$-

© 1999 NRC Canada

moieties, 4.5% as *trans*-[SbF_4]- moieties, and 3.5% as $[Sb_2F_{11}]^-$ in the x_{SbF_5} = 0.489 system.

Summary and conclusion

The results presented here depart from previous work by Commeyras et al. (17, 19) in two important aspects:

(*i*) Concentrations of the monomeric anions *cis*- and *trans*-$[SbF_4(SO_3F)_2]^-$ are at any mole fraction of SbF_5 considerably higher than the concentration of $[SbF_6]^-$ (see Table 3). Hence, formation of the bis-fluorosulfato anions $[SbF_4(SO_3F)_2]^-$ solely by ligand redistribution of $[SbF_5(SO_3F)]^-$ (eq. [9]) becomes improbable. Instead solvolysis of SbF_5 or possibly of $SbF_4(SO_3F)$ in HSO_3F (eqs. [12] and [13]) and subsequent complex formation with either SO_3F^- or F^- is much more likely. The byproduct HF is rapidly converted by reaction with glass to H_2O (eq. [12]), which functions as a base to give the oxonium ion $[H_3O]^+$. The $[H_3O]^+$ ion is identified by ^1H NMR and structurally characterized as $[H_3O][Sb_2F_{11}]$ (22).

(*ii*) In oligomeric anions or in segments of oligomers, bridging by μ-SO_3F groups, originally suggested by Gillespie et al. (16, 18) for dilute solutions is now observed even at high SbF_5 concentrations. A μ-fluoro group is only found in $[Sb_2F_{11}]^-$. Oligomeric anions with fluorobridges and terminal SO_3F-groups of the type $[(SbF_5)_n(SO_3F)]^-$ (n = 2–4) all previously identified by Commeyras and co-workers (19) are not detectable with modern NMR techniques.

Their postulated formation by reaction of *cis*-F-bridged oligomeric $(SbF_5)_n$ (n = 2–4) with the selfionization SO_3F^- according to

$$[22] \quad (SbF_5)_n + SO_3F^-_{(solv)} \xrightarrow[HSO_3F]{} [(SbF_5)_n(SO_3F)]^- \qquad n = 2\text{–}4$$

is not supported by our findings. The *cis*-F-bridges found in liquid SbF_5 do not persist in magic acid, when samples are prepared as described in the experimental section. Our results are consistent with spectroscopic findings for the ansolvo species $SbF_4(SO_3F)$ (29, 30), $SbF_3(SO_3F)_2$ (30), and others (31–33) where in all instances only fluorosulfato bridges are observed.

The evidence for solvolysis of the Lewis acids SbF_5 and $SbF_4(SO_3F)$ (eqs. [12] and [13]) with HF and, via interaction with glass, of H_2O as intermediates, presented here and elsewhere (22), is reason for concern. Protonation of H_2O, which is a base in HSO_3F, is expected to reduce the proton acidity of magic acid drastically.

It is conceivable, that the difference in proton acidity between HF–SbF_5 and HSO_3F–SbF_5 noted by Sommer et al. (14, 15) is due to water formed in these side reactions. In spite of this limitation, the convenience of working in glass outweighs in most cases the slight reduction in proton acidities (14, 15). To study the effect water has on the types and concentrations of anions observable by ^{19}F NMR in magic acid we have recently completed an identical study in a glass free environment[2] and will report shortly on the results.

Temperature dependence of the creatine kinase reaction measured in rat brain in vivo by ^{31}P NMR saturation transfer

Richard Buist, Scott Kroeker, and James Peeling

Abstract: Creatine kinase (CK) catalyzes the reversible phosphorylation of MgADP by phosphocreatine and thus regulates cellular concentrations of ADP and ATP. The temperature dependence of this reaction has been determined in rat brain in vivo between 30 and 40°C using ^{31}P NMR saturation transfer measurements. The pseudo-first-order rate constant for the forward CK reaction, k_f, varies little with temperature over this range, with an apparent activation energy E_a = 14.2 ± 4.9 kJ/mol. This is considerably lower than the values of E_a for isolated CK enzymes. However, when changes in [MgADP] and [H^+] with temperature are considered, a substrate concentration-independent value of E_a = 65.3 ± 9.7 kJ/mol is obtained for the maximum forward reaction velocity V_{max}. This agrees well with literature values for the isolated brain-type isoform of CK.

Key words: creatine kinase, activation energy, temperature, brain, rat.

Résumé : La kinase de créatine (KC) catalyse la phosphorylation réversible de MgADP par la phosphocréatine et régularise ainsi les concentrations cellulaires des di- et triphosphates d'adénosine. Faisant appel à des mesures de transfert de saturation en RMN du ^{31}P, on a déterminé la dépendance de cette réaction sur la température dans un cerveau de rat, in vivo, entre 30 et 40°C. Sur cette plage de températures, la constante de vitesse de pseudo-premier ordre pour la réaction normale de la KC, k_f, ne varie que très peu et son énergie d'activation apparente, E_a = 14,2 ± 4,9 kJ/mol. Cette valeur est de beaucoup inférieure aux valeurs de E_a mesurées avec des enzymes KC isolés. Toutefois, lorsqu'on considère les variations de [MgADP] et de [H^+] en fonction de la température, on obtient une E_a qui est indépendante de la concentration de substrat et dont la valeur est égale à 65,3 ± 9,7 kJ/mol pour la valeur maximale de la vitesse de la réaction normale, V_{max}. Cette valeur est en bon accord avec les valeurs rapportées dans la littérature pour des isoformes de KC isolées du cerveau.

Mots clés : kinase de créatinine, énergie d'activation, température, cerveau, rat.

[Traduit par la Rédaction]

Introduction

The creatine kinase (CK; EC 2.7.3.2) reaction (eq. [1]):

[1] $$PCr^{2-} + MgADP^{-} + H^{+} \rightleftarrows Cr + MgATP^{2-}$$

where PCr is phosphocreatine and Cr is creatine, plays an important role in regulating in vivo concentrations of ADP and ATP (1–4). The major isoenzymes of CK found in the brain are brain-type CK (BB-CK) and mitochondrial CK (mito-CK) (5), although recently, the presence of small amounts of muscle-type CK (MM-CK) has been reported in discrete areas of human (6), chicken (7), and rat (6) brain.

Measurements of the temperature dependence of CK activity in vitro yield Arrhenius activation energy (E_a) values in the range of 42–142 kJ/mol (8–13) for the forward rate constant k_f. For the related enzyme arginine kinase (AK), measurements of the temperature dependence of k_f in vitro give values for E_a ranging from 42 to 100 kJ/mol. E_a = 46.8 kJ/mol for k_f of AK in intact crayfish (14) and 126 kJ/mol in crab muscle (15) in vivo, while in vivo measurements on tail muscle in shrimp (16) and ex vivo measurements on single barnacle muscle fibers (17) show little temperature dependence of k_f.

The in vivo temperature dependence of the creatine kinase reaction in brain has not been characterized, but may give insight into the temperature dependence of cerebral oxygen metabolic rate and energy utilization rate. The results of an in vivo ^{31}P NMR spectroscopy saturation-transfer study of the creatine kinase reaction in rat brain from 30–40°C are described here.

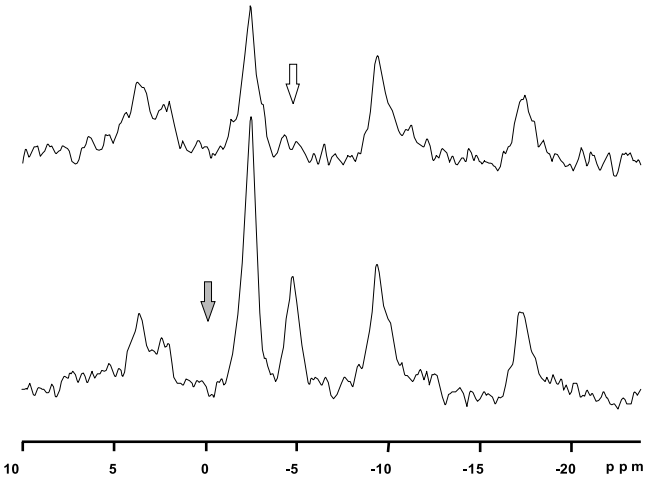
Fig. 1. ^{31}P NMR spectra of rat brain saturated at the γ-ATP resonance (top) and at the mirror position about the PCr resonance (bottom). Saturation positions are indicated by arrows.



Experimental

The experiments used 14 adult male Sprague–Dawley rats weighing 300–350 g, handled and cared for in accordance with the guidelines of the Canadian Council on Animal Care. Each rat was used for a maximum of three separate sessions with measurements being made at 1–4 temperatures each time. For each experimental session, the rat was mechanically ventilated using 1.0% halothane, 30% O_2, and balance N_2O. An arterial line was placed in either the tail artery or a femoral artery to monitor blood pressure and blood gases. Arterial blood pressure was recorded once during each acquisition. Blood gases and blood pH were normalized by adjusting ventilator parameters before beginning a series of acquisitions at each temperature. The alpha-stat model of acid–base balance at temperatures differing from normal was used to regulate ventilation (18). This model requires that blood pH vary with temperature such that when normal body temperature is restored, normal blood gases and pH are obtained.

A thermocouple was inserted into the inner ear through the tympanic membrane to monitor brain temperature (19). Brain temperature was adjusted and maintained using a cylindrical thermostatted water bath about the head and a thermostatted water blanket for the body, together with air cooling and heating. Body temperature was monitored using a rectal probe, and the rectal temperature corresponded closely to the brain temperature.

NMR spectroscopy experiments were carried out on a Bruker Biospec 7 T, 21 cm horizontal bore scanner using a 1.5 × 2 cm elliptical surface coil tuned to the ^{31}P resonance frequency (121.5 MHz) sewn onto the scalp in an identical position relative to the brain of the rat for each experiment. No changes in the adjustable matching capacitors, and only small changes in tuning, were required for different rats and different temperatures, so that an identical pulse length (80 μs) was used for each experiment to ensure localization to the same part of the brain each time. ^{1}H MR images obtained with a surface coil of identical dimensions but tuned to the proton frequency showed that the contribution of underlying scalp and temporalis muscle to the spectra was minimal (20). Shimming was carried out to obtain a water ^{1}H NMR line width of 0.3–0.4 ppm using the ^{31}P coil to observe the water proton signal.

The saturation rf power level was carefully adjusted to completely eliminate the γ-ATP resonance while having a minimal direct saturation effect on the PCr resonance. To correct for direct saturation, a control spectrum was obtained with irradiation for an identical length of time at the mirror position as shown in Fig. 1. A saturation time of 4 s just prior to acquisition and a recycle delay of 6 s were used. At each temperature, three pairs of spectra were obtained at each saturation position using 64 averages for each spectrum. Thus the total acquisition time for a rate constant determination at a given temperature was 19.2 min. An acquisition size of 1024 points was used with a sweep width of 10 kHz. The FIDs were Fourier transformed after zero-filling to 2048 points and applying exponential line-broadening of 30 Hz. The intensity ratios from the three pairs of phased spectra were averaged to yield the final estimate of the extent of saturation transfer.

Preliminary experiments were carried out using similar parameters to those described above but with several different values for the saturation time t (0.1, 0.25, 0.5, 1, 2, and 4 s). A non-linear three-parameter fit to eq. [2] was carried out,

$$[2] \qquad M_t = M_\infty(1 + k_f T_1^{PCr} \exp(-t/T_{1app}^{PCr}))$$

where M_t and M_∞ represent the PCr magnetization at t and ∞, T_1^{PCr} is the longitudinal relaxation time for PCr in the absence of exchange but in the presence of saturation, and T_{1app}^{PCr} is the relaxation time of PCr in the presence of exchange and saturation. T_1 was not dependent on temperature in the range 30°C to 40°C (p = 0.39), with an average T_1^{PCr} = 2.44 s, in agreement with previously reported values (21, 23–25). Subsequently, k_f was calculated using this value of T_1^{PCr} and eq. [3] (26):

$$[3] \qquad k_f = \left(\frac{M_0}{M_\infty} - 1\right) \frac{1}{T_1^{PCr}}$$

where M_0 is the magnetization of PCr in the presence of the mirror saturation.

Intracellular pH could not be determined accurately from the ^{31}P NMR spectra due to the low signal-to-noise ratio and overlap of the broad inorganic phosphate (P_i) peak with neighbouring peaks (21, 27). However, under the alpha-stat regime of pH management, intracellular pH, pH_i, decreases with increasing temperature, with d(pH)/dT = –0.011 U/°C and normothermic pH = 7.06 in rat brain (22). These data were used to calculate [H^+] at each experimental temperature. To determine [PCr] and [MgADP] at each temperature, [PCr]/[ATP] was measured directly from the experimental spectra at each temperature by curve-fitting the PCr and ATP peaks using the deconvolution software built into the spectrometer system. Lorentzian line-shapes were used throughout. [ATP] was assumed to be 4.6 mM (21) and to be independent of temperature (28), and total creatine concentration (Cr plus PCr) was assumed to be 15.0 mM (21) and

[a]1 mmHg = 133.3 Pa.

independent of temperature (28). [MgADP] at each temperature was calculated using the CK equilibrium constant K_{eq} = 1.66 × 10^9 M^{-1} at 38°C (29) and the van't Hoff equation with ΔH = –2 kJ/mol (22). The concentration of free Mg^{2+} was assumed to be temperature independent.

The CK rate equation, eq. [4] (21, 30, 31), was used to calculate the temperature dependence of enzyme activity independent of substrate concentration.

$$[4] \qquad v_{for} = k_{for}[PCr] = \frac{V_{max}[ADP][PCr]}{DK_m(ADP)K_i(PCr)}$$

where

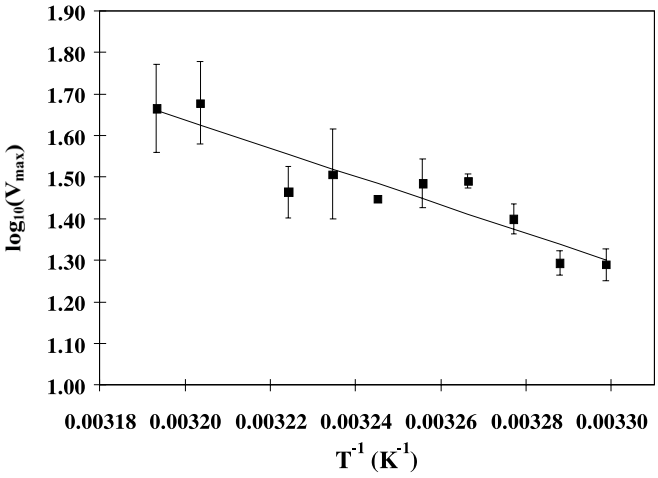
$$D = 1 + \frac{[ADP]}{K_i(ADP)} + \frac{[PCr]}{K_i(PCr)} + \frac{[ATP]}{K_i(ATP)} + \frac{[Cr]}{K_i(Cr)} + \frac{[ADP][PCr]}{K_m(ADP)K_i(PCr)} + \frac{[ATP][Cr]}{K_m(ATP)K_i(Cr)} + \frac{[ADP][Cr]}{K_m(ADP)K_i(Cr)}$$

v_{for} is the forward velocity, V_{max} is the maximum forward reaction velocity independent of substrate concentration, K_m are Michaelis constants and K_i are inhibition constants for the substrates (indicated in parentheses). The values for K_m and K_i were taken from ref. 21 with the exception of K_m(ADP) for which a value of 27 μM was used (13, 32). V_{max} at each temperature was calculated from these equations.

Data were obtained from 3–6 rats at each temperature. The mean values of k_f and V_{max} obtained at each temperature were fit to Arrhenius plots to obtain activation parameters.

The dependence of blood gas parameters and blood pressure on temperature was tested using one-way ANOVA followed by Scheffé's post-hoc comparisons. The dependence of k_f on blood gas parameters and blood pressure was tested using multi-way ANOVA with temperature as one of the variables. Parameters derived from linear regression are shown with standard errors calculated from the standard errors of the fitted parameters. The *p*-value shown is that for the comparison with a slope of zero, and *R* is the correlation coefficient.

Fig. 2. Plot of $\log_{10}(V_{max})$ vs. T^{-1} for the maximum forward reaction velocity of the creatine kinase reaction in rat brain between 30 and 40°C. The solid line is the least-squares best fit to the data, giving E_a = 65.3 ± 9.7 kJ/mol (p = 0.0002, R = 0.92).



Results

Physiological parameters are listed in Table 1. Blood gas parameters and blood pressure were independent of temperature; k_f was not correlated with any physiological parameter besides temperature.

Typical ^{31}P spectra of rat brain with and without saturation of the γ-ATP resonance are shown in Fig. 1. An average reduction in PCr peak height of 55 ± 4 (mean ± SD)% was observed in the γ-ATP saturated spectrum compared to control.

[PCr]/[ATP] varied significantly with temperature (p = 0.011, R = 0.76), as shown in Fig. 2. Average values for k_f, [MgADP], and V_{max} at each temperature are given in Table 2 along with the number of determinations at each temperature. Each determination at a given temperature represents data from a different rat.

A linear least-squares fit of $\log_{10}(k_f)$ vs. T^{-1} gave E_a = 14.2 ± 4.9 kJ/mol significantly different from zero (p = 0.021, R = 0.71). The temperature dependence of V_{max} is shown in Fig. 3. A linear least-squares fit of $\log_{10}(V_{max})$ vs. T^{-1} gave E_a = 65.3 ± 9.7 kJ/mol (p = 0.0002, R = 0.92).

Discussion

The values for k_f obtained in this study (0.43–0.55 s^{-1}) fall into the range of k_f values for the CK reaction in rat and mouse brain (0.31–0.68 s^{-1}) reported in the literature (21, 23–25, 33). Similarly, the average value found for T_1 for PCr (2.44 s) is in accord with literature values (1.7–3.9 s) (21, 23–25).

The k_f data show little temperature dependence. This differs from the results of studies carried out on isolated CK enzymes in vitro for which E_a ranges from 50–142 kJ/mol (8–12), and from a study on perfused rat heart, which found E_a = 42 kJ/mol (13). However, k_f measured in vivo for the related enzyme AK also has a small temperature dependence in shrimp (16) and barnacle (17) muscle, although there may be a pronounced species dependence for AK activity (14, 15).

The regulation of the CK reaction in vivo and in vitro has been studied in detail (13, 21, 30, 32, 34, 35). A change in [MgADP] with temperature will change the value of k_f directly as can be seen from eq. [4], the CK rate equation. This can obscure the true temperature dependence of enzyme activity. Indeed, pH decreases in rat brain in vivo as temperature increases (22), and the observed significant increase with temperature in the [PCr]/[ATP] ratio suggests a substantial decrease in [MgADP] with temperature. When the temperature dependence of [MgADP] is considered, the calculated value of V_{max} is temperature dependent with E_a = 65.3 ± 9.7 kJ/mol. This falls into the range measured in vitro for BB-CK, 58–72 kJ/mol (8–10). It should be noted that the calculated V_{max} = 30 mM/s at 37°C (using K_m = 27 μM), a value that is very close to the in vitro value for BB-CK (21). The value for E_a is not strongly dependent on the value of K_m(ADP); for K_m(ADP) = 11 or 110 μM, the extreme range of values reported in the literature (36, 37), E_a changes from 58.8 to 70.0 kJ/mol, respectively.

The values for the concentration ratio [PCr]/[ATP] determined in this study, ranging from 1.8 at 30°C to 2.2 at 40°C, are in good agreement with the results of previous studies (21, 22). However, the increase in [PCr]/[ATP] with increasing temperature is at variance with other literature data. In rat brain, previous studies have shown [PCr]/[ATP] to decrease slightly (28) or to remain constant (38) over a temperature range similar to that in this study. The reason for these differences is not clear but may relate to differences in experimental conditions.

In addition to altering the CK equilibrium position, changes in pH can also have a direct intrinsic effect on CK enzyme activity (39–41), perhaps by inducing conformational changes or hydrogen bonding changes that alter the active site. This too could affect the measured activation energy. Using the previously reported temperature dependence of pH in rat brain (22) and published data showing the dependence of enzyme activity on pH in vitro (39), the direct effect of pH may increase the activation energy by about 4 kJ/mol.

One limitation of this study is the possible contribution to the observed NMR signal of resonances from phosphorus metabolites in muscle adjacent to the brain. NMR images obtained with a coil of identical size to that used for the spectroscopy measurements showed that the contribution of such muscle to the ^{31}P NMR spectra was small. This was confirmed by the experimental value of 2.0 (averaged over all experiments) for [PCr]/[ATP], a value in agreement with literature values for rat brain (21, 22). A larger value for [PCr]/[ATP] is observed for muscle (21), and any significant contribution of muscle to the spectra would have increased the value of [PCr]/[ATP] above that observed. At any rate, any small undetected contribution of muscle to the spectra would be similar at each temperature and for each experi-

© 1999 NRC Canada

mental animal, and it is unlikely that this would dramatically alter the temperature dependence of the rate constant, and hence E_a.

Another possible source of error in this study is the use of a constant value for T_1^{PCr} over the temperature range 30–40°C. Although no temperature dependence was observed experimentally, the data were not precise enough to exclude a small temperature dependence. Previous studies have shown T_1^{PCr} to increase slightly with increasing temperature for the isolated enzyme (11) and in perfused rat heart (13). The effect of a similar (undetected) small temperature dependence in the present study would be to decrease the calculated value of k_f with increasing temperature (eq. [3]) and therefore decrease E_a for k_f and V_{max}. However, since the temperature dependence of T_1^{PCr} is small, any effect on E_a is likely to be less than about 10 kJ/mol.

In conclusion, the experimental values of the rate constant for the creatine kinase forward reaction in rat brain have a very small temperature dependence in vivo over the range 30–40°C. When the temperature dependence of the substrate concentration is considered, V_{max} for this enzyme in vivo depends on temperature with a value for E_a, which agrees well with the literature values for the enzyme in vitro.

Solid-state nuclear magnetic resonance studies of triphenylsilyl-, triphenyltin-, and triphenyllead(pentacarbonyl)manganese(I) complexes

Dharamdat Christendat, Ian S. Butler, Denis F.R. Gilson, and Frederick G. Morin

Abstract: The solid-state CP MAS (^{29}Si, ^{119}Sn, and ^{207}Pb) NMR spectra of the triphenylsilyl-, triphenyltin-, and triphenyllead(pentacarbonyl)manganese(I) complexes, $(Ph_3E)Mn(CO)_5$ (E = Si, Sn, Pb), have been analyzed to give the chemical shifts, one-bond spin–spin coupling constants, $^1J_{E-Mn}$, the "effective-dipolar" coupling constants ($D - \Delta J/3$), the chemical shift tensors, and the spin–spin anisotropy (ΔJ), where the analysis permits. For the tin and lead compounds, three and four sets of chemical shifts, respectively, were observed, and two different polymorphs occur for the lead complex, depending on the solvent used for recrystallization. The average values of the reduced coupling constants, $^1K_{Mn-Si}$ (2.64×10^{20} T^2 J^{-1}), $^1K_{Sn-Mn}$ (1.25×10^{20} T^2 J^{-1}), and $^1K_{Pb-Mn}$ (4.18×10^{20} T^2 J^{-1}) showed a linear correlation with the *s*-electron densities at the respective metal nuclei. The principal components of the chemical shift tensors have been determined for the tin and lead compounds.

Key words: manganese-group-14 compounds, solid-state ^{29}Si, ^{119}Sn, and ^{207}Pb CP MAS NMR, spin–spin coupling, chemical shift anisotropy, quadrupole coupling.

Résumé : On a analysé les spectres RMN (^{29}Si, ^{119}Sn et ^{207}Pb) obtenus à l'état solide, à l'aide de la technique de CPMAS, pour les complexes triphénylsilyl-, triphénylétain- et triphénylplomb(pentacarbonyl)manganèse(I), $(Ph_3E)Mn(CO)_5$ (E = Si, Sn, Pb) et, dans les cas où cela était possible, on en a tiré les déplacements chimiques, les constantes de couplage spin–spin à travers une liaison, $^1J_{E-Mn}$, les constantes de couplage « dipolaires effectives » ($D - \Delta J/3$), les tenseurs des déplacements chimiques et l'anisotropie spin–spin (ΔJ). Dans les cas des composés de l'étain et du plomb, on a observé respectivement trois et quatre ensembles de déplacements chimiques et on a observé deux polymorphes différents pour le complexe du plomb suivant la nature du solvant utilisé pour la recristallisation. Les valeurs moyennes des constantes de couplage réduites, $^1K_{Mn-Si}$ ($2{,}64 \times 10^{20}$ T^2 J^{-1}), $^1K_{Sn-Mn}$ ($1{,}25 \times 10^{20}$ T^2 J^{-1}) et $^1K_{Pb-Mn}$ ($4{,}18 \times 10^{20}$ T^2 J^{-1}) donnent une corrélation linéaire avec les densités d'électrons-*s* au niveau des noyaux des métaux respectifs. On a déterminé les principales composantes des tenseurs des déplacements chimiques pour les composés de l'étain et du plomb.

Mots clés : composés du manganèse-éléments du groupe 14; RMN (^{29}Si, ^{119}Sn et ^{207}Pb) à l'état solide, à l'aide de la technique de CPMAS; constante de couplage; anisotropie du déplacement chimique; couplage quadripolaire.

[Traduit par la Rédaction]

Introduction

Magic-angle spinning (MAS) is a technique commonly used for averaging anisotropic interactions in solid-state nuclear magnetic resonance experiments, but if a spin-1/2 nucleus is bonded to a quadrupolar nucleus, spin > 1/2, then a residual coupling remains, due to second order contributions involving the product of the dipolar and nuclear quadrupolar coupling constants (1–3). By using the resonance of the spin-1/2 nucleus as a probe, it is possible to determine the spin–spin coupling constant, *J*, and the nuclear quadrupole coupling constant, χ, and, at slow spinning speeds, the chemical shift anisotropy of the probe nucleus. These quantities are not usually obtainable from solution state NMR spectra of either the spin-1/2 or the quadrupolar nucleus since rapid relaxation of the quadrupolar nucleus leads to decoupling.

The purpose of the present work was to examine the various parameters obtained from the solid-state CP MAS NMR

spectra of triphenylsilyl-, triphenyltin-, and triphenyllead complexes of (pentacarbonyl)manganese(I), $(Ph_3E)Mn(CO)_5$ (E = Si, Sn, Pb), where ^{55}Mn (S = 5/2, NA = 100%) is the quadrupolar nucleus. The other member of group 14, germanium, has no spin-1/2 isotope. These covalent bimetallic compounds offer a unique opportunity to examine the chemical shift anisotropy and the spin–spin coupling between the elements of a main group and a transition metal. The crystal structures of the silicon and tin compounds have been determined previously (4, 5), and the nuclear quadrupole coupling constants have been measured by solid-state, broadline ^{55}Mn NMR spectroscopy of single crystals of the triphenylgermanium, triphenyltin, and triphenyllead complexes (6). However, no NMR or NQR results have been reported for the triphenylsilyl complex.

Experimental

The triphenylsilane complex was prepared by the reaction of dimanganese decacarbonyl and triphenylsilane in an evacuated tube at 250°C (7) and the tin complex by reacting triphenyltin chloride with the sodium pentacarbonylmanganese salt (8). Triphenyllead acetate was reacted with sodium pentacarbonylmanganese in tetrahydrofuran solvent at room temperature to give the lead compex. The complexes were recrystallized from either octane or a benzene–octane mixture. Solution state NMR spectra were obtained for concentrated $CDCl_3$ solutions at room temperature (21°C) on a Varian XL-300 spectrometer operating at a field strength of 7.05 T. Solid-state, proton decoupled, CP MAS spectra were obtained using a Chemagnetics CMX-300 spectrometer operating at 59.5, 111.7, and 62.7 MHz, for the ^{29}Si, ^{119}Sn, and ^{207}Pb resonances, respectively. Spectra were also recorded for ^{29}Si at 19.8 MHz using a Chemagnetics CMX-100 spectrometer. Powdered samples were contained in 7.5 mm diameter zirconia pencil-type rotors. Spinning rates in the range 3.0–5.0 kHz were used to identify the isotropic chemical shifts. Experimental details, contact times, pulse delays, and number of transients are given in the figure captions. The chemical shifts of the ^{29}Si, ^{119}Sn, and ^{207}Pb nuclei were referenced to external tetramethylsilane, tetramethyltin, and tetramethyllead, respectively, using the chemical shifts of 2,2-dimethyl-2-silapentane-5-sulfonate (0.80 ppm), tetracyclohexyltin (–97.0 ppm), and tetraphenyllead (–135.0 ppm) as external secondary references for the solid-state measurements. Line broadening of 0 and 10 Hz was applied, and the FIDs were zero filled to 8 and 4 K data points on the Chemagnetics CMX-300 and CMX-100 instruments, respectively, before transformation. The resonance lines in all sidebands were fitted with Lorentzian line shapes using the program Peakfit (Jandel Scientific) and the errors given in Tables 1 and 2 are from the averages of the fitted parameters. Calculation of the shift tensors was performed with the aid of a computational package developed by Kentgens et al. (9). X-ray diffraction measurements were made using a Rigaku AFC6S diffractometer at 20°C with Mo-Kα radiation (λ = 0.7107 Å).

Results and discussion

Provided the ratio of the nuclear quadrupole coupling constant, χ, to the resonance frequency, ν_S, is small, i.e., $\chi/4S(2S - 1)\nu_S << 1$, then the splittings that are retained in the solid-state spectra obtained under magic-angle-spinning conditions are given (2) by eq. [1]

$$[1] \qquad \Delta\nu_m = -mJ + (3\chi D''/10\nu_s)[S(S + 1) - 3m^2]/[S(2S - 1)]$$

where D'' is the effective dipolar coupling constant, modified by an angular term, eq. [2]

$$[2] \qquad D'' = 1/2(D - \Delta J/3)(3\cos^2\beta^D - 1 + \eta\sin^2\beta^D\cos 2\alpha^D)$$

D is the direct dipole coupling constant, $(\mu_0/4\pi)(h\gamma_I\gamma_S/r_{IS}^3)$, ΔJ is the anisotropy in the spin–spin coupling, α^D and β^D are, respectively, the azimuthal and polar angles relating the internuclear vector to the principal axes of the electric field

gradient, and η is the asymmetry in the field gradient. For ^{29}Si and ^{119}Sn, where the magnetogyric ratios are negative, the modified form (3) of eqs. [1] and [2] was used. The local symmetry about the Mn—E bonds in the $(Ph_3E)Mn(CO)_5$ complexes is sufficiently high that the angle β^D is equal to 0°, and thus eq. [2] is reduced to a much simpler form

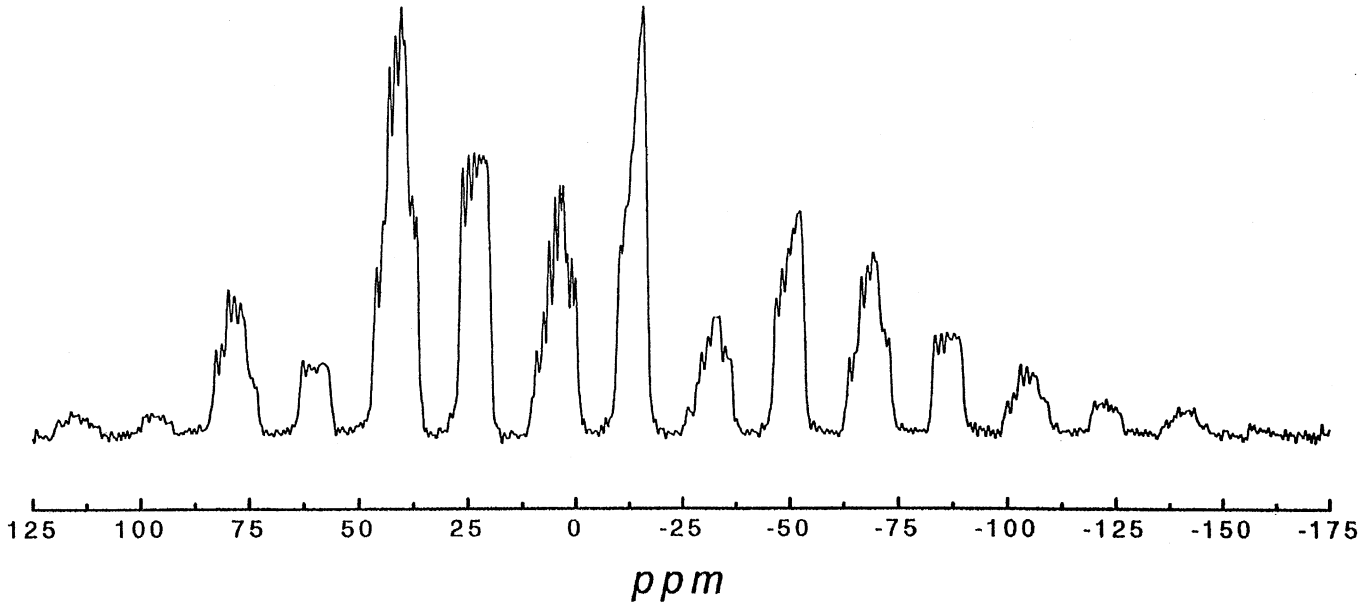
Fig. 2. Solid-state CP-MAS ^{119}Sn spectrum of $Ph_3SnMn(CO)_5$ at 111.7 MHz. Contact time 1 ms; pulse delay 10 s; spinning speed 4.5 kHz; 6000 transients.



The CP MAS spectra of the triphenylsilyl complex are shown in Fig. 1 and the NMR parameters are given in Table 3, together with the solution-state chemical shifts. The chemical shift anisotropy is too small and spinning sidebands were not obtained, and therefore, the shift anisotropy could not be determined. The crystal structure (5) showed that two molecules occur in the asymmetric unit cell, and so, two chemical shifts and a total of 12 lines are expected in the spectrum. Clearly, the solid-state NMR spectrum cannot be fitted easily; therefore, the spectrum was also measured at 19.8 MHz where the second-order splitting is increased by a factor of three while the chemical shift dispersion, in Hz, is reduced by a factor of three (the perturbation condition still holds at the lower field). The extra information this provides made it possible to fit both spectra and obtain consistent values for the second-order splitting, the spin–spin coupling, and the chemical shifts (Table 3).

The spectrum of the tin complex, Figs. 2 and 3, shows that there are three chemical shifts, but the highest field centre band arises from the overlap of two resonances. This is consistent with the crystal structure (4), where there are four molecules in the asymmetric unit. The differences in the molecular structures lie in the variations in the dihedral angles of the phenyl rings. These lie in quite narrow ranges, but are associated with two pairs of molecules (4). Two of the dihedral angles, at 41° and 60°, are within 1° for all four molecules, but the third rings are at 66° in one pair and 59° in the other. These differences are the probable cause of the different chemical shifts.

The spectra of the lead complex, Figs. 4 and 5,were also complicated by the presence of crystallographically induced chemical shift differences, with four sets of chemical shifts for both polymorphs, which, like the tin complex, occur in pairs and result in two sets of 12 peaks. The spin–spin couplings of the high-field resonances were 22 Hz smaller than those of the low-field centre band, Table 2, and were assigned the larger value of the nuclear quadrupole coupling constant, 12.04 MHz, rather than the value of 10.6 MHz (6). This distinction was based on the fact that the ^1J coupling is inversely proportional to the nuclear quadrupole coupling

Fig. 3. The centre band of the CP-MAS ^{119}Sn NMR spectrum of $Ph_3SnMn(CO)_5$ at 111.7 MHz, showing three chemical shifts. Low-field isotropic centre bands are due to overlap of two slightly different tin chemical shifts.

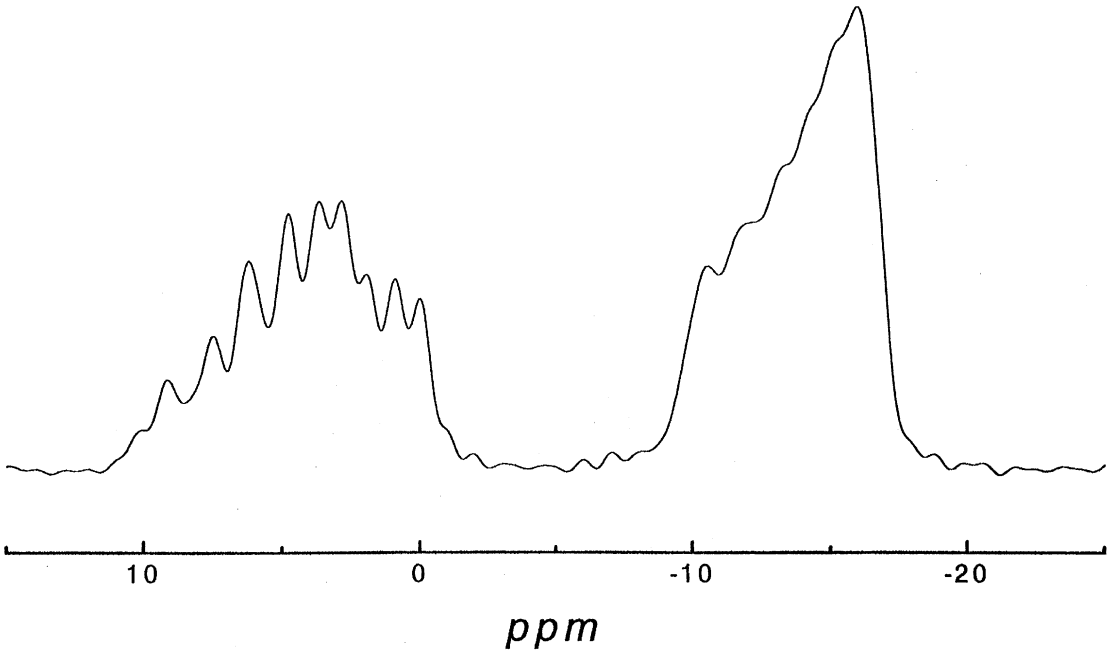

Fig. 4. Solid-state CP-MAS ^{207}Pb spectrum of $Ph_3PbMn(CO)_5$ at 62.7 MHz. Low-field and high-field isotropic centre bands are due to two slightly different lead chemical shifts, resulting in sets of 12 peaks in each centre band. (*a*) Recrystallized from octane; contact time 2 ms; pulse delay 25 s; spinning speed 5.0 kHz; 4000 transients. (*b*) Recrystallized from 50/50 benzene/octane mixed solvent; contact time 2 ms; pulse delay 25 s; spinning speed 5.0 kHz; 4000 transients.

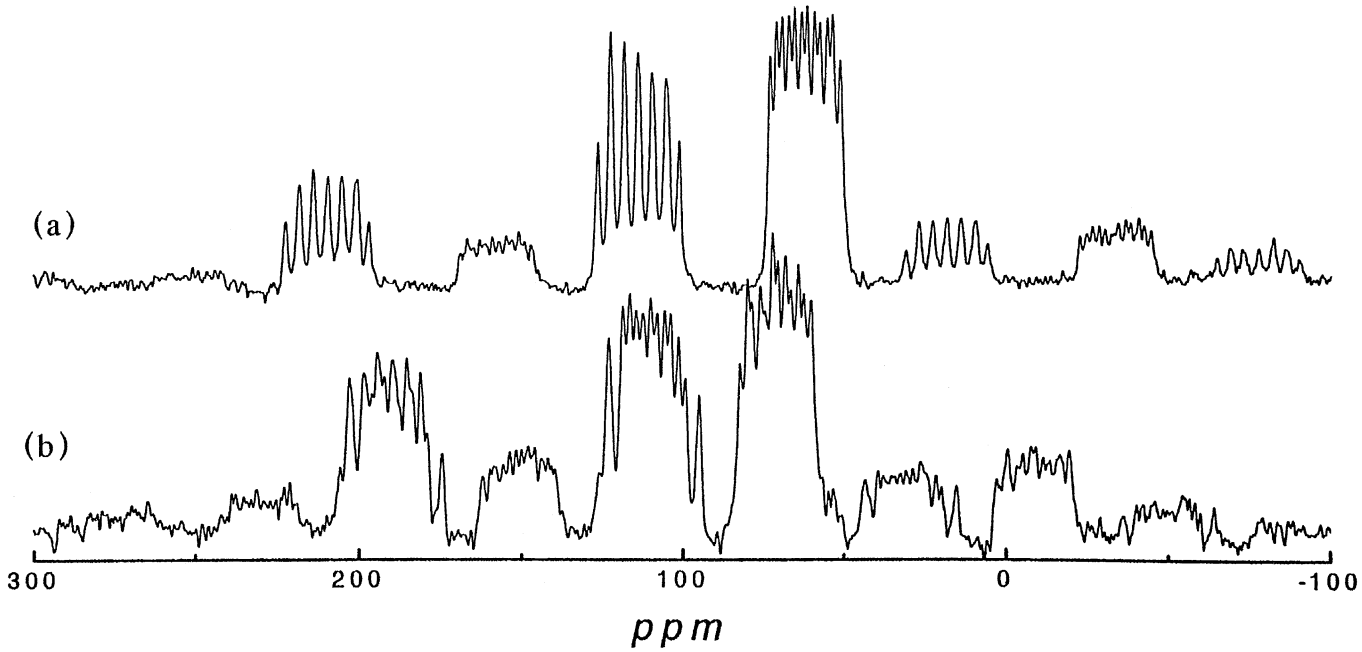

constant (10, 11) if the Fermi contact term is the dominant mechanism of spin–spin coupling (12). It was suggested, from the results of the single-crystal broad-line ^{55}Mn NMR experiment (6), that this triphenyllead-(pentacarbonyl)manganese(I) complex would crystallize in a monoclinic space group and have 2/*m* symmetry with two crystallographically independent sites across a mirror plane. In the present work, it was found that the ^{207}Pb chemical shifts for the lead complex recrystallized from octane differed from those obtained from a sample recrystallized from a 50/50 mixture of benzene and octane. A determination of the crystal structures of these two different polymorphs was attempted, but sample decomposition and persistent twinning prevented the determination of the full structures, but unit cell dimensions

Fig. 5. The centre band of the CP-MAS ^{207}Pb NMR spectra of $Ph_3PbMn(CO)_5$ at 62.7 MHz, showing four chemical shifts. (*a*) Recrystallized from octane. (*b*) Recrystallized from benzene–octane.

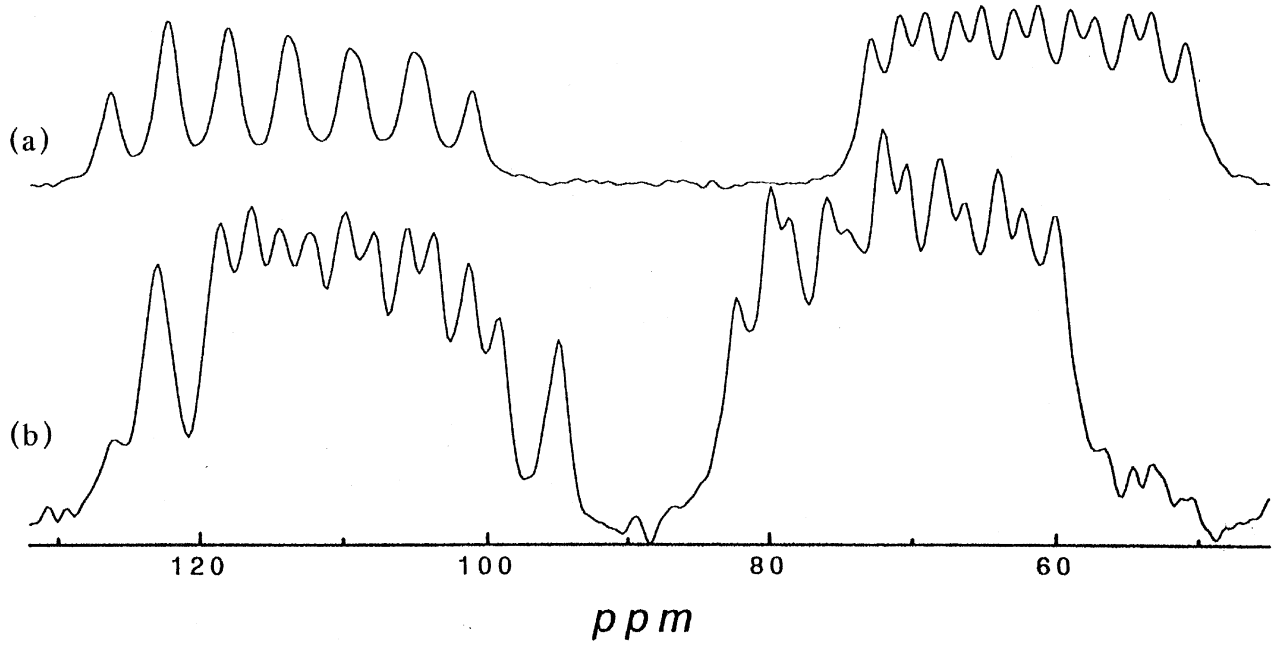

Fig. 6. Plot of the one-bond reduced spin–spin coupling constants $|^1K_{Mn-E}|$ (in $10^{21} \times T^2\ J^{-1}$) vs. electron density, $|\Psi(0)|^2$ at the Group 14 (IVA) nucleus.

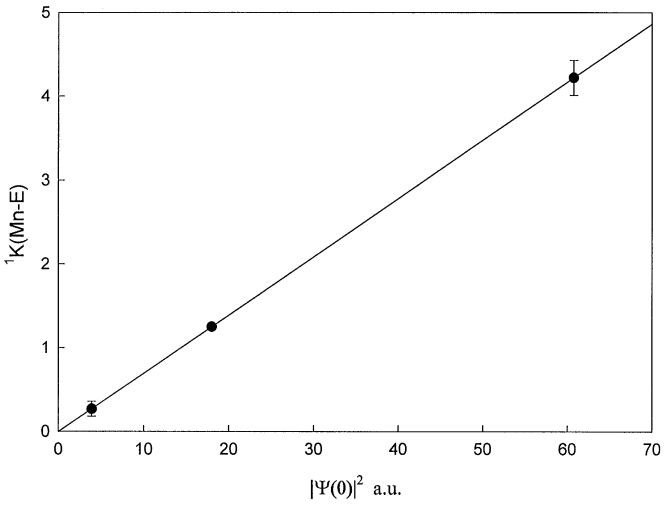

were obtained. The complex crystallized in two different space groups; *I*2/*m* from octane, a = 12.2090(3) Å, b = 64.5767(6) Å, c = 11.4994 Å, β = 90.70°, Z = 16 with four molecules in the asymmetric unit, and $P2_1$ from a benzene–octane mixture, a = 12.221(5) Å, b = 32.262(8) Å, c = 11.508(6) Å, β = 90.54(4)°, Z = 8, with four molecules in the asymmetric unit. Thus the difference in the two structures is a doubling of the *b* direction of the unit cell. The triphenylgermanium complex is also capable of crystallizing in two different forms (13, 14).

The lack of accurate Pb—Mn bond lengths precluded the calculation of the direct dipole coupling constant and a complete analysis of the data. However, Harris and co-workers (15) have shown that the effective dipolar coupling constant, *D*″, can be obtained from an analysis of chemical shift anisotropy for each of the spinning sideband manifolds. A plot of the shift anisotropy, determined from the Herzfeld–Berger analysis, versus the spin state, m, of the S nucleus will give a slope of $2(D - \Delta J/3)$ and an intercept of $\Delta\delta$. The components of the shift tensors for the tin and lead complexes, Tables 1 and 2, show that the differences between the solid state chemical shifts arise primarily from changes in the δ_{22} components. The spans of the chemical shift tensors, $\delta_{33} - \delta_{11}$, for triorganolead(IV) compounds (16–18), are typically larger than 600 ppm. The values obtained in our studies are the smallest observed for Ph_3PbX (when X ≠ Ph). Comparison of the spans for the tin and lead complexes showed the expected increase as the size of the valence *p*-electron radius, $\langle r^{-3}\rangle_{np}$ increases and the ratio of the spans, 1.5, is in good agreement with the ratio $\langle r^{-3}\rangle_{6p}/\langle r^{-3}\rangle_{5p}$. The span for the silyl complex is very small and could not be determined from the ^{29}Si CP MAS experiment.

The contributions to the coupling arise from the diamagnetic spin-orbit (DSO), paramagnetic spin-orbit (PSO), spin dipolar (SD), and Fermi contact (FC) interactions. The first two terms are usually much smaller and of opposite sign (19) than the latter two, which are the major terms. To compare the spin–spin coupling constants without the dependence on the nuclear properties, it is necessary to use the reduced coupling constants, $K_{Mn-E} = 4\pi^2 J_{Mn-E}/(h\gamma_{Mn}\gamma_E)$, which are proportional to the product of the *s*-electron densities at the nuclei and the *s*-character of the hybrid orbitals used to form the bond and divided by an average excitation energy, ΔE, (12, 19, 20). Using the *s*-electron densities given by Pyykko and Weisenfeld (21), with a non-relativistic value for silicon and relativistic values for the heavier elements, a plot of the reduced couplings, $|K_{Mn-E}|$, against the *s*-electron densities, $|\Psi(0)|^2$, for the silicon, tin, and lead nuclei,

© 1999 NRC Canada

Fig. 6, gave a linear relationship, indicating that the FC term dominates the coupling, and the *s*-bond order and the average excitation energy are nearly the same in all cases. However, the results obtained for the tin complex showed that the anisotropy in the coupling constants is finite and, therefore, the FC/SD contribution is still important.

Probing the motion of the η^2-dideuterium ligand by solution and solid-state ^{2}H NMR spectroscopy[1]

Glenn A. Facey, Tina P. Fong, Dmitry Gusev, Peter M. Macdonald, Robert H. Morris, Marcel Schlaf, and Wei Xu

Abstract: Variable temperature ^{2}H NMR is used to measure the T_1^{min} values of the η^2-D_2 and D ligands in *trans*-$[M(\eta^2\text{-}D_2)(D)(dppe)_2]^+$, M = Ru (**1**) and Os (**2**) in solution. The rapid spinning motion of the η^2-D_2 ligand results in a much longer T_1^{min} than that of the terminal deuteride. The quadrupole coupling constant (C_Q) for the terminal deuteride is calculated to be 79 kHz for **1** and 81 kHz for **2** while motion-reduced coupling constant (C_Q^{eff}) for the D in the η^2-D_2 ligands in **1** and **2** are in the range 19–22 and 27–31 kHz, respectively. The actual C_Q for these ligands with short D—D distances (<1 Å) should be at least $2C_Q^{eff}$ and probably greater than that of the terminal deuteride but less than that of D_2(g), 227 kHz. A fast spinning (>>61 MHz) and tilting of the primary electric field gradient component of between 90° and 60° or between 50° and 40° with respect to the axis of D_2 rotation is an explanation for the small C_Q^{eff}. Therefore neither D—D nor M—D bonding dominates the electric field gradient direction in these M(η^2-D_2) bonds. The complex $[RuD_2(C_5Me_5)(dppm)]^+$ **3**, which exists in solution as a 3.3:1 mixture of Ru(D···D) (**3a**) and $Ru(D)_2$ (**3b**) tautomers, has T_1^{min}(D) values that provide C_Q^{eff} values of 66 kHz for **3a** and 71 kHz for **3b**. The elongated D···D ligand in **3a** with d(D···D)≅ 1.10 Å may be "static" compared to the 61.4 MHz ^{2}H spectrometer frequency and therefore have "compressed dihydride" character and display similar Ru—D bonds as in **3b**. However, it is more likely that the static C_Q for the D of **3a** is much larger than that of a terminal Ru-D but averaged to 66 kHz by a 180° flip of the D_2 as observed in **7**. The complexes *trans*-$[M(D\cdots D)(Cl)(dppe)_2]PF_6$, M = Ru (**4**), Os (**5**), and Ru(η^2-D_2)(dppb)(μ-Cl)$_3$RuCl(dppb) (**6**) also have motion-reduced C_Q values. Some ^{2}H NMR quadrupole echo wide-line spectra of **1**, **4**, and $Os(D\cdots D)(Cl)_2(CO)(P^iPr_3)_2$ (**7**) (contaminated with 20% Os(H···D)) were recorded in the solid phase from 293 to 123 K. These also indicate that the C_Q^{eff} of the D in the D_2 ligands are motion-reduced. Simulation of the spectra of **7** are suggestive of a twofold reorientation of a D_2 ligand with a static C_Q value in the range of 120–167 kHz, a tilt angle of the electric field gradient of about 50°, and an asymmetry parameter near to zero. Significantly, the MAS ^{2}H spectrum of **7** has a broad doublet, possibly due to a non-averaged D–D dipolar/quadrupolar interference phenomenon; this is first time this has been observed. Variable temperature T_1 data for solid **7** are also reported, which allow the evaluation of the activation barrier to the twofold flipping motion of the D_2; the only other way of quantifying such an energy barrier is by use of an inelastic neutron scattering method.

Key words: dihydrogen, deuterium, NMR, ruthenium, osmium, complexes, dynamics, hydride, bonding.

Résumé : On a fait appel à la RMN du ^{2}H à température variable pour mesurer les valeurs de T_1^{min} des ligands η^2-D_2 et D dans les *trans*-$[M(\eta^2\text{-}D_2)(D)(dppe)_2]^+$, M = Ru (**1**) et Os (**2**), en solution. Le mouvement de rotation rapide du ligand η^2-D_2 fait que la valeur de T_1^{min} est beaucoup plus élevée que dans le cas d'un deutérure terminal. On a calculé que la constante de couplage quadripolaire (C_Q) d'un deutérure terminal est égale à 79 kHz pour le produit **1** et de 81 kHz pour le produit **2** alors que la constante de couplage réduite du mouvement (C_Q^{eff}) du D dans les ligands η^2-D_2 des produits **1** et **2** sont respectivement de l'ordre de 19 à 22 et de 27 à 31 kHz. Les valeurs minimales réelles de C_Q pour ces ligands comportant de faibles distances D—D (<1 Å) devraient être égales à $2C_Q^{eff}$, probablement plus

grandes que celles d'un deutérure terminal, mais inférieure à celle du D_2(g), 227 kHz. Pour expliquer la faible valeur du C_Q^{eff}, il faut faire appel à une rotation rapide (>>61 MHz) et à une inclinaison de la composante du gradient du champ électrique primaire d'une valeur allant de 90° à 60° ou de 50° à 40° par rapport à l'axe de rotation de D_2. En conséquence, dans ces liaisons M(η^2-D_2), aucune des liaisons D—D ou M—D ne domine la direction du gradient du champ électrique. Le complexe $[RuD_2(C_5Me_5)(dppm)]^+$ (**3**), qui existe en solution sous la forme d'un mélange 3,3:1 des tautomères Ru(D···D) (**βa**) et $Ru(D)_2$ (**3b**), présente des valeurs de T_1^{min}(D) qui permettent de déduire des valeurs de C_Q^{eff} de 66 kHz pour **3a** et de 71 pour **3b**. Le ligand D···D allongé de **3a**, pour lequel la *d*(D···D) = 1,10 Å, peut être « statique » par comparaison avec la fréquence du spectromètre ^{2}H (61,4 MHz), il peut présenter un caractère de « dihydrure comprimé » et il peut présenter des longueurs de liaisons Ru—D qui sont semblables à celles observées avec **3b**. Toutefois, il est vraisemblablement plus probable que la valeur de C_Q statique du D de **3a** est beaucoup plus grande que celle du Ru-D terminal, mais que sa valeur moyenne est ramenée à 66 kHz par une inversion de 180° du D_2, telle qu'on peut l'observer avec **7**. Les complexes du *trans*-$[M(D\cdots D)(Cl)(dppe)_2]PF_6$, M = Ru (**4**), Os (**5**), et ceux du Ru(η^2-D_2)(dppb)(μ-$Cl)_3$RuCl(dppb) (**6**) possèdent aussi des valeurs de C_Q réduites pour le mouvement. Opérant à l'état solide, de 293 à 123 K, on a enregistré quelques spectres RMN du ^{2}H à bandes larges avec écho quadripolaire pour les composés **1**, **4** et $Os(D\cdots D)(Cl)_2(CO)(P^iPr_3)_2$ (**7**) contaminé avec 20% de Os(H···D). Ceux-ci indiquent que les valeurs de C_Q^{eff} du D dans les ligands de D_2 sont réduites par le mouvement. Une simulation du spectre du produit **7** suggère qu'il se produit une réorientation binaire du ligand D_2 avec une valeur de C_Q statique de l'ordre de 120 à 167 kHz, un angle d'inclinaison du gradient du champ électrique d'environ 50° et un paramètre d'asymétrie pratiquement égal à zéro. Il est significatif que le spectre ^{2}H « MAS » du composé **7** présente un large doublet qui pourrait résulter d'un phénomène d'interférence dipolaire/quadripolaire D–D pour lequel il ne s'est pas établi de moyenne. On a aussi déterminé les valeurs de T_1 par RMN à température variable du solide **7**; elles permettent d'évaluer la barrière d'activation pour le mouvement d'inversion binaire de D_2. La seule autre façon de quantifier une telle barrière d'énergie est d'utiliser la méthode de dispersion inélastique de neutrons.

[Traduit par la Rédaction]

Introduction

Transition metal dihydrogen complexes (1–4) display a fascinating range of dynamic properties including torsional libration, rapid spinning, and quantum mechanical tunnelling as detected by ^{1}H NMR and inelastic neutron scattering (5–7). Deuterium NMR provides valuable dynamic information for many systems (8) but has so far only been applied to a few dihydrogen complexes (9–13). Table 1 lists the deuterium quadrupole coupling constants determined in two types of investigations: solid-state ^{2}H NMR and solution ^{2}H NMR. The complex W(η^2-D_2)$(CO)_3(P^iPr_3)_2$ is reported to have a quadrupole coupling constant ($C_Q = e^2q_{zz}Q/h$) of 124 kHz on the basis of a width of 62 kHz between singularities in the wide-line spectrum at room temperature and the assumption of large angle motion of the D_2 ligand (9). A more thorough variable temperature study with line-fitting analysis is needed to determine C_Q for this complex. However for comparison purposes in Table 1, we calculate the effective (motion-averaged) quadrupole coupling (C_Q^{eff}) to be 62 × 4/3 = 83 kHz on the basis of the reported splitting. For comparison, a terminal W—D bond has a C_Q^{eff} of about 55 kHz (Table 1) as determined in a study of T_1 of $WD(CO)_2(NO)(PMe_3)_2$ in solution. The solution T_1 studies of the D_2 ligand in some Re and Os complexes suggest C_Q^{eff} in the range of 60–74 kHz (Table 1) (11–13). These are thought to be motion-averaged values. The true values are thought to be greater than the C_Q for terminal Re-D or Os-D (65–75 or 87 kHz, see Table 1) and possibly to be in the range 120–175 kHz depending on assumptions about the spinning motion, the asymmetry parameter η, and the angle between the D–D vector and the major axis of the electric field gradient (12). The C_Q values of other classical deuteride ligands in transition metal complexes range from 55 to 158 kHz depending on the ionic character of the bond and the M—D bond distance (13). Ab initio calculation by Guo et al. (10) of the C_Q of Rb(η^2-D_2) with *d*(Rb—D) = 1.75 Å, *d*(D—D) = 0.85 Å gives a value of about 155 kHz with η 0.62. This work also shows that the C_Q undergoes a dramatic change from 225 kHz for free D_2(g) to 155 kHz for Rb(η^2-D_2) and then to 20 kHz for the product of oxidative addition, $DRbD^+$, as the D—D distance changes from 0.74 to 0.85 Å and then to greater than 0.85 Å. The true C_Q value for a dihydrogen complex is therefore expected to fall between that of free D_2 and of a dideuteride complex with no D—D bonding (Fig. 1). The direction of q_{zz} should change from along the D—D bond in free D_2 to some intermediate angle in the M(η^2-D_2) complex and finally along the M—D bond in the dideuteride. Therefore, these parameters should be sensitive indicators of D—D and M—D bonding. Little is known about the relative importance of these components in M(η^2-H_2) bonding.

However the determination of the true C_Q value instead of the motion-averaged one is still a challenge because not enough is known about the exact motion of the D_2 ligand in the complexes described so far. Fortunately the D_2 ligands in the complexes *trans*-$[M(D_2)D(dppe)_2]^+$ M = Ru (**1**) and Os (**2**), dppe = $PPh_2CH_2CH_2PPh_2$ (Fig. 2), in solution should have well-defined motion: "fast spinning" (>>400 MHz) internal motion superimposed on isotropic tumbling of the molecule, on the basis of previous ^{1}H T_1 studies of the hydrogen-containing isotopomers (14–16). A good contrast to these compounds is $[Ru(D\cdots D)(C_5Me_5)(dppm)]^+$ (**3a**) dppm = $PPh_2CH_2PPh_2$; the hydrogen analog has an H_2 ligand elongated to 1.10 Å and static in solution with respect to the motion of the molecule (17). A useful property of this complex for

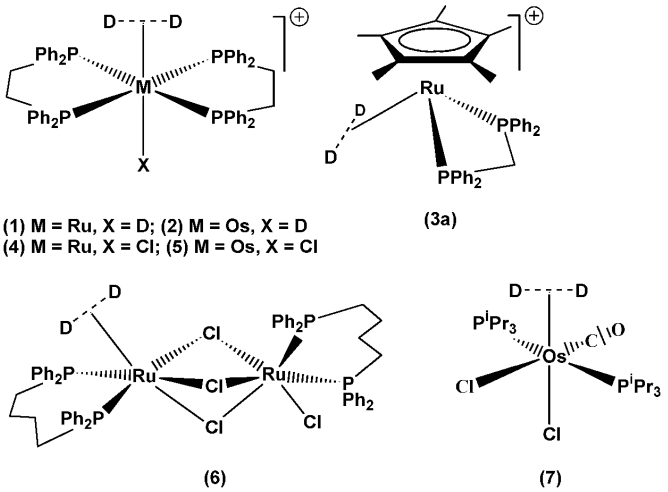
comparison purposes is that it exists in solution as a mixture of **3a** and its dideuteride tautomer $[Ru(D)_2(C_5Me_5)(dppm)]^+$ (**3b**). An intriguing type of H_2 motion occurs in the complex *trans*-$[Os(H\cdots H)(Cl)(dppe)_2]^+$ where the dihydrogen ligand has a frequency of motion similar to that of the tumbling of the complex in solution (18). Therefore the complexes *trans*-$[M(D\cdots D)(Cl)(dppe)_2]^+$ M = Ru (**4**) and Os (**5**) are also worth studying. The structures of all of these compounds have been determined by NMR methods as well as single crystal X-ray and neutron diffraction methods (except **4**) (18, 19). Very low temperature (down to 5 K) spectra of **4** provide evidence for tunneling of the D nuclei (20). Also included in the present study is an interesting dimeric complex $Ru(\eta^2\text{-}D_2)(dppb)(\mu\text{-}Cl)_3RuCl(dppb)$ (**6**) (dppb = $PPh_2(CH_2)_4PPh_2$); the H_2 complex was described by Joshi and James (21). A more comprehensive solid-state NMR study on $Os(D\cdots D)(Cl)_2(CO)(P^iPr_3)_2$ (**7**) is described here, which provides evidence for a twofold reorientation of the elongated D_2 ligand. The evidence for the 1.1 Å D···D distance in this complex comes from ^{1}H NMR studies (22), since no single crystal structure determination has been done. In **4**, **5**, and **7** the D···D distances are elongated because they are *trans* to the weak field chloride ligand (23, 24).

Experimental section

General

All of the experiments were performed under a dry D_2 or Ar atmosphere by use of standard Schlenk techniques. All of the samples were handled under an Ar atmosphere and exposed to D_2 before NMR measurements. All of the solvents were dried by standard methods and freshly distilled before use. ^{1}H, ^{2}H, and ^{31}P NMR spectra of solutions were obtained on Varian Unity-400 and Varian Gemini-300 spectrometers.

Fig. 2. Structures of the non-classical dideuterium complexes.



The purity of the samples was verified by ^{1}H, ^{31}P{^{1}H} NMR and ^{2}H NMR measurements.

Sample preparation

trans-*[Ru(D$_2$)D(dppe)$_2$]PF$_6$*, ***1***

This was prepared from *trans*-$[Ru(H_2)H(dppe)_2]PF_6$ by H/D exchange with D_2 at room temperature in CH_2Cl_2 (16). Some deuteration occurred at the CH_2 and Ar-H groups of the phosphine ligands. ^{2}H NMR (CH_2Cl_2) δ: 7.5 (br, Ar-D), 2.0 (br, CDH), –5 (br, η^2-D_2), and –10.5 (br, RuD). Temp. (K)/T_1D$_2$/T_1D (ms): 295/1167 ± 10/62 ± 10; 253/572 ± 1/32 ± 1; 233/413 ± 1/22 ± 1; 213/255 ± 1/15 ± 1; 193/181 ± 1/15 ± 1; 183/196 ± 1/29 ± 1.

trans-*[Os(D$_2$)D(dppe)$_2$]PF$_6$*, ***2***

A mixture of *cis*-$OsBr_2(dppe)_2$ (560 mg, 0.49 mmol) (18), NaO-*t*-Bu (50 mg, 0.5 mmol) and $NaPF_6$ (350 mg, 2 mmol) in 20 mL THF and 20 mL of CH_2Cl_2 was stirred under an excess of D_2(g) (1 atm) for 5 h. The solvent was evaporated in vacuo. The residue was dissolved in 15 mL CH_2Cl_2 and filtered to remove NaBr/$NaPF_6$. The addition of 40 mL hexanes caused the precipitation of the product as an off-white solid (yield 370 mg, 68%). ^{31}P{^{1}H} NMR (CD_2Cl_2) –103.6 ppm (s). There were small impurity peaks at 25 (s, $[Os(O_2)(D)(dppe)_2]^+$ (25) and 18 (s) ppm that were not removed by recrystallization from CH_2Cl_2/Et_2O. ^{1}H NMR: no

© 1999 NRC Canada

hydride peaks. ^{2}H NMR (CH_2Cl_2, 253 K): –6.6 (br, η^2-D_2), –8.8 (br, OsD). Temp. (K)/T_1D_2/T_1D (ms): 253/76/44; 238/100/19; 223/98/15; 208/94/14; 193/115/21; 183/172/not observed.

[Ru(D$_2$)(C$_5$Me$_5$)(dppm)]BF$_4$, ***3a***

A 100 mL Schlenk tube was charged with RuCl(C_5Me_5)(dppm) (0.4 g, 0.56 mmol) (26), $AgBF_4$ (0.11 g, 0.56 mmol) and CH_2Cl_2 (15 mL). This mixture was stirred vigorously under an N_2 atmosphere for 1 h. Then the Schlenk tube was put under vacuum and refilled with D_2 with stirring. The same procedure was repeated after 0.5 h and the stirring was continued for another 0.5 h. The AgCl was removed by filtration. Et_2O was diffused into the filtrate slowly. A light yellow solid (0.22 g, 88%) was obtained, which was washed with Et_2O and dried under vacuum. ^{2}H NMR (CH_2Cl_2), 293 K: –5.9 (23% **3b**, T_1 164 ms), –6.7 (77% **3a**, 178 ms); 273 K: –5.8 (20%, 100 ms), –6.6 (80%, 135 ms); 253 K: –5.9 (19%, 60 ms), –6.6 (81%, 84 ms); 233 K: –5.9 (19%, 38 ms), –6.6 (81%, 51 ms); 213 K: –5.9 (20%, 23 ms), –6.5 (80%, 30 ms); 193 K: –5.9 (shoulder on **3a** peak, 18 ms); –6.4 (**3a**, 21 ms); 183 K: –6.3 (br, 23 ms).

trans-*[Ru(D$_2$)Cl(dppe)$_2$]PF$_6$,* ***4***

Under Ar, [RuCl(dppe)$_2$]PF_6 (2.0 g, 1.8 mmol) (27) was dissolved in 30 mL CH_2Cl_2. The resulting red solution was cooled to 248 K (monitored with a thermometer) using a dry ice – acetone bath. Deuterium gas was bubbled into the solution until the color changed to yellow (approx. 5 min). Then Ar was immediately purged through the system to remove the excess deuterium gas. Diethyl ether (100 mL) that had been precooled to 248 K was quickly added to precipitate the product. When the precipitate settled, the ether was syringed out, and the cream-colored product was dried under a stream of Ar. ^{2}H NMR (CH_2Cl_2, 253 K): –12.4 ppm (s). When the sample was warmed to 293 K or if the sample was prepared at room temperature, the ^{2}H NMR also revealed resonances at 7.3 and 1.5 ppm caused by D/H exchange between the Ru(D_2) and C-H sites. Temp. (K)/T_1D_2 (ms): 294/272 ± 6; 253/127 ± 2; 233/88 ± 3; 213/54 ± 3; 193/48 ± 3; 183/54 ± 4.

trans-*[Os(D$_2$)Cl(dppe)$_2$]PF$_6$,* ***5***

D_2(g) was reacted with [OsCl(dppe)$_2$]PF_6 in CH_2Cl_2 (18). ^{2}H NMR (CH_2Cl_2): –11.5 (br). Temp. (K)/T_1D_2 (ms): 253/76 ± 7; 233/37 ± 3; 213/19 ± 2; 193/25 ± 2; 178/23 ± 4.

(η^2-D$_2$)(dppb)Ru(μ-Cl)$_3$Ru(Cl)(dppb), ***6***

The same method that was used for the η^2-H_2 complex was followed starting from (dppb)Ru(μ-Cl)$_3$Ru(Cl)(dppb) (21) but under a D_2 atmosphere. Some deuteration occurred at the CH_2 and Ar-H groups. ^{2}H NMR (CH_2Cl_2) δ: 2.0 (br), –11.3 (br). Temp. (K)/δ D_2/T_1D_2 (ms): 293/–11.3/245 ± 5; 273/–11.3/158 ± 1; 253/–11.4/93 ± 1; 233/–11.5/60 ± 1; 213/–11.6/46 ± 1; 193/–11.7/53 ± 1; 183/–11.7/54 ± 4.

Os(D$_2$)(Cl)$_2$(CO)(P^{i}Pr$_3$)$_2$, ***7***

The reported preparation of Os(HD)Cl_2(CO)(P^{i}Pr$_3$)$_2$ from Os(D)Cl(CO)(P^{i}Pr$_3$)$_2$ (80% OsD, 20% OsH) (22), was used with the following modification: 37 wt.% DCl in D_2O (99.5 atom % D, Aldrich) was used instead of HCl in toluene. ^{1}H NMR (C_6D_6 under D_2) –7.46 (residual η^2-HD, 1:1:1 t, J_{HD} 20.1 Hz, 0.2 H). Therefore, the sample was 20% Os(HD) and 80% Os(D_2) as determined by integration.

Solution NMR deuterium T_1 measurements

The measurement of T_1 of concentrated samples in CH_2Cl_2 was done on a Varian Unity-400 spectrometer using the inversion-recovery method (π-τ-π/2). A nonlinear three-parameter fitting routine of the spectrometer was used to calculate the T_1 values. The pulses were calibrated at each probe temperature. The errors of such T_1 determinations were lower than 5% and the relaxation rates were mono-exponential. The temperatures were calibrated by ^{1}H NMR with a standard methanol sample.

Solid-state deuterium NMR spectroscopy

Deuterium NMR spectra of **1, 3**, and **4** were recorded on a Chemagnetics CMX300 spectrometer operating at 45.98 MHz, using a Chemagnetics broadline deuterium probe equipped with a 5 mm diameter solenoid coil. The quadrupolar echo pulse sequence (90*x*–τ–90*y*–τ–acq) (28) was employed using quadrature detection with complete phase cycling of the pulse pairs. The 90° pulse length was 2 μs, the interpulse delay was 30 μs, the recycle delay was 5 s, the spectral width was 1 MHz, and the data size was 2K. The samples (~200 mg) sealed in 5 mm tubes were cooled to the desired temperature using the boil-off from liquid nitrogen, and regulated at that temperature using a feedback loop controlled resistive heater. Samples were temperature equilibrated for at least 30 min prior to beginning data acquisition.

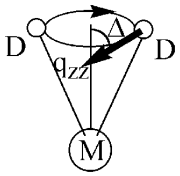
Compound **7** (150 mg) was sealed in a standard 5 mm NMR tube 30 mm in length under 1 atm N_2 gas. The spectra for **7** were collected on a Bruker ASX 200 NMR spectrometer. The ^{2}H CPMAS spectrum was acquired by placing the sample tube into a Bruker 7 mm o.d. zirconia stretch rotor. The Hartman Hahn match was set directly on the sample. The ^{1}H 90° pulse was 4.5 μs, and the contact time was 4 ms, 8K time domain points were collected for 3860 scans with a sweep width of 0.25 MHz using a 2 s relaxation delay. The spinning speed was 5.000 kHz and was stable to within 1 Hz. The ^{2}H wideline spectra were acquired with the quadrupolar echo sequence using a Bruker wideline probe with a 5 mm insert. The 90° pulses were 3.5 μs and the echo delays were 35 μs. The temperature was regulated with the instrument's variable temperature unit to within 1 K, but the temperature of the sample was measured directly with a thermocouple inserted at the top of the magnet bore such that it was in contact with the coil of the probe. The accuracy of the measured temperatures was within 1 K. The T_1 relaxation times were measured using the inversion recovery method with the 90° read pulse replaced with a quadrupolar echo. Each measurement was made with 12 τ values. All simulations were carried out on an SGI Indigo using the MXET1 program kindly provided by Dr. R.R. Vold.

Calculations

The calculation of C_Q (eq. [1]) from the minimum T_1 with respect to temperature of the deuterium in a complex isotropically tumbling in solution has been described previously (13). The temperature dependence of T_1 is given by eqs. [2] and [3].

© 1999 NRC Canada

Fig. 3. Definition of the angle Δ in a fast-spinning D_2 complex.



$$[1] \qquad C_Q = \frac{e^2 q_{zz} Q}{h}$$

$$[2] \qquad \frac{1}{T_1(D_2)} = 0.3\pi^2(1+\eta^2/3)(C_Q)^2\left\{A\frac{\tau_c}{1+\tau_c{}^2\omega^2} + A\frac{4\tau_c}{1+4\tau_c{}^2\omega^2}\right\}$$

$$[3] \qquad \tau_c = \tau_o e^{(E_a/RT)}$$

where C_Q is the static quadrupole coupling constant, $\eta = (\Delta\nu_{yy} - \Delta\nu_{xx})/\Delta\nu_{zz}$ is the asymmetry parameter of the electric field gradient, A is 1 for the case of a deuterium nucleus tumbling with the molecule with no additional internal motion, τ_c is the correlation time of the molecule, and ω is $2\pi\nu$, where ν is the spectrometer frequency. For $\tau_c = 0.62/\omega$ the spectral density function $J(\omega) + 4J(2\omega)$ reaches a maximum value which leads in turn to a T_1 minimum. Equation [2] then simplifies to eq. [4] where ν is in MHz and $T_1{}^{min}$ is in seconds (12).

$$[4] \qquad (C_Q)^2 = 1.489(\nu/(T_1{}^{min}(1 + \eta^2/3)))$$

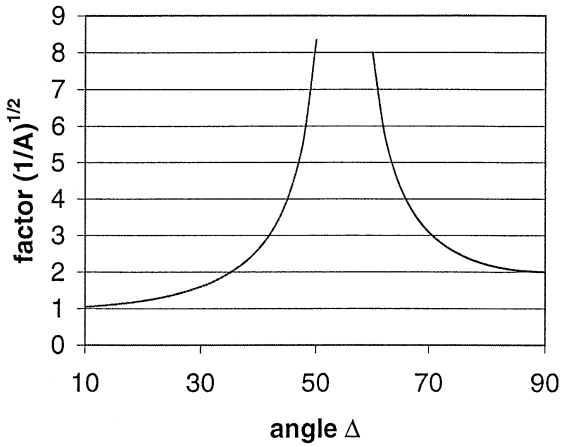
The value of η is usually not known but ranges from 0 to 1. This leads to an uncertainty in the value of C_Q of 10% or less.

This equation needs to be modified for the case of rapid spinning (or rapid, random reorientation in a plane) of a D_2 ligand with the q_{zz} of each D oriented at an angle Δ with respect to the coordination axis, which is also the axis of rotation (Fig. 3). Because the $M(D_2)$ bonding involves both D-D and M-D components, at least for short D—D distances, then Δ will not in general be equal to 90°. If there is no D—D bonding (i.e., a dihydride structure) then q_{zz} would be expected to point along the M—D bond. Therefore, a determination of the angle Δ would provide valuable information about the bonding.

Woessner (29, 30) has provided the spectral density functions to describe axially symmetrical internal motion superimposed on isotropic molecular tumbling with an axis of relaxation at an angle Δ with respect to the axis of rotation or other symmetrical motion. There are three additive functions of the diffusion constants of motion that contain coefficients $A = (3\cos^2\Delta - 1)^2/4$, $B = 3\sin^2\Delta\cos^2\Delta$, and $C = 3(\sin^4\Delta)/4$, respectively. With rapid internal rotation or diffusion of the nucleus, the functions with the B and C terms become very small and leave the spectral density function as in eq. [5].

$$[5] \qquad J(\omega) = \frac{(3\cos^2\Delta - 1)^2}{4}\,\frac{\tau_c}{1+\tau_c{}^2\omega^2}$$

Fig. 4. Relationship between the angle Δ and the factor $(1/A)^{1/2}$ from eq. [6].



When Δ is 90°, the well-known result of $A = (3\cos^2\Delta - 1)^2/4 = 0.25$ is obtained. This factor has been used to correct $T_1{}^{min}$ values of ^1H in "fast-spinning" dihydrogen complexes where the dipolar relaxation is at 90° to the axis of rotation (15). Equation [4] now becomes eq. [6].

$$[6] \qquad C_Q = 1.220(1/A)^{1/2}(\nu/(T_1{}^{min}(1 + \eta^2/3)))^{1/2}$$

The remarkable dependence of the factor $(1/A)^{1/2}$ on the angle Δ is illustrated in Fig. 4. As Δ approaches the "magic angle" of 54° this factor becomes enormous. Equation [6] is not accurate near the singularity. However, it illustrates that large corrections may be needed to calculate C_Q from $T_1{}^{min}$ if there is rapid, symmetrical motion with an angle involving q_{zz} between 40° and 70°.

Results and discussions

Preparation of the deuterated materials

All of the complexes except **7** could be prepared from deuterium gas by various synthetic methods. Complexes **4**–**6** could be prepared by direct reaction of $D_2(g)$ with solutions of the unsaturated starting complexes $[MCl(dppe)_2]^+$ or $Ru_2Cl_4(dppb)_2$. The ruthenium complexes in solution gradually become deuterated at some of the methylene and aromatic C—H bonds. The deuteration of the methylene C-H likely requires the dissociation of a Ru—P bond and coordination of the C—H bond to allow exchange with Ru—D bonds (31).

Complex **1** was prepared by displacement of H_2 and then HD ligands from *trans*-$[Ru(H_2)H(dppe)_2]^+$ by use of excess $D_2(g)$. This reaction proceeds via intermediate formation of $[Ru(D_2)H(dppe)_2]^+$ with the release of H_2 (16). Intramolecular exchange of H and D produces $[Ru(HD)(D)(dppe)_2]^+$, which reacts with D_2 releasing HD(g) and producing **1**. Some deuteration of both aromatic and methylene C—H bonds also occurred by an uncharacterized mechanism.

Since the η^2-D_2 ligand of *trans*-$[Os(H_2)H(dppe)_2]^+$ is not very labile a bromide displacement route was employed to make the deuterated analogue **2**. We have shown that *cis*-$OsBr_2(dppe)_2$ is an excellent starting material for osmium dppe chemistry (18). In particular, it can be converted into the required complex **2** in one pot (eq. [7]) (32) while avoid-

ing protic reagents that might cause unwanted hydrogen incorporation (excess $NaPF_6$ is actually required for this reaction).

[7] $$OsBr_2(dppe)_2 + NaPF_6 + NaO\text{-}t\text{-}Bu + 2D_2 \rightarrow [Os(D_2)D(dppe)_2]PF_6 + 2NaBr + DO\text{-}t\text{-}Bu$$

The deuteration to produce complex **3** proceeded via displacement of dinitrogen by D_2 from [Ru(C_5Me_5)(N_2)(dppm)]BF_4 that was first generated in situ from Ru(C_5Me_5)Cl(dppm) and $AgBF_4$ (33). It is interesting that there appears to be a significant isotope effect on the equilibrium constant between the Ru(D···D) and Ru(D_2) isotopomers. Integration of the solution ^{2}H NMR signals provides a ratio of 3.3:1 for Ru(D···D): Ru(D_2) at 20°. The ratio for Ru(H···H): Ru(H_2) was reported to be 2:1 (34).

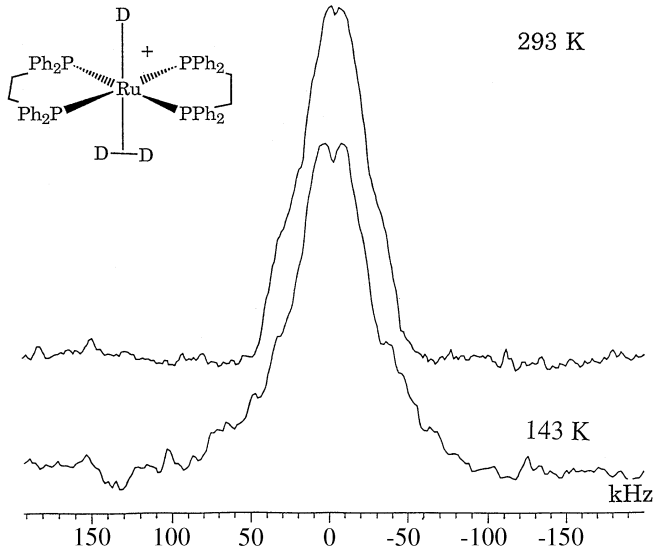
The deuteration in **7** relied on the addition of DCl to Os(D)Cl(CO)(P^{i}Pr$_3$)$_2$/Os(H)Cl(CO)(P^{i}Pr$_3$)$_2$ (80/20%). Complex **7** was found to contain 80% D_2 and 20% HD ligand.

Solid-state deuterium NMR results

Some preliminary attempts were made to obtain C_Q from wide-line solid-state spectra (see Table 2). It must be born in mind that such spectra will be super-positions of signals from all deuterons in the sample and that the detailed line shapes will reflect all motions present including those of the deuterons themselves as well as the molecules to which they are attached.

Figure 5 shows the spectra of **1** at 293 and 143 K. At 293 K the spectrum appears to be characteristic of intermediate time scale motional narrowing. Distinct spectral components for the two types of deuterons (Ru-D and Ru-D_2) cannot be resolved, making assignments or analysis difficult. At 143 K an additional broad component appeared, likely attributable to a slow moving component. A reasonable interpretation is that the broad component is associated with the Ru—D bond

Fig. 5. ^{2}H wide-line spectra of **1** at 46 MHz, 143 K (bottom) and 293 K (top).

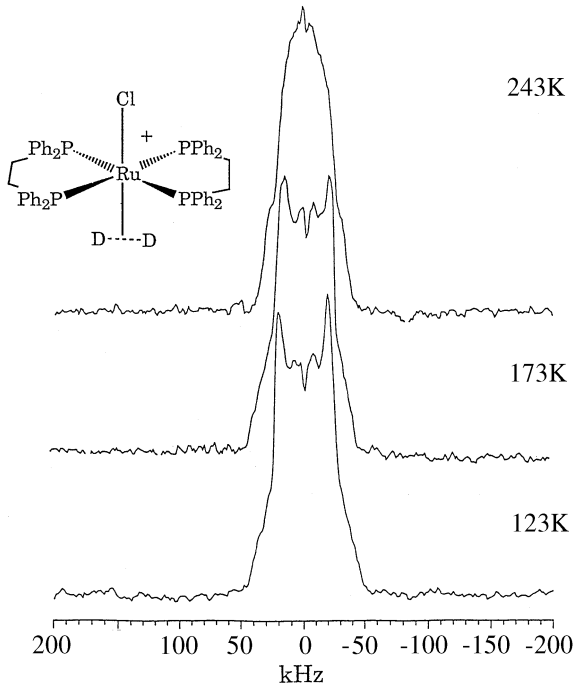


with a C_Q of about 75 kHz (cf. solution study of **1** below) while the narrow central component is due to the mobile D_2 group with a motion-reduced C_Q (cf. the fast-exchange spectra of **7** in Fig. 8 below). Only one spectrum was recorded for **3** at 143 K. This also appeared to have narrow and broad components, somewhat similar to the fast exchange spectra of **7**.

The spectra of **4** are shown in Fig. 6. There are clearly two components in these spectra as well. At the higher temperature (243 K) the spectrum is dominated by a component having a non-zero asymmetry parameter ($\eta \approx 0.7$) and $C_Q \approx$ 50 kHz. Evidently, there is motion of the deuterons, but it cannot be stated whether it is due to D–D rotation/libration and (or) flexing of the rest of the molecule. At the lower

© 1999 NRC Canada

Fig. 6. Variable temperature ^{2}H wide-line spectra of **4** at 46 MHz.

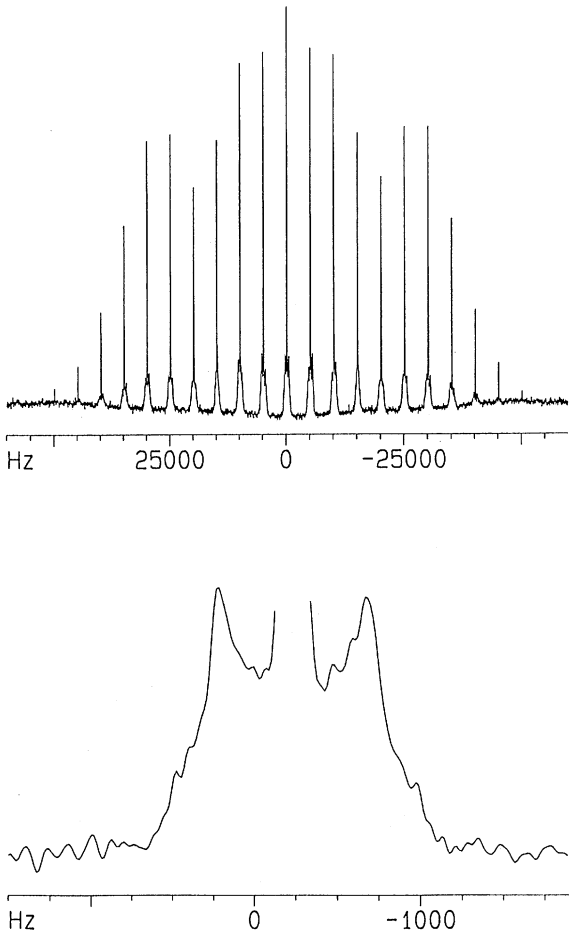


temperature (123 K) the spectrum is dominated by a component having an asymmetry parameter near zero ($\eta \approx 0.15$) and C_Q equal to 54 kHz. More recent results of Buntkowsky et al. (20) indicate that there continue to be line shape changes down to 5 K with the static C_Q evaluated to be 107 kHz, and the primary electric field gradient tilted at $\Delta = 45°$ and $\eta < 0.1$. This analysis indicates that the motion is some combination of rotational diffusion and twofold reorientation of the D_2 ligand.

To obtain more detailed information from the spectra of **1** and **3** regarding mechanisms and rates of motion, detailed temperature-dependent relaxation time and line shape analyses will be necessary.

A more detailed study of **7** was conducted. The ^{2}H CPMAS spectrum of the solid containing 80% Os(D_2), 20% Os(HD) is shown in Fig. 7. Each band in the spectrum consists of a narrow signal ($\Delta\nu_{1/2}$ = 80 Hz) and a broad doublet signal reminiscent of a partially averaged powder pattern with a width of 890 Hz at the inner singularities and 1680 Hz at the base. Both signals are centred at ~–8 ppm in the centre band. There is no evidence for a peak at ~1 ppm for CD bonds that might have formed as a result of H/D exchange. One can see that the envelope of spinning sidebands is the same for both signals and that it does not approximate a Pake doublet. This indicates that there is an anisotropic motion of the HD and D_2 ligands and (or) that the electric field gradient tensor, $\boldsymbol{V_{ii}}$, of the deuterium atoms has a large asymmetry parameter, η. The overall width of the sideband envelope (~80 kHz) suggests that the former is true. The intensity ratio of the broad to narrow components agrees fairly closely with that measured from the solution spectrum despite the fact the CPMAS spectrum is difficult to integrate as all of the sidebands must be considered, there is overlap between the signals and the CP experiment is not quantitative.

Fig. 7. ^{2}H CPMAS spectrum at 30.7 MHz of solid **7** containing 80% Os(D_2), 20% Os(HD). The top spectrum shows the complete spinning side band envelope, while the bottom spectrum shows the incompletely averaged D-D dipolar powder pattern at the base of the peak at –8 ppm.



Therefore, one can assign the broad component to the D_2 ligand and the narrow component to the HD ligand. For the HD ligand, magic angle spinning and high power proton decoupling will eliminate the first-order quadrupolar interaction, the dipolar coupling between the H and D nuclei and the indirect *J* coupling; thus, a single isotropic line is expected. The situation is much more complicated for the D_2 ligand. In this case magic angle spinning will not completely remove the second-order quadrupolar interaction, and the effects will be evident in the spectrum through the homonuclear dipolar coupling between the two deuterons (2.13 kHz based on a 1.1 Å separation). This phenomenon has been reviewed for the case of heteronuclear spin 1/2 – quadrupolar spin pairs and is referred to as "residual dipolar coupling" (35). The MAS spectra of the spin 1/2 isotopes in these cases exhibit residual powder patterns resulting from the second-order quadrupolar interaction of the quadrupolar nucleus and the heteronuclear dipolar interaction. To our knowledge the case of a D–D spin pair has not been studied in this regard but it is expected that the second-order quadrupolar effects will show up in the spectrum as a result of the homonuclear dipolar coupling between the deuterons. We have not, as yet, undertaken a detailed analysis of the

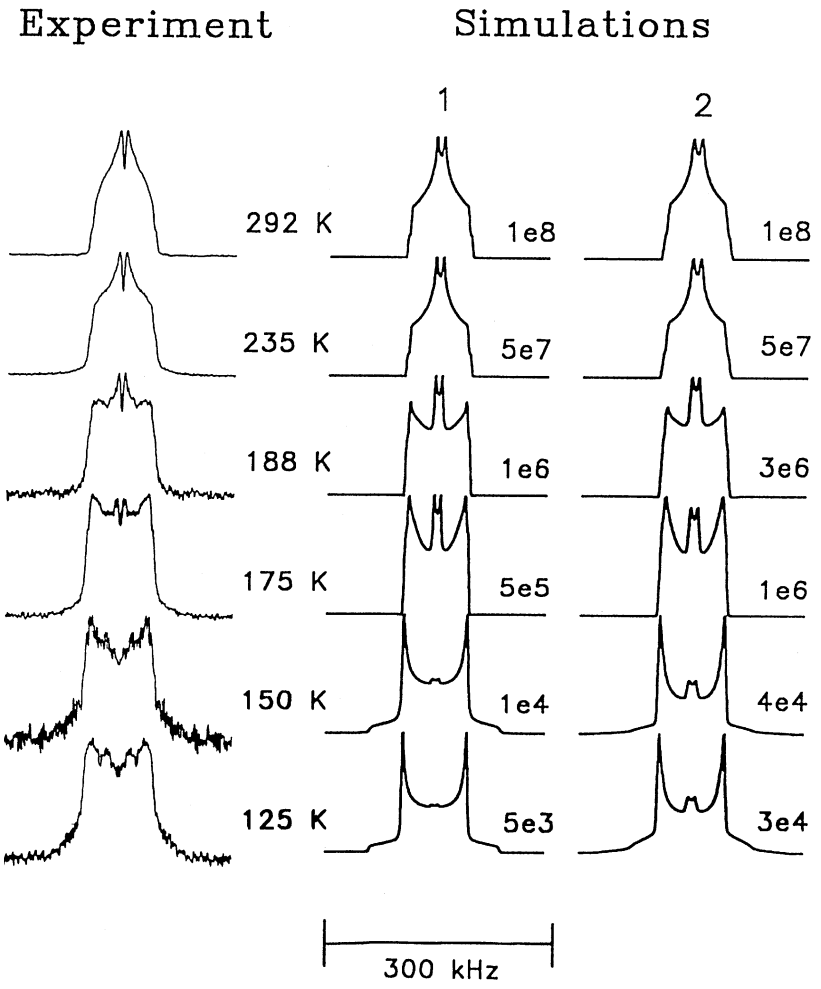
Fig. 8. Wide line ^{2}H NMR spectra of **7** at 30.7 MHz. Observed spectra are on the left and simulated spectra are on the right with model 1: C_Q = 120 kHz, η = 0, Δ = 52.5°; and model 2: C_Q = 166.7 kHz, η = 0.28, Δ = 49.7°.



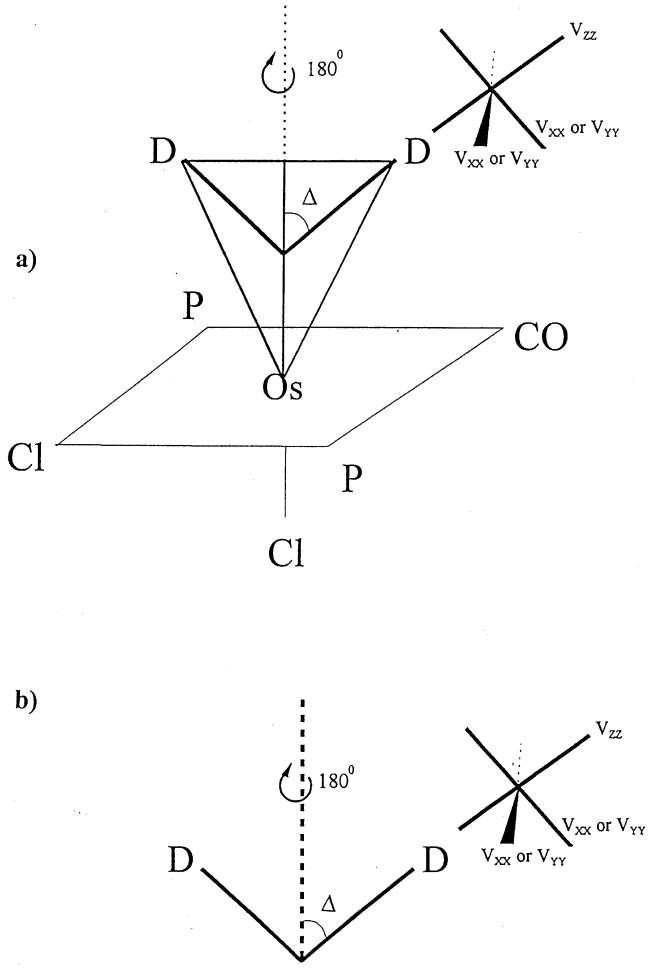
spectrum. It is complicated by the effects of molecular motion and the possible interference between this motion and the MAS. We do not expect the indirect *J* coupling to have a significant effect as it is very small. Preliminary experiments have revealed that the appearance of the spectrum is dependent on both spinning speed and field strength. Further study is required to completely understand the spectrum.

Wide line ^{2}H NMR spectra **7** were collected as a function of temperature and are shown in Fig. 8. One can see that the line shapes are very temperature dependent, indicating without doubt that the D_2 ligand is mobile. The interpretation of this data is made difficult, since one does not have available the static quadrupolar coupling constant, C_Q, asymmetry parameter, η, nor the orientation of the electric field gradient tensor, $\boldsymbol{V}_{ii}$, with respect to the molecule. Despite this lack of information one can conclude with certainty that the D_2 moiety is not undergoing an equally populated *n* site rotation ($n \geq 3$) about the coordinating axis. This would give rise to an axially symmetric spectrum, which is not the case. The spectrum recorded at 292 K is a fast motion limit spectrum, whereas all spectra recorded at lower temperatures are distorted by the molecular motion occurring at a rate comparable to the reciprocal of the static quadrupolar coupling constant. The frequency difference between one pair of singularities in each spectrum remains constant throughout the entire temperature range; thus, one component of the electric field gradient tensor must be unaffected by the motion. This would be the case for a twofold flip about the coordinating axis where the component of the electric field gradient tensor perpendicular to the Os D–D plane would remain constant. Furthermore, the spectra agree qualitatively with those previously calculated for similar complexes (36) assumed to show a mutual incoherent exchange of the deuterons.

The spectra were fit to a two-site model where the dihydrogen moiety undergoes 180° flips about the coordinating axis (Fig. 9*a*). To fit the data we had to guess at C_Q as our equipment does not permit us to record spectra at temperatures where the motion would be frozen out. We also had to provide an estimate for Δ, the angle between the largest component of the electric field gradient tensor, $\boldsymbol{V}_{zz}$, and the axis of the motion (see Fig. 9*b*). Typically $\boldsymbol{V}_{zz}$ lies along an X—D bond, however, in this case where the deuterons participate in a three centre interaction, one would expect that $\boldsymbol{V}_{zz}$ would be directed at a point on the coordinating axis intermediate between the midpoint of the D—D bond and the Os atom. Therefore, the angle Δ is restricted to values be-

© 1999 NRC Canada

Fig. 9. (*a*) Axis system defining the electric field gradient components. (*b*) Δ, the angle between the largest component of the electric field gradient tensor, V_{zz}, and the axis of the motion.

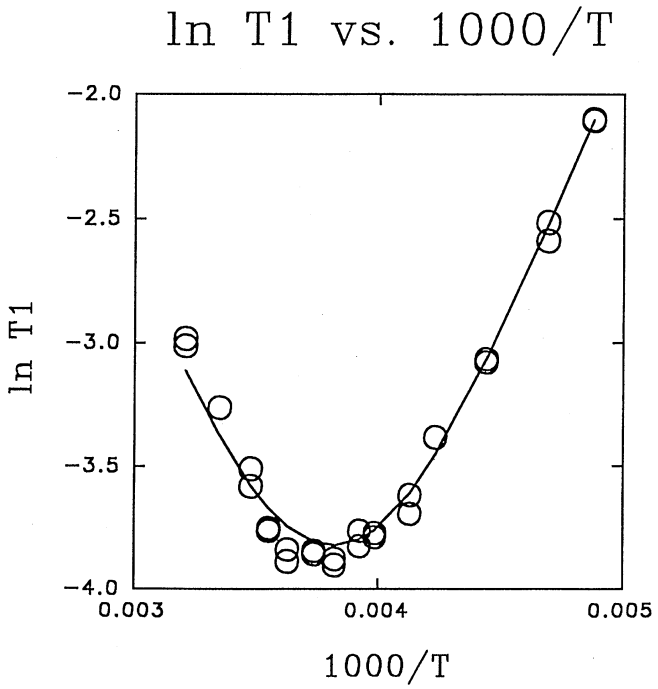


tween 19.7° and 90°, since the D—D bond length was estimated to be 1.1 Å by use of ^{1}H T_1 and J(HD) data, and the Os—D bond is estimated to be ~1.63 Å.

A series of ^{2}H line-shape simulations (37) were carried out varying C_Q, η, Δ, and the rate of the motion. The best fits are shown in Fig. 8(1) and (2). At temperatures greater than ~175 K, the fits are very nearly identical. At the lower temperatures however there are considerable differences. Unfortunately, spectra with high signal to noise ratios are difficult (i.e., time consuming) to acquire at low temperatures due to attenuated echo signals arising from the intermediate rate motion, long T_1's, and small amounts of deuterium. As a result, we are unable to distinguish between the two cases but believe that these data support the two-site reorientation model for the D_2 moiety. Other motions not included in the simulation to account for the differences are torsional libration of the D_2 and tunneling of the D nuclei through the rotational barrier. In addition, broadening of the peaks may be caused by a distribution of activation barrier energies due to solid-state effects.

According to the fitting procedure, the values of C_Q might range from 120 to 167 kHz depending on the asymmetry parameter and angle Δ. This magnitude of C_Q is greater than

Fig. 10. Observed and calculated temperature dependence of T_1 of the D in solid **7**.



the 87 kHz reported for the terminal Os—D bond in Os(η^2-D_2)D(CO)(Cl)(P^{i}Pr$_3$)$_2$ (Table 1) as expected because of the D—D bonding character in **7**. The C_Q for **7** is also greater than the C_Q^{eff} = 74 kHz for the D_2 ligand of the osmium complex in Table 1 and the C_Q^{eff} = 59–68 kHz for the D_2 ligand in **5** (Table 2). This indicates that the static quadrupole coupling constant for the D_2 ligands in Os(η^2-D_2)D(CO)(Cl)(P^{i}Pr$_3$)$_2$ and **5** must be greater than the motion-reduced C_Q^{eff} value. The value Δ of 49°–53° is also indicative of some D—D and some Os—D bonding. A D_2 ligand with the primary electric field gradient tilted at such an angle should experience a large increase in T_1(D) if rotation (or torsional libration) about the Os–D_2 coordination axis contributes to the overall motion (cf. Fig. 4).

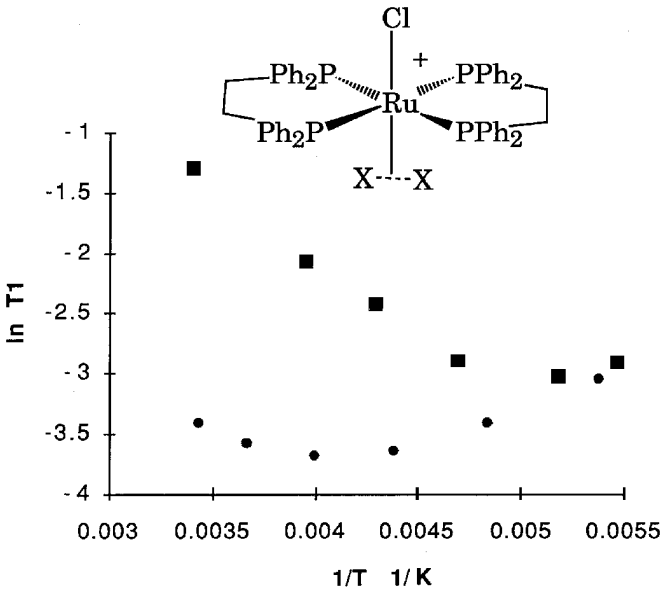
^{2}H T_1 relaxation times were measured as a function of temperature and are plotted in Fig. 10. The T_1 data were fit with the BPP spectral density function, eq. [8] (38), and the Arrhenius

$$[8] \qquad \frac{1}{T_1} = C\left(\frac{\tau_c}{1+\omega^2\tau_c^{\,2}} + \frac{2\tau_c}{1+4\omega^2\tau_c^{\,2}}\right)$$

relation (eq. [3]) to obtain the activation energy, E_a, for the D_2 reorientation. The fitted curve is represented by the solid line in Fig. 10. The activation energy was found to be 19.7 ± 0.5 kJ/mol. This low barrier is consistent with the gradual line shape changes observed over a wide temperature range (Fig. 8). The activation energy is higher than those measured by inelastic neutron scattering (<10 kJ/mol) (6, 39) for dihydrogen complexes with H—H distances of 0.85–1.0 Å. This indicates that the complex studied here has a considerable degree of dihydride character. The T_1 goes through a minimum at 260 K when $1/\tau_c$ is approximately $2\pi\nu \approx 10^8$ Hz, where ν is the spectrometer frequency of 30.7 MHz. The fact

© 1999 NRC Canada

Fig. 11. The temperature dependence of the 400 MHz ^{1}H T_1 of the H_2 ligand in $[Ru(H_2)(Cl)(dppe)_2]^+$ (●) compared to that of the 61.4 MHz ^{2}H T_1 of **4** (■).

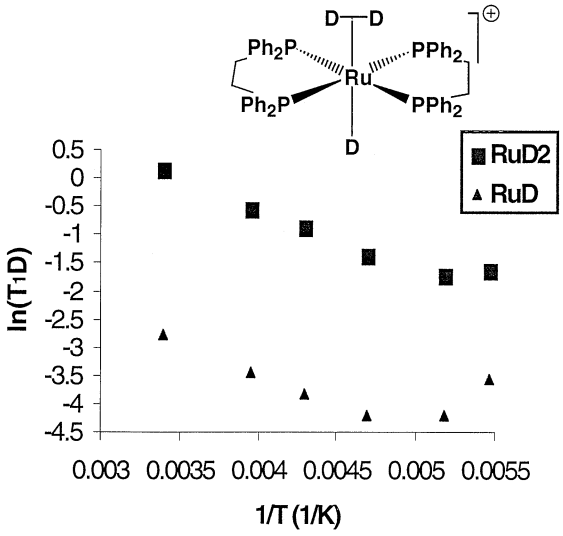


that the rate of twofold reorientation at this temperature is of this magnitude (see Fig. 8) is consistent with our interpretation of the motion of the deuterium. It is clear that the D_2 motion causes a significant increase in the T_1 value over that expected for a "static" deuterium nucleus with a C_Q of 120–167 kHz. For example, the observed T_1^{min}(D) is 20 ms at 260 K, 30.7 MHz, while that calculated by use of eq. [4] is approx. 3 ms (with C_Q = 120 MHz). It is interesting that a pure twofold reorientation would have no influence on the T_1 of the hydrogen nuclei in a dihydrogen ligand since the flip is along the same axis as the dipole–dipole relaxation vector. Therefore, D NMR is a better probe of motion in this regard. Equation [6], which refers to a free rotor motion, is not applicable to the flipping D_2 motion in **7**.

Solution deuterium NMR results

The T_1 of a deuterium resonance can be conveniently measured by a standard inversion-recovery pulse sequence, and its value reflects the quadrupole interaction (eq. [2]). Locating the minimum T_1 is a challenge. Because of the small gyromagnetic ratio of deuterium relative to hydrogen, T_1^{min} occurs at a lower temperature for deuterium than hydrogen. For example, Fig. 11 compares the temperature dependence of the 400 MHz ^{1}H T_1 of the H_2 ligand in $[Ru(H_2)(Cl)(dppe)_2]^+$ compared to that of the 61.4 MHz ^{2}H T_1 of **4**; the lower frequency D nucleus has a minimum T_1 at a much lower temperature than the ^{1}H T_1. However, we have found that the use of concentrated solutions increases solution viscosity and significantly increases the correlation time of the molecule.[3] Therefore, our investigations were done using concentrated CH_2Cl_2 solutions of the complexes (150–200 mg/mL).

Fig. 12. Observed ^{2}H T_1 for D_2 (■) and D (▲) of **1** in CH_2Cl_2 at 61.4 MHz.



The T_1 data for both D_2 and D ligands of complex **1** are plotted in Fig. 12. The T_1^{min} and C_Q values are listed in Table 2. The D_2 ligands in **1** and **2** have dramatically longer T_1^{min} than the terminal deuteride (by a factor of 12.3 and 6.7, respectively). Therefore fast motion (>>61 MHz) must be influencing the relaxation of the D_2 ligands. The quadrupole coupling constant for the terminal deuteride is calculated by use of eq. [4] with $\eta = 0$ to be 79 kHz for **1** and 81 kHz for **2**, while motion-averaged C_Q^{eff} for the η^2-D_2 ligands in **1** and **2** could range from 19 ($\eta = 1$) to 22 ($\eta = 0$) and from 27 ($\eta = 1$) to 31 ($\eta = 0$) kHz, respectively. If D—D bonding were to dominate q_{zz} then the angle Δ would be 90° and the correction factor $(1/A)^{1/2} = 2$. In this case $C_Q = 2C_Q^{eff}$ = 44 and 62 for **1** and **2**, respectively with $\eta = 0$. These are the minimum possible values of C_Q for the complexes, but they seem unlikely because they are smaller than the coupling constant of a terminal deuteride. The actual C_Q for the deuterons in these ligands with short D—D distances (<1 Å) should probably be greater than that of the terminal deuteride but less than that of D_2(g), 227 kHz. Since it is known that the hydrogen analogues of **1** and **2** have rapidly spinning (>>400 MHz) H_2 ligands it is reasonable to use to eq. [6] to account for the motion-reduction of the C_Q value. Therefore the multiplying factor $(1/A)^{1/2}$ should likely be between 79/21 and 227/21 for C_Q of the D in the D_2 ligand in **1**. By use of Fig. 4 this corresponds to two possible ranges of angles Δ: either between 59° and 66° or 45° and 51°. Similarly for **2**, the factor $(1/A)^{1/2}$ falls between 81/30 and 227/30 and the angle ranges are 61°–71° or 40°–49°. If M—D bonding were to dominate then the angle would be half of the DMD bond angle (15° for **1** and 16° for **2**, see Table 2). Therefore, neither D—D nor M—D bonding dominates the electric field gradient direction as shown in Fig. 1. Complex **1** has more D-D character than complex **2** on the basis of longer M—H distances and a shorter H—H distance (Table 2). Also, the unexpectedly weak acidity of **1** and **2** implies the presence of a strong H—H bond (40). One might

[3] For example the ^{1}H T_1^{min} at 400 MHz of the H_2 ligand of $[Ru(H)(H_2)(dppe)_2]BPh_4$ in a concentrated CD_2Cl_2 solution (150 mg/1 mL) occurs at 273 K, while a dilute solution occurs at 40° lower. Both determinations give the same value of T_1 = 20 (± 2) ms.

© 1999 NRC Canada

expect **1** to have the larger C_Q and Δ values, but the uncertainties in the values are too large to make a conclusion.

Complex **3a** that contains an elongated 1.1 Å D···D ligand has an effective quadrupole coupling constant (66 kHz with $\eta = 0$) of magnitude near to that of the terminal Ru—D bonds in **3b** and **1** (71–79 kHz). The D···D ligand in **3a** may be "static" compared to the 61.4 MHz ^{2}H spectrometer frequency, considering that the H···H ligand in [Ru(H···H)Cp*(dppm)]BF_4 has no internal motion that influences T_1(H) relative to the ca. 400 MHz frequency of molecular tumbling (17). Therefore, the C_Q^{eff} value suggests that the bond has mainly Ru-D character and that **3a**-(H···H) is a "compressed dihydride." This interpretation is supported by the fact that the pK_a of this complex is also dihydride-like (40). On the other hand, the T_1(H) studies would not have detected a pure 180° flip of the H_2 ligand, since the dipolar relaxation vector is colinear with this motion. If such a rapid twofold reorientation of the D_2 ligand is occurring, then the static C_Q value for **3a** might be much larger than 66 kHz. The one solid-state spectrum of **3a** has features of such a motion. Also we have evidence that D···D distances of 1.0–1.1 Å should give C_Q >100 kHz on the basis of the work with **4** and **7**.

Complexes **4**–**6** have small C_Q^{eff} values, which are also likely to be motion-averaged values. This is certainly true for **4** where C_Q^{eff} is about 40 kHz while the static C_Q is 107. T_1 studies of their hydrogen analogues suggest that in all of these complexes the H_2 ligands reorient with frequencies comparable or greater than 400 MHz (7). The nature of the motion is unknown but could involve wide angle libration or hopping between fourfold sites of unequal population (7). One feature of the T_1^{min} value of complex **6** is that it occurs at a temperature that is 20° higher than those of the other complexes of Table 2. This is consistent with the larger size and correlation time of this dimeric molecule.

Conclusions

A range of dideuterium complexes **1**–**7** that are suitable for study by solid and solution ^{2}H NMR spectroscopy has been prepared by different synthetic routes. The great difference in relaxation time between the terminal deuteride and dideuterium ligands in complexes **1** and **2** clearly demonstrates that internal motion of the η^2-D_2 ligand is rapid and that the major component of the electric field gradient is not directed along the D–D vector but is instead probably tilted toward the metal. A range of possible tilt angles can be estimated by use of eq. [6] to solve for the factor *A*. These angles indicate that there is a major concentration of electron density at the center of the MD_2 triangle for these complexes with H—H distances of less than one Å. The T_1^{min} values of the terminal deuterium ligands in **1** and **2** lead to reasonable Ru-D and Os-D C_Q values of 79 and 81 kHz, respectively. The elongated dideuterium complex **3a** has C_Q^{eff} = 66 kHz, similar to the C_Q of its dideuteride tautomer (**3b**) according to the T_1^{min} measurements on solutions. The D···D ligand in **3a** might be "static" compared to the 61.4 MHz ^{2}H spectrometer frequency. In this case the C_Q^{eff} value results from the Ru-D character and therefore **3a**-(H···H) is a "compressed dihydride." A more likely possibility is that the D_2 ligand undergoes rapid 180° flips even at 143 K so that a large static C_Q > 100 kHz is motion-averaged to C_Q^{eff} = 66 kHz. The complexes **4**–**6** also have motion-reduced C_Q values.

The ^{2}H NMR quadrupole echo wide-line spectra of **1**, **4**, and **7** also indicate that the C_Q of the D in the D_2 ligands in these complexes are motion-reduced in the solid state at room temperature. The estimates for the static C_Q of 107 kHz for **4** and 120–167 kHz for **7** are the first such determinations for dideuterium complexes. The determination of the barrier to twofold orientation of the D_2 ligand of 19.7 kJ/mol for **7** is the first such determination by a method other than inelastic neutron scattering (INS). The D NMR method is an attractive method of obtaining such information because the amount of sample required is much less than INS (0.1–0.2 g vs. 1–2 g) and more accessible equipment is available. However, it is likely that these two methods will be complementary, with the INS providing barriers for sample when less than 10 kJ/mol, while D NMR, when greater than 10 kJ/mol.

The first MAS D NMR spectrum has been recorded of a D_2 complex. The first evidence has been provided for an incompletely averaged D–D dipolar interaction.

