order with respect to H_2O_2 (Tables 1–3 and Fig. 1). Sulfonation of the more reactive sulfides, and the rapidity of the oxidations, limits the concentration of H_2SO_4 that can be used. In addition, formation of peroxymonosulfuric acid in more concentrated H_2SO_4 introduces a new reaction path (16). There is, however, no indication of complete protonation of H_2O_2 and, based on the data of Evans and Uri (21), Edwards (6) estimated $pK_a \approx -4.7$ for $H_3O_2^+$.

Substituent effects

Electron-donating substituents in the 4-position increase k_2 (Table 4) and the Hammett equation is obeyed with σ_p parameters and $\rho = -1.15$. This value is similar to that for oxidation by HSO_5^- where $\rho = -1.0$ (8). Similar substituent effects are reported for oxidation of sulfides by IO_4^- (10).

The esters are very much less reactive than the sulfides, by factors of ca. 10^4 (Tables 3 and 5). These structural effects on reactivity are also qualitatively similar to those observed for reactions with HSO_5^-, and can be rationalized on the same basis (9, 11).

Temperature effects

Oxidations of some sulfides were followed over a range of temperature (Table 6). These oxidations, like those by HSO_5^- (9, 11) and IO_4^- (10), have relatively low activation energies and low pre-exponential terms. These low activation energies (or enthalpies) and low pre-exponential terms (or negative activation entropies) are typical of oxygen transfers (9–11, 21). Activation energies are, however, higher for these oxidations than for those with HSO_5^- (9, 11), in part because of the contribution of the equilibrium protonation of H_2O_2 (5, 22).

Time dependence of rate constants

Except at the higher concentrations of H_2SO_4, values of k_2 were unaffected by leaving mixtures of H_2O_2 and H_2O–H_2SO_4 before addition of the substrate, but with the less reactive substrates, which could be studied in the more acidic solutions, there was a time dependence of k_2 (Table 7).

We assume that the rate increases are due to a relatively slow equilibration with peroxymonosulfuric acid (16). In confirmation, we observed a second-order rate constant of 2.2 M^{-1} s^{-1} for the reaction of Ph(EtO)PO·SEt and peroxymonosulfuric acid in 65.3 wt.% H_2SO_4 (extrapolated to the time of making up the solution) and over 10 h it decreased to ca. 0.5 M^{-1} s^{-1}, which is close to the value obtained by using a mixture of H_2O_2 and H_2SO_4 (Table 7).

	10^4 k_2, M^{-1} s^{-1}	6.31	36.0	64.2

There was almost no change in the value of k_2 for reaction of peroxymonosulfuric acid in 52.6 wt.% H_2SO_4 over a period of 4 h. Therefore equilibration of H_2O_2 and peroxymonosulfuric acid is kinetically important only in the more concentrated H_2SO_4.

Reactions in $HClO_4$ and $MeSO_3H$

We followed a few reactions in $HClO_4$–H_2O_2 (Table 8 and Fig. 1). As in H_2SO_4–H_2O, k_{obs} varied linearly with $[H_2O_2]$ (Fig. 1) and second-order rate constants, k_2, increased sharply with increasing acid. These values are similar to those in corresponding wt.% compositions of H_2SO_4, as expected from the protonating power of the two acids (17–20), and consistent with our conclusion that formation of peroxymonosulfuric acid is not essential for oxidation.

Methanesulfonic acid catalyzes the oxidation of **1e** (Table 9) although it is considerably less effective than H_2SO_4 or $HClO_4$ (Tables 7, 8, and 9), as expected in view of the differences in protonating power as given by values of H_0, e.g., with 5 M acid H_0 is more negative by 0.82 for H_2SO_4 than for $MeSO_3H$ (23). However, rate constants are only approximately comparable because the data for $MeSO_3H$ are at 22°C and in 20 vol.% MeCN. There is no indication of formation of a peroxysulfonic acid. Oxidation was also catalyzed by sulfonic acid ion-exchange resins. Qualitative evidence is given in the experimental section.

Discussion

Oxidation of sulfides by H_2O_2 is acid catalyzed, and rate constants increase more steeply than does stoichiometric acidity, as for many acid-catalyzed reactions (17–20).

Several factors can be responsible for this catalysis; e.g., equilibrium protonation of H_2O_2 (5), a kinetic solvent effect of H_2SO_4, and formation of peroxymonosulfuric acid (16). In principle, the ester **4a**, **b** could be initially hydrolyzed, followed by rapid oxidation of the thiol (8), but this reaction would be zero order in H_2O_2.

Formation of peroxymonosulfuric acid (16) is the probable reaction path in more concentrated H_2SO_4, 52 wt.%, (Table 7). Conversely, for reaction with HSO_5^-, k_2 decreases if solutions are left standing. These observations indicate that interconversion of H_2O_2 and HSO_5^- is relatively slow and unimportant with less than ca. 52 wt.% H_2SO_4. Catalysis by $HClO_4$ (Table 8 and ref. 6) confirms that protonation of H_2O_2 can increase the rate of oxidation without formation of a peroxyacid. It appears that, except in the more concentrated H_2SO_4, $H_3O_2^+$ is the oxidant because OH^+ is excluded as an intermediate (5).

Except at the higher concentrations the relation between k_2 and the concentration of H_2SO_4 depends on the equilibrium protonation of H_2O_2 (5, 6) and the kinetic solvent effect upon the reaction of $H_3O_2^+$ with substrate. The problem of separating these medium effects of strong acids is general for reactions in moderately concentrated acids, although most emphasis has been given to hydrolyses, where the role of water in the rate-limiting step has to be considered (12, 19, 24).

Relation between reactivity and acid concentration

Rate constants of A-1 reactions, i.e., hydrogen ion catalyzed reactions in which water is not involved nucleophilically, or as a base, increase more rapidly than stoichiometric acidity. For many of these reactions plots of log k_{obs} against Hammett's acidity function, $-H_0$, are linear with slopes close to unity (17, 18). However, this scale of acidity is based on the protonation of aromatic primary amines, and acidity functions have been evaluated by using a variety of indicator types, including the $-H_A$ scale for protonation of amides (24).

[b]$[H_2O_2]$ = 0.026–0.081 M.
[c]$[H_2O_2]$ = 0.014–0.048 M.

Plots of log k_{obs} against either $-H_0$ (17) or $-H_A$ (24) are linear, with slopes that are, respectively, lower or higher than unity. They depend slightly upon the substrate, i.e., they depend not only upon protonation of H_2O_2 but also upon the medium effects of moderately concentrated H_2SO_4 upon the reaction of $H_3O_2^+$ and the substrates.

Various extensions of the original relationships between log k_{obs} and acidity functions have been suggested (17–20, 22) For example, Bunnett and Olsen (18) wrote protonation of weak bases, B, in the form of eq. [3], and applied eq. [4] to acid-catalyzed reactions (19).

$$[3] \qquad \log \frac{[B]}{[BH^+]} = H_0 - \phi(H_0 + \log[H^+]) - pK_a$$

$$[4] \qquad \log k + H_0 = \phi(H_0 + \log [H^+]) + \text{constant}$$

[b]Mean of values from 10^4 k_{obs}, s^{-1} = 4.71, 5.05, 6.76, 9.19, and 10.2 with $[H_2O_2]$, M = 0.031, 0.031, 0.047, 0.06, and 0.06, respectively.

They showed that values of ϕ are characteristic of reaction mechanism, but their treatment involves selection of primary amines as indicators.

An alternative approach involves estimation of "excess acidity," *X*, above that predicted by stoichiometry, and independent of the selected indicators (eq. [5]) (20). Both eqs. [3] and [5] fit protonation data (25), $m^* \approx 1 - \phi$ (19), and m^* is a function of the base.

$$[5] \qquad \log \frac{[B]}{[BH^+]} = -\log[H^+] - {}^* X - pK_a$$

For a reaction catalyzed by a hydrogen ion the relation becomes (25):

$$[6] \qquad \log k_2 - \log[H^+] = m^* m^{\ddagger} X + \text{constant}$$

where, for the present reaction, m^* describes protonation of H_2O_2, and $m^{\ddagger}$ includes the activity coefficients of the transition state and substrate (26). As a result, slopes of plots of log k_2 – log$[H^+]$ against *X* (Table 10) depend modestly upon the nature of the substrate. The Bunnett–Olsen eq. [4] also

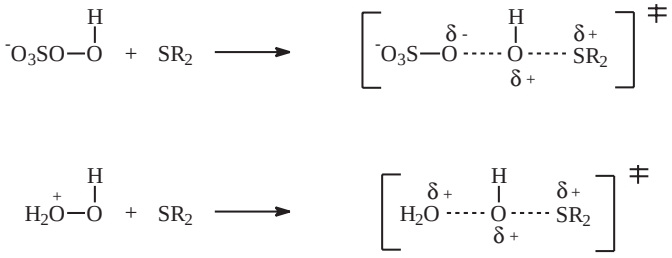
Scheme 4.



fits the rate data (not shown), with modest dependence of ϕ on substrate, consistent with the analysis of protonation equilibria (25). The excess acidity method has also been used to treat hydrolysis of acyl imidazoles where protonation inhibits reaction by forming dead-end species (27).

Values of m^* are less than 1 for protonations of amides and benzophenones on oxygen (20); this generalization should apply to protonation of H_2O_2, and therefore values of $m^‡$ should be close to 1, based on data in Table 10. For some substrates few data points were used in estimating $m^*m^‡$, but the mean value is 0.76 and most are within 0.1 of this value (Table 10), even though concentrations of H_2O_2 and H_2SO_4 differ for the more, and less, reactive substrates. The constant term in eq. [6] is the logarithm of the third-order rate constant, k_3, with respect to substrate, H_2O_2 and H^+ estimated by extrapolation by a linear regression to dilute acid where $X \rightarrow 0$ (Table 10). These values are least reliable for the unreactive substrates where there is a long extrapolation, based on few data points.

Protonation of H_2O_2 is the most important factor in controlling overall rate constants. To the extent that these oxygen transfers to sulfur involve "early" transition states (8, 9, 11, 21) and limited charge redistribution, we would not expect large solvent effects upon these reactions of $H_3O_2^+$. Oxidations by HSO_5^-or IO_4^- are sensitive to medium polarity (8, 10, 11), and rate constants follow values of Y (15) or Y_{OTs} (14) in mixed solvents and aqueous H_2SO_4, respectively (8, 10–12), with high sensitivities to medium polarities. Differences in kinetic medium effects upon oxygen transfers from HSO_5^- and $H_3O_2^+$ are understandable in terms of differences in charge redistributions in transition state formation, especially as regards the numbers of hydrogen-bonding centers (Scheme 4), consistent with $m^‡ \approx 1$ for oxygen transfers from $H_3O_2^+$ (δ indicates partial charge and has no quantitative significance). The marked solvent effect on oxidations by HSO_5^- is consistent with development of positive charge on both sulfur and the transferred oxygen, and the similar values of ρ in oxidations by IO_4^-, HSO_5^-, and H_2O_2 point to modest charge development on sulfur (Table 5 and refs. 8 and 10).

A problem in separating medium effects upon proton transfers from those on subsequent kinetic steps is that the parameters are often related. Bentley et al. (13) found that Y_{OTs} is linearly related to Hammett's acidity function, H_0 (in up to 60 wt.% H_2SO_4), with $H_0 = -3.76\ Y_{OTs} + 15.2$. There is also a linear relation between N_{OTs} and Y_{OTs} (or H_0), and variations of N_{OTs} and Y_{OTs} approximately follow changes in log a_{H_2O} in H_2O–H_2SO_4 (13). These relations indicate the dependence of these medium parameters upon hydration changes in the processes under consideration (17–20).

A plot of Y_{OTs} (13) against X (20) is linear in up to 60 wt.% H_2SO_4 and follows eq. [7].

$$[7] \qquad Y_{OTs} = 4.08 + 0.37\ X$$

(The value of Y_{OTs} in water ($X \equiv 0$) is uncertain within ±0.1 (13)). Values of log k for oxidations of sulfides and related esters by HSO_5^- in aqueous H_2SO_4 are linearly related to Y_{OTs} (12), and we expected to find a corresponding relation between log k and X. Slopes of plots of log k against X for reaction with HSO_5^- in H_2SO_4 (12) are as follows: 4-$O_2NC_6H_4SMe$, 0.40 (1.3); Ph_2S, 0.57 (1.4); $PhCO{\cdot}SC_6H_4Me$, 0.48 (1.6); PhCO·SPh, 0.46 (1.5); $Ph_2PO{\cdot}SPh$, 0.41 (1.5); Ph(EtO)PO·SEt, 0.37 (1.1). Slopes of plots of log k against Y_{OTs} (13) are in parentheses, and there is an approximate correspondence between these two sets of slopes.

These correlations between X and log k for both non-acid-catalyzed S_N1 reactions (13) and oxygen transfers (12) are not unexpected, and they illustrate the problem in separating the factors that control rate constants of acid-catalyzed reactions in aqueous media. The decrease in protonating power due to hydration of the hydronium ion is well recognized and explains the approximate correlations between water activity and acidity functions, e.g., H_0 (17, 23, 28). Hydration and solvent polarity are key factors in reactions of polar or ionic reactants in aqueous media, even though water may not be involved covalently. It is therefore difficult to separate parameters such as m^* and $m^‡$ (eq. [6]) (25), unless m^* can be measured directly, or estimated, based on data for protonation of structurally similar, but unreactive, bases (20, 25–27). The relation between structure and values of m^* has been analyzed (29). However, relations between rate constants and acidity functions provide valuable mechanistic information (17–20, 26), especially as regards the covalent involvement of water in reactions. Recent work by Marziano et al. (30) extends studies of protonation by analyzing the solvent–solute interactions, which are of particular importance in concentrated acids.

Experimental

Materials

Substrates were materials used earlier (8, 11). Solutions of moderately concentrated acids were made up by weight with redistilled deionized water. Except as noted, kinetic solutions of H_2O_2 were used promptly. Ion-exchange resin in the acid form was washed with H_2O, then with 3% H_2O_2, and finally with H_2O. It was air dried.

Kinetics

Reactions were followed spectrophotometrically by the decreasing absorbance in HP 8450 double-beam or 8451 single-beam diode array spectrometers as described for reactions with HSO_5^- (8, 11). In earlier experiments with HSO_5^- (as OXONE) we had erratic results with some substrates when reactions were followed in the single-beam spectrometer. We did not have this problem in oxidations by H_2O_2 and we followed reactions of the sulfides in the single-beam spectrometer and reaction of $Ph_2PO{\cdot}SEt$ in the double-beam spectrometer. Reaction of Ph(EtO)PO·SEt was followed in both instruments and results agreed.

Reactions were followed at the following wavelengths (nm) (wavelengths at isobestic points are in parentheses): $MeOC_6H_4SMe$, 260–265 (253); MeC_6H_4SMe, 256–270 (242); PhSMe, 250–260 (235); ClC_6H_4SMe, 260–280 (245); $O_2NC_6H_4SMe$, 340–360 (305); Ph_2S, 270–280 (240); $PhSCH_2CH_2Cl$, 255–265; $Ph_2PO{\cdot}SEt$, 240; Ph(EtO)PO·SEt, 240–245.

Substrate concentrations were in the range of (0.75–1.5) × 10^{-5} M (cf. Table 1) and $[H_2O_2]$ was varied between ca. 10^{-2} and 0.26 M depending on the reactivity of the substrate and the acid concentration. Substrates were added in MeCN and the kinetic solution contained 0.5 vol.% MeCN. Sulfonation of the more reactive thiols limited the usable concentration of H_2SO_4.

Catalysis by acidic ion-exchange resins

The reaction of **1e** with H_2O_2 was catalyzed by several ion-exchange sulfonate resins in their acidic forms. The resins were Dowex 50 W-4 (20–50 mesh), Baker CGC-241 (200–400 mesh), and Baker C-350 (16–50 mesh). We used 2 × 10^{-5} M **1e** in 10 mL of unstirred water at room temperature (ca. 22°C). Reaction was followed by the decreasing absorbance at 340 nm, which reached final values similar to those with reactions in aqueous H_2SO_4, and approximate half-lives were obtained by inspection (Table 11). These half-lives decrease with increasing amounts of resin and $[H_2O_2]$, but are apparently not very sensitive to the brand of resin. Control experiments showed that the decreases in absorbance were not due to uptake of **1e** by the resins. Due to the heterogeneity of the system these results are qualitative and merely show that acidic resins catalyze these oxidations by H_2O_2. We also used ^{1}H NMR spectroscopy at 200 MHz to demonstrate reaction of 2 × 10^{-3} **1a** with 0.5 M H_2O_2 in 2.6 mL of D_2O with 6 vol.% CD_3CN and 0.051 g Dowex 5O W-4. After 35 min, with shaking at room temperature, signals of the sulfide had disappeared, and we observed the signal of the sulfoxide ($SO{\cdot}CH_3$) at 2.86 ppm. The corresponding signal of **1a** at 2.45 ppm had disappeared and there was no signal of the sulfone. Oxidation by HSO_5^- gives both sulfoxide and sulfone (8); the SCH_3 ^{1}H signal of the latter is at 3.15 ppm, referred to δ = 4.80 ppm for HOD. Control tests showed that **1a** is not significantly bound by the resin.

Quantitative investigations of the aggregation behaviour of hydrophobic anilino squaraine dyes through UV/vis spectroscopy and dynamic light scattering

James Wojtyk, Andrew McKerrow, Peter Kazmaier, and Erwin Buncel

Abstract: In continuing studies of the aggregation behaviour of squaraine dyes in DMSO–water mixtures, we have examined a series of symmetrical anilino-based squaraines with increasing *N*-alkyl chain length (*n*-butyl, *n*-octyl, and *n*-dodecyl). The aggregation behaviour was assessed through UV/vis spectroscopic and Dynamic Light Scattering (DLS) studies with quantitative interpretation based on exciton theory. This class of *N*-alkyl squaraines forms two distinct solution aggregates, Type J and Type H, depending on the composition of the DMSO–water medium. DLS measurement of the aggregates in the Type J and Type H morphologies showed that (*i*) the particle diameter increased with increasing hydrophobicity; (*ii*) DMSO has a large effect on the aggregate size; (*iii*) Type J aggregates are of equal dimensions with Type H aggregates. Moreover, even though as the DMSO–water solvent composition is varied the UV/vis spectra of Type H and Type J aggregates remained unchanged, the number of molecules comprising each aggregate varies widely. It is proposed that the dynamic conversion (J → H) results from intramolecular reorganization of individual molecules within the aggregate. Quantification of aggregation through DLS has further developed the "kinetic" versus "thermodynamic" control model of dye aggregation.

Key words: squaraine, dynamic light scattering, DMSO–water mixtures, self-assembly, kinetic/thermodynamic control.

Résumé : Dans le cadre de nos études sur le comportement d'agrégation des colorants de la squaraïne dans des mélanges DMSO–eau, on a étudié une série de squaraïnes symétriques à base anilino portant des chaînes *N*-alkyles de longueur variable (*n*-butyle, *n*-octyle et *n*-décyle). On a évalué le comportement d'agrégation par le biais de la spectroscopie UV/visible et d'études de diffusion dynamique de la lumière (DDL) avec interprétation quantitative basée sur la théorie de l'exciton. Cette classe de squaraïnes *N*-alkylées forme deux types distincts d'agrégats en solution, Type J et Type H, suivant la composition du milieu DMSO–eau. L'étude des morphologies des agrégats de Type J et de Type H par des mesures de DDL montrent que: (*i*) le diamètre des particules augmente avec une augmentation de l'hydrophobicité; (*ii*) le DMSO a un effet prononcé sur la taille des agrégats et (*iii*) les dimensions des agrégats de Type J sont égales à celles des agrégats de Type H. De plus, même si l'on fait varier la composition du solvant DMSO–eau, les spectres UV/visible des agrégats de Type H et de Type J demeurent inchangés; le nombre de molécules formant chaque agrégat varie considérablement. On suggère que la conversion dynamique (J → H) résulte d'une réorganisation intramoléculaire des molécules individuelles dans l'agrégat. La quantification de l'agrégation à l'aide de la DDL a permis de mieux développer le modèle de contrôle « cinétique » / « thermodynamique » de l'agrégation du colorant.

Mots clés : squaraïne, diffusion dynamique de la lumière, mélanges DMSO–eau, auto-assemblage, contrôle cinétique/thermodynamique.

a variety of these symmetrical and unsymmetrical dyes have been synthesized; those that absorb in the near-IR region of the spectrum have potential applications in xerography, organic solar cells and optical recording media (1).

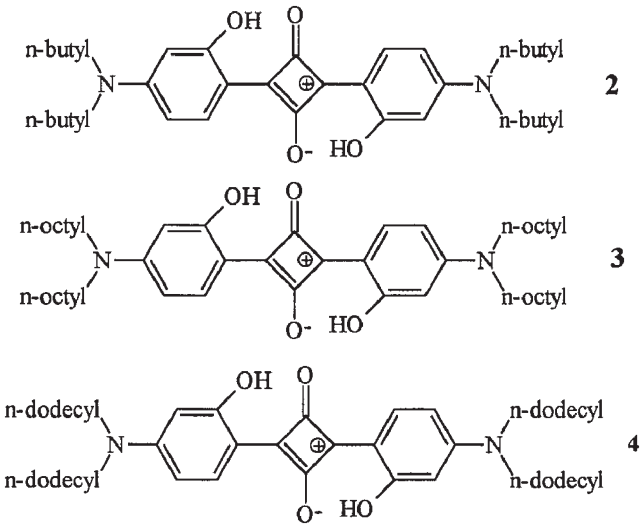
Symmetrical anilino-squaraines, **1**, are characterized by having an intense, long-wavelength absorption (620–680 nm, $\varepsilon \approx 300\,000\ M^{-1}\ cm^{-1}$) as a result of an intramolecular charge transfer occurring in both the ground and excited states (2). The squaraine chromophore provides the essential properties for photoconduction in the solution state. In the solid state, the assembly of squaraine molecules into aggregates causes a misalignment of the donor and acceptor moieties within the aggregate. As a result, the efficiency of the intermolecular charge transfer is severely hindered, and the photophysical properties are severely depleted.

Detailed understanding of the relationship of photophysical properties to structure has in the past focused primarily on the role of the molecular chromophore and not on the role of crystal packing. More recently, studies have shown that there exists a large dependence of color on crystal packing, i.e., crystallochromy (3). In particular, photoconductive dyes such as squaraines, phthalocyanines, perylenes, azobenzenes, and stilbenes which exhibit polymorphism have also been labeled as crystallochromic (4). Studies of these crystallochromic dyes have shown that through understanding of the interrelationship between crystal packing and the wavelength shift relative to solution, it is possible to correlate the change in electronic structure with the photoconductive behaviour of the pigments.

Previously, detection of squaraine aggregates was accomplished through single-crystal studies (5) and through the formation of Langmuir–Blodgett (LB) films (6). However, a novel method of observing aggregates of squaraine dyes in the solution state was developed in our laboratory using binary DMSO–water mixtures, which allowed detection of aggregates through UV/vis spectroscopy and facilitated examination of the relationship of molecular structure to aggregation behaviour (7). Depending on solvent composition, two different aggregate types with characteristic spectral features were observed for symmetrical anilinosquaraine dyes that varied in the *N*-alkyl substituents. In a subsequent study, Whitten and co-workers (8) investigated the aggregation behaviour of unsymmetrical surfactant squaraine dyes in DMSO–water mixtures and bilayer vesicles. The aggregates were found to be blue-shifted and circular dichroism measurements showed the aggregate to be chiral; the basic aggregate unit was proposed as a chiral "pin-wheel" structure.

In the present study of squaraines **2**–**4**, the aggregation behaviour as observed by UV/vis spectroscopy has been combined with Dynamic Light Scattering (DLS) in order to determine aggregate size and thereby examine the effect of hydrophobicity of the squaraine as well as the effect of solvent composition on the aggregate size. DLS studies of photoactive pigments enable the determination of the aggregate size and the relationships between particle size, solvent, temperature, and electrolyte concentration (9–11).

A higher order hydrophobic squaraine has been synthesized, **4**, and a study of the effect of hydrophobicity on aggregation behaviour is reported. Spectrophotometric study of **4** in DMSO–water solutions has shown that two specific aggregate types are formed, and a dynamic conversion between the two can be followed using UV/vis spectroscopy. DLS measurement of the dyes was performed in solutions of specific percentages of DMSO where Type J or the Type H aggregates were dominant and where the Type J $\rightarrow$ H aggregate interconversion could be monitored. The DLS measurements permitted quantification of all squaraine aggregates including estimation of the number of molecules/aggregate of each aggregate in various DMSO–water compositions.



Experimental

Synthesis and procedures

Squaraine dyes were prepared using the method of Sprenger and Ziegenbien (12) in which 2 equiv. of aromatic dialkylamine were condensed with 1 equiv. of squaric acid in a toluene–1-butanol solvent system. Preparation of the dialkylanilines was accomplished through the reaction of the appropriate dialkylamine with resorcinol. A representative procedure for the synthesis of these class of squaraines is described.

*3-(*N,N-*Dialkylamino)phenol*

A mixture of dialkylamine (0.03 mol) and resorcinol (0.06 mol) was sealed and heated in a teflon-lined acid digestion bomb with an internal temperature of 185°C. The reaction was followed through TLC (10:1 hexanes/EtOAc) and was complete after 3 days. The bomb was then opened, the mixture dissolved in CH_2Cl_2 and washed with (3 × 250 mL) water, followed by evaporation to a yellow oil. Flash chromatography of the oily liquid (20:1 hexanes/EtOAc) yielded a clear yellow oil which was stored under nitrogen at 0°C.

*3-(*N,N-*Dioctylamino)phenol*: Yield: 67%. ^{1}H NMR (400.1 MHz) in $CDCl_3$, δ: 6.92 (1H, d, J = 8.5), 6.18 (3H, m), 3.16 (4H, t, J = 7.5), 1.54 (4H, br,), 1.24 (20H, br), 0.85 (6H, t, J = 6.1).

*3-(*N,N-*Didodecylamino)phenol*: Yield: 67%. ^{1}H NMR (400.1 MHz) in $CDCl_3$, δ: 6.90 (1H, d, J = 8.5), 6.16 (3H, m), 3.10 (4H, t, J = 7.5), 1.45 (4H, br,), 1.24 (36H, br), 0.84 (6H, t, J = 6.1).

Bis(4-di-n-*alkyl-2-hydroxyphenyl)squaraine*

A 250 mL three-necked round bottom flask was fitted with a Dean–Stark apparatus, thermometer, stirbar, N_2 inlet, and dropping funnel. The flask was charged with 50 mL toluene, 20 mL *n*-butanol, and squaraic acid (1.44 g, 0.013 mol) and heated to 110°C. Once the squaric acid was dissolved, 3-(*N*,*N*-dialkylamino)phenol (0.03 mol) in 10 mL toluene was added dropwise over a period of 30 min, and the mixture was refluxed for 3 h. After cooling, the dark green precipitate that formed was filtered and washed with EtOAc. The crystals were recrystallized twice from EtOH, giving metallic-green crystals.

*Bis(4-di-octyl-2-hydroxyphenyl)squaraine (**3**)*: Yield: 57%, mp: 128.5–130.0°C. ^{1}H NMR (400.1 MHz, $CDCl_3$), δ: 7.76 (1H, d, *J* = 9.3), 6.50 (1H, d, *J* = 9.3), 6.12 (1H, s), 3.43 (4H, t, *J* = 7.1,-NCH_2-), 1.60 (4H, m, -CH_2-), 1.30 (10H, m, -$(CH_2)_5$-), 0.86 (6H, t, *J* = 7.1, -CH_3). Bis(4-di-n-*dodecyl-2-hydroxyphenyl)squaraine (**4**)*: Yield: 65%, mp: 96.5–98.0°C. ^{1}H NMR (400.1 MHz, $CDCl_3$), δ: 7.80 (1H, d, *J* = 9.3), 6.53 (1H, d, *J* = 9.3), 6.18 (1H, s), 3.45 (4H, t, *J* = 7.1,-NCH_2-), 1.60 (4H, m, -CH_2-), 1.30 (36H, m, -$(CH_2)_5$-), 0.86 (6H, t, *J* = 7.1, -CH_3). Anal. calcd. for $C_{64}H_{108}O_4N_2$: C 79.33, H 11.15, N 2.89; found: C 79.50, H 11.20, N 2.85.

Spectrophotometric method

Preparation of solutions used in the aggregation spectrophotometric and DLS studies followed the procedure described previously (7*b*). The appropriate DMSO–water mixture (2 mL) was injected directly into the UV/vis quartz cuvette fitted with a rubber septum under nitrogen. An aliquot (20 μL) of the dye stock solution (1.0×10^{-3} M) in the organic solvent (2,2,2-trifluoroethanol:*n*-butyl, acetone:*n*-octyl, *n*-dodecyl; max. final composition 0.5% v/v) was injected into the mixture, which was stirred for 30 s and then sonicated for 60 s. The solution was placed in a Hewlett–Packard 8452A Diode Array UV-vis spectrophotometer, and the absorption spectrum was recorded immediately (ca. 1 min after mixing) and at intervals of 12 min for a minimum of 1 h or until there was no visible change. Spectra were then recorded at intervals of 1 and 3 days. These experiments were performed in triplicate. Use of the above protocol ensured consistent results, although neither the stirring time nor the sonication time was found to have an effect on the aggregation behaviour.

Dynamic light scattering

Particle sizing experiments were performed using a NICOMP Dynamic Light Scattering instrument that used a He/Ne laser as the light source (λ = 628 nm). The statistical treatment used to measure the diameter of solid particles was Gaussian volume-weighted distributions. All measurements were performed in manual mode with the number of photons of scattered light averaging 300 000 per second (300 kHz). Measurements of the stable aggregate forms were carried out for 20 min, and the dynamic interconversion was monitored for 2 h. Prior to each measurement in the DMSO–water mixtures, the appropriate refractive index and viscosity of the solution at ambient temperature was determined to ensure that correct diffusion coefficient data was obtained.

An aliquot of each UV/vis sample (0.6 mL) was placed in a NICOMP particle size analyzer fitted with thermostatted cell compartment (*T* = 298 K). The particle size was determined in tandem with the solution state of aggregation through UV/vis spectroscopy. This ensured that the DLS measured particle size corresponded to the correct aggregate type as determined by UV/vis spectroscopy. The aggregate size was unaffected by concentration of the dye solution or the incident laser wavelength.

Two latex standards (91 and 248 nm diam.) were used to calibrate the analyzer. Solutions of the standards were diluted until a significant amount of scattered-light intensity was observed, nominally 300 kHz. The observed particle diameter for each standard, using Gaussian analysis volume-weighted distribution, was 90.5 ± 9 and 245 ± 25 nm. On this basis, values reported for aggregate diameters are believed to be accurate to ±10%.

For all acquired particle sizing data, the distribution of diameters was narrow. Based on the latex calibration standards used, a 10% deviation is inherently incorporated into the NICOMP DLS instrument for monodisperse samples. In addition, the observation of particle size distribution is facilitated by the Gaussian volume-weighted statistical treatment performed to acquire the actual diameter. The use of Gaussian treatments is valid for monodisperse and polydisperse samples, but the presence of a polydisperse sample increases the "chi-squared" value to >3. Polydispersity broadens the Gaussian curve over a wider range and significantly alters the ability of the treatment to adequately fit all the data. All of the samples that were analyzed by DLS had χ^2-values less than unity, indicating a true Gaussian fit to the data and a monodisperse sample.

Molecular modelling calculations

Molecular modelling calculations were performed to determine the physical dimensions of the monomeric squaraines using Spartan 3.0. Semi-empirical calculations were done using PM3 and all geometrical optimizations performed with MM2+ restrictions.

Results

1. Spectrophotometric study

As listed in Table 1, the squaraines in organic media exhibit long wavelength, intense absorptions (λ_{max} ca. 640 nm, ε ca. 3×10^5 M^{-1} cm^{-1}) with a limited positive solvatochromism (637 nm in Et_2O; 642 nm in DMF). When

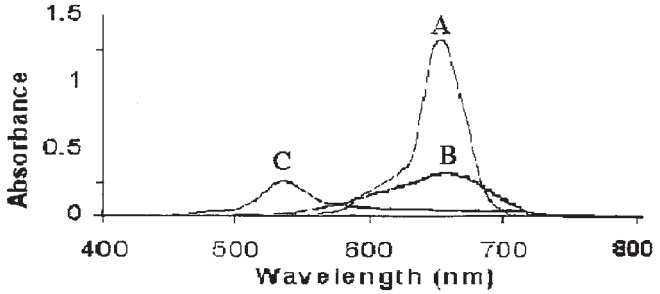
Table 2. Observed aggregate forms (UV/vis) of the three squaraine dyes as a function of percentage DMSO.

Squaraine	Type J aggregate	Type J → Type H % DMSO	Type H aggregate
2 R = *n*-butyl	0–20	30–50	50–70
3 R = *n*-octyl	0–70	80	N/A[a]
4 R = *n*-dodecyl	0–80	90	N/A[a]

[a]Solution was not stable in high percentages of DMSO due to degradation of squaraine chromophore (see text).

Fig. 1. Overlay spectra comparing the absorption properties of **4**: (*A*) monomer; (*B*) Type J aggregate; (*C*) Type H aggregate.

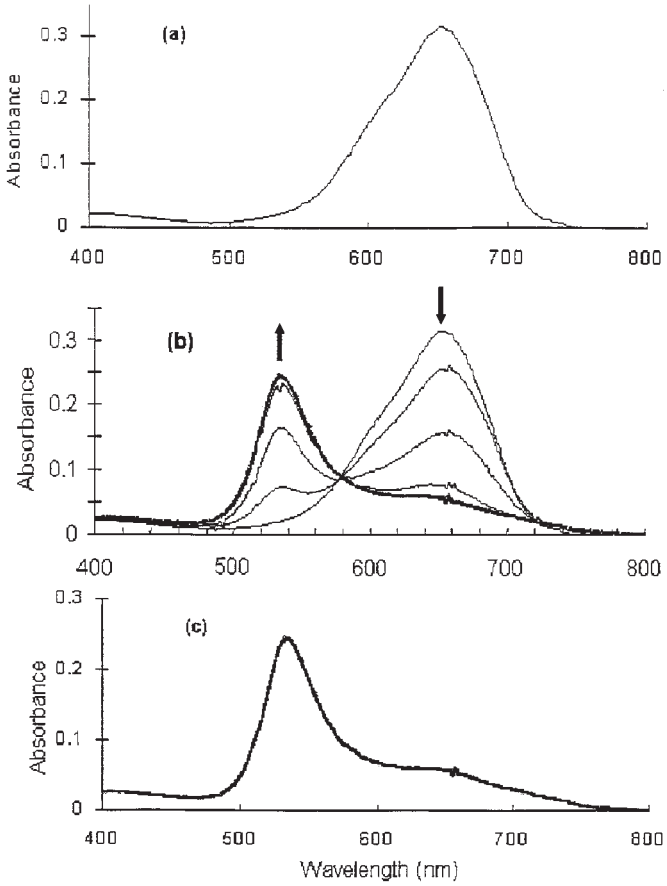


injected into solutions of varying DMSO–water content, two aggregate species are formed instantly; these have been classified as Type H and J, with characteristic spectroscopic properties that are markedly different from the monomer spectrum (Fig. 1).

The aggregation behaviour for the three squaraine dyes was investigated by injection of a 10^{-3} M stock solution (20 μL) to DMSO–water mixtures, giving final concentrations of 10^{-5}–10^{-6} M. The aggregation behaviour of squaraines **2** and **3** has been reported previously, and the solvent compositions in which each aggregate species is formed are listed in Table 2 (7*b*). In solutions ranging from 0–80% DMSO, the self-association of squaraine **4** resulted in a spectrum with a broad absorption (λ = 650 nm, ε = 80 000 M^{-1} cm^{-1}) relative to the monomer, identifying the aggregate as Type J (Fig. 2*a*), which was stable over a 3 day monitoring period. In contrast, addition of the monomer **4** stock solution to 90% DMSO produced a spectrum that corresponded initially to a Type J aggregate. Over the 3 h time period, there was a decrease in the absorption at 650 nm and an increase in the absorption at 530 nm corresponding to a dynamic conversion to the Type H aggregate, with an isobestic point at 560 nm (Fig. 2*b*). After the dynamic conversion was complete, a stable Type H aggregate (Fig 2*c*) was observed to be hypsochromically shifted relative to Type J by 120 nm (λ = 530 nm, ε = 80 000 M^{-1} cm^{-1}).

Injection of the monomeric forms of squaraine **4** into 100% DMSO, resulted initially in a broad absorption and a bathochromic-shift relative to the monomer, characteristic of the Type J aggregate. However, instead of dynamically converting to the Type H aggregate, the absorption corresponding to the Type J aggregate decreased over time until no optical absorption remained. This behaviour was related to the slow precipitation of the dye and hydroxide attack on the squaric ring that becomes more reactive on increasing the DMSO content.

Fig. 2. (*a*) Spectra of **4**, Type J aggregate, in 0–80% DMSO–water mixtures. (*b*) Overlay spectra of **4** acquired every 12 min in 90% DMSO–water, depicting the dynamic conversion of Type J aggregate to Type H aggregate. (*c*) Spectra of **4** as Type H aggregate following completion of dynamic conversion from Type J form in 90% DMSO–water.



2. Particle sizing data

In DLS, the frequency spectrum of scattered light from particular species in solution is determined. The relaxation time for fluctuation in the scattered light depends solely on the diffusion behaviour of the aggregates. For aggregates, the translational diffusion constant, D, is given by the Stokes–Einstein relation

$$[1] \qquad D = kT/6\pi\eta r$$

where k is Boltzmann's constant, T is the absolute temperature, η is the viscosity of the solution, and r is the hydrodynamic radius of the aggregate. The relaxation time, τ, is then given by

$$[2] \qquad \tau = (2Dq^2)^{-1}$$

where $q = 2k_m \sin(\theta/2)$ and θ is the scattering angle, and measurement of τ therefore determines the hydrodynamic radius of the aggregates, which is the largest dimension of the aggregate present in this solution that is developing a sphere through rotational and translational motion.

Solutions of aggregates for squaraines **2**, **3**, and **4** in 10, 50, 70, and 90% DMSO–water were analyzed by Dynamic Light Scattering. Since the UV/vis measurements carried out simultaneously characterized the aggregates in solution as Type J or Type H, the particle size of each aggregate type in the different solvent media could be determined from the DLS measurements. The results are presented in Table 3.

DLS analysis of **2** in 10% DMSO where the aggregate is known to be Type J, gave a particle size of 67.4 and 81.8 nm. Measurements in higher DMSO content solutions were not attempted as the Type H aggregate was not stable for the time period required for accurate measurements to be taken.

For **3** in 10 and 50% DMSO where UV/vis results show the Type J aggregate to be present, the measured size in 10% DMSO was ~100 nm, while in 50% DMSO the size was 153 nm. For **3** in 70% DMSO, where the Type J aggregate is initially present, the DLS measurement gave a diameter of 151 nm. After the dynamic conversion had occurred to the Type H aggregate, the diameter for the Type H aggregate was found to be 146 nm.

Squaraine **4** was analyzed by DLS in 10, 50, 70, and 90% DMSO, since the Type J aggregates of **4** have been found to be the most stable over the widest range of solvent compositions used in this study. In 10% DMSO, the diameter of the aggregate was determined to be 128 nm, corresponding to the Type J aggregate. In 50 and 70% DMSO, the Type J aggregate was still the only form present and was found to have a diameter of 111 and 145 nm, respectively. The last set of measurements taken was in 90% DMSO where the Type J aggregate converts dynamically to Type H from the UV/vis studies. As with squaraine **3,** the DLS at the onset of the dynamic conversion identified the aggregate as Type J. After the conversion was complete and there was no further increase in Type H aggregate absorption, the particle size was again determined. In this way, the dimensions for the Type J and Type H aggregates obtained in 90% DMSO were found to be 100 and 106 nm, respectively.

The aggregate number was then calculated from DLS measured diameter. Based on single crystal studies and X-ray diffraction patterns of squaraine aggregates, the intermolecular spacing between aggregates was calculated to be 0.35 nm (5, 6, 13, 14). Hence, the aggregate number is simply given by the measured diameter of the particle divided by the interplanar distance, 0.35 nm. Results are given in Tables 4–7.

Discussion

1. Dye aggregation

In this work, we have investigated the aggregation of squaraine dyes through the dual approaches of UV/vis spectroscopy and Dynamic Light Scattering (DLS). These two approaches provide information, respectively, on the type of aggregate that is formed and on the degree of aggregation (particle size). Our study pertains to aggregation in solution (DMSO–water mixtures) as contrasted from the traditional studies of aggregation on the surface of a liquid as in Langmuir–Blodgett (LB) films or in a crystalline matrix (6, 15).

Several studies have examined the molecular orientations of squaraine aggregates with two predominant morphologies occurring (6, 15). Through studies of crystalline solids, it was found that formation of specific aggregates with "red-shifted" spectra — characteristic of a J aggregate — were stabilized by intermolecular charge-transfer interactions between adjacent molecules that were 3.5 Å apart (13). These interactions were the result of a specific alignment of the electron-deficient squarylium moieties with the electron-rich dialkylamino phenyl groups (Fig. 3*a*). Conversely, the aggregates exhibiting hypsochromic shifts — characteristic of an H aggregate — resulted from the alignment of the transition dipole moments, enforcing a "face–face" stacking of the molecules that are 3.5 Å apart (14). This particular geometry of the aggregate (Fig. 3*b*) leads to very poor photoconduction due to inefficient intermolecular charge transfer, which is observed in both UV/vis studies and LB films.

In our previous studies, the squaraine aggregates that were formed in solution were classified as "Class A" and "Class B." However, these aggregates exhibit similar spectral characteristics that can be more appropriately described through the adaptation of Exciton theory (16). Even though classical exciton treatments relay qualitative explanations of the spectral trends observed in dimers with equal interchromophore distances, the solution aggregates formed in this study can also be described as Type H and J because of the following common features: (*i*) bathochromic shift of λ_{max} relative to the monomer due to the effects of intermolecular charge-transfer stabilization and proper donor–acceptor alignment in the Type J (B) aggregate; (*ii*) hypsochromic shift of λ_{max} relative to the monomer due to the face–face alignment of transition dipole moments in the Type H (A) aggregate; (*iii*) large decrease in molar absorptivity coefficient for both aggregate forms (300 000 M^{-1} cm^{-1} → 80 000 M^{-1} cm^{-1}); and (*iv*) similar intermolecular spacing within the aggregates.

Limitations of exciton theory are that it only explains the observation of single bands equally spaced from the monomer absorption that arise from the formation of dimers, whereas the Type H and Type J aggregates being described in the present study are of a much higher order with a large increase in number of transitions that are dependent on the relative spatial orientation of the molecules (6, 7). Thus, exciton theory is too simplistic to provide a thorough theoretical understanding of the aggregation described herein but is in accord with spectral evidence that the molecules that comprise the aggregate in our systems have similar intermolecular spacing and defined intermolecular interactions.

2. Effects of increasing hydrophobicity on squaraine aggregation

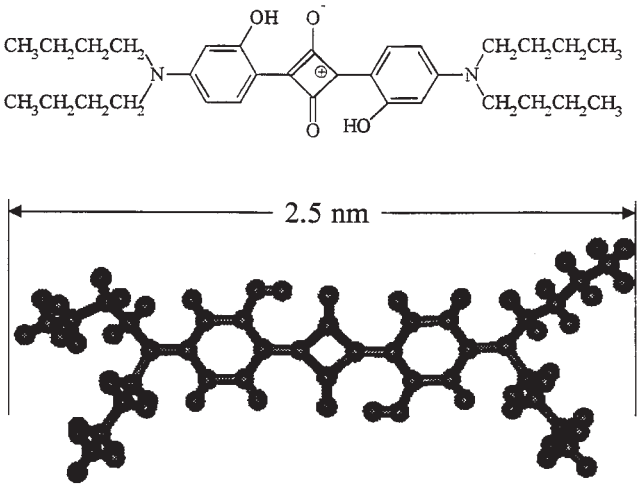
Comparison of the aggregation behaviour of the three squaraines in this study shows that the main determining factor is the length of the *N*-alkyl substituent. Since the hydroxyphenyl functionality and squaraine ring remain constant throughout the series, the difference in aggregation characteristics can be attributed to the increase in hydrophobic interactions resulting from the increasing chain length of the alkyl substituent.

The results of the spectrophotometric studies for the *n*-butyl, *n*-octyl, and *n*-dodecyl substituents are shown in Table 2 and reveal the role of hydrophobic interactions on aggregation of the squaraine dyes. It is seen that the expected increase of hydrophobic interactions that would attend increasing the alkyl substituent chain length significantly alters the aggregation states present in different DMSO compositions. Thus, upon lengthening the alkyl chain, the Type J aggregates that are formed in water-rich media become the dominant form in solutions with increasing percentages of DMSO and conversion from Type J to Type H does not occur until much higher DMSO compositions. For all the squaraines studied, it was found that the Type J aggregate was formed initially. The two main driving forces for formation of the Type J aggregate are (*i*) intermolecular charge-transfer interactions between the donor and acceptor moieties and (*ii*) the hydrophobic interactions associated with the *N*-alkyl chains. These two types of interactions stabilize the Type J aggregate and prevent the dynamic conversion to the Type H form.

In assessing the relative contribution of each interaction for squaraines **2**, **3**, and **4**, it is considered that the intermolecular charge-transfer interaction remains constant while the hydrophobic interactions become increased along this series. Since the dynamic conversion to Type H is observed when the concentration of DMSO is increased, this must destabilize the aggregate to reorganize to a more energetically favourable form; i.e., in solutions of high DMSO con-

© 1999 NRC Canada

Fig. 4. Illustration of the individual monomer length measurement for **2** using molecular mechanics (Spartan 3.0).



tent, the most favorable aggregate is the Type H. However, with the increase in the hydrophobic interactions on going from *n*-butyl to *n*-dodecyl, it becomes much more difficult for the solvent to destabilize the Type J aggregate for it to convert to the Type H form. This is the main reason that the Type J aggregates formed from squaraines **3** and **4** persist in solutions with a wider range of DMSO percentages compared to the *n*-butyl case. The UV/vis results show that the decrease in hydrophobic interactions in the squaraine monomer facilitates the formation of Type H aggregates.

3. Particle sizing

The use of UV/vis spectroscopy to study aggregation phenomena in a quantitative fashion is not definitive, as it is difficult to differentiate new bands that correspond to dimers or higher order aggregates (17). Hence, dynamic light scattering measurements were performed in parallel with the spectrophotometric study to: (*i*) quantify the aggregate size; (*ii*) calculate the number of molecules associated with each aggregate; (*iii*) determine the influence of solvent on aggregation; and (*iv*) provide further evidence for the kinetic versus thermodynamic product control associated with each aggregate type.

In Table 3 is presented a summary of the DLS measurements. However, in the ensuing discussion, for clarity, the data is broken down so as to highlight the different factors that control aggregation, such as *N*-alkyl chain length, the DMSO–water solvent composition, and the dynamic conversion from Type J to Type H. Combined with these measurements is the actual aggregate number, calculated by dividing the hydrodynamic diameter by the intermolecular spacing within the aggregate.

(a) Effect of increasing hydrophobic interactions

The first trend observed in the DLS data is the effect of increasing hydrophobic interactions on the measured diameter for the Type J aggregate. Table 4 lists the particle size measurements for each of the squaraines in 10% DMSO solution. In this solution, all of the squaraines have aggregated to form the Type J species, as indicated by the UV/vis study. The trend apparent in comparing the DLS data of each Type J aggregate is the increase in particle size while traversing the *n*-butyl to *n*-dodecyl series. It is interesting that whereas the individual monomer lengths vary only modestly, *n*-butyl = 2.5 nm, *n*-dodecyl = 4.8 nm (Fig. 4), yet the hydrodynamic diameter of these species is widely different. The *n*-butyl aggregate in 10% DMSO solution has an aggregate number of ~210 molecules; evidently, in this aggregate comprising ~200 molecules, efficient charge-transfer interactions are occurring and give rise to the observed spectral characteristics.

It is further shown in Table 4 that the aggregate numbers for the *n*-octyl and *n*-dodecyl Type J aggregate, 290 and 365, respectively, increase in the 10% DMSO solution relative to the *n*-butyl Type J aggregate. The *n*-octyl has an aggregate number of ~290 molecules, i.e., almost 100 more molecules than for the *n*-butyl case. Similarly, the *n*-dodecyl Type J aggregate has an aggregate number of ~365 molecules, much larger than the values calculated for both the *n*-butyl and the *n*-octyl systems. Clearly, there is a relationship between the degree of aggregation and hydrophobicity; i.e., the hydrophobic effect increases the degree of self-association along the series *n*-butyl, *n*-octyl to *n*-dodecyl.

The formation of aggregates in DMSO–water media by the squaraine monomers is driven by the hydrophobic effect (18). Squaraine dyes are aggregated in water-rich media but self-association is expected to be entropically unfavorable, since a considerable degree of translational, vibrational, and rotational freedom is lost. However, the loss in energy resulting from association of the dye molecules is offset by the release of solvent molecules surrounding the dye molecule. A specific type of aggregate is formed that is dependent on the degree of hydrophobic interactions that influence monomer aggregation. As the level of hydrophobic interactions increases in the system so does the degree of association.

(b) Effect of solvent composition on aggregate size

Typically, the absorption spectra of dyes are a function of dye concentration resulting from the formation of dimers and higher order aggregates. However, in the present systems the spectral characteristics are determined by the DMSO–water solvent composition, since the dye concentration remains constant. Table 5 shows the DLS results obtained for the *n*-dodecyl squaraine Type J aggregate as observed through UV/vis spectroscopy in 10, 50, 70, and 90% DMSO–water mixtures. The effect of solvent composition on aggregate particle size is best exemplified with *n*-dodecyl, since this exists in the Type J aggregate form throughout the largest range of solvent media and where the UV/vis results indicate dynamic conversion from Type J to Type H occurring only at 90% DMSO.

It is noted that the effect of solvent on the Type J aggregate size can not be deduced from the UV/vis data, but rather from the corresponding DLS measurements, since the spectral properties of the Type J aggregate remain constant throughout the solvent range in which it is observed. However, the DLS results exhibit a marked effect on the aggregate size depending on the region of DMSO composition even though the UV/vis spectra are identical. Thus, the results in Table 5 show that the particle size of the *n*-dodecyl aggregate decreases steadily as the percentage of DMSO is

© 1999 NRC Canada

increased from 10 to 70%, and then remains constant at 90%.

Studies of DMSO–water mixtures have demonstrated that their properties deviate considerably from those that would be expected on the basis of additive relative contributions from both pure solvents (19). There are two distinct regions of behaviour for these binary solvent systems, a water-rich zone and a DMSO-rich zone. The break point between these regions occurs at approximately 60% (v/v) (33 mol%) DMSO. Up to 60% DMSO, the DMSO and water act as a structure-maker resulting in the strengthening of the hydrogen bond network. This unusual extension of the hydrogen-bonding network orders the solution and decreases the aggregate number as the DMSO percentage increases. As the DMSO content is increased, water molecules are forming hydrogen bonds with DMSO that are stronger than the hydrogen-bonding between water molecules themselves. The increase in structure of the solvent places limitations on the number of molecules that form the Type J species. The ordering of the solvent restricts the formation of higher order aggregates due to a decrease in the release of solvent molecules to offset the energetically unfavourable association of these dyes.

The maximum structure in this binary mixture occurs at 60% DMSO (v/v) (33 mol%) and corresponds roughly to two molecules of water binding with one molecule of DMSO (20). Beyond 60% DMSO, deviations from ideal behaviour are not observed. This is believed to be the result of a relatively consistent solvent structure as the majority of water molecules are involved in strong hydrogen bonding interactions with DMSO. The results from the DLS study indicate that there is no further change in the particle size beyond the 60% v/v breakpoint. Thus, once DMSO becomes the predominant solvent component, the ordered nature of the solvent molecules is not as profound and results in aggregates of the same number of molecules being formed.

(c) DLS measurement of Type J to Type H conversion

The dynamic conversion of squaraines **3** and **4** from the Type J aggregate to the Type H aggregate forms was examined, and each form was quantified through DLS. In DMSO–water media where the UV/vis studies showed that dynamic conversion was occurring from Type J to Type H aggregate, the DLS method was unable to follow the rate process. In the procedure adopted to circumvent the problem, DLS measurements were made immediately after injection of the dye solution into the given solvent mixture, and then again once the dynamic conversion was complete. Prior to each DLS measurement, the UV/vis spectrum was recorded to ascertain the particular Type J and Type H aggregates formed. In this way, the particle size could be obtained initially for the Type J aggregate and finally for the Type H aggregate.

Tables 6 and 7 show the DLS results for the dynamic conversion from Type J to Type H aggregate forms. Table 6 presents the dynamic conversion of the *n*-octyl squaraine in 70% DMSO solution. The DLS calculated aggregate number for both the *n*-octyl Type J and Type H system was found to be ~430, i.e., interconversion between the two forms resulted in the same aggregate number being calculated. Measurement of each aggregate type by DLS showed no change in the aggregate size or in the aggregate number. This was further apparent on measurement of the *n*-dodecyl dynamic J $\rightarrow$ H conversion where the DLS calculated aggregate number was found to be ~300 for each form. It follows from these results that the number of molecules in the Type J and the Type H aggregate is the same in these systems.