Acknowledgments

We thank Prof. B.R. James for providing the precursor to complex **6**, Dr. G. Kubas for sending the spectrum of $W(D_2)(CO)_3(P^iPr_3)_2$, Nick Plavac for some solution D NMR spectra, and Prof. R. Hembre for details on the synthesis of **3**. We thank Dr H. Grondey, Dr. G. Buntkowsky, and Prof. H.-H. Limbach for useful suggestions. This research was supported by a grant to R.H.M. and a postdoctoral fellowship to W.X. from the Natural Sciences and Engineering Research Council of Canada (NSERC) and by a loan of platinum metals from Johnson–Matthey.

Symmetry, disorder, and dynamics in solid crown ether complexes: ^{2}H NMR studies of 15-crown-5·NaI, 15-crown-5·$NaClO_4$, and 21-crown-7·KI

G.W. Buchanan, M. Gerzain, and C.I. Ratcliffe

Abstract: ^{2}H NMR line shapes have been obtained as a function of temperature for partially deuteriated 15-crown-5·NaI, 15-crown-5·$NaClO_4$ and 21-crown-7·KI. Sudden changes in the line shapes above 330 K correspond to phase transitions: DSC shows transitions at 338, 347 K for 15-crown-5·NaI, and 356, 374, 383 K for 15-crown-5·$NaClO_4$. The ^{2}H NMR line shapes for the room temperature (RT) phases show the onset of a motion of the macrocycles above 200K, which is rapid a little above room temperature. Through detailed analysis of the complicated line shapes it has been shown that the most consistent interpretation of the dynamics in these RT phases is a "merry-go-round" type of motion similar to that found for 18-crown-6 and 12-crown-4 complexes in which O-CH_2-CH_2 units exchange sites around the ring, simultaneously adjusting their conformation to fit the site. In the high-temperature phases of all three complexes all the ring atoms are dynamically equivalent. This can only happen through a combination of increased symmetry and disorder for which possible models have been devised.

Key words: ^{2}H NMR, crown ether complexes, dynamics, disorder.

Résumé : On a déterminé les formes des bandes des spectres RMN du ^{2}H en fonction de la température pour des 15-couronne-5·NaI, 15-couronne-5·$NaClO_4$ et 21-couronne-7·KI partiellement deutérées. Les changements brusques qui se produisent dans les formes des bandes au-dessus de 330 K correspondent à des transitions de phases: l'analyse calorimétrique différentielle met en évidence la présence de transitions à 338 et 347 K pour la 15-couronne-5·NaI et à 356, 374 et 383 K pour la 15-couronne-5·$NaClO_4$. Les formes des bandes des spectres RMN du ^{2}H pour les phases qui existent à la température ambiante mettent en évidence la mise en route d'un mouvement des macrocycles au-dessus de 200 K et celui-ci devient rapide au-dessus de la température ambiante. Une analyse détaillée des formes de bandes compliquées, a permis de suggérer que l'interprétation la plus appropriée pour la rythmique des ces phases implique un mouvement de type carrousel semblable à celui observé avec les complexes des 18-couronne-6 et 12-couronne-4 dans lequel les unités O-CH_2-CH_2 changent de sites autour du cycle, avec un ajustement simultané de leur conformation pour équilibrer le site. Dans les phases à températures élevées, tous les atomes cycliques des trois complexes sont dynamiquement équivalents. Ceci ne peut se réaliser que par la combinaison d'une augmentation de la symétrie et du désordre pour lesquels on a développé divers modèles possibles.

Mots clés : RMN du ^{2}H, complexes d'éthers couronnes, dynamique, désordre.

Introduction

Complexes of crown ethers and their derivatives are widely recognised as simple model systems for molecular recognition (for reviews see refs. 1, 2). The great flexibility of many of the crowns means that they can adapt their conformation to achieve optimum complexation of a guest atom or molecule via their O atoms, Fig. 1.

Very many crystal structures of such complexes have been determined and the fact that the atoms are usually located at specific sites may give the impression that in their crystalline complexes the macrocycles are static. In fact, in recent studies of molecular complexes of 18-crown-6 and 12-crown-4 it has become apparent that in the solid state these macrocycles have considerable motional freedom. From ^{13}C CP/MAS, ^{1}H, and ^{2}H NMR studies, evidence was found that 18-crown-6 invariably undergoes a large amplitude motion in the neighbourhood of room temperature (3–5). For the malononitrile

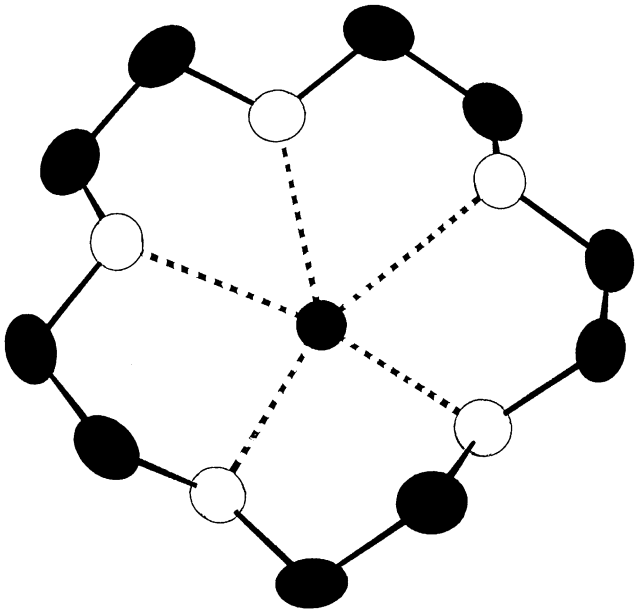
Fig. 1. A 15-crown-5·Na^+ complex showing the Na^+ coordinated by the O atoms of the five -O-CH_2-CH_2- units that constitute the macrocycle.



complex 18-crown-6·2$CH_2(CN)_2$, in which the macrocycle adopts a pseudo-D_{3d} conformation, it was demonstrated by means of ^{2}H NMR that the whole ring rotates within itself with an activation energy of 47.6 kJ/mol. (5). Each -O-CH_2-CH_2- unit visits six sites around the ring, simultaneously adjusting its conformation to suit each crystallographic site being visited. The motion resembles that of a "merry-go-round," as each C atom moves up or down on either side of the plane of the ring as it goes from site to site, and is essentially invisible in X-ray diffraction studies. The solid complex of 12-crown-4·LiNCS also shows a similar kind of motion, but complicated by a 50:50 disorder in the C atom positions, which gives rise to a concomitant up-down flip motion as the carbons jump between the disordered sites independently of the rotation of the ring (6). Effects of the ring dynamics on the ^{23}Na and ^{133}Cs NMR spin-lattice relaxation times in Cs^+(18-crown-6)$_2Na^-$ and Cs^+(15-crown-5)$_2Na^-$ have also been reported (7) from which activation energies of 31.2 and 35.4 kJ/mol. respectively were determined.

The current paper extends ^{2}H NMR studies to the complexes 15-crown-5·NaI, 15-crown-5·$NaClO_4$, and 21-crown-7·KI, which have odd numbers of -O-CH_2-CH_2- units, with a view to determining whether merry-go-round (m-g-r) dynamics is a general feature of all unsubstituted crown ether complexes.

Experimental

Synthesis

The partially deuteriated materials 15-crown-5-d_8·NaI, 15-crown-5-d_4·$NaClO_4$, and 21-crown-7-d_{12}·KI were synthesised as outlined in Scheme 1. The preparations followed literature precedents for 15-crown-5 (8–13) and 21-crown-7 (14).

Solid-state NMR

^{2}H NMR powder spectra were recorded on a Bruker AMX 300 spectrometer at 46.05 MHz as a function of temperature by using a variable temperature N_2 gas-flow probe (5 mm sample) with a Eurotherm temperature controller. A phase alternated quadrupole echo pulse sequence (15) was used with a delay time of 35 μs between X and Y pulses of 2.6–3.0 μs duration. Variable temperature ^{13}C CP/MAS NMR spectra were obtained at 45.26 MHz on a Bruker CXP-180 spectrometer using a Doty Scientific Inc. 7mm VT Probe (spin rates 3–4kHz).

Differential scanning calorimetry

DSC was performed using a Seiko SSC5200 instrument with a heating rate of 10° per minute from 273–373 K, with a nitrogen flow rate of 50 mL per minute.

^{2}H NMR background

The following provides a short description of the underlying principles of ^{2}H NMR line-shape analysis. All the basic theory has been described in detail elsewhere (16–21), and we will follow the same treatment as before (5). Briefly, ^{2}H (spin $I = 1$) NMR in solids is dominated by a perturbation of the Zeeman interaction by the quadrupole coupling tensor, which itself arises from the interaction of the nuclear quadrupole moment (Q) with the electric field gradient (eq) around the nucleus. The ^{2}H powder line shape, which is a summation of resonance line pairs for a distribution over all crystallite orientations, has either two or three pairs of characteristic features (edges, shoulders and peaks) separated by frequencies

$$\Delta\upsilon_{zz} = 3\chi/2$$

$$\Delta\upsilon_{yy} = 3\chi(1 + \eta)/4 \quad [1]$$

$$\Delta\upsilon_{xx} = 3\chi(1 - \eta)/4$$

where χ is the quadrupole coupling constant = e^2qQ/h in Hz and the asymmetry parameter $\eta = (\Delta\upsilon_{yy} - \Delta\upsilon_{xx})/\Delta\upsilon_{zz}$. The $\Delta\upsilon_{ii}$ are proportional to the principal axis components of the effective quadrupole coupling tensor, but information regarding signs of these is lost.

Molecular motion at sufficiently high rates can cause changes in the ^{2}H NMR line shape. Differing degrees of line shape averaging are observed depending on the rate of reorientation and the orientations of the principal axes of the e.f.g. tensor relative to the rotation axis. In the fast motion limit (f.m.l.) at reorientation rates about 10^7 jumps/s or faster, analytical expressions for the line shapes are relatively easy to obtain (17, 18, 21). The orientation of the tensor must first be described in a final reference frame in terms of the Euler angles

$$V(\alpha, \beta, \gamma) = RV_{pas}R^{-1} \quad [2]$$

where R is the Euler angle rotation matrix describing the coordinate transformation and V_{pas} is the tensor in its principal axis system. The fast motion line shape is then given by an effective tensor, which is the population weighted average of the tensor components in the final frame for all the sites (orientations) visited during the motion.

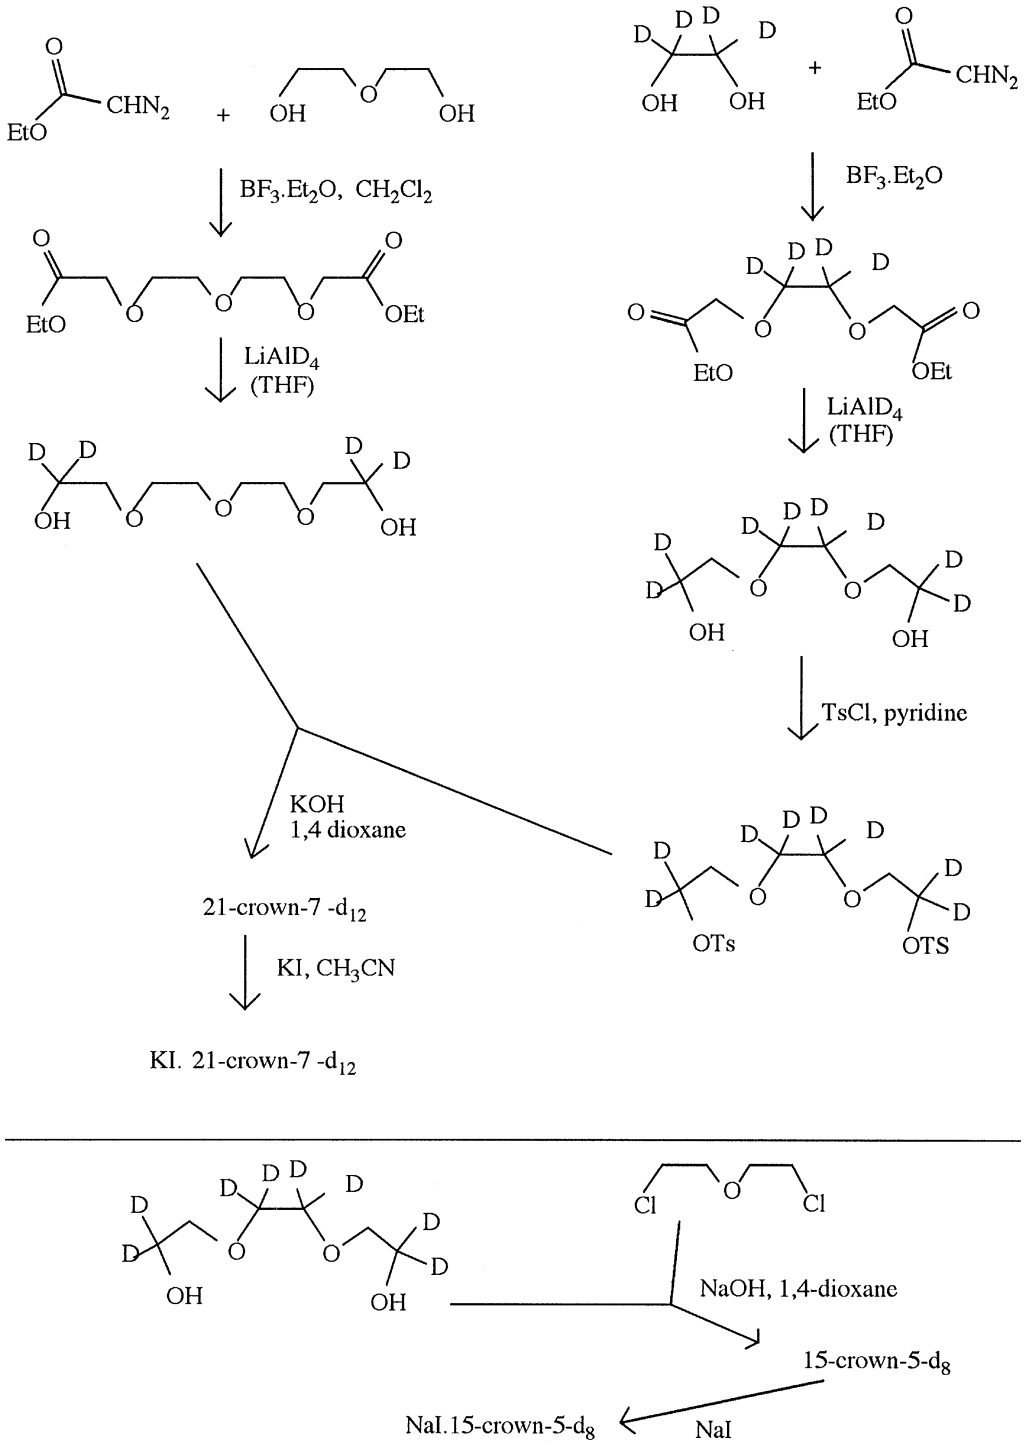
Scheme 1.



[3] $V_{eff} = \Sigma_{i=1,n} V_i(\alpha, \beta, \gamma) p_i / \Sigma_{i=1,n} p_i$

where p_i is the population factor of site i.

Intermediate rate line shapes depend on the specific rate of motion and the experimental details (e.g., on the echo delay time), and have to be calculated numerically. Methods for doing this are well established (17–20). Calculations were performed using a much modified version of an algorithm originally due to Vega and Luz (20).

Results and discussion

DSC results

It was immediately apparent from inspection of the ^2H NMR line shapes that all three complexes showed at least one phase transition (characterized by a sudden change in the line shape with temperature), and possibly more (suggested by more subtle but unexpected changes in line shape). DSC scans on the 15-crown-5 complexes, Fig. 2, indeed

© 1999 NRC Canada

confirmed the sharp transitions and located others: 15-crown-5·NaI has 2 transitions peaking at 338 K (onset ~302 K) and 347 K; 15-crown-5·$NaClO_4$ has three transitions peaking at ~356, 374, and 383 K.

^{13}C NMR spectra

The ^{13}C CP/MAS NMR spectra of 15-crown-5·NaI were examined between 210–330 K. There is a single isotropic resonance over this range with no spinning sidebands (chemical shift 70.1 ppm at room temperature). A dramatic line-broadening occurs as the temperature decreases; halfwidths were 12 Hz at 330 K and 230 Hz at 210 K. This behaviour is characteristic of the fade-out effect seen previously for 18-crown-6 complexes (4), and is explained by interference of the incoherent averaging processes caused by dynamics of the macrocycle with the coherent averaging effects of the ^{1}H decoupling, as first described by Rothwell and Waugh (22).

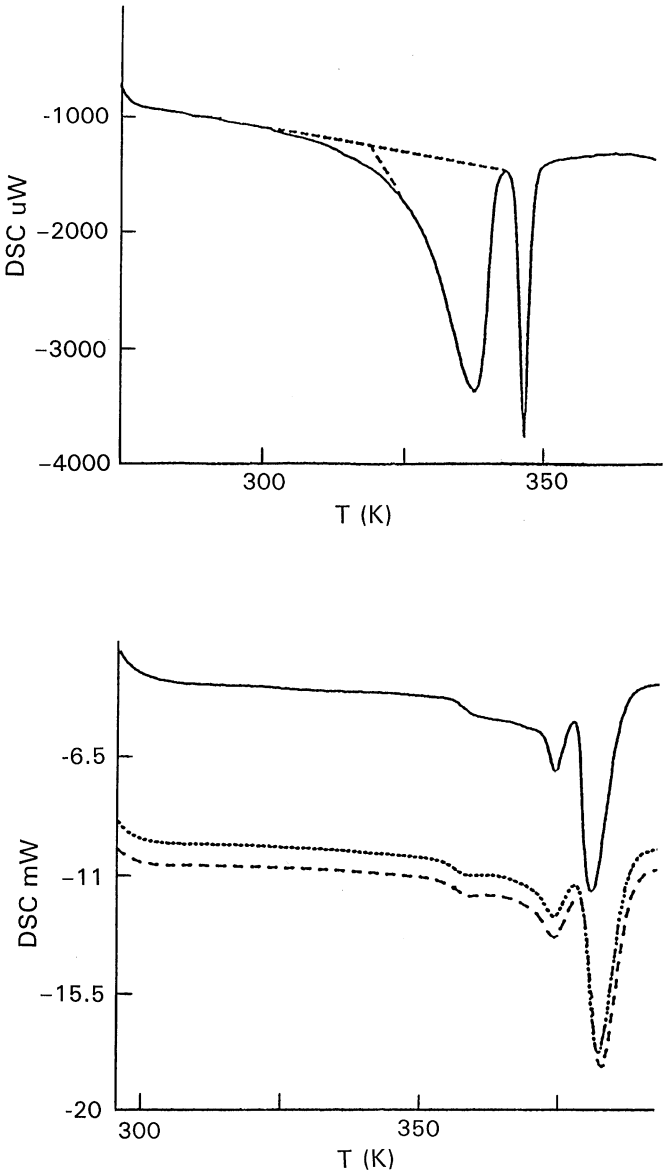
^{2}H NMR spectra

The ^{2}H NMR spectra of 15-crown-5·NaI, 15-crown-5·$NaClO_4$ and 21-crown-7·KI as a function of temperature are shown in Figs. 3, 4, 5 and the widths of the numerous measurable line-shape features (peaks, edges) are plotted in Figs. 6, 7, 8 respectively. All three complexes show sharp isotropic lines in the centre of the spectra at temperatures above about 250 K, which are interpreted as solution spectra arising from traces of occluded solvent. The room temperature phases of all three complexes appear to be stable at least down to the temperatures where essentially static limit line shapes are observed; at 238, 225, and 206 K, respectively. These static line-shape parameters are given in Table 1. Also included in Table 1 for comparison are the values for the 18-crown-6·$2CH_2(CN)_2$ complex (5). As the temperature increases, all show pronounced changes in line shape and intensity, which are consistent with intermediate rate dynamics, and line shapes corresponding to the fast motion limit are achieved a little above room temperature (by about 327, 306, and 302 K, respectively). These f.m.l. line shapes are very complicated, showing numerous identifiable features that must arise from several overlapping powder patterns. The development of the intermediate rate and the f.m.l. line-shape patterns are very similar for the two 15-crown-5 complexes, though the changes for the NaI complex are offset by about 20° to higher temperature than in the $NaClO_4$ complex.

In all three cases there are sharp changes in line shape due to phase transitions: 15-crown-5·NaI between 337–345 K (cf. 338 K, DSC); 15-crown-5·$NaClO_4$ at 374 K (cf. 374 K, DSC); 21-crown-7·KI at 338 K. Above these transitions the line shapes for both 15-crown-5 complexes are axially symmetric, whereas that for the 21-crown-7 complex has a large asymmetry parameter (parameters in Table 1). More significantly these high-temperature line shapes represent a single tensor indicating that all the deuteriums have become dynamically equivalent! There is no significant further change in the line shapes for the 15-crown-5 complexes even on passing through the next higher phase transitions at 347 (15-crown-5·NaI) and 383 K (15-crown-5·$NaClO_4$).

Hysteresis is observed in 15-crown-5·NaI, which, on cooling, shows the high-temperature line shape down to 322 K (and down to 312 K in the presence of the room temperature phase), and similarly for 15-crown-5·$NaClO_4$ down to 369 K. 21-crown-7·KI shows mixed phases on cooling below 338 K and slowly transforms at 335 K.

Fig. 2. DSC scans for (top) 15-crown-5·NaI and (bottom) 15-crown-5·$NaClO_4$. Repeat scans for the latter (offset scales) are also shown (dashed and dotted curves).



15-Crown-5·$NaClO_4$ also shows subtle changes in the line shapes in the region of 348–359 K (best seen in the feature width versus temperature plot, Fig.7), which can be associated with the 356 K phase transition.

The line shapes for 15-crown-5·$NaClO_4$ and 21-crown-7CKI also display a significant temperature dependence of the feature widths in the intermediate temperature region between room temperature and the HT phase transitions, Figs. 7, 8.

Analysis and model

With the knowledge of the components of the static quadrupole coupling tensors it now remains to find dynamic

models, which give averaged line shapes consistent with the experimental data. Our analysis will focus largely on (*a*) the room temperature (RT) phases and (*b*) the high-temperature (HT) phases where the ^{2}H NMR line shape has simplified to a single component. It is not possible to extract much useful information from the spectra in the short temperature regions corresponding to the intermediate phases of 15-crown-5·$NaClO_4$, though one might expect the dynamics to be intermediate between those of the RT and HT phases.

Room temperature phases

The X-ray diffraction structures are known for both 15-crown-5·NaI at 193 K (23) and 15-crown-5·$NaClO_4$ at room temperature (24). The ring conformation in both structures

Fig. 6. Widths of the measureable features (shoulders, peaks) of the ^{2}H NMR line shapes as a function of temperature for 15-crown-5·NaI. The dotted connecting lines are a visual aid to indicate where there is an apparent continuity of the measured feature between one temperature and the next.

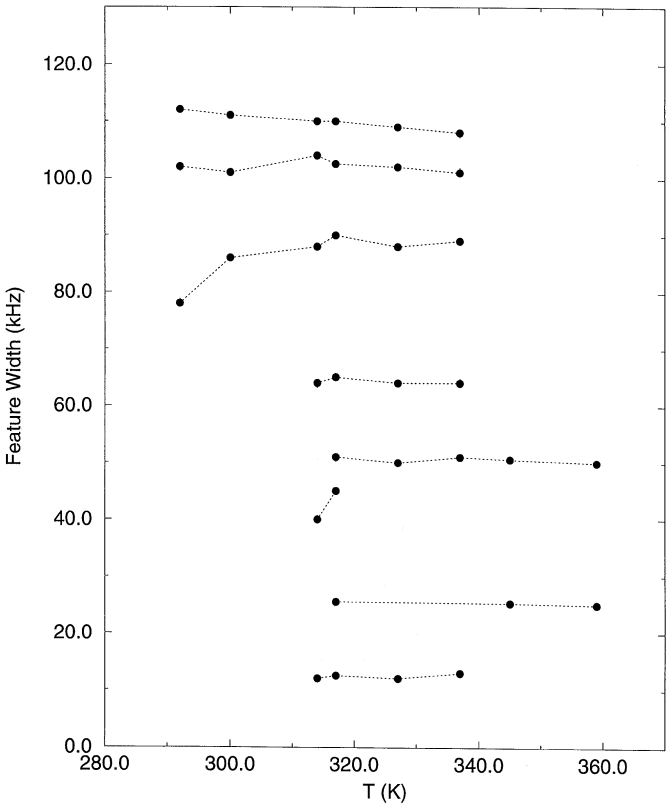

Fig. 7. Widths of the measureable features (shoulders, peaks) of the ^{2}H NMR line shapes as a function of temperature for 15-crown-5·$NaClO_4$. The dotted connecting lines are a visual aid to indicate where there is an apparent continuity of the measured feature between one temperature and the next.

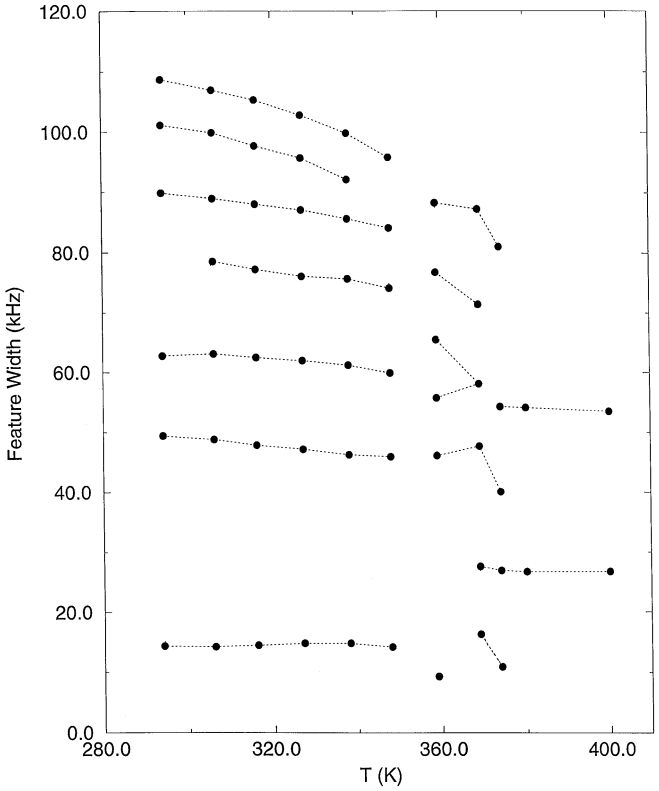


apparently corresponds to the one that is most commonly found for 15-crown-5·Na^+ complexes and which calculations also show to have the lowest energy (25). An important point to note from the start is that all the deuterons are involved in the dynamics, since there are no traces of the static ^{2}H line shape in the f.m.l. spectra.

Two dynamic models that might lead to the very complicated f.m.l. ^{2}H line shapes in the RT phases were considered:

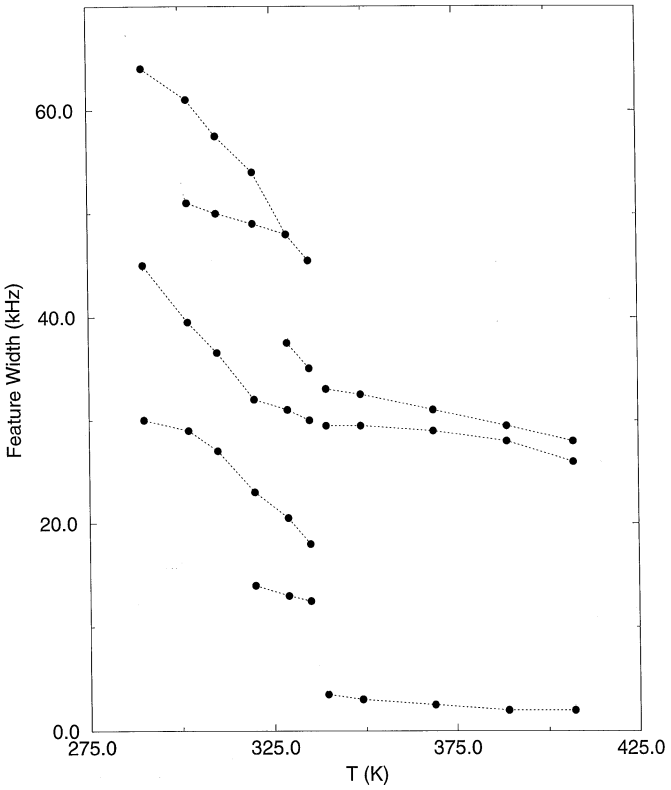
(1) The first model has no ring reorientation but individual CD_2 groups undergoing up-down flips through different angles. There would therefore be 10 pairs of exchanging sites (note the two Ds on the same C must flip through the same angle), resulting in a superposition of 10 distinct averaged line shapes. However, this model was rejected on two counts: (*a*) The X-ray diffraction structures do not show any kind of disorder, which would be an implicit requirement for such a two-site flip, i.e., the CD_2 groups only have one site if the ring is not rotating; (*b*) if such up-down flips were to occur then, no matter what the flip angle between the two sites, the averaged line shapes should always have one component with a width roughly half of the static line shape's widest component (the XX component of the static tensor should be largely unaffected by the averaging, since it is known (5) to be perpendicular to the DCD plane). Consequently, considerable intensity should build at the position of this feature (width about 110–112 kHz). No such strong feature is observed, and in fact nearly all the line-shape components observed are narrower than this.

(2) The second model is the merry-go-round type of motion, and the following detailed analysis ultimately leads to the conclusion that this is the best model consistent with the experimental data. In the m-g-r motion each O-CD_2-CD_2 unit exchanges among all O-CD_2-CD_2 sites around the ring, changing its conformation to fit the site it currently sits on. However, because the four Ds within each unit cannot physically exchange with each other the ring reorientation always implies averaging of four independent sets of Ds giving four distinct averaged line shapes, i.e., there are four sets of 5D in 15-crown-5, or four sets of 7D in 21-crown-7. In both of the 15-crown-5 complexes studied the crystal symmetry of the RT phase is such that the four sets of exchanging Ds are inequivalent. Consequently the f.m.l. line shape could have up to 12 distinct pairs of features, though this number will likely be reduced because of overlaps.

Since the crystal structures are known for the two 15-crown-5 complexes it is possible to calculate the averaging effects of the m-g-r motion on the ^{2}H NMR line shapes for the specific geometries of the macrocycle, and thus verify if this model is consistent with the experimental results. This requires the orientations of the principal tensor components

© 1999 NRC Canada

Fig. 8. Widths of the measureable features (shoulders, peaks) of the ^{2}H NMR line shapes as a function of temperature for 21-crown-7·KI. The dotted connecting lines are a visual aid to indicate where there is an apparent continuity of the measured feature between one temperature and the next.



for all the D atom sites to be defined. In the case of C—D bonds the principal ZZ axis of the electric field gradient and quadrupole coupling tensors is, to a first approximation, oriented along the bond direction, and in the present case it can be assumed that the XX component of the tensor will be perpendicular to the CD_2 plane (a result of the 18-crown-6 analysis (5)). Unfortunately the exact orientation of the C—D bonds is not known because the diffraction does not permit good refinement of the H positions. However, based on the crystal structures of the two complexes, the orientations of all the C—D bonds were estimated by assuming a D-C-D angle of 100°, with the 2 D atoms in a plane at right angles to the O-C-C plane and equally displaced on either side of the OCC bisector. (In the 18-crown-6 analysis this was a successful approximation.) Euler angles were then calculated (for each D atom) to transform the ^{2}H quadrupole coupling tensors into the chosen reference frame, which was arbitrarily defined in the case of 15-crown-5C$NaClO_4$ by a mean plane containing the O atoms and the perpendicular to this plane as the *Z* axis, and in the case of 15-crown-5C·NaI the Na—-I axis was chosen as the *Z* axis.

Dynamic averaging via the merry-go-round motion was then calculated, using the observed low-temperature static ^{2}H NMR line-shape parameters for the starting tensor, for each of the four sets of 5 D sites. The averaged tensors were diagonalised to obtain the principal components for the f.m.l. powder line shape. The resulting numbers are given in

Table 2. Calculated averaged line-shape components (kHz) for 15-crown-5·NaI for the four sets of exchanging deuterons.[a]

Tensor	$\Delta\upsilon_{xx}$	$\Delta\upsilon_{yy}$	$\Delta\upsilon_{zz}$
1	12.9 (13)	89.1 (89)	102.0 (102)
2	0.2 (14)	60.8 (50)	61.0 (64)
3	9.1 (9)	101.4 (101)	110.5 (110)
4	5.2 (12)	99.2 (88)	104.4 (100)

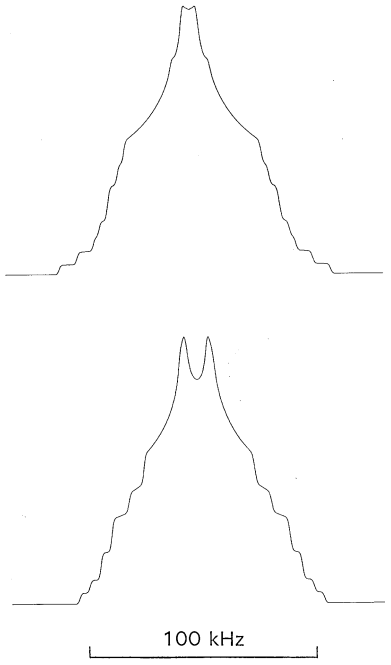
[a]Based on crystal structure with <DCD = 100°. Values in parentheses are one set of adjusted values that produce a line shape that reasonably approximates the observed shape of the spectra at 327–337 K.

Table 3. Calculated averaged line-shape components (kHz) for 15-crown-5·$NaClO_4$ for the four sets of exchanging deuterons.[a]

Tensor	$\Delta\upsilon_{xx}$	$\Delta\upsilon_{yy}$	$\Delta\upsilon_{zz}$
1	6.0 (14)	60.8 (49)	66.8 (63)
2	5.4 (10.5)	84.0 (78.5)	89.4 (89)
3	1.8 (10.5)	75.0 (78.5)	76.8 (89)
4	16.0 (9)	104.0 (99)	120.0 (108)

[a]Based on crystal structure with <DCD = 100°. Values in parentheses are one set of adjusted values that produce a line shape that reasonably approximates the observed shape of the spectra at 306–348 K.

Fig. 9. Simulated fast motion limit line shapes for the merry-go-round motion in 15-crown-5·$NaClO_4$: (top) based on the crystallographic data with <DCD = 100°; (bottom) based on slightly modified averaged tensors.

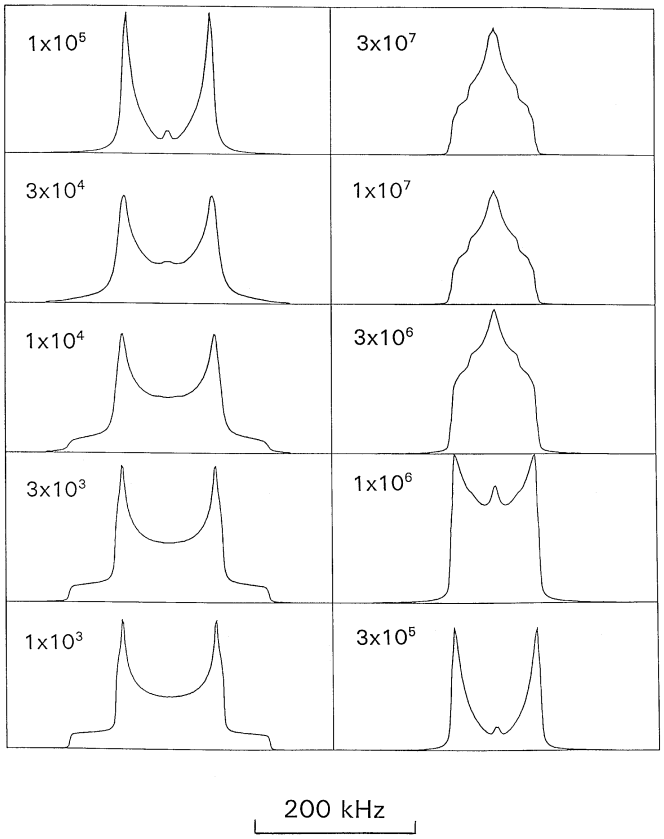


Tables 2, 3. The final calculated spectrum was then obtained by superimposing the four averaged line shapes, see Fig. 9, top, for 15-crown-5·$NaClO_4$.

The comparisons with the fast motion limit experimental spectra are very encouraging and, since we do not really expect that all the C—D bonds will have the orientations artificially defined by the <DCD = 100°, it is not too unreasonable to expect that small changes should bring the observed and calculated patterns into agreement. Indeed, in

© 1999 NRC Canada

Fig. 10. Simulated line shapes for the merry-go-round motion in 15-crown-5·NaI as a function of jump rate (s^{-1}), based on the crystallographic data with <DCD = 100°.



this regard the simulations are very useful in that they indicate how the features of the observed spectra might be broken down into four overlapping tensor line shapes. Possible tensors, determined in this way, are given in parentheses in Tables 2, 3, and the corresponding simulated line shapes for both complexes compare very favourably with experiment, e.g., compare Fig. 9, bottom with Fig. 4.

Further support for the model comes from a comparison of the behaviour of the intermediate rate line shapes. Simulations were performed (with the <DCD = 100° orientations) using a kinetic exchange matrix that allowed jumps between adjacent -OCD_2CD_2- sites and results are shown for 15-crown-5·NaI in Fig. 10. The observed and calculated spectra both follow the same basic development: There is an initial loss of intensity of the wings and centre of the static spectrum to form a two-horned line shape, followed by a gradual in-filling of the centre of the spectrum to form a block shape and eventually the multi-featured f.m.l. line shape, which has an overall conical–pyramidal appearance.

What this exercise has shown is that the ^2H NMR line shapes for the RT phases of the 15-crown-5 complexes are consistent with the merry-go-round motion. The consistency of this model, together with the precedent of m-g-r motion in 18-crown-6 and 12-crown-4 complexes and the fact that no other motion that could fit the observables has been conceived, gives confidence that this model is indeed correct. In this work the analysis has had to be rather more qualitative than quantitative because of the complexity of the problem: due to the lack of simplifying symmetry there are just too many unknowns for a rigorous solution.

Unfortunately the RT structure of 21-crown-7·KI is not available, so interpretation of the NMR data is therefore more speculative. Of the very few crystal structures known, none have 21-crown-7 complexed with Na^+ (26–28). However, all of these structures have the 21-crown-7 in an elongated and distinctly non-planar rather than circular form, and in general 21-crown-7 would be expected to have considerably more possible conformations than 15-crown-5. The ^2H NMR results again indicate that all D atoms are involved in the dynamics of the RT phase, however, the line shapes develop a little differently from the 15-crown-5 complexes. In the f.m.l. for the RT phase there are four pairs of strong features that cannot be matched to two distinct tensors and closer inspection reveals other weaker features. This suggests that the spectrum is a composite of more than two averaged line shapes. The spectra are too narrow for up/down CD_2 flips, so once again the most probable motion is m-g-r. There is in fact no reason to expect the line shapes to develop in the same way as the 15-crown-5 complexes that were similar by virtue of their very similar conformations. Furthermore the equivalence of all the D atoms in the HT phase requires m-g-r motion to be involved in the overall dynamics of this phase (see below). The fairly strong temperature dependence of the f.m.l. line shapes between 290 K and the phase transition may be explained by a gradually changing conformation.

High-temperature phases

The HT phases are quite remarkable in having dynamic equivalence of all the deuterons. In terms of the ^2H NMR this means that the 4 independent sets of exchanging D sites are all behaving identically. It remains to answer how this can happen. Structural information would help, but unfortunately none of the HT phase crystal structures are known. However, clues can be found by observing how equivalence is achieved in the 18-crown-6·$2CH_2(CN)_2$ and 12-crown-4·LiCNS complexes. (Note that the statements made below refer to equivalence under m-g-r motion and do not necessarily apply to the static molecule):

In 18-crown-6·$2CH_2(CN)_2$ the symmetry alone (pseudo-D_{3d}) makes the 4 sets of 6 exchanging sites equivalent. Each C-D is either axial or equatorial and during each site-to-neighbouring-site jump switches from one to the other. Mirror planes perpendicular to the ring make the 2 C atoms in the O-CD_2-CD_2 unit equivalent, and an inversion centre ensures that "top" and "bottom" D atoms are equivalent, i.e., both sides of the ring are identical. No disorder is necessary.

In 12-crown-4·LiCNS the dynamically averaged spectrum shows a superimposition of two nonaxially symmetric line shapes, which indicates that there are two distinct groups of deuteron sites. A mirror plane perpendicular to the ring ensures equivalence of the 2 C atoms, but in this case it also creates a 50:50 positional disorder. This makes pairs of sets equivalent. The two faces of the 12-crown-4 ring are not identical (the ring coordinates to Li^+ positioned at the top side), so the pairs of sets correspond to Ds on the top or on the bottom.

Contrast these with the RT phases of the 15-crown-5 complexes where the ring has no symmetry: The Na^+ is to one

Table 4. Comparison of factors involved in the dynamics of several crown ether complexes.

Crown complex	Equivalence of four sets of D	Top/bottom equivalence	Disorder	No. of sites for each D
18-Crown-6·$2CH_2(CN)_2$ (5)	All equivalent			6
12-Crown-4·LiCNS (6)	Two pairs equivalent			8
15-Crown-5·NaI or $NaClO_4$ RT phases	All *non*-equivalent			5
15-Crown-5·NaI or $NaClO_4$ HT phases	All equivalent			$n \times 10^a$, $n > 2$
21-Crown-7·KI HT phase	All equivalent			14 or $n \times 14$

[a]Multiple of 10 required to account for axial symmetry.

side of the ring, so top and bottom faces are different, and there is no mirror plane, so the 2 C are inequivalent. All four sets of D remain inequivalent.

Thus it can be seen that various combinations of symmetry and dynamic disorder produce different degrees of equivalence. To make all four sets of exchanging D dynamically equivalent there are two major requirements:

(*a*) the two C atoms in an O-CD_2-CD_2 unit must be made equivalent.

(*b*) the top and bottom faces of the ring must be made equivalent.

The first can be achieved by having *(i) a mirror plane perpendicular to the ring*, and in many cases this will imply a positional disorder. The second can be achieved in several ways *(ii) an inversion centre*; *(iii) a mirror plane in the ring plane*; *(iv) a C_2 axis in the ring plane.* In some cases this will impart disorder.

Clearly (*a*) and (*b*) must apply to the HT phases of 15-crown-5·NaI, 15-crown-5·$NaClO_4$ and 21-crown-7·KI. For the 15-crown-5 complexes the averaged HT line shape is also axially symmetric. Axial symmetry in an averaged line shape is generally indicative of reorientation about an *n*-fold axis ($n > 2$). It is possible that this could be from a fivefold symmetric molecular conformation, but in general fivefold conformations are not energetically favoured (25, 29), although one complex, (15-crown-5)$_2$·$BaBr_2$·$2H_2O$, with a pseudo-C_5 conformation is known (30). Also, true fivefold symmetry in crystals is not common. A more likely alternative is to have dynamic disorder of a non-fivefold molecular conformation about a crystal symmetry axis with $n > 2$; quite possibly $n = 4$, perhaps in a tetragonal structure. For the 21-crown-7 complex the averaged HT line shape is non-axially symmetric with ~1, so this cannot have any *n*-fold symmetry. This is in keeping with the elongated forms of the known structures. Table 4 compares the factors involved in dynamic averaging in all the crown complexes discussed above. Another point of interest is that in transforming from the RT to HT phases there will have to be a rearrangement of the guest atoms so that both faces of the ring are identical.

Conclusions

It has been shown that the solid crown ether complexes 15-crown-5·NaI, 15-crown-5·$NaClO_4$, and 21-crown-7·KI have several solid phases.

^{2}H NMR line-shape studies of the room temperature phases show onset of a crown motion above 200 K that is rapid, with respect to the reciprocal of the static quadrupolar coupling constant, a little above room temperature. Detailed analysis leads to the conclusion that this motion is similar to the merry-go-round motion observed in 18-crown-6 complexes, where O-CH_2-CH_2 units exchange sites around the ring, simultaneously adjusting their conformation to fit the site. The rather complicated line shapes are composed of four superimposed line shapes that arise from four inequivalent sets of exchanging deuterons.

In the high-temperature phases all the deuteron sites around the rings become dynamically equivalent, and, though the structures are not known, it has been demonstrated how this may be brought about through a combination of crystal symmetry and disorder on top of the m-g-r motion. It is likely that the 15-crown-5 dynamics involve reorientation about an *n*-fold ($n > 2$) crystal axis involving disorder. It would be very interesting, though experimentally challenging, to obtain the HT X-ray crystal structures to confirm these inferences.

It is remarkable that motion in these large macrocycles is so easy in the solid state, and it is probably the fact that the molecule rotates within itself that allows this to occur with a relatively small activation energy.

Finally, these complexes will make fine new additions to the rides at "the molecular fairground."

Assignment of ^{1}H and ^{13}C spectra for polyprenol-12, a molecule with severe ^{1}H and ^{13}C spectral crowding, with the aid of high-resolution, ^{13}C-detected, ^{13}C–^{1}H shift correlation spectra

William F. Reynolds, Stewart McLean, Helen Jacobs, and Wayne W. Harding

Abstract: Polyprenol-12 contains a linear sequence of 12 isoprene units. As a result, there is severe crowding in several regions of the ^{1}H and ^{13}C spectra. Nevertheless, it is possible to assign a substantial majority of individual resonances as well as to confirm the number and sequence of *E* and *Z* isoprene units with the aid of high-resolution (0.001 ppm along each axis) ^{13}C-detected ^{13}C–^{1}H shift correlation spectra. By contrast, the corresponding ^{1}H-detected sequences (e.g., HSQC and HMBC) do not have sufficient resolution to allow these assignments, in spite of their higher sensitivity.

Key words: ^{13}C-detected 2D shift correlation, polyprenol 12, spectral assignments.

Résumé : Le polyprénol-12 comporte une séquence linéaire de 12 unités isopréniques. Il en résulte que, pour ce composé, plusieurs régions des spectres RMN du ^{1}H et du ^{13}C présentent un important encombrement. Faisant appel aux spectres du ^{13}C, à haute résolution (0,001 ppm sur chacun des axes), avec corrélation ^{13}C–^{1}H des déplacements, il est toutefois possible de faire l'attribution de la majorité des résonances individuelles. Toutefois, malgré leur sensibilité plus élevée, les spectres des séquences correspondantes avec détection du ^{1}H (par exemple, « HSQC » et « HMBC ») ne conduisent pas à des résolutions qui permettent de faire ces attributions.

Mots clés : corrélation bidimensionnelle des déplacements de raies de ^{13}C observées, polyprénol 12, attributions spectrales.

[Traduit par la Rédaction]

Introduction

Due to their significant sensitivity advantages, ^{1}H-detected ^{13}C–^{1}H shift correlation sequences such as HSQC (1), HMQC (2), and HMBC (3) have largely replaced the earlier ^{13}C-detected versions of these experiments. However, the price that one pays for the higher sensitivity is that the intrinsic resolution obtainable with the former sequences (particularly along the F_1 or ^{13}C axis) is poorer than with ^{13}C-detected sequences. First, the ^{1}H multiplet structure for each cross-peak also appears along the F_1 axis in HMQC and HMBC (but not HSQC) spectra (4). Second, with ^{1}H-detected sequences, it is the much wider ^{13}C axis that is time-incremented, increasing the difficulty of obtaining excellent ^{13}C resolution. The latter problem can be partially overcome by using forward linear prediction to increase the number of t_1 data points (5). However, even with very extensive linear prediction (e.g., prediction of 256 F_1 data out to 4096 with zero filling to 8192 for an HSQC spectrum with a ^{13}C spectral window of 6300 Hz (5)), we find that the best obtainable ^{13}C resolution using linear prediction is ca. 4 Hz. This is considerably broader than typical natural line widths of ^{13}C peaks, suggesting a not surprising limitation in the ability of linear prediction to precisely define line shapes. The limiting ^{13}C resolution is generally much worse for HMQC and HMBC spectra where it is determined by ^{1}H multiplet widths. These multiplet widths also determine effective F_2 resolution in many cases.

On the other hand, ^{13}C-detected sequences with ^{1}H decoupling during acquisition provide singlets along the F_2 (^{13}C) axis. Since the acquisition time is usually a small fraction of the experiment time, one can acquire a large number of t_2 data points to give excellent ^{13}C resolution without paying a high cost in time. By contrast, doubling the

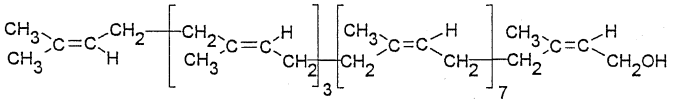
number of t_1 (^{13}C) increments in a ^1H-detected 2D experiment doubles the experiment time. Second, several of the ^{13}C-detected sequences provide partial or full ^1H–^1H decoupling along the F_1 (^1H) axis. For example, inclusion of a BIRD pulse (6) in the basic HETCOR sequence (7) eliminates all ^1H–^1H coupling except geminal coupling between non-equivalent methylene protons (8). Alternatively, we have developed a constant time version of HETCOR that provides full ^1H–^1H decoupling (9). For *n*-bond (n = 2 or 3) correlation experiments, Kessler's constant time COLOC sequence (10) provides full ^1H–^1H decoupling while our FLOCK sequence (11) provides partial ^1H–^1H decoupling.

Thus, it is possible with ^{13}C-detected sequences to obtain high-resolution ^{13}C–^1H shift correlation spectra with each peak being a singlet along F_1 and a singlet or partially collapsed multiplet along F_2. While the improved resolution that these sequences provide is often not needed, in some cases it is absolutely essential for structural and (or) spectral assignments (12). Furthermore, we have recently shown that the use of modern microprobe and microtube technology can significantly reduce the amount of sample needed for these experiments (13). We now provide a particularly striking example of the use of ^{13}C-detected experiments to determine the structure and to assign almost all resolved carbons of a natural product with severe ^1H and ^{13}C spectral crowding. The compound is the polyprenol, **1**, composed of a chain of 12 isoprene units.



1

Results and discussion

After isolation (see Experimental), **1** was initially characterized in $CDCl_3$ solution by a combination of ^1H, ^{13}C, and DEPT-edited ^{13}C spectra. Although showing severe overlap in several ^1H and ^{13}C spectral regions, the spectra suggested that **1** was composed of a chain of isoprene units, including terminal isoprene units **2A** and **2B** and a number of internal *E* (**2C**) and *Z* (**2D**) units.

The integrated ^1H spectrum suggested the presence of 13 CH_3 groups, i.e., a total of 12 isoprene units. This was confirmed by a high-resolution mass spectrum that showed a parent ion corresponding to $C_{60}H_{98}O$. The ^{13}C spectra showed weak overlapping peaks near δ 16 and δ 40, respectively consistent with the chemical shifts of CH_3 groups and CH_2 groups *gem* to CH_3 in *E* units (14). The areas of these peaks relative to other resolved CH_3 and CH_2 signals suggested the presence of 2 or more likely 3 *E* units, with the ambiguity due to the spectral overlaps.

A search of the literature suggested that **1** was a member of a class of compounds called polyprenols (15). Polyprenols from plant sources usually have 9–13 isoprene units with 11 or 12 being most common (15). Due to the biosynthetic origin of these compounds (16), they typically have a sequence of 2 or 3 *E* units adjacent to the ω terminal isoprene unit, **2A**, followed by a number of *Z* units and terminated by a hydroxylated isoprene unit, **2B**. However, polyprenols with only *E* units are also known (15).

Characterization of these polyprenols has relied heavily on empirical ^1H (16) and ^{13}C (14) chemical shift correlations. It has been demonstrated that the ^1H spectra of polyprenols, particularly in the CH_3 region, are much better resolved in C_6D_6 than in $CDCl_3$ (17). However, there have been no attempts to carry out complete and rigorous spectral assignments for these polyprenols or to use detailed 2D investigations to confirm stereochemical sequences. Consequently, we decided to investigate the extent to which it was possible to assign the structure and the ^1H and ^{13}C spectra of **1**, with the aid of high-resolution ^{13}C-detected ^1H–^{13}C shift correlation sequences.

Spectra were obtained at 500 MHz (^1H) and 125 MHz (^{13}C) at 25°C, using a 3 mm microprobe optimized for ^{13}C detection. The sample contained 12 mg of **1** dissolved in ca. 160 μL of C_6D_6, with 0.1% TMS as internal standard. A microprobe was used since, in our experience (13), this gives better resolution than a 5 mm probe and high resolution was considered critical. The observed ^1H resolution, non-spinning, was 0.42 Hz for the TMS signal. The ^1H spectrum for the CH_3 region showed reasonable spectral dispersion (see Fig. 1*a*). $CDCl_3$:C_6D_6 solvent mixtures were also tried but they gave poorer resolution of overlapping peaks. Decoupling in the center of the olefinic region combined with resolution enhancement allowed clear resolution of 9 of the 13 CH_3 signals while the other 4 seemed completely overlapped. (See Fig. 1*b*). However, the olefin and methylene proton regions were still badly overlapped, in part due to the presence of vicinal coupling. By contrast, a preliminary ^{13}C spectrum suggested that the individual peaks were very narrow. Consequently, we obtained a ^{13}C spectrum with unusually good data point resolution (65 536 data points for a spectral window of 18 431 Hz, with zero-filling to 524 288). While zero filling to 524 288 gives a data point resolution of ca. 0.07Hz/point, defining resolved line positions to better than 0.001 ppm, zero filling beyond a factor of two does not result in any further line narrowing of resolved lines (18). Consequently, the narrowest observable lines should be about 18 431/65 536 ≈ 0.3 Hz. In fact, the average observed line width (with no weighting function) was 0.4 Hz for CH_3 carbons and non-protonated olefinic carbons and 0.6 Hz for the remaining carbons. This is considerably less than one would normally expect for protonated carbons in a compound of over 800 molecular weight, suggesting a high degree of internal chain motion in **1**. This is not surprising, since **1** resembles a short segment of natural rubber. It has long been known that internal chain mobility allows one to observe relatively sharp ^{13}C lines even in a solid sample of

natural rubber (19). The excellent resolution allowed the observation of three completely resolved CH_3 signals between δ 16.124–16.140, i.e., within two Hz at 125 MHz. This and the observation of three resolved CH_2 signals in the range δ 40.206–40.250 confirmed the presence of 3 *E* isoprene units. Overall, 47 of the possible 60 ^{13}C signals were observed, including 11 of 12 non-protonated olefinic ^{13}C signals and 10 of 12 protonated olefinic ^{13}C signals. Figure 2 shows an expansion of part of the non-protonated olefinic region. Six signals are observed in a region of only 0.11 ppm, five corresponding to single carbons and the sixth corresponding to two unresolved carbons. The resolution of CH_2 and CH_3 signals is not as complete with 9 of 13 CH_3 signals and 17 of 23 CH_2 signals observed. The partial overlap is not surprising since the proposed structure has a sequence of seven identical *Z* isoprene units.

A series of ^{13}C-detected ^{1}H–^{13}C shift correlation spectra was next acquired in an attempt to assign ^{1}H and ^{13}C spectral peaks for **1** as completely as possible, as well as to confirm the presumed sequence of internal *E* and *Z* units. First, two one-bond ^{1}H–^{13}C shift correlation spectra were obtained using the version of HETCOR incorporating a BIRD pulse (8). Since **1** contains no chiral carbons, this sequence provides a singlet for each ^{1}H signal. One spectrum covered the aliphatic carbon – proton spectral regions while the second covered the olefinic carbon/proton spectral windows. In each case, the data point resolution was better than 0.01 ppm along each spectral axis (see Experimental for details). Two spectral expansions from the aliphatic carbon/proton spectrum are illustrated in Figs. 3 and 4, respectively corresponding to *E* CH_2 units at δ_C 40.2 and *E* CH_3 units at δ_C 16.1. These illustrate the excellent resolution obtainable for both

^{1}H and ^{13}C axes using the ^{13}C-detected sequence. In fact, due to full ^{1}H–^{1}H decoupling by the BIRD pulse, the ^{1}H resolution is actually better for the 2D spectra than for the corresponding 1D spectra where ^{1}H–^{1}H multiplet structure leads to spectral overlap, particularly for CH_2 protons. To confirm the resolution advantages of the ^{13}C-detected spectra, a pair of HSQC spectra were obtained for the same spectral regions, making use of extensive linear prediction to give comparable data point resolution along the two axes (see Experimental for details). The inferior resolution of the ^{1}H-detected HSQC spectra is obvious in Figs. 3 and 4. This reflects (*i*) the intrinsically limited ^{13}C resolution with HSQC (see above) and (*ii*) the presence of ^{1}H–^{1}H multiplet structure along the ^{1}H axes of the HSQC spectra, particularly for CH_2 groups. Obviously, it is possible to make spectral assignments from the HETCOR spectra, which are impossible with the HSQC spectrum. It should be noted that the spectral resolution would be even worse with an HMQC spectrum due to the presence of ^{1}H–^{1}H multiplet structure along both F_1 and F_2. Finally, it should also be noted that the HETCOR spectrum was obtained in absolute value mode while the HSQC spectrum was obtained in phase sensitive mode. The latter should give better resolution due to the better line shapes in phase sensitive mode. Thus, the resolution advantages of HETCOR should be even greater if the spectrum were obtained in phase sensitive mode.

The HETCOR spectra allowed assignment of ^{1}H chemical shifts of protons to their directly bonded carbons. Next, to complete the assignments of carbons and hydrogens to individual isoprene units as well as the sequences of isoprene units, two *n*-bond (n = 2 or 3) ^{13}C-detected ^{13}C–^{1}H shift correlation spectra were obtained. These were obtained using the phase-sensitive version (20) of our FLOCK sequence (11). Arguably, there are advantages to using COLOC (10) over FLOCK, since each proton signal appears as a singlet with COLOC, while FLOCK provides only partial ^{1}H–^{1}H decoupling. However, there also disadvantages to COLOC (11). COLOC is a "constant time" sequence in which ^{1}H chemical shift information is generated by incrementally moving a pair of ^{1}H and ^{13}C 180° pulses through the evolution period prior to polarization transfer from ^{1}H to ^{13}C. For ^{1}H singlets, optimum polarization transfer occurs when the

constant time, $T \approx (1/2)^n J_{CH}$. However, for ^1H multiplets, proton coupling vectors also evolve and signal intensity disappears if $T = (1/2)^n J_{HH}$. Since $^n J_{CH}$ and $^n J_{HH}$ are similar in magnitude in **1** and since there is a range of $^n J_{CH}$ values, it is difficult to find an optimum value for *T*. While these problems can be minimized by choosing a value of *T* that is considerably smaller than 1/2 $^n J_{CH}$, this severely limits the attainable $F_1(^1H)$ resolution. Second, in order to obtain a phase sensitive spectrum, it is necessary that no ^1H chemical shift evolution occurs at $t_1 = 0$. In the case of COLOC, this requires that the pair of 180° pulses be initially at the midpoint of *T*, further limiting the attainable F_1 resolution.

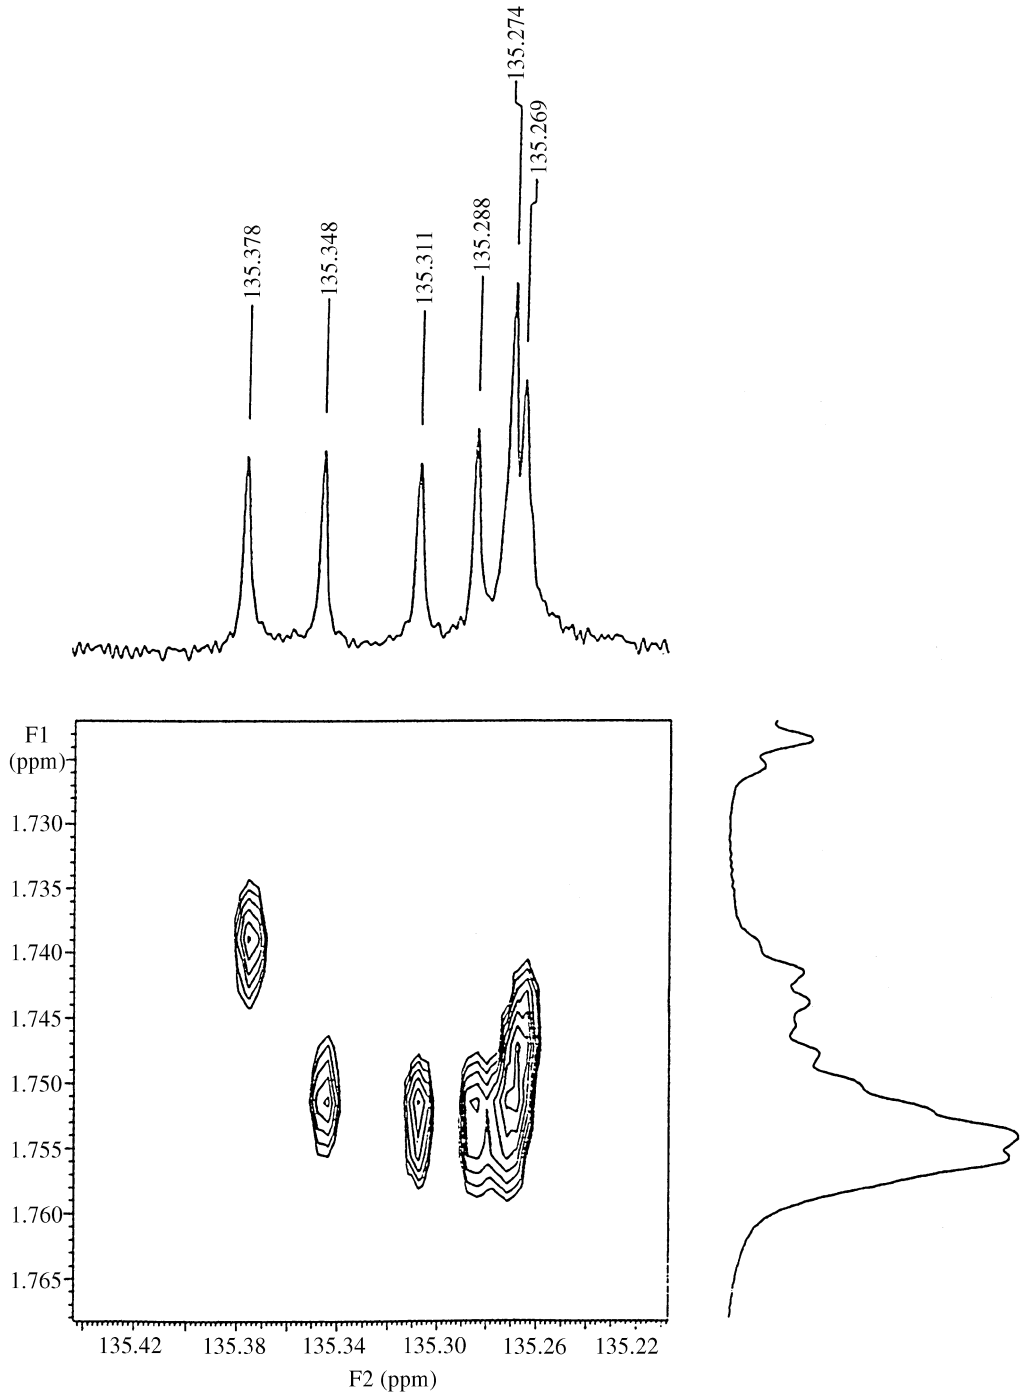
Fig. 5. Expansion of phase-sensitive FLOCK spectrum of **1**, illustrating two-bond cross-peaks between CH_3 groups and non-protonated olefinic carbons.

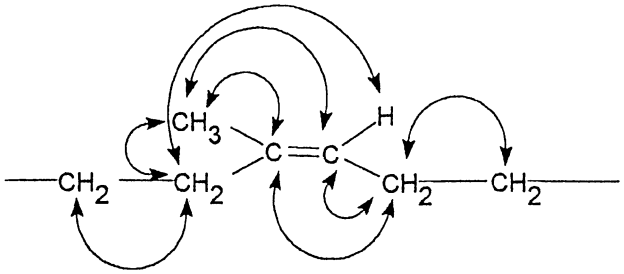


Therefore, we chose phase sensitive FLOCK that has no intrinsic limitations on the attainable F_1 resolution.

Two FLOCK spectra were recorded. In each case, the full ^1H spectral window was used while the ^{13}C spectral window was narrowed on either the aliphatic or olefinic ^{13}C spectral window. As a result of the wider ^1H spectral window, this ^1H resolution was slightly poorer than for the HETCOR spectra (or 2 Hz/point, i.e., 0.004 ppm/point), but still with excellent ^1H resolution. In each case, the ^{13}C resolution was identical to that in the HETCOR spectrum for the same carbon region (see Experimental for details).

A representative expansion of one of the FLOCK spectra is illustrated in Fig. 5. This illustrates the cross-peaks between CH_3 protons and some of the olefinic carbons. As a result of this spectral expansion and similar expansions for other olefinic carbons, it was possible to correlate 9 of 13

© 1999 NRC Canada



3

CH_3 ^1H signals with pairs of olefinic carbons in individual isoprene units. The remaining four CH_3 signals could not be definitively assigned since their chemical shifts were identical (see Fig. 1). Other regions of the two FLOCK spectra establish correlations for CH_3 protons to geminal CH_2 carbons, CH_2 protons to olefinic carbons, and ^1H–^{13}C correlations within coupled CH_2–CH_2 units, (see **3** for an illustration of key *n*-bond cross-peaks). The former cross-peaks allowed completion of the ^1H and ^{13}C assignments for eight of the 12 isoprene units, while the two-bond ^1H–^{13}C correlations within coupled CH_2–CH_2 units allowed determination of the sequence of isoprene units.

For the remaining four internal isoprene units, ^1H chemical shifts for corresponding protons in the four units are identical within 0.01 ppm. Thus, even though there is partial resolution of olefinic carbons, it is not possible to unambigously assign these carbons to individual isoprene units. Nevertheless, the fact that one can assign so many of the carbon and hydrogen signals in a compound with such severe spectral crowding, clearly demonstrates the great value of ^{13}C-detected shift correlation sequences for this kind of assignment problem. The completed assignments are given in Table 1.

Experimental

Extraction and isolation

The compound was isolated from *Guarea Jamaicensis* (Meliaceae). The plant material was collected at Gourie Forest, Manchester, Jamaica, in September 1996. Voucher specimens are preserved in the Herbarium, University of the West Indies, Mona, Jamaica. Dried, milled leaves and twigs of *G. Jamaicensis* (2.1 kg) were percolated with hexane (3 × 4 L) and the combined hexane solutions concentrated in vacuo to yield a green gum (20 g). The gum was subjected to column chromatography in acetone–hexane mixtures (5–20% acetone). The residue from the fractions eluted with 5% acetone–hexane (1.33 g) was rechromatographed by column chromatography in 3% ethyl acetate–hexane to provide polyprenol-12 (439 mg) as a colourless viscous oil.

NMR spectroscopy

Initial ^1H and ^{13}C spectra were obtained at 200 MHz (50 MHz for ^{13}C) on a Varian GEMINI-200 spectrometer, using 50 mg of **1** in 1 mL of $CDCl_3$ in a 5 mm tube at ambient temperature. Most subsequent spectra were obtained on a Varian Unity 500 spectrometer equipped with a 3 mm Nalorac microprobe optimized for ^{13}C detection (^{13}C 90° pulse width = 6.5 μs, ^1H decoupler 90° pulse width = 10 μs). Comparison HSQC and HMBC spectra were obtained with a 3 mm Nalorac inverse detection probe. Twelve milligrams of **1** were dissolved in ca. 160 μL of $CDCl_3$ containing 0.1% tetramethylsilane. Spectra were acquired under variable temperature control at 25°C. ^1H (500 MHz) and ^{13}C (125 MHz) spectra were respectively obtained with a 3240 Hz spectral window with 32 758 data points (zero filled to 131 072) and for an 18 431 Hz spectral window with 65 536 data points (zero filled to 524 288). No weighting was initially used for either spectrum but the ^1H spectrum was subsequently reprocessed with a resolution enhancement function. The 2D BIRD-decoupled HETCOR spectrum for the aliphatic region had a ^{13}C (F_2) spectral window of 3737 Hz and a ^1H (F_1) spectral window of 595 Hz with 4096 data points (zero filled to 8192), 256 time increments, 24 transients per increment, and a relaxation delay of 0.75 s. The spectrum was acquired in absolute value mode with ^1H WALTZ decoupling during acquisition. The 256 F_1 increments were linearly predicted to 512 points with zero filling to 1024 points. π/3 shifted sine bell processing was applied along each axis. For the olefinic HETCOR spectra, the ^{13}C spectral window was 532 Hz and the ^1H spectral window was 335 Hz with 512 data points (zero filled to 1024) and 256 time increments, linearly predicted to 512 points with zero filling to 1024 points. Two phase sensitive FLOCK spectra were obtained. The spectrum for the ^{13}C aliphatic region used the same ^{13}C spectral window and data points as the corresponding HETCOR spectrum as previously. However, the spectrum covering the ^{13}C olefinic region used a ^{13}C spectral width of 2058 Hz (with 2048 data points zero filled to 4096) to include both protonated and non-protonated olefinic carbons. A common ^1H spectral window of 2149 Hz with 2 × 256 time increments with linear prediction of each data set to 1024 and zero filling to 2048. Sixty-four transients were collect per time increments and Gaussian weighting was applied along each axis.

The comparison HSQC and HMBC spectra were obtained using a Nalorac inverse detection 3 mm microprobe. In each case, parameters were chosen to give the same data point resolution as the corresponding ^{13}C detected experiments, e.g., for the phase sensitive HSQC spectrum for the aliphatic region, the ^1H (F_2) spectral width was 595 Hz with 512 data points (zero filled to 1024) while the ^{13}C (F_1) spectral window was 3737 Hz with 2 × 512 time increments, with each data set linearly predicted to 4096 points and zero filled to 8192. GARP ^{13}C decoupling was applied during acquisition and Gaussian weighting was used for each axis.

Acknowledgments

Dr. George R. Proctor and Mr. Jonathan Littau assisted with the plant collection and identification. Financial assistance from the Natural Sciences and Engineering Research Council of Canada (NSERC) (W.F.R.), the CIDA–UWI Institutional Strengthening fund (W.W.H.), and the UWI Research Fund (H.J.) is gratefully acknowledged. Finally, W.F.R. acknowledges his great debt to Professor Ted Schaefer for introducing him to NMR spectroscopy and for encouraging him to pursue a career in research.

Tris{(diphenylphosphino)dimethylsilyl}methane: a sterically hindered tripod

Dawn M. Friesen, Robert McDonald, and Lisa Rosenberg

Abstract: The synthesis and characterization of a new tripodal tris(phosphine) molecule, $HC(Me_2SiPPh_2)_3$ (**3**) is described. The impact of dimethylsilyl "elbows" on the conformational preferences of this tris(dimethylsilyl)methane core in solution and in the solid state was assessed for **3** and its precursor $HC(Me_2SiBr)_3$ (**2**). Hindered rotation around the "arms" of **3**, evident from its solid state structure, has been probed in solution by variable temperature, $^1H\{^{31}P\}$ NMR spectroscopy, and molecular modelling studies based on the solid state structure of **2** also indicate significant barriers to rotation in this molecule. The susceptibility of **3** to cleavage of the P—Si bonds by protic reagents is described.

Key words: tripodal tris(phosphine), polyphosphine, trisilylmethane, C_3-symmetry.

Résumé : On décrit la synthèse et la caractérisation d'une nouvelle molécule tris(phosphine) tripodale, $HC(Me_2SiPPh_2)_3$ (**3**). On a évalué l'impact des « coudes » diméthylsilyles du composé **3** et de son précurseur, $HC(Me_2SiBr)_3$ (**2**), sur les préférences conformationnelles de ce noyau tris(diméthylsilyl)méthane en solution et à l'état solide. La rotation empêchée autour des « bras » du composé **3**, évidente dans la structure à l'état solide, a été étudiée en solution à l'aide de la spectroscopie RMN du $^1H\{^{31}P\}$ à température variable; des études de modélisation moléculaire sur la structure du composé **2** à l'état solide indiquent qu'il existe aussi des barrières importantes à la rotation dans cette molécule. On décrit la susceptibilité du composé **3** au clivage des liaisons P-Si par des réactifs protiques.

Mots clés : tris(phosphine) tripodale, polyphosphine, trisilylméthane, symétrie C_3.

[Traduit par la Rédaction]

Introduction

The rich transition metal chemistry of tripodal tris(phosphine) ligands has evolved from a desire to exploit the general utility of the ancillary phosphine while establishing a greater degree of control over coordination environment during the activation of small molecules at metal centres (see, for example ref. 1). These facially-binding, chelating ligands promote reactivity at the coordinated metal centre by directing incoming substrates to coordination sites that are mutually *cis* and that are *trans* to the strongly labilizing phosphines. However, dissociation of a single arm of the coordinated phosphine during catalysis or stoichiometric reactions of tripodal phosphine complexes, (1*o*, 1*p*, 2) while in some cases necessary to allow coordination of substrate molecules, can complicate the reaction mechanisms and result in a loss of stereocontrol. The ease of this dissociation may be encouraged by flexibility at the "elbows" of tripodal ligands: rotation around bonds to the central atom of the tripod (and (or) around the P—X bonds) is required to allow the dissociated phosphine arm to move out of the metal's coordination sphere. If the barriers to such rotations can be increased, dissociation of a single arm should become entropically disfavoured. The conformational rigidity of such P_3 units may also be exploited to enforce specific macromolecular geometries, through their incorporation in larger organic or inorganic frameworks. We have begun investigating the effect of substituents at these elbows on the barriers to rotation in the arms of tripodal phosphine molecules, and report here the synthesis and characterization of a new tripod, tris{(diphenylphosphino)dimethylsilyl)}methane (**3**), which exhibits hindered rotation at its elbows as a result of the methyl substituents at silicon.

Results and discussion

Synthesis of tris{(diphenylphosphino)dimethylsilyl}methane, 3

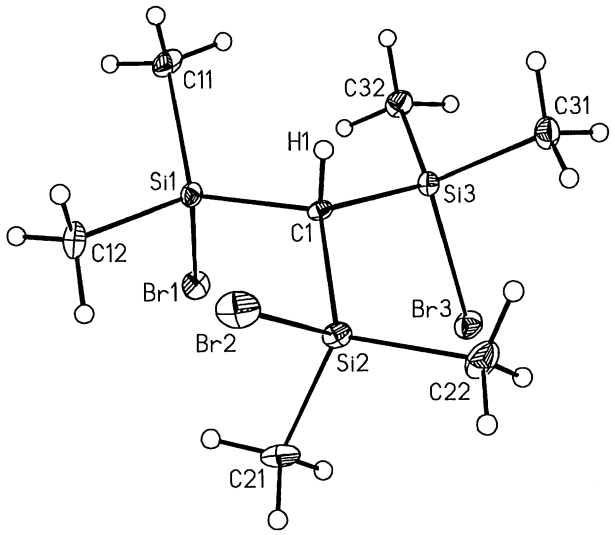
The tris-brominated trisilylmethane fragment, **2**, was used previously to prepare a range of tridentate amide ligands for early transition metals and complexes of the group 14 elements (4). Addition of three equivalents of lithium diphenylphosphide to **2** gives quantitative conversion, as determined by NMR spectroscopy, to tris{(diphenylphosphino)dimethylsilyl}methane, **3**, which can be isolated as a white powder in 62% yield after toluene extraction from the reaction residue (eq. [1]).[2]

Tripod **3** has some solubility in non-polar hydrocarbons and is extremely soluble in aromatic hydrocarbons, ethers, and chlorinated solvents. While only mildly susceptible to oxidation, both in solution and in the solid state, **3** does slowly decompose in air via hydrolysis of the P—Si bonds (vide infra).

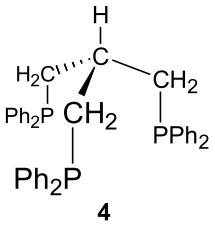
The effect of the $SiMe_2$ elbows on tripod conformation

Triphos ($H_3CC\{CH_2PPh_2\}_3$) and related tripodal tris(phosphine) ligands typically exhibit relatively unhindered rotation about the C—P bonds of each arm, which manifests itself in average solution structures of C_{3v} symmetry (5). Crystallographic studies of these molecules generally show unsymmetric solid state structures where inequivalent conformations at each of the three arms are attributed to solid state effects (6). An interesting exception is the structure of $HC(CH_2PPh_2)_3$ (**4**), an analogue of **3** with CH_2 elbows, in which a staggered conformation along each $C_{methine}$—CH_2 bond, with gauche $H_{methine}$-C-C-P torsion angles,[3] gives rise to a molecule of pseudo C_3 symmetry (7). The handedness of the resulting chiral conformation of this molecule is evident from the clockwise distribution of phosphine groups around the base of the tripod (anti-clockwise for the other enantiomer, which is present in equal abundance). Maximum separation of the phenyl rings in this C_3-symmetric structure is manifest in a "gearing" of the PPh_2 groups. However, the ^1H and $^{31}P\{^1H\}$ NMR spectra of **4** are consistent with its C_{3v} symmetry in solution, similar to other tripodal P_3 molecules. As described below, the decreased rotational barriers that should result from replacing C—P bonds in this molecule with Si—P bonds, as in **2** and **3** (an average bond lengthening of about 0.42 Å), appear to be offset by the steric requirements of the methyl substituents on silicon in these compounds.

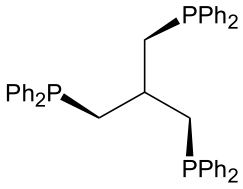
Fig. 1. Molecular structure of $HC(Me_2SiBr)_3$ (**2**). Non-hydrogen atoms are represented by Gaussian ellipsoids at the 20% probability level. Hydrogen atoms are shown with arbitrarily small thermal parameters.



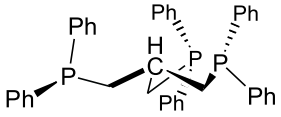
The precursor tripod, $HC(Me_2SiBr)_3$ (**2**) exhibits free rotation around bonds to the $SiMe_2$ elbows in solution. ^1H NMR spectra of **2** at varying temperatures as low as 90°C show negligible peak broadening, and the sharp singlet due to equivalent SiMe groups is consistent with an average structure of high symmetry (C_{3v}) for this molecule in solution. However, an X-ray crystallographic study of a single crystal of **2** shows it to be less symmetric in the



4



top view, solid state



side view, solid state

[2] An alternative synthesis of **3**, and some of its properties, were reported while this manuscript was in preparation. The authors report an 89% yield, but microanalysis indicates the presence of impurities (1.5% high in carbon, 1.3% low in phosphorus) (3*a*).
[3] In **4** these torsion angles are 48.5°, 51.0°, and 44.8°.

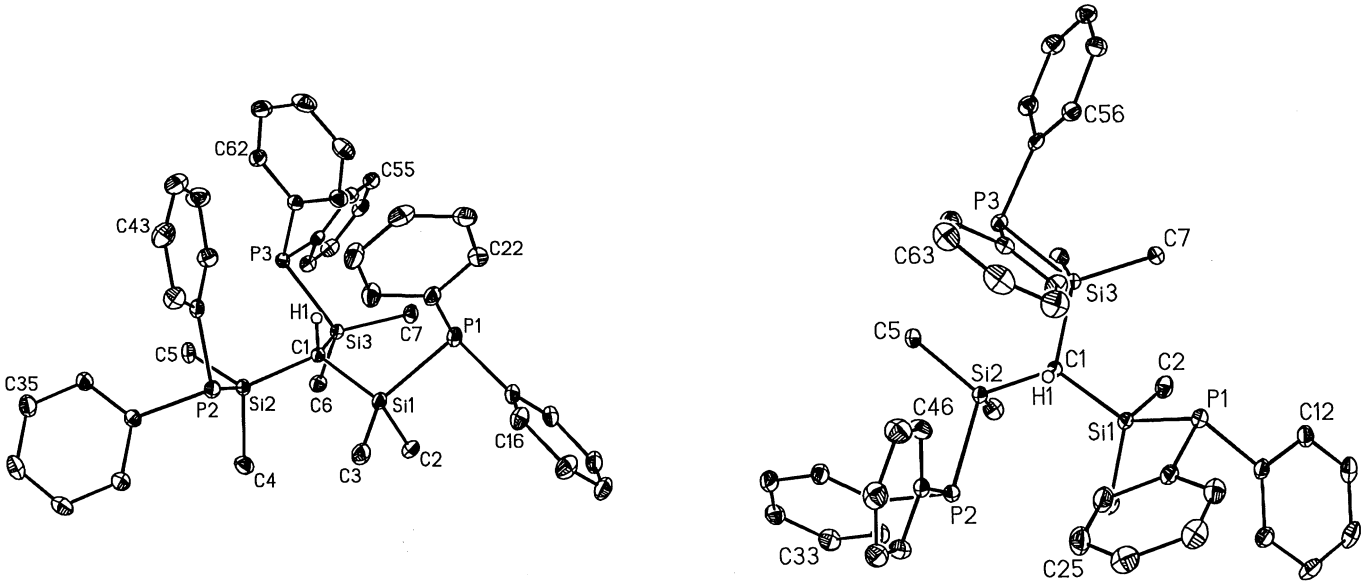
Fig. 2. Two views of the molecular structure of $HC(Me_2SiPPh_2)_3$ (**3**) (with methyl and phenyl hydrogen atoms omitted). The view on the right, approximately along the methine H1—C1 bond, illustrates the geared conformation of the PPh_2 groups, resulting in a pseudo-C_3 symmetry of the molecule.



and torsional angles.)[4] Molecular models of **2** built and minimized with HyperChem software (AM1) suggest the solid state structure is one of two lowest energy conformers, the second having a *syn–syn–anti* conformation. Both of these structures maximize the distance between $SiMe_2$ protons, alleviating steric repulsions around the Si_3 base of the tripod. Conformational stability of approximately 2–3 kcal/mol is thus obtained, relative to a more symmetric structure in which all three Si–Br's eclipse the central C—H bond (all *syn*) or one in which the Br's are all *anti* to the central C—H bond. Based on the crystallographically-determined molecular structure of **2**, the calculated barrier to rotation around a single arm ($C_{central}$–Si) of **2** is approximately 5 kcal/mol. The impact of the methyl substituents on silicon in this molecule is further demonstrated by a widening and flattening of the Si_3 tripodal base in its solid state structure: the Si-C-Si bond angles have widened from typical tetrahedral values to an average value of 115.2(4)°, the basal plane containing the three silicon atoms being only 0.418(8) Å from the central carbon. Such splaying of the three C—Si bonds has been observed for a tripodal tris(amine) compound and other molecules containing this tris(dimethylsilyl)methane core,(4*b*, 3*b*) while normal tetrahedral angles are observed at the central carbon for the less bulky $HC(CH_2PPh_2)_3$ (**4**) ($C\text{-}C_{central}\text{-}C$ (avg) = 110.3°) (7).

The steric effects of the $SiMe_2$ groups in the tris(dimethylsilyl)methane core are amplified upon replacement of the bromines in **2** with diphenylphosphine moieties. An X-ray crystallographic study of a single crystal of **3**[4,5] shows that in the solid state, the tripod exhibits pseudo-C_3 symmetry, similar to the molecular structure of $HC(CH_2PPh_2)_3$ (**4**). (Views of one of the two enantiomeric forms of **3** (present in equal abundance in the crystal lattice) are shown in Fig. 2, and some relevant bond distances and angles, and torsional angles are shown in Table 3.) As for **4**, this pseudo-chirality arises from gauche conformations along each of the three H–C–Si–P fragments, and is accompanied by a "geared" distribution of phenyl substituents on phosphorus, around the base of the tripod. Staggered conformations along the C—Si bonds in this structure direct one silylmethyl group on each arm toward the lone pair on phosphorus on the adjacent arm. The second silylmethyl group on each arm points down, approximately *anti* to the $H_{methine}$. Maximum distance between phenyl and methyl substituents is thus achieved. As for compound **2**, a widening of the Si···Si distances in **3** to accomodate the methyl substituents on silicon gives an average Si-C-Si angle of 113.74(11)° and the central carbon is just 0.484(2) Å from the plane containing all three silicons.

The solid state, geared structure of **3** appears to be maintained in solution: variable temperature, $^1H\{^{31}P\}$ NMR spec-

[4] Tables of atomic coordinates for all atoms, a complete listing of bond lengths and angles, torsional angles, least-squares planes, anisotropic thermal parameters, derived positions for the hydrogen atoms, and ORTEP diagrams for the structures of compounds **2** and **3** are available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. Bond lengths and angles and hydrogen positions for compound **2** have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. Structure factors are no longer being deposited and can be obtained on request from the author.

[5] The X-ray structure of **3** reported here is identical to one published by Avent et al. (3) while this manuscript was in preparation. To simplify our discussion of the solid state and solution structures of **3**, and our comparison of the solid state structures of **2** and **3**, we have included some details of our crystallographic results.

Table 4. Phosphorus–silicon bond cleavage reactions.

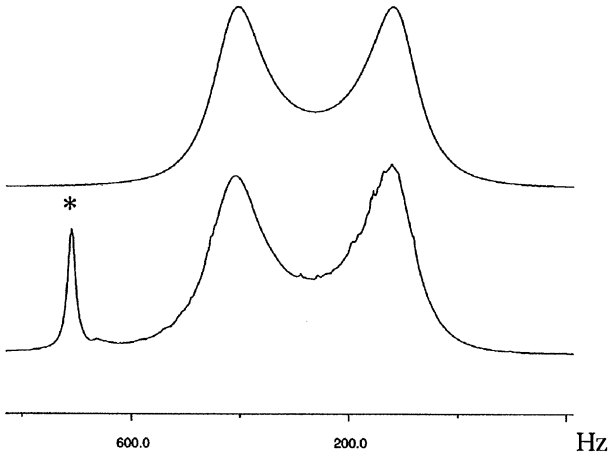
Expt.	Concentration of **3** (M)	Solvolysis conditions[a]	Result
1	0.057	H_2O, 100 equiv.[b], 25°C	14% cleavage in 7.5 h 100% cleavage in 3.5 days
2	0.057	H_2O, 100 equiv.[b], 123°C	100% cleavage in 6.5 h
3	0.051	CH_3OH, 100 equiv., 25°C	26% cleavage in 4 h 100% cleavage in 3 days
4	0.051	CH_3OH, 100 equiv., 123°C	100% cleavage in 3.5 h
5	0.057	0.01 M HCl (aq)[c], 25°C	100% cleavage in 4 h

[a]All solvolysis reactions carried out in d_8-toluene in sealed NMR tubes.

[b]Total H_2O in sealed sample, both dissolved and undissolved in d_8-toluene.

[c]100 equiv. H_2O[b].

Fig. 3. The SiMe region of the $^1H\{^{31}P\}$ NMR spectrum of **3** at 190 K: the upper trace is the calculated spectrum, the lower is the experimentally observed spectrum (an asterisk marks the signal due to the $H_{methine}$).



troscopy (500 MHz) confirms the mutual exchange of silylmethyl groups between two diastereotopic sites on each of the three $SiMe_2$ moieties in the molecule, consistent with a ground state solution conformation of C_3 symmetry. When a sample of **3** in d_8-toluene is cooled, the slightly broad singlet observed at 0.53 ppm in the room temperature spectrum undergoes decoalescence at about 195 K. Two broad singlets of equal relative intensity and centred around the original signal are observed in the spectrum of the sample at 180 K, the lowest temperature studied. At no temperature are signals observed by ^1H or $^{31}P\{^1H\}$ NMR that correspond to a less symmetric solution conformation, such as the solid state, *syn–anti–anti* conformation of compound **2**. The H_{ortho} and H_{meta} signals in the aromatic region of the $^1H\{^{31}P\}$ NMR spectrum of **3** also decoalesce as the sample temperature is lowered, while the H_{para} signal remains unchanged, apart from very slight broadening. Due to the complexity of overlapping signals in this region, only the H_{ortho} signals are clearly resolved at the low-temperature limit: again, the low-temperature pattern is consistent with a simple two-site exchange.[6]

The observed exchange of silylmethyl groups between diastereotopic sites in a ground state, C_3-symmetric conformation represents conversion between the two atropisomers of **3**, which are present in equal amounts (ie. the molecule is not optically active in solution). Such exchange requires rotation around the three $C_{methine}$—Si bonds in **3**, and the barrier to this rotation was evaluated through line-shape analysis of the SiMe peaks in the $^1H\{^{31}P\}$ NMR spectra recorded for **3** at low temperature. (See, for example, Fig. 3.) Rate constants calculated for the exchange process at various temperatures gave an energy of activation (E_a) for the two site exchange of 10.9 kcal/mol, when substituted into the Arrhenius equation. An Eyring plot gave activation parameters for the exchange: $\Delta H^{\ddagger}$ = 10.5 kcal/mol, $\Delta S^{\ddagger}$ = 9.1 cal/K mol, and therefore $\Delta G^{\ddagger}$ (300 K) = 7.7 kcal/mol. These values are consistent with a thermodynamically-enforced conformational preference for **3** in solution: it is an unusually rigid tripodal framework.

Reactivity studies

Of concern in the synthesis and subsequent reactivity of transition metal complexes of **3** is the generally-accepted sensitivity of P—Si bonds to cleavage by water and protic solvents (8). To gauge the tolerance of **3** for such reagents, we undertook a series of reactivity studies. The tripod is not soluble in water or methanol, and shows only slight degradation when stirred as a suspension in either solvent. The sensitivity of **3** to these protic reagents in solution was probed by NMR experiments in which approximately 100 equiv of water, methanol, or dilute HCl(aq) was added to **3** in d_8-toluene. The results (summarized in Table 4) indicate that P—Si bond cleavage occurs relatively slowly for **3** in the presence of water or methanol, with quantitative conversion to cleavage products requiring approximately three days at room temperature (Expts. 1 and 3, Table 4). These rates are accelerated at higher temperatures, with quantitative conversion to cleavage products occurring in 3–6 h in samples heated to 123°C (Expts. 2 and 4, Table 4). Slightly slower rates observed for water relative to methanol in these reactions are probably due to its lower solubility in toluene. (We observe signals in the ^1H NMR spectra due to both dissolved and undissolved water.) The rate of hydrolysis also accelerates with the addition of a catalytic amount of acid (Expt. 5, Table 4), whereupon complete cleavage of the P—Si bonds in **3** occurs at room temperature within 4 h.

[6] $\Delta G^{\ddagger}$ values for decoalescence of the H_{ortho} and SiMe signals (calculated simply from coalescence temperatures and peak separations at the low-temperature limit) are equal within experimental error, suggesting both decoalescences arise from the same exchange process. See the experimental section for details.

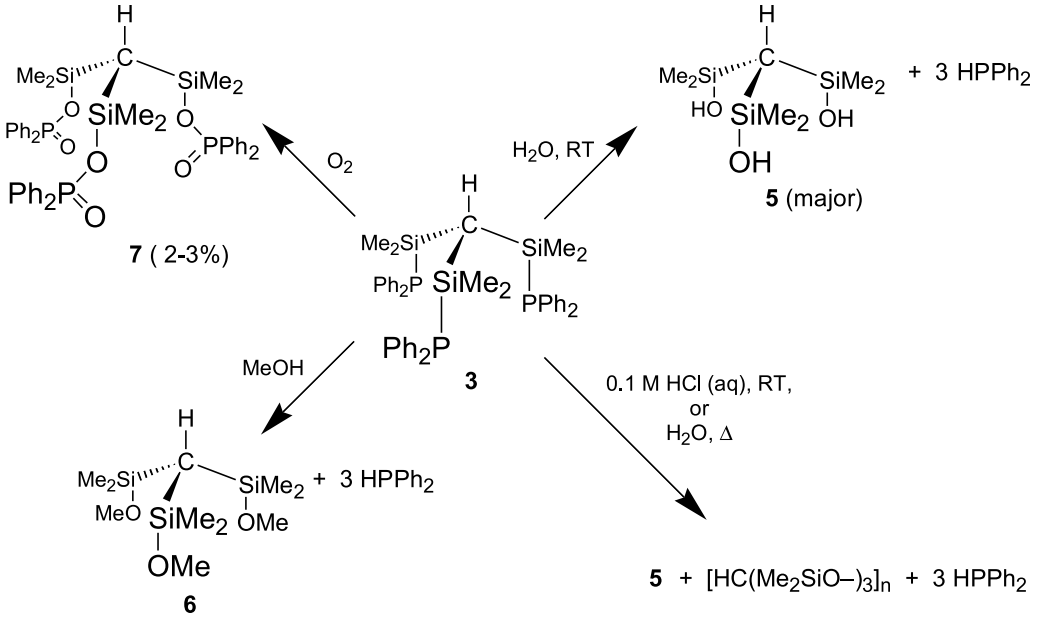
Scheme 1.



In the above solvolysis reactions, $HPPh_2$ is the phosphorus-containing cleavage product, but the fate of the silicon-containing tripodal core depends on the reagents and reaction conditions (Scheme 1). At room temperature, hydrolysis of the P—Si bond in **3** produces principally the tris(silylalcohol), $HC\{(CH_3)_2Si(OH)\}_3$ (**5**) (9), as determined by ^1H NMR spectroscopy. However, self condensation of the SiOH groups in **5** gives some oligomeric siloxane impurities, resulting in a range of small peaks from 0–0.1 ppm in the ^1H NMR spectrum, and a slight cloudiness in the sample.[7] When the reaction is carried out at high temperature, monomeric **5**, initially the major product, undergoes more extensive oligomerization, as determined by relative integration of SiMe signals in the ^1H NMR spectra before and after complete hydrolysis. The formation of polysiloxanes in this reaction is also evident from the appearance of a gelatinous white precipitate in the NMR tube. Similarly, in the reaction of **3** with dilute acid, the initial hydrolysis product, **5**, is rapidly joined in the reaction mixture by oligomerization products, which give broad peaks due to SiMe and SiOH groups (0–0.6 ppm) in the ^1H NMR spectrum and a slight cloudiness in the NMR sample. In the presence of excess methanol, **3** is cleanly converted to $HPPh_2$ and $HC\{Me_2Si(OMe)\}_3$, **6**, at room temperature or higher (9). Compound **6** does not oligomerize, and could probably be isolated from larger scale reaction mixtures by fractional distillation. While the tripod is sensitive enough to these reagents that we must avoid their use in the preparation of metal complexes of **3**, these reactivity studies suggest that if we wish to capitalize on the conformational rigidity of **3** in the templated incorporation of three phosphine units into a variety of macromolecular structures, we may cleave and recover the trisilylmethane core in a controlled manner via methanolysis.

Despite the complexity of the ^1H NMR spectra acquired during the hydrolysis of **3**, we observed no intermediate, partially hydrolyzed, podand species in these reactions: the $^{31}P\{^1H\}$ NMR spectra were clean and simple, showing only unreacted tripodal starting material and free diphenyl phosphine. In the methanolysis reactions (room temperature and high temperature), traces of a possible, unidentified intermediate are observed in the initial NMR spectra.[8] The observed signals account for less than 2% of the total phosphorus-containing material, and disappear before P–Si cleavage is complete.

As described earlier, the tris(phosphine) **3** is relatively stable to oxidation both in the solid state and in solution (Scheme 1). Bubbling oxygen through solutions of **3** (or passing oxygen over a solid sample of **3**) for 15 min gives only trace amounts of the oxidation product $HC(Me_2SiOP(=O)Ph_2)_3$ (**7**) (10), as determined by ^1H and ^{31}P NMR spectroscopy.[9]

Conclusions

Steric hindrance arising from the introduction of dimethylsilyl elbows in a tripodal molecule has given a significantly rigid tris(phosphine) compound (**3**). We are currently exploring the coordination chemistry of this chelating ligand. While the sensitivity of the P—Si bonds to cleavage by protic reagents limits the range of solvents available for reactions of **3** with transition metals, clean methanolysis of these bonds will allow the recovery of the tripodal core. Future work will capitalize on this feature of the reactivity of **3** in synthetic strategies requiring the regio- or stereospecific delivery of three phosphine units into a variety of macromolecular structures.

[7] This cloudiness is in addition to that due to the emulsion arising from the low solubility of water in toluene.
[8] $^{31}P\{^1H\}$: δ –50.6 ppm, ^1H: δ 0.20 ppm (SiMe).
[9] Hydrolysis by trace water in the oxygen gas gives some P–Si cleavage (3%).

Experimental

General procedures and reagent syntheses

Unless otherwise noted, all reactions and manipulations were done under an N_2(g) atmosphere in a glovebox or using conventional Schlenk techniques. Hexanes, ether, and THF were purified by distillation from sodium/benzophenone under argon, toluene was distilled from sodium under argon, benzene was vacuum transferred from over sodium/benzophenone, and methanol was purified by distillation from Mg under nitrogen. Deuterated solvents were purchased from Cambridge Isotopes, degassed and vacuum transferred from over sodium/benzophenone (d_6-benzene, d_8-toluene) or calcium hydride (d_1-chloroform). Tris(dimethylsilyl)methane (4*a*, 9), lithium diphenylphosphide (11), and *tert*-butylchloride (12) were prepared according to literature procedures. Bromine (≥ 99.5%) was purchased from Anachemia and used as received without further purification.

NMR spectra were obtained on a Bruker AM 300 operating at 300.133 MHz for ^{1}H, 121.496 MHz for ^{31}P, 75.469 MHz for ^{13}C, and 59.6 MHz for ^{29}Si, or on a Bruker AMX 500 operating at 500.13 MHz for ^{1}H and 202.46 MHz for ^{31}P. Chemical shifts are reported (in ppm) for 300 K unless otherwise stated. ^{1}H chemical shifts are referenced to residual protonated solvent peaks at 7.15 ppm (C_6D_5H), 2.09 ppm ($PhCD_2H$), and 7.29 ppm ($CHCl_3$). ^{13}C chemical shifts are referenced to C_6D_6 at 128.0 ppm and $CDCl_3$ at 77.5 ppm. Both ^{1}H and ^{13}C chemical shifts are reported relative to tetramethylsilane. ^{31}P chemical shifts are reported relative to 85% H_3PO_4(aq). Microanalysis was performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada. Mass spectroscopic analysis was carried out by Mr. Wayne Buchannon, in the Department of Chemistry, University of Manitoba.

Modified synthesis of $HC(Me_2SiBr)_3$, 2 (22, 38)

A 3.0 M solution of bromine in benzene was added dropwise over 3 h to a solution of $HC(Me_2SiH)_3$ (**1**, 10.46 g, 54.91 mmol) in benzene (10.0 mL). A stream of nitrogen was passed through the flask and allowed to exit via a dispersion tube submerged in a 0.85 M solution of *cis*-cyclooctene in toluene (400 mL), to trap product HBr(g) and any unreacted Br_2(g). The addition of Br_2 was stopped when the orange colour of bromine persisted in the reaction mixture (total volume 35 mL, 105 mmol Br_2). The solvent was removed in vacuo to give a pale beige paste, which was dissolved in ether or benzene (3.0 mL) for transfer by syringe to a distillation flask. Distillation under reduced pressure gave the product, a white crystalline solid that solidified in the condenser and had to be transferred over using a heat gun; bp 70–87°C (0.1 mmHg) (1 mmHg = 133.3 Pa). Yield: 42.5% (9.97 g). ^{1}H NMR (300 MHz, C_6D_6, δ): 0.67 (s, 18H, SiCH_3), 0.27 (s, 1H, C*H*). ^{13}C{^{1}H} NMR (75 MHz, C_6D_6, δ): 15.15 (s, *C*H), 7.47 (s, SiCH_3).

Synthesis of $HC(Me_2SiPPh_2)_3$, 3

In a 100 mL two-neck round-bottom flask equipped with an air-cooled reflux condenser, PPh_3 (9.7 g, 37 mmol) was dissolved in THF (25 mL). To this solution was added lithium metal (0.51 g, 74 mmol) in thin strips, and the mixture was left stirring until most of the lithium had been consumed. After 2 h, *tert*-butylchloride (4.0 mL, 37 mmol) was added slowly to the dark red $LiPPh_2$ solution by syringe, giving a white ppt and the evolution of gaseous isobutene. A 250 mL, two-neck round-bottom flask equipped with a pressure-equalizing dropping funnel and an air-cooled reflux condenser was charged with **2** (5.3 g, 12 mmol) in THF (25 mL). The $LiPPh_2$ solution was filtered by cannula into the dropping funnel, and added dropwise to the solution of **2** in THF over 30 min, giving a yellow solution with a white precipitate. The clear yellow solution was filtered by cannula into a small Schlenk tube, the solvent was removed in vacuo and the residue extracted with toluene (75 mL). The resulting solution was filtered through Celite on a sintered glass frit, and the toluene removed under vacuum. The product, a white powder, was washed with pentane (3 × 10 mL), and dried under vacuum. Yield: 62% (5.68 g); mp (uncorrected) 197–203°C. ^{1}H NMR (300 MHz, C_6D_6, δ): 7.53 (br m, 12H, *o*-C_6H_5), 7.01 (br m, 18H, *p*-, *m*-C_6H_5), 1.20 (q, $^3J_{PH}$ = 3.5 Hz, 1H, C*H*), 0.53 (br s, 18H, SiCH_3). ^{1}H NMR (300 MHz, $CDCl_3$, δ): 7.30–7.40 (m, 12H, *o*-C_6H_5), 7.10–7.20 (m, 18H, *p*-, *m*-C_6H_5), 0.85 (q, $^3J_{PH}$ = 3.5 Hz, 1H, C*H*), 0.39 (br s, 18H, SiCH_3). ^{13}C NMR (75 MHz, C_6D_6, δ): 134.68, 128.81 (m, C_6H_5), 2.10 (m, 6C, SiCH_3). ^{13}C NMR (75 MHz, $CDCl_3$, δ): 135.85 (m, *ipso*-C_6H_5), 134.22 (m, *o*-C_6H_5), 128.42 (m, *m*-C_6H_5), 127.45 (s, *p*-C_6H_5), 1.86 (m, SiCH_3), 1.24 (q, $^2J_{PC}$ = 10.7 Hz, *C*H). ^{31}P{^{1}H} NMR (121 MHz, C_6D_6, δ): –51.1 (s, 3P, PPh_2). ^{31}P{^{1}H} NMR (121 MHz, $CDCl_3$, δ): –51.3 (s, *P*Ph_2). ^{29}Si{^{1}H} NMR (60 MHz, C_7D_8, δ): 7.8–8.4 (br m). Anal. calcd. for $C_{43}H_{49}P_3Si_3$: C 69.51, H 6.65; found: C 69.28, H 6.74. MS (EI, 70 eV) *m*/*z*: 557 [M – PPh_2], 372 [M – 2 PPh_2], 186 [M – 3 PPh_2]. See Table 5 and text for variable temperature NMR data for **3**.

Reaction of $HC(Me_2SiPPh_2)_3$ (3) with H_2O

(a) At room temperature

Tris{(diphenylphosphino)dimethylsilyl}methane (**3**) (0.5 mL of a 0.0644 M standard solution in d_8-toluene, 0.032 mmol) was placed in a sealable NMR tube, which was attached to the vacuum line via a needle valve adapter. Deionized water (60 μL, 3.32 mmol, degassed by three freeze–pump–thaw cycles) was added under a flow of nitrogen, the mixture was degassed by one freeze–pump–thaw cycle, and the sample was sealed under vacuum. The progress of the reaction was monitored by ^{31}P{^{1}H} and ^{1}H NMR spectroscopy. For $HC(Me_2SiOH)_3$ (**5**): ^{1}H NMR (300 MHz, C_7D_8, δ): 0.37 (s, 3H, SiO*H*), 0.27 (s, 18H, SiCH_3), –0.11 (s, 1H, C*H*).

(b) At 123°C

A sealed NMR tube containing **3** (0.50 mL of a 0.0644 M standard solution in d_8-toluene, 0.032 mmol) and deionized water (60 μL, 3.32 mmol), prepared as described above, was placed in an oil bath at 123°C and was removed periodically for assessment of the progress of reaction by ^{31}P{^{1}H} and ^{1}H NMR spectroscopy.

Reaction of $HC(Me_2SiPPh_2)_3$ (3) with CH_3OH

(a) At room temperature

A sealed NMR tube containing **3** (0.5 mL of a 0.0644 M standard solution in d_8-toluene, 0.032 mmol) and methanol (130 μL, 3.23 mmol) was prepared as described above. The

[d]H_m.
[e]Some peaks were lost under solvent signals.

progress of the reaction was monitored by $^{31}P\{^1H\}$ and ^1H NMR spectroscopy. For $HC(Me_2SiOMe)_3$ (**6**): ^1H NMR (300 MHz, C_7D_8, δ): 3.22 (s, 9H, $SiOCH_3$), 0.21 (s, 18H, $SiCH_3$), 0.01 (s, 1H, C*H*).

(b) At 123°C

A sealed NMR tube containing **3** (0.50 mL of a 0.0644 M standard solution in d_8-toluene, 0.032 mmol) and methanol (130 μL, 3.23 mmol), prepared as described above, was placed in an oil bath at 123°C and was removed from the bath periodically to assess the progress of reaction by $^{31}P\{^1H\}$ and ^1H NMR spectroscopy.

Reaction of $HC(Me_2SiPPh_2)_3$ (3) with 0.1 M HCl (aq), at 25°C

A sealed NMR tube containing **3** (0.50 mL of a 0.0644 M standard solution in d_8-toluene, 0.032 mmol) and 0.1 M HCl (60 μL, 3.3 mmol H_2O, 0.006 mmol H_3O^+, degassed by three freeze–pump–thaw cycles) was prepared as described above. The progress of the reaction was monitored by $^{31}P\{^1H\}$ and ^1H NMR spectroscopy.

Reaction of $HC(Me_2SiPPh_2)_3$ (3) with O_2

(a) In the solid state

In a Schlenk, solid tris{(diphenylphosphino)dimethylsilyl}methane, **3** (20 mg, 0.03 mmol), was placed under an atmosphere of oxygen gas (99.9%) for 15 min, then the oxygen was removed under vacuum. The sample was dissolved in d_6-benzene (0.6 mL) and the solution was transferred to an NMR tube, for analysis by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy. For $HC(Me_2SiP\{=O\}Ph_2$: ^1H NMR (300 MHz, C_6D_6, δ): 0.41 (s, 18H, $SiCH_3$), other peaks were lost in the baseline; $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, δ): 98.9 (s, $P(=O)Ph_2$).

(b) In solution

Oxygen gas (99.9%) was bubbled through a solution of **3** (20 mg, 0.03 mmol) in toluene (5.0 mL) in a Schlenk for 15 min. After removal of the oxygen and toluene under vacuum, a white, oily, solid residue was dissolved in d_6-benzene (0.6 mL) and transferred to an NMR tube for analysis by ^1H and $^{31}P\{^1H\}$ NMR spectroscopy.

Molecular modeling of $HC(Me_2SiBr)_3$ (2)

Atomic coordinates from the crystallographically-determined molecular structure of **2** were imported into the HyperChem modeling program.[10] This structure was used as the starting point for semi-empirical, AM1 calculations, employing a Polak–Ribiere conjugate gradient for geometry minimization. To determine the barrier to rotation around the $C_{methine}$—Si bonds, one torsional angle (H1-C1-Si2-Br2) was varied between 0° and 360°: for each calculation the rest of the molecule was allowed to relax around this constrained angle. Once the minimization was complete, the torsion constraint was removed and the heat of formation was calculated. Rotational barriers were determined from a plot of the heat of formation versus torsion angle.

Line-shape analysis of 3 and related calculations

Line-shape analysis was carried out on the SiMe region of $^1H\{^{31}P\}$ NMR (500 MHz) spectra recorded for compound **3** in d_8-toluene at 220, 210, 200, and 190 K, using XSIM[11] and a modified version of DNMR3 (13). Rate constants (*k*) for the two-site exchange were determined iteratively at each

[10]Hypercube, Inc., Gainesville, Fla.
[11]K. Marat. Winnipeg, 1999.

© 1999 NRC Canada

temperature, giving well-matched simulated and experimental spectra (see Fig. 3). Estimated errors in k varied from 2–6%, temperatures are ±5 K. Thermodynamic parameters were obtained from the slope and intercept of an Eyring plot (ln (k/T) vs. 1/T, R = 1.000): $\Delta H^{\ddagger}$ = 10.5 kcal/mol, $\Delta S^{\ddagger}$ = 9.1 cal/K mol. These yielded $\Delta G^{\ddagger}$(300 K) = 7.7 kcal/mol (± 2.5%). Energy of activation, E_a = 10.9 kcal/mol, was determined from the slope of an Arrhenius plot (ln k vs. 1/T, R = 1.000) (14).

$\Delta G^{\ddagger}$ was also calculated for decoalescence of both the H_{ortho} and SiMe signals in the variable temperature $^1H\{^{31}P\}$ NMR (500 MHz) spectra recorded for compound **3** using the value for the rate constant k_C (where $k_C = \pi\Delta\nu_C/(2)^{1/2}$) in the Eyring equation

$$\Delta G^{\ddagger} = -RT_C \ln [k_C h)/(k_B T_C)]$$

where R = the gas constant, T_C = coalescence temperature, $\Delta\nu_C$ = peak separation at the low-temperature limit, h = Planck's constant, and k_B = Boltzmann constant (14). For the two-site exchange of (*i*) H_{ortho} groups: T_C = 185 ± 5 K, $\Delta\nu_C$ = 145 Hz, $\Delta G^{\ddagger}$ = 8.5 ± 0.2 kcal/mol; (*ii*) SiMe groups: T_C = 195 ± 5 K, $\Delta\nu_C$ = 395 Hz, $\Delta G^{\ddagger}$ = 8.6 ± 0.2 kcal/mol.

Nuclear magnetic resonance investigations of azo-hydrazone, acid–base equilibria of FD&C Yellow No. 5 (tartrazine)

Eugene P. Mazzola, Sandra J. Bell, Saleh A. Turujman, Julie N. Barrows, John E. Bailey, Jr., Joseph B. McMahon, Tania K. Germann, and William F. Reynolds

Abstract: Azo-hydrazone, acid–base equilibria were examined for the water-soluble, food color additive FD&C Yellow No. 5 (Y5), with the observation of dynamic NMR effects near, and at, pH 10, where the food colorant converts from a predominantly hydrazone tautomer (acidic to moderately basic pH) to a prevailing azo-anion resonance hybrid (high pH). Potentiometric titrations further indicate that the pK_a of Y5 is ca. 10. These data suggest that observed NMR line broadening is due to slow proton transfer between a hydrazone-NH and water.

Key words: ^{1}H, ^{13}C, and ^{15}N NMR, azo-hydrazone/acid–base equilibria, FD&C Yellow No. 5.

Résumé : On a étudié l'équilibre acide–base, azo-hydrazone, du colorant jaune FD&C No. 5 (Y5) qui est soluble dans l'eau et qui est utilisé comme additif alimentaire. À cette fin, on a fait appel aux effets RMN dynamiques à (ou près d') un pH de 10 auquel le colorant passe d'une forme tautomère hydrazone prédominante (pH acide à modérément basique) à un hybride de résonance azo-anionique (pH élevé). Des mesures de titrages potentiométriques indiquent de plus que le pK_a du Y5 est d'environ 10. Ces données suggèrent que l'élargissement des raies observées dans les spectres RMN résulte d'un transfert lent de proton entre l'eau et un NH de l'hydrazone.

Mots clés : RMN du ^{1}H, du ^{13}C et du ^{15}N, équilibre acide–base/azo-hydrazone, jaune FD&C No. 5.

[Traduit par la Rédaction]

Compounds exhibiting azo-hydrazone tautomerism have been extensively investigated in a variety of organic solvent systems (1). However, partly because of the difficulty of obtaining IR spectra of aqueous solutions, their water-soluble analogs have still received limited attention. Several years ago the azo-hydrazone, acid–base equilibria of FD&C Yellow No. 5 (Y5, **1**) was examined by ^{15}N NMR, and significant change was observed from pH 7 to 12 (2). At pH 7, chemical shift values were –168.9 and –11.2 ppm (relative to $NH_4{}^{15}NO_3$). The former is typical of those reported for hydrazone sp^3-hybridized nitrogens, whereas the latter is characteristic of imino nitrogens (3). These resonances were assigned to the α- and β-nitrogens, respectively, and were interpreted as evidence that Y5 exists predominantly as a hydrazone below pH 9, as shown in the *anti*-configuration, **1a**.

At pH 12, signals were observed at 40.5 and 97.5 ppm (also relative to $NH_4{}^{15}NO_3$) (2), which are in the range found for azo compounds (4). They were assigned by comparison with the chemical shift of the β-^{15}N-labeled isotopomer of Y5 ([β-^{15}N]-Y5), which appears at 97.0 ppm. The resonance at 97.5 ppm was, therefore, assigned to the β-nitrogen. These chemical shifts were interpreted as demonstrating that Y5 occurs almost exclusively as an azo-anion, e.g., **1b**, above pH 11. The extremely large changes in ^{15}N chemical shifts with pH (ca. 210 ppm for N_α), corresponding to a major fraction of the total ^{15}N chemical shift range (5), supported the belief that deprotonation in Y5 is associated with substantial electronic reorganization. More recently we have determined the ^{15}N NMR spectra of the bisaryl compound FD&C Yellow No. 6 (Y6, **2**) at neutral and basic pH and found that it exhibits similar behavior (6). We now report on the complete investigation of the azo-hydrazone, acid–base equilibria of Y5. ^{13}C NMR was used to characterize Y5 at a variety of pH values between 2 and 12. Total proton and carbon NMR signal assignments were

made, and the pK_a value for Y5 was determined potentiometrically.