The UV/vis spectra accompanying the dynamic conversion show that there is an hypsochromic shift of the absorption maximum. Previously, it was thought that the hypsochromic shift arises from higher orders of aggregates being formed, but it appears from the above results that the spectroscopic behaviour is due to a realignment of the charge-transfer moieties within the associated form. Thus, the interactions between the aggregate and the DMSO cosolvent provides the driving force to form a more stable aggregate form.

One can explain the effect of DMSO on the interconversion of Type J aggregate to Type H on the basis of the properties inherent to DMSO–water media and interactions with the nonpolar solute. Essentially, the Type J aggregate is being destabilized to the Type H aggregate as the percentage of DMSO in solution increases.[2] The actual percentage of DMSO where this occurs is directly related to the hydrophobic interactions associated with the aggregation. The destabilization by DMSO must overcome the stability produced by hydrophobic interactions to ensure that the conversion does occur. This is the primary reason that squaraine **4** forms Type J aggregates that predominate over the largest range of solvent. Once the destabilization effect of the DMSO overcomes the hydrophobic interactions, the alignment of the dipole–dipole interactions of the solvent with the C-O squaraine ring becomes the driving force to form the Type H aggregate. The dipole moment of DMSO is much larger than that of water (3.9 D vs. 1.8 D). In single crystal studies of DMSO, it has been shown that the structure of DMSO molecules is the face–face alignment of the dipoles (21). The DMSO molecules exert the same effect on the squaraine aggregates by forcing the alignment of the squaraine molecules such that the major dipole moments located along the C–O axis of the squaric acid moiety are coincidental, as in Type H aggregate (Fig. 3*b*).

3. Kinetic vs. thermodynamic control of aggregation

In our previous paper concerned with structure–property relationships of squaraine dyes, a model of aggregation behaviour was proposed in which the basis for formation of Type J and Type H aggregates was the thermodynamic relationship between these two forms: the Type J aggregate is a product of "kinetic" control, while the Type H aggregate is a product of "thermodynamic" control.

The results are consistent with Type J aggregates being a product of kinetic control because this aggregate type is initially formed upon injection of squaraine solution in an organic solvent into DMSO–water media As the percentage of

[2] It has been suggested by a referee that increased DMSO concentration may alternatively shift the equilibrium by stabilizing the H-aggregate. Differentiation between these alternatives will await studies now in progress with other binary solvent systems. We thank the referee for the suggestion.

© 1999 NRC Canada

DMSO in the system increases, the Type H aggregate becomes the product of thermodynamic control, as it is only formed following the dynamic interconversion. Even though the Type J species has not been observed for the *n*-butyl squaraine in media >50% DMSO, the conversion to Type H from Type J may be so rapid in this system that the experimental protocol can not detect the short-lived kinetic species. Also, the conversion of Type J to Type H aggregate can be induced on the addition of DMSO to a 10% DMSO solution of *n*-butyl squaraine. However, the opposite is not observed, i.e., dilution of the Type H aggregate in 50% DMSO with water does not result in the conversion to Type J aggregate. Thus, the irreversibility of this process is a direct result of the more thermodynamically favored aggregate–solution interaction.

Type J aggregates are formed in water-rich media immediately upon injection into the solvent. The UV/vis studies show that the stability of these aggregate types is increased as the alkyl chain length is increased. The DLS measurements readily support this as the aggregation number is found to increase in the order *n*-butyl < *n*-octyl < *n*-dodecyl. Being a product of kinetic control, the effect of the hydrophobic interactions is to increase the size of the aggregate formed as well as hindering the dynamic conversion to the Type H form. However, the Type H aggregate is ultimately formed in higher percentages of DMSO as the thermodynamic product, as the result of more favorable interaction with solvent molecules.

Importantly, the DLS measurements have shown that the Type H aggregates are formed with the same number of molecules in the aggregate as for the Type J. It has been found (Table 2) that for both the *n*-octyl and *n*-dodecyl substrates, the dynamic conversion results from the solvent molecules overcoming the hydrophobic interactions within the aggregate, since DMSO compositions of 80 and 90%, respectively, are required to bring about the change. In solutions of high DMSO content, the most energetically favorable form is the Type H, but this is only formed over time. Hence, the Type H aggregate is not formed from the combination of a number of Type J aggregates; rather, the molecules in the aggregate undergo an intramolecular reorganization of the individual molecules. The driving force for the formation of Type H is attributed to the dipole–dipole interactions between solvent and aggregate; alignment of the molecules in Type H formation minimizes the energy within the system.

Conclusions

Our DLS analysis of squaraine aggregates has given further insight into the mechanism of aggregation, the effect of hydrophobic interactions on the size of aggregate as observed spectroscopically, and the effect of solvent stabilization/destabilization on aggregates. From the UV/vis studies, it was concluded that the *n*-dodecyl squaraine aggregate had the most persistent formation of Type J aggregate in the widest range of DMSO–water mixtures due to the increase in hydrophobic interactions associated with the aggregate. Our results indicate that the nature of the squaraine aggregate is markedly affected by the tailored substituents and also by the effect of solvent. Hydrophobic interactions and the interactions of the aggregate with the solvent molecules further dictate the size of the aggregate that is formed in various DMSO–water media. In addition, the transition between aggregate forms, Type J and Type H, is a direct result of intramolecular reorganization, as there is no change in aggregate size during this process.

These studies provide an informative view on the structure and photophysical properties that may be applicable to incorporation of these dyes into technology. The knowledge gained from this study, plus the fact that squaraine application to technology is hindered by the formation of Type H aggregates, reiterates the importance of optimizing the molecular architecture to form solely the Type J aggregate in the solid state; the Type J has the most beneficial photophysical properties. The DLS has shown that the more efficient charge transfer is not a result of the aggregate size being smaller, but that the intermolecular charge transfer which is essential for photoconduction will occur in extended forms of the aggregate. Based on the UV/vis data and the DLS results, it is envisaged that an efficient model will be developed to aid in the understanding of the aggregation of photoconductors; optimization of the Type J aggregate through molecular engineering may result in a superior photoconductor applicable to technology. This in turn will lead to a better design and molecular engineering strategy to optimize the physical properties of photoconductors in the solid-state, using solution-state experiments.

Vicinal–diaryl interactions in stilbenoid hydrocarbons as observed in the through-space charge delocalization of their cation radicals

Rajendra Rathore and Jay K. Kochi

Abstract: The conformational preference of vicinal or 1,2-phenyl groups is probed in two classes of ring-substituted 1,2-diphenylbicyclooctene (stilbenoid) hydrocarbons **1a**–**1d** and **2a**–**2c.** UV–vis spectroscopy reveals, and X-ray crystallography verifies, the intramolecular (edge-to-face) orientation for the phenyl–phenyl interaction in stilbenoids **1a**–**1d.** Most importantly, when two pairs of *ortho*-methyl substituents are present, the cofacial phenyl groups in the stilbenoid donors are established by X-ray crystallography and spectrally observed in the cation radicals (**2a**$^{+\bullet}$–**2c**$^{+\bullet}$) by the appearance of new bands with strong absorptions in the near IR with λ_{max} = 1100–1315 nm, analogous to those previously observed in intermolecular (aromatic) interactions of aromatic cation radicals.

Key words: stilbenoid hydrocarbon, cation radical, aryl–aryl interaction.

Résumé : On a étudié la préférence conformationnelle de groupes phényles vicinaux (ou en positions 1,2) de deux classes d'hydrocarbures, des 1,2-diphénylbicycloocènes (stilbénoïdes) substitués sur le cycle, **1a–1d** et **2a–2c**. La spectroscopie UV-visible révèle, et la diffraction des rayons X permet de confirmer, l'orientation intramoléculaire (arête vers la face) de l'interaction phényle-phényle dans les stilbénoïdes, **1a-1d**. La diffraction des rayons X a permis d'établir un fait encore plus important, à savoir que, lorsque deux paires de substituants *ortho*-méthyles sont présents, les groupes phényles des stilbénoïdes donneurs sont coaxiaux et on peut les observer spectralement dans les cations radicaux (**2a**$^{+\bullet}$–**2c**$^{+\bullet}$) par l'apparition de nouvelles bandes de forte intensité dans le proche infrarouge, avec un λ_{max} de 1100–1315 nm, analogues à celles observées antérieurement dans les interactions intermoléculaires (aromatiques) des cations radicaux aromatiques.

Mots clés : hydrocarbure stilbénoïde, cation radical, interaction aryle–aryle.

[Traduit par la Rédaction]

Introduction

The through-space interaction between a pair of vicinal aromatic π-systems is known to decrease the ionization potential in a variety of aromatic hydrocarbons such as 1,1,2,2-tetraphenylethane, 1,2-diarylethanes, triptycenes, cyclophanes, benzpinacols, etc. (1–3). In the latter, Penn et al. (4) noted that such cofacial aryl–aryl interactions can explain the increased electron-transfer reactivity in carbon–carbon bond cleavage. Recently, Gano et al. (5) pointed out that similar 1,2-diaryl interactions are also responsible for the observed decrease in the ionization potentials in (*Z)*-stilbenes as compared to the corresponding (*E)* isomers. Since these findings suggest that the cation-radical intermediates resulting from 1-electron oxidation of such systems may be unusually stable species, a detailed (UV–vis) spectroscopic analysis of these cationic intermediates must be carried out to further explore the structural requirements of aryl–aryl interactions. As such, the observation of new electronic transitions in multichromophoric assemblies would provide valuable information regarding the spatial (electronic) interactions amongst the various chromophores. For example, *intermolecular* interactions of aromatic hydrocarbons (ArH) have been previously observed by the presence of new broad absorption bands in the near-IR region in the electronic absorption spectra of a variety of dimeric aromatic cation radicals (6, 7), and the broad NIR absorption bands have been assigned to charge-resonance transitions within the dimeric cation radicals $(ArH)_2^{+\bullet}$ arising from the favorable π, π-orbital overlap between the two coplanar arene moieties arranged in a sandwich-like structure (also compare ref. 8).

In this study, we report the preparation of cation-radical salts of various stilbenoid donors with cofacially juxtaposed aryl groups, and show how analysis of the electronic absorption spectra provides spectroscopic evidence for direct 1,2-diaryl interactions. The two series of stilbenoid donors in Chart 1 are readily synthesized by an efficient palladium-catalyzed synthetic method (9). The spatial arrangements of the neighboring aryl groups in these stilbenoid donors are evaluated by monitoring the UV–vis spectra (and chemical reactivity) and further confirmed by X-ray crystallography. Moreover, the spectral comparison of the cation radical de-

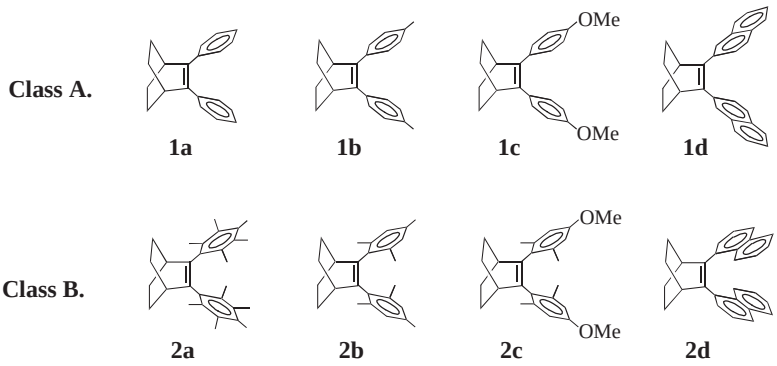
Chart 1. Stilbenoid donors.



rived from other cofacial π-systems oriented at different dihedral angles (such as *m*-cyclophane and a cofacially oriented phenylene donor) sheds additional light on the angular requirements for such cofacial aryl–aryl interactions.

Results and discussion

1. Synthesis of stilbenoid donors

The various stilbenoid donors in Chart 1 were readily prepared by the palladium-catalyzed coupling of aryl Grignard reagents with a dibromoalkene, e.g.

[1] 
In a typical example, a freshly prepared solution of phenylmagnesium bromide (2.1 equiv.) was mixed with a solution of 2,3-dibromobicyclo[2.2.2]oct-2-ene in anhydrous tetrahydrofuran containing a catalytic amount of bis(triphenylphosphine)palladium(II) chloride (10) under an argon atmosphere at 25°C. The resulting pale-yellow solution was refluxed for 8 h, and a standard aqueous work-up, followed by recrystallization, afforded 2,3-diphenylbicyclo[2.2.2]oct-2-ene (**1a**) in essentially quantitative yield. The generality of the procedure was demonstrated by coupling various arylmagnesium bromides (with increasing substitution) with dibromobicyclooctene to afford the diarylbicyclooctenes listed in Table 1 in excellent yields.

Table 1. Synthesis of various stilbenoid donors by the Pd-catalyzed coupling of arylmagnesium bromides with 1,2-dibromobicyclooctene in tetrahydrofuran.[a]

Stilbenoid hydrocarbon	Time[b] (h)	% Yield[c]

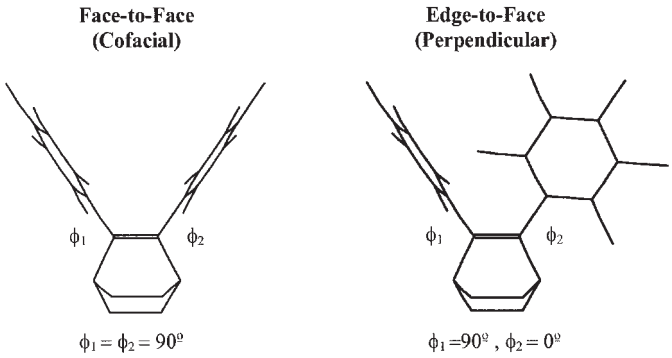
2. Conformational analysis of stilbenoid donors

Owing to the rigid backbone structure, the various stilbenoid donors can attain one of the two stable (idealized) conformations, i.e., face-to-face (cofacial) (11) or edge-to-face (perpendicular) (12), as diagrammatically presented in Chart 2. Optimum π–π interactions between aryl groups in various stilbenoid donors are expected to arise from the cofacial arrangement of the aryl groups, and we will determine how such a preferred conformation can be achieved by varying the substituents on the aryl groups as follows.

Chart 2. Aromatic–aromatic orientations.



X-ray crystallography

Single crystal structure analysis was performed on **1a** in class A and **2a**/**2b** in class B in order to ascertain the molecular structures and conformations of the stilbenoid donors. For the sake of simplicity, we identify the structural parameters used for the comparison of all three structures as *d*, the olefinic C=C bond length; *l*, the C–C bond length to the aryl group; θ, the twist of the olefinic C=C bond; and ϕ_1/ϕ_2, the coplanarity of aryl groups with the C=C bond (as designated in the generic structure in Table 2). (Note that equal values of $\phi_1$and ϕ_2 indicate that the aryl groups are cofacial.)

Comparison of the various parameters *d*, *l*, θ, ϕ_1, and ϕ_2 for **1a**, **2a**, and **2b** in Table 2 shows that the stilbenoid donors (**2a** and **2b**), that contain *ortho*-methyl groups have essentially the same molecular structure that is characterized by the presence of *cofacial* aryl groups. It is clear that steric hindrance of the *ortho*-methyl groups forces both aryl groups to lie parallel to each other and (almost) orthogonal to the ethylenic bond with $\phi_1 = \phi_2 = 65°$, and the rotations of the aryl groups (around the C_1–C_3 and the C_2–C_5 bonds) are strongly coupled (i.e., mutually dependent), as indicated by the identical values of ϕ_1 and ϕ_2 in **2a** and **2b**. By contrast, the absence of *ortho*-methyl groups in the parent analog **1a**

[d]Torsional angle C_1-C_2-C_5-C_6.

allows a greater degree of rotational freedom around the C_1–C_3 or the C_2–C_5 bond, as indicated by the different torsion angles ϕ_1 (46°) and ϕ_2 (60°).[2] Furthermore, an arbitrary superposition of the molecular structures of **1a** and **2b** (such as that illustrated in Fig. 1[3]) shows that at least one of the phenyl groups in **1a** can readily acquire a coplanar conformation with the olefinic bond.

Electronic (UV–vis) spectra

Structural analysis (vide supra) reveals that the presence of four *ortho*-methyl groups in various stilbenoid donors in class B forces both aryl groups to lie orthogonal to the olefinic bond, and thus effectively prevents π-conjugation with the olefinic bond. As such, the UV–vis spectral data show that all donors in class B absorb at $\lambda_{max} < 260$ nm, whereas the class A derivatives show well-defined absorption bands that are relatively red-shifted to $\lambda_{max} \geq 260$–310 nm (see Experimental). Importantly, the UV–vis absorption spectra of various derivatives in class A are strongly reminiscent of those of the parent stilbenes (14). In contrast, the cofacial stilbenoid donors in class B show absorption spectra that closely resemble those of the *isolated* (non-conjugated) aryl groups.

Reactivity and steric crowding

The olefinic carbons in class B donors are completely entombed due to the presence of four *ortho*-methyl groups (as well as the bicyclooctene framework), as shown by the space-filling representation of **2a** in Fig. 2. Such steric crowding around the olefinic bonds makes these donors completely inert to hydrogenation and epoxidation reactions. (Note that the

Fig. 1. The superimposition of the molecular structures of diphenyl- (**1a**, light lines) and dimesityl- (**2b**, dark lines) bicyclooctenes to show the coplanarity of a single phenyl group with the olefinic bond in **1a**.

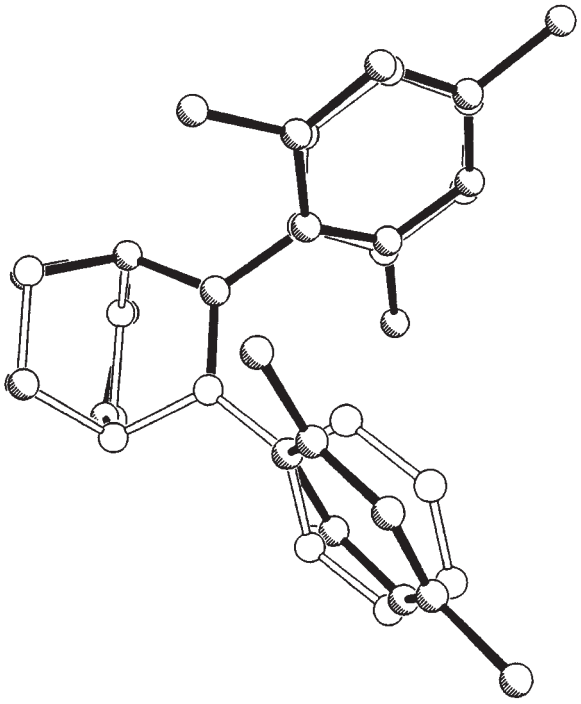

Fig. 2. Space-filling representation of **2a** to show the complete entombment of the olefinic carbons (darkened spheres) by four *ortho*-methyl groups and the bicyclooctene framework.

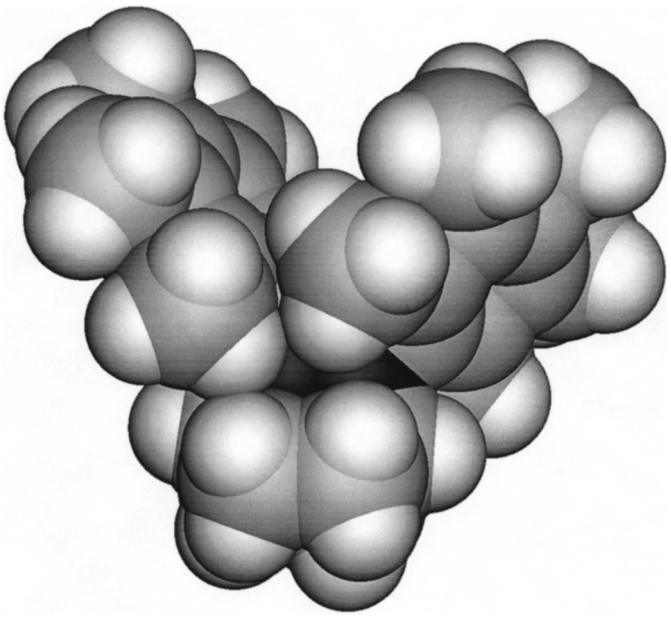

[2] Such a restricted rotation around the C–Ar single bond can lead to atropisomers as observed in a variety of biphenyls (ref. 13). For example, spectral (NMR) analysis of naphthyl derivative **1d** showed the presence of two isomers (see Experimental) that could not be separated or interconverted by heating up to 180°C. A (molecular mechanics) minimization of the molecular structure of **2d** with the aid of the QUANTA graphics (Molecular Simulation Inc., 16 New England Executive Park, Burlington, MA 081803) confirmed the presence of two (*syn* and *anti*) atropisomers. An X-ray structural study (in progress) should establish this point.
[3] All eight of the carbon atoms of the bicyclooctene moiety in **1a** were superimposed on those of **2a** for Fig. 1.

© 1999 NRC Canada

1-naphthyl derivative **2d** is similarly unreactive.[4]) In contrast, the class A derivatives (which lack *ortho*-methyl groups) readily undergo hydrogenation and epoxidation reactions owing to a greater rotational freedom of the aryl groups.[4, 5]

3. Cation radicals of the stilbenoid donor

Methods of oxidation

All the stilbenoid donors in Chart 1 undergo reversible electrochemical oxidation in the range E^0_{ox} = 0.98–1.45 V vs. SCE[6] (see Table 3). The electrochemical reversibility in such an easily accessible potential range allows the ready preparation of the corresponding cation radicals by either chemical or electrochemical oxidation in dichloromethane solution. For example, the chemical oxidation can be readily carried out by electron exchange with stable aromatic cation-radical salts $\mathbf{MA}^{+\bullet}$ and $\mathbf{EA}^{+\bullet}$, as selective organic oxidants with reversible reduction potentials that differ by only 190 mV, as listed in Chart 3 (16). Similarly, a mixture of

Chart 3. Cation-radical oxidants.

	$\mathbf{MA}^{+\cdot}$	$\mathbf{EA}^{+\cdot}$	
E^o_{red}	1.11	1.30	(V *vs* SCE)

chloranil and methanesulfonic acid (15) can also serve as an effective oxidant for the preparation of dichloromethane solutions of the cation radicals of the various stilbenoid donors in Chart 1. Moreover, the isolation of crystalline cation-radical salts from a number of stilbenoid donors can be effected with triethyloxonium hexachloroantimonate (17) as the 1-electron oxidant (see Experimental). Alternatively, the stable cation-radical solutions from stilbenoid donors in Chart 1 can be obtained by anodic oxidation in anhydrous dichloromethane containing tetrabutylammonium hexafluorophosphate as the supporting electrolyte (see Experimental).

Electronic absorption spectra

A solution of stilbenoid derivative **1c** when mixed with 1 equiv. of $\mathbf{MA}^{+\bullet}SbCl_6^-$ in dichloromethane (under an argon atmosphere at 25°C) immediately turned red, and the UV–vis absorption spectrum showed the characteristic twin absorption bands, at λ_{max} = 546 nm (band I) and 880 nm (band II), of dianisylbicycloctene cation radical $\mathbf{1c}^{+\bullet}$, as shown in Fig. 3*a*. Quantitative spectral analysis of the magenta solution (log ε_{546} = 4.16) indicated that the electron exchange in eq. [2] was displaced completely to the right, i.e.,

$$[2] \qquad \mathbf{1c} + \mathbf{MA}^{+\cdot} \rightarrow \mathbf{1c}^{+\cdot} + \mathbf{MA}$$

The same exchange procedure was used for the preparation of the UV–vis absorption spectra of the other stilbenoid cation radicals in Fig. 3*a*. It is important to emphasize, however, that the spectra were not dependent on the method of oxidation of the neutral donors, i.e., either electrochemical or chemical oxidation (vide supra). Thus the absorption spectra for the various stilbenoid cation radicals presented in Figs. 3 and 4 were obtained by at least three independent methods of oxidation and found to be the same, as follows.

Class A stilbenoid cation radicals

The class A stilbenoid cation radicals showed the characteristic (UV–vis) absorption spectra (in Fig. 3*a*) with twin absorption bands I and II (consisting of similar band shapes and fine structure in the high-energy band). These spectra are strongly reminiscent of the absorption spectrum previously observed for the transient cation radical of the parent (*Z*)-stilbene in frozen matrices (18) (see Fig. 3*b*). Interestingly, a change of the aryl group from phenyl to tolyl to anisyl in class A stilbenoid cation radicals leads to a monotonic red shift in the absorption maxima of both bands I and II as well as a hyperchromic increase in the (relative) intensity of band II. Such an observation is in accord with the increasing stabilization of the cationic charge by a coplanar aryl group containing a *para* substituent (19) in the order: H < CH_3 < OCH_3.

Class B stilbenoid cation radicals

In marked contrast, the various class B stilbenoid cation radicals in Fig. 4*a* showed an intense new (broad) absorption band (band III) in near-IR region (1100–1315 nm) in addition to the twin absorption bands I and II in the UV–vis region. It is important to reemphasize that the NIR absorption band III was completely absent in all the class A stilbenoid cation radicals, as shown in Fig. 4*b*.

Such a remarkable difference in the electronic absorption spectra of class A and B stilbenoid cation radicals can be ascribed to the steric effects of the *ortho*-methyl groups. Thus, in class A derivatives, the absence of *ortho*-methyl groups allows ready attainment of a conformation (edge-to-face) in which one of the aryl groups is coplanar with the ethylenic bond. However, such a coplanar conformation is strongly discouraged in class B derivatives due to the presence of *ortho*-methyl groups, and leads to only a face-to-face (cofacial) conformation (for example, see Chart 4). The observation of new electronic absorption bands in the NIR region (band III in Fig. 4*a*) is thus ascribed to charge-resonance transitions between the rigidly held cofacial aryl groups in **2a–2d** cation radicals. Such a spectral assignment is in accord with the observations of Badger and Brocklehurst (6) and Rodgers (7), who showed the presence of in-

[4] A palladium-catalyzed hydrogenation of **2d** under high pressure led to a partial reduction of the naphthyl moiety. For the hydrogenation procedures, see R. Rathore et al. (9)

[5] A standard epoxidation procedure using *m*-chloroperbenzoic acid was employed, see ref. 15.

[6] (*a*) Reversible electrochemical oxidation potentials (E^0_{ox} in V vs. SCE) were measured for the various stilbenoid donors (5 mM) by cyclic voltammetry in dichloromethane (containing 0.2 M tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte). Note that the naphthyl derivative **1d** was irreversibly oxidized even at a scan rate of v = 2 V s^{-1}. (*b*) It is noteworthy that E^0_{ox} values of the class B donors are not significantly less positive than those of the class A analogues, despite the presence of additional electron-releasing methyl groups (24). No doubt part of the discrepancy lies in the orthogonal aromatic rings, which completely remove them from ethylene conjugation. We hope to develop other qualitative methods for determining the stabilization energy of the through-space delocalized cation radicals $\mathbf{2a}^{+\bullet}$–$\mathbf{2c}^{+}$.

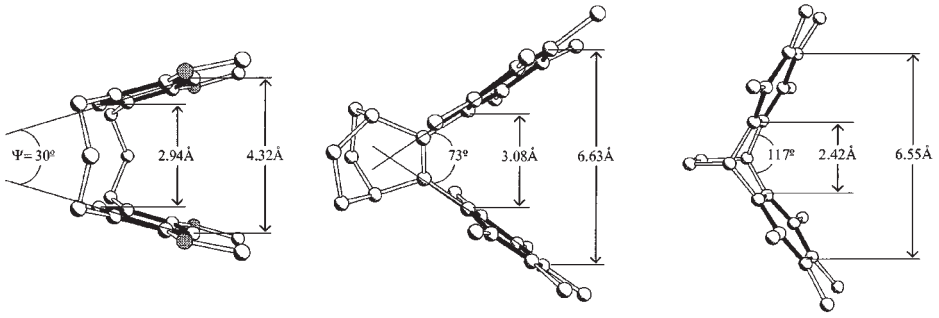
Chart 4. Interplanar dihedral angles.



3 **2a** **4**

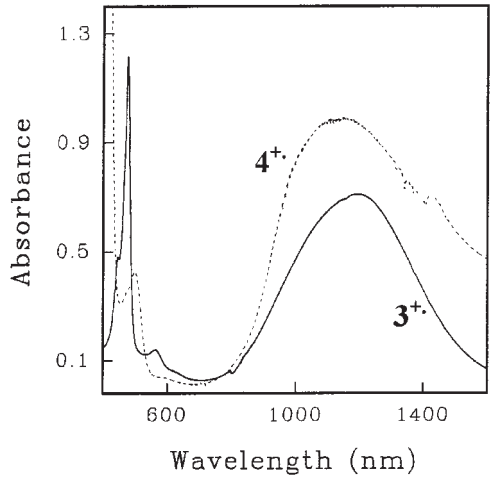
tense NIR absorption bands in the electronic spectra of a variety of (intermolecular) dimeric aromatic cation radicals. They further suggested that the efficient orbital overlap between the parallel aromatic π-systems (in a sandwich-like structure) is the structural basis for the observed charge-resonance transitions (i.e., NIR absorption bands). Note that a sandwich-like arrangement of the dimeric aromatic cation radicals (of naphthalene and its derivatives) has been verified by isolation of single crystals and their X-ray crystallographic characterization (for a review, see ref. 20).

Angular requirements for the charge-resonance transitions

Intense charge-resonance absorption bands of the stilbenoid cation radicals **2a**–**2d** are observed despite the fact that the interplanar (dihedral) angle of Ψ > 70° between the two aryl π-systems deviates significantly from that of a parallel arrangement (see Chart 4). To address the question of the angular requirements for observation of charge-resonance transitions in the cation radicals, we extend the donors to a cyclophane (2,4,2′,4′-tetramethoxy-*m*-cyclophane, **3** (21)) and a phenylene donor (octamethyl-9,10-dihydro-9,10-ethanoanthracene **4** (22)) in which the cofacial π-systems are oriented at different interplanar Ψ angles as established by X-ray crystallography (see Chart 4). (Also note that the closest interplanar contacts between two aromatic π-systems in **2a**, **3**, and **4** are 3.08, 2.94, and 2.42 Å, which are much shorter than the sum of van der Waals thickness 2*r* = 3.4 Å.)

Cyclophane **3** and the phenylene donor **4** undergo reversible electrochemical oxidation in dichloromethane at potentials of E^0_{ox} = 0.80 V and 1.41 V vs. SCE, respectively, which are lower by 380 and 230 mV than those of the parent 4,6-dimethyl-1,3-dimethoxybenzene (E^0_{ox} = 1.18 V vs. SCE) (23) and hexamethylbenzene (E^0_{ox} = 1.64 V vs. SCE) (24). Furthermore, the cofacial donors **3** and **4** were both readily oxidized to the corresponding cation radicals by electron exchange with $\mathbf{MA}^{+\bullet}$ and chloranil – methanesulfonic acid mixture (vide supra), and the UV–vis spectral analysis of the yellow-green solutions in both cases showed intense charge-resonance absorption bands at 1200 and 1180 nm, respectively (see Fig. 5). Such an observation of the NIR absorption bands in **2a**, **3**, and **4**, with drastically varied interplanar angles from Ψ = 30°–117°, suggests that minimal orbital overlap between interacting π-systems is sufficient for charge-resonance transitions to occur. Thus, a close, but not necessarily complete, cofacial approach of π-systems in various cation radicals (see Chart 4) leads to strong electronic interactions between the two aryl moieties, and results in

Fig. 5. The NIR bands in the UV–vis absorption spectra of the cation radicals from cofacial donors **3** and **4** (as indicated) showing the presence of intense charge-resonance bands in the 1200-nm region.



charge-resonance transitions in the UV–vis–NIR absorption spectra similar to those observed for the dimeric cation radicals. Theoretical analysis and quantitative comparison of the (NIR) charge-resonance absorption bands with changes in various structural parameters in a variety of mixed-valence cation-radical salts are currently under investigation.

Summary and conclusions

The efficient synthesis of the stilbenoid donors in Chart 1 allows the steric requirement for the cofacial interaction of aromatic groups to be established. Thus the presence of *ortho*-methyl substituents in the class B donors **2a**–**2c** forces the aromatic rings to lie parallel and orthogonal to the ethylenic bond (Fig. 1). As a result, the electronic (UV–vis) transitions in the cation radicals $\mathbf{2a}^{+\bullet}$–$\mathbf{2c}^{+\bullet}$ show strong new absorption bands in the near-IR region (1100 –1315 nm) arising from the charge-resonance interaction between cofacial aromatic rings. However, the energy of such a through-space charge delocalization is not sufficient to overcome the through-bond conjugation inherent to stilbene cation radicals, and the UV–vis spectra of the cation radicals of the class A donors **1a**–**1d** (with no *ortho* substituents) are singularly bereft of the near-IR absorption. We believe, however, that 1,2-diaryl interactions of the type described for stilbenoids **2a**–**2c** in this study will also pertain to the saturated analogues such as

© 1999 NRC Canada

vicinal diarylalkanes, etc. (1–3), in which restricted (single) bond rotations and through-bond conjugation will be less restrictive.

Experimental

Materials

The synthesis of 2,3-dibromobicyclo[2.2.2]oct-2-ene (25), *2*, 4, 2′, 4′-tetramethoxy-[3.3]-*m*-cyclophane (**3**) (21), and 1,2,3,4,5,6,7,8-octamethyl-9,10-dihydro-9,10-ethanoanthracene (**4**) (22) have been described previously. Bis(triphenylphosphine) palladium(II) chloride and triethyloxonium hexachloroantimonate (Aldrich) were stored in a Vacuum Atmosphere HE-493 dry box kept free of oxygen. The cation radicals $\mathbf{MA}^{+\bullet}$ and $\mathbf{EA}^{+\bullet}$ were readily obtained as the stable hexachloroantimonate salts in quantitative yields from the reaction of corresponding neutral hydroquinone ethers **MA** (9,10-dimethoxy-1,4:5,8-dimethano-1,2,3,4,5,6,7,8-octahydroanthracene) and **EA** (9,10-dimethoxy-1,4:5,8-dimethano-1,2,3,4,5,6,7,8-octahydroanthracene), respectively, with antimony pentachloride (16) or triethyloxonium hexachloroantimonate (17).

Synthesis of 2,3-diarylbicyclo[2.2.2]oct-2-enes

General procedure

An approximately 0.4 M solution of pentamethylphenylmagnesium bromide was prepared from bromopentamethylbenzene (5.0 g, 22 mmol) and excess magnesium turnings (2.4 g, 100 mmol) in tetrahydrofuran, under an argon atmosphere by refluxing for 3 h. The Grignard solution thus obtained was transferred via a cannula to a Schlenk flask containing a solution of 2,3-dibromobicyclo[2.2.2]oct-2-ene (25) (2.66 g, 10 mmol) and a catalytic amount of bis(triphenylphosphine)palladium(II) chloride (0.10 g, 0.15 mmol) in anhydrous tetrahydrofuran (20 mL). The resulting yellow mixture was refluxed for 18 h, cooled to room temperature, and quenched with saturated aqueous ammonium chloride (100 mL). The organic layer was separated and the aqueous phase was further extracted with diethyl ether (3 × 50 mL). The combined organic extracts were washed with water, followed by brine solution, and dried over anhydrous magnesium sulfate. Evaporation of the solvent afforded a pale yellow residue that was filtered through a short pad of silica gel with ether:hexanes (1:1) as the eluent. The resultant product was further purified by recrystallization from ethanol to afford bis(pentamethylphenyl) bicyclooctene **2a** as colorless prisms (3.7 g).

The characteristic spectral data for the various diarylbicyclooctenes obtained using the above general procedure are given as follows.

*2,3-Diphenylbicyclo[2.2.2]oct-2-ene (**1a**)*: Yield 96%, mp 126–127°C (ethanol); UV–vis (CH_2Cl_2) λ_{max}: 228, 280 nm; ^{1}H NMR ($CDCl_3$) δ: 1.68 (sym m, 4H), 1.82 (sym m, 4H), 3.03 (s, 2H), 7.14–7.28 (m, 10H); ^{13}C NMR ($CDCl_3$) δ: 26.20, 37.49, 125.85, 127.83, 124.83, 140.23, 141.02; GC–MS *m*/*z*, calcd. for $C_{20}H_{20}$: 260; found (M^+): 260. Anal. calcd. for $C_{20}H_{20}$: C 92.26, H 7.74; found: C 91.98, H 7.78.

*2,3-Bis(4-methylphenyl)bicyclo[2.2.2]oct-2-ene (**1b**)*: Yield 92%, oil; UV–vis (CH_2Cl_2) λ_{max}: 227, 283 nm; ^{1}H NMR ($CDCl_3$) δ: 1.70 (d, *J* = 7.5 Hz, 4H), 1.81 (d, *J* = 7.5 Hz, 4H), 2.40 (s, 6H), 3.04 (br s, 2H), 7.10 (d, *J* = 8.4 Hz, 4H), 7.14 (d, *J* = 8.4 Hz, 4H); ^{13}C NMR ($CDCl_3$) δ: 21.10, 26.23, 37.52, 128.28, 128.56, 135.26, 138.23, 139.52; GC–MS *m*/*z*, calcd. for $C_{22}H_{24}$: 288; found (M^+): 288. Anal. calcd. for $C_{22}H_{24}$: C 91.61, H 8.39; found: C 91.45, H 8.35.

*2,3-Bis(4-methoxyphenyl)bicyclo[2.2.2]oct-2-ene (**1c**)*: Yield 94%, mp 72–73°C (ethanol); UV–vis (CH_2Cl_2) λ_{max}: 237, 291 nm; ^{1}H NMR ($CDCl_3$) δ: 1.62 (br d, 4H), 1.74 (br d, 4H), 2.94 (s, 2H), 3.79 (s, 6H), 6.77 (d, *J* = 8.7 Hz, 4H), 7.09 (d, *J* = 8.7 Hz, 4H); ^{13}C NMR ($CDCl_3$) δ: 26.23, 37.44, 54.97, 113.23, 129.44, 133.63, 138.60, 157.59; GC–MS *m*/*z*, calcd. for $C_{22}H_{24}O_2$: 320; found (M^+): 320. Anal. calcd. for $C_{22}H_{24}O_2$: C 82.46, H 7.55; found: C 82.38, H 7.53.

*2,3-Bis(2-naphthyl)bicyclo[2.2.2]oct-2-ene (**1d**)*: Yield 91%, mp 195–196°C (ethanol); UV–vis (CH_2Cl_2) λ_{max}: 270, 315 nm; ^{1}H NMR ($CDCl_3$) δ: 1.73 (d, *J* = 8.7 Hz, 4H), 1.83 (d, *J* = 8.7 Hz, 4H), 3.16 (s, 2H), 7.18–7.78 (m, 14 H); ^{13}C NMR ($CDCl_3$) δ: 26.48, 38.01, 125.44, 125.81, 126.66, 127.20, 127.59, 127.82, 132.07, 133.60, 138.73, 140.85; GC–MS *m*/*z*, calcd. for $C_{28}H_{24}$: 360; found (M^+): 360. Anal. calcd. for $C_{28}H_{24}$: C 93.29, H 6.71; found: C 93.12, H 6.54.

*2,3-Bis(pentamethylphenyl)bicyclo[2.2.2]oct-2-ene (**2a**)*: Yield 94%, mp 239–240°C (ethanol); UV–vis (CH_2Cl_2) λ_{max}: 227, 251 nm; ^{1}H NMR ($CDCl_3$) δ: 1.77 (br d, *J* = 7.4 Hz, 4H), 1.91 (br d, *J* = 7.4 Hz, 4H), 2.14 (s, 12H), 2.18 (s, 6H), 2.19 (s, 12H), 2.63 (br s, 2H); ^{13}C NMR ($CDCl_3$) δ: 16.63, 16.81, 19.83, 27.28, 37.79, 131.96, 132.08, 132.05, 139.45, 142.71; GC–MS *m*/*z*, calcd. for $C_{30}H_{40}$: 400; found (M^+): 400. Dichloromethane (Mallinckrodt analytical reagent) was repeatedly stirred with fresh aliquots of concentrated sulfuric acid (~20% by volume) until the acid layer remained colorless. After separation, it was washed successively with wa-

© 1999 NRC Canada

ter, aqueous sodium bicarbonate, water, and aqueous sodium chloride, and dried over anhydrous calcium chloride. The dichloromethane was distilled twice from P_2O_5 under an argon atmosphere and stored in a Schlenk flask equipped with a Teflon valve fitted with Viton O-rings. The hexane and toluene were distilled from P_2O_5 under an argon atmosphere and then refluxed over calcium hydride (~12 h). After distillation from CaH_2, the solvents were stored in the Schlenk flasks under an argon atmosphere.

Instrumentation

The UV–vis absorption spectra were recorded on HP 8453 diode array and Varian CARY 5 (UV–vis–NIR) spectrometers. The ^1H and ^{13}C NMR spectra were obtained on a General Electric QE-300 FT NMR spectrometer. Electrochemical apparatus and the procedures for the determination of oxidation potentials and for the preparation of cation radicals have been described elsewhere (9).

Oxidation of various stilbenoid donors

General procedure

A stock solution of $\mathbf{EA}^{+\bullet}$ (λ_{max} = 486 nm, log ε_{486} = 3.66 M^{-1} cm^{-1}) was obtained by dissolving a known quantity of $\mathbf{EA}^{+\bullet}SbCl_6^-$ (4.25 mg, 6.92 × 10^{-5} mmol) in anhydrous dichloromethane (50 mL) at 22°C and under an argon atmosphere. A 5 mL aliquot of the red-orange solution was transferred to a 1 cm quartz cuvette equipped with a Schlenk adapter (under an argon atmosphere). A solution of the stilbenoid donor **2c** (1 equiv.) was added at 25°C. The reaction mixture immediately turned bright green and the UV–vis spectral analysis confirmed the formation of $\mathbf{2c}^{+\bullet}$ (λ_{max} = 428, 700, and 1315 nm, log ε_{1315} = 3.98 M^{-1} cm^{-1}). In a similar manner, various stilbenoid donors in Chart 1 were quantitatively oxidized to corresponding cation radicals, and the UV–vis absorption maxima are compiled in Table 3. Various donors with E^0_{ox}<1.2 V vs. SCE were readily oxidized with $\mathbf{MA}^{+\bullet}$ (λ_{max} = 518 nm, log ε_{518} = 3.86 M^{-1} cm^{-1}, whereas donors with E^0_{ox} >1.2 V were oxidized with $\mathbf{EA}^{+\bullet}$ (λ_{max} = 518 nm, log ε_{486} = 3.66 M^{-1} cm^{-1}). Oxidation procedures with chloranil – methanesulfonic acid (method B) (15) and triethyloxonium hexachloroantimonate (method C) (17) have been described in detail.

Preparative isolation of stilbenoid cation radical salts using Et_3O^+ $SbCl_6^-$

A 200 mL flask equipped with a Schlenk adapter was charged with triethyloxonium hexachloroantimonate (657 mg, 1.5 mmol), and a solution of **1c** (320 mg, 1 mmol) in anhydrous dichloromethane (25 mL) was added under an argon atmosphere at –20°C. The heterogeneous mixture immediately took on magenta coloration, which intensified with time. The dark-red mixture was stirred for 1 h to yield a magenta-red solution of $\mathbf{1c}^{+\bullet}$ (λ_{max} (nm) = 546, 880; see Fig. 3*a*). The dark magenta solution was cooled to –50°C in an Dry Ice – acetone bath, and anhydrous toluene (100 mL) was added to precipitate the dissolved salt. The dark-red precipitate was filtered under an argon atmosphere, washed with hexane (3 × 25 mL), and dried in vacuo. The cation radical $\mathbf{1c}^{+\bullet}$ $SbCl_6^-$ (vide infra) was obtained in essentially quantitative yield (550 mg, 0.84 mmol).

The purity of the isolated cation radical $\mathbf{1c}^{+\bullet}$ $SbCl_6^-$ was determined by iodometric titration as follows. A solution of $\mathbf{1c}^{+\bullet}$ $SbCl_6^-$ (65.5 mg, 0.01 M) in dichloromethane was added to a dichloromethane solution containing excess tetra-*n*-butylammonium iodide (1 mmol, 0.1 M) at 22°C, under an argon atmosphere, to afford a dark-brown solution. The mixture was stirred for 5 min and was titrated (with rapid stirring) by slow addition of a standard aqueous sodium thiosulfate solution (0.005 M) in the presence of a starch solution as internal indicator. Based on the amount of thiosulfate solution consumed (57.4 mL), purity of the cation radical was determined to be >97%. With the same procedure, the crystalline cation radical salts of **2a** and **2c** were also isolated in 76 and 81% yields, respectively.

X-ray crystallography

The intensity data for all the compounds were collected with the aid of a Siemens SMART diffractometer equipped with a CCD detector using Mo-Kα radiation (λ = 0.71073 Å), at –150°C unless otherwise specified. The structures were solved by direct methods (26) and refined by full-matrix least-squares procedure with IBM Pentium and SGI Indigo computers. The details of the X-ray structure of the various compounds have been deposited.[7]

*2,3-Diphenylbicyclo[2.2.2]oct-2-ene (**1a**) ($C_{20}H_{20}$)*

An X-ray quality crystal (0.20 × 0.20 × 0.20 mm) of diphenylbicyclooctene was obtained from an ethanol–dichloromethane mixture at –30°C. MW = 260.36, orthorhombic, space group $P2_12_12_1$, a = 6.0645(1), b = 12.1491(3), and c = 19.4396(5) Å, D_c = 1.207 Mg m^{-3}, V = 1432.28(6) $Å^3$, Z = 4. The total number of reflections measured were 6492, of which 6492 reflections were symmetrically non-equivalent. Final residuals were $R1$ = 0.0477 and $wR2$ = 0.1017 for 6492 reflections with $I > 2\sigma(I)$.

*2,3-Bis(pentamethylphenyl)bicyclo[2.2.2]oct-2-ene (**2a**) ($C_{30}H_{40}$)*

An X-ray quality crystal (0.3 × 0.2 × 0.1 mm) of **2a** was obtained from an ethanol–dichloromethane mixture at –30°C. MW = 400.62, monoclinic, space group $P2_1/n$, a = 8.6608(7), b = 13.223(1), and c = 20.401(2) Å, β = 91.519(2)°, D_c = 1.139 Mg m^{-3}, V = 2335.6(3) $Å^3$, Z = 4. The total number of reflections measured were 8416, of which 3237 reflections were symmetrically non-equivalent. Final residuals were $R1$ = 0.0730 and $wR2$ = 0.1259 for 3073 reflections with $I > 2\sigma(I)$.

[7] Supplementary material, including tables of crystal data and structure refinement, atomic coordinates, isotropic and anisotropic displacement parameters, and bond lengths and angles for 2,3-diphenylbicyclo[2.2.2]oct-2-ene (**1a**), bis(pentamethylphenyl)bicyclooct-2-ene (**2a**), bis(2,4,6-trimethyl-phenyl)bicyclooct-2-ene (**2b**), and 2,4,2′,4′-tetramethoxy-*m*-cyclophane (**3**)·chloranil molecular complex may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of the anisotropic displacement parameters, this material has also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

*2,3-Bis(2,4,6-trimethylphenyl)bicyclo-[2.2.2]oct-2-ene (**2b**) ($C_{26}H_{32}$)*

An X-ray quality crystal (0.5 × 0.4 × 0.2 mm) of **2b** was obtained from an ethanol–dichloromethane mixture at –30°C. MW = 344.52, orthorhombic, space group *Pbcn*, a = 21.6486(1), b = 8.7822(1), and c = 21.7995(2) Å, D_c = 1.104 Mg m^{-3}, V = 4144.57(6) Å^3, Z = 8. The total number of reflections measured were 50 440, of which 9646 reflections were symmetrically non-equivalent. Final residuals were $R1$ = 0.0584 and $wR2$ = 0.1342 for 9638 reflections with $I > 2\sigma(I)$.

2,4,2′,4′-Tetramethoxy-[3.3]-m-*cyclophane (**3**)–chloranil molecular complex ($C_{22}H_{28}O_4{\cdot}C_6Cl_4O_2$).*

X-ray quality crystals (0.35 × 0.30 × 0.20 mm) of the charge-transfer complex of **3**·chloranil were obtained by slow evaporation of a equimolar solution of **3** and chloranil in dichloromethane at 25°C. MW = 602.30, orthorhombic, space group *Pnma*, a = 13.464(3), b = 20.144(4), and c = 10.033(2) Å, D_c = 1.470 Mg m^{-3}, V = 2721.1(9) Å^3, Z = 4. The total number of reflections measured were 6618, of which 2161 reflections were symmetrically non-equivalent. Final residuals were $R1$ = 0.0388 and $wR2$ = 0.0948 for 2153 reflections with $I > 2\sigma(I)$. (Note that the molecular structure of the cyclophane moiety in the **3**·chloranil complex is quite similar to that previously observed for the uncomplexed cyclophane (21).)

How does organic structure determine organic reactivity? The effect of *ortho*-dimethyl groups on the nucleophilic substitution and alkene-forming elimination reactions of ring-substituted cumyl derivatives

Tina L. Amyes, Tadeusz Mizerski, and John P. Richard

Abstract: The addition of a pair of *ortho*-methyl groups to ring-substituted cumyl derivatives to give the corresponding 2,6-dimethylcumyl derivatives X-**1**-Y leads to modest (<5-fold) changes in the observed rate constant for reaction in 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$). The reactions of X-**1**-Y proceed by a stepwise mechanism through the liberated 2,6-dimethylcumyl carbocations X-**2** that partition between nucleophilic addition of solvent and deprotonation to give good yields (≥ 67%) of the corresponding 2-(2,6-dimethylaryl)propenes X-**3**. The carbocations X-**2** are also trapped by nucleophilic addition of azide ion to give good yields (≥ 68% at $[N_3^-]$ = 0.50 M) of the corresponding 2,6-dimethylcumyl azides X-**1**-N_3. In the presence of high concentrations of azide ion there are constant limiting yields of the alkenes X-**3,** which shows that X-**2** also undergo significant reactions with azide ion as a Brønsted base. The product rate constant ratios for partitioning of the 2,4,6-trimethylcumyl carbocation Me-**2** between reaction with azide ion as a Lewis and a Brønsted base, k_{az}/k_B, the nucleophilic addition of azide ion and solvent, k_{az}/k_s (M^{-1}), and deprotonation by solvent, k_{az}/k_e (M^{-1}), were combined with $(k_{az} + k_B) = 5 \times 10^9$ M^{-1} s^{-1} for the diffusion-limited reaction of azide ion to give absolute rate constants for the reactions of Me-**2**. The data show that the addition of a pair of *ortho*-methyl groups to the 4-methylcumyl carbocation to give the sterically hindered Me-**2** results in a 70-fold decrease in the rate constant for nucleophilic addition of solvent to the benzylic carbon, but a 60-fold *increase* in the rate constant for deprotonation of the carbocation by solvent.

Key words: carbocation, *ortho*-substituent effects, steric effects, solvolysis, elimination.

Résumé : L'addition d'une paire de groupes méthyles en *ortho* de dérivés cumyles substitués sur le cycle donne les dérivés 2,6-diméthylcumules X-**1**-Y; leurs vitesses de réaction dans un mélange 50 : 50 (v : v) de trifluoroéthanol–eau (I = 0,50, $NaClO_4$) sont légèrement augmentées (par un facteur d'environ 5). Les réactions des produits X-**1**-Y se produisent par un mécanisme par étapes, par le biais des carbocations 2,6-diméthylcumyles libérés, X-**2**, qui réagissent en partie par une addition nucléophile du solvant ou par une déprotonation conduisant à des bons rendements (≥ 67%) des 2-(2,6-diméthylaryl)propènes correspondants, X-**3**. Les carbocations X-**2** peuvent aussi être piégés par l'addition nucléophile de l'ion azoture qui fournit de bons rendements (≥ 68%, à des $[N_3^+]$ = 0,50 M) des azotures de 2,6-diméthylcumyle correspondants, X-**1**-N_3. En présence d'une concentration élevée d'ion azoture, on observe la formation des alcènes X-**3** avec des rendements limites constants; ceci démontre que les ions X-**2** subissent aussi des réactions significatives avec l'ion azoture agissant comme base de Brønsted. Dans le but de déterminer les constantes de vitesse absolue des réactions de Me-**2**, on a combiné la constante de vitesse de réaction de l'ion azoture limitée par la diffusion ($(k_{az} + k_B) = 5{,}0 \times 10^9$ M^{-1} s^{-1}) avec les rapports de constante de vitesse des réactions du carbocation 2,4,6-triméthylcumyle, Me-**2**, avec l'ion azoture comme base de Lewis et comme base de Brønsted, k_{az}/k_B, par addition nucléophile de l'ion azoture et du solvant, k_{az}/k_s (M^{-1}), et par déprotonation par le solvant, k_{az}/k_e (M^{-1}). Les données montrent que l'addition d'une paire de groupes méthyles en *ortho* du carbocation 4-méthylcumyle provoque un empêchement stérique qui engendre une diminution (par un facteur de 70) de la constante de vitesse d'addition nucléophilique du solvant sur le carbone benzylique et une augmentation (par un facteur de 60) de la constante de vitesse de déprotonation du carbocation par le solvant.

Mots clés : carbocation, effets de substituants en *ortho*, effets stériques, solvolyse, élimination.

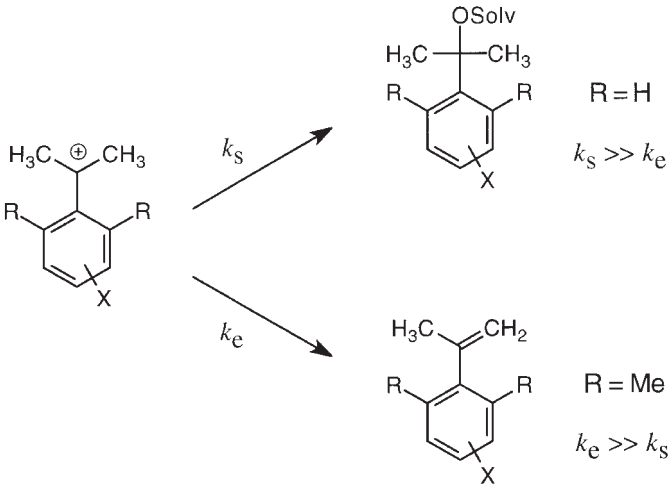
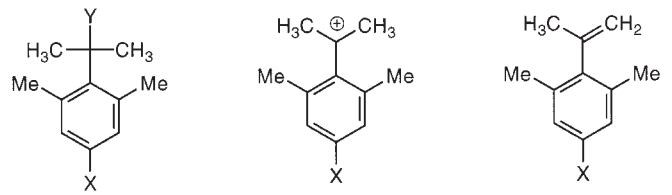
Scheme 1.



Introduction

We are interested in the effects of changing substrate structure on the stepwise reactions of simple α-methylbenzyl derivatives $XC_6H_4CMe(R)Y$ in nucleophilic solvents. These studies have shown that changes in the α-substituent R result in large changes in the thermodynamic stability of the carbocation intermediates $XC_6H_4CMe(R)^+$ (1, 2), but that the usual fate of these carbocations is their almost exclusive capture at the benzylic carbon by solvent and (or) added nucleophiles. For example, in 50:50 trifluoroethanol–water, liberated ring-substituted cumyl carbocations $XC_6H_4CMe_2^+$, generated from the ionization of cumyl 4-nitrobenzoates or the acid-catalyzed cleavage of cumyl methyl ethers, partition to give >99% of the products of solvolysis and <1% of the α-methylstyrene product of elimination (R = H, $k_s >> k_e$, Scheme 1) (3, 4). This stands in sharp contrast with the report of Creary et al. that in acetic acid or trifluoroethanol, 2,6-dimethylcumyl trifluoroacetate (H-**1**-(trifluoroacetate)) undergoes stepwise reaction through the 2,6-dimethylcumyl carbocation H-**2** to give the alkene H-**3** as the sole product (5). This is a dramatic example of an "*ortho* effect" (6–8), and it suggests that the addition of a pair of *ortho*-methyl groups results in a fundamental change in the partitioning of cumyl carbocations, from the almost exclusive nucleophilic addition of solvent to the benzylic carbon (R = H, $k_s >> k_e$, Scheme 1) to the exclusive loss of a proton to give the corresponding α-methylstyrene (R = Me, $k_e >> k_s$, Scheme 1).

We report here a study of the nucleophilic substitution and elimination reactions of a series of ring-substituted 2,6-dimethylcumyl derivatives X-**1**-Y (X = MeO, Me, H) in 50:50 (v:v) trifluoroethanol–water. The results show that X-**1**-Y undergo stepwise reactions through the liberated carbocations X-**2** that are trapped by the nucleophilic addition of solvent and azide ion to the benzylic carbon. To the best of our knowledge, these reactions represent the first examples of the conversion of a disubstituted sp^2-hybridized carbon attached to a 2,6-disubstituted aryl moiety into a stable tetrahedral adduct. The carbocations X-**2** also undergo proton transfer to solvent and azide and acetate ions to give the alkenes X-**3**. The data provide relative and absolute rate constants for the formation and reaction of the sterically hindered carbocations X-**2** with Brønsted and Lewis bases.



X-**1**-Y X-**2** X-**3**

Experimental section

Materials

2-Bromo-*m*-xylene, 2-bromomesitylene, 3,5-dimethylanisole, 4-methoxybenzoyl chloride, 4-nitrobenzoyl chloride, butyllithium, acetone, and 2,2,2-trifluoroethanol were purchased from Aldrich. Sodium azide was purchased from Fluka. 9-Methyl-9-fluorenol was available from a previous study (9). Tetrahydrofuran was distilled from sodium–benzophenone. All other chemicals were reagent grade and were used without further purification. Water for HPLC analysis and kinetic studies was distilled and then passed through a Milli-Q purification system.

Synthesis

^{1}H NMR spectra were recorded in $CDCl_3$ on Varian spectrometers. Chemical shifts are reported downfield of an internal tetramethylsilane standard at 0 ppm. Melting points were determined using a Mel-Temp apparatus and are uncorrected.

4-Bromo-3,5-dimethylanisole (10), 2-(2,6-dimethylphenyl)-2-propyl alcohol [H-**1**-OH] (5) and 2-(2,4,6-trimethylphenyl)-propene [Me-**3**] (11) were prepared by literature procedures.

2-(2,4,6-Trimethylphenyl)-2-propyl alcohol

Me-**1**-OH was prepared from 2-bromomesitylene by the literature procedure (5) used for the preparation of 2-(2,6-dimethylphenyl)-2-propyl alcohol. Purification by column chromatography on silica gel, eluting with 1:3 ethyl acetate – hexanes, gave the alcohol in 23% yield as a white solid: mp 111–112°C (lit. (12) 111–112°C); ^{1}H NMR (200 MHz) δ: 6.83 (2H, s, Ar), 2.51 (6H, s, $(CH_3)_2Ar$), 2.23 (3H, s, CH_3Ar), 1.72 (6H, s, $(CH_3)_2$), 1.67 (1H, s, OH).

2-(4-Methoxy-2,6-dimethylphenyl)-2-propyl alcohol

MeO-**1**-OH was prepared from 4-bromo-3,5-dimethylanisole by the literature procedure (5) used for the preparation of 2-(2,6-dimethylphenyl)-2-propyl alcohol. Purification by column chromatography on silica gel, eluting with 1:3 ethyl acetate – hexanes, gave the alcohol in 22% yield as a white solid: mp 96–97°C; ^{1}H NMR (400 MHz) δ: 6.55 (2H, s, Ar), 3.77 (3H, s, OCH_3), 2.52 (6H, s, $(CH_3)_2Ar$), 1.71 (6H, s, $(CH_3)_2$), 1.66 (1H, s, OH).

2-(2,6-Dimethylphenyl)-2-propyl 4-methoxybenzoate

H-**1**-(4-methoxybenzoate) was prepared by adaptation of a literature procedure (13). Butyllithium (4.4 mL of a 1.6 M solution in hexanes, 7.0 mmol) was added to a solution of 2-(2,6-dimethylphenyl)-2-propyl alcohol (1.06 g, 6.5 mmol) in dry tetrahydrofuran (8 mL) at room temperature under argon and the mixture was stirred for 0.5 h. 4-Methoxybenzoyl chloride (1.2 g, 7.0 mmol) in dry tetrahydrofuran (5 mL)

© 1999 NRC Canada

was added and the mixture was heated under reflux for 2 h. The solvent was removed by evaporation and the residue was dissolved in dichloromethane (50 mL), washed with water (50 mL), dried with $MgSO_4$, and evaporated. The resulting yellow crystals were decolorized with activated charcoal and recrystallized twice from hexane to give the ester (0.65 g, 34%) as white crystals: mp 86–87°C; ^{1}H NMR (200 MHz) δ: 8.00 (2H, d, J = 9 Hz, Ar), 6.98 (3H, m, Ar), 6.92 (2H, d, J = 9 Hz, Ar), 3.87 (3H, s, OCH_3), 2.44 (6H, s, $(CH_3)_2Ar$), 2.00 (6H, s, $(CH_3)_2$).

2-(2,4,6-Trimethylphenyl)-2-propyl 4-methoxybenzoate

Me-**1**-(4-methoxybenzoate) was prepared from 2-(2,4,6-trimethylphenyl)-2-propyl alcohol by the procedure described above for 2-(2,6-dimethylphenyl)-2-propyl 4-methoxybenzoate. Recrystallization from hexane gave the ester in 50% yield: mp 106–107°C; ^{1}H NMR (200 MHz) δ: 8.00 (2H, d, J = 9 Hz, Ar), 6.92 (2H, d, J = 9 Hz, Ar), 6.80 (2H, s, Ar), 3.87 (3H, s, OCH_3), 2.41 (6H, s, $(CH_3)_2Ar$), 2.21 (3H, s, CH_3Ar), 1.99 (6H, s, $(CH_3)_2$).

2-(4-Methoxy-2,6-dimethylphenyl)-2-propyl 4-methoxybenzoate

MeO-**1**-(4-methoxybenzoate) was prepared from 2-(4-methoxy-2,6-dimethylphenyl)-2-propyl alcohol by the procedure described above for 2-(2,6-dimethylphenyl)-2-propyl 4-methoxybenzoate. Purification by column chromatography on silica gel, eluting with 1:1 ethyl acetate – hexanes, followed by recrystallization from hexane gave the ester in 22% yield as plates: mp 86–87°C; ^{1}H NMR (400 MHz) δ: 7.99 (2H, d, J = 9 Hz, Ar), 6.91 (2H, d, J = 9 Hz, Ar), 6.52 (2H, s, Ar), 3.86 (3H, s, OCH_3), 3.74 (3H, s, OCH_3), 2.43 (6H, s, $(CH_3)_2Ar$), 1.98 (6H, s, $(CH_3)_2$).

2-(2,4,6-Trimethylphenyl)-2-propyl 4-nitrobenzoate

Me-**1**-(4-nitrobenzoate) was prepared from 2-(2,4,6-trimethylphenyl)-2-propyl alcohol and 4-nitrobenzoyl chloride by the procedure described above for 2-(2,6-dimethylphenyl)-2-propyl 4-methoxybenzoate. Recrystallization from ether gave the ester in 18% yield as needles: mp 232–233°C (sl. dec.); ^{1}H NMR (400 MHz) δ: 8.28 (2H, d, J = 9 Hz, Ar), 8.20 (2H, d, J = 10 Hz, Ar), 6.81 (2H, s, Ar), 2.39 (6H, s, $(CH_3)_2Ar$), 2.22 (3H, s, CH_3Ar), 2.03 (6H, s, $(CH_3)_2$).

2-(4-Methoxy-2,6-dimethylphenyl)propene

MeO-**3** was prepared by dehydration of 2-(4-methoxy-2,6-dimethylphenyl)-2-propyl alcohol by the literature procedure (11) for the preparation of 2-(2,4,6-trimethylphenyl)propene. Purification by distillation gave the alkene in 96% yield: bp 82°C (1 Torr (= 133.3 Pa)); ^{1}H NMR (400 MHz) δ: 6.60 (2H, s, Ar), 5.27 (1H, broad, CH_2), 4.75 (1H, br, CH_2), 3.78 (3H, s, OCH_3), 2.25 (6H, s, $(CH_3)_2Ar$), 1.94 (3H, s, CH_3).

Product studies

Unless stated otherwise, product studies were carried out in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$). Reactions were initiated by making a 100-fold dilution of a solution of substrate in acetonitrile into the appropriate reaction mixture and product distributions were determined by HPLC analysis. For reactions at $[N_3^-] \leq 0.05$ M the solutions were buffered with 25 mM cacodylate, 80% anion, which prevented acid-catalyzed breakdown of the solvolysis products. Aqueous solutions containing sodium azide were adjusted to pH ≈ 7 with concentrated $HClO_4$ before use.

The products of the reactions of Me-**1**-(4-methoxybenzoate) ([S] = 2 mM) in the absence of azide ion were analyzed after 2–30 halftimes for reaction of the substrate and were shown to be stable during this time. For reactions in the presence of azide ion the products were analyzed after 30–40 halftimes, because the substrate and the azide ion adduct Me-**1**-N_3 coeluted from the HPLC column. At these long reaction times there was slight (≤5%) breakdown of Me-**1**-N_3 that resulted in significant increases in the relatively small fractional yields of the solvent adducts Me-**1**-OSolv. For the reactions in the presence of 0.05 M azide ion and increasing concentrations of acetate ion the solutions were buffered with acetate, 95% anion. UV spectroscopy showed that under these conditions more than 97% of the azide is in the anionic form. In all cases the HPLC peak area for the elimination product Me-**3** was corrected for the 7.0% of this alkene that was present as a contaminant of the substrate.

The products of the reactions of Me-**1**-(4-nitrobenzoate) ([S] = 1 mM) were analyzed after 5–20 halftimes for reaction of the substrate and were shown to be stable during this time.

Product studies for the relatively fast reactions of MeO-**1**-(4-methoxybenzoate) ([S] = 0.1–0.5 mM) were carried out at room temperature, 22 ± 2°C. It has been shown in previous work that there is no detectable difference between product ratios determined at room temperature and at 25°C (1, 14). For reactions in the absence of azide ion the products were analyzed after 20–70 halftimes for reaction of the substrate and were shown to be stable during this time. For reactions in the presence of azide ion the substrate concentration was at least 10-fold smaller than that of azide ion, in order to maintain pseudo-first-order conditions. For reactions at $[N_3^-]$ = 1–5 mM the azide ion adduct MeO-**1**-N_3 was unstable and the products were analyzed within the first 3 halftimes for reaction of the substrate, during which breakdown of MeO-**1**-N_3 is insignificant. For reactions at $[N_3^-] \geq 0.05$ M, the azide ion adduct Me-**1**-N_3 was stabilized by a common ion effect and the products were analyzed after 10–20 halftimes for reaction of the substrate. The substrate and the trifluoroethyl ether solvolysis product MeO-**1**-OCH_2CF_3 coeluted from the HPLC column. Therefore, for reactions that were analyzed before complete disappearance of the substrate, the total HPLC peak area for the solvent adducts was calculated with the assumption that the ratio of the HPLC peak areas for the solvolysis products MeO-**1**-OH and MeO-**1**-OCH_2CF_3 is the same as that determined in the absence of azide ion. In all cases, the HPLC peak area for the elimination product MeO-**3** was corrected for the 1.6% of this alkene that was present as a contaminant of the substrate.

HPLC analyses

Unless noted otherwise, the products of the reactions of X-**1**-Y were cleanly separated by reverse-phase HPLC as described previously (14, 15), with peak detection by a Waters 996 diode array detector. The products were detected by their UV absorbance at 280 nm for MeO-**1**-Y and at 269 nm for Me-**1**-Y and H-**1**-Y. These wavelengths are λ_{max} for the corresponding alcohols X-**1**-OH. The products of solvolysis

© 1999 NRC Canada

and nucleophilic substitution by azide ion were identified as described previously (14, 15). The products of the elimination reactions of MeO-**1**-Y and Me-**1**-Y were identified as MeO-**3** and Me-**3**, respectively, by showing that their retention times were identical with those for authentic samples.

Ratios of product yields, $[P_1]/[P_2]$, were calculated using eq. [1], where A_1/A_2 is the ratio of the HPLC peak areas for the two products, and $\varepsilon_2/\varepsilon_1$ is the ratio of the molar extinction coefficients of the two products at the wavelength of the analysis.

$$[1] \qquad [P_1]/[P_2] = (A_1/A_2)(\varepsilon_2/\varepsilon_1)$$

Ratios of $\varepsilon_{alkene}/\varepsilon_{ROH}$ = (220 M^{-1} cm^{-1})/(210 M^{-1} cm^{-1}) = 1.0 at 269 nm for Me-**3** and Me-**1**-OH and $\varepsilon_{alkene}/\varepsilon_{ROH}$ = (1270 M^{-1} cm^{-1})/(860 M^{-1} cm^{-1}) = 1.5 at 280 nm for MeO-**3** and MeO-**1**-OH in 50:50 (v:v) methanol–water were determined using authentic materials. The extinction coefficients of the azide ion adduct Me-**1**-N_3 and the alkene Me-**3** at 269 nm were shown to be identical by comparison of the decrease in the HPLC peak area for the alkene and the increase in the sum of the peak areas of the solvent and azide ion adducts for reaction of a constant amount of substrate when the concentration of azide ion was increased from zero to 0.50 M. The extinction coefficients of the azide ion adduct MeO-**1**-N_3 and the alcohol MeO-**1**-OH at 280 nm were assumed to be identical because the extinction coefficients of the solvent and azide ion adducts to a wide range of α-substituted 4-methoxybenzyl carbocations are identical at λ_{max} for the corresponding alcohol (1). The extinction coefficients of the alcohols X-**1**-OH and trifluoroethyl ethers X-**1**-OCH_2CF_3 were assumed to be identical because it has been shown in previous work that the extinction coefficients of ring-substituted cumyl alcohols and trifluoroethyl ethers are identical at λ_{max} for the alcohols (4).

Calculation of product yields and rate constant ratios

Fractional yields of the solvolysis and elimination products of the reactions of X-**1**-Y were calculated as the ratio of the HPLC peak area for the product divided by the sum of the peak areas for all products, with correction where necessary for differences in the extinction coefficients of the various products (see above).

Dimensionless product rate constant ratios for the nucleophilic substitution reactions of water and trifluoroethanol with X-**1**-Y were calculated from the ratio of the yields of the corresponding alcohols and trifluoroethyl ethers using eq. [2]. Dimensionless product rate constant ratios for the partitioning of X-**1**-Y between solvolysis and elimination were calculated directly as the ratio of the yields of the products of these reactions using eq. [1].

$$[2] \qquad k_{HOH}/k_{TFE} = [\text{X-}\mathbf{1}\text{-OH}][CF_3CH_2OH]/[\text{X-}\mathbf{1}\text{-}OCH_2CF_3][HOH]$$

Rate constant ratios k_{az}/k_s (M^{-1}) for the partitioning of Me-**1**-(4-nitrobenzoate) and MeO-**1**-(4-methoxybenzoate) between nucleophilic substitution by azide ion and solvent were calculated from the ratio of the yields of the azide ion and solvent adducts using eq. [3]. The values of k_{az}/k_s (M^{-1}) determined at five or more values of $[N_3^-]$ agreed within the experimental error of ±10%.

$$[3] \qquad k_{az}/k_s\ (M^{-1}) = [\text{X-}\mathbf{1}\text{-}N_3]/(\sum\ [\text{X-}\mathbf{1}\text{-OSolv}][N_3^-])$$

Kinetic methods

Kinetic studies were carried out in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$). Reactions were initiated by making a 100-fold dilution of a solution of substrate in acetonitrile into the appropriate reaction mixture. For reactions in the absence of azide ion, the solutions were buffered with 25 mM cacodylate, 80% anion, which prevented acid-catalyzed breakdown of the solvolysis products. Aqueous solutions containing sodium azide were adjusted to pH ≈7 with concentrated $HClO_4$ before use.

Rate constants for the reaction of MeO-**1**-(4-methoxybenzoate) ([S] = 0.1 mM) were determined spectrophotometrically by following the disappearance of the substrate at 270 nm or at 280 nm for reactions in the presence of azide ion. Rate constants for the reactions of Me-**1**-(4-nitrobenzoate) ([S] = 0.2 mM) were determined spectrophotometrically by following the increase in absorbance at 297 nm.

Rate constants for the reactions of Me-**1**-(4-methoxybenzoate) ([S] = 2 mM) and H-**1**-(4-methoxybenzoate) ([S] = 1 mM) were determined by following the disappearance of the substrate by HPLC, with peak detection at 285 nm. For Me-**1**-(4-methoxybenzoate) the reaction mixtures contained 9-methyl-9-fluorenol (1.7×10^{-5} M) as an internal HPLC injection standard. For H-**1**-(4-methoxybenzoate) the solution was unbuffered and contained 3-(4-methoxyphenyl)-1-propanol (4×10^{-4} M) as an internal HPLC injection standard.

In all cases, good first-order kinetics were observed over at least three reaction halftimes. First-order rate constants, k_{obsd}, were determined from the slopes of semilogarithmic plots of reaction progress against time. Rate constants determined spectrophotometrically were reproducible to ±5% and those determined by HPLC were reproducible to ±10%.

Results

Table 1 gives observed first-order rate constants, k_{obsd}, for the reactions of 4-substituted 2,6-dimethylcumyl derivatives X-**1**-Y in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$) that were determined by monitoring the reaction progress by UV spectroscopy or HPLC analysis, as described in the Experimental section. There was no significant change in k_{obsd} for the reactions of MeO-**1**-(4-methoxybenzoate), Me-**1**-(4-methoxybenzoate), and Me-**1**-(4-nitrobenzoate) when the concentration of azide ion was increased from zero to 0.50 M (I = 0.50, $NaClO_4$) (Table 1). The reactions of these substrates in the presence of 0.50 M azide ion result in the following good yields of the corresponding azide ion adducts: MeO-**1**-(4-methoxybenzoate), 93%; Me-**1**-(4-methoxybenzoate), 67%; Me-**1**-(4-nitrobenzoate), 68%.

Table 2 gives the yields of the solvolysis and elimination products of the reactions of MeO-**1**-Y and Me-**1**-Y in 50:50 (v:v) trifluoroethanol–water at I = 0.50 ($NaClO_4$) that were determined by HPLC analysis. The reaction mixtures were buffered with 25 mM cacodylate, 80% anion, which prevented acid-catalyzed breakdown of the solvolysis products X-**1**-OSolv to the alkenes X-**3**. In a control experiment, the yields of the products of the reaction of Me-**1**-(4-methoxybenzoate) in the absence of buffer determined during 10

MeO	5.8×10^{-3} [b]	
	(5.5×10^{-3}) [c,d]	
Me	3.3×10^{-4} [e]	3.2×10^{-3} [f]
	(3.0×10^{-4}) [e,d]	(2.9×10^{-3}) [f,d]
H	2.2×10^{-5} [e,d]	

[a]Determined in the presence of 25 mM cacodylate buffer, 80% anion, unless noted otherwise. Values in parentheses are for reaction in the presence of 0.50 M azide ion.

[b]Determined spectrophotometrically by following the disappearance of the substrate at 270 nm.

[c]Determined spectrophotometrically by following the disappearance of the substrate at 280 nm.

[d]Determined in unbuffered solution.

[e]Determined by following the disappearance of the substrate by HPLC.

[f]Determined spectrophotometrically by following the increase in absorbance at 297 nm.

Table 2. Yields of solvolysis and elimination products from the reactions of 4-substituted 2,6-dimethylcumyl derivatives X-**1**-Y in 50:50 (v:v) trifluoroethanol–water at I = 0.50 ($NaClO_4$).[a]

		Yield of product		
Ring substituent X	Leaving group Y	X-**1**-OH	X-**1**-OCH_2CF_3	X–**3**
MeO	4-Methoxybenzoate [b]	31.0%	1.8%	67.2%
Me	4-Methoxybenzoate [c]	13.1%	1.2%	85.7%
	4-Nitrobenzoate [d]	13.0%	1.3%	85.7%

[a]Determined in the presence of 25 mM cacodylate buffer, 80% anion, which prevented acid-catalyzed conversion of the solvent adducts to the alkenes. Product yields were determined by HPLC analysis.

[b]Product yields were determined at room temperature, 22 ± 2°C, after 20–70 halftimes for reaction of the substrate, and were stable during this time.

[c]Product yields were determined at 25°C after 2–30 halftimes for reaction of the substrate and were stable during this time.

[d]Product yields were determined at 25°C after 5–20 halftimes for reaction of the substrate and were stable during this time.

halftimes for reaction of the substrate were extrapolated to zero time. The absolute difference between the yields of Me-**1**-OSolv (14.6%) and Me-**3** (85.4%) obtained from this extrapolation and those determined in the presence of 25 mM cacodylate buffer (Table 2) is only 0.3%. The reaction of H-**1**-(4-methoxybenzoate) in 50:50 (v:v) trifluoroethanol–water at I = 0.50 ($NaClO_4$) gave a high yield of the alkene H-**3** along with the alcohol H-**1**-OH. The yield of H-**3** was not quantified, but this alkene represented ca. 94% of the total HPLC peak area of the products.

Table 3 gives the dimensionless product rate constant ratios k_{HOH}/k_{TFE} for partitioning of X-**1**-Y between nucleophilic substitution by water and trifluoroethanol in 50:50 (v:v) trifluoroethanol–water that were calculated from the ratio of the yields of the corresponding alcohols X-**1**-OH and trifluoroethyl ethers X-**1**-OCH_2CF_3 using eq. [2]. The dimensionless product rate constant ratios k_s/k_e for partitioning of X-**1**-Y between solvolysis and elimination (Table 3) were calculated directly as the ratio of the yields of the products of these reactions using eq. [1].

The products of the reactions of X-**1**-Y in 50:50 (v:v) trifluoroethanol–water in the presence of increasing concentrations of azide ion (I = 0.50, $NaClO_4$) were determined by HPLC analysis. Table 3 gives the rate constant ratios k_{az}/k_s (M^{-1}) for partitioning of MeO-**1**-(4-methoxybenzoate) and Me-**1**-(4-nitrobenzoate) between nucleophilic substitution by azide ion and solvent that were calculated from the ratio of the yields of the azide ion adducts X-**1**-N_3 and the solvent adducts X-**1**-OSolv using eq. [3]. For Me-**1**-(4-methoxybenzoate) the reaction products had to be analyzed at long reaction times, during which the azide ion adduct was unstable and broke down to give exalted yields of the solvolysis products (see Experimental section). Therefore, the value of k_{az}/k_s (M^{-1}) determined by direct product analysis was unreliable and this rate constant ratio was obtained from nonlinear least-squares analysis of the product data (see Discussion).

Figure 1 shows the effect of increasing concentrations of azide ion on the fractional yields of the nucleophilic substitution and elimination products of the reaction of MeO-**1**-(4-methoxybenzoate) in 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$).

Figure 2 shows the effect of increasing concentrations of azide ion on the fractional yields of the nucleophilic substitution and elimination products of the reaction of Me-**1**-(4-nitrobenzoate) in 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$). The yields of the azide ion adduct Me-**1**-N_3 and the alkene Me-**3** from these reactions agreed with those from the reaction of Me-**1**-(4-methoxybenzoate) under the same conditions, within the experimental error of ±10%.

Figure 3 shows the effect of increasing concentrations of acetate ion on the fractional yields of the nucleophilic substitution and elimination products of the reaction of Me-**1**-(4-methoxybenzoate) in the presence of 0.05 M azide ion in 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$). In these experiments, the solutions were buffered with acetate, 95% anion, and there was no detectable formation of the acetate ion adduct.

[g]Dimensionless ratio of second-order rate constants for reaction of the carbocation with azide ion as a Lewis and a Brønsted base.

[h]Average of values determined at five concentrations of azide ion in the range 0.001–0.005 M.

[i]Calculated as $(k_{az}/k_s)(k_s/k_e)$.

[j]Determined from the nonlinear least-squares fit of the product data to eqs. [4] and [5], see text.

[k]Average of values determined at eight concentrations of azide ion in the range 0.005–0.300 M.

Fig. 1. Dependence of the fractional yields of the azide ion adduct MeO-**1**-N_3 (●), the solvent adducts MeO-**1**-OSolv (▼), and the alkene MeO-**3** (■) from the reaction of MeO-**1**-(4-methoxybenzoate) on the concentration of azide ion in 50:50 (v:v) trifluoroethanol–water at room temperature, 22 ± 2°C, and I = 0.50 ($NaClO_4$). For $[N_3^-] \leq 0.05$ M the solutions were buffered with 25 mM cacodylate, 80% anion. The solid lines show the nonlinear least-squares fits of the data to eqs. [4]–[6] (see text).

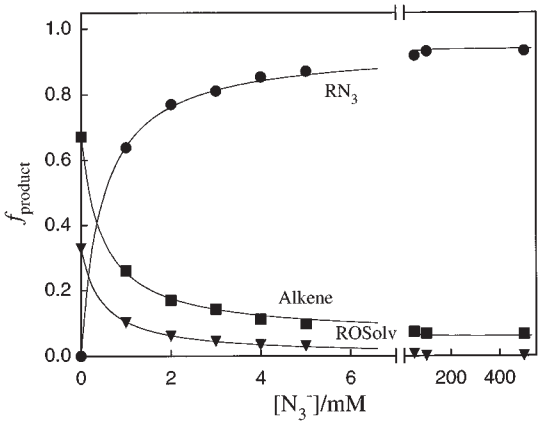

Fig. 2. Dependence of the fractional yields of the azide ion adduct Me-**1**-N_3 (●), the solvent adducts Me-**1**-OSolv (▼), and the alkene Me-**3** (■) from the reaction of Me-**1**-(4-nitrobenzoate) on the concentration of azide ion in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$). For $[N_3^-] \leq 0.05$ M the solutions were buffered with 25 mM cacodylate, 80% anion. The solid lines show the nonlinear least-squares fits of the data to eqs. [4]–[6] (see text).

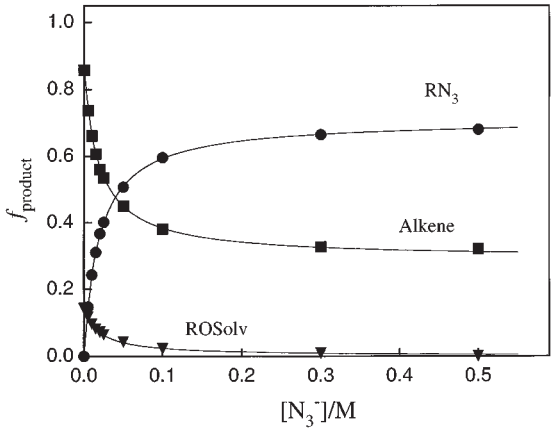

Discussion

In 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$) the ring-substituted 2,6-dimethylcumyl derivatives X-**1**-Y undergo nucleophilic substitution by solvent to give the corresponding alcohols X-**1**-OH and trifluoroethyl ethers X-**1**-OCH_2CF_3 (Table 2). However, the major products of the reactions of X-**1**-Y are those of elimination, the alkenes X-**3** (Table 2). The yield of the alkene X-**3** increases as the ring substituent at X-**1**-Y is made more electron withdrawing, from 67% for MeO-**1**-(4-methoxybenzoate) to 86% for Me-**1**-(4-methoxybenzoate) and Me-**1**-(4-nitrobenzoate) (Table 2).

Reaction mechanism

We have shown previously that the nucleophilic substitution reactions of ring-substituted cumyl 4-nitrobenzoates ($XC_6H_4CMe_2$(4-nitrobenzoate)) and the acid-catalyzed reactions of ring-substituted cumyl alcohols ($XC_6H_4CMe_2OH$) in 50:50 (v:v) trifluoroethanol–water proceed by a stepwise mechanism through cumyl carbocation intermediates, $XC_6H_4CMe_2^+$. The reactions of the 2,6-dimethylcumyl derivatives MeO-**1**-Y and Me-**1**-Y in 50:50 (v:v) trifluoroethanol–water in the presence of 0.50 M azide ion give good yields (≥67%) of the azide ion adducts X-**1**-N_3 at the expense of both the solvent adducts X-**1**-OSolv and the alkenes X-**3** (Figs. 1 and 2). The absence of any increases in k_{obsd} for these reactions in the presence of azide ion (Table 1), and the identical yields of the substitution and elimination products from the reactions of Me-**1**-(4-methoxybenzoate) and

Scheme 2.

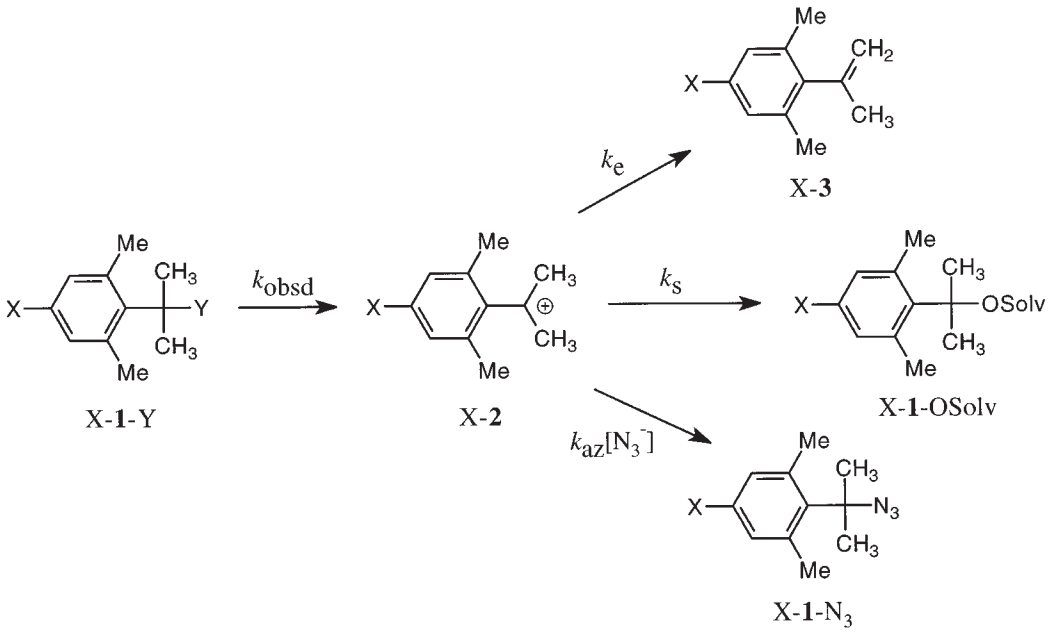

Fig. 3. Dependence of the fractional yields of the alkene Me-**3** (■), the azide ion adduct Me-**1**-N_3 (●), and the solvent adducts Me-**1**-OSolv (▼) from the reaction of Me-**1**-(4-methoxybenzoate) on the concentration of acetate ion in the presence of 0.05 M azide ion in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$). The solutions were buffered with acetate, 95% anion.

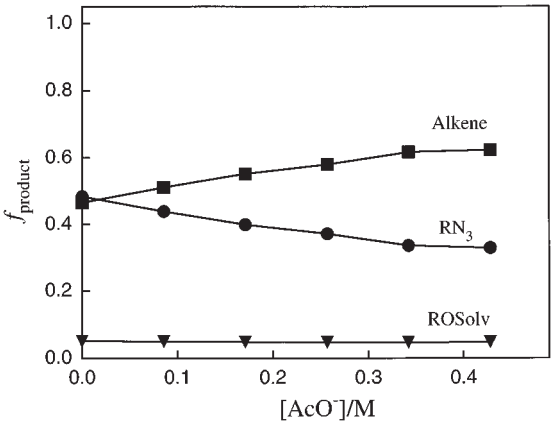

Me-**1**-(4-nitrobenzoate), which have different leaving groups, provide strong evidence that X-**1**-Y also react by a stepwise $D_N + A_N$ (S_N1) (16) mechanism through the liberated 2,6-dimethylcumyl carbocations X-**2** (Scheme 2). Similarly, the elimination reactions of H-**1**-(trifluoroacetate) in acetic acid and trifluoroethanol have been reported to proceed by a stepwise mechanism through the 2,6-dimethylcumyl carbocation H-**2**, which undergoes proton loss to give the alkene H-**3** as the sole product (5). Therefore, the rate constant ratios k_{az}/k_s (M^{-1}) and k_s/k_e for the reactions of X-**1**-Y that were determined by product analysis (Table 3) represent rate constant ratios for partitioning of the 2,6-dimethylcumyl carbocation intermediates X-**2** between nucleophilic addition of azide ion and solvent to the benzylic carbon, and nucleophilic addition of solvent and deprotonation, respectively (Scheme 2).

Effect of *ortho*-methyl groups on the formation of cumyl carbocations

The effects of *ortho* substituents on the reactivity of aromatic substrates are difficult to interpret because their close proximity to the reaction site may result in gross changes in the energy of the ground state and (or) the transition state that are not related to the polar and resonance effects of these substituents (6–8).

Table 4 gives relative rate constants for the stepwise reactions of ring-substituted cumyl 4-nitrobenzoates (data from previous work (1)[2]) and the corresponding 2,6-dimethylcumyl 4-nitrobenzoates (data from this work) in 50:50 (v:v) trifluoroethanol–water. The data show that the addition of a pair of *ortho*-methyl groups to $XC_6H_4CMe_2Y$ results in relatively small (<5-fold) changes in the rate constant for cleavage of the substrate to give the corresponding carbocation. This is surprising, because the simple expectation is that *ortho*-methyl substituents should result in large increases in the rate constant for carbocation formation, as a result of both electron donation from the *ortho* methyl groups and increased steric crowding at the sp^3-hybridized benzylic carbon in the ground state that is relieved on moving towards sp^2-hybridization in the transition state. A crude analysis, based on the assumption that the effect of each *ortho*-methyl group is the same as that of a 4-Me group at $XC_6H_4CMe_2Y$, suggests that formation of the 2,4,6-trimethylcumyl carbocation Me-**2** from Me-**1**-Y should be ca. $(40)^2$ = 1600-fold faster than the formation of 4-$MeC_6H_4CMe_2^+$ from 4-$MeC_6H_4CMe_2Y$. However, although the solvolyses of both benzyl chloride and 1-phenylethyl chloride are accelerated by the addition of an *ortho*-methyl group, for both compounds the effect is ca. 2-fold smaller than the effect of a 4-Me group (17). This suggests that any steric or other un-

Table 4. Relative rate constants, k_{rel}, for the reactions of ring-substituted cumyl 4-nitrobenzoates and the corresponding 2,6-dimethylcumyl 4-nitrobenzoates in 50:50 (v:v) trifluoroethanol–water.[a]

Ring substituent	k_{rel} Cumyl	k_{rel} 2,6-Dimethylcumyl	2,6-Me_2/2,6-H_2[b]
4-MeO	1840[c]	1150[d]	0.63
4-Me	39[e]	65[f]	1.7
4-H	1	4.4[d]	4.4

[a]At 25°C and I = 0.50 ($NaClO_4$). Relative rate constants are normalized to k_{obsd} = 4.9 × 10^{-5} s^{-1} for the reaction of cumyl 4-nitrobenzoate that was determined by interpolation of the data in Fig. 4 (T. L. Amyes. Unpublished results).

[b]Ratio of rate constants for reaction of 2,6-dimethylcumyl and cumyl 4-nitrobenzoates with the same aromatic ring substituent.

[c]k_{obsd} = 0.09 s^{-1} (1).

[d]Calculated from data for 2,6-dimethylcumyl 4-methoxybenzoates (Table 1) with the assumption that the change to a 4-nitrobenzoate leaving group results in the same 9.7-fold increase in k_{obsd} as that observed for Me-**1**-(4-methoxybenzoate) (Table 1).

[e]k_{obsd} = 1.9 × 10^{-3} s^{-1} (T.L. Amyes. Unpublished results).

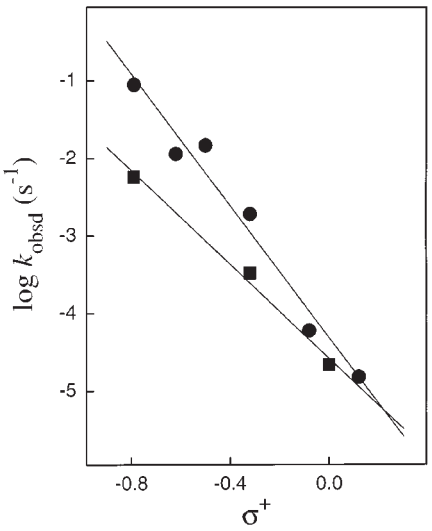
[f]Calculated from data in Table 1.

usual *ortho* effects (6–8) associated with the addition of a single *ortho*-methyl group to 1-phenylethyl chloride are small. Therefore, if the effects of *ortho*-methyl groups at $XC_6H_4CMe_2Y$ are additive, the cleavage of Me-**1**-Y to give Me-**2** is expected to be $(40/2)^2$ = 400-fold faster than the cleavage of 4-$MeC_6H_4CMe_2Y$ to give 4-$MeC_6H_4CMe_2^+$. The observation that the formation of Me-**2** is only 1.7-fold faster than the formation of 4-$MeC_6H_4CMe_2^+$ (Table 4) suggests there is an offsetting 240-fold *decrease* in the rate of carbocation formation due to an *ortho* effect. Similar analyses for the formation of MeO-**2** and H-**2** suggest that the cleavage reactions of MeO-**1**-Y and H-**1**-Y are 630-fold and 90-fold slower, respectively, than expected on the basis of additivity of the effects of *ortho*-methyl groups. The origin of these large effects is undoubtedly adverse steric interactions between the *ortho*-methyl groups and the α-methyl groups at the benzylic carbon in the carbocations X-**2** and in the transition state leading to their formation. These steric interactions are expected to lead to significant decreases in coplanarity and overlap of the π-orbitals of the aromatic ring with the empty *p*-orbital at the benzylic carbon of X-**2**, resulting in a decrease in the resonance stabilization of X-**2** and increases in the energy of both these carbocations and the transition state leading to their formation. Such effects have long been recognized and termed "steric inhibition of resonance" (11, 18). Consistent with this, the addition of a pair of *ortho*-methyl groups to the less sterically congested 1-phenylethyl derivatives should result in a smaller degree of "steric inhibition," and the solvolysis of 1-(2,4,6-trimethylphenyl)ethyl chloride is only 5-fold slower than expected on the basis of additivity of the effects of *ortho*-methyl groups at 4-$MeC_6H_4CH(Me)Cl$ (17).

Structure–reactivity correlations

The data in Table 4 show that there is a 7-fold decrease in the *relative* rate constant for cleavage of X-**1**-Y and the corresponding $XC_6H_4CMe_2Y$ in 50:50 (v:v) trifluoroethanol–water as the aromatic substituent X is made more electron donating. In fact, the addition of two electron-donating *ortho*-methyl groups to 4-$MeOC_6H_4CMe_2Y$ to give MeO-**1**-Y actually leads to a 1.6-fold *decrease* in the rate constant for cleavage of the substrate to give the corresponding carbocation! Figure 4 shows the Hammett correlation of k_{obsd} for the reaction of ring-substituted cumyl 4-nitrobenzoates in 50:50 (v:v) trifluoroethanol–water (data from previous work (1)[2]) with σ^+ substituent constants (19) and the correlation of the more limited set of data from this work for the reactions of 2,6-dimethylcumyl 4-methoxybenzoates in the same solvent (Table 1). The data are correlated by ρ^+ = –4.3 for the reactions of $XC_6H_4CMe_2$(4-nitrobenzoate) and by a somewhat smaller value of ρ^+ = –3.0 for the reactions of X-**1**-(4-methoxybenzoate). Decreased Hammett ρ values and small Yukawa–Tsuno *r* values have been observed for the solvolysis reactions of benzyl derivatives substituted with very bulky alkyl groups at the α-carbon (20).

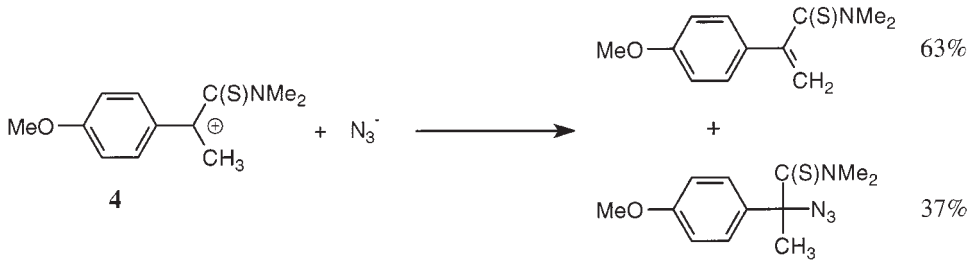
Fig. 4. Logarithmic correlations of observed first-order rate constants, k_{obsd} (s^{-1}), for the reactions of ring-substituted cumyl 4-nitrobenzoates (●, data from previous work (1)[2]) and 4-substituted 2,6-dimethylcumyl 4-methoxybenzoates (■, data from Table 1) in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$) with Hammett σ^+ substituent constants (19). The slopes of the plots give ρ^+ = –4.3 for cumyl 4-nitrobenzoates and ρ^+ = –3.0 for 2,6-dimethylcumyl 4-methoxybenzoates.



The substantial negative value of ρ^+ = –3.0 for the reactions of X-**1**-Y shows that, despite the above estimated 630-fold decrease in the rate constant for formation of MeO-**2** resulting from decreased overlap between the π-orbitals of the aromatic ring and the developing empty p-orbital at the benzylic carbon, the 4-MeO group results in a significant 3.3 kcal/mol stabilization of the transition state for carbocation formation from X-**1**-Y (Table 4). For the corresponding simple cumyl system, the addition of a 4-MeO group results in stabilization of the transition state for carbocation formation by 4.4 kcal/mol (Table 4). Therefore, only 25% of the stabilization of the transition state for formation of $XC_6H_4CMe_2^+$ from $XC_6H_4CMe_2Y$ by resonance delocalization of positive charge at the benzylic carbon onto the 4-MeO group is lost as a result of the increased steric requirements of the *ortho*-methyl groups in the transition state for formation of X-**2** from X-**1**-Y. The crystal structure of

© 1999 NRC Canada

Scheme 3.



$C_6H_5CMe_2^+ \cdot SbF_6^-$ shows that the cumyl carbocation is almost completely planar: the aromatic ring is twisted out of the plane of the benzylic carbon by only 8° (21). By contrast, the small value of λ_{max} for the 2,4,6-trimethylcumyl carbocation suggests that there is considerable twisting about the bond between the aromatic ring and the benzylic carbon in this carbocation (11). Our results suggest that, despite the nonplanar structures of X-**2**, electron-donating aromatic substituents can provide substantial resonance stabilization of these carbocations.

Mechanism of elimination reactions of *ortho*-dimethylcumyl derivatives

Figures 1 and 2 show that the addition of azide ion results in the formation of good yields of the azide ion adducts X-**1**-N_3 from the stepwise reactions of MeO-**1**-(4-methoxybenzoate) and Me-**1**-(4-nitrobenzoate) in 50:50 (v:v) trifluoroethanol–water (I = 0.50, $NaClO_4$). At high concentrations of azide ion, the yields of the solvent adducts X-**1**-OSolv approach zero, as required by the mechanism shown in Scheme 2. By contrast, the yields of the alkenes decrease to essentially constant limiting values of 7% MeO-**3** from the reaction of MeO-**1**-(4-methoxybenzoate) (Fig. 1) and 32% Me-**3** from the reactions of Me-**1**-(4-nitrobenzoate) (Fig. 2) and Me-**1**-(4-methoxybenzoate) (data not shown). The simple mechanism shown in Scheme 2, in which the solvent and azide ion adducts and the alkenes are formed by partitioning of a common carbocation intermediate, requires that, like the solvent adducts, the yields of the alkenes also approach zero in the presence of high concentrations of azide ion. However, the results show that only 93% of the reaction of MeO-**1**-Y and 68% of the reaction of Me-**1**-Y proceed through the liberated carbocation intermediate X-**2** that can be trapped by nucleophilic addition of azide ion. The remainder proceeds through an additional pathway that results in formation of the alkenes X-**3**. There are several mechanistic possibilities for this additional pathway for the elimination reactions of X-**1**-Y to give the alkenes X-**3**.

Mechanism 1: The substrates X-1-Y undergo concerted elimination

The constant limiting yields of the alkenes X-**3** in the presence of high concentrations of azide ion may result from a concerted elimination reaction of X-**1**-Y that bypasses the carbocation intermediate of the stepwise reaction and has an observed rate constant that is independent of the concentration of added azide ion (3). This possibility can be excluded because the quantitative elimination reaction of H-**1**-(trifluoroacetate) in acetic acid has been shown to proceed by a stepwise mechanism through the carbocation H-**2** (5). The change in solvent from acetic acid (Y = –1.64) (22) to the more ionizing solvent of 50:50 (v:v) trifluoroethanol–water ($Y \approx 2.0$)[3] used in this work is expected to increase rather than decrease the importance of the stepwise reaction pathway through the carbocations X-**2**.[4]

Mechanism 2: The carbocations X-2 undergo proton transfer to the leaving group within an ion pair intermediate

The carbocation-leaving group ion-pair intermediates of the reactions of ring-substituted cumyl derivatives are too shortlived to undergo trapping by azide ion because they undergo fast diffusional separation to give the free ions (24, 25). Therefore, any proton transfer from the carbocation to the leaving group within the ion pairs X-**2**$\cdot Y^-$ would provide a pathway for formation of the alkenes X-**3** that is insensitive to added azide ion. The yields of α-methylstyrenes from the ion-pair intermediates of the reactions of ring-substituted cumyl 4-nitrobenzoates with electron-donating substituents are negligible (3). Therefore, this possibility would require that the addition of a pair of *ortho*-methyl groups to ring-substituted cumyl derivatives result in a large increase in the rate constant for proton transfer from the carbocation to the leaving group within an ion pair, relative to that for diffusional separation of the ion pair to give the free carbocation. It is difficult to exclude rigorously the formation of small amounts of the alkenes X-**3** from deprotonation within an ion-pair intermediate. However, the observation of identical limiting yields of 32% Me-**3** from the reactions of Me-**1**-(4-nitrobenzoate) and Me-**1**-(4-methoxybenzoate) with leaving groups of different basicities provides strong evidence against the formation of large amounts of Me-**3** from proton transfer to the leaving group within an ion-pair intermediate.

Mechanism 3: The carbocations X-2 react with azide ion as both a Brønsted and a Lewis base

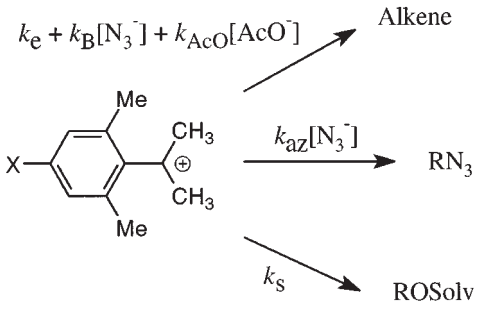
Azide ion usually undergoes reaction with α-methylbenzyl carbocations exclusively as a nucleophile (Lewis base). However, we have recently shown that the α-thioamide substituted 4-methoxybenzyl carbocation **4** reacts with azide ion in 50:50 (v:v) methanol–water predominantly as a Brønsted

[3] Calculated by linear interpolation of the values of Y = 2.23 and 1.89 for 50:50 (w:w) and 60:40 (w:w) trifluoroethanol–water, respectively (23), to 58:42 (w:w) trifluoroethanol–water which corresponds to 50:50 (v:v) trifluoroethanol–water.

[4] A change to a more ionizing solvent results in a smaller increase in the rate constant for concerted pericyclic elimination of simple cumyl derivatives with electron-withdrawing ring substituents than in the rate constant for the concurrent solvolysis reaction (3).

© 1999 NRC Canada

Scheme 4.



base (63% deprotonation) rather than a Lewis base (37% nucleophilic addition, Scheme 3) (2). In the absence of azide ion, **4** undergoes loss of a proton to solvent to give the corresponding alkene as the only detectable product ($k_s/k_e \leq 0.01$) (2). This surprising reactivity of azide ion as a Brønsted base was attributed to the large stability of the corresponding α-thioamide substituted alkene relative to the nucleophile adducts, and the resulting strong tendency of **4** to undergo loss of a proton rather than nucleophilic capture (2).

The values of $k_s/k_e = 0.49$ for partitioning of MeO-**2** and $k_s/k_e = 0.17$ for partitioning of Me-**2** in 50:50 (v:v) trifluoroethanol–water (Table 3) are much smaller than $k_s/k_e > 100$ for the partitioning of simple cumyl carbocations $XC_6H_4CMe_2^+$ between addition of solvent to the benzylic carbon and deprotonation in the same solvent (3, 4). Therefore, the 2,6-dimethylcumyl carbocations X-**2** also show an unusual tendency to undergo loss of a proton to solvent rather than nucleophilic capture at the benzylic carbon. We propose that the constant limiting yields of the alkenes X-**3** observed in the presence of high concentrations of azide ion result from reaction of azide ion with the carbocations X-**2** as a Brønsted rather than a Lewis base (k_B, Scheme 4).