Results and discussion

^{13}C and ^{1}H NMR spectra and signal assignments

The ^{13}C NMR spectra of Y5, at 20 MHz, exhibit similar behavior, with changing pH, to those of Y6, i.e., as the pH is increased from 2 to 10, most of the ^{13}C NMR signals exhibit broadening along with either upfield or downfield shifts, and maximum line broadening occurs at pH 10. As the solution pH is further increased to 12, the broadened resonances sharpen and continue their respective migrations. This dynamic behavior suggests, as is the case for Y6, the existence of one or more intermediate (on the NMR timescale) equilibrium processes (7).

Assignment of the ^{13}C and ^{1}H NMR signals of Y5 was complicated by the existence of two *p*-sulfophenyl groups (rings A and C) whose ^{13}C and ^{1}H NMR resonances are very similar (Table 1). In addition, the carbons of the pyrazole (B) ring and that of its only substituent (the carboxylate group at C-3) are all quaternary, thus eliminating the possibility of their chemical shift assignments via long-range proton–carbon connectivities. However, the β-^{15}N-labeled isotopomer of Y5 was easily prepared. Observed ^{15}N–^{13}C couplings in this compound together with (*i*) pyrazolone model compounds (8), and (*ii*) direct heteronuclear (HETCOR) and long-range, heteronuclear chemical shift correlation (FLOCK) (9) experiments permitted assignment of all the carbon and proton NMR signals of Y5. The assignment of these resonances is described below.

Comparison of the ^{13}C NMR spectra of Y5 and [β-^{15}N]-Y5 at pH 7 revealed four couplings between the ^{15}N-nucleus and carbons in the A- and B-rings (Table 2). The signal at 163.4 ppm was assigned to the B-ring, oxygen-bearing C-5, thus distinguishing it from the carboxy C-6. The resonance at 143.7 ppm was ascribed to the A-ring, nitrogen-bearing carbon (1″), the double-intensity signal at 117.5 ppm to C-2″/6″, and the most shielded (quaternary) resonance at 126.2 ppm to the imino C-4 (10).

4″	0	<1

[a]Taken from the dissertation submitted in partial fulfillment of the requirements for the Ph.D. degree (S.J.B.) awarded by The George Washington University, Washington, D.C.

A HETCOR experiment permitted assignment of the signal at 7.37 ppm to H-2″/6″, and the *ortho*-coupled (8.4-Hz) resonance at 7.71 ppm was then attributed to H-3″/5″. The HETCOR experiment now allowed assignment of the double-intensity signal at 128.0 ppm to C-3″/5″. Additionally, a FLOCK experiment showed 3-bond connectivities between H-2″/6″ and C-4″ at 140.6 ppm and H-3″/5″ and C-1″ (143.7 ppm) thus completing the assignments of the A-ring. The HETCOR experiment further demonstrated direct couplings between the proton signals at 7.79 and 7.80 ppm and the carbon resonances at 120.4 and 127.3 ppm, respectively. Moreover, the FLOCK experiment revealed 3-bond connectivities between (*i*) the proton resonance at 7.79 ppm and the carbon at 140.4 ppm and (*ii*) the proton signal at 7.80 ppm and the carbon resonance at 140.1 ppm.

Without corresponding isotopic enrichment at N-1, unequivocal assignments for the C-ring protons and single- and double-intensity carbons could not be made. However, signals at 127.3 ppm, which are pH-invariant over the range 2–12, have been observed for carbons 3′/5′ of pyrazolone T (**3**), which are similar to C-3′/5′ of Y5 (8). The resonances of Y5 at 127.3 ppm, at pH 7 and 12, were, therefore, also assigned to C-3′/5′. The rest of the signals of the C-ring are then as given in Table 1. Finally, the remaining resonances at 140.8 ppm (pH 7) and 146.9 ppm (pH 12) can be ascribed to C-3 by default. The signals of Y5 at pH 12 (Table 1) were assigned by means of similar ^{15}N–^{13}C couplings (Table 2) and chemical shift correlation experiments described above.

Molecular conformations and configurations

^{13}C and ^{15}N NMR spectra have provided evidence that Y5 exists predominantly as a hydrazone at neutral pH (vide supra). Further information concerning the geometry about the hydrazone linkage was obtained by examination of the 2-bond, ^{15}N–^{13}C coupling constants between the β-nitrogen and carbons 3 and 5 in the ^{13}C NMR spectrum of [β-^{15}N]-Y5 at pH 7. An 11.8 Hz coupling was observed to C-5 and essentially no coupling to C-3 (Table 2). The difference in magnitude between these two coupling constants indicates that C-5 is situated *cis* to the lone-pair electrons of the β-nitrogen (11). Y5, therefore, occurs as the *anti*-hydrazone (**1a**) at pH 7.

Y5 has also been inferred to be present as an azo-anion species at basic pH. The corresponding couplings between the β-nitrogen of [β-^{15}N]-Y5 and carbons 3 and 5 at pH 12 are the following: 5 Hz to C-3 and 2.5 Hz to C-5 (Table 2). These data suggest that the overall shape of the Y5 molecule has changed in going from neutral to high pH 12, viz. C-3 is now located *cis* to the β-nitrogen lone-pair electrons (11). Y5 thus exists as the *trans*-azo compound (**1b**) at pH 12.

Dynamic NMR effects

As previously mentioned, at 20 MHz the ^{13}C NMR spectra of Y5 exhibit significant line broadening between pH 9 and 11. This signal broadening can be ascribed to an acid–base equilibrium, involving species **1a** and **1b** (Scheme 1), in a manner similar to that seen for the dye, Y6 (**2**) in Scheme 2 (6). This interpretation is supported by the pK_a of Y5, which has been determined potentiometrically to be 10.03.[2] Interestingly, at 100 MHz, *separate* signals for the azo and hydrazone species are observed for the ^{13}C NMR spectra of Y5 at pH values close to the pK_a. Apparently, the fivefold increase in resonance frequency provides just enough chemical shift separation to move the equilibrium process from the *near-fast* exchange regime at 20 MHz to the *intermediate* exchange regime at 100 MHz. Like Y6, the Y5 system is atypical in that the azo-anion conjugate base

[a]Not exchange broadened.

[b]Considerable error due to slight broadening and very small $\Delta\delta$.

[c]Obscured.

[d]Not observed.

(**1b**) is considerably different structurally from the hydrazone acid (**1a**) from which it is derived. The relatively slow (on the ^{13}C NMR timescale) proton transfer for this nitrogen–acid system (between the hydrazone-NH and water) was not completely unexpected, since NH–OH exchange is anticipated to be slower than the more commonly encountered OH–OH exchange in oxygen acids.

The existence of line broadening in the 20 MHz, ^{13}C NMR spectra permits calculation of average lifetimes for the hydrazone and azo-anion species. The standard practice of variable-temperature experiments is largely precluded in these systems because of the temperature dependence of solution pH. In addition, more accurate line widths could be determined for exchange-broadened, *averaged* signals at 20 MHz than for *individual* ones at 100 MHz. Therefore, as an approximate alternative, the line widths of four carbon resonances were measured at pH 7, 10, and 12. If the assumption is made that the pK_a occurs at pH 10, these line widths, together with the chemical shift separations, can be inserted into the following equation for the *near-fast* exchange regime (12):

$$(T_2)^{-1} = N_A(T_{2_A})^{-1} + N_B(T_{2_B})^{-1} + N_A^2N_B^2\,(\omega_A - \omega_B)^2\,(\tau_A + \tau_B)$$

where N_A and N_B are the respective mole fractions of the hydrazone and azo species, T_{2_A} and T_{2_B} are the natural line widths (widths at half-height), ω_A and ω_B represent the chemical shift separation, $T_{2'}$ is the line width at pH 10, and τ_A and τ_B are the lifetimes. Three average lifetimes ($1/2[\tau_A + \tau_B]$) were obtained, which are in excellent agreement with each other (Table 3) and are, for the sake of consistency, also in the range of $0.1–10^{-5}$ s, where dynamic NMR effects are observed (7*c*).

Analysis of ^{13}C NMR line broadenings for the hydrazone and azo species of Y5 and Y6 yields average lifetimes of ca. 23 and 2 ms (6), respectively. In addition, the pK_a values of Y5 and Y6 were determined to be 10 and 12 (6), respectively. The kinetic and thermodynamic acidities of the hydrazone NHs are, therefore, seen to be reversed in the two dyes.

Experimental

The trisodium salt of 4,5-dihydro-5-oxo-1-(4-sulfophenyl)-4-(4-sulfophenyl)azo-1*H*-pyrazole-3-carboxylic acid (Y5, **1**) (Hilton–Davis) was used without further purification. The β-^{15}N-labeled isotopomer ([β-^{15}N]-Y5) was prepared by diazotization of 4-amino-benzenesulfonic acid (Fisher) with $Na^{15}NO_2$ (95 at.% ^{15}N, Merck) and coupling to the disodium salt of 4,5-dihydro-5-oxo-1-(4-sulfophenyl)-1*H*-pyrazole-3-carboxylic acid (Hilton–Davis).

Proton, ^{13}C, and ^{15}N NMR spectra were recorded at 400, 100, and 40 MHz, respectively, in D_2O on a Varian NMR Instruments VXR-400S spectrometer. In addition, ^{13}C NMR spectra were obtained at 20 MHz in D_2O on a Varian NMR Instruments FT-80A spectrometer. Both ^{13}C (at 100 MHz) and proton chemical shifts are reported relative to TMS (Table 1). ^{15}N chemical shifts are reported relative to the $^{15}NO_3^-$ resonance using aqueous, saturated ammonium [^{15}N]nitrate solution as the external standard.

Directly bonded, heteronuclear chemical shift correlation (HETCOR) NMR spectra were obtained at 100 MHz with spectral widths of 1300 and 250 Hz in the carbon and proton dimensions, respectively, and with 256 data points in the ^{13}C dimension. Sixty-four incremented ^{13}C spectra of 32 scans each were acquired by using 11.5 μs (90°) ^1H pulse widths and a 1 s repetition rate. Free-induction decays in both dimensions were processed as a 128 × 512 matrix with appropriate zero filling and modified pseudo-echo weighting. The value $^1J(CH)$ = 165 Hz was used for calculating the delays Δ_1 and Δ_2.

Long-range, heteronuclear chemical shift correlation (FLOCK) NMR spectra were recorded at 100 MHz with spectral widths of 6000 and 250 Hz in the carbon and proton dimensions, respectively, and with 1024 data points in the ^{13}C dimension; 192 incremented ^{13}C spectra of 256 scans each were acquired by using 11.5 μs (90°) ^1H pulse widths and a 1 s repetition rate. Free-induction decays in both dimensions were processed as a 512 × 2048 matrix with appropriate zero filling and modified pseudo-echo weighting. The value $^nJ(CH)$ = 7.5 Hz was used for calculating the delays Δ_1 and Δ_2, and $^1J(CH)$ = 165 Hz was used for τ in the bilinear rotation decoupling (BIRD) (13) pulses.

The second dielectric virial coefficient of the dipolar Gay–Berne fluid

A.D. Buckingham and Y. Tantirungrotechai

Abstract: We report the second dielectric virial coefficient B_ε of a nonpolarizable dipolar Gay–Berne fluid. The second dielectric virial coefficient is evaluated for several sets of shape parameters and temperature. The second dielectric virial coefficient for rodlike molecules is negative while it is large and positive for disklike molecules. It decreases to zero on increasing the temperature.

Key words: dipolar fluids, dielectric constant, intermolecular forces, shape parameters.

Résumé : On a mesuré le deuxième coefficient du viriel diélectrique, B_ε, d'un fluide dipolaire non polarisable de Gay–Berne. On a évalué le deuxième coefficient du viriel diélectrique pour plusieurs ensembles de paramètres de forme et de température. Pour les molécules en forme de tige, le deuxième coefficient du viriel diélectrique est négatif alors que sa valeur est positive et élevée pour les molécules en forme de disque. Il tend vers zéro par augmentation de température.

Mots clés : fluids dipolaires, constante diélectrique, forces intermoléculaires, paramètres de forme.

[Traduit par la Rédaction]

Introduction

At low densities, the Clausius–Mossotti function of a fluid can be written as a virial expansion of the total dielectric polarization ${}_TP$ in the density $\rho = V_m^{-1}$ where V_m is the molar volume (1)

$$[1] \qquad {}_TP = \frac{\varepsilon_r - 1}{\varepsilon_r + 2}\rho^{-1} = A_\varepsilon + B_\varepsilon\rho + C_\varepsilon\rho^2 + \ldots$$

ε_r is the dielectric constant of the fluid and A_ε, B_ε, C_ε, $\cdots$ are the first, second, third dielectric virial coefficients. The first dielectric virial coefficient A_ε consists of two terms, one representing the polarization due to the polarizability and the other the orientation polarization

$$[2] \qquad A_\varepsilon = \frac{N_A}{3\varepsilon_0}(\bar{\alpha} + \frac{\mu^2}{3k_BT})$$

where N_A is Avogadro's number and ε_0 is the permittivity of a vacuum. Measurements of A_ε as a function of temperature yield the molecular dipole moment μ and the static polarizability $\bar{\alpha}$ (2). The second dielectric virial coefficient B_ε relates to pair interactions, which are absent in the ideal gas, and can be written (1) as

$$[3] \qquad B_\varepsilon = \frac{N_A^2}{3 \cdot \Omega \cdot \varepsilon_0}\int d(12)\,\frac{1}{2}[\Delta\bar{\alpha} + \frac{\Delta\mu^2}{3k_BT}]\exp(-\frac{W_{12}}{k_BT})$$

where W_{12} is the dimer interaction energy, $\Delta\bar{\alpha} = (\alpha_{12,\alpha\alpha} - \alpha^{(0)}_{1,\alpha\alpha} - \alpha^{(0)}_{2,\alpha\alpha})/3$, $\Delta\mu^2 = (\boldsymbol{\mu}_1 + \boldsymbol{\mu}_2)^2 - \mu_1^{(0)2} - \mu_2^{(0)2}$ and $\int d(12) = V_m\,\Omega$ (1). This integration is performed over all possible dimer separations and orientations and for linear molecules $d(12) = R^2\,dR\,\sin\theta_1\,d\theta_1\,\sin\theta_2\,d\theta_2\,d\phi$ with the coordinates defined as in Fig. 1, so $\Omega = 2$. As for A_ε, the contributions to B_ε consist of two similar terms but in the form of the changes in the mean polarizability and mean-square dipole moment due to the pair interaction. For dipolar fluids, the orientation contribution $\Delta\mu^2/3k_BT$ is generally much larger than that due to the induced polarizability $\Delta\bar{\alpha}$ and may be positive or negative (1). A comprehensive review of this field of study up to 1970 has been given by Sutter (3).

Molecular shape is known to play an important role in B_ε (1). Several models have been proposed to take into account the anisotropic potential, such as the Kihara model (4), the shape factor proposed by Buckingham and Pople (1, 5), the "off-centre" dipole model of Lawley and Sutton (6), the asymmetrical hard dumbbell model of Ohba and Nomura (7), and the hard ellipsoid model of Muckenfuss, Curtiss, and Bird (8). This last model coupled with a point dipole was used by Joslin to study the effect of molecular shape on the second virial coefficients of the pressure, dielectric constant, Kerr effect, and the depolarized light scattering (9). In this paper, we report a study of B_ε of the nonpolarizable dipolar Gay–Berne fluid.

Received March 3, 1999.

This paper is dedicated to Professor Ted Schaefer in recognition of his outstanding contributions to Canadian chemistry.

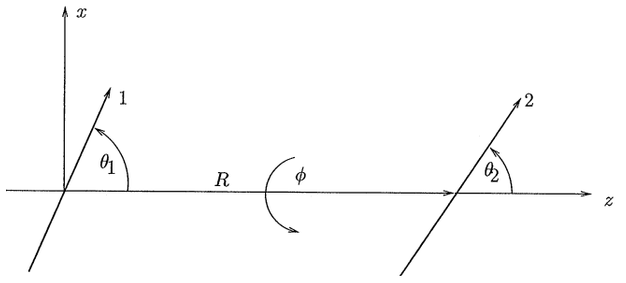
Fig. 1. The intermolecular coordinates used to define the relative molecular position and orientation. Molecule 1 is fixed in the *xz* plane. θ_1 and θ_2 are the angles of the symmetry axes of molecules 1 and 2 measured from the *z*-axis. ϕ denotes the torsional angle of molecule 2 with respect to the *xz* plane. *R* is the intermolecular distance between the origins in molecules 1 and 2.



Gay and Berne have modified the overlap potential between two ellipsoidal Gaussians of Berne and Pechukas (10) that leads to the single-site orientation-dependent potential (11). The so-called Gay–Berne potential takes the form (12)

$$[4] \qquad W_{GB}\,(\boldsymbol{r}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2) = 4\varepsilon(\hat{\boldsymbol{r}}_{12},\boldsymbol{e}_1,\,\boldsymbol{e}_2)[\rho_{12}^{-12}-\rho_{12}^{-6}]$$

where $\boldsymbol{e}_1$, $\boldsymbol{e}_2$ are orientation unit vectors of the axially symmetric particles 1 and 2 separated by the intermolecular vector $\boldsymbol{r}_{12} = r_{12}\,\hat{\boldsymbol{r}}_{12}$. The shifted-distance ρ_{12} is $(r_{12} - \sigma\,(\hat{\boldsymbol{r}}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2) + \sigma_0)/\sigma_0$ where $\sigma(\hat{\boldsymbol{r}}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2)$ is the distance for a given orientation at which the potential is zero. This orientation-dependent impact parameter $\sigma(\hat{\boldsymbol{r}}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2)$ takes the form

$$[5] \qquad \sigma(\hat{\boldsymbol{r}}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2)$$

$$= \sigma_0\left\{1-\frac{\chi}{2}\left[\frac{(\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_1+\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_2)^2}{1+\chi(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)}+\frac{(\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_1-\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_2)^2}{1-\chi(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)}\right]\right\}^{-1/2}$$

where $\chi = (\kappa^2 - 1)/(\kappa^2 + 1)$, $\kappa = \sigma_{\parallel}/\sigma_{\perp}$ is a parameter defining the molecular length over the molecular diameter, and σ_0 is a constant defining the length scale that is equal to the cross-sectional diameter $\sigma_{\perp}$. The orientation-dependent well depth $\varepsilon\,(\hat{\boldsymbol{r}}_{12},\,\boldsymbol{e}_1,\,\boldsymbol{e}_2)$ is given by

$$[6] \qquad \varepsilon(\hat{\boldsymbol{r}}_{12},\boldsymbol{e}_1,\boldsymbol{e}_2) = \varepsilon^0\,\varepsilon_1^{\nu}(\boldsymbol{e}_1,\boldsymbol{e}_2)\,\varepsilon_2^{\mu}(\hat{\boldsymbol{r}}_{12},\boldsymbol{e}_1,\boldsymbol{e}_2)$$

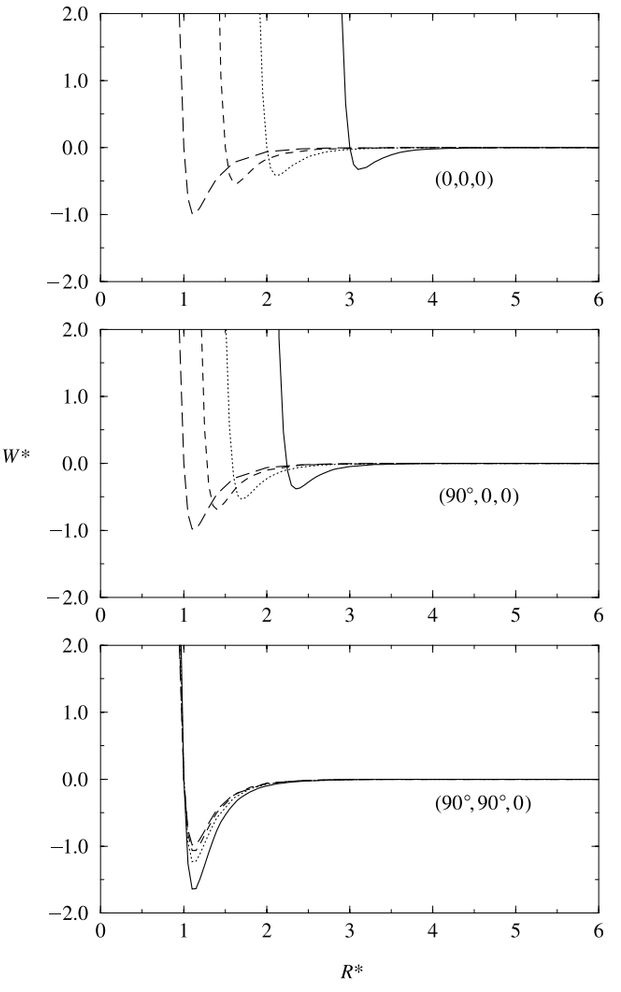
$$[7] \qquad \varepsilon_1(\boldsymbol{e}_1,\boldsymbol{e}_2) = [1-\chi^2(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)^2]^{-1/2}$$

$$[8] \qquad \varepsilon_2(\hat{\boldsymbol{r}}_{12},\boldsymbol{e}_1,\boldsymbol{e}_2)$$

$$=1-\frac{\chi'}{2}\left[\frac{(\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_1+\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_2)^2}{1+\chi'(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)}+\frac{(\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_1-\hat{\boldsymbol{r}}_{12}\cdot\boldsymbol{e}_2)^2}{1-\chi'(\boldsymbol{e}_1\cdot\boldsymbol{e}_2)}\right]$$

where $\chi' = (\kappa'^{1/\mu} - 1)/(\kappa'^{1/\mu} + 1)$, $\kappa' = \varepsilon_{ss}/\varepsilon_{ee}$. ε_{ss} and ε_{ee} are the well depths of side-by-side and end-to-end configurations, and ε^0 is a parameter setting the energy scale of this potential. The original set of parameters, $\kappa = 3$, $\kappa' = 5$, $\nu = 1$, and $\mu = 2$, was obtained by fitting this potential form to the site–site potential of a four-site Lennard-Jones molecule (11). Other sets of parameters have been proposed since then, for example, the new set of exponents of Luckhurst et al. (13) and the "disk-like" parameters of Emerson et al.

Fig. 2. The reduced rodlike Gay–Berne potential $W^* = W/\varepsilon^0$ as a function of the reduced intermolecular distance $R^* = R/\sigma_<$ and shape parameters κ and κ'. Plots in long-dashed, broken, dotted, and solid lines are used to represent $(\kappa, \kappa') = (1.0, 1.0)$, (1.5, 2.0), (2.0, 3.0), and (3.0, 5.0), respectively. The dimer relative configurations are defined by $(\theta_1, \theta_2, \phi)$ as in Fig. 1.



(14). We keep $\nu = 1$, $\mu = 2$ and vary κ and κ'. An extension and generalization of this model has been made by Cleaver et al. (15). These authors give the general expression for the interaction between two nonequivalent uniaxial particles; they report parameters for a rod–disk dimer obtained from the interaction energy of *p*-terphenyl and triphenylene.

The Gay–Berne potential has been employed extensively in the simulation of liquid crystals in which the anisotropic potential is crucial (13, 14). Satoh et al. studied mesophase formation of the dipolar Gay–Berne fluid using the Monte Carlo technique (16).

Model

For the nonpolarizable dipolar fluid we can write B_ε as

$$[9] \qquad B_\varepsilon = \frac{N_A^2}{3\cdot\Omega\cdot\varepsilon_0}\int d(12)\left[\frac{\boldsymbol{\mu}_1\cdot\boldsymbol{\mu}_2}{3k_BT}\right]\exp\left(-\frac{W_{12}}{k_BT}\right)$$

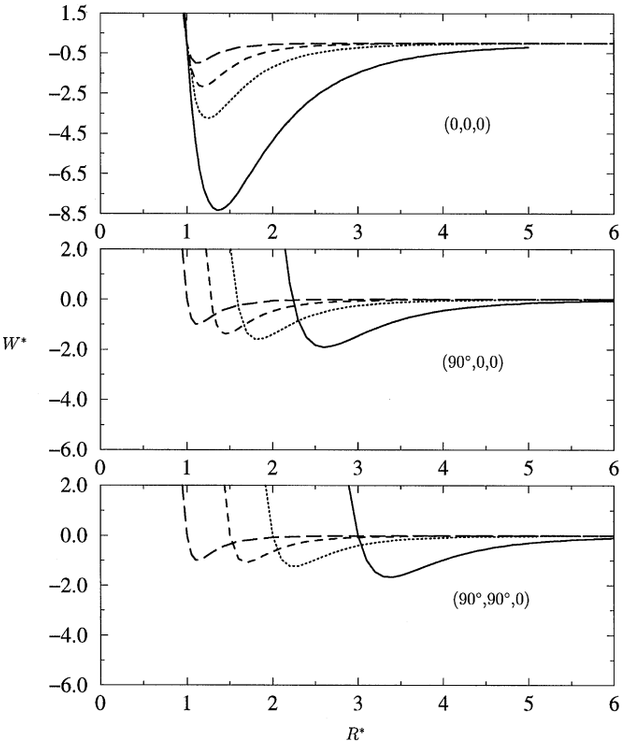
Fig. 3. The reduced disklike Gay–Berne potential $W^* = W/\varepsilon^0$ as a function of the reduced intermolecular distance $R^* = R/\sigma_<$ and shape parameters κ and κ'. Plots in long-dashed, broken, dotted, and solid lines are used to represent $(\kappa,\kappa') = (1.0, 1.0)$, (2/3, 1/2), (1/2, 1/3), and (1/3, 1/5), respectively.



Following the suggestion of Joslin (9), we modified this formula to reduce the errors of the numerical integration

$$[10] \qquad B_\varepsilon = \frac{N_A^2}{3\cdot\Omega\cdot\varepsilon_0}\int d(12)\left[\frac{\boldsymbol{\mu}_1\cdot\boldsymbol{\mu}_2}{3k_BT}\right]\left\{\exp\left(-\frac{W_{12}}{k_BT}\right)-1\right\}$$

We report all quantiites in the reduced dimensionless units, which are defined as

$$T^* = \frac{k_BT}{\varepsilon^0}, \quad \mu^{2*} = \frac{\mu^2}{4\pi\varepsilon_0\varepsilon^0\sigma_<^3}, \quad B_\varepsilon^* = \frac{B_\varepsilon}{N_A^2\sigma_<^6}$$

where $\sigma_<$ is $\sigma_\perp$ for rodlike molecules and $\sigma_\parallel$ for disklike molecules. In our study, the interaction energy of the Gay–Berne nonpolarizable dipolar fluid is the same as used by Satoh et al. (16) and is given by

$$[11] \qquad W_{12} = W_{GB} + W_{elec}$$

where W_{GB} is defined as in eq. [4] and

$$W_{elec} = -\frac{1}{4\pi\varepsilon_0}\frac{\{3(\mu_{1\alpha}R_\alpha)(\mu_{2\beta}R_\beta) - R^2(\mu_{1\alpha}\mu_{2\alpha})\}}{R^5}$$

We use the original set of parameters $(\kappa,\kappa', \nu, \mu)$ suggested by Gay and Berne (11) in this study. Other sets of (κ, κ') for rodlike molecules are obtained from a linear interpolation between $(\kappa = 3, \kappa' = 5)$ and $(\kappa = 1, \kappa' = 1)$. Parameters of disklike molecules are the inverse of those of rodlike molecules.

In the case of disklike molecules we fix $\sigma_\parallel$ at the same value as the $\sigma_\perp$ of the rodlike molecules, hence requiring σ_0 (disk) = σ_0 (rod) κ(rod). Plots of Gay–Berne potentials in reduced units for selected sets of shape parameters and orientations are shown in Figs. 2 and 3 for rodlike and disklike molecules, respectively.

The second dielectric virial coefficient (see eq. [10]) is evaluated numerically in two steps. The angular integration is performed first using the Monte Carlo technique with a quasi-random generator (Sobol sequence) (17). The radial integration is performed afterwards with the Romberg integration scheme (17). The second dielectric virial coefficients B_ε are calculated for several sets of μ^{2*}, T^*, and (κ, κ'). These results are given in Tables 1–4.

Results and discussion

For both the rodike and disklike molecules considered, the second dielectric virial coefficient increases in magnitude as μ^{2*} increases and decreases exponentially to zero on increasing T^*. The results (see Tables 1–3) show that rodlike molecules ($\kappa > 1$) have negative B_ε while disklike molecules have positive B_ε for all μ^{2*}, T^* considered. This implies that rodlike molecules statistically favour side-by-side configurations while the disklike favour end-to-end configurations. The magnitude of B_ε for the rodlike molecules is less than that of their complimentary disklike molecules. This is due to a much deeper well in the Gay–Berne potential of the disklike molecules than for the rodlike molecules. Another factor contributing to a larger magnitude of B_ε for a disklike fluid is the dipole–dipole interaction energy in which a head-

to-tail ($\rightarrow\cdots\hookrightarrow$) dipole alignment is more stable than an antiparallel ($\uparrow\cdots\downarrow$) alignment at the same separation. In other words, the most stable configuration in a dimer of disklike molecules is the most stable configuration in both the Gay–Berne potential and the dipolar potential, whereas the most stable configuration in a dimer of rodlike molecules is the most stable configuration in the Gay–Berne potential but a local minimum configuration on the dipolar surface. In a dipolar nonpolarizable soft sphere fluid (see Table 4), the dipole–dipole interaction energy is the factor determining the relative orientation. This leads to the positive B^*_ε at all μ^{2*} and T^* (1) and possibly to the nonexistence of the liquid phase in dipolar hard sphere fluids when the dipole strength is large (18).

Plots of the reduced angular integrand of B^*_ε as a function of $R^* = R/\sigma_<$ for ($T^* = 1.0$, $\mu^{2*} = 1.0$) are shown in Fig. 4. This reduced angular integrand B^*_ε(ang) is related to B^*_ε by $B^*_\varepsilon = \int B^*_\varepsilon(\text{ang})\, R^{2*}\, dR^*$. B^*_ε arises mostly from B_ε(ang) in the R^* region from ~1 to $1.5\sigma_<$. For rodlike molecules with large κ, B^*_ε(ang) is negative for all R^*. This reflects the dominant shape effect upon the dipolar (head-to-tail) interaction. As κ decreases, B^*_ε(ang) at large R^* becomes positive, i.e., the dipole term becomes important and configurations other than side-by-side become more accessible, and the minimum shifts toward small R^*. The maximum of B^*_ε(ang) of the disklike molecules increases as κ decreases to zero since the Gay–Berne energy is more attractive and configurations other than head-to-tail or head-to-head or tail-to-tail are less accessible. For small κ (large anisotropy), both the Gay–Berne energy and the electrostatic energy favour the head-to-tail configuration, leading to the large positive B^*_ε(ang) at large R^*. As κ increases towards 1, other configurations become more accessible, which leads to small negative values at large R^*. When $\kappa = 1$, which is the case for a Stockmayer fluid (19), the molecular shape becomes unimportant in determining B_ε; therefore B^*_ε(ang) becomes positive for all R^* due to a favorable dipolar head-to-tail configuration.

Conclusions

Second dielectric virial coefficients of the nonpolarizable dipolar Gay–Berne fluid are reported for several shape parameters and temperatures. The anisotropic repulsion, reflecting the effect of molecular shape, is crucial for the sign of B_ε, i.e., dipolar disklike and spherical dipolar molecules have a positive sign while dipolar rodlike molecules have a negative sign. The attractive term in the Gay–Berne potential increases the magnitude of B_ε, especially in disklike molecules. In real molecules, however, there are other long-range interactions in addition to the simple dipole–dipole interaction described in this work. For example, HCN, although a rodlike molecule, should have a positive B_ε at low temperatures due to the strong hydrogen bond that

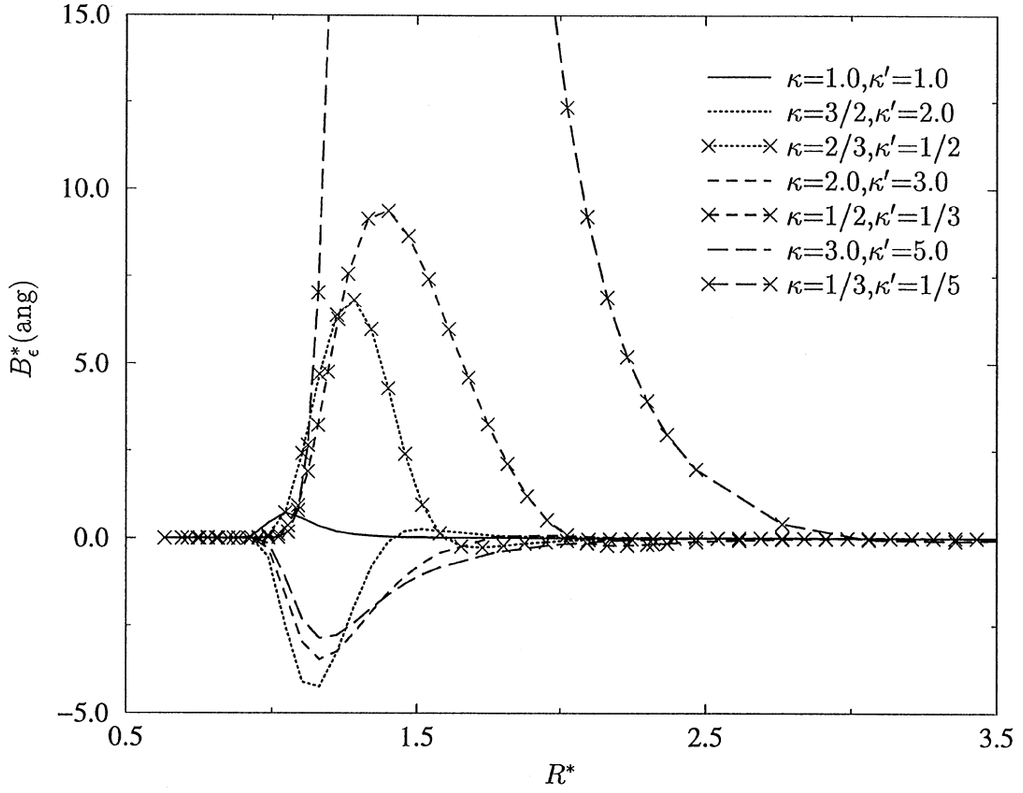
Fig. 4. The reduced angular integrand of B_ε^* for the Gay–Berne fluid with different shape parameters κ and κ' as a function of the reduced intermolecular distance $R^* = R/\sigma_<$ at $T^* = 1.0$ and $\mu^{2*} = 1.0$.



favors a head-to-tail configuration (20),[2] and polarizability can have a major effect on B_ε for dipolar fluids (1).

Since molecular shape is important to the second dielectric virial coefficient, it is interesting to anticipate the B_ε for mixtures of molecules of different shape. Using the generalization of Cleaver et al. (15), results have been obtained and will be published separately.

^{31}P chemical shielding as a function of bond angle: phosphorus chemical shielding surface of phosphinoborane $R_2PBR'_2$

Michael J.T. Ditty and William P. Power

Abstract: The phosphorus chemical shielding surface of phosphinoborane $R_2PBR'_2$ has been investigated via molecular orbital theory calculation and experimental measurement of selected derivatives. Ab initio calculations of phosphorus chemical shielding tensors were determined for the phosphinoboranes H_2PBH_2 and $(CH_3)_2PB(CH_3)_2$. Changes in the angle from planarity, i.e., that between the P-BR'_2 plane and the bisector of the RPR angle, are reflected in the orientations and magnitudes of the three principal components of the phosphorus chemical shielding tensor. To determine the validity of the calculated phosphorus chemical shielding surface, three phosphinoborane compounds with different angles from planarity were synthesized and studied by solid-state ^{31}P NMR spectroscopy. The ^{31}P NMR powder patterns provided experimental magnitudes of the principal components of the phosphorus chemical shielding tensor for each compound, which compared well to the calculated predictions; where orientations of these tensors could be determined experimentally, they also agreed well with the calculated results. The combined experimental and theoretical results provide a good description of the effects on changes in bond angle on phosphorus chemical shielding as the molecule is distorted from a planar to folded geometry.

Key words: chemical shielding, solid-state NMR, phoshinoborane, ab initio calculations.

Résumé : On a étudié la surface de blindage chimique du phosphore dans des $R_2PBR'_2$ par le biais de calculs d'orbitales moléculaires et de mesures expérimentales sur des dérivés choisis. Faisant appel à des calculs ab initio, on a déterminé les tenseurs du blindage chimique du phosphore dans les phosphinoboranes, H_2PBH_2 et $(CH_3)_2PH(CH_3)_2$. Les changements dans l'angle de planarité, c'est-à-dire l'angle entre le plan du P-BR'_2 et la bissectrice de l'angle RPR, se reflètent dans les orientations et les amplitudes des trois principales composantes du tenseur de blindage chimique du phosphore. Afin de déterminer la validité de la valeur calculée de la surface de blindage chimique du phosphore, on a réalisé la synthèse de trois composés phosphinoboranes présentant des déviations différentes de planarité et on les a étudiés par spectroscopie RMN du ^{31}P à l'état solide. Les patrons des spectres RMN du ^{31}P des poudres permettent d'obtenir les amplitudes expérimentales des principales composantes du tenseur de blindage chimique du phosphore pour chacun des composés et ces valeurs se comparent bien avec les valeurs calculées; dans les cas où les orientations de ces tenseurs peuvent être déterminées de façon expérimentale, elles sont aussi en bon accord avec les résultats des calculs. Une combinaison des résultats expérimentaux et théoriques permet d'obtenir une bonne description des effets des changements dans l'angle de liaison sur le blindage chimique du phosphore lorsqu'on déforme la molécule d'une géométrie plane à une autre repliée.

Mots clés : blindage chimique, RMN à l'état solide, phosphinoborane, calculs ab initio.

Introduction

Phosphorus chemical shielding has been the focus of much recent interest, particularly in terms of efforts to reliably predict its values through ab initio approaches in a variety of different environments (1–10). These efforts have resulted from an attempt to rationalize the general trends observed in ^{31}P NMR, predominantly using the isotropic chemical shift values obtained in solution NMR studies (11–13). What has become evident is that the changes in phosphorus chemical shielding are best reflected in changes of the complete chemical shift (or shielding) tensor, as the isotropic average of this tensor often masks clear trends in the changes of individual principal components of the tensor (14, 15). In one such effort, we have recently shown the effect of changes in bond length on the phosphorus chemical shielding of a series of isoelectronic R_3PX compounds, where X = BH_3, CH_2, NH, and O (16). That study indicated the phosphorus

chemical shielding of each compound followed the same general chemical shielding surface, and changes in the shielding were due to the changes in P–X bond length through the series.

In this article, we demonstrate a similar approach to the effects of bond angle on phosphorus chemical shielding, through calculation of the chemical shielding surface in phosphinoborane, $R_2PBR'_2$, where R = R′ = H (**1**), CH_3 (**2**), and experimental measurements of the phosphorus chemical shift tensors in $(2,4,6\text{-}(CH_3)_3C_6H_2)_2PB(2,4,6\text{-}(CH_3)_3C_6H_2)_2$ (Mes_2PBMes_2, **3**), $(C_6H_5)_2PB(2,4,6\text{-}(CH_3)_3C_6H_2)_2$ (Ph_2PBMes_2, **4**), and $(C_{10}H_{13})(H)PB(2,4,6\text{-}(CH_3)_3C_6H_2)_2$ ((1-Ad)(H)$PBMes_2$, **5**). The structures of these five compounds are given in Fig. 1. The compounds characterized experimentally (**3**–**5**), originally by Pestana and Power, (17) exhibit a range of angles ϕ between the PBR'_2 and the bisector of the R-P-R angle, ranging from 2° (planar molecule) to 62°, with minimum twist angles (<8°) about the P—B bonds. The experimental results show that the predictions from ab initio methods are reliable models of the changes in phosphorus chemical shielding when the angle ϕ is varied between 0° (planar geometry) and 90° (folded geometry). The phosphinoborane system is an interesting example of changes in phosphorus chemical shielding because, in addition to the range of ϕ angles these compounds demonstrate, there is also a significant change in the degree to which the phosphorus "lone pair" and the vacant B 2*p* orbital can interact.

Experimental

Calculations

Computational methods used to calculate phosphorus chemical shielding tensors were based solely on Gaussian 94 (18), which utilizes the gauge invariant (including) atomic orbital method (GIAO) (19). All calculations were completed using a Silicon Graphics Indigo^2 XL workstation. Two geometry parameter sets were utilized to create the chemical shielding surfaces (*i*) an optimized geometry for each molecule (frozen geometry) H_2PBH_2 and $(CH_3)_2PB(CH_3)_2$ changing only the angle ϕ between the P—B bond plane and the PR_2 plane and (*ii*) optimized geometries, for each molecule, at each angle ϕ. Calculations utilized the B3LYP hybrid method for the geometry optimization and Hartree–Fock (HF) method for the ^{31}P NMR shielding calculations, using the basis set 6-311+G(3d,2p) for all atoms.

Sample preparation

All synthetic procedures were performed using modified Schlenk techniques. Solvents were distilled under nitrogen from sodium metal and benzophenone. The compounds 1-adamantyl dichlorophosphonic acid ((1-Ad)$P(O)Cl_2$) (20), 1-adamantyl phosphine ((1-Ad)PH_2) (20), chlorobis(mesityl)phosphine (Mes_2PCl) (21, 22), dimesityl phosphine (Mes_2PH) (22), (dimesitylphosphino)dimesitylborane (Mes_2PBMes_2, **3**) (17), (diphenylphosphino)dimesitylborane (Ph_2PBMes_2, **4**) (17, 23), and (1-adamantylphosphino)dimesitylborane ((1-Ad)(H)$PBMes_2$, **5**) (17) were prepared according to literature methods. Diphenylphosphine (Ph_2PH), dimesitylboron fluoride (Mes_2BF), *n*-butyllithium (*n*-BuLi, 1.6 M in hexanes), 2-mesitylmagnesium bromide (MesMgBr, 1 M in tetrahydrofuran, THF), 1-adamantyl bromide ($C_{10}H_{13}Br$), phosphorus trichloride (PCl_3), aluminum bromide ($AlBr_3$), and lithium aluminum hydride ($LiAlH_4$) were obtained from the Aldrich Chemical Company. Samples for subsequent solid-state NMR spectroscopy (**3**–**5**) were characterized by high resolution ^1H and ^{31}P NMR, electron ionization mass spectrometry and melting points, which all matched literature data (17).

Solid-state NMR spectroscopy

All solid-state NMR spectra were obtained at 11.75 T and 295 K on a Bruker AMX-500 NMR spectrometer, operating at 202.46 MHz for ^{31}P and 500.13 MHz for ^1H. The ^{31}P NMR spectra were referenced to an external sample of solid $NH_4H_2PO_4$, which has a chemical shift of +0.81 ppm with respect to 85% H_3PO_4(aq). All ^{31}P solid-state NMR spectra were obtained with cross-polarization (CP) and high-power ^1H decoupling, with ^1H 90° pulse widths of 4–5 μs and contact times of 5 ms. Simulated spectra were obtained on a PC microcomputer using the WSOLIDS computer program of Eichele and Wasylishen (24) incorporating the POWDER interpolation scheme (25).

Results

The primary goal of this study was to correlate the effects of structural changes, specifically bond angles, on phosphorus chemical shielding. We have used a combination of theoretical predictions and experimental measurements to provide a proper description of these effects, and we illustrate the results of the theoretical predictions first.

Computational

The model phosphinoboranes investigated by ab initio methods were H_2PBH_2 (**1**) and $(CH_3)_2PB(CH_3)_2$ (**2**), chosen for reasons of computational accessibility. A general view of their structures is provided in Fig. 1. Each of these molecules was subjected to a geometry optimization that resulted in the structural parameters outlined in Table 1; these results agreed well with previous calculations performed on this class of compounds (26). Since our focus was the effect of bond angle changes at phosphorus, we manipulated the structures of these molecules as a function of the angle ϕ, where this angle lies between the P—B bond direction and the bisector of the HPH (or CPC) bond angle. Structural "surfaces" were achieved by varying this angle in 10° steps between a planar geometry (ϕ = 0°) and a folded geometry (ϕ = 90°) in two distinct fashions. In the first case, that of a "frozen" geometry, the structural parameters other than the angle ϕ were held at their optimized values. In the second, called an "optimized" geometry, the structure was allowed to relax to a minimum energy for the defined value of ϕ. The construction of these two surfaces was undertaken to separate the influence of strict bond angle changes from the aspects of the phosphinoborane structure covariant with this changing angle. The frozen geometry implies no change in the structure save for that of the angle from planarity. The optimized geometry displayed systematic variation in several structural parameters, most notably in the P—B and P—H (or P—C) bond lengths, and the HBH and HPH (or CPC) bond angles. Details are provided in Table 2. All other structural parameters were invariant to within 0.5% of their fully optimized values.

The results from these two geometric surfaces were then used to predict the magnetic shielding properties of phosphorus as a function of the angle from planarity ϕ. The results from these calculations are given in Fig. 2. While it is normal to report chemical shielding in terms of the standard definitions, $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$, we have opted to use, as an alternative, a molecular reference frame that is more meaningful for comparisons detailed in this investigation (see Fig. 3). In this molecular fixed frame, the *z* axis lies along the bisector of the HPH (or CPC) angle, the *y* axis lies in the HPH (or CPC) plane perpendicular to *z*, and *x* lies perpendicular to the HPH (or CPC) plane. Consequently, in the planar geometry (ϕ = 0°), *x* lies perpendicular to the plane of the molecule, while *y* lies in the molecular plane and perpendicular to the P—B bond. In the folded geometry (ϕ = 90°), *y* still lies perpendicular to the P—B bond, and *x* lies along the P—B bond. While these directions provide a good reference with respect to the changes in molecular structure, the results from the calculations show that the principal components of the phosphorus chemical shielding tensor do not follow these directions rigorously. In fact, the rotation of the tensor about the *y* direction, implied by the rotation of the HPH (or CPC) plane about this axis, is restricted to a large degree, such that the tensor follows the same sense of rotation but at a slower rate. Hence, as the angle ϕ is increased, the principal components σ_x and σ_z deviate from the *x* and *z* axes by values indicated in Fig. 2.

There are three key areas of interest on the H_2PBH_2 and $(CH_3)_2PB(CH_3)_2$ surfaces. These are the data points where the tensor components correspond to the planar angles, ϕ = 2.2, 42.1, and 61.6°. These data points are of special interest because the three phosphinoborane compounds, Mes_2PBMes_2 (**3**), Ph_2PBMes_2 (**4**), and (1-Ad)(H)$PBMes_2$ (**5**), demonstrate the corresponding angles from planarity.

The importance of these compounds is that they will provide experimental data to test the predictive potential of the chemical shielding surfaces.

Experimental

The solid-state ^{31}P CP static NMR spectra of **3**–**5** are given in Fig. 4, together with their best-fit simulations. The relevant spectral parameters resulting from these simulations are listed in Table 3. The anisotropic ^{31}P NMR line shapes $\nu_P(\theta, \varphi)$ arise from the orientation dependence (given in spherical polar coordinates by the polar and azimuthal angles θ and φ with respect to B_o, the magnetic field direction) of the ^{31}P anisotropic chemical shift and the ^{31}P–^{11}B direct dipolar coupling, as well as the relative orientation of these two interactions (27), given by the equation

$$[1]\quad \nu(\theta, \varphi) = \nu_o[1 - (\sigma_{11}\sin^2\theta\cos^2\varphi + \sigma_{22}\sin^2\theta\sin^2\varphi + \sigma_{33}\cos^2\theta)] + m_B R_{PB}[3(\sin\beta\sin\theta\cos(\alpha - \varphi) + \cos\beta\cos\theta)^2 - 1]$$

where ν_o is the ^{31}P Larmor frequency, σ_{ii} (i = 1, 2, 3) are the principal components of the ^{31}P chemical shielding tensor, m_B = +3/2, +1/2, –1/2, –3/2 are the equally probable spin states of the adjacent ^{11}B (I = 3/2) nucleus, R_{PB} is the ^{31}P–^{11}B dipolar coupling constant, and the angles α and β are the azimuthal and polar angles, respectively, describing the orientation of the P–B dipolar vector (i.e., the P—B bond) in the principal axis system of the ^{31}P chemical shielding tensor. The quality of the spectral simulations for all three compounds was markedly improved if the contributions from the 19.58% naturally-abundant ^{10}B(I = 3) nuclear isotope were included as well, with a ^{31}P–^{10}B dipolar coupling constant of 0.334 87 (i.e., $\gamma(^{10}B)/\gamma(^{11}B)$) of that of ^{31}P–^{11}B dipolar coupling. There was no evidence of indirect P–B J coupling in any of the ^{31}P solid-state NMR spectra, although the ^{31}P CPMAS NMR spectrum of **3** (Fig. 4*a*) showed substantial residual dipolar coupling to the quadrupolar boron isotopes directly adjacent to phosphorus, in spite of rapid sample rotation of 9.5 kHz. The centreband at 20 ± 20 ppm, spans 7000 Hz. In the planar geometry in which this molecule is found, the electric field gradient around boron must be very large, resulting in a ^{11}B quadrupolar coupling constant of approximately 400 MHz.[2]

In practice, absolute chemical shielding values, expressed in ppm with respect to a bare ^{31}P nucleus, are not measured; rather, the chemical shifts relative to an accepted reference compound are determined. Thus the principal components of the ^{31}P chemical shift tensor, given by δ_{ii} (i = 1, 2, 3), are determined experimentally, where δ_{11} corresponds to the least shielded component σ_{11}, etc., in accord with convention (28). The chemical shift values with respect to 85%

Fig. 2. Phosphorus chemical shielding surfaces for **1** and **2** in frozen and optimized geometries. The fully optimized geometries, including optimum values of the angle from planarity, ϕ, are included for H_2PBH_2 at 68.16° and $(CH_3)_2PB(CH_3)_2$ at 62.67°. The chemical shielding surfaces display the dependence of the molecular-frame principal components (σ_x, ◆; σ_y, ▲; σ_z, ■; these directions are defined in the text and in Fig. 3) of the phosphorus chemical shielding tensor as a function of the angle from planarity, ϕ. Also included with the symbol × are the deviation angles of the *x* and *z* shielding components from the *x* and *z* molecular axes; the vertical scale on the right pertains to these values only.

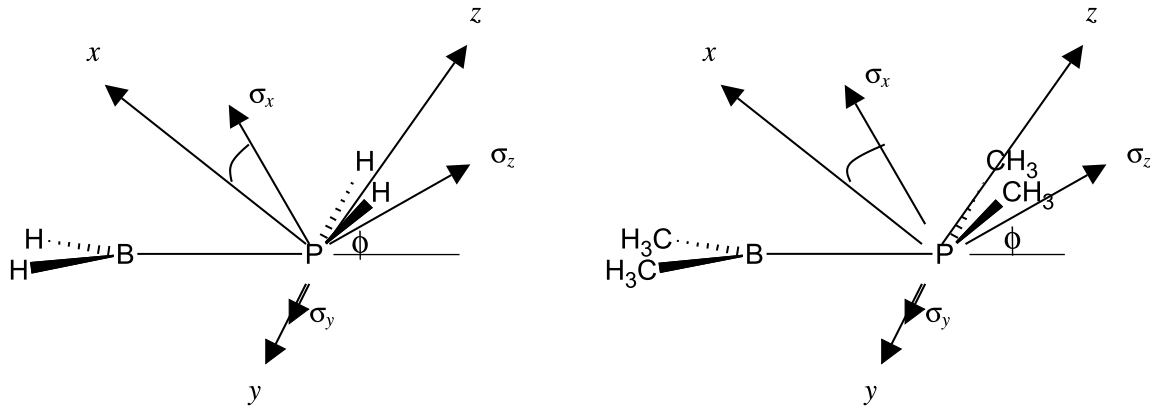
Fig. 3. Definition of the (*x, y, z*) molecular-frame axis system, as well as the molecular-frame principal components (σ_x, σ_y, σ_z) of the phosphorus chemical shielding tensor. The deviation angle lies between the *x* (*z*) axis and the σ_x (σ_z) components.



H_3PO_4(aq) may be converted to chemical shielding using the absolute chemical shielding scale for phosphorus established by Jameson et al. (29) given by

[2] $\sigma_{ii} = 328.35 \text{ ppm} - \delta_{ii}$

where *ii* = 11, 22, 33, or *iso*.

The ^{31}P solid-state NMR spectra display significant chemical shift anisotropies, ranging in spans ($\delta_{11} - \delta_{33}$) from 182 ppm for **3**, to 98 ppm for **4**, and to 194 ppm for **5**. Compounds **3** and **4** display approximately axially symmetric phosphorus chemical shift tensors, although with the sense of the axial symmetry reversed between the two. Compound **5** displays complete nonaxial symmetry of its phosphorus chemical shift tensor. The ^{31}P–^{11}B dipolar coupling constants, which depend on the internuclear separations of the two nuclear isotopes, become smaller in magnitude as the geometry of these molecules move further from planarity, in accord with expectations based on the bond length changes observed through this series by X-ray crystallography (17).

Compounds **3**–**5** are air sensitive compounds, decomposing to the corresponding phosphine and boryloxide upon prolonged contact with air (30). To limit this process, the samples were packed and sealed in MAS rotors under a nitrogen atmosphere prior to spectral acquisition. In addition, it was difficult to completely purify these compounds from their parent phosphines. Consequently, the spectra of **3** (see Fig. 4*a*), in particular, contain some spectral intensity at low frequencies corresponding to the phosphine Mes_3P (–39 ppm) (21). The ^{31}P static NMR spectrum of the solid phosphine Mes_3P overlaps partially with that of the phosphinoborane. The identity of this impurity was confirmed by solid-state ^{31}P NMR of the pure phosphine (spectrum not shown), and simulation of the relevant phosphinoborane was completed by exclusion of the phosphine's spectrum from the fitting analysis. Since this impurity masks the low frequency end of the anisotropic ^{31}P NMR powder pattern of **3**, the errors in both δ_{33} and β are larger than the other parameters. The broad feature near 30 ppm is particularly sensitive to the value of α.

Discussion

The chemical shielding surface generated by calculation enables us to evaluate the relative magnitude of the anisotropy over a range of angles. It is believed that this chemical shielding surface can be used as a predictive tool, of anisotropy and magnitudes of tensor components for similar phosphorus compounds. Chemical shielding calculations for H_2PBH_2 and $(CH_3)_2PB(CH_3)_2$ revealed that changes in the angle from planarity affected the orientations and magnitudes of the three principal components of the chemical shielding tensor significantly. The first set of calculations used the frozen geometry parameters over the entire range of ϕ. A significant trend that is observed for both H_2PBH_2 and $(CH_3)_2PB(CH_3)_2$ is that they converge to a minimum anisotropic span at their fully optimized geometries 177 ppm at $\phi = 68.16°$ and 93 ppm at $\phi = 62.67°$, respectively.

The tensor component σ_y that is perpendicular to the phosphorus–boron bond and is coplanar with the boron substituents is governed by the movement of the substituents on the phosphorus atom out of the P—B bond plane. Its orientation is unchanged and its magnitude becomes progressively more shielded as the angle is increased. The tensor component σ_z that is oriented as the bisector of the PR_2 plane, and parallel to the phosphorus–boron bond, initially has a large shielding value that decreases sharply until 60°; its shielding changes very little after this angle. The tensor component σ_x that is oriented along the phosphorus lone pair increases linearly until an angle of 60°; at angles greater than 60° the shielding increases rapidly.

The second set of shielding calculations utilized the optimized geometry parameters (frozen geometry) of the respective molecule for each calculation. It has been observed, that as the planar angle was changed from 0 to 90° some of the bonding angles and bond lengths change. The changes include an increase in both the P—B bond length and the P—H bond lengths with a concomitant decrease in the H-P-H angle. These trends are also observed in the crystallographic data reported by Pestana and Power (17).

Both the frozen and optimized geometry chemical shielding surfaces for H_2PBH_2 display nonaxially symmetric powder patterns. The main differences between the two surfaces are the greater shielding for all tensor components in the frozen geometry surface and the angle at which the minimum chemical shielding anisotropy is produced, at 0° for the frozen geometry compared to fully optimized angle on the optimized geometry surface. Also, an identical trend to that encountered in a frozen geometry is followed by the σ_z

tensor component in the optimized geometry surface. Since a frozen geometry was used, changes in the degree of phosphorus lone pair donation to the empty boron 2*p* orbital do not play a key role in the shielding of the σ_y or σ_z tensor components. This set of calculations with a "frozen" structure did not permit a "relaxation" of the structure with concomitant changes in the character of the lone pair. The lone pair remains localized on phosphorus and resulting in very little change in the shielding of these components. Much the same trends can be deduced for the calculations involving **2**, the methylated phosphinoborane.

The most relevant test of the calculated surfaces involves comparison to experimental values obtained for phosphinoboranes with different angle of planarity, and it was on this basis that compounds **3**–**5** were chosen for investigation. Ideally, the calculated surfaces should provide some predictive value for phosphorus chemical shielding. The experimental and calculated results compare well, providing some support for the validity of the trends extracted from the calculated surfaces. The magnitudes of the chemical shielding principal components are lower (less shielded) in the compounds characterized experimentally. This is a consequence of the difference in the attached R and R′ groups (H, CH_3 vs. Mes, Ph, 1-Ad) between the calculated and experimental compounds. The trend to decreased shielding with bulkier substitution is properly represented between the H and CH_3 surfaces, so this difference is consistent with the calculations. More significant are the relative trends, in terms of the orientations of the various principal components as the angle from planarity is changed. Here, the agreement between the two calculated surfaces, and between the calculated surfaces and experimental results, is quite reasonable. For the planar molecule, **3**, the anisotropic chemical shielding spans 182 ppm; as the angle is increased to 42°, this span is significantly reduced to 98 ppm for **4**; and the span increases markedly beyond that, to 194 ppm for **5**, where the angle from planarity is 62°. The orientations of the principal components follow those predicted from the surface. For compound **3**, the P—B bond lies perpendicular to the most shielded principal component, in accord with the calcula-

Table 3. Spectral parameters used to provide best-fit simulations of the experimental ^{31}P CP static NMR spectra of solid samples of Mes_2PBMes_2 (**3**), Ph_2PBMes_2 (**4**), and (1-Ad)(H)$PBMes_2$ (**5**). Phosphorus chemical shift (or chemical shielding) values are given in ppm with respect to 85% H_3PO_4(aq) (or the bare nucleus, respectively). Errors in the chemical shifts (chemical shieldings) are less than ±3 ppm, unless indicated otherwise. R_{PB} denotes the strength of the ^{31}P–^{11}B direct dipolar coupling constant, with an error of less than ±60 Hz; the dipolar coupling to ^{10}B (I = 3, 19.58% natural abundance) was also included in the calculated spectra, with a magnitude of 0.33487 × R_{PB}. Errors in the angles α and β are less than ±7° and ±3°, respectively, unless indicated otherwise. Line broadening of 500–1000 Hz was applied to each calculated spectrum to improve the fit to the experimental spectrum.

Compound	Mes_2PBMes_2, **3**	Ph_2PBMes_2, **4**	(1-Ad)(H)$PBMes_2$, **5**
Angle φ	2.2°	42.1°	61.6°
δ_{11} (σ_{11}) (ppm)	122 (206)	87 (241)	87 (241)
δ_{22} (σ_{22}) (ppm)	75 (253)	0 (328)	–3 (331)
δ_{33} (σ_{33}) (ppm)	–60 ± 10 (388)	–6 (334)	–107 (435)
R_{PB} (Hz)	2400	2430	1900
α (degrees)	75 ± 5	0	60
β (degrees)	90 ± 10	20	40

tions. However, the calculations fail to correctly predict the orientation of the least shielded component, σ_z; the calculations place this component along the P—B bond, whereas it lies 75° from this vector in **3**. This is probably due to the substituents, most notably the twists experienced by the mesityl rings in the crystal lattice (17). As the angle is increased to approximately 40°, the calculations predict that σ_x and σ_z deviate from the molecular *x*, *y*, *z* axes, by about 10°, resulting in an expected value for β of 40° – 10° = 30°, in accord with the experimental results for **4**. The intermediate component, σ_y in the calculated surfaces and δ_{22} in the experimental results, is substantially more shielded in the experimental results, a difference that is most likely due to the different identity of the substituents on phosphorus between the calculated and experimental molecules. Finally, at the largest experimental angle of 62°, the orientation of the most shielded component for **5** is in accord with the expectations from the surface, when the angle from planarity and the deviation angle of the σ_x and σ_z components from the *x* and *z* axes are taken into account. The sole discrepancy here is the apparent interchange of the orientations of the δ_{11} and δ_{22} components. This interchange can be attributed to the substitution of phosphorus in **5**, since hydrogen is one substituent. It can be argued that the H_2PBH_2 is a better model of the surface for this molecule than $(CH_3)_2PB(CH_3)_2$, in which case these components (σ_y and σ_z) are anticipated to follow this trend. It is clear that the general features of the calculated chemical shielding surfaces, large anisotropy at a planar geometry, reducing to a minimum value near the optimized geometry, then increasing significantly at angles beyond.

Conclusions

The phoshorus chemical shielding surface for phosphinoboranes of the form $R_2PBR'_2$ have been investigated from a calculated and experimental viewpoint. The calculations show clear trends in the phosphorus shielding as the bond angles at phosphorus are changed, from a planar molecule to a folded form. Experimental data obtained for compounds that sample different regions of this surface provide support for the predictive value of the calculated surface. It is hoped that these ongoing contributions involving calculated and experimental values of phosphorus chemical shielding tensors in a variety of different molecules and geometries will provide further insights into the factors influencing the wide range of phosphorus chemical shifts.

A multinuclear magnetic resonance study of crystalline tripotassium tetracyanocuprate

Scott Kroeker and Roderick E. Wasylishen

Abstract: Direct NMR observation of copper-63/65 nuclei in solid $K_3Cu(CN)_4$ provides the first experimental example of anisotropic copper chemical shielding. Axially symmetric by virtue of the space group symmetry, the shielding tensor spans 42 ppm, with the greatest shielding when the unique axis is perpendicular to the applied magnetic field. The nuclear quadrupole coupling constant is also appreciable, $C_Q(^{63}Cu)$ = –1.125 MHz, reflecting a deviation of the $Cu(CN)_4^{3-}$ anion from pure tetrahedral symmetry. Spin–spin coupling to ^{13}C nuclei in an isotopically enriched sample is quantified by line-shape simulations of both ^{13}C and $^{63/65}Cu$ magic-angle spinning (MAS) NMR spectra to be 300 Hz. It is shown that this information is also *directly* available by $^{63/65}Cu$ triple-quantum (3Q) MAS NMR. The relative merits of these three approaches to characterizing spin–spin couplings involving half-integer quadrupolar nuclei are discussed. Chemical shielding tensors for nitrogen-15 and carbon-13 are obtained from NMR spectra of non-spinning samples, and are compared to those of tetrahedral group 12 tetracyanometallates. Finally, $^2J(^{63/65}Cu,^{15}N)$ detected in ^{15}N MAS experiments are found to be 19 and 20 Hz for the two crystallographically distinct cyanide ligands.

Key words: NMR, quadrupolar nucleus, chemical shielding tensor, multiple-quantum magic-angle spinning, metal cyanide, spin–spin coupling.

Résumé : Une observation RMN directe des noyaux cuivre-63/65 du $K_3Cu(CN)_4$ est le premier exemple expérimental du blindage chimique anisotrope du cuivre. De symétrie axiale en raison de la symétrie de son groupe d'espace, le tenseur de blindage s'étale sur 42 ppm; le blindage le plus important se produit lorsque l'axe unique est perpendiculaire au champ magnétique appliqué. La constante de couplage quadripolaire nucléaire est importante, $C_Q(^{63}Cu)$ = –1,125 MHz et elle est un reflet d'une déviation de l'anion $Cu(CN)_4^{3-}$ par rapport à une symétrie tétraédrique pure. Sur la base de la simulation de la forme des bandes des spectres RMN du ^{13}C et du $^{63/65}Cu$ par rotation à l'angle magique (« MAS »), on a pu établir que la valeur du couplage spin–spin avec le noyau ^{13}C d'un échantillon isotopiquement enrichi est égale à 300 Hz. On a démontré que cette information est aussi disponible *directement* par RMN MAS à triple quantum (3Q) du $^{63/65}Cu$. On discute des mérites relatifs de ces trois approches pour la caractérisation des couplages spin–spin impliquant des noyaux quadripolaires à demi-unités. On a obtenu les tenseurs de blindage chimique de l'azote-15 et du carbone-13 à partir de spectres RMN d'échantillons immobiles et on les a comparés à ceux des tétracyanométallates tétraédriques du groupe 12. Enfin, on a trouvé que les constantes $^2J(^{63/65}Cu,^{15}N)$ détectées lors d'expériences MAS du ^{15}N sont égales respectivement à 19 et 20 Hz pour les deux ligands cyanures cristallographiquement distincts.

Mots clés : RMN, noyau quadripolaire, tenseur de blindage chimique, rotation à l'angle magique à multiples quanta, cyanure métallique, couplage spin–spin.

[Traduit par la Rédaction]

Introduction

Simple inorganic salts containing cyanide ligands complexed to copper(I) combine in a variety of ratios, displaying diverse structural characteristics (1). Potassium dicyanocuprate, for example, comprises spiralling polymer chains of composition $[Cu(CN)_2^-]_\infty$ (2) and $KCu_2(CN)_3\cdot H_2O$ forms two-dimensional sheets involving $[Cu_2(CN)_3^-]_\infty$ (3). By contrast, $K_3Cu(CN)_4$ consists of discrete $Cu(CN)_4^{3-}$ tetrahedra (4). In terms of copper coordination, the one-to-one complex, CuCN, contains two-coordinate copper atoms (5–7), whereas both $KCu(CN)_2$ and $KCu_2(CN)_3\cdot H_2O$ possess copper centres bound to three cyanide ligands in a nearly trigonal planar arrangement, and $K_3Cu(CN)_4$ includes four copper–carbon linkages. Given this diversity, these systems serve as excellent model compounds for studying geometric effects on the carbon and nitrogen NMR parameters.

In addition to their attractiveness as well-characterized model compounds, the chemistry of cyanometallates, in general, is a popular means of constructing supramolecular as-

semblies (8). The particular utility of tetracyanocuprate tetrahedra as building blocks has been highlighted in a recent review (9). Since then, other related reports have appeared. The reaction of $K_3Cu(CN)_4$ with Me_3SnCl and 4,4′-bipyridine produces a porous structure of $[Cu_2(\mu\text{-}CN)_2(CN)_2]$ sheets bridged by bipyridine "pillars" (10). One- and two-dimensional materials result from hydrothermal reactions of CuCN and $Cu(NO_3)_2\cdot 2.5H_2O$ with organonitrogen ligands (11).

Toward the development of a more systematic understanding of NMR parameters in cyanocuprates, a comprehensive investigation of crystalline tripotassium tetracyanocuprate, $K_3Cu(CN)_4$, has been performed. The structure of this compound consists of distorted tetrahedral $Cu(CN)_4^{3-}$ units in the solid phase, with a C_3 rotation axis defining the unique Cu—C—N bond (4). This geometric arrangement simplifies the analysis of NMR line shapes by fixing the orientation of certain tensor components.

The relatively high symmetry at the copper centre also makes it possible to directly probe the metal using copper NMR. Both naturally occurring isotopes, ^{63}Cu (69.1%) and ^{65}Cu (30.9%), are spin-3/2. Their magnetogyric ratios, γ, are comparable to that of carbon-13. They have sizeable quadrupole moments, eQ, with the consequence that their powder NMR spectra are observed only when the nucleus is situated in a symmetrical environment where the electric field gradient (EFG) is small. There are a number of reports of copper NMR in solutions (12, 13), but few in solid samples. In spite of the inherent challenges of copper NMR, interesting experiments have been successfully performed on systems ranging from simple cubic ionic solids (14) to high-T_c cuprate superconductors (see ref. 15 for example). Of particular relevance to the present work, copper-63/65 NMR has been used to probe cyanide ordering in the host/guest framework compounds "$N(CH_3)_4CuM(CN)_4\cdot G$," where M = Zn, Cd, Pt and G = CCl_4, $CHCl_3$, CH_3CCl_3, and $CHBr_3$ (16). A principal objective of these studies was to unambiguously identify Cu–C–N–Zn connectivities in $N(CH_3)_4CuZn(CN)_4$ by NMR of both copper-63/65 and carbon-13 (16*a*). For that compound, copper atoms exist in perfectly tetrahedral environments, rendering the EFG at that site zero, and its line shape isotropic. Less definitive were copper-63 NMR studies of some of the other compounds, where second-order quadrupolar line shapes compromised site distinction (16*b*).

The work presented herein concerns a cyanocuprate of *known* structure, which may be used to assess the sensitivity of the quadrupole coupling to deviations from cubic symmetry. Moreover, $K_3Cu(CN)_4$ is an ideal model for evaluating the feasibility of triple-quantum magic-angle spinning investigations involving nearly tetrahedral copper centres, in view of the growing importance of this structural motif.

Experimental

Materials

Tripotassium tetracyanocuprate was prepared by addition of CuCN to an aqueous solution containing a stoichiometric excess of KCN. Small, white crystals formed as the water evaporated. Isotopically enriched samples were prepared using an appropriate ratio of ^{13}C-, ^{15}N-, or ^{13}C^{15}N-enriched and natural abundance KCN. The resulting solids were characterized by Raman spectroscopy, using the well-documented cyanide stretching frequency as a means to establish chemical identity and purity (17). Some difficulties were encountered in isolating $K_3Cu(CN)_4$ crystals free from $KCu(CN)_2$ and $KCu_2(CN)_3\cdot H_2O$ contaminants. Repeated recrystallization resulted in a mixture of $K_3Cu(CN)_4$ and $KCu(CN)_2$ estimated to be 4:1. Although the copper quadrupolar interaction in the latter compound is too large to adversely affect the copper-63/65 NMR spectra of $K_3Cu(CN)_4$ (18, 19), its presence interfered with the analysis of carbon-13 and nitrogen-15 NMR spectra. This problem was resolved by subtracting the MAS NMR spectra of nearly pure $KCu(CN)_2$ from those of impure $K_3Cu(CN)_4$.

NMR spectroscopy

Spectra were acquired using Bruker spectrometers and probes: an MSL-200 operating at 4.7 T with a 7 mm double-bearing magic-angle spinning (MAS) probe and an AMX-400 at 9.4 T with a 4 mm double-bearing triple-resonance MAS probe. Although $K_3Cu(CN)_4$ is a piezoelectric material (vide infra), we did not encounter problems with acoustic ringing (20). Carbon-13 and nitrogen-15 NMR spectra were acquired using single-pulse excitation, with 60° pulses and recycle delays of 90 s or longer, due to long spin-lattice relaxation times. Carbon-13 chemical shifts are referenced with respect to TMS using solid adamantane as a secondary reference. Nitrogen-15 chemical shifts are reported with respect to liquid ammonia, referenced using solid $^{15}NH_4NO_3$, which has a shift of +23.80 ppm relative to liquid ammonia at 20°C.

Copper-63/65 single-pulse excitation MAS spectra of the central transition were collected using pulse durations which maximized the signal amplitude of the central transition — typically 2 μs. For $^{63/65}$Cu MAS NMR spectra of the satellite transitions and for non-spinning samples, very short pulses (<1 μs) were applied to minimize inhomogeneous radiofrequency (rf) excitation over the spectral region of interest. Triple-quantum (3Q) MAS experiments were performed using strong rf pulses ($\nu_{rf} \approx 167$ kHz), the durations of which were adjusted to provide optimal excitation (4.0 μs) and transfer (1.2 μs) of 3Q coherences. A six-phase cycle designed to simultaneously select the echo and anti-echo coherence pathways was employed (21). The 1D isotropic projection was constructed by plotting the echo maximum for each t_1 slice as a function of the total evolution time, $t_1 + t_2$, prior to Fourier transformation (22). Copper-63/65 chemical shifts are referenced to an aqueous solution containing KCN/NaCN/CuCN corresponding to a CN:Cu molar ratio of about six, to ensure that $Cu(CN)_4^{3-}$ is the predominant copper–cyanide species present (23). The copper chemical shift of this system is reported to be 494 ppm with respect to 1.0 M $[Cu(NCCH_3)_4][BF_4]$ in acetonitrile (24).

Line-shape simulations

Spectral calculations were carried out using programs developed in this laboratory. WSOLIDS is a Windows-based C++ program designed to compute frequency–domain NMR line shapes resulting from the influence of a variety of spin interactions. The following models were employed in this study: (*a*) central transition MAS line shape of a $^{63/65}$Cu nucleus accounting for, where necessary, spin–spin coupled ^{13}C

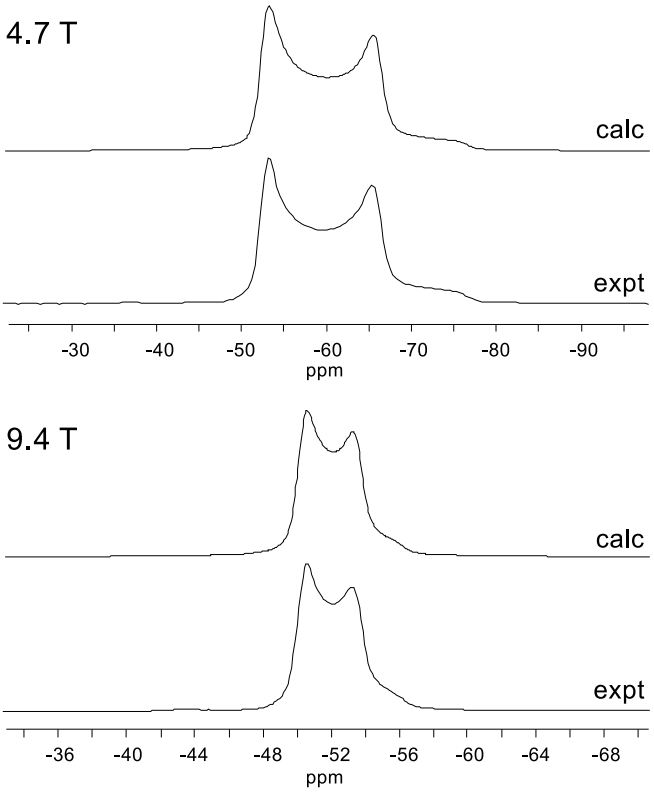
Fig. 1. Copper-63 MAS NMR spectra of the central transition in natural abundance $K_3Cu(CN)_4$ at 4.7 and 9.4 T. Experimental spectra are the result of 1000 transients at a sample spinning frequency of 6.45 kHz (4.7 T) and 128 transients at 8.00 kHz (9.4 T). Displayed regions at both fields span 4 kHz.



nuclei; (*b*) line shape of the $^{63/65}$Cu central transition in a non-spinning sample, subject to anisotropic chemical shielding and quadrupolar interactions; (*c*) MAS spectral line shape of ^{13}C and ^{15}N nuclei, spin–spin coupled to quadrupolar $^{63/65}$Cu spins, including residual dipolar effects as a first-order perturbation to the pure *J*-split multiplets. A second program, QUADSPIN, includes some extensions of the models described above, and was used for (*a*) calculating stationary spectra of ^{13}C and ^{15}N spin–spin coupled to quadrupolar nuclei ($^{63/65}$Cu and (or) ^{14}N), quadrupolar perturbations accounted for by first-order perturbation theory, and (*b*) the time-domain calculation of an isolated copper-63/65 nucleus evolving under the influence of both anisotropic shielding and first-order quadrupolar effects, subject to MAS at any speed (i.e., spinning sidebands). Essential to both programs is the POWDER algorithm of Alderman et al. (25), which provides an efficient means to simulate a powder pattern for which all possible crystallite orientations must be considered. All frequency–domain MAS line shapes are computed under the "infinite spinning speed" assumption, which does not account for the spinning sidebands generally observed when the spinning frequency is less than the inhomogeneously broadened powder pattern. Hence, in order to establish meaningful comparisons between experimental and calculated spin-1/2 MAS line shapes, it was necessary to construct an "isotropic MAS powder spectrum" by adding the spinning sidebands to the centreband (26).

Results and discussion

Copper NMR

Copper-63 MAS NMR spectra[2] of the central (1/2 ↔ –1/2) transition (27–30) of $K_3Cu(CN)_4$ in natural elemental abundance are shown in Fig. 1, along with the best-fit calculated spectra. A single copper site with an isotropic chemical shift of –49 ppm (corrected for second-order quadrupolar effects) is observed by NMR, consistent with the crystal structure (4). Also in agreement with the crystal structure is the presence of an axially symmetric EFG at the copper nucleus, manifesting in a line shape that is characteristic of the second-order quadrupolar interaction (27, 28). The space group for this compound includes a C_3 axis along one of the Cu—CN bonds ($r_{Cu—C}$ = 2.014 ± 0.011 Å; angle CuCN 180°), with slight structural differences between this and the other three ligands ($r_{Cu—C}$ = 1.992 ± 0.007 Å; angle CuCN 173.7° ± 0.6°) (4). This minor distortion from tetrahedral symmetry, however, is sufficient to induce a substantial electric field gradient at the copper, resulting in a quadrupole coupling constant, C_Q, of magnitude 1.125 ± 0.010 MHz for ^{63}Cu and 1.040 ± 0.010 MHz for ^{65}Cu. Since C_Q reflects the product of eQ and the largest component of the EFG at the nucleus, V_{33}, these experimental values testify to the extreme sensitivity of copper quadrupole coupling constants to molecular symmetry. This deviation from pure tetrahedral symmetry is also evident from its piezoelectric (31) and pyroelectric properties (32).

In fact, the copper quadrupole coupling tensor in this compound was first determined in 1951 by Becker (33), who analyzed the orientation-dependence of a 3.5 cm long by 1.4 cm diameter cylindrical crystal with respect to a 1.1 T magnetic field. Quadrupole coupling constants of 1.113 ± 0.003 and 1.030 ± 0.003 MHz were reported for the two isotopes. The differences between values obtained in the present study and those of the previous study are not *statistically* significant; however, if these values are suggestive of a true disparity, it may reside in Becker's failure to account for anisotropic chemical shielding. These effects would be very small (~500 Hz) at such a low applied field, but could skew the analysis subtly. The ratio of the quadrupole coupling constants in both studies agrees with that anticipated on the basis of the quadrupole moments: $Q(^{63}Cu)/Q(^{65}Cu)$ = 1.081 (34).

Copper-63/65 NMR spectra of the central transition in a non-spinning sample of $K_3Cu(CN)_4$ were also acquired at 4.7 and 9.4 T. Figure 2 contains the experimental spectra along with the best-fit calculations for ^{63}Cu, incorporating, in addition to the quadrupolar interaction as determined by MAS NMR, effects due to anisotropic chemical shielding (Table 1). Whereas there is generally no a priori justification for assuming coincidence of the interaction tensor orientations (35), full advantage was taken in these analyses of the

[2] Analogous spectra were collected and analysed for the copper-65 isotope, and yielded results consistent with the ratios of their respective magnetogyric ratios, $\gamma(^{63}Cu)/\gamma(^{65}Cu)$ = 0.933 53, and quadrupole moments, $Q(^{63}Cu)/Q(^{65}Cu)$ = 1.081 (34).

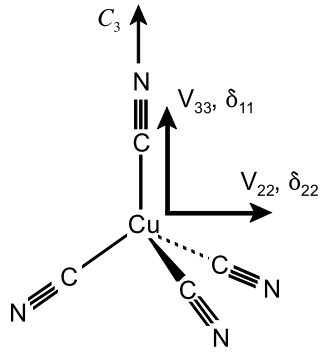
molecular three-fold rotational symmetry in identifying the mutual EFG and shielding tensor orientation. The presence of a C_3 axis demands that the unique component of the axially symmetric interaction tensors be aligned with the rotation axis. Because the EFG tensor is traceless, the largest component is unique; its orientation in the molecular frame is fixed. For the magnetic shielding tensor, however, the

Fig. 3. Schematic of anion structure in crystalline $K_3Cu(CN)_4$. Also depicted are the copper EFG and chemical shielding tensor orientations.



unique component may be the most- or least-shielded element, corresponding to $\kappa = +1$ or -1, respectively:

$$[1] \qquad \kappa = \frac{3(\delta_{22} - \delta_{iso})}{\delta_{11} - \delta_{33}}$$

where the most shielded direction is along δ_{33} and the least shielded direction lies along δ_{11}. If $\kappa = +1$, for instance, the unique components of the EFG and shielding tensors are coincident, whereas if $\kappa = -1$, V_{33} and δ_{11} are aligned with the rotation axis. The choice between these possibilities is straightforward based on the observed line shapes (36). It is found that the copper shielding tensor spans 42 ± 1 ppm, the least shielded component lying parallel to V_{33}. This is depicted in Fig. 3. Simulated spectra illustrating how the quadrupolar and shielding interactions combine are presented in Fig. 4. This appears to be the first experimental determination of anisotropic nuclear magnetic shielding for copper. The anisotropic character is relatively small compared to the total range of copper shielding, estimated to be about 1000 ppm (12). This is not surprising, based on the nearly tetrahedral symmetry at the copper centre, and can be contrasted with the shielding anisotropy of approximately 1200 ppm in gas-phase CuCl, as calculated from $^{63/65}Cu$ spin–rotation data (37).[3]

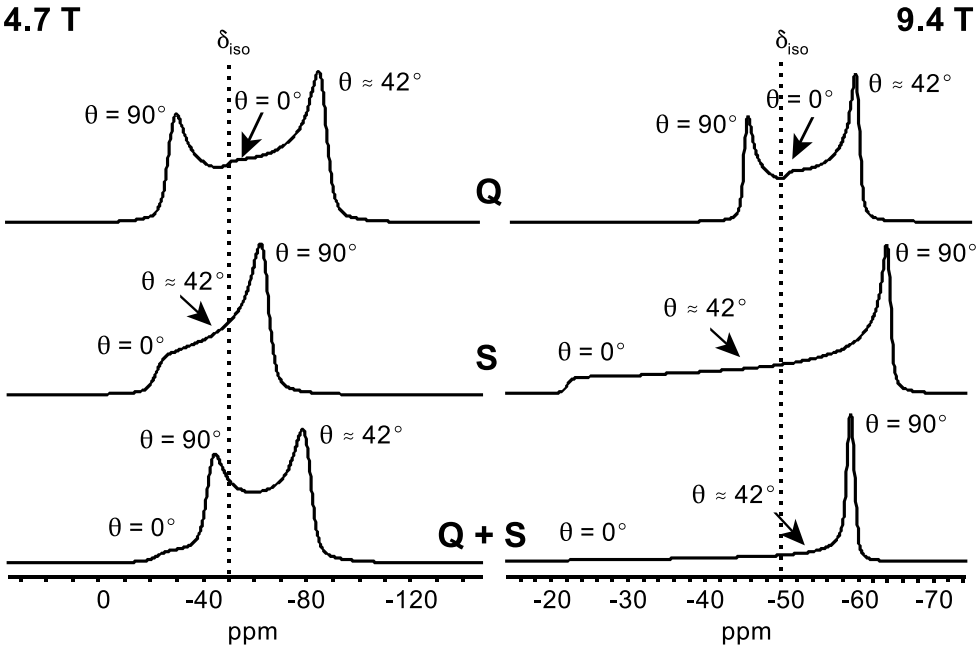
Fig. 4. NMR central transition line-shape simulations for copper-63 in a non-spinning $K_3Cu(CN)_4$ powder sample depicting the orientation dependence of the two dominant internal interactions: quadrupolar (Q), shielding (S), and their combined effect (Q + S). The Larmor frequency is 53.10 MHz, corresponding to ^{63}Cu at 4.7 T, and 106.05 MHz for ^{63}Cu at 9.4 T (see Fig. 1). The orientation of the unique tensor component with respect to the applied magnetic field direction is indicated by θ for selected spectral features. The isotropic chemical shift is denoted by the broken vertical line.



Also apparent from Fig. 4 is the opposite magnetic field dependence of the second-order quadrupolar and chemical shielding interactions. At 4.7 T, second-order quadrupolar effects are marginally more prominent, whereas at 9.4 T, anisotropic shielding clearly dominates the line shape. This differing field dependence implies that reliable characterizations of shielding and quadrupole coupling tensors are aided by analyzing spectra acquired at multiple magnetic fields — especially when tensor orientations are not fixed by crystal symmetry. Moreover, it is likely that shielding tensors of quadrupolar nuclei will be more frequently reported, as the magnetic field strength available for NMR continues to increase.

In spite of generally good agreement between the calculated and experimental spectra, a slight discrepancy is observed in the intensities of the stationary 4.7 T spectrum (Fig. 2). A likely explanation involves consideration of weak spin–spin coupling interactions between copper nuclei and surrounding ^{14}N nuclei. Two-bond *J*-couplings are 14 Hz (vide infra), and dipolar couplings, $R_{DD}(^{63}Cu,^{14}N)$, are calculated from the internuclear separation, $r_{Cu,N}$, to be about 75 Hz:

$$[2] \qquad R_{DD}(I, S) = \left(\frac{\mu_0}{4\pi}\right)\left(\frac{\hbar}{2\pi}\right)\gamma(I)\gamma(S)\left\langle r_{I,S}^{-3}\right\rangle$$

Although these constants are small in comparison with the quadrupolar and shielding interactions, their effects will be magnified by two factors. First, ^{14}N has a spin, $S = 1$, so the copper signal will be split into three subspectra (i.e., $2S + 1$). Second, the high natural abundance of ^{14}N (99.63%) implies that each copper centre will be coupled to four nitrogen-14 nuclei. These effects may result in nearly 1 kHz of additional broadening. More importantly, however, the splitting due to dipolar coupling depends on the orientation, β, of the copper–nitrogen internuclear vector with respect to the applied magnetic field. To a good approximation, the magnitude of the ^{14}N,$^{63/65}$Cu dipolar splitting varies as $(1/2)R_{DD}(3\cos^2\beta - 1)$. Thus, for crystallite orientations where the rotation axis (that is, V_{33} and δ_{11}) is parallel to the field direction ($\theta = 0°$), three chemically equivalent ^{14}N nuclei will be situated with $\beta \approx 70°$, and the dipolar splitting will be scaled by –0.3. By contrast, for $\theta = 90°$, the three ^{14}N nuclei will be nearly aligned with the field, $\beta \approx 20°$, and the scaling of R_{DD} will be minimal, 0.85. The low-frequency feature represents orientations with V_{33} and δ_{11} at 42°, for which the other three ^{14}N nuclei will have β ranging from 30° to 70°, bracketing the magic angle, where R_{DD} is scaled to zero. Of course, these "splittings" are too small to be observed, but their net effect is a broadening which will be more effective for some orientations than others. With reference to Fig. 2, greater broadening at the singularity corresponding to $\theta = 90°$ may manifest as an *apparent loss* of signal intensity with respect to the singularity at $\theta = 42°$, where less dipolar "broadening" will result in an *apparent augmentation* of the intensity. Thus, the observed line shape of the stationary sample may be accounted for by consideration of the second-order quadrupolar interaction, anisotropic copper shielding, *and* heteronuclear spin–spin interactions between copper-63/65 and nitrogen-14.

Another approach to the characterization of quadrupolar and chemical shielding tensors in solids is satellite transition spectroscopy (SATRAS). Originally proposed as a more precise measurement of the quadrupole coupling tensor than central transition line-shape modelling (38), this technique has developed into a valuable means for obtaining detailed

Fig. 5. Copper-65 MAS NMR spectrum of the central and satellite transitions in $K_3Cu(CN)_4$ at 9.4 T. (Spinning rate: 12.00 kHz; number of transients: 2560) The calculated spectrum is based on a time-domain calculation involving anisotropic shielding and the first-order quadrupolar interaction, according to the tensors determined from non-spinning samples. The central transition in both traces is truncated to exhibit the spinning sideband envelope of the satellite transitions.

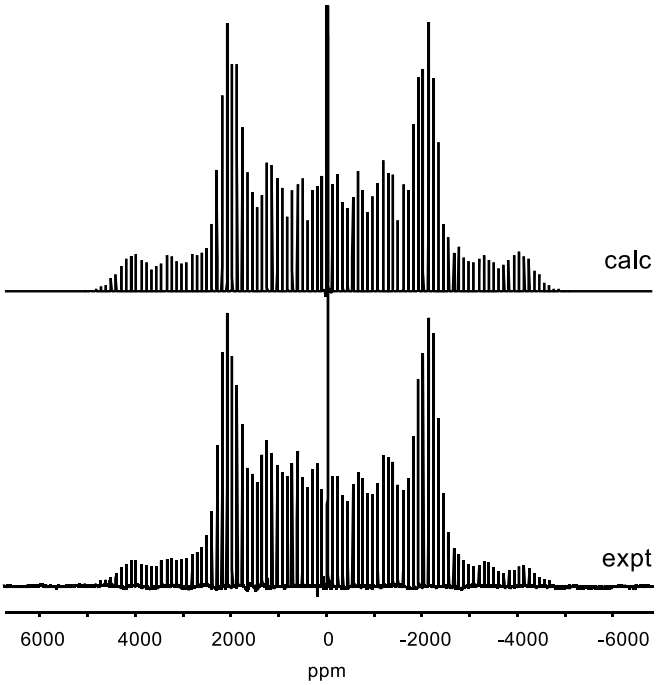

Fig. 6. Copper-63 MAS NMR spectra of the central transition in 30% ^{13}C-enriched $K_3Cu(CN)_4$ at 4.7 and 9.4 T. At 4.7 T, 1200 transients were collected with a 3.00 kHz spinning speed; 32 transients were acquired at 9.4 T, with a spinning frequency of 6.40 kHz. The depicted regions each span 4 kHz.

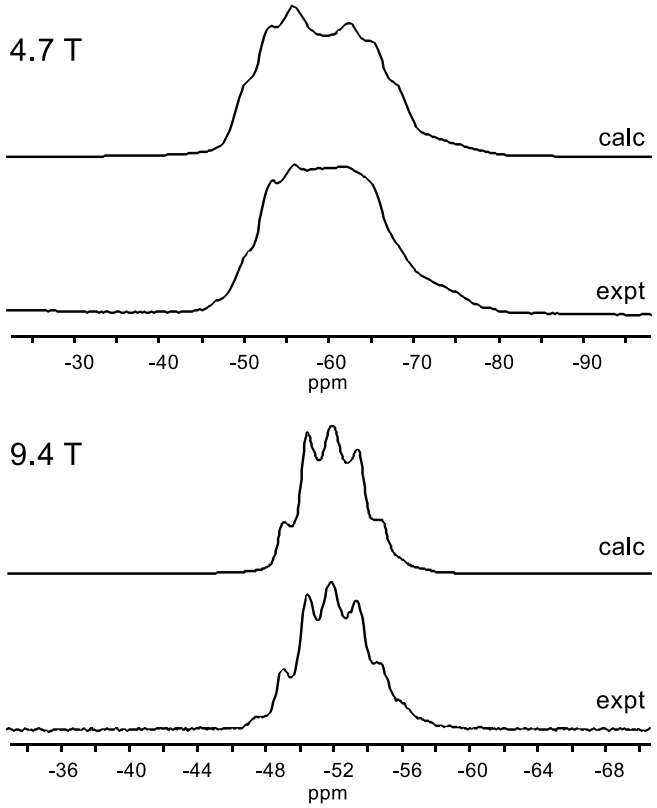

information about the magnitudes and relative orientation of shielding and quadrupole coupling tensors (39). Figure 5 depicts the spinning sideband (ssb) manifold for the copper-65 satellite transitions (+3/2 ↔ +1/2, –1/2 ↔ –3/2) along with simulations based on the parameters given in Table 1. Although the agreement appears to be quite good, a number of considerations, both experimental and theoretical, limit the usefulness of this method in the present case. For example, instrumental demands include spinning rates that are high and very stable, and rf pulses that are strong and homogeneous over the entire detection range. In this case, a strong, broad signal due to the presence of copper in the probe is observed 1500 ppm to high frequency of aqueous $Cu(CN)_4^{3-}$. While this interference has been artificially "removed" in the data processing stage, spinning sideband intensities in the region of overlap may be unreliable. From the programming point of view, only first-order quadrupolar effects were considered in the simulation, with the consequence that no second-order line shapes or peak shifts due to quadrupolar effects are calculated. This approximation substantially reduces the required computation time, while still yielding a useful simulation of the data (39*b*, 40). Fundamentally, however, the chemical shielding interaction in this compound is simply too small relative to the quadrupolar interaction for the satellite transition ssb calculations to be sensitive to modifications of its magnitude or orientation. Line-shape modelling of the central transition in a non-spinning sample is the best way to characterize the shielding tensor in this case. In spite of these limitations, Fig. 5 illustrates that high-quality copper-63/65 SATRAS NMR spectra may be obtained, confirming the quadrupolar parameters obtained from the central transition. The utility of this method for gaining precise information from calculations of the spinning sidebands may be profitably applied in select cases where the quadrupolar and shielding interactions are of comparable magnitude, or where the shielding can be neglected altogether.

Given the relative ease with which one may observe copper-63/65 NMR signals in this sample, how easy is it to measure *J*-couplings by directly probing the copper nucleus? A sample of $K_3Cu(CN)_4$, enriched to about 30% in ^{13}C, was analyzed by MAS NMR at 4.7 and 9.4 T. From the spectra in Fig. 6, it is apparent that the line shape loses its characteristic definition, becoming a series of humps and shoulders about 800 Hz wide. These spectra represent the superposition of overlapping copper sites weighted by the statistical abundances of copper nuclei coupled to zero, one, two, three, and four carbon-13 nuclei (0.24:0.41:0.26:0.08:0.01). With the knowledge of C_Q and δ_{iso} gained from NMR analyses of the unlabelled compound, these line shapes may be simulated to obtain estimates of *J*, assuming as a first approximation that coupling to zero and one ^{13}C nucleus dominate the observed peaks at this level of isotopic enrichment. However, because of the lack of definition in the line shape, reasonable fits can be obtained for a range of subspectral

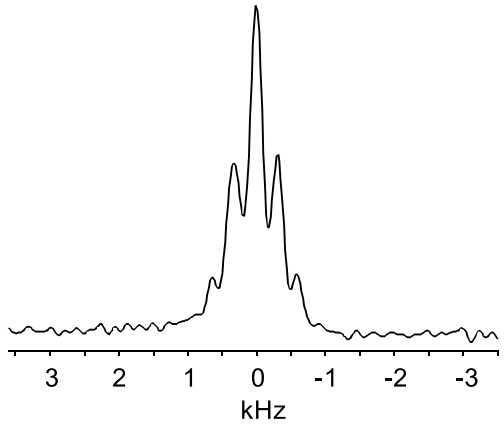
Fig. 7. Isotropic reconstruction of ^{63}Cu triple-quantum MAS NMR data in 30% ^{13}C-enriched $K_3Cu(CN)_4$. Two-hundred forty transients were collected for each of the 128 t_1 slices. The interpulse delay was incremented by 25.7 μs. The central peak has been set to zero for convenience.



amplitudes and positions, yielding $^1J(^{63}Cu,^{13}C)$ = 300 ± 15 Hz. Additional complications resulting from residual dipolar coupling to ^{14}N nuclei may also influence the spectral appearance, especially at lower field, resulting in experimental line shapes which are difficult to calculate without introducing a variety of additional parameters and assumptions.

Recent progress has made it possible to obtain "high-resolution" NMR spectra of half-integer quadrupolar nuclei in solids (41–43). The thrust of these advances is the averaging of residual anisotropic line shapes generally observed even under conditions of magic-angle spinning, leaving only isotropic peaks. Essential to one such technique is its utilization of single- and multiple-quantum coherences under MAS to produce an *echo* corresponding to complete removal of orientation-dependent line-shape contributions at a particular point in the time evolution of the spin system (44). Multiple-quantum (MQ) MAS takes advantage of the fact that anisotropic contributions to symmetric transitions under rapid sample rotation are multiplied by a factor which depends only on the spin, S, and the $m \leftrightarrow -m$ transition of interest (denoted simply by m) (44):

$$[3] \qquad A_4(S, m) = 2m[18S(S+1) - 34m^2 - 5]$$

The sign of this coefficient may be changed by selecting the opposite coherence pathway, $p = 2m$, with the consequence that the time evolution of orientation-dependent terms is effectively "undone" by an appropriate choice of coherences. In practice, the experiment consists of an initial excitation pulse designed to generate MQ coherence followed by a variable delay, t_1, and a second pulse for converting the MQ coherence into the single-quantum ($p = -1$) central transition for detection. The echo is observed at a time, t_2, corresponding to the refocussing of all anisotropic contributions:

$$[4] \qquad t_2 = \frac{-A_4(S, m)}{A_4(S, -1/2)} t_1 = kt_1$$

When performed in a standard two-dimensional manner with regular increments of t_1, this approach yields purely isotropic peaks.

An idiosyncracy of this technique is that peak positions in the isotropic spectrum are not simply their chemical shifts, but are modified by both chemical shift and quadrupolar effects. Moreover, it was recently shown that splittings due to J-coupling, "J_{MQ}," are no longer equal to the value of J, but depend on both S and the MQ coherence chosen to effect the desired averaging (45):

$$[5] \qquad J_{MQ} = \left(\frac{k - 2m}{1 + k}\right) J$$

For triple-quantum MAS (3QMAS) of a spin-3/2 nuclide (m = –3/2), J-coupling will manifest in the isotropic spectrum as a splitting 2.125 times[4] the true value of J (45). Thus, 3QMAS aids in the direct observation of J-coupling both by elimination of quadrupolar "broadening" and by an amplification of J.

In Fig. 7, the ^{63}Cu 3QMAS spectrum of the ^{13}C-enriched sample exhibits a central peak representing uncoupled copper-63 nuclei, flanked by a doublet with a splitting of 640 Hz. $^1J(^{63}Cu,^{13}C)$ can be computed from this splitting to be 301 Hz. Also observed in this spectrum are smaller peaks separated by 1260 Hz, which can be attributed to copper-63 coupled to *two* carbon-13 nuclei. The advantage of this approach is that the J-coupling can be obtained directly — aside from a constant factor — from the isotropic spectrum, without requiring tedious line-shape fitting or prior knowledge of the quadrupolar parameters.

Carbon-13 NMR

Carbon-13 MAS NMR spectra of a $K_3Cu(CN)_4$ sample enriched to 30% in $^{13}C^{15}N$ were acquired at both 4.7 and 9.4 T (Fig. 8). To a first approximation, the observed line shapes represent two sites, each coupled to a spin-3/2 nucleus with isotropic J-couplings given by the separation between peaks. The isotropic chemical shifts are the average value of the four peaks, amounting to a difference of one ppm between the sites. The intensities of the interleaved quartets clearly identify the sites as arising from the cyanide ligand lying along the rotation axis ("site 1"), and the three remaining chemically equivalent cyanides ("site 2").

A more detailed analysis reveals that the splittings between adjacent peaks for a given site are unequal. These subtleties may be understood in terms of first-order perturbation theory as residual dipolar shifts originating in the quadrupolar nature of the coupled copper nuclei (46):

$$[6] \qquad \Delta\nu_m = \left(\frac{3R_{DD}C_Q}{20\nu_L}\right)\left[\frac{S(S+1) - 3m^2}{S(2S-1)}\right] \times (3\cos^2\beta - 1 + \eta\sin^2\beta\cos 2\alpha)$$

[4] It should be noted that different data processing conventions have been propagated in the literature, which will influence the magnitude of this multiplicative constant. It is, therefore, essential to use the factor that is appropriate to the method of processing spectral data. See ref. 22 for a comprehensive discussion of this matter.

Fig. 8. Carbon-13 MAS NMR spectra of 30% $^{13}C^{15}N$-enriched $K_3Cu(CN)_4$ at 4.7 and 9.4 T. For the experimental spectrum at 4.7 T, 208 transients were acquired at a 3.50 kHz rotation rate. For the 9.4 T spectrum, 608 transients were collected at a rotation rate of 8.00 kHz.

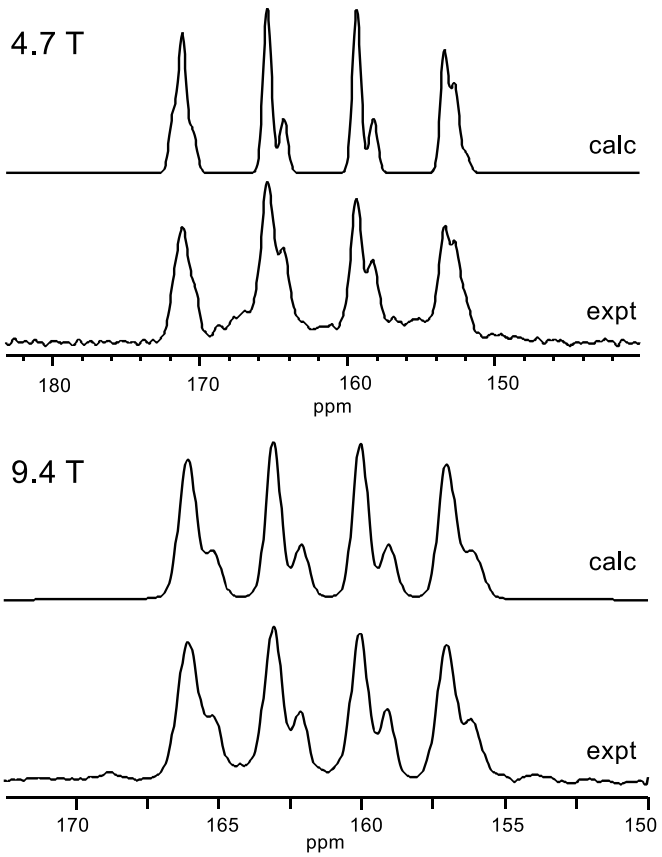

Fig. 9. Nitrogen-15 MAS NMR spectra of 75% ^{15}N-enriched $K_3Cu(CN)_4$ at 4.7 and 9.4 T. Forty-six and 16 transients were coadded for the 4.7 and 9.4 T spectra, respectively. The spinning rates were 2.91 and 10.00 kHz.

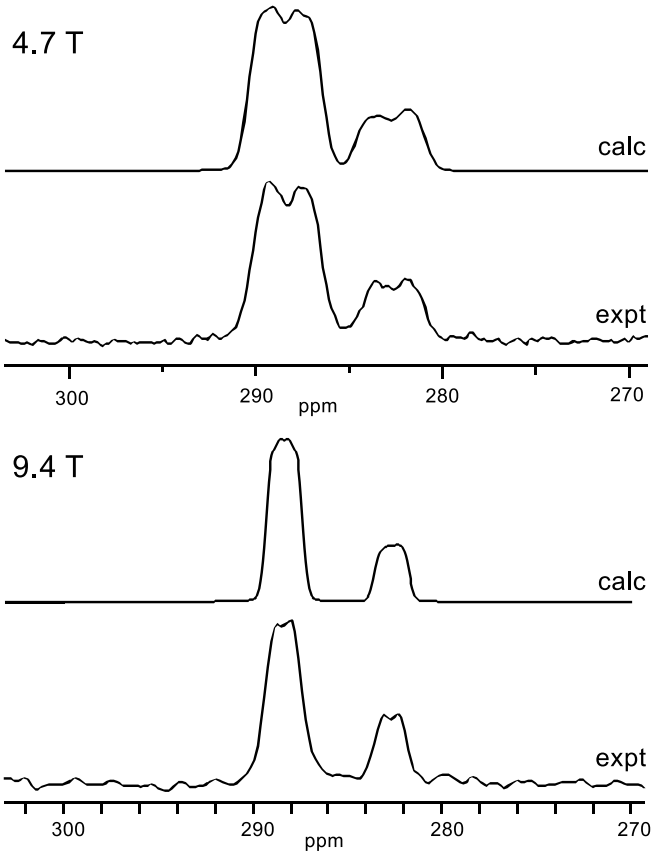

where (α, β) are polar angles defining the orientation of the copper-carbon internuclear vector in the EFG principal axis system, and η designates the *asymmetry* of the EFG tensor in terms of the principal elements, ($|V_{33}| \geq |V_{22}| \geq |V_{11}|$), $\eta = (V_{11} - V_{22})/V_{33}$. The Larmor frequency of the quadrupolar nucleus is denoted by ν_L. Employing the approach of Olivieri et al. (47), these line-shape distortions may be precisely simulated, yielding the values listed in Table 1.

It is important to emphasize that successful calculations of this sort rely on a great deal of prior information. In this case, the crystal structure provides estimates of the dipole–dipole coupling constants, R_{DD}, which were calculated from internuclear separations to be 983 and 1015 Hz to copper-63 for sites 1 and 2, respectively (see eq. [2]).[5] The molecular symmetry inherent in the crystal structure also fixed the relative orientations of the internal interactions, and the orientation of $r_{Cu,C}$ relative to V_{33} was determined from the bond angles. Although coupling to both spin-active copper nuclei was included, parameters were varied according to the ratio of their magnetogyric ratios, $\gamma(^{63}Cu)/\gamma(^{65}Cu) = 0.933\,53$ (34). Finally, the magnitude of C_Q determined from copper-63/65 MAS NMR was used in the calculations.

A careful inspection of eq. [6] reveals that in addition to J and δ_{iso}, this analysis yields information about the relative signs of R_{DD} and C_Q. For this particular case, axial symmetry ($\eta = 0$) and the spin factors ($S = 3/2$; $m = \pm 1/2, \pm 3/2$) may be introduced to simplify expression [6]:

$$[7] \qquad \Delta\nu_{\pm 1/2} = +\left(\frac{3R_{DD}C_Q}{20\nu_L}\right)(3\cos^2\beta - 1)$$

$$[8] \qquad \Delta\nu_{\pm 3/2} = -\left(\frac{3R_{DD}C_Q}{20\nu_L}\right)(3\cos^2\beta - 1)$$

The dipolar coupling constant being positive by virtue of like signs for $\gamma(^{63/65}Cu)$ and $\gamma(^{13}C)$ (eq. [2]), and the orientational term depending in a predictable fashion on the struc-

[5] These values of R_{DD} are upper limits, since any librational motion of the anion or cyano groups will lead to an averaging and hence a reduction of dipolar interactions. Unfortunately, reliable anisotropic thermal parameters are unavailable for $K_3Cu(CN)_4$ (4). Furthermore, NMR experiments are sensitive not to R_{DD} itself, but to an *effective* dipolar coupling constant, R_{eff}, modified by the anisotropy in the ***J*** tensor (48). Since excellent spectral fits were achieved by assuming $R_{eff} = R_{DD}$ (calculated from X-ray data (4)), it appears that any librational motions result in minimal motional averaging of dipolar coupling constants and that the anisotropy in the indirect spin–spin coupling constant is small compared to R_{DD}.

© 1999 NRC Canada

ture, the sign of C_Q governs the direction of the line shifts. Since the high-frequency peak splitting for site 1 is stretched, and the low-frequency splitting squeezed, C_Q must be negative. For site 2, the sign of the orientational term is negative ($\beta = 70°$), justifying the observation that the high-frequency splitting is squeezed, leading again to a negative quadrupole coupling constant. On the other hand, the sign of *J* is not available from calculations based on first-order perturbation theory (46).

The values of $^1J(^{63/65}Cu,^{13}C)$ obtained from copper-63/65 NMR experiments must be re-evaluated in light of the information garnered from carbon-13 MAS NMR spectra. The most glaring difference is that neither $^{63/65}Cu$ MAS nor 3QMAS could resolve couplings to the two crystallographically distinct carbon nuclei present in solid $K_3Cu(CN)_4$, whereas even a cursory examination of the carbon-13 MAS spectra makes this obvious. A second difference is that the uncertainties in *J* estimated from line-shape modelling of carbon-13 MAS spectra are ±2 Hz, much smaller than those of the copper NMR spectra, estimated to be ±15 Hz for both 1D MAS and 2D 3QMAS. (Uncertainties in the 3QMAS spectra are mainly due to low digital resolution, and could be improved at the expense of total experiment time by decreasing the t_1 increment.) These advantages may be offset, however, by the stringent symmetry requirements and high degree of prior knowledge necessary for reliable line-shape calculations of ^{13}C MAS spectra in the presence of coupled quadrupolar nuclei. Copper-63/65 MAS spectral calculations yield reasonable estimates of *J*, but are limited as a general strategy by the need to have control over the level of isotopic enrichment so as to obtain the quadrupolar parameters in an independent experiment. It should also be emphasized that copper-63/65 chemical shifts are more sensitive than ^{13}C or ^{15}N shifts to thermal gradients due to rapid rotation of the sample (49). The effect of this temperature dependence is to "smear out" the line shape so that the singularities are less well-defined, and simulations less precise. Another interesting contrast is that whereas spin-1/2 MAS spectra may be perturbed by spin–spin coupling to a quadrupolar nucleus, the symmetric transitions involved in 3QMAS are free from distortions arising from the dipolar interaction, in the limit of first-order perturbation theory (50). What emerges from this comparison is that choosing the ideal experiment to obtain a given parameter will depend critically on the particularities of the spin system as well as on the available experimental resources.

A ^{13}C NMR spectrum of a non-spinning sample of 30% ^{13}C-labelled $K_3Cu(CN)_4$ was also acquired at 4.7 T (not shown). The powder pattern is indicative of an axially symmetric shielding tensor, with the chemical shift for perpendicular orientations, $\delta_\perp$, easily identified. Given the complexity of the spin system (i.e., simultaneous coupling to both $^{63/65}Cu$ and ^{14}N), no attempt was made to calculate the spectrum; however, $\delta_\perp$ was estimated to be 275 ± 5 ppm. Individual carbon-13 sites are not resolved, suggesting that the *local* molecular symmetry of site 2 is sufficient to produce essentially axial symmetry in the shielding tensor, even though it is not dictated by the space group symmetry. From the measured values of δ_{iso} and $\delta_\perp$, $\delta_\parallel$ may be calculated to yield a span, $\Omega = \delta_\perp - \delta_\parallel$, for the cyano ^{13}C shielding tensors of 340 ± 5 ppm.

The carbon shielding in $K_3Cu(CN)_4$ may be compared with other cyanide-containing compounds. First, the isotropic chemical shifts of 161 and 162 ppm agree with the value obtained in aqueous solution, δ_{iso} = 161.6 ppm (51). These shifts appear to be more deshielded than any other organic or inorganic cyanide compound investigated in the solid phase by NMR (52), and slightly more *shielded* than the "free" CN anion in solution (166.2 ppm) (51). Whereas organic nitriles tend to appear around 120 ppm, the tetrahedral group 12 tetracyanometallates possess δ_{iso} between 148 and 153 ppm (53). The similar species, $N(CH_3)_4CuZn(CN)_4$, exhibits an isotropic shift of 157 ppm (16*a*). Even more shielded are the square-planar group 10 tetracyanometallates, having δ_{iso} ranging from 128 to 139 ppm (54). The spans of the related tensors exhibit less variability and correspondingly less obvious trends, with organic nitriles generally having $\Omega \approx 320$ ppm and the tetracyanometallates displaying spans of approximately 330 ppm (group 12 tetrahedra) and 350 ppm (group 10 square-planars). For $Cu(CN)_4^{3-}$ tetrahedra in $N(CH_3)_4CuZn(CN)_4$ and $K_3Cu(CN)_4$, the spans fall between these values. By implication, these general observations suggest that *all* carbon-13 shielding tensor elements are modified on moving from organic- to metal-bound cyanides.

Nitrogen-15 NMR

A 75% ^{15}N-enriched sample of $K_3Cu(CN)_4$ was prepared and analyzed by ^{15}N NMR. Figure 9 depicts the isotropic powder line shapes under conditions of MAS at 4.7 and 9.4 T. The two types of chemically equivalent cyanide ligands are clearly evident from the 1:3 intensity ratio, the more shielded lying along the symmetry axis. The difference in the isotropic ^{15}N chemical shifts is larger than the ^{13}C shift difference by a factor of six. Indeed, nitrogen shifts are generally more sensitive to structural differences than carbon shifts, manifesting in a larger overall range of nitrogen-15 chemical shifts (52). In constrast to the ^{13}C NMR results, the isotropic chemical shifts of 282.5 and 288.5 ppm are less shielded than the "free" cyanide ligand in water, 274.2 ppm (55).

Fine structure is observed in the individual line shapes corresponding to the two sites. Since 98.9% of the carbon in the sample is the spin-inactive isotope carbon-12, these features must be due to two-bond *J*-coupling to copper-63/65. Following the same protocol as for the carbon-13 MAS spectra, simulations yield $^2J(^{63}Cu,^{15}N)$ = 19.0 ± 1 and 20.0 ± 1 Hz for sites 1 and 2, respectively. Dipolar coupling constants, $R_{DD}(^{63}Cu,^{15}N)$, calculated from structural data are –107 and –104 Hz, according to eq. [2].

Spectra of the non-spinning sample were also acquired, with results similar to the carbon-13 spectra (not shown). The low-frequency end of the axially symmetric powder pattern lacks definition, and the two chemically distinct sites are unresolved, but $\delta_\perp$ may be easily extracted. Calculating $\delta_\parallel$ as above, the nitrogen-15 shielding tensor spans nearly 500 ppm (Table 1), with the most shielded component aligned with the Cu—C—N bond.

These NMR results may be compared with those obtained for solid $K_2Hg(CN)_4$ (26), in which the mercury atom occupies a site of pure tetrahedral symmetry. The isotropic ^{15}N chemical shift is 280.9 ppm in this compound, very similar to the values 282.8 and 288.5 ppm found for $K_3Cu(CN)_4$.

© 1999 NRC Canada

The measured shielding anisotropies are also similar, (477 ppm in $K_2Hg(CN)_4$ from a Herzfeld–Berger analysis (56) of spinning sideband intensities), with the same tensor orientation. The shielding results for tetrahedral cyanometallates contrast with organic nitriles, which typically exhibit spans of 400 ppm and isotropic shifts near 260 ppm (52). The origin of these differences appears to lie in lower shielding perpendicular to the M—C—N bond for cyanometallates than for R—C—N moieties.

Conclusions

Tripotassium tetracyanocuprate has been thoroughly examined by a variety of NMR methods to characterize chemical shielding tensors for carbon-13, nitrogen-15, and copper-63/65, as well as quadrupole coupling tensors for the latter. This appears to be the first example of copper shielding anisotropy determined by NMR. Isotropic one- and two-bond *J*-couplings to the copper centre have been measured for both cyanide sites. This comprehensive investigation of NMR properties in a "simple" model compound of known crystal structure is suggestive of the powerful capacity of NMR in the characterization of supramolecular framework materials based on tetrahedral $Cu(CN)_4^{3-}$ building blocks. Where multiple copper sites exist in a given solid, triple-quantum MAS appears to be a viable method for resolving individual resonances, given its capacity to resolve splittings arising from *J*-coupling. Solid $K_3Cu(CN)_4$ exhibits excellent NMR sensitivity, is straightforward to prepare, and may serve as a useful standard for copper-63/65 NMR of solids. These results also underscore the merits of utilizing modest levels of $^{13}C^{15}N$-enrichment to obtain high-quality carbon-13 and nitrogen-15 MAS NMR spectra, while simultaneously simplifying the ^{13}C spectral analysis by removing quadrupole-perturbed ^{13}C–^{14}N dipolar interactions (16*a*). In combination with a related study of solid CuCN (5), the work decribed here represents a starting point for a systematic study of copper(I) cyanide complexes.

Solid-state phosphorus-31 NMR study of phosphine- and phosphite-substituted cobaloximes

Robert W. Schurko, Roderick E. Wasylishen, Scott J. Moore, Luigi G. Marzilli, and John H. Nelson

Abstract: Solid-state ^{31}P NMR spectra of two phosphite- and 17 phosphine-substituted cobaloximes have been acquired under conditions of magic-angle spinning (MAS) and cross polarization (CP) at two applied magnetic fields. In the majority of cases, eight-peak multiplets are observed in the ^{31}P CPMAS NMR spectra, arising from one-bond indirect spin–spin coupling to cobalt (spin S = 7/2). The spacings between adjacent peaks gradually increase or decrease from low to high frequency, due to the presence of residual dipolar coupling between the cobalt and phosphorus nuclei. Values of $^1J(^{59}\text{Co},^{31}\text{P})$ were estimated from the spacing between the central peaks of the eight-peak multiplets. For the phosphine-substituted cobaloximes, values of $^1J(^{59}\text{Co},^{31}\text{P})$ range from 225 to 372 Hz, while in the phosphite derivatives this coupling is considerably larger, from 420 to 615 Hz. From comparison with cobaloximes for which the cobalt nuclear quadrupole coupling interaction is fully characterized, the residual dipolar shift, d, and sense of the ^{31}P NMR spectrum can be utilized to infer the electric field gradient (EFG) orientations at the cobalt nucleus in cobaloximes for which such data are unavailable. The magnitudes of $^1J(^{59}\text{Co},^{31}\text{P})$ and d, as well as the sense of the spectra, are shown to be dependent upon the nature of the axially-substituted ligands. Phosphorus-31 CPMAS NMR spectra of several cobaloximes exhibit broad peak shapes at room temperature. Variable-temperature ^{31}P NMR experiments reveal that the cobalt nucleus is effectively self-decoupled at room temperature; however, splittings due to $^1J(^{59}\text{Co},^{31}\text{P})$ were observed in spectra acquired at low temperatures.

Key words: solid-state ^{31}P NMR, ^{59}Co–^{31}P spin–spin coupling constants, ^{59}Co electric field gradient tensors, cobaloximes.

Résumé : Opérant à l'état solide, dans des conditions de rotation à l'angle magique (« MAS ») et de polarisation croisée (« CP ») de deux champs magnétiques appliqués, on a déterminé les spectres RMN du ^{31}P de dix-neuf cobaloximes, dont deux substituées par du phosphite et dix-sept portant des phosphines substituées. Dans la majorité des cas, les spectres RMN « CPMAS » du ^{31}P présentent tous des multiplets à huit pics qui découlent du couplage spin–spin indirect à travers une liaison avec le cobalt (spin S = 7/2). En raison des couplages dipolaires résiduels entre les noyaux de cobalt et de phosphore, les séparations entre les pics adjacents augmentent ou diminuent graduellement en passant des basses aux hautes fréquences. On a déterminé les valeurs de $^1J(^{59}\text{Co},^{31}\text{P})$ à partir des séparations entre les pics centraux des multiplets à huit pics. Pour les cobaloximes substituées par des phosphines, les valeurs de $^1J(^{59}\text{Co},^{31}\text{P})$ varient entre 225 et 372 Hz alors que, pour les dérivés portant des phosphites, cette valeur est beaucoup plus élevée, allant de 420 à 615 Hz. Par comparaison avec des cobaloximes pour lesquelles l'interaction de couplage quadripolaire nucléaire du cobalt a été bien caractérisée, le déplacement dipolaire résiduel, d, et le sens du spectre RMN du ^{31}P peuvent être utilisés pour déduire les orientations du gradient du champ électrique (GCE) au niveau du noyau de cobalt des cobaloximes pour lesquelles de telles données sont disponibles. On a démontré que les amplitudes de $^1J(^{59}\text{Co},^{31}\text{P})$ et de d ainsi que le sens des spectres dépendent de la nature des ligands substitués de façon axiale. À la température ambiante, les spectres RMN « CPMAS » du ^{31}P de plusieurs cobaloximes se présentent sous la forme de pics à larges bandes. Des expériences de RMN du ^{31}P à température variable mettent en évidence que, à la température ambiante, le noyau de cobalt s'autodécouple efficacement; toutefois, à l'aide des spectres acquis à basse température, on peut observer les dédoublements provoqués par le couplage $^1J(^{59}\text{Co},^{31}\text{P})$.

Mots clés : RMN du ^{31}P à l'état solide, constantes de couplage spin–spin ^{59}Co–^{31}P, tenseurs du gradient du champ électrique dans ^{59}Co, cobaloximes.

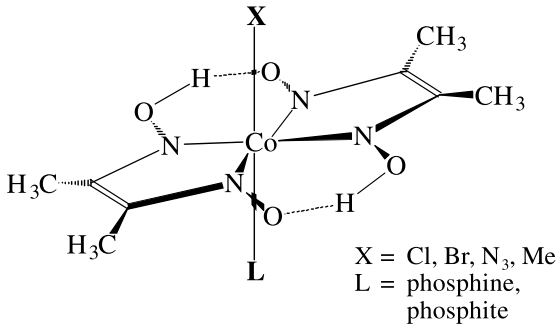
Fig. 1. Structure of cobaloximes, where L = neutral ligands (i.e., phosphines, phosphites) and X = anionic species (i.e., Cl^-, Br^-, N_3^-, and Me^-).



Introduction

Recently, there has been much interest in solid-state NMR spectra of spin-1/2 nuclei which are spin-coupled to quadrupolar nuclei (spin $S \geq 1$) (1–3). One reason for this interest is that acquisition of solid-state magic-angle spinning (MAS) NMR spectra allows for the measurement of indirect spin–spin couplings (*J*-couplings), which are not readily available from analogous solution NMR experiments. In solution, the relaxation of quadrupolar nuclei is generally very efficient, resulting in "self-decoupling" of the quadrupolar nucleus (4). As a consequence, sharp transitions corresponding to the discrete spin states of the quadrupolar nucleus are not observed in the spin-1/2 NMR spectrum.

A second reason for interest in such spin pairs is the appearance of residual dipolar coupling in the spin-1/2 MAS NMR spectra. In general, the spin states of a quadrupolar nucleus are not quantized exactly along the direction of the magnetic field because of perturbations from the quadrupolar interaction. Consequently, the spin states of the quadrupolar nucleus must be described by mixing of the pure Zeeman spin states. In such cases, MAS fails to completely average the dipolar interaction between the *I* and *S* nuclei, due to the presence of non-secular terms in the dipolar hamiltonian. Residual dipolar coupling is manifested in the MAS NMR spectrum as a "distortion" in the multiplet resulting from *J*-coupling between the *I* and *S* nuclei; that is, rather than observing $2S + 1$ evenly-spaced peaks in the multiplet, the peaks are shifted such that there is either a uniform decrease or increase in spacing between adjacent peaks on going from low to high frequency across the multiplet (vide infra). Analysis of spectra exhibiting these quadrupolar induced distortions may provide information about the orientation of the electric field gradient (EFG) tensor at the quadrupolar nucleus, the magnitude and sign of the quadrupolar coupling constant, C_Q, and in some cases, the asymmetry parameter, η. First-order perturbation (5–7) and exact (8, 9) theories have been developed to treat this problem.

The phosphorus–cobalt spin pair in a series of phosphine- and phosphite-substituted cobaloximes is considered in this paper. Cobaloximes are pseudo-octahedral complexes with two bidentate dimethylglyoxime (DH) moieties in a rectangular planar arrangement about the central cobalt atom (Fig. 1). A variety of ligands can be substituted into the axial positions, with typical cobaloximes possessing one neutral ligand (L) and one anionic ligand (X). Cobaloximes have been widely studied for over 40 years (10), due to their diverse coordination chemistry (11), interesting reactivity in solution (12), and potential as model complexes for larger, biologically-relevant molecules such as cobalamine (vitamin B_{12}), and methylcobalamin B_{12} (13). A number of solution NMR studies have been conducted on the cobaloximes (14), and several solid-state NMR studies have been reported in the literature, including a preliminary investigation of the ^{31}P, ^{59}Co spin pair in cobaloximes by our group (15), a solid-state ^{59}Co NMR study of cobaloximes and related complexes (16), and a recent letter discussing solution and solid-state NMR of triphenylphosphine-substituted cobaloximes (17).

In this paper, which is an extension of our previous work (15), we present solid-state ^{31}P CPMAS NMR spectra of cobaloximes, $LCo(DH)_2X$, where X = Cl^-, Br^-, N_3^-, and Me^- (Me = methyl), and L is a phosphine or phosphite ligand. Values of one-bond indirect spin–spin coupling constants, $^1J(^{59}Co,^{31}P)$, are estimated directly from the MAS NMR spectra. Well-characterized cobaloximes, i.e., cobaloximes for which there are ^{59}Co nuclear quadrupolar parameters and crystallographic data, are discussed first, as independent knowledge of these parameters aids in ensuring proper spectral analysis. Discussion is then extended to systems for which there is an absence of such data. Difficulties associated with multiparameter spectral analysis where two or more parameters are covariant are addressed. Variations in $^1J(^{59}Co,^{31}P)$ for the series of compounds investigated here are discussed qualitatively in terms of conventional steric and electronic effects arising from particular axial ligands. Finally, variable-temperature solid-state ^{31}P CPMAS NMR spectra of two cobaloximes are presented, which exhibit clearly resolved multiplets at low temperatures, and self-decoupling of ^{59}Co at room temperature. A rough estimate of the upper limit of the ^{59}Co spin-lattice relaxation time at room temperature can be obtained from measurements of the peak widths.

Experimental

Cobaloximes were synthesized using standard literature methods (13*c*, 18–20) and new procedures described elsewhere (21). Solid-state ^{31}P NMR spectra were acquired at 81.033 MHz (4.7 T) and 161.982 MHz (9.4 T) on Bruker MSL-200 and AMX-400 spectrometers, under conditions of cross-polarization, magic-angle spinning, and high-power proton decoupling. Microcrystalline samples were thoroughly powdered and packed into 4 mm (9.4 T) and 7 mm (4.7 T) o.d. zirconium oxide rotors. Typical pulse widths, contact times, and relaxation delays were 5 μs, 5 ms, and 4 s, respectively. Spinning rates for the 7 mm rotors ranged from 2.0 to 4.5 kHz, and for the 4 mm rotors from 3.0 to 9.0 kHz. Experiments required the acquisition of 500–8000 scans, depending on the amount of sample available. All ^{31}P NMR spectra were referenced with respect to 85% H_3PO_4 (aq) by setting the phosphorus resonance of solid $NH_4H_2PO_4$ to 0.81 ppm. Low-temperature NMR experiments were performed by passing dry nitrogen gas from liquid N_2 boil-off. Dry N_2 was passed through a heat-exchange coil that was

immersed in liquid nitrogen. The temperature of the sample was controlled by carefully adjusting the gas flow and heater in a complementary fashion, and was stable to within ±3 K. Temperatures inside of the MAS rotors were not calibrated with an internal NMR standard. The spinning sidebands were summed to produce an isotropic MAS pattern representative of the centreband at an infinite spinning rate (22). All spectra were analyzed with the WSolids program, which was developed in this laboratory, and incorporates the POWDER routine of Alderman et al. (23) for the efficient calculation of solid-state NMR powder patterns.

Results and discussion

First-order perturbation treatment of residual dipolar coupling

A treatment based on first-order perturbation theory has been developed by Olivieri et al. (5, 7, 24) and others (6), which is valid in the limit $C_Q/(4S(2S-1)) << \nu_S$, where ν_S is the Larmor frequency of the quadrupolar nucleus. Thus, for ^{59}Co (S = 7/2), the first-order perturbation approach is valid provided that $C_Q/84\nu_S << 1$, which is the case for the majority of complexes examined here. The transition frequencies in the MAS spectrum of a spin-1/2 nucleus, ν_m, are displaced by a residual dipolar shift, d, such that

$$[1] \qquad \nu_m = \nu_{iso} - m_S J_{iso} + \frac{S(S+1) - 3m_S^2}{S(2S-1)} d$$

where J_{iso} is the isotropic indirect spin–spin coupling constant, $m = S, S-1, ..., -S$, and

$$[2] \qquad d = \left(\frac{3C_Q R_{eff}}{20\nu_S}\right)[(3\cos^2\beta^D - 1) + \eta\sin^2\beta^D\cos^2\alpha^D]$$

In eq. [2], β^D and α^D are polar angles describing the orientation of the I–S dipolar vector, r_{IS}, with respect to the EFG tensor at the S nucleus. It is impossible to separate contributions from dipolar coupling and the anisotropy of the J-coupling (25); thus, the effective dipolar coupling constant, $R_{eff} = R_{dd} - \Delta J/3$, where $R_{dd} = (\mu_0/4\pi)(\gamma_I\gamma_S\hbar/2\pi)\langle r_{IS}^{-3}\rangle$, and $\Delta J = J_{\parallel} - J_{\perp}$. The quadrupolar coupling constant and asymmetry parameter are defined as $C_Q = eQV_{33}/h$ (where Q is the nuclear quadrupole moment) and $\eta = (V_{11} - V_{22})/V_{33}$. The V_{ii} are principal components of the EFG in its principal axis system, defined such that $|V_{33}| \geq |V_{22}| \geq |V_{11}|$. Thus, increased distortions resulting from residual dipolar coupling are directly proportional to the magnitude of C_Q and R_{eff}, and inversely proportional to the strength of the applied magnetic field. The sense of the spectrum (i.e., the direction in which the spacings between adjacent peaks are increasing) is defined as follows: if the spacings between adjacent peaks increase from high to low frequency, the sense of the spectrum is positive, and d is positive. Alternatively, if the spacings decrease from high to low frequency, the spectral sense and d are negative. Note that our definition of d differs in sign from some previous studies. This is irrelevant provided that one is consistent.

Well-characterized cobaloximes

In previous work by our group, the cobaloximes $PBu_3Co(DH)_2Cl$ (**I**) (Bu = *n*-butyl) and $PPh_3Co(DH)_2Me$ (**II**) were characterized by solid-state ^{31}P CPMAS NMR experiments (15). Both of these complexes have also been studied by ^{59}Co nuclear quadrupole resonance (NQR), from which values of C_Q and η were obtained (26). From a combination of these data, it was found that in **I**, the intermediate component of the EFG tensor, V_{22}, is directed along the Co, P bond, whereas in **II**, the smallest component, V_{11}, adopts this orientation (see Table 1). The remaining components lie in the plane of the DH moieties, oriented such that one bisects the N-Co-N angle of the heterocyclic ring, and the other bisects the inter-ring N-Co-N angle. Clearly, substitution of different ligands into the axial positions have significant effects on the EFG tensor orientation. Thus, if the magnitude of C_Q and η are known, and the dipolar coupling constant can be calculated from known interatomic distances, analysis of the MAS spectrum of the spin-coupled spin-1/2 nucleus can yield information on the orientation of the EFG tensor at the quadrupolar nucleus, as well as the sign of C_Q.

$PPh_3Co(DH)_2Cl$ (**III**) has been characterized by both ^{59}Co NQR and NMR (26, 27), and X-ray crystallographic studies (28). LaRossa and Brown (26, 27) report C_Q = +60.45 MHz and η = 0.81, with the proposed sign of C_Q determined via an empirical partial field gradient model described in their papers. Using this model, they also suggest that the largest component of the EFG tensor, V_{33}, is oriented along the direction of the Co, P bond. The Co, P internuclear distance is reported as 2.327 Å (28) from which R_{dd} is calculated to be

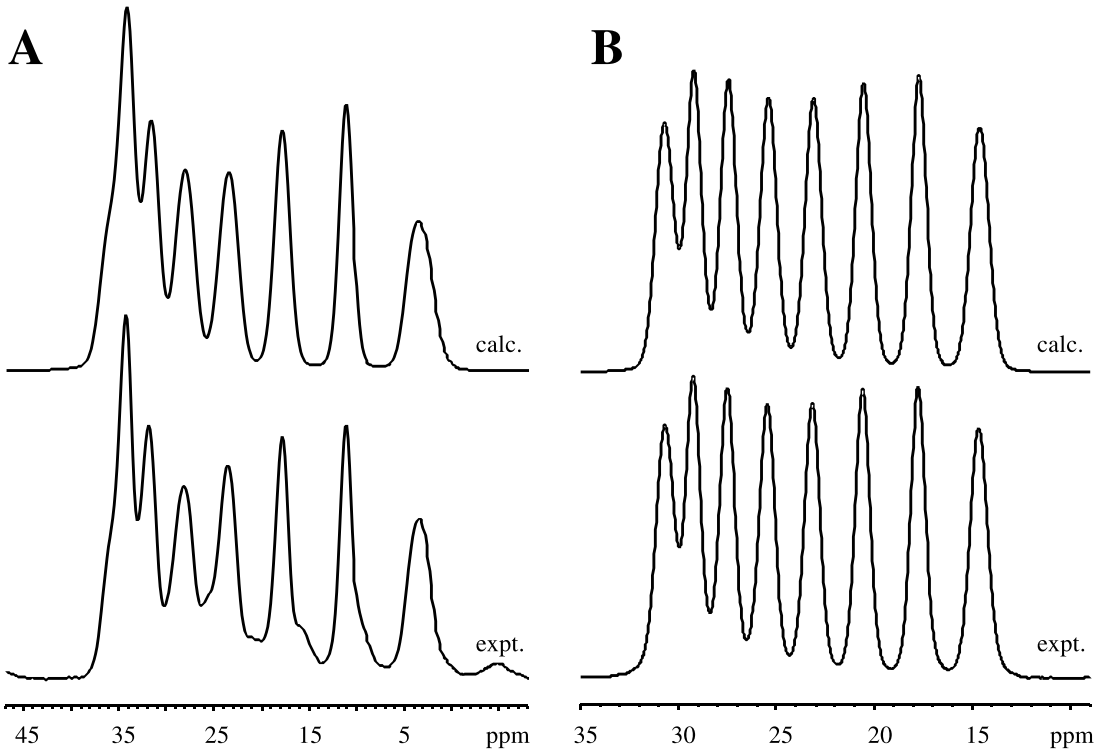
Fig. 2. Experimental and calculated ^{31}P CPMAS NMR spectra of $PPh_3Co(DH)_2Cl$ (**III**) at (A) 4.7 and (B) 9.4 T. Some small peaks resulting from sample impurity are observed in (A).



910 Hz. The *J*-coupling can be measured from the central spacing of the ^{31}P CPMAS NMR spectra (Fig. 2); $^1J(^{59}Co,^{31}P)$ = 371 Hz. Using the positive sign of C_Q proposed by LaRossa and Brown, the spectra cannot be simulated with $\beta^D = 0°$; however, with C_Q = –60.45 MHz, β^D = 90°, and α^D = 90°, an excellent fit can be obtained. This corresponds to the intermediate component of the EFG tensor, V_{22}, being aligned along the Co, P bond. Similar disagreement in the sign of C_Q and orientation of the EFG tensor was found for $PPh_3Co(DH)_2Me$ (**II**) in our previous work (15).

There are several interesting observations to make regarding the data in Table 1. First, the presence of the methyl group (X = Me^-) results in a large decrease in $^1J(^{59}Co,^{31}P)$ compared to the chloro-substituted cobaloximes. Changing the nature of the phosphorus ligand results in much smaller variation in $^1J(^{59}Co,^{31}P)$. The sense of the spectra for **II** is negative (as indicated by *d*), whereas for **I** and **III** the senses are positive. The magnitude of the residual dipolar shift is largest for **III**, which has the largest $|C_Q|$. However, other factors determine the size of *d*, such as R_{eff}, the EFG tensor orientation and η; thus, direct correlation between the magnitudes of *d* and C_Q cannot be assumed. If $\boldsymbol{r}_{Co,P}$ were coincident with V_{33} (i.e., $\beta^D = 0°$), then such correlations may exist (vide infra).

The uncertainties in R_{eff} given in Table 1 reflect the degree to which R_{eff} can be varied while simulating the spectra without creating any apparent differences between the calculated and experimental spectra. The residual dipolar shifts observed in the MAS spectra are not very sensitive to small changes in R_{eff} of ca. 20 or 30 Hz. If ΔJ is smaller than or on the order of $^1J(^{59}Co,^{31}P)$, the maximum contribution would be ca. 100–125 Hz, which would be detectable given the uncertainties in R_{eff}. If there is a contribution to R_{eff} from ΔJ, it must be less than 90 Hz (contribution to R_{eff} is $\Delta J/3$ = 30 Hz). For the purposes of this work, it is assumed that $R_{eff} \simeq R_{dd}$.

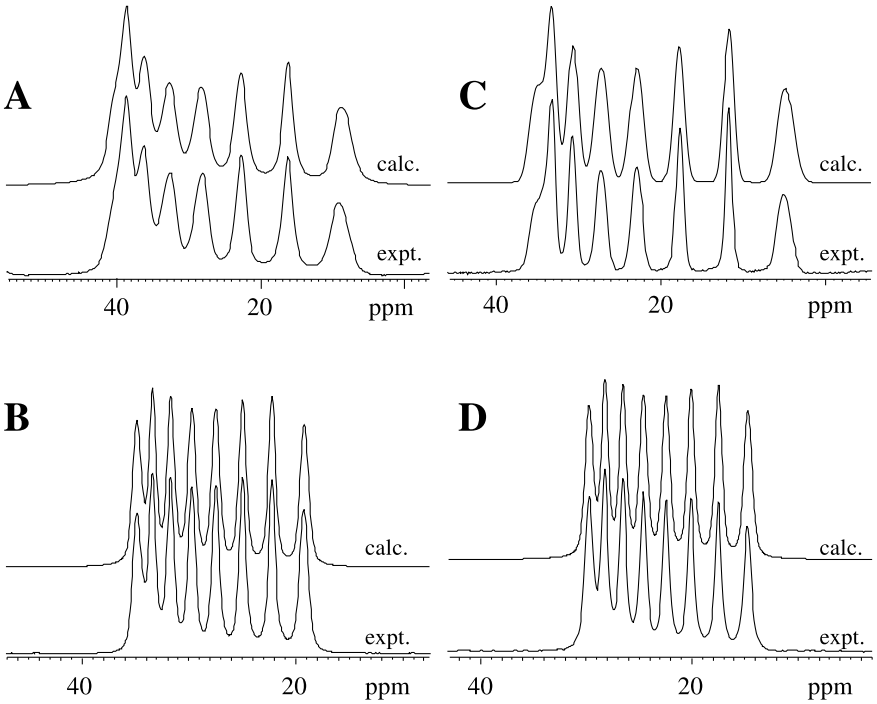
Cobaloximes for which quadrupolar data are unknown

If ^{59}Co quadrupolar data are unavailable, or reasonable assumptions cannot be made regarding the EFG tensor orientation, the only parameters available from the ^{31}P MAS NMR spectrum are δ_{iso}, $^1J(^{59}Co,^{31}P)$, and *d*. The residual dipolar shift is proportional to C_Q, R_{eff}, and the angular factor in eq. [2], whose magnitude is dependent upon η, β^D, and α^D. The covariance of these parameters means that it is possible to calculate identical MAS NMR spectra using substantially different parameters. As an example, for a hypothetical Co, P spin pair with $^1J(^{59}Co,^{31}P)$ = 350 Hz and R_{eff} = 900 Hz, spectra may be calculated which appear almost identical using C_Q = +40 MHz and $\beta^D = 0°$ or C_Q = –80 MHz and β^D = 90° ($\alpha^D = 0°$, $\eta = 0$). In systems where the EFG tensor orientation is given by $\beta^D = 0°$, the parameters α^D and η do not play a role in determining the magnitude of *d*. In such cases, it is possible to gain information on either R_{eff} or C_Q if one of these parameters is known independently. However, the EFG tensor orientation was found to vary in the three well-characterized cobaloximes, so general assumptions permitting this type of analysis are not possible. Nevertheless, valuable information is still available from these spectra.

First, cobaloximes with chloride or azide anions as the anionic axial species are considered. No structural or quadrupolar data are available for $P(tol)_3Co(DH)_2Cl$ (**IV**) (tol = tolyl); however, the only difference between $PPh_3Co(DH)_2Cl$

© 1999 NRC Canada

Fig. 3. Experimental and calculated ^{31}P CPMAS NMR spectra of P(*p*-tol)$_3$Co(DH)$_2$Cl (**IV**) at (A) 4.7 and (B) 9.4 T and PPh$_3$Co(DH)$_2$N$_3$ (**V**) at (C) 4.7 and (D) 9.4 T.



(**III**) and **IV** is the presence of the *para*-methyl groups on the phenyl rings of the phosphine ligand. The spectra of **IV** (Fig. 3A, B) are remarkably similar to those of **III** (Fig. 2), as evidenced by the spectral parameters (see Table 2). The isotropic chemical shifts and $^1J(^{59}Co,^{31}P)$ are also very similar in these complexes. Another structurally similar cobaloxime is PPh$_3$Co(DH)$_2$N$_3$ (**V**). In the crystal structure of this compound, the reported Co, P bond length is 2.311(1) Å (29), which corresponds to R_{dd} = 929(1) Hz. It has been suggested that the Co, P bond length is very similar to that in **III** since the N_3^- species is a weak *trans*-influencing ligand (30, 31) similar to Cl^- (29), and hence, should have comparable effects on overall molecular structure. The spectra of **III**, **IV,** and **V** (Fig. 3C, D) have positive residual dipolar shifts, similar δ_{iso}, and comparable $^1J(^{59}Co,^{31}P)$ values. Given the structural similarity of these cobaloximes, it is likely that the EFG orientation is the same in all three complexes (i.e., β^D = 90°, α^D = 90°, V_{22} along the Co, P bond).

Parameters for several other chloro- and azidocobaloximes are presented in Table 2. The magnitude of $^1J(^{59}Co,^{31}P)$ and the δ_{iso} for PMePh$_2$Co(DH)$_2$Cl (**VI**) and PMe$_2$PhCo(DH)$_2$N$_3$ (**VII**) coincide with prior examples. Comparing PBz$_3$Co(DH)$_2$Cl (**VIII**) and PBz$_3$Co(DH)$_2$N$_3$ (**IX**) (Bz = benzyl), reductions in both $^1J(^{59}Co,^{31}P)$ and *d* are observed in the azidocobaloxime, similar to that observed for **III** and **V**.

The ^{31}P CPMAS NMR spectra of methyl-substituted cobaloximes are now discussed. Alkyl groups are strong electronic *trans*-influencing ligands (30, 31) compared to the halide and azide anions. The presence of the axially-substituted methyl group results in a lengthening of the Co, L bond; this has been documented for a number of cobaloximes involving both phosphorus- and nitrogen-coordinated ligands (10, 32). Accordingly, R_{dd}(Co,P) is generally smaller (ca. 10–15%) in phosphorus-substituted alkyl cobaloximes.

Quadrupolar data are not available for PMe$_3$Co(DH)$_2$Me (**X**). The Co, P bond length is reported as 2.293(1) Å (33), corresponding to R_{dd} = 951(1) Hz. This bond length is significantly shorter than average Co, P bond lengths in phosphorus-substituted alkylcobaloximes ($r_{Co,P} \geq 2.41$ Å) due to the small size of the PMe$_3$ ligand. As a result, R_{dd} is on the order of those observed in the halogen- and azido-substituted cobaloximes. The value of $^1J(^{59}Co,^{31}P)$ is ca. 70 Hz less than the smallest *J*-coupling in the halide- and azide-substituted cobaloximes, demonstrating that a shorter Co, P bond length does not necessarily lead to an increased value of $^1J(^{59}Co,^{31}P)$.

The X-ray crystal study of **X** reveals that there are two crystallographically distinct molecules in the unit cell. This is also evident in the ^{31}P CPMAS NMR spectra of **X** (Fig. 4), as two sites with distinct isotropic chemical shifts are resolved. It is noted that the sense of the spectrum is negative, as is the case for PPh$_3$Co(DH)$_2$Me (**II**), and the remainder of the spectra of the alkyl-substituted cobaloximes discussed in this paper (vide infra). The phosphorus nucleus in **X** is the most shielded of all the examples reported in this paper. This is reasonable given that the phosphorus nucleus in uncoordinated PMe$_3$ is more shielded than in other phosphine ligands considered here (34).

In Table 2, spectral data are presented for several alkylcobaloximes, which are similar to **II**, such as P(*p*-FC$_6$H$_4$)$_3$Co(DH)$_2$Me (**XI**), P(*p*-ClC$_6$H$_4$)$_3$Co(DH)$_2$Me (**XII**), P(Me$_2$Ph)Co(DH)$_2$Me (**XIII**), and P(Et$_2$Ph)Co(DH)$_2$Me (**XIV**) (see Fig. 5 for spectra of **XII**, **XIII**, and **XIV**). In **XI** and **XII**, $^1J(^{59}Co,^{31}P)$, δ_{iso} and *d* are very similar to those ob-

served for **II**. In the latter complexes, which have significantly different phosphine groups, the magnitude of $^1J(^{59}Co,^{31}P)$ increases slightly, with a larger residual dipolar shift in comparison to **II**, **XI**, and **XII**. This is indicative of either a substantial increase in C_Q, or a change in the orientation of the EFG tensor. In all cases, the values of $^1J(^{59}Co,^{31}P)$ in the alkylcobaloximes are significantly smaller than in the chloro- and azide-substituted species. Possible reasons for this are discussed below.

Phosphite-substituted cobaloximes have very different NMR spectra than phosphine-substituted cobaloximes. $P(OEt)_3Co(DH)_2N_3$ (**XV**) was considered in our first study on the cobaloximes, and was found to have $^1J(^{59}Co,^{31}P)$ = 615(2) Hz, the largest for all of the cobaloximes considered

(15). In addition, the phosphorus nucleus is deshielded by ca. 50 ppm relative to the range of δ_{iso} reported for the phosphine-substituted cobaloximes, in accordance with trends previously observed in solution ^{31}P NMR studies (10, 14*f*). Neither crystallographic nor quadrupolar data have been obtained for P(OPh)$_3$Co(DH)$_2$Me (**XVI**). The spectra of **XVI** reveal that there are two crystallographically non-equivalent sites, with $^1J(^{59}Co,^{31}P)$ = 430(2) Hz and 420(2) Hz, and δ_{iso} = 108.2(1) ppm and 106.8(1) ppm, respectively (Fig. 6). The values of $^1J(^{59}Co,^{31}P)$ are large enough that the transitions arising from the two sites are completely resolved, unlike in the spectra of **X** (Fig. 4). The value of $^1J(^{59}Co,^{31}P)$ is reduced compared to **XV**, undoubtedly due to the substitution of the Me into the axial position; notwithstanding, $^1J(^{59}Co,^{31}P)$ in **XVI** is still larger than those for all of the phosphine cobaloximes. In addition, the residual dipolar shifts are of opposite sign in **XV** and **XVI**, indicating either that the EFG tensor orientations and (or) the signs of C_Q are different.

© 1999 NRC Canada

Finally, we consider systems where the first-order perturbation treatment appears to fail. Phosphorus-31 CPMAS NMR spectra of $PPh_3Co(DH)_2Br$ (**XVII**) acquired at both 4.7 and 9.4 T display an interesting anomaly (Fig. 7): at the lower field, there are only six peaks resolved, and at the higher field, only seven. Eight peaks are resolved in the high-field spectra of all of the other cobaloximes, with seven or eight peaks resolved at the lower field, depending on the degree of residual dipolar coupling and the magnitude of $^1J(^{59}Co,^{31}P)$. Attempts to simulate the spectra of **XVII** at both fields were unsuccessful, as the degree of distortion in peak spacings could not be duplicated exactly with the expressions derived from first-order perturbation theory. This result was also observed for **XVII** by Asaro et al. (17) in their recent work. Calculations using full theory were unsuccessful; however, we are presently limited to spectral simulations involving full diagonalization of the combined Zeeman and quadrupolar hamiltonian for cases in which $\eta = 0$. Interestingly, the crystal structure obtained for this compound reveals that $r_{Co,P}$ is almost identical to that in $PPh_3Co(DH)_2Cl$ (**III**), with no significant differences in molecular structure (35). As well, the values of $^1J(^{59}Co,^{31}P)$ in **III** and **XVII** are very similar. The magnitude of C_Q is assumed to be quite large in **XVII**, resulting in the severely distorted multiplet, though the source of the increase in V_{33} is unknown. Similar difficulties in calculating spectra using the first-order perturbation approach were encountered with $PEt_3Co(DH)_2Me$ (**XVIII**), which is one of the complexes exhibiting temperature-dependent ^{59}Co self-decoupling (vide infra).

General trends in the NMR parameters obtained in this study are as follows:

1. The magnitude of $^1J(^{59}Co,^{31}P)$ is significantly reduced if the anionic species, X, is an alkyl group, for both phosphine- and phosphite-substituted cobaloximes.

2. Examination of the complexes with the same L ligands and X = Cl^- or N_3^- (i.e., **III** and **V**, L = PPh_3; **VIII** and **IX**, L = PBz_3; **I** and **XIX**, L = PBu_3), reveals that there is a small reduction in $^1J(^{59}Co,^{31}P)$ in the azidocobaloximes compared to the corresponding chloro species (ca. 2 to 5%).

3. For the phosphine alkylcobaloximes, $^1J(^{59}Co,^{31}P)$ increases with decreasing steric bulk of the phosphine.

4. Values of $^1J(^{59}Co,^{31}P)$ in phosphite-substituted cobaloximes are much larger than in phosphine-substituted cobaloximes.

5. The isotropic coordination chemical shifts are as follows: for phosphines, the coordination chemical shift, $\Delta = \delta_{iso}(\text{coord.}) - \delta_{iso}(\text{free ligand})$ is positive (i.e., the ^{31}P nucleus becomes deshielded upon coordination to the cobaloxime). For the phosphites, it is negative. This is in accord with ^{31}P coordination shifts measured in solution (14*f*).

6. Isotropic ^{31}P chemical shifts in the cobaloximes behave in an identical fashion to those of the corresponding uncoordinated ligands. The phosphorus becomes deshielded in the phosphite-substituted cobaloximes and the span of the chemical shift tensor increases. Phosphorus nuclei are most shielded with small phosphine groups and X = Me^-.

7. In chloro- and azidocobaloximes the residual dipolar shift, *d*, is positive; for alkylcobaloximes, *d* is negative, and for several compounds, quite small.

The small negative values of the residual dipolar shift, *d*, in the alkylcobaloximes likely result from a reduced angular factor ($3\cos^2\beta^D - 1 + \eta\sin^2\beta^D\cos 2\alpha^D$), and not simply from decreased $C_Q(^{59}Co)$ in these compounds. If $\beta^D = 90°$ and $\alpha^D = 0°$, as in the case of **II**, the angular factor is $-1 + \eta$, which can be quite small. Alternatively, if $\beta^D = 90°$ and $\alpha^D = 90°$, as in **I** and **III**, the angular factor is $-1 - \eta$. The fact that *d* is consistently positive and larger for the chloro- and azido-substituted cobaloximes, and negative and smaller for the majority of the methyl-cobaloximes, suggests that the EFG tensor orientations may be similar within each series of compounds.

Interpretation of the indirect spin–spin coupling constants, $^1J(^{59}Co,^{31}P)$

Indirect spin–spin couplings between phosphorus and metal nuclei have often been interpreted in terms of the Fermi-contact mechanism, which is the dominant coupling mechanism for light nuclei such as protons and first-row nuclei (36). The interactions between the nuclear spins are mediated by electrons, and are described by a non-relativistic hyperfine hamiltonian which, according to Ramsey (37), can be decomposed into terms characterizing individual contributions from (*i*) the orbital motion of the electrons (orbital mechanism, OB), (*ii*) nuclear and electron spin dipolar interaction (spin–dipolar mechanism, SD), and (*iii*) the Fermi-contact (FC) mechanism, which accounts for direct coupling between the electron and nuclear spins. There is also a FC, SD cross term that makes no contribution to J_{iso}, but can make significant contributions to the ***J*** tensor. The Fermi contact term is isotropic, and contributions from this mechanism reflect the unpaired electron populations of *s* atomic orbitals of nuclei involved in the coupling (36, 38).

The assumption of the direct correspondence between *s*-character of involved nuclei and the magnitude of J_{iso} must be regarded with caution, since certain *J*-couplings between phosphorus and heavy nuclei which had previously been assumed to be dominated by the FC mechanism have been shown to have large contributions from other coupling mechanisms (vide infra). It has been proposed that the lengthening of the M, P bond (M = metal, e.g., Pt or Hg), say from the presence of a strong *trans*-influencing ligand, results in a reduction of *s*-character of the M atom involved in the M, P bond, leading to a decrease in the magnitude of J_{iso} (assuming that *J* is dominated by the FC mechanism) (39). Changes in the magnitude of J_{iso} have also been attributed to decreasing or increasing *s*-character resulting from different hybrid molecular orbitals at the metal nucleus, which are dependent on the coordination number and electron-donating abilities of the coordinated ligands (39; see for example, ref. 40). Solid-state ^{31}P NMR experiments on powder samples and single crystals have demonstrated that there are significant *J*-anisotropies, and therefore contributions from mechanisms other than the FC mechanism in $^1J(^{195}Pt,^{31}P)$ in square planar complexes (41), $^1J(^{199}Hg,^{31}P)$ in tetrahedral mercury phosphines (42) and $^1J(^{63/65}Cu,^{31}P)$ in linear copper(I) phosphines (43). In heavy atoms, relativistic effects, which may make a contribution to J_{iso}, cannot be ignored (44).

As discussed above, spectral calculations for cobaloximes in which dipolar and quadrupolar coupling constants are known reveal that ΔJ is probably less than 90 Hz; hence, it is possible that the FC mechanism is dominant in $^1J(^{59}Co,^{31}P)$.

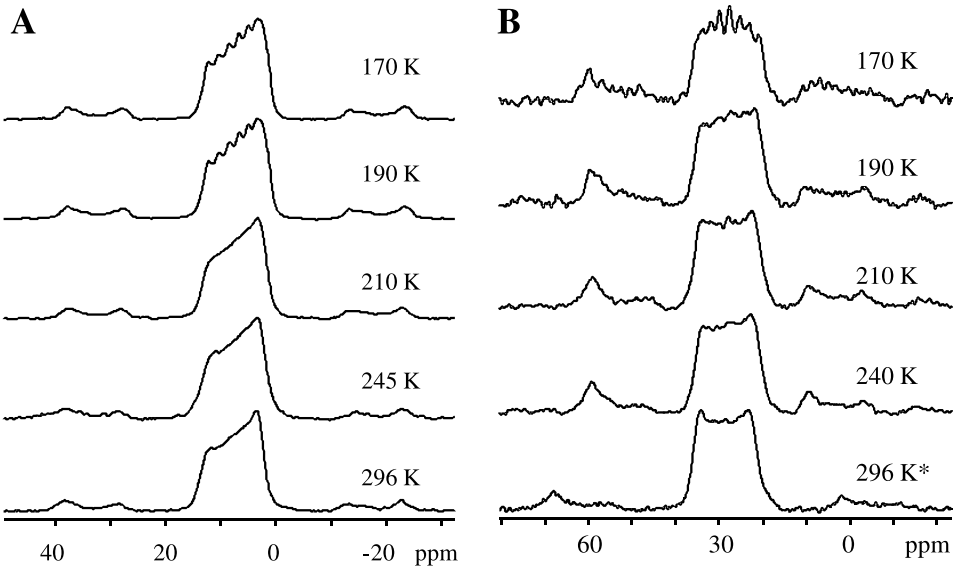
[a]Data from ref. 47.

Fig. 8. Variable-temperature ^{31}P CPMAS NMR of (A) $PEt_3Co(DH)_2Me$ (**XVIII**) and (B) $PBu_3Co(DH)_2N_3$ (**XIX**) at 9.4 T. All spectra of **XVIII** acquired with ν_{rot} = 4136 Hz. Spectrum marked with asterisk was acquired with ν_{rot} = 5383 Hz; for other spectra of **XIX**, ν_{rot} = 4000 Hz.



However, the exact contributions of the SD and OB terms, which affect both the anisotropic and isotropic components of the ***J***-tensor, to $^1J(^{59}Co,^{31}P)$ are unknown at this time. If the FC mechanism is dominant, a qualitative explanation of the changes in $^1J(^{59}Co,^{31}P)$ may be formulated as follows: the presence of a methyl group, which is a strong σ-donor and *trans*-influencing ligand, may result in a decrease in the 4*s*-electron density concentrated in the Co, P bond, resulting in a reduced value of $^1J(^{59}Co,^{31}P)$. Similarly, the presence of a phosphite ligand may result in an increase in the 4*s*-electron density in the Co, P bond, resulting in an augmented value of $^1J(^{59}Co,^{31}P)$. Comparable effects of methyl, halide, phosphine and phosphite ligand substitution on $^1J(M,^{31}P)$ have been observed in a large number of cases for phosphorus bonded to transition metals (39). Some examples include $^1J(^{195}Pt,^{31}P)$ in square planar phosphine- and phosphite-substituted platinum(II) complexes (45), $^1J(^{183}W,^{31}P)$ in octahedral phosphine- and phosphite-substituted pentacarbonyl tungsten compounds (46) and the very close correspondence with $^1J(^{103}Rh,^{31}P)$ from ^{31}P NMR studies of the rhodium analogs of the cobaloximes, the rhodoximes (vide infra) (47).

In isostructural complexes with different metals in the same group of the periodic table, indirect spin–spin coupling constants, $^1J(M,^{31}P)$, are normally compared by two different methods. The first is to consider the reduced coupling constants, $K(N,N') = 4\pi^2 J(N,N')/(h\gamma_N\gamma_{N'})$, which eliminates the dependence of the *J*-coupling on the magnitudes and signs of the magnetogyric ratios (48). It has also been proposed that $^1J(M,^{31}P)$ for two different metals should be equivalent to the ratio of their *s*-electron densities and magnetogyric ratios, $\gamma|s(0)|^2$ (39). Comparing *J*-couplings to phosphorus involving ^{59}Co and ^{103}Rh, $^1J(^{59}Co,^{31}P)$ is predicted to be approximately 4.38 times larger than $^1J(^{103}Rh,^{31}P)$ (49). In Table 3, $^1J(^{59}Co,^{31}P)$ and $^1J(^{103}Rh,^{31}P)$ are compared in several analogous cobaloximes and rhodoximes. The reduced coupling constants are two times as large in the rhodoximes, whereas the ratio of $\gamma|s(0)|^2$ underestimates $^1J(^{59}Co,^{31}P)$. Qualitatively, $^1K(^{59}Co,^{31}P)$ and $^1K(^{103}Rh,^{31}P)$ increase by the same factors in the alkylated cobaloximes and rhodoximes. The reduced coupling constant increases as the atomic number of the metal, *Z*, increases in a series of isostructural compounds (48). This is thought to be due to increasing $|s(0)|^2$ upon descending any group of the periodic table.

Temperature-dependent self-decoupling of cobalt

Previously, we observed the manifestation of self-decoupling of the ^{59}Co nucleus in the ^{31}P CPMAS NMR spectra of $PBu_3Co(DH)_2Cl$ (**I**) acquired at room temperature (4). The fine structure resulting from the *J*-coupling is not

© 1999 NRC Canada

present in these spectra; rather, broad resonances are observed. Additional examples are presented here (Fig. 8), for $PEt_3Co(DH)_2Me$ (**XVIII**) and $PBu_3Co(DH)_2N_3$ (**XIX**). As the samples are cooled down to 170 K, the multiplet structure is observed in both cases. The self-decoupling of the cobalt nucleus is attributed to shorter values of the cobalt spin-lattice relaxation times, $T_1(^{59}Co)$, at higher temperatures. Since the ^{31}P nucleus is indirectly spin–spin coupled to a rapidly relaxing quadrupolar nucleus (^{59}Co) through an interaction of the form $J\mathbf{I}\cdot\mathbf{S}$, scalar relaxation of the second kind becomes the dominant spin–spin relaxation mechanism at the ^{31}P nucleus. If the ^{59}Co nucleus has a short relaxation time, $T_1(^{59}Co)$, compared with the magnitude of $J(^{59}Co,^{31}P)^{-1}$, then fluctuating magnetic fields arise which induce efficient spin–spin relaxation of ^{31}P. As a result, the ^{31}P NMR spectra do not exhibit the expected multiplet structure, but have broadened lineshapes indicating self-decoupling of the ^{59}Co nucleus. Rough deconvolution of the powder patterns provides estimates of individual peak widths, from which upper limits on $T_1(^{59}Co)$ of 8 and 9 ms are calculated for **XVIII** and **XIX**, respectively. It is not surprising that self-decoupling is observed in **XIX**, since the neutral ligand in this complex (PBu_3) is the same as that in **I**. However, for **XVIII**, which is similar to $PMe_3Co(DH)_2Me$ in structure, the observance of the self-decoupling phenomenon is somewhat more surprising. Self-decoupling at room temperature was also observed in the ^{31}P CPMAS NMR spectra of $PBu_3Co(DH)_2Me$ and $P(OMe)_3Co(DH)_2N_3$; however, variable-temperature NMR spectra of these complexes are not presented here.

The ^{31}P CPMAS NMR spectra of $P(p\text{-}ClC_6H_4)_3Co(DH)_2Me$ (**XII**) are quite broad at room temperature (see Fig. 5A, B), though multiplet structure is discernible. Low-temperature experiments conducted on this sample down to 165 K revealed no significant changes in the linewidths of the peaks. Peak-broadening mechanisms in the ^{31}P CPMAS NMR spectra of the cobaloximes must arise from sources other than the quadrupolar-dominated spin-lattice relaxation of the cobalt nucleus (e.g., sample non-crystallinity, magnetic susceptibility effects, etc.). Given the variety of the ligands present in complexes which exhibit the temperature-dependent self-decoupling phenomenon, the exact nature of the molecular motion giving rise to fluctuating EFGs at the cobalt nucleus (which induce efficient spin-lattice relaxation) is unknown at this time.

Conclusions

NMR parameters determined from the ^{31}P CPMAS NMR spectra of 19 cobaloximes have been presented. The ^{59}Co quadrupolar parameters and EFG tensor orientations vary with substitution of different axial ligands. The orientations of the EFG tensors determined for three "well-characterized" cobaloximes provide information on possible EFG tensor orientations in cobaloximes for which structural and quadrupolar data are not available. For example, in phosphine-substituted alkylcobaloximes, d is negative, suggesting an orientation in which V_{11} is along the Co, P bond. In several of the phosphine-substituted chloro- and azidocobaloximes, d is positive, intimating that V_{22} is along the Co, P bond.

The magnitude of $^1J(^{59}Co,^{31}P)$ varies according to the nature of the neutral and anionic axial ligands. Specific trends in $^1J(^{59}Co,^{31}P)$ can be qualitatively related to the steric bulk and electronic nature of the neutral ligands and the *trans*-influencing ability of the anionic species. No correlation is found between the Co, P internuclear distance and the magnitude of $^1J(^{59}Co,^{31}P)$. The Fermi-contact mechanism can be used to qualitatively explain why $^1J(^{59}Co,^{31}P)$ is reduced in methylcobaloximes and increased in phosphite-substituted cobaloximes.

Variable-temperature ^{31}P NMR experiments reveal that ^{59}Co is partially self-decoupled at room temperature, and "re-coupled" at temperatures on the order of 170 K or lower, opposite to trends observed in the extreme-narrowing limit in solution. Upper limits on $T_1(^{59}Co)$ are estimated from the line widths of the ^{31}P MAS NMR spectra, assuming that scalar relaxation of the second kind is operative at the phosphorus nuclei.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for funding (R.E.W.) and the Atlantic Regional Magnetic Resonance Centre (ARMRC) for the solid-state NMR facilities. R.W.S. thanks the Killam Foundation and Walter C. Sumner Foundation for graduate fellowships. R.E.W. thanks the Canada Council for a Killam Research Fellowship. A comparison of NMR distance determinations in the solid state by cross polarization, REDOR, and TEDOR techniques

Colin A. Fyfe, Andrew R. Lewis, and Jean-Michel Chézeau

Abstract: Solid-state NMR distance determinations using Hartmann–Hahn cross polarization between spin-1/2 nuclei ($^{19}F/^{29}Si$) are reported. $^{19}F \rightarrow {}^{29}Si$ polarization transfer for the T-1 silicon site in the clathrasil octadecasil shows an oscillatory behaviour as a function of the contact time. These oscillations were observed for non-spinning powder samples and also for different spinning speeds at the various MAS sideband matching conditions. Three analytical functions that allow efficient nonlinear least-square regression analyses of the experimental data to determine the internuclear distances for non-spinning powder samples as well as at the ±1 and ±2 MAS sideband matching conditions are reported. Using these functions, a $^{19}F—^{29}Si$ distance of 2.53 ± 0.04 Å was determined for the T-1 silicon in octadecasil from fitting of the oscillatory behaviour. This distance is in good agreement with that known from the X-ray structure and the previous $^{19}F/^{29}Si$ REDOR and TEDOR distance measurements. The advantages and limits of the different dipolar-based NMR techniques for heteronuclear distance determinations are examined and discussed.

Key words: cross polarization (CP), NMR distance measurements, octadecasil, $^{19}F—^{29}Si$ distances, REDOR, TEDOR.

Résumé : La polarization croisée, dans les conditions de résonance de Hartmann–Hahn, est utilisée pour mesurer des distances entre noyaux de spin 1/2 ($^{19}F/^{29}Si$) par RMN à l'état solide. Le transfert de polarisation $^{19}F \rightarrow {}^{29}Si$, pour les atomes en site T-1 dans le clathrasil octadecasil, présente des oscillations jusqu'à des temps de contact d'environ 10 ms. Ces oscillations, observées en absence de rotation de l'échantillon, mais également pour différentes vitesses de rotation à l'angle magique, ont été paramètrées. Les fonctions qui permettent l'analyse de la courbe expérimentale par régression non-linéaire des moindres carrés sont données pour les diverses conditions expérimentales : échantillon statique et, lors de la rotation à l'angle magique, accord sur les bandes latérales ±1 et ±2 par rapport aux conditions statiques. La distance $^{19}F—^{29}Si$ obtenue, 2,53 ± 0,04 Å, est en bon accord avec les précédentes déterminations par diffraction des rayons X et par les méthodes REDOR et TEDOR. Les avantages et les limites des différentes méthodes de RMN permettant de déterminer des distances par mesure du couplage dipolaire hétéronucléaire sont examinés et discutés.

Mots clés : polarisation croisée (CP), détermination des distances par RMN, octadecasil, distances $^{19}F—^{29}Si$, REDOR, TEDOR.

Introduction

Solid-state NMR spectroscopy has considerable potential in solid-state structure investigations via the direct determination of internuclear distances from experiments based on the through-space dipolar interactions between selected pairs of nuclei. The dipolar coupling, D, between two nuclei, I and S, depends on the gyromagnetic ratios of the two nuclei, γ_I, γ_S, and on the internuclear distance r (eq. [1]) (1).

$$[1] \qquad D = \mu_0 \gamma_I \gamma_S h/(16\pi^3 r^3)$$

In eq. [1] μ_0 is the magnetic field constant in a vacuum, and h is Planck's constant. Furthermore, since $D \propto r^{-3}$, moderately accurate values of dipolar couplings can yield very accurate values for the corresponding internuclear distances, with the most unambiguous distance measurements coming from systems where I and S interact as isolated spin pairs.

In high-resolution solid-state NMR, magic angle spinning (MAS) is used to narrow the otherwise extremely broad (up to several kHz) resonances. Under MAS conditions the heteronuclear dipolar interaction becomes time dependent (eq. [2]) (1),

[2] $$D(\alpha, \beta, t) = 0.5D[\sin^2 \beta \cos 2(\alpha + \omega_r t) - \sqrt{2} \sin 2\beta \cos (\alpha + \omega_r t)]$$

α and β are the polar angles describing the orientation of the *I–S* internuclear vector with respect to a MAS rotor-fixed coordinate system with its *z*-axis along the spinning axis. MAS does not remove the dipolar interaction, but averages the effective dipolar coupling to zero over each complete rotor cycle (1). Thus, in its simplest form, the use of MAS precludes a direct measurement of *D*.

Recently, there has been considerable interest in heteronuclear distance determinations using the Rotational-Echo Double Resonance (REDOR) (1, 2) and Transferred-Echo Double Resonance (TEDOR) (3, 4) experiments introduced by Schaefer and co-workers. These employ radio frequency (r.f.) pulses applied at specific points in each rotor period to prevent the complete averaging out of the dipolar interactions, and thus allow the effects of dipolar dephasing to accumulate. Using appropriate analysis (1, 4–10), the magnitudes of the dipolar couplings can be experimentally measured and accurate interatomic distances determined. Because these techniques are based on the dipolar interaction that acts through space, there is no requirement that the nuclei be chemically bonded.

REDOR and TEDOR have been applied to amino acids (1–4), peptides (4, 6, 11), proteins (7, 12), semiconductors (13), oxides (14), polymers (15), and molecular sieve frameworks (16–21). In cases where the distances are known independently from X-ray diffraction measurements, those obtained from REDOR and TEDOR experiments are in very good agreement (2, 11, 16).

In the cross polarization (CP) experiment, spin polarization, and thus net magnetization, is transferred via dipolar interactions from abundant *I* spin system (usually ^{1}H) to the dilute *S* spins (e.g., ^{13}C, ^{15}N, or ^{29}Si). The *S* spin FID is then recorded with decoupling applied to the *I* spins. Often, there are significant sensitivity gains associated with the use of CP. These arise because of the enhancement of the order of γ_I/γ_S (compared to a one-pulse NMR experiment on the *S* spins), and the ability to use shorter recycle delays if the T_1 of the *I* spins is less than that of the *S* spins.

Commonly, CP experiments are carried out where the signal intensity is monitored as a function of the contact time τ. The initial build-up of intensity is related to the strength of the *I–S* dipolar couplings, and thus analysis of CP experiments should permit discrimination between different *I–S* distances and, ideally, yield quantitative estimates for these distances if the spins are sufficiently isolated. Measurements of average *I–S* dipolar couplings or distances determined from CP have been reported in the literature (22–26).

In cases where there are a large number of *I* spins coupled to each *S* spin, oscillations at many frequencies interfere, and the signal intensity observed for the *S* spins exhibits an exponential rise to a maximum followed by an exponential decay (27, 28). The dynamics of this process have been extensively described in the literature (27, 29–33).

Oscillations in the ^{1}H/^{13}C cross polarization signal intensity were first reported for a single crystal of ferrocene by Müller et al. (34). Similar oscillations have since been reported in the literature for non-spinning powder samples (23, 35), liquid crystals (36), and oriented lipid bilayers (25). Müller et al. (34) presented a theoretical description of this behaviour and showed that the frequency of this transient oscillation is related to the heteronuclear dipolar coupling constant. An oscillatory behaviour as a function of contact time should be observable whenever the *IS* dipolar interaction is dominated by a few nearest neighbour *I* spins; effectively meaning isolated I_NS spin systems with *N* less than about four (23). However, these oscillations can be damped by other heteronuclear and homonuclear interactions (32).

Stejskal and Schaefer (27, 37) reported transient oscillations under MAS in ^{1}H/^{13}C/^{15}N double cross polarization experiments, and demonstrated the effects of MAS on the CP matching condition. Since then, only relatively few examples of oscillatory behaviour in CP MAS experiments have been reported (23, 24, 26, 38–40). In some cases (24, 26, 39), the authors used slight modifications of the equation derived for the stationary single crystal case by Müller et al., but the modifications proposed ignored the effects of MAS or powder averaging. Consequently, the dipolar couplings and distance information obtained must be viewed as invalid. Hawkes et al. (38) recognized the need to include the effects of MAS on the dipolar coupling (eq. [2]), but did not give an explicit equation describing the CP behaviour.

Recently, Hediger (23, 41) incorporated the effects of sideband matching, powder averaging and MAS for spin-1/2 systems using Floquet theory (42, 43) and applied it to determine the ^{1}H/^{13}C dipolar coupling in a powder sample of co-crystallized C_{60}(ferrocene)$_2$. This sound theoretical analysis means that the CP MAS experiment should now be a viable method for heteronuclear distance determinations in systems of isolated spin pairs.

In previous work we reported ^{19}F—^{29}Si distance determinations in octadecasil by REDOR and TEDOR experiments, and noted that an oscillatory behaviour was observed for the T-1 Si during ^{19}F/^{29}Si CP experiments (16). In the present paper the results of our investigation of this system using ^{19}F/^{29}Si cross polarization are presented. Three analytical functions were derived, which allow efficient nonlinear least-square regression analysis of the experimental data to determine the internuclear distances for non-spinning powder samples as well as at the sideband matching conditions under MAS. The advantages and limits of the different dipolar-based heteronuclear distance determination experiments are also discussed.

Experimental

The pure, highly crystalline octadecasil sample (crystal size 80 μm), was kindly provided by Dr. P. Caullet. The structure was checked by powder X-ray diffraction, ^{19}F, and ^{29}Si MAS NMR measurements, all of which agreed with previously reported results (44, 45). Fluorine contents in these materials are usually in the range 2.3–2.6% (45), which corresponds to occupancies of 80–100% of the D4R units by fluoride ions. The idealized elemental composition of octadecasil is $Si_{20}O_{40}\cdot 2(Q^+F^-)$ where Q^+ is the quinuclidinium cation.

All experiments were carried out using a Bruker MSL-400 spectrometer. The Bruker MAS probe was modified by tuning the high-frequency channel to 376.44 MHz. Approxi-

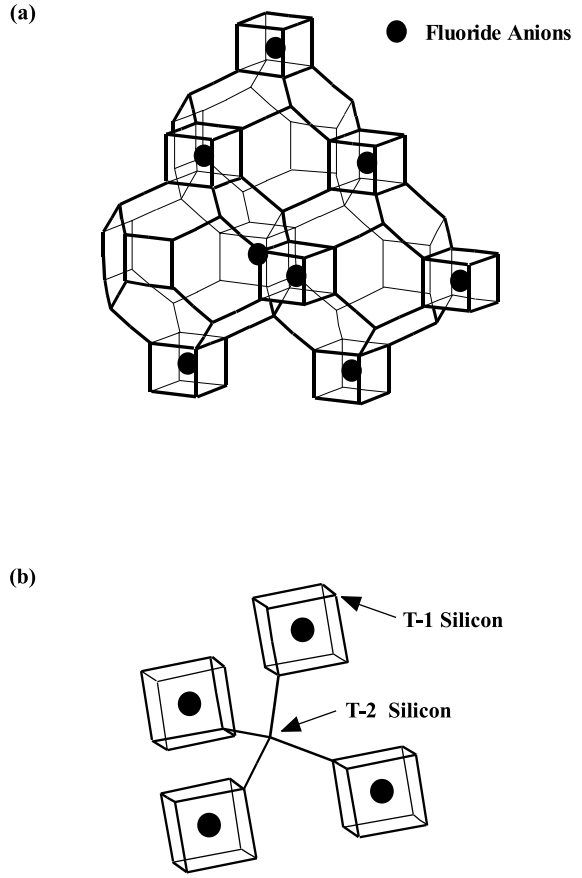
Fig. 1. (*a*) Schematic representation of the framework structure of octadecasil showing the packing arrangement of the two types of cages: the large [$4^6 6^{12}$]-cages and the small [4^6]-cages (D4R units). Each vertex represents a silicon atom, and oxygen atoms (not shown) lie approximately midway between these. Thick lines indicate connections closer to the viewer. (*b*) Portion of the octadecasil framework showing the four D4R units surrounding each T-2 silicon. T-1 silicons are connected to three other T-1 sites in the same D4R unit and to one T-2 silicon. Fluoride anions, which lie at the center of approximately 90% of the D4R units, are 2.63 Å from each T-1 silicon and 5.69 Å from the nearest T-2 silicon. The distance between fluoride anions in adjacent D4R units is 9.33 Å.



mately 250 mg of sample was packed in a 7 mm diameter rotor and spinning speeds in the range of 2.0–4.2 kHz were used. The ^{19}F r.f. field was generated by amplifying a frequency-tripled 125.48 MHz signal. In some cases external attenuators were necessary to attain the r.f. powers needed to observe the different matching conditions. The reflected power was monitored on both channels throughout the experiments to ensure the probe remained matched and tuned. The experimental data were integrated to determine peak areas and nonlinear least-squares fitting was performed as described below.

Programs were written using Mathematica software (46) to simulate the *IS* spin behaviour in terms of both numerical integration and Bessel functions, the latter being much more efficient. In the actual functions used to fit the data, a scaling factor (which was optimized during the fitting) was used to match the theoretical and experimental intensities. Initial visual fitting was done to find suitable starting values for the various parameters, and in some cases, it was necessary to hold one or more parameters constant to ensure convergence.

Results and discussion

Structure of octadecasil

Figure 1(*a*) shows the structure of completely siliceous octadecasil, as determined by single crystal X-ray diffraction (45). The framework can be built by linking octadecahedral [$4^6 6^{12}$] cages through all their common six-membered ring faces. Since these octadecahedral cages do not completely fill three-dimensional space, another type of void, the very small [4^6]-cage or double four-membered ring (D4R) unit, is created. When prepared from a fluoride-containing medium, the product crystallizes in a tetragonal phase (space group *I*4/*m*, no. 87), with the quaternary ammonium templating cation (quinuclidinium in this case) in the large cages, and the fluoride ion in the D4R units. The fluoride ion is needed to balance the positive charge of the organic cation. The octadecasil framework contains two types of T-sites: the vertices of the D4R units (designated as T-1), and the vertices that are shared by four six-rings (T-2 sites). Each T-2 Si is connected to T-1 silicons from four different D4R units (Fig. 1(*b*)). These sites occur in the ratio 4 T-1:1 T-2, which means there are 16 T-1 and 4 T-2 sites per unit cell. Elemental analysis indicates that ca. 90% of the D4R units contain a fluoride ion. From the X-ray crystal structure data, the T-1 silicons are 2.63 Å from the fluoride ion inside their D4R unit and more than 7 Å from the fluoride ions in the adjacent D4R units. The T-2 silicons are 5.69 Å from (up to) four equivalent fluoride ions, and the closest F—F distance is 9.33 Å. Because of the distances involved and the low natural abundance of ^{29}Si (4.8%), the ^{19}F/^{29}Si interactions for the T-1 silicons approximate well the case of isolated spin pairs.

The quantitative ^{29}Si MAS NMR spectrum shows two sharp resonances as expected from the structure (Fig. 2), and based on their relative intensities, these can be unambiguously assigned as indicated. For a non-spinning sample, a symmetrical, featureless peak with a full width at half-height of 6200 Hz is observed. The ^{19}F MAS NMR spectrum (not shown) consists of a single sharp resonance at –38.2 ppm with respect to $CFCl_3$, which is consistent with its location within the D4R unit in the structure (44, 45, 47).

Hartmann–Hahn matching profiles

For spin-1/2 nuclei, efficient *I*–*S* magnetization transfer occurs in a stationary sample when the standard Hartmann–Hahn matching condition (29) (eq. [3]) is fulfilled (31).

$$[3] \qquad \omega_{1I} = \omega_{1S}$$

Here $\omega_{1I} = -\gamma_I B_{1I}$, $\omega_{1S} = -\gamma_S B_{1S}$, and B_{1I}, B_{1S} are the radio frequency fields applied to the *I* and *S* spins, respectively. However, when MAS is used, Stejskal et al. (27) showed that under certain conditions, the matching condition centered at $\omega_{1I} = \omega_{1S}$ splits into narrow sideband matching conditions $\omega_{1I} = \omega_{1S} + n\omega_r$ (n = 0, ±1, ±2, ±3,...) separated by the rotation frequency ω_r. These sideband matching conditions will appear whenever the MAS frequency is comparable to, or exceeds, the width of the abundant *I* spin

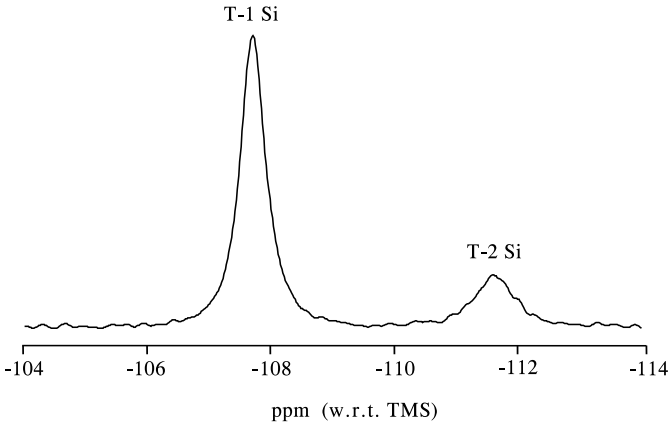
Fig. 2. Quantitative ^{29}Si MAS NMR spectrum of octadecasil showing the two resonances assigned to the T-1 and T-2 silicons, respectively. The relative peak intensities (4:1) are as expected from the crystal structure. The spectrum was acquired using 48 scans, a spinning speed of 2.2 kHz, pulse width of 8 μs, and a 110 s relaxation delay. No ^{1}H or ^{19}F decoupling was used.



resonance and the heteronuclear dipolar coupling frequencies (27, 37, 48). If the MAS frequency is slow compared to the homogeneous line width of the abundant *I* spins, sample spinning does not significantly influence the polarization transfer obtained by Hartmann–Hahn cross polarization (HHCP) (27, 48).

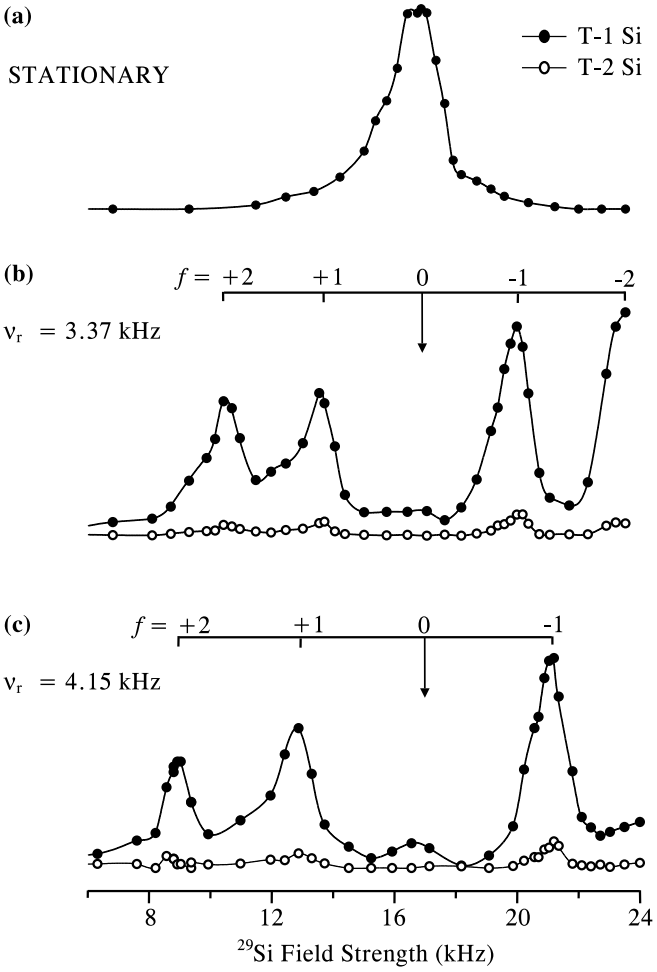
For systems of isolated *IS* spin pairs spinning sufficiently rapidly to reach the fast MAS regime ($\omega_r/2\pi >> D$), Hediger et al. (41) has shown that for HHCP between spin-1/2 nuclei, the matching condition splits into only four sideband matching conditions described by eq. [4].

$$[4] \qquad \omega_{1I} = \omega_{1S} + f\omega_r, \qquad f = \pm 1 \text{ or } \pm 2$$

An identical result was derived by Marks and Vega (49). These sidebands arise because MAS modulates the dipolar interactions by ω_r and $2\omega_r$ (eq. [2]) (27). No polarization transfer is expected at the centerband position ($f = 0$), although this is sometimes observed due to flip-flop processes between remote *I* spins (27, 50), and due to polarization transfer through heteronuclear scalar (*J*) coupling (48, 51). This effect had been previously observed by Schaefer et al. (37) in their double cross polarization experiment on ^{13}C-^{15}N labelled glycine and asparagine.

Figure 3 shows the matching profiles obtained for a powder sample of octadecasil using ^{19}F–^{29}Si Hartmann–Hahn CP. These profiles were determined by measuring the peak area(s) in the ^{29}Si NMR spectra as a function of the ^{29}Si r.f. field strength, with the contact time and ^{19}F field strength held constant. For non-spinning samples, a single match condition was found (Fig. 3(*a*)) that corresponded to the exact Hartmann–Hahn condition (eq. [3]) as expected. Under MAS almost no polarization transfer was observed at the exact Hartmann–Hahn match, but up to four other matching conditions separated by integral multiples of the spinning speed were found, as expected (Figs. 3(*b*, *c*)). For the highest spinning speeds used the available ^{29}Si r.f. power was not sufficient to observe all four matching conditions. The

Fig. 3. Hartmann–Hahn ^{19}F–^{29}Si CP matching profiles for the two T-sites in octadecasil: (*a*) non-spinning sample, (*b*) 3.37 kHz MAS, and (*c*) 4.15 kHz MAS. The ^{19}F r.f. field strength was 17 kHz, and contact times of 2 ms and 10 ms were used for the static and MAS experiments, respectively. For the MAS experiments, the sideband matching conditions, *f*, are also indicated.



matching profiles for the T-2 Si seem to mimic the behaviour seen for the T-1 Si (Figs. 3(*b*, *c*)), however the signal to noise ratio for the T-2 Si was quite poor at the 10 ms contact time employed.

According to several authors (27, 52, 53), the relative intensities of the peaks in the Hartmann–Hahn matching profile should be symmetrical about the center-matching condition, $\omega_{1I} = \omega_{1S}$. However, Hartmann–Hahn matching profiles reported in the literature rarely show this, and in the present case, a very non-symmetrical profile was observed (Fig. 3). Although some of this asymmetry could perhaps arise from experimental artifacts (for example, the behaviour of the NMR probe, filters, attenuators and amplifiers used), Ding and McDowell (50, 54) have attributed this effect to the magnitude of the applied r.f. fields. They report that the cross relaxation rate has a direct dependence on the product of the r.f. amplitudes of the spin locking fields on both the *I* and *S* nuclei, and the magnitude of this factor will therefore change because the strength of one of the r.f. fields is varied.

Table 1. Functions describing HHCP behaviour for isolated *IS* spin pairs in powder samples at various matching conditions.[a]

Matching condition	Function	Exact integral	In terms of Bessel functions
Stationary sample	$g_0(\tau)$	$\frac{1}{2}\int_0^{\pi}\cos[\pi D\tau(3\cos^2\beta-1)]\sin\beta\,d\beta$	$\cos\left(\frac{\pi D\tau}{2}\right)J_0\left(\frac{3\pi D\tau}{2}\right) - 2\sum_{k=1}^{\infty}\left[\frac{1}{(4k^2-1)}J_k\left(\frac{3\pi D\tau}{2}\right)\cos\left(\frac{\pi D\tau}{2}+\frac{k\pi}{2}\right)\right]$
MAS $f = \pm 1$	$g_{\pm1}(\tau)$	$\frac{1}{2}\int_0^{\pi}\cos\left[\frac{\pi D\tau}{\sqrt{2}}\sin 2\beta\right]\sin\beta\,d\beta$	$J_0\left(\frac{\pi D\tau}{\sqrt{2}}\right)+2\sum_{k=1}^{\infty}\left[\frac{1}{(1-4(2k)^2)}J_{2k}\left(\frac{\pi D\tau}{\sqrt{2}}\right)\right]$
MAS $f = \pm 2$	$g_{\pm2}(\tau)$	$\frac{1}{2}\int_0^{\pi}\cos\left[\frac{\pi D\tau}{2}\sin^2\beta\right]\sin\beta\,d\beta$	$\cos\left(\frac{\pi D\tau}{2}\right)J_0\left(\frac{\pi D\tau}{2}\right) - 2\sum_{k=1}^{\infty}\left[\frac{(-1)^k}{(1-4k^2)}J_k\left(\frac{\pi D\tau}{2}\right)\cos\left(\frac{\pi D\tau}{2}+\frac{k\pi}{2}\right)\right]$

[a] D in Hz, τ is the contact time in seconds, k is an integer.

In the present case, it was the ^{29}Si field strength that was varied, and the intensity of the matching conditions increased with increasing r.f. field strengths.

Although the spinning speeds employed were only about three times greater than the largest ^{19}F–^{29}Si dipolar coupling calculated from the crystal structure (1230 Hz for the T-1 Si), the matching profiles indicate that ^{29}Si nuclei in both T-sites are behaving as isolated I_NS spin systems to a good approximation. This is in agreement with the previous REDOR and TEDOR experiments (16). The small amount of polarization transfer observed at the centerband ($f = 0$) matching condition may be due to flip-flop processes between remote ^{19}F spins or polarization transfer mediated through heteronuclear *J*-coupling.

Theoretical Hartmann–Hahn cross polarization behaviour for powder samples

In their investigation of the ^{1}H–^{13}C polarization transfer in a stationary single crystal of ferrocene, Müller et al. (34) showed that the oscillatory behaviour of the ^{13}C magnetization M as a function of the contact time τ could be described by

$$[5]\qquad M(\tau) = M_0\,[1 - 0.5\exp(-k_1\tau)\cos[0.25D(1 - 3\cos^2\theta)\tau] - 0.5\exp(-k_2\tau)]$$

where M_0 is the equilibrium I spin magnetization obtained by a single $\pi/2$ pulse, k_1 and k_2 are first-order rate constants that describe the decay of the transient oscillation and the increase in the net magnetization respectively, and θ is the angle between the *I–S* internuclear vector and the magnetic field direction vector. In eq. [5] the effects of decay due to spin lattice relaxation of the *I* spins in the rotating frame are assumed to be negligible (i.e., $T_{1\rho} \rightarrow \infty$). Müller et al. assumed that the spin system could be described by a Hamiltonian limited to the strongly coupled *IS* spin pair, with the effect of more remote *I* spins represented by an isotropic random-field spin–diffusion relaxation mechanism. These authors also set $k_1 = 3k_2/2$, but Hediger (23) has since shown that these rate constants are better treated as independent variables in order to fit the behaviour at longer contact times. Equation [5] is only valid if the rate constant describing the *I* spin diffusion is smaller than the heteronuclear couplings. If this is not the case then the spin system will be dominated by homonuclear interactions and no transient oscillations will be seen (23).

Hediger (23) has reported that, considering the *S* spin quasi-equilibrium polarization at long times ($\langle S_z\rangle_{qe}$), eq. [5] can be extended to the case of a stationary powder sample by including the effect of the individual crystallites' orientations. This yields eq. [6]

$$[6]\qquad \langle Sz\rangle(\tau) = \omega_{0I}\left\{0.5[1-\exp(-k_1\tau)g_0(\tau)] + \left[\frac{\langle S_z\rangle_{qe}}{\omega_{0I}} - 0.5\right][1-\exp(-k_2\tau)]\right\}$$

Here $\langle S_z\rangle(\tau)$ is the expectation value of the polarization on the *S* spin, ω_{0I} is Larmor frequency of the *I* spins, and $\langle S_z\rangle_{qe}$ is defined by eq. [7] (23).

$$[7]\qquad \langle S_z\rangle_{qe} = N\omega_{0I}/(N+1)$$

For truly isolated *IS* spin pair, $N = 1$, and thus $\langle S_z\rangle_{qe} = \omega_{0I}/2$, which means that half of the initial polarization on the *I* spin is transferred to the *S* spin, and that there is no spin diffusion with remote *I* spins (i.e., no k_2 term). However in a "real" isolated spin system where there is a strongly coupled *IS* spin pair and *N*-1 remote (weakly coupled) *I* spins, $\langle S_z\rangle_{qe}$ can have values between $\omega_{0I}/2$ (ideal two-spin system, no k_2) and ω_{0I} (*N* large; as assumed by Müller et al. in the derivation of eq. [6]).

The function $g_0(\tau)$ in eq. [6] that describes the oscillatory behaviour of the polarization as it shuttles between the *I* and *S* spin is given in Table 1 and corresponds to the calculation of *D* averaged for a powder. This powder average normally involves integration over two angles (α and β) (1), however in this case (isolated spin pairs), it is only necessary to integrate over a single angle (β) because it is not possible to detect the phase of the dipolar coupling (S. Hediger, personal communication, 1997).

Assuming that the decay is dominated by $T_{1\rho}$ relaxation of either the *I* or *S* spins, the effect of $T_{1\rho}$ relaxation can be incorporated (26) in eq. [6], giving

© 1999 NRC Canada

$$[8]\qquad \langle S_z\rangle(\tau) = \omega_{0I}\left\{0.5[\exp(-\tau / T_{1\rho}) - \exp(-k_1\tau)g_0(\tau)] + \left[\frac{\langle S_z\rangle_{qe}}{\omega_{0I}} - 0.5\right][\exp(-\tau / T_{1\rho}) - \exp(-k_2\tau)]\right\}$$

Hediger also derived equations that describe the HHCP behaviour of isolated spin-1/2, *IS* spin pairs under MAS conditions. In the high-speed limit ($\omega_r/2\pi >> D$), eq. [8] can be extended to the case of a powder undergoing MAS by replacing the oscillatory term $g_0(\tau)$ with the appropriate function $g_f(\tau)$ to yield eq. [9] (23).

$$[9]\qquad \langle S_z\rangle(\tau) = \omega_{0I}\left\{0.5[\exp(-\tau / T_{1\rho}) - \exp(-k_1\tau)g_f(\tau)] + \left[\frac{\langle S_z\rangle_{qe}}{\omega_{0I}} - 0.5\right][\exp(-\tau / T_{1\rho}) - \exp(-k_2\tau)]\right\}$$

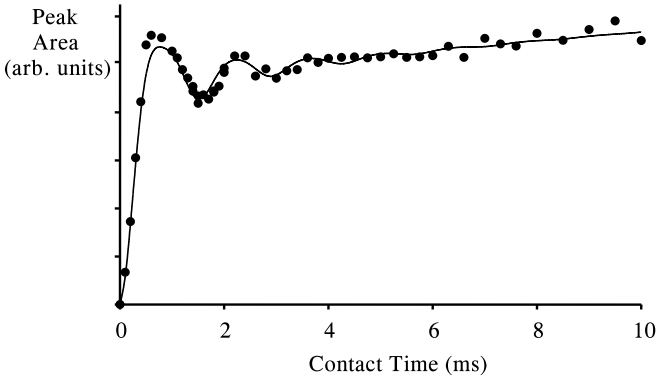
The evolution of the spin system will be different at the $|f| = 1$ and $|f| = 2$ matching conditions, but identical when $f = 1$ or –1, and when $f = 2$ or –2. The two functions $g_f(\tau)$ (23) that describe the oscillation of the polarization between the *I* and *S* spins at the four MAS matching conditions described by eq. [4] are given in Table 1. These functions incorporate the effects of MAS on the dipolar coupling and the averaging of the *I*–*S* internuclear vectors over the crystallite orientations in a powder sample.

The functions $g_0(\tau)$ and $g_f(\tau)$ may be evaluated using numerical integration but this can be computationally intensive. However, using the general methodology reported by Mueller (5), it is possible to re-express these integrals in terms of Bessel functions of the first kind. These functions were derived and are given in Table 1. The function for the non-spinning sample is has the same form as that reported previously for the SEDOR experiment, (5) and that for the $f = \pm 1$ MAS matching condition corresponds to that reported for the Double Cross Polarization experiment by Vogt et al. (55) although the arguments are different due to the different nature of the experiments. To our knowledge, the equation describing the HHCP behavior at $f = \pm 2$ MAS matching condition in terms of Bessel functions has not been presented elsewhere. When expressed in this form, nonlinear least-squares fitting of the experimental data using eqs. [8] and [9] becomes much more efficient.

Variable contact time experiments on stationary samples

Figure 4 shows the area of the ^{29}Si resonance for a stationary sample as a function of the contact time. At short contact times a clear oscillatory behavior is seen, which is progressively damped at longer times. A slight upward trend is also apparent with increasing contact time. Although this resonance includes signals from both of the T-1 and T-2 silicons, the contribution to the total area from the T-2 silicons is expected to be small enough to neglect. In fact, for contact times up to 10 ms under MAS conditions (where the two T-sites are well resolved), the T-2 signal intensity is less than 10% that of the T-1 Si (Fig. 5). This is about the same as the uncertainty in the peak area determined by integration for the stationary sample, and on this basis, the analysis and fitting of the data in terms of only the T-1 silicons is considered valid. Note that efficient (and maximum) polarization transfer is obtained using a relatively short contact time (ca. 0.5 ms). Significant decay due to $T_{1\rho}$ relaxation effects was observed at long contact times as can be seen in Fig. 5.

Fig. 4. ^{19}F–^{29}Si CP behaviour for the T-1 Si in a stationary octadecasil (powder) sample as a function of the contact time. The line shows the fit calculated using eq. [8] with D = 1440 Hz, $\langle S_z\rangle_{eq}/\omega_{0I}$ = 0.9, k_1^{-1} = 2.2 ms, k_2^{-1} = 25.5 ms, and $T_{1\rho}$ = 2 s. The ^{19}F r.f. field strength was 17 kHz.



The increase in the signal amplitude as the contact time was increased up to 10 ms indicates that there is additional polarization transfer from other, more distant ^{19}F nuclei, and therefore, the spin system cannot be considered as a *completely* isolated spin pair. This implies that $\langle S_z\rangle_{qe}/\omega_{0I}$ must be greater than 0.5. However, $\langle S_z\rangle_{qe}$ and k_2 are strongly correlated (eq. [8]). For this reason the value of $\langle S_z\rangle_{qe}/\omega_{0I}$ was held constant in order to ensure reliable fitting between different data sets. From the X-ray structure of octadecasil, it was determined that there are (up to) eight fluoride ions within a 12 Å-radius sphere surrounding a T-1 silicon (corresponding to ^{19}F–^{29}Si dipolar couplings >15 Hz). Using eq. [7], and taking into consideration the statistical occupancy of the D4Rs (ca. 90%), a value of 0.9 was found for $\langle S_z\rangle_{qe}/\omega_{0I}$.

The ^{19}F–^{29}Si dipolar coupling was determined by fitting the experimental data to eq. [8] using the procedure described above. The best fit was obtained with k_1^{-1} = 2.2 ms, k_2^{-1} = 25.5 ms, and $T_{1\rho}$ = 2 s. The actual values of these parameters do not affect the dipolar coupling since this is defined by the period of the oscillations. Once suitable values for these five parameters were found, nonlinear least-squares regression gave D = 1440 Hz, corresponding to a Si—F distance of 2.49 Å (eq. [1]), which is slightly shorter than the 2.63 Å determined from X-ray diffraction. The resulting theoretical curve calculated using these values is overlaid on the experimental data in Fig. 4 and is in quite good agreement. The largest discrepancies occur at contact times up to 1 ms, and are attributed to the slight variation (decrease) in the output of the ^{19}F amplifier power with increasing contact time. In this case the Hartmann–Hahn match had been optimized for a 2 ms contact time. It is interesting to note that it

Fig. 5. ^{19}F–^{29}Si CP behaviour for the two T-sites in octadecasil under MAS conditions as a function of the contact time at the $f = -1$ sideband matching condition. The oscillatory behaviour for the T-1 Si and the decay due to $T_{1\rho}$ are clearly seen. The theoretical fit calculated using eq. [9] for the T-1 Si with D = 1360 Hz is also shown.

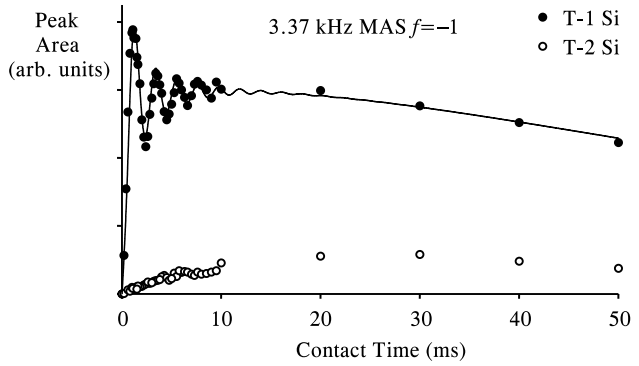

Fig. 6. ^{19}F–^{29}Si CP behaviour for the T-1 Si in octadecasil at the $|f| = 1$ sideband matching conditions under various MAS speeds. Curves calculated using eq. [9] with D = 1340 Hz (ν_r = 3.37 kHz, $f = -1$), D = 1380 Hz (ν_r = 3.37 kHz, $f = +1$), and D = 1360 Hz (ν_r = 4.66 kHz, $f = -1$) are overlaid. The intensities have been arbitrarily scaled to separate the curves.

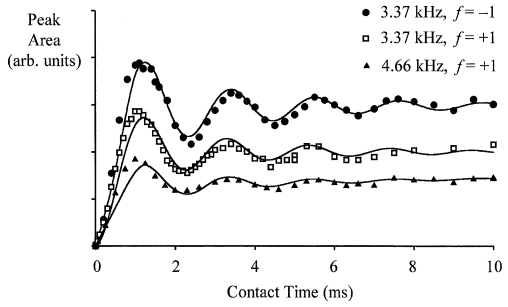

was possible to determine this distance although there was no obvious dipolar structure in the ^{29}Si spectrum of the stationary sample. The slightly larger dipolar coupling found from fitting of the experimental data may reflect the contribution from fluoride ions in other D4R's, and to a lesser extent the T-2 intensity.

MAS experiments at the $f = \pm1$ and $f = \pm2$ sideband matching conditions

Under MAS conditions, the transient oscillations became significantly more pronounced than for the stationary sample as can be seen by a comparison of Figs. 4–7. The oscillatory behaviour at the $f = +1$ sideband matching condition should be identical to that observed when the $f = -1$ match is used, and the period should be independent of the spinning speed. As seen in Fig. 6, the periodicity of the transient oscillations observed for the T-1 silicons is very similar at equivalent sideband matching conditions and different spinning speeds, in good agreement with the theoretical predictions.

Fitting of the experimental data to eq. [9] (expressed in terms of Bessel functions) was done as described for the non-spinning data. Because the oscillations are quite clearly defined at contact times of up to 8–10 ms, more periods of the oscillations are available to check the goodness of fit for given dipolar couplings, which reduces the uncertainty in the final D values. The reduction in the rate of damping of the oscillatory behavior with increasing spinning speed (and the corresponding increase in the values of k_1 used in the fitting) is as anticipated: at higher spinning speeds the effects of the relatively weak ^{19}F–^{19}F interactions are progressively "spun out."

Values of the parameters determined from the fittings were $T_{1\rho}$ = 70–400 ms, k_1^{-1} = 3.5–6 ms, and k_2^{-1} = 20–80 ms with $\langle S_z \rangle_{qe}/\omega_{0I}$ fixed at 0.9. In Figs. 5 and 6 the data from three experiments are presented with the theoretical curves determined from the nonlinear regression analyses. Because of the hardware limitations, the CP matching conditions were optimized using a 10 ms contact time to ensure that good matching was maintained over the period of the oscillations and also at the longer contact times (50–60 ms) required to observe the effects of $T_{1\rho}$ decay. This compromise results in a poor fit to the data acquired at very short (<1 ms) contact times, but does not affect the distance determination from fitting of the oscillatory behaviour. The dipolar couplings determined from fits to seven experimental data sets acquired at the $f = +1$ and -1 matching conditions range from D = 1330 to 1400 Hz with a mean of 1360 Hz and estimated standard deviation of 50 Hz. This corresponds to a Si—F distance of 2.54 (0.03) Å, which is slightly shorter than the distance determined from X-ray diffraction.

The oscillatory behaviour at the $f = +2$ and -2 sideband matching conditions should have a longer period compared to those observed at the $f = \pm1$ matches, exactly as was observed in the experimental data acquired for the T-1 Si under MAS conditions with appropriately adjusted r.f. field strengths. Fitting of the data to eq. [9] with the appropriate function $g_f(\tau)$ was carried out as described above and similar values of the various parameters were found. Experimental data obtained for the T-1 Si at the $f = +2$ matching condition for a spinning speed of 4.15 kHz are shown in Fig. 7 together with the curve calculated using the parameters listed in the caption. As previously, the matching was optimized for the time period in which the oscillatory behaviour is observed at the expense to the goodness of fit to the initial part of the curve. At the $f = +2$ matching condition only two periods of the oscillation were observed up to a contact time of 10 ms compared with the three to four seen when $f = \pm1$ (Figs. 5, 6). For this reason the uncertainty in the dipolar couplings is increased somewhat compared to those obtained from data acquired at the $f = \pm1$ matching conditions, and is closer to that determined from the stationary sample data.

The CP behavior observed for the T-2 Si at the $f = -1$ sideband matching condition is shown in Fig. 5. Similar behavior was observed at the other MAS matching conditions. No clear (reproducible) oscillatory behavior was seen for these silicons. For the T-2 silicons, a Si—F distance of 5.69 Å was calculated from the X-ray structure. However, depending on the exact occupancy of the D4R units, there can be up to four fluoride anions in a (partial) tetrahedral arrangement around each T-2 Si (and thus equidistant from it). This represents a much more complicated case than for the T-1 silicons because the experiment no longer involves isolated ^{19}F–^{29}Si spin pairs. Assuming a binomial distribution with 90% occupancy of each D4R unit by a fluoride ion, the probabilities that four, three, two, one, or none of the D4R

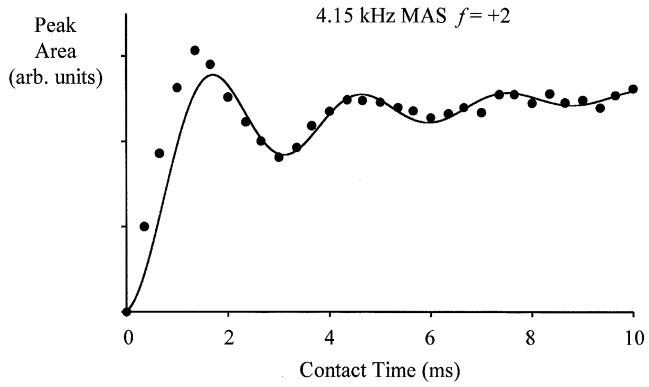
Fig. 7. ^{19}F–^{29}Si CP MAS behaviour for the T-1 Si in octadecasil at the $f = +2$ sideband matching condition. The line shows the fit calculated using eq. [9] with $D = 1400$ Hz, $\langle S_z \rangle_{eq}/\omega_{0I} = 0.9$, $k_1^{-1} = 6$ ms, $k_2^{-1} = 13$ ms, and $T_{1\rho} = 125$ ms. The spinning speed was 4.15 kHz and the ^{19}F r.f. field strength was 17 kHz.



units surrounding a given T-2 Si are occupied are 0.6561, 0.2916, 0.0486, 0.0036, and 0.0001, respectively (16).

Oscillatory HHCP behavior has been observed previously in a few systems, which most probably contain I_NS spin systems with $N \leq 4$ (24, 26, 40). The (apparent) lack of oscillations in the T-2 CP data as a function of contact time may be a consequence of the significantly lower signal-to-noise ratio for this peak, but may also result from "destructive interference" of the oscillations expected for the I_NS spin systems (N = 1–4). Fitting of T-2 data was not attempted.

In light of the analysis presented by Vogt et al. (55) the application of non linear least-squares fitting succeeds in the present case as a result of the high signal-to-noise ratio in the experimental data, which means that the oscillations are very clearly defined. In cases where the data are not of such high quality, the use of an alternative approaches (such as the Tikhonov regularization method) may permit the dipolar couplings, and subsequently the internuclear distances, to be determined (55).

Comparison with distance determinations from other NMR techniques

The average of the dipolar couplings determined from fitting of the CP data at the five possible matching conditions (stationary and MAS) for the T-1 Si is given in Table 2 together with the Si—F distances determined from REDOR, TEDOR, and X-ray diffraction experiments. Comparison of these data reveals that, for isolated spin pairs, analyses of variable contact time HHCP experiments can yield heteroatomic distances almost as reliable and accurate as REDOR and TEDOR experiments provided clear oscillatory behaviour is observed. In general, REDOR and TEDOR will be affected by the finite pulse lengths, r.f. field inhomogeneities, and variations in the spinning speed, all of which will reduce the efficiency of the evolution of the dipolar dephasing, and yield a smaller dipolar coupling and larger distances. Cross polarization experiments are less affected by the rotor period related effects, and as expected give shorter distances than REDOR and TEDOR (Table 2). Compared to the X-ray diffraction distance, *r* measured from CP experiments is somewhat shorter. This is probably due to the $1/r^3$ based averaging over motions of the fluoride ion for the CP measurements whereas diffraction uses a simple unweighted averaging, placing the fluoride ion at the center of the D4R units (45). It is expected that the motions of the fluoride ion will be larger than, for example, covalent bond vibrations.

The choice of the most appropriate experiment in a given situation will depend on a number of factors. The relaxation characteristics of the nuclei are important parameters that should be carefully considered. All three NMR techniques are affected by the T_1 value of the excited nuclei. In addition, CP will be limited by very short $T_{1\rho}$ values, REDOR by the *S* spin T_2 value, and TEDOR by the T_2 values of both *I* and *S* spins. In cases where there are a number of different *S* spins and more than one *I* spin, but still isolated *IS* pairs, CP and TEDOR will be preferred over REDOR as they can easily be extended to multidimensional experiments because they involve *I* to *S* coherence transfer (19, 56). Furthermore, because TEDOR and CP involve polarization transfer, only signals from *S* spins coupled to *I* spins are observed, and there is no need to acquire two experiments per data point to achieve normalization as is the case for REDOR experiments.

Hardware considerations are also important; CP is demanding in terms of r.f. stability, particularly if relatively small dipolar couplings are being measured since relatively long contact times will be necessary. All three techniques are sensitive to variations in the spinning speed during the experiment. Changes in the spinning speed will cause mismatching of the r.f. field strengths during the HHCP experiment, which will directly affect the efficiency of the polarisation transfer. For REDOR and TEDOR, the r.f. pulses will no longer be rotor-synchronized, and as a conse-

© 1999 NRC Canada

quence, the dephasing observed will be smaller than it should be. At very high MAS speeds REDOR and TEDOR experiments are not feasible due to finite pulse lengths (10, 57), however, several variations of the CP experiment have been developed that are less sensitive to the matching conditions and are still applicable under these conditions (40, 41, 48, 58–61).

The amplitude of the oscillations in the HHCP experiments is larger than for REDOR and TEDOR, which in principle allows the dipolar coupling to be measured more reliably from fitting of the experimental data. In general HHCP experiments to determine *I–S* distances in spin pairs will be best when done at the $f = \pm 1$ matching conditions under MAS for three reasons. Firstly, greatly improved spectral resolution may be achieved using MAS. Secondly, the intensity of the signal should be greater at the $f = \pm 1$ matching conditions than at $f = \pm 2$. Thirdly, the higher frequency of the oscillations compared to that for stationary samples and at $f = \pm 2$ (which should permit more periods to be observed and thus increase the reliability of the dipolar coupling determination).

For the T-2 silicon in octadecasil, the curves calculated assuming the correct statistical occupancy and spatial arrangement of the ^{19}F spins fit multi-spin TEDOR and REDOR data well (see Table 2) (16, 62). And although it is possible to calculate the CP behavior for small spin clusters (63) as can be done for REDOR and TEDOR (6, 62, 64), such calculations require the explicit knowledge of the number of spins as well as the geometry of the spin system. This is information that will usually not be known a priori and without this, distance determinations in multiple spin systems will not be possible. Recently Gullion and Pennington (65) reported a modified REDOR experiment, θ-REDOR. In theory, this technique allows the behaviour for I_NS spin systems to be separated into a linear combination of two-spin *I–S* systems. θ-REDOR may thus provide a possible solution to the problem of determining heteronuclear distances in multiple-spin systems. At present it is very difficult to extract this information from analysis of CP data.

Conclusions

The present work demonstrates that accurate heteronuclear distances (which are in good agreement with those obtained from X-ray diffraction) can be measured in the solid state from cross polarization NMR experiments on spin-1/2 nuclei. These measurements were successfully carried out for stationary powder samples and also under MAS conditions. Previously, the only reliable CP distance determinations reported for powder samples undergoing MAS were average distances (23, 24, 26). Expressions describing the HHCP behaviour for both non-spinning and MAS conditions were derived in terms of Bessel functions. These equations permit efficient nonlinear least-squares regression analysis of experimental data, and allow the *I–S* dipolar couplings and distances to be determined.

The choice of which dipolar-based heteronuclear distance determination technique (CP, REDOR, or TEDOR) is most appropriate for a given sample requires consideration of the relative magnitudes of the various nuclear relaxation parameters (T_1, T_2, and $T_{1\rho}$) in addition to the performance (and limitations) of the available NMR hardware. As for REDOR and TEDOR, the distances obtained from fitting of the oscillatory CP behavior are only reliable if the spin system under investigation can be considered (or closely approximates) an *isolated IS* spin pair. Verification that this is indeed the case must come from independent sources (e.g., samples prepared with specific isotopic labelling, or physical dilution in unlabelled compound, etc.) as the presence of oscillations in CP, REDOR, or TEDOR data does not by itself prove that this situation exists.

A nuclear magnetic resonance investigation of the micellar properties of a series of sodium cyclohexylalkanoates

Judith A. MacInnis, R. Palepu, and D. Gerrard Marangoni

Abstract: The micellar properties of a family of surfactants, the sodium cyclohexylalkanoates, have been investigated in aqueous solution using multinuclear NMR spectroscopy. C-13 chemical shift measurements have been used to determine both the cmc values and the micellar aggregation numbers (N_s values) of these surfactants. The cmc values and the degrees of counterion binding were estimated from ^{23}Na chemical shift measurements. The critical micelle concentrations (cmc's) and the aggregation numbers determined from the NMR experiments indicate that these amphiphiles have high cmc's and low aggregation numbers when compared to other single-headed surfactants (most notably the sodium alkanoates). The conformational changes incurred by the carbon atoms upon micelle formation have been deduced from the ^{13}C chemical shift differences ($\delta_{surf,mic} - \delta_{surf,aq}$). These results are used to discuss the formation of the aggregates of the sodium cyclohexylalkanoate surfactants as a function of the length of the alkanoate side chain.

Key words: micelles, surfactants, NMR spectroscopy, chemical shifts, aggregation numbers, degree of counterion binding, conformational changes.

Résumé : Opérant en solutions aqueuses et faisant appel à la spectroscopie RMN multinucléaire, on a étudié les propriétés micellaires d'une famille d'agents de surface, les cyclohexylalcanoates de sodium. On a utilisé des mesures de déplacement chimique du ^{13}C pour déterminer les valeurs des concentrations micellaires critiques (cmc) et les nombres d'agrégation micellaire (valeurs N_s) de ces agents de surface. Les valeurs des cmc et les degrés d'agrégation des contre-ions ont été évalués à l'aide de mesures de déplacement chimique du ^{23}Na. Les cmc et les nombres d'agrégation déterminés à l'aide de la RMN indiquent que, pour ces amphiphiles, les valeurs des cmc sont élevées et celles des nombres d'agrégation sont faibles lorsqu'on les compare à celles d'autres agents de surface à une seule tête (en particulier, les alcanoates de sodium). On a fait appel aux différences de déplacements chimiques du ^{13}C ($\delta_{surf.mic} - \delta_{surf.aq}$) pour déduire les changements conformationnels subis par les atomes de carbones lors de la formation des micelles. On utilise ces résultats pour discuter de la formation des agrégats des agents de surfaces des cyclohexylalcanoates de sodium en fonction de la longueur de la chaîne latérale alcanoate.

Mots clés : micelles, agents de surface, spectroscopie RMN, déplacements chimiques, nombres d'agrégation, degré d'agrégation du contre-ion, changements conformationnels.

[Traduit par la Rédaction]

Introduction

Surfactants (surface active agents) contain mainly a polar or ionic head group and a linear or branched hydrocarbon or fluorocarbon chain. The unusual behaviour of surfactants in solution can be attributed to the amphiphilic nature of the surfactant monomer. The polar or ionic headgroup interacts with its aqueous environment and is solvated due to dipole–dipole or ionic-dipole interactions. The nonpolar chain interacts very weakly with water resulting in the formation of ordered water molecules in the area surrounding the nonpolar chains (hydrophobic effect). This subtle interplay of attractive and repulsive forces leads to the formation of aggregates after a certain concentration of surfactant is reached. This concentration is known as the critical micelle concentration (cmc). It has been found that a large number of experimental observables change rapidly over a very narrow concentration range (the cmc region).

The bulk properties of sodium *n*-alkanoates have been extensively reported in the literature (1, 2) but very little attention has been given to the physicochemical properties of compounds that contain a cyclohexyl ring in the place of a long hydrocarbon or fluorocarbon chain. The generic structure of this surfactant family is given below.

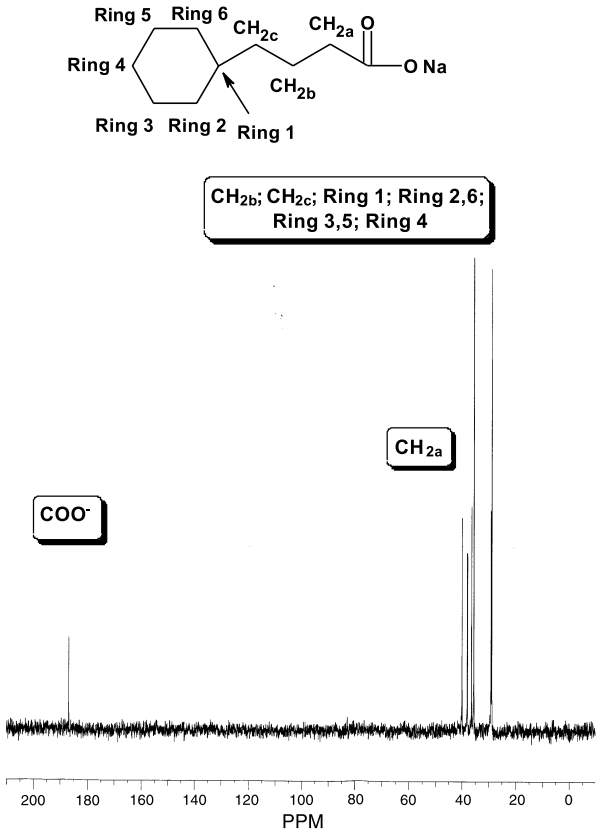
Fig. 1. ^{13}C NMR spectrum of sodium cyclohexylbutanoate (SChBu).



The main area of interest for these compounds is the presence of the cyclohexyl ring, as these surfactants are similar in molecular structure to compounds that are found in petroleum products (3). These petroleum acids, containing mainly short chain alkyls attached to saturated, partially saturated, or aromatic structures, have been postulated to play an important role in the reduction of interfacial tensions during alkaline water flooding of oil reservoirs (3). Hence, a comprehensive study of the properties of these surfactants may be important in the determination of their structure/performance relationships.

Nuclear magnetic resonance is a powerful tool that can be used to investigate the physicochemical properties of micellar systems (4–28). The transfer of monomer from the bulk solution into the micellar phase is generally accompanied by changes in a number of NMR parameters (e.g., chemical shifts and relaxation rates). These changes can be used to estimate a variety of parameters that characterize the micelle formation process (cmc values (4–8), counterion binding (7–11), aggregation numbers (6, 12–15), and the degree of solubilization of additives (16–19). In addition, conformational changes upon micellisation have been investigated using ^{13}C chemical shift changes and paramagnetic relaxation enhancement experiments (6, 12, 15, 20). The dynamics of the chains within the micellar interior have been determined by NMR ^{13}C, ^{31}P, ^{2}H, and ^{14}N relaxation time measurements (21–24). The application of NMR spectroscopy to the study of the formation of micelles and other aggregated systems has been the subject of several excellent reviews (25–28).

The purpose of this paper is to characterize the aggregation properties of the sodium cyclohexylalkanoate surfactants. ^{13}C and ^{23}Na chemical shift measurements were used to obtain the cmc values, the surfactant aggregation number and the degree of counterion binding for the sodium cyclohexylalkanoate surfactants in water. Conformational changes upon micelle formation have been determined from the ^{13}C chemical shift changes after the onset of micellisation. These results have been used to probe the effect of the increase in the length of the alkanoate side chain on the formation of aggregates of the sodium cyclohexylalkanoates.

2. Experimental

Preparation and purification of surfactants

Cyclohexylalkanoic acid, purchased from Aldrich (99% purity, used as received), were dissolved in triply deionized water and converted to the corresponding sodium salts by neutralization with analytical grade NaOH to pH ≅ 10. The surfactants (SChAc ≡ Sodium cyclohexylacetate, SChPr ≡ sodium cyclohexylpropanoate, SChBu ≡ sodium cyclohexylbutanoate, SChPe ≡ sodium cyclohexylpentanoate) were recovered by carefully removing the solvent under vacuum and extracting the solid with diethyl ether for 2–5 days. The surface tensions vs. log ($C_{surf,t}$) (where $C_{surf,t}$ is the total concentration of the surfactant) plots were free of any minima, indicating that the final product was free of surface-active impurities.

NMR experiments

The NMR spectra (^{1}H and proton decoupled ^{13}C) were obtained on a Bruker AC-200 at St. F.X. University and a Bruker AC-250 NMR at the Atlantic Region Magnetic Resonance Centre (ARMRC) at Dalhousie University. A typical ^{13}C spectrum for the cyclohexylalkanoate surfactants is presented in Fig. 1. ^{23}Na chemical shifts were obtained on a Bruker AMX-400 NMR spectrometer at the ARMRC. Homonuclear and heteronuclear 2-D NMR spectra (COSY and ^{13}C-detected HETCORR) were obtained on the AC-200 spectrometer using the standard pulse programs from the Bruker software library in order to assign the proton and the carbon peaks of the surfactants. Deuterium oxide (D_2O) was used as a solvent for all NMR experiments. The ^{1}H spectra were referenced to the HOD peak ($\delta = 4.81$ ppm) while the ^{13}C chemical shift signals were referenced to the deuterium lock signal using the method of Söderman and Guering (12). The ^{23}Na chemical shifts were measured with a 1.00 M solution of NaCl as the reference, and are reported with respect to the chemical shift of the counterion at infinite dilution.

3. Results and discussion

A. cmc values

The cmc values for the sodium cyclohexylalkanoates were obtained from ^{13}C and ^{23}Na chemical shift measurements. The methodology for the determination of the cmc values from the ^{13}C chemical shift measurements will be described in this section first.

For the ^{13}C measurements, if we assume that the surfactant ion exists in two states, the "free" state (in the aque-

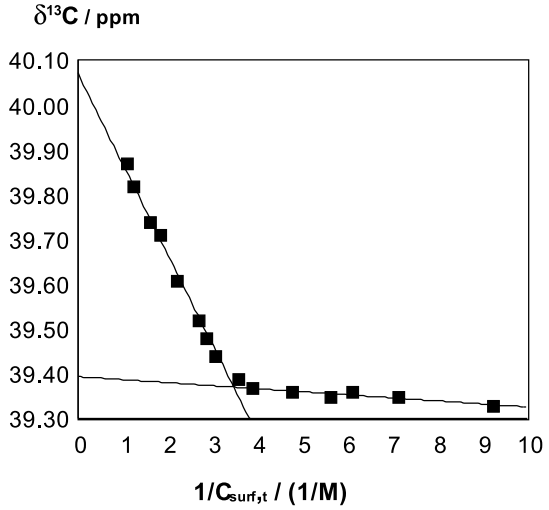
Fig. 2. ^{13}C chemical shifts (ppm) vs. the inverse of the surfactant concentration for the methylene carbon adjacent to the cyclohexyl ring of the sodium cyclohexylbutanoate.



ous phase) and the "bound" state (in the micellar phase), the observed ^{13}C chemical shifts can be written as follows

$$[1] \qquad \delta_{surf,obs} = p\,\delta_{surf,mic} + (1 - p)\delta_{surf,aq}$$

where $\delta_{surf,obs}$ is the averaged (observed) chemical shift of the surfactant ion, $\delta_{surf,aq}$ is the ^{13}C NMR chemical shift of the surfactant ion in the aqueous phase, and $\delta_{surf,mic}$ is the NMR chemical shift of the surfactant ion in the micellar phase. If we define the *p* value of the surfactant as

$$[2] \qquad p = \frac{C_{surf,mic}}{C_{surf,tot}}$$

and substituting the definition of the *p* value into the two-site model (eq. [1] above), we obtain the following for the ^{13}C or the counterion chemical shifts.

$$[3] \qquad \delta_{surf,obs} = \left(\frac{C_{surf,mic}}{C_{surf,t}}\right)\delta_{surf,mic} + \left(\frac{C_{surf,aq}}{C_{surf,t}}\right)\delta_{surf,aq}$$

where $C_{surf,t}$ is the total concentration of the surfactant, $C_{surf,aq}$ and $C_{surf,mic}$ are the concentrations of the surfactant ion or counterion in the aqueous phase ("free") and the micellar phase ("bound"). For the surfactant ions, a plot of the observed ^{13}C chemical shift vs. the inverse of total surfactant concentration should, therefore, yield two linear regions that intersect at the inverse of the critical micelle concentration for the surfactant. A sample plot of the observed ^{13}C chemical shifts against the inverse of the total surfactant concentration is given in Fig. 2 for the methylene carbon adjacent to the cyclohexyl ring of the sodium cyclohexylbutanoate. The averaged cmc values for the sodium cyclohexylalkanoates were obtained from the breaks in the ^{13}C vs. the inverse of the surfactant concentration for each of the carbon resonance's for the n = 1–4 cyclohexyl alkanoates. These values are given in Table 1. It should be noted that these values are in excellent agreement with those reported in the literature (3).

B. Degree of counterion binding: β

The degree of counterion binding of a surfactant (the β value) is defined as

$$[4] \qquad \beta = \frac{C_{c,mic}}{C_{surf,mic}}$$

where $C_{c,mic}$ is the concentration of the counterion absorbed at the micellar surface. For a sodium ion (counterion) under conditions of fast exchange between the aqueous phase and the micellar phase, the observed counterion chemical shifts ($\delta_{c,obs}$) can be written as follows.

$$[5] \qquad \delta_{c,obs} = \left(\frac{C_{c,mic}}{C_{c,t}}\right)\delta_{c,mic} + \left(\frac{C_{c,aq}}{C_{c,t}}\right)\delta_{c,aq}$$

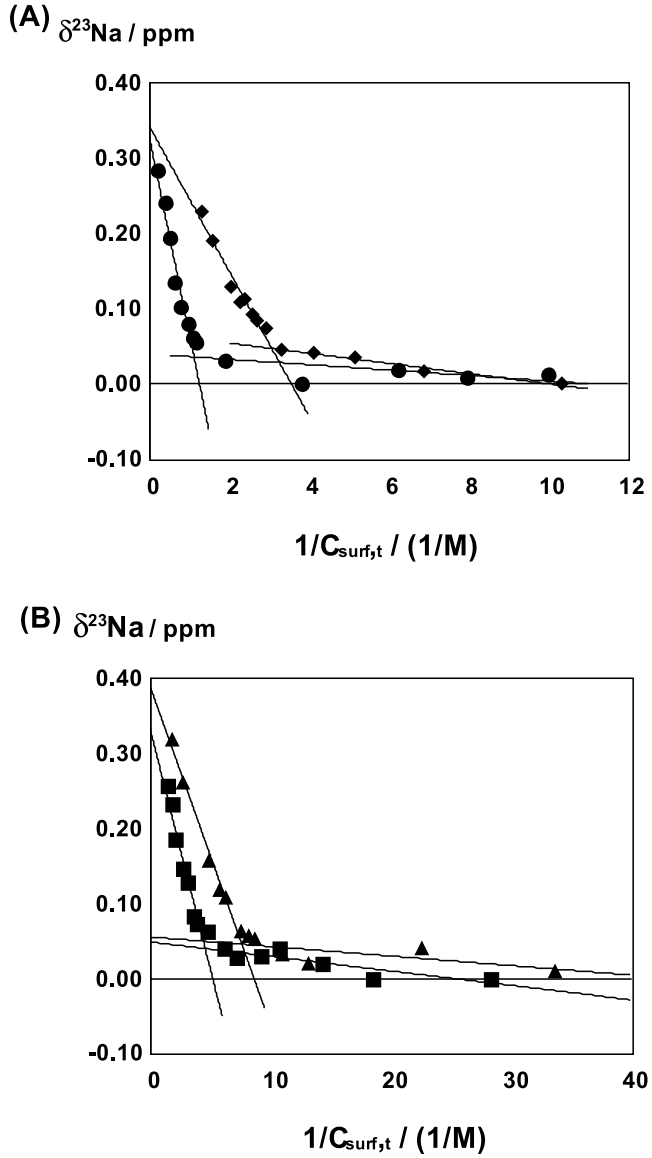
where $C_{c,t}$ is the total concentration of the counterion, $C_{c,aq}$ and $C_{c,mic}$ are the concentrations of the counterion in the free and bound states, respectively. Hence, the combination of eq. [5] with eq. [4] (definition of the β value) yields the following for the ^{23}Na chemical shifts.

$$[6] \qquad \delta_{c,obs} = \delta_{c,aq} + \beta(\delta_{c,mic} - \delta_{c,aq})\left(1 - \frac{cmc}{C_{c,t}}\right)$$

A plot of the observed ^{23}Na chemical shifts vs. the inverse of the total counterion concentration should yield two linear regions that intersect at the inverse of the cmc value of the surfactant. The ^{23}Na chemical shift data are given in Fig. 3*a* for the SChAc and the SChPr surfactants and Fig. 3*b* for the SChBu and the SChPe systems. To be consistent with refs. 7 and 8, these chemical shifts are plotted relative to the chemical shift of a sodium counterion at infinite dilution. The cmc values obtained from the breaks in these plots are also given in Table 1. We note that the agreement between the cmc values from the ^{13}C chemical shifts and the ^{23} Na chemical shifts is reasonable. However, since the cmc value is not a true critical point, we do not expect perfect agreement between the cmc values measured from different experimental methods (29).