The solid lines in Figs. 1 and 2 show that there is a good fit of the observed product yields for the reactions of MeO-**1**-(4-methoxybenzoate) and Me-**1**-(4-nitrobenzoate) to eqs. [4]–[6], which were derived for the mechanism shown in Scheme 4, using the values of k_s/k_e and k_{az}/k_e (M^{-1}) = $(k_{az}/k_s)(k_s/k_e)$ that were determined directly from product analysis (Table 3). The nonlinear least-squares fits of the product data to eqs. [4] and [5] gave $k_B/k_e = 191 \pm 12$ M^{-1} and 17.4 ± 0.2 M^{-1} for the partitioning of MeO-**2** and Me-**2** between deprotonation by azide ion and by solvent, respectively. These rate constant ratios were combined with the values of k_{az}/k_e (M^{-1}) to give values of $k_{az}/k_B = (k_{az}/k_e)(k_e/k_B)$ for partitioning of X-**2** between reaction with azide ion as a nucleophile and as a Brønsted base (Table 3). For the reactions of Me-**1**-(4-methoxybenzoate), the value of k_{az}/k_s (M^{-1}) determined directly from product analysis was unreliable (see Results). Therefore the product data were fitted to eqs. [4] and [5] using the only the observed value of k_s/k_e (Table 3) to give values of $k_{az}/k_e = 42$ M^{-1}, $k_B/k_e = 19$ M^{-1}, and $k_{az}/k_s = (k_{az}/k_e)(k_e/k_s) = 250$ M^{-1}, which are in good agreement with those for partitioning of Me-**2** generated from the cleavage of Me-**1**-(4-nitrobenzoate) (Table 3).

$$[4] \qquad f_{alk} = \frac{1 + (k_B/k_e)[N_3^-]}{1 + (k_s/k_e) + (k_B/k_e + k_{az}/k_e)[N_3^-]}$$

$$[5] \qquad f_{az} = \frac{(k_{az}/k_e)[N_3^-]}{1 + (k_s/k_e) + (k_B/k_e + k_{az}/k_e)[N_3^-]}$$

$$[6] \qquad f_{solv} = \frac{(k_s/k_e)}{1 + (k_s/k_e) + (k_B/k_e + k_{az}/k_e)[N_3^-]}$$

The rate constant ratio for partitioning of the α-thioamide substituted 4-methoxybenzyl carbocation **4** between reaction with azide ion as a nucleophile and a Brønsted base, $k_{az}/k_B = 0.59$ (2), is 27-fold smaller than $k_{az}/k_B = 15.9$ for the presumably much more hindered carbocation MeO-**2**. This suggests that the unusual reactivity of azide ion as Brønsted base for deprotonation of X-**2** is not due simply to steric hindrance to nucleophilic attack at the benzylic carbon, because this should be less favored for MeO-**2** than for **4**.

The pK_a's of acetic acid (4.76) and hydrazoic acid (4.72) are similar (26), so that acetate and azide ions would be expected to show similar reactivities as Brønsted bases for deprotonation of X-**2**. We determined the relative reactivity of azide and acetate ions as general bases for the deprotonation of Me-**2** from the effect of increasing concentrations of acetate ion (0.086–0.430 M) on the product distribution for the reaction of Me-**1**-(4-methoxybenzoate) in 50:50 (v:v) trifluoroethanol–water in the presence of a fixed concentration of azide ion (0.05 M) at $I = 0.50$ ($NaClO_4$). Figure 3 shows that increases in the concentration of acetate ion result in increases in the fractional yield of the alkene Me-**3** at the expense of the azide ion adduct Me-**1**-N_3. The constant yields of the solvent adducts Me-**1**-OSolv in the presence of increasing concentrations of acetate ion is not expected on the basis of the mechanism of Scheme 4, but it can be attributed to general base catalysis by acetate ion of the nucleophilic addition of solvent to the carbocation (27, 28). Acetate ion is less nucleophilic towards carbocations than azide ion (14) and there was no detectable formation of the acetate ion adduct in these experiments. Conversely, the very high reactivity of azide ion as a nucleophile towards unstable carbocations (29, 30) precludes the observation of general base catalysis by azide ion of the addition of solvent to Me-**2**. Figure 5 shows that the *ratio* of the fractional yields of the alkene Me-**3** and the azide ion adduct Me-**1**-N_3 formed in these experiments, f_{alk}/f_{az}, shows a linear dependence on the concentration of added acetate ion, according to eq. [7], derived for the mechanism shown in Scheme 4. The solid line through the data in Fig. 5 is the least-squares fit to eq. [7] with slope $(k_{AcO}/k_{az}[N_3^-]) = 2.29$ M^{-1} ($r = 0.992$), which gives $k_{AcO}/k_{az} = (2.29\ M^{-1} \times 0.05\ M) = 0.115$. This was combined with the average value of $k_{az}/k_B = 2.3$ from Table 3 to give $k_B/k_{AcO} = 3.8$ as the relative reactivities of azide and acetate ions as Brønsted bases for deprotonation of Me-**2**. A very similar 4.5-fold greater reactivity of azide than of acetate ion was determined for deprotonation of the α-thioamide substituted 4-methoxybenzyl carbocation **4** (2).

$$[7] \qquad f_{alk}/f_{az} = \left(\frac{k_B[N_3^-] + k_e}{k_{az}[N_3^-]}\right) + \left(\frac{k_{AcO}}{k_{az}[N_3^-]}\right)[AcO^-]$$

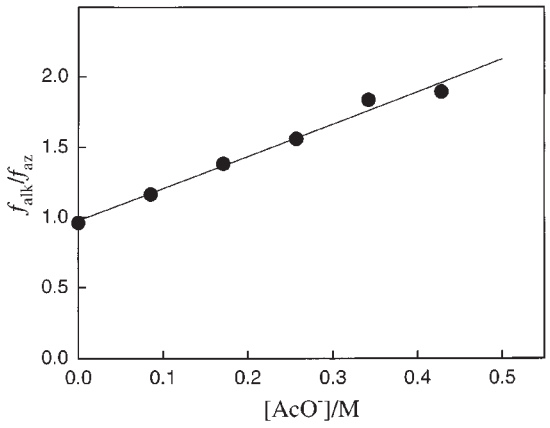
[a]At room temperature 22 ± 2°C. Rate constants are upper limits calculated from the rate constant ratios in Table 3 using values of $(k_{az} + k_B) \leq 5 \times 10^9$ M^{-1} s^{-1} and k_{az}/k_B = 15.9, see text.

[b]Calculated from the rate constant ratios in Table 3 using $(k_{az} + k_B) = 5 \times 10^9$ M^{-1} s^{-1} and the average value of k_{az}/k_B = 2.3, see text.

[c]Calculated from k_{az}/k_s = 5 M^{-1} (31) and $k_{az} = 5 \times 10^9$ M^{-1} s^{-1} for the diffusion limited reaction of azide ion with unstable carbocations, see text.

[d]Calculated from k_e/k_s = 0.0014 determined from product analysis of the acid-catalyzed cleavage of 4-methylcumyl methyl ether (T. L. Amyes. Unpublished results).

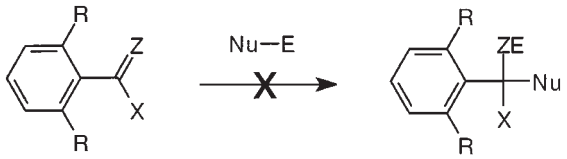
Fig. 5. Dependence of the ratio of the fractional yields of the alkene Me-**3** and azide ion adduct Me-**1**-N_3 from the reaction of Me-**1**-(4-methoxybenzoate), f_{alk}/f_{az}, on the concentration of acetate ion in the presence of 0.05 M azide ion in 50:50 (v:v) trifluoroethanol–water at 25°C and I = 0.50 ($NaClO_4$). The solutions were buffered with acetate, 95% anion. The solid line shows the least-squares fit of the data to eq. [7]. The slope of this line is $k_{AcO}/k_{az}[N_3^-]$ = 2.29 M^{-1} (r = 0.992) for partitioning of the carbocation Me-**2** between deprotonation by acetate ion and nucleophilic addition of azide ion (see text).



Effect of *ortho*-methyl groups on the reactions of cumyl carbocations

The azide ion selectivities k_{az}/k_s (M^{-1}) for nucleophilic capture of the 2,6-dimethylcumyl carbocations MeO-**2** and Me-**2** by azide ion and a solvent of 50:50 (v:v) trifluoroethanol–water (Table 3) are significantly larger than the corresponding values of k_{az}/k_s = 380 M^{-1} (1, 31) and 5 M^{-1} (31) for the corresponding simple cumyl carbocations 4-$MeOC_6H_4CMe_2^+$ and 4-$MeC_6H_4CMe_2^+$, respectively, which shows that X-**2** are moderately selective carbocations. The reaction of azide ion with a range of unstable α-substituted 4-methoxybenzyl carbocations in 98:2 (v:v) trifluoroethanol–water is diffusion controlled, with $k_{az} = 5 \times 10^9$ M^{-1} s^{-1} (29), and the rate constant for reaction of azide ion with ring-substituted triarylmethyl carbocations in 1:2 (v:v) acetonitrile–water does not drop significantly below this value until the azide/solvent selectivities become larger than $k_{az}/k_s \approx 10^4$ M^{-1} (30). This diffusion-limited reaction of azide ion with carbocations acts as a "clock" for other reactions of the carbocation (15, 32, 33). Therefore, the values of k_{az}/k_B, k_{az}/k_s (M^{-1}), and k_{az}/k_e (M^{-1}) for the partitioning of Me-**2** (Table 3) can be combined with $(k_{az} + k_B) = 5 \times 10^9$ M^{-1} s^{-1} for the diffusion-controlled reaction of azide ion (29, 30) to give the absolute values of k_B, k_s, and k_e for the reactions of Me-**2** given in Table 5. The large value of k_{az}/k_s = 6200 M^{-1} for partitioning of MeO-**2** is approaching the azide/solvent selectivity at which the reactions of triarylmethyl carbocations with azide ion drop below the diffusion limit, and a value of $k_{az} = 4 \times 10^9$ M^{-1} s^{-1} has been determined for the reaction of azide ion with 4-$MeOC_6H_4CMe_2^+$ (29). Therefore, the partitioning ratios for MeO-**2** (Table 3) were combined with $(k_{az} + k_B) \leq 5 \times 10^9$ M^{-1} s^{-1} to give the upper limits on the absolute rate constants for the reactions of MeO-**2** given in Table 5.

Scheme 5.



5 **6**

The data in Table 5 show that the effect of the pair of *ortho*-methyl groups on the *overall* reactivity of Me-**2** is small: a 10-fold decrease in $(k_s + k_e)$ compared with the simple 4-methylcumyl carbocation. However, the addition of a pair of *ortho*-methyl groups to 4-$MeC_6H_4CMe_2^+$ to give Me-**2** results in a larger 70-fold decrease in k_s for nucleophilic capture by solvent of the carbocation at the benzylic carbon (Table 5) and a 60-fold *increase* in k_e for deprotonation of the carbocation by solvent. The steric requirements of proton transfer from the β-carbon of Me-**2** should be similar to those for deprotonation of 4-$MeC_6H_4CMe_2^+$. Therefore, the greater reactivity of Me-**2** than of 4-$MeC_6H_4CMe_2^+$ towards proton transfer suggests that, relative to the corresponding alkenes, 2,6-dimethylcumyl carbocations are intrinsically less stable than simple cumyl carbocations. This decreased stability of X-**2** relative to X-**3** is very likely due to a nonplanar conformation of these species in which overlap between the π-orbitals of the aromatic ring and the *p*-orbital at the sp^2-hybridized benzylic carbon is decreased relative to that at $XC_6H_4CMe_2^+$ and ring-substituted α-methylstyrenes. This would tend to increase the energy of X-**2** relative to X-**3**, because there is more demand for resonance stabilization of the positive charge at the benzylic carbon of X-**2** than of the alkene double bond at X-**3**. The very low extinction coefficient of Me-**3** (220 M^{-1} cm^{-1}, this work) provides strong

© 1999 NRC Canada

evidence that the alkene double bond is twisted out of the plane of the aromatic ring by a considerable amount (34), and the UV spectrum of Me-**3** resembles that of benzene rather than an α-methylstyrene (11).

Formation of *ortho*-methyl cumyl derivatives

The very large yield of 93% of the products of nucleophilic substitution from the reaction of MeO-**1**-(4-methoxybenzoate) in the presence of high concentrations of azide ion (Fig. 1) represents, to the best of our knowledge, the first example of the formation of stable products of the addition of nucleophiles to disubstituted sp^2-hybridized carbon attached to a 2,6-disubstituted aryl moiety. Compounds of general structure **5** are known to be extremely unreactive (35) and 2,6-disubstituted α-methylstyrenes (**5**, X = CH_3, Z = CH_2) are inert to addition across the olefinic double bond (11, 12) (Scheme 5). For example, Me-**3** reacts with bromine to give the products of electrophilic substitution rather than addition (36, 37), and it does not undergo polar addition of hydrogen chloride (12) or radical addition of 1-butanethiol (34). The observations that the basic hydrolysis of methyl 2,4,6-trimethylbenzoate proceeds by the usual attack of hydroxide ion at the carbonyl carbon (38), and that the acid-catalyzed hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether proceeds by the normal mechanism involving nucleophilic attack of water at the benzylic carbon of the oxocarbenium ion intermediate (39), show that nucleophilic attack at the benzylic carbon of species of general structure **5** is not prohibited. However, in both of these cases, the ultimate product is itself of general structure **5** rather than the more sterically congested **6**. Our results suggest that the apparent inaccessibility of species of general structure **6** results primarily from their much smaller thermodynamic stability relative to **5**, so that **6** can be formed only when the reaction conditions do not permit for its rapid conversion to the more stable and sterically less congested **5**.

The hydration of ketene and carbon dioxide: an examination of the kinetics in terms of No Barrier Theory

J. Peter Guthrie

Abstract: Rate constants for hydration of carbon dioxide and ketene can be calculated by applying No Barrier Theory, which needs only equilibrium constants and distortion energies, the latter calculated using molecular orbital theory. The calculated free energies of activation are in satisfactory agreement with experiment: the rms error in free energy of activation is 2.38 kcal/mol. These compounds can also be described using Marcus Theory or Multidimensional Marcus Theory using the transferable intrinsic barrier appropriate to simple carbonyl compounds; in this case the rms error in free energy of activation is 2.19 kcal/mol. The two methods agree on preferred mechanistic path except for uncatalyzed hydration of ketene where Multidimensional Marcus Theory leads to a lower activation free energy for addition to the C=O, while No Barrier Theory leads to a lower free energy of activation for addition to the $C=CH_2$. A rate constant for hydroxide ion catalyzed hydration of ketene can be calculated and is in accord with preliminary experimental results.

Key words: ketene, carbon dioxide, hydration, Marcus Theory, No Barrier Theory.

Résumé : On a calculé les constantes de vitesse d'hydratation du dioxyde de carbone et du cétène en utilisant la théorie sans barrière qui ne nécessite que les constantes d'équilibre et les énergies de distorsion; ces dernières sont calculées par la théorie des orbitales moléculaires. Les énergies libres d'activation calculées sont en bon accord avec les valeurs expérimentales : l'erreur sur l'énergie libre d'activation est de 2,38 kcal/mol. On peut aussi décrire ces composés à l'aide de la théorie de Marcus ou de la théorie multidimensionnelle de Marcus en utilisant la barrière intrinsèque transférable appropriée aux composés carbonylés simples; dans ce cas, l'erreur sur l'énergie libre d'activation est de 2,19 kcal/mol. À l'exception de l'hydratation non catalysée du cétène pour laquelle la théorie multidimensionnelle de Marcus conduit à une énergie libre d'activation plus faible pour l'addition au groupe C=O alors que la théorie sans barrière conduit à une énergie d'activation plus faible pour l'addition sur le $C=CH_2$, les deux méthodes sont concordantes en ce qui a trait à la voie mécanistique préférée. On peut calculer une constante de vitesse pour l'hydratation du cétène catalysée par l'ion hydroxyde et elle est en accord avec les résultats expérimentaux préliminaires.

Mots clés : cétène, dioxyde de carbone, hydratation, théorie de Marcus, théorie sans barrière.

[Traduit par la Rédaction]

Introduction

Ketene is a highly reactive molecule, which undergoes very facile hydration. It has only recently become possible to measure the rate constants for this reaction in aqueous solution (1, 2). Carbon dioxide, a closely analogous molecule, has long been studied because of its biological importance (3, 4). We have recently reported an analysis of the hydration of carbonyl compounds in terms of No Barrier Theory (5). I wish now to report an application of this theory to the hydration of ketene and carbon dioxide. Ketene shows an interesting switch in mechanism from C-protonation in acidic or neutral solution to carbonyl hydration in basic solution. This paper will demonstrate that both the mechanistic path, and the absolute value of the free energies of activation, follow directly from application of No Barrier Theory to these reactions. The rate constant for the hydroxide-catalyzed hydration of ketene will also be predicted.

No Barrier Theory is a recent development (6, 7), following in the spirit of Marcus Theory (8–10), but requiring no intrinsic barrier. The idea is that if only one thing happens in a reaction, then there is no kinetic barrier: the common observation of an intrinsic kinetic barrier is a consequence of almost all reactions requiring more than one thing to happen in the rate- determining step to produce an observable chemical change. For additions of a nucleophile to a simple carbonyl compound, the two simple things are formation of a bond between nucleophile and carbon and change in geometry at carbon from sp^2 to sp^3.

Table 1. Thermodynamic quantities for compound discussed in this paper.[a]

(*a*) Compounds for which ΔG_f(aq) has not previously been reported.

Compound	ΔH_f(g)	$S°$(g)	ΔG_f(g)[b]	ΔG_t	ΔG_f(aq)
CH_2=C=O	–11.40 ± 0.60[c]	59.18 ± 0.06[c]	–11.59 ± 0.60[c]	+1.95 ± 1.00	–9.64 ± 1.16
$CH_3C{\equiv}O^+$					–14.10 ± 3.00[d]

(*b*) Compounds for which ΔG_f(aq) has previously been reported.

Compound	ΔG_f(aq)	Compound	ΔG_f(aq)	+Compound	ΔG_f(aq)
H_2O	–56.69 ± 0.01[c]	CH_3COOH	–94.35 ± 0.06[e]	CO_2	–92.25 ± 0.06[c]
HO^-	–37.58 ± 0.01[c]	CH_2=$C(OH)_2$	–67.90 ± 1.67[f]	$CO(OH)_2$	–145.13 ± 0.09[g]
				HCO_3^-	–140.24 ± 0.06[c]

[a]All at 25°C; enthalpies and free energies are in kcal/mol, entropies are in cal deg^{-1} mol^{-1}, standard states are the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, enthalpies of formation are from ref. 12, entropies are from ref. 13, free energies of formation in the gas phase are calculated from the corresponding enthalpies of formation and the standard entropies, and free energies of formation in aqueous solution are calculated from the corresponding free energies of formation in the gas and free energies of transfer.

[b]Free energy of transfer from the gas at 1 atm to 1 M aqueous solution.

[c]Reference 14; errors are stated to be between 8 and 80 in the last figure given in these tables (in kJ/mol). The geometric mean, 25, was used to calculate numerical values of these limits.

[d]Calculated as described in the text.

[e]Reference 15.

[f]Reference 16.

[g]Calculated from the free energy of formation of aqueous CO_2, and the equilibrium constant for hydration (3).

It was found in this work that Multidimensional Marcus Theory (11), using the average intrinsic barriers that worked well for all but the most reactive carbonyl compounds, led to satisfactory predictions for ketene or CO_2. No Barrier Theory also permitted calculation of the rate constants for these reactions with similar precision and no empirical parameters.

No Barrier Theory requires molecular orbital calculations to evaluate distortion energies, but gives satisfactory results at much lower levels of theory than are required for direct calculation of transition state structures and energies.

Results

First, Multidimensional Marcus Theory will be applied to the hydration reactions of ketene and carbon dioxide. Then No Barrier Theory in the form that successfully described simple carbonyl compounds (5) will be employed. For both of these treatments we require equilibrium constants for the overall reactions and for various proton transfer equilibria involved in the mechanisms. For No Barrier Theory we will also require various distortion energies.

We first require free energies of formation for the various species involved. For CO_2 these are readily available: see Table 1. For ketene, the enthalpy of formation (14) and the standard entropy (14) have been reported for the molecule in the ideal gas standard state. Naturally enough there is no value for the free energy of transfer of ketene from the gas phase to aqueous solution, so we must estimate this quantity. We do so starting with the free energies of transfer from the gas phase to aqueous solution of carbon dioxide, ΔG_t = 2.00 kcal/mol (14), and allene, for which the value was assumed to be the same as that for acetylene, ΔG_t = 1.89 kcal/mol (15), since the solubilities of acetylene and allene in propylene carbonate (which is the only solvent for which solubility data for allene could be found) are very similar (17), and more similar than the solubilities of allene and propyne, which might have been assumed to be isosteric. Thus the approach is to use the hypothetical disproportionation reaction [1], for which it is assumed that the total free energies of transfer for the products and reactants are the same.

[1] $O{=}C{=}O + H_2C{=}C{=}CH_2 \rightleftharpoons H_2C{=}C{=}O + H_2C{=}C{=}O$

From the free energies of transfer of carbon dioxide, 2.00 kcal/mol, and allene, 1.89 kcal/mol, a value of 1.95 kcal/mol for ketene was estimated, and assigned an uncertainty of ±1.0 kcal/mol.

This estimated free energy of transfer leads to a value of –9.64 ± 1.16 kcal/mol[2] for the free energy of formation of aqueous ketene. We previously reported (18) the free energy of formation of ketene hydrate (acetic acid enol) in aqueous solution as –67.90 ± 1.67 kcal/mol (16). Thus the free energy change upon covalent hydration of ketene to form ketene hydrate is $\Delta G°$ = –1.57 ± 2.03 kcal/mol, and the free energy change for hydration of ketene to acetic acid is $\Delta G°$ = –28.02 ± 1.16 kcal/mol.

The free energy of formation of acetylium ion was estimated from that of acetic acid (15) with the pK_R value calculated (19) from data of Deno et al. (20). The extrapolation involved was long and consequently uncertainties are large but it is not clear how to estimate them. In the hope of being conservatively pessimistic, an uncertainty of ±3.0 kcal/mol was assigned.

To carry out Multidimensional Marcus Theory or No Barrier Theory calculations we require pK_a values for various intermediates or potential intermediates in the hydrolysis pathways. These have been estimated using analogy and linear free energy relationships. The values that we estimated are found in Table 2. In the gas phase, ketene has a proton

[2]Thermodynamic quantities are normally given to two decimal figures in this paper; these are in many cases only guard figures to ensure reproducibility of calculations. The error limits will indicate how many figures are significant.

[b]Estimated as described in the text.

[c]For loss of a proton to give the zwitterion.

[d]For loss of a proton to give ketene.

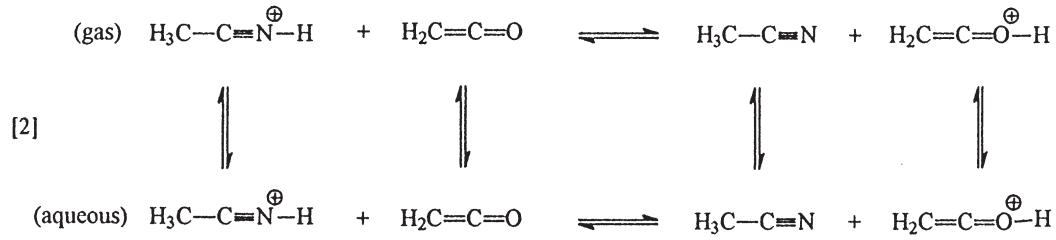
[e]For loss of a proton to give the neutral hydrate.

[f]For loss of a proton to give the zwitterion.

[g]For loss of a proton to give the neutral hydrate.

affinity of 198 kcal/mol (21), similar to that of acetone, 202 kcal/mol (21). Kebarle and co-workers concluded that the proton affinity of ketene referred to acetylium formation (22). To estimate the proton affinity of ketene for protonation on oxygen we calculated the energies of the isomeric cations by ab initio MO methods (23) at the B3LYP/3-21+G* level. The difference in energy was such that O-protonation is 38.17 kcal less favorable than C-protonation, implying a proton affinity of 160 kcal/mol.

The aqueous solution pK_a of O-protonated ketene was estimated by comparison with N-protonated acetonitrile, which has a very similar shape and overall size.



A correlation has been reported between the difference in free energies of transfer of acids and the corresponding methyl esters, and was believed to be dominated by hydrogen bond formation by the acid. This will now be used as a measure of hydrogen bond strength to solvent, and it will be assumed that the difference in free energy of transfer for protonated ketene and protonated acetonitrile will be estimated by this correlation. One can then deduce that the free energy change in water for process [2] is given by:

$$-1.366*(pK_a^{\text{protonated acetonitrile}} - pK_a^{\text{protonated ketene}} = -\Delta G_t^{\text{ketene}} + \Delta G°_{\text{gas}} + \Delta G_t^{\text{acetonitrile}} + 0.732(pK_a^{\text{protonated ketene}} - pK_a^{\text{protonated acetonitrile}})$$

The pK_a of protonated acetonitrile has been reported as –12 (24). Substituting values and solving leads to a very approximate value of $pK_a^{\text{protonated ketene}} = -23$.

Ketene hydrate, CH_2=C(OH)$_2$, has not yet been studied in aqueous solution; its pK_a may be estimated by analogy with the enol of mandelic acid, which has been studied (25): pK_a 6.6. The enol of acetaldehyde has a pK_a of 10.5 (26). We will estimate the effect of a second OH on the same carbon as the first by comparing ethanol, pK_a 15.9 (27), and acetaldehyde hydrate, pK_a 13.48 (28); the difference, 2.4 pK_a units, will be assumed to apply to the change from acetaldehyde enol to acetic acid enol as well; the pK_a so predicted for acetic acid enol is 8.1. The enol of *trans*-phenylacetaldehyde enol is 9.46 (26), for a pK_a shift of 1.0 from the addition of a phenyl; this leads to a predicted pK_a of 7.1 for the enol of phenylacetic acid. Finally, the pK_a of catechol is 9.48 (28), symmetry corrected 9.78, while that of phenol is 9.95 (28), for a pK_a shift of 0.17. Thus we arrive at a pK_a of 6.96 for the enol of mandelic acid. The approximate agreement suggests that the procedure is reasonable. We will take the pK_a of acetic acid enol as 8.1. This differs from a previous suggestion (16, 18) that was based on the pK_a of *o*-phenylphenol, 9.93 (28), implying that the phenyl would have a very small effect. There remains the question of why a phenyl substitutent has such different effects depending on environment.

To estimate pK_a values for O-protonated ketene hydrate, CH_2=C(OH)(OH_2^{+}), protonated phenol was used as a model, assuming that ΔpK_a for Ph-OH_2^{+}, pK_a = –7.04 (29) vs. PhOH, pK_a = 9.95 (28), will be the same, with suitable symmetry corrections, as for CH_2=C(OH)(OH_2^{+}) vs. CH_2=C(OH)$_2$. This leads to a pK_a of –9. The pK_a for conversion to a zwitterion was estimated by analogy with the corresponding pK_a values previously estimated for acetone hydrate (30), i.e., assuming Δ pK_a for CH_2=C(OH)(OH_2^{+}) vs. CH_2=C(OH)$_2$ is the same as for $(CH_3)_2$C(OH)(OH_2^{+}), pK_a=10.34 (31) vs. $(CH_3)_2$C(OH)$_2$, 14.19 (31). This leads to a pK_a of 4.2. Now the pK_a of CH_2=C(O^{-})(OH_2^{+}) is defined by the values already estimated, as –5.1.

© 1999 NRC Canada

C-Protonated ketene is acetylium ion, for which the pK_a can be calculated as 3.27 from the free energies of the species involved, a rather strong carbon acid, though a rather weakly acidic carbocation (which it could be considered to be: CH_3-C≡O^+ ↔ CH_3-C^+=O).

Finally, we need a pK_a for acetic acid protonated on the OH, CH_3-CO-OH_2^+. This value can be estimated following the procedure suggested by Fastrez (32) (for estimating hydration energies), i.e., by using the barrier to rotation about the HO—CO bond to estimate the cost of losing conjugation, and then treating the acyl substituent as an electron-withdrawing group perturbing the pK_a of the protonated OH. $\rho^* = -0.89$ will be used as for protonated alcohols (31) and σ^* for $CH_3CO = 1.81$ (33). The barrier for rotation is taken as that in methyl acetate, 13 kcal/mol (34). These values lead to a pK_a for CH_3-CO-OH_2^+ of –13.

It is also necessary to estimate analogous pK_a values for carbonic acid. For carbonic acid itself, the true pK_a is 3.49; this is derived from the apparent pK_a, 6.35 (28), and the equilibrium constant for covalent hydration of CO_2, 720 (3). For hydroxyl protonated carbonic acid, a procedure analogous to that for hydroxyl protonated acetic acid was used: the barrier to rotation of the OH was taken as that in methyl acetate. This led to a pK_a for HO-CO-OH_2^+ of –13.5. It was assumed that ΔpK_a for O=C(OH)(OH_2^+) vs. O=C$(OH)_2$ is the same as for $(CH_3)_2$C(OH)(OH_2^+) vs. $(CH_3)_2$C$(OH)_2$ (30); this led to a pK_a of –0.40 for HO-CO-OH_2^+ going to the zwitterion. Now the pK_a of O=C(O^-)(OH_2^+) is defined, by the values already estimated, as –9.6.

In calculating the energies of various encounter complexes involved in the mechanisms it is necessary to consider partial desolvation processes. Hydroxide ion in contact with a carbon must have lost one of its solvating waters. As before (35), this was estimated as 7.1 kcal/mol. When the carbon is the *sp* hybridized carbon of an acylium ion, which will bear significant positive charge, it is assumed that electrostatic and other interactions will compensate for the loss of hydrogen bonding. It is less clear what should be assumed for hydroxide in contact with ketene or carbon dioxide bent into the geometry for addition of water leading to acetic acid or carbonic acid. In this geometry the C=O π-bond is relatively undisturbed, but the central carbon has changed from *sp* to sp^2 geometry, and consequently overlap with the neighboring carbon or oxygen is drastically impaired. To the extent that this new sp^2 hybrid orbital is unoccupied, interaction with a nonbonded hydroxide would be more favorable than unfavorable. Two assumptions were tested: one that the standard desolvation applies for hydroxide in contact with such a carbon; the other that there is no desolvation cost for such contact. The calculations were insensitive to these assumptions, so it seems best for the moment only to assume a desolvation cost for bringing hydroxide into contact with linear ketene or carbon dioxide. Water molecules in liquid water are extensively hydrogen bonded, as shown by the remarkably high boiling point for such a small molecule, even though they are no longer in the perfect array of four hydrogen bonds per molecule found in ice. The energetics of partially desolvating water, by removing one face of the tetrahedron (two H faces, two lone-pair faces) from contact with appropriately polarized neighbors and bringing it into contact with something of the opposite polarity is taken as one quarter of the hydrogen-bonding energy of an average water molecule at 25°C. This in turn is taken as the difference in free energies of transfer (gas at 1 atm (101.3 kPa) to 1 M aqueous solution) between water and methane. This desolvation energy is 2.08 kcal/mol. Water molecules are of course in contact with any molecule fully dissolved in water, but will be oriented to optimize polarity matching. In the C-protonation of ketene there is a necessary initial mismatch if the final ion is to be appropriately solvated. In view of the much larger solvation energies for ions than for neutrals, it seems plausible to assume that the needs of the ion take precedence. The oxygen of ketene has partial negative character, but in acetylium the oxygen becomes strongly positive. Thus the initial orientation of water at equilibrium for ketene will be all wrong for acetylium ion. If the initial orientation of the waters is correct for acetylium ion, this initial state will have three partially desolvated waters, oriented with lone pairs directed at the oxygen of ketene in order to be in place to solvate the developing positive charge. If the oxygen of ketene has approximately four nearest neighbors, as seems appropriate for a small atom, then there would be three such waters; if this oxygen acted as if it had two lone pairs that might have attracted very weak hydrogen bonds, then there would be two. In the calculations that follow, a total of three partially desolvated molecules was used, though the calculations are not extremely sensitive to the number.

A serious problem in applying Marcus theory, either in its traditional one-dimensional form or as Multidimensional Marcus Theory, is that one requires intrinsic barriers as well as thermodynamic barriers in order to predict rate constants. In a case such as the present one, where ketene is distinctly different from almost any model reaction, this is a serious problem. Although intrinsic barriers are approximately transferable within families of "similar" reactions, they cannot be expected to remain independent of major changes in structure. The closest available values are the intrinsic barrier for addition of water (or hydroxide) to carbonyl compounds, for which a value of 7.36 was found to be a good average value (36), and the intrinsic barrier for protonation of an enol ether, for which a value of 12.3 was found (18).

Nonetheless, Multidimensional Marcus Theory was applied to the hydration of ketene and carbon dioxide. The results, see Table 3, were free energies of activation for water attack that were too high, implying that the effective intrinsic barriers for ketene or CO_2 would be lower than for simple carbonyl compounds. On the other hand the calculated free energy of activation for the hydroxide reaction of CO_2 was too low, implying that the intrinsic barrier was too small. Since these compounds are structurally different from the sp^2 hybridized carbonyl compounds used to determine the intrinsic barrier, and are quite reactive, it is not very surprising that a model appropriate to simple carbonyl compounds did not fit well.

Fortunately, No Barrier Theory, which requires no intrinsic barriers, has been developed (6, 7, 36), and can be applied to the present reactions. This theory assumes that for simple reaction processes there is no kinetic barrier, but simply a quadratic potential. The kinetic barrier commonly encountered for real reactions results from the need for more than one simple reaction process for almost any real chemi-

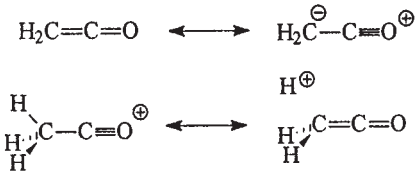
[i]Acid catalysis of carbonyl hydration.

cal transformation. In the case of ketene hydration, there will be both bond-making processes and geometry-changing processes.

To apply No Barrier Theory we require distortion energies corresponding to only one of the possible dimensions into which the overall chemical transformation is resolved: see Fig. 1. Thus for addition to a carbonyl the dimensions are bond formation and geometry change at the carbonyl carbon. The energy costs of these distortions were calculated by ab initio quantum mechanics at the B3LYP/3-21+G* level. In calculating the distortion energies of the ketene hydrate or its anion, or of carbonic acid or its anion, the angles and dihedrals specifying geometry about the central carbon were locked. For the anions, the bond length of the bond to the perpendicular OH had to be locked to prevent dissociation. In calculating the distortion energies of ketene or CO_2 the angle at the central carbon was locked.

The distortions needed for C-protonation of ketene are shown in Fig. 2. For these distortions, it was found that direct calculation using ketene and acetylium gave surprisingly small distortion energies. This was attributed to the fact that the calculations are done for the gas phase where these small, relatively unstable, molecules or ions are in severe need of stabilization by whatever means they can find. Thus relative to solution, the importance of some resonance-contributing forms is enhanced.



This is reminiscent of the situation encountered in calculating distortion energies for enolate ions, where gas phase calculations for the distortion of the CR_2 of an enolate, CH_2=C(O-)R, gave unreasonably low distortion energies, and distortion energies based on the enols were used instead in a treatment of rates of protonation/deprotonation of enolates/carbonyl compounds (6).

In the present case the most similar possible models have been used, lacking only the charge or tendency for charge separation, i.e., allene, CH_2=C=CH_2, as a model for ketene, CH_2=C=O, and acetonitrile, CH_3-C≡N, as a model for acetylium, CH_3-C≡O^+. With these model compounds distortion energies more in accord with naive expectation were obtained, and led to successful calculation of the rates of reaction. The problem appears to be general and requires that care be taken in transferring gas phase calculations to solution.

A number of possible mechanisms were examined for each term in the rate law for the hydration reactions, and for every case it was necessary to calculate the energies of each of the hypothetical corner intermediates where only one (or two or...) of the possible simple processes had occurred. The energies so calculated are found in the supplementary material.[3] In carrying out these calculations allowance was made for the entropic cost of bringing species together, any hydrogen-bonding interactions, any electrostatic interactions, any proton transfer equilibria, any desolvations required to bring a reactive lone pair into contact with a nonpolar center, and the strain energies required for geometrical distortion.

The reactions of carbon dioxide were examined as possible models for the ketene reactions. The advantage is that the solution thermodynamics are well established, as are the pK_a values for carbonic acid.

For the uncatalyzed reaction of carbon dioxide with water two models were examined: see Fig. 3. The first involved attack of water with a second water acting as general base (to

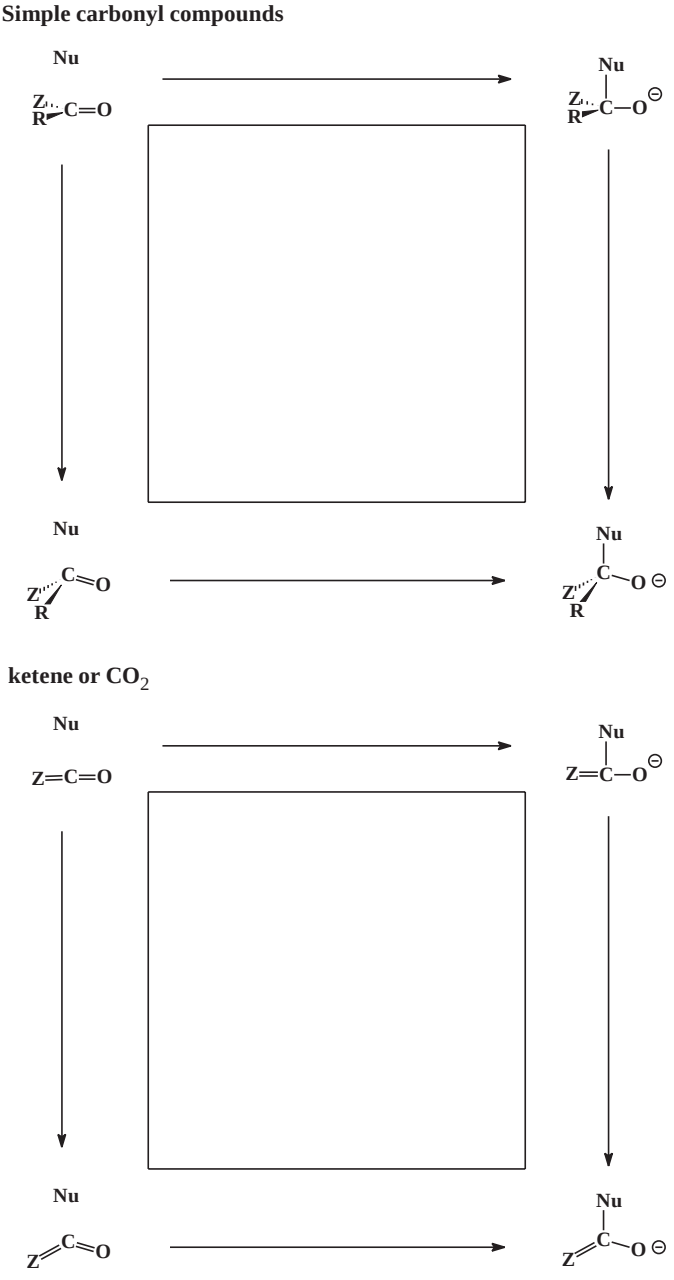
Fig. 1. Distortions required for addition to carbonyl compounds or to ketene/CO_2.



avoid formation of the zwitterion of carbonic acid), leading to a hydronium bicarbonate ion pair. The second involved a cyclic reaction with three waters leading directly to carbonic acid. For carbon dioxide the cyclic process led to the lower activation barrier, with an energy of 21.63 kcal/mol: see Table 3. This is in good agreement with the observed 19.60 kcal/mol. The barrier to these reactions comes from the extremely high distortion energies for carbonic acid. The conclusion that the hydration processes involves a cyclic array of three water molecules is in complete accord with the conclusions from a high-level ab intitio molecular orbital study (37).

For the hydroxide-catalyzed hydration of CO_2, the model used begins with hydroxide separated from CO_2 by one water, see Fig. 3. The final diffusional step bringing OH^- into

Fig. 2. Distortions required for the C-protonation of ketene.

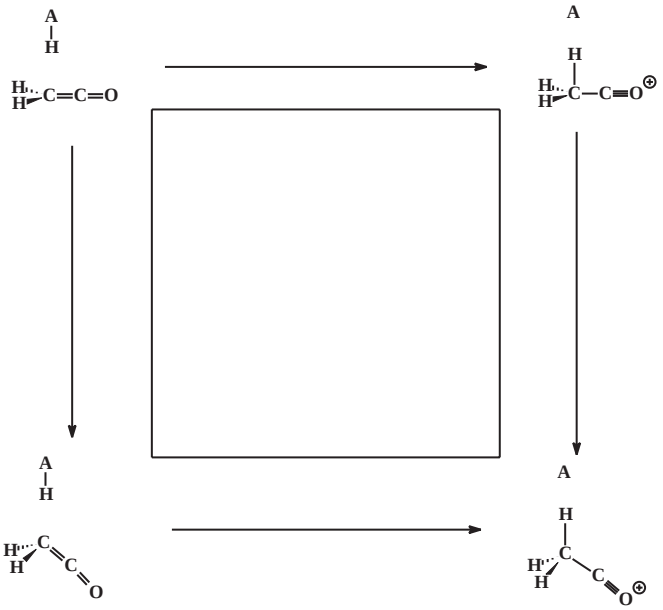


Fig. 3. Mechanistic possibilities for the hydration of carbon dioxide.

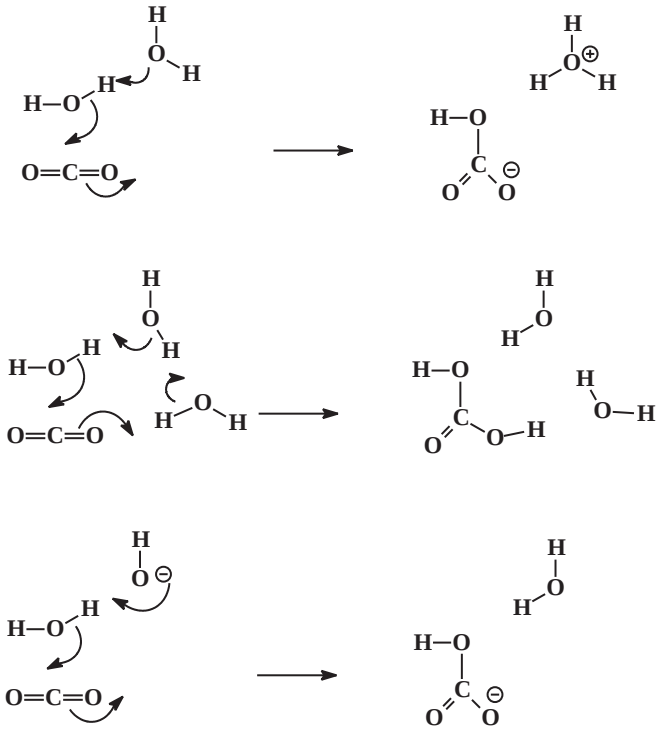

contact with CO_2 imposes a severe desolvational barrier, and thus is expected to occur only as part of a concerted reaction process. For this path the calculated barrier is in very satisfactory agreement with experiment.

Four models were examined for the uncatalyzed hydration of ketene: see Fig. 4. The first was a cyclic mechanism with three water molecules in a potentially concerted path, attacking the carbonyl carbon and ultimately transferring a proton to the carbonyl oxygen. The second mechanism involved attack of water on the carbonyl with general base catalysis

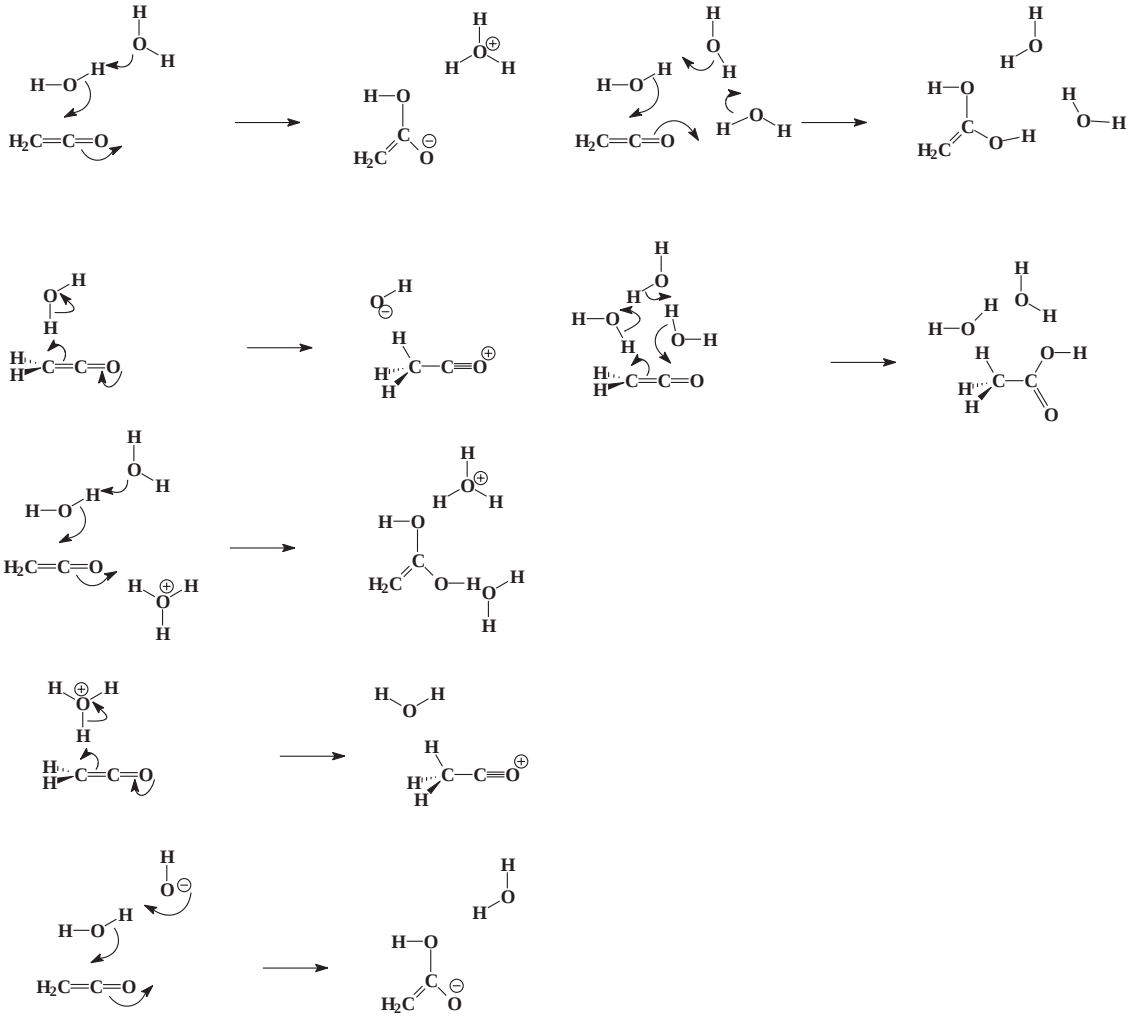
Fig. 4. Mechanistic possibilities for hydration of ketene.



by a second water. The third involved attack of water acting as a general acid, protonating ketene at carbon, to give a short-lived hydroxide–acetylium ion pair. The fourth was a cyclic mechanism with three water molecules in a potentially concerted path, with a proton transferred to the CH_2, and oxygen of a water attacking the carbonyl carbon. This path, with three proton transfer dimensions, one C—O bond formation, and two carbons undergoing geometry changes, involves a six-reaction dimension hypercube model.

Although the general base catalyzed path is predicted to be lower energy than the cyclic path for hydration of ketene, both are 5–6 kcal/mol higher than the observed free energy of activation: see Table 3. By contrast, the C-protonation path gives a reasonable match to the observed value. This path leads to a hydroxide–acetylium ion pair, which after a short lateral diffusion bringing the charges closer together can collapse to acetic acid. However, the calculated transition state for formation of acetylium ion is very close to the product, so that there is essentially no barrier to reversion to starting material. By consideration of the cyclic mechanism we can calculate the barrier for conversion of the hydroxide–acetylium ion pair to acetic acid (since this is another section of the cyclic reaction path) and find that the barrier for this path is 3.40 kcal/mol, for a total reaction barrier of 18.82 kcal/mol. Although we examined the full six-dimensional potentially cyclic concerted path for addition of water to the $C{=}CH_2$ of ketene, we were unable to find the lowest energy fully concerted path through this hypercube; this is apparently a defect in the algorithm currently being used, because various paths involving successively lower dimensional stages could be found, using the same corner energies, which corresponded to lower barriers than the best six-dimensional transition state that could be found (which had a transition state free energy of 19.85 kcal/mol). Better algorithms are being sought. The lowest energy path found so far is the one mentioned above, with a free energy of activation of 18.82 kcal/mol. This is in fair agreement with the observed value of 15.32 kcal/mol.

For acid-catalyzed hydration we considered two possibilities: attack of hydronium ion at the CH_2 and at the carbonyl oxygen. The preferred transition state had the hydronium ion attack the CH_2, and led to a calculated free energy of activation in good agreement with the observed value.

Finally, we examined the hydroxide-catalyzed reaction. We consider the possibility that the hydroxide may act directly as a nucleophile or indirectly as a general base, removing a proton from water as it attacks. It was found that the general base path leads to the lower free energy of

© 1999 NRC Canada

activation. The predicted free energy of activation is 13.89, corresponding to a rate constant of $10^{2.6}$ M^{-1} s^{-1}.

Discussion

The conclusion that uncatalyzed hydration of ketene occurs by initial C-protonation followed by rate-limiting hydroxide attack on acetylium ion flies in the face of the accepted mechanism for this reaction, namely, that it occurs by nucleophilic attack on the carbonyl (1, 2, 38–45). The strongest evidence for this path was the small normal isotope effect of k_H/k_D=1.9 (1). However, this is actually in reasonable accord with initial C-protonation and rate- determining attack of hydroxide.[4] Plausible values of fractionation factors for the protons involved in the transition state lead to a predicted isotope effect of 1.4; there are enough unusual features involving imperfect solvation that this could be consistent with the observed value. If the reaction path were water attack on the carbonyl, leading initially to the zwitterion of ketene hydrate, proton transfer from the cationic site to water would be expected to be superfast, and indeed to have happened before the zwitterion was fully formed. This implies a primary kinetic isotope effect; however, the calculations reported here suggest that the proton transfer will be very little advanced at the transition state and so the primary isotope effect will be very small. Secondary solvent isotope effects could give rise to an effect somewhat larger than that observed; a plausible estimate leads to a value of 2.6. Estimation of kinetic isotope effects is found in Appendix S1.[3] No model could be found, even with rather extreme assumptions about solvation requirements, which could overcome the high barriers to distortion of the rigid ketene and ketene hydrate structures and allow nucleophilic attack on the carbonyl as rate-limiting process to have a lower free energy of activation than attack on CH_2. It should be noted that Multidimensional Marcus Theory, using the average intrinsic barrier for attack on carbonyls, predicted that nucleophilic attack would be competitive with protonation by water (again using an average intrinsic barrier, derived from enol ether protonation reactions) and actually would be the preferred path. Other than this one case, the conclusions from the present study are in full agreement with those reached by other workers.

In a number of cases Kresge and co-workers (46–50) have shown that substituted ketones do add water to give enols of carboxylic acids. These are strongly perturbed systems, with substituents known to stabilize enols, and might well have reversals in relative rates of the two modes of reaction. The two modes of reaction of water with ketene are found to be competitive by both theories employed in the present work.

Gas phase calculations on the uncatalyzed hydration of ketene favor the carbonyl attack option rather that $C{=}CH_2$ attack (39, 51, 52). However, the calculated preference depends on the basis set used; the transition state for C=O addition is lower than that for $C{=}CH_2$ addition by 11 kcal at STO-3G (39), 10 kcal at RHF 3-21G (51), and by only 1.9 kcal at MP4(SDTQ)/6-31G*//RHF/6-31G* (52). In solution the situation appears to be reversed, and the No Barrier Theory calculations reported here show $C{=}CH_2$ attack favored over C=O attack. This seems reasonable enough because ionic intermediates or very polar transition states are much less unfavorable in polar solvent than in the gas phase. In the case of very highly hindered ketenes, bis(pentamethylphenyl)ketene and bismesitylketene, the initial products were shown to be the ene-1,1-diols. It does not seem surprising that crowding in these very hindered compounds should have caused a switch in the relative rates of the two modes of reaction.

The conclusion from the calculations reported in this work concerning acid-catalyzed hydration of ketene, namely, that the mechanism involves protonation at carbon, leading initially to acetylium ion, is in full accord with the accepted mechanism (2, 40, 41).

In constructing models for these reactions it was assumed that water is in contact with reactants, and that, at negligible cost in free energy, it will at least part of the time have H's directed at even weakly negative atoms, so that hydrogen bonding can develop as reaction proceeds, to yield fully solvated products. It was also assumed that the Stahl–Jencks equation (53) can be used to estimate the strengths of hydrogen bonds, even those involving hydrogen acids, provided vertical pK_a's are used, corresponding to the hypothetical dissociation of H^+ with no geometry change at carbon. This assumption has been used in a treatment of enolate-forming reactions (6). In the present context it means that acetylium ion is solvated to a significant extent by hydrogen bonding to the CH's, for which the vertical pK_a is 15.7 (the equilibrium pK_a is 3.3).

The rates of hydration reactions of these two unusual compounds, CO_2 and ketene, have been successfully calculated by No Barrier Theory, which uses no kinetic information in the calculation of $\Delta G^{\neq}$. These reactions could also be treated by Marcus Theory or Multidimensional Marcus Theory even though it seemed unlikely that the intrinsic barriers determined for simple carbonyl compounds would also apply to these *sp* hybridized carbon centers.

The enol content of acetic acid has been determined by indirect thermodynamic calculations (16, 18) and by molecular orbital calculations (54). The two approaches are in good agreement.