© 1999 NRC Canada

Fig. 3. ^{23}Na chemical shifts (ppm) vs. the inverse of the surfactant concentration. (A) ● SChAc, ◆ SChPr; (B) ■ SChBu, ▲ SChPe.



With an estimate of the counterion NMR chemical shift in the micellar phase, $\delta_{c,mic}$, the degree of counterion binding can be determined from eq. [5]. The slopes and the intercepts of the plots of the counterion chemical shift vs. inverse counterion concentration above the cmc value yield the product of $\beta\delta_{Na,mic}$; these are also reported in Table 1. As we clearly see from Table 1, the product $\beta\delta_{Na,mic}$ does not change significantly in value as the length of the alkyl chain in the sodium cyclohexylalkanoates is increased. This is also the case for single-headed and two-headed surfactants of comparable chain length (7, 8, 15). In the work of Gustavsson and Lindman (7, 8), the $\beta\delta_{Na,mic}$ values of alkyl sulfates were observed to be constant (–0.28 ± 0.04) as the chain length of the surfactant increased. Hence, we can assume that the electronic environment of the ^{23}Na counterion in the cyclohexylalkanoate aggregates does not change significantly as we increase the alkyl chain length. We have calculated our values of β employing the $\delta_{Na,mic}$ values for the alkyl carboxylate micelles obtained by Gustavsson and Lindman (7, 8). These counterion binding values are also presented in Table 1. It appears that the sodium cyclohexylalkanoates are characterized by very large cmc values and small degrees of counterion binding. It would follow, therefore, that this family of surfactants have small aggregation numbers.

It is generally assumed that the chemical shift changes of the counterion are dominated by changes in the paramagnetic shielding term of the ion at infinite dilution. For a hydrated, monatomic counterion, the paramagnetic shielding term is mostly due to the overlap of the outer orbitals of the sodium counterion and the oxygen of the hydrating water molecule i.e., direct ion-ion interactions are usually unimportant. For these surfactants, the electronic environment of the headgroup leads to significant positive values of the product $\beta\delta_{Na,mic}$. These large, positive values are consistent with the sodium ion bound at the carboxylate micellar surface undergoing a significant amount of polarisation, likely due to the H-bonding between the negatively charged O atom in the carboxylate anion and the protons on the water molecules surrounding the counterion. Since the $\beta\delta_{Na,mic}$ values for the cyclohexylalkanoates are not much different from those of the straight chain alkanoates, it is safe to assume that the chemical shift of the sodium counterion at the micellar surface is the same for both surfactant families, and that the small differences are due to the difference in the degree of counterion binding between both sets of surfactants. We note that the β values determined from conductivity experiments are indeed smaller for the cyclohexyl surfactants compared to the straight chain alkanoates.[2] Hence, our assumption that the $\delta_{Na,mic}$ values are the same for both of these carboxylate surfactants is reasonable.

Using the cmc values and the β values of these surfactants from the NMR experiments,

we have calculated the Gibbs energy of micellisation ($\Delta_{mic}G°$ values) using the charged pseudo-phase model of micelle formation (31), which for a single headed surfactant with monovalent counterions is as follows.

$$[7] \qquad \Delta_{mic}G° = RT(1 + \beta) \ln X_{cmc}$$

The $\Delta_{mic}G°$ values for the cyclohexylalkanoate surfactants are given in Table 2 and plotted in Fig. 4 as a function of the surfactant chain length. The slope of the plot of the $\Delta_{mic}G°$ values against the total number of carbon atoms in the surfactant yields an estimate of –3.0 kJ/mol for the Gibbs energy of transfer of a CH_2 group from the aqueous phase to the micellar interior, which agrees well with the literature values (1, 30). The $\Delta_{mic}G°$ values of the sodium alkylcarboxylates, the sodium alkylsulfates, and the sodium alkylsulfonates are also plotted in Fig. 5. When we compare the $\Delta_{mic}G°$ values of the cyclohexylalkanoates with those of the straight chain alkanoates, we see, for example, that the SChAc surfactant (a total of 8 carbon atoms) has a $\Delta_{mic}G°$ value that is ≈ 6 kJ/mol less than that of sodium octanoate;

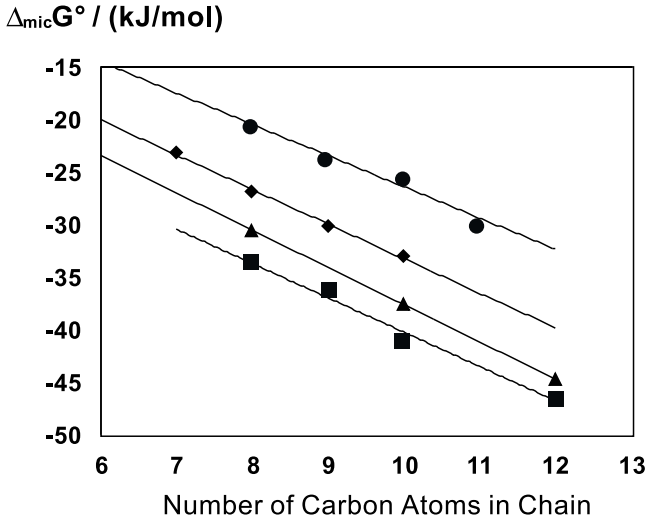

Fig. 5. Plot of the calculated chemical shifts (from eq. [10]) as a function of the inverse surfactant concentration for the CH_{2c} carbon of SChBu.

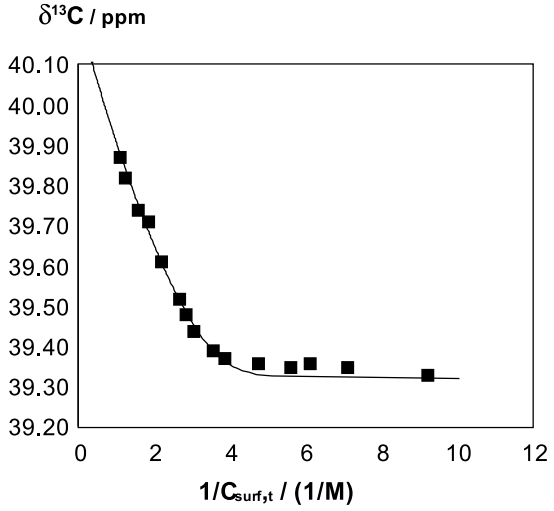

the SChBu surfactant (10 carbon atoms) has a $\Delta_{mic}G°$ value ≈ 6 kJ/mol less than that of sodium decanoate. Hence, we can conclude from the Gibbs energies for micelle formation that the cyclohexyl ring appears to behave as a four carbon chain (i.e., a difference of two CH_2 groups), indicating that the presence of the six carbon ring structure makes micelle formation thermodynamically less favourable for the sodium cyclohexylalkanoate surfactants vs. the well-known sodium alkanoate surfactants having the same total number of carbon atoms.

C. Surfactant aggregation numbers

Aggregation numbers can also be determined from ^{13}C chemical shifts. This is based on several assumptions (12–14, 25). A simplified situation is said to exist where the surfactant is present in only two forms — either as a free monomer or in a micelle with aggregation number, N_s. The chemical shifts are different in the two states and the monomer and micelle shift, $\delta_{surf,aq}$ and $\delta_{surf,mic}$, are assumed to be independent of surfactant concentration. The mean aggregation numbers of the surfactants were estimated from the ^{13}C chemical shift data from the mass action model, employing the method outlined by Lang (13) and Gao et al. (14). With the above assumptions in mind, the equilibrium between the surfactant monomers in the aqueous phase and the micellar phase can be written as follows

$$[8] \qquad N_s S \Leftrightarrow S_{N_s}$$

Here, N_s is the surfactant aggregation number and S_{N_s} and S represent the surfactant in aggregated form and in aqueous solution, respectively. The equilibrium constant for the above reaction is written (neglecting activity corrections)

$$[9] \qquad K = \frac{C_{mic}}{(C_{surf,aq})^{N_s}}$$

where C_{mic} is the concentration of aggregates having an aggregation number N_s (i.e., $C_{mic} = C_{surf,mic}/N_s$) and $C_{surf,aq}$ is the concentration free monomer in solution. The free monomer concentration is written in terms of the total surfactant concentration, $C_{surf,t}$. Since $C_{surf,t} = C_{surf,mic} + C_{surf,aq}$, the equilibrium constant expression is rewritten as follows.

$$[10] \qquad K = \frac{C_{surf,t} - C_{surf,aq}}{N_s(C_{surf,aq})^{N_s}}$$

If the observed chemical shift is written in terms of the total surfactant concentration according to eq. [3], then substituting for $C_{surf,aq}$ in eq. [8] yields

$$[11] \qquad \frac{1}{C_{surf,t}} = (KN_s)^{\frac{1}{N_s-1}}(\delta_{surf,mic} - \delta_{surf,aq})^{-1} \times (\delta_{surf,mic} - \delta_{surf,obs})^{\frac{N_s}{N_s-1}}(\delta_{surf,obs} - \delta_{surf,aq})^{\frac{1}{1-N_s}}$$

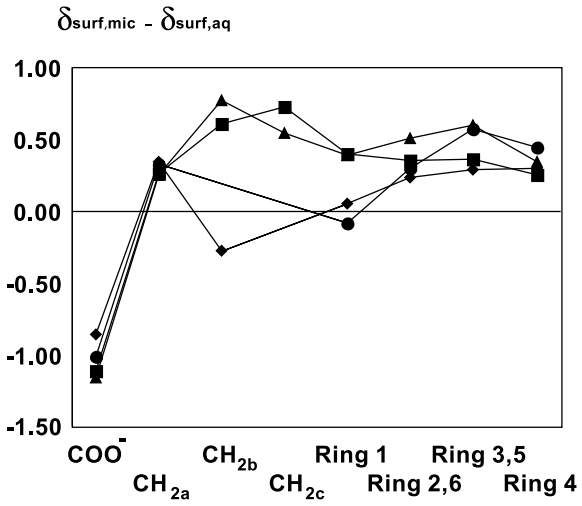
Fig. 6. Plot of the chemical shift change upon micelle formation ($\delta_{surf,mic} - \delta_{surf,aq}$) as a function of carbon number for ● SChAc, ◆ SChPr, ■ SChBu, ▲ SChPe.



The aggregation number is then deduced from the variation of the ^{13}C $\delta_{surf,obs}$ values as a function of $C_{surf,t}$. By fitting eq. [11] to the concentration dependence of the observed shifts, it is possible to extract an estimate of N_s, the micellar aggregation number. A plot of the experimental chemical shifts fitted to eq. [10] is presented in Fig. 5 for a carbon contained in the cyclohexyl ring of sodium cyclohexylpropanoate. The aggregation numbers are shown in Table 1. It is clear from this table that the aggregate formed by the sodium cyclohexylalkanoates are indeed small, and as such, cannot be considered true micelles. It is also clear however, that as the chain length increases, the aggregate size increases, and the self-assembled units likely take on some of the characteristics of true micelles. It should be pointed out that the use of ^{13}C chemical shifts to obtain surfactant aggregation numbers from the application of the mass action model has been criticized by several authors as yielding low aggregation numbers for typical surfactants (like sodium dodecylsulfate (12)). However as a function of the carbon chain length, it does qualitatively predict the trends in the aggregation number. It should be noted that these values are in good agreement with the aggregation numbers determined via viscosity measurements.[2]

D. Chemical shift changes upon micelle formation

The ^{13}C chemical shift changes upon micellisation can give qualitative information about conformational changes that surfactant molecules undergo when forming micelles. Generally, a high frequency shift is associated with an increase in the number of *trans* conformers, whereas a low frequency shift is interpreted in terms of an increasing probability of *gauche* configurations (4–7, 12, 25). It should be noted that there are other contributions to the chemical shift changes upon micelle formation including headgroup interactions and hydration changes (31), but that the conformational arguments for the chemical shift changes upon micelle formation appear to be supported by other experimental techniques (32, 33). The ^{13}C chemical shift changes upon micelle formation, $\delta_{surf,mic} - \delta_{surf,aq}$, are plotted in Fig. 6 and given in Table 3 for all the sodium cyclohexylalkanoates. It can be seen from Fig. 6 that for all the sodium cyclohexylalkanoate surfactants studied, the carboxylate carbon undergoes a low frequency shift on micelle formation and the first methylene group on the chain (CH_{2a}) undergoes a high frequency shift change upon micelle formation. For the remaining alkyl chain carbons and the ring carbons however, there appear to be two definite patterns for the ^{13}C chemical shift changes upon micelle formation. In the case of the SChAc and the SChPr, the first carbon atom on the ring (Ring 1) is characterized by a very slight change in its chemical shift upon micelle formation. In addition, the chemical shift changes for the ring carbons for the SChAc and the SChPr tend to increase towards a maximum value near the end of the cyclohexyl ring. In the case of the second methylene group on the carboxylate chain (CH_{2b}) for the SChPr, we observe a large negative chemical shift change upon micelle formation. In addition, for the headgroup carbon, the ^{13}C chemical shift differences appear to be relatively constant upon increasing the length of the carboxylate chain in the surfactant.

Table 3. Chemical shift changes ($\delta_{surf,mic} - \delta_{surf,aq}$) upon micelle formation for sodium cyclohexylalkanoate surfactants.

Carbon group	SChAc	SChPr	SChBu	SChPe
COO^-	–1.01	–0.86	–1.11	–1.16
CH_{2a}	0.33	0.35	0.27	0.26
CH_{2b}	—	–0.27	0.61	0.78
CH_{2c}	—	—	0.73	0.55
Ring 1	–0.08	0.06	0.40	0.39
Ring 2, 6	0.30	0.24	0.36	0.51
Ring 3, 5	0.58	0.29	0.37	0.60
Ring 4	0.45	0.30	0.26	0.35

With the assumption that the shift changes upon micelle formation are due to conformational changes and (or) hydration differences only, it appears that the shift changes indicate a different mode of aggregation for the two lower members of the sodium cyclohexylalkanoates. A less strained configuration for the ring carbons (i.e., an increase in the number of *trans* conformers) is predicted as the carboxylate carbon chain length increases. According to Grant and Cheney (34), the ^{13}C chemical shift would change by a maximum of 4.8 ppm for a complete *gauche – trans* isomerisation. Hence, in the case of the cyclohexylalkanoate surfactants, we propose that the first carbon of the cyclohexylalkanoates (the headgroup carbon) has a predominately *gauche* configuration, and that the carbons bearing the headgroups do not suffer significant changes in their micellar environment as the alkyl chain length increases. We note that for the cyclohexyl ring carbons, the chemical shift changes upon micelle formation are essentially all positive and that there is a definite increase in the magnitude of the $\Delta\delta$ values for the surfactant ring carbons as the alkanoate chain length increases. Given the ^{13}C chemical shift differences, the small aggregation numbers, and the high cmc values of the SChAc and the SChPr, we conclude that these surfactants form very loose, heavily hydrated aggregates that possibly employ a stack-like aggregation process. The longer members of this family have a more normal pattern of $\Delta\delta$ values, and hence a more

© 1999 NRC Canada

typical (more micellar like) aggregation process ensues. Note that the $\delta_{surf,mic} - \delta_{surf,aq}$ values for the ring carbons appear to increase with an increasing number of methylene groups in the carboxylate chain. This is likely due to more motional freedom in the interior of the cyclohexylalkanoate aggregate, resulting from the differences in the mode of aggregation of the longer chain sodium cyclohexylalkanoate surfactants. We are currently determining the dynamics of the carbon nuclei inside the micelle via NMR ^{13}C spin-lattice relaxation time measurements. These results will be the subject of a future paper.

4. Conclusions

Multi-nuclear NMR spectroscopy has been used to obtain the equilibrium micellar properties (the critical micelle concentration, the degree of counterion binding and surfactants aggregation numbers) of the sodium cyclohexylalkanoates as a function of the length of the alkanoate chain attached to the cyclohexyl ring. The environment of the counterion at the micellar surface has been probed using surfactant counterion chemical-shift measurements. These surfactants resemble the long chain sodium alkanoate surfactants in that the cmc values decrease and the aggregation numbers increase with an increase in the total number of carbon atoms in the surfactant. In terms of the Gibbs energy of micelle formation, these surfactants are identical to a sodium alkanoate surfactant with two less CH_2 groups. The ^{13}C chemical shift measurements indicate the aggregation process differs for the first two members of the series (SChAc and SChPr) than for the other two higher chain length members investigated. This is due to the fact that as CH_2 groups are added to the alkyl chain, the cyclohexyl ring carbons appear to obtain more conformational freedom upon aggregate formation. This indicates that as the length of the alkanoate side chain increases, the cyclohexyl rings experience a more nonpolar environment in the interior of the micelle.

Curves in chemistry: supramolecular materials taking shape[1,2]

Geoffrey A. Ozin

Abstract: A large part of the development of mathematics was driven by the desire to understand why objects in nature are found in a myriad of shapes and sizes and why certain forms are preferred over others. The area of mathematics called the calculus of variations has been utilized to handle the optimal forms in geometry and nature. It has been used to comprehend morphogenesis and the similarity, yet variety, of forms in the natural world. The mathematical underpinnings of natural form are beginning to influence the inorganic materials world, especially the unusual morphologies that arise in the field of self-assembly. These morphologies often exhibit curved shapes resembling those of minimal surfaces rather than familiar Platonic, polyhedral crystal habits. The curved shapes of mesostructured inorganic materials synthesized by supramolecular templating are striking examples of minimal surface area and energy principles at work in their growth and form.

Key words: mesoporous materials, morphosynthesis, silica, supramolecular.

Résumé : Une grande partie du développement des mathématiques a été stimulée par le désir de comprendre pourquoi les divers objets que l'on retrouve dans la nature adoptent une myriade de formes et de tailles et pourquoi il y a une préférence pour certaines formes. La partie des mathématiques que l'on nomme calcul des variations a été utilisée pour traiter de la question des formes optimales en géométrie et dans la nature. On l'a utilisée pour comprendre la morphogénèse et la similarité dans la variété des formes que l'on rencontre dans la nature. Les bases mathématiques de la forme naturelle commencent à influencer le monde des matériaux inorganiques, particulièrement les morphologies inhabituelles que l'on rencontre dans le domaine des autoassemblages. Ces morphologies présentent souvent des formes arrondies qui ressemblent à celles des surfaces minimales plutôt qu'aux formes cristallines polyédriques platoniques familières. Les formes arrondies des matériaux inorganiques à structures méso obtenus à l'aide de matrices supramoléculaires sont des exemples frappants de la mise en oeuvre des principes de minimisation de l'énergie et de la superficie de la surface lors de leur croissance et leur formation.

Mots clés : matériaux mésoporeux, morphosynthèse, silice, supramoléculaire.

Introduction

On viewing the unusually curved silica shape displayed in Fig. 1, Jean Marie Lehn commented "you have synthesized a facsimile of a Brancusi sculpture that I have just seen in the New York museum of modern art." This brought to mind Jean Marie Lehn's axiom in his classic text Supramolecular Chemistry (1), "if it exists it can be synthesized." Having synthesized such uniquely curved shapes we felt compelled to investigate their growth and form, and coined the term morphosynthesis (2). This is what my group has been working on for the past few years. A brief personal perspective of this research forms the subject of my award lecture presentation and paper. The reader is directed to the original references of our published papers to appreciate the analytical details underlying our contributions to this emerging and highly active field of materials chemistry.

Planes and curves

Both of the materials shown in Fig. 1 are composed only of silica. The one on the top is dodecasil 3C and the one on the bottom is hexagonal mesoporous silica. Notably, the familiar octahedral shape with planar faces, sharp edges, and

pointed apices has crystalline microporosity (IUPAC convention, length scale of pores <2 nm), while the unfamiliar curved object has crystalline mesoporosity (2–50 nm) but is amorphous at the microscale. Single organic molecules facilitate the production of micropores in dodecasil 3C, whereas a supramolecular assembly of organic amphiphiles enables the creation of ordered mesopores in silica. The morphology and microstructure of the former is determined by crystallographic physics, space groups, planar symmetry elements, and thermodynamics and kinetics of crystal nucleation and growth. Traditional concepts of this type, however, do not explain the periodic mesoscale porosity, growth, and highly curved form of the latter.

Supramolecular materials taking shape

Presented is a synopsis of our work aimed at elucidating principles that underpin the growth and form of hexagonal mesoporous silica over all three spatial dimensions. The research required a paradigmatic shift in materials synthesis and the development of a "language of shape" to explain morphogenesis of inorganic materials with curved form. It brings complexity into inorganic chemistry and introduces hierarchy to inorganic materials. The thinking behind the work can be traced to the idea that a noncovalently bound assembly of surfactant molecules, like the one illustrated in Fig. 2A, can direct the organization and hydrolytic polycondensation of silicate species to create silica replicas of the templating mesophase (3*a*). A transmission electron micrograph (TEM) image that clearly displays a hexagonal close-packed array of 5-nm-diameter channels in a surfactant-templated, hexagonal symmetry mesoporous silica is shown in Fig. 2B.

Research scientists at Mobil first demonstrated that this kind of self-assembly synthesis can be orchestrated to yield silica materials with hexagonal, cubic, and lamellar mesostructures, as well as various disordered versions of these basic structures (3*a*). At that time the mechanism of formation of these materials was proposed to involve the co-assembly of inorganic and organic building units with charge, geometrical, and structural complementarity at the interface between interacting moieties. Subsequently, others researchers extended the paradigm of surfactant templating of silica species through judicious variations of pH (acid and base catalysis); the nature of the surfactant (cationic, neutral, anionic); the relative concentration of precursors; and the use of aqueous, nonaqueous solvents, co-solvents and co-surfactants, to create silica mesostructures (3*b*).

The resemblance of the supramolecular templating pathway to organic matrix-mediated biomineralization processes

in nature is important and inspires a biomimetic way of thinking about the synthesis of hierarchical structures on length scales unparalleled in inorganic materials chemistry (4, 5). Interactions between inorganics and organics comprising the supramolecular assembly are envisioned to be of the electrostatic, ion pair, metal–ligand, covalent and hydrogen-bonding type and has become the accepted way to describe the chemistry involved in the self-assembly synthesis of a cornnucopia of mesostructured materials (6).

Studies on the mode of formation of the hexagonal symmetry form of mesoporous silica are founded on the co-assembly of silica-based moieties with surfactant micellar and liquid crystal species. Mechanistic studies, for example by in situ EXAFS, EPR, and fluorescence probe techniques, although differing slightly in detail, more-or-less support the co-assembly scheme. These studies, however, are not able to say anything about the shape of the resulting mesoporous silica material (7).

Our research effort has focused not only on shape control of mesoporous silica but also on morphogenesis, the origin and growth of a particular form (2, 4, 5, 8). An illustration of hexagonal mesoporous silica morphologies that we have managed to synthesize, in a reproducible fashion, from initially clear dilute aqueous solutions of surfactant and silica reagents under acid catalyzed conditions are shown in Fig. 3. These comprise fibers, supported oriented film at solid–liquid interfaces, free-standing oriented film at air–liquid interfaces, spheres, highly curved and patterned shapes, Archimedian screws, and micron scale soft lithographically defined patterns on gold surfaces (9–19).

The research necessitated crossing boundaries between subdisciplines of chemistry. It depended on an integration of chemical and physical concepts, synthetic methods, processing strategies, and analytical techniques in surfactant, sol–gel, liquid crystal, surface, colloid, and crystal growth sciences. This entailed taking command over topological defects, director fields, surface charge, elastic deformations, and differential contraction of polymerizable silicate micelles and liquid crystals. With this knowledge it proved possible to control the co-assembly of surfactants and silicates over three spatial dimensions and angstrom to millimetre length scales, to yield a desired morphology of hexagonal mesoporous silica. Key relations between synthesis conditions, mesostructure, and morphology were established by different kinds of microscopy, diffraction, spectroscopy, thermal, and adsorption analytical techniques. This research led to examples of mesostructured inorganic materials with hierarchical architectures and complex form. It led to the concept of "panoscopic materials" and a new materials chemistry tool box in which materials synthesis is conducted over "all" length scales (20). Thinking of this type inspired ideas about the potential utility of mesostructured materials in a diversity of areas from catalysis to bone implants, chemical delivery systems to membranes, batteries to fuel cells, and electronics to photonics (20, 21).

Synthesis-shape diagrams

To develop a model for the nucleation, growth, and form of hexagonal mesoporous silica curved shapes we first investigated the relations between synthesis conditions and the emergence of a particular shape (14, 16). This involved establishing a novel kind of synthesis-shape "phase diagram" for mesoporous silica morphologies. No additives, co-solvents, or salts were used in these preparations. The synthesis was based on quiescent, acidic, aqueous ambient temperature and pressure conditions, with only pH control over the notably narrow range of –1 to +1. These acidities are below the isoelectric point of silica (pH < 2–3) and therefore the chemistry involves acid-catalyzed condensation polymerization of protonated silicates in the microphase-separated domains of a lyotropic silicate mesophase.

In all of the work described in this paper, the material that forms is exclusively the hexagonal form of mesoporous silica with essentially the same composition and channel structure. It is found that fiber, gyroid/discoid, and sphere morphologies are favored in greater than 90% yield in specified regions of the synthesis-space diagram. Fiber shapes are formed under the most acidic conditions. The range of acidity in which these shapes are formed is only two pH units. This illustrates the sensitivity of the system on the acid side to small changes in pH. Interestingly, hybrid mesoporous silica morphologies such as "tadpoles" and "telephones," composed of fibers growing off one of two gyroids, are formed in regions of the diagram that lie between particular shapes. Above pH ~ 1, which favors spheres, the material that forms is amorphous silica, devoid of a mesostructure or a recognizable shape. On moving to the basic pH range, one again observes the formation of hexagonal mesoporous silica with interesting morphologies. Hence there is a range of pH between ~1 and 10 in which the interactions between the micellar assembly and the silica species is insufficient to support a silica-based mesophase and cannot lead to a hexagonal mesoporous silica replica.

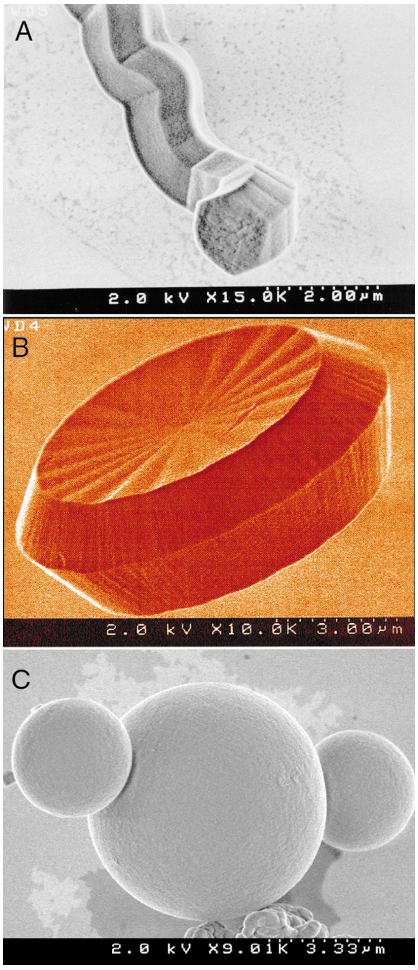

Fig. 5. Representative TEM images of whole mounted hexagonal mesoporous fiber (A) and discoid morphologies (B). The silica channel walls are spaced by about 5 nm.

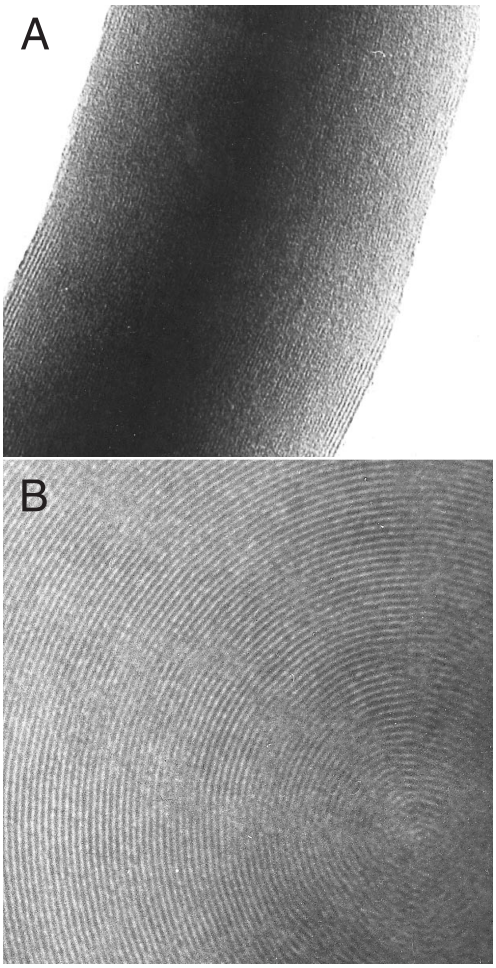

Some representative examples of scanning electron micrographs (SEMs) that demonstrate morphology control of hexagonal mesoporous silica are shown in Fig. 4. The relation between morphology and mesostructure for some of these shapes can be determined from TEM images of whole mounted specimens (Fig. 5). A summary of the results of SEM, TEM, and atomic force microscopy (AFM) imaging studies depict the relation between surface topology, mesostructure, and morphology. The relative disposition of the channels in the surface and bulk regions, the root mean square surface roughness, and the texture of these shapes provide valuable information on the processes responsible for morphogenesis. The channels run down the axis of the fibers and whirl concentrically around the axis of the gyroids/discoids, and both of these morphologies have very smooth bodies with a 5- to 10-nm surface mesostructure that mirrors that of the bulk. These shapes are to be contrasted with the spheres formed under the least acidic conditions, which display a granular texture with a less ordered channel structure. The spheres have an order of magnitude rougher surface (~50 nm) composed of ~50-nm grains with a ~5-nm surface mesostructure. They are best described as hexagonal mesoporous silica in the form of a nanocrystalline flocculate.

Shapes in time

This work led to the first experiments designed to probe nucleation and growth processes that are responsible for a particular mesoporous silica shape (15). Morphokinetics, a term coined to describe the nucleation and growth of these mesoporous silica shapes, was probed through a combination of dynamic light scattering (DLS) and the time dependence of crystalline mass yield, together with AFM and TEM studies of the earliest stage growth nuclei. Results of DLS for fiber, gyroid/discoid, and sphere syntheses are expressed graphically in terms of the evolution of the hydrodynamic radius of a specific mesoporous silica shape. This is obtained from the Stokes–Einstein equation, where the diffusion coefficient is calculated from the autocorrelation function of the scattered light. The DLS results reveal the existence of an embryonic species with an initial diameter of around 7 nm. This species grows in size by about 1 nm during an "incubation time," which increases in magnitude as the acidity decreases, and preferentially forms fibers, then gyroids/discoids, and finally spheres.

Representative results for the temporal dependence of the crystalline mass yield of mesoporous silica fiber and

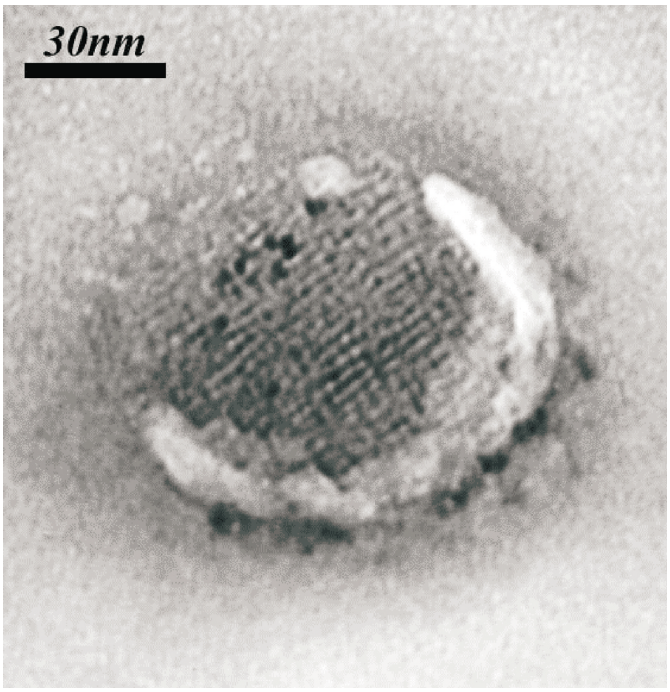
gyroid/discoid shapes is displayed in Fig. 6. The data fit well to the three-parameter Avrami equation, which is usually expressed in the following form:

$$[1] \qquad m(t)/m(\infty) = 1 - \exp\,[-k(t - \tau)^n]$$

where k is the crystallization rate constant, τ is the incubation time, and n is the dimensionality index of the growth process. This equation is often applied in the literature to describe the nucleation and crystallization of polymers, and was deemed a reasonable starting model to explain the nucleation, silicification, and growth of hexagonal mesoporous

Fig. 8. TEM image of the earliest stage growth nuclei on a copper grid observed in a hexagonal mesoporous silica fiber synthesis.



silica shapes. The extracted crystallization rate constants (k) were found to be 1.33 ± 0.05 and 0.41 ± 0.06 for the fiber and discoid/gyroid shapes. Corresponding incubation times (τ) were 0.18 ± 0.02 and 1.42 ± 0.13 h, and the Avrami dimensionality indices (n) were 0.77 ± 0.06 and 1.09 ± 0.11. The value of n turns out to reflect one- and two-dimensional growth processes, which is expected for the fiber and discoid/gyroid shapes, respectively.

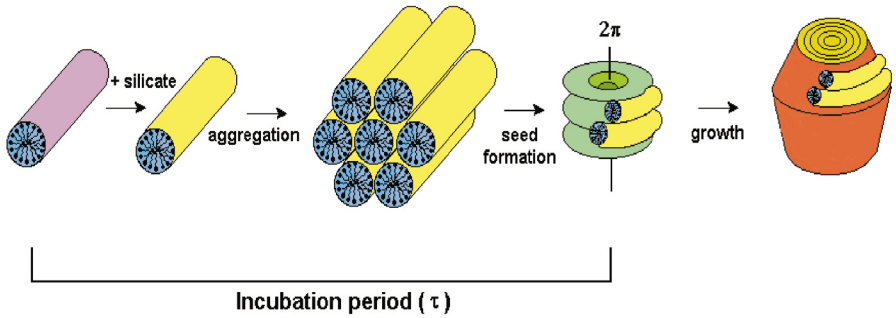
Incubating the seed

Experiments were designed to look for viable growth nuclei at early times of the synthesis to probe their size, shape, rigidity, and mesostructure, and the presence of defects (15). The approach for sample preparation, although not ideal, involved dipping a piece of freshly cleaved graphite or a copper TEM grid into synthesis mixtures of different hexagonal mesoporous silica shapes at the earliest possible stage of a preparation. A tapping mode AFM image using phase detection reveals soft objects of around 50–70 nm in diameter (Fig. 7). This is the gentlest way of imaging and interrogating the mechanical properties of a fragile object with minimal perturbation of the structure. TEM images of these early stage species reveal roughly 50- to 70-nm-diameter "mesostructured nanoparticles," which seem to be best described as silicate liquid crystal growth nuclei (Fig. 8).

The collective results of these morphokinetic studies allow the formulation of a scheme to describe the growth of mesoporous silica shapes under quiescent dilute aqueous acidic synthesis conditions (Fig. 9). In the case of the gyroid/discoid shapes the steps that occur during the incubation period τ are described in order: (*i*) spontaneous assembly of ~7-nm-diameter cetyltrimethylammonium chloride

© 1999 NRC Canada

Fig. 9. Morphogenesis of a hexagonal mesoporous silica gyroid shape.



rod micelles and acid-catalyzed hydrolysis of tetraethoxyorthosilicate to soluble silicate species, (*ii*) incorporation of silicate into the headgroup region to form ~ 8-nm-diameter silicate rod micelles, (*iii*) aggregation of silicate micelle rods, and (*iv*) genesis of a gyroid/discoid-shaped silicate liquid crystal seed of size ca. 50–70 nm with a concentric director field whirling around the main rotation axis.

Processes that lead to the observed crystalline mass yield $m(t)/m(\infty)$ are described in order: (*v*) continuous accretion through "side-on" planar anchoring of silicate micelle rods on the surface mesostructure of the silicate liquid crystal seed, (*vi*) simultaneous polymerization of silicate in the microphase separated region between silicate micelles, and (*vii*) formation of rigid mesoporous silica with a well-defined gyroid/discoid shape.

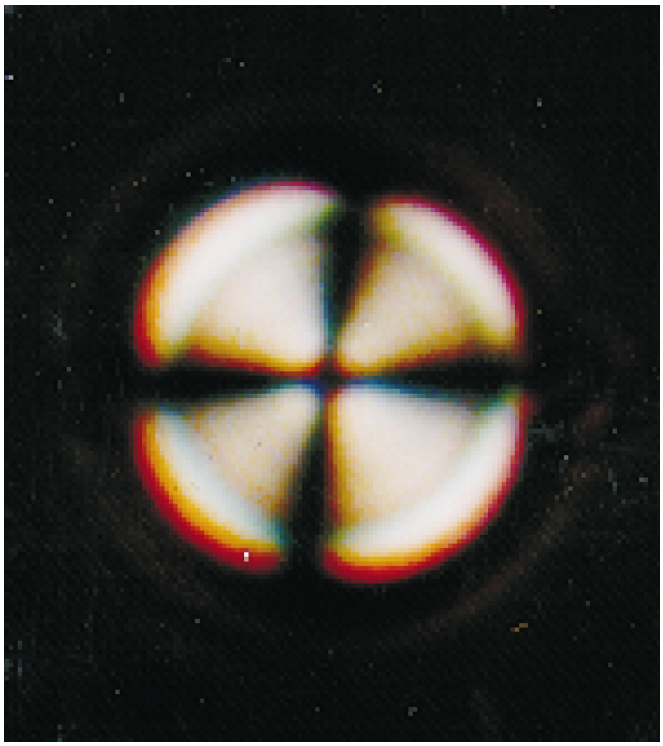
The computed Avrami index *n* falls in the range expected for such a two-dimensional growth process that is to be anticipated for the morphogenesis of a gyroid/discoid shape. Similar considerations apply to the formation of fiber morphologies, except that the lower pH favors "end-on" homeotropic anchoring of the silicate micelle rods to a silicate liquid seed. Once the shape of the mesoporous silica has been established in the incubation stage, the surface mesostructure can be considered to template the growth of that shape.

Topological defects

Studies of the synthesis, bulk and surface mesostructure, morphology, and morphokinetics of hexagonal mesoporous silica emphasize the pervasive occurrence of curved shapes. This raises the issue of the origin of the curvature. A likely place to start looking for the origin of curves in this kind of materials chemistry is the deformation of an elastic liquid crystal medium. The role of splay, twist, and bend deformations of liquid crystals is well documented and usually treated by the theory of elasticity (22). Free energy minimization of the mesophase in terms of the three basic types of distortion yields patterns of stable director fields, topological defects, and optical birefringence textures for different classes of liquid crystals.

Topological defects can be line disclinations and dislocations, with micron dimensions and small energies of formation. They control the properties of liquid crystals and can be expected to play an important role in the nucleation, growth, and form of hexagonal mesoporous silica from silicification of a lyotropic hexagonal liquid crystal.

Fig. 10. Maltese cross optical birefringence pattern observed for a surfactant-free and annealed hexagonal mesoporous silica discoid between crossed polars in an optical microscope.

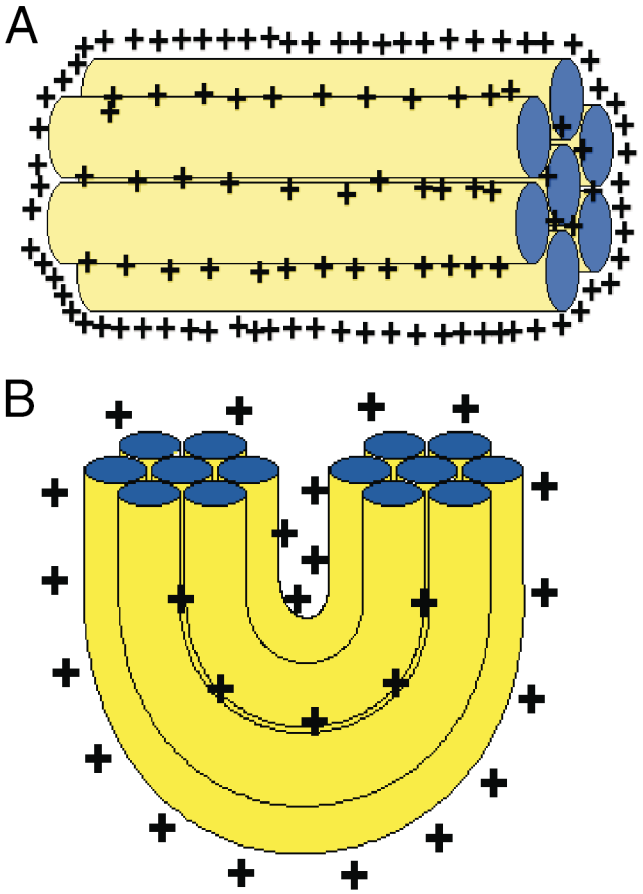


Topological defects manifest themselves in interesting ways for liquid crystals in complex geometries (23). Specifically, liquid crystal droplets show distinct director field patterns for different energy topological defects. Such defects and director field patterns may be preserved in silicate liquid crystal droplets through silicification. It is possible to envision that the growth of a particular mesoporous silica shape might be initiated by a specific kind of topological defect in a silicate liquid crystal droplet. This could apply to the early growth nuclei described above.

In this context, a relation has been found to exist between a specific type of defect and a particular mesoporous silica shape (16). Silicification essentially quenches the topological defect and its associated director field pattern as a mesoporous silica replica. An example of this is seen in the Maltese Cross optical birefringence pattern of a hexagonal

© 1999 NRC Canada

Fig. 11. Effect of the degree of surface positive charge on the structure of a hexagonal lyotropic liquid crystal growth nucleus: (A) highly protonated and (B) lightly protonated.

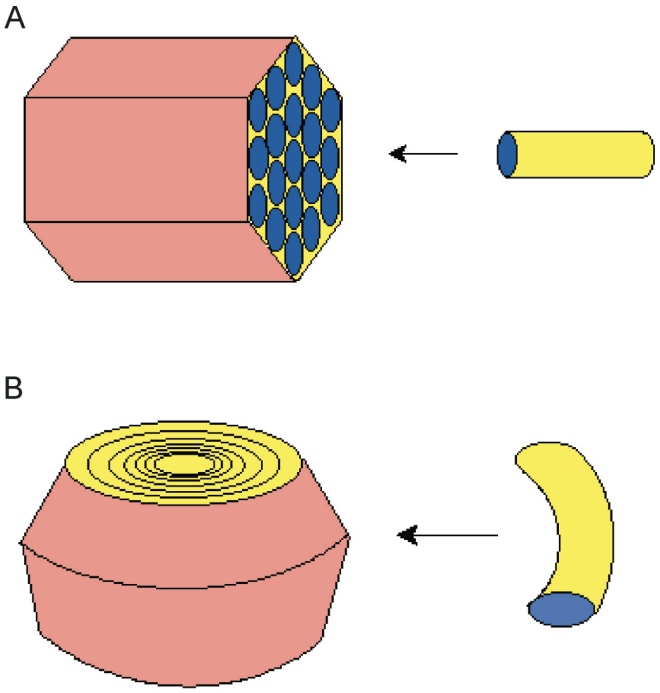


mesoporous silica discoid shape from which the surfactant had been removed and that had been annealed at 600°C to remove any micelle or strain based anisotropy (Fig. 10). The observed optical anisotropy and birefringence of the discoid must arise from the polarization response of an average electron density distributed around a concentric coaxial array of hexagonal close-packed channels. From the results it can be deduced that the surface director field of a silicate liquid crystal droplet serves to template its own polymerization and growth. The surface charge on the silicate liquid crystal and the nature of the growth medium act to control which defect is favored. In the simplest terms, a strongly acidic environment promotes a high electrical double layer repulsion and the formation of less curved shapes like fibers, while lower acidity surroundings promote more curved shapes like gyroids/discoids.

Colloidal crystallization

Collecting together the results of the above studies enables the formulation of a detailed mechanism for the growth and form of mesoporous silica shapes that is based upon the concept of colloidal crystallization. The model is founded upon the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory of colloidal interactions and control of the electrical double-layer repulsion between colloidal dimension silicate micelles and silicate liquid crystal growth nuclei (24). To amplify, it is known that the ionic atmosphere around a charged colloidal particle in solution develops an electrical potential Ψ that decreases exponentially with distance z from the surface of the particle according to the Poisson–Boltzmann equation:

Fig. 12. Growth of hexagonal mesoporous silica fiber and gyroid/discoid morphologies. (A) "End-on" homeotropic addition of a highly charged silicate rod micelle to a highly charged silicate/silica fiber shaped seed. (B) "Side-on" planar addition of a lightly charged silicate rod micelle to a highly charged silicate/silica gyroid/discoid-shaped seed.



$$[2] \qquad \Psi = \Psi^{\circ} \exp(-\kappa z)$$

where κ^{-1} denotes the electrical double-layer thickness:

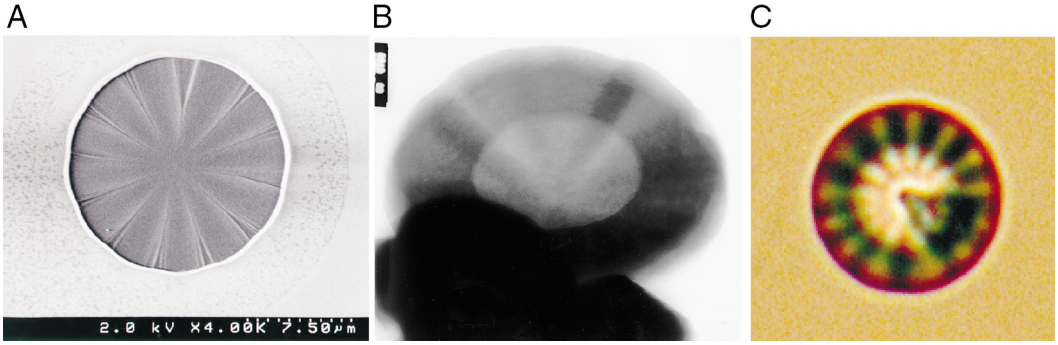
$$[3] \qquad \kappa^{-1} = \epsilon kT/e^2 \Sigma c_i^2 z_i^2$$

This shows that the electrical double-layer thickness can be reduced, by increasing the ionic strength $\Sigma c_i^2 z_i^2$, decreasing the dielectric constant ϵ, or decreasing the temperature T of the medium. It suggests that these synthetic parameters are "adjustable" and play an important role in the mechanism of formation of a mesoporous silica. The concept of colloidal crystallization provides a rational way of probing morphogenesis in this archetypal system, that is, experiments intentionally designed to establish the origin and growth of a particular curved shape.

This idea brings forth the relation between surface charge and shape of silicate liquid crystal growth nuclei. The concept is expressed in Fig. 11, which implies under strongly acidic conditions the elastically deformable cylindrical micelle assembly is heavily protonated and hence bears a strong positive charge. Bending is unfavorable under these conditions owing to unfavorable electrostatic repulsion, and

© 1999 NRC Canada

Fig. 13. (A) SEM, (B) TEM, and (C) POM images of radially patterned hexagonal mesoporous silica discoids.



so silicate micelle growth nuclei tend towards fiber shapes. Using less acidic conditions, the micelle assembly is lightly protonated and less positively charged and is able to bend due to favorable Van der Waals attraction, so silicate micelle growth nuclei move towards discoid shapes.

The implication of the model, in the language of liquid crystals, is that at higher acidity the growth process is based upon the "end-on" homeotropic addition of silicate micelle rods to a fiber-shaped, silicate liquid crystal growth nucleus. By contrast lower acidity favors the addition of micelle rods in a "side-on" planar fashion to a discoid-shaped growth nucleus, as illustrated in Fig. 12. A colloidal crystallization description of the growth and form of fiber and gyroid/discoid mesoporous silica shapes leads naturally to the idea that at the lowest acidities a low electrical double-layer repulsion favors flocculation of silicate liquid crystal seeds. Conditions of lower acidity favor a slower rate of polymerization and a higher elasticity for the silicate mesophase. This allows the flocculate to minimize the surface-free energy and emerge as a mesoporous silica sphere shape as observed in practice.

Further evidence in support of the colloidal crystallization growth mechanism is obtained by systematically varying the electrical double-layer repulsion between silicate micelle rods and liquid crystal seeds by changing the ionic and dielectric strength of the synthesis medium. Addition of increasing amounts of a lower dielectric constant solvent than water, like ethanol, reduces the electrical double-layer repulsion and smoothly transforms a fiber preparation first to one that favors a gyroid/discoid and then to one that promotes a sphere shape. Similarly, the addition of increasing quantities of a large polarizable cation, like tetraethylammonium, to a fiber preparation creates a lower charge density in the Stern layer of the colloidal reactant particles, which results in a lower electrical double-layer repulsion, and the formation of gyroids/discoids and then spheres. Therefore the outcome of decreasing the dielectric constant and ionic strength is the same as decreasing the degree of protonation of the silicates in the micelle rods and liquid crystal seeds. The results provide compelling support for the colloidal crystallization mechanism for the formation of hexagonal mesoporous silica (14, 16).

Patterning

Intriguing designs have been found on the surface of mesoporous silica shapes (17). Radial patterns observed on discoid and gyroid morphologies are particularly impressive, as judged from the examples given in Fig. 13. While the aforementioned studies of the relation between bulk and surface mesostructure, optical birefringence, and morphology provided a useful insight into morphogenesis of curved mesoporous silica shapes, the origin of surface patterns remained an enigma and a challenge for materials chemistry.

A representative SEM image of a radially patterned discoid, bearing 12 nodes is shown in Fig. 13A. Analysis of the radial patterns of a large number of discoids showed the nodal frequency spans from 0 to over 100 with no obvious trend in the observed values. A TEM image of a whole mounted discoid specimen that displays the concentric channel structure in relation to its morphology is displayed in Fig. 13B. The optical birefringence pattern of a radially patterned discoid observed between crossed polars in an optical microscope is displayed in Fig. 13C. It is interesting to note that periodic variations in the channel director field appear to be mirrored by the frequency of radial surface patterns on a discoid and can be readily visualized in the polarizing optical microscope (POM); however they are less apparent when viewed in the electron microscope. Clearly, any periodic undulation of the channels as they whirl around the rotation axis of a discoid must be small.

Complexity

Upon thinking about an inherently simple system like the nucleation of a silicate mesophase that can grow by the accretion of silicate micelle rods and simultaneously polymerize, it is worth considering three physicochemical phenomena that could give rise to complex radial patterns on mesoporous silica discoid shapes (18). They are based on coupled chemical reactions involving activation and inhibition steps, thermally excited surface vibrational waves, and elastic deformations in a silicate liquid crystal. While these are all potentially pattern-generating systems, it is not immediately obvious which applies best and which stage in the growth process the pattern is created and rigidified as a mesoporous silica discoid.

To gain an insight into the morphogenesis of radial patterns in mesoporous silica discoid shapes, the theory of elasticity for nematics with some modification is considered a logical starting point (17). The standard model deals with a liquid crystal and a director field without a boundary. In the case of the hexagonal lyotropic silicate mesophase a boundary does exist and it turns out to be very important for the

Fig. 14. Discoid-shaped hexagonal liquid crystal with a 2π line disclination lying along the unique rotation axis *z*.

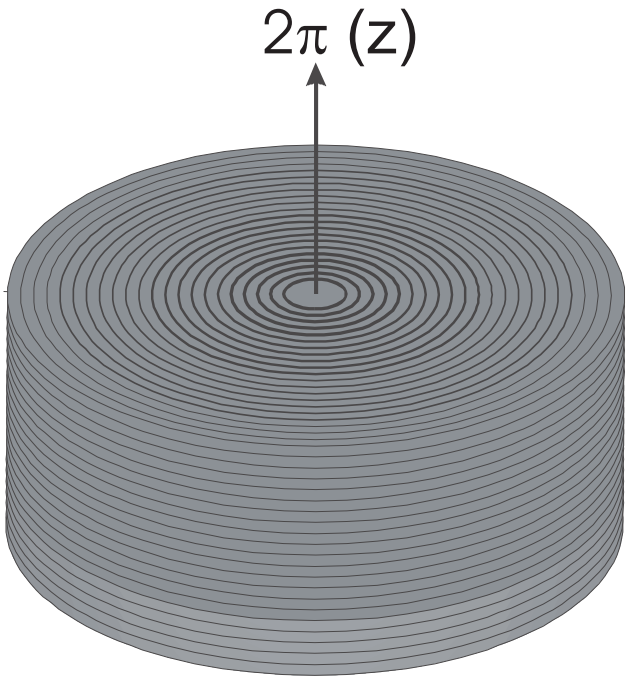

Fig. 15. Representative example of a calculated elastic distortion radial pattern of a discoid- shaped hexagonal liquid crystal.

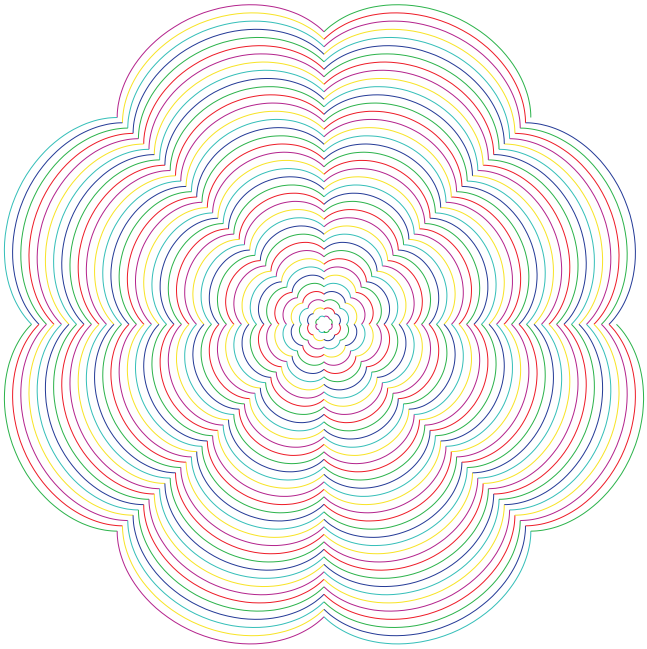

Fig. 16. (A) Observed and (B) calculated discoid hexagonal mesoporous silica morphologies with sunken shapes.

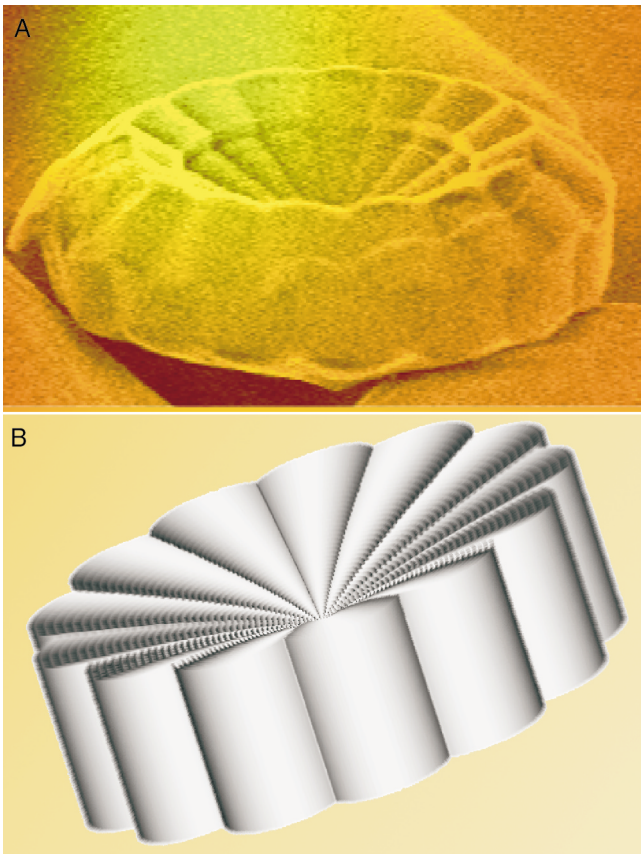

study of shape (Fig. 14). Therefore the surface tension contribution to the overall shape is considered in determining the free energy of the discoid mesophase. The equilibrium shape of a hexagonal silicate mesophase confined to a regular discoid geometry has been obtained by integrating the free energy density F_d over the volume of the liquid crystal, taking into account the surface tension term:

$$[4] \qquad F_d = \int \left\{ \frac{K_1}{2} (\mathrm{div}\,\vec{n})^2 + \frac{K_2}{2} (\vec{n}\, rot\, \vec{n})^2 + \frac{K_3}{2} (\vec{n}\, rot\, \vec{n})^2 \right\} dV + \sigma \int_{\text{surface}} \frac{|\nabla \vec{n}|}{2}\, dS$$

In this equation, K_1, K_2, and K_3 represent the splay, twist, and bend elastic deformation constants, σ is the surface tension constant, and *n* is the unit vector of the director field. It is found that the minimum energy of the regular discoid mesophase shown in Fig. 14 is attained by an elastic deformation to create a discoid with a nodal pattern, such as that illustrated in Fig. 15. Patterns of this type are similar to radial patterns observed on mesoporous silica discoid shapes.

Although calculations predict that radial patterns can appear on a planar discoid, it is found experimentally that radial patterns often occur on corrugated and (or) sunken discoid shapes (Fig. 16). Clearly, some other distortion is operative in the silicate discoid mesophase besides just spontaneous elastic deformation and that has not been taken into account in the free energy calculations.

This missing contribution to the growth process is believed to originate from longitudinal and radial differential contraction of micelle rods that comprise the liquid crystal discoid and that is induced by polymerization of silicate to silica. Because growth of a discoid is imagined to occur from the center and radially outwards, the inner portion of the discoid is expected to be more polymerized than the outer region. The outcome of including polymerization-induced differential contraction effects into the calculation

of the shape of the radially patterned mesoporous silica discoid is to create sunken discoid shapes like those shown in Fig. 16.

Supramolecular origami

Similar kinds of polymerization-induced differential contractions but now confined to a patch of hexagonal mesoporous silica film has been found to be responsible for the morphogenesis of hollow helicoids of mesoporous silica (19). It is found that a low acidity and high ionic strength medium favor a slow rate of silicification in a patch of mesoporous silca film. Hence polymerization-induced differential contraction of silicate micelle rods becomes influential in the formation of hollow helicoids rather than the formation of a mesoporous silica film (9, 10). Powder X-ray diffraction (PXRD) clearly defines the materials as hexagonal mesoporous silica and SEM images reveal morphologies consisting of extraordinary hollow helicoid shapes that resemble a screw thread (Fig. 17). TEM images recorded for whole-mounted helicoids reveal that they are hollow with a ca. 1-µm-thick "shell" (Fig. 18). They are composed of hexagonally close-packed ca. 5-nm-diameter channels which have an ca. 1-nm silica wall and appear to spiral around the major axis of the helicoid.

The dimensions of a significant collection of hollow helicoids have been analyzed by measurements of SEM images (Fig. 19A). It is striking that diagnostic dimensions of the screw, namely pitch width and angle, flute width, and inside and outside diameter, are found to span a rather narrow

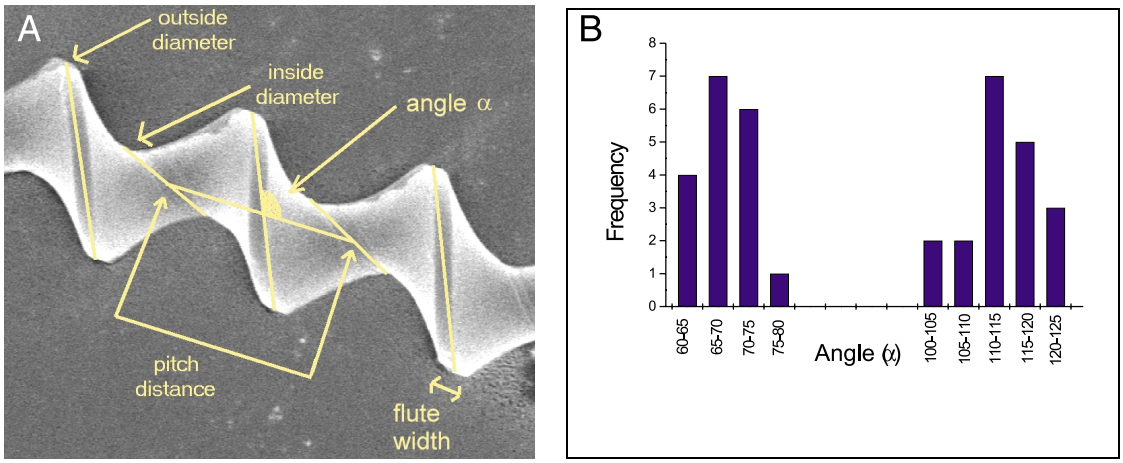
Fig. 19. Screw parameters of (A) a mesoporous silica hollow helicoid and (B) histogram of number of right- and left-handed forms observed in a synthesis.



range. Notably, the pitch angle α centers around 70 and 110°, which respectively correspond to left- and right-handed helices that occur in essentially equal numbers within the same synthesis batch (Fig. 19B).

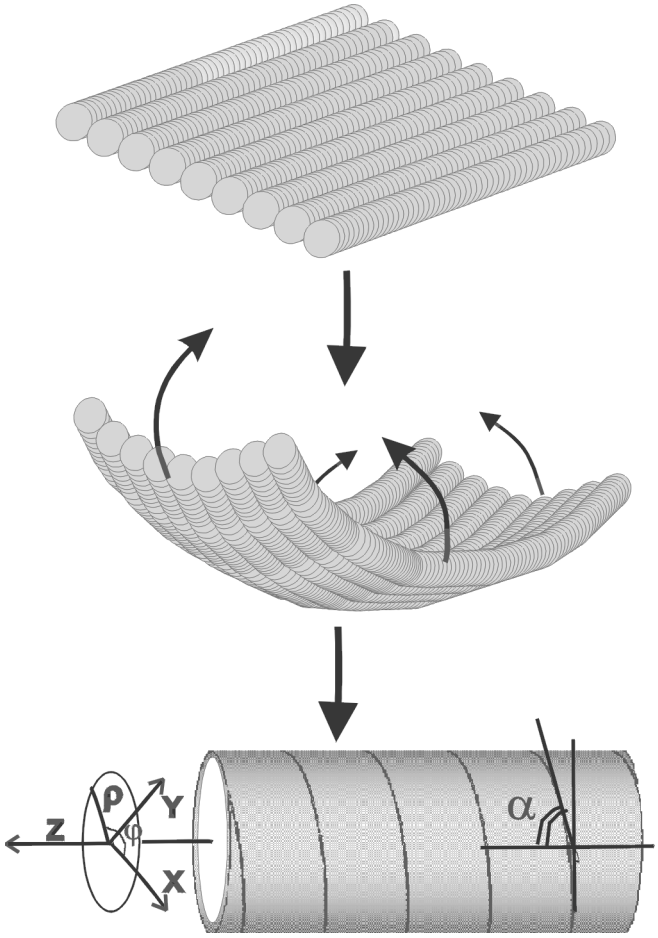
In developing a model for the morphogenesis of mesoporous silica hollow helicoids it is noted that in a synthesis they are typically accompanied by a larger yield of open-ended mesoporous silica hollow cylinders. SEM and TEM images of whole mounted specimens define well-ordered channels whirling concentrically around the axis of the cylinder. One also notices the co-existence of folded sheets, helical ribbons, hollow cones, and incomplete tubes. All of these objects are composed of the same hexagonal mesoporous silica material. Selected area electron diffraction (SAED) defines the relation between the hexagonal channel structure and morphology of a folded sheet. From the collective evidence we conclude that helical hollow cylinders originate from polymerization-induced differential contraction of a silicate liquid crystal "patch," which contracts further into hollow helicoids made of mesoporous silica (Fig. 20).

The folding mechanism emerges from both radial and longitudinal contractions across and parallel to the rods and channels, respectively, both of which are induced by polymerization of a hexagonal silicate mesophase to mesoporous silica. As the patch grows in area and thickness, older rods must undergo more polymerization and contraction than younger ones. Provided radial and longitudinal differential contractions in thickness are considered, they lead to diagonal bending of the patch because these two contractions act in mutually orthogonal directions. Within this diagonally folded patch, the volume of the micelle rods changes solely by contraction but not deformation. Therefore, the folded patch is stress free, that is, an energetically favorable configuration.

Parameters for such a configuration emerge from a purely geometrical approach and turn out to be a cylinder in which the micellar rods are pitched with a constant angle α relative to the principal axis:

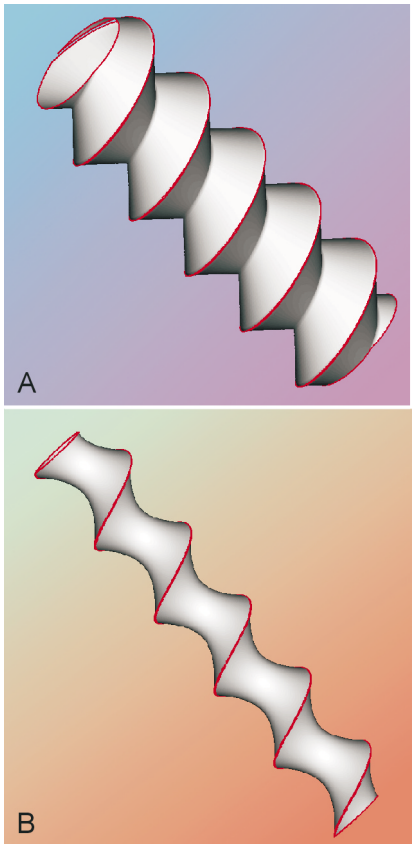
$$[5] \qquad \alpha = \arctan\frac{1-\gamma_L}{1-\gamma_R}$$

Fig. 20. Supramolecular origami: polymerization-induced differential contraction and folding of a patch of hexagonal silicate liquid crystal film to give a mesoporous silica hollow cylinder.



© 1999 NRC Canada

Fig. 21. Supramolecular origami: polymerization-induced differential contraction and folding of a patch of hexagonal silicate mesophase to give a mesoporous silica hollow helicoid: (A) linear and (B) quadratic contraction factor.



$$[6] \qquad \gamma_R \equiv \frac{\gamma_R(R_{in})}{\gamma_R(R_{out})}$$

$$[7] \qquad \gamma_L \equiv \frac{\gamma_L(R_{in})}{\gamma_L(R_{out})}$$

where γ_L and γ_R are longitudinal and radial contraction factors, and R_{in} and R_{out} are internal and external radii of the resultant cylinder, respectively. The contraction factor γ_R has been obtained from X-ray diffraction data, which provides the rod center-to-center distance before and after polymerization. It is estimated to be in the range from 0.6 to 1. The value of γ_L is obtained from the contraction expected for the condensation process SiOH + HOSi $\rightarrow$ SiOSi. It is estimated around 0.6 for complete polymerization.

To understand the case of both orthogonal and parallel differential contractions with respect to the surface of the patch, it is convenient to artificially separate the effect of bending due to polymerization in these two directions. This is possible because the configuration is free of internal stresses and therefore one stage is unlikely to influence the other. Orthogonal differential contraction gives the aforementioned hollow helical cylinder constructed from a set of N rods and described by the following set of equations:

$$[8] \qquad x_i = \rho \cos \varphi$$

$$[9] \qquad y_i = \rho \sin \varphi$$

$$[10] \qquad z_i = \left(\varphi + \sum_{k=1}^{i} \frac{d}{\rho \cos \alpha} \right) \frac{\rho}{\tan \alpha} = \frac{\rho \varphi}{\tan \alpha} + \frac{id}{\sin \alpha}$$

where i = 1, 2, 3...N is the rod number and d is the rod diameter.

Consider next differential contraction parallel to the surface of the cylinder. If we consider an infinite cylinder in which the contraction is independent of the position on the rod, then each point on the rod experiences the same tension in opposite directions. Therefore only rearrangements perpendicular to the rods, in the radial direction of the cylinder, can occur. From this one can derive that $\rho_i/(\tan \alpha_i)$ is independent of i, where ρ_i and α_i are the helicoid radius and angle of the ith rod just after beginning the second stage. From the geometry of the hollow helical cylinder the radius of the ith rod must change according to $\rho_{Li} \rightarrow \gamma_{Li}\rho$. Taking all of these into account one can obtain the equation of the contracted hollow tube:

$$[11] \qquad x_i = \gamma_{Li}\rho \cos \varphi$$

$$[12] \qquad y_i = \gamma_{Li}\rho \sin \varphi$$

$$[13] \qquad z_i = \left(\varphi + \sum_{k=1}^{i} \frac{d}{\gamma_{Li}\rho \cos \alpha} \right) \frac{\rho}{\tan \alpha}$$

An example of this simulation for linear and quadratic contractions is shown in Fig. 21. One can see an obvious resemblance to the experimental images.

In the past, helical shapes in nature have inspired such inventions as the water screw for agriculture, the retaining screw for wine presses, and architectural designs for spiral staircases. Today similarly helical-shaped DNA, proteins, and carbon nanotubes evoke great interest in biotechnology and nanotechnology. Also biomimetic synthesis of helical morphologies of calcium carbonate, barium sulfate, and silica provides insight into morphogenesis of mineralized spiral forms in biology and suggests new opportunities in materials science (19). In our work we have discovered a self-organizing synthesis involving a new kind of growth mechanism that reproducibly produces hollow helicoids of hexagonal mesoporous silica.

The understanding that has emerged from this study may reveal new ways of controlling the growth and form of composite inorganic–organic mesostructured materials with novel topologies. Siliceous hollow helicoids with spiraling channels may find utility for separating viral or bacterial particles, in chiral catalysis of macromolecules, and as micromolds for the fabrication of magnetically activated screws in microelectromechanical, microfluidic, and microanalytical devices. The ability to intentionally synthesize micron-sized shaped objects, like mesoporous silica fibers, discoids, gyroids, toroids, spheres, hollow cylinders, and hollow helicoids, begins to point the way to the idea of self-assembling "synthetic" microelectromechanical machines (SMEMS), like the one imagined in Fig. 22. One might be able to employ SMEMS as an alternative or adjunct to currently employed MEMS techniques, which rely on the fabrication of components. This paradigm raises some intriguing possibilities for future research aimed at the organization and inte-

gration of synthetically shaped materials for functional devices (20, 21, 25).

Language of shape

Research on morphogenesis of mesoporous silica curved shapes required the crossing of boundaries between subdisciplines of chemistry. It involved the integration of chemical and physical concepts, synthetic methods, processing strategies, and analytical techniques, in surfactant, sol–gel, liquid crystal, surface, colloid, and crystal growth science. This entailed an appreciation of the role of topological defects, director fields, surface charge, elastic deformations, and polymerization-induced differential contraction in the nucleation and growth of mesoporous silica from a silicate mesophase.

A "language of shape" has emerged from studies of morphogenesis of mesoporous silica. The alphabet and words, sentences and paragraphs, and the pages of this story are laid out below.

Co-assembly
- Silicate rod micelles
- Silicate liquid crystal seeds

Growth nuclei
- Soft silicate mesophase, defects, director field patterns
- Initiates and directs growth to a particular shape

Growth
- Seed–rod, planar or homeotropic anchoring
- Seed–seed flocculation

Morphology and patterns
- Electrical double-layer effects
- Colloidal crystallization growth mechanism
- Elastic deformation surface patterns
- Polymerization induced differential contraction distortions

Hierarchy
- Distinct building rules at increasing length scales
- Shape and pattern generation
- Integration of structural components

Value of form

Ultimately, the scientific and technological impact of any new class of materials depends on the ability to control the size, morphology, and aggregate structure of primary particles. Self-assembling supramolecular materials are no exception in this respect. They introduce hierarchy for the first time into materials chemistry and bode well for the development of materials with novel properties, new functions, and perceived utility in a range of applications. Possibilities include mesostructured materials for large molecule catalysis, membrane separation and sensing, fuel cell electrodes, battery electrolytes, solar cells, chromatography supports, chiral separation stationary phases, bone implants, chemical delivery vehicles, enzyme immobilization, polymer composites, toxic cleanup of water streams, and acoustic and thermal insulation. The future looks very bright for self-assembling supramolecular materials.

Acknowledgements

The research described in this summary of my Pure or Applied Inorganic Chemistry Award Lecture has profoundly influenced my way of thinking about materials chemistry. Novel concepts in self-assembly, hierarchy, complexity, and topology that could lead to the networking of structural components over different length scales, to ultimately create a purely synthetic integrated chemical system, have been introduced and hopefully will make a difference to the way materials research evolves in the new millennium.

None of this would have been possible without the contributions of my co-workers Drs. Hong Yang, San Ming Yang, Neil Coombs, and Igor Sokolov who challenged me every day with important, insightful and creative ideas and suggestions. Dr. Charles Kresge championed the mesochemistry research in the group from 1994 to 1999 and was a regular visitor in Toronto for many memorable brainstorming sessions, both in the laboratory and at Avalon. During this exciting period of research, G.A.O. was awarded an Issac Walton Killam Memorial Fellowship from the Canada Council and H.Y. was awarded the 1998 NSERC Prize for the top Ph.D. Thesis in Canadian Natural Sciences. G.A.O. is also grateful to the Natural Sciences and Engineering Research

Council for financial support of this phase of the work. The sustained support and encouragement from the Chairman of the Chemistry Department, Dr. Martin Moskovits, is appreciated. G.A.O. is deeply indebted to Dr. Alan MacKay of Birkbeck College London University for stimulating discussions in the early stages of morphosynthesis and for translating the last book of Ernst Haeckel, Crystal Souls, an important work in the history of morphology (26). And last, but not least, I wish to express my gratitude to my best friend Linda Ozin who tries to make my writing more lucid.

Spectroscopic conformational study of PMS 952, a specific imidazoline ligand. Experimental results

Marie-Hélène Baron, Sabine Halut-Desportes, Hai-Fen Ye, Jack Huet, and Edith Favre

Abstract: X-ray analysis of PMS 952 displays two kinds of very strong hydrogen bonds, an intramolecular one stabilizing the conformer **A** and an intermolecular one that associates conformers **A** to form two infinite chains. The ^{1}H NMR study of vicinal coupling constants based on dihedral angle values, evidences that PMS 952 takes up an eclipsed conformation, in CCl_4 and $CDCl_3$ solutions, closely related to the conformation in solid state. Deuterium exchange in methanol-d_4 points out the presence of a tautomeric form. However, as there is spectral evidence neither from NMR nor from FTIR studies for such a tautomer, this specie cannot be taken into account to explain the complexity of the FTIR spectra. NMR data also reveal that the imidazoline ring freely rotates while FTIR analysis allows characterizing two conformers (**A** and **B**), with lifetime shorter than NMR time scale. These two conformers are stabilized by two different intramolecular H-bonds. Taking into account that conformer **A** could exist in two states (monomer **A** and $\mathbf{(A)}_n$-chains), an equilibrium between **A**, $\mathbf{(A)}_n$, and **B** entities allowed the assignment of all main bands of the IR spectra, assigned to νNH, νOH, νCH, and νCN modes. The strength of hydrogen bonds is solvent dependent. Polar solvents, either proton donor or acceptor stabilized the conformer **A**, while CCl_4 favors the conformer **B**.

Key words: hydrogen bonds, X-ray, NMR, FTIR, imidazoline derivative.

Résumé : L'analyse du PMS 952 par diffraction X met en évidence deux types de liaisons hydrogène très fortes. Une liaison intramoléculaire stabilise les molécules sous forme de conformères **A** qui s'associent par liaisons intermoléculaires en deux chaînes paralèlles. L'étude RMN montre que dans un solvant apolaire ou peu polaire la conformation de la molécule dans le solide est conservée, alors que dans le méthanol, qui pertube les liaisons hydrogène il n'y a plus de rotamère privilégié. L'échange de protons dans le méthanol deutérié met en évidence une forme tautomère mais en quantité trop faible pour être décelée par spectroscopies RMN ou IR. Enfin l'équivalence magnétique des protons des deux méthylènes du cycle imidazolinique montre que celui-ci tourne librement, l'échelle de temps de la RMN ne permettant pas d'identifier des rotamères. Cette caractérisation se fait cependant par analyse IR qui met en évidence deux conformères **A** et **B** stabilisés par deux liaisons hydrogène intramoléculaires différentes. Le conformère **A** pouvant exister sous forme de monomère et sous forme associée $\mathbf{(A)}_n$, l'équilibre entre les espèces **A**, $\mathbf{(A)}_n$ et **B** permet d'attribuer les principales bandes des spectres aux modes νNH, νOH, νCH et νCN des différentes espèces. La polarité des solvants module la force des liaisons hydrogène intramoléculaires, les solvants polaires stabilisent le conformère **A**, alors que le CCl_4 stabilise le conformère **B**.

Mots clés : liaisons hydrogène, diffraction X, spectroscopies RMN, IRTF, dérivé imidazolinique.

Introduction

A vast array of α and β-adrenoceptor agonists and antagonists (α_1, α_2, β_1, β_2, β_3, and their subtypes) have been synthesized for decades. These compounds present many different pharmacological applications, i.e., antihypertension, obesity, non insulino dependant diabetes, analgesia, depression, etc., (1). On the other hand, over the past it has been established that many of adrenergic agents can interact with discrete imidazoline receptors I_1 and 1_2, named Imidazoline Prefering Binding Sites (IPBS) (2). The ubiquitous affinity on α and I receptors of the main part of these molecules makes the interpretation of the mechanism inducing the therapeutical effects difficult.

PMS 952

PMS 952 or 1-(2′-methylimidazolyl)-2-hydroxyindane presents interesting in vitro results, highly potent on I_1-PBS with an inhibition constant of 22 nM, and a significant specificity versus α_2 affinity (I_1/α_2 = 145).

The originality of this molecule is due to the presence of a hydroxyl group, generally absent of such potent molecules, except in the natural ligands (epinephrine and norepinephrine). The current paper is focused on conformational study. Structurally, hydrogen bondings may occur between this hydroxyl group and either NH entity or sp^2 nitrogen atom of the imidazoline ring. X-ray diffraction and spectroscopic studies were performed on PMS 952 to investigate this possible competition. Analysis of ^{1}H NMR spectra were carried out to reveal possible favored conformations, and FTIR spectroscopy is performed to study the occurrence and the strength of the H-bonds. Moreover, the very low time scale in IR allows characterizing conformers, which cannot be identified by NMR.

Experimental

For spectroscopic experiments deuterated solvents, CD_3OD, $CDCl_3$, CD_3CN, and DMSO-d_6 from SdS Company (France) were directly used. CCl_4 from Prolabo was dried on 5 Å molecular sieves.

PMS 952 was prepared by Ye (3).

X-ray analysis

A single crystal was selected and mounted on an automatic CAD-4F diffractometer using monochromated Mo Kα radiation. Unit cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 well-centered reflections. The intensities of two standard reflections, measured every hour throughout the data collection, show nonsignificant decay. Crystallographic data and other information are summarized in Table 1.

C(5′)	0.3380(7)	0.761(1)	0.0322(4)	0.060(2)	

Corrections were made for Lorentz and polarization effects. An extinction correction was necessary. Computations were performed by using the PC version of CRYSTALS (4). Atomic form factors for neutral O, N, C, and H were taken from ref. 5. Real and imaginary parts of anomalous dispersion were taken into account. The structure was solved by direct methods using the SHELXS86 program (6) and successive Fourier maps. All hydrogen atoms have been located on difference maps, their positions were not refined, and they were given an overall thermal parameter.

Because of the few number of reflections only nitrogen and oxygen atoms were anisotropically refined, the other atoms were refined with an isotropic thermal parameter. Full matrix least-squares refinements were carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. Models converged with $R = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ and $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2]^{1/2}$ to values listed in Table 1.

In the last stages of the refinement, each reflection was assigned a weight unity. Criteria for a satisfactory complete analysis were the ratio of rms shift to standard deviations being less than 0.2, and no significant features in the final difference map.

Atomic coordinates are given in Table 2.

Supplementary material available includes interatomic distances and bond angles, tables of anisotropic thermal parameters, coordinates of hydrogen atoms, bond distances and angles concerning hydrogen atoms and temperature factors.[2]

NMR experiments

^{1}H NMR spectra were recorded for CD_3OD, $CDCl_3$, and CCl_4 solutions using hexamethyldisyloxane as internal standard on a Bruker AC-200 FT instrument. For deuterium exchange experiments a 4.60×10^{-2} mol L^{-1} CD_3OD solution was used.

Transmission FTIR

FTIR spectra were recorded on a Perkin Elmer 1720 instrument equipped with a DTGS detector. Resolution was set at 4 cm^{-1}, using boxcar. A Balston air dryer from Whatman (U.K.) dried before and during measurements the spectrometer. Solutions at various concentrations from 10^{-3} to 10^{-1} mol L^{-1} were introduced into CaF_2 cells with 100, 200, or 500 μm spacers. For the solid phase, suspensions in Nujol/Fluorolub dispersives were inserted between two CaF_2 plates without spacer. A KBr pellet was also prepared with the powdered compound. For the solutions, difference spectra were computed between spectra of solutions and corresponding solvents. The spectral decomposition of the difference spectra were performed in the 2500–3480 cm^{-1} spectral range with a least-squares iterative program (Levenberg–Marquardt) (7). For these decompositions the number of bands and their frequencies at maximum were measured on second derivative spectra. Self-deconvolution procedure gave the same number of spectral components at similar frequencies, respectively (7). In most cases it has been possible to maintain close frequencies and specific empirical half-band width at half-band height for each kind of absorption bands, as CH and bonded or unbounded OH and NH groups. Lorentzian band profile was introduced for any band. Thus, only the area of each peak was adjusted to fit the overall spectra range. Changes in relative intensity according to solvent are qualitatively related to conformation changes.

Results and discussion

Crystallography

Structural analysis of PMS 952 shows a *trans* configuration for the methylene C10 and the hydroxyl group linked to the indane backbone. The OH group is involved in an intramolecular hydrogen bond with the N3 atom, forming a seven-membered ring.

[2] Supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of tables of anisotropic thermal parameters and temperature factors, these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

© 1999 NRC Canada

Fig. 1. Perspective view of the structure of PMS 952.

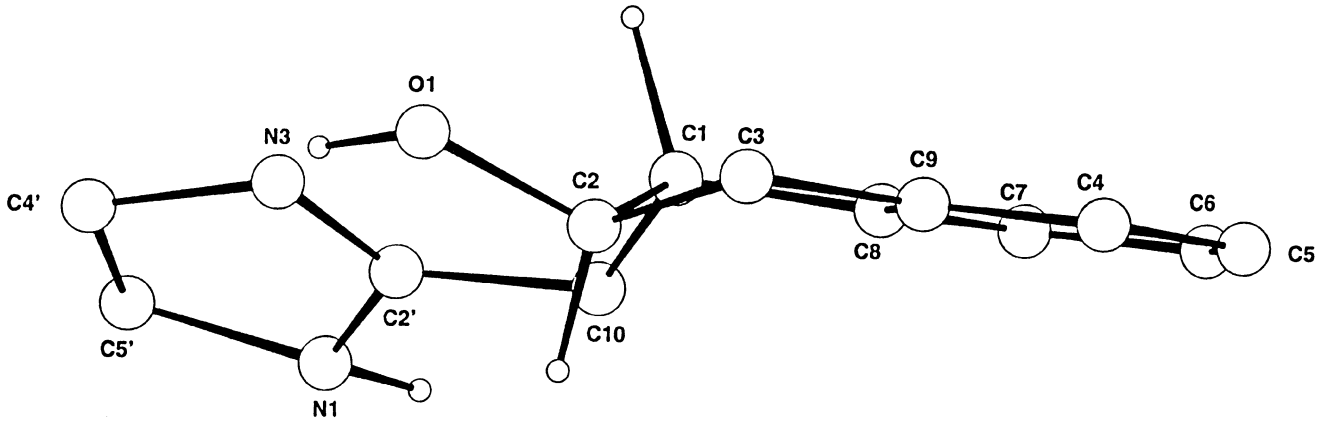

Fig. 2. Projection on *bc* plane showing chains including hydrogen bonds.

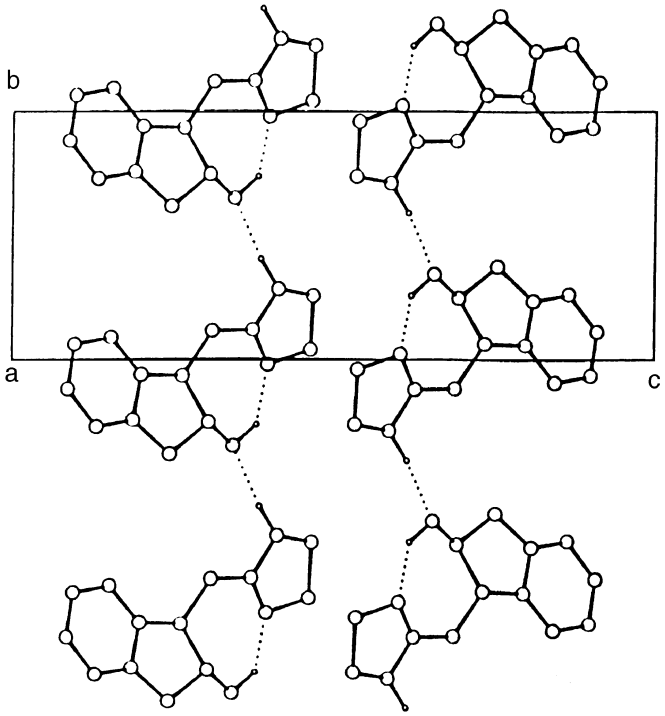

The molecule is shown on Fig. 1 with atom numbering using CAMERON (8).

The overall geometry is characterized by two main planes defined respectively by the atoms C1, C3, and the phenyl ring and by the atoms of imidazoline. The seven-membered ring connects these two planes (Fig. 1).

Eight over the nine atoms of the indane backbone are coplanar, the maximum distances to the plane being –0.017 Å for C1 and 0.024 Å for C8. The ninth atom C2 is located 0.451 Å out of the plane inducing an envelope conformation. The imidazoline ring is almost planar with distances to the plane: 0.087 Å for C5′ and 0.076 Å for C4′. The angle between this plane and the indane backbone is 151°. The seven-membered ring has a cycloheptane chair like conformation, C1, C10, C2′, and N3 being nearly coplanar. Within this ring the hydrogen atom H201 is involved in a strong intramolecular hydrogen bond with a distance H201···N3 = 1.77 Å and an angle N3···H201-O1 = 143°. In addition there is an intermolecular hydrogen bond between H200 atom (linked to N1) and O1 atom to form two infinite chains parallel to the *b* axis (distance H200···O1 = 1.88 Å and angle N1-H200···O1 = 168°). Figure 2 displays the molecular arrangement with inter- and intramolecular hydrogen bonds.

As a conclusion, PMS 952 appears conformationally blocked in the solid state, NMR and IR studies providing dynamic aspects in solutions are described hereafter.

NMR study

Spectra were recorded in three solvents, CD_3OD, $CDCl_3$, and CCl_4. Table 3 displays chemical shifts (^1H, δ ppm) and geminal coupling constants (^2J, Hz) for diasterotopic protons linked to C3 and C10 carbon atoms, and Fig. 3 gives atom positions and numbering. Signal assignments for spectra recorded in CD_3OD was readily achieved as all signals were clearly discernible, except for the H10 signal, which partially overlaps with the residual CH_3OH peak. In addition, the total deuterium exchange of H100 and H101 simplified the spectrum. Irradiation of the signal at 854 Hz, relative to H20, allowed assigning the singlet at 3.38 ppm to H10 unambiguously and also confirmed chemical shifts for H30 and H31 that appeared as two doublets. There is an overall similarity between proton chemical shifts and splitting patterns observed in CD_3OD, $CDCl_3$, and CCl_4, then the assignment of proton resonances for $CDCl_3$ and CCl_4 solutions was achieved by a comparison with chemical shifts observed for CD_3OD solutions. To control these attributions, the spectrum of PMS 952 with fully deuterated methylene C10 was also run in $CDCl_3$, and irradiation of H20 was performed.

A noteworthy detail is that the four imidazoline protons give rise to a singlet in the three solvents used. The magnetic equivalence of these protons implies that imidazoline ring freely rotates around the C10—C2′ bond on NMR time scale (ca. 10^{-6} s).

The general coupling pattern is observed for the diasterotopic protons of methylenes C3 and C10. Table 4 displays experimental and theoretical values of dihedral angles and vicinal coupling constants. Theoretical values were computed (PC MODEL program)[3] from the fractional parameters

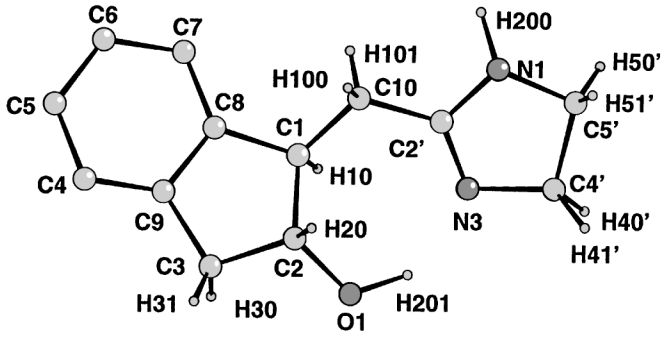
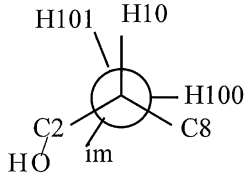
Fig. 3. Cameron view of PMS 952 with atom numbering.



determined by X-ray analysis, according to Karplus rule. As expected dihedral angle values from PC MODEL program and those from X-ray analysis, both deriving from the same X-ray parameters, give the same results. Interestingly, theoretical coupling constants and experimental ones relative to $CDCl_3$ and CCl_4 solutions fit perfectly for all vicinal protons. In methanol solutions no correlation exists.

PMS 952 spectra display two ABX systems, (H30, H31, H20) and (H100, H101, H10). The protons of the first system are bonded to the semi-rigid part (five-membered ring) of the indane backbone, and then the relative dihedral angles (H30-C3-C2-H20) and (H31-C3-C2-H20) cannot freely fluctuate, resulting in experimental ^3J values ($^3J_{H20,H30}$ and $^3J_{H20,H31}$) in the same range for $CDCl_3$ and CCl_4 solutions (Table 4, entries *a*, *b*). These dihedral angle values of 142° and 26°, respectively, are relevant with the envelope conformation of the cyclopentane ring pointed out by X-ray analysis. This also holds true for the dihedral angle (H10-C1-C2-H20) of 147° (Table 4, entry *c*).

In the second ABX system, free rotation round C1—C10 bond may be allowed. But, in fact, a favored conformation exists in $CDCl_3$ and CCl_4 solutions, this conformation in dilute solutions is closely related to the conformation in solid state as stated by the similarity with theoretical and experimental ^3J values relative to $^3J_{H10,H100}$ and $^3J_{H10,H101}$ (Table 4, entries *d*, *e*). Such similarity in conformation between solution and crystalline state had been observed with norepinephrine (1). According to dihedral angles values θ (for H101-C10-C1-H10) of 5.1°, the conformation observed in $CDCl_3$ and CCl_4 solutions is eclipsed (**a**).



(**a**)

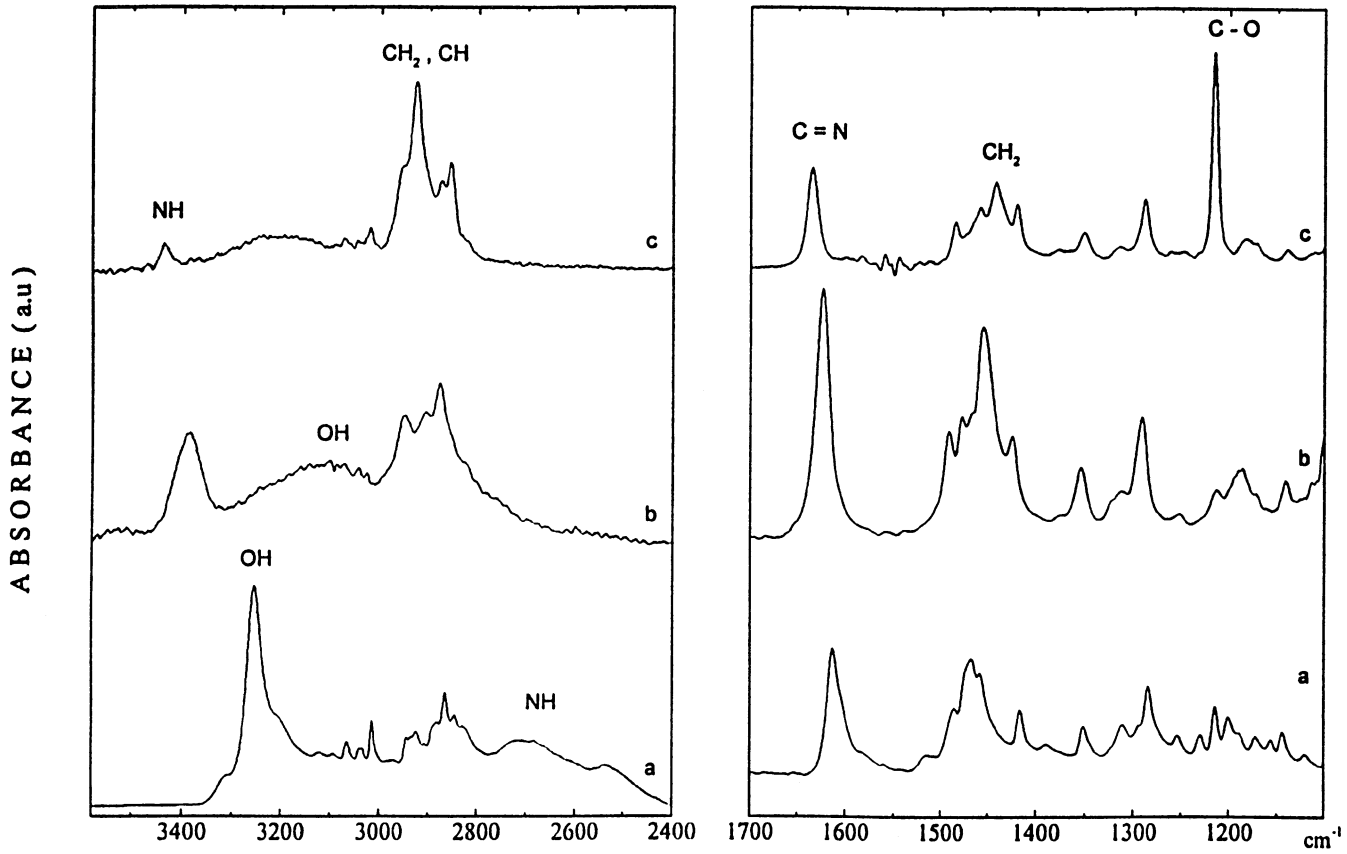
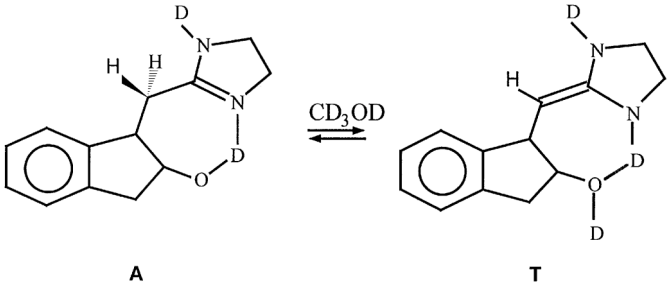
Fig. 4. FTIR transmission spectra of PMS 952. Fluorolub mull until 1300 cm^{-1}, then Nujol mull (*a*); difference spectra for solutions 10^{-2} mol L^{-1} in CD_3CN (*b*), in CCl_4 (*c*).



In this conformation H100 is distorted from the eclipsed position with a dihedral angle θ (H100-C10-C1-H10) of 74.6°.

Taking into account, on one hand, the experimental values of the vicinal coupling constants ^3J (11.7 and 3 Hz) and the values of the chemical shifts (2.26 and 2.66 ppm) of H100 and H101 and, on the other hand, the values of dihedral angle (5.1° and 74.6° from X-ray or theoretical data), we can state that H100 rises at 2.26 ppm and H101 at 2.66 ppm. Exactly similar reasoning shows that H30 rises at 2.88 ppm and H31 at 3.20 ppm.

In methanol solutions the experimental values of vicinal coupling constants do not fit with any dihedral angle or theoretical coupling constant values. This is related to an average value between several rotamers, resulting in the impossibility to attribute the coupling constant values $^3J_{H20,H30}$ and $^3J_{H20,H31}$ (Table 4, entries *a*, *b*) and $^3J_{H10,H100}$ and $^3J_{H10,H101}$ (Table 4, entries *d*, *e*). This could be due to the perturbation of the intramolecular H-bonds induced by methanol, when this solvent interacts either with the N3 atom (CD_3O-D···N3) or with the O1 atom (CD_3O-D···O1).



The deuterium exchange in CD_3OD of the protons H100 and H101, used for signal assignment, also pointed out the existence of a tautomeric form **T** in equilibrium with form **A**.

However, no olefinic proton resonance is detected in the 4–7 ppm range. The tautomeric form should exist in a very small amount, lower than 5%, as usually observed for enol form in keto–enol equilibrium when enol is not stabilized. This parallelism may be carried on, as the deuterium exchange was slow. The decrease of integrated signals versus time shows that the two diasterotopic protons H100 and H101 exchange at different rate. From kinetic curves $t_{1/2}$ = 6 h for the proton at 2.43 ppm and 12 h for the second one at 2.66 ppm.

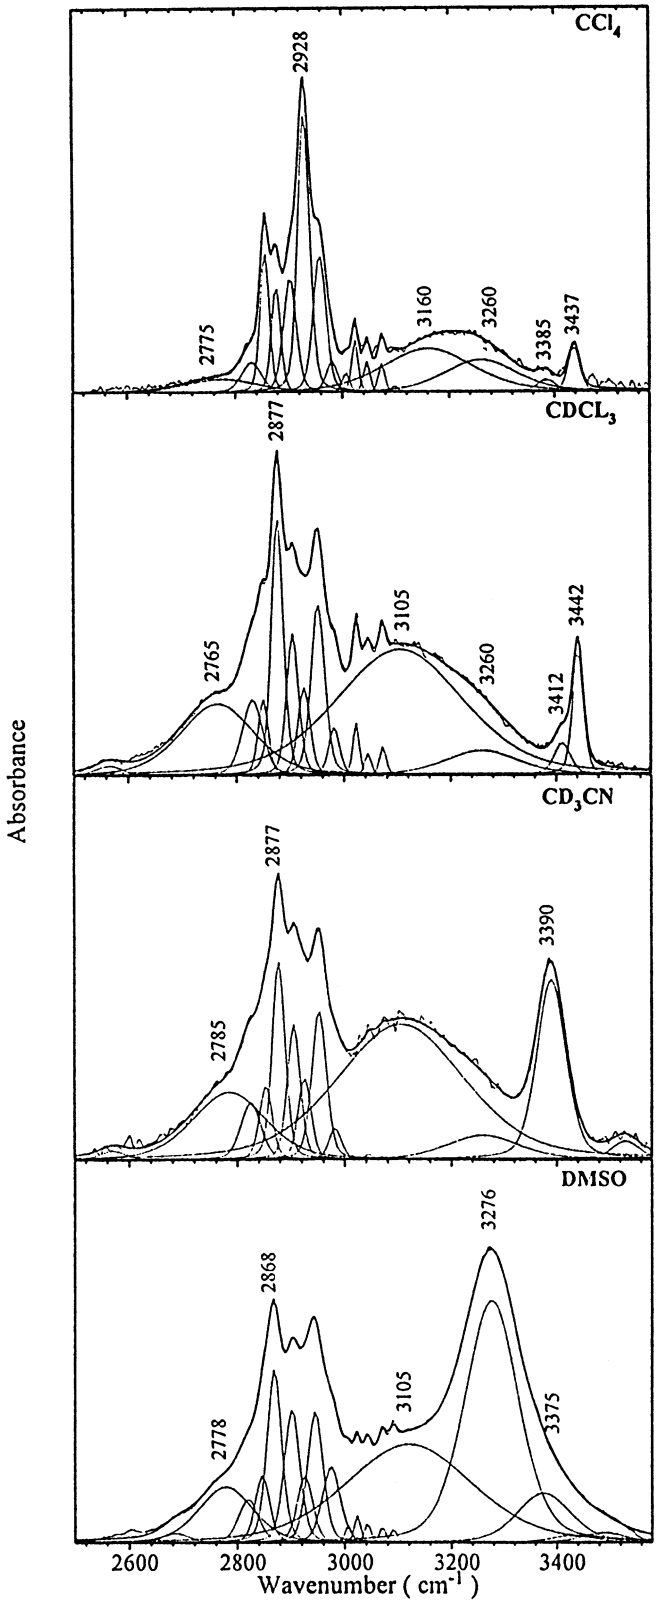
FTIR vibrational analysis

Solid state

X-ray analysis of PMS 952 in the crystalline state points out the occurrence of strong intra and intermolecular hydrogen bonds. As expected, FTIR spectra of KBr pellet or fluorolub dispersion display these hydrogen bonds (Fig. 4*a*). Because it becomes much weaker on spectra for the solutions (see further), the very broad band centered at 2700 cm^{-1} is assigned to the NH stretching mode of the imidazoline ring involved in the intermolecular hydrogen bond (N1-H200···O1) described in X-ray study. The sharper band at 3255 cm^{-1} is attributed to the stretching vibration (νOH) of the OH group involved both in intra (O1-H201···N3) and

© 1999 NRC Canada

Fig. 5. FTIR transmisson difference spectra of PMS 952 in solution 2×10^{-2} mol L^{-1}. The spectral decompositions were performed following the procedure described in the experimental section.



intermolecular (N1-H200···O1) bonds. Two shoulders are also detected in this spectral range. The one at 3208 cm^{-1} should also correspond to OH groups but only involved in the intramolecular hydrogen bond for molecules standing at the end of the polymeric chains described in X-ray analysis (Fig. 2). Compared to the other νOH mode the 47 cm^{-1} downshift reflects an enhancement of the strength of the intramolecular H-bond when the O1 oxygen atom is no more influenced by the intermolecular H-bond. The other shoulder at 3360 cm^{-1} might correspond to the free NH group on molecules located at the other extremity of the polymeric chains.

In the 1100–1700 cm^{-1} range the ν(C=N) mode arises at 1613 cm^{-1}. This low value for a ν(C=N) mode is relevant with a (N1-C2′-N3) conjugated system in this imidazoline ring, as currently observed in conjugated imine (9, 10).

Solutions

Spectra are recorded for solutions in CCl_4, as apolar solvent, $CDCl_3$, as proton donor, and CD_3CN and DMSO-d_6, as proton acceptor solvents.

Spectra for $CDCl_3$ (not shown) and CD_3CN (Fig. 4*b*) solutions display similar absorption profiles. DMSO only induces band broadening and frequency shifts. In CCl_4 large intensity changes are denoted (Fig. 4*c*). For a better identification of the individual vibrational modes, all absorption profiles have been decomposed in the 3000–3400 cm^{-1} range (Fig. 5). The number of bands for OH and NH modes largely exceeded that expected for a single molecular entity. Added to changes in relative intensity depending on solvents, the overall features reflect the presence of different species in equilibrium (see further for the detailed FTIR spectral analysis). From the X-ray and solid state FTIR analyses, the major species in the solid state is the conformer **A** in self-associated form $\mathbf{(A)}_n$, stabilized by both intramolecular H-bond (O1-H201···N3) and intermolecular H-bond (N1-H200···O1), giving the bands νOH and νNH at 3255 cm^{-1} and ca. 2700 cm^{-1}, respectively. In solution at 10^{-2} mol L^{-1} concentration, the conformer **A** could stay partly self-associated $\mathbf{(A)}_n$ via the intermolecular H-bond (N1-H200···O1), in agreement with a remaining component centered ca. 2700 cm^{-1}. In $CDCl_3$, CD_3CN, and DMSO-d_6 no significant spectral change was observable with the PMS 952 dilution from 10^{-1} to 10^{-3} mol L^{-1}, suggesting that such dilutions do not notably modify the molecular structure of the product. (In the apolar solvent CCl_4, PMS 952 was not soluble at 10^{-1} mol L^{-1}). In any solvent, spectra recorded at 10^{-3} mol L^{-1} were too weak to evaluate the expected decrease of the 2700 cm^{-1} shoulder.

Besides, NMR study has shown that in solution imidazole ring rotates around the C10—C2′ bond. This rotation could allow the formation of a second type of conformer, conformer **B**, stabilized by the intramolecular H-bond between H200 and O1 atoms (N1-H200···O1), instead of the exclusive (O1-H201···N3) intramolecular H-bond evidenced by X-ray for the solid. Indeed, in absence of self-association, the ratio between **A** and **B** species differing only by intramolecular linkages should be concentration independent. For polar solvents PMS 952 spectra are similar for 10^{-1} and 10^{-2} mol L^{-1}, indicating that A/B ratio is not significantly modified. This is in agreement with only a few amounts of self-associated species in these solvents. NMR would not detect the con-

B **A** **(A)n**

former **B** due to a too short lifetime for NMR time scale (ca. 10^{-6} s). Conversely, it could be detected by the IR technique characterized by a much shorter time scale (ca. 10^{-13} s). An equilibrium between three species effectively fit the overall set of NH and OH stretching vibrations observed for OH and NH groups involved, or not, into hydrogen bonds:

A "free" NH group and an OH function involved in the intramolecular (O1-H201···N3) bond are both associated to the monomeric conformer **A**.

Intra (O1-H201···N3) and intermolecular (N1-H200···O1) H-bonds and "free" NH groups are attributed to self-associated conformers $(\mathbf{A})_n$.

The NH group involved in an intramolecular H-bond (N1-H200···O1) is associated to conformer **B**. In this case the oxygen atom becomes an acceptor site for H200. Then, for conformer **B**, not only bonded N1-H, but also O1-H and C-O1 stretching modes, are modified with respect to conformer **A**.

N-H stretching modes: Spectra shown in Fig. 5 display relatively sharp bands standing between 3442 and 3390 cm^{-1}. They are assigned to the νNH mode of the conformer **A** (Table 5). Compared to the νNH frequency for the solution in CCl_4 (3437 cm^{-1}) the weak increase with $CDCl_3$ (3442 cm^{-1}) implies a direct influence of this proton donor solvent on the hybridization state at the N1 nitrogen level (11). The down-shift of the νNH frequency to 3390 cm^{-1} with CD_3CN results from a direct H-bond of H200 with the C≡N moiety of this solvent (N1-H200···N≡C). Such H-bond increases with DMSO (N1-H200···O=S) as shown by the enhanced intensity and larger down shift of the νNH vibration (3276 cm^{-1}) (12).

The broad absorption bands in the 2800–2700 cm^{-1} range are assigned to the νN1-H200···O1 modes of self-associated conformers $(\mathbf{A})_n$ (Fig. 5). In the solid state, for $(\mathbf{A})_n$ species, this band raises ca. 2700 cm^{-1} (see above). In solutions this interaction is slightly solvent dependent (Table 5). It is noteworthy that dilution to 10^{-2} mol L^{-1} does not wholly prevent PMS 952 from self-association, via intermolecular H-bond, even in the very polar solvent such as DMSO.

The broad and relatively weaker absorption centered at 3260 cm^{-1} for the solutions in CCl_4, $CDCl_3$, and CD_3CN are associated to NH groups involved in the intramolecular N1-H200···O1 hydrogen bond in conformers **B** (Table 5). With DMSO this νNH mode for the conformer **B** could be overlapped by the νNH mode of the conformer **A** when its NH is bonded to the solvent.

O-H stretching modes: The broad bands in the 3100–3200 cm^{-1} range (Fig. 5) are assigned to the νOH mode for the H-bonded OH group of the conformer **A** (O1-H201···N3) (Table 5). In the solid state the corresponding band is not only sharper, but also at higher frequency (3255 cm^{-1})

© 1999 NRC Canada

because the O1 atom is simultaneously proton donor and electron acceptor when conformers **A** are self-associated (Fig. 2 and 4*a*). In solution the proportion of monomers over oligomers is much larger, and a mixture of **A** and $\mathbf{(A)}_n$ species explains the averaged increase of the internal H-bond strength and the broadness of the bands.

The νOH mode, centered at 3160 cm^{-1} for the CCl_4 solution, is shifted down to 3105 cm^{-1} with CD_3CN and DMSO. This means that the intramolecular H-bond (O1-H201···N3) is stronger in the proton acceptor solvents than in the apolar solvent. It should be related to the direct interaction of acetonitrile or DMSO with the N1-H group, increasing the local electron donor character on the conjugated N3 nitrogen on the imidazoline ring (12)..

The νOH mode for conformer **A** arises in the same range (3105 cm^{-1}) in the proton donor solvent $CDCl_3$. Compared to CCl_4 the increase of the strength of the intramolecular (O1-H201···N3) bond in $CDCl_3$ is this time, connected to the interaction of chloroform on the N1 atom. This entails a change in the hybridization state on the N1 atom, also influencing the conjugated (N1-C2′-N3) system (11).

In the 3400 cm^{-1} range, spectra for CCl_4 and $CDCl_3$ solutions display a weak and narrow band assigned to the νOH mode of conformer **B**. With CCl_4 this mode arises at 3385 cm^{-1}, while it is at slightly higher frequency with $CDCl_3$ (3412 cm^{-1}). Direct proton donor effect of chloroform on O1 is assumed, as on N1, for the conformer **A**, to explain this 17 cm^{-1} shift. At lower frequency, with increased intensity and strong broadening, the band in DMSO at 3375 cm^{-1} accounts for the relatively strong H-bond expected between the OH group and this basic solvent for the conformer **B**. In CD_3CN this band is assumed to be overlapped by the N-H stretching mode of the conformer **A** (3390 cm^{-1}).

Comparing intensities of bands relative to the intramolecular bonded νOH and νNH assigned to conformers **A** and **B**, respectively, it appears that the ratio A/B is smaller in CCl_4 than in $CDCl_3$ or CD_3CN solutions. The shift of the conformational equilibrium from conformer **A** to conformer **B** in CCl_4 is relevant with the weaker strength in this solvent, of the intramolecular (O1-H201···N3) bond relative to conformer **A**, which should facilitate the rotation of the imidazoline ring.

C-H stretching modes: The dependence on solvents of the A/B conformer ratio is connected with large intensity changes in the spectral range related to the aliphatic CH stretching modes (3000–2800 cm^{-1}). Accounting for the number of aliphatic CH of PMS 952, a tenth of individual νCH modes is expected for each conformer. However, only seven peaks are intense and resolved enough to be clearly identified on the second derivative absorption profiles. Only slight frequency shifts have been detected depending on solvents. However, the intensity of two components (2877 and 2928 cm^{-1}) is obviously solvent dependent. The component at 2877 cm^{-1}, relatively strong for $CDCl_3$, CD_3CN, and DMSO solutions, has a much weaker relative intensity for the CCl_4 solution. Conversely, the component at 2928 cm^{-1} weak for the solutions in polar solvents becomes strong in the apolar solvent. Accounting for the increase of the conformer **B** ratio versus **A** in CCl_4, the 2928 cm^{-1} band is assigned to conformer **B**, the 2877 cm^{-1} band to conformer **A** (Fig. 5, Table 5). Accordingly, changes associated to CH_2 deformation modes occur in the 1450 cm^{-1} spectral range (Fig. 4).

Compared to the solid state, no significant change occurs in the 3000–3100 cm^{-1} range for any solution corresponding to aromatic and ethylenic νC-H modes. This is relevant with NMR data: a significant amount of tautomer **T** should have resulted in the appearance of a specific ethylenic νC-H band.

C-O stretching mode: A band at 1216 cm^{-1} is strongly enhanced in CCl_4 (Fig. 4*b* and 4*c*). It might be assigned to the νC-O mode. Its strong enhancement when the proportion of the conformer **B** increases over conformer **A** might be due to an important electronic change on the C-OH functional group. Instead of being proton donor in the intramolecular O1-H···N3 of conformer **A**, the O1 atom becomes proton acceptor in the N1-H···O1 linkage for conformer **B**.