There are two problems with the No Barrier Theory treatment for the reactions of ketene. The calculations on the uncatalyzed reaction did not lead to a value in satisfactory agreement with experiment; the error was 3.5 kcal/mol, where normally the theory leads to values within 2 kcal/mol of the observed value. Since the best algorithm that we have devised so far for searching hyperspace did not lead to a value for the full six-reaction coordinate system as low as could be found by manual search of lower dimensional subsections, it seems clear that the algorithm is failing in this high-dimensional space. Thus it is still possible that there is a concerted path through the reaction hyperspace that has not yet been found. There is also a problem with the hydroxide-catalyzed reaction where the disagreement is also disappointingly large. One possibility that must be considered is that the assumption of a desolvation cost for bringing a

[4] I thank a referee for suggesting that rate-limiting attack of hydroxide on acetylium could lead to the observed solvent deuterium isotope effect.

© 1999 NRC Canada

hydroxide ion into contact with a carbonyl group may not be correct. On general principles this had seemed a valid assumption but direct evidence is hard to find. It may be that the polar nature of C=O is such that there is no such desolvation cost, and other interactions balance the missing hydrogen bond. If the calculations are carried out with no such desolvation cost, the only significant changes are in the free energies of activation for the reaction of hydroxide with CO_2 and ketene, which become 10.84 and 10.98 kcal/mol, respectively. Both are in good agreement with experiment. Clearly a reexamination of the assumption concerning desolvation of hydroxide is in order.

Despite these difficulties, No Barrier Theory permits calculation of free energies of activation with useful precision, and requires only calculation of some distortion energies, which demand only relatively low levels of molecular orbital theory. Direct attack on the problem, by calculating transition state structures and energies by ab initio methods with full incorporation of solvation effects, is far more demanding of CPU time. For example, Nguyen et al. (37) were able to come within a few kcal of the transition state energy (23.8 calcd., vs. 19.6 expt.), but this required QCISD(T)/6-31G**//MP2/6-31G** calculations combined with Monte Carlo and reaction field simulations.

Acknowledgments

I thank the Natural Sciences and Engineering Research Council of Canada for financial support of this work. I thank Professor A.J. Kresge, University of Toronto, for communicating a preliminary value of the rate constant for the reaction of hydroxide with ketene prior to its publication.

Exploring zero-point energies and hydrogen bond geometries along proton transfer pathways by low-temperature NMR

Sergei N. Smirnov, Hans Benedict, Nikolai S. Golubev, Gleb S. Denisov, Maurice M. Kreevoy, Richard L. Schowen, and Hans-Heinrich Limbach

Abstract: We have followed by NMR the zero-point energy changes of the hydrogen bond proton in 1:1 acid–base complexes AHB ≡ {A—H···B ↔ $A^{\delta-}$···H···$\overset{\delta+}{B}$ ↔ A^{-}···H—B^{+}} as a function of the proton position between A and B. For this purpose, the isotopic fractionation factors *K* between the acid–base complexes AHB + Ph_3COD···B ⇆ ADB + Ph_3COH···B, where AH represents a variety of acids and B represents pyridine-^{15}N, were measured around 110 K, using a 2:1 mixture of liquefied $CDClF_2$–CDF_3 as solvent. As under these conditions the slow hydrogen bond exchange regime is reached, the values of *K* could be obtained directly by integration of appropriate proton NMR signals. Using the valence-bond order concept established previously by crystallography, the fractionation factors and corresponding zero-point energy changes (ΔZPE) are related in a quantitative way to the hydrogen bond geometries, the ^{1}H chemical shift of the hydrogen bond proton, and the pyridine-^{15}N chemical shift. The *K* values are related in a quasi-linear way to the chemical shifts of the hydrogen bond proton, where the slope depends on whether the proton is closer to oxygen or nitrogen. In the region of the strongly hydrogen-bonded quasi-symmetric complexes, which are characterized by a strong hydrogen bond contraction, the variation of *K* is very small in spite of substantial proton displacements.

Key words: NMR, isotopic fractionation, hydrogen bonding, acid–base complexes, proton transfer, geometric isotope effects.

Résumé : Faisant appel à la RMN, on a suivi les changements d'énergie du point zéro du proton de la liaison hydrogène de complexes acide–base 1 : 1 AHB ≡ {A—H···B ↔ $A^{\delta-}$···H···$\overset{\delta+}{B}$ ↔ A^{-}···H—B^{+}} en fonction de la position du proton entre A et B. À cette fin, opérant à environ 110 K et utilisant un mélange 2 : 1 liquéfié de $CDClF_2$: CDF_3 comme solvant, on a mesuré les facteurs de fractionnement isotopiques, *K*, entre les complexes acide–base, AHB + Ph_3COD···B ⇆ ADB + Ph_3COH···B, dans laquelle AH représente une variété d'acides et B correspond à pyridine-^{15}N. Dans de telles conditions, on atteint un régime d'échange lent de la liaison hydrogène et il est possible de déduire les valeurs de *K* directement par intégration des signaux RMN des protons appropriés. Utilisant le concept d'ordre de la liaison de valence mis au point antérieurement par cristallographie, on peut établir une corrélation quantitative entre les facteurs de fractionnement ou les changements correspondants dans les énergies de point zéro (« ΔZPE ») et les géométries de la liaison hydrogène, le déplacement chimique ^{1}H du proton de la liaison hydrogène et le déplacement chimique de la pyridine-^{15}N. On peut établir une corrélation pratiquement linéaire entre les valeurs de *K* et les déplacements chimiques du proton de la liaison hydrogène; la pente dépend de la distance entre le proton et l'oxygène ou l'azote. Dans la région de forte liaison hydrogène où les complexes sont pratiquement symétriques et qui est caractérisée par une forte contraction de la liaison hydrogène, la variation de *K* est très faible malgré le fait que les déplacements de proton soient importants.

Mots clés : RMN, fractionnement isotopique, liaison hydrogène, complexes acide–base, transfert de proton, effets isotopiques géométriques.

Introduction

It has been known for a long time that H/D isotopic fractionation between different proton donor sites is mainly caused by zero-point energy changes between the sites (1). The measurement of fractionation factors using a variety of methods is, therefore, an established tool of isotopic research (2). On the other hand, fractionation factor theory in combination with transition state theory constitutes the classical theory of kinetic H/D isotope effects of proton transfer reactions (1, 3). However, proton tunneling through the reaction barrier is another source of kinetic isotope effects (4), and it is thus often difficult from an experimental standpoint to decide which effect causes the observed kinetic H/D isotope effects. As proton transfer is an elementary step of many organic and biochemical reactions (5–7) and is interesting from a theoretical standpoint, it would be desirable if one could follow directly the proton transfer pathways and the associated zero-point energy changes. Since this is experimentally very difficult, the study of model hydrogen-bonded systems is of great help where each system models a typical point or region of the reaction coordinate. For example, using a series of hydrogen-bonded anions, Kreevoy and Liang (2*a*) determined fractionation factors as a function of the hydrogen bond geometry using UV spectroscopy. However, using this method it is difficult to follow, at the same time, changes in the hydrogen bond geometries.

Recently some of us (8) have proposed a model series for the pathway of a proton from an acid (AH) to a base (B) that can conveniently be studied by low-temperature liquid state NMR (9) around 110 K using liquefied deuterated gases as solvents. This method allows one to distinguish different hydrogen-bonded species $(AH)_nB_m$ in the slow-exchange regime, in contrast to the usual NMR spectroscopy where only average signals are observed. Thus, the NMR properties of simple neutral 1:1 complexes of the type AHB ≡ {A—H···B ↔ $A^{\delta-}\cdots H\cdots B^{\delta+}$ ↔ $A^-\cdots H$—B^+} could be studied, in which the proton was gradually displaced from the acid AH to the acceptor B, ≡ pyridine-^{15}N, by changing the proton-donating power of AH. The optical spectroscopy of such complexes is well known (for references concerning properties of pyridine – carboxylic acid complexes, see ref. 10). During this displacement, characteristic changes of NMR chemical shifts and coupling constants were observed, including H/D isotope effects in the former that were qualitatively related to associated changes of the hydrogen bond geometries (8*d*). Such effects were quantified in other model systems using solid state NMR and theoretical methods (11).

In this paper we extend the low-temperature NMR technique to the measurement of the equilibrium constants *K* of isotopic fractionation between AHB with respect to a reference XH or XHB. Therefore, the fractionation factors measured here are defined by the equations

$$[1] \qquad AHB + XDB \overset{K}{\rightleftarrows} ADB + XHB$$

$$[2] \qquad K = \frac{x_{XHB}\, x_{ADB}}{x_{XDB}\, x_{AHB}} \approx \exp\left(-\Delta ZPE/RT\right)$$

R is the gas constant, *T* the temperature, *x* the mole fractions or concentrations, and ΔZPE the zero-point energy difference given by

$$[3] \qquad \Delta ZPE = ZPE(XHB) - ZPE(XDB) + ZPE(ADB) - ZPE(AHB)$$

The idea was that using the low-temperature NMR technique it should be possible to determine *K* directly by integration of appropriate NMR signals as the slow hydrogen bond and proton exchange regime can be reached. However, as this concept had not yet been realized, the setup of the technique was not trivial. Especially difficult was the choice of the reference proton donor XH. We tried out different acids and found that acetic acid (AcOH) is a good choice from the standpoint of the experimental technique. In a later stage of this study we found that triphenylmethanol is a reference that is more closely related than AcOH to the usual standard, water, because the fractionation factor of Ph_3COH in acetonitrile with respect to water is unity; moreover, this alcohol shows little evidence of self-association (2*a*). Thus we succeeded in measuring *K* for a number of AHB complexes with respect to the 1:1 complex of Ph_3COH with pyridine.

In the following, after a short experimental section, the results are presented and discussed qualitatively in terms of an appropriate hydrogen bond geometry correlation analysis.

Experimental section

All NMR experiments reported in this paper were performed on a Bruker NMR AMX 500 instrument operating at 500.13 MHz for ^{1}H. The details of these experiments have been reported previously (8*d*). Pyridine-^{15}N (95% enriched) was purchased from Chemotrade, Leipzig, Germany. CH_3COOD was purchased from Aldrich; the other acids were deuterated using either D_2O or CH_3OD. The deuterated freon solvent mixture $CDClF_2$:CDF_3 (2:1) freezes below 90 K. It was synthesized, as described previously (9), at 100°C and elevated pressures (between 30 and 60 bar (1 bar = 100 kPa)) from $CDCl_3$ via fluorination with $SbF_3/SbCl_5$. The solvent was handled on a vacuum line and stored over basic alumina in order to remove traces of acids and water. The vacuum line also served to prepare the samples using well-established techniques (4*d*). No special effort was made to remove water from the solutes employed as water traces precipitate in freons at low temperature. Each sample consisted of comparable amounts of the partially deuterated acid for which the fractionation factor was to be determined, of acetic acid-*d*, of a small excess of pyridine-^{15}N with respect to both acids, and of about 0.5 mL of the solvent. The concentrations of the solutes refer to room temperature and were determined prior to the sample preparation either by weighing, in the case of solids, or by volumetric measurements on the vacuum line in the case of liquid components as described previously (4*d*). The fractionation factors *K* for a given complex AHB referring to $Ph_3COH\cdots B$ were determined from the low-temperature ^{1}H NMR spectra using the equation

$$[4] \qquad K' = K/K'(Ph_3COH) = \frac{I_{CH}\left(I_{CH} - I_{AHB}\right)}{I_{AHB}\left(I_{CH3}/3 - I_{AcHB}\right)}$$

© 1999 NRC Canada

which can easily be derived from eq. [2]. $K'(Ph_3COH)$ is the H/D-fractionation factor for $Ph_3COH\cdots B$ with respect to the acetic acid – pyridine complex, I_{CH3} the intensity of the methyl group signal of acetic acid, I_{CH} the sum of the intensities of the CH proton signals for AHB and ADB, I_{AcHB} the intensity of the H-bonded proton signal for the 1:1 acetic acid – pyridine complex, I_{AHB} the intensity of the H-bonded proton signal for AHB. The relative solute mole fractions determined by signal integration of the low-temperature spectra were slightly different from those calculated from the total concentrations determined as described above. However, as the absolute concentrations do not enter eq. [4] and as small variations of the concentrations do not affect the intrinsic chemical shifts of the acid–base complexes, no attempt was made to determine the correct concentrations, which are also temperature dependent because of the temperature dependence of the solvent density.

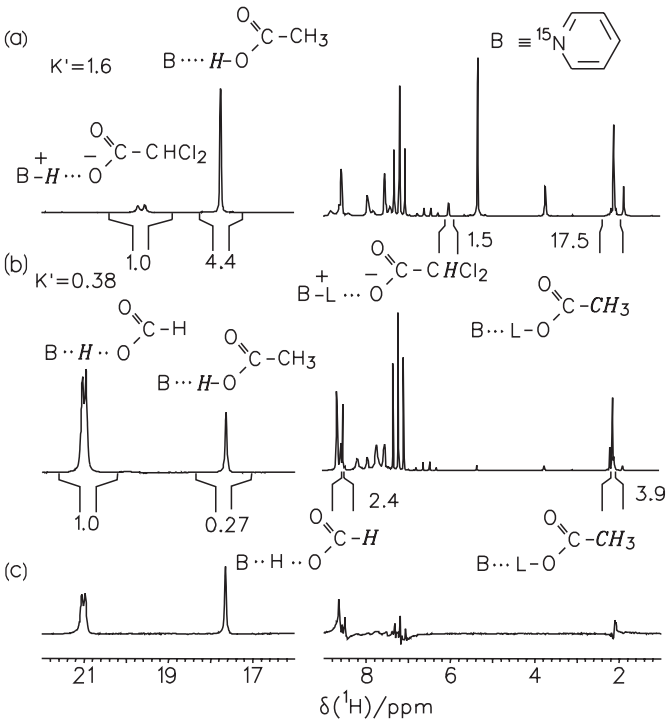
Results

Typical low-temperature ^1H NMR spectra of equilibrated solutions containing a partially deuterated acid, AL (L = H, D), a comparable amount of CH_3COOL (AcOL), and of pyridine-^{15}N in small molar excess over both acids combined, dissolved in a 2:1 mixture of liquefied $CDClF_2$:CDF_3, are shown in Figs. 1*a* and 1*b*. Under these conditions the acids form only 1:1 complexes with pyridine, B (8*d*), and the complexation of the acids is essentially complete. Each solution gives rise to two low-field signals in its ^1H NMR spectrum: one for AHB and one for the complex with acetic acid, AcOHB. As the slow hydrogen bond regime is reached, the chemical shifts observed are the intrinsic values referring to the 1:1 complexes and are not affected by small concentration variations. As discussed previously (8*e*, 8*h*), the intrinsic chemical shifts depend on temperature because of a temperature-dependent solvent ordering causing changes in the hydrogen bond geometries. The mobile protons in the two sites exchange slowly on the timescale of seconds, as shown by a differential NOE experiment depicted in Fig. 1*c*, where the acetic acid peak at 17.65 ppm was irradiated and a positive formic acid – pyridine peak at 21 ppm indicated a slow magnetization transfer by chemical exchange between the two mobile proton sites. However, the exchange is complete on the timescale of many minutes, as shown by the invariance with time of the relative integrated areas. The fractionation factors are easily obtained by signal integration using eq. [4]. The results of the measurements are assembled in Table 1 and Fig. 2, which contain also the ^1H and ^{15}N chemical shifts reported previously (8d); the shifts of triphenylmethanol, methylaniline, and 4-*tert*-butylphenol were determined in this study.

Discussion

We have measured the H/D fractionation factors *K* of 1:1 hydrogen-bonded complexes of various proton donors with pyridine by low-temperature NMR spectroscopy in the slow hydrogen bond exchange regime, using Ph_3COH with an excess of pyridine as a reference. We note from Table 1 that the OH chemical shift of this donor is around 10 ppm at 112 K, as compared to the neat compound exhibiting an OH

Fig. 1. Partial 500 MHz ^1H NMR spectra of solutions of pyridine-^{15}N (B)/acetic acid (AcOH)/variable acid AH in a 2:1 mixture of $CDClF_2$:CDF_3 at non-zero deuterium fractions *D* in the mobile proton sites. (*a*) AH ≡ dichloroacetic acid, uncorrected concentrations at room temperature C_B = 0.058, $C_{AH} + C_{AD}$ = 0.011 mol L^{-1}, $C_{AcOH} + C_{AcOD}$ = 0.038 mol L^{-1}, *T* = 107 K. (*b*) AH ≡ formic acid, uncorrected concentrations at room temperature C_B = 0.033 mol L^{-1}, $C_{AH} + C_{AD}$ = 0.019 mol L^{-1}, $C_{AcOH} + C_{AcOD}$ = 0.011 mol L^{-1}, *T* = 109 K. (*c*) NOE difference spectrum of the sample in Fig. 1*b*, where the hydrogen-bonded proton of acetic acid at 17.65 ppm was irradiated.



chemical shift of about 5 ppm at room temperature. The ^{15}N chemical shift of pyridine in the presence of Ph_3COH is slightly shifted upfield, indicating that Ph_3COH forms a weak 1:1 hydrogen bond with pyridine. Therefore, we conclude that the complex $Ph_3COH\cdots B$ is the true reference for the fractionation factors *K*, as indicated by eqs. [1] and [2]. As the fractionation factor between Ph_3COH and water in acetonitrile is close to unity (2*a*), the fractionation factors reported here are good estimates for those referring to water.

To facilitate the discussion of our results we first review the concept of the valence bond order for the estimation of hydrogen bond geometries. This concept goes back to the valence bond – length relationship developed by Pauling and Brown (14). It states that one can associate with any bond between two atoms *i* and *j* an empirical valence bond order p_{ij}, which decays exponentially with the bond distance r_{ij}, i.e.,

$$[5] \qquad p_{ij} = \exp\{-(r_{ij} - r_{ij}^0)/b_{ij}\}$$

where b_{ij} is a decay parameter and r_{ij}^0 the distance where $p_{ij} = 1$. A hydrogen-bonded system, e.g., an O—H···N hydrogen bond (Scheme 1), is then characterized by two bond orders p_{OH} and p_{HN} involving the hydrogen-bonded proton. As the total valency of hydrogen is unity,

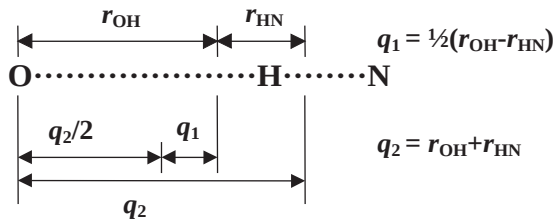
Scheme 1.



$$[6] \quad p_{OH} + p_{HN} = 1 = \exp\{-(r_{OH} - r_{OH}^0)/b_{OH}\} + \exp\{-(r_{HN} - r_{HN}^0)/b_{HN}\}$$

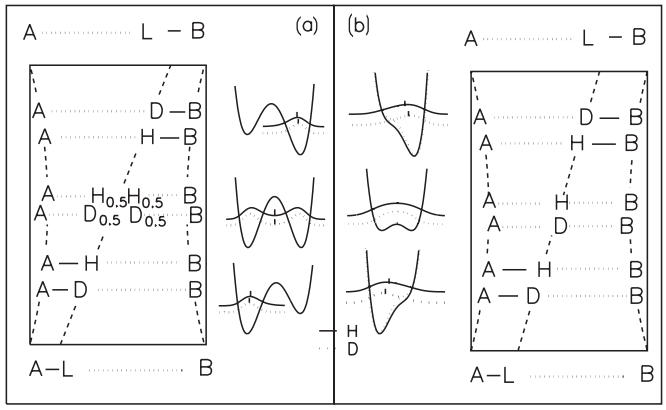
it follows that the two bond distances r_{OH} and r_{HN} cannot be varied independently. Naturally, this prediction implies at the same time a correlation between q_1 and q_2, defined in Scheme 1. For a linear hydrogen bond, q_1 corresponds to the distance of the proton or deuteron from the center of the hydrogen bond, i.e., it represents the proton transfer coordinate, and q_2 is equal to the A···B distance (11*b*) The dependence of q_1 as a function of q_2 can be obtained easily from the definition in Scheme 1 and eq. [6].

Hydrogen bond correlations have been established by crystallography (15) by comparing the neutron crystal structures of a large number of systems exhibiting hydrogen bonds of weak and medium strength. The curves depend only on the type of donor and acceptor atoms, i.e., OHO, OHN, and NHN bonds exhibit different parameters in eq. [6]. The NHN bond correlation has been verified by some of us (11*b*) using solid state NMR and theoretical calculations. In conclusion, the valence bond order model does not distinguish qualitatively but only quantitatively between the covalent bond and the hydrogen bond.

For the case of O—H···N bonds, Steiner (15*d*) has proposed the parameter set $r_{OH}^0 = 0.942$ Å, $r_{HN}^0 = 0.992$ Å, $b_{OH} = 0.371$ Å, $b_{HN} = 0.385$ Å. Using these values, we have calculated the correlation curve $q_1 = f(q_2)$ depicted in Fig. 2*a*. The curve indicates that when the proton is transferred from O to N the O···N distance first shortens, then reaches a minimum in the quasi-symmetric complex, and finally widens again as the zwitterionic complex is approached.

Figure 3 shows in more detail, in a qualitative way, what exactly may happen during the transfer process. Two limiting cases are represented. In Fig. 3*a* the proton exhibits a medium barrier for proton transfer at the quasi-symmetric midpoint whereas such a barrier is absent in Fig. 3*b*. In the case of Fig. 3*a* the solute–solvent interaction may easily break the symmetry of the potential, leading to a proton transfer equilibrium between two strongly hydrogen-bonded states, characterized by a common value of q_2 but different values $-q_1$ and $+q_1$, i.e., q_2 will not reach the minimum value. Generally, deuteration leads to a primary geometric H/D isotope effect on q_1 and to a secondary effect on q_2 (8*d*, 11*b*). The latter effect was found by Ubbelohde and Gallagher (16) and is also called the Ubbelohde Effect. If there is a barrier to the proton motion, the secondary isotope effect is always directed in such a way that the A···B distance increases after deuteration. On the other hand, the primary geometric isotope effect implies a larger distance to the hydrogen bond center for the deuteron than for the proton (11*b*). The primary and secondary geometric isotope effects are similar in the no-barrier case of Fig. 3*b*, as well as around the quasi-symmetric midpoint where the A···B distance can contract slightly after deuteration because of the smaller width of the deuteron wave function in the vibrational ground state (12*b*).

Fig. 3. One-dimensional hydron (L = H, D) potentials and geometric changes during the transfer of a hydron from A to B characterized by the reaction coordinate $q_1 = 1/2(r_1 - r_2)$. The squares of the wave functions of the vibrational ground states for H and D, i.e., the proton and deuteron distribution functions, are included. (*a*) Case involving a medium proton transfer barrier at the quasi-symmetric midpoint. (*b*) Case involving a very small or no barrier at the quasi-symmetric midpoint. For further explanation see text. Adapted from ref. 8*d*.



In the latter paper, the hydrogen bond correlation concept was extended to other hydrogen bond properties. Thus, empirical equations were presented relating the geometric H/D isotope effects, zero-point energy changes, ^{1}H and ^{15}N chemical shifts to derivatives, or combinations of various derivatives of the correlation of eq. [7]. However, the equations presented referred only to the symmetric case of NHN hydrogen bonds. Here, we had to treat the unsymmetrical NHO case. During this work we found that it is possible to expand all correlations directly in terms of the valence bond orders, which constitutes a considerable simplification. For example, we observe that the ^{15}N chemical shifts can be expressed by

$$[7] \quad \delta_N = \delta_N^\infty - (\delta_N^\infty - \delta_{HN}^0)p_{HN}$$

$$\delta_N^\infty = 264 \text{ ppm and } \delta_{HN}^0 = 138 \text{ ppm}$$

where the parameters δ_N^∞ and δ_{HN}^0 are the values of free pyridine and of the isolated pyridinium where $r = r_{HN}^0 = 0.992$ Å. For the ^{1}H chemical shifts we find empirically that

$$[8] \quad \delta(^1H) = 4\Delta_H\, p_{OH}\, p_{HN} + \delta_{OH}^0\, p_{OH} + \delta_{HN}^0\, p_{HN}$$

$$\Delta_H = 17.25 \text{ ppm}, \ \delta_{OH}^0 = 2 \text{ ppm, and } \delta_{HN}^0 = 8 \text{ ppm}$$

Δ_H is the excess chemical shift of the quasisymmetric complex and δ_{OH}^0 and δ_{HN}^0 the limiting chemical shifts corresponding to the distances $r_{OH}^0 = 0.942$ Å and $r_{HN}^0 = 0.992$ Å. It is clear that, because of eq.[6], $\delta(^1H)$ must be correlated with $\delta(^{15}N)$, which is indeed the case as depicted by the dotted line in Fig. 2*b*. This curve was generated by calculating

© 1999 NRC Canada

$\delta(^1H)$ and $\delta(^{15}N)$ from an arbitrary grid of q_1 values. The parameters in eqs. [7] and [8] were adjusted by "eye-fitting" the calculated dotted line in Fig. 2*b* to the experimental values taken from ref. 8*d*. The agreement is very satisfactory. We note that the $\delta(^1H)$ vs. $\delta(^{15}N)$ correlation curve exhibits a principal difference from the q_1 vs. q_2 curve of Fig. 2*a* because the distance between the separate residues AH and B can be varied in an infinite number of ways during which their chemical shifts remain constant. Therefore, the dotted correlation line in Fig. 2*b* ends at the left and the right sides as illustrated by the vertical bars. Finally, we note that the experimental chemical shift data of Fig. 2*b* can be easily converted into distances as indicated by the filled circles of Figs. 2*a* and 2*b*.

Let us now discuss the graph of Fig. 2*c* where we have plotted the fractionation factors *K* of Table 1 (lower graph) and the corresponding values of ΔZPE (upper graph), as defined in eq. [2], as a function of $\delta(^{15}N)$. Previously (11*b*), we had noted for the NHN case that ΔZPE is proportional to the square of the second derivative of q_2. Here, we find a simpler equation, valid also in the unsymmetric NHO case, i.e.,

$$[9]\qquad \Delta ZPE = \Delta ZPE^{o}(4p_{OH}p_{HN})^2 + \Delta ZPE(OH)^0 p_{OH} + \Delta ZPE(HN)^0 p_{NH}$$

$$\Delta ZPE^0 = -2.44 \text{ kJ mol}^{-1},$$

$$\Delta ZPE(OH)^0 = +0.4 \text{ kJ mol}^{-1},$$

$$\Delta ZPE(HN)^0 = +0.7 \text{ kJ mol}^{-1}$$

Here, $\Delta ZPE(OH)^0$ and $\Delta ZPE(HN)^0$ are the zero-point energy differences of the limiting states where $r_{OH}{}^0 = 0.942$ Å and $r_{HN}{}^0 = 0.992$ Å with respect to our reference complex $Ph_3COH\cdots B$. ΔZPE^0 determines the total drop of the zero-point energy at the quasi-symmetric midpoint with respect to the limiting states. Again, the parameters of eq. [9] were adapted by eye-fitting the calculated values of ΔZPE as a function of $\delta(^{15}N)$ to the experimental values reported in Table 1, leading to the upper dotted line in Fig. 2*c*. We find that the reference $Ph_3COH\cdots B$ exhibits a small drop in the zero-point energy of 0.4 kJ mol^{-1} with respect to the hypothetical free proton donor ROH. Moreover, the experimental value of ΔZPE^0 is smaller than the value of –4 kJ mol^{-1} calculated previously (11*b*) for the anion $[C{\equiv}N\cdots H\cdots N{\equiv}C]^-$. In this case the situation corresponds to Fig. 3*b*. The lower graph in Fig. 2*c* is the straightforward extension of the upper graph, considering eq. [2] and the average temperature of about 120 K at which the experiments were performed. The fractionation factor of 0.2 at 110 K would correspond to about 0.5 at 298 K. The experimental finding of a reduced isotopic fractionation as compared to $[C{\equiv}N\cdots H\cdots N{\equiv}C]^-$ is then consistent with the situation depicted in Fig. 3*a*, where solute–solvent interactions, however, destabilize the quasi-symmetric configurations, hence leading to a smaller extent of the maximum zero-point energy losses. On the other hand, it could also be that the real drop of the hydrogenic stretching frequency in $[C{\equiv}N\cdots H\cdots N{\equiv}C]^-$ is smaller than was calculated and is partly compensated for by an increased in-plane and (or) out-of-plane bending vibrational frequency that was not included in the calculations of ref. 11*b*.

In any case, Fig. 2*c* indicates a quite flat central region in which the fractionation factors *K* do not exhibit major changes although the proton is displaced by about 0.3–0.4 Å in this region, as estimated from Fig. 2*a*. If we take the series of complexes presented in this paper as models of transition states of proton transfer and the fractionation factors as classical kinetic H/D isotope effects, this result would mean that proton motions in strong hydrogen bonds may fail to appear to be contributing substantially to the overall observed kinetic isotope effect, as discussed recently by some of us (5*m*).

Finally, we have plotted in Fig. 2*d* the experimental fractionation factors as a function of the ^1H chemical shifts. The calculated dotted line was here obtained from eqs. [8] and [9]. We find that, in addition to some curvature, *K* is an almost linear function of $\delta(^1H)$, exhibiting, however, a different slope on both sides of the quasi-symmetric complex characterized by the lowest value of *K* and the largest value of $\delta(^1H)$. The slopes are different depending on whether the proton is closer to oxygen or nitrogen. Thus, $\delta(^1H)$ is a qualitative measure, not only of the A···B distance but also of the fractionation factor.

Conclusions

In conclusion, the development of low-temperature NMR makes it possible not only to obtain information on the geometries and on geometric H/D isotope effects but also of isotopic H/D fractionation in a series of intermolecular low-barrier hydrogen-bonded 1:1 acid–base complexes because the slow hydrogen bond exchange regime is reached. Thus, interesting information can be obtained about zero-point energy changes along the reaction pathways of proton transfer. A task of the future will be to study experimentally the hydrogen bond vibrations in this series and to provide a full theoretical treatment of the experimental findings.

Aminolysis of naphthyl acetates catalyzed by cyclodextrins

Oswald S. Tee and Michael J. Boyd

Abstract: The effects of cyclodextrins (CDs) on the rate of nucleophilic attack on 1- and 2-naphthyl acetates (1-NA and 2-NA) in aqueous solution have been investigated. Analysis of the variation of the pseudo-first-order rate constants with [nucleophile] and [CD] affords rate constants for reaction of the nucleophiles with free ester (k_N) and with ester bound to the CD (k_{cN}). The reaction of 1-NA and 2-NA with the trifluoroethoxide anion is slowed down by β-CD as the ratios k_{cN}/k_N are 0.11 and 0.30, respectively. For reaction with the anion of 2-mercaptoethanol in the presence of α-CD, β-CD, "hydroxypropyl-β-CD" (hp-β-CD) and γ-CD, the reactivity ratios k_{cN}/k_N vary between 0.04 and 2.4, ranging from strong retardation to modest catalysis; the retardations arise with β-CD and hp-β-CD, which bind the esters strongly. By contrast, the attack of primary alkylamines is generally accelerated, and in many cases substantially so. For the aminolysis of 1-NA in the presence of β-CD, values of k_{cN}/k_N range from 7 to 460, assuming that free amine reacts with CD-bound ester. Alternatively, if the CD-catalyzed reaction involves free ester reacting with CD-bound amine, with rate constant k_{Nc}, the ratios k_{Nc}/k_N vary from 43 to 140. *Either way, there is appreciable catalysis of the aminolysis of 1-NA by β-CD*. For the aminolysis of 2-NA, the effects are less dramatic: the ratios k_{cN}/k_N range from 0.19 to 17, and values of k_{Nc}/k_N vary from 17 to 110. The reaction of 1-NA with *n*-hexylamine is also catalyzed by γ-CD. The variations of kinetic parameters with alkylamine chain length suggest that the CD-catalyzed aminolysis basically takes place by the attack of CD-bound amine on the free ester. However, there must be some stabilizing interactions between the aryl group of the ester and the CD during the reaction, since the transition state stabilization is different for 1-NA and 2-NA, as well for other esters.

Key words: aminolysis, catalysis, cyclodextrin, ester cleavage, kinetics.

Résumé : On a étudié les effets de cyclodextrines (CD) sur la vitesse d'attaque nucléophile sur les acétates de 1- et 2-naphtyle (1-NA et 2-NA) en solution aqueuse. Une analyse de la variation des constantes de vitesse de pseudo-ordre un avec les concentrations de nucléophile et de CD permet de déterminer les constantes de vitesse pour la réaction de nucléophiles avec l'ester libre (k_N) et avec l'ester lié à la CD (k_{cN}). La réaction des 1-NA et 2-NA avec l'anion trifluoroéthanolate est ralentie par la β-CD alors que les rapports k_{cN}/k_N sont égaux respectivement à 0,11 et 0,30. Pour la réaction avec l'anion du 2-mercaptoéthanol, en présence d'α-CD, de β-CD, d'hydroxypropyl-β-CD (hp-β-CD) et de γ-CD, les rapports k_{cN}/k_N varient entre 0,04 et 2,4, qui correspondent à des influences qui vont d'un ralentissement important à une catalyse modeste; les retards se produisent avec la β-CD et la hp-β-CD qui lient fortement les esters. Par opposition, l'attaque des alkylamines primaires est généralement accéléré et, dans plusieurs cas, d'une façon importante. Pour l'aminolyse du 1-NA en présence de β-CD, les valeurs de k_{cN}/k_N vont de 7 à 460 si l'on fait l'hypothèse que l'amine libre réagit avec l'ester lié à la CD. Par ailleurs, si la réaction catalysée par la CD implique un ester libre qui réagit avec une amine liée à la CD et une constante de vitesse k_{Nc}, les rapports k_{Nc}/k_N varient de 43 à 140. *Quelle que soit le type de liaison avec la CD, la β-CD provoque une accélération importante de la réaction d'aminolyse du 1-NA.* Pour l'aminolyse du 2-NA, les effets sont moins dramatiques: les rapports k_{cN}/k_N vont de 0,19 à 17 alors que les valeurs de k_{Nc}/k_N varient de 17 à 110. La réaction du 1-NA avec l'hexylamine est aussi catalysée par la γ-CD. Les variations des paramètres cinétiques avec la longueur de la chaîne suggèrent que l'aminolyse catalysée par la CD se produit essentiellement par une attaque de l'acétate libre par une amine liée à la CD. Toutefois, lors de la réaction, il doit exister des interactions entre le groupe aryle de l'ester et la CD puisque la stabilisation de l'état de transition est différente pour les 1-NA, 2-NA et d'autres esters.

Mots clés : aminolyse, catalyse, cyclodextrine, clivage d'esters, cinétiques.

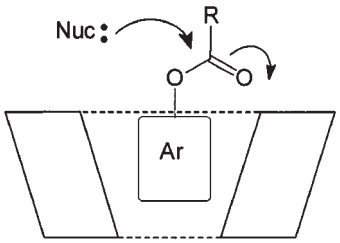
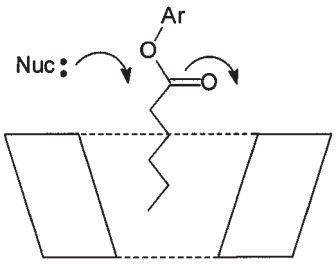
Introduction

Recently, we embarked on a series of studies of the effects of cyclodextrins (1) on the reactions of aryl esters with amines and other nucleophiles (2–4).[2] In the first instance, we wished to find out if esters bound to cyclodextrins (CDs) are more or less reactive towards nucleophiles, which do not bind to CDs, and to ascertain how the reactivities vary with the ester, the CD, and the nucleophile (2). Accordingly, we studied the reaction of *p*-nitrophenyl acetate and hexanoate with hydroxylamine, imidazole, and the anions of trifluoroethanol (TFE) and 2-mercaptoethanol (2-ME), in the presence of three CDs (2). It was established that the free and CD-bound esters have quite similar reactivities towards the nucleophiles, implying that when the esters are bound to CDs, their carbonyl groups are reasonably exposed to the bulk medium and accessible to nucleophiles in it.

From our initial study, it was not possible to tell the orientation of the ester during the attack by the nucleophile (Nuc), which could occur with the aryl group of the ester included in the CD cavity, as in **1**, or with the acyl group in the cavity, as in **2**. To address this question, we carried out a second study on the effects of CDs on the reaction of the TFE and 2-ME anions with *p*-nitrophenyl alkanoates having acyl chain length from C_2 to C_{10} (3).[2] Broadly speaking, it was found that the CD-bound esters are somewhat less reactive than the free esters. However, from the biphasic variation in the reactivities of the CD-bound esters with acyl chain length, we concluded that there is a change in the mode of transition state binding at about C_6: shorter esters reacting with aryl group inclusion (**1**), whereas longer esters react with acyl group inclusion (**2**).

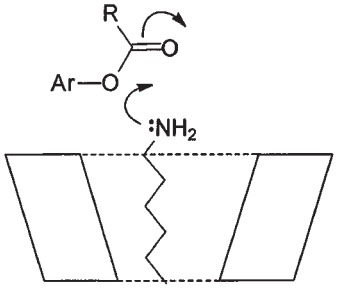


1



2

We have also carried out a detailed study of the reaction of primary alkylamines (C_3 to C_8) with *p*-nitrophenyl alkanoates (C_2 to C_7) in the presence of CDs.[2] Inherently, the situation is more complicated because binding of both the esters (5, 6) and the amines (7) to CDs must be accounted for in the data analysis. Overall, it appears that short amines react with short esters by the attack of free amine on aryl-bound ester (cf. **1**), whereas with longer amines, the ester is free and the alkylamine is CD-bound (**3**). The reaction of long esters with long amines, which is catalyzed by β-CD and γ-CD, also takes place with inclusion of the amine (**3**), but there may be partial inclusion of either the acyl group (β-CD) or the aryl group (γ-CD) of the ester, as well. For none of the ester–amine–CD combinations studied, did reaction of acyl-bound ester with free amine (cf. **2**) appear to be important.[2]



3

In a related study of the effect of β-CD on the reaction of amino acid anions with *p*-nitrophenyl acetate, we concluded that free and CD-bound ester have similar reactivities towards the nucleophiles (4), unlike an earlier report (8). Rate ratios for the two species ranged from 0.76 to 3.5, with ratios greater than one only arising with amino acid anions that bind significantly to β-CD. In such cases, the CD-catalyzed aminolysis may entail reaction of free ester with CD-bound nucleophile, comparable to the depiction in **3**.

The present paper reports investigations of the reactions of 1- and 2-naphthyl acetate (1-NA and 2-NA) with two nonbinding nucleophiles, and with several alkylamines, in the presence of cyclodextrins. The reactivities of these two esters towards hydroxide ion are very similar, but they show subtle differences in their cleavage by CDs, due to differences in their initial state and transition state binding (9). Consequently, it was natural for us to wonder how binding of the two naphthyl esters to CDs would influence their attack by other nucleophiles.

Results

We first measured the kinetics of the cleavage of the reaction of 1-NA and 2-NA with the anions of 2,2,2-trifluoroethanol (TFE) and 2-mercaptoethanol (2-ME), with and without added CDs. Following the methodology established in previous work (2–4), pseudo-first-order rate constants (k_{obs}) determined at various [Nuc] and [CD] were analyzed to yield rate constants for reaction of the nucleophiles with

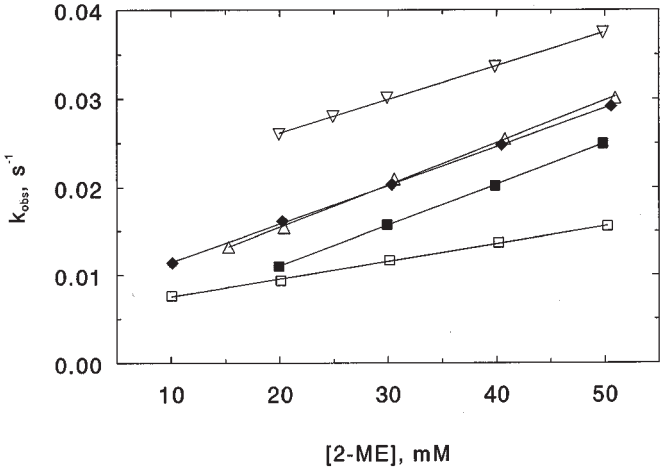
Fig. 1. Rate constants for the cleavage of 1-naphthyl acetate as a function of [2-ME], at pH 10.60, in the absence and presence of cyclodextrins, plotted as follows: ■, no CD; △, 5.0 mM α-CD; ▽, 2.0 mM β-CD; □, 5.0 mM hp-β-CD; ◆, 5.0 mM γ-CD. From eq. [5], the slopes of the straight lines are $(k_N K_S + k_{cN}[CD])/(K_S + [CD])$, at fixed [CD].



free and CD-bound ester. In the analysis, allowance is made for four processes: hydrolysis of the ester (S) in basic medium (eq. [1]); ester cleavage through an {ester·CD} complex (eq. [2]); reaction of the free (unbound) ester with the nucleophile (Nuc) (eq. [3]); and reaction of the CD-bound ester complex with the nucleophile (eq. [4]). For these four processes in competition, the expected variation of k_{obs} with [Nuc] and [CD] is given by eq. [5], assuming that [S] is low enough that it does not significantly alter [CD].

[3] $$S + Nuc \xrightarrow{k_n} \text{products}$$

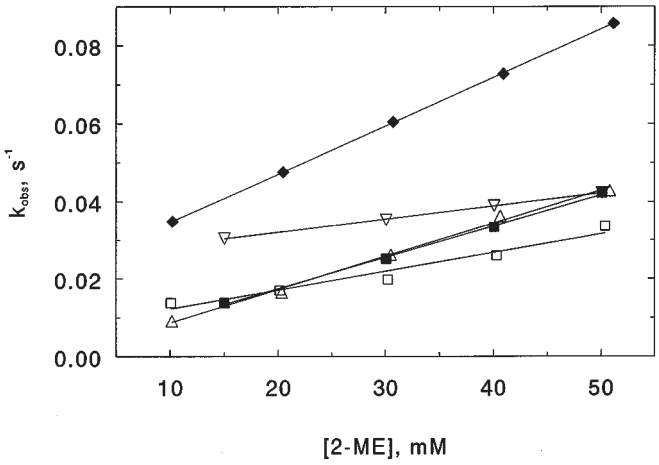
[4] $$S \cdot CD \xrightarrow{k_{cN}} \text{products}$$

[5] $$k_{obs} = \frac{(k_u K_S + k_c[CD]) + (k_N K_S + k_c N[CD])[Nuc]}{(K_s + [CD])}$$

Figure 1 shows plots of k_{obs} against [Nuc] for the reaction of 1-NA with the anion of 2-ME in the absence and presence of four CDs: α-CD, β-CD, hp-β-CD,[3] and γ-CD (1); Fig. 2 has comparable data for the analogous reaction of 2-NA. The experiments were carried out at pH 10.60 where 2-ME is largely ionized (pK_a = 9.5) (10), and competition from the background reactions (eqs. [1] and [2]) is not large.

The plots in Fig. 1 show linear dependences of k_{obs} on [Nuc], at fixed [CD], as required by eq. [5], with slopes (in M^{-1} s^{-1}) as follows: no CD, 0.46; α-CD, 0.48; β-CD, 0.38; hp-β-CD, 0.20; γ-CD, 0.44. According to eq. [5], these slopes

Fig. 2. Rate constants for the cleavage of 2-naphthyl acetate as a function of [2-ME], at pH 10.60, in the presence and absence of cyclodextrins, with symbols as in Fig. 1.



are equal to $(k_N K_S + k_{cN}[CD])/(K_S + [CD])$, and so variations in them reflect the relative magnitudes of k_{cN} and k_N. In the case of α-CD and γ-CD, the slopes imply that $k_{cN} \sim k_N$, whereas for β-CD and especially for hp-β-CD $k_{cN} < k_N$. Similar considerations apply to the plots for 2-NA in Fig. 2, but the trends are slightly different, and in particular, the slope is greater with γ-CD present, meaning that $k_{cN} > k_N$ in that case. These trends are quantified by analysis of the data in terms of eq. [5], using an approach that has been thoroughly tested in previous studies (2–4).[2]

To simplify the data analysis, eq. [5] is linearized by dividing it by the fraction of free substrate, $f_S = K_S/(K_S + [CD])$, to produce eq. [6].[4] According to this equation, k_{obs}/f_s varies linearly with [Nuc], at fixed [CD], and from the slope of $(k_N + k_{cN}[CD]/K_S)$, we can estimate k_{cN}, knowing k_N from experiments with no added CD, and taking K_S from earlier work (9). In the case of 2-ME, the first two terms of eq. [6], which comprise the intercept at fixed CD, are sensitive to pH, but the second two terms in [Nuc] are not, since the 2-ME is largely ionized at pH 10.6. Thus, errors from small variations in pH are minimized, and the rate constants k_N and k_{cN}, and especially the ratio k_{cN}/k_N, can be obtained with good reliability from the slopes of the plots k_{obs} vs. [2-ME] at zero CD and fixed CD, respectively.

[6] $$k_{obs}/f_S = k_u + k_c[CD]/K_S + k_N[Nuc] + k_{cN}[CD][Nuc]/K_S$$

Application of the above approach gave the rate constants k_N and k_{cN} for reaction with 2-ME (see Table 1), which justify the statements made about them, above. Table 1 also contains constants for the effects of β-CD on the reaction of 1-NA and 2-NA with TFE at pH 11.6, where TFE is about 14% ionized (pK_a = 12.4) (11); the actual data are shown in Fig. 3. In both cases, the CD-bound ester is less reactive than the free naphthyl ester towards the anion of TFE.

[3] The hydroxypropyl-β-cyclodextrin (hp-β-CD) used was β-CD in which about six of the seven primary hydroxyl groups are substituted with 2-hydroxypropyl groups (1*c*, *d*).

[4] The form of f_S assumes that $[CD] >> [S \cdot CD] \leq [S]_0$, which was valid for the ester concentrations used. The requisite values of K_S were taken from our previous study of the cleavage of 1-NA and 2-NA by CDs under basic conditions (9).

Table 1. Constants for the reaction of nonbinding nucleophiles with 1-naphthyl and 2-naphthyl acetate (1-NA and 2-NA) in the presence of cyclodextrins.[a]

Reaction	CD	K_S (mM)	k_N (M^{-1} s^{-1})	k_{cN} (M^{-1} s^{-1})	k_{cN}/k_N
1-NA + 2-ME	None		0.464 ± 0.004[b]		
	α	38.7		0.580 ± 0.090	1.25
	β	6.29		0.111 ± 0.025	0.24
	hp-β	3.13		0.0360 ± 0.0083	0.08
	γ	10.7		0.378 ± 0.015	0.81
2-NA + 2-ME	None		0.810 ± 0.021[c]		
	α	25.1		1.09 ± 0.20	1.35
	β	1.32		0.029 ± 0.010	0.04
	hp-β	0.729		0.437 ± 0.072	0.54
	γ	7.92		1.91 ± 0.01	2.40
1-NA + TFE	None		1.18 ± 0.01		
	β	6.29		0.251 ± 0.068[d]	0.21
2-NA + TFE	None		2.00 ± 0.06		
	β	1.32		0.607 ± 0.224[e]	0.30

[a]At 25°C, in aqueous solution; TFE = 2,2,2-trifluoroethanol; 2-ME = 2-mercaptoethanol. Values of K_S are taken from an earlier study (9). Experiments with TFE (pK_a = 12.4) were carried out at pH 11.60 (0.20 M phosphate buffer) whereas those with 2-ME (pK_a = 9.5) employed a lower pH of 10.60 (0.10 M carbonate buffer) to reduce competition from the background reactions (eqs. [1] and [2]). For the experiments to find k_{cN} for 2-ME, the solutions contained 5.0 mM of α-CD, 2.0 mM of β-CD, 5.0 mM of hp-β-CD, or 5.0 mM of γ-CD. The actual data are shown in Figs. 1 and 2.

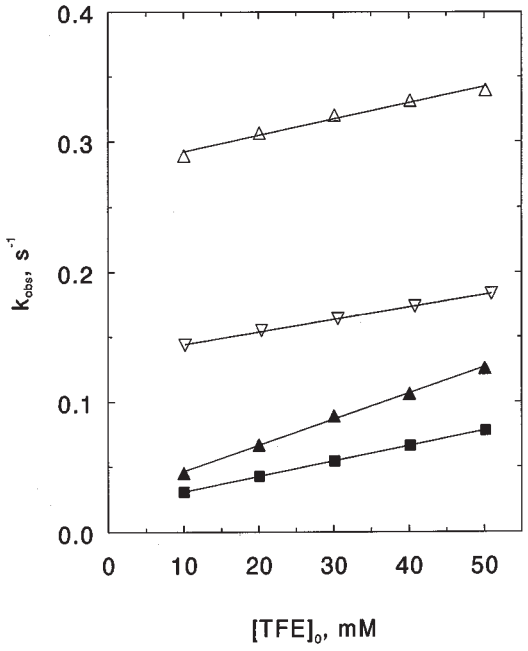
[b]Initial experiments in the phosphate buffer at pH 11.60 gave k_N = 0.519 ± 0.019 M^{-1} s^{-1}.

[c]Initial experiments in the phosphate buffer at pH 11.60 gave k_N = 0.847 ± 0.008 M^{-1} s^{-1}.

[d]From experiments with [β-CD] = 2.0 mM and varying [TFE] (see Fig. 3).

[e]From experiments with [β-CD] = 1.0 mM and varying [TFE] (see Fig. 3).

Fig. 3. Rate constants for the cleavage of 1-naphthyl and 2-naphthyl acetate (1-NA and 2-NA) as a function of [TFE], at pH 11.60, in the presence and absence of β-CD. The symbols are for 1-NA: ■, no CD; ▽, 2.0 mM β-CD; for 2-NA: ▲, no CD; △, 1.0 mM β-CD.



The major part of the present work entailed with studies of the effects of β-CD on the reactions of 1-NA and 2-NA with *n*-alkylamines (C_3 to C_7), cyclopentylamine, and cyclohexylamine. These studies were more demanding for three main reasons. First and foremost, because there is CD-amine binding (eq. [7]), as well as CD-ester binding (9), a more elaborate data analysis is required, and both [CD] and [amine] (= [Nuc]) must be corrected for the CD-amine binding (4).[2] Second, with the larger amines there comes a point where one cannot get enough of the amine into solution for aminolysis to compete effectively with the background processes (eqs. [1] and [2]). Third, in cases where the CD-mediated aminolysis makes only a small contribution, it can be hard or even impossible to quantitate. The reaction medium was buffered at pH 11.6 in which the amines are largely present as their reactive, free base forms ($pK_a \approx 10.6$) (12).

$$[7] \qquad \text{CD} + \text{amine} \underset{K_N}{\rightleftharpoons} \text{CD} \cdot \text{amine}$$

In the absence of a cyclodextrin, the kinetics of aminolysis of 1-NA and 2-NA are simple, with $k_{obs} = k_u + k_N[\text{amine}]_o$, as shown by the linear plots in Fig. 4, and as reported earlier by Bruice et al. (13) for the reaction of *n*-butylamine with 1-NA.[5] Rate constants, k_N, obtained from such plots, are collected in Table 2, along with dissociation constants (K_N) for β-CD·amine complexes, determined previously (7).[2]

For aminolysis in the presence of a CD, the variation of k_{obs} with $[\text{amine}]_o$ is not simple (e.g., Fig. 5) because the amine binds to the CD. In two previous studies (4),[2] our analysis made use of multiple linear regression (14) of the

[5]Ester aminolysis in nonaqueous solvents generally shows both first- and second-order dependence on [amine], but the reactions of "activated" esters in aqueous solution do not. Background references can be found in our previous paper.[2]

Fig. 4. Rate constants for the cleavage of 1-NA (open symbols) and 2-NA (closed symbols), as a function of $[amine]_o$. The slopes afford k_N values for aminolysis. The amines are *n*-butylamine, ■, □; *n*-pentylamine, ▼, ▽; cyclopentylamine, ▲, △.

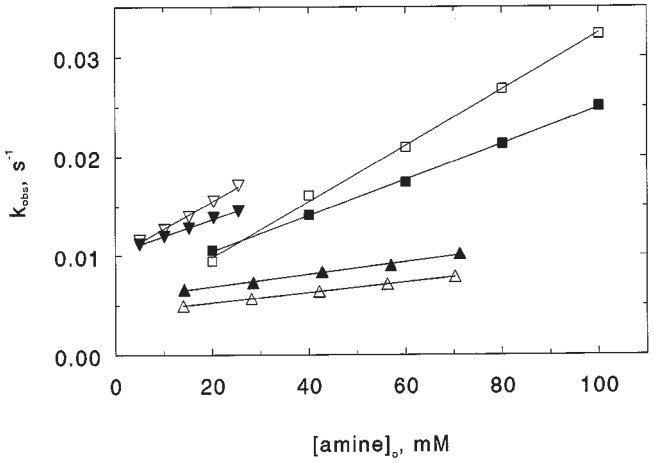

Table 2. Rate constants for the reaction of amines with 1- and 2-naphthyl acetate (1-NA and 2-NA), and dissociation constants of amine.β-CD complexes.[a,b]

	k_N (M^{-1} s^{-1})		
Amine	1-NA	2-NA	K_N, mM
n-Propyl	0.172 ± 0.003	0.349 ± 0.002	108
n-Butyl	0.181 ± 0.003	0.282 ± 0.007	35.6
n-Pentyl	0.166 ± 0.007	0.273 ± 0.013	11.4
n-Hexyl	0.194 ± 0.009	0.225 ± 0.018	2.62[c]
n-Heptyl	0.194[d]	0.225[d]	0.955
Cyclopentyl	0.0621 ± 0.0034	0.0515 ± 0.0002	13.5
Cyclohexyl	0.0415 ± 0.0015	—	1.83

[a]At 25°C, in aqueous solution at pH 11.60. At this pH, the amines are ~91% ionized ($pK_a \approx 10.6$) (12).