C=N stretching mode: According both to NMR and IR results excluding the presence of a significant amount of tautomer species, only one double bond is detected in the 1600–1700 cm^{-1} range. The band arising ca. 1620 cm^{-1} is assigned to the νC=N stretching mode of both conformers **A** and **B** and not to the νC=C mode of the tautomer.

No splitting is detected for νC=N vibration that could be related to the A/B conformational equilibrium. Indeed, this mode is expected to be much less sensitive to the H-bond network than the νOH and νNH modes. However, the νC=N frequency decreases with polar solvents (Table 5). So far this is relevant to a decrease of C=N bond order related to specific effects of the solvents on the conjugated N1-C-N3 system, already mentioned. Once more the affinity of $CDCl_3$ (proton donor) for the N1 nitrogen atom and the affinity of basic solvents for N1-H200 proton have qualitatively similar electronic consequences.

Conclusions

Intra and intermolecular hydrogen bonds pointed out by X-ray analysis of PMS 952 in the solid state appeared to be very strong. They are still observed by FTIR spectroscopy in solutions, even in polar solvents. Furthermore, ^1H NMR study of vicinal coupling constants, based on dihedral angle values, evidences that the conformation about C1—C10, C1—C2, and C2—C3 bonds in CCl_4 and $CDCl_3$ solutions are closely related to the conformation in solid state. So, little changes in solvent polarity do not affect the rigidity of this part of the molecule. However the restricted rotation are not observed in methanol, which is a competing agent for H-bonds. In addition, NMR spectra show that, for all solvents used, the imidazoline ring freely rotates around the C2′—C10 bond on NMR time scale, but this rotation does not notably modify dihedral angle values. On the other hand, the FTIR analysis pointed out the occurrence of two species, **A** and **B** conformers, deducing each other by a rotation around the C2′—C10 bond, and stabilized by two kinds of intramolecular hydrogen bonds. These entities should have too short lifetime to be detected by NMR. Their ratio depends on solvent effects. Polar solvents, either proton donor or acceptor, increase the strength of the (O1-H201···N3) intramolecular H-bond, versus the (N1-H200···O1) one, favouring conformer **A** over **B**. Conversely conformer **B** is

© 1999 NRC Canada

stabilized in the apolar solvent CCl_4. This emphasizes that structurally and electronically the imidazoline side of PMS 952 displays a large adaptability to various binding sites. This is relevant to its ability to bind I_1, I_2, α_1, and α_2 receptors, even if it is much more efficient on the I_1 binding site.

Acknowledgments

Preparation of *N*-aryl-substituted spiro-β-lactams via Staudinger cycloaddition

Victor Barba, Cecilia Hernández, Susana Rojas-Lima, Norberto Farfán, and Rosa Santillan

Abstract: The interest in the study of β-lactams continues due to their therapeutic importance as antibiotics. In this work, six spiro-β-lactams (**7a**–**7c**, **8a**–**8c**) have been prepared using the [2+2] cycloaddition of isomaleimides to acid chlorides. The heterobicyclic structures obtained have been characterized by mass spectrometry, IR, NMR spectroscopy, and for compounds **7a**, **7b**, and **8b** the X-ray crystallographic study showed a nearly planar arrangement for the β-lactam ring.

Key words: β-lactams, azetidinone, isomaleimides, ketenes, X-ray crystallography.

Résumé : L'intérêt dans l'étude des β-lactames se maintient en raison de leur importance thérapeutique comme antibiotiques. Dans ce travail, on a préparé six spiro-β-lactames (**7a**–**7c**, **8a**–**8c**) en faisant appel à une cycloaddition [2+2] d'isomaléimides sur des chlorures d'acyles. Les structures hétérobicycliques obtenues ont été caractérisées par spectrométrie de masse, IR, spectroscopie RMN et, pour les composés **7a**, **7b** et **8b**, une étude par diffraction des rayons X montre que le cycle β-lactame existe dans un arrangement pratiquement plan.

Mots clés : β-lactames, azétidinone, isomaléimides, cétènes, diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Although a number of pharmacologically active mono- and bicyclic β-lactams are known (1–3), the interest in the synthesis of these types of heterocycles continues and various elegant preparative methods have been developed (4–7). Among the numerous methods for the synthesis of monocyclic β-lactams, the ketene–imine cycloaddition or its equivalent, the acid chloride – imine method, has proven to be an exceedingly effective route for the asymmetric construction of the azetidinone nuclei (8–11); specially, the β-lactams with defined stereochemistry represent an important synthetic target for a number of biologically active compounds containing this heterocyclic framework (12).

In the search for new 2-azetidinone nuclei, several spiro-β-lactams derived from [2+2] cycloaddition reaction of iminolactones with ketenes have been recorded in the literature (13–16). In this work we report the synthesis of four new spiro-β-lactams (**7c**, **8a**–**8c**) derived from isomaleimides (**4a**–**4c**) with acid chloride **5** or **6** by using the Staudinger reaction. Furthermore, the X-ray analysis for **8b** and two previously reported spiro-β-lactams (**7a**, **7b**) (13) was obtained.

Experimental

Instrumentation

^{1}H- and ^{13}C NMR spectra, in $CDCl_3$ and DMSO-d_6, were recorded on Jeol GSX-270 MHz and Jeol Eclipse +400 MHz NMR spectrometers. Special techniques (COSY, HETCOR, NOESY) were applied when necessary to assign the spectra adequately. Chemical shifts (ppm) are relative to $(CH_3)_4Si$. Coupling constants are quoted in Hz. Infrared spectra were recorded on a Perkin–Elmer 16F-PC FT-IR spectrophotometer. Melting points were obtained on a Gallenkamp MFB-595 apparatus and are uncorrected. Ultraviolet spectra were recorded on a Perkin–Elmer UV–vis λ 2S spectrophotometer from ethanol solutions. Mass spectra were recorded on a Hewlett–Packard 5989A spectrometer. Elemental microanalyses were determined by Oneida Research Services, Whitesboro, New York. Crystals suitable for X-ray diffraction of compounds **7a**, **7b**, and **8b** were obtained when the products were recrystallized from a mixture of ethyl ether – hexane.

X-ray diffraction studies of monocrystals were determined on an Enraf–Nonius CAD4 diffractometer (λ_{MoK_α} = 0.71073 Å, monochromator: graphite, T = 293 K, ω-2θ scan). Crystals were generally mounted in Lindeman tubes. Absorption correction was not necessary; corrections were made for

Lorentz and polarization effects. Solution and refinement: direct methods (SHELXS-86) for structure solution and SHELXS (version 1.8, 1993) software package for refinement and data output. Hydrogen atoms were determined by difference Fourier maps and their positions as well as one overall isotropic thermal parameter were refined.

Reagents

All starting materials were commercially available. Solvents were used without further purification, but single crystals were grown from spectrophotometric-grade solvents.

General procedure for the preparation of arylmaleamic acids 3a–3c

To prepare the arylmaleamic acids **3a**–**3c**, equimolar quantities of the corresponding arylamine with maleic anhydride were mixed in 30 mL of dry THF at 0°C and stirred for 2 h at room temperature. The solvent was removed by filtration and the solid washed with THF; the product obtained was used without further purification. The preparation and spectroscopic data have already been published (17–18).

*4-(Phenylamino)-4-oxo-(Z)-2-butenoic acid (**3a**)*: mp 220–221°C (lit (17) = 196°C).

*4-(4′-Methoxy-phenylamino)-4-oxo-(Z)-2-butenoic acid (**3b**)*: mp = 213–214°C (lit (18) = 181–182°C).

*4-(4′-Hydroxy-phenylamino)-4-oxo-(Z)-2-butenoic acid (**3c**)*: mp = 220–223°C (lit (17) = 210°C).

General procedure for the preparation of isomaleimides 4a–4b

Arylmaleamic acids **3a**–**3b** were dissolved in 50 mL of dry dichloromethane, and dicyclohexylcarbodiimide was added with magnetic stirring at –78°C. The solution was stirred for 3–4 h at room temperature and the solvent was evaporated under reduced pressure; the solid obtained was washed with dry dichloromethane and used without further purification. The preparation and spectroscopic data have already been published (16, 19).

N-*Phenylisomaleimide (**4a**)*: mp 61–62°C (lit (19) = 57–62°C).

N-P-*Methoxy-phenylisomaleimide (**4b**)*: mp 70–73°C (lit (16) = 73–74°C).

N-P-*Acetoxy-phenylisomaleimide (**4c**)*: A solution containing 3 g (14 mmol) of compound **3c** and 10 mL (105 mmol) of acetic anhydride in 20 mL of dry dichoromethane was stirred at –78°C for 1 h, followed by the addition of 6 g (29 mmol) of dicyclohexylcarbodiimide. The mixture was stirred for 24 h at room temperature to give, after work-up, a yellow solid (2.35 g, 10 mmol) mp 127–129°C, 70% yield. EI (70 eV) *m/z* (%): 231 (M^+, 10), 190 (12), 189 (100), 145 (15), 119 (24), 99 (1), 77 (2), 54 (21); IR (KBr): 3082, 1792, 1680, 1198 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ: 7.43 (2H, d, *J* = 9.0, H-2′,6′), 7.34 (1H, d, *J* = 5.5, H-3), 7.08 (2H, d, *J* = 9.0, 3′,5′), 6.63 (1H, d, *J* = 5.5, H-2), 2.26 (3H, s, CO—CH_3) ppm; ^{13}C NMR (67.8 MHz, $CDCl_3$) δ: 169.3 (C-1), 167.1 (OCO), 150.1 (C-4), 148.2 (C-4′) 143.3 (C-3), 141.1 (C-1′), 130.8 (C-2), 124.7 (C-2′,6′), 121.9 (C-3′,5′), 21.1 (CH_3) ppm.

General procedure for the preparation of β-lactams 7a–7c and 8a–8c

To a stirred solution of isomaleimide **4a**–**4c** in anhydrous dichloromethane at –78°C was added dropwise a solution of acid chloride in 10 mL of dry dichloromethane, followed by dropwise addition of a solution of triethylamine in dichloromethane. The reaction mixture was maintained at –78°C for 2 h, the resulting suspension was left to warm to room temperature and stirred for 36 additional hours.

The reaction mixture was brought to neutral pH and poured into dichloromethane and washed with water, the organic layer was separated, dried over magnesium sulfate, and evaporated under reduced pressure. The resulting crude product was purified by column chromatography using silica gel and hexane – ethyl acetate, 8:2, as the eluent. The preparation and spectroscopic data (IR, ^1H NMR) of **7a** and **7b** have been reported (16).

*3-Chloro-1-phenyl-5-oxa-1-azaspiro[3,4]oct-7-en-2,6-dione (**7a**)*: Compound **7a** was prepared from 0.5 g (2.9 mmol) of compound **4a** and 0.8 mL (10 mmol) of chloroacetyl chloride. The resulting product obtained was a colorless solid (0.24 g, 0.96 mmol) mp 132–133°C (lit (16) = 127–128°C), 33% yield. EI (70 eV) *m/z* (%): 249 (M^+, 6), 130(8.4), 119(100), 117(2), 102(9), 91(19), 77(11), 51(10); UV (EtOH) λ_{max}: 245 nm (log ε = 4.1); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 167.53 (C-6), 157.77 (C-2), 149.93 (C-8), 134.84 (C-1′), 129.61 (C-3′,5′), 127.89 (C-7), 126.73 (C-4′), 118.46 (C-2′,6′), 96.34 (C-4), 64.66 (C-3) ppm.

*3-Chloro-1-*p*-methoxyphenyl-5-oxa-1-azaspiro[3,4]oct-7-en-2,6-dione (**7b**)*: Compound **7b** was prepared from 0.5 g (2.5 mmol) of compound **4b** and 0.51 mL (6.4 mmol) of chloroacetyl chloride. The product obtained was a colorless solid (0.23 g, 0.82 mmol) mp 128–130°C (lit (16) 132–133°C), 33% yield. EI (70 eV) *m/z* (%) : 279 ($M^{+\cdot}$, 7), 203 (2), 188 (2), 160 (2), 149 (100), 134 (37), 106 (13), 78 (11). UV (EtOH) λ_{max}: 258 nm (log ε = 4.1); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 167.62 (C-6), 158.28 (C-2), 157.71 (C-4′), 149.81 (C-8), 127.79 (C-7), 127.37 (C-1′), 120.97 (C-2′,6′), 114.76 (C-3′,5′), 96.62 (C-4), 64.58 (C-3), 55.52 (OMe) ppm.

*3-Chloro-1-*p*-acetoxyphenyl-5-oxa-1-azaspiro[3,4]oct-7-en-2,6-dione (**7c**)*: Compound **7c** was prepared from 0.5 g (2.16 mmol) of compound **4c** and 0.51 mL (6.4 mmol) of chloroacetyl chloride. The product obtained was a colorless solid (0.22 g, 0.72 mmol) mp 118–119°C, 33% yield. Results and discussion

When the arylamines **1a**–**1c** are treated with maleic anhydride (**2**), the arylmaleamic acids (**3a**–**3c**) are formed in excellent yields (17–18). The reaction of these acids with dicyclohexylcarbodiimide affords isomaleimides **4a**–**4c** in good yields (16, 19). In no case was the formation of *N*-arylmaleimides observed under these conditions.

The isomaleimides **4a**–**4c** underwent [2+2] cycloaddition reaction (Staudinger reaction) with two acid chlorides (**5**, **6**) in the presence of triethylamine to give regioselectively the spiro-β-lactams (**7a**–**7c** and **8a**–**8c**) in 27–34% yields (Scheme 1). The structure of these compounds was confirmed by mass spectrometry where molecular ions were detected in all cases.

The structures of β-lactams **7a**–**7c** and **8a**–**8c** were established by ^1H and ^{13}C NMR spectroscopy. ^1H NMR analysis of products **7a**–**7c** and **8a**–**8c** showed a singlet in the range of 5.31–5.74 ppm corresponding to H-3 of the β-lactam ring. Comparison of the ^1H NMR data for this signal shows that in the case of compounds **8a**–**8c** the signal is shifted to higher field ($\Delta\delta \approx 4$ ppm) than for **7a**–**7c**. These differences are due to the presence of electron-donating or -withdrawing substituents at the C-3 position (chlorine for **7a**–**7c** and oxygen for **8a**–**8c**). All of them display signals for vinylic protons (AB system) between 6.54 and 7.59 ppm for **7a**–**7c** and 6.49 and 7.70 ppm for **8a**–**8c**, with a coupling constant from 5.6 to 5.8 Hz; this AB system remained intact in the course of the cyclization.

The ^{13}C NMR spectra exhibited two carbonyl signals at 167–169 and 157–159 ppm for C-6 and C-2, respectively. The most interesting observation is the extreme high-field shift of the C-3 (88.5, 88.3, 88.4 ppm, for **8a**–**8c**) compared with the downfield shift for the same carbon in **7a**–**7c** (64.7, 64.6, 64.8 ppm). The susbtituent effects may explain these differences.

The relative configuration at C-3 and C-4 was established on the basis of evidence from NMR spectra and NOE studies. Thus, the proton attached to C-8 in **7b** showed NOE interaction with H-2′ in the 400 MHz NOESY spectrum. The fact that no effect was observed between H-8 and H-3 supports the conclusion that the chlorine atom at C-3 and the oxygen atom at C-4 have a *trans* relationship.

The structures of **7a**, **7b**, and **8a** were determined by X-ray crystallography, which confirmed the structures and stereochemistries of these compounds. The molecular structures of **7a**, **7b,** and **8a** are shown in Figs. 1–3. The crystal data are summarized in Table 1. Selected bond angles, interatomic distances, and torsion angles are given in Tables 2 and 3 and have been deposited.[2]

The X-ray analysis shows that the arrangement of bonds around the nitrogen atom is approximately planar. The C(12)—N(1) bond distances are 1.416(4)/1.412(4), 1.415(3)/1.414(3), and 1.426(6) Å for **7a**, **7b,** and **8b**, respectively, and are considerably shorter than the usual value of 1.47 Å, and indicate double bond character. Similar bond lengths (1.41(1) and 1.409(4) Å) have been reported for two similar β-lactams, **9** and **10** (20, 21) (Scheme 2). Additionally, the C(2)—N(1) bond distances of 1.383(4)/1.375(4), 1.377(3)/1.374(3), and 1.369(6) Å for **7a**, **7b,** and **8b**, respectively, are consistent with N=C double bonding. These results are in accordance with the observation than the C(12)-N(1)-C(2) bond angle is 3° larger than the corresponding bond angle for the C(12)-N(1)-C(4) fragment, which can be attributed to π-delocalization between the amide group and the aromatic ring.

The high ring strain can be seen from the internal angles, which show that the larger bond angle is C(2)-N(1)-C(4),

Fig. 1. Molecular structure of compound **7a**; the thermal ellipsoid probability level is 25%.

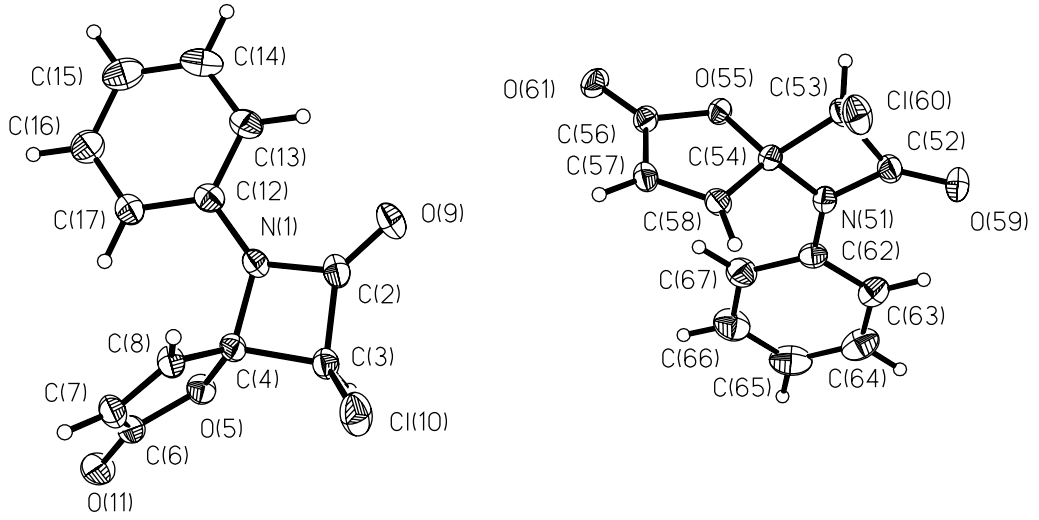

Fig. 2. Molecular structure of compound **7b**; the thermal ellipsoid probability level is 25%.

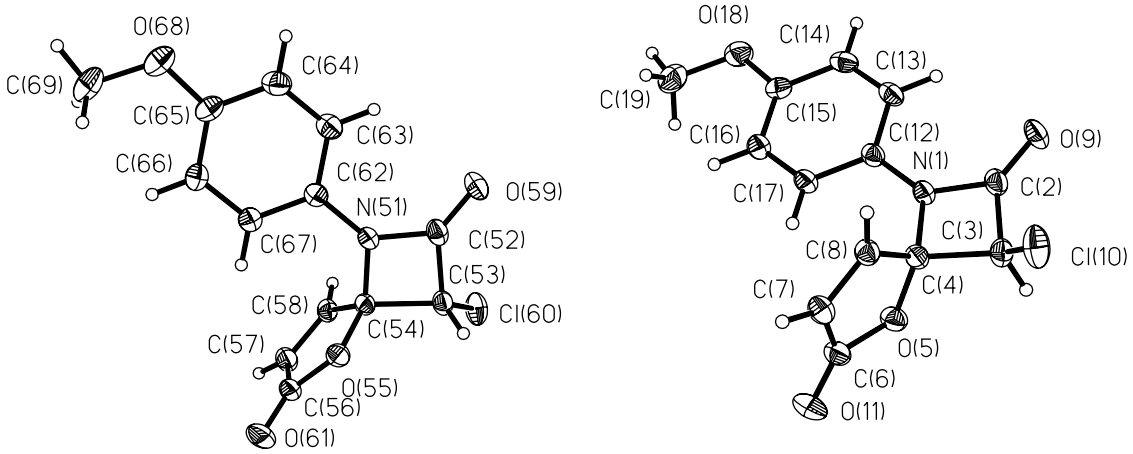

Fig. 3. Molecular structure of compound **8b**; the thermal ellipsoid probability level is 25%.

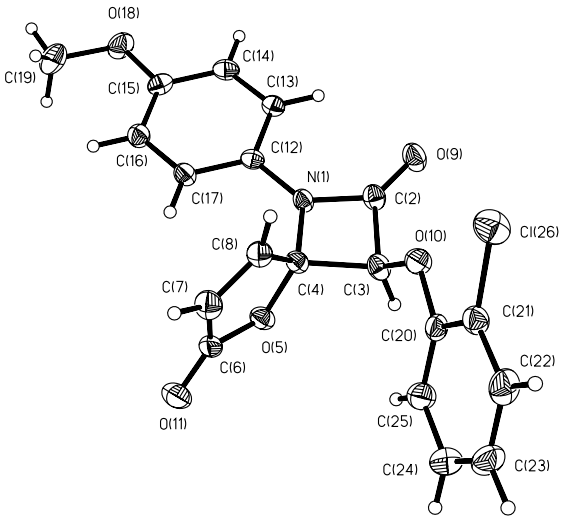

94.6(2)/94.9(2), 94.8(2)/95.0(2), and 95.2(3)° and the smaller bond angle is C(2)-C(3)-C(4), 86.2(2)/85.6(2), 86.0(2)/85.6(2), and 85.7(3)° for **7a**, **7b**, and **8b,** respectively.

The internal torsion angles indicate the nonplanarity of the β-lactam ring, in agreement with literature data on structural analogues (12, 20–22). The torsion angles in the β-lactam ring range from 4.6 to 9.1° (in absolute values). The dihedral angles between the plane of the phenyl ring and the β-lactam ring are 3.4/1.2, –1.2/7.5, and 2.9° for C(2)-N(1)-C(12)-C(13) and –2.3/7.9, –7.9/11.9, and –4.2° for C(4)-N(1)-C(12)-C(17), corresponding to **7a**, **7b**, and **8b**, respectively.

The mean values of the internal bond angles in the β-lactam ring are 89.6/89, 89.85/ 89.87, and 89.82° for **7a**, **7b**, and **8b**, respectively, indicating that the ring strain is very similar in these heterocycles.

In conclusion, the regioselective synthesis of four new spiro-β-lactams with a *trans* stereochemistry was shown by NOE experiments and X-ray diffraction analysis. The molecular perspective of these compounds shows a nearly planar arrangement for the β-lactam ring and the *N*-phenyl group.

Cationic iron(III) complex with a hexadentate N_2,N'_2,O_2-aminopyridylphenolate ligand

Ika A. Setyawati, Steven J. Rettig, and Chris Orvig

Abstract: Iron(III) complexation with potentially hexadentate H_2bbpen (*N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)ethylenediamine) was studied. The resulting monocationic complex, $[Fe(bbpen)]^+$ as its NO_3^- and PF_6^- salts, was characterized by infrared spectroscopy, mass spectrometry, elemental analyses, cyclic voltammetry, and X-ray crystallographic analysis. Crystals of $[Fe(bbpen)]NO_3 \cdot CH_3OH$ are monoclinic, space group $P2_1/c$, a = 10.2640(13), b = 14.7526(10), c = 18.3172(5) Å, β = 97.904(1)°, and Z = 4. The structure was solved by heavy-atom Patterson methods and refined to an R factor of 0.039 for 3526 reflections with $I > 3\sigma(I)$. The structure of the $[Fe(bbpen)]^+$ cation showed that the ligand is bound in a hexadentate fashion to the central Fe(III) ion, resulting in a distorted octahedral geometry. Magnetic susceptibility measurements indicated the presence of a high-spin Fe(III) ion, and the UV–vis spectrum of $[Fe(bbpen)]NO_3$ exhibits absorption maxima, λ_{max}, at 575 nm (ε = 5400 M^{-1} cm^{-1}), 323 (8900), and 275 (13 500). The cyclic voltammogram of $[Fe(bbpen)]NO_3$ showed a quasi-reversible, one-electron process corresponding to $[Fe^{III}(bbpen)]^+ + e^- \leftrightarrow [Fe^{II}(bbpen)]$ at –0.47 V vs. SCE.

Key words: cationic, iron(III), phenolate, pyridyl, hexadentate.

Résumé : On a étudié la complexation du fer(III) avec le H_2bbpen (*N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-méthylpyridyl)éthylènediamine) qui peut être hexadentate. Faisant appel à la spectroscopie infrarouge, à la spectrométrie de masse, aux analyses élémentaires, à la voltampérométrie cyclique et à la diffraction des rayons X, on a caractérisé le complexe monocationique qui en résulte, $[Fe(bbpen)]^+$, sous la forme de ses sels NO_3^- et PF_5^-. Les cristaux de $[Fe(bbpen)]NO_3 \cdot CH_3OH$ sont monocliniques, groupe d'espace $P2_1/c$, avec a = 10,2640(13), b = 14,7526(10) et c = 18,3172(5) Å, β = 97,904(1)° et Z = 4. On a résolu la structure par la méthode des atomes lourds de Patterson et on l'a affinée jusqu'à un facteur R de 0,039 pour 3526 réflexions avec $I \geq 3\sigma(I)$. La structure du $[Fe(bbpen)]^+$ montre que le ligand est lié au Fe(III) central d'une façon hexadentate et que la géométrie octaédrique est déformée. Des mesures de susceptibilité magnétique suggèrent la présence d'un ion Fe(III) à spin élevé et le spectre UV–vis du $[Fe(bbpen)]NO_3$ présente des maxima d'absorption, λ_{max}, à 575 nm (ε = 5400 M^{-1} cm^{-1}), 323 (8900) et 275 (13 500). Le voltampérogramme cyclique du $[Fe(bbpen)]NO_3$ met en évidence un processus à un électron pratiquement réversible correspondant à $[Fe(III)(bbpen)]^+ + e^- \leftrightarrow [Fe(II)(bbpen)]$, à –0,47 V vs. SCE.

Mots clés : cationique, fer(III), phénolate, pyridyle, hexadentate.

[Traduit par la Rédaction]

Introduction

In iron-tyrosinate proteins, the interactions of iron with one or more phenolate moieties of the amino acid tyrosine play important roles in the functions and the stabilization of the geometries of the active sites. Some examples of iron-tyrosinate proteins are transferrin (1, 2), lactoferrin (3, 4), catecholate dioxygenases (5, 6), and purple acid phosphatases (7–10). Model compounds have been synthesized to mimic the environment in the active sites of iron-tyrosinate proteins (1, 2, 6, 9, 11–14). Most of the model small molecules studied contain ligands with nitrogen (aliphatic and (or) aromatic) and oxygen (phenolate and (or) carboxylate) donor atoms. Pyridyl (py) groups have been used in metalloprotein modeling studies as a mimic of the histidine amino acid in the active sites (11–13); moreover, polypyridyl ligands also have a potential application as heavy-metal chelators in biochemical studies. *N*,*N*,*N*′,*N*′-Tetrakis(2-pyridylmethyl)ethylenediamine (tpen) was used in studies of the effect of iron-chelating agents on the toxicity of doxorubicin to MCF-7 human breast cancer cells (15). In a recent in vitro study, Fe^{II}-tpen was found to exhibit a hepatoprotective effect on CCl_4-induced liver injury in rats (16).

In this paper, the coordination chemistry of Fe(III) with potentially hexadentate H_2bbpen (*N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)ethylenediamine) is presented. This ligand contains three types of donor atoms (tertiary amine nitrogen, pyridyl nitrogen, and phenolate oxygen atoms), which may serve as a potential model of iron tyrosinate proteins. The reactions of Ga(III) and In(III) with H_2bbpen, H_2Clbbpen, and H_2Brbbpen ligands were previously undertaken in our group (17), resulting in the formation of monocationic $[M(L)]^+$ complexes (M = Ga, In). Model com-

Received June 29, 1999.

pound studies of metalloenzymes incorporating manganese (18) and vanadium (19–22) with H_2bbpen have also been reported.

Experimental

Materials

Hydrated iron(III) nitrate, ethylenediamine, salicylaldehyde, sodium borohydride, 2-picolyl chloride hydrochloride, hexadecyltrimethylammonium bromide, anhydrous sodium acetate, sodium hexafluorophosphate, and tetra-*n*-butylammonium hexafluorophosphate [(TBA)PF_6] were obtained from Aldrich or Alfa and used without further purification. *N*,*N*′-Bis(salicylidene)ethylenediamine (H_2salen) (23), *N*,*N*′-bis(2-hydroxybenzyl)ethylenediamine (H_2bben), and *N*,*N*′-bis(2-hydroxybenzyl)-*N*,*N*′-bis(2-methylpyridyl)ethylenediamine (H_2bbpen) were prepared as described in the literature (17).

Instrumentation

IR (infrared) spectra were recorded as KBr discs, in the range 4000–500 cm^{-1}, on a Galaxy Series 5000 FTIR spectrometer. Mass spectra (Cs^+, LSIMS (Liquid Secondary Ion Mass Spectrometry)) were obtained on a Kratos Concept II H32Q, with thioglycerol as the matrix. C, H, and N analyses were performed by Mr. Peter Borda, in this department. The room temperature magnetic susceptibility was measured on a Johnson Matthey magnetic susceptibility balance using $Hg[Co(NCS)_4]$ as the susceptibility standard. UV–vis spectra were recorded on a Shimadzu UV-2100 spectrophotometer using acetonitrile. Electrochemical measurements were conducted on a Pine AFCBP1 bipotentiostat using a Pt disc working electrode, Pt coil wire-counter electrode, and Ag wire-reference electrode. Cyclic voltammetry experiments were performed at room temperature in CH_3CN solutions containing 0.25 M [(TBA)PF_6] as supporting electrolyte. Decamethylferrocene was used as an internal standard ($E_{1/2}$ = –0.12 V vs. SCE (Standard Calomel Electrode)), and the $E_{1/2}$ value is reported referenced against SCE.

Synthesis of metal complexes

[Fe(bbpen)]NO_3·CH_3OH

To a mixture of H_2bbpen (89 mg, 0.19 mmol) and NaOAc (sodium acetate) (34 mg, 0.41 mmol) in 5 mL methanol, solid $Fe(NO_3)_3.9H_2O$ (80 mg, 0.20 mmol) was added. Upon this addition, the solution turned purple immediately, and the solution was stirred for 30 min at room temperature. Suitable crystals for X-ray structural analysis were obtained by slow evaporation of the solvent at room temperature. The resulting purple solid was removed by filtration, yielding 35 mg (29%). IR (cm^{-1}, KBr disk): 1605(m), 1594(m), 1476(s), 1453(s) ($\nu_{C=N,\ C=C}$); 1289(s), 1270(s) (δ_{C-O}); 1382(s) (free ν_{NO3}-). UV-vis (in CH_3CN): λ_{max} (ε, M^{-1} cm^{-1}): 575 nm (5400), 323 (8900), 275 (13 500). $E_{1/2}$ = –0.47 V vs. SCE. Mass spectrum (LSIMS), *m*/*z*: 508 ([Fe(bbpen)]$^+$), 402 ([Fe($C_{21}H_{22}N_4O$)]$^+$), 296 ([Fe($C_{14}H_{16}N_4$)]$^+$). Anal. calcd. (found) for [Fe(bbpen)]NO_3·CH_3OH ($C_{29}H_{32}FeN_5O_6$): C 57.82 (58.04); H 5.35 (5.11); N 11.62 (11.65).

[Fe(bbpen)]PF_6

H_2bbpen (140 mg, 0.31 mmol) and NaOAc (56 mg, 0.68 mmol) were dissolved in a solution of warm methanol (5 mL). To this mixture, $Fe(NO_3)_3·9H_2O$ (120 mg, 0.30 mmol) was added, and stirring was continued at room temperature for 15 min. $NaPF_6$ (76 mg, 0.45 mmol) was then added, and the solution was stirred for another 30 min. The resulting purple solid was removed by filtration, yielding 125 mg (63%). IR (cm^{-1}, KBr disk): 1605(m), 1594(m), 1478(s), 1451(s) ($\nu_{C=N,\ C=C}$); 1291(s), 1270(s) (δ_{C-O}); 841(s) (free $\nu_{PF_6^-}$). Mass spectrum (LSIMS), *m*/*z*: 508 ([Fe(bbpen)]$^+$), 402 ([Fe($C_{21}H_{22}N_4O$)]$^+$), 296 ([Fe($C_{14}H_{16}N_4$)]$^+$). Anal. calcd. (found) for [Fe(bbpen)]PF_6 ($C_{28}H_{28}F_6FeN_4O_2P$): C 51.47 (51.08), H 4.32 (4.22), N 8.58 (8.45). The solid-state magnetic moment was 5.91 BM.

X-ray crystallographic analyses

Selected crystallographic data are presented in Table 1. The final unit-cell parameters were based on 14 343 reflections with 2θ = 4.0–61.6°. The data were processed[2] and corrected for Lorentz and polarization effects. The structure was solved by heavy-atom Patterson methods and expanded using Fourier techniques. The oxygen atom of the methanol molecule was modeled as twofold disordered. The non-hydrogen atoms were refined anisotropically. Methanol O-H hydrogen atoms were placed in difference map positions, but

were not refined. The remaining hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å, thermal parameters 1.2 times those of the parent atoms, and methyl group orientations based on difference map peak positions. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (24). Final atomic coordinates and equivalent isotropic thermal parameters appear in Table 2. Complete tables of crystallographic data, hydrogen atom parameters, anisotropic thermal parameters, bond lengths, bond angles, torsion angles, intermolecular contacts, and least-squares planes have been deposited as supplementary material.[3]

Results and discussion

The deep purple coloured monocationic $[Fe(bbpen)]^+$ complex was prepared from reactions of hydrated iron(III) nitrate with one equivalent of H_2bbpen and two equivalents of sodium acetate in methanol. Both the nitrate and hexafluorophosphate salts of this complex were isolated, and the latter was synthesized to obtain a higher yield of the monocationic complex for the measurement of its magnetic moment. Both salts are soluble in common organic solvents, such as methanol, acetonitrile, and acetone. They were characterized by spectroscopic methods (IR, LSIMS, UV–vis), elemental analyses, and magnetic and electrochemical techniques, and the nitrate salt by X-ray crystallography.

The IR spectra of the monocationic complex in each salt show medium bands around 1600 cm^{-1} and strong bands between 1480–1450 cm^{-1} corresponding, respectively, to C=N (py) and C=C stretching vibrations of the aromatic rings. These are consistent with the reported values for the analogous Ga(III) and In(III) complexes (17). The deformation bands of the phenolate C-O group appear in the range 1290–1279 cm^{-1}, similar to those found in the Ln(III) complexes[4]. The free (uncoordinated) anionic NO_3^- and PF_6^- have stretching vibrations at 1382 and 860 cm^{-1}, respectively.

The LSI-mass spectra show the $[Fe(bbpen)]^+$ parent peak, as well $[Fe(C_{21}H_{22}N_4O)]^+$ and $[Fe(C_{14}H_{16}N_4)]^+$ fragments, consistent with the loss of one and two phenolate arms, respectively, from the parent ion. This type of fragmentation is also observed in the Ln(III) [4] and $[Re^{V}O]^{3+}$ [5] complexes with the same ligand.

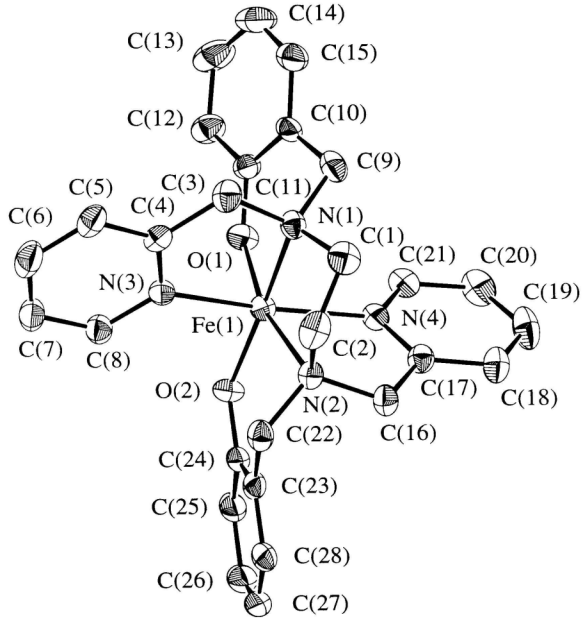
Fig. 1. ORTEP drawing of the $[Fe(bbpen)]^+$ cation in $[Fe(bbpen)]NO_3 \cdot CH_3OH$ showing the crystallographic numbering. Thermal ellipsoids for the non-hydrogen atoms are drawn at the 33% probability level.



Crystals of $[Fe(bbpen)]NO_3 \cdot CH_3OH$ suitable for X-ray analysis were grown by slow evaporation of a methanol solution at room temperature. An ORTEP drawing of the cation in $[Fe(bbpen)]NO_3 \cdot CH_3OH$ is shown in Fig. 1.

The structure shows that hexadentate $bbpen^{2-}$ is bound to the central Fe(III) ion via two amine nitrogen atoms (ethylenediamine backbone), two pyridyl nitrogen atoms, and two phenolate oxygen atoms, the six atoms of which comprise a distorted octahedral geometry. Each half of the ligand forms a *fac*-N_2O arrangement: N1, N3, O1 being one face of the octahedron, while N2, N4, and O2 being the other face. The two amine nitrogen atoms and the two phenolic oxygen atoms are each *cis* pairs, and they form an equatorial plane, relative to which the two pyridyl nitrogen atoms are *trans* in axial positions. This structure is essentially identical to the Mn(III) (18), V(III) (19), Ga(III), and In(III) (17) analogues. The structure of $[Ru(bbpen)]^+$, however, showed two amine nitrogen, two pyridyl nitrogen, and two phenolate oxygen atoms, all as *cis* pairs (25).

Selected bond lengths and bond angles are listed in Table 2. The Fe—O bond lengths have an average of 1.873 Å, similar to those in bis(methanol)bis[2-(5-methylpyrazol-3-yl)phenolato]iron(III) nitrate (1.888 Å) (26), and in a trigonal bipyramidal iron(III) complex with a tetradentate tripodal amine phenolate (NO_3 donor set) and monodentate methylimidazole ligand ($[Fe\{N(CH_2\text{-}O\text{-}C_6H_4O)_3\}(1\text{-}Meim)]$) (1.876 Å). (27). The average Fe—N(amine) bond length of 2.231 Å and Fe—N(py) bond length of 2.135 Å in $[Fe(bbpen)]^+$ are comparable to those found in the dinuclear iron complexes with H_3bhpp (1,3-bis[(2-hydroxybenzyl)(2-pyridylmethyl)amino]-2-propanol) and H_3bhpmp (2,6-bis[(2-hydroxybenzyl)(2-pyridylmethyl)aminomethyl]-4-methylphenol) (11).

The three *trans* angles O1-Fe-N2, O2-Fe-N1, and N3-Fe-N4 are 165.52(7)°, 164.93(7)° and 165.86(7)°, respectively, a deviation of ~15° from 180°. The *cis* N1-Fe-N2 (amines) angle is 80.04(7)°, and the *cis* N(amine)-Fe-N(py) angles (N1-Fe-N3 and N2-Fe-N4) within the two five-membered chelate rings are 77.28(7)° and 77.71(7)°, respectively. All other *cis* angles in the complex are close to 90°, except the *cis* O1-Fe-O2 angle of 103.64(6)°, a deviation of ~14° from 90°. This deviation is similar to that found in the V(III) (19) and In(III) congeners (17), but was not observed in the Ga(III) (17) and Mn(III) (18) analogues, even though the ionic radius of high-spin Fe(III) (0.643 Å) is similar to those of Ga(III) (0.62 Å), V(III) (0.640 Å), and Mn(III) (0.645 Å), but significantly smaller than that of In(III) (0.800 Å) (28).

The solid-state magnetic moment of $[Fe(bbpen)]PF_6$ at room temperature was measured to be 5.91 BM. This value is in excellent agreement with the spin-only value of 5.92 BM for a high-spin Fe(III) ion.

The electronic spectrum of $[Fe(bbpen)]NO_3$ in CH_3CN is presented in Fig. 2. It consists of three maxima (λ_{max}) at 575 nm (ε = 5400 M^{-1} cm^{-1}), 323 (8900), and 275 (13 500). The electronic spectrum of H_2bbpen does not show any absorption maximum above 300 nm (18); thus, the two lower energy bands are assigned as ligand-to-metal charge-transfer bands (LMCT). Due to the intense LMCT bands, spin forbidden *d–d* transitions in the high-spin d^5 Fe(III) ion were not observed in this complex.

The 575 nm band is assigned to the charge-transfer transition from the $p\pi$ orbital of the phenolate oxygen to the $d\pi^*$ orbital of Fe(III) (11, 26, 29, 30). This band is similar to that in the dinuclear iron(III) complex with $bhpp^{3-}$ and two diphenyl phosphato ligands, λ_{max} = 586.5 (sic) nm (ε = 1150 M^{-1} cm^{-1}/Fe); the geometry around each iron(III) center was octahedral with a N_2O_4 donor set (two oxygen atoms from two diphenyl phosphato ligands) (11). However, the $p\pi \rightarrow d\pi^*$ transition is at a lower energy compared to that in the iron(III) complex of tetradentate *N,N′*-bis(2-hydroxybenzyl)ethylenediamine (H_2bben) and two monodentate imidazole ligands (490 nm) (26). Ainscough et al. (26) suggested a structure for $[Fe(bben)(Im)_2]^+$ with two *cis* phenolate oxygen atoms and two *trans* imidazole nitrogen atoms, similar to that of $[Fe(bbpen)]^+$, reported herein, with the *trans* pyridyl nitrogen atoms replacing those of imidazole in the former. The bathochromic shift of the charge-transfer bands of $[Fe(bbpen)]^+$ is consistent with the tighter bonding of the hexadentate ligand $bbpen^{2-}$, which gives a better phenolate-iron overlap, compared to a combination of one tetradentate (N_2O_2) and two monodentate imidazole ligands. The ligand field strengths of imidazole and pyridyl ligands may also play a role in this red-shifted absorption maximum. A relationship between the energy of the phenolate to iron(III) charge-transfer transition and the field strength of ligands coordinated to iron(III) has been observed previously (26, 31).

Another similar complex, that of iron(III) with the linear N_4O_2 amine phenolate ligand (26) (1,12-bis(2-hydroxyphenyl)-2,5,8,11-tetraazadodecane, also known as H_2bad (32)), has λ_{max} = 507 nm. By analogy to the structure of the Ga(III) complex with hexadentate bad^{2-} (32), the Fe(III) structure with the same ligand (26) can be postulated to have a similar distorted octahedral geometry, in which all four adjacent amine nitrogen atoms are *cis* to one another because of the steric constraints of the trien (triethylenetetra-

Fig. 2. UV–visible spectrum of 62 μM [Fe(bbpen)]NO_3 in acetonitrile.

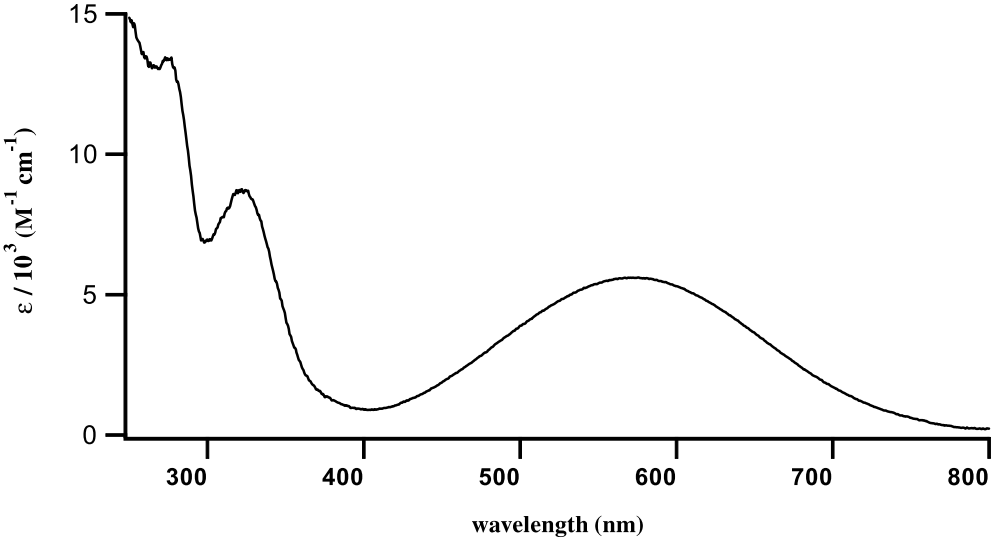

Fig. 3. Cyclic voltammogram of [Fe(bbpen)]NO_3 in CH_3CN (0.25 M (TBA)PF_6), scan rate is 100 mV s^{-1}.

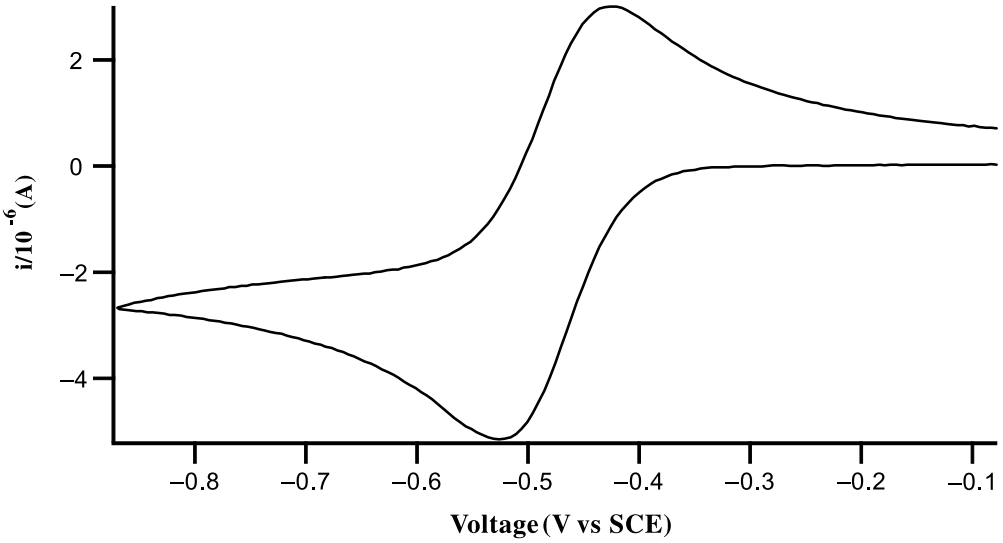

mine) backbone. If this were the case, the N_4O_2 donor atom set of $[Fe(bad)]^+$ (26) would be similar to that of $[Fe(bbpen)]^+$; however, the former would have a more sterically constrained structure, dictated by the presence of three five-membered chelate rings instead of two in the latter complex. The reduced steric strain in $[Fe(bbpen)]^+$ should improve the phenolate to iron orbital overlap, thus facilitating the charge-transfer transition, giving a lower energy LMCT band.

The higher energy LMCT band at 323 nm is associated with the transition from the phenolate $p\pi$ orbital to iron(III) $d\sigma^*$ orbital (11, 26, 29, 30). The energy difference between the two LMCT bands (~13 500 cm^{-1}) is a measure of 10 Dq for this octahedral complex. This value is similar to that of octahedral $[Fe(EDDHA)]^-$ complex (~11 000 cm^{-1}) (29) and $[Fe(OH_2)_6]^{3+}$ (13 700 cm^{-1}) (33).

The cyclic voltammogram of [Fe(L1)]NO_3 was recorded in acetonitrile in the range of –0.9 to 0.1 V versus SCE (Fig. 3). It exhibits a reversible reduction wave at $E_{1/2}$ = –0.47 V ($\Delta E\ p$ = 100 mV). This quasi-reversible one-electron redox process is assigned to $[Fe^{III}(L1)]^+ + e^- \leftrightarrow [Fe^{II}(L1)]$.

Conclusions

Monocationic $[Fe(bbpen)]^+$ was isolated with two different counter anions (NO_3^- and PF_6^-). Magnetic susceptibility measurements confirmed the presence of a high-spin iron(III) ion. The crystal structure of [Fe(bbpen)]$NO_3 \cdot CH_3OH$ showed a distorted octahedral geometry around iron(III) with two *cis* amine nitrogen atoms, two *cis* oxygen phenolate atoms, and two *trans* pyridyl nitrogen atoms, an arrangement similar to those found in the V(III) (19), Mn(III) (18), Ga(III), and In(III) congeners (17). The electronic absorption spectrum of [Fe(bbpen)]NO_3 exhibited two LMCT bands at 575 and 323 nm. The 575 nm band is similar to that noted in model studies of purple acid phosphatases'

© 1999 NRC Canada

active sites (11); however, it is at a lower energy compared to other iron(III) complexes with small ligands, used as models of transferrin and lactoferrin active sites (26, 29). The 10 Dq value of octahedral $[Fe(bbpen)]^+$ is calculated to be approximately 13 500 cm^{-1}, in good agreement with other iron(III) octahedral complexes (29, 33).

Fluctuations in aqueous methanol, ethanol, and propan-1-ol: amplitude and wavelength of fluctuation

Yoshikata Koga

Abstract: Density, heat capacity, and isentropic compressibility data for aqueous methanol, ethanol, and propan-1-ol by Benson's group were used to evaluate two kinds of fluctuations; mean-square fluctuation densities; and (mean-square) normalized fluctuations, respectively, in volume, entropy, and cross (entropy/volume) effect. The mean-square fluctuation densities provide measures for the amplitude (intensity) of the fluctuation, while the normalized fluctuations contain information regarding the wavelength (extensity) of the fluctuation. Furthermore, their composition derivatives, the partial molar fluctuations of alcohols were calculated. These quantities signify the effect of additional solute on the respective fluctuations. These data were interpreted in terms of mixing schemes learned earlier in this laboratory by using the data of excess partial molar enthalpy, entropy, and volume, and the respective alcohol–alcohol interaction functions, i.e., the composition derivatives of partial molar quantities.

Key words: aqueous methanol, ethanol, and propan-1-ol; fluctuation density; normalized fluctuation; partial molar fluctuations of alcohol.

Résumé: Utilisant des données relatives à la densité, la capacité calorifique et la compressibilité isoentropique de solutions aqueuses de méthanol, éthanol et propan-1-ol, obtenues par le groupe du professeur Benson, on a évalué deux types de fluctuations, soit les fluctuations quadratiques moyennes de la densité ainsi que les fluctuations (quadratiques moyennes) normalisées respectivement pour le volume, l'entropie et l'effet croisé (entropie/volume). Les fluctuations quadratiques moyennes de la densité donnent des mesures de l'amplitude (intensité) de la fluctuation alors que les fluctuations normalisées comportent des informations relatives à l'influence de la longueur d'onde sur la fluctuation. De plus, on a calculé les dérivées de composition, les fluctuations molaires partielles des alcools. Ces grandeurs indiquent l'effet de soluté additionnel sur les fluctuations respectives. On a interprété ces données en fonction de schémas de mélanges développés antérieurement dans ce laboratoire en utilisant les données d'enthalpie, d'entropie et de volume molaires partiels en excès et les fonctions respectives d'interaction alcool–alcool, c'est-à-dire les dérivées de composition des quantités molaires partielles.

Mots clés : aqueux, méthanol, éthanol, propan-1-ol; fluctuation de densité; fluctuation normalisée; fluctuations molaires partielles d'alcool.
[Traduit par la Rédaction]

1. Introduction

It is fair to state that Canadian researchers including Benson, Desnoyers, Hepler, and Patterson have made important contributions in the thermodynamic studies of aqueous solutions. Their data are precise and thorough, and have provided keys to deepen the insights into this mysterious system, the aqueous solution. Their papers are too numerous to quote here.

In this paper, we limit our attention to a series of three papers by Benson et al. (1–3) on aqueous solutions of methanol (Me), ethanol (Et), and propan-1-ol (1P). For the three alcohols (AL), the densities were measured at several temperatures (1). Heat capacities (2), and isentropic compressibilities (3) were obtained at 25°C. All of these data were determined accurately and in small increments in the mole fraction of alcohol. From the volume data at 15, 25, and 35°C, thermal expansivities, α_p, can be calculated at 25°C. Thus, all three response functions, C_p, κ_T, and α_p can be obtained at 25°C accurately and in small increments of the mole fraction of AL, x_{AL} (AL = Me, Et, or 1P). They are all proper thermodynamic functions for the Gibbs (p, T, n_i) system, in a sense that they are all second derivatives of G with respect to the independent variables (p, T, n_i), where n_i is the amount of the ith component.

Response functions are related to mean-square fluctuations through standard statistical thermodynamics (4). Implicit in the derivation of such relationships, however, is that a local *thermodynamic value* must be determined in a coarse grain, the size of which must be large enough for a *thermodynamic quantity* to be defined but small enough so that the fluctuation can be detected. The appropriate size may depend on the situation in question and may not be fixed universally. Hence when a mean-square fluctuation is cited, the size of the coarse grain must be specified. The problem is that we do not know

Table 1. Response functions and fluctuations: H_2O vs. *n*-hexane.

	Eq. no.	H_2O	*n*-Hexane
V_m ($cm^3\ mol^{-1}$)		18.07	135.3
κ_T (TPa^{-1})		452.5	1567.2
C_p ($J\ K^{-1}\ mol^{-1}$)		75.15	196.4
α_p ($10^{-4}\ K^{-1}$)		2.572	12.88
For N_z = 1 mole			
$< (\Delta V)^2 > /k$	1	2.44×10^6	63.2×10^6
$< (\Delta S)62 > /k$	2	75.15	196.4
$< (\Delta S)(\Delta V) > /k$	3	46.47×10^{-4}	1742.7×10^{-4}
${}^{V}\delta$	4	1.35×10^5	4.67×10^5
${}^{S}\delta$	5	4.16	1.45
${}^{SV}\delta$	6	1.38	51.93
${}^{V}\Delta$	8b	0.0624	0.0287
${}^{S}\Delta$	9b	1.91	0.0891
${}^{SV}\Delta$	10b	0.0353	0.0236

its proper size a priori. This difficulty may be circumvented by using mean-square fluctuation densities, in which the size of the coarse grain becomes implicit. As discussed below, fluctuation densities provide a measure for fluctuation amplitude, or intensity of fluctuation. However, the peculiar characteristics of liquid H_2O may be a manifestation of the collective fluctuations in the hydrogen-bond network involving a large number of H_2O molecules (5–8). Namely, the wavelength, or the extensity of fluctuation may be larger in H_2O than in a normal liquid. Hence, it would be convenient to have some information about the size of the coarse grain that is related to the wavelength (or the extent) of the fluctuation. The normalized fluctuations introduced by us earlier (9–12) serve this purpose, as discussed below.

Aqueous alcohols (AL) have been studied extensively and the papers up to the early 1980's have been comprehensively reviewed (13). Our more recent studies (14–16) basically supported earlier understandings (13). Additional findings may include

(*a*) AL forms the so-called iceberg in its immediate vicinity with concomitant reduction in the hydrogen-bond probability of bulk H_2O away from AL.

(*b*) Up to a threshold value of x_{AL}, the hydrogen-bond probability of bulk H_2O is still high enough to retain the hydrogen-bond connectivity throughout the entire bulk of H_2O, i.e., the hydrogen-bond percolation is intact. We call this mode of mixing, "mixing scheme I".

(*c*) Above the threshold value of x_{AL}, the percolation nature of H_2O is lost and the solution consists of two kinds of clusters rich in H_2O and AL, respectively. This is called mixing scheme II.

(*d*) The transition from mixing scheme I to scheme II is associated with anomalies in the third derivatives of G. It takes place within a small x_{AL} region. The transition starts at point X and ends at point Y. We interpret this as that at point X the strongest hydrogen bonds in the distribution reach the percolation threshold, while the weakest hydrogen bonds lose percolation nature at point Y. Hence, beyond point Y, there is no hydrogen-bond connectivity and the solution consists of two kinds of clusters, i.e., mixing scheme II.

(*e*) The larger the hydrophobic moiety, the lower the x_{AL} value of the boundary region.

2. Fluctuations

Mean-square fluctuations related to the response functions in the Gibbs variable system are written as (4),

$$[1] \qquad \frac{< (\Delta V)^2 >}{k} = T < V > \kappa_T$$

$$[2] \qquad \frac{< (\Delta S)^2 >}{k} = < C_p >$$

$$[3] \qquad \frac{< (\Delta V)(\Delta S) >}{k} = T < V > \alpha_p$$

where $< V >$ and $< C_p >$ are the average values in the coarse grain containing N_z molecules. The problem is that we do not know the proper size of the coarse grain, N_z, a priori. When a comparison is made between H_2O and *n*-hexane, for example, we are forced to choose arbitrarily $N_z = 1$ mole, say, for both. Table 1 shows the mean-square fluctuations, eqs.[1]–[3], comparing H_2O and *n*-hexane. Due to forcing N_z to be equal for both cases, mean-square fluctuations look larger for *n*-hexane than for H_2O, which seems to be against our common understanding since the bent hydrogen bond model (5). Thus, N_z must be larger for H_2O than for *n*-hexane. Indeed, recent molecular dynamics simulations (6,7) and an X-ray scattering study (8) indicated that collective fluctuations involving a large number of H_2O molecules are prevalent in liquid H_2O.

The mean-square fluctuation densities, below, make N_z implicit, and thus show a measure of the amplitude, or the intensity, of respective fluctuations.

$$[4] \qquad {}^{V}\delta \equiv \frac{< (\Delta V)^2 >}{(k < V >)} = T\kappa_T$$

$$[5] \qquad {}^{S}\delta \equiv \frac{< (\Delta S)^2 >}{(k < V >)} = \frac{< C_p >}{< V >}$$

$$[6] \qquad {}^{SV}\delta \equiv \frac{< (\Delta S)(\Delta V) >}{(k < V >)} = T\alpha_p$$

The partial-molar mean-square fluctuation densities are defined as,

$$[7] \qquad {}^{q}\delta_i \equiv N\left(\frac{\partial^q \delta}{\partial n_i}\right)_{p,T,nj} = (1 - x_i)\left(\frac{\partial^q \delta}{\partial x_i}\right)$$

©1999 NRC Canada

where $q = V$, S, or SV. These quantities signify the effect of incoming ith component on ${}^{q}\delta$. We note that ${}^{q}\delta$'s do not contain information about N_z. Earlier, we introduced the (mean square) normalized fluctuations ${}^{q}\Delta$'s as eqs. [8b]–[10b] below (9–12). First we normalized the deviation of a local value (a value in a coarse grain) from its global average by the mean volume of the coarse grain, and then took its mean-square.

$$[8a] \quad \left\langle \left(\frac{\Delta V}{< V >} \right)^2 \right\rangle = \frac{kT\kappa_T}{< V >}$$

$$[9a] \quad \left\langle \left(\frac{\Delta S}{< V >} \right)^2 \right\rangle = \frac{k < Cp >}{< V >^2}$$

$$[10a] \quad \left\langle \left(\frac{\Delta V}{< V >} \right) \left(\frac{\Delta S}{< V >} \right) \right\rangle = \frac{kT\alpha_p}{< V >}$$

By taking N_z arbitrarily equal to 1 mole and converting k to R we defined ${}^{q}\Delta$'s as (9-12)

$$[8b] \quad {}^{V}\Delta \equiv \frac{RT\kappa_T}{V_m}$$

$$[9b] \quad {}^{S}\Delta \equiv \frac{RC_{pm}}{V_m^2}$$

$$[10b] \quad {}^{SV}\Delta \equiv \frac{RT\alpha_p}{V_m}$$

where V_m is the molar volume and C_{pm} is the molar heat capacity. The partial-molar normalized fluctuations of the ith component, ${}^{q}\Delta_i$, were defined as (9,11,12),

$$[11] \quad {}^{q}\Delta_i \equiv (1 - x_i)\left(\frac{\partial {}^{q}\Delta}{\partial x_i} \right)$$

In eqs. [8]–[10], the right-hand sides, after averaging, contain N_z-dependent $< V >$, or V_m for $N_z = 1$ mole, in the denominator. This fact turned out to be convenient for conveying qualitative information about the appropriate size of N_z, and hence the wavelength, or the extensity, of fluctuation. When making a comparison between H_2O and *n*-hexane, for example, we have no other choice but choose the same value for N_z, say 1 mole. If the appropriate size of N_z is in fact larger for H_2O, we are dividing in eqs. [8]–[10] by an unduly smaller value of $< V >$ for H_2O, and hence the value of ${}^{q}\Delta$ becomes apparently larger for H_2O than otherwise if the appropriately larger value for N_z was used. Thus, ${}^{q}\Delta$ for H_2O conveys qualitative information that H_2O has a larger fluctuation than *n*-hexane in terms of wavelength as well as amplitude.

We now turn to aqueous methanol, ethanol, and propan-1-ol. We calculate ${}^{q}\delta$, eqs. [4]–[6], and ${}^{q}\delta_i$, eq. [7], to gain information about the amplitude of fluctuations, and ${}^{q}\Delta$, eqs. [8b]–[10b], and ${}^{q}\Delta_i$, eq. [11] for the amplitude plus the wavelength of respective fluctuations. We thus attempt to gain a deeper insight into the mixing schemes (mixing scheme I in particular) of these aqueous solutions. We note in passing that the coarse grain in aqueous AL solutions must be chosen such that the numbers of AL and H_2O molecules in the coarse grain, N_{AL}^Z and N_{W}^Z, ($N_Z = N_{\mathrm{AL}}^Z + N_{\mathrm{W}}^Z$) are in the same composition as the global one. Namely, $N_{\mathrm{AL}}^Z/(N_{\mathrm{AL}}^Z + N_{\mathrm{W}}^Z) = x_{\mathrm{AL}}$. Since we are in the Gibbs ensemble, the independent variables, p, T, and n_i are kept fixed.

3. Data analysis and results

The first step is to draw a smooth curve through all the data points (1)–(3), and to read values off the smooth curve drawn at fixed predetermined increments. We used the following method to avoid losing the number of significant figures in the graphical smoothing process. A simple function, $f(x_i)$ was devised such that the residuals from data points $y_i(x_i)$, $r_i = y_i - f(x_i)$, are all within the last three significant figures, while the data themselves, y_i, have typically five to six significant figures. The values of r_i were plotted, and a smooth curve was drawn through all the (x_i, r_i) data points. The values of r_j were then read off the smooth curve drawn at x_j in predetermined increments, and the values of y_j were recovered using $y_j = r_j + f(x_j)$. All the smoothed values of V_m^E at 15, 25, and 35°C, C_p and κ_S at 25°C, are listed in the Supplementary Table deposited in CISTI.[1] The α_p data at 25°C were calculated using V_m data at 15, 25, and 35°C (8), and the κ_T data at 25°C using κ_S, V_m, C_p, and α_p. The α_p and κ_T data are also listed in the supplementary table.

From V_m^E data at 25°C, the excess partial molar volume of AL, V_{AL}^E, were calculated and are shown in Fig. 1. Using the proper response functions listed in Table 1, the mean-square volume-, entropy-, and cross fluctuation densities ${}^{V}\delta$, ${}^{S}\delta$, and ${}^{SV}\delta$ were calculated using eqs. [4]–[6]. Also the normalized volume, entropy, and cross fluctuations, ${}^{V}\Delta$, ${}^{S}\Delta$, ${}^{SV}\Delta$ were calculated using eqs. [8b]–[10b]. The effect of additional AL on the respective fluctuations, the partial molar fluctuations of AL were calculated using eqs. [7] and [11]. All these fluctuations and partial molar fluctuations are shown in Figs. 2–9.

4. Discussion

Our general understanding of the mixing schemes of aqueous alcohols mentioned briefly in the introduction was based on the composition and temperature dependency of the excess partial molar enthalpy, $H_{\mathrm{AL}}^{\mathrm{E}}$; entropy, $S_{\mathrm{AL}}^{\mathrm{E}}$; and volume, $V_{\mathrm{AL}}^{\mathrm{E}}$ of solute AL, which are other second derivatives of G. Furthermore, we used their composition derivatives (third derivatives of G) as a measure of solute–solute interaction. For example, the enthalpic interaction function, $H_{\mathrm{AL-AL}}^{\mathrm{E}}$, among alcohol molecules is defined as

$$[12] \qquad H_{\mathrm{AL-AL}}^{\mathrm{E}} \equiv N\left(\frac{\partial H_{\mathrm{AL}}^{\mathrm{E}}}{\partial n_{\mathrm{AL}}}\right) = (1 - x_{\mathrm{AL}})\left(\frac{\partial H_{\mathrm{AL}}^{\mathrm{E}}}{\partial x_{\mathrm{AL}}}\right)$$

This quantity signifies the effect of incoming AL on the partial molar enthalpy, i.e., the actual enthalpic situation, of AL. If $H_{\mathrm{AL-AL}}^{\mathrm{E}} < 0$, incoming AL molecules make the enthalpic situation of existing AL more favourable and thus we say the AL–AL interaction is attractive in terms of enthalpy. Similarly, a positive $H_{\mathrm{AL-AL}}^{\mathrm{E}}$ indicates a repulsive enthalpic in-

[1] Supplementary table,"Smoothed volumes at 15, 25, and 35°C and response functions at 25°C, for aqueous methanol, ethanol, and propan-1-ol." has been deposited in CISTI. teraction between AL molecules. This together with entropy and volume analogs were used to gain an understanding of the mixing schemes, particularly for aqueous *tert*-butanol and 2-butoxyethanol (14,15).

As for methanol, ethanol, and propan-1-ol, the excess partial molar enthalpy data (16) behaved in the same way. The excess chemical potential and hence entropy data (17, see also footnote [2]) also showed the same trend. The excess partial molar volume data, V^{E}_{AL}, shown in Fig. 1 also display the same dependence as for higher alcohols (18). Hence, the general mixing schemes and the transition between two mixing schemes mentioned above in the introduction is indeed applicable to lower alcohols also. In particular, the fact that V^{E}_{AL} shows the initial decrease on addition of AL supports the fact that AL, even methanol, forms an "iceberg" in its immediate vicinity but reduces the hydrogen-bond network of bulk H_2O away from AL molecules, as discussed at some length earlier (14,15). Briefly, the excess partial molar volume of AL is negative due primarily to the size difference between AL and H_2O. However, H_2O is not just small solvent molecules but makes the hydrogen-bond network. Thus, H_2O is bulkier than the size determined by Van der Waals' radius. Due to the H_2O's bulkiness, there is a positive contribution resulting in the still

negative net value of V^{E}_{AL} at infinite dilution. As x_{AL} increases, the positive contribution is progressively reduced, (hence V^{E}_{AL} decreases), since the hydrogen-bond probability in the bulk H_2O away from existing solute AL is progressively reduced. This trend turns around at about the onset of the transition from mixing scheme I to scheme II.

Figure 2 shows the volume fluctuations, ${}^{V}\delta$ (amplitude) and ${}^{V}\Delta$ (amplitude as well as wavelength) decrease on increasing x_{AL}. This indicates that the tendency of putative momentary formation and destruction of icelike patches decreases on addition of AL. The effect is stronger for larger alcohols. This suggests two points:

(1) The iceberg formed in the immediate vicinity of AL is rigid enough not to participate in fluctuations.

(2) The hydrogen-bond probability in the bulk H_2O away from the iceberg is decreasing progressively to reduce the tendency of putative momentary formation and destruction of icelike patches.

The effects are apparent for both the amplitude and wavelength of the fluctuations. The partial molar volume fluctuations (Fig. 3) suggest that for both amplitude and wavelength the effect of incoming AL on the volume fluctuations is initially negative, but becomes less negative reaching almost zero, particularly for ${}^{V}\Delta_{AL}$ at the completion of the transition to mixing scheme II, point Y_{AL} in Fig. 3.

Figure 4 shows the entropy fluctuations. The amplitude of the entropy fluctuation, ${}^{S}\delta$, increases on addition of AL in mixing scheme I with less increase for smaller alcohols and with almost zero increase for methanol. ${}^{S}\Delta$, the amplitude and the wavelength, on the other hand, decreases as x_{AL} increases. The entropy fluctuation $< (\Delta S)^2 >$ can be translated as the fluctuation of the hydrogen-bond strength in aqueous solutions, since $T^2 < (\Delta S)^2 > = < (\Delta H)^2 >$. In terms of the bent-hydrogen-bond model, $< (\Delta S)^2 >$ reflects how widely the hydrogen bonds bend. Thus, H_2O molecules in the bulk that are fluctuating are perhaps forced to bend more near the icebergs, causing the hydrogen bonds to break more easily. At the same time, the wavelength of the fluctuation must be diminishing rapidly to compensate for the initial increase in amplitude, ${}^{S}\delta$. Figure 5 shows the transition from point X_{AL} to Y_{AL} as a shift of the branch in ${}^{S}\delta_{AL}$, and ${}^{S}\Delta_{AL}$ from mixing scheme I to mixing scheme II.

The peculiarity of H_2O is most conspicuous in the cross fluctuation, in that there is a negative contribution in the product $(\Delta S)(\Delta V)$ unlike normal liquids. Namely, the volume increase in fluctuation due to putative and momentary formation of icelike patches is associated with a negative ΔS. Thus, Fig. 6 indicates that the negative contribution diminishes rapidly on increasing x_{AL} for both ${}^{SV}\delta$ and ${}^{SV}\Delta$. The rate of decrease in the negative contribution, or that of increase in ${}^{SV}\delta$ and ${}^{SV}\Delta$,

©1999 NRC Canada

slows down quickly at about the boundary between mixing schemes I and II. This is more clearly seen in the partial molar cross fluctuations of methanol (Fig.7), ethanol (Fig. 8), and propan-1-ol (Fig. 9). The effect of AL on the negative contribution to the cross fluctuations decreases as x_{AL} increases up to the onset of transition, point X_{AL}, then drops sharply to the end point of transition, Y_{AL}. In the figures the enthalpic AL–AL interactions, H^{E}_{AL-AL}, are also plotted with an arbitrary scaling factor. The match between the partial molar cross fluctuation and the enthalpic AL–AL interaction is striking for propan-1-ol, (particularly for ${}^{SV}\Delta_{1P}$, Fig. 9*b*) while those for methanol and ethanol are not as impressive. The same exact match was observed for aqueous *tert*-butanol (12), but for aqueous 2-butoxyethanol they are only similar (11). Considering the uncertainties in both third-derivative quantities (a few per cent at best), and that there could be unknown systematic errors in the original data of the second derivatives, it may be safe to state that the x_{AL} dependence is similar between H^{E}_{AL-AL} and ${}^{SV}\delta_{AL}$ or ${}^{SV}\Delta_{AL}$. This could mean that the AL–AL interaction in terms of enthalpy (and of entropy also) and the AL's contribution to the cross fluctuations share the same fundamental cause. We suggest that the AL–AL interaction is operative via the bulk H_2O in solution, where putative occurrence of icelike patches causes the negative contribution to ${}^{SV}\delta$ and ${}^{SV}\Delta$. In mixing scheme I, the bulk H_2O remains still waterlike with the hydrogen bond probability high enough for bond percolation, and the interactions between iceberg clad AL's are operative through fluctuating bulk H_2O.

Temperature and pressure dependence of the volumetric properties of binary mixtures containing polyhaloalkanes

Carmen Jarne, Manuela Artal, José Muñoz Embid, Inmaculada Velasco, and Santos Otín

Abstract: Densities of binary mixtures of 1,1,2-trichlorotrifluoroethane + dibromomethane, + bromochloromethane, or + bromotrichloromethane were measured over their entire composition ranges at 288.15 and 308.15 K. Thermal expansion coefficients (α) and excess molar volumes (V^{E}_{m}) were calculated. Moreover, densities at 298.15 K and pressures up to 80 bar (1 bar = 100 kPa) were determined for these same mixtures. Isothermal compressibilities (κ_T) of the pure liquids and their mixtures were obtained.

Key words: density, excess volume, thermal expansion coefficient, isothermal compressibility.

Résumé : Opérant à 288,15 et à 308,15 K, on a mesuré les densités des mélanges binaires du 1,1,2-trichlorotrifluoroéthane avec le dibromométhane, le bromochlorométhane ou le bromotrichlorométhane sur l'ensemble des compositions. On a calculé les coefficients d'expansion thermique (α) et les volumes molaires en excès, (V^{E}_{m}). De plus, opérant sur les mêmes mélanges, on a mesuré les densités à 298,15 K à des pressions allant jusqu'à 80 bar (1 bar = 100 kPa). On en a déduit les compressibilités isothermiques (κ_T) des liquides purs et de leurs mélanges.

Mots clés : densité, volume en excès, expansion thermique, compressibilité isothermique.

[Traduit par la Rédaction]

Introduction

The thermodynamic study of different halogenated aliphatic compounds and their mixtures is of both theoretical and industrial interest. To correlate the structures of molecules with the thermodynamic properties of their mixtures it is necessary to have systematic information on the behaviour of substances with different specific groups. On the other hand, monohaloalkanes and different types of polyhaloalkanes represent a class of technically important compounds, used in industry as either intermediates or final products (refrigerants, blood substitutes, fire extinguishers, surfactants for extraction processes involving supercritical fluids, etc.). In view of the variety of possible mixtures, a large number of systems should be experimentally investigated in order to obtain the data necessary for the design of distillation columns and other stills for chemical plants.

Experimental data of the thermodynamic properties of polyhaloalkane binary mixtures with different halogen atoms in the same molecule are very scarce (1–6). In this work, the densities of binary mixtures of 1,1,2-trichlorotrifluoroethane + dibromomethane, + bromochloromethane, or + bromotrichloromethane were measured at 288.15 and 308.15 K, and thermal expansion coefficients (α) and excess molar volumes (V^{E}_{m}) were calculated over the entire composition range. Moreover, densities of these same mixtures at 298.15 K and pressures up to 80 bar were determined. Isothermal compressibilities (κ_T) of the pure liquids and their mixtures were calculated.

Experimental

The liquids used were dibromomethane (99 mol%), bromochloromethane (>98 mol%), and 1,1,2-trichlorotrifluoroethane (99.5 mol%), obtained from Fluka AG Buchs, and bromotrichloromethane (99 mol%), obtained from Aldrich. All the liquids were used without further purification. The densities of the pure liquids are listed in Table 1.

The excess molar volumes V^{E}_{m} were calculated for T = 288.15 K and T = 308.15 K from density measurements obtained by a vibrating-tube digital densimeter (Anton–Paar model DMA 60) equipped with a DMA 602 cell. The densimeter calibration was performed at atmospheric pressure using doubly distilled and degassed water, benzene, and tetrachloromethane using TRC references data (7). The vibrating-tube temperature was measured by an Anton–Paar DM 100-30 digital thermometer and was regulated to better than ±0.01 K using a Neslab RTE-210 thermostat. The thermometer was previously checked against the vapor pressure of benzene (Merck, >99.9%) along with the equation of Ambrose (8) relating temperature (T_{68}) with pressure by means of a sum of Chebyshev polynomials up to degree six (as recommended by IUPAC (9)).

 © 1999 NRC Canada

Table 1. Densities, ρ, of the pure liquid at 298.15 K.

	ρ (g cm^{-3})	
Substance	Experimental	Literature (7)
Dibromomethane	2.48083	2.4842
Bromochloromethane	1.92246	1.923
Bromotrichloromethane	2.00109	2.001
1,1,2-Trichlorotrifluoroethane	1.56327	1.5643

The mixtures were gravimetrically prepared and the mole-fraction error was estimated to be less than $\pm 10^{-4}$. Duplicate densities of the pure liquids and mixtures studied agreed to within 2×10^{-5} g cm^{-3}.

The densities (ρ) of the pure components and binary mixtures over the complete composition range were measured at T = 298.15 K and pressure range 3–80 bar, using the same vibrating-tube digital densimeter with a DMA 512 high pressure cell. High pressure was generated by a pressure amplifier (model AA-30; Haskel Inc.). Pressure was measured with a pressure gauge (CBI200; E. Cella S.P.A.). The accuracy on measured pressures is about 0.4 bar. The oscillation period (τ) of sample in the vibrating U tube was converted into density (ρ) via

$$[1] \qquad \rho = A(\tau^2 - B)$$

where A and B are instrument constants determined, at high pressure, by using isooctane (10), pure water (11), and 1,2-dichloroethane (10) as standard fluids. The values of parameter A, determined from the calibration, were treated as a function of pressure:

$$A = 0.652\,85 - 3.17(10^{-6})\,P$$

B is assumed to be temperature and pressure-independent (B = 15.1489).

The accuracy of the reported densities was estimated to be 1×10^{-4} g cm^{-3}.

Results and discussion

The calculated values of the excess molar volume V^{E}_{m} for the studied mixtures are listed in Tables 2–4 and plotted against x in Fig. 1. Each set of results was fitted by the ordinary (unweighted) least-squares method to a polynomial of the form:

$$[2] \qquad V^{E}_{m}/(\text{cm}^3\ \text{mol}^{-1}) = x(1-x)\ \Sigma\, A_i\ (2x-1)^i$$

where x is the mole fraction.

The values of the coefficients A_i determined by the least-squares analysis and the standard deviations σ given by

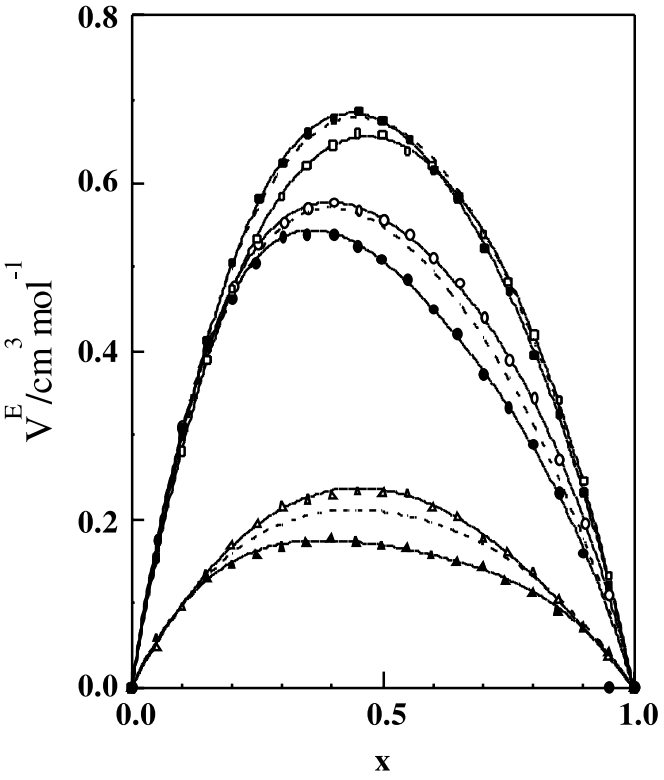
$$[3] \qquad \sigma(V^{E}_{m}) = [\Sigma(V^{E} - V^{E}_{exp})^2 / (N - M)]^{1/2}$$

where N is the number of experimental points and M is the number of fitting coefficients, are reported in Table 5.

To obtain the thermal expansion coefficients of the pure liquids, the experimental values of the obtained densities for each system, along with those published previously (5), have been fitted to a polynomial function:

$$[4] \qquad \rho/(g\ cm^{-3}) = \sum_{i=1}^{3}\sum_{j=1}^{3} A_{ij}(T - T_0)^{j-1} x^{i-1}$$

Fig. 1. Excess molar volumes, V^{E}_{m}, as a function of mole fraction: $(1 - x)$ 1,1,2-trichlorotrifluoroethane + x dibromomethane (circles), + x bromochloromethane (squares), or + x bromotrichloromethane (triangles). Open points, T = 288.15 K; closed points T = 308.15 K. Broken lines previous measurements (5) at T = 298.15 K.



where T_0 = 278.15 K.

The coefficients A_{ij} are reported in Table 6.

The thermal expansion coefficients α are therefore obtained at T = 298.15 K by using the equation:

$$[5] \qquad \alpha/K^{-1} = -1/\rho\ (\delta\rho/\delta T)_P$$

We have obtained the following values of α for pure liquids: $\alpha(CH_2Br_2) = 1.211 \times 10^{-3}$ K^{-1}; $\alpha(CH_2BrCl) = 1.369 \times 10^{-3}$ K^{-1}; $\alpha(CBrCl_3) = 1.260 \times 10^{-3}$ K^{-1}; $\alpha(C_2Cl_3F_3) = 1.700 \times 10^{-3}$ K^{-1}. Figure 2 shows the values of α for the studied systems at the temperature 298.15 K.

The measured densities for the pure liquids and binary mixtures at 298.15 K and pressure range 3–80 bar are reported in Tables 7–9. The isothermal compressibilities, $\kappa_T = -V^{-1}(\delta V/\delta P)_T$, were obtained at 298.15 K and 1 bar, and are reported in Table 10.

The "excess" compressibility, defined as

$$[6] \qquad \kappa^{E} = -V^{-1}\ (\delta V^{E}/\delta P)_T = \kappa - \phi_1\kappa_1 - \phi_2\kappa_2$$

where ϕ_1 and ϕ_2 are the volume fractions, is widely used. The values of κ^{E} of the studied systems are plotted against x in Fig. 3.

As shown in Fig. 2 and Table 10, dibromomethane and 1,1,2-trichlorotrifluorethane respectively exhibit the minima and maxima values of the thermal expansion coefficient and isothermal compressibility. This behaviour points to a relation between the increase in the molecular complexity of the

Fig. 2. Thermal expansion coefficient, α, as a function of mole fraction at 298.15 K: (1 – *x*) 1,1,2-trichlorotrifluoroethane + *x* dibromomethane (squares), + *x* bromochloromethane (circles), or + *x* bromotrichloromethane (triangles).

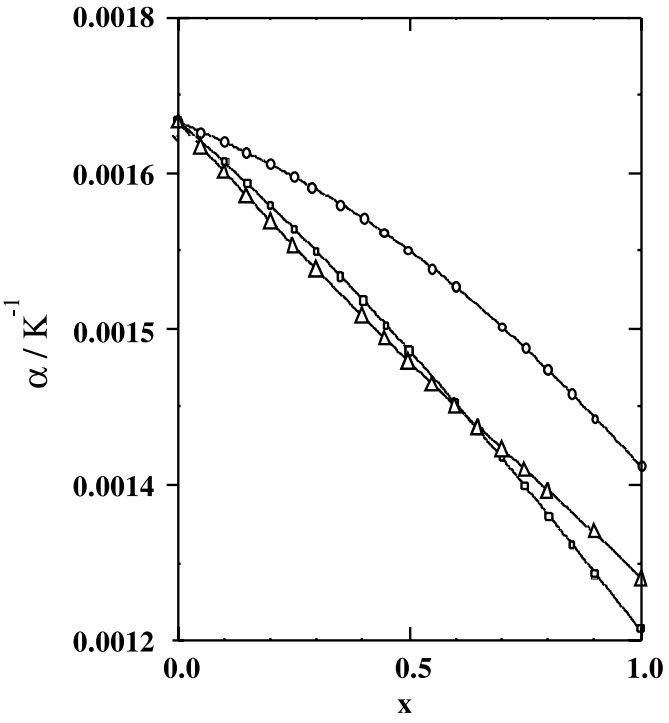

Fig. 3. Excess isothermal compressibility, κ^E, as a function of mole fraction at 298.15 K: (1 – *x*) 1,1,2-trichlorotrifluoroethane + *x* dibromomethane (—), + *x* bromochloromethane (---), or + *x* bromotrichloromethane (–·–·–).

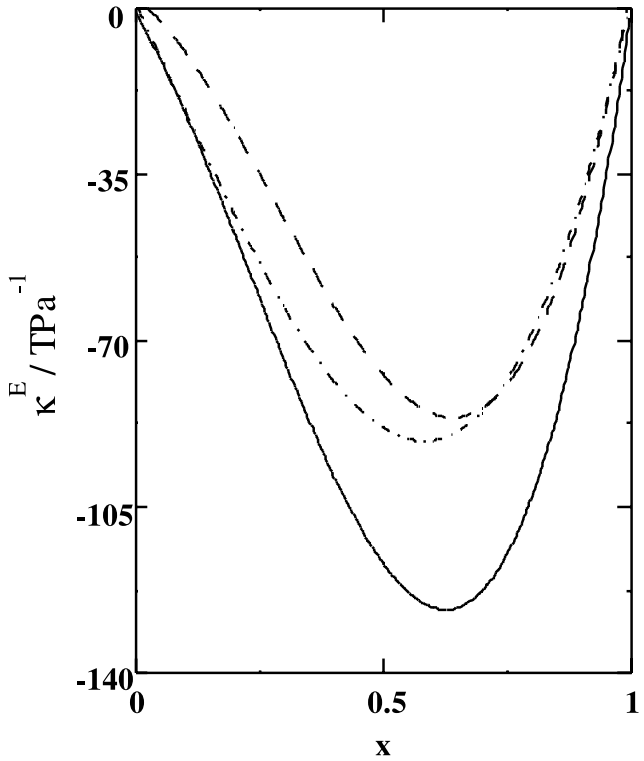

haloalkane (number of different halogen atoms in the molecule) and the corresponding increase of α and κ_T values. On the other hand, the density of these haloalkanes seems to change in the opposite direction to that of isothermal compressibility, demonstrating that any increase in the density of the haloalkane could decrease the intermolecular free space and thereby the molecule's ability to be compressed.

The excess molar volumes (V_m^E) for all the studied mixtures are positive and increase according to the sequence: 1,1,2-trichlorotrifluoroethane + bromochloromethane > + dibromomethane > + bromotrichloromethane. Although in principle this volumetric behaviour is qualitatively similar to the calorimetric one (12), the geometrical ("free volume") effects in the mixture might be important contributors to V_m^E. The excess isothermal compressibilities (κ^E) are negative; however, the mixture 1,1,2-trichlorotrifluoroethane + dibromomethane shows the maximum deviation from the ideal. The explanation of this behaviour is difficult to provide with only these kinds of measurements, given the variety and complexity of the interactional and geometrical effects present in the pure polyhaloalkanes.

Semiempirical quantum chemical PM3 computations and evaluations of redox potentials, basicities, and dipole moments of the diphenylamine series as analytical reagents

Alexei N. Pankratov[1] and Andrew E. Shchavlev

Abstract: By evaluating the obtained results of PM3 computations, the following correlations were found: (*i*) the diarylamines redox potentials (*E*) with the first ionization potentials (*I*); (*ii*) the pK_a values characterizing both the amines nitrogen protonation and the carboxy substituted reagents dissociation via the COOH group, with the proton affinities of the corresponding diphenylamines and COO^--containing anions; (*iii*) the experimental values of the molecules dipole moments (μ) with the theoretical ones. The feasibility of the simple semiempirical quantum chemical evaluation of *E*, pK_a, and μ of the diphenylamine series as redox reagents was determined.

Key words: diphenylamine series, redox potential, pK_a, dipole moment, semiempirical quantum chemical evaluation.

Résumé : L'évaluation des résultats de calculs PM3 a permis d'établir les corrélations suivantes: (*i*) les potentiels redox de diarylamines (*E*) avec les premier potentiels d'ionisation (*I*); (*ii*) les valeurs de pK_a qui caractérisent la protonation de l'azote d'amines ainsi que la dissociation de réactifs portant des groupes carboxy via le groupe COOH avec les affinités protoniques des diphénylamines et des anions COO^- correspondants; (*iii*) les valeurs expérimentales des moments dipolaires des molécules (μ) et les valeurs théoriques. On a mis en évidence la possibilité de faire une évaluation chimique quantique semiempirique simple des paramètres *E*, pK_a et μ de la série diphénylamine comme réactifs redox.

Mots clés : série de la diphénylamine, potentiel redox, pK_a, moment dipolaire, évaluation chimique quantique semiempirique.

[Traduit par la Rédaction]

Introduction

Diphenylamine (DPA) and its substituted derivatives are widely distributed analytical redox reagents (1–4), antioxidants (5, 6), and drugs (7–9).

Homogeneous catalytic reactions of diarylamines oxidation catalyzed by copper(II), gold(III), manganese(II), ruthenium(IV), and iridium(IV) compounds are used for highly-sensitive, selective kinetic determination of these elements with the content level of 10^{-2} down to 10^{-6}% in different subjects, the lower limit of detectable concentrations being 1×10^{-3} down to 1×10^{-6} mg/mL. The corresponding techniques are characterized by a relative standard deviation s_r of 0.01 up to 0.13 and distinguished for the simple experimental procedures (3, 4, and refs. therein). The mechanism of the above catalytic processes includes most likely an increase in oxidation number of the element-catalyst (it's just an element to be determined) when interacting with an oxygen-containing large oxidant anion ($S_2O_8^{2-}$, VO_3^-, $Cr_2O_7^{2-}$, IO_3^-, IO_4^-). The catalyst with a greater oxidation number reacts with a DPA series compound to produce a deeply colored *N,N′*-diaryl-*p*-diphenoquinonediimine dication (1, 10–14). The analytical signal is registered spectrophotometrically.

Thus, the diphenylamines application is based on their oxidation reactions. The analytical significance of DPA derivatives, their selectivity to different oxidants (including the catalysts for the metals kinetic determination) and other important properties are due to the standard redox potentials $E°$ (instead of those, essentially the same formal potentials E^f found by the Walden method (15) are often used).

The diarylamines and their structural analogs capability for being oxidized in acidic media depends on the amines basicity, which is responsible for their reactive particles state, as well as for the reaction mechanism details (1, 10–14, 16, 17). The chemical behaviour of the carboxy substituted re-

agents on the oxidation in alkaline solutions is influenced by the acidic dissociation via the carboxy group (2, 18).

The diarylamines reactivity is also caused by their hydration (solvation), nonspecific contribution to which is related to the molecules dipole moments (μ). The μ values allow one to conclude on the feasibility and character of the interaction between the reactive species of any polarity.

Computational methods

The computations by means of the SCF MO LCAO PM3 method (19) were performed using the software from the MOPAC package (20, 21) with the complete geometry optimization (Broyden–Fletcher–Goldfarb–Shanno function minimizer) (22) involving Thiel's fast minimization algorithm (23). The preliminary optimization was realized by the molecular mechanics method (the MMX procedure) (24) with the software of the PCMODEL complex (24). In quantum chemical computations, the condition of the gradient norm not exceeding 0.02 kcal mol^{-1} $Å^{-1}$ was preset. In some cases, a sufficient decrease in gradient norm was achieved by means of abandonment of the Thiel's fast minimization routine (the key word NOTHIEL of the MOPAC package was applied), or under optimization with the Davidon–Fletcher–Powell method (key word DFP) (22), or by conducting double precision calculations (key word PRECISE), as well as using combined approaches involving the key words NOTHIEL, DFP, and PRECISE.

In calculating the rotational contributions to thermodynamic functions the symmetry number was taken as unity.

In the case of diphenylamines, whose molecules contain primary amino group NH_2, the primary nitrogen was considered to be protonated (25).

The linear regression analysis was performed with a confidence level of 0.95.

Results and discussion

The controlled-property molecular design of diphenylamines involves a priori evaluation of $E°$ (E^f), pK_a (K_a is either the acidity constant of the organic reagent's conjugate acid or the dissociation constant of diarylamine by the COOH group) and μ. Moreover, the aforesaid values measurement is often related to the experimental difficulties.

Protolytic, oxidative-reductive and polar properties of amino compounds could be predicted by means of quantum chemical methods. Earlier (26) we have found a correlation of the E^f values for DPA and its derivatives with the differences in total energies (computed by the INDO method) between cation radicals (oxidation intermediates in acidic media) and molecules. The polarographic oxidation half-wave potentials depend linearly upon the higher occupied molecular orbitals energies of depolarizers (27) and, hence, in accordance with Koopmans theorem (28), also upon their ionization potentials (I). An analogous relationship between $E°$ (E^f) and I may be reasonably suggested. The pK_a value can be determined to a significant extent by proton affinity (PA). The latter represents reaction enthalpy for a proton breaking-off in the gaseous phase:

$$BH^+ \rightarrow B + H^+$$

and is calculated by the formula (29, 30):

$$PA = \Delta H_f\ (B) + \Delta H_f\ (H^+) - \Delta H_f\ (BH^+)$$

where ΔH_f (H^+) = 367.163 kcal/mol (29, 30). When considering the amines protonation, we will assume B to be a reagent molecule. On studying the carboxy substituted diphenylamines dissociation, B means an anion with a COO^- group.

The aim of the present work is to reveal correlations between: (*i*) the experimental redox potentials (E) for the diphenylamine derivatives and the computed values of the first ionization potentials; (*ii*) pK_a for the diphenylamine series compounds and proton affinities; (*iii*) μ_{exper} and μ_{theor}.

The validity of the PM3 quantum chemical computations performed is confirmed for DPA by the reproduced standard gaseous-phase thermodynamic quantities: heat of formation (ΔH_f), entropy (S), Gibbs energy of formation (ΔG_f):

	ΔH_f, kcal/mol	S, cal mol^{-1} K^{-1}	ΔG_f, kcal/mol
Experiment (31)	48.20	97.5	82.00
Computed	51.33	102.6	83.59

Besides, for the series of organic compounds belonging to different classes and possessing various functional groups, we have established an accuracy of the most important thermodynamic and molecular characteristics reproduction by the MNDO, AM1 and PM3 methods (32, 33), as well as of the electronegativity, inductive and mesomeric parameters of the atomic groups (34). Among the mentioned methods, PM3 seems to provide satisfactory results in obtaining the heats of formation for nitro derivatives (19, 32) and dimethylsulphone (32). Many of the NO_2 and SO_2 group containing species are the subjects of our investigation. That is the reason for selecting the PM3 method for the purposes of this work.

The results obtained in the present work are shown in Tables 1–4.

We have found the following correlations (m is the number of considered points, r is the correlation coefficient, s_0^2 is the adequacy variance, e is the electron charge):

[1] $pK_a = A + B \times PA$ (kcal/mol)
$m = 10$, $A = -119.28 \pm 27.10$
$B = 0.5510 \pm 0.1259$ (mol/kcal)
$r = 0.9627$, $s_0^2 = 0.4280$

(for protonation of the nitrogen atom)

[2] $pK_a = A + B \times PA$ (kcal/mol)
$m = 7$, $A = -90.20 \pm 41.48$
$B = 0.2830 \pm 0.1241$ (mol/kcal)
$r = 0.9348$, $s_0^2 = 0.0436$

(for dissociation of the carboxylic group)

[3] $E = A + BI$
$m = 32$, $A = -2.4594 \pm 0.5347$ (V)
$B = 0.3822 \pm 0.0641$ (e^{-1})
$r = 0.9121$, $s_0^2 = 0.0039$

(for diarylamines)

Table 2. Computed heats of formation of anions (B) and molecules (BH^+) of carboxy substituted diarylamines, proton affinities and experimental pK_a values of COOH groups dissociation.

Compound	Heat of formation, kcal/mol		PA, kcal/mol	pK_a[a]
	ΔH_f (B)	ΔH_f (BH^+)		
2-Carboxy-DPA	–70.01	–35.84	332.99	3.99
2-Carboxy-2′-methyl-DPA	–76.33	–45.70	336.53	4.90
2-Carboxy-3′-methyl-DPA	–79.49	–45.97	333.64	3.94
2-Carboxy-3′-methoxy-DPA	–107.82	–73.18	332.52	4.18
2-Carboxy-4′-methoxy-DPA	–107.73	–74.78	334.21	4.44
2,2′-Dicarboxy-DPA	–153.48	–123.02	336.70	5.26
2-Carboxy-2′-nitro-DPA	–75.41	–40.90	332.65	3.85

[a]Taken from ref. 36. Experimental pK_a values determined by spectrophotometric method (for 2,2′-dicarboxy-DPA, by potentiometric technique).

[4] $E = A + BI$
$m = 34$, $A = -0.7085 \pm 0.2452$ (V)
$B = 0.1183 \pm 0.0199$ (e^{-1})
$r = 0.9058$, $s_0^2 = 0.0035$

(for diarylammonium cations)

[5] $\mu_{exper} = B\mu_{theor}$,
$m = 37$, $B = 0.9675 \pm 0.0737$
$r = 0.9337$, $s_0^2 = 0.7755$

The occurrence of the [1] and [2] type dependences is remarkable (in spite of the fact that 24 and 6 compounds, respectively (35, 36, 41, 46), were not included in the above relationships), because, in general, there is no simple relationship between acid–base properties of protolytes in aqueous solutions and proton affinities in the gaseous phase due to a substantial role played by the medium.

The linear correlation of redox potentials (35–46) with the amines' conjugate acids is ionization potentials is in agreement with the data from (1, 10, 11) concerning the participation of the reagents' protonated forms in redox reactions taking place in acidic media.

The μ_{exper} and μ_{theor} values for 3-nitro-DPA, 2,2′-dihydroxy-DPA, 2-nitro-*N*-methyl-DPA, 2,2′-dicarboxy-DPA, 4,4′-dicarboxy-DPA, and 2,2′-dinitro-4-methyl-4′-methoxy-DPA were excluded from the correlation series $\mu_{exper} = B\mu_{theor}$ because for the listed reagents the discrepancy between the experimental and theoretical dipole moments is close to 2D (in the case of 2-nitro-*N*-methyl-DPA) or exceeds 2D. Therefore, agreement between experimental and computed dipole moments was used as a criterion for inclusion of the compounds in the correlation calculations. The above mentioned discrepancy may well be due to factors not taken into account in the computations, such as atomic vibrations, internal rotation of the molecules, and the possibility of the latters' existence as mixtures of conformers.

Using eqs. [1]–[5], one can predict the *E*, pK_a, and μ values for the DPA series redox reagents, construct the compounds with the desired protolytic, oxidative–reductive properties, as well as polarity. The relatively high dipole moments of the diphenylamine molecules serve as a premise to the facilitated amines interaction with charged or polar oxidant species, to the amines effective solvation by polar solvents and, therefore, to the oxidation mechanisms' similarity with respect to different diarylamines (1, 10–14).

We have demonstrated the predictive power of eqs. [3] and [4] on the following example. Recently Mushtakova et al. (51) synthesized new redox reagents 4-sulphotriphenylamine (**1**), 4,4′-disulphotriphenylamine (**2**), 2-nitro-4′-sulpho-DPA (**3**), 3-nitro-4′-sulpho-DPA (**4**), 4-nitro-4′-sulpho-DPA (**5**), and determined their E^f_{exper} values. Using the PM3 method, for compounds **1**–**5** and their conjugate acids we computed first ionization potentials. Inserting the latter in [3] and [4] lets one obtain E^f_{theor} values, which are in good agreement with the experimental data:

[a]Taken from refs. 47–50. Measured by the second Debye method.

The proposed approach in the present work for estimating *E*, pK_a, and μ values of the diarylamines aims to evaluate the molecular structure and may possibly be extended to other classes of analytical reagents and organic compounds in general.

Reactions of monovalent ions with a versatile building block $[Cr(phen)(C_2O_4)_2]^-$. Molecular and crystal structures of $NaCr(phen)(C_2O_4)_2 \cdot 3H_2O$, $KCr(phen)(C_2O_4)_2 \cdot DMF \cdot 0.5H_2O$, 4-$NH_3py[Cr(phen)(C_2O_4)_2] \cdot 2H_2O$, *N*-(*n*-butyl)$_4[Cr(phen)(C_2O_4)_2]$, and $PPh_4[Cr(phen)(C_2O_4)_2]$

Fernande D. Rochon and Gassan Massarweh

Abstract: The molecular and crystal structures of the products of the reaction between the building block $[Cr(phen)_2(C_2O_4)_2)]^-$ and several monovalent ions, two from the alkaline group (Na^+, K^+) and 4-NH_3pyridine$^+$, *N*-(*n*-butyl)$_4^+$, and PPh_4^+ were studied by crystallographic methods. $Na(Cr(phen)_2(C_2O_4)_2) \cdot 3H_2O$ (**1**) is monoclinic, $P2_1/c$, a = 9.129(2), b = 13.867(2), c = 17.934(5) Å, β = 117.52(2)°, Z = 4 and R = 0.0623. The sodium atom is surrounded by six oxygen atoms at distances between 2.363(6) and 2.484(8) Å. The Na···Na distance is 3.693(7) Å. The compound has an extended structure forming layers, held together by H bonds. $K(Cr(phen)_2(C_2O_4)_2) \cdot DMF \cdot 0.5H_2O$ (**2**) is monoclinic, $P2_1/n$, a = 11.298(2), b = 14.048(5), c = 14.240(5) Å, β = 108.19(2)°, Z = 4 and R = 0.0647. The material also possesses an extended 2D structure, but quite different from the one of the sodium compound. The coordination number around the K atom is 6 with K—O distances between 2.663(13) and 2.920(9) Å. The K···K distance is 3.939(9) Å. The other crystals 4-NH_3py$[Cr(phen)_2(C_2O_4)_2] \cdot 2H_2O$ (**3**), *N*-(*n*-butyl)$_4[Cr(phen)_2(C_2O_4)_2]$ (**4**), and $PPh_4[Cr(phen)(C_2O_4)_2]$ (**5**) have simple discrete ionic structures. Crystal **3** is monoclinic, *Cc*, a = 17.282(5), b = 15.037(3), c = 9.563(2) Å, β = 115.25(2)°, Z = 4, and R = 0.0386. The ions are held together by an extensive hydrogen bonding system involving the two molecules of water located in the lattice. Crystal **4** is monoclinic, $P2_1/c$, a = 12.329(3), b = 14.471(3), c = 18.181(3) Å, β = 97.75(2)°, Z = 4, and R_1 = 0.076 and finally, **5** is monoclinic, $P2_1/c$, a = 13.231(2), b = 14.410(2), c = 18.758(4) Å, β = 106.00(1)°, Z = 4, and R_1 = 0.0517.

Key words: crystal structure, chromium, oxalato, phenanthroline, sodium, potassium, 4-aminopyridinium, tetrabutylammonium, tetraphenylphosphonium.

Résumé : Les structures moléculaires et cristallines des produits de réaction entre la brique $[Cr(phen)_2(C_2O_4)_2]^-$ et plusieurs ions univalents, dont deux du groupe alkalin (Na^+ et K^+) et 4-NH_3pyridine$^+$, *N*-(*n*-butyl)$_4^+$, et PPh_4^+ ont été déterminées par diffraction des rayons-X. La réaction avec l'ion sodium a produit un composé contenant une structure étendue, formant des feuillets liés par des ponts hydrogènes. $Na(Cr(phen)_2(C_2O_4)_2) \cdot 3H_2O$ (**1**) est monoclinique, $P2_1/c$, a = 9.129(2), b = 13.867(2), c = 17.934(5) Å, β = 117.52(2)°, Z = 4 et R = 0.0623. Les atomes de sodium sont entourés de six atomes d'oxygène à des distances variant de 2.363(6) à 2.484(8) Å. La distance Na···Na est 3.693(7) Å. $K(Cr(phen)_2(C_2O_4)_2) \cdot DMF \cdot 0.5H_2O$ (**2**) est monoclinique, $P2_1/n$, a = 11.298(2), b = 14.048(5), c = 14.240(5) Å, β = 108.19(2)°, Z = 4 et R = 0.0647. Ce produit possède aussi une structure étendue 2D, mais différente de celle du cristal **1**. Le nombre de coordination du K est 6, avec des distances K—O de 2.663(13) à 2.920(9) Å. La distance K···K est 3.939(9) Å. Les autres cristaux 4-NH_3py$[Cr(phen)_2(C_2O_4)_2] \cdot 2H_2O$ (**3**), *N*-(*n*-butyl)$_4[Cr(phen)_2(C_2O_4)_2]$ (**4**) et $PPh_4[Cr(phen)_2(C_2O_4)_2]$ (**5**) possèdent des structures ioniques simples. Le cristal **3** est monoclinique, *Cc*, a = 17.282(5), b = 15.037(3), c = 9.563(2) Å, β = 115.25(2)°, Z = 4 et R = 0.0386. Les ions sont liés par un système important de ponts hydrogènes impliquant les deux molécules d'eau du réseau. Le cristal **4** est monoclinique, $P2_1/c$, a = 12.329(3), b = 14.471(3), c = 18.181(3) Å, β = 97.75(2)°, Z = 4 et R_1 = 0.076 et finalement, **5** est monoclinique, $P2_1/c$, a = 13.231(2), b = 14.410(2), c = 18.758(4) Å, β = 106.00(1)°, Z = 4 et R_1 = 0.0517.

Mots clés : structure cristalline, chrome, oxalato, phénanthroline, sodium, potassium, 4-aminopyridinium, tétrabutylammonium, tétraphénylphosphonium.

Introduction

The search for new molecular based magnets (1) and precursors in the synthesis of superconducting materials (2) has recently greatly increased the interest in 2D and 3D oxalato-bridged compounds. Several homometallic (3–8), heterometallic (9–12) and mixed-valent complexes have lately been reported (13).

We have recently started a study on the ability of a new building block for the design of heteropolymetallic magnetic systems. This versatile building block, $[Cr(AA)(C_2O_4)_2]^-$ (AA = bipy or phen) is able to generate extended structures systems with quite novel topologies of the metallic centers (14, 15). The synthetic approach takes advantage of the well known bridging ability of the oxalato groups and of the relative inertness of the chromium(III) complexes towards substitution reactions. The synthetic route is straightforward and consists normally in reacting a barium-chromium precursor with the appropriate metal sulfate. We have shown (14, 15) that the $[Cr(bipy)(C_2O_4)_2]^-$ complex anion can efficiently act as a ligand towards bivalent cations (Ba^{2+}, Mn^{2+}, Co^{2+}, and Cu^{2+}), leading to completely different structures, in spite of the stoichiometric similarity of some of the crystalline materials: $MCr_2(bipy)_2(C_2O_4)_4(H_2O)_n{\cdot}mH_2O$, M = Ba(II), Co(II), Cu(II), $n = 2$, $m = 1$ (1.5 for Cu(II)); M = Mn(II), $n = 0$, $m = 0$. The overall structures of these heterometallic systems are strongly influenced by the coordination number of the bivalent metal ion. The barium derivative is a scaffolding-like material with a three-dimensional structure and 10-coordinated barium atoms, the manganese derivative exhibits a new type of heterobimetallic chains with octacoordinated manganese atoms, whereas the structures of the cobalt(II) and copper(II) compounds consist in discrete linear Cr-M-Cr trinuclear species and hexacoordinated metal atoms.

To study the role of the oxidation state of the assembling cation on the coordinating properties of the building block $[Cr(phen)(C_2O_4)_2]^-$, we have undertaken a study on monovalent cations. We have already studied the influence of the stoichiometry on the overall structure of the heterometallic system, with the reaction with a monovalent cation, namely silver(I) with the $[Cr(bipy)(C_2O_4)_2]^-$ brick. The results have shown that the crystal contains discrete tetranuclear cycles formed by two chromium and two silver atoms bridged by the oxalato groups (15). The silver atoms are pentacoordinated, exhibiting distorted trigonal bipyramidal geometries. It became interesting to determine how other monovalent ions, especially the non-transitional metals, can influence the self-assembling process. The product of the reaction of the $[Cr(bipy)(C_2O_4)_2]^-$ brick with sodium was recently reported (16). The results have shown that the product has a two-dimensional structure. We have now studied a similar reaction between the $[Cr(phen)(C_2O_4)_2]^-$ brick with five monovalent non-transitional ions; two from the alkaline group (Na and K ions) and three organic ions: 4-aminopyridinium, tetra-*n*-butylammonium and tetraphenylphosphonium. The Na and K ions are smaller in size than the Ba atom. The 4-aminopyridinium ions are interesting since they can form bonds with metallic centers and they also usually form H bonds with the oxalato ligands. Tetraalkylammonium or tetraphenylphosphonium ions, on the contrary, cannot bind to metals nor form any H bonds. But, the latter crystals could contain molecules of solvent able to generate H-bonding systems. Even without the presence of solvation, the results on discrete structures present some interest for comparison with extended structures. The results of this study on the reactions of these five univalent ions with the building block $[Cr(phen)(C_2O_4)_2]^-$ are described below.

Experimental

The chemicals were purchased from Aldrich and all manipulations were performed using materials as received. The IR spectra (KBr pellets) were recorded on a Perkin–Elmer 783 spectrometer. The two compounds, $Ba(Cr(phen)(C_2O_4)_2)_2{\cdot}4H_2O$ and $KCr(phen)(C_2O_4)_2$ were synthesized as described in the literature (17, 18). The K compound was recrystallized from a 1:1 mixture solution of DMF and H_2O and crystals identified by crystallographic methods as $K(Cr(phen)_2(C_2O_4)_2){\cdot}DMF{\cdot}0.5H_2O$ (**2**) were isolated. The Na compound (**1**) was also isolated following the same method used to prepare the K compound, substituting $K_2C_2O_4$ by $Na_2C_2O_4$. It was recrystallized in water.

$M(Cr(phen)(C_2O_4)_2)$ (M = Na (1), K (2)):

The Na and K compounds were also prepared by this second method. A suspension of $Ba(Cr(phen)(C_2O_4)_2)_2{\cdot}4H_2O$ (0.5 mmol) in 50 mL of water was reacted with a stoichiometric amount of M_2SO_4 dissolved in 10 mL of water. The mixture was then stirred at room temperature for about 15 h to promote the complete precipitation of barium sulfate, which was removed by filtration. Reddish crystals were obtained by slow concentration of the aqueous solution. The yields were about 80%. The compounds were recrystallized from water (**1**) or from a mixture of water and DMF (**2**).

A third method was used, especially for the preparation of the 4-pyNH$_3$ (**3**), (n-butyl)$_4$) (**4**) and the PPh$_4$ compounds (**5**). A suspension of $Ba(Cr(phen)(C_2O_4)_2)_2{\cdot}4H_2O$ (0.05 mmol) in 20 mL of water was reacted with a stoichiometric amount of Ag_2SO_4 dissolved in 10 mL of water. The mixture was then stirred at room temperature for about 15 h to promote the complete precipitation of barium sulfate, which was removed by filtration. A methanol solution (0.12 mmol) of the chloride salt of 4-pyNH$_3^+$ (for **3**), (n-butyl)$_4^+$ (for **4**)$^+$, or PPh$_4^+$ (for **5**) was then added and the AgCl precipitate removed by filtration. Red crystals were obtained by slow evaporation of the H_2O–CH_3OH solution. Crystals adequate for crystallographic studies were grown from H_2O–CH_3OH (**4** and **5**), water (**3**), or DMF (**4**).

Crystallographic measurements and structure resolution

The crystals were selected after examination under a polarizing microscope for homogeneity. The data collection was made at room temperature on a Siemens P4 diffractometer with graphite-monochromatized MoKα radiation (λ = 0.71073 Å). The Siemens XSCANS program was used for the data collection. The unit cell parameters were obtained by least-squares refinement of the angles 2θ, ω and χ for about 40 well-centered reflections. Crystal **4** (*N*-Bu$_4^+$ salt) was smaller than the other crystals and it appeared of poorer quality. Attempts to obtain better crystals were not successful. Two different crystals were measured and the results presented here are those which gave the best results. The K$^+$ compound (crystal **2**) was not stable and decomposed regularly on the diffractometer. A great number of crystals coated with different kinds of grease or glue were studied without success. Finally one crystal gave suitable data. The data collection stopped when the three standard reflections were below 50% of their initial intensity. About 65% of the data collection had then been measured. Therefore, the structure was solved and refined with a partial data collection. The high-angle reflections were missing. For this reason, the number of observed data is limited, but the results are excellent considering the problems encountered. An absorption correction based on the equations of the crystal faces was made for crystal **2**.

The coordinates of the heavy atoms were determined from direct methods and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The refinement of the structures was done by full-matrix least-squares analysis, except for crystal **2** (K$^+$ compound) which was refined in blocks due to the limited number of observed data and the high number of parameters. All the non-H atoms were refined anisotropically. The H atoms, except those of the water molecules, were fixed at their calculated positions (riding model). Most of the H atoms on the water molecules were located and refined. Crystal **1** contains three water molecules. W1 and W3 are located in the crystal lattice while W2 was found in the close environment of the Na atom, disordered on two close positions with occupation factors of 0.6 and 0.4. W3 is also disordered on three positions with occupation factors of 0.4, 0.3, and 0.3. Crystal **2** contains one molecule of DMF in the close environment of K and 0.5 molecule of water in the lattice close to an inversion centre, while crystal **3** contains two lattice molecules of water. The calculations were done on a SHELXTL[2] system. The refinement was done on F for crystals **1**, **2**, **3** and on F^2 for crystals **4** and **5**. The crystallographic data and the most pertinent information are summarized in Table 1.[3]

Results and discussion

Our synthetic approach towards monovalent ion–chromium(III) complexes, involve the reaction of the Ba(Cr(phen)(C$_2$O$_4$)$_2$)$_2$ precursor with a stoichiometric quantity of the corresponding sulfate salt. This method is very simple and seems to have a large applicability with almost any monovalent or divalent ions.

$$\mathrm{Ba(Cr(phen)(C_2O_4)_2)_2 + M_2SO_4 \rightarrow 2MCr(phen)(C_2O_4)_2 + BaSO_4}$$

The Na$^+$ and K$^+$ complexes were prepared following this method. If the metal is Ag, it can, in a further step, be precipitated with the chloride salt of the required cation as follows:

$$\mathrm{AgCr(phen)(C_2O_4)_2 + MCl \rightarrow MCr(phen)(C_2O_4)_2 + AgCl}$$

Crystals **3** (4-NH$_3$py), **4** (*n*-butyl)$_4$), and **5** (PPh$_4$) were prepared following this procedure.