[b]The rate constants k_N were determined in this work (e.g., Fig. 4); the dissociation constants K_N are taken from earlier studies (7).[2]

[c]For *n*-hexylamine binding to γ-CD, K_N = 9.29 mM.[2]

[d]Not easily determined and so taken to be the same as for *n*-hexylamine.

variation of k_{obs}/f_s with [CD], [amine], and [amine][CD] (eq. [6]), to obtain their coefficients k_c/K_S, k_N, and k_{cN}/K_S, and from the last of these a value of k_{cN} was extracted.[6] The procedure worked well in the earlier work, but in the present work it is not satisfactory because in most cases there is a considerable disparity between the contributions of the two aminolysis terms to k_{obs} (see later). To circumvent the problem, we adopted a slightly different approach that separates the four terms in eq. [6] into two pairs. Since the rate constants k_u and k_N are readily available (e.g., from Fig. 4), it is feasible to subtract away the first two terms of [6], due to the reactions of the free ester ([1] and [3]), and to isolate the terms due to the two processes involving the CD ([2] and [4]). Thus, eq. [6] is transformed into eq. [8], which requires a linear variation of k_{corr} with [amine].

Fig. 5. Rate constants for the cleavage of 1-NA in the presence of amines and β-CD. The closed symbols (and solid curves) are for the observed rate constants, while the open symbols (and broken curves) are rate constants, calculated assuming that $k_{cN} = k_N$. The four amines are *n*-butylamine, ■, □; *n*-pentylamine, ▼, ▽; cyclopentylamine, ▲, △; cyclohexylamine, ◆, ◇. The concentrations of β-CD are given in Table 3.

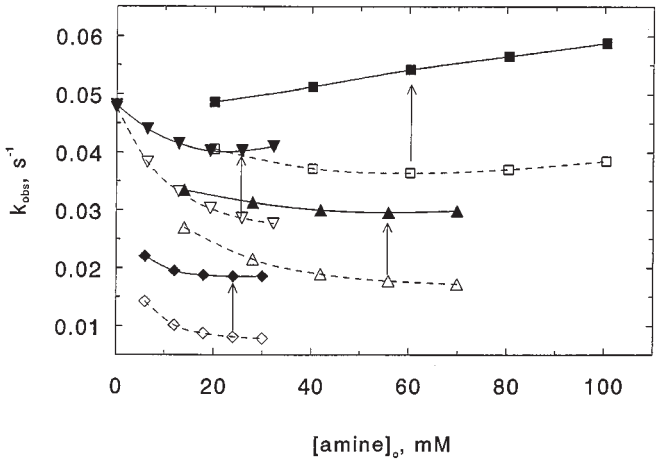

Fig. 6. Analysis for CD-catalyzed aminolysis, with data plotted according to eq. [8], and against [amine] corrected for CD-amine binding. The slopes of the linear plots provide estimates of the rate constants k_{cN}. The symbols are *n*-butylamine, ■; *n*-pentylamine, ▼; cyclopentylamine, ▲; cyclohexylamine, ◆; *n*-hexylamine, ●. The raw data for the first four cases are displayed in Fig. 5.

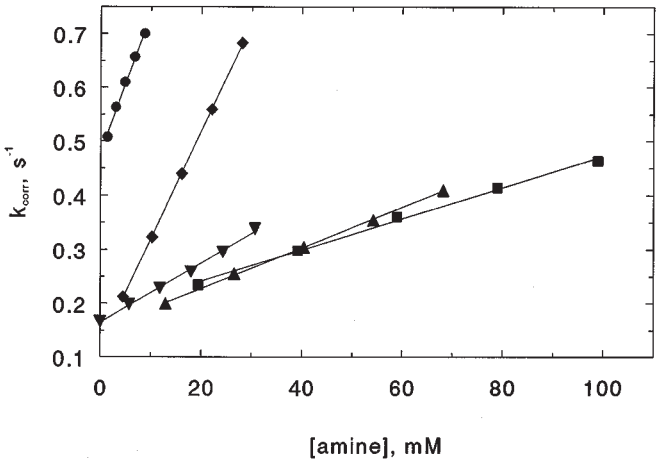

[8] $$k_{corr} = (k_{obs}/f_S - k_u - k_N[amine])K_S/[CD]$$
$$= k_c + k_{cN}[amine]$$

Figure 6 shows five examples of data plotted in accord with eq. [8], which include the four cases in Fig. 5. The

[6]The combined kinetic data from two or more sets of experiments (one without CD and one or more with CD) were analyzed to obtain the coefficients of [CD], [amine], and [amine][CD] in eq. [6], where both [CD] and [amine] were corrected for CD-amine binding (4).[2] For the purposes of further analysis, a more accurate value of k_N was taken from the experiments where $[CD]_o = 0$.

[a]As in Table 2.

[b]Values of K_S for the esters and CDs are in Table 1. Values of k_{cN} were obtained by the variation of k_{corr} with [amine] (eq. [8]), for data from experiments with $[\beta\text{-CD}]_o$ = 2.00 mM, and varying $[\text{amine}]_o$ (e.g., Figs. 5 and 6), except where noted otherwise.

[c]$[\beta\text{-CD}]_o$ = 1.00 mM.

[d]$[\beta\text{-CD}]_o$ = 4.00 mM. For an experiment with $[\beta\text{-CD}]_o$ = 2.00 mM, the analysis was poorer, and it gave k_{cN} = 55.1 ± 2.3 M^{-1} s^{-1}.

[e]$[\beta\text{-CD}]_o$ = 4.00 mM.

[f]Obtained from experiments with constant $[\text{amine}]_o$ = 14.82 mM and varying $[\beta\text{-CD}]_o$ (2.00–10.00 mM). The analysis was poorer because k_{corr} and [amine] did not vary greatly under these conditions. Nevertheless, the value of k_{cN} agrees well with those from the other two experiments.

[g]$[\gamma\text{-CD}]_o$ = 2.50 mM.

[h]$[\gamma\text{-CD}]_o$ = 5.00 mM.

[i]CD-mediated aminolysis was barely detectable.

[j]Experiments unsuccessful because aminolysis barely competes with ester cleavage by β-CD at the amine concentrations accessible.

good linearity of the plots strongly support the model used,[7] and the significant slopes, which equal k_{cN}, imply appreciable catalysis of aminolysis by β-CD. Values of k_{cN} obtained in this way are presented in Table 3, along with the rate constants k_3 and k_{Nc} for the processes [9] and [10], which will be used in Discussion. Because the processes [4], [9], and [10] are kinetically equivalent, the three relevant rate constants are related through the expression: $k_3 = k_{cN}/K_S = k_{Nc}/K_N$.

[9] $\text{S} + \text{CD} + \text{Nuc} \xrightarrow{k_3} \text{products}$

[10] $\text{S} + \text{CD} \cdot \text{Nuc} \xrightarrow{k_{Nc}} \text{products}$

For the purposes of subsequent discussion, Table 3 also contains "dissociation constants," K_{TS}, which provide a measure of the strength of CD-binding in the transition states of CD-mediated reactions (15). In the present case, K_{TS} is defined as in eq. [11] to be the apparent dissociation constant of the transition state of the CD-mediated aminolysis (TS·CD) into the transition state of normal aminolysis (TS) and the CD. Analogous constants were used in our previous discussions of the effects of CDs on the reactions of nucleophiles with *p*-nitrophenyl esters (2–4),[2] as well as in much of our other recent work (6, 9, 15).

[11] $$K_{TS} = [\text{TS}][\text{CD}]/[\text{TS}\cdot\text{CD}] = k_N/k_3 = k_N K_S/k_{cN} = k_N K_N/k_{Nc}$$

Discussion

Even a cursory viewing of the results presented in Figs. 1–6 and Tables 1–3 reveals that cyclodextrins retard or have little effect on cleavage of the naphthyl acetates by the anions of TFE and 2-ME but they significantly catalyze ester cleavage by alkylamines. The extent of the CD-catalyzed aminolysis can be estimated using the rate constants obtained by experiment, as outlined below.

[7]The linearity of the plots in Fig. 6 also means that our values of K_N and K_S are not seriously in error.

Fig. 7. Variation of the first-order contributions of the pathways [1]–[4] to k_{obs} with $[amine]_o$ for the cleavage of 1-NA in the presence of cyclohexylamine and β-CD, with $[\beta\text{-CD}]_o$ = 2.00 mM. At the highest $[amine]_o$, the contribution of CD-catalyzed pathway reaches 58%. See Table 4 for this case and several others.

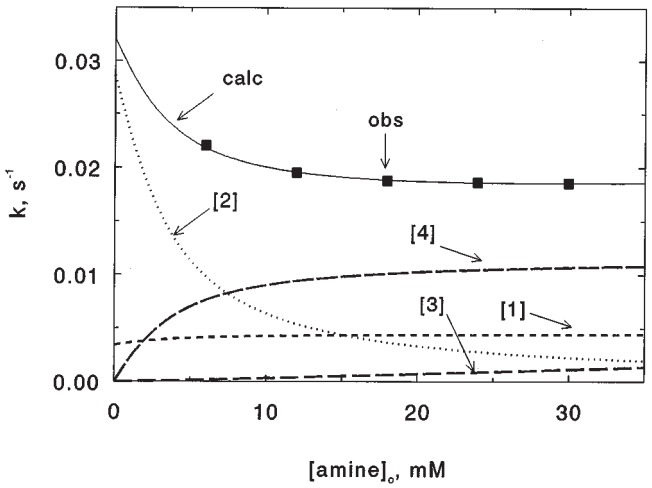

Table 4. Contributions from the processes [1]–[4] to k_{obs} for the cleavage of 1-naphthyl acetate in the presence of β-CD and amines.[a]

Amine	$[Amine]_{max}$ (mM)	$[CD]_o$ (mM)	Contribution (%) [1]	[2]	[3]	[4]
n-Propyl	267	2.00	12	19	41	27
n-Butyl	100	2.00	11	24	28	37
n-Pentyl	32	2.00	23	32	12	33
n-Hexyl	10.3	1.00	34	37	4	25
n-Hexyl	10.3	2.00	22	52	2	24
n-Heptyl	5.70	4.00	14	68	1	17
Cyclopentyl	69.8	2.00	18	26	13	43
Cyclohexyl	29.9	2.00	24	12	6	58
Cyclohexyl	29.9	4.00	15	14	4	67
n-Hexyl	10.8	2.50[b]	24	19	3	55
n-Hexyl	10.8	5.00[b]	15	28	2	55

[a]$[Amine]_{max}$ is the highest amine concentration used in the experiments (e.g., Fig. 5). The CD-catalyzed aminolysis pathway is designated as process [4], but it should be remembered that the processes [9] and [10] are kinetically equivalent.

[b]Experiments with γ-CD (see Table 3).

The curved plots of k_{obs} vs. $[amine]_o$, such as those in Fig. 5, arise from the varying contributions of four cleavage pathways [1]–[4],[8] and the shapes of the curves are understandable when one works out how these contributions vary with $[amine]_o$. For example, Fig. 7 shows the contributions to k_{obs} for 1-NA reacting with cyclohexylamine in the presence of β-CD.[9] As $[amine]_o$ is increased, the amount of free CD drops quickly, due to CD-amine binding, causing a sharp decline in the CD-mediated ester cleavage (eq. [2]) and a modest increase in background hydrolysis of free ester, [1]. At the same time, the contributions of the two aminolysis pathways ([3] and [4]) increase with $[amine]_o$, especially that due to CD-catalyzed aminolysis ([4]), which levels off at high $[amine]_o$ as the CD becomes saturated with the amine. Overall, k_{obs} decreases with $[amine]_o$ but much less than if the CD-catalyzed aminolysis was small or negligible.

The same features apply to the other amines, but the shapes of their curves (e.g., Fig. 5) vary somewhat because of the different rate constants, the dissociation constants for CD-amine binding, and the ranges of $[amine]_o$ used. This point is emphasized in Table 4, which shows the percentage contributions made by the four kinetic processes, at the highest amine concentration used, for 1-NA reacting with the various amines in the presence of β-CD and, in two cases, γ-CD. In the most favourable case, which involves reaction with cyclohexylamine, the percentage contribution of CD-catalyzed aminolysis exceeds 65%.

Substrate reactivity (k_N)

Before discussing CD-catalyzed aminolysis in detail, it is necessary to remark upon the reactivities of the esters towards nucleophiles in the absence of CDs. Towards hydroxide ion, the two naphthyl acetates, 1-NA and 2-NA, have very similar reactivities: k_{OH} = 2.03 and 1.85 M^{-1} s^{-1}, respectively (9). However, with the other nucleophiles (TFE anion, 2-ME anion, and *n*-alkylamines), 2-NA is 1.2–2.0 times as reactive as 1-NA (k_N, Tables 1 and 2), except with cyclopentylamine where 1-NA is slightly more reactive. For the *n*-alkylamines (C_3 to C_6), there is little variation of k_N for both naphthyl esters, but the two cyclic amines are appreciably less reactive because they have branching next to the reacting amino group. These observations were anticipated, since similar behaviour had been observed for the aminolysis of *p*-nitrophenyl alkanoates.[2] Overall, the two naphthyl esters have fairly similar reactivities towards nucleophiles, so that any appreciable differences seen for their reactions in the presence of CDs must be attributable to differences in substrate binding and (or) the transition state binding.[10]

Reactivity ratios (k_{cN}/k_N and k_{Nc}/k_N)

The ratio k_{cN}/k_N measures the relative reactivities of the bound and free forms of the ester towards the nucleophile, assuming the CD-mediated reaction takes place between bound ester and free nucleophile (eq. [4]). The reactions of the two naphthyl acetates with the anions of TFE and 2-ME, both nonbinding nucleophiles (2, 3), are slowed down appreciably (k_{cN}/k_N = 0.04–0.5, Table 1) by ester binding to β-CD and hp-β-CD. By contrast, reactions of the esters with the 2-ME anion are hardly affected by α-CD (k_{cN}/k_N = 1.25 and 1.35) and in different ways by γ-CD (k_{cN}/k_N = 0.81 for 1-NA, and 2.4 for 2-NA). Roughly speaking, there is an in-

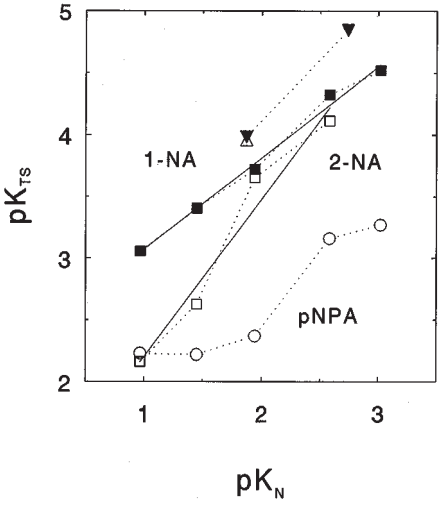
[8]The CD-catalyzed aminolysis pathway is designated as process [4], but it should be remembered that the processes [9] and [10] are kinetically equivalent.

[9]To calculate the contributions to k_{obs}, we have taken the rate constants k_u and k_N from the variation of k_{obs} with $[amine]_o$ (e.g., Fig. 4), and k_c and k_{cN} from the linear dependence of k_{corr} on [amine], corresponding to eq. [8] (e.g., Fig. 6).

[10]For the most part, 2-NA *reacts* faster than 1-NA with CD anions, but there is considerable variation in the rate ratio because of binding of the 1- and 2-naphthyl groups to the CDs in the initial state and the transition state (9).

© 1999 NRC Canada

Fig. 8. Variation of transition state stabilization (pK_{TS}) with the strength of amine binding (pK_N) for the aminolysis of 1-naphthyl acetate, 2-naphthyl acetate, and *p*-nitrophenyl acetate (1-NA, ■; 2-NA, □; pNPA, ○) catalyzed by β-cyclodextrin. Additional points are for 1-NA reacting with cyclopentylamine and cyclohexylamine (▼), and for 2-NA reacting with cyclopentylamine (△). The dotted lines are to aid the eye; the solid lines are the correlation lines for 1-NA and 2-NA. The data for pNPA are taken from ref. 3.



verse relationship between the strength of binding of the ester and the reactivity ratio: the stronger the binding, the lower the ratio. The relationship is not exact, of course, because of differences in the sizes of the CD cavities (1) and in the modes of inclusion of the two esters (9).

The effects of β-CD on aminolysis of the two esters are much more dramatic than those on the reactions with the TFE and 2-ME anions, since most of the ratios k_{cN}/k_N *are much greater than one* (Table 3), ranging from 0.2 all the way up to 460.[11] Moreover, since alkylamines bind to CDs (7),[2] we also consider reaction between free ester and CD-bound amine (eq. [10]) for which the relevant ratios are all significantly greater than one (k_{Nc}/k_N = 17–140, Table 3). Thus, regardless of whether the reaction takes place as in eq. [4] or in eq. [10], *the aminolysis of the two naphthyl acetates is catalyzed by the* β*-CD in almost all cases*.[12]

It will be noted that the ratios k_{cN}/k_N increase appreciably with the amine chain length, and they are large for the two cyclic amines, suggesting a sensitivity to the ability of the amine to bind to β-CD (see K_N in Table 2), which seems inconsistent with reaction taking place as in eq. [4]. At the same time, the ratios k_{Nc}/k_N vary much less (only from 30 to 140 for 1-NA; 16 to 50 for 2-NA), as one would expect if the reaction proceeded more or less as in eq. [10], and through a transition state structure like that in **3**.

One further point to be noted is that for a given amine, both reactivity ratios are larger for 1-NA than for 2-NA (Table 3), indicating stronger catalysis for 1-NA, and implying some difference in the interactions of the two naphthyl groups with β-CD in the transition state for CD-catalyzed aminolysis, even though it mainly involves alkylamino group binding (**3**).

Third-order reactivity (k_3)

An unbiased view of the CD-mediated ester aminolysis is afforded by the rate constants evaluated for the third-order process in eq. [9]. Values of k_3 for 1-NA and 2-NA reacting with the primary *n*-alkylamines in the presence of β-CD increase appreciably with the chain length of the amine, and they are comparatively large for cyclopentylamine and cyclohexylamine (Table 3), especially since these two amines are inherently less reactive (see k_N in Table 2). All of the values are consistent with the third-order reaction (eq. [9]) taking place with the alkylamino group in the CD cavity and the naphthyl group of the ester more or less outside (**3**).

Transition state binding (pK_{TS})

The quantity $pK_{TS} = -\log K_{TS}$ is a measure of the stabilization of a transition state afforded by the CD and its variations with structure can provide information about transition state binding (15). Figure 8 shows values of pK_{TS} for the two naphthyl esters, reacting with amines in the presence of β-CD, plotted against pK_N for the binding of the amines to β-CD.

The first thing to note is that pK_{TS} increases steeply with pK_N, and for both esters the slopes are near one (0.74 for 1-NA and 1.27 for 2-NA). Thus, both sets of data are quite consistent with a transition state structure in which binding of the alkylamino group in the CD cavity is most important, with the ester moiety being largely outside (**3**), as suggested above. However, since there are large differences between the values of pK_{TS} for the two naphthyl esters when the amine is relatively short, there must be differences between the interactions of the 1- and 2-naphthyl groups with the edge or rim of the β-CD cavity, in the transition state.

A clear indication that there are significant *favorable* interactions between the naphthyl groups of the esters and the β-CD cavity (or its rim) in the transition state is given by the larger pK_{TS} values for aminolysis of the two naphthyl acetates (3.06–4.85 for 1-NA; 2.16–4.11 for 2-NA), as compared to those for *p*-nitrophenyl esters reacting with the same amines (pK_{TS} = 2.23–3.15 for the acetate; 2.30–3.76 for the hexanoate).[13] Correspondingly, the rate ratios, k_{cN}/k_N and k_{Nc}/k_N, are generally much higher for the naphthyl esters than for the *p*-nitrophenyl ester,[2] and so the evidence for catalysis of aminolysis by β-CD is more clear-cut in this present work.

Conclusions

Binding of 1-naphthyl and 2-naphthyl acetates to CDs affects their reactivities to nonbinding nucleophiles to different extents, depending on the CD. Reactions of the esters with the anions of TFE and 2-ME are slowed down appreciably by β-CD and hp-β-CD, both of which bind the esters strongly. By contrast, their reactions with the 2-ME anion

[11]The largest ratio was obtained for the reaction of 1-NA with cyclohexylamine, catalyzed by β-CD. For this case, three different experiments gave essentially the same value of k_{cN} and, hence, of this ratio (Table 3).
[12]Additionally, it was shown in two experiments that the reaction of *n*-hexylamine with 1-NA is catalyzed by γ-CD (Table 3).
[13]From K_{TS} values in Table 3 of ref. 3.

© 1999 NRC Canada

are hardly affected by α-CD and γ-CD, which bind the esters less strongly.

Aminolysis of both esters by alkylamines is catalyzed by β-CD. The catalysis appears to arise primarily from binding of the alkylamino group in the CD cavity in the transition state (**3**), since the extent of the catalysis increases strongly with the ability of the alkylamine to bind to β-CD (Fig. 8). However, there must be additional factors involving the aryl groups of the esters, which contribute to transition state stabilization, since pK_{TS} values are not the same for the two naphthyl esters reacting with short amines, and these values are generally greater than those for *p*-nitrophenyl acetate and hexanoate reacting with the same amines, under the same reaction conditions.[2]

Experimental

The alkylamines, naphthyl esters, and most of the other required chemicals were the best grades available from the Aldrich Chemical Co. Cyclodextrins were obtained from Aldrich and from Wacker Chemie (Munich, Germany). To be compatible with earlier studies (2, 3, 6, 7, 9), the "hydroxypropyl-β-cyclodextrin" used had an average molecular weight of 1500, consistent with alkylation of about six of the seven primary hydroxyl groups of β-CD by 2-hydroxypropyl groups (1*c*, *d*).[14] Aqueous buffers were made from the requisite reagents and water that had been ion-exchanged and doubly distilled from glass.

Kinetics procedures were basically the same as those used in previous, related work (2–4, 9). Reactions were initiated by mixing equal volumes of a solution of the nucleophile in buffer with a solution of the ester (with or without a CD), in a stopped-flow apparatus. The ester concentrations used were 50 or 100 μM, after mixing.

The reactions of the esters with TFE and with amines were carried out at pH 11.60, to be compatible with previous studies (2, 3, 7, 9). Initial experiments with 2-ME were also performed at pH 11.60, but the results were unsatisfactory due to the small change in k_{obs}. Consequently, most of the experiments with 2-ME were executed at pH 10.60, in a 0.10 M carbonate buffer, where competition from the background reactions (eqs. [1] and [2]) is less significant (Figs. 1 and 2), and k_N and k_{cN} are more easily evaluated. The range of [TFE] and [2-ME] used can be judged from Figs. 1–3.

For aminolysis, the amine solutions were all set to pH 11.60 in a buffer, as in the previous studies (3). For the less soluble *n*-hexylamine and *n*-heptylamine, a phosphate buffer (0.40 M before mixing) was used; for the others, the buffer was made using the amine itself. The range of amine concentrations used was the same as previously,[2] as can be seen in Figs. 4 and 5. The concentrations of CDs used are noted in Tables 1 and 3.

The kinetics of naphthyl ester cleavage were followed by monitoring the first-order appearance of the naphthoxide ion at 330–350 nm (9), using an Applied Photophysics SX17MV stopped-flow spectrophotometer, with the cell temperature maintained at 25.0 ± 0.1°C. In general, 5–10 good absorbance traces, each containing 400 data points, were averaged, and the pseudo-first-order rate constant k_{obs} was estimated from the average trace by nonlinear least-squares fitting of an exponential increase to the data.

Analyses of the kinetic data based on eqs. [5], [6], and [8], as outlined in the text and detailed elsewhere (2–4), require the use of known values of K_S and K_N for binding between CDs and the reactants. These values were available from earlier studies (7, 9),[2] as indicated in the Tables 1 and 2. The use of eqs. [6] and [8] for the analysis of aminolysis requires values of [CD] and [amine] to be corrected for binding of the amine to the CD (eq. [7]). Details of the calculation of such corrected concentrations have been given already (4).

The surprising formation of structurally distorted *ap*-9-(*o-tert*-butylphenyl)-9-methylthiofluorene and its facile homolysis into *sp*-9-(*o-tert*-butylphenyl)-3-methylthiofluorene and *sp*-9-(*o-tert*-butylphenyl)fluorene

Yuqing Hou and Cal Y. Meyers

Abstract: The continued study of rotationally restricted 9-(*o-tert*-butylphenyl)fluorenes has provided surprising results. Treatment of *sp*-9-(*o-tert*-butylphenyl)-9-fluorenol (**1**) with ethanol or methanol under acidic conditions affords *sp*-9-(*o-tert*-butylphenyl)-9-ethoxyfluorene (**2b**) and *sp*-9-(*o-tert*-butylphenyl)-9-methoxyfluorene (**3b**), respectively, but similar treatment with methanethiol converts **1** into the rotamerically opposite *ap*-9-(*o-tert*-butylphenyl)-9-methylthiofluorene (**4a**). While all three products reflect reaction with inversion at C-9, **2b** and **3b** reflect subsequent rotation, which is not the case with **4a**. X-ray diffraction shows **4a** to be highly distorted and strained, but apparently favored thermodynamically over its *sp* rotamer. Homolysis of **4a** is observed at room temperature, and at elevated temperatures accounts for the formation of *sp*-9-(*o-tert*-butylphenyl)fluorene (**6b**) and *sp*-9-(*o-tert*-butylphenyl)-3-methylthiofluorene (**7c**) as major products. X-ray diffraction shows **6b** and **7c** to be virtually devoid of distortion. Methylation of **6b** via its anion also proceeds with inversion without rotation to form *ap*-9-(*o-tert*-butylphenyl)-9-methylfluorene (**4c**). Dynamic NMR unexpectedly showed that in these *ap* configurations 9-CH_3 (of **4c**) has a greater bulk effect than 9-CH_3S (of **4a**) in forcing the *o-tert*-butyl group into the fluorene plane.

Key words: fluorene, rotamer, distortion, homolysis, carbanion, carbocation, radical.

Résumé : La suite de nos études sur les 9-(*o-tert*-butylphényl)fluorènes à rotation empêchée a fourni des résultats surprenants. Les réactions du *sp*-9-(*o-tert*-butylphényl)-9-fluorénol (**1**) avec l'éthanol et le méthanol dans des conditions acides conduisent respectivement au *sp*-9-(*o-tert*-butylphényl)-9-éthoxyfluorène (**2b**) et *sp*-9-(*o-tert*-butylphényl)-9-méthoxyfluorène (**3b**); toutefois, une réaction avec le méthanethiol transforme le composé **1** au rotamère opposé, le *ap*-9-(*o-tert*-butylphényl)-9-méthylthiofluorène (**4a**). Même si les trois produits sont le reflet d'une inversion en C-9, les produits **2b** et **3b** reflètent une rotation subséquente, ce qui n'est pas le cas avec **4a**. La diffraction des rayons X montre que le composé **4a** est tendu et très déformé, mais qu'il est apparemment thermodynamiquement favorisé par rapport à son rotamère sp. On observe de l'homolyse du produit **4a** à la température ambiante et, à des températures plus élevées, elle peut expliquer la formation des *sp*-9-(*o-tert*-butylphényl)fluorène (**6b**) et *sp*-9-(*o-tert*-butylphényl)-3-méthylthiofluorène (**7c**) comme produits majeurs. La diffraction des rayons X montre que les composés **6b** et **7c** sont pratiquement sans distorsion. La méthylation du produit **6b** par le biais de son anion se produit avec inversion, sans rotation, pour former le *ap*-9-(*o-tert*-butylphényl)-9-méthylfluorène (**4c**). La RMN dynamique a montré d'une façon inattendue que, dans des configurations *ap*, le 9-CH_3 (du composé **4c**) présente un effet stérique plus important que celui du 9-CH_3S (du composé **4a**) pour forcer le groupe *o-tert*-butyle dans le plan du fluorène.

Mots clés : fluorène, rotamère, distorsion, homolyse, carbanion, carbocation, radical.

[Traduit par la Rédaction]

Introduction

As part of our recent studies of rotationally restricted 9-substituted fluorenes (1), we reported that the parent structure in our series, 9-(*o-tert*-butylphenyl)fluorene (**6b**), as well as 9-(*o-tert*-butylphenyl)-9-fluorenol (**1**), exists only in their *sp* form in solution at ambient temperatures and crystalline state (2).[2] While treatment of **1** with CH_3CH_2OH or

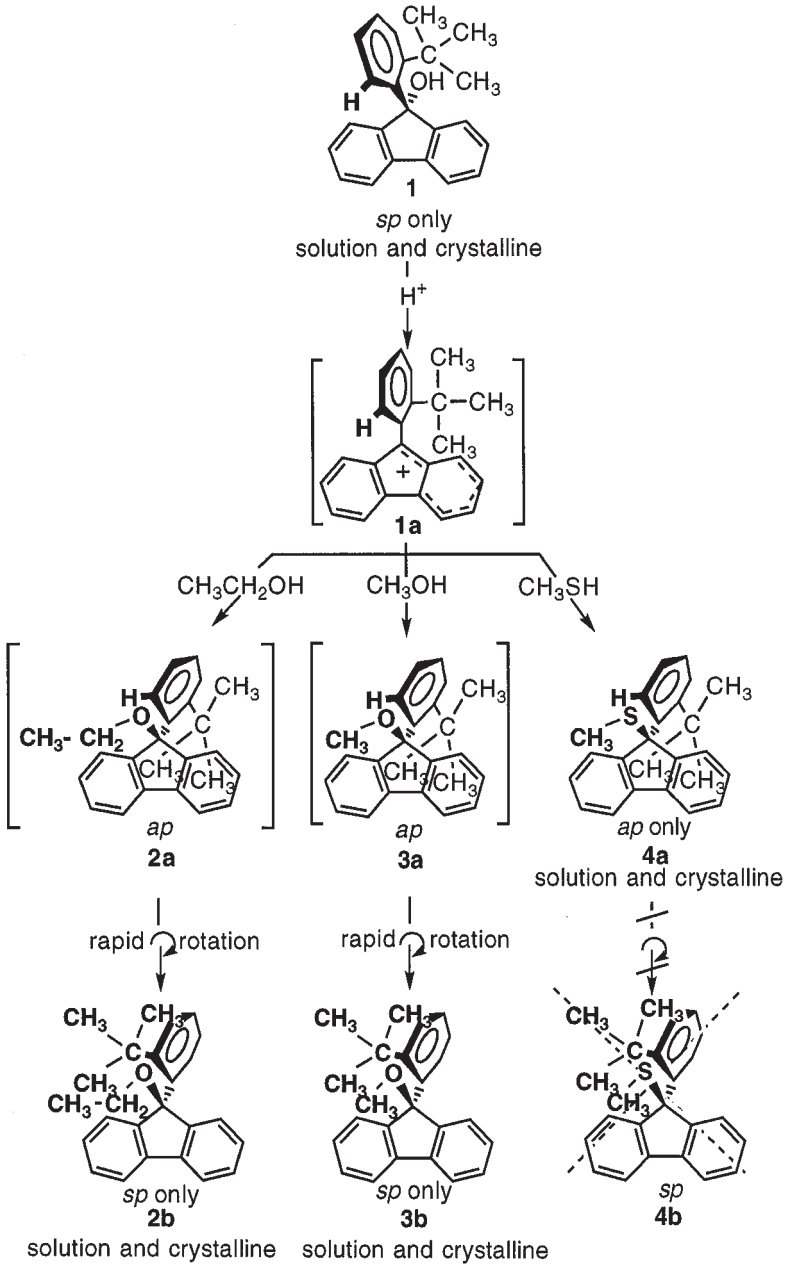
Scheme 1.



CH_3OH in the presence of strong acid also provided only the corresponding *sp*-9-alkoxy rotamers, *sp*-9-(*o-tert*-butylphenyl)-9-ethoxyfluorene (**2b**), and *sp*-9-(*o-tert*-butylphenyl)-9-methoxyfluorene (**3b**), respectively, similar treatment of **1** with CH_3SH unexpectedly provided only the rotamerically opposite *ap*-9-methylthio derivative, *ap*-9-(*o-tert*-butylphenyl)-9-methylthiofluorene (**4a**), in solution and crystalline form (3, 4) (Scheme 1).

The *ap* conformation in the series of 9-(*o-tert*-butylphenyl)fluorenes provokes a strong steric repulsion between the *tert*-butyl group and the fluorene π cloud, which raises the ground-state energy making it, in most cases, highly unstable relative to the *sp* conformation (3, 5–7). This strong shielding of the *tert*-butyl methyls by the fluorene-ring *p* electrons in the *ap* conformation accounts for their correspondingly high upfield ^{1}H NMR resonance, near 0.6 ppm. In contrast, in the *sp* conformation these methyls are maintained in the deshielding zone of the fluorene ring, giving rise to a much lower field resonance, near 1.8 ppm. This distinction has provided a ready means to differentiate between the two rotameric configurations of these fluorene derivatives in solution (3, 5–7). For the rotameric structure characterization of their solid states and the corresponding bonding parameters, we have relied on X-ray crystallography (2, 4, 8–10).

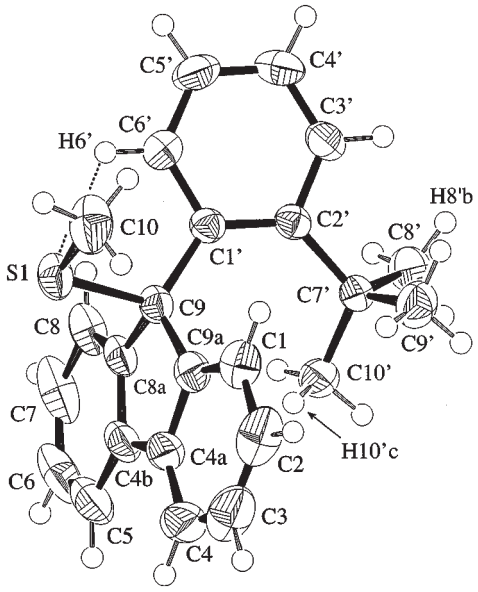
Results and discussion

Highly distorted/strained structure of *ap*-9-(*o-tert*-butylphenyl)-9-methylthiofluorene (4a)

The X-ray structure of **4a** (Fig. 1), whose geometric parameters have been reported in detail (4), clearly displays

© 1999 NRC Canada

Fig. 1. X-ray structure of **4a**.



extensive distortions. Our finding that **4a** exists exclusively in its *ap* conformation tells us that the 9-methylthio group enforces this conformation, which, although highly energetic per se, is thermodynamically favored over the *sp* conformation *in this case*.[3] Nonetheless, *ap* **4a** is highly distorted, provoking the strain that is clearly responsible for its unusual instability, which promotes its facile homolytic decomposition at room temperature, in contrast to the thermal stability of the *sp* compounds, e.g., **1**, **2b**, **3b**, and **6b** (2, 3). The major source of the strain emanates from the enforced impinging of a methyl of the *tert*-butyl group on the face of the fluorene ring. As a result, the bond between the *tert*-butyl group and phenyl, C2′—C7′, is considerably bent, angle C1′-C2′-C7′ being almost 18° larger than the corresponding angle C3′-C2′-C7′. In turn, angle C2′-C7′-C10′ is greatly distorted relative to the corresponding angles C2′-C7′-C9′ and C2′-C7′-C8′. For the same reason, the bond between the phenyl and fluorene rings, C1′—C9, is bent, making the angle C2′-C1′-C9 some 13° larger than the corresponding angle C6′-C1′-C9 and forcing the S1—C9 bond more towards perpendicularity with the fluorene plane, the angle between the S1-C9 vector and the fluorene ring plane being 99.09 (7)°. In turn, torsion angle C4b-C8a-C9-C1′ is almost 53° larger than its counterpart S1-C9-C9a-C4a. These enforced strains provoke an unusual distortion from planarity of the phenyl ring, the average deviation of the atoms of the C1′-to-C6′ ring from the least-squares plane being 0.028 (2) Å, while the corresponding values for the fluorene C1-to-C9a and C4b-to-C8a phenyl rings are 0.010 (2) and 0.005 (2) Å, respectively. The molecular distortion is manifested in unusually intimate intramolecular nonbonding contacts, e.g., C9a···C10′, C1···C10, C9a···H10′c, C8′···H3′, C3′····H8′b, and C4a···H10′c, all of whose distances are smaller than the sum of their respective van der Waals radii.

In this regard, the very close contact of S1···H6′, 2.42 Å, and S1···C6′, 2.96 Å (4), could give rise to a "hydrogen bond" reflected in the unusually low field signal of H6′, near δ 9.0, in its ^{1}H NMR spectrum (1, 3). Similar aromatic-H downfield shifts have been previously reported but were not associated with hydrogen bonding (11; cf. 12). While hydrogen bonding involving an aromatic H is unusual, it has been suggested from time to time (for related studies see ref. 13) and is supported in **4a** by comparison to a related structure, 9-(*o*-*tert*-butylphenyl)-9-methylfluorene (**4c**), in which such a possibility is absent. Compound **4c** is the only other 9-substituted 9-(*o*-*tert*-butylphenyl)fluorene we have so far prepared that exists solely in its *ap* conformation in solution, eq. [1]. While the *tert*-butyl group of **4c**, like that of **4a**, impinges onto the face of the fluorene ring (viz. the upfield ^{1}H NMR resonance of these methyls, δ 0.63 and 0.65, respectively) and thereby forces the 9-methyl and H6′ into close proximity, the ^{1}H NMR resonance of H6′, δ 8.0, is normal for an aromatic H held in the deshielding zone of the fluorene moiety. In comparing the thermodynamic favorability of the *ap* rotamer over the *sp* rotomer of both **4a** and **4c**, it is important to note that the 9-S atom and 9-CH_3 group exert a similar steric influence, which is not exerted by the 9-O atom in related structures whose *sp* rotamers are thermodynamically preferred (vide infra).

Facile homolysis of 4a into *sp*-9-(*o*-*tert*-butylphenyl)fluorene (6b) and *sp*-9-(*o*-*tert*-butylphenyl)-3-methylthiofluorene (7c)

It was not unexpected that such a highly strained molecule like **4a** would undergo facile decomposition. Such a consequence indeed was initially exhibited by the appearance of a blue cast taken on by the originally colorless crystals on standing in a sealed vial at room temperature over the period of a day or two. In attempting a dynamic ^{1}H NMR study of **4a** in DMSO-d_6 to examine the effect of temperature on the rotation of the sterically encumbered *tert*-butyl group (vide infra), little change was observed between 20 and 100°C. Slightly above this temperature, however, the resonances of **4a** began to deteriorate as other resonances appeared. Subsequently, a sample from the NMR tube was examined by TLC, which indicated the absence of **4a** but the presence of two new compounds. In a larger scale study, a DMSO solution of crystalline **4a**, heated for 30 min in a 155°C oil bath, afforded the same TLC results. The two products were identified as *sp*-9-(*o*-*tert*-butylphenyl)fluorene (**6b**, 24%) and *sp*-9-(*o*-*tert*-butylphenyl)-3-methylthiofluorene (**7c**, 48%), suggesting that the decomposition of **4a** was homolytic (Scheme 2). In contrast to **4a**, both products have the *sp* conformation, and their X-ray diffraction parameters (**6b** (2); **7c** (8)) show them to be nearly free of distortion and strain, as illustrated in Figs. 2 and 3.

Mechanisms

Our recent studies with the enantiomers of 9-(*o*-*tert*-butylphenyl)-2-methylfluorenes show that the 9-anion, -cation, and -radical of 9-(*o*-*tert*-butylphenyl)fluorene are

[3] That the *ap* conformation is thermodynamically preferred is supported by energy minimization calculations of both the *ap* (**4a**) and *sp* (**4b**) conformations using the AM1 method with a closed-shell (restricted) wave function and then comparing the energies of the heats of formation. The results showed that the *ap* conformation is favored over the *sp* conformation by 21.3 kJ/mol. We are indebted to a referee of our X-ray paper (4) for performing these calculations and transmitting them to us.

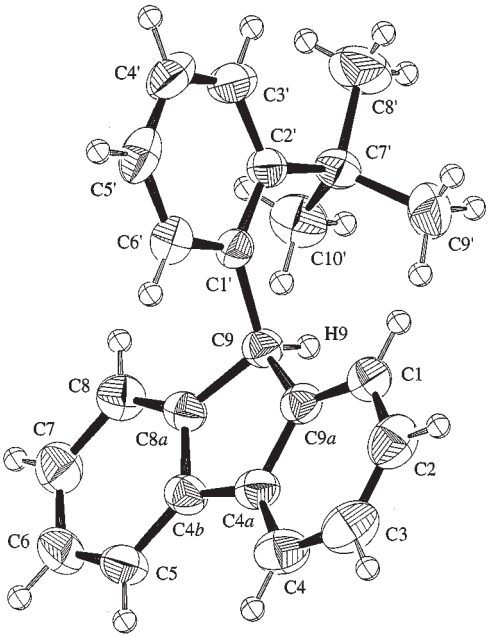

Fig. 3. X-ray structure of **7c**.

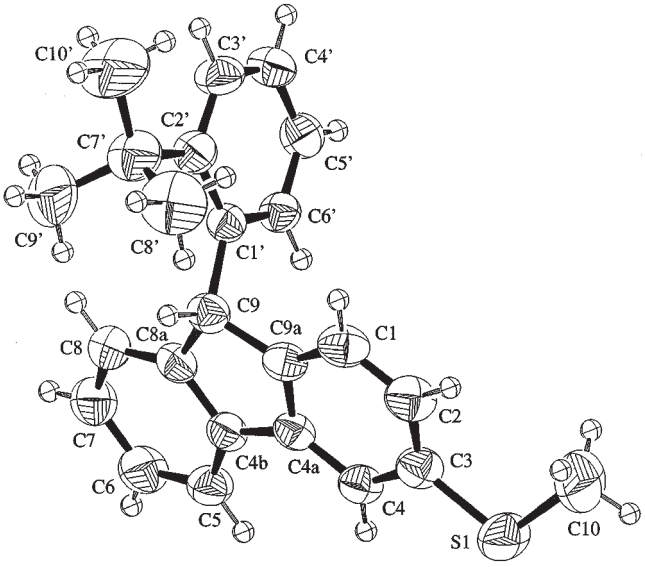
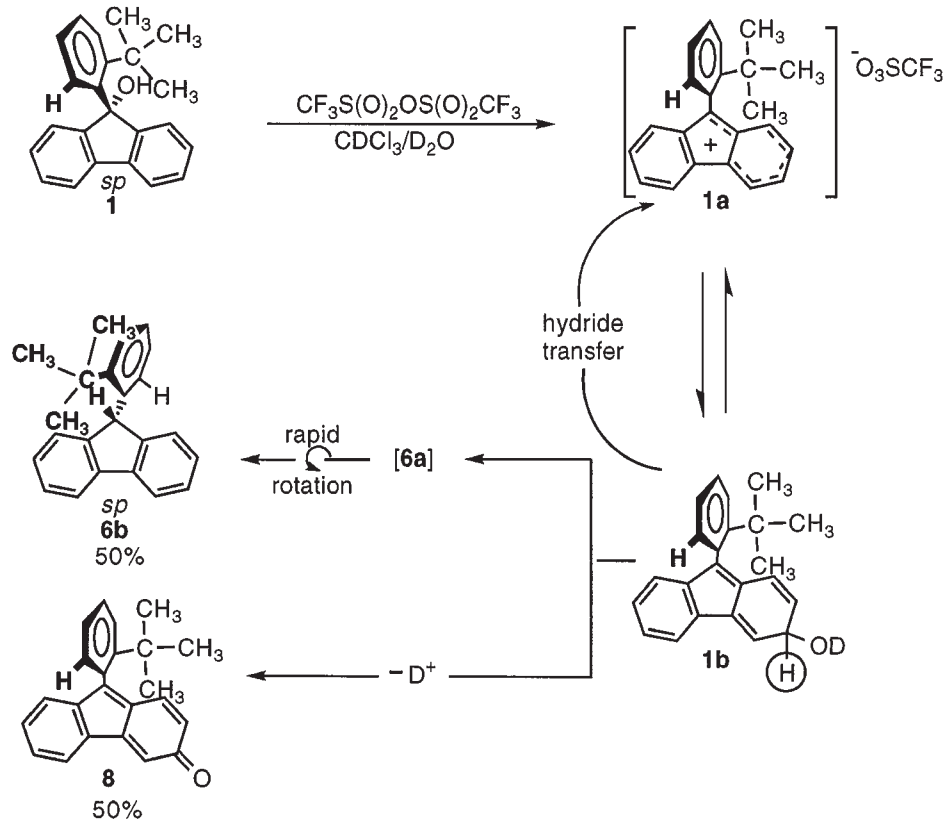


largely sp^2 hybridized and are generally attacked from the less hindered face of the fluorene plane (1, 3). It follows, and we indeed found, that *sp*-9-(*o*-*tert*-butylphenyl)fluorenes that undergo 9-substitution reactions involving the respective 9-anion, -cation, or -radical will produce the products of *inversion* and *ap* conformation. In most cases, however, these products undergo rapid rotation to the energetically favored *sp* rotamers. In rare instances, the initially formed *ap* rotamer is thermodynamically preferred and is the one isolated.

Shown in Scheme 1 is the conversion of *sp*-**1** into cation **1a** and its subsequent reaction with ethanol, methanol, or methanethiol leading to the respective *ap* products, **2a**, **3a**, and **4a**. The former two quickly undergo rotation to their more stable *sp* isomers, **2b** and **3b**, while *ap*-**4a**, being thermodynamically preferred over its *sp* rotamer, **4b**, remains

© 1999 NRC Canada

Scheme 3.



the exclusive product. In a similar manner, but via anion **1b**, *sp*-**6b** is methylated with inversion into *ap*-**4c**, which, like **4a**, does not undergo rotation and consequently is the exclusive product, eq. [1].

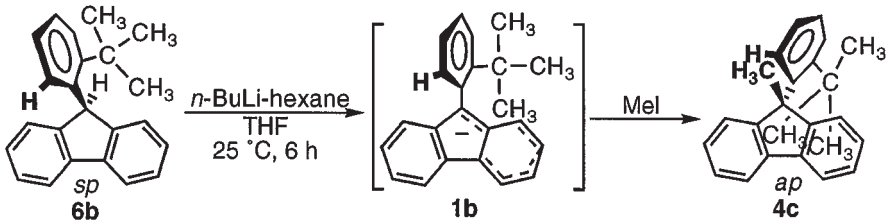
As illustrated in Scheme 2, the concurrent formation of **6b** and **7c** is homolytically initiated. This is the consequence of the highly distorted and strained structure of **4a**, the low C—S bond strength, and the formation of the relatively stable methylthio free radical and free radical **5**, whose formation greatly relieves the distortion and strain characterizing **4a**. Hydrogen-atom transfer from $CH_3S\cdot$ to **5** produces *ap*-**6a**, which undergoes rapid rotation to *sp*-**6b** (24% yield). Concurrently, $CH_3S\cdot$ also adds to **5** at its unhindered 3-position forming **7a**; 1,5-H migration provides *ap*-**7b**, which undergoes rotation to the more stable *sp*-**7c** (48% yield).

Via a similar but heterolytic pathway shown in Scheme 3, **1** is converted to cation **1a** by treatment with triflic anhydride. We utilized $CDCl_3$ containing some D_2O as the solvent to determine the mechanism more precisely. Addition of D_2O to **1a** provides **1b** reversibly and permits a hydride transfer from **1b** to **1a**, converting the latter into **6a**, which undergoes rapid rotation to **6b**. The transfer of hydride from **1b** is followed by loss of D^+ from the residual cation, thereby providing 9-(*o*-*tert*-butylphenyl)-3*H*-fluorenone (**8**). Both products were formed in 50% yield, which supports the suggested disproportionation mechanism. Moreover, the fact that **6b** was formed exclusively bearing 9-H and not 9-D proves that the H transfer emanated solely from the fluorene 3-H even when the solvent was $CHCl_3$–H_2O.

Dynamic NMR study

As already noted, in the *ap* conformation of these structures, the *o*-*tert*-butyl is forced into the fluorene plane, an effect which is amplified with 9-methylthio and 9-methyl substituents. Surprisingly, a dynamic NMR study showed that 9-methyl exerts a larger effect than 9-methylthio. ^1H NMR spectra of **4a** in CD_2Cl_2 taken between 20 and –85°C and in DMSO-d_6 between 20 and 100°C consistently exhibited one sharp singlet for the *tert*-butyl methyls, showing that rotation of the *tert*-butyl group was faster than NMR acquisition time, even at –85°C, and therefore was not sterically impeded. The 6′-H remained a doublet within this temperature range. However, a similar study with **4c** in $CDCl_3$ showed at 20°C, after a broad singlet of nine protons for the *tert*-butyl methyls, but whose signal height was similar to that of the three protons for the 9-methyl. The 6′-H ap-

[1]



© 1999 NRC Canada

peared to be a broad doublet. At 50°C, the *tert*-butyl signal had narrowed, and its height was commensurate with nine protons relative to that for three protons of the 9-methyl, and the 6′-H became a much sharper doublet. These results indicate that, at 20°C, rotation of the *tert*-butyl group of **4c** is noticeably impeded by steric encumbrance, becoming close to or slower than NMR acquisition time, so that the methyls are detected as being "almost" nonequivalent.

Experimental

Melting points are corrected. NMR spectra were taken on a Varian VXR-300 spectrometer, 300 MHz for ^{1}H and 75 MHz for ^{13}C, in $CDCl_3$ with TMS as internal standard, except for the dynamic NMR studies, which were carried out in CD_2Cl_2, $CDCl_3$, or DMSO-d_6, as described in the discussion.

sp-9-(*o*-*tert*-Butylphenyl)-9-fluorenol (1)

Following the method recently reported for the X-ray study (2), **1** was prepared from the reaction of *o*-*tert*-butylphenylmagnesium bromide with fluorenone in 76% yield, 97% conversion based on unrecovered fluorenone; colorless crystals (from isooctane), mp 158–159°C (lit. (5) mp 156.5–158°C).

sp-9-(*o*-*tert*-Butylphenyl)-9-ethoxyfluorene (2b)

To a colorless solution of 9-(*o*-*tert*-butylphenyl)-9-fluorenol (1) (50.2 mg, 0.16 mmol) and 5 mL of ethanol in a 10 mL round-bottomed flask, 2 g of 48% HBr (9.9 mmol) was added. The reaction mixture, which became light yellow, was stirred overnight at room temperature and then extracted with hexanes (20 mL × 3). The combined extracts were washed with water, aq $NaHCO_3$, and again with water, dried (anhyd $MgSO_4$), and rotary evaporated to give a sticky oil that slowly crystallized (53.6 mg, 98.5%); colorless crystals, mp 100.5–101.5°C. ^{1}H NMR showed them to be almost pure (**2b**), δ: 1.08 (t, 3 H, *J* = 6.9 Hz), 1.81 (s, 9 H), 2.92 (q, 2 H, *J* = 6.9 Hz), 6.41 (dd, 1 H, *J* = 8.1, 1.5 Hz), 6.71 (ddd, 1 H, *J* = 1.5, 8.1, 7.2 Hz), 7.01 (ddd, 1 H, *J* = 1.5, 7.2, 8.1 Hz), 7.20 (ddd, 2 H, *J* = 1.2, 7.5, 7.2 Hz), 7.27 (dd, 2 H, *J* = 1.2, 7.5 Hz), 7.33 (ddd, 2 H, *J* = 1.5, 7.2, 7.5 Hz), 7.55 (dd, 1 H, *J* = 8.1, 1.5 Hz), 7.67 (dd, 2 H, *J* = 7.5, 1.2 Hz). ^{13}C NMR, δ: 15.06, 34.16, 37.61, 58.48, 92.74, 119.62, 124.95, 125.48, 126.01, 127.72, 128.46, 132.09, 140.37, 140.61, 149.31, 151.15. Anal. calcd. for $C_{25}H_{26}O$: C 87.68, H 7.65; found: C 87.37, H 7.62.

sp-9-(*o*-*tert*-Butylphenyl)-9-methoxyfluorene (3b)

To an Erlenmeyer flask containing a colorless solution of **1** (500 mg, 1.6 mmol) in methanol (10 mL), 1 mL of 9 M sulfuric acid (9 mmol) was added. After the flask was swirled at room temperature for 10 min, TLC showed that all the starting material was consumed; only one spot, reflecting a less polar compound, was observed. The reaction mixture was transferred to a separatory funnel with the aid of 40 mL of hexanes to rinse the flask. The mixture was washed with water, aq $NaHCO_3$, and water again. The organic layer was separated, dried over anhyd $MgSO_4$, and evaporated in vacuo, leaving a colorless oil (**3b**) (510 mg, 97.6%) that slowly crystallized at room temperature; mp: 87–89°C. Recrystallization from methanol provided crystals mp 89.5–90.5°C. ^{1}H NMR, δ: 1.76 (s, 9 H); 2.76 (s, 3 H), 6.43 (dd, 1 H, *J* = 8.1, 1.5 Hz), 6.72 (ddd, 1 H, *J* = 1.5, 8.4 Hz), 7.02 (ddd, 1 H, *J* = 1.5, 7.2, 8.1 Hz), 7.18–7.27 (m, 4 H), 7.31–7.37 (m, 2 H), 7.52 (dd, 1 H, *J* = 8.1, 1.5 Hz), 7.67 (dd, 2 H, *J* = 7.5, 0.9 Hz). ^{13}C NMR, δ: 33.93, 37.66, 49.62, 93.05, 119.59, 124.88, 125.56, 125.99, 127.72, 128.39, 128.54, 131.93, 140.36, 140.53, 141.16, 150.26. Anal. calcd. for $C_{24}H_{24}O$: C 87.76, H 7.36, found: C 87.86, H 7.32.

ap-9-(*o*-*tert*-Butylphenyl)-9-methylthiofluorene (4a)

A stoppered 10 mL round-bottomed flask containing **1** (33.6 mg, 0.107 mmol) was kept in the freezer (–15°C) for 2 h. Methanethiol (–15°C, 3 mL) was then added with a precooled pipet; the solution remained colorless. Precooled 48% HBr solution (ca. 1 mL, 8.8 mmol) was added, and the reaction mixture immediately turned light yellow. This mixture was maintained at –15°C overnight, the residual methanethiol was then evaporated in the hood and the residue extracted with hexanes (3 × 20 mL). The combined extracts were washed with water, dilute aq $NaHCO_3$, and water again. Rotary evaporation left a light yellow solid (36 mg, ca.100% yield); mp 110–113.5°C (dec., bubbling, probably MeSSMe or CH_2=S; color deepens at 90°C). ^{1}H NMR showed the solid was essentially pure **4a**, δ: 0.65 (s, 9 H), 1.70 (s, 3 H), 7.14 (d, 2 H, *J* = 7.5 Hz), 7.27 (ddd, 2 H, *J* = 7.5, 1.2 Hz), 7.30 (ddd, 1 H, *J* = 1.8, 8.1 Hz), 7.37 (ddd, 1 H, *J* = 1.8, 7.5 Hz), 7.39 (ddd, 2 H, *J* = 7.5, 1.2 Hz), 7.59 (dd, 1 H, *J* = 7.8, 1.8 Hz), 7.80 (dd, 2 H, *J* = 7.5, 0.6 Hz), 8.92 (d, 1 H, *J* = 8.4 Hz). ^{13}C NMR, δ: 16.69, 32.81, 37.42, 67.60, 120.64, 123.79, 125.36, 127.08, 127.30, 127.49, 131.43, 134.78, 133.47, 139.27, 150.71, 150.79. Recrystallization from hexanes provided colorless single crystals for X-ray analysis (4). During X-ray diffraction, the crystal became yellow. Within a few days standing on the desktop under normal fluorescent lighting, crystalline **4a** developed a deep blue coloration suggestive of homolytic decomposition.

ap-9-(*o*-*tert*-Butylphenyl)-9-methylfluorene (4c)

A 10 mL round-bottomed flask containing **6b** (2) (140 mg, 0.47 mmol) was flushed with argon and sealed with a rubber septum. Freshly distilled THF (3 mL) was syringed into the flask and to this colorless solution an *n*-BuLi solution (1.0 mL, 1.6 M, 1.6 mmol) was added via syringe. The mixture, which turned red immediately, was stirred at room temp for 6 h after which time iodomethane (0.10 mL, 1.6 mmol) was syringed dropwise into the flask. The red solution became colorless within 5 min. TLC produced two spots, the minor one matching that of the starting material. The solvent was removed in vacuo leaving a pale yellow solid. Water (5 mL) was added, the resulting slurry was extracted with hexanes, and the combined extracts were concentrated in vacuo to give a white solid, 135 mg, shown by ^{1}H NMR to be essentially **4c** and a small amount of residual **6b**. Purification via column chromatography (silica gel, hexanes) yielded colorless crystalline *ap*-**4c**, 120 mg (82% yield), mp 89.5–90.5°C. ^{1}H NMR, δ: 0.63 (bs, 9 H), 1.72 (s, 3 H), 7.10 (d, 2 H, *J* = 7.5 Hz), 7.12 (ddd, 2 H, *J* = 7.5, 1.5 Hz), 7.30 (m, 2 H), 7.33 (ddd, 2 H, *J* = 7.5, 1.2 Hz), 7.59

© 1999 NRC Canada

(m, 1 H), 7.77 (d, 2 H, J = 7.8 Hz), 8.05 (br d, 1 H, J = 6.3 Hz). ^{13}C NMR, δ: 32.92, 37.46, 38.62, 56.89, 120.61, 123.12, 125.23, 126.56, 126.74, 127.33, 130.85, 131.45, 138.73, 139.23, 150.74, 156.42. ^{1}H NMR at 50°C: the chemical shifts of the peaks were essentially the same, but the peaks at δ 0.63, 1.72, and 8.05 were much sharper. Anal. calcd. for $C_{24}H_{24}$: C 92.26, H 7.74; found: C 92.21, H 7.46.

Homolysis of 4a. Formation of *sp*-9-(*o*-*tert*-butylphenyl)fluorene (6b) and *sp*-9-(*o*-*tert*-butylphenyl)-3-methylthiofluorene (7c)

A solution of **4a** (115 mg, 0.334 mmol) in 5 mL of DMSO in a 25 mL round-bottomed flask was magnetically stirred for 30 min while heated in an oil bath maintained at 155°C. The reaction mixture was cooled to room temperature and transferred to a separatory funnel, the residue was transferred by several washings with ether, and the combined solution was washed with water to remove DMSO. The ethereal solution was dried (anhyd $MgSO_4$) and evaporated in vacuo, leaving a black sticky oil. ^{1}H NMR showed the presence of two major products, and only a trace amount of **4a**. The two products were separated and isolated by "dry-column chromatography" (silica gel; hexane). From the first fraction **6b** (24 mg, 24.1% yield) was isolated and identified by mp (179.5–180.5°C), NMR, and X-ray crystallography (2). Evaporation of the second fraction produced **7c** (55 mg, 47.8% yield), which had almost the same R_f value as **4a** in TLC (10:1 hexanes:ether). Recrystallization from hexanes gave almost colorless crystals of **7c**, mp 156.5–157.5°C (no dec.), which were used for X-ray analysis (8). ^{1}H NMR, δ: 1.70 (s, 9 H), 2.58 (s, 3 H), 5.83 (s, 1 H), 6.22 (dd, 1 H, J = 7.8, 1.5 Hz), 6.87 (ddd, 1 H, J = 7.8, 7.2, 1.2 Hz), 7.11 (ddd, 1 H, J = 8.1, 7.2, 1.8 Hz), 7.14 (d, 2 H, J = 1.2 Hz), 7.23 (m, 2 H), 7.38 (m, 1 H), 7.48 (dd, 1 H, J = 8.1, 1.5 Hz), 7.73 (dd, 1 H, J = 1.2 Hz), 7.81 (dd, 1 H, J = 7.5, 1.2 Hz). ^{13}C NMR, δ: 16.51, 32.57, 35.62, 50.62, 118.37, 119.88, 125.21, 125.43, 125.79, 126.19, 126.34, 126.42, 127.10, 127.70, 130.82, 137.09, 139.76, 140.47, 141.89, 147.32, 148.14, 150.39.

Reaction of 1 with triflic anhydride in $CDCl_3$–D_2O. Formation of equimolar quantities of 6b and 9-(*o*-*tert*-butylphenyl)-3*H*-fluorenone (8)

To a stirred colorless solution of **1** (63.2 mg, 0.20 mmol) in 1.0 mL of $CDCl_3$, three drops of D_2O followed by 0.1 mL of triflic anhydride (0.059 mmol) were added. The reaction mixture turned deep red immediately. The reaction flask was glass-stoppered and the mixture stirred at room temperature for 6 h during which time it gradually turned brown. TLC (9:1 hexanes:ether) showed mainly the presence of **1**, **6b**, and a red compound. The mixture was put on a silica-gel column through which $CDCl_3$ was passed, leaving the triflic acid and D_2O on the column. The first fraction collected provided a slightly off-white solid, 42 mg, shown by ^{1}H NMR to be composed only of **1** and **6b** (with no D atom on C-9). The second fraction yielded a red solid, 18 mg; recrystallization from hexanes provided red crystals, mp 142.5–143.5°C, identified as **8**. The yield (by NMR) of **6b** as well as **8** was 29%, or close to 50% of each, based on unrecovered starting material. IR (film on salt plate): 3055 (w), 2962 (m), 2930 (m), 2865 (w), 1640 (m), 1620 (s), 1597 (m), 1562 (m), 755 (m), 740 (s) cm^{-1}. ^{1}H NMR of **8**, δ: 1.32 (s, 9 H), 6.03 (dd, 1 H, J = 1.8, 9.6 Hz), 6.61 (d, 1 H, J = 1.8 Hz), 6.77 (dd, 1 H, J = 1.5, 6.9 Hz), 6.84 (d, 1 H, J = 9.9 Hz), 7.00 (dd, 1 H, J = 1.8, 7.5 Hz), 7.12 (ddd, 1 H, J = 1.2, 7.5 Hz), 7.17 (ddd, 1 H, J = 1.5, 7.8 Hz), 7.26 (ddd, 1 H, J = 1.2, 7.5 Hz), 7.39 (dd, 1 H, J = 1.8, 8.1 Hz), 7.42 (ddd, 1 H, J = 1.2, 7.5 Hz), 7.62 (dd, 1 H, J = 1.2, 8.1 Hz). ^{13}C NMR, δ: 32.30, 36.58, 121.53, 121.94, 124.36, 125.63, 127.27, 127.64, 128.79, 129.09, 129.71, 130.03, 130.51, 131.99, 134.10, 136.40, 146.67, 149.25, 150.92, 157.05, 189.03. Anal. calcd for $C_{23}H_{20}O$: C 88.43, H 6.45; found: C 88.59, H 6.47.

^{13}C, ^{15}N, and ^{18}O equilibrium isotope effects and fractionation factors[1]

Mark A. Rishavy and W.W. Cleland

Abstract: A listing of ^{13}C, ^{15}N, and ^{18}O equilibrium isotope effects and fractionation factors for atoms in specific positions is provided. Empirical factors that can be used to adjust these fractionation factors for more complex structures are presented and discussed. While much work needs to be done to determine equilibrium isotope effects for these heavy atoms, the values tabulated here should be useful to anyone working with isotope effects involving these atoms.

Key words: equilibrium isotope effects, fractionation factors, ^{13}C, ^{15}N, ^{18}O.

Résumé : On présente une liste des effets isotopiques d'équilibre et des facteurs de fractionnement du ^{13}C, du ^{15}N et du ^{18}O relatifs à des atomes dans des positions spécifiques. On présente et on discute des facteurs empiriques qui peuvent être utilisés pour ajuster ces facteurs de fractionnement dans les cas de structures plus complexes. Même si beaucoup de travail reste à faire pour déterminer les effets isotopiques d'équilibre pour ces atomes lourds, les valeurs rapportées ici devraient s'avérer utiles pour quiconque s'intéresse aux effets isotopiques impliquant ces atomes.

Mots clés : effets isotopiques d'équilibre, facteurs de fractionnement, ^{13}C, ^{15}N et ^{18}O.

[Traduit par la Rédaction]

Substitution of a heavier isotope for a lighter one not only affects the rates of chemical reactions, but also changes equilibrium constants if the isotopic atom is more stiffly bonded in the reactant than in the product or vice versa. Since the equations for kinetic isotope effects include the equilibrium isotope effect in one of the numerator terms (1), it is important for anyone trying to interpret kinetic isotope effects to know these values.

Equilibrium isotope effects are commonly expressed as the ratio of K_{eq} for the light isotope to K_{eq} for the heavy one. A leading superscript indicates the isotope involved. Thus, $^{13}K_{eq}$ is $K_{eq\ C\text{-}12}/K_{eq\ C\text{-}13}$. $^{14}K_{eq}$, $^{15}K_{eq}$, and $^{18}K_{eq}$ are equilibrium isotope effects caused by replacement of ^{12}C, ^{14}N, or ^{16}O by ^{14}C, ^{15}N, or ^{18}O, respectively. Values greater than unity show that the heavy isotope is enriched in the reactant, while values less than unity show enrichment in the product. The equilibrium isotope effect in the back reaction is the reciprocal of that in the forward reaction. For comparison of ^{14}C and ^{13}C equilibrium isotope effects (2),

$$[1] \qquad {}^{14}K_{eq} = 1 + 1.9({}^{13}K_{eq} - 1)$$

When a chemical reaction has sat long enough for both chemical and isotopic equilibrium to be reached (we usually allow 10 times longer for the latter to ensure that true isotopic equilibrium has been reached), the equilibrium isotope effect is readily measured by determining the mass ratio at the atom of interest in both the reactant and product. This is particularly simple for enzyme-catalyzed reactions, as the enzyme can be denatured or filtered off with an ultrafiltration apparatus to leave a mixture of reactant and product that can be separated and analyzed at one's leisure. Isotope ratio mass spectrometry is the usual method of analysis used for ^{13}C, ^{15}N, and ^{18}O because of the precision that can be obtained (3). Radioactive counting to determine ^{14}C isotope ratios is generally an order of magnitude less precise. Other methods such as NMR may also be used. The effect of ^{18}O substitution on the acid dissociation constant of any carboxylic acid, phenol, or alcohol containing ^{13}C attached to the oxygen, or in any phosphate group, is readily determined by titrating a 50–50 mixture of ^{16}O and ^{18}O-containing species and determining the separation between the ^{13}C or ^{31}P signals for the ^{16}O and ^{18}O species (the latter resonating slightly upfield) as the chemical shift changes with pH (4). If there is an ^{18}O equilibrium isotope effect on the pK, the ^{16}O species ionizes at a slightly lower pH than the ^{18}O one, and this separation in signals will increase to a

maximum at the average of the p*K* values and then decrease again as the titration is continued. The method gives excellent values because the separation between the ^{16}O and ^{18}O-containing species is so small compared with the change in chemical shift seen during the titration. NMR has also been used to determine equilibrium isotope effects in carbenium ions where the hydride shift between adjacent atoms is fast (5).

It is convenient for many purposes to tabulate fractionation factors, which are equilibrium isotope effects for exchange of heavy isotope between the compound of interest and a reference molecule. Hartshorn and Shiner (6) originally used acetylene as the reference for deuterium and ^{13}C isotope effects, but biochemists have found it more convenient to use H_2O as the reference for deuterium and ^{18}O isotope effects and aqueous CO_2 and NH_3 for ^{13}C and ^{15}N isotope effects, respectively, and these reference molecules will be used in our tabulations.[3] A fractionation factor greater than unity means the heavy isotope becomes enriched in the compound of interest rather than in the reference molecule, while a value less than unity indicates that the heavy isotope becomes enriched in the reference molecule.

Several tabulations of fractionation factors for deuterium are available (7, 8), but the data for ^{13}C, ^{15}N, and ^{18}O are scattered. In the present article, we tabulate those values known to us, including several previously unpublished numbers. We also show how several empirical rules can be used to extend the usefulness of the experimental or calculated fractionation factors for small molecules to ones with more complex structures. Hopefully, we will stimulate research in this field, since there are still numerous fractionation factors that are not well known, and the empirical rules for extending them need further verification.

^{13}C equilibrium isotope effects and fractionation factors

Table 1 shows a number of experimental ^{13}C equilibrium isotope effects. Most were measured enzymatically using isotope ratio mass spectrometry. These should be reasonably accurate, but except for decarboxylations, where CO_2 is one component of the reaction, the actual fractionation factors of the carbons involved expressed relative to aqueous CO_2 are less certain. By using the data in Table 1 and fractionation factors calculated by Hartshorn and Shiner (6) for various small molecules (see Table 2), however, certain empirical rules based on these values can be used to calculate approximate ^{13}C fractionation factors for other molecules.

Replacing a hydrogen on the isotopic carbon with a CH_3 group multiplies the fractionation factor by 1.013 (compare ethane and methane in Table 2), while replacing it with OH multiplies it by 1.019 (methanol vs. methane). Replacement of H by NH_2 and NH_3^+ raises fractionation factors by 1.012 and 1.016, respectively (neutral or protonated methylamine vs. methane). These increases are largely due to effects on the stretching vibrations. A C-H stretch is not very ^{13}C-sensitive because most of the motion is by the lighter hydrogen atom, but C-C, C-N, and C-O stretches are ^{13}C-sensitive. While these increases in fractionation factors apply to modifications of methane, they will be smaller for changes to more stiffly bonded atoms. For example, the increase in fractionation factor for replacing H with C drops to 1.010 for replacement on a carbon of ethane to give propane with the center atom the isotopic one.

When we consider the effects of replacing hydrogen with a heavier atom on a carbon (or other heavy atom) attached to the isotopic one, the major effects will be on bending vibrations. A [C]-C-H bending vibration is not very sensitive to ^{13}C in the bracketed carbon because the lighter hydrogen undergoes most of the motion. Note the small equilibrium isotope effect of 0.9986 (1/1.0014) in Table 1 for protonating benzoic acid, which adds a [C]-O-H bending vibration. A [C]-C-C bending vibration, however, *is* ^{13}C-sensitive. The increase in fractionation factor for replacing H with CH_3 in this situation appears to be 1.004 (terminal carbon of propane (0.960) vs. that of ethane (0.956)), at least for the first replacement.

The increase in fractionation factor should be somewhat higher for replacement by oxygen or nitrogen because of their increased mass. For example, 6-phosphogluconate has a CHOH group at C-2, while malate has a CH_2 group at C-3. Both have a CHOH group at the next carbon (C-3 of 6-phosphogluconate; C-2 of malate). The fractionation factor of C-1 of 6-phosphogluconate is higher than that of C-4 of malate by a factor of 1.008 ± 0.001 (second and third entries of Table 2). This is bigger than the factor of 1.004 for replacement of hydrogen by CH_3, but may be a valid indication of the greater effect of oxygen than carbon in stiffening vibrational modes.

The effect of replacing hydrogen with a heavier atom on the second carbon from the isotopic one will largely be on the torsional vibrations. Again, a [C]-C-C-H torsional vibration is not very sensitive to ^{13}C in the bracketed carbon, but a [C]-C-C-C one will be. Shiner and co-workers (6, 8) did not include any four carbon molecules in their calculations, but we can get some estimate of this effect by comparing the fractionation factors of two of the carboxylic acids which have been equilibrated with CO_2.

The structure of isocitrate differs from that of malate by having a carboxymethyl group attached to C-3 of malate (the carbon next to the isotopic carboxyl). The CH_2 group of this addition is expected to raise the fractionation factor of the carboxyl removed by isocitrate dehydrogenase by 1.004, but the overall increase in fractionation factor from C-4 of malate to the carboxyl of isocitrate is a factor of 1.015 ± 0.001 (first and third entries in Table 2). While some of the increase in fractionation factor of 1.015/1.004 = 1.011 is certainly caused by the added torsional [C]-C-C-C vibration, some may come from other effects such as steric crowding as the isotopic carbon is now secondary, not primary, and some may represent experimental error. This example illustrates the effect that torsional vibrations can have on fractionation factors. Changes in torsional frequencies have been invoked to explain ^{15}N isotope effects on carbamyl-*P* hydrolysis (9) and the differing fractionation factors of the two cysteine SH protons in the active site of proline racemase (10).

[3] The deuterium fractionation factors of Shiner are readily converted to the H_2O reference by division by his fractionation factor of water (see ref. 7, footnote *c*, p. 109), while the ^{13}C ones are corrected by division by his fractionation factor for CO_2 (see footnote *r*, p. 110, of ref. 7).

Calculated fractionation factors for keto acids

In the cases of oxaloacetate and pyruvate, corrections have to be made to the equilibrium isotope effects in Table 1 for the degree of hydration and enolization of these molecules. Pyruvate is 6% hydrated at 25°C (11), while the dianion of oxaloacetate is 18% hydrated and 8% enolized (12). In calculating the fractionation factors for the keto structures, we can use the empirical rules above to apportion the observed equilibrium isotope effect among the various structures.

© 1999 NRC Canada

As an example of this procedure, consider C-2 of L-malate. Relative to C-2 of propane (fractionation factor 0.966), a hydrogen is replaced by OH at C-2, three hydrogens are replaced by two oxygens at C-1, and a hydrogen is replaced by a carboxyl group at C-3. To evaluate the fractionation factor of C-2, we multiply 0.966 by 1.019 for the hydroxyl at C-2, by 1.008 twice for the oxygen replacements at C-1, by 1.004 for the addition of C-4, and by 1.011 twice for the two oxygens attached to C-4 to give 1.026.[4]

For the hydrate of oxaloacetate, we multiply 1.026 by 1.019 for the extra hydroxyl at C-2 to get 1.046. For the enol form of oxaloacetate, we start with ethylene (0.955) and multiply by the same factors as for malate, except that we must also multiply by 1.010 for the addition of C-1, giving 1.013. Since the apparent fractionation factor of C-2 of oxaloacetate is higher than that of malate by 1.009 (third and fourth entries in Table 2), we can write:

$$[2] \qquad 1.026 \times 1.009 = 1.0352$$

$$= 0.18 \times 1.046 + 0.08 \times 1.013 + 0.74X$$

where X is the fractionation factor of the keto form, which is 74% of the total, the rest being 18% hydrate and 8% enol. Solution of this equation gives 1.035 for C-2 of the keto form, so the fractionation factor for the keto carbon is higher than that for a CHOH carbon (1.026) by 1.009. The fact that a keto carbon is more stiffly bonded than a CHOH one by 0.8–0.9% is born out by the equilibrium isotope effect for the conversion of glucose-6-*P* to 6-*P*-gluconolactone, which is 0.992 (Table 1). In comparison, the aldehyde carbon of benzaldehyde is more stiffly bonded than the CH_2OH carbon of benzyl alcohol by 1.5% (Table 1). Thus, the stiffening effect of replacing H with C on the carbonyl carbon diminishes the difference between carbonyl and hydroxyl-bound carbons. This is clear evidence that the empirical factors are not fully multiplicative. However, the $^{13}K_{eq}$ value of 1.003 for dehydration of glyceraldehyde hydrate is only slightly less than the value of 1.004 predicted from a value of 1.015 for reduction of an aldehyde to a CH_2OH group, divided by 1.019 for subsequent replacement of H with OH to give the hydrate.

Application of this method to C-2 of lactate involves replacing H with OH at C-2 of propane and replacing three hydrogens with two oxygens at C-1. For the fractionation factor of C-2 we get $0.966 \times 1.019 \times 1.008 \times 1.008 = 1.000$. The hydrate of pyruvate will then have a fractionation factor 1.019 times this or 1.019. Since the observed fractionation factor of C-2 of pyruvate is less than that of C-2 of malate (calculated above as 1.026) by a factor of 1.01 (Table 1), we can write:

$$[3] \qquad 1.026/1.01 = 1.0158 = 0.06 \times 1.019 + 0.94X$$

where X is the fractionation factor of the keto form, which makes up 94% of the mixture at 25°C, the rest being hydrate. Solution of this equation gives 1.016 as the fractionation factor for C-2 of ketopyruvate.

We can compare this value with the one computed above for oxaloacetate by mutiplying the value of 1.016 for pyruvate by 1.004 for adding C-4 and twice by 1.011 for adding the two oxygens at C-4. The resulting value of 1.042 is higher than the value of 1.035 computed above, suggesting that the correction factors being used may be too large, especially when two of them are being applied at the same time. Thus, the torsional correction may be 1.011 for the first added atom, but smaller for the second, or the value is too high for experimental reasons. Clearly, more experimental equilibrium isotope effects are needed to clarify how these empirical rules should be applied and to pin down their values more accurately.

It is of interest to note that the keto carbon of pyruvate has a higher fractionation factor than the $CHNH_3^+$ carbon of alanine by 1.012 (Table 1). This implies that a CHOH carbon, which we have estimated above to have a fractionation factor lower than a keto carbon by 1.009, has a higher fractionation factor than a $CHNH_3^+$ one by 1.012/1.009 = 1.003. The calculated fractionation factor for methanol is higher than that for protonated methylamine by the same ratio (Table 2).

A similar analysis can be carried out for C-3 of malate and oxaloacetate. Applying the correction factors discussed above gives 1.0153 for the fractionation factor of C-3 of malate, 1.0234 for C-3 of the hydrate, and 1.0008 for the enol. With the equilibrium isotope effect of 0.996 for the reduction of oxaloacetate to malate, solution of the equations gives 1.0094 for the fractionation factor of C-3 of the keto form, or 0.6% lower than the estimate of 1.0153 for C-3 of malate. This difference, if real, may represent the effect of hyperconjugation.

However, when the same analysis is applied to C-3 of lactate, one estimates that the fractionation factor should be 0.989, while comparison of pyruvate with malate (Table 1) suggests a value of 1.005 for C-3 of pyruvate. The difference here is in the opposite direction from that for malate and oxaloacetate, suggesting that some of the empirical factors may not be correct, or the experimental numbers are off. The near equivalence of the fractionation factors for C-3 of pyruvate and alanine (Table 1) suggests that the latter is probably correct, and the effect of hyperconjugation is less than 0.5%.

Other ^{13}C fractionation factors

Replacement of H or O with S has some interesting results on ^{13}C fractionation factors. Methyl mercaptan actually has a lower fractionation factor (0.943) than methane (0.944 in Table 2), so replacement of H with S does not stiffen the bonding in this case.

The fractionation factor of an aldehyde carbon is less than that of its hydrate by a maximum of 1.003, while the thiohemiacetal is less stiffly bonded than the free aldehyde by a maximum value of 1.004, for an overall ratio of 1.007 between hydrate and thiohemiacetal. Since a thioester is only stiffer than a hydrated aldehyde by 1.002 (compare re-

[4] It is not clear that it is valid to multiply these factors together in this way. For ^{15}N equilibrium isotope effects (see below) the effect of a second substitution is diminished. In the present calculation, errors will largely cancel out, however, as many of the same factors are applied to both of the molecules being considered. Thus, the calculated fractionation factors for the individual molecules may be too high, but the difference between two molecules is likely to be more accurate.

actions of both to give an acyl phosphate), we might expect that the ^{13}C equilibrium isotope effect for oxidation of a thiohemiacetal to a thioester would be less inverse than that for oxidation of a hemiacetal by 1.005. The actual ratio is 1.002 (compare glucose-6-*P* and 5-thioglucose-6-*P* oxidations), suggesting that the difference between hydrated aldehyde and a thiohemiacetal is only 1.004, rather than 1.007. In any case, S replacement for O makes much less difference in these molecules than it does between methanol and methyl mercaptan, where the ratio is 1.02. The small difference between acetyl-CoA and acetyl-*P* is another example.

Two at first surprising entries in Table 1 are those for the hydride shift in the dimethyl-*tert*-butylcarbenium ion and for the ionization of triphenylmethyl chloride (in contrast to the other entries that relate to aqueous solution, these equilibria were measured in SbF_5/SO_2ClF or liquid SO_2). Opposite to intuition, ^{13}C is enriched in the carbenium ion carbon, rather than in the neighboring sp^3 carbon. The explanation is the high degree of hyperconjugation that increases the bond order of the bonds to the carbenium ion carbon. Similarly, ^{13}C is enriched in the ionized triphenylmethyl carbenium ion, rather than in triphenylmethyl chloride, as the result of conjugation with the phenyl rings.

^{15}N equilibrium isotope effects and fractionation factors

Table 3 shows ^{15}N equilibrium isotope effects that have been determined experimentally. The value for NH_3 in the gas phase was determined from the mass ratio of ammonia gas in equilibrium with aqueous ammonia. The NH_4^+–NH_3 equilibrium isotope effect was determined by letting ammonia equilibrate between two compartments separated by a membrane that will pass NH_3 and not NH_4^+, with one compartment containing excess NH_4^+. O'Leary (unpublished) tried to determine this value by sampling the first portion of ammonia passing through such a membrane from a compartment containing ammonia and excess NH_4^+, but his unpublished value of 1.039 included the kinetic isotope effect on diffusion through the membrane, which could easily be 2%.

When ammonium ion is deuterated, the ^{15}N equilibrium isotope effect on deprotonation is 0.5% greater, and a similar increase of 0.4% is seen for deprotonation of pyridinium ion in D_2O. This effect depends on the numbers of deuterons on each side of the reaction. Thus when a positively charged imine (=ND_2^+) is hydrolyzed to ND_4^+, there are four deuterons attached to nitrogen on the right side and two on the left

side of the equation, so the equilibrium isotope effect is 0.99, or a 1% change in this case (13). Similarly, a difference of 0.8% in the ^{15}N equilibrium isotope effect is seen for the aspartate transcarbamylase reaction in D_2O where two protons are lost during the conversion of aspartate to carbamylaspartate (14). Similar changes should apply to other reactions run in D_2O where the number of deuterium atoms attached to nitrogen is different on the two sides of the reaction.

Table 4 shows ^{15}N fractionation factors relative to aqueous NH_3. The experimentally determined ones can be used with some confidence, but the calculated ones must be treated with caution, since they are gas-phase calculations and do not take into account the effects of hydration in aqueous solution. For example, the ratio of calculated fractionation factors for NO_3^- and NO is 1.125, while the ratio of the experimental values in Table 3 is only 1.086. Still, these calculated values can be used as a rough guide to the stiffness of bonding of nitrogen in different molecules.

Just as with ^{13}C, we can use empirical factors to correct the fractionation factor of a small molecule to one with a more complicated structure. The ratio of fractionation factors for methylamine and ammonia in the gas phase is 1.013, which is slightly higher than the value of 1.011 for replacing H with CH_3 for ^{13}C isotope effects. We do not have good numbers on which to base the effects of replacing H with C on a carbon attached to nitrogen, although the ratio of fractionation factors for CH_3CN and HCN is 1.0033. This is a reasonable value, since a C-C-N bend should be slightly less sensitive to ^{15}N substitution than a C-C-C bend is to ^{13}C substitution, because nitrogen is heavier than carbon. The effects of replacing H with C on the second carbon from a nitrogen, which will generate an ^{15}N-sensitive torsional mode, cannot be estimated at this time, although the effects should be present.

What can be noted is that while an unprotonated amino acid has a fractionation factor higher than NH_3 by 1.0163, the factor between a protonated amino acid and NH_4^+ is only 1.0138. Thus, the empirical factors for adjusting fractionation factors are less when the nitrogen is already strongly bonded than when it is more weakly bonded, and thus these factors cannot be used in a completely mutiplicative sense. If we take 1.013 for the first carbon of the amino acid and 1.0033 for the ones attached to it, the predicted fractionation factor of an unprotonated amino acid nitrogen would be 1.0197, which exceeds the observed value of 1.0163 before any allowance is made for torsional effects of atoms further removed. With a protonated amino acid nitrogen, the discrepancy is even larger. The failure of the empirical correction factors to be multiplicative with ^{15}N suggests that they probably are not so for ^{13}C, either. Clearly, more experimental equilibrium isotope effects need to be measured to put all of this analysis on a sounder footing.

We draw attention to the equilibrium ^{15}N isotope effect in Table 3 at the N-1 position during reduction of acetylpyridine-NAD to acetylpyridine-NADH. It was thought originally on the basis of poorly defined kinetic isotope effects that there might be a sizeable equilibrium isotope effect caused by N-1 of the pyridine ring changing from trigonal to tetrahedral during reduction and the bond order dropping

[a]The atom in brackets is the isotopic one, the replacement of which with ^{18}O gives the equilibrium isotope effect. $^{18}K_{eq}$ is the K_{eq} for ^{16}O divided by that for ^{18}O.

from 4 to 3. The small value of 1.0042 shows, however, that dipolar resonance forms contribute heavily to the structure of the reduced nucleotide, and N-1 remains largely planar with bond order close to 4.

^{18}O equilibrium isotope effects and fractionation factors

Table 5 includes a number of experimental ^{18}O equilibrium isotope effects. A number of these are for ionization of phenols, phosphates, or carboxylic acids. These vary from 1.5–2.0%, with lower values seen for substituted phosphates, or for *p*-nitrophenol, where the quinonoid resonance form that contributes to the structure of the ion provides double bond character to the phenoxide oxygen. Deuteration increases the equilibrium isotope effect by ~0.5%, as is the case with ^{15}N isotope effects.

There are several values in Table 5 for inert coordination of water or *p*-nitrophenyl phosphate to Co(III). Clearly, the inert coordination bonds result in stiffening of the bonding to the coordinated oxygen. This is in contrast to coordination by Mg^{2+} or similar ions, which seems not to affect the fractionation factor of coordinated oxygens (15).

Only a few ^{18}O equilibrium isotope effects have been determined experimentally for other reactions. The known ^{18}O fractionation factors (Table 6), however, are sufficient for many purposes, especially the ones for H_3O^{+} and OH^{-}. Table 6 includes a number of values calculated from the force fields of small molecules. These allow empirical rules to be developed for the effects of substitution, as was done above for ^{13}C and ^{15}N. The effect on the ^{18}O fractionation factor of replacing H with CH_3 on the isotopic oxygen is 1.022, which is double the effect seen with ^{13}C. Likewise, the effect of replacing H with CH_3 on a carbon attached to the oxygen (1.008) is twice the value seen with ^{13}C. Application of these factors accurately predicts the sequence from methane to methanol to ethanol to malate.

Only one fractionation factor is known for a carboxylic acid; 1.0345 for formic acid. While carboxylic acids exchange their oxygens with water at low pH, it is only the fact that I_2 in dimethyl sulfoxide oxidizes anhydrous sodium formate to CO_2 without oxygen exchange that permitted the determination of this fractionation factor. One might expect that going from formic to acetic acid might raise the fractionation factor by ~1.008, but this needs experimental verification. It is interesting to note that the experimental fractionation factor of 1.0345 for formic acid is close to the average of the calculated gas phase fractionation factors in Table 6 for the two types of oxygen in formic acid (1.037 for the -OH and 1.030 for the =O).

When one applies the ^{18}O equilibrium isotope effect for deprotonation for formic acid, one calculates the formate fractionation factor as 1.0124. This is higher than the value from the force field (1.008), suggesting a problem with the latter. It is interesting to note that the fractionation factor of formate is higher in the crystal by 1.0016, and when ion paired on Dowex-1 by 1.0042. In an ion pair with tetrabutylammonium ion in $CHCl_3$, the increase is 1.0040 (16). The ion pair effect is thought to be a stiffening caused by vibration in an electric field of opposite charge.

A number of ^{18}O fractionation factors are not known, however. Thus, we do not have values for bicarbonate, phosphates, or phenols, although these can all be equilibrated with water under appropriate conditions or in the presence

of appropriate enzymes. The difficulty is in designing sufficiently accurate methods for determining ^{18}O mass ratios in the equilibrated species.

Experimental

Materials

Malic, α-ketoglutaric, glutamic, and aspartic acids were from Aldrich. Oxaloacetic acid, sodium pyruvate, glucose-6-*P*, NADP, NAD, NADH, malic enzyme, malate dehydrogenase, glutamic-pyruvic transaminase, glutamic-oxaloacetic transaminase, lactate dehydrogenase, and *n*-octane were from Sigma. Oxidized glutathione was from Acros. *n*-Octane was washed with concentrated sulfuric acid and then 5% sodium carbonate prior to use.

Equilibrium isotope effects between oxaloacetate and malate

A solution containing 400 μmol each of oxaloacetic and L-malic acids, 80 μmol of NAD, and 2 mmol of sodium pyrophosphate in 40 mL 50 mM potassium phosphate, pH 7, was titrated to pH 9.0, and 10 mL of the solution was set aside. To the remainder at 4°C was added 800 units of malate dehydrogenase. At 40 min intervals, 10 mL aliquots were withdrawn and passed through an Amicon filter with a 10 000 MW cutoff. Each deproteinized sample, as well as the initial one from before the enzyme addition, was titrated to pH 4.0 with conc. sulfuric acid, and 1 mL of 10 mM aluminum sulfate was added to degrade the oxaloacetate to pyruvate. After 12 h at 22°C, the samples were titrated to pH 7, loaded onto a 3 × 50 cm anion exchange column (AG 1-X8-Cl, 200–400 mesh), and eluted with a linear gradient from 0 to 0.1 N HCl.

Fractions containing malate were located with an assay containing 2 mL of 100 mM potassium phosphate, pH 7.0, 0.3 mL of 30 mM $MgCl_2$, 0.3 mL of 1 mM NADP, 0.1 units of malic enzyme, and 0.1 mL of column eluent. The pooled malate fractions were evaporated to dryness, taken up in 10 mL of water, acidified with three drops of concentrated sulfuric acid, and subjected to continuous extraction with ethyl acetate for 48 h. The ethyl acetate solutions were evaporated to dryness, taken up in 20 mL of 0.01 N HCl, and evaporated to dryness again. This process was repeated three times to eliminate contamination with acetic acid. The malic acid samples were then dissolved in a solution containing 150 μmol of oxidized glutathione, 2 mg of NADP, and

© 1999 NRC Canada

3 mM $MgCl_2$ in 15 mL of 50 mM potassium phosphate, pH 7. These solutions were titrated to pH 7.2, and 5 units of malic enzyme and 18 units of glutathione reductase were added. After 3 h, 0.3 mL of 3% H_2O_2 was added to oxidize the pyruvate to acetate.

After overnight reaction at room temperature, the samples were acidified to pH 2 with conc. sulfuric acid and placed in a 1 L flask with 500 mL of *n*-octane. Acetic acid was removed by azeotropic distillation until the vapor temperature remained at 124°C for several minutes, with four drops of 5 N KOH placed in the receiving flasks. The aqueous portion of the distillate was neutralized to pH 6.0 with HCl and the samples sparged overnight with N_2 scrubbed with Ascarite to remove CO_2. The samples were then evaporated to dryness and the acetate salt analyzed as described below.

Fractions from the original anion exchange column containing pyruvate were located with an assay containing 2 mL of 100 mM potassium phosphate, pH 7.0, 0.3 mL of 1 mM NADH, 1 unit of lactate dehydrogenase, and 0.1 mL column eluent. The pooled pyruvate fractions were loaded onto a 3 × 25 cm desalting column (AG 11-A8 ion retardation resin), which was then washed with deionized water until all of the pyruvate was eluted. To each sample was added 5 mL of 100 mM potassium phosphate, pH 7.0, and the samples were reduced to 10 mL by evaporation. Then, 0.3 mL of 3% H_2O_2 was added, and after overnight reaction, the samples were acidified to pH 2, and the acetic acid was recovered by azeotropic distillation with *n*-octane as described above.

Equilibrium isotope effects between pyruvate and alanine

A solution containing 700 μmol each of glutamic acid and sodium pyruvate in 35 mL of 50 mM potassium phosphate was titrated to pH 7.5 with KOH and a 5 mL portion removed. The concentration of pyruvate in the remainder was determined by an endpoint assay containing 1 unit of lactate dehydrogenase, 1 mL of 100 mM potassium phosphate, pH 7, 1.69 mL of water, 0.3 mL of 1 mM NADH, and 0.01 mL of sample containing pyruvate. Glutamic-pyruvic transaminase (100 units) was then added, and the concentration of pyruvate was determined by endpoint assay until equilibrium was reached (2 h). The alanine concentration was determined by difference between the initial and final pyruvate concentrations. At 2 h and at 1 h intervals after this, 10 mL aliquots were filtered through an Amicon filter (10 000 MW cutoff) and set aside. When all samples had been collected, each was loaded on a 3 × 50 cm anion exchange column (AG 1-X8-Cl, 200-400 mesh) and eluted with a linear gradient from 0 to 0.1 N HCl. Fractions containing pyruvate were located with the lactate dehydrogenase assay and oxidized to acetate as described above. The mass ratios of C-2 or C-3 of alanine were calculated from the corresponding mass ratios of initial and final pyruvate and the pyruvate/alanine ratio at equilibrium.

Equilibrium isotope effects between oxaloacetate and aspartate

A solution containing 400 μmol each of aspartic and oxaloacetic acids in 40 mL of 50 mM potassium phosphate, pH 7.0, was titrated to pH 7.5, and 10 mL was set aside. To the remainder at 4°C was added 250 units of glutamic-oxaloacetic transaminase. At 20 min intervals, 10 mL aliquots were withdrawn and passed through an Amicon filter with a 10 000 MW cutoff. Each deproteinized sample, as well as the initial one from before enzyme addition, was titrated to pH 4.0 with conc. sulfuric acid and loaded onto a 3 × 1.5 cm column of AG50W-X2-H^+ cation exchange resin, and the columns were washed with water until 25 mL had been collected. These samples were titrated to pH 4.0 with KOH, and to each was added 2 mL of 10 mM aluminum sulfate to degrade the oxaloacetate to pyruvate. After 10 h the pyruvate was purified and analyzed as described above to give the mass ratios from oxaloacetate.

The cation exchange columns were then eluted with 50 mL of 0.4 N ammonia. The eluates were evaporated to dryness, and the residual aspartate samples were each taken up in a solution contining 120 μmol α-ketoglutaric acid, 120 μmol of glucose-6-*P*, and 5 mg of NADH in 10 mL of potassium phosphate, pH 7. These solutions were titrated to pH 7.5 with KOH, and to each was added 40 units of malate dehydrogenase, 25 units of glucose-6-*P* dehydrogenase, and 20 units of glutamic-oxaloacetic transaminase. After 16 h at 22°C, the malate product of these reactions was purified and analyzed as described above to give the mass ratios in aspartate.

Equilibrium isotope effects between pyruvate and lactate

A solution was prepared containing 700 μmol of sodium pyruvate, 350 μmol of glucose-6-*P*, 1750 μmol of sodium pyrophosphate, and 100 mg NAD in 35 mL of water. The solution was titrated to pH 9.0 with KOH, and 5 mL were set aside. The concentration of pyruvate in the remainder was determined by a lactate dehydrogenase assay as described above. Lactic dehydrogenase (2000 units) and 100 units of glucose-6-*P* dehydrogenase were then added. The concentration of pyruvate was followed until equilibrium was reached after 2 h. At intervals of 1, 5, and 9 h following attainment of chemical equilibrium, 10 mL aliquots were passed through an Amicon filter with a 10 000 MW cutoff. The pyruvate in these and the initial sample from before enzyme addition was purified and analyzed as above. The mass ratios in lactate at equilibrium were calculated from the initial and final mass ratios in pyruvate and the pyruvate/lactate ratio at equilibrium.

Analysis of the isotopic content of acetate

Each acetate sample was divided into two parts. One part was oxidized totally to CO_2 by being placed in a quartz tube (25 cm × 9 mm, 2 mm thick) with a layer of 0.5 g diatomaceous earth followed by 10 g of CuO. The tubes were evacuated, sealed with a torch, and heated to 850°C for 2 h. The cooled tubes were cracked on the vacuum line and the CO_2 distilled through two dry ice – isopropanol traps and collected in a trap cooled with liquid nitrogen. The $^{13}C/^{12}C$ mass ratio in the CO_2 samples was determined with a Finnegan Delta E isotope ratio mass spectrometer.

The second portion of the acetate was degraded to produce methane from C-2 (17). The acetate was placed in a 2.5 × 25 cm pyrex tube with 0.3 g of NaOH. The tube was evacuated and heated to 200°C for 15 min with two dry ice – isopropanol traps between the tube and the vacuum pump to remove water. The pump was disconnected (but the vacuum

© 1999 NRC Canada

maintained), a liquid nitrogen trap was added to trap CO_2, and the tube was heated to 400°C for 5 min with the methane produced collected on molecular sieves cooled with liquid nitrogen. The methane was later allowed to expand into an evacuated 1 m combustion tube. The bottom 30 cm of this tube contained 20 g CuO and was composed of quartz. The middle 30 cm was a quartz to glass gradient and the final 40 cm was glass equipped with a stopcock. The quartz portion was placed in an oven and heated to 850°C for 12 h. The CO_2 gas produced in this combustion was analyzed in similar fashion to that from the oxidation of acetate. Since this CO_2 is from C-2 of acetate, the mass ratio of C-1 was calculated from this value and the average value of both carbons determined in the total oxidation of acetate.

Data analysis

The isotopic composition of C-2 and C-3 of malate and oxaloacetate at equilibrium were both measured directly and compared to determine the equilibrium isotope effect. This reaction reached isotopic equilibrium before the first time point was taken, as shown by the equivalence of compositions at C-2 and C-3 of both malate and oxaloacetate at all three time points. The equilibrium isotope effects between aspartate and oxaloacetate were determined in the same manner. The isotopic composition of C-2 and C-3 of pyruvate was measured directly, and the isotopic composition of C-2 and C-3 of alanine was determined by calculation. Since all of the alanine was formed by the transamination of pyruvate, the isotopic composition at C-2 or C-3 of alanine was calculated from the known isotopic composition of the pyruvate starting material. This reaction also reached isotopic equilibrium before the first time point was taken. The equilibrium isotope effects between pyruvate and lactate were determined in the same manner.

The decomposition of methyl hemiacetals of benzaldehyde in aqueous solution: a study of the effect of aromatic substitution

Karen M. Engell, Robert A. McClelland, and Poul E. Sørensen

Abstract: The acid–base catalysed decomposition of hydrates and hemiacetals of carbonyl compounds are classical examples of reactions where (slow) proton transfer is coupled with heavy atom reorganization, i.e., C—O bond breaking and solvent reorganization. We have studied the influence of *m*- and *p*-substitution in the carbonyl electrophile on the kinetics of the acid and base catalysis of the decomposition of methyl hemiacetals of benzaldehyde. The experimental data are well described by three-dimensional More O'Ferrall – Jencks energy contour diagrams according to principles developed by Jencks (the BEMA HAPOTHLE). Thus, for acid catalysis, a Cordes cross-interaction coefficient $p_{xy'} = \partial\rho/\partial \mathrm{p}K_a = 0.15$ indicates the coupled nature of the rate-limiting step in a *class e* mechanism, similar to conclusions reached from systematic substitution in the nucleophile. Our more extensive set of data for base catalysis permits a more rigorous analysis according to the BEMA HAPOTHLE. The data are consistent with a *class n* mechanism as also suggested earlier on the basis of substitution in the nucleophile. A slight upward curvature observed in the Hammett plots for the various catalysts is described by the direct correlation parameter $p_y = -\partial\rho/\partial\sigma = -0.11$. This second derivative demonstrates the concerted nature of the C—O bond cleavage and O-H formation in the transition state, which changes with changing substituent. A *class n* mechanism for base catalysis is also supported by the observation of a Cordes cross-interaction parameter $p_{xy} = -\partial\rho/\partial \mathrm{p}K_a = -\partial\beta/\partial\sigma = 0.03$, which describes the experimentally observed decrease in Hammett ρ with increasing $\mathrm{p}K_a$ of the catalyst. This change may be rationalized by the movement of a saddle point on a diagonal reaction coordinate in the energy contour diagram, as a resultant of shifts parallel and perpendicular to the coordinate, when the energy along one side of the diagram is changed. It is concluded that observed rate changes as a result of substitution in the electrophile are consistent with and present further confirmation of earlier suggested mechanisms of hemiacetal decomposition reactions.

Key words: methyl hemiacetals of benzaldehydes, acid–base catalysed breakdown, Hammett plots, More O'Ferrall – Jencks diagrams.

Résumé : La décomposition, catalysée par les acides et les bases, des hydrates et des hémiacétals de composés carbonylés fourni des exemples classiques de réactions dans lesquelles le transfert (lent) d'un proton est couplé à une réorganisation des atomes lourds, comme le bris de la liaison C—O et la réorganisation du solvant. Nous avons étudié l'influence des substituants en m et en *p* du carbonyle électrophile sur la cinétique des décompositions catalysées par les acides et les bases d'hémiacétals de méthyle du benzaldéhyde. Les données expérimentales sont bien décrites par les diagrammes tridimensionnels de contour d'énergie de More O'Ferrall – Jencks selon les principes de Jencks (BEMA HAPOTHLE). Ainsi, pour la catalyse acide, un coefficient d'interaction croisée de Cordes, $p_{xy'} = \partial\rho/\partial \mathrm{p}K_a = 0{,}15$, est une indication de la nature couplée de l'étape cinétiquement limitante dans un mécanisme de *classe e* et ceci est semblable aux conclusions découlant d'une substitution systématique dans le nucléophile. Le large ensemble de nos données rend possible une analyse rigoureuse en fonction de BEMA HAPOTHLE. Les données sont en accord avec un mécanisme de *classe n*, tel qu'il avait été suggéré antérieurement sur la base de substitutions dans le nucléophile. Une observation directe du paramètre $p_y = -\partial\rho/\partial\sigma = -0{,}11$, nous permet aussi de décrire une courbe légèrement remontante dans les droites de Hammett pour les diverses catalyses. Cette deuxième dérivée démontre la nature concertée du clivage de la liaison C—O et de la formation de la liaison O-H dans l'état de transition qui est accompagnée de changements lors de changements de substituants. Un mécanisme de *classe n* pour la catalyse basique est aussi supporté par l'observation d'un paramètre d'interaction croisée de Cordes, $p_{xy} = -\partial\rho/\partial \mathrm{p}K_a = -\partial\beta/\partial\sigma = 0{,}03$, qui décrit la diminution observée expérimentalement de la constante ρ de Hammett avec une augmentation du $\mathrm{p}K_a$ du catalyseur. On peut rationaliser ce changement par le mouvement d'un point de selle sur une coordonnée de réaction en diagonale dans le diagramme de contour d'énergie, qui serait le résultat de déplacements parallèle et perpendiculaire à la

coordonnée, lorsqu'on modifie l'énergie sur un côté du diagramme. On conclut que les changements de vitesse observés lors de substitutions dans l'électrophile sont en accord avec, et confirment, les mécanismes suggérés antérieurement pour les réactions de décomposition des hémiacétals.

[Traduit par la Rédaction]

The importance of proton transfer reactions in elementary chemistry and the life sciences is indisputable. Our present knowledge of the nature of these reactions and their coupling with other (heavy atom) processes or relocations is originally based on some careful and now almost historical experimental studies of acid–base catalysis. J.N. Brønsted (1879–1947) and R.P. Bell (1907–1996), who created a school with a large number of pupils, are commonly regarded as two of the scientific fathers of this discipline. In relation to the present paper, it is appropriate to focus on two of the pupils by mentioning the outstanding contributions by W.P. Jencks, and by A.J. Kresge, the former through his studies of the O—H bond, the latter, the C—H bond.

Protons and hydrogen continue to fascinate scientists. Recently, proton flips in thin silica discs have been suggested as memory units in future "molecular computers" with a 1000-fold enhancement in memory capacity (1). In addition, our steadily growing interest in biology (enzymology) keeps putting a strong demand on the need for knowledge of the basic nature of proton transfer reactions.

The mechanisms of acid–base catalysed reactions have been roughly defined in many cases, and our continuous goal is to improve the understanding of the more intimate details of all the parameters involved. In (classical) carbonyl addition reactions like the formation/decomposition of hemiacetals, one way of doing this is to introduce small but systematic variations in the various reactive sites and to observe the resulting effect on chemical rates. Thus, in a series of papers published during the period 1960–1990, Jencks has taught and convinced us that such studies are relevant in relation to understanding and visualizing reaction mechanisms, especially in coupled systems. Jencks has introduced the acronym BEMA HAPOTHLE — from the names of some key physical organic chemists — to characterize the principle of applying three-dimensional energy contour diagrams (More O'Ferrall – Jencks diagrams) in explaining complex chemical mechanisms (2).

In relation to Scheme 1, several (relatively easy) studies of changing R_3 in the nucleophile/leaving group, combined with systematic series of acid–base catalysts, have been performed and analysed according to the BEMA HAPOTHLE (2–5). However, very few extensive and systematic substitutions in the carbonyl electrophile have been reported so far, although as for carbon acids (6) such (supplementary) studies might also bring about important information on transition state structures.

In continuation of earlier work and as an attempt to fill this gap, we report in the present paper results from studies of the decomposition of methyl hemiacetals of a series of *m*- and *p*-substituted benzaldehydes.

It will be obvious from below that our results may be treated according to the BEMA HAPOTHLE. The fact that earlier suggestions concerning the reaction mechanisms are confirmed by our data give further support to the general validity of the principle.

Experimental section

Materials

Benzaldehyde dimethyl acetal and all benzaldehydes needed for the synthesis of corresponding acetals and hemiacetals were commercially available. Solids were sublimed before use. The *dimethyl acetals* of the substituted benzaldehydes were made as described by Davis et al. (7) apart from for 3- and 4-fluoromethylbenzaldehyde, where a method of Langvad (8) using dimethyl sulphate was applied. Solid acetal products were recrystallized from methanol, and liquids were purified by fractional spinning band distillation. In a few cases for aldehydes of low reactivity, we were not able to isolate the pure dimethyl acetal, i.e., an equilibrium mixture of acetal, and the benzaldehyde builds up in methanol. However, samples from these mixtures could still be used to initiate reaction, although a higher background absorption was present in these cases from unreacted benzaldehyde.