The sodium compound was also synthesized directly by the method reported for the preparation of the K$^+$ compound (17, 18) in a 1:1 DMF–H$_2$O mixture. The 4-aminopyridinium compound was also obtained in an attempt to isolate a nickel compound. NiSO$_4$ was added to Ba(Cr(phen)(C$_2$O$_4$)$_2$)$_2$ and after the removal of BaSO$_4$, 4-aminopyridine was added to the solution. Crystals which proved to be 4-NH$_3$py [Cr(phen)(C$_2$O$_4$)$_2$]·2H$_2$O (**3**) were characterized by crystallographic methods. All these compounds are relatively easy to prepare, but crystals suitable for crystallographic analysis are difficult to prepare.

The results of the crystallographic studies of the Na$^+$ and K$^+$ compounds have shown that the materials are different even if the size of the two ions are not very different. The coordination number around the alkali metal is the same but the binding mode of the Cr-oxalato group is quite different.

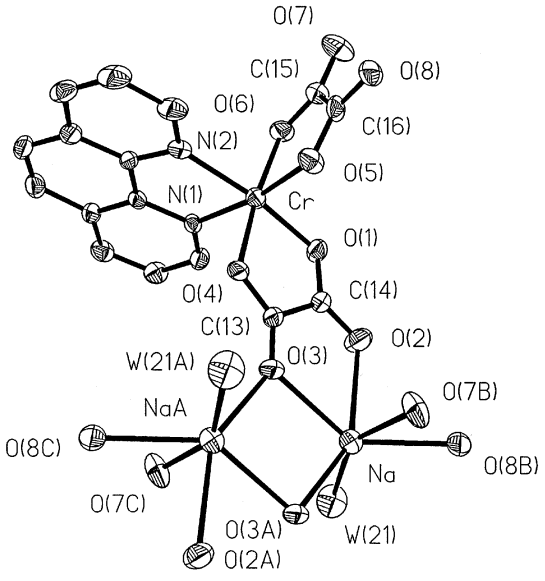
Fig. 1. Drawing of $NaCr(phen)(C_2O_4)_2 \cdot 3H_2O$ (**1**) showing the environment around the Na atoms, with the atom-numbering scheme. For clarity, only the main component is shown for the aqua ligand (W(21)). (The ellipsoids correspond to 30% probability.)



$Na(Cr(phen)(C_2O_4)_2) \cdot 3H_2O$ (1)

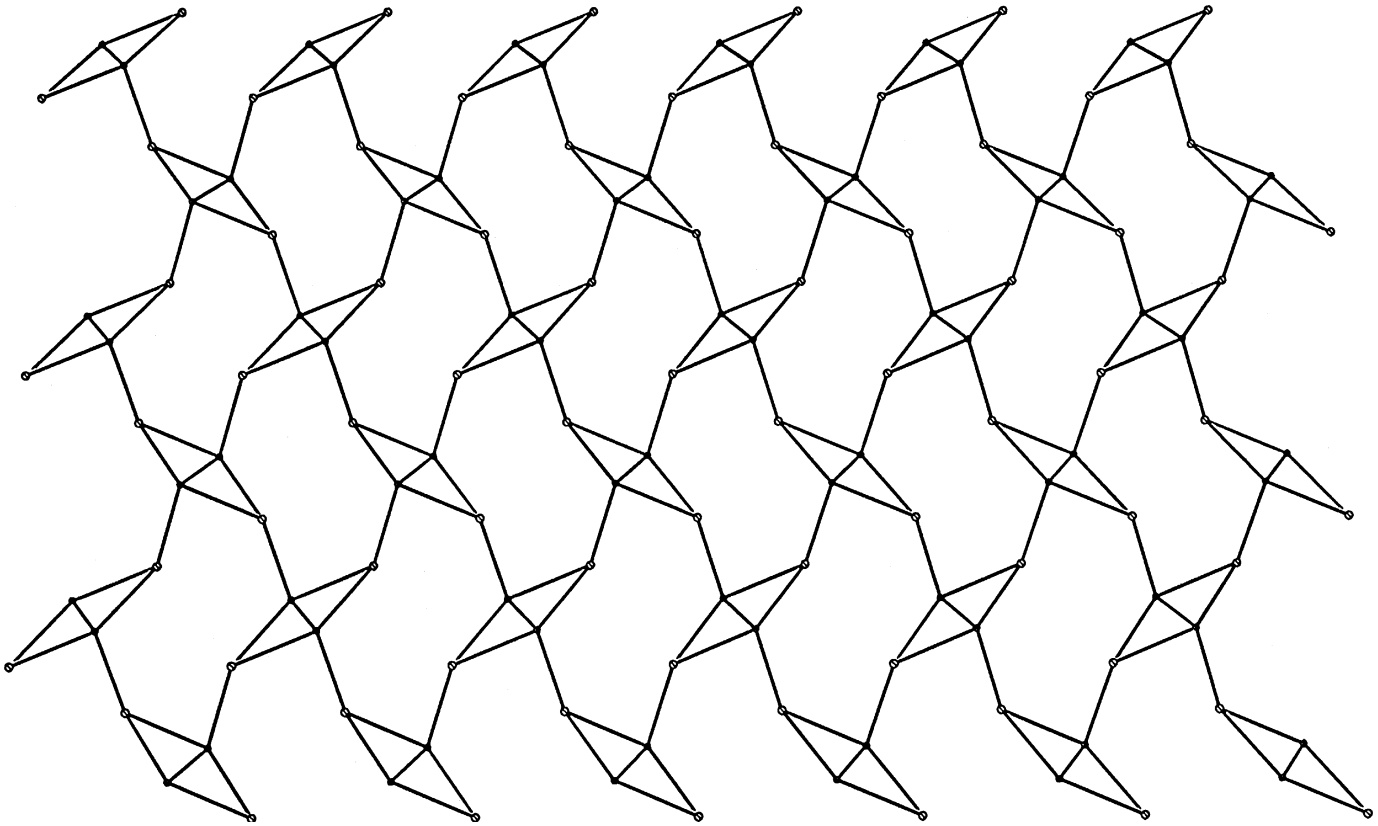
Crystals of the sodium compound $Na(Cr(phen)(C_2O_4)_2) \cdot 3H_2O$ (**1**) have an extended layer structure, where the sodium atoms join the chromiun complexed ions. The inversion center is between the two Na atoms. The Na···Na distance is relatively short, 3.693(7) Å. A labelled diagram showing the environment around the Na atoms is shown in Fig. 1. The environment of the sodium atoms has a distorted octahedral geometry with five short Na···O(oxalato) distances from 2.363(6) to 2.484(8) Å. One of the oxalato oxygen atoms, O(3), forms a bridge between the two Na atoms at distances Na—O(3) = 2.456(7) Å and Na—O(3A) = 2.363(6) Å. The sixth position is occupied by an aqua ligand which is disordered on two close positions with Na—W2 distances = 2.447(13) and = 2.367(20) Å. Selected bond distances and angles are shown in Table 2. The Cr—O bonds vary between 1.952(5) and 1.967(5) Å, while the Cr—N bonds are 2.051(7) and 2.080(7) Å. The angles around Cr are normal with chelate angles being smaller (O-Cr-O = 83.0(2)°, 83.6(3)°, and N-Cr-N = 79.8(3)°) than the other angles, as expected.

There are two different modes of bonding for the oxalato ligands (Scheme 1). The first type is the normal bridging bidentate mode, while in the second type, one O atom (O(3)) forms a further bond with the second metallic center of the pillar. There are two types of C—O bonds in the oxalato ligands. Those bonded to Cr have an average bond length of 1.285(9), while those in the close environment of the Na atoms are shorter, with an average value of 1.223(10) Å, indicating a lower multiplicity of the C—O bonds attached to Cr than those around the Na atoms. The O(3)—C(13) bond forming the bridge between the two Na atoms is not different 1.220(9) Å. The angles around O(3) are Na-O(3)-C(13) = 115.4(5)°, Na-O(3)-NaA = 100.1(2)°, and NaA-O(3)-C(13) = 144.4(5)°.

The 2D structure of the compound is quite interesting. The two oxalato ligands act as bridges between the sodium and the chromium atoms with Cr···Na distances of 5.570, 5.713, and 5.865 Å. One sheet of material can be seen in Fig. 2, which shows only the Na and Cr atoms. The two Na atoms can be considered as forming a pillar and have been

© 1999 NRC Canada

Fig. 2. Diagram of one sheet in the crystal $NaCr(bipy)(C_2O_4)_2 \cdot 3H_2O$ (**1**) showing only the Cr and Na atoms. The two Na atoms 3.693(7) Å apart have been joined and are in the center of the elongated parallelograms.



joined in the middle of the elongated parallelograms. The inversion center is also in the center of the two Na atoms. Large cycles containing four Cr and four Na atoms form large cavities (see Fig. 2) where the phenanthroline ligands are located (not shown in the figure). This structure could be compared to the 3D structure of the Ba-Cr(bipy) compound where the Ba and Cr atoms form chicken-wire sheets (14) which are further interconnected forming a 3D structure. The barium atoms have a coordination number of 10. Sodium atoms are smaller and should possess a lower coordination number. Therefore it cannot form a 3D structure, like the barium compound. In the present structure, the coordination number of the Na atoms is six including one aqua ligand.

Hydrogen bonds play an important stabilizing role in the crystal packing energy. The H-bonding system involving the lattice molecules of water and the aqua ligand with the oxalato O atoms is particularly important. The lattice molecules of water are located between the sheets, holding the different layers together. The O···O distances are acceptable but most of the molecules of water are disordered. Aromatic π–π stacking interaction of the phenanthroline ligands seem also to play an important role. The distances between the aromatic planes is about equal to the distance of the Na···Na atoms (3.7 Å).

$K(Cr(phen)(C_2O_4)_2)\cdot DMF\cdot 0.5H_2O$ (2)

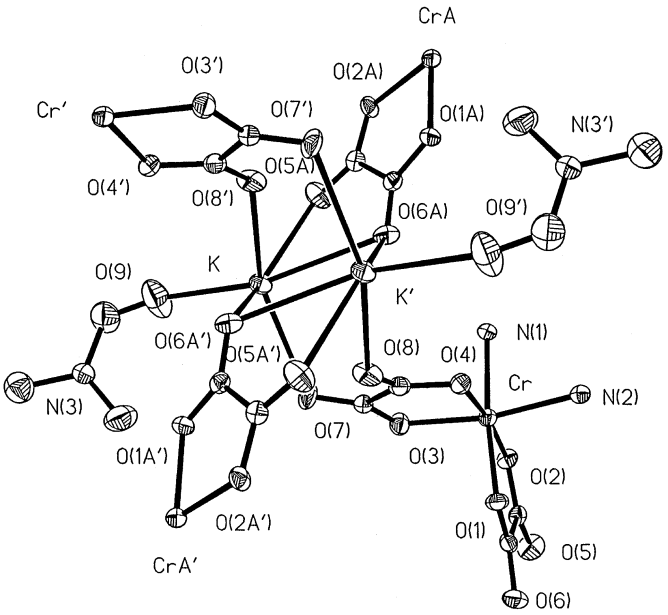
$K(Cr(phen)(C_2O_4)_2)\cdot DMF\cdot 0.5H_2O$ is unstable and it proved difficult to obtain a suitable set of data. This material crystallized with a molecule of DMF, bonded to the K atom through the O atom and 0.5 molecule of water located in the lattice, close to an inversion center. A labelled diagram showing the environment around the K atoms is shown in Fig. 3. The K atoms have a coordination number of six forming a very distorted octahedron. There are five O atoms from the oxalato ligands with K—O distances between 2.713(10) and 2.981(11) Å and the sixth K—O(DMF) bond is 2.663(13) Å. The K···K distance is quite short, 3.939(9) Å, and the center of inversion is located between the two K atoms, which can be described again as a pillar. This pillar is longer than the one in the Na compound (3.693(7) Å, but shorter than the one observed in the Ba-Cr(bipy) compound (4.138(3) Å) (14).

The K atoms are bridged by the chromium(III) complexed ions. There are two different bridging modes of the oxalato groups as shown in Scheme 1. Contrary to the Na compound, each oxalato ligand binds the two different K atoms which form the pillars. One oxalato ligand bonded to Cr through O(3) and O(4) is bonded to two different K atoms through O(7) and O(8). The second oxalato ligand, which is bonded to Cr through O(1) and O(2) is also bonded to two different K atoms through O(5) and O(6). Furthermore, O(6) is bonded to the second K atom of the pillar forming a bridge between the two K atoms (Fig. 3).

Selected bond distances and angles are shown in Table 2. The Cr—O bonds vary between 1.963(8) and 1.997(10) Å, while the Cr—N bonds are 2.092(7) and 2.083(9) Å. The angles around Cr are normal with chelate angles being smaller

© 1999 NRC Canada

Fig. 3. Structure of $KCr(phen)(C_2O_4)_2 \cdot DMF \cdot 0.5H_2O$ (**2**) showing the environment around the Na atoms, with the atom-numbering scheme (only the N of phen are shown).



(O-Cr-O = 83.7(4)°, 82.8(4)°, and N-Cr-N = 80.0(3)°) than the other angles, as expected.

The structure of the compound consists in infinite thick layers parallel to the ab plane. The 2D network containing only the Cr and the K atoms is shown in Fig. 4. The two K atoms forming the pillar are connected by four oxalato bridges to four different Cr atoms. The eight bridging K···Cr units form a four-tipped star around the K···K pillars. The K···Cr distances are 5.812 and 6.125 Å. These thick sheets are very similar to the ones found in the 3D compound $(BaCr_2(bipy)_2(C_2O_4)_4(H_2O))_n \cdot nH_2O$ described recently (14). In the latter structure, the Ba and Cr atoms form chicken-wire sheets, which are further inter-connected by second layers which are formed of four-tipped stars around the Ba···Ba pillars resulting in a scaffolding material with a unique neutral three-dimensional framework. The latter second sheets are exactly the same as those found in the K compound (crystal **2**). Barium atoms can accept a large coordination number because of its larger size. In this particular case, it is ten. The number of Cr-oxalato bridges between the Ba atoms is twice as large as the number found in the alkali compounds. It is quite remarkable that the K compound is so similar to the Ba complex, except for the third dimension, which is absent in the K compound.

The two differences between the Ba material (14) and the K and Na compounds described here, are the charges on the ions and their sizes. It would be most pertinent now to prepare a larger alkali compound (Rb or Cs) where the metal size would be closer to the one of the Ba compound. This work is in progress.

The K compound crystallized with a disordered molecule of water in the lattice close to an inversion center. Therefore, the occupation factor of the molecule is 0.5. The positions of the two H atoms of the water molecules seem to be disordered. The DMF ligands bonded to the K atoms are oriented towards the outside of the layers where the water molecules are also located. The water molecules form H bonds be-

Fig. 4. Diagram of one layer in the crystal $KCr(phen)(C_2O_4)_2 \cdot DMF \cdot 0.5H_2O$ (**2**) showing only the Cr and K atoms.

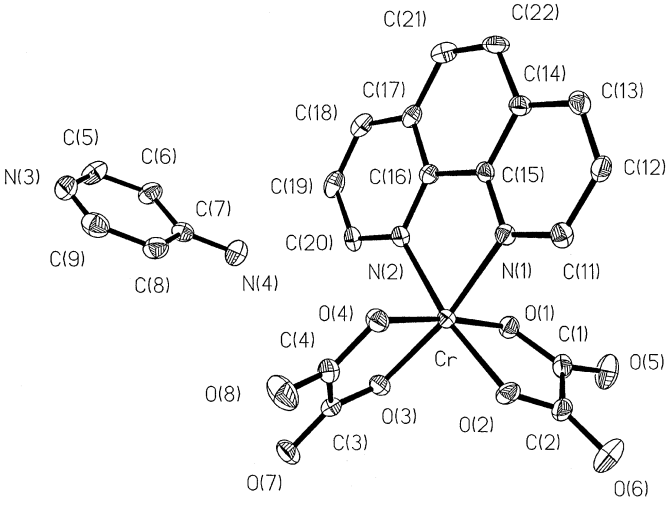
Fig. 5. Molecular structure of 4-NH_3py[Cr(phen)(C_2O_4)$_2$]·2H_2O (**3**) with the atom-numbering scheme. (The ellipsoids correspond to 30% probability.)



tween the different layers with W···O distances of 2.888 and 3.065 Å.

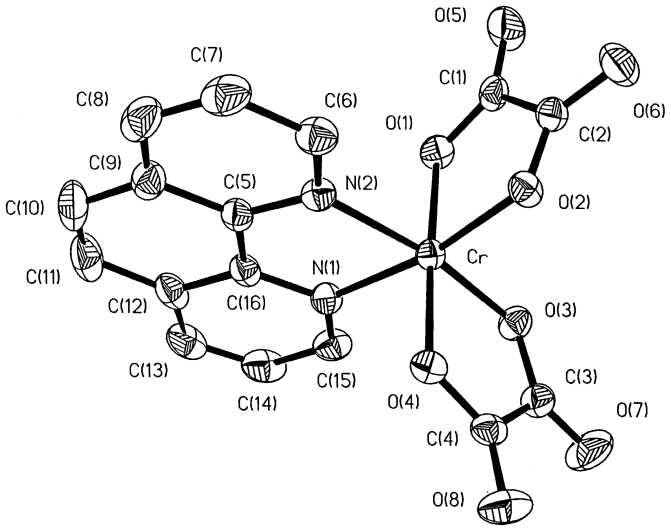
4-NH_3py[Cr(phen)(C_2O_4)$_2$]·2H_2O (3)

The structure of **3** consists of discrete 4-aminopyridinium and [Cr(phen)(C_2O_4)$_2$]$^-$ ions and two molecules of water located in the crystal lattice. A labelled diagram of the ions is shown in Fig. 5. Selected bond distances and angles are collected in Table 2. The geometry around Cr is a distorted octahedron with Cr—O bond distances between 1.945(4) and 1.980(4) Å and Cr—N bonds of 2.073(4) and 2.079(4) Å. The oxalato chelate angles are 82.7(1)° and 82.5(1)°, while the N-Cr-N angle is 79.9(2)°. The other *cis* angles are slightly greater than 90°, while the *trans* angles vary between 169.7(1)° and 174.2(1)°. The [Cr(phen)(C_2O_4)$_2$]$^-$ ions contain terminal oxalato ligands. As expected, the C—O bonds which are coordinated to Cr are significantly longer (avg. 1.293(5) Å) than the terminal C—O bonds (avg. 1.221(6) Å).

Surprisingly, the proton could not be located even if the structure was well refined and the residual electronic density was found quite low (<0.28 e Å^{-3}). The amino group (N(4)) on the pyridine ligand is the most basic, but only two H atoms were located and refined. The angles C(7)-N(4)-H are 115.4(12)° and 118.0(12)°. These larger values seem to confirm that the additional proton is effectively on the amino group. A free pair of electrons on N(4) would reduce the C(7)-N(4)-H angles to <109°. The internal angle at the pyridine N atom is 120.6(4)°. The pyridine ring is planar and N(4) is also in the same plane. The C(7)—N(4) bond is 1.323(5) Å and the internal angle around C(7) is slightly smaller (117.4(4)°) than the five others (119.6(5)–121.5(5)°).

The ions are held together by an elaborate hydrogen bonding system involving the two molecules of water located in the lattice, forming an extensive H-bonded 3D network. The protonated amino group is hydrogen bonded to O(6) (N(4)···O(6) = 2.950 Å) and to one molecule of water (N(4)···W(1) = 2.847 Å) with reasonable angles C(7)-N(4)···W(1) = 127.9° and C(7)-N(4)···O(6) = 114.9°. W(1) is also H-bonded to O(8) (distance = 2.854 Å) and to the second molecule of water (W(1)···W(2) = 2.938 Å). There are three other short contacts around W(2) with O(7) at 2.807 and 2.870 Å and with N(3) at 2.801 Å. Aromatic stacking interactions seem to play a stabilizing role in the crystal packing. The phenanthroline planes are all parallel to the *b* axis.

Fig. 6. Labelled diagram of the complexed anion in PPh_4[Cr(phen)(C_2O_4)$_2$] (**5**). The ellipsoids correspond to 30% probability. The labelling scheme for the Cr(III) anion is the same in crystal **4**.



N-(*n*-Butyl)$_4$[Cr(phen)(C_2O_4)$_2$] (4) and PPh_4[Cr(phen)(C_2O_4)$_2$] (5)

The structure of crystals **4** and **5** consists of discrete (*N*-(*n*-butyl)$_4$)$^+$ or (P(Ph)$_4$)$^+$ and [Cr(phen)(C_2O_4)$_2$]$^-$ ions, but it crystallized without any molecules of solvent. These crystals were recrystallized from a mixture of H_2O–CH_3OH. Identical crystals of **4** were also obtained from a DMF solution. Therefore, no H-bonds are expected in these crystals. A labelled diagram of the [Cr(phen)(C_2O_4)$_2$]$^-$ ion in **5** is shown in Fig. 6. The selected bond distances and angles are shown in Table 2. The same labelling scheme was used for the anions in crystals **4** and **5**. The results on both crystals are very similar, except for the higher standard deviations of crystal **4**, due to the limited number of observed data, as discussed in the experimental section.

As for the other crystals, the geometry around Cr is a distorted octahedron with Cr—O bond distances between 1.939(3)–1.960(4) Å for **4** and 1.941(2)–1.954(2) Å for **5**. The Cr—N bonds are 2.077(4), 2.104(4) Å, and 2.065(2), 2.087(2) Å for **4** and **5** respectively. The oxalato chelate angles are 82.8(2)°, 83.0(2)°, and 83.08(8)°, 82.96(8)°, while the N-Cr-N angle is 77.9(7)° and 79.62(9)° for **4** and **5** respectively. The other *cis* angles are close or slightly greater than 90°, while the *trans* angles vary between 170.8(2)° and 176.5(2)° for **4** and between 170.51(8)° and 177.68(8)° for **5**.

The [Cr(phen)(C_2O_4)$_2$]$^-$ ions contain terminal oxalato ligands. The C—O bonds coordinated to Cr are significantly longer (avg. 1.288(7) Å for **4** and 1.292(3) Å for **5**) than the terminal C—O bonds (avg. 1.216(6) and 1.211(3) Å, respec-

tively) as observed in **3**. It is interesting to compare these distances with those observed in the sodium and potassium materials. In crystals **1** and **2**, the C—O bonds in the close environment of the alkali metals are also shorter (avg. 1.223(10) Å for **1** and 1.231(14) Å for **2**) than those bonded to Cr (avg. 1.285(9) Å for **1** and 1.290(14) Å for **2**). The values observed for the bonds in the close environment of the alkali metals seem very slightly longer than the terminal bonds observed in crystals **4** and **5**. But the standard deviations on several values are quite high and the small observed differences are not significant at the moment. Further work is needed to confirm this hypothesis.

The (*N*-(*n*-butyl)$_4$)$^+$ ions seem normal. They are slightly flattened in order to occupy more space as shown by the slightly larger angles, especially those far from the N atom. The PPh$_4^+$ ions seem normal with an average P—C bond distance of 1.793(3) Å, and an average C-P-C angle of 109.45(13)°. Aromatic stacking interactions of the phenanthroline ligands seem to play a stabilizing role in the crystal packing as observed in other crystals.

Conclusions

In this paper, we have illustrated some new examples of the self-assembly of the building block $[Cr(phen)(C_2O_4)_2]^-$ with different univalent ions. The presence of metallic ions is an excellent synthetic strategy towards the preparation of heteronuclear complexes with extended structure and generates a rich coordination chemistry. Alkali metals like sodium and potassium studied in this work have produced very interesting 2D networks. The coordination number around the alkali metals in these compounds is six. The size of the metals is probably too small to produce 3D materials. Work is underway on the study of the reactions with heavier alkali metals. Organic ions like 4-aminopyridinium seem interesting, because of their abilities to form H-bonds and in some cases to bind metals, while other ions like tetraalkylammonium or tetraphenylphosphine ions, which cannot bind metals nor form H-bonds, are not useful in generating extending structures. But the crystallographic results of the ionic entities are useful for comparison with the extended structures. For example, these results have shown that the terminal C=O bonds of the oxalato ligands seem very slightly shorter than those coordinated to the alkali metals, although the differences might not seem significant at the moment.

The variety of structures described here and in the two previous papers (14, 15) on the reactions of metals with the building block $[Cr(bipy)(C_2O_4)_2]^-$ show the importance of the four following factors: the size, the stereochemical preference and the oxidation state of the assembling cation, and the very versatile coordination behavior of the oxalato ion. Scheme 1 illustrates all the different functions identified in the products of the reaction of the monovalent ions with the building block $[Cr(A\text{-}A)_2(C_2O_4)_2)]^-$ characterized by our research group.

Further types of oxalato bonding were observed in compounds containing bivalent cations (Ba^{2+}, Mn^{2+}, Co^{2+}, Cu^{2+}) which we have reported with the bipyridine brick $[Cr(bipy)(C_2O_4)_2]^-$ (14,15). Other factors, like hydrogen bonding and aromatic stacking interactions, can also play an important stabilizing role in the overall crystal architecture of these materials.

Lifetimes and UV-visible absorption spectra of benzyl, phenethyl, and cumyl carbocations and corresponding vinyl cations. A laser flash photolysis study

Frances L. Cozens, V.M. Kanagasabapathy, Robert A. McClelland, and Steen Steenken

Abstract: Benzyl (4-MeO, 4-Me, and 4-methoxy-1-naphthylmethyl), phenethyl (4-Me_2N, 4-MeO, 3,4-$(MeO)_2$, 4-Me, 3-Me, 4-F, 3-MeO, 2,6-Me_2, parent, and 4-methoxy-1-naphthylethyl) and cumyl (4-Me_2N, 4-MeO, 4-Me, parent) cations have been studied by laser flash photolysis (LFP) in 2,2,2-trifluoroethanol (TFE) and 1,1,1,3,3,3-hexafluoroisopropanol (HFIP). In most cases styrene or α-methylstyrene precursors were employed for the phenethyl and cumyl ions, the intermediate being obtained by solvent protonation of the excited state. Benzyl cations were generated by photoheterolysis of trimethylammonium and chloride precursors. While a 4-MeO substituent provides sufficient stabilization to permit observation of cations in TFE, cations with less stabilizing substituents usually require the less nucleophilic HFIP. Even in this solvent, the parent benzyl cation is too short-lived (lifetime <20 ns) to be observed. When generated in HFIP, phenethyl cations can be seen to react with unphotolyzed styrene, giving rise to dimer cations that are observed to grow in as the initial phenethyl cation decays. The dimer cations, in common with the oligomer cations seen in cationic styrene polymerization, have a λ_{max} 15–20 nm higher than the monomer and react with both solvent and styrene several orders of magnitude more slowly. This stabilization relative to the phenethyl may reflect an interaction with the aryl group present at the γ-carbon. Cations 4-$MeOC_6H_4C^+(R)$-CH_3 (R = Me, Et, i-Pr, *t*-Bu, cyclopropyl, C_6H_5, 4-$MeOC_6H_4$) were generated in TFE via the photoprotonation route. The alkyl series shows that steric effects are important in the decay reaction. The cation with R = cyclopropyl is a factor of 1.5 less reactive than the cation where R = phenyl. Several vinyl cations have also been generated by photoprotonation of phenylacetylenes. $ArC^+=CH_2$ has a reactivity very similar to that of its analog ArC^+H-CH_3, the vinyl cation being slightly (factors of 2–5) shorter-lived. For the various series of cations, including vinyl, substituents in the aryl ring have a consistent effect on the λ_{max}, a shift to higher wavelength relative to hydrogen of 15 nm for 4-Me, 30 nm for 4-MeO, and 50 nm for 4-Me_2N.

Key words: photogenerated carbocations, carbocation lifetime, styrene, photoprotonation.

Résumé : Faisant appel à la photolyse éclair au laser (« LFP »), on a étudié les cations de type benzyles (4-MeO et 4-Me ainsi que 4-méthoxy-1-naphtylméthyle), phénéthyle (4-Me_2N, 4-MeO, 3,4-$(MeO)_2$, 4-Me, 3-Me, 4-F, 3-MeO, 2,6-Me_2 et le fondamental ainsi que le 4-méthoxy-1-naphtyléthyle) et cumyle (4-Me_2N, 4-MeO, 4-Me et le fondamental) dans le 2,2,2-trifluoroéthanol (TFE) et le 1,1,1,3,3,3-hexafluoroisopropanol (« HFIP »). Dans la plupart des cas, des précurseurs de type styrène ou α-méthylstyrène ont été utilisés pour les ions de type phénéthyle et cumyle, obtenus par solvatation de l'état excité à l'aide d'un solvant. Les cations de type benzylique ont été générés par photohétérolyse de précurseurs triméthylammonium et chlorure. Un substituant 4-MeO fournit assez de stabilisation pour permettre d'observer les cations dans le TFE; toutefois, pour observer des cations portant des substituants moins stabilisants, il faut utiliser le « HFIP » qui est moins nucléophile. Même dans ce solvant, le temps de vie du cation benzyle fondamental est trop court (<20 ns) pour qu'on puisse l'observer. Quand on les génère dans le « HFIP », on peut observer la réaction des cations phénéthyles avec le styrène qui n'a pas réagi; cette réaction donne lieu à la formation de cations dimères dont on observe la croissance avec la décroissance du cation phénéthyle initial. Les cations dimères, comme les cations oligomères observés lors de la polymérisation cationique du styrène, ont un λ_{max} de 15 à 20 nm plus élevé que celui du monomère et leurs vitesses de réaction avec le solvant et le styrène sont de plusieurs ordres de grandeur plus faibles. La stabilisation relative du phénéthyle peut être un reflet d'une interaction avec le groupe aryle

présent sur le carbone γ. On a généré les cations 4-$MeOC_6H_4C^+(R)$-CH_3 (R = Me, Et, i-Pr, *t*-Bu, cyclopropyle, C_6H_5, 4-$MeOC_6H_4$) dans le TFE par le biais d'une réaction de photoprotonation. Les séries alkyles montrent que les effets stériques sont importants dans la réaction de désactivation. La réactivité du cation avec R = cyclopropyle est 1,5 fois moins grande que celle du cation dans lequel R = phényle. On a aussi généré plusieurs cations vinyliques par photoprotonation de phénylacétylènes. La réactivité d'ion $ARC^+=CH_2$ est très semblable à celle de son analogue ArC^+H-CH_3, le temps de vie du cation vinylique étant légèrement plus court (de 2 à 5 fois plus court). Pour les diverses séries de cations, y compris le cation vinyle, les substituants du cycle aromatique apportent un effet régulier sur le λ_{max}, soit des déplacements d'environ 15 nm (pour le 4-Me), 30 nm (pour le 4-MeO) et de 50 nm (pour le 4-Me_2N) vers une longueur d'onde plus grande par rapport au produit fondamental, portant un hydrogène.

Mots clés : carbocations photogénérés, temps de vie d'un carbocation, styrène, photoprotonation.

[Traduit par la Rédaction]

Laser flash photolysis (LFP) has been employed for a number of years for the observation of reactive intermediates and for the direct measurement of rate constants of their decay reactions. Photolyzing some precursor with a laser pulse initiates a rapid photochemical transformation to the reactive species of interest. This is detected by some method, in most cases absorption spectroscopy, and the decay directly monitored. In recent years, a number of applications involving carbocations have appeared, with the intermediate being generated and directly studied under normal solvolytic conditions, i.e., with water or an alcohol as solvent (1, 2). In this respect, detailed studies have been reported involving species such as xanthylium (3, 4), triarylmethyl (5–8), diarylmethyl (6–11), and fluorenyl cations (12–14). These ions are relatively conjugated, with the formal cationic center bearing at least two aromatic rings. Carbenium ions bearing a single stabilizing aryl ring are inherently more reactive, and thus in principle more difficult to study. In spite of this, such cations are accessible by LFP under appropriate conditions, and in two preliminary communications we have outlined aspects of this work (15, 16). This paper provides the full details, with a discussion of the photochemical methods employed to generate such cations in LFP experiments, and a comparison of the effect of solvent, cation structure, and aryl substituent. Comparisons with analogous vinyl cations are also presented.

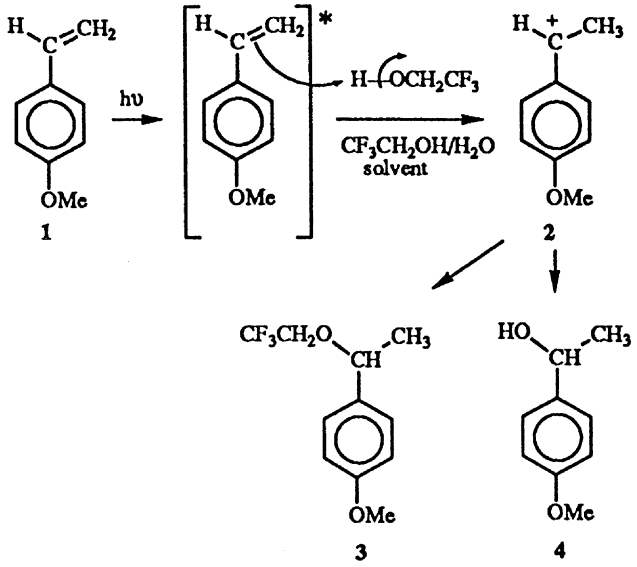
Results and discussion

In total, 32 cations have been investigated. Table 1 provides their structure, absorption maxima, and decay rate constants in 2,2,2-trifluoroethanol (TFE) and (or) 1,1,1,3,3,3-hexafluoroisopropanol (HFIP). These solvents are necessary with most of the ions in Table 1, since their lifetimes in more nucleophilic solvents such as methanol, ethanol and water are less than 20 ns, the limit of detection with our LFP apparatus. Even then a 4-methoxy substituent (or 4-Me_2N) is usually required for the cation to be observed in TFE, and the less stabilized ones require HFIP. Changing from TFE to HFIP increases the lifetime by a factor of 10^3–10^4. Water, on the other hand, is three orders of magnitude more reactive than TFE.

4-Methoxyphenethyl cation

Two general photochemical routes were employed, styrene photoprotonation and photoheterolysis, and the results with the 4-methoxyphenethyl cation are typical. Photoprotonation, where it can be used, is the better method. This possibility was suggested through the observation of Markovnikov hydration upon irradiation of styrenes in aqueous acid, with the proposed mechanism involving protonation of the excited styrene to give intermediate phenethyl cations (17–19). With TFE (and HFIP) as solvent, addition proceeds smoothly without added acid, as illustrated in Scheme 1 for 4-methoxystyrene **1** where the ether **3** is the only product (Scheme 1). The protonation must be occurring with the solvent OH proton. This is perhaps not surprising, since the protonation of excited styrenes is general-acid catalyzed with a relatively small Bronsted α value (19).

Scheme 1.



LFP of 4-methoxystyrene in TFE reveals a relatively strong transient with λ_{max} at 340 nm, coupled with significant negative optical density below 300 nm (Fig. 1A). The bleaching signal is the negative of the spectrum of 4-methoxystyrene and arises from use of the precursor solution as the optical density reference. The absorbance changes measured immediately after the laser pulse at both 340 and 255 nm are linear in laser intensity, indicating the occurrence of a monophotonic process. The absorbance above 300 nm decays to essentially zero at all wavelengths with the same rate constant of $(3.9 \pm 0.3) \times 10^5$ s^{-1}. This implies a single transient, and we assign this to the 1-(4-methoxy-

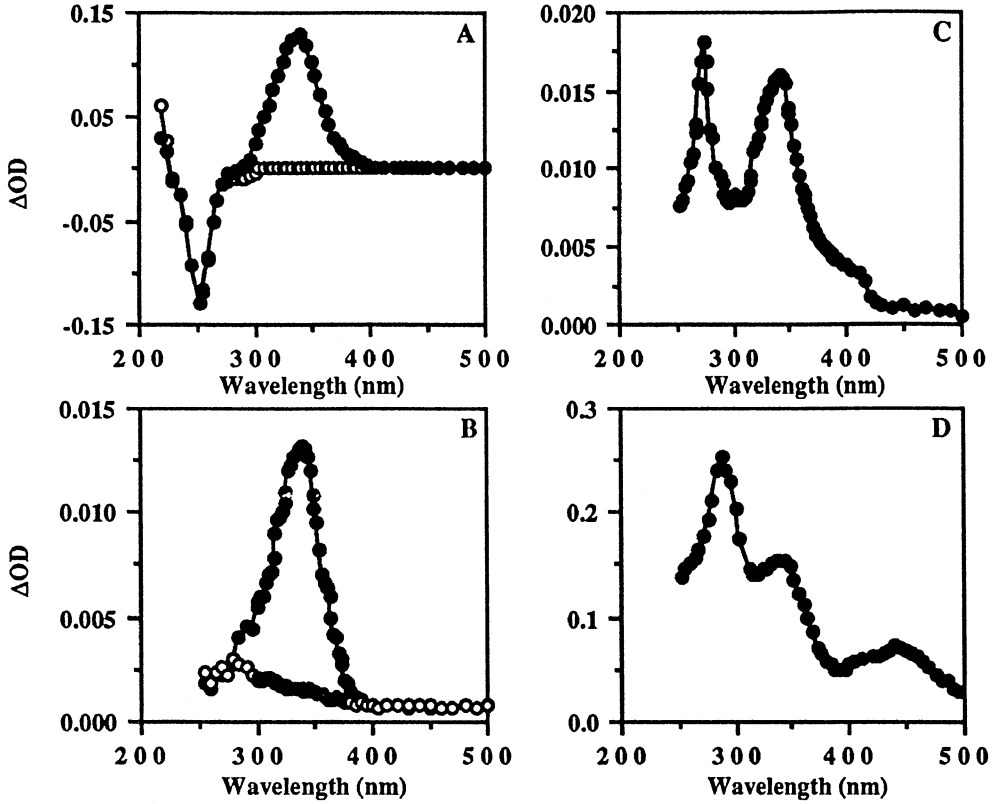
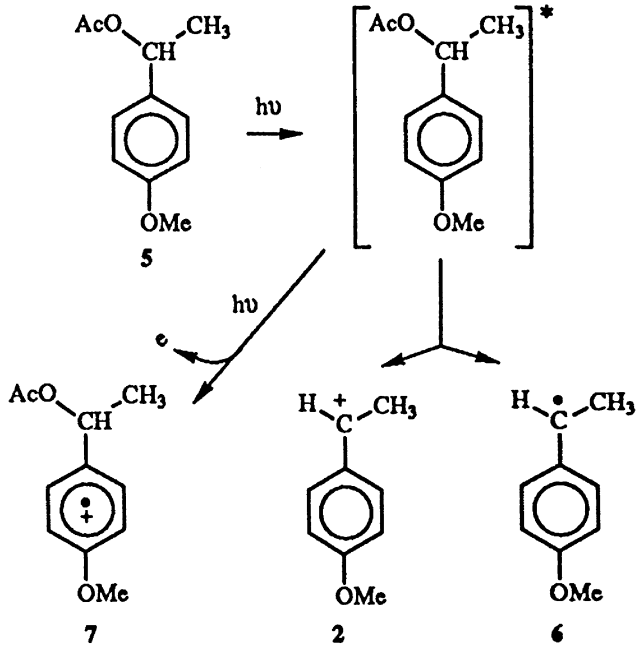
Fig 1. Transient spectra following 248 nm laser irradiation of 0.1 mM 4-methoxystyrene (A) and 1 mM 1-(4-methoxyphenyl)ethyl acetate (B – D) in TFE. Spectra B – D were obtained on the same solution; B, at a laser dose of 6 mJ and with oxygen saturation, C, 6 mJ and with argon, and D, 75 mJ and with oxygen saturation. Spectrum A was obtained at 25 mJ and with argon saturation. This spectra was unchanged on saturating with oxygen. The spectra in C and D, and the initial spectra in A and B were obtained at 50–100 ns after the laser pulse. The final spectra in A and B were obtained at 25–30 μs.



Scheme 2.



phenyl)ethyl cation **2** implicated by the Markovnikov ether photo-product **3**. The transient does exhibit kinetic behavior characteristic of carbocations (2), being quenched by nucleophiles such as bromide and azide, while oxygen has no effect.

Additional evidence is the observation of the same intermediate from a different precursor, 1-(4-methoxyphenyl)ethyl acetate **5** (Scheme 2). The photochemical reaction here is a photoheterolysis, and, as is typical of this route (2, 6), there are competing photo-reactions. Thus, as shown in Fig. 1C, irradiation of the ester results in two transients, the one with λ_{max} at 340 nm and a second at 275 nm. The former is the same as the transient from the styrene precursor. It has an identical spectrum, decays in TFE alone with the same rate constant, $(4.2 \pm 0.4) \times 10^5$ s^{-1}, and is quenched in an identical manner by bromide and azide ions. The 275 nm transient does not decay by exponential kinetics in argon-saturated solution and, while nucleophiles have no effect, oxygen is a very effective quencher. In fact, in the experiment in oxygen-saturated TFE, the 275 nm signal is no longer seen (Fig. 1B). This intermediate can be assigned as the 1-4-methoxyphenethyl radical **6**, the result of a competing photohomolysis. At higher laser doses additional absorbances appear: a band with λ_{max} near 295 nm and a second smaller broad peak at 400–500 nm. The 295 signal overlaps that of the radical but can be seen clearly in experiments with oxygen saturation (Fig. 1D). The two new bands appear to represent the same intermediate, since they decay with the same rate constant, with $k \sim 1 \times 10^5$ s^{-1}. A clue to the identity is the square dependence on the laser dose of the

Table 2. Effect of water on the irradiation of 4-methoxystyrene.

%(v/v) TFE	k_{decay} (s^{-1})	% Ether product	Initial OD (340 nm)[a]
100	4.0×10^5	100	1.00
95	1.5×10^6	90	0.85
90	3.6×10^6	80	0.70
80	6.3×10^6	40	0.60
70	9.6×10^6	Trace	0.50
60	1.3×10^7	0	0.40

[a]Relative to 100% TFE. This is equivalent to a relative quantum yield, since the measurements involve solutions of the same concentration of styrene being irradiated at 248 nm under identical conditions.

optical densities measured at 420 nm. This points to a biphotonic process, and suggests that this intermediate is the cation radical **7**, the result of a two-photon ionization. In fact the spectrum is that expected for the cation radical of an anisole derivative (20). The 340 nm transient on the other hand follows a linear dependence on laser intensity. Thus, as summarized in Scheme 2, the initial excited state, presumably the singlet, reacts to produce the cation and radical and, in competition, is further excited resulting in electron ejection. These experiments do not distinguish mechanisms for the formation of the cation and radical. There is the suggestion with benzyl carboxylates, including 4-methoxybenzyl acetate, that the primary event is photohomolysis with the cation being subsequently produced by electron transfer within the so-formed radical pair (21, 22).

A important feature with the styrene precursor is that there is no return of the absorbance below 300 nm as the cation decays back to the baseline above 300 nm. This is consistent with studies of thermal alkene additions that show that protonation in general is irreversible (23). In other words, the cation reacts predominantly by solvent addition, with little styrene being regenerated by elimination of a proton at the β-position.

As expected, addition of water significantly increases the rate constant for the decay of the cation. In addition, the alcohol **4** is produced at the expense of the ether (Table 2). Interestingly, the initial increase in rate constant is much greater than predicted on the basis of the amount of alcohol product. For example, 10% water results in only 20% of the alcohol product, but the rate constant for the decay of the cation is increased by almost 10-fold. This is consistent with a mechanism where, in addition to its direct nucleophilic combination, water accelerates the decay of the cation by acting as a general base to assist the TFE addition (24). Water also decreases the quantum yield for photoprotonation, as shown in the last column of Table 2. Coupled with the rate accelerating effect, this makes it increasingly difficult to study the cation in highly aqueous mixtures.

Substituted phenethyl cations by styrene protonation

In the same way, other phenethyl and cumyl cations are observed upon irradiation of the appropriate substituted styrene in TFE and (or) HFIP. Spectra of three cumyl cations and a naphthalene derivative are shown in Figs. 2 and 3A respectively. The other examples are available as supplementary material.[2] These show the same features discussed above for 4-methoxystyrene — a positive absorbance above 300 nm representing a single intermediate as shown by common decay kinetics across the entire spectrum,[3] effective quenching by bromide[4] and (or) azide ion, and bleaching due to depletion of the precursor. Spectra under stable ion conditions are available for the cumyl cation, λ_{max} = 326 and 390 nm (ε = 11 000 and 1400 respectively) and the 1,1-diphenylethyl cation, λ_{max} = 312 and 422 nm, (ε = 11 050 and 37 000 respectively) (25). The essentially identical spectra obtained here provide further confidence in the assignment of cation intermediates (see the spectrum for the cumyl ion in Fig. 2).

A further feature in common with 4-methoxystyrene is the lack of return of the bleaching as the absorbance of the cation decays. Thus the cations in general react by solvent addition. One exception is the 2,6-dimethylphenethyl cation where a competing deprotonation is indicated by the significant return of the precursor absorbance at the same rate constant as that obtained for cation decay. This aspect of 2,6-dimethyl systems has been recently demonstrated in a study of solvolysis of cumyl derivatives (26). While solvent addition is retarded by the steric effect of the *ortho* substituents, the rate constants for elimination are actually increased relative to analogs without the 2,6-dimethyl groups (26).

Styrene dimerization

The other exception occurs in HFIP with styrene and its 3- and 4-substituted derivatives. One indication of the difference is that the rate constants depend on the precursor concentration. This dependence is linear (eq. [1]), implicating a reaction of unphotolyzed precursor with the cation. With the

[2] Supplementary material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Ontario, Canada, K1A 0S2.

[3] The one exception is α-*tert*-butyl-4-methoxystyrene, where the decay requires fitting to a double exponential, with rate constants of 7×10^5 and 1.6×10^4 s^{-1}. The spectrum of the intermediate responsible for the slow decay, obtained at longer times when the faster one is complete, shows a λ_{max} of 370 nm. This is assigned to the α-*tert*-butyl-4-methoxyphenethyl cation on the basis of the close similarity with the spectra of the other α-alkyl-4-methoxyphenethyl derivatives. The faster decaying transient has its λ_{max} between 330 and 340 nm and has not been identified.

[4] With some of the cations, bromide addition shows reversible behavior. This has been seen previously (5) and occurs when the ionization of the bromide product has a rate constant similar to the quenching rate constant. With the very stable cations where ionization of the C—Br bond becomes faster than nucleophile–cation combination, bromide does not react at all. These cations are still quenched by azide ion.

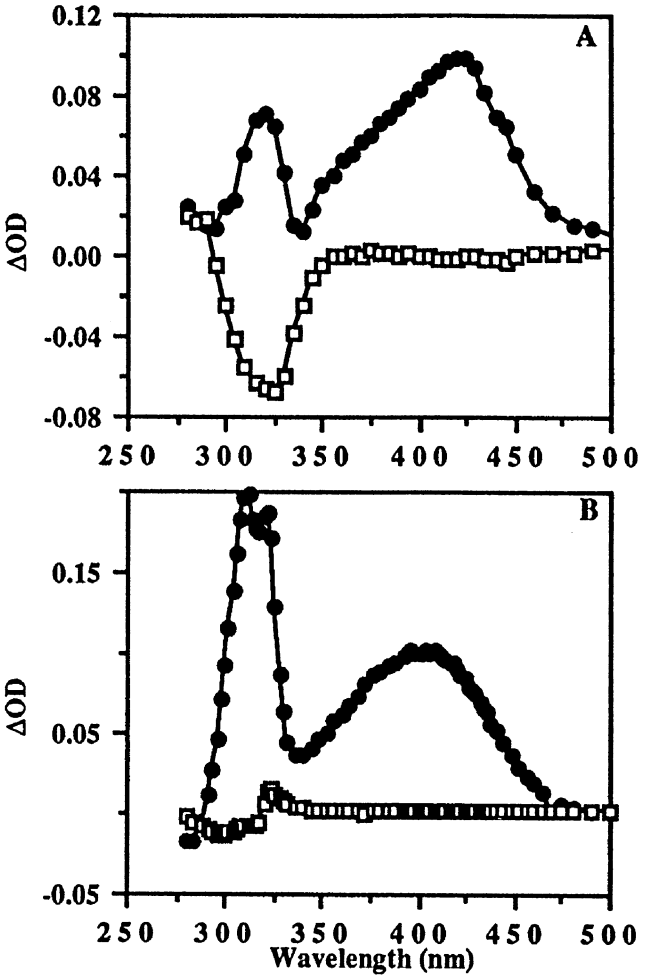
Fig. 3. Transient spectra following 248 nm irradiation of ~0.0001 M 4-methoxy-1-vinylnaphthalene (A) and 4-methoxy-1-napthylmethylammonium acetate (B) in argon-saturated TFE. Data points were obtained immediately after the laser pulse and at the completion of the exponential decay.



assumption (see Experimental) that the concentration of styrene is effectively unchanged in the laser pulse, the slopes of these plots (Table 3) are the second-order rate constants for the dimerization. The intercepts are the rate constants for the solvent reaction (the numbers in Table 1 for these cations).

$$[1] \qquad k_{obs}/s^{-1} = k_{HFIP} + k^1_{sty}[ArCH=CH_2]$$

Spectral changes provide further evidence. Figure 4 shows an example where dimerization dominates and a high laser intensity is employed to provide strong signals. After the initial "prompt" bleaching at 240 nm, there is a further exponential decay occurring at the same rate as at the higher wavelengths. Thus additional styrene is reacting. Moreover as the cation decays, a new species appears. There is considerable overlap, but it is clear that this absorbs at a slightly higher wavelength, with a λ_{max} around 345 nm for the product in Fig. 4. Similar observations are made with the other $ArCH=CH_2$, with a shift of ~20–30 nm in each case. The new absorbance is much more stable than the original one but there is decay at very long times, for example, with styrene (at 340 nm) with a rate constant of ~0.1 s^{-1}. (This is only approximate because of detector instability at very long times).

A similar situation has been observed for cations generated in strong acid solution. For example, when styrene is added to 98–100% sulfuric acid, the species observed is the bis-styryl cation, not the initially-formed phenethyl cation (27, 28). With α-methylstyrene, the cumyl cation is sufficiently stable to be seen, but it is not stable, reacting to give a new, long-lived, species with a higher λ_{max} identified as the bis-cumyl cation (27, 28). In a similar manner, we propose that phenethyl cations **9**, when generated by styrene photoprotonation in HFIP, react in part with residual styrene forming much more stable bis-styryl cations **10** (Scheme 3).

The dimerization is obviously the first step in the propagation sequence of the acid-initiated polymerization of styrenes. The dimer ions **10** in fact appear similar to the oligomeric **11** that have been detected during polymerization. With styrene, for example, the propagating cation has a λ_{max} of 340 nm (29, 30), the same as the cation **10** (X = H) observed in this work. One interesting observation is that the monomer ions **9** have a slightly slower λ_{max}. A possible explanation is that

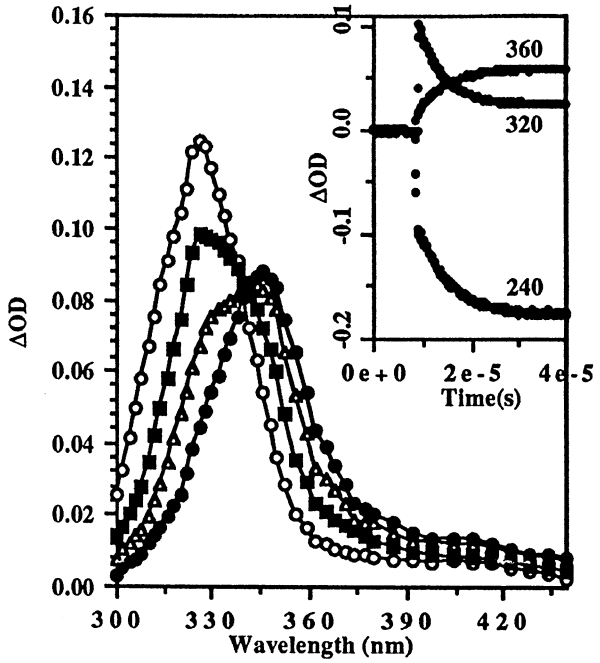
Fig. 4. Transient spectra following 248 nm irradiation of 0.0004 M 4-methylstyrene in HFIP. The open circles were obtained immediately after the laser pulse and the closed circles at the completion (40 μs) of the exponential process. The other two traces were obtained at intermediate times. The Inset shows the absorbance change at the three indicated wavelengths. The rate constants (s^{-1}) are 1.6×10^5 (240 nm), 2.0×10^5 (320 nm) and 1.85×10^5 (360 nm).

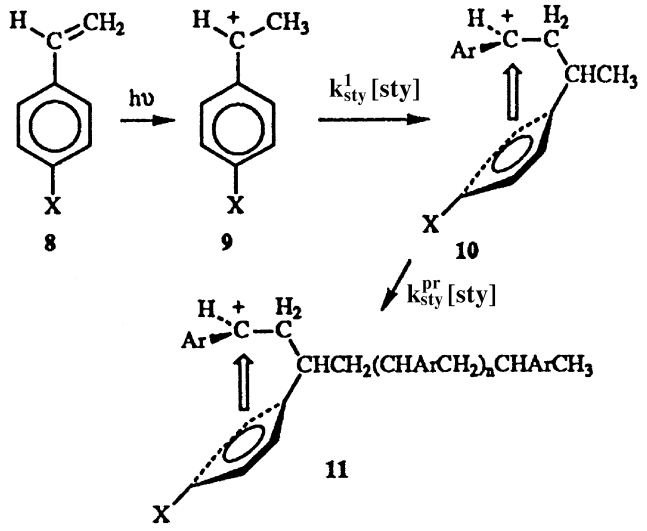


in **10** and **11** there is an interaction of the aryl group at the γ carbon with the positive charge at the α-carbon, as shown in structures in Scheme 3. Another interesting feature is that the dimer cation is much more stable than the monomer. This is also true of the oligomer. The rate constant for styrene propagation (k_{sty}^{pr} of Scheme 3) is ~10^5 M^{-1} s^{-1} at 20°C (29, 30), four orders of magnitude slower than the rate constant k_{sty}^{1} for the phenethyl cation reacting with styrene. It is interesting that the difference in stability between phenethyl and dimer/oligomer cations was suggested in 1968, and the interaction with the adjacent phenyl group in the latter proposed as the explanation (27).

We can be confident that it is the dimer cation **10** being observed at the end of the exponential process in the LFP experiments, and not an oligomer. One argument is based on the observation (Fig. 4) that the "slow" decay of styrene follows clean exponential kinetics, moreover reaching a stable absorbance at the completion of the change. If styrene were continually adding to a growing oligomeric cation, one would have expected a downward drifting absorbance. The other argument is that subsequent reactions with styrene are much slower than the first one, as discussed above. In other words, the reaction of the dimer cation with further styrene occurs on a much longer time scale than the initial reaction. Experimental limitations unfortunately preclude observation at long times at the lower wavelengths, i.e., where further depletion of styrene would be observed.

Cumyl cations do not show any sign of reacting with the residual α-methylstyrene in HFIP. This would appear to be a

Scheme 3.



steric effect, since the reactivities of both the cation and the nucleophile are not that different from the those in the $ArCH{=}CH_2$ series. There is no dimerization with any of the cations in TFE. Here the more nucleophilic solvent can successfully compete with the low concentrations of precursor.

Benzyl cations

Styrene photoprotonation cannot be applied for the generation of $ArCH_2^+$; therefore we were forced to return to photoheterolysis. For 4-methoxybenzyl, both chloride and trimethylammonium (BF_4^- salt) precursors give a transient that can be assigned to the cation, although the former is limited to TFE solutions containing greater than 50% acetonitrile because of rapid ground state solvolysis. The cation is identified by several criteria. Its λ_{max} (320 nm, Fig. 5A) fits in a comparison with the 4-methoxyphenethyl (340 nm) and 4-methoxycumyl (360 nm) cations. The decay kinetics are typical of cations, a very efficient quenching by bromide, and a large difference between HFIP and TFE (Table 1). The same transient is observed with the two precursors, with the same decay rate constant, 9.0×10^6 s^{-1} and 8.6×10^6 s^{-1} for the chloride and ammonium salt respectively in 1:3 TFE:acetonitrile. Finally, product analysis following irradiation of the ammonium salt in TFE shows the presence of 4-methoxybenzyl 2,2,2-trifluoroethyl ether, the product derived from trapping of the cation by solvent. The other product formed in about the same amount is 4-methylanisole. This indicates the presence of a radical intermediate as well (31, 32), and, in argon-saturated solvents, LFP of both precursors shows a large band with λ_{max} at 290 nm, presumably due to the 4-methoxybenzyl radical. With 4-methoxybenzyl acetate in TFE, only the 290 absorbance of the radical is seen at low laser doses, while, like the phenethyl analog, absorbance for a cation radical dominates at higher intensities. Thus, this precursor results in so little cation that the intermediate cannot be detected in competition with the other pathways. In fact, 4-methoxybenzyl acetate is known to result in only low yields of photosolvolysis product when irradiated in alcohol solvents (22, 33).

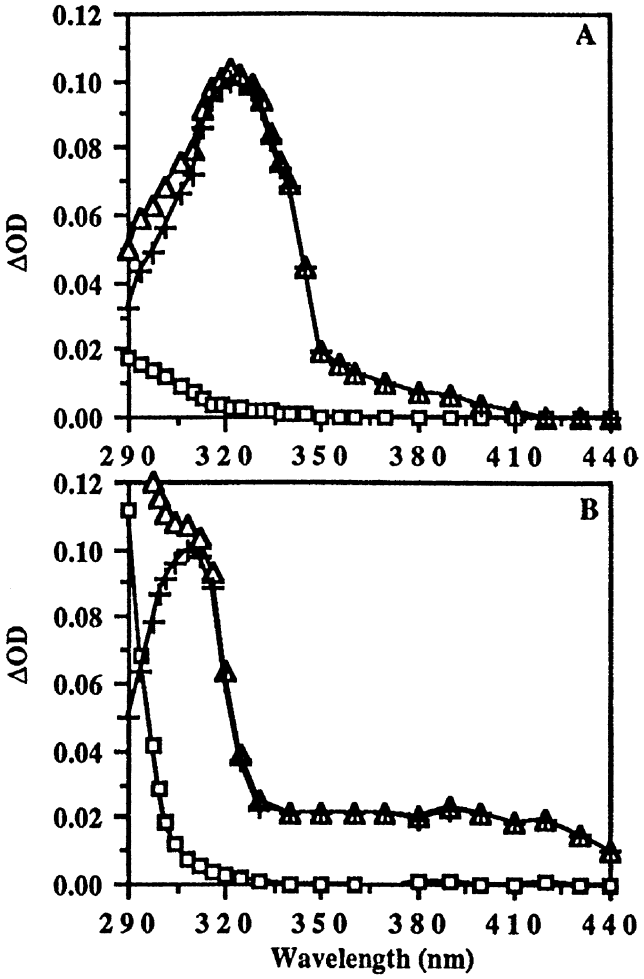
Fig. 5. Transient spectra following 248 nm irradiation of ~0.001 M 4-methoxybenzyl chloride (A) and 4-methylbenzyl chloride (B) in oxygen-saturated 1:3 TFE: acetonitrile and HFIP respectively. Triangles are the ΔOD immediately after the laser pulse, and squares, ΔOD at the completion of the exponential decay that is observed. The crosses are the difference in the two.



As shown in Fig. 3B, the 4-methoxy-1-naphthylmethyltrimethylammonium ion gives a strong signal that can be assigned to the primary cation. The evidence here is the efficient quenching by nucleophiles and the close similarity with the secondary cation obtained by photoprotonation. There is little indication of the presence of radical intermediate, as shown by very similar spectra being obtained under argon and oxygen.

For the 4-methylbenzyl cation, the chloride could be used as a precursor in HFIP. Spectra in oxygen-saturated solvent are shown in Fig. 5B. Below 300 nm a large non-decaying band of uncertain origin is observed. A shoulder above 300 nm does decay in an exponential fashion. By taking the difference between the initial and final absorbances, this species is found to have a λ_{max} of 310 nm with a weaker absorbance extending out above 400 nm. As will be discussed, this fits the expectation for this cation. The absorbance at 310 is quenched by bromide ion, with the ratio k_{Br}:k_{HFIp} equal to 5.0×10^3 M^{-1}. This allows for confirmation that this is due to the cation, through a comparison

Scheme 4.

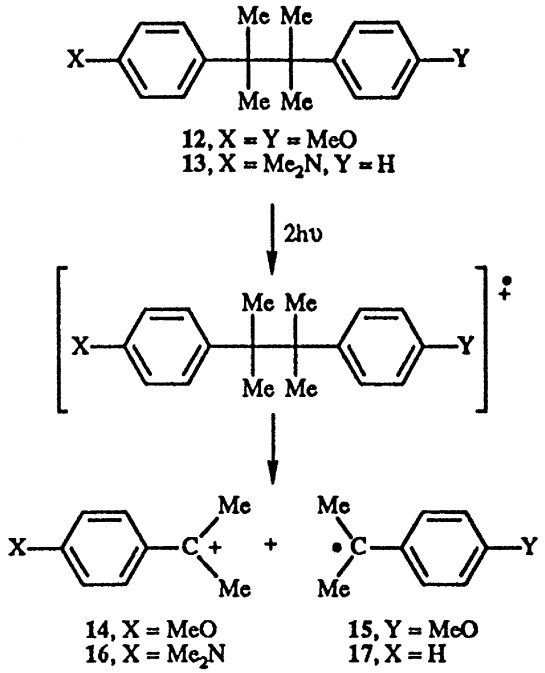


Table 4. Rate constants at 25°C for the solvolysis of 4-methylbenzyl bromide (20 μM) in HFIP in the presence of tetrabutylammonium bromide.

$[Bu_4N^+ Br^-]$	k_{solv} (s^{-1})
0	2.01×10^{-4} [a]
0.0003	8.26×10^{-5}
0.0006	5.15×10^{-5}
0.0009	3.92×10^{-5}
0.0012	2.94×10^{-5}
0.0015	2.32×10^{-5}

[a]Based on initial rate.

with a ratio obtained from the kinetics of ground state solvolysis of 4-methylbenzyl bromide in HFIP. As shown in Table 4, added bromide results in significant common ion inhibition. By fitting to $k_{solv} = k_{ion}$:$(1 + k_{Br}$:$k_{HFIP}[Br])$, k_{Br}:k_{HFIP} is found to be $(4.8 \pm 0.2) \times 10^3$, the same number obtained from the transient spectroscopy.

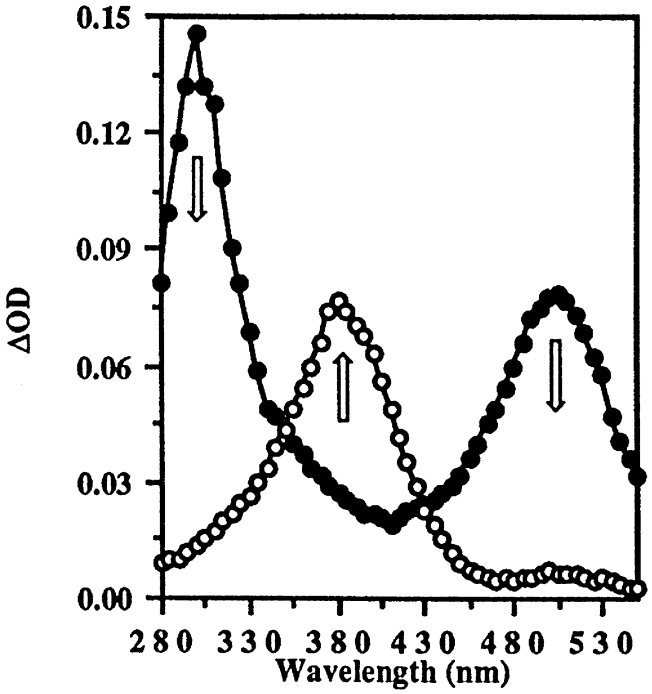
All attempts to generate detectable amounts of the parent benzyl cation in HFIP failed to provide any evidence of the cation. Precursors of benzyl chloride, benzyl bromide and benzyl acetate were employed. There were transients, but these could be attributed to radicals, or products from the radicals. A comparison of the 4-H and 4-Me derivatives in the phenethyl and cumyl series (Table 1) suggests that the benzyl cation is at least an order of magnitude more short-lived than 4-methylbenzyl. Thus the lifetime of $PhCH_2^+$ in HFIP is less than 50 ns. Even if this were the lifetime, the cation would be very difficult to detect unless the photochemical route to it was very efficient.

Radical cation fragmentation

By using photoprotonation, the 4-methoxycumyl cation can be studied in aqueous TFE until about 70% water is

© 1999 NRC Canada

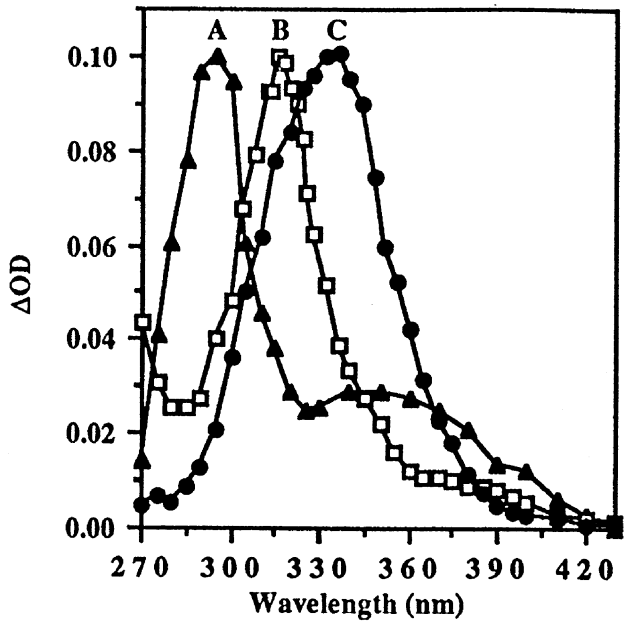
Fig. 6. Transient spectra following 248 nm irradiation of 4-dimethylaminobiscumene **13** in oxygen-saturated 2:1 water:acetonitrile. Closed circles obtained immediately after the laser pulse are attributed to the cation radical $\mathbf{13}^{+\bullet}$. Open circles obtained near the end of the completion of the exponential decay are due to the 4-dimethylaminocumyl cation **16**. Rate constants measured at 275, 380 and 500 nm are respectively 8.8×10^4, 1.12×10^5, and 1.03×10^5 s^{-1}, respectively.



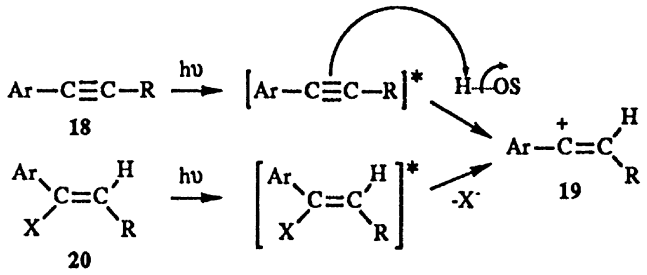
present. At this point the cation decays with a rate constant of 7.9×10^6 s^{-1}, still below the 20 ns limit. However, the amount of intermediate being produced upon irradiation is so small that further increases in water content are not possible. To obtain a water rate constant, we turned to bis-4-methoxycumene **12** as a precursor (Scheme 4). The photochemistry here involves a two photon ionization to the cation radical, which fragments within the laser pulse to cation **14** and radical **15** (34). With 2:1 water:acetonitrile as solvent, the cation can just be detected, with a decay of $\sim 4 \times 10^7$ s^{-1}. While the acetonitrile is required in this experiment to dissolve the precursor, a similar decay is expected in pure water, because rate constants in water:acetonitrile do not vary a great deal with solvent composition (6).

The very stable 4-dimethylaminocumyl cation is generated from the biscumene **13** in the same water:acetonitrile mixture. In this case the cation radical is much more stable so that it is this species that is present after the laser pulse, and the fragmentation occurs on the microsecond time scale (Fig. 6). This observation has been reported previously (35), although the fragmentation of $\mathbf{13}^{+\cdot}$ in the aqueous solvent of the present study is significantly faster than that for the same cation radical in solvents previously used. The 4-dimethylaminocumyl cation can be observed to grow in as the cation radical decays. This has a λ_{max} at 380 nm (382 nm, ref. 35), and a lifetime in the aqueous solvent of 7 ms.

Fig. 7. Spectra of vinyl cations $4\text{-}XC_6H_4C^+{=}CH_2$ obtained upon 248 nm laser irradiation of ~0.1 mM solutions of $4\text{-}XC_6H_4C{\equiv}CH$ — (A) X = H in HFIP, (B) X = Me in HFIP and (C) X = MeO in TFE. ΔOD values have been adjusted so that the maximum is 0.1 in each case.



Scheme 5.



Phenylacetylenes as precursors of vinyl cations

Laser flash photolysis of *p*-methoxyphenylacetylene in both TFE and HFIP, and *p*-methylphenylacetylene, 2,4,6-trimethylphenylacetylene, diphenylacetylene, and phenylacetylene itself in HFIP results in transient spectra (see Fig. 7) that can be assigned to vinyl cations produced by photoprotonation (Scheme 5). With each precursor, there is a single intermediate, as shown by the absorbance above 300 nm decaying to near zero with the same rate constant at all wavelengths. Nucleophiles such as bromide ion have a pronounced quenching effect, evidence that these are cations. Vinyl cations, usually with two substituents on the β-carbon, have been produced in the past by photoheterolysis of halide precursors (36–39). As seen in Table 1, the 1-(4-methoxyphenyl)vinyl cation produced from the acetylene has a similar λ_{max} to that of the 2,2-dimethyl analog produced from the bromide. Even more compelling is the case of the 2,4,6-trimethylphenyl derivative, where the same cation was produced in the two different ways. Like styrenes, substituted phenylacetylenes have been shown to undergo photo-

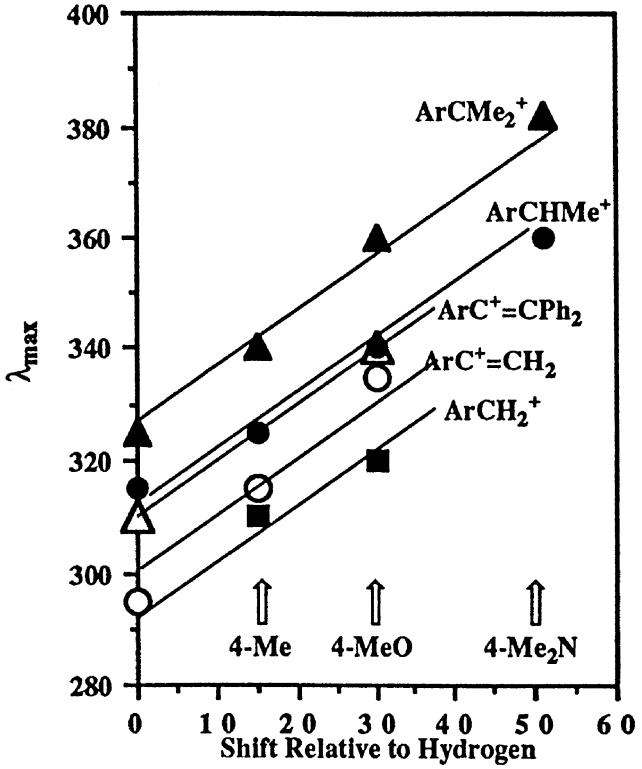
Fig. 8. Substituent effect on the λ_{max} for benzyl, phenethyl, cumyl, 1-phenylvinyl, and 2,2-diphenyl-1-phenylvinyl cations. See text for explanation of *x* axis. Lines have been drawn with a slope of unity.



hydration in aqueous acids, with the ultimate product an acetophenone (17, 18). Flash photolysis investigations have revealed the presence of the enol intermediate (40–42), the immediate product of the hydration of the vinyl cation. The cations themselves were not detected. As discussed above, they would be too short-lived in water for detection by ns LFP.

Absorption maxima

Substituents affect λ_{max} in the order H < 4-Me < 4-MeO < 4-Me_2N. The effect is essentially the same for a given type of cation with, on average, a shift relative to H of 15 nm for 4-Me, 30 nm for 4-MeO, and 50 nm for 4-Me_2N. This is demonstrated in Fig. 8 where the observed λ_{max} are plotted against these factors. Recognizing that λ_{max} is only determined to ±5 nm, the correlations are excellent. Also apparent from this figure are the similar λ_{max} values for the vinyl and benzylic series. This was previously commented upon in a comparison of the 4-methoxy-substituted ions (15). In an arylvinyl cation, the π systems of the aryl ring and the alkene are orthogonal to one another (43). Thus the aryl ring interacts with the formally empty *p* orbital on the α-carbon in exactly the same way as it does in a benzylic cation.

For the same aryl group, the order of λ_{max} is $ArCH_2^+$ < $ArCHMe^+$ < $ArCMe_2^+$, with about a 20 nm difference between each pair. A weaker absorbance at higher wavelength is also apparent with some of the systems. The trend appears to be exactly opposite that of the larger absorbance at lower wavelength, and this is true both in terms of the aryl substituent and the α-methyl substituents. In fact the band at higher wavelength is usually not visible for the 4-MeO and 4-Me_2N substituted cations.

There has been some question as to the spectrum of the parent benzyl cation. An early theoretical calculation showed bands at 400–500 nm and 300 nm, with the latter being significantly stronger (44). This paper also suggested that a report of the benzyl cation in strongly acidic solutions (45) was incorrect. In agreement with the more intense absorbance, a band at 290 nm assigned to the cation was observed in an experiment involving photodissociation in a mass spectrometer (46). A more recent pulse radiolysis experiment in neat benzyl chloride is also in agreement, suggesting a strong band at 303 ± 2 nm and a weak band near 500 nm (47). In contrast, there have been several assignments to the benzyl cation where the λ_{max} is around 360 nm. These are based upon experiments by Dorfmann and coworkers who claimed to have generated the benzyl cation by pulse radiolysis in chlorocarbon solvents (48–50). The basis of this assignment was quenching of the observed transient by nucleophiles, and the fact that the approach does work for the triphenyl- and diphenylmethyl cations. A similar band was then observed and assigned to the benzyl cation following photoionisation of benzyl bromide in an argon matrix (51), and upon photolysis of dibenzyl ketone in vacuum-dried Nafion membranes (52).

While the parent cation has not being observed in this work, the data in Table 1 clearly shows that it must have λ_{max} around 300 nm with a weaker absorbance extending into the visible spectrum. This is in agreement with the first set of results discussed in the previous paragraph. The ~360 nm transient cannot be the benzyl cation. The pulse radiolysis approach requires fragmentation of a cation radical and we suspect that under the conditions employed by Dorfman and coworkers this is not occurring. In fact this is exactly what happens when precursors of the 9-fluorenyl cation are employed; there is no fragmentation and the intermediate that is observed is the cation radical of the precursor (13). Based on estimated pK_R values, the 9-fluorenyl cation is more stable than benzyl (53). Thus, if the approach does not work for 9-fluorenyl it is unlikely to have worked for benzyl. It can also be noted that the nucleophilic reactivities of the 360 nm transient have been criticized as not being appropriate for the benzyl cation (54). As a final comment, we note that even in those cases where the ~300 nm absorbance for the benzyl cation has been observed, this is clearly not the only species present. In other words there has not yet being a study showing a clean spectrum of this cation.

Substituent effects on rate constants

(a) Vinyl vs. phenethyl cations

As was noted previously in the case of the 4-methoxy derivatives (15) there is remarkably little difference in the lifetime of a vinyl cation $ArC^+=CH_2$ relative to that of a phenethyl cation $ArC^+H\text{-}CH_3$ with the same aryl group. The vinyl cation is slightly more reactive, but the differences are only 3.3 (TFE) and 1.4 (HFIP) for Ar = 4-$MeOC_6H_4$, 4.4 for 4-MeC_6H_4 in HFIP, and 2.5 for C_6H_5 in HFIP. As with the explanation for the similar spectra, this is consistent with the idea that the aryl ring interacts with the *p*-orbital on the α-carbon in exactly the same way in the two series.

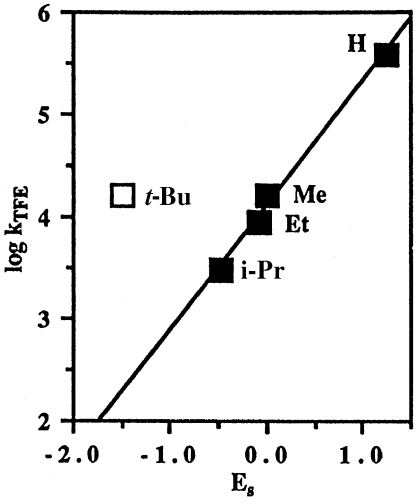
Fig. 9. Correlation of log k_{TFE} for 4-$MeOC_6H_4C^+(R)CH_3$ vs. $E_s(R)$.



(b) α-Alkyl effects

For a given aryl group the rate constant for solvent addition follows the expected order cumyl < phenethyl < benzyl. Interestingly, the second methyl group exerts a greater kinetic stabilization than the first. In the 4-methoxy series in TFE, for example, there is a 11-fold difference between benzyl and phenethyl, but this increases to 24-fold for phenethyl and cumyl. The same comparisons for the 4-Me cations in HFIP lead to ratios of 28 and 120. This suggests that it is unlikely that it is electron donation alone that is important. A steric effect would account for the difference, the second methyl group increasing the steric bulk around the α-carbon to such a degree that nucleophilic addition is hindered to an extent greater than that of the first methyl substitution.

While there is insufficient data to perform a detailed breakdown into steric and electronic contributions, steric effects are clearly important. As shown in Fig. 9, there is a good correlation of the data for 4-methoxyphenethyl cations in TFE against the Taft steric parameter E_s, and this includes the point for the secondary cation. The correlation against the polar parameter σ^* is marginally poorer. In particular, this requires a difference in rate constant smaller than the one observed between i-Pr and Et.

An additional steric effect is probably responsible for the deviation of the point for the *tert*-butyl derivative. In this case, unfavorable interactions between the *ortho* hydrogens and the *tert*-butyl group twist the aryl ring, diminishing the resonance interaction with the *p* orbital on the α carbon. In fact MM2 calculations indicate a twist of 80 degrees. This argument is reinforced by the slow rate of solvolysis of 3,3-dimethyl-2-phenyl-2-chlorobutane, which has also been attributed to steric inhibition of resonance (55).

(c) Cyclopropyl versus phenyl

While an α-cyclopropyl group on a carbocation is strongly stabilizing, there has been some dispute whether the effect is greater or less than that of phenyl (56). In terms of the reactivities of fully-formed cations, a series $ArCH^+$-R where R = phenyl and cyclopropyl have been compared by LFP in TFE (57). For a given Ar, the reactivities are similar. However the phenyl series shows a greater effect of changing substituents in Ar. The result is that the cyclopropyl cation is slightly more stable (kinetically) when Ar is phenyl, but less stable when Ar is 4-methoxyphenyl.

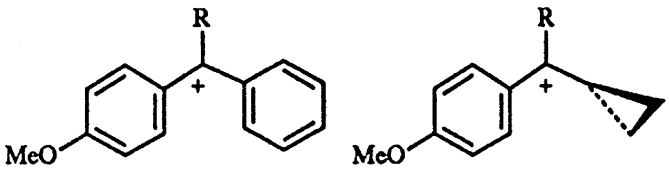
The difference in the latter comparison is a factor of 10 (**21** vs. **22** in Scheme 6). Interestingly, the methylated analogs **23** and **24** studied in this work show a slightly greater stabilization (1.5-fold) for the cyclopropyl system. This can be traced to the substitution of α-hydrogen with methyl resulting only in a threefold rate constant diminution in the diarylmethyl cation, but a 42-fold diminution in the arylcyclopropyl pair. We attribute this to steric inhibition of resonance in the former. In these cations, maximum stabilization occurs when both aromatic rings are fully planar with the plane of the α-carbon. We suspect that methyl substitution results in additional twisting, so that while there is electronic and steric stabilization due to the methyl group, this is compensated by some loss of resonance interaction. The steric problem is not as severe in the cyclopropyl series, since the cyclopropyl is perpendicular to the π system.

Table 5. Values of ρ^r, ρ^n, and r^+ obtained by fitting rate constants for solvent capture of 1-arylethyl cations to eqs. [2] and [3].

Parameter	HFIP	TFE:water[a]
ρ^r	4.7	6.1
ρ^n	2.7	2.7
r^+	1.7	2.3

[a]Reference 58, as corrected in ref. 14.

Scheme 6.



21, R = H, $k_{TFE} = 1.5 \times 10^3$ **22**, R = H, $k_{TFE} = 1.4 \times 10^4$
23, R = Me, $k_{TFE} = 5.1 \times 10^2$ **24**, R = Me, $k_{TFE} = 3.3 \times 10^2$

(d) Aryl substituent effects

Since the initial studies of Richard et al. (58) it has been known that rate constants for solvent capture of benzylic carbocations do not correlate with σ^+, as might have been expected. This has been observed now with several systems (2). What occurs is that σ^+ considerably underestimates the stabilizing effect of *para* π-donors like 4-methoxy. This is revealed by fitting to the two parameter Yukawa–Tsumo equation (eq. [2]), where r^+ values significantly greater than 1 result. Fitting to the modified eq. [3] (18), ρ_r is found to be larger than ρ_n.

$$[2] \qquad \log (k/k_o) = \rho\{\sigma + r^+(\sigma^+ - \sigma)\}$$

$$[3] \qquad \log (k/k_o) = \rho_n\sigma^n + \rho_r(\sigma^+ - \sigma^n)$$

The study of Richard et al. (58) actually involved 1-arylethyl cations, with the rate constants being obtained through use of the azide-clock method in 1:1 TFE:water as solvent. Six

© 1999 NRC Canada

such cations were studied directly in HFIP in this work (Table 5). A comparison of the parameters obtained by fitting to the above equations is given in Table 5. Since the two series do not involve the same substituents, and, moreover, since there are a limited number of substituents in each, the two sets of parameters can be regarded as being equivalent. This is perhaps surprising since the cations are 10^6-fold less reactive in HFIP.

(e) Styrene dimerization

For the reaction of a substituted phenethyl cation with its precursor styrene, there is a decrease in rate constant with increased electron donation (Table 3). Because of the manner in which this experiment is performed, the substituent is changing in both the electrophile and the nucleophile, and thus there will be compensating effects. Increased electron donation will stabilize the cation but at the same time increase nucleophilicity of the styrene. What the data show is that the former is more important. This is consistent with studies of benzylic-type cations where data are available for the reaction in both the formation and decay directions, in particular the finding that there is imbalance in the reaction coordinate (2, 58). In the direction where the cation is the reagent, the resonance interaction has decreased at the transition state to a greater extent than bond making. The reverse is true in the direction forming the cation, where the developing resonance interaction in the cation lags. In the present case, it can be seen that a benzylic-type cation (**9** in Scheme 3) is being replaced by a benzylic-type cation (**10**) where the positive charge is stabilized by the same aryl group. What we argue is that in the transition state, the resonance interaction in the reagent cation has diminished to a greater extent than the resonance interaction in the product cation that has developed. Thus, in changing from styrene to 4-methoxystyrene, the stabilizing effect of the 4-methoxy group is more important in the starting cation than it is in on the developing cation in the transition state. Thus, the initial state is stabilized more than the transition state and the reaction is slower.

Experimental section

TFE and HFIP were dried over 4 Å molecular sieves and distilled under nitrogen through a 40 cm Vigreux column prior to use. Water was purified with a Millipore-Q system. The nucleophiles tetrabutylammonium bromide and sodium azide were used as received.

Table 6 provides the precursors that were employed and their sources. In most cases the compounds were commercially available or were prepared by a literature method. Where the compounds were solids the mp was in agreement with values in the literature. The ^{1}H NMR spectra were in all cases fully consistent with the structure.

4-Methoxy-1-vinylnapthalene was prepared from 4-methoxy-1-napthaldehyde by reacting Tebbe's reagent following standard procedures (77–79). ^{1}H NMR ($CDCl_3$) δ (ppm): 3.99 (s, 3H), 5.33–5.39 (dd, 1H), 5.64–5.74 (dd, 1H), 6.79 (dd, 1H), 7.32–7.57 (m, 2H), 8.04–8.32 (m, 4H). HRMS: 184.0886 (calcd.: 184.0888). Anal. calcd.: C 84.75, H 6.56; found: C 84.70, H 6.60.

α-Isopropyl-4-methoxystyrene was prepared by reacting Tebbe's reagent with 2-methyl-4′-methoxyacetophenone. ^{1}H NMR ($CDCl_3$) δ (ppm): 1.10 (d, 6H), 2.82 (sept., 1H), 3.82 (s, 3H), 4.97 (dd, 1H), 5.10 (dd, 1H), 6.86 (d, 2H), 7.31 (d, 2H). Elem. anal. calcd.: C 81.77, H 9.15; found: C 81.44, H 9.02.

4-Methoxybenzyl 2,2,2-trifluoroethyl ether was prepared by adding 4-methoxybenzyl chloride to 2,2,2,-trifluoroethanol containing pyridine. After removal of the solvent, the residue was taken up in ether, washed with water, dilute HCl, and water. The ether was dried over $MgSO_4$, and after filtering to remove the drying agent, the solvent removed. ^{1}H NMR ($CDCl_3$) δ (ppm): 3.75 (q, 2H), 3.79 (s, 3H), 6.90 (d, 2H), 7.28 (d, 2H). EIMS (70 ev), *m*/*z*: 220 (30%, M^+), 189 (8%, $M^+ - OCH_3$), 135 (12%, $M^+ - CH_2CF_3$), 121 (100%, $M^+ - OCH_2CF_3$).

4-Methoxyphenethyl 2,2,2-trifluoroethyl ether was prepared by irradiating a solution of 4-methoxystyrene in 2,2,2-trifluoroethanol until there was no more styrene left. The ether was isolated as described in the previous paragraph. ^{1}H NMR ($CDCl_3$) δ (ppm): 1.45 (d, 3H), 3.65 (q, 2H), 3.81 (s, 3H), 4.56 (q, 1H), 6.90 (d, 2H), 7.28 (d, 2H). EIMS (70 ev), *m*/*z*: 234 (32%, M^+), 219 (100%, $M^+ - CH_3$), 135 (80%, $M^+ - OCH_2CF_3$).

Laser flash photolysis experiments were carried out with equipment in Mulheim and in Toronto. The carbocation precursors were photolyzed with 20 nanosecond pulses, typically of 30 mJ, of 248 (KrF^*) or 308 nm ($XeCl^*$) monochromatic light. A pulsed Xenon light provided the monitoring beam. This was passed through the cuvette containing the substrate, then through a monochromator onto a photomultiplier tube. The signal was digitized by Tektronix 7612 and 7912 transient recorders, and the digitized signal sent to various computers for data analysis. Stock solutions of the substrates of concentrations 0.1–0.01 M were prepared in acetonitrile or dichloromethane. A small amount of this solution was then added to the appropriate TFE, HFIP, or aqueous solution. This was then introduced into a flow cell apparatus, where, if desired, the solution was saturated with argon or oxygen by bubbling with the appropriate gas for 5–10 min. Absorption spectra were constructed point-by-point, with the solution being flowed through the cuvette so that there was unreacted substrate of the same concentration at each wavelength. The average optical density over a small time period was then determined at each wavelength and plotted against the latter to generate the spectrum. Rate constants were obtained by fitting the decay data to the exponential equation. five to seven kinetic runs were performed with each solution and the rate constants averaged. Observed rate constants refer to 20 ± 2°C, and were reproducible to ±2% in TFE and ±10% in HFIP. The nucleophile quenching experiments involved 5–6 solutions of tetrabutylammonium bromide or sodium azide varying in concentration from 5×10^5 to 0.001 M. Plots of the observed rate constant were linear in the concentration of the added nucleophile. The second-order rate constants were obtained as the least-squares slopes. The rate constants for the styrene quenching in Table 3 were obtained with initial styrene concentrations of 5×10^{-5} to 5×10^{-4} M. A low laser dose (5–10 mJ) was em-

Consideration of end effects of DNA hybridization in selection of fluorescent dyes for development of optical biosensors

S.C. Jakeway and U.J. Krull

Abstract: Intercalating fluorescent dyes are in widespread use to detect the presence of double-stranded DNA. Applications include the development of biosensors that rely on the attachment ("tethering") of a dye molecule by a short hydrocarbon chain to the terminus of a strand of DNA so that dye is continuously available and the biosensor is fully reversible. Double strands of DNA have end effects that limit the stability of hybridization and dye intercalation near the termini of the duplexes. Therefore, the selection of the dye must be based on consideration of spectroscopic properties and also issues associated with tether length and the stoichiometry of the binding of the dye with double- and single-stranded DNA. Ethidium bromide (EB) has been used extensively to detect hybridization of DNA in applications such as electrophoresis, gene chips, and biosensors. A number of dyes with greater quantum efficiency than EB for detection of hybridization have been reported. Furthermore, other practical spectroscopic advantages can be gained in terms of improved S/N by use of dyes that have excitation that is red shifted relative to EB. Pyrilium iodide has been disclosed as an intercalator of high quantum efficiency and long excitation wavelength. This work investigates pyrilium iodide in comparison to EB as a candidate for preparation of a tethered dye for detection of hybridization of DNA 20-mers.

Key words: biosensors, DNA, hybridization, fluorescence, end effects.

Résumé : L'utilisation de colorants fluorescents intercalés pour détecter la présence d'ADN à double brin est très répandue. Les applications comprennent le développement de biosenseurs qui dépendent de la fixation d'une molécule de colorant à une extrémité d'un brin d'ADN à l'aide de courtes chaînes d'hydrocarbures de façon à rendre le colorant continuellement disponible; le biosenseur est entièrement réversible. L'ADN à doubles brins conduit à des effets dus aux extrémités qui limitent la stabilité de l'hybridation et de l'intercalation du colorant près des extrémités des duplexes. Il en résulte que la sélection du colorant doit être faite sur la base d'une considération des propriétés spectroscopiques ainsi que des questions associées à la longueur de l'attache et à la stoechiométrie de la fixation du colorant sur l'ADN à un et à deux brins. Le bromure d'éthidium (« EB ») est couramment utilisé pour détecter l'hybridation de l'ADN dans des applications telles que l'électrophorèse, les puces géniques et les biosenseurs. Un certain nombre de colorants d'efficacité quantique supérieure à celle d'EB pour la détection de l'hybridation ont été suggérés. De plus, on peut obtenir des avantages spectroscopiques pratiques en termes d'amélioration du rapport S/N en utilisant des colorants pour lesquels l'excitation est déplacée vers le rouge par rapport au EB. Il a été démontré que l'iodure de pyrilium peut être utilisé pour intercaler avec une efficacité quantique et une longueur d'onde d'excitation élevées. Dans ce travail, on a comparé l'iodure de pyrilium et l'EB comme candidats pour la préparation d'un colorant fixé permettant de détecter l'hybridation d'ADN 20mères.

Mots clés : biosenseurs, ADN, hybridation, fluorescence, effets des extrémités.

[Traduit par la Rédaction]

Introduction

The use of DNA as a chemically selective "receptor" for the detection of complementary DNA or RNA has been proposed as the basis for development of gene chips and biosensors. Early work was pioneered in the area of electrochemistry where reduction of adenine and cytosine residues, and oxidation of guanine residues were shown to permit detection of DNA (1). Significant extension of early efforts had already been reported by the mid-1980s for a number of sensor platforms (2), and more recently work has focused on biosensors and gene chips (3, 4). In many methods, hybridization of a target strand of nucleic acid is detected by use of a reagent that interacts with double-stranded DNA. Intercalating dyes represent one type of reagent that has been widely used for detection of hybridization. One example is based on the development of a fibre-optic DNA biosensor where the surface of a cleaned optical fibre is derivatized

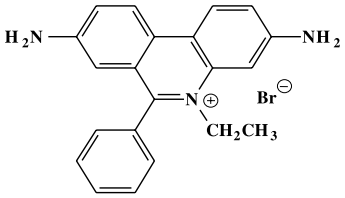
pyrylium iodide (PYI)



ethidium bromide (EB)

with a linker onto which a 20-mer of single-stranded DNA (ssDNA) is grown through automated synthesis (5, 6). A fluorescent intercalating dye such as ethidium bromide (EB) can be present in solution or tethered covalently to the ssDNA. The concept of a tether is based on localization of the dye near where intercalation occurs, and has been demonstrated in principle by attachment of EB by a hydrocarbon chain to the terminus of immobilized dT_{20} (6). The dye can intercalate if hybridization of target strands from a sample solution occurs with the ssDNA on the surface of the fibre. The dye can emit fluorescence if it is exposed to excitation radiation that is passed through the optical fibre, and fluorescence can be captured by the optical fibre and carried to a detector such as a photomultiplier tube (5). Interesting questions arise from the consideration of how many dye molecules should be tethered per oligomer. For example, can incorporation of dye at high density into double-stranded DNA (dsDNA) lead to unwanted effects such as self-quenching, can the selectivity that is associated with hybridization be altered, and can high local concentrations of dye lead to predominance of association with DNA by processes other than intercalation?

A wide variety of fluorescent dyes have been used to detect the presence of dsDNA. These include dyes such as EB (5), 4,6-diamidino-2-phenylindole (DAPI) (7), fluorescein (8), and thiazole orange (9). The majority of these fluorescent probes are deficient in one or more characteristics when considering their use in a biosensor where real world samples are to be analyzed. For example, real world samples contain both AT and GC base pairs in varying ratios and varying sequences. Hoechst 33258 preferentially binds to AT-rich regions in dsDNA, and this would lead to a different response from different samples based on the availability of AT sites rather than on the concentration of dsDNA alone. Biological samples may also contain several constituents that could potentially cause background fluorescence. Biological samples often contain species such as tryptophan or porphyrins, which can emit fluorescence when stimulated by UV and visible radiation. To reduce the background observed from other biological molecules, spectral absorption and emission characteristics of the probe should be selected to lie towards the red or near-IR wavelength region (10).

We have investigated the use of pyrylium iodide (Fig. 1) in contrast to the commonly used intercalator EB (Fig. 1), as a fluorophore for the detection of DNA hybridization, with the long-term goal being development of a tethered dye. Pyrylium iodide (PYI) was chosen because it is an intercalator, the emission and excitation spectra are red shifted with respect to EB, it has a larger fluorescence enhancement than EB (quantum yield not reported), emission results in a large Stokes' shift (65 nm) that is significant for provision of wavelength windows to separate emission from excitation radiation, and it binds preferentially to dsDNA (11). This dye maybe preferred to EB for use in the biosensor developed by Piunno et al. (5, 6, 12). The fluorescence properties of PYI and the optimal number of probe molecules that bind to dsDNA needs to be investigated to establish conditions for use in biosensors.

Our experiments have measured the fluorescence enhancement of PYI in solution to be about 4000% greater than EB under similar conditions involving intercalation into dsDNA in solution. Taken together with the red-shifted spectral characteristics and minimal binding to ssDNA, PYI appears to be a better choice of probe than EB. Our results suggest that the optimal loading ratio of PYI to a 20-mer of DNA is 1:1, as suited for a tethered dye, whereas the optimal loading ratio for EB to a 20-mer of DNA is in a higher range of at least 2:1 (dye:DNA). We have also observed that the bases near the terminal ends of the double-stranded oligonucleotide 20-mers may not hybridize with the same thermodynamic stability as areas towards the centre of the duplex, thus leading to a reduction of the number of dye molecules that can intercalate into the duplex.

Experimental

Chemicals

Ammonia solution (concd.) and boric acid were obtained from BDH (Toronto, Ont.). Rhodamine 6G, formamide, and bromophenol blue (Aldrich Canada, Oakville, Ont.), and xylene cyanole FF, Tris base, and EDTA (Sigma Canada, Oakville, Ont.) were used as received. Polyacrylamide and sodium chloride were obtained from Caledon (Georgetown, Ont.). All phosphoramidites were supplied by Dalton Chemical Laboratories Inc. (Toronto, Ont.). EB was purchased from Molecular Probes, Inc. (Eugene, Oreg,). PYI was a generous gift from Canon Research Centre (Japan). Sterile water was produced using glass double-distilled water by treatment with diethyl pyrocarbonate (Sigma) and autoclaving (120ºC and 4 atm (1 atm = 101 kPa)).

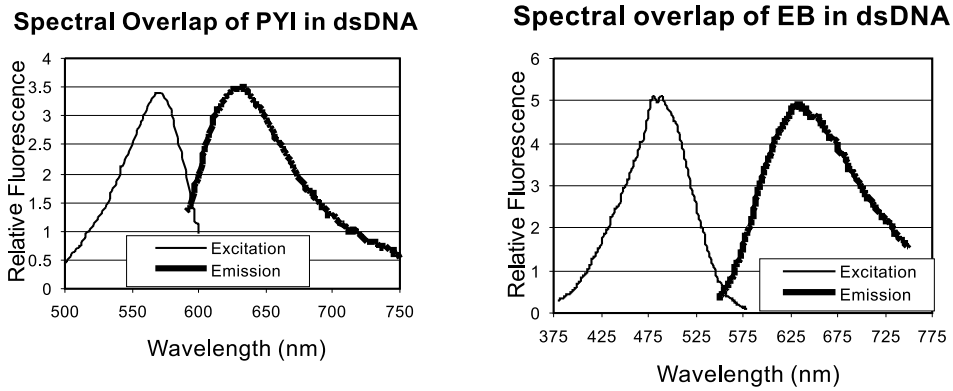
Fig. 2. Spectral overlap of excitation and emission curves for PYI and EB when in the presence of dT_{20} with dA_{20} (i.e., dsDNA). The oligomers and dye were each at a concentration of 3×10^{-6} M.



Purification of dT_{20} for use in hybridization studies

Oligonucleotide composed of 20 identical nucleotides was prepared by automated synthesis using an Applied Biosystems 391 DNA synthesizer PCR-MATE (Applied Biosystems Inc., Mississauga, Ont.), using the standard phosphoramidite method provided by ABI (13). The ssDNA was removed from the support (control pore glass, CPG) by using concentrated ammonia solution for 1 h. Gel electrophoresis was used to purify ssDNA. The concentration of each fraction was determined by absorption spectroscopy (A_{260}). The purified DNA was stored in at –20°C until further use.

Dye fluorescence in the presence of DNA

One litre of hybridization buffer was made by dissolving 58.44 g sodium chloride, 2.99 g NaH_2PO_4 (BDH), and 3.45 g $NaHPO_4 \cdot H_2O$ (BDH) or 3.89 g sodium dihydrogen orthophosphate (BDH) in 1 L of water. The pH was set to 7.0. The dyes (Fig. 1) and ssDNA were dissolved in hybridization buffer until the desired concentration of 3×10^{-6} M was reached for each. The fluorescence spectra of the dyes in solution were collected using a spectrofluorimeter (SLM–Aminco 8100, SLM Instruments, Urbana, Ill.) using 4-nm slit widths and a temperature of 20°C. The reference channel was based on use of 3 g/L of rhodamine dye in ethanol. Fluorescence spectra for the dyes were first collected in the absence of DNA. Fluorescence spectra of the dyes were then obtained in the presence of 20-mer ssDNA, and the concentration of dye and ssDNA was kept constant when the complementary strand of DNA replaced the portion of hybridization buffer. Finally, fluorescence spectra were obtained in the presence of ssDNA and complementary DNA (cDNA), and the ratio of dye:DNA was varied in the range from 1:1 to 6:1.

Results and discussion

The selection of a dye for study was based on avoiding certain factors that could limit analytical applications. Dyes with small Stokes' shifts (less than about 35 nm) were of little interest due to the difficulty of signal isolation from excitation wavelengths. It was also recognized that a small Stokes' shift could lead to a significant spectral overlap integral, thereby increasing the probability of self-quenching of the probe. Groove binding dyes were not used in this particular study because of their preference for DNA sequences rich in AT base pairs (14). EB was used for the purpose of comparison in these experiments because it has very well established binding properties, no sequence selectivity, and is currently used as the fluorescent probe to detect DNA hybridization for the biosensors that are being studied in our research group.

The expected spectral shifts were noted for both EB and PYI (11, 15) when the spectrum of the dye in solution was compared with the spectrum of the dye in dsDNA. The presence of the spectral shifts indicated that the dye was in a different environment from that in aqueous solution and consistent with the intercalation of the dyes into dsDNA. When EB was placed in solution with dsDNA at a 1:1 ratio, the excitation spectra red-shifted 15 nm with respect to the free dye, while the emission spectrum blue-shifted 10 nm with respect to the free dye in solution. At a 1:1 ratio of EB to ssDNA, the observed fluorescence in ssDNA (dT_{20} or dA_{20}) was not significantly different from the fluorescence of the free dye.

The emission from EB showed a larger Stokes' shift than that from PYI (134 nm compared with 61 nm, respectively). The spectral overlap of the excitation and emission spectra provides an indication of the potential for self-quenching.It was determined that the spectral overlap of EB was less than 0.5%, whereas that of PYI was 5.4% (Fig. 2). Therefore, self-quenching and inner-filter effects would be of greater consequence to calibration and sensitivity by a factor of approximately 10 when using PYI instead of EB.

Little or no fluorescence intensity increase was expected when the PYI was in contact with ssDNA (dT_{20}, dA_{20}, dG_{20}, or dC_{20}). PYI showed a dramatic increase in fluorescence intensity when bound to dsDNA relative to that of EB. The excitation maximum for PYI in dsDNA was 570 nm, which represents at least a 65-nm red shift in contrast to the corresponding experimentally determined value for EB.

The intensity of fluorescence was observed to increase by a factor of 47.7 ± 1.7 over that of the free dye in solution when PYI was added to a 1M hybridization buffer solution containing dT_{20} and dA_{20} in a 1:1:1 ratio (Fig. 3). PYI in the presence of dT_{20} showed a fluorescence intensity increase of 2.6 relative to that of the free dye in the absence of the ssDNA, and similarly, a twofold increase was observed from

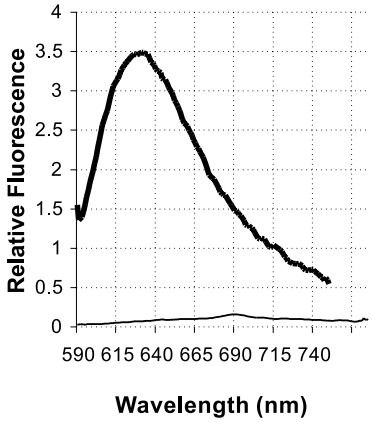
Fig. 3. Emission spectra of PYI in solution (-) compared with PYI that had associated with dsDNA (-). The ratio of dye:dsDNA was 1:1 and the concentrations of each species in all cases was 3×10^{-6} M.



PYI in the presence of dA_{20}. An important point to consider when doing quantitative comparisons is that the excitation wavelength was held constant (suitable for maximum absorption of free dye in solution) when measuring the emission spectra of free dye in solution, dye with ssDNA, and dye with dsDNA. This implies that the fluorescence intensity enhancement is reported on the basis of what might be observed from a biosensor that is set to operate at fixed excitation wavelength, using a wavelength that is set to maximize signal for a background reference.

An examination of the effect of varying the ratio of PYI:dsDNA in the range 1:1 to 6:1, resulted in the fluorescence enhancements shown in Fig. 4 (relative enhancements based on comparison to free dye without any DNA at 632 nm). The reduction of fluorescence enhancement that is seen in Fig. 4 can be explained in terms of self-quenching. Self-quenching can be a result of spectral overlap and distance-dependent quenching phenomena such as coulombic (Förster) interactions (16).

Figure 4 suggests that the maximum number of PYI dye molecules that can intercalate into a dsDNA 20-mer would be 3, based on the lack of change in fluorescence when the dye concentration is increased from 4:1 to 6:1. The length of a dsDNA 20-mer is on the order of 68 Å, suggesting an average separation distance between the dye molecules of 23 Å (assuming an even distribution of dye throughout the double helix). However, if end effects (discussed below) are taken into account, the average distance between intercalated dye molecules might be as small as 13 Å. The optimum ratio of dye molecules for short dsDNA complexes is 1:1 to maximize S/N, based on the experimentally determined ratio of relative fluorescence of bound to free dye, which is an ideal ratio for a tethered dye. Experiments were not conducted where the ratio of dye:dsDNA was less than 1:1 because at least one dye molecule is needed to detect every DNA hybridization (recognition) event in the case where tethered dye is used for biosensor preparation.

EB on average intercalates into every fifth base pair in long DNA duplexes (17). EB usually intercalates into dsDNA, but at very high concentrations of EB there is evidence of a second form of interaction in which EB binds to

Fig. 4. The ratio of the relative fluorescence intensity at 632 nm between PYI in the presence of dsDNA and the dye in solution, for various dye:dsDNA concentrations. Excitation was held at 568 nm for all cases.

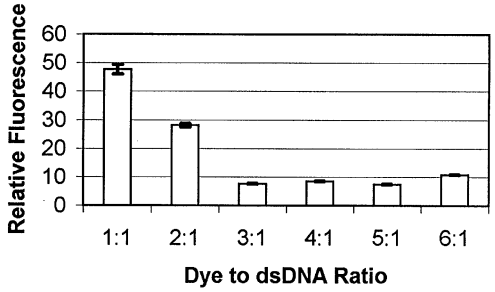


Fig. 5. The ratio of the relative fluorescence intensity at 623 nm between EB in the presence of dsDNA and the dye in solution, for various dye:dsDNA concentrations. Excitation was held constant at 500 nm for all cases.

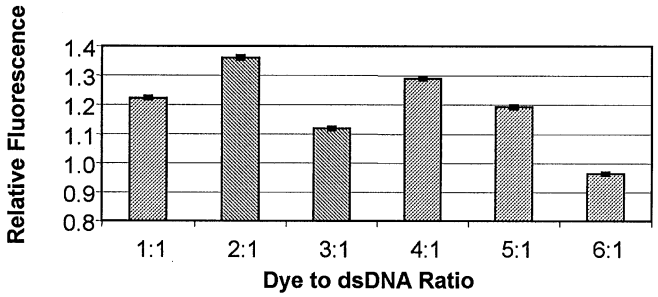

dsDNA in the major groove (17). The results of Fig. 5 indicate that the largest increase of fluorescence intensity occurs at a molar ratio of 2:1, for EB:dsDNA. In terms of device construction, a tethering protocol that provides two intercalants per immobilized ssDNA would be more difficult to achieve than for the 1:1 dye:DNA system.

It is well known that the terminal base pairs of dsDNA are not as thermodynamically stable and rigidly confined to the double helix structure, and the dynamics of "breathing" are greater than for the corresponding base pairs located away from the ends of dsDNA (18). End effects would be expected to have a proportionally larger impact on smaller dsDNA strands than for longer dsDNA strands on the presumption that the number of bases involved in the end effects remains constant regardless of strand length. An extrapolation of the work of Waring (17) suggests that a 20-mer might be able to accommodate up to four molecules of EB. However, the results obtained here suggest that a maximum of three EB molecules in a dA_{20}:dT_{20} structure is possible under the conditions used herein before a second competitive binding motif became significant. This would suggest that the effective length of the hybridized DNA 20-mer may be on the order of 12–16 base pairs, and 4–8 base pairs at the ends of dsDNA may not be sufficiently bound as complementary pairs to fully stabilize intercalation of EB. Dye molecules that do intercalate into a region that experiences end effects may provide a lesser fluorescence enhancement. The breathing of the DNA duplex would reduce the average quantum yield and therefore the fluorescence intensity from dye that binds near the ends of the dsDNA. The

© 1999 NRC Canada

determination that end effects may include perhaps three to four nucleotides at the end of dsDNA provides insight into the length of the tether that is required for attachment of dye to the terminus of DNA for development of a biosensor.

The increase in fluorescence intensity that is seen when the ratio of EB:dsDNA is increased to 4:1 can be explained by the secondary binding of EB to dsDNA. Waring suggests that secondary binding of EB becomes more prominent when the ratio of dye to base pairs becomes more than 1:5. Dye bound in this second motif would not have the same orientation as dye molecules that are intercalated into the double helix and thus would not be quenched with the same efficiency because of distance and the different orientations of the dipoles.

Conclusions

Pyrylium iodide showed several traits that would make it a favourable substitute for EB. The excitation maximum was experimentally confirmed to be 65 nm longer than the excitation maximum for EB. Our work showed that the fluorescence enhancement of PYI when intercalated into dsDNA was almost 4000% greater than that for EB at similar dye:dsDNA ratios. The maximum loading of PYI in a dA_{20}:dT_{20} duplex was determined to be three dye molecules. Importantly, the maximum response from PYI occurred when the ratio of dye:dsDNA was 1:1, which is optimal for tethering where one dye molecule would be attached to each immobilized ssDNA. The maximum loading ratio of EB to a 20-mer was determined to be three dye molecules for a mechanism involving intercalation. In the case of EB, the maximum fluorescence intensity enhancement occurred at a dye:dsDNA ratio of 2:1 (for a 20-mer). The end effects occurring at the termini of the short dsDNA used in this work reduced the extent of average binding of EB to oligonucleotides by intercalation.

A further series of experiments are underway in which base pair mismatches are deliberately positioned near the ends of 20-mer dsDNA. Measurements of the variations in the melt curves from these systems will help to quantitatively establish the energetics of end effects (thermodynamic effects), as well as the distance that end effects can extend from the termini of short strands of dsDNA.

Crystal structure and solution studies of the product of the reaction of β-mercaptoethanol with vanadate

Sudeep Bhattacharyya, Raymond J. Batchelor, Frederick W.B. Einstein, and Alan S. Tracey

Abstract: Reaction of β-mercaptoethanol with vanadate under slightly alkaline conditions provided a crystalline complex that was characterized by X-ray diffraction and FTIR spectroscopy. The complex was dimeric in structure with a central $[VO]_2$ core and a pentacoordinate, crudely trigonal bipyramidal arrangement about each vanadium atom with a sulphur occupying a pseudo-axial position. A single ^{51}V NMR signal was observed for this complex when dissolved in water, chloroform or acetonitrile. A large influence of acetonitrile on the vanadium chemical shift suggested the possibility of reaction with acetonitrile. FTIR showed the presence of two complexes in acetonitrile solution but only one in chloroform or water. Mixed solvent studies were carried out in an effort to further characterize the solution complexes. Crystal structure of $[\{VO_2(OC_2H_4S)\}_2][NEt_4]_2$: monoclinic, space group $P2_1/n$,. a = 8.3451(17), b = 16.954(4), c = 10. 2064(25) Å; β = 101. 271(18)°; V = 1416.2 Å^3; Z = 2; R_F = 0.048 for 1355 data ($I_o \geq 2.5\sigma(I_o)$) and 147 variables.

Key words: mercaptoethanol, vanadate, vanadium NMR, X-ray diffraction, FTIR, thiolate.

Résumé : La réaction du β-mercaptoéthanol avec du vanadate dans des conditions faiblement alcalines conduit à la formation d'un complexe cristallin dont on a déterminé la structure par diffraction des rayons X et par spectroscopie IR à transformée de Fourier. Le complexe a une structure dimère avec un noyau central $[VO]_2$ et un arrangement pentacoordiné vaguement trigonal bipyramidal autour de chaque atome de vanadium dans lequel un soufre occupe une position pseudo-axiale. Pour ce complexe en solution dans l'eau, le chloroforme ou l'acétonitrile, on n'a observé qu'un seul signal en RMN du ^{51}V. La spectroscopie IR par TF met en évidence la présence de deux complexes dans l'acétonitrile et seulement un en solution dans le chloroforme ou l'eau. Afin de mieux caractériser les complexes en solution, on a effectué des études dans des solvants mixtes. Les cristaux du $[\{VO_2(OC_2H_4S)\}_2][NEt_4]_2$ sont monocliniques, groupe d'espace $P2_1/n$, avec a = 8,3451(17), b = 16,954(4) et c = 10,2064(25)Å; β = 101,271(18)°; V = 1416,2Å^3; Z = 2; R_F = 0,048 pour 1355 observations (avec $I_o \geq 2{,}5\sigma(I_o)$) et 147 variables.

Mots clés : mercaptoéthanol, vanadate, RMN du vanadium, diffraction des rayons X, IR à transformée de Fourier, thiolate.

Introduction

The aqueous chemistry of vanadium sulphur compounds has been attracting increasing attention over recent years (1–3). Amongst other things, sulphovanadium complexes are found in certain nitrogen-fixing enzymes where they provide an alternative to the more frequently encountered molybdenum-dependent nitrogenases (4). Furthermore, sulphur is frequently encountered (as the thiol group in cysteine) in the active site of enzymes that are inhibited by vanadate or vanadate complexes (5). Of paramount interest in this class of enzymes are the protein tyrosine phosphatases (PTPases) which are key regulators of many fundamental cell processes including cell mitosis, T-cell activation, and insulin responses (6, 7). Vanadate is a well known potent inhibitor of PTPases. X-ray characterization of PTPase/vanadate complexes shows vanadate in a pentacoordinate trigonal bipyramidal structure with the sulphur of the active site cysteine being covalently bound in an apical position. The three equatorial positions and the remaining apical position are occupied by oxo and hydroxo ligands that in turn donate or accept hydrogen bonds from adjacent active site residues (8).

Although the insulin-mimetic influences of vanadium are well known and attempts are being made to exploit this in therapeutic applications (9), there are many unanswered questions concerning the aqueous vanadate sulphur chemistry of relevance to such an application. Indeed, there is a marked paucity of information available. Our understanding

of the influences of ligands that contain sulphhydryl groups on the aqueous chemistry of vanadium in its higher oxidation states of vanadium is clouded. The statement or inference that vanadate (V(V)) is rapidly reduced to vanadyl (V(IV)) by sulphhydril groups is very frequently encountered. It is virtually dogma that in vivo vanadate is reduced fully to vanadyl by cellular glutathione. This tenet has been disputed and a number of factors regulating the redox equilibrium pointed out (10). More recently, evidence suggesting that the efficacy of reduction is lower than is frequently assumed has been presented (11).

Recently we have shown that, although peroxovanadate rapidly oxidizes the thiol groups of dithiothreitol, oxidation in the presence of the vanadate ion tends to be quite slow, particularly above neutral pH (12). Instead of rapid oxidation, a complexation reaction leading to formation of two products, both of V_2L stoichiometry was observed. The generation of a $[VO]_2$ cyclic core with the sulphhydryl group complexed in an auxiliary position was proposed for these materials (12). On the basis of a close correspondence in vanadium chemical shifts and because product formation is favored, a similar coordination, in a V_2L_2 stoichiometry was proposed for the product of the reaction of β-mercaptoethanol with vanadate (12). Somewhat inadvertently, during studies of the reactions of hydroxamidovanadate complexes with sulphur-containing ligands (13), a β-mercaptoethanol complex that contained no hydroxylamine and had a V_2L_2 stoichiometry was obtained in crystalline form. Better methods for its preparation were developed and its structure was established by X-ray crystallography. NMR studies of the dissolution of this product were carried out in an effort to obtain a correspondence between the solution and solid structures.[2]

Experimental section

Materials

All chemicals used in this work are reagent grade. Divanadium(V) pentoxide and β-mercaptoethanol (Aldrich Chemical Co.), tetraethylammonium hydroxide (20% aqueous solutions) (Sigma Chemical Co.) were used without further purification. Unless mentioned otherwise, all the solutions were prepared in dry solvents in a millimolar scale.

Synthesis of $[\{VO_2(OC_2H_4S)\}_2][(NEt_4)_2]$

A solid sample of V_2O_5 (0.10 g, 0.55 mmol) was added to a mixture of 20% aqueous solution of tetraethylammonium hydroxide (1 mL) and water (2 mL). The resultant slurry was warmed to 60°C with continuous stirring to obtain a clear colorless solution of tetraethylammonium vanadate. The pH of this solution was about 11.0. A stoichiometric amount of β-mercaptoethanol (0.1 mL, 1.43 mmol), was added in a dropwise fashion. The solution color immediately changed to orange. The pH of the resultant solution was maintained at about pH 8.5. An excess of tetraethylammonium chloride (0.5 g, 3 mmol) was added to this solution and it was kept standing overnight under a stream of air for rapid evaporation. A yellowish crystalline solid of the desired product was obtained after 10 h. The product was filtered, washed with acetone and ether, and finally dried in vaccuo. The crude product was recrystallized from acetonitrile. Yield: 0.22 g (35%). Anal. calcd. for $C_{20}H_{48}N_2O_6S_2V_2$: C, 41.5, H, 8.3, N, 4.8; found: C, 41.78, H, 8.30, N, 4.72.

Preparation of chloroform solutions

To about 0.05 g (~0.1 mmol) of $[\{VO_2(OC_2H_4S)\}_2][(NEt_4)_2]$, suspended in 5 mL of chloroform, was added a stoichiometric amount of bis(triphenylphosphoranyl)iminium chloride. The compound immediately dissolves with formation of a yellow solution with subsequent precipitation of $(NEt_4)Cl$. The solution was filtered and stored.

Spectroscopy

^{51}V NMR spectra were obtained from a Bruker AMX400 NMR spectrophotometer operating at 105.2 MHz at ambient temperature in the unlocked mode. Vanadium chemical shifts are reported relative to the chemical shift of $VOCl_3$ at 0 ppm. The following NMR parameters were used: pulse width 60° (20 μs); spectral width 62.5 kHz; aquisition time 0.065 s; line broadening, 40.0 Hz; frequency domain size 8 K. FTIR spectra were obtained from a BOMEM MB-102 instrument. All solution spectra were observed with a 0.15 mm zinc selenide cell. Aqueous solutions were prepared with water at pH 7.0. In each of the mixed solutions spectra, the aborbance of individual solvent mixtures were recorded and used as reference.

UV–vis spectra of the product complex, 0.69 mM in dimethylformamide, were obtained (1 cm pathlength cell) from an HP8452A diode array spectrophotometer.

X-ray diffraction

Crystals, which slowly decompose in air, were gently wedged and then sealed in glass capillaries, using a trace of epoxy glue as an adhesive. This was the method that yielded the final sample used. Several attempts using different methods of mounting did not produce a stable arrangement. The probable reason for this is the slow degradation of the crystals, producing a thin liquid layer on the surface. Even the best mounting attained required regular reorientation during data acquisition. Data were recorded with an Enraf Nonius CAD4F diffractometer using graphite monochromatized Mo Kα radiation. Data reduction included corrections for Lorentz and polarization effects.

Anisotropic displacement parameters were refined for the non-hydrogen atom sites. Hydrogen atoms were placed in calculated positions and were made to ride on their respective carbon atoms during refinement. Isotropic thermal parameters for all methylene hydrogen atoms were constrained

to have identical shifts during refinement, as were those for all methyl hydrogen atoms.

The data collection was performed using the program DIFRAC[3]. The programs used for absorption corrections, data reduction, structure solution and graphical output were from the NRCVAX Crystal Structure System (14). Full matrix least-squares refinement was carried out using CRYSTALS[4]. Complex scattering factors for neutral atoms (15) were used in the calculation of structure factors. Computations were carried out on a Pentium computer. Crystal data and experimental details are given in Table 1. The atomic coordinates, equivalent isotropic thermal parameters and site occupancies for the non-hydrogen atoms are listed in Table 2.

Results and discussion

$[\{VO_2(OC_2H_4S)\}_2]^{2-}$ was obtained as a crystalline tetraethylammonium salt by reacting tetraethylammonium vanadate and β-mercaptoethanol in a 1:1 mol ratio in water under slightly alkaline conditions. The crystals are hygroscopic and lose their sharpness overnight on being exposed to air. The compound is quite soluble in water, other protic solvents, and in acetonitrile. The compound was found to have low solubility in nonprotic solvents such as chloroform, acetone, and dichloromethane. A chloroform solution was, however, prepared by changing the cation as described in the experimental section. In water, the complex undergoes hydrolysis to establish an equilibrium between complex, vanadate, and free ligand as observed in the ^{51}V NMR spectra. In solvents such as acetonitrile and chloroform, it has sufficient stability (>2 h) to allow investigation of its solution state characteristics.

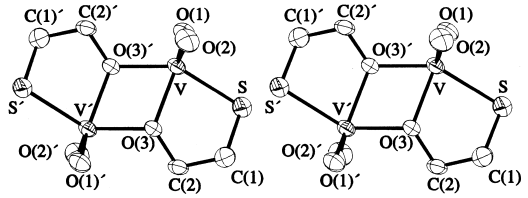
[a]U_{eq} is the mean of the principal axes of the displacement ellipsoid.

Fig. 1. Stereoscopic view of $[\{VO_2(OC_2H_4S)\}_2]$. The planarity of the four-membered ring of the $[VO]_2$ core and the nonplanar five-membered ring formed by the chelated β-mercaptoethanol ligand are evident in this view. 50% probability thermal ellisoids are shown for nonhydrogen atoms.



The crystal structure

A stereographic representation of the molecular structure of the $[\{VO_2(OC_2H_4S)\}_2]^{2-}$ anion is shown in Fig. 1. The anion has crystallographic inversion symmetry and the tetraethylammonium cation is in a general position. The only intermolecular distances significantly less than the sums of the appropriate accepted van der Waals radii are between the sulphur atom and one of the ethyl groups of the cation (S—C(12) 3.319(8) Å and S—C(21) 3.373(7) Å) and are not unusual.

A set of unique bond distances and bond angles for the anion are listed in Table 3. The bonds from vanadium to the

[a] ′ represents the symmetry operation $2 - x, -y, -z$.

bridging oxygen atom are slightly but significantly asymmetric (V—O(3) 2.029(4) Å; V—O(3)′ 1.980(4) Å, where ′ represents the symmetry operation $2 - x, - y, -z$). The V-S-C(1)-C(2)-O(3) ring has an envelope conformation with C(1) constituting the flap (cf. the bond torsion angles: S-V-O(3)-C(2) = –0.3(2)°, O(3)-V-S-C(1) = –22.2(2)°, V-S-C(1)-C(2) = 44.2(3)°, V-O(3)-C(2)-C(1) = 29.2(3)°, S-C(1)-C(2)-O(3) = –48.6(3)°). The arrangement around O(3) is also close to planar (cf. the sum of the three bond angles at O(3) is 358.1°).

The structure shows two identical dioxovanadium centers, bridged to each other by the oxygen of the β-mercaptoethanol ligand to form a core $[VO]_2$ cyclic structural element. The coordination about vanadium is pentacoordinate in a crude trigonal bipyramidal arrangement about each vanadium atom. A pseudo-axial sulphur occupies one coordination site on each vanadium. The central $[VO]_2$ core is planar while the five-membered ring generated by the chelating ligand is highly distorted from planarity as can be judged from the stereoscopic representation of the structure (Fig. 1). Though several thiolato bound monooxovanadates have been reported (2, 3), the dioxovanadium center of this complex so far is unique to this thiolate ligand although it has previously been suggested for other thiolate ligands (12).

The axial coordination of the sulphur atom in trigonal bipyramidal coordination is a structural property also found in vanadate bound in the active site of protein tyrosine phosphatases (8, 16). The V—S bond length measured here (2.3803(19) Å) is considerably longer than that in a number of dithiolates (2.249 Å) where the sulphur occupies an equatorial location in the complexes (2, 3). The V—S bond length measured here is a little shorter than that reported for the V—S distance of the apical sulphur in the two protein tyrosine phosphatases, 2.5 Å (16), and 2.4 Å (8) under the much poorer resolution conditions of the protein structure determination.

^{51}V NMR and FTIR

Dissolution studies of the crystalline compound have been carried out in water and organic solvents. ^{51}V NMR and the FTIR (V=O stretching) spectroscopic studies were carried out in these solvents with a view toward obtaining information about structural changes in the molecule by monitoring the electronic environment around the metal center as reflected, for example, on the V=O stretching frequency. The results are collected in Table 4.

In aqueous solution, $[\{VO_2(OC_2H_4S)\}_2]^{2-}$ gives a ^{51}V NMR signal at –362 ppm (Fig. 2*a*) in the range typical for a thiol-coordinated vanadium center of this type (17). Other ^{51}V signals (Fig 2, insert) occur in the upfield range and correspond to vanadate and various of its oligomers that are produced by dissociation of the complex (18). A time course study showed that, in a dilute aqueous solution (~1–2 mM), the dissociation process required about 1 h to reach its endpoint. Since dissociation requires about an hour and, as there is no observable change in the ^{51}V chemical shift, it is likely that the solution NMR signal corresponds to the dimeric product of the solid state structure. Also, the observation of only one signal at –362 ppm throughout the hydrolysis process strongly suggested that the two dioxovanadium centres remain chemically equivalent until dissociation occurs. It is not very likely that dissociation to a monomer is fast while hydrolysis of the monomer is slow. In fact, it most likely is the cyclic $[VO]_2$ core that provides the stability to the complex. In the similar situation with glycolato complexes based on nucleosides, dimerization to afford the $[VO]_2$ core certainly is a major driving force for product formation (19). This $[VO]_2$ structural motif is a frequently encountered one and seems to be one of the defining properties of vanadate chemistry (20).

When a more concentrated solution (~50 mM) was studied, it was observed to maintain an equilibrium between initial complex and vanadate and its oligomers for several days. Generation of a green solution showed that oxidative decomposition occurred during this time period, but clearly, decomposition was not a rapid process. These observations suggest that the dimeric complex itself is oxidatively quite stable and that the oxidative decomposition of mercaptoethanol, and possibly similar ligands, by vanadate may involve minor or intermediate complexes generated during the

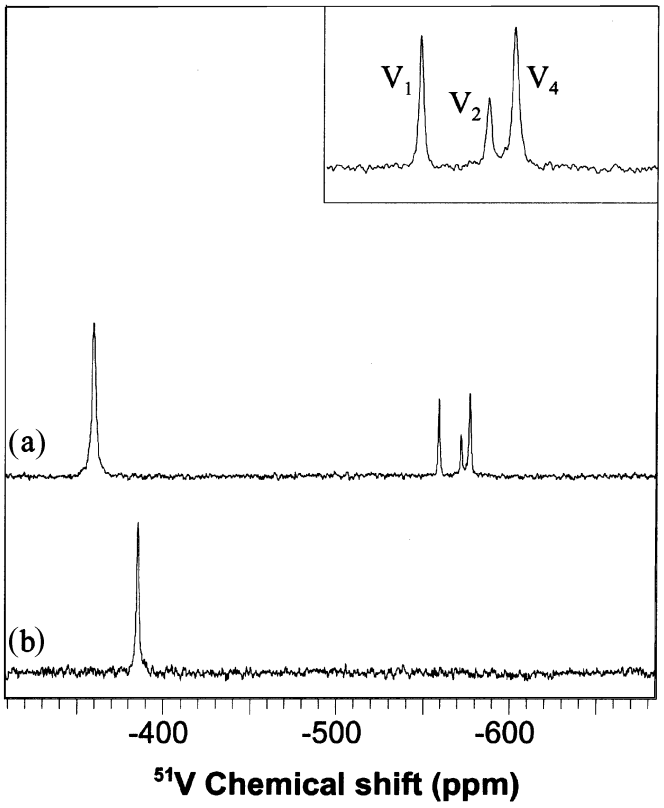
Fig. 2. ^{51}V NMR spectrum of $[\{VO_2(OC_2H_4S)\}_2][NEt_4]_2$ (*a*) in 50 mM aqueous solution at pH 7.0; (*b*) in acetonitrile. The inset identifies the products of partial hydrolysis.



complexation process. Having started here from the pure complex, such compounds would be formed only after a degree of initial dissociation followed by a reassociative process. Under different conditions, oxidation of the ligand by vanadate could well be rapid. Certainly, it would be expected to be so under even moderately acid conditions.

In acetonitrile a single resonance, at –385 ppm (Fig. 2*b*), is observed and it remains unaltered for a prolonged period of time. Compared to water, this signal is shifted upfield by ca. 23 ppm. This seems a bit large to be accounted for by a solvation effect. In the noncoordinating chloroform solvent, the corresponding signal occurs at –376 ppm. The question then arises as to whether these three chemical shifts represent unique structural species or not. When mixtures of acetonitrile and chloroform, in different proportions, were used, a single signal but with a systematic change in chemical shift was observed (Table 4). This, however, does not exclude the possibility of two species which are in rapid interconversion. In this case, the rate of this interconversion is faster than the time scale of these NMR experiments (millisecond timescale). If, in fact, there are two species, one would expect to see them by employing an instrument with a time resolution faster than the rate of this interconversion.

Solution studies were therefore carried out using FTIR spectroscopy. Initial studies in chloroform solution suggested that there was no change in structure from that of the solid state. In both cases the V=O stretching band appears as a singlet, at 910 cm^{-1}. On the other hand, a solution of the β-mercaptoethanol complex in acetonitrile has a second stretching vibration at 930 cm^{-1} with an intensity comparable to the 910 cm^{-1} signal (Fig. 3*a*). Stepwise addition of chloroform (Table 4) into the acetonitrile solution causes a systematic decrease in intensity of the 930 cm^{-1} signal (Fig. 3). This gives strong support to the proposal that two independent species are found in acetonitrile solution. One of these (910 cm^{-1}) apparently has a structural form similar to that in the solid state (Fig. 1) while the second is dependent on the availability of the acetonitrile in the solution.

FTIR absorbances at 937 cm^{-1} have been observed for V(IV) thiolate complexes (21). However, we have observed absorbances close to 930 cm^{-1} for V(V) complexes other than those studied here. The finding that the 930 cm^{-1} absorbance decreases in intensity in a systematic way with addition of chloroform to an acetonitrile solution of the complex certainly mitigates the possibility that what is being observed actually is a V(IV) complex. It seems very unlikely that the oxidation state would be significantly influenced by going from an acetonitrile to chloroform solution. Also, the

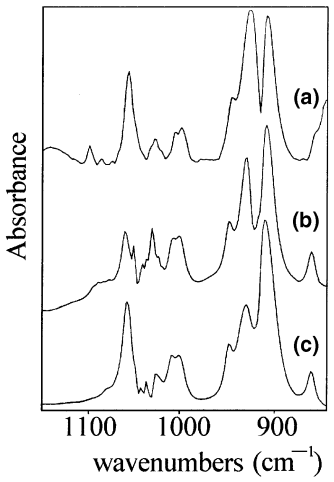
Fig. 3. FTIR spectrum of $[\{VO_2(OC_2H_4S)\}_2][NEt_4]_2$ in (*a*) pure acetonitrile; (*b*) acetonitrile with 25% chloroform; (*c*) acetonitrile–chloroform 1:1 mixture.

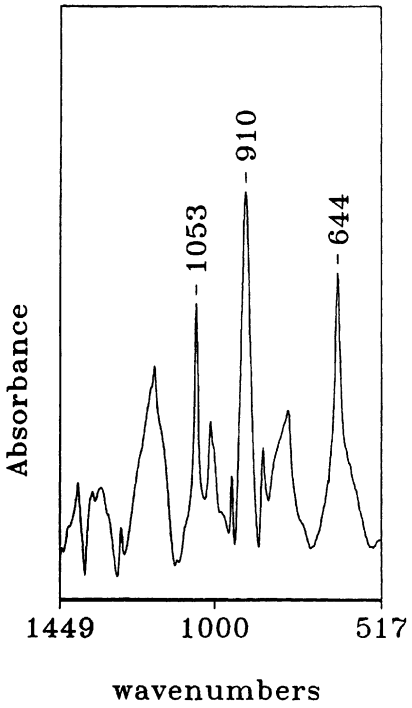


solutions are only slightly yellow and a V(IV) complex would be expected to be highly coloured because of intense transition bands in the visible region of the spectrum. For the above reasons, and also because the crystalline material was itself obtained from an acetonitrile solution, the 930 cm^{-1} frequency is assigned to a V(V) not a V(IV) complex.

In an attempt to learn more about the second species, FTIR dissolution studies were extended to a mixed water–acetonitrile system. In pure water, the complex gives a relatively broad stretching band at ca. 912 cm^{-1} which gradually loses its intensity and breaks into multiplets as it hydrolyzes to generate other vanadates, as confirmed in the NMR spectra (Fig. 2*a*). The close correspondence of this V=O vibration to that in $CHCl_3$ or KBr (910 cm^{-1}) suggests that a structure similar to the solid state is also present in water. In the mixed water–acetonitrile solvent system, two FTIR signals similar to those in pure acetonitrile (Fig. 3*a*) are obtained when the quantity of water is low. When the percentage of water in the solution is increased, the V=O stretching band at 910 cm^{-1} is unaltered (Table 4) but the 930 cm^{-1} signal decreases in intensity, indicating the loss of the second product. This is reminiscent of the chloroform–acetonitrile experiment. However, unlike in the chloroform–acetonitrile system, the 930 cm^{-1} signal also undergoes a gradual increase in wavelength and shifts toward the 910 cm^{-1} band and ultimately coalesces with it (Fig. 4) at a water concentration of about 10%.

The interconversion process between the two species in acetonitrile solvent is quite fast. Judging from the ^{51}V NMR chemical shifts observed in water and in acetonitrile and from the observation of only a single signal in the mixed solvent system, an interconversion rate faster than about 10^4 s^{-1} can be deduced. In the FTIR spectrum the two V=O stretches clearly are observed but the timescale here is in the picosecond range. The rate of the interconversion process suggests that any major structural changes arising from rearrangement of ligands is unlikely. Still, a possibility such as ring opening followed by accepting an acetonitrile molecule into the coordination sphere may describe what is happening. Alternative structures that do not invoke acetonitrile

Fig. 4. FTIR of $[\{VO_2(OC_2H_4S)\}_2][NEt_4]_2$ in acetonitrile with 10% water.



complexation, such as a macrocyclic structure similar to that seen with a chloroalkoxovanadate (22), seem unlikely although they have been invoked in order to explain the rather slow chemical exchange observed in glycolatovanadate systems (20, 23).

The UV–vis spectrum of the mercaptoethanol complex in dimethylformamide showed a single absorbance with a maximum at 286 nm (ε = 4850 M^{-1} cm^{-1}). The solutions of this complex and also those formed with dithiothreitol (12) are pale yellow. This contrasts with that reported for the highly coloured vanadium complex formed with $(HSCH_2CH_2)_3N$ where strong charge transfer bands at 375 and 500 nm were observed (3). Apparently, it is the multiple sulphur ligation in this latter complex that leads to the strong absorbance in the visible region.

Conclusions

Reaction of vanadate with β-mercaptoethanol in aqueous solution yielded a solid crystalline compound of moderate stability. The crystal structure revealed two thiolato bound dioxovanadium centers coupled through a $[VO]_2$ core. The $[VO]_2$ core in this molecule helps stabilize the complex in a manner not well known in vanadium-thiolate chemistry but that is, however, frequently encountered with bidentate oxygen donors (24) and apparently is one of the more important structural motifs of vanadium(V) chemistry.

In chloroform, FTIR spectroscopy suggests there is a close structural correspondence between the solid and solution structures (V=O stretch, 910 cm^{-1}). In acetonitrile the complex exists in two different structural forms, one of which appears to be similar to that found in the solid state. The second species requires the presence of acetonitrile and, in view of the lack of viable structural alternatives, this im-

© 1999 NRC Canada

plies that the acetonitrile is coordinated. In water and mixed acetonitrile/water solvents the frequency of the FTIR signal suggests an aqueous structure that corresponds to the solid state structure. Unfortunately, the results are somewhat equivocal as the signal of the acetonitrile-derived complex (930 cm^{-1}) does not only decrease in intensity but it also shifts in position with increase in water content until it overlaps the second V=O signal (910 cm^{-1}). This raises the possibility that water can replace acetonitrile in the 930 cm^{-1} complex. Unfortunately, because of the shift in signal position with increase in water content, the juxtaposition of the FTIR signals of the solid and aqueous solution at 910 cm^{-1} cannot be taken to be a good indicator of the coordination in aqueous solution. Indeed, the observation of a reaction with the weakly complexing solvent, acetonitrile, makes it very difficult to rule out the possibility that there is a coordination change from the solid state structure when the complex is dissolved in water. However, the loss in intensity of the 930 cm^{-1} that accompanies its frequency shift with increase in water content suggests conversion to the 910 cm^{-1} (crystal) structure probably is completed at high water concentrations.

Schiff base insertion in titanium alkyls; reduction of imine functions by benzyl addition

Simon J. Coles, Michael B. Hursthouse, David G. Kelly, Andrew J. Toner, and Neil M. Walker

Abstract: $TiBz_4$ reacts with *N*-2-fluorenyl(salicylideneimine) to afford a crystallographically characterized titanium(IV) complex containing two conventional bidentate Schiff base ligands and two O-bound ligands in which the imine function has been reduced by the addition of benzyl and hydrogen moieties.

Key words: insertion, nucleophilic additions, Schiff bases, titanium

Résumé : Le $TiBz_4$ réagit avec la *N*-2-fluorényl(salicylidèneimine) pour conduire à un complexe du titane(IV), caractérisé cristallographiquement, qui contient deux bases de Schiff bidentates conventionnelles comme ligands et deux ligands liés à l'oxygène dans lesquels la fonction imine a été réduite par l'addition de benzyle et d'hydrogène.

Mots clés : insertion, additions nucléophiles, bases de Schiff, titane.

[Traduit par la Rédaction]

The application of titanium complexes as asymmetric catalysts is developing quickly (1), and producing renewed interest in titanium–salen derivatives (2). Studies of organometallic Schiff base complexes have focused on tetradentate N_2O_2 Schiff base ligands and employed two synthetic strategies: group 4 complexes with Schiff base and chloride ligands have been alkylated with s-block alkylating agents (3, 4) or $AlMe_3$ (5); and alternatively, group 4 alkyls have been reacted directly with Schiff bases (6). Three basic forms of reactivity are observed: metal-centred alkylation, combined metal–ligand alkylation, and alkylation–reduction (Fig. 1). Dialkylated species are often the primary goal of studies, since such complexes have been demonstrated to function as active ethylene polymerization catalysts in both homogeneous and heterogeneous studies (6–8). To understand the relationship between catalytically active and inactive complexes, and the deactivation pathways of the former, it is essential to fully elucidate the potential reactivity of alkyl/aryl functions and Schiff base ligands within the group 4 coordination sphere. It has already been demonstrated that complexes in the +4 oxidation state, as depicted in Fig. 1, often undergo thermally induced migrations to fluxional and uncharacterizable products at or below ambient temperature. In some instances such products are obtained without the isolation of stable and well-defined intermediates. Reactions are presumed to result from alkyl migration to the Schiff base imine function (4*a*, 6). The present work identifies a new alternative form of reactivity in which benzyl and hydrogen moieties are added to the coordinated Schiff base ligand reducing the C=N function to a secondary amine.

Reaction of *N*-2-fluorenyl(salicylideneimine) (flusalH) with a –20°C hexane solution of $TiBz_4$ results in the precipitation of a brown solid. The ^1H NMR spectrum (270 MHz, benzene-$^2H_6$) of this material is complex, but presumably contains both *bis*-alkylated metal and reduced ligand species. Other groups have encountered similar spectra in their attempts to isolate group 4 organometallic Schiff base complexes (4*a*, 6). In our own experiments similar reactivity occurs between $TiBz_4$ and the tetradentate Schiff base ligands $salenH_2$ and $salphenH_2$, but the latter systems have proved as resistant to characterization as those considered by other workers. In contrast, extraction of the solid obtained from the $TiBz_4$–flusalH reaction with toluene results in its transformation to **1**; an orange crystalline complex which is isolated in a yield of 25% with respect to flusalH. Single crystal X-ray diffraction analysis indicates the presence of two deprotonated bidentate Schiff base ligands coordinated as conventional N,O chelates (Fig. 1). The remaining sites

completing the octahedral geometry are occupied by O-bound reduced Schiff bases.[2]

Whilst hydrogen atoms are not detected in the crystallographic determination of **1**, comparison with free ligand structures, such as that of salenH_2 (9), clearly indicates a shift from double bond imine to single bond amine character. The coordinated C=N distance in **1** is 1.317(10) Å and that of the free amine 1.449(10) Å. Infrared spectroscopy and ^{1}H NMR are also indicative of coordinated imine and free amine functions in **1**. Titanium coordination geometry and the remaining bond lengths and angles within Schiff base and reduced Schiff base ligands are typical of such species.[3]

[2] Crystal data, **1**: 0.5 C_7H_8, $C_{100}H_{72}N_4O_4Ti$, M = 1441.52, monoclinic, space group $C2/c$, a = 14.526(4), b = 19.753(4), c = 26.753(10) Å, β = 93.307(10)°, V = 7663.5(39) Å^3, Z = 4, T = 293(2) K, μ = 0.170 mm^{-1}, 12 443 measured reflections were reduced to 5505 independent reflections of $I > 2\sigma(I)$. Final R = 0.0620, wR = 0.0850. Data collection and structure solution were carried out by published methods (2*c*). All non-hydrogen atoms were refined anisotropically, hydrogens were refined in positions and with thermal parameters defined by their respective hydrogen bearing atoms. Complete X-ray data are available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. Crystallographic data have also been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-111691. Copies of the data may be obtained free of charge on application to The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. (fax: (+44)1223-336-033; e-mail: deposit@ccdc.cam.ac.uk).

[3] Synthesis. FlusalH was isolated from the conventional condensation of amine and salicylaldehyde followed by recrystallization and characterization by ^{1}H and elemental analysis. **1** was prepared by the following procedure: in an N_2 atmosphere, flusalH (500 mg, 1.75 mmol) was added in a single portion to a hexane solution (20 mL) of $TiBz_4$ (870 mg, 2.10 mmol) at –20°C. The dark brown precipitate which formed over 0.5 h was filtered, washed with hexane, and extracted with toluene. The resultant brown solution became progressively pale orange. Addition of hexane and storage at –20°C affords toluene solvated **1** over ca. 3 days. Satisfactory elemental analysis. ^{1}H NMR (270 MHz, $CDCl_3$) δ: 3.22 (m, 4H, PhCH_2CHNH), 3.72 (s, 4H, 9-fluorene CH_2), 3.96 (s, 4H, 9-fluorene CH_2), 4.18 (s, 2H, PhCH_2CH*NH*), 4.60 (m, 2H, PhCH_2*CH*NH), 6.67–7.86 (m, 54H, aromatic), 8.75 (s, 2H, *CH*) ppm; IR (Nujol, cm^{-1}): ν(C=N) 1612 (s) cm^{-1}, ν(N-H) 3376 (s), 3389 (s) cm^{-1}.

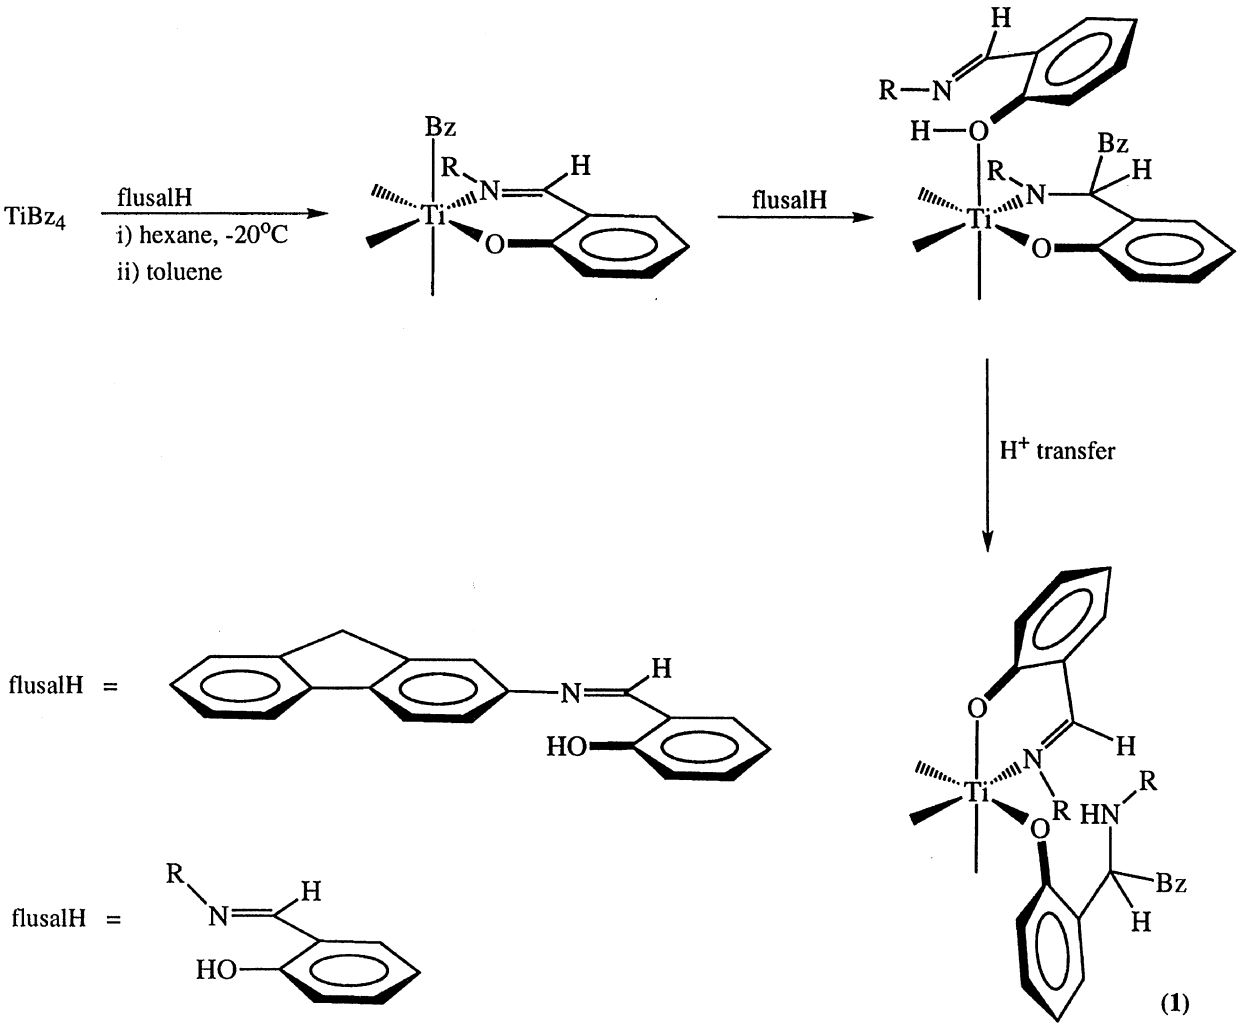
Scheme 1. Formation of **1**, full molecule generated by C_2 rotation.



Although the formation of **1** cannot be followed mechanistically due to the complex spectrum attributed to the intermediate brown product(s), it is feasible to postulate a realistic reaction mechanism in harness with previous results involving similar transformations (3–6) (Scheme 1). Thus initial reactivity may be viewed as Schiff base insertion into a Ti–Bz moiety, or alkyl migration to a coordinated Schiff base. There are numerous examples of the former in which insertion into C≡O and C≡NR affords acyl or iminoacyl species, respectively (10). For the latter mechanistic approach, supporting evidence may be obtained from a similar migration in the reaction of MesMgBr and [$TiCl_2$(salen)] which is thought to result in the observed [TiMes(Mes-salen)] (4*a*). In this reaction the steric bulk of the mesityl ligand was considered to be significant in stabilizing the complex towards further reactivity or decomposition. In the formation of **1** the steric influence of the flusalH ligand may be equally important, with this sterically demanding Schiff base ligand inducing congestion at the metal centre and providing an alternative ligand-based coordination site to relieve this congestion. Similar transformations may occur with other ligands, but it is significant that **1** can be isolated and characterized when similar reactions result in intractable materials. Again the presence of the fluorenyl substituent may be crucial; π–π interactions between these planar substituents producing the unusual *cis* orientated reduced ligands which are evident in **1** (Fig. 1). These interactions appear to lock the molecule, preventing the fluxional behaviour and further reactivity which has plagued the characterization of other complexes.

The formation of **1** inevitably involves protonation of the alkylated imine function. This affords the characterized amine complex, rather than the imines observed in other group 4 species (Fig. 1). The hydroxyl group of flusalH is identified in Fig. 2 as the proton source. Concern always arises from the potential for reactivity with adventitious moisture. However, in this instance, the preparation and manipulation of the highly moisture sensitive $TiBz_4$ using identical solvents and procedures offers circumstantial support for the successful exclusion of moisture.

The formation of **1** and the observed reduction of imines to amines defines a further form of reactivity or deactivation for group 4 Schiff base complexes. Moreover, this reactivity may be applicable to a wider range of complexes which are not as readily characterized as the *N*-fluorenyl system employed here. Whilst there is no evidence that **1** is itself an

Influence des ions fluorure et de la silice amorphe sur la solubilité des gels de zircone et caractérisation des fluoro-complexes de zirconium en milieu moyennement acide

Rémi Valéro, Bernard Durand, Jean-Louis Guth et Thierry Chopin

Résumé : La solubilité des gels de zircone en fonction du pH est étudiée afin d'appréhender d'abord l'influence des ions F^- seuls, puis l'influence de la présence simultanée d'ions F^- et de silice amorphe. Deux concentrations [F^-] sont choisies, 0,094 et 0,314 mol L^{-1}, correspondant à des rapports molaires initiaux F/Zr = 0,6 et 2,0. Les fluorocomplexes métalliques formés aux pH 0,5 et 2,5 sont caractérisés par ^{19}F RMN. L'influence des ions fluorures sur la solubilité du zircon est aussi étudiée. Il est montré que la formation de complexes siliciques riches en fluor déplace les équilibres entre les fluorocomplexes de zirconium vers les complexes pauvres en fluor et que, en présence de F^-, la synthèse hydrothermale est susceptible d'engendrer la cristallisation du zircon pour tous les pH compris entre 0 et 10.

Mots clés : gel de zircone, silice, zircon, ions fluorure, solubilité, ^{19}F RMN.

Abstract: The solubility of zirconia gels versus pH is studied in order to state first the influence of F^- ions alone, then the influence of the simultaneous presence of F^- and amorphous silica. Two concentrations of F^- ions are chosen, 0.094 and 0.314 mol L^{-1}, corresponding to initial molar ratios F/Zr = 0.6 and 2.0. Metal fluorocomplexes formed at pH 0.5 and 2.5 are characterized by ^{19}F NMR. The influence of F^- on the solubility of zircon is also studied. It is shown that the formation of silicon complexes rich in fluorine shifts the equilibriums between the zirconium fluorocomplexes toward the complexes poor in fluorine and that, in the presence of F^-, the crystallization of zircon by hydrothermal synthesis can be forecasted, for pH values in the range 0–10.

Key words: zirconia gels, silica, zircon, fluoride ions, solubility, ^{19}F NMR.

1. Introduction

Seulement quelques articles concernaient la synthèse hydrothermale du zircon et impliquaient des traitements mettant en jeu soit des pressions dépassant 500 bars (1 bar = 100 kPa) (1–3), soit des durées de plusieurs centaines d'heures (2, 4) soit des températures largement supérieures à 200°C (1–3, 5). Collette et Frondel (2) remarquaient cependant dès 1957, que la formation de zircon était favorisée par l'addition d'ions fluorure au milieu hydrothermal.

Il était bien connu en effet, qu'en l'absence d'ions fluorure, la silice amorphe ne présente une solubilité appréciable, qu'aux pH basiques supérieurs à 9, due à la formation d'ions $Si(OH)_3O^-$ par des réactions de dépolymérisation de la silice (6). Dixon (7) indiquaient aussi, dès 1946, que l'addition d'ions fluorure augmente la solubilité à pH acide ou neutre. Marcuccilli (8) a cependant montré que, pour des valeurs très faibles de [F^-], la solubilité peut être inférieure à ce qu'elle est en l'absence d'anion fluorure, en raison de la fixation superficielle d'atomes de fluor qui rend la silice hydrophobe. Pour des valeurs plus élevées de [F^-], l'augmentation de solubilité est attribuée principalement à la formation d'ions hexafluorosilicate SiF_6^{2-} (9). Toutefois, Ciavatta et al. (10), puis Marcuccilli (8) ont mis en évidence, par RMN du fluor 19, la présence à côté des ions SiF_6^{2-} d'espèces siliciques hexacoordinées hydrofluorées et aquofluorées. Selon Marat et Janzen (11) les échanges intermoléculaires d'ions fluorure entre les fluorocomplexes de silicium sont catalysés par la présence d'acide fluorohydrique et d'eau et, en l'absence de ces deux réactifs considérés comme des impuretés, les échanges intermolculaires rapides d'ions fluorure dans les systèmes SiF_4 – SiF_5^-, SiF_5^- – SiF_6^{2-} et SiF_4 – SiF_6^{2-} sont correlés à des changements de coordination selon les équilibres [1]; ils impliquent la formation intermédiaire de complexes disiliques à fluor pontant.

Axon et Klinowski (12) ont confirmé que, dans les milieux renfermant des ions fluorure et de la silice, un équilibre est rapidement établi entre le solide et la solution dans lequel la silice est dépolimérisée par les ions fluorure. Un rapport F/Si en solution proche de 5 leur a fait envisager l'existence d'espèce $SiF_5(H_2O)^-$ ou la présence en quantités équivalentes des espèces hexacoordinées SiF_6^{2-} et $SiF_4(H_2O)_2$ impliquées dans l'équilibre [2].

[2] $$SiF_6^{2-} \rightleftarrows SiF_5(H_2O)^- \rightleftarrows SiF_4(H_2O)_2 \rightleftarrows SiF_3(H_2O)_2\ (OH)$$

La largeur des pics RMN ^{29}Si et ^{19}F attribués à l'espèce SiF_6^{2-} est interprétée par un échange dynamique rapide d'ions fluorure entre les différentes espèces de l'équilibre [2]; des espèces à fluor pontant peuvent aussi se former.

D'après plusieurs auteurs (9, 13, 14), en l'absence d'anion fluorure, les gels de zircone sont essentiellement solubles en milieu très acide, la concentration [Zr] pouvant atteindre 10^{-2} à 10^{-1} mol L^{-1} à pH 0 et environ 10^{-3} mol L^{-1} à pH 1. Entre les pH 3 et 9, la solubilité devient quasiment nulle ($[Zr] < 2 \times 10^{-5}$ mol L^{-1}); elle augmente faiblement au-delà de pH 9 sans dépasser 2×10^{-2} mol L^{-1} même à pH 14. Dans les solutions aqueuses diluées et acides, les espèces solubles du zirconium sont généralement polynucléaires (15–17). L'espèce prédominante est le tétramère cyclique caractérisé par Clearfield (18). Une espèce monomérique du type $[Zr(H_2O)_nCl_m]^{(4-m)}$ se forme en milieu HCl concentré et différentes espèces plus condensées sont engendrées par hydrolyse du tétramère lorsque le pH augmente (19). Dans des solutions renfermant des ions nitrate, des polycations linéaires ont été mis en évidence (20). Dans les milieux aqueux renfermant des ions fluorure les espèces polymériques du zirconium sont détruites. Livage et al. (21) suggèrent qu'à pH acide les anions fluorure pénètrent dans la première sphère de coordination du zirconium en formant des espèces monomériques, mais qu'ils ne sont plus complexants au-delà de pH 5. Aja (14) confirme, d'une part, que la stoechiométrie des espèces fluorées dépend du pH et de l'activité des anions fluorure dans le milieu et, d'autre part, que lorsque le pH augmente la diminution du pouvoir complexant des anions fluorure provoque, selon leur concentration, soit la gélification de la solution, soit la formation intermédiaire d'espèces hydroxyzirconiques solubles. Des stoechiométries allant de ZrF^{3+} à ZrF_7^{3-} ont été proposées, mais seule l'espèce hexafluorée ZrF_6^{2-} a été précisément identifiée par spectrométrie Raman (22, 23) et ^{19}F RMN (22).

Aucune information précise concernant la solubilité des gels de zircone en milieu aqueux fluoré n'avait été trouvée dans la littérature. Avant d'aborder l'étude de la synthèse hydrothermale du zircon, sous pression autogène et à des températures situées dans la gamme 100 à 200°C, dans le but d'en déterminer le mécanisme (24), il était utile de préciser le rôle des ions fluorure sur la solubilité des gels de zircone et sur celle du zircon. Il importait aussi d'appréhender l'effet de la présence de silice amorphe dans le milieu hydrothermal sur la solubilité des gels de zircone. Ce mémoire présente également la caractérisation des espèces dissoutes du zirconium par RMN du fluor 19.

2. Techniques expérimentales et analytiques

Les gels de zircone ont été préparés à partir de solutions aqueuses renfermant 0,16 mol L^{-1} d'oxychlorure de zirconium (Fluka), par addition d'ammoniaque (Fluka 20%) jusqu'à pH 4. La teneur en zirconium déterminée par analyse chimique dans les xérogels est $4{,}4 \times 10^{-3}$ mol g^{-1}. Pour les préparations mettant en jeu simultanément zirconium et silicium, de la silice amorphe (Aérosil 130 Degussa) a été introduite dans la solution d'oxychlorure de zirconium de façon à obtenir un milieu équimolaire en Zr et Si, puis le pH a été comme auparavant ajusté à 4. Les ions fluorure ont été introduits par dissolution de fluorure d'ammonium avant la neutralisation à pH 4; deux concentrations ont été utilisées : 0,094 et 0,314 mol L^{-1}. Dans la suite, l'expression « ions fluorure » désignera l'ensemble des espèces dissoutes du fluor, à l'exception des complexes fluorés du zirconium ou du silicium : HF, F^-, FHF^- ou $F(HF)_n^-$. Les mélanges réactionnels, versés dans des flacons en polyéthylène ont été chauffés à l'étuve à 60°C pendant 24 h. Le pH a été maintenu constant pendant les expériences par addition d'ammoniaque (20%) ou d'acide chlorhydrique (37%). Les études de solubilité du zircon ont été conduites à partir de suspensions renfermant 0,16 mol L^{-1} de zircon (Aldrich), traitées comme les milieux précédents pour introduire des ions fluorure et ajuster le pH.

Les solubilités ont été déterminées par mesure des concentrations en zirconium et silicium. Pour le zirconium, il a été fait appel à la colorimétrie du complexe Zr (8–hydroxyquinolinol) qui possède une bande d'absorption à 395 nm (25, 26) et pour le silicium à l'absorption atomique. Dans les deux cas, les ions fluorure et le deuxième métal n'interfèrent pas.

Les spectres RMN ont été enregistrés sur un spectromètre Brucker AC250 opérant à une fréquence de 235 MHz et avec un angle d'inclinaison de 70°. Ils ont été accumulés en utilisant des impulsions de 4 μs et des délais de recyclage de 6 s. Pour les déplacements chimiques $CFCl_3$ a été pris comme référence. Les échantillons ont été préparés à partir d'une solution aqueuse de $ZrOCl_2$ (4.66×10^{-2} mol L^{-1}) à laquelle ont été ajoutées des quantités appropriées de NH_4F pour obtenir des rapports molaires F/Zr dans la gamme 3,0 à 6,5. Pour spectres tracés en présence de SiO_2, de la silice amorphe (Aérosil 130) a été ajoutée en proportion équimolaire au zirconium. Le pH a été ajusté soit à 0,5 soit à 2,5 et les échantillons ont été maintenus pendant 24 h à température ambiante.

3. Études de solubilité

3.1. Influence des ions fluorure sur la solubilité des gels de zircone en milieu aqueux

La solubilité des gels zircone, analysée dans la gamme de pH 1 à 11 (fig. 1), est accrue aux pH acides et moyennement basiques, par la formation de fluorocomplexes de zirconium, de façon d'autant plus importante que la concentration initiale en ions fluorure est élevée

Avec la concentration en ions fluorure la plus faible, 0,094 mol L^{-1}, la solubilité à pH 1,5, $2{,}5 \times 10^{-2}$ mol L^{-1}, correspond à une concentration spécifique de 3,75 F^- par Zr

Fig. 1. Solubilité du gel de zircone en fonction du pH : (*a*) [F⁻] = 0,314 mol L^{-1}, (*b*) [F⁻] = 0,094 mol L^{-1}.

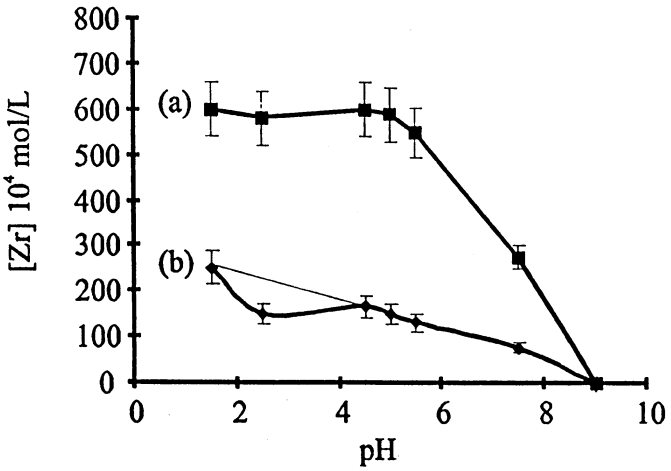

Fig. 2. Influence de la silice amorphe sur la solubilité du gel de zircone en fonction de pH avec [F⁻] = 0,094 mol L^{-1} : (*a*) [Zr], (*b*) [Si].

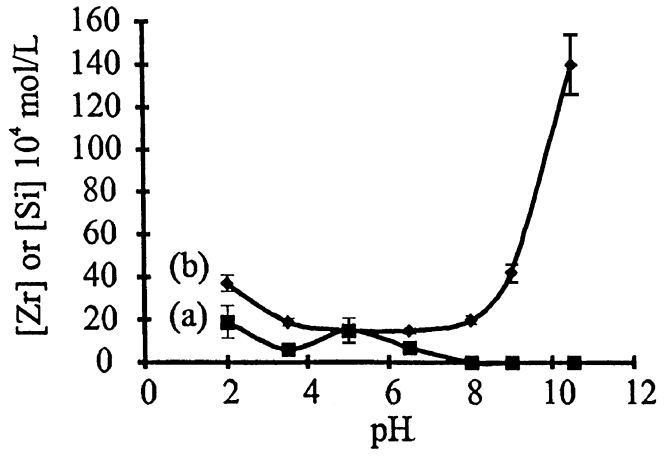
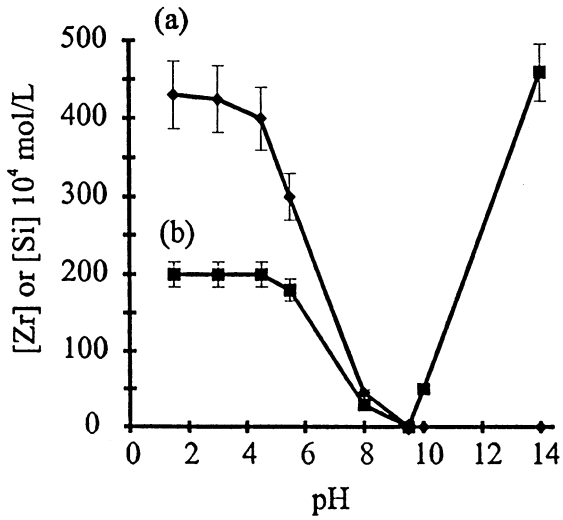


dissous. L'évolution générale avec l'augmentation du pH est une diminution linéaire de la solubilité qui atteint une valeur quasiment nulle à pH 9. Conformément aux observations de Aja (14) et Livage (21), la diminution de la solubilité est attribuée à une baisse du pouvoir complexant des anions fluorure et à une évolution de la stoechiométrie des fluorocomplexes du zirconium au fur et à mesure que le pH augmente. La valeur anormalement faible de la solubilité à pH 2,5, $1,5 \times 10^{-2}$ mol L^{-1}, pourrait être expliquée par une diminution de la concentration en ions fluorure due à la formation de fluorocomplexes de zirconium riches en fluor. La concentration spécifique en F^- atteint alors 6,25. Babu et al. (27) remarquent en effet que ces complexes se forment avec une cinétique maximale au voisinage de ce pH.

Avec la concentration en ions fluorures la plus élevée, 0,314 mol L^{-1}, la formation de fluorocomplexes de zirconium riches en fluor permet d'atteindre une solubilité de $5,8 \times 10^{-2}$ mol L^{-1} à pH 1,5. La concentration spécifique est alors voisine de 5,4 et la solubilité conserve la même valeur jusqu'à pH 5. Au-delà, les fluorocomplexes deviennent

Fig. 3. Influence de la silice amorphe sur la solubilité du gel de zircone en fonction du pH avec [F⁻] = 0,314 mol L^{-1} : (*a*) [Zr], (*b*) [Si].



instables et la solubilité chute rapidement pour atteindre une valeur quasiment nulle également à pH 9.

3.2. Influence de la présence de silice sur la solubilité des gels de zircone en milieu aqueux fluoré

Pour la concentration en anions fluorure de 0,094 mol L^{-1}, l'introduction de silice dans le milieu hydrothermal n'affecte pas l'allure générale de la courbe de solubilité du gel de zircone (fig. 2, courbe *a*), mais diminue la concentration en zirconium dissous d'un facteur 10. Ainsi cette concentration diminue de 2×10^{-3} mol L^{-1} à une valeur pratiquement nulle lorsque le pH augmente de 2 à 8. La solubilité reste cependant plus élevée que celle observée pour un gel de zircone seul en l'absence d'anion fluorure qui selon Adair (9) est inférieure à 10^{-4} mol L^{-1} dans la même gamme de pH. En dessous de pH 8, la solubilité de la silice (fig. 2, courbe *b*) semble légèrement supérieure à celle du gel de zircone, mais l'écart ne devient appréciable qu'aux pH plus basiques. En outre, la comparaison avec les résultats obtenus par Iler (6), pour la silice seule, montre que la présence d'anions fluorure à faible concentration et de gel de zircone ne modifie ni l'allure de la courbe, ni les valeurs des concentrations en silicium dissous.

Pour la concentration en anions fluorure de 0,314 mol L^{-1}, l'apport de silice dans le milieu hydrothermal ne change pas non plus l'allure de la courbe de solubilité du gel de zircone (fig. 3, courbe *a*), mais la diminution de la concentration en zirconium dissous est moins accentuée. [Zr] conserve une valeur voisine de $4,2 \times 10^{-2}$ mol L^{-1} entre les pH 2 et 5, puis diminue régulièrement pour devenir quasiment nulle au-delà de pH 9,5. L'augmentation de la concentration en ions fluorure multiplie environ par 10 la solubilité de la silice (fig. 3, courbe *b*). [Si] atteint alors des valeurs moitié moindres que [Zr] lorsque le pH augmente de 1,5 à 9,5. Aux pH plus élevés la solubilité de la silice augmente, alors que celle du gel de zircone reste négligeable. Entre les pH 2 et 5, la concentration spécifique en ions F^- est voisine de 7,8 ou 5,2 selon qu'elle soit rapportée à la seule concentration en Zr ou à la somme des concentrations en Zr et Si. Si l'on as-

Fig. 4. Solubilité du zircon en fonction du pH avec [F^-] = 0,094 mol L^{-1} : (*a*) [Zr], (*b*) [Si].

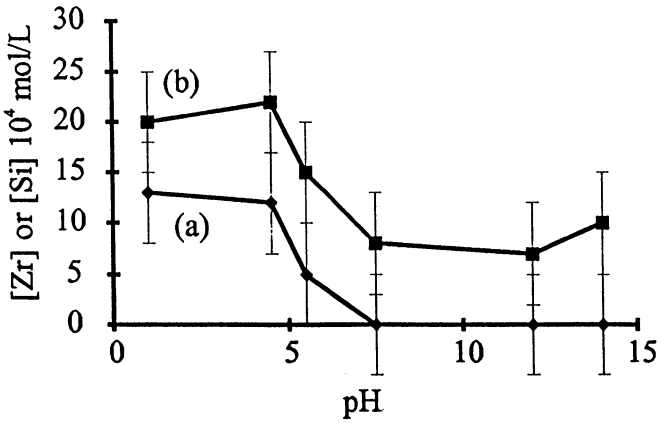

Fig. 5. Solubilité du zircon en fonction du pH avec [F^-] = 0,314 mol L^{-1} : (*a*) [Zr], (*b*) [Si].

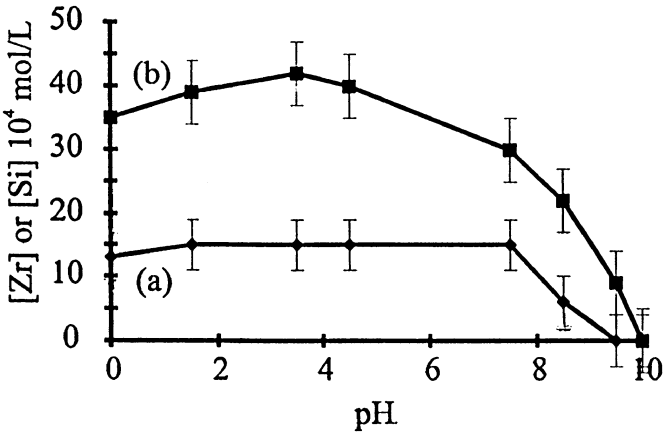

sume que le silicium est complexé sous la forme d'ions SiF_6^{2-} et qu'il ne se forme pas d'acide fluorhydrique, la concentration spécifique en ion F^- par rapport au zirconium dissous est voisine de 4,6.

3.3. Influence des ions fluorure sur la solubilité du zircon

En l'absence d'ion fluorure, le zircon est quasiment insoluble, quel que soit le pH dans la gamme 0 à 14. La teneur en silicium dissous est en de ça de la limite de détection (5×10^{-4} mol L^{-1}). Des traces de zirconium dissous sont décelées (environ 10^{-5} mol L^{-1}).

L'addition d'ions fluorure à la concentration de 0,094 mol L^{-1} accroît la solubilité à une valeur voisine de $1,5 \times 10^{-3}$ mol L^{-1} pour les pH compris entre 1 et 4 (fig. 4). Pour les pH plus élevés, la solubilité diminue. Les profils des courbes de variation en fonction du pH de [Zr] et [Si] sont similaires et [Si] (courbe *b*) semble supérieure à [Zr] (courbe *a*), mais le recouvrement des intervalles d'incertitude ne permet pas de conclure à une dissolution non congruente. L'augmentation de [F^-] à 0,314 mol L^{-1} accroît beaucoup plus fortement [Si] que [Zr] (fig. 5) et révèle indubitablement une dissolution non congruente pour les pH dans la gamme 0–9.

Dans les deux cas, la comparaison des figures, 2 et 4 d'une part, et 3 et 5 d'autre part, révèle une solubilité plus faible pour le zircon que pour le gel de zircone et la silice amorphe avec des écarts plus ou moins importants selon le pH et la concentration [F^-].

Fig. 6. Spectre ^{19}F RMN d'une solution d'oxychlorure de zirconium $4,66 \times 10^{-2}$ M contenant des ions F^- : F/Zr = 4, pH = 2,5.

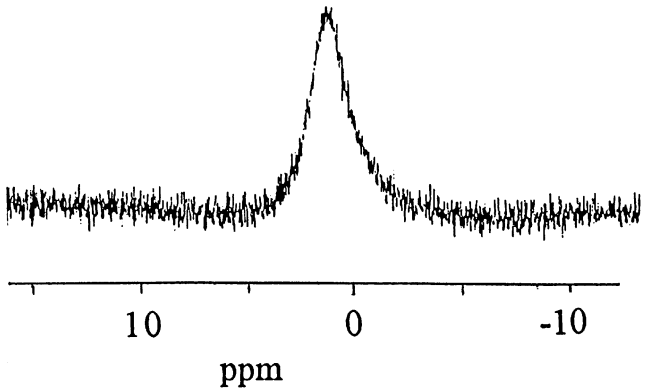

Fig. 7. Spectre ^{19}F RMN d'une solution d'oxychlorure de zirconium $4,66 \times 10^{-2}$ M en présence d'ions F^- et de silice amorphe : F/Zr = 4, Si/Zr = 1, pH = 2,5.

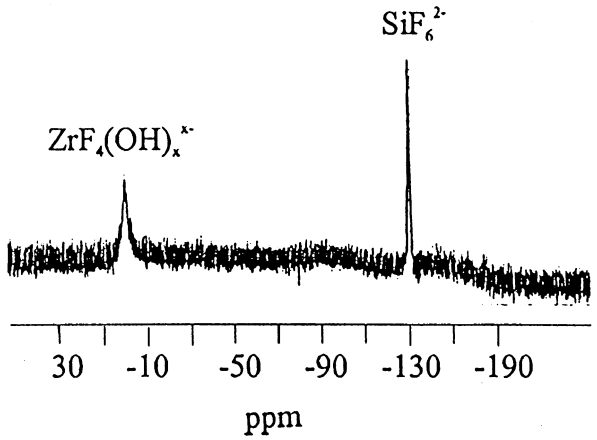

4. Caractérisation des fluorocomplexes du zirconium par ^{19}F RMN

4.1. Résultats

En l'absence de silice et pour les deux pH étudiés (0,5 et 2,5), les spectres RMN ne présentent qu'un seul pic large quel que soit le rapport F/Zr des concentrations dans l'intervalle 3,5 à 6,5, comme le montre la figure 6 pour pH = 2,5 et F/Zr = 4,0. A température ambiante, le déplacement chimique rapporté à $CFCl_3$ varie de +10 à –35 ppm lorsque le rapport F/Zr augmente de 3,5 à 6,5 pour la solution à pH 0,5 (fig. 9, courbe *b*) et de +3 à –19 ppm pour la solution à pH 2,5 (24). Simultanément la largeur à mi-hauteur du signal s'accroît (fig. 8). Pour les rapports F/Zr < 5,8 l'abaissement du pH de 2,5 à 0,5 ne modifie pas le profil des courbes; seule, une très faible augmentation des largeurs à mi-hauteur est observée. Par contre, pour les rapports F/Zr > 5,8, la largeur à mi-hauteur accuse une très forte élévation.

En présence de silice, le pic caractéristique des fluorocomplexes du zirconium est conservé, mais il apparaît quel

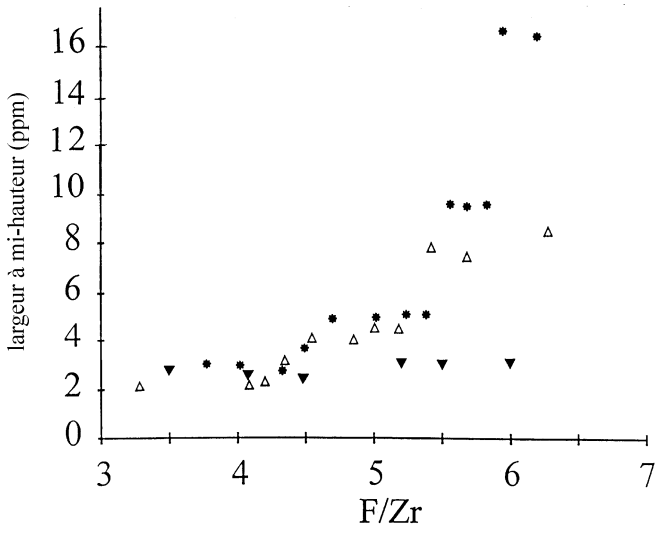
Fig. 8. Influence du rapport F/Zr sur la largeur à mi-hauteur du signal RMN des fluorocomplexes du zirconium dans une solution 4,66 $\times 10^{-2}$ M d'oxychlorure de zirconium : (✹) solution à pH = 0,5, (Δ) solution à pH = 2,5, (▼) solution à pH 2,5 et renfermant de la silice amorphe en proportion équimolaire au zirconium.



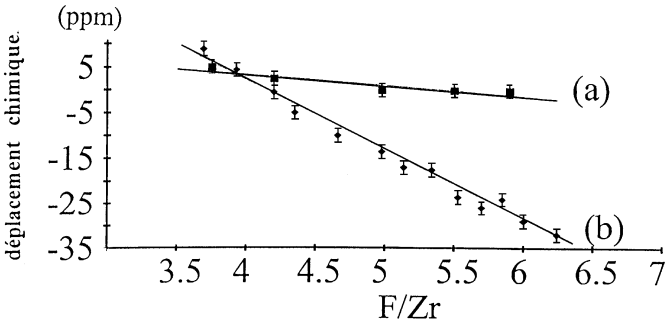
que soit le pH, mais uniquement pour les rapports F/Zr > 4, un second signal plus étroit au voisinage de –131 ppm, ainsi qu'en témoigne la figure 7 pour F/Zr = 4,0 et pH = 2,5. La variation du déplacement chimique du signal des fluorocomplexes est très significativement réduite puisqu'il n'évolue plus qu'entre +5 et –2,5 ppm lorsque le rapport F/Zr croît de 3,5 à 6,5 dans le milieu à pH 0,5 (fig. 9, courbe *a*). À pH 2,5, la réduction est moindre, le déplacement chimique passant de 0 à –12 ppm (24). Quant à la largeur du signal à mi-hauteur, elle demeure, quelque soit le pH, pratiquement constante et voisine de 2 ppm sur tout l'intervalle comme le montre la figure 8 (courbe ▼) ; elle a une valeur sensiblement égale à celle observée en l'absence de silice pour les plus petites valeurs du rapport F/Zr.

4.2. Discussion

À température ambiante, la RMN du fluor 19 ne permet pas de séparer les espèces dissoutes du fluor, autres que les fluorocomplexes métalliques : F^-, HF, FHF^-, $F(HF)_n^-$: elles se manifestent toutes par un seul signal situé habituellement au voisinage de –120 ppm. Aucun signal n'ayant été observé dans cette région, il semble donc que la majeure partie des ions fluorure introduits dans le milieu se combinent aux métaux pour former des fluorocomplexes et participent à des échanges dynamiques rapides entre différents fluorocomplexes.

Par ^{19}F RMN, le signal caractéristique des ions SiF_6^{2-} est fréquemment obtenu vers –128 ppm. Le pic au voisinage de –131 ppm dans les spectres des milieux renfermant de la silice et pour les rapports F/Zr > 4, doit donc être attribué à l'existence de fluorocomplexes de silicium hexacoordinés. Sa faible largeur à mi-hauteur pourrait traduire la prédominance de l'ion SiF_6^{2-}. Toutefois, la formation d'aquofluorocomplexes en équilibre avec SiF_6^{2-} selon [2] ainsi que celle de complexes siliciques à fluor pontant ne peuvent être exclues.

Fig. 9. Influence de la présence de silice amorphe sur l'évolution du déplacement chimique, en fonction du rapport F/Zr, du signal ^{19}F RMN des fluorocomplexes de zirconium, dans une solution 4,66 $\times 10^{-2}$ M d'oxychlorure de zirconium : (*a*) courbe tracée en présence de silice en proportion équimolaire au zirconium, (*b*) courbe tracée en absence de silice.



Par analogie avec les interprétations proposées par Janzen et al. (11) et Axon et al. (12) pour les fluorocomplexes de silicium, les largeurs à mi-hauteur élevées des pics caractéristiques des fluorocomplexes de zirconium peuvent être imputées à des échanges inter- et intramoléculaires dynamiques rapides d'ions fluorure entre différents fluorocomplexes du zirconium coexistant en équilibre dynamique complexe dans la solution. Ces échanges impliquent probablement la formation intermédiaire de complexes polyzirconiques à fluor pontant. En l'absence de silicium, l'augmentation du déplacement chimique au fur et à mesure que le rapport des concentrations F/Zr croît traduit vraisemblablement une évolution de la coordination du zirconium de 4 vers 6, voire 7 avec des changements de coordination Zr: $4 \rightleftarrows 5 \rightleftarrows 6 \rightleftarrows 7$ et F: $1 \rightleftarrows 2$. Une explication de l'augmentation simultanée de la largeur à mi-hauteur pourrait être que le déplacement des équilibres vers les complexes riches en fluor réduit la concentration des autres fluorozirconates impliqués dans la formation des espèces intermédiaires à fluor pontant, Zr···F···Zr. Les échanges d'ions fluorures devraient alors être nécessairement ralentis. On pourrait aussi avancer que l'acroissement du rapport F/Zr multiplie le nombre des fluorocomplexes susceptibles d'être formés et qu'il en résulte une augmentation de la largeur à mi-hauteur.

La réduction considérable des effets provoqués par l'augmentation du rapport F/Zr, lorsque de la silice est ajoutée dans le milieu en quantité équimolaire au zirconium, pourrait être interprétée en admettant, qu'aux faibles concentrations (F/Zr < 4), les ions F^- sont consommés pour former des fluorocomplexes de zirconium pauvres en fluor ($ZrF_4(OH)_x^{x-}$) préférentiellement à des fluorocomplexes de silicium, d'où l'absence de signal caractéristique de ces derniers. Pour les concentrations plus élevées (F/Zr ≥ 4) la formation d'ions hexafluorosilicate à côté des fluorocomplexes zirconiques pauvres en fluor consomme des quantités importantes d'ions F^- et s'oppose au déplacement des équilibres vers les fluorocomplexes zirconiques riches en fluor. La stabilité thermodynamique des ions SiF_6^{2-} serait alors intermédiaire entre celle des ions $ZrF_4(OH)_x^{x-}$ et celles des espèces zirconiques plus riches en fluor.

Une autre interprétation, plus conforme aux travaux de Janzen et al. (11) reviendrait à considérer qu'aux pH acides,

© 1999 CNRC Canada

l'acide fluorhydrique réagit avec la silice amorphe pour produire SiF_4 et que les réactions de SiF_4 avec les fluorocomplexes de zirconium riches en fluor aboutissent à un enrichissement en fluor des fluorocomplexes de silicium et un appauvrissement en fluor des fluorocomplexes de zirconium. Ces réactions impliqueraient la formation intermédiaire de complexes bimétalliques à fluor pontant selon par exemple les équations [3] et [4].

[3] $$ZrF_7^{3-} + SiF_4 \rightleftarrows F_6Zr\cdots F\cdots SiF_4 \rightleftarrows ZrF_6^{2-} + SiF_5^-$$

[4] $$ZrF_6^{2-} + SiF_5^- \rightleftarrows F_5Zr\cdots F\cdots SiF_5 \rightleftarrows ZrF_5^- + SiF_6^{2-}$$

Des réactions analogues pourraient être écrites pour ZrF_6^{2-} et ZrF_5^-.

5. Conclusion

En l'absence d'ion fluorure, la synthèse hydrothermale n'est susceptible de produire du zircon qu'aux pH basiques, la solubilité des deux précurseurs étant en effet plus importante que celle du zircon. En milieu moyennement acide (pH 2–7), les solubilités sont du même ordre de grandeur. En milieu plus acide (pH 0–2), la solubilité du gel de zircone est cent fois supérieure à celle de la silice amorphe.

Pour les pH moyennement acides, l'addition d'ions fluorure au milieu accroît la solubilité des gels de zircone, d'autant plus que leur concentration est élevée, par formation de fluorocomplexes de zirconium monomères. Leur stoechiométrie dépend d'autant plus du pH que la concentration en ions fluorure est faible. L'augmentation du pH au-delà de 4,5 à 5 déstabilise les fluorocomplexes et favorise la formation d'espèces polymères qui provoque une diminution de la solubilité du gel ; elle devient quasi nulle lorsque le pH dépasse 9.

L'introduction de silice amorphe dans le milieu hydrothermal diminue la solubilité du gel de zircone de façon d'autant plus significative que la concentration en ions fluorure est faible. Aux faibles concentrations ($[F^-]$ = 0,094 mol L^{-1}), la solubilité de la silice n'est pas modifiée et seuls des fluorocomplexes de zirconium pauvres en fluor semblent se former. Pour les concentrations plus élevées ($[F^-]$ = 0,314 mol L^{-1}), les mesures de solubilité et la caractérisation des espèces dissoutes par RMN du fluor 19 fournissent des résultats concordants prouvant que la formation de fluorocomplexes de silicium riches en fluor (SiF_6^{2-}) déplace les équilibres entre les fluorocomplexes de zirconium vers les complexes tétrafluorés.

En présence d'anions fluorure, la synthèse hydrothermale sera susceptible de produire du zircon, quel que soit le pH dans la gamme 0 à 10. Du côté acide, le gel de zircone et la silice amorphe présentent des solubilités très supérieures à celle du zircon. Cependant, en raison de la dissolution non congruente du zircon, des zircons non stoechiométriques déficitaires en silicium pourront cristalliser. Du côté basique, l'anticipation est plus difficile car la solutilité des deux précurseurs est fortement diminuée par la déstabilisation des fluorocomplexes. Les solubilités demeurant toutefois légèrement supérieures à celle du zircon, la cristallisation de zircons stoechiométriques pourrait se produire. L'investigation des possibilités de synthèse hydrothermale du zircon en présence d'anions fluorure et sous pression autogène à 150°C a confirmé ces prévisions en montrant notamment que des fluorozircons, dont le déficit en tétraèdres SiO_4 est compensé par des nids tétraédriques $[F_4 (OH)_{4-n}]$, cristallisent à pH acide (24, 28) alors que des zircons stoechiométriques exempts de fluor et à morphologie inédite se forment en milieu basique (24, 29).

Temperature-dependent structural properties of a solid urea inclusion compound containing chiral guest molecules: 2-bromotetradecane/urea

Lily Yeo and Kenneth D.M. Harris

Abstract: Periodic structural properties of the 2-bromotetradecane/urea inclusion compound have been investigated as a function of temperature. Differential scanning calorimetry between 298 and 98 K identified three well-defined regimes, denoted the high-, intermediate-, and low-temperature phases. The structural properties of each phase (at 293, 207, and 142 K, respectively) have been investigated by single crystal X-ray diffraction. In the high-temperature phase, the inclusion compound has the hexagonal urea tunnel structure ($P6_122$) characteristic of the conventional urea inclusion compounds, with substantial orientational disorder of the guest molecules. In the intermediate-temperature phase, the symmetry is lowered to orthorhombic ($C222_1$), although the host structure remains close to the hexagonal tunnel structure of the high-temperature phase and there is no clear evidence for increased orientational ordering of the guest molecules. In the low-temperature phase, the urea tunnel structure is monoclinic ($P2_1$), and is based on a $2 \times 2 \times 1$ supercell of the hexagonal cell of the high-temperature structure. There are four independent types of tunnel, three of which are strongly distorted from hexagonal geometry. Within these distorted tunnels, there is a comparatively narrow distribution of guest molecule orientations, which correlate well with the observed distortions of the tunnels. The 2-bromotetradecane/urea inclusion compound highlights several issues of wider relevance concerning the structural properties of solid inclusion compounds.

Key words: urea inclusion compounds, X-ray diffraction, phase transitions, chiral recognition, incommensurate solid, 2-bromotetradecane/urea.

Résumé : On a étudié les propriétés structurales périodiques du composé d'inclusion 2-bromotétradécane/urée en fonction de la température. La calorimétrie à balayage différentielle entre 298 et 98 K permet d'identifier trois régimes bien définis dénommés phases à haute température, à température intermédiaire et à basse température. On a étudié les propriétés structurales de chacune des phases (à 293, 207 et 142 K, respectivement) à l'aide de la diffraction des rayons X par un cristal unique. Dans la phase à haute température, le composé d'inclusion comporte une structure hexagonale ($P6_122$) avec tunnel d'urée qui est caractéristique des composés d'inclusions usuels de l'urée. Dans la phase de température intermédiaire, la symétrie est abaissée à orthorhombique ($C222_1$) même si la structure hôte reste toujours proche de la structure hexagonale à tunnel de la phase à haute température; de plus, rien ne suggère que l'orientation des molécules incluses est augmentée. Dans la phase de basse température, la structure du tunnel d'urée est monoclinique ($P2_1$) et elle est basée sur une supercellule $2 \times 2 \times 1$ de la cellule hexagonale de structure à température élevée. On observe quatre types différents de tunnels, dont trois sont fortement déformés par rapport à la symétrie hexagonale. Dans ces tunnels déformés, la distribution des orientations des molécules incluses est relativement étroite en bonne corrélation avec les distorsions observées des tunnels. Le composé d'inclusion 2-bromotétradécane/urée illustre plusieurs points qui présentent une importance plus générale concernant les propriétés structurales des composés d'inclusion solides.

Mots clés : composés d'inclusion d'urée, diffraction des rayons X, transitions de phase, reconnaissance chirale, solide incommensurable, 2-bromotétradécane/urée.

[Traduit par la Rédaction]

1. Introduction

There is currently considerable interest in the diverse range of physicochemical properties associated with solid urea inclusion compounds (1–3). In conventional urea inclusion compounds, the urea molecules form a hydrogen-bonded host structure that contains linear, parallel tunnels (4, 5). This urea tunnel structure is stable only when the tunnels are filled with a dense packing of guest molecules. The effective diameter of the urea tunnel (defined on the basis of van der Waals radii) varies between about 5.5 and 5.8 Å as a function of position along the tunnel (6), and as a consequence of this rather confined geometry, only guest molecules based on a sufficiently long *n*-alkane chain and with a sufficiently

small degree of substitution are able to form these inclusion compounds with urea.

Several structural aspects of urea inclusion compounds are of interest, including: (*i*) the nature of the host structure and its dependence on temperature; (*ii*) the mode of ordering of the guest molecules within the host structure (in some cases there is only one-dimensional ordering of the guest molecules along the tunnels, whereas in other cases well-defined modes of inter-tunnel ordering also exist); (*iii*) the structural relationship between the host and guest subsystems, concerning mainly the commensurate versus incommensurate nature of the inclusion compound; (*iv*) the conformational properties of the guest molecules; (*v*) the orientational characteristics of the guest molecules with respect to reorientation about the tunnel axis; and (*vi*) for unsymmetric guest molecules of the type $X(CH_2)_nY$, the question of the orientation ($X(CH_2)_nY$ or $Y(CH_2)_nX$) adopted by the guest molecules along the tunnel, leading to different possible types of end-group interaction (X···X, Y···Y, and X···Y). In this paper we focus on issues relating to (*i*), although the work reported here also sheds light on some of the other structural aspects highlighted above.

To a first approximation, the space group of the average urea host structure in the conventional urea inclusion compounds at ambient temperature is $P6_122$ or $P6_522$ (see refs. 5 and 7 for detailed discussion of structural and symmetry properties of urea inclusion compounds). The urea tunnel is constructed from hydrogen bonded spirals of urea molecules, and a single crystal either contains only right-handed spirals (space group $P6_122$) or only left-handed spirals (space group $P6_522$). The chirality of the urea tunnel structure is generated spontaneously during crystal growth, and there is clearly considerable potential to exploit this property of urea inclusion compounds. For chiral guest molecules, such opportunities devolve upon the extent of chiral recognition between the host structure and the two enantiomers of a chiral guest species (which could be a reactant molecule, a transition state, or a reaction product). Among the potential applications, asymmetric synthesis could be achieved by carrying out a chemical reaction between achiral guest molecules to generate an enantiomeric excess of a chiral product guest molecule, with the chiral host environment influencing the preferred production of one enantiomer of the chiral product. Applications based on separation of the two enantiomers of a chiral guest may also be achieved. The opportunity to exploit the chiral nature of the urea tunnel structure in such applications depends on the extent to which the interaction between the host tunnel of a given chirality (e.g., $P6_122$) is different for the two enantiomers (*R* and *S*) of a chiral guest (note that the *R*-guest/($P6_122$)-host and *S*-guest/($P6_122$)-host systems have a diastereoisomeric relationship, and therefore correspond (in general) to different energies). Recent computational studies (8, 9) have provided insights into the characteristics of host-guest interaction that underlie this chiral recognition. For example, for chiral 2-bromoalkane guest molecules in the $P6_122$ urea tunnel structure, a clear preference for the *R* enantiomer over the *S* enantiomer is found.

In general, the opportunities to exploit the chirality of urea inclusion compounds are limited by the difficulty of accommodating, within the urea tunnel, guest molecules containing a side-group on the *n*-alkane chain (as required to have a chiral centre). Early work by Schlenk (10–14) demonstrated experimentally that urea inclusion compounds can indeed exhibit some degree of chiral recognition, but almost all subsequent studies of urea inclusion compounds (1) have focused on achiral guest molecules. Recently, in conjunction with our computational studies (8, 9) discussed above, we have prepared the urea inclusion compound containing the chiral guest molecule 2-bromotetradecane, and have begun a series of investigations into the physicochemical properties of this material. In this paper, we focus on the structural properties of the 2-bromotetradecane/urea inclusion compound, and particularly the temperature dependence of these properties. We note that, at a sufficiently low temperature, most urea inclusion compounds undergo phase transitions which, in general, are associated with changes in the symmetry of the host structure (15–18) and changes in the dynamic properties of the guest molecules (16, 19–23). Here we focus on structural aspects of these phase transitions in the 2-bromotetradecane/urea inclusion compound.

2. Experimental

Crystals of the 2-bromotetradecane/urea inclusion compound were prepared from commercially available reagents using the following method. A racemic sample of 2-bromotetradecane was added in excess (with respect to the expected guest/host molar ratio in the inclusion compound) to a saturated solution of urea in methanol in a conical flask under ultrasonic agitation at 55°C. A sufficient amount of 2-methylbutan-2-ol was added to render the liquid 2-bromotetradecane completely miscible with the methanol (we note that neither of the solvent molecules (methanol and 2-methylbutan-2-ol) used here is known to form a stable inclusion compound with urea, and there is no evidence (from other studies) for co-inclusion of these solvent molecules within the urea tunnel structure in the 2-bromotetradecane/urea inclusion compounds prepared here). Crystals (urea inclusion compound) that precipitated immediately at this stage were dissolved by adding a further small amount of methanol. The flask was then transferred to an incubator, in which it was cooled systematically from 55 to 15°C over 24 h, and then left at 15°C for several days. When sufficiently large crystals had grown, they were collected and washed with 2,2,4-trimethylpentane.

The crystals were long hexagonal needles, and their behaviour in the polarizing microscope was consistent with conventional urea inclusion compounds (hexagonal crystal system). Powder X-ray diffraction confirmed that the crystals had the conventional urea tunnel structure at ambient temperature, and that the sample did not contain any significant amount of the "pure" crystalline phase of urea (the crystal structure of which differs substantially from the urea substructure in urea inclusion compounds).

Differential scanning calorimetry was carried out on a Perkin–Elmer DSC-7 instrument, with the polycrystalline sample subjected to cooling and heating cycles at a rate of 10 K min^{-1}. The differential scanning calorimetry results identify three different temperature regimes (see Sect. 5.1), and our diffraction studies have been carried out for each of these phases.

Table 1. Data collection parameters for single crystal X-ray diffraction experiments.

	Temperature (K)		
	293	207	142
Number of frames recorded	18	23	23
Oscillation angle per frame (°)	10	8	8
Exposure time per frame (min)	10	15	10
Crystal-to-detector distance (mm)	120	80	90

Single crystal X-ray diffraction experiments were carried out using graphite-monochromated MoK_α radiation (λ = 0.710 73 Å) on a Rigaku R-Axis II diffractometer equipped with an area detector. For experiments below ambient temperature, a standard MSC low-temperature device (temperature stability ca. ±2 K) was used. There is no evidence that the phase transitions are associated with crystal twinning, allowing the structural properties to be investigated readily from single crystal diffraction data (note that crystal twinning is often found to accompany transitions from high-temperature to low-temperature phases in such systems). At each temperature, about 2 h was allowed for the crystal to reach thermal equilibrium before starting the X-ray diffraction measurements.

To provide an initial qualitative understanding of the diffraction patterns, single crystal X-ray diffraction rotation photographs were recorded at ambient temperature (293), 207, and 142 K, with the oscillation axis parallel to the needle axis of the crystal morphology (tunnel axis of the urea host structure). Single crystal X-ray diffraction data collections were carried out at ambient temperature (293), 207, and 142 K. Parameters relating to the data collections at each temperature are summarized in Table 1. Different crystals were used for the experiments at each temperature.

3. Structural description of conventional urea inclusion compounds

For most urea inclusion compounds, there is an incommensurate relationship between the periodic repeat distances of the host and guest substructures (denoted c_h and c_g, respectively) along the tunnel axis (classically, for an incommensurate system, sufficiently small integers p and q cannot be found for which $pc_h \approx qc_g$). Although the host and guest substructures are chemically distinguishable from each other, and possess different structural periodicities, these two substructures are not independent, and through their mutual interaction each substructure must exert a structural perturbation (modulation) on the other substructure. As the basic periodicities (c_h and c_g) of the two substructures are incommensurate, the modulation exerted upon a given substructure must be incommensurate with the basic periodicity of that substructure. Thus, the host substructure can be considered in terms of a "basic structure" (with period c_h along the tunnel) which is subjected to an incommensurate modulation (with period c_g along the tunnel) through its interaction with the guest substructure. The basic structure can be described using conventional crystallographic principles (e.g., three-dimensional space group symmetry). Similarly, the guest substructure can be considered in terms of an incommensurately modulated "basic structure." The incommensurate modulations describe perturbations to the basic structures that result from host-guest interaction.

Considering both the host and guest components together in a unified description of the crystal structure, four basis lattice vectors $\{\boldsymbol{a}_h, \boldsymbol{b}_h, \boldsymbol{c}_h, \boldsymbol{c}_g\}$ are required to define the periodicity of the composite inclusion compound (as the system is incommensurate, the value of c_h/c_g is irrational, or approximated by a rational number with high denominator). Correspondingly, the symmetry of the composite inclusion compound is described by a four-dimensional superspace group (7, 24). On transforming this structural description to reciprocal space, the diffraction pattern is described by four basis reciprocal lattice vectors $\{\boldsymbol{a}_h^*, \boldsymbol{b}_h^*, \boldsymbol{c}_h^*, \boldsymbol{c}_g^*\}$ and four integer Miller indices ($hklm$). Thus, a reciprocal lattice vector $\boldsymbol{S}$ is defined by the linear combination

$$\boldsymbol{S} = h\,\boldsymbol{a}_h^* + k\,\boldsymbol{b}_h^* + l\,\boldsymbol{c}_h^* + m\,\boldsymbol{c}_g^*$$

with integer coefficients h, k, l and m. Previously (5), the term "h" (host) diffraction pattern has been used to refer to the ($hkl0$) subset of the complete diffraction pattern, which arises from diffraction by the basic host structure (and by the incommensurate modulation to the basic guest structure). Similarly, the term "g" (guest) diffraction pattern has been used to refer to the ($hk0m$) subset of the complete diffraction pattern, which arises from diffraction by the basic guest structure (and by the incommensurate modulation to the basic host structure). In addition, the subset of the diffraction pattern comprising reflections ($hklm$) with $l \neq 0$ and $m \neq 0$ arises from the intermodulation of the host and guest substructures, and conveys important information on this structural aspect.

Descriptions of the symmetry properties of incommensurate urea inclusion compounds in superspace groups have been developed (7), and an attempt to determine the modulations in the host and guest substructures of an *n*-alkane/urea inclusion compound, by solving the structure in a superspace group, has been reported (25). Much recent research (26–28, footnote 2) has been devoted to studies of all aspects of the diffraction patterns from incommensurate urea inclusion compounds (particularly *n*-alkane/urea inclusion compounds), including measurement of incommensurate satellite reflections and detailed characterization of different forms of diffuse scattering.

4. Analysis of the h diffraction data

The single crystal X-ray diffraction data measured in this work constitutes the h diffraction pattern (($hkl0$) reflections). As discussed in ref. 5, structure determination calculations using the h diffraction data allow the basic host structure to be determined, and also provide some information concerning the guest substructure. First, the ($hk00$) reflections (which are common to both the h and g diffraction patterns) provide two-dimensional information on the basic guest structure projected on to the plane perpendicular to the

[2] C.L. Bauer, B.M. Kariuki, and K.D.M. Harris. Unpublished results.

© 1999 NRC Canada

tunnel axis. Second, the h reflections ($hkl0$) with $l \neq 0$ convey information on the incommensurate perturbations to the basic guest structure (these perturbations arise from host-guest interaction and have the same periodicity (c_h) as the basic host structure). This "perturbation electron density" represents the difference in electron density between the true guest substructure averaged over the periodicity of the basic host structure and the basic guest structure averaged over the periodicity of the basic host structure. Although this perturbation electron density conveys important structural information, it is more satisfactory to obtain a comprehensive understanding of the incommensurate modulations in incommensurate inclusion compounds by structure determination of the composite inclusion compound in a 4-dimensional superspace group. However, such analysis is not feasible in the present case as there are no sharp Bragg diffraction maxima of significant intensity in the g diffraction pattern. In summary, structure determination calculations using the h diffraction data yield: (*i*) the average basic host structure; and (*ii*) an averaged guest electron density (averaged over the periodicity of the basic host structure) which has a straightforward physical interpretation when projected on to the plane perpendicular to the tunnel axis.

In structure refinement, the method for introducing the contributions to the h diffraction pattern due to scattering from the guest molecules requires special attention, and the following strategy was followed. For the non-hydrogen atoms of the urea molecules, positional parameters (taken initially from the structure solution) and anisotropic displacement parameters were refined in the conventional manner. The difference Fourier map for this "host-only" structural model contains significant maxima located within the tunnel, representing guest electron density (as discussed above). A carbon atom was added in the position of the highest maximum in the difference Fourier map, and its positional parameters and isotropic displacement parameter were refined together with the parameters for the non-hydrogen atoms of the host structure (as expected, the refined values of the isotropic displacement parameters for the carbon atoms in the tunnel are significantly higher than the equivalent isotropic displacement parameters for the atoms of the urea molecules). This procedure was repeated, adding one carbon atom at a time, until the highest peak in the difference Fourier map represented a hydrogen atom of a urea molecule. Finally, hydrogen atoms were added to the urea molecules according to standard geometries and were refined using a "riding" model in which the same coordinate shifts are applied to a hydrogen atom and the nitrogen atom to which it is bonded. For each hydrogen atom, the isotropic displacement parameter was taken as 1.2 times the equivalent isotropic displacement parameter of the nitrogen atom to which it is bonded.

Structure solution calculations were carried out using the direct methods program SIR-92 (29), and structure refinement calculations were carried out using the SHELXL-93[3] program. Standard agreement factors R and R_w were considered.

5. Results and discussion

5.1 Identification of phase transition temperatures

Differential scanning calorimetry data (Fig. 1) were recorded[4] for a polycrystalline sample of 2-bromotetradecane/urea subjected to a cycle of cooling from 298 to 98 K and then heating from 98 to 298 K. On cooling the sample from 298 K, an exotherm is observed at 235 K (enthalpy change –0.029 J g^{-1}) and two further exotherms (which overlap significantly) are observed in the region between 198 and 168 K. As the latter exotherms overlap each other significantly, it is not possible to establish reliable enthalpy changes, and we have not attempted to investigate the structural properties at temperatures between 198 and 168 K. On subsequently warming the sample to ambient temperature, two endotherms (again overlapped significantly) are observed in the region between 186 and 200 K and one endotherm is observed at 256 K (enthalpy change 0.022 J g^{-1}). Clearly there is significant hysteresis in these transitions. The differential scanning calorimetry results identify three temperature regimes, which we denote the high-temperature phase (above 235 K on cooling), the intermediate-temperature phase (between 235 and ca. 198 K on cooling) and the low-temperature phase (below ca. 168 K on cooling). Further studies are required to elucidate the behaviour of the system between ca. 198 and 168 K, in the region of the two overlapping transitions.

We now focus on the structural properties in the high-temperature, intermediate-temperature and low-temperature phases.

5.2 Structural properties of the high-temperature phase

At ambient temperature (293 K), powder X-ray diffraction indicates that the 2-bromotetradecane/urea inclusion compound has the hexagonal basic host structure characteristic of conventional urea inclusion compounds. The single crystal X-ray diffraction rotation photograph for 2-bromotetradecane/urea at ambient temperature is shown in Fig. 2. The structure determined from the measured h diffraction data is shown, viewed along the tunnel axis, in Fig. 3 and structural parameters are listed in Table 2. This structure is completely consistent with the conventional hexagonal urea tunnel structure determined previously (4, 5) for urea inclusion compounds containing other types of guest molecules. From assessment of the Flack parameter,[3] no reliable information on the absolute configuration of the crystal may be obtained.

From the rotation photograph, no discrete diffraction maxima are discernible within the g diffraction pattern, which comprises only diffuse layer lines (suggesting that there is no long-range three-dimensional ordering of the guest molecules). The diffuse scattering comprises sheets in reciprocal space perpendicular to the tunnel axis, implying that the guest molecules exhibit an average periodicity along the tunnel but do not exhibit long-range ordering in other directions (i.e., no inter-tunnel ordering). The average periodicity along the tunnel (ca. 19.7 Å) is close to the length of one guest molecule in the type of extended conformation required to fit

inside the urea tunnel structure. The intensity of scattering in the g diffraction pattern is substantially weaker than the intensities of the Bragg diffraction maxima in the h diffraction pattern.

5.3 Structural properties of the intermediate-temperature phase

The single crystal X-ray diffraction rotation photograph recorded at 207 K is shown in Fig. 4, from which there is no evidence for any decrease in crystal quality on entering the intermediate-temperature phase. The h diffraction pattern recorded at this temperature does not contain any additional layer lines, indicating that there is no superstructure along the tunnel direction in the intermediate-temperature phase. The number and arrangement of discrete diffraction maxima within each layer line in the h diffraction pattern is very similar to that for the high-temperature phase. Although no sharp Bragg diffraction maxima are discernible, regions of locally increased intensity are observed within the diffuse scattering in the g diffraction pattern, suggesting the introduction of some extent of weak inter-tunnel ordering of the guest molecules.

Within experimental errors in the single crystal X-ray diffraction data collection for the h diffraction pattern, the metric symmetry of the basic host structure in the intermediate-temperature phase is hexagonal, with essentially the same unit cell as the high-temperature phase. However, although the Laue symmetry of h diffraction data for the intermediate-temperature phase fairly closely approximates 6/*mmm* (as for the high-temperature phase), it is more correctly described as *mmm*. We recall that a lattice with hexagonal metric symmetry may be described alternatively on a C-centred orthorhombic (orthohexagonal) unit cell. Following transformation to this orthorhombic description, the h diffraction data are found to be most consistent with space group is $C222_1$.

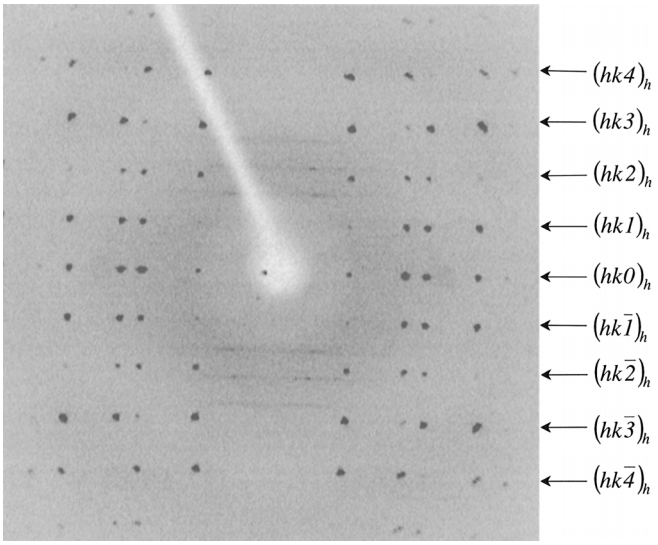
Fig. 4. Single crystal X-ray diffraction rotation photograph, recorded at 207 K, for the 2-bromotetradecane/urea inclusion compound rotating about the tunnel axis. Layer lines of the h diffraction pattern are indexed (the X-ray scattering between these layer lines represents the g diffraction pattern).



The structure determined (in space group $C222_1$) from the h diffraction data at 207 K is viewed along the tunnel axis in Fig. 5. As discussed above, although the Laue symmetry is strictly orthorhombic *mmm*, the deviations from hexagonal Laue group 6/*mmm* are relatively minor, and not surprisingly the host structure determined in space group $C222_1$ for the intermediate-temperature phase remains very close to the hexagonal tunnel structure of the high-temperature phase. Indeed, attempts to refine the structure of the intermediate-temperature phase using space group $P6_122$ (as for the high-temperature phase) also proceeded satisfactorily. Given the approximations inherent in the approach used here (for example, the method for introducing contributions to the h diffraction data due to scattering from the guest molecules), it is perhaps not surprising that subtle structural issues such as this may be difficult to resolve.

From the structure (Fig. 5) determined from the h diffraction data, there is no clear evidence that the guest molecules are more ordered in the intermediate-temperature phase than the high-temperature phase, although we recall (see Sect. 4) that the h diffraction data convey only limited information concerning the nature of the guest substructure. Presumably the lowering of the symmetry from hexagonal (high-temperature phase) to orthorhombic (intermediate-temperature phase) originates from some aspect that influences the h diffraction data sufficiently to detect the lowering of symmetry, but does not express a major effect on the basic host structure. The dynamic properties of the guest molecules, or other aspects of ordering of the guest molecules, may be important in this regard. The subtle structural distinction between the high-temperature and intermediate-temperature phases clearly merits more detailed investigations using other experimental techniques (for example, optical microscopy (to distinguish whether the crystals are uni-axial or bi-axial in the intermediate temperature phase) and high-resolution solid state ^{13}C NMR (which may be able to indicate directly the number of

urea molecules in the asymmetric unit (1 urea molecule for $P6_122$; 1.5 urea molecules for $C222_1$)).

5.4 Structural properties of the low-temperature phase

The single crystal X-ray diffraction rotation photograph recorded at 142 K is shown in Fig. 6. From this photograph, there is no significant decrease in crystal quality on entering the low-temperature phase. The h diffraction pattern at 142 K does not contain any new layer lines (in addition to those for the intermediate-temperature and high-temperature phases), indicating that no new superstructure is generated along the tunnel direction in the low-temperature phase. On the other hand, the number and arrangement of discrete diffraction maxima within each layer line in the h diffraction pattern is very different from that in the high-temperature and intermediate-temperature phases.

The g diffraction pattern for the low-temperature phase has increased localization of intensity within the diffuse bands (compared with the high-temperature phase), suggesting that there is some increase in the extent of three-dimensional ordering of the guest molecules. However, the data do not allow a reliable assessment of the mode of inter-tunnel ordering (as defined by the parameter Δ_g (30)) of the guest molecules. The relative positions of the layer lines for the h and g diffraction patterns in Fig. 6 implies that there is an incommensurate relationship between the periodicities of the host and guest substructures along the tunnel axis in the low-temperature phase, with no evidence that the host and guest substructures lock into a commensurate relationship at any temperature studied.

From analysis of the h diffraction pattern, the metric symmetry of the basic host structure in the low-temperature phase is monoclinic, and represents an approximate $2 \times 2 \times 1$ supercell of the hexagonal cell of the basic host structure in the high-temperature phase. The Laue group is $2/m$ and the diffraction data are consistent with space group $P2_1$.

The structure determined from the measured h diffraction data at 142 K is viewed along the tunnel axis in Fig. 7, and structural parameters are listed in Table 3. From assessment of the Flack parameter,[3] no reliable information on the absolute configuration of the crystal could be obtained. The host structure contains four independent types of tunnel (parallel to the *b* axis) per unit cell, with irregular hexagonal geometry when projected on to the plane perpendicular to the tunnel axis (***ac*** plane). In contrast, the corresponding projections for the high-temperature phase and the intermediate-temperature phase are regular hexagons (exact for the high-temperature phase, and a close approximation for the intermediate-temperature phase). The degree of distortion of the tunnels in the low-temperature phase may be assessed by considering the "diameters" (see Fig. 8) between opposite corners of the irregular hexagonal projections. For three of the four independent types of tunnel (type A), one diameter is significantly longer than the other two, whereas for the other type of tunnel (type B), all three diameters are approximately the same. For tunnels of type A, we may expect that the planes of the guest molecules should be oriented (in projection) along the long diameter. For tunnels of type B, on the other hand, there may be no preferred orientation (in projection) of the planes of the guest molecules. These expectations are supported by the projection of the guest electron density (determined from the h diffraction pattern, see Sect. 4) on to the plane perpendicular to the tunnel axis, from which it is evident that the geometric distortions of the host tunnels are related to orientational ordering of the guest molecules. Thus, there is a significant increase in the orientational ordering of the guest molecules in the low-temperature phase, although we recall that several other aspects of disorder must remain in the guest substructure (see Sect. 5.5). The distribution of guest molecule orientations observed in tunnels of type B may represent a static average of three orientations related by 120° rotation about the tunnel axis.

5.5 Comments on disorder within the guest substructure

The lack of significant three-dimensional ordering of the guest molecules in the 2-bromotetradecane/urea inclusion compound is not unexpected in view of the different contributions to disorder that are known to exist in the guest substructure. First, the 2-bromotetradecane/urea inclusion compound studied here was prepared from a racemic sample of 2-bromotetradecane, and thus, although a given single crystal will have a preference to incorporate one particular enantiomer of 2-bromotetradecane (as discussed in Sect. 1), it is probable that each crystal contains a significant proportion of each enantiomer (we note that the chiral discrimination on forming urea inclusion compounds with chiral guest molecules is less than 100% (10–14)). Second, it is already known from bromine K-edge EXAFS spectroscopy (31) and Raman spectroscopy[5] of the 2-bromotetradecane/urea inclusion compound that there is disorder in the conformational properties of the -$CH(Br)CH_3$ end-group of the guest mole-

cules, with substantial populations of guest molecules in the conformation with the CH_3 substituent trans and substantial populations of guest molecules in the conformation with the Br substituent trans. Third, 2-bromotetradecane is an unsymmetric guest of the general type $X(CH_2)_nY$ discussed in Sect. 1 (X = H_3C-, Y = -$CH(Br)CH_3$). Thus, in general, disorder concerning the orientation of the guest molecules along the tunnel may be expected, together with disorder in the types of end-group interactions. Solid state NMR studies should provide more insight into this structural aspect of the 2-bromotetradecane/urea inclusion compound. Fourth, in most urea inclusion compounds the guest molecules undergo a variety of dynamic processes at sufficiently high temperature. Although the dynamic properties of 2-bromoalkane/urea inclusion compounds have not yet been investigated, it is plausible that there is some degree of dynamic disorder within the guest substructure, at least in the higher temperature phases.

6. Concluding remarks

In general, the phase transitions in urea inclusion compounds reflect the cooperative behaviour of the host and guest components. At ambient temperature, the high symmetry (hexagonal) of the average host structure reflects the time-averaged and space-averaged distribution of the guest molecules. At sufficiently low temperature, the guest molecules adopt a well-defined orientation (or a restricted set of orientations) with respect to the host, as a consequence of a diminution in the dynamics of the guest molecules. Concom-

[a]C13 to C39 denote carbon atoms introduced within the tunnel to represent the contribution to the h diffraction pattern from scattering by the guest molecules. The asymmetric unit of the host structure comprises 12 independent urea molecules, giving a total of 24 urea molecules in the unit cell.

© 1999 NRC Canada

itantly, the host structure distorts to a lower symmetry that reflects the static orientational distribution of the guest molecules. The intimate interplay of both host and guest components is crucial in controlling the overall behaviour of these phase transitions.

In view of this synergy between host and guest properties, it is not surprising that the mode of distortion of the host structure in the low-temperature phases of urea inclusion compounds is found to depend critically on the type of guest molecule. At a qualitative level, the alkane/urea (32) and α,ω-dibromoalkane/urea (33) inclusion compounds behave in a similar way with respect to the phase transitions. In both cases, the host structure in the low-temperature phase is orthorhombic and is based on a distortion from the orthohexagonal description of the high-temperature structure. The 1,10-decanedicarboxylic acid/urea inclusion compound, on the other hand, exhibits more complicated structural behaviour in the low-temperature phase (34), with the formation of a large superstructure in directions perpendicular to the tunnel axis — this superstructure contains four independent types of tunnel exhibiting different modes of distortion. The structural properties of the 2-bromotetradecane/urea inclusion compound reported here represent another illustration of diversity of low-temperature structural properties for different types of guest molecules in urea inclusion compounds. Clearly the subtle interactions between the host and guest subsystems, which depend critically on the molecular structure of the guest, are crucial in controlling the evolution of the structural properties of these inclusion compounds with temperature.

Given the interest in the chiral recognition properties of 2-bromoalkane/urea inclusion compounds, knowledge of the structural properties (reported here) and the conformational properties of the guest molecules (reported elsewhere (31, footnote 5)) are important pre-requisites before the chiral recognition properties can be understood in depth.

Acknowledgements

We are grateful to Ciba Specialty Chemicals and the University of Birmingham for the award of a studentship to L.Y. We thank Dr. Eduardo Bocanegra (Universidad del Pais Vasco, Spain) for recording the differential scanning calorimetry data discussed in the text.

ARTICLES

Stephen G. Withers 1998 Hoffmann La Roche Award Lecture
Understanding and exploiting glycosidases **1**

Luc Ruest, Carl Berthelette, Marco Dodier, Laurence Dubé, and David St-Martin Ryanoids and related compounds. Isolation and characterization of four minor ryanoids from the plant *Ryania speciosa* Vahl: 8,9-didehydroryanodine, 10-*O*-acetylryanodol, 3-*O*-benzoylryanodol, and a first natural 4-deoxyryanoid: 4-deoxy-8_{ax}-hydroxy-10-*O*-methyl-10-epiryanodine (4-deoxyester A) **12**

Pierre D. Harvey and Christian Reber Distortions in square-planar palladium(II) halides: a nonempirical molecular orbital model study **16**

Germán Cavigliasso and Delano P. Chong Accurate density-functional calculation of core-electron binding energies with a scaled polarized triple-zeta basis set. VI: Extension to boron-containing molecules. **24**

Sean E. O'Brien and Paul L.A. Popelier Quantum molecular similarity. Part 2: The relation between properties in BCP space and bond length **28**

H. Golchoubian, W.L. Waltz, and J.W. Quail Synthesis, structure, and reactivity of macrocyclic heterobimetallic complexes of (Co, Cu), (Co, Ni), (Co, Zn), (Zn, Cu), (Zn, Ni) combinations **37**

Verónica Daier, Sandra Signorella, Marcela Rizzotto, María Inés Frascaroli, Claudia Palopoli, Carlos Brondino, Juan Manuel Salas-Peregrin, and Luis F. Sala Kinetics and mechanism of the reduction of Cr^{VI} to Cr^{III} by D-ribose and 2-deoxy-D-ribose **57**

Stephen A. Decker and Mariusz Klobukowski The energy barrier for CO migration in $Mn_2(CO)_6(H_2PCH_2PH_2)_2$: a PM3(tm) study **65**

Gennady V. Shustov and Arvi Rauk Dioxirane oxidation of nitrosoamines. An ab initio study **74**

R.F.W. Bader Can there be more than a single definition of an atom in a molecule? **86**

April J. Angel, Anne E. Finefrock, Kristen L. French, Douglas R. Hurst, Angela R. Williams, Mary E. Rampey, Shannon L. Studer-Martinez, and Charles F. Beam Preparation of *N*-aryl-4-oxo-4*H*-1-benzothiopyran-2-acetamides from trilithiated acetoacetanilides and lithiated methyl thiosalicylate **94**

Jacques Mortier, Michel Vaultier, Barbara Plunian et Sourisak Sinbandhit Réactions d'addition conjuguée d'organolithiens aux acides carboxyliques α,β-insaturés **98**

Ian W.J. Still, Rosanne Natividad-Preyra, and F. Dean Toste A versatile synthetic route to 1,5-dithiocins from *o*-mercapto aromatic aldehydes **113**

Alpha O. Diallo, Claude Meyer, and Nguyen Van-Thanh The molecular complexes of deoxycholic acid and cholesterol with CH_3COOD studied by infrared spectroscopy **122**

Martha S. Morales-Ríos, Oscar R. Suárez-Castillo, Celina Alvarez-Cisneros, and Pedro Joseph-Nathan ^{13}C NMR and crystallographic evidence of push–pull effects in furoindolic β-enamino esters **130**

Zhaopeng Li, Johan van Lier, and Clifford C. Leznoff Heterocyclic aromatic amide protecting groups for aryl and phthalocyaninesulfonic acids **138**

Russell A. Bell, Kieran C. Dickson, and John F. Valliant The total synthesis of a technetium chelate – tamoxifen complex **146**

© 1999 NRC Canada

COMMUNICATION

Zengquan Qin, Hilary A. Jenkins, Simon J. Coles, Kenneth W. Muir,and Richard J. Puddephatt **155**
Self-assembly of one-dimensional polymers by coordination and hydrogen bonding in palladium(II) complexes

IUPAC Recommendations / IUPAC recommendation **iii**

ARTICLES

Alex G. Fallis 1998 Alfred Bader Award Lecture **159**
Tangents and targets: The synthetic highway from natural products to medicine

Charles R. Clark, Allan G. Blackman, M. Ross Grimmett, and Akbar Mobinikhaledi C(2)-H isotopic exchange in coordinated imidazoles revisited. The case of the $[Co(NH_3)_5ImH]^{3+}$ ion **178**

Jeffrey J. Posakony, Russell C. Pratt, Steven J. Rettig, Brian R. James, and Kirsten A. Skov Porphyrins incorporating heterocyclic *N*-oxides: (oxidopyridyl)porphyrins, porphyrin-*N*-oxides, and a tirapazamine–porphyrin conjugate **182**

Stephen A. Westcott, Nicholas J. Taylor, and Todd B. Marder Reactions of $(\eta^5\text{-}C_9H_7)Rh(\eta^2\text{-}C_2H_4)_2$ with quinones: molecular structure of $[(\eta^5\text{-}C_9H_7)Rh(2,3,5,6\text{-}C_6O_2(CH_3)_4)]$ **199**

Stephen A. Westcott, Ashok K. Kakkar, Nicholas J. Taylor, D. Christopher Roe, and Todd B. Marder Synthesis, structure, and solution dynamics of indenyl rhodium complexes containing bulky phosphine ligands: molecular structures of $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(\eta^2\text{-}C_2H_4)(PCy_3)$ (Cy = cyclohexyl) and $(\eta^5\text{-}1\text{-}CH_3\text{-}C_9H_6)Rh(dcpe)$ (dcpe = $Cy_2PCH_2CH_2PCy_2$) **205**

Oludotun A. Phillips, K.S. Keshava Murthy, Charles Y. Fiakpui, and Edward E. Knaus Synthesis of 5-phenyl-10-methyl-7*H*- pyrimido[4,5-*f*][1,2,4]triazolo[4,3-*a*][1,4]diazepine and its evaluation as an anticonvulsant agent **216**

Robert Chênevert, Ghodsi Mohammadi-Ziarani, Dave Caron, and Mohammed Dasser Chemoenzymatic enantioselective synthesis of (–)-enterolactone **223**

Richard A. Walker, D. Gerrard Marangoni, and Truis Smith-Palmer A capillary electrophoretic determination of the kinetics of tetradecanedisulfate hydrolysis **227**

Jianji Wang, Kelei Zhuo, Qiufen Zhang, and Jinsuo Lu Thermodynamics of the interaction of HCl with D-xylose in water at 278.15–318.15 K **232**

Mirta P. Mischne, Silvia N. Huber, and Juan Zinczuk Photochemical reaction of β-ionone derivatives in the presence of oxygen. A convenient synthesis of substituted 1,2,4-trioxanes **237**

Komla Oscar Awitor, Laurent Bernard, Olivier Bonnin, Bernard Coupat, Jean Paul Fournier et Philippe Verdier Préparation du chlorure mercureux et mesure de sa pression de vapeur **243**

Raphaël Sabbah et Safi Ider Energétique des liaisons inter- et intramoléculaires dans les trois acides carboxypyridiniques (acides picolinique, nicotinique et isonicotinique) **249**

Tomihiro Nishiyama, Hideaki Kameyama, Hideki Maekawa, and Kouhei Watanuki Ether synthesis using trifluoromethanesulfonic anhydride or triflates under mild reaction conditions **258**

Catherine Barré, Sophie Carret, Michel Guerro, Philippe Le Grel, and Michèle Baudy-Floc'h α-Halogenohydrazides: useful starting material for the synthesis of hydrazinoazapeptides and azauracils **263**

Ronald Kluger, Krisztina Paal, and J. Gordon Adamson An ether-linked tetrafunctional acylating reagent and its cross-linking reactions with hemoglobin **271**

Brian Pettitt and Werner Danchura Symmetry in double-diffusive convection **1834**

Pamela S. Bromberg, Kathleen M. Gough, and Ian M.C. Dixon Collagen remodeling in the extracellular matrix of the cardiomyopathic Syrian hamster heart as assessed by FTIR attenuated total reflectance spectroscopy **1843**

James A.W. Shoemaker and J. Stephen Hartman Chelated fluoroboron cations. I. Synthesis and NMR studies involving the tertiary-amine ligands *N*,*N*,*N*′,*N*′-tetramethylethylenediamine and *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine **1856**

Dingliang Zhang, Markus Heubes, Gerhard Hägele, and Friedhelm Aubke A ^{19}F nuclear magnetic resonance study of the conjugate Brönsted–Lewis superacid $HSO_3F–SbF_5$. Part 1 **1869**

Richard Buist, Scott Kroeker, and James Peeling Temperature dependence of the creatine kinase reaction measured in rat brain in vivo by ^{31}P NMR saturation transfer **1887**

Dharamdat Christendat, Ian S. Butler, Denis F.R. Gilson, and Frederick G. Morin Solid-state nuclear magnetic resonance studies of triphenylsilyl-, triphenyltin-, and triphenyllead(pentacarbonyl)manganese(I) complexes **1892**

Glenn A. Facey, Tina P. Fong, Dmitry Gusev, Peter M. Macdonald, Robert H. Morris, Marcel Schlaf, and Wei Xu Probing the motion of the η^2-dideuterium ligand by solution and solid-state ^2H NMR spectroscopy **1899**

G.W. Buchanan, M. Gerzain, and C.I. Ratcliffe Symmetry, disorder, and dynamics in solid crown ether complexes: ^2H NMR studies of 15-crown-5·NaI, 15-crown-5·$NaClO_4$, and 21-crown-7·KI **1911**

William F. Reynolds, Stewart McLean, Helen Jacobs, and Wayne W. Harding Assignment of ^1H and ^{13}C spectra for polyprenol-12, a molecule with severe ^1H and ^{13}C spectral crowding, with the aid of high-resolution, ^{13}C-detected, $^{13}C–^1H$ shift correlation spectra **1922**

Dawn M. Friesen, Robert McDonald, and Lisa Rosenberg Tris{(diphenylphosphino)dimethylsilyl}methane: a sterically hindered tripod **1931**

Eugene P. Mazzola, Sandra J. Bell, Saleh A. Turujman, Julie N. Barrows, John E. Bailey, Jr., Joseph B. McMahon, Tania K. Germann, and William F. Reynolds Nuclear magnetic resonance investigations of azo-hydrazone, acid–base equilibria of FD&C Yellow No. 5 (tartrazine) **1941**

A.D. Buckingham and Y. Tantirungrotechai The second dielectric virial coefficient of the dipolar Gay–Berne fluid **1946**

Michael J.T. Ditty and William P. Power ^{31}P chemical shielding as a function of bond angle: phosphorus chemical shielding surface of phosphinoborane $R_2PBR'_2$ **1951**

Scott Kroeker and Roderick E. Wasylishen A multinuclear magnetic resonance study of crystalline tripotassium tetracyanocuprate **1962**

Robert W. Schurko, Roderick E. Wasylishen, Scott J. Moore, Luigi G. Marzilli, and John H. Nelson Solid-state phosphorus-31 NMR study of phosphine- and phosphite-substituted cobaloximes **1973**

Colin A. Fyfe, Andrew R. Lewis, and Jean-Michel Chézeau A comparison of NMR distance determinations in the solid state by cross polarization, REDOR, and TEDOR techniques **1984**

Judith A. MacInnis, R. Palepu, and D. Gerrard Marangoni A nuclear magnetic resonance investigation of the micellar properties of a series of sodium cyclohexylalkanoates **1994**