The various dimethyl acetals were typically checked and identified in two ways: (*i*) verification of the ^{1}H NMR spectrum from a solution in $CDCl_3$ run on a Bruker AD-250 instrument at 250 MHz (Me_4Si internal reference). In the NMR spectra of all acetals, a singlet appears at $\delta = 5.35 \pm 0.05$, typical of the aldehyde proton, which is shifted from around $\delta = 9.94$. For the dimethyl acetal type, the identity is further supported by a singlet at $\delta = 3.31 \pm 0.05$, six times the intensity of the aldehyde proton peak. (*ii*) Verification of the UV spectrum of the corresponding benzaldehyde after a hydrolysis of the acetal in weak HCl. Details are as follows:

Benzaldehyde dimethyl acetal (1,1-dimethoxy-1-phenylmethane): δ_H ($CDCl_3$): 5.39 (1 H, s, $HC(OMe)_2$), 3.31 (6 H, s, OMe), 7.3–7.5 (5 H, m, ArH) (lit. (9), δ_H ($CDCl_3$): 5.40, 3.32, 7.20–7.70, respectively); λ_{max} (H_2O)/nm 250 (lit. (9), λ_{max} (C_6H_{12})/nm 241).

4-Methylbenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-methylphenyl)methane): bp 102–103°C at 18 Torr (1 Torr = 133.3 Pa) (lit. (7), bp 54°C at 1.1 Torr); δ_H ($CDCl_3$): 5.35 (1 H, s, $HC(OMe)_2$), 3.31 (6 H, s, OMe), 2.33 (3 H, s, ArMe), 7.1–7.2 (2 H, br d, half of AB system, 2 × ArH), 7.35–7.45 (2 H, br d, half of AB system, 2 × ArH); λ_{max} (H_2O)/nm: 261.6 (lit. (7, 9), λ_{max}/nm: 262, λ_{max} (MeOH)/nm: 255).

3-Methylbenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(3-methylphenyl)methane): bp 95.5–96.5°C at 12 Torr; δ_H ($CDCl_3$): 5.32 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 2.35 (3 H, s, ArMe), 7.1–7.3 (4 H, m, ArH); λ_{max} (H_2O)/nm: 254.9, 297.3 (lit. (9), λ_{max} (MeOH)/nm: 249, 289).

© 1999 NRC Canada

4-Methoxybenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-methoxyphenyl)methane): bp 125–126°C at 15 Torr (lit. (7), bp 86°C at 1.6 Torr); δ_H ($CDCl_3$): 5.32 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 3.80 (3 H, s, ArOMe), 6.85–6.95 (2 H, br d, half of AB system, 2 × ArH), 7.3–7.4 (2 H, br d, half of AB system, 2 × ArH); λ_{max} (H_2O)/nm: 285.8 (lit. (7, 9), λ_{max}/nm: 283.5, λ_{max} (MeOH)/nm: 273).

3-Methoxybenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(3-methoxyphenyl)methane): bp 127–128°C at 15 Torr; δ_H ($CDCl_3$): 5.32 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 3.80 (3 H, s, ArOMe), 6.8–7.5 (4 H, m, ArH); λ_{max} (H_2O)/nm: 257.1, 314.3 (lit. (9), $\lambda\lambda_{max}$ (MeOH)/nm: 218.5, 251.5, 310).

3-Bromobenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(3-bromophenyl)methane): bp 121–121.5°C at 14 Torr; δ_H ($CDCl_3$): 5.36 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 7.2–7.7 (4 H, m, ArH); λ_{max} (H_2O)/nm: 254.5 (lit. (9), $\lambda\lambda_{max}$ (MeOH)/nm: 244.5, 291).

4-Dimethylaminobenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-dimethylaminophenyl)methane): bp 163.5–164.5°C at 18 Torr; δ_H ($CDCl_3$): 5.30 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 3.10 (6 H, s, ArNMe), 6.65–6.75 (2 H, d triplet, half of AB system, 2 × ArH), 7.7–7.8 (2 H, d triplet, half of AB system, 2 × ArH); λ_{max} (H_2O)/nm: 245.9, 353.2 (lit. (9), λ_{max} (MeOH)/nm: 242, 340).

4-Trifluoromethylbenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-trifluorophenyl)methane): bp 60–62°C at 10 Torr; δ_H ($CDCl_3$): 5.46 (1 H, s, $HC(OMe)_2$), 3.32 (6 H, s, OMe), 7.6–7.75 (4 H, dd, AB system, 2 × 2 × ArH); λ_{max} (H_2O)/nm: 240.

3-Chlorobenznzaldehyde dimethyl acetal (1,1-dimethoxy-1-(3-chlorophenyl)methane): λ_{max} (H_2O)/nm: 251.5 (lit. (9), λ_{max} (MeOH)/nm: 243, 289.5).

4-Bromobenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-bromophenyl)methane): λ_{max} (H_2O)/nm: 264.2 (lit. (7, 9), λ_{max}/nm: 258, λ_{max} (MeOH)/nm: 245.5).

4-Nitrobenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-nitrophenyl)methane): λ_{max} (H_2O)/nm: 270.2 (lit. (9), λ_{max} (MeOH)/nm: 265).

4-Hydroxybenzaldehyde dimethyl acetal (1,1-dimethoxy-1-(4-hydroxyphenyl)methane): λ_{max} (H_2O)/nm: 244.4, 340.0 (lit. (9), λ_{max} (MeOH)/nm: 218.5, 253, 314.5).

Two *mixed acetals* were synthesized according to prescriptions by Anderson and Capon (10) where the respective benzaldehyde dimethyl acetals are initially converted by thionyl chloride to the corresponding α-chlorobenzyl methyl ether, which is then reacting with methyl salicylate. The final products were purified by HPLC and (or) fractional distillation: the compounds so prepared were benzaldehyde 2-(carbomethoxy)phenyl methyl acetal (1-methoxy,1-(2-carbomethoxyphenoxy)-1-phenyl-methane) and 4-methylbenzaldehyde 2-(carbomethoxy)phenyl methyl acetal (1-methoxy, 1-(2-carbomethoxyphenoxy)-1-(4-methylphenyl)methane). Spectroscopic and kinetic specifications were as described by Anderson and Capon (10).

Methyl hemiacetals of the various benzaldehydes are too unstable to be isolated. However, sufficient concentrations of the hemiacetals with substituents more electron withdrawing than 4-methyl can be obtained by simply dissolving the appropriate benzaldehyde in methanol and leaving the solution for about 1 h. Addition of small amounts of base (sodium carbonate or calcium hydride) shifts the equilibrium towards the hemiacetal even further and at the same time prevents the formation of acetal.

Kinetics

The decomposition of acetals and hemiacetals of the various substrates can be easily followed spectrophotometrically because of the benzaldehyde reaction product, which has distinct UV absorption maxima deriving from the aromatic aldehyde group. Three spectrophotometric techniques have been applied:

(a) Conventional spectrophotometry

For reactions with half-lives >30 s. A small sample of the substrate — usually about a microliter of a methanolic solution of acetal or hemiacetal was transferred by a micro syringe to a thermostatted quartz cell containing the aqueous reaction medium (Shimadzu UV-150-02 spectrophotometer). The reaction was initiated by quick stirring with a small Teflon stirrer before data collection.

(b) Conventional stopped-flow spectrophotometry

For reactions with half-lives <30 s. This technique was primarily used in our study of the specific acid-catalysed reaction, through the stepwise decomposition of the full acetal. This produced s-shaped absorbance–time traces for the benzaldehyde appearance that could be analysed to give simultaneously H^+-catalytic constants for hemiacetal and acetal decomposition. A slightly alkaline aqueous solution of the acetal was mixed in the instrument (Durrum or HiTech Scientific stopped-flow spectrophotometer) with varying concentrations of excess HCl, followed by measuring the pH in the final mix after each experiment. This stopped-flow technique was also used in studying the decomposition of the mixed acetals. A slightly alkaline, aqueous solution of the substrate was mixed in the apparatus usually with a buffer containing enough HCl to neutralize the "alkalinity" of the substrate solution.

(c) Double-mixing stopped-flow spectrophotometry

(HiTech Scientific PQ/SF-53 instrument). As shown earlier for equivalent studies of acetophenones (11, 12), this technique, which is essentially a fast pH jump method, offers an advantage in the (fast) recording of absorbance–time traces for the buffer-catalysed decomposition of aromatic hemiacetals. As suggested in Scheme 1, a certain percentage (depending on aromatic substituent) of hemiacetal intermediate builds up during acetal hydrolysis in acid. The time of maximum buildup may be calculated, and if the pH of the reaction mixture is jumped to a higher value at that time, further acetal breakdown will stop, and we are left with a situation where the decomposition of accumulated hemiacetal can be studied separately. In a typical double-mixing experiment an aqueous solution of 5×10^{-4} M acetal in 0.002 M NaOH was first mixed (1:1) with 0.004 M aqueous HCl. After "incubation" for 2–30 s (depending on the substrate), this mixture was then jumped to a higher pH by a second mixing in the instrument (1:1) with an appropriate

buffer (acetate, cacodylate, phosphate, or TRIS), and the increase in absorbance with time was recorded.

All experiments are carried out in such a way that ionic strengths of 1.0 M (KCl) are obtained in the reaction medium. Temperatures were kept at 25.0 ± 0.2°C.

Results and discussion

Specific acid catalysis

The consecutive reaction in Scheme 1 leads to s-shaped absorbance–time plots when the appearance of the final (aldehyde) product is followed spectrophotometrically. The exception to this are cases where the rate constant $k_1 >> k_2$ or vice versa, where the reaction will approach a single exponential nature. This is generally what is observed for the (acidic) hydrolysis of acetals ($k_1 << k_2$). However, as pointed out by Jensen and Lenz (13) and Finley et al. (14), for certain symmetric acetals like the diethyl and dimethyl acetals of benzaldehydes and of acetophenones, the rate constants k_1 and k_2 are sufficiently close to cause a detectable accumulation of hemiacetal, and an s-shaped kinetic trace.

An example is shown in Fig. 1 for the hydrolysis of the dimethyl acetal of benzaldehyde, the absorbance recorded for the appearance of the aromatic carbonyl peak at λ_{max} = 250 nm. The trace is an average of six single runs of 600 points per run. The solid line derives from a least-squares computer fit (MINSQ)[2] based on a double exponential expression of the type $\Delta A = Me^{-k_1 t} + Ne^{-k_2 t} + P$. This procedure produces two first-order rate constants, k_1 and k_2, of which one is approximately 10 times bigger than the other. We know from experience and from a single (slow) acetal hydrolysis experiment at about pH 6 ($t_{1/2} \approx 10^4$ s) that the smaller rate constant can be assigned to acetal hydrolysis, i.e., the first step in Scheme 1. At pH 6, this step is solely rate-limiting because the hemiacetal step is accelerated by hydroxide catalysis (vide infra).

Fig. 2. Specific acid catalysis of the hydrolysis of benzaldehyde dimethylacetal (closed squares) and methyl hemiacetal (closed circles).

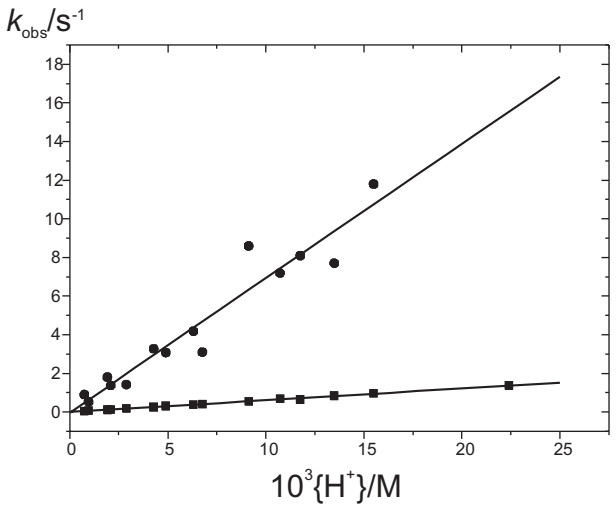

Figure 2 shows a plot of results from experiments at 15 different pH values in the range pH = 1.65–3.13 for the hydrolysis of benzaldehyde dimethyl hemiacetal ($\{H^+\}$ taken as 10^{-pH}). It is clear that the (faster) hemiacetal rate constants (k_2) are not as well defined as the corresponding k_1 values. The observed relative standard deviation on k_2 being 5–10%, while it is less than 0.5% for k_1. Nevertheless, in both cases, catalytic constants (k_H) for H^+ catalysis may be derived from Fig. 2 as indicated by the least-squares lines based on $k_{obs} = k_H\{H^+\} + k_w$. In these plots, the water values k_w are too small to be determined with certainty.

Table 1 summarizes all the results from the acid catalysis experiments for 11 aromatic substituents (primary data in the supplementary Table S1).[3]

The aromatic substituent effects on the H^+-catalysed breakdown of benzaldehyde acetals and hemiacetals in Table 1 are conveniently visualized in a Hammett plot. We have applied the Young and Jencks (19) version in eq. [1] where the contributions from polar and resonance effects are separated where possible, i.e., σ (Table 1) are taken for σ^n or σ^+ if no specific values are available for those parameters.

[b]Reference 16.

[c]t_{max} is the time of maximum buildup of hemiacetal B (d[B]/dt = 0) in the reaction scheme A → B → C, calculated as t_{max} = (ln (k_1[H^+]) – ln (k_2[H^+]))/(k_1[H^+] – k_2[H^+]) where [H^+] is taken as 0.001 M.

[d]B_{max} (%) at t_{max}, calculated as 100[B]/A_0 = 100(k_1[H^+]/((k_2[H^+]) – (k_1[H^+]))(exp (–(k_1[H^+]t_{max}) – exp (–(k_2[H^+]t_{max})).

[e]Reference 17 (T = 298 K, μ = 1.25 M).

[f]Reference 18 (T = 298 K, μ = 0.5 M).

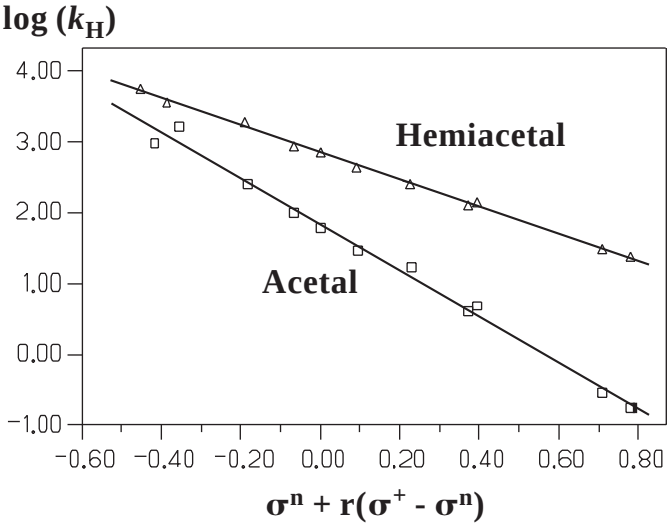

Fig. 3. Modified Hammet plots (Young and Jencks (19)) for the H^+-catalysed decomposition of some *m*- and *p*-substituted benzaldehyde dimethyl acetals and methyl hemiacetals. Data taken from Table 1.

[1] $$\lg (k/k_0) = \rho\sigma^n + \rho^r(\sigma^+ - \sigma^n) = \rho[\sigma^n + r(\sigma^+ - \sigma^n)]$$

where r (= ρ^r/ρ) is a parameter ranging from 0 (no resonance) to 1 (full resonance).

The resulting two Hammett plots are shown in Fig. 3 as two straight lines. A least-squares analysis according to eq. [1] $(MINSQ)^2$ gives the following results: acetal hydrolysis, ρ = –3.24 ± 0.16 with r = 0.30 ± 0.06 (correlation coefficient 0.996); hemiacetal hydrolysis, ρ = –1.89 ± 0.04 with r = 0.35 ± 0.04 (correlation coefficient 0.999). For a corresponding study of benzaldehyde *ethyl* acetals, Jensen et al. (20) found ρ(acetal) = –3.16 ± 0.02 with r = 0.34 ± 0.01 (T = 298 K, μ = 0.25 M, correlation coefficient 0.9998). Similarly, Przystas and Fife (21) found in a less extensive study for the hemiacetal breakdown of benzaldehyde *ethyl* hemiacetals ρ (hemiacetal) = –1.90 ± 0.05 (correlation coefficient 0.9997).

The observed change in hemiacetal buildup (%B_{max} in Table 1, last column) with the aromatic substituent clearly has its origin in the differing slopes in Fig. 3, a fact that was also observed for acetophenone acetal and hemiacetal breakdown (11, 12).

Buffer catalysis

Kinetics of the breakdown of a number of substituted benzaldehyde methyl hemiacetals were studied rather extensively for general catalysis by buffers. This section describes measurements in acetate buffer where catalysis can be seen from both Hac and ac. Experiental techniques (*a*) and (*b*) were applied. The double-mixing experimental technique (*c*) was employed where there was primarily only catalysis by the basic buffer components. These results are presented in the next section.

Each substrate was typically studied at three different buffer ratios. As usual, the observed first order rate constants are given as $k_{obs} = k_w + k_H\{H^+\} + k_{Hac}[Hac] + k_{ac}[ac] + k_{OH}\{OH\}$. As an alternative to classical plotting procedures, we have applied a least-squares multiparameter fitting procedure by $MINSQ^2$ based on this equation and leading to the "best" values for all catalytic constants involved. Detailed results from such a calculation for the decomposition of 3-methylbenzaldehyde methyl hemiacetal are shown in Table 2, where the derived catalytic constants are given at the bottom of the table. The pH of the acetate buffers are low enough to prevent any catalysis of the reaction by hydroxide ion (vide infra). The value in the table of k_H = (7.9 ±

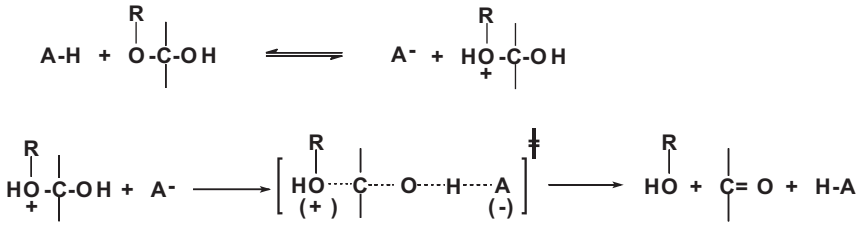
[a] k_W = (0.013 ± 0.008) s^{-1}; k_{OH} = 0.0 M^{-1} s^{-1} (fixed); k_H = (7.9 ± 1.1) × 10^2 M^{-1} s^{-1}; k_A = (0.37 ± 0.04) M^{-1} s^{-1}; k_{HA} = (0.19 ± 0.04) M^{-1} s^{-1}; correlation coefficient = 0.993.

Scheme 2.



1.1) × 10^2 M^{-1} s^{-1} compares well with k_H = (8.7 ± 0.3) × 10^2 M^{-1} s^{-1} from the experiments reported previously in more acidic solution (Table 1).

The supplementary Table S2 contains results for the remaining 12 substituents (acetate catalysis), and the final results are summarized in Table 3.

Base catalysis

Catalysis by the buffers cacodylate, phosphate, and TRIS were studied by the double-mixing technique (*c*) described in the experimental section. The buildup to a maximum of hemiacetal takes place in the first mix at a pH around 3 and at a speed that varies from compound to compound. After the second mix, the base-catalysed breakdown of the acetal is followed spectrophotometrically. A drifting infinity line in most cases is due to a slight background reaction from continued hydrolysis of acetal even at higher pH. As before, the observed first-order rate constants depend on the concentration of the various catalysts as described by equation k_{obs} = k_w + k_H{H^+} + k_{Hac}[Hac] + k_{ac}[ac] + k_{OH}{OH}. In almost all cases, however, only contributions from k_A and k_{OH} were relevant in the pH range studied, and this equation reduces to k_{obs} = k_{ac}[ac] + k_{OH}{OH}. Again, a MINSQ[2] procedure was used to evaluate the best values of the catalytic constants. Primary results are contained in the supplementary Table S3, and final results are summarized in Table 3 together with other relevant data from the literature.

Acid catalysis and the BEMA HAPOTHLE

The specific as well as general acid-catalysed breakdown of carbonyl adducts such as hemiacetals and hydrates is believed to take place by a so-called class e mechanism (24), where the (concerted) proton transfer takes place from the electrophile (carbonyl group) in the transition state of the rate-limiting (second) step as shown in Scheme 2.

According to Jencks and Jencks (4), the mathematical description of the saddle point in a More O'Ferrall – Jencks energy contour diagram visualizing this rate-limiting concerted step is given in eq. [2], the primes referring to the fact that "diagonal" substituent effects are involved, i.e., effects of substituents on the central carbonyl oxygen atom.

$$[2] \quad -\log (k/p) = 1/2p_x(pK_a)^2 + 1/2p_{y'}(\sigma)^2 - p_{xy'}(pK_a)\sigma + x_o(pK_a) - y_o\sigma + F$$

The chemical interpretation of p_x, $p_{y'}$, and $p_{xy'}$ is as follows:

$$p_x = \partial\alpha/\partial pK_a$$

direct correlation expressing curvature in the Brønsted plot.

Scheme 3.

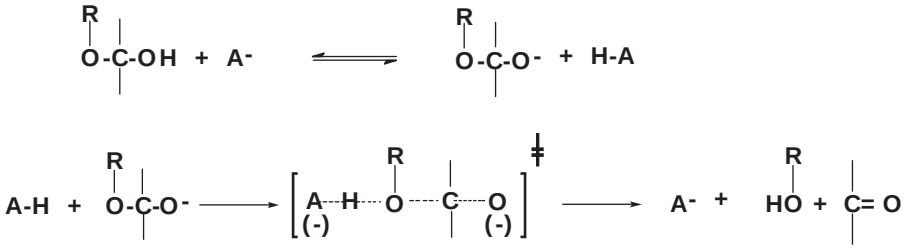

Fig. 4. A More O'Ferrall – Jencks diagram for the rate-limiting step in the acid-catalysed breakdown of benzaldehyde methyl hemiacetal (step 2 in Scheme 2) in a class e mechanism (24). The actual value of Hammett ρ throughout the diagram is a compromise between the values of ρ indicated at the corners of the diagram. These corner values represent the experimentally observed or estimated sensitivity of the various carbonyl forms to aromatic substitution with reference to the upper left corner (22). The location of the saddle point (transition state) is shown with horizontal and vertical level lines (i.e., a diagonal reaction coordinate). The bold arrow indicates the expected direction of movement of the transition state for a weaker acid catalyst, i.e., toward higher ρ values ($p_{xy'}$ positive, see text).

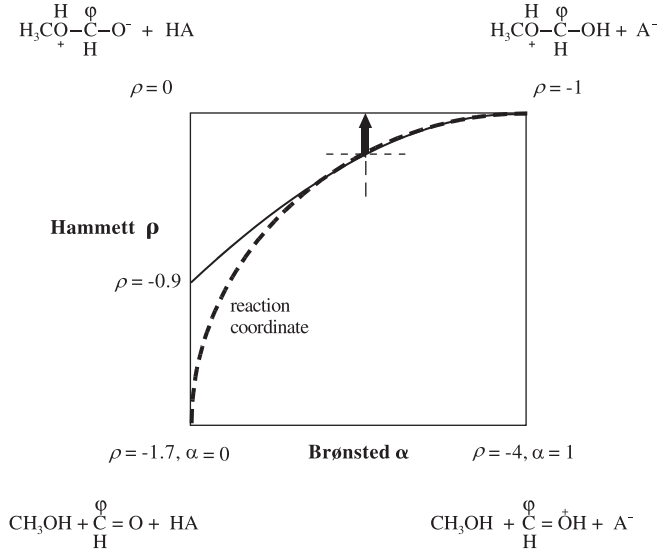

$$p_{y'} = -\partial\rho/\partial\sigma$$

direct correlation expressing curvature in the Hammett plot.

$$p_{xy'} = \partial\rho/\partial pK_a = -\partial\alpha/\partial\sigma$$

Cordes cross-interaction coefficient.

The values x_0 and y_0 are fixpoints defined as $x_0 = \alpha_0$ (α extrapolated to σ = 0, i.e., for the parent compound); $y_0 = \rho_0$ (ρ extrapolated to $pK_a = 0$ for the catalyst). The value of F is taken to fit the absolute value of the observed rate constants.

No detailed data for a reliable Brønsted plot analysis is carried out in this work, but in a similar study by Cox et al. (23), no curvature was observed within experimental error in the Brønsted plots for acid catalysis. Similarly, the Hammett plots, as discussed above, are linear, implying that p_x and $p_{y'}$ are both equal to zero. The two "level lines" of the saddle point are therefore perpendicular to each other and parallel to the x and y axes in the More O'Ferrall – Jencks diagram, leading to a diagonal reaction coordinate. In this case, a value of $p_{xy'} > 0$ is required to produce a saddle point in the diagram in the right direction (4).

A diagram based on data in the present paper for the acid-catalysed breakdown of hemiacetals is illustrated in Fig. 4. A value of $\rho_0 = -1.6$ is estimated from an interpolation based on the data in Table 3. A value of $\alpha_0 = 0.55$ is estimated from Brønsted $\alpha = 0.47 \pm 0.01$ for 3-nitro- and $\alpha = 0.50 \pm 0.01$ for 3,4-dichlorobenzaldehyde ethyl hemiacetal breakdown, based on a series of carboxylic acids (23). The coordinates of the saddle point in Fig. 4 are taken as $\rho = -1.9 - (-1) = -0.9$ (for H^+-catalysis) and $\alpha = 0.55$ (for the parent compound). Based on Hammond and anti-Hammond effects, the bold arrow represents the expected resulting movement of the transition state when a weaker acid catalyst is introduced, i.e., an increase in ρ as observed experimentally and in accordance with a positive value of $p_{xy'}$ (see next paragraph).

The result from a statistical treatment, based on eq. [1] $(MINSQ)^2$ of our (limited) set of experimental data for acid catalysis (Tables 1 and 3), is that a small positive value of $p_{xy'}$ is obtained, but with a large standard deviation. Alternatively, a rather crude plot of ρ versus pK_a for the three acids H_3O^+, HAc, and $H_2PO_4^-$, according to $p_{xy} = \partial\rho/\partial pK_a$, leads to a value of $p_{xy'} = 0.15$ for the methyl hemiacetals of benzaldehyde. This value is in good agreement with a value of $p_{xy'} = 0.12$ found by McClelland and Coe (22) and by Cox et al. (23) for dehydration of benzaldehyde hydrates.

The literature contains many studies where the effect of systematic substitution in the nucleophile/leaving group has been investigated and analysed (2). However, there are not many equivalent studies dealing with the electrophile. While we realise that our body of experimental data for acid catalysis is too incomplete to perform a rigorous statistical analysis according to the Jencks formalism, it does show that a systematic variation by substitution in the *electrophile* leads to experimentally observable effects that follow the rules stated by this formalism.

Base catalysis and the BEMA HAPOTHLE

In this section, we are dealing with a more complete set of catalytic data (Table 3) and a rather detailed mechanistic analysis is therefore possible.

Figure 5 shows Hammett plots where all bases are included. Rate constants are plotted against σ^+ throughout as a result of the fact that a (perhaps) more rigorous plot against $\sigma^n + r(\sigma^+ - \sigma^n)$ leads to values of $r \geq 1$, indicating a predominant influence of resonance effects by the substituents, as

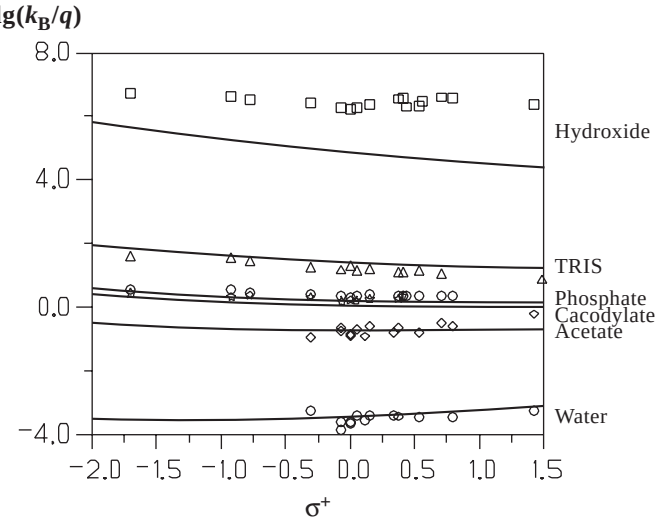
Fig. 5. Hammett plots for the base-catalysed decomposition of benzaldehyde hemiacetals. Solid lines are simulated by a least-squares procedure on the basis of eq. [3] and data from Table 3.



best reflected by σ^+. The curves drawn in the figure are simulated based on the statistical analysis reported below.

According to Jencks, the general base-catalysed breakdown of hemiacetals is believed to take place by a *class n* mechanism, where the concerted proton transfer in the transition state occurs to the leaving nucleophile as shown in Scheme 3 (24).

As for acid catalysis, the saddle point in an energy contour diagram for the rate-limiting (second) step may be characterized by an equation of the type (4):

$$[3] \quad -\log (k/q) = 1/2p_x(\mathrm{p}K_a)^2 + 1/2p_y(\sigma)^2 + p_{xy}(\mathrm{p}K_a)\sigma + x_o(\mathrm{p}K_a) - y_o\sigma + F$$

where again the chemical interpretation of p_x, p_y, and p_{xy} is as follows:

$$p_x = -\partial\beta/\partial \mathrm{p}K_a$$

direct correlation expressing curvature in the Brønsted plot.

$$p_y = -\partial\rho/\partial\sigma$$

direct correlation expressing curvature in the Hammett plot.

$$p_{xy} = -\partial\rho/\partial \mathrm{p}K_a = -\partial\beta/\delta\sigma$$

Cordes cross-interaction coefficient.

The values x_0 and y_0 are fixpoints defined as $x_0 = \beta_0$ (β extrapolated to $\sigma = 0$, i.e., for the parent compound); $y_0 = \rho_0$ (ρ extrapolated to $\mathrm{p}K_a = 0$ for the catalyst). The value of F is taken to fit the absolute value of the observed rate constants. No primes are assigned here because the central oxygen atom of the transition state is not involved in substitution.

The limited number of catalyst bases implied in this work means that no reliable Brønsted analysis could be performed, but from the rather extensive investigations by Jensen (see reference in footnote *b*, Table 3) and by Cox et al. (23), including the breakdown of benzaldehyde ethyl hemiacetals, we are convinced that there is no observable curvature in Brønsted plots, i.e., $p_x = 0$, and eq. [3] reduces to eq. [4]

$$[4] \quad -\log (k/q) = 1/2p_y(\sigma)^2 + p_{xy}(\mathrm{p}K_a)\sigma + x_o(\mathrm{p}K_a) - y_o\sigma + F$$

where $y_0 = \rho_o$ is the slope in the Hammett plot for a theoretical base with $\mathrm{p}K_a = 0$. It may be clear from a quick inspection of Fig. 5 that all the Hammett plots have slopes around zero, but with a tendency of ρ to increase with decreasing $\mathrm{p}K_a$ (p_{xy} positive). Thus, a good starting guess of ρ_o in eq. [4] will be $\rho_o \approx 0$; β_o is Brønsted β for the unsubstituted benzaldehyde methyl hemiacetal. Cox et al. (23) found $\beta = 0.52 \pm 0.02$ for 3-nitro- and $\beta = 0.50 \pm 0.02$ for 3,4-dichlorobenzaldehyde ethyl hemiacetal based on carboxylic acids. Therefore, a good starting guess of β_o is expected to be $\beta_o \approx 0.5$.

All our data for the methyl hemiacetal decomposition, catalysed by the five general bases in Table 3 (incl. water) were now fitted to eq. [4] by a least-squares procedure (MINSQ)[2] and the following results were obtained, with a correlation coefficient of 0.993:

$$p_x = 0.0 \text{ (fixed)}, \; p_y = -0.11 \pm 0.08, \; p_{xy} = 0.03 \pm 0.02$$

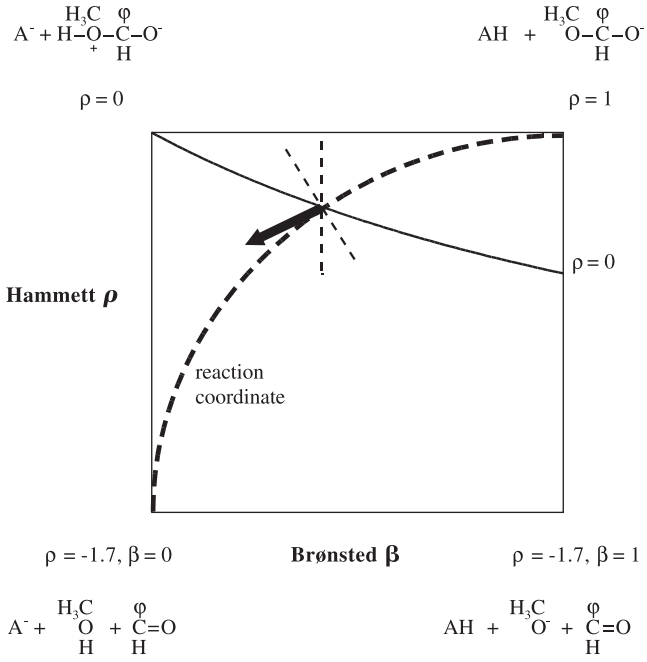
$$\beta_o = 0.48 \pm 0.01, \; \rho_o = 0.10 \pm 0.10, \; F = 2.84 \pm 0.05$$

The direct correlation coefficient p_y was found to be small and negative in consequence of a slight upward curvature of the Hammett plots. Experiments on leaving-group effects (substitution in the nucleophile) for formaldehyde and acetaldehyde (3, 5) lead to a value of $p_{y'} = -0.20$. The U-shaped curvature characterized by negative values of p_y and $p_{y'}$ represent the balance between the amount of C—O bond cleavage and O—H bond formation in the transition state, which changes with changing substituents. This is strong evidence for a concerted mechanism that involves both processes in the transition state (2, 4).

A positive value of $p_{xy} = 0.03$ is in accordance with a *class n* mechanism and has been observed in several studies before, as a result of the fact that when the carbonyl electrophile becomes less stable the observed Brønsted β value for base catalysis decreases (2). This phenomenon may be rationalized from and visualized in Fig. 6, which shows a energy contour diagram for a *class n* mechanism corresponding to step two in eq. [3]. A decrease in stability of the electrophile (carbonyl) by introducing a more electronegative substituent, as illustrated by an increase in energy of the electrophile at the bottom of the diagram, leads to a shift of the transition state toward the upper left corner, perpendicular to the the reaction coordinate, and towards the lower left corner, parallel to the reaction coordinate. The resultant of these effects moves the transition state to the left in the diagram, leading to a decrease in Brønsted β, as observed. The same diagram may be used to demonstrate the increase in ρ with decreasing $\mathrm{p}K_a$ of the catalyst, as observed in the present study. A decrease in $\mathrm{p}K_a$ due to introducing a weaker base raises the energy of the right-hand site of the diagram, leading to a shift of the transition state toward the upper right corner, parallel to the reaction coordinate, and toward the upper left corner, perpendicular to the

© 1999 NRC Canada

Fig. 6. More O'Ferrall – Jencks diagram for the rate-limiting step in the base-catalysed breakdown of benzaldehyde methyl hemiacetal (step 2 in Scheme 3) in a class n mechanism (24). The actual value of Hammett ρ throughout the diagram is a compromise between the values of ρ indicated at the corners of the diagram. These corner values represent the experimentally observed or estimated sensitivity of the various carbonyl forms to aromatic substitution with reference to the upper left corner (22). The location of an actual saddle point (transition state) is shown in the diagram with one vertical level line parallel to the *y*-axis ($p_x = 0$) and one turned 151° clockwise from vertical. This angle may be calculated according to Jencks and Jencks (4) when the the parameters p_x, p_{xy}, and p_y are known. The bold arrow indicates the expected shift in the transition state for a less stable carbonyl electrophile, i.e., toward lower Brønsted β values (p_{xy} positive, see text).



the reaction coordinate. The resulting effect is a vertical movements of the transition state toward higher ρ values.

In catalysis by the *hydroxide ion* (specific base catalysis), the points in Fig. 5 (Table 3) are seen to lie remarkably above the simulated curve, and the points are not included in the statistical analysis above. This seems to be a generally observed phenomenon in this type of chemical system (12, 22, 23, 25), presumably predicting a different mechanism with direct expulsion of the leaving group with no assistance from the conjugated acid (water) in step two. In Fig. 6, this situation may be described by a reaction coordinate running along the right hand edge of rather than across the diagram. It was observed by Cox et al. (23) that the positive deviation for the OH^- point on a Brønsted plot decreases with increasing Brønsted β, indicating that the Hammett plot for specific base catalysis will be less steep than expected from the general bases. This effect seems to be a general one and is confirmed from inspection of the data in the present work (Fig. 5). The disappearance of a positive deviation for k_{OH} for Hammett as well as Brønsted plots, when more electron-donating substituents are introduced in the electrophile, may be the result of a change in rate-limiting step for specific base catalysis. If Scheme 3 is considered, it is plausible that the pre-equilibrium step (step one) gradually becomes rate-limiting under such circumstances.

In conclusion, we can state that our experimental data for general base catalysis show all the essential elements expected for a concerted class n mechanism. The observation of a negative value of the direct interaction coefficient p_y — as a result of upward curvature in the Hammett plots — is new and represents a further confirmation of this mechanism. It also confirms the general validity of the More O'Ferrall – Jencks energy contour diagram as a useful tool in describing a complex chemical system.

Acknowledgements

This paper is dedicated to Professor A. Jerry Kresge for his many contributions to understanding the mechanisms of proton transfer reactions and for his friendship over the years. The paper is also dedicated to the memory of Professor James L. Jensen for his interest in our work and support over the years. This work was supported by a NATO collaborative research grant, CRG no. 900990. We also wish to thank Statens naturvidenskabelige Forskningsraad og Forskerakademiet for grants (K.M.E.).

Versatility of helix–loop–helix catalysts — cooperative $HisH^+$–His sites that span both helices

Jonas Nilsson, Kerstin S. Broo, Richard S. Sott, and Lars Baltzer

Abstract: Peptides with 42 amino acid residues have been designed to fold into helix–loop–helix motifs that dimerize to form four-helix bundles and catalyze the hydrolysis of *p*-nitrophenyl esters. Their reactivities depend on nucleophilic and general-acid catalysis by cooperative $HisH^+$–His pairs. The peptide catalyst MNV with the $HisH^+$–His pair separated by three residues within the helical segment catalyzes the hydrolysis of *p*-nitrophenyl fumarate with a second-order rate constant of 0.034 M^{-1} s^{-1} at pH 5.1 and 290 K. This *i*, *i*+3 site is a factor of three more efficient than the corresponding *i*, *i*+4 site. Helix–loop–helix peptides having histidines situated at opposing helices were designed and exhibited cooperative $HisH^+$–His catalytic pairs. The peptide H11,34K hydrolyzed *p*-nitrophenyl acetate and *p*-nitrophenyl valerate with second-order rate constants of 0.044 and 0.15 M^{-1} s^{-1}, respectively, at pH 5.1 and 290 K, indicating that the hydrophobic substituent was recognized by the catalyst.

Key words: de novo design, helix–loop–helix, four-helix bundle, histidine, catalysis.

Résumé : Des peptides à 42 résidus d'acides aminés ont été conçus pour se replier et former des motifs à hélice–boucle–hélice qui pourraient se dimériser pour former des faisceaux à quatre hélices et catalyser l'hydrolyse des esters *p*-nitrophényle. Leurs réactivités dépendent d'une catalyse nucléophile et acide générale par coopération de paires $HisH^+$–His. Le catalyseur peptidique MNV comportant une paire $HisH^+$–His séparée par trois résidus dans le segment hélicoïdal catalyse l'hydrolyse du fumarate de *p*-nitrophényle avec une constante de vitesse du deuxième ordre de 0,034 M^{-1} s^{-1}, à un pH de 5,1 et une température de 290 K. Ce site *i*, *i* +3 est plus efficace par un facteur de trois que le site correspondant *i*, *i* +4. Les peptides à hélice–boucle–hélice comportant des résidus histidines situés dans des hélices opposées ont été conçus et les paires catalytiques $HisH^+$–His donnent lieu à de la coopération. Le peptide H11,34K permet d'hydrolyser les acétate et valérate de *p*-nitrophényle avec des constantes de vitesse respectives de 0,044 M^{-1} s^{-1} et 0,15 M^{-1} s^{-1}, à un pH de 5,1 et une température de 290 K; ces résultats indiquent que le substituant hydrophobe est reconnu par le catalyseur.

Mots clés : conception de novo, hélice–boucle–hélice, faisceau à quatre hélices, histidine, catalyse.

Introduction

De novo designed folded polypeptides provide model systems of sufficient size and complexity to test intricate reaction mechanisms and to allow the construction of novel catalysts that perform enzyme-like reactions. The ultimate goal is the elucidation of the principles that control the functions of the natural enzymes and the understanding of how to design new enzymes for reactions not catalyzed by nature. Polypeptide supersecondary structures can now be constructed using nonnatural sequences that approach 100 residues in size as demonstrated by the successful design of folded polypeptides with well-defined tertiary structures such as helix–loop–helix motifs (1, 2), monomeric triple-stranded β-sheets (3, 4), a ββα motif (5), a triple helix collagen mimic (6), and coiled coils (7). Some of these motifs, which can all be produced by solid-phase techniques on automated synthesizers, have sufficient inherent stability to withstand the decreased free energy of unfolding that is a consequence of introducing several reactive residues. Others are readily repacked to regain the conformational stability that may be lost upon modification. These motifs are therefore suitable as scaffolds or templates for the construction and systematic modification of reactive sites in the engineering of new catalysts. So far, a small number of designed catalysts have been reported that are capable of rate enhancements of three orders of magnitude over those of the uncatalysed reactions (8–10) with at least partial understanding of their function. While the complexity of natural enzymes has been demonstrated in these designed catalysts,

the efficiencies and selectivities are far from those of their natural role models. It is therefore timely to address the issue of optimization of reactive site geometries to explore the scope and limitations of polypeptide catalysts. We have previously reported on histidine-based helix–loop–helix motifs that catalyse hydrolysis, transesterification, and amidation reactions of *p*-nitrophenyl esters (10). Their reactivities are due to cooperative nucleophilic and general-acid catalysis by unprotonated and protonated His residues four positions apart in a helical segment (11). We now wish to report on a systematic investigation of the reactive site geometries in helix–loop–helix motifs and the conditions required for cooperativeness between His residues. Such studies form the basis for the further development of designed polypeptide catalysts with tailored specificities and, eventually, for the engineering of artificial enzymes.

Experimental

The peptides were synthesized on a PerSeptive Biosystems Pioneer peptide Synthesizer using PerSeptive Biosystems standard Fmoc protocols, and the N-terminals were acetylated using acetic anhydride (0.3 mM in DMF). A PAL-PEG-PS polymer (PerSeptive Biosystems) was used that gave the C-amidated peptide upon cleavage by a mixture of TFA (13.5 mL), anisole (0.15 mL), thioanisole (0.35 mL), and ethanedithiol (0.20 mL) for 2 h at room temperature. The crude peptides were precipitated and washed with cold diethylether, and then lyophilized. They were purified isocratically by reversed phase HPLC on a semipreparative C-8 Kromasil column using 35–42% 2-propanol in 0.1% TFA with a flow rate of 7 mL/min and UV-detection at 229 nm. The identity and purity of the peptides were checked using electro-spray mass spectrometry, and the molecular weights were within 1 au from the theoretical values. No high molecular weight impurities were detected for the HPLC-purified peptides, and they are estimated to be more than 95% pure.

Kinetic measurement

The rate of hydrolysis of the *p*-nitrophenyl esters were measured on Varian Cary 100 or Cary 500 spectrophotometers equipped with Varian temperature controllers. The release of *p*-nitrophenol was followed at 320 nm and 290 K using 1 mm cuvettes. Stock solutions of the peptides were prepared by weighing (0.4 mM in 100 mM acetate buffer, pH 5.1), assuming that the peptides contain 25% water, and the concentrations of the stock solutions were determined by quantitative amino acid analysis. The pH was adjusted to 5.1 and readjusted after centrifugation if necessary. Solutions at concentrations of 0.2 and 0.3 mM were prepared by diluting the stock solution, and the same peptide solutions were used for all substrates. The peptide solutions (270 μL) were transferred by pipette to three cuvettes and temperature equilibrated for at least 20 min at 290 K in the temperature-controlled sample compartment of the spectrometer. The substrate (5 μL, 7.15 mM) was added to give a total substrate concentration of 0.13 mM. The poorly water-soluble substrates *p*-nitrophenyl acetate and *p*-nitrophenyl valerate were dissolved in acetonitrile, and mono-*p*-nitrophenyl fumarate was dissolved in 50% buffer 50% acetonitrile. The reactions were followed for more than two half-lives, and a single exponential function was fitted to the experimental data using Igor Pro software. The resulting pseudo-first-order rate constants were plotted as a function of the peptide concentrations, and the second-order rate constants were obtained by linear regression analysis. The error limits in the reported rate constants are probably ±10% due to possible errors in the amino acid analysis and the linear regression analysis.

CD and NMR spectroscopy

CD spectra were recorded on a JASCO-720 spectropolarimeter, routinely calibrated with (+)-camphor-10-sulfonic acid. The peptide solutions from the kinetic experiments were used, in 0.1 mm cuvettes, and the spectra were recorded in the wavelength interval 260–200 nm. The ^{1}H-NMR spectra of 0.4 mM peptide solutions in D_2O at 319 K were recorded at 400 or 500 MHz using Varian Unity spectrometers. The chemical shifts of the histidine ring protons were measured versus pH, under the usual assumption that the isotope effect on the electrode potential is cancelled by the isotope effect on the dissociation constant of the histidinium ion. A function describing the dissociation of a monoprotonic acid was fitted to the experimental result using Igor Pro software.

Results and discussion

The reactivity of histidine catalysts

Recently, we reported on histidine-based polypeptide catalysts, their reaction mechanisms, and their capacity for substrate recognition and discrimination (10–12). They were all derived from KO-42 (Fig. 1, Table 1, entry *b*), a 42-residue peptide that catalyzes the hydrolysis, transesterification, and amidation reactions of *p*-nitrophenyl esters (10). The hydrolysis of mono-*p*-nitrophenyl fumarate (**I**) was catalyzed by KO-42 with a second-order rate constant that is more than three orders of magnitude larger than that of the 4-methyl imidazole catalyzed reaction in aqueous solution at 290 K and pH 4.1. The catalyst was designed to fold into a helix–loop–helix supersecondary structure and dimerize to form a four-helix bundle. Its catalytic efficiency was based on six histidine residues His-11, His-15, and His-19 in helix **I**, and His-26, His-30, and His-34 in helix **II**. Histidine residues can function as nucleophiles and general base catalysts in their unprotonated form, and as general acid catalysts and

hydrogen-bond donors in their protonated form. The versatility of histidine is due to its pK_a that is typically in the range of 5–7 in a helix–loop–helix motif, depending on the nature of the flanking residues. The design principle in the engineering of the KO-42 catalyst was that unprotonated His residues should be flanked by protonated His residues, and that these residues should be four residues apart in the sequence.

The histidine residues in KO-42 were assigned by NMR spectroscopy, and the pK_a values measured and found to be 6.9, 5.4, 7.0, 7.2, 5.3, and 5.2 for His-11, His-15, His-19, His-26, His-30, and His-34, respectively (Table 2, entry *b*). The pH dependence of the second-order rate constant and the kinetic solvent isotope effect showed that the catalysis was due to cooperative reactive sites formed from protonated and unprotonated $HisH^+$–His pairs.

To elucidate the reaction mechanism of KO-42, seven 42-residue polypeptides with two or three histidine residues in positions occupied by histidine residues in KO-42 were synthesized (11), and the positions formerly occupied by histidines were replaced by the "unreactive" amino acids found in the template peptide SA-42 (13). The sequences of the peptides in this report were based on those of SA-42 (13) and KO-42 (10) that were thoroughly investigated by NMR spectroscopy, CD spectroscopy, and equlibrium sedimentation ultracentrifugation. They were shown to fold into the designed hairpin motifs and dimerize to form antiparallel four-helix bundles. The CD spectra showed the negative maxima at 222 and 208 nm that are characteristic of helical peptides. The mean residue ellipticities at 222 nm are –25 000 ± 1000 deg cm^2 $dmol^{-1}$ for KO-42 and –24 000 ± 1000 deg cm^2 $dmol^{-1}$ for SA-42, which corresponds to helical contents of 60–70% (14, 15). The sequences of the peptides reported here differ from those of SA-42 or KO-42 by less than 5 residues, and the measured mean residue ellipticities at 222 nm are in the range from –17 000 to –25 000 deg cm^2 $dmol^{-1}$. We therefore conclude that these peptides also fold into antiparallel four-helix bundles, although complete structural analyses have not been carried out for all peptides.

[a]Reference 13.

[b]Reference 10.

[c]Reference 11.

[d]Reference 17.

The efficiency of the histidine sites varied by almost an order of magnitude. For example, the second-order rate constants were 0.010 M^{-1} s^{-1} (JNI, His-26, His-30), 0.054 M^{-1} s^{-1} (JNII, His-30, His-34), and 0.007 M^{-1} s^{-1} (JNIII, His-26, His-34) for the hydrolysis of **I** at pH 5.1 and 290 K (Table 1, entries *c*–*e*).

The considerable difference in reactivity between JNII and JNI that both have His residues separated by four positions in the sequence could be explained by a model where the catalytic efficiency depends on the pK_a values of the histidine residues that determine their degree of protonation and intrinsic nucleophilicity. The second-order rate constant (k_2) for nucleophilic catalysis depends on the pK_a of the corresponding acid of the nucleophile and that for general-acid catalysis depends on the pK_a of the acid according to the Brønsted eqs. [1] and [2].

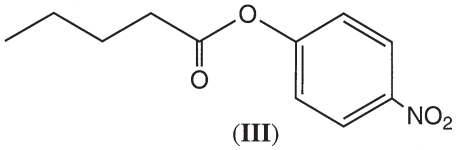
$$[1] \qquad \log k_2 = A + \beta pK_a$$

$$[2] \qquad \log k_2 = A - \alpha pK_a$$

The Brønsted coefficient β is 0.8 for imidazole catalysis of *p*-nitrophenyl acetate hydrolysis (16). Under the assumption that this value is valid also for histidine catalysis, a histidine with a low pK_a is more reactive than a histidine with a high pK_a if the reaction is carried out at a pH that is lower than its pK_a. This is because the nucleophilicity decreases with pK_a as $10^{0.8pKa}$, but the concentration of unprotonated histidine residues increases as 10^{pKa}. A His residue with a low pK_a is also a more efficient general acid catalyst than a residue with a high pK_a, under the same conditions. To test this model, the reactivities of histidine sites with different pK_a values were compared at a single pH. In the polypeptide JNI, the pK_a values of the reactive histidine residues are 6.9 (His-26) and 5.6. (His-30), and in the peptide JNII, the pK_a values are 5.6 for both His-30 and His-34 (Table 2, entries *c*–*d*). By comparing the rates of the JNII catalyzed reaction with that of JNI, it was shown that the relative catalytic efficiencies of JNI and JNII fitted this model if His-34 is the nucleophile and His-30 is the proton donor, and that the lower the pK_a values of both residues, the better the catalytic efficiency at a pH below the pK_a values. The comparison of reactivities using the Brønsted equations is therefore a good measure of cooperativity in His-based catalysis.

Transition-state binding of the carboxylate residue of *p*-nitrophenyl fumarate was accomplished by introducing basic amino acids in helix **I** of JNII(12) to supplement the His site in helix **II**. The most efficient catalyst for the hydrolysis of **I** at pH 5.1 and 290 K was JNIIRK (k_2 = 0.134 M^{-1} s^{-1}), where His-30 and His-34 were supplemented with an arginine in position 11 and a lysine in position 15. The hydrolysis of *p*-nitrophenyl acetate (**II**) (k_2 = 0.088 M^{-1} s^{-1}) is less efficient, which shows that there is significant binding of the fumaryl anion in the transition state of the hydrolysis reaction.

The peptide catalyst JNIII contains the histidine residues, His-26 and His-34, and hydrolyzes **I** with a k_2 of 0.007 M^{-1} s^{-1} but *p*-nitrophenyl valerate (**III**) with a k_2 of 0.097 M^{-1} s^{-1} (Table 1, entry *e*). The rate enhancement of a factor of 14 shows that there is considerable binding of the aliphatic substituent. The recognition of a substrate that has both a negatively charged and hydrophobic substituent, such as the monoester of a dicarboxylic acid that has an aliphatic substituent, should therefore give rise to a rate enhancement of more than a factor of 70 if the binding is cooperative. This has not yet been accomplished perhaps because of the transition state geometry imposed by the structure of the helix.



(**III**)

To reach a higher level of efficiency and selectivity in $HisH^+$–His catalysis, the requirements for cooperativity in substrate binding must be defined, something that has not yet been accomplished with the *i*, *i*+4 sites of the KO-42 derived catalysts. We tried therefore to elucidate if other

© 1999 NRC Canada

$HisH^+$–His sites could be employed in four-helix bundle motifs where cooperative binding of two or more substituents of a single substrate could be achieved. In particular, the possibility of having each residue in separate secondary structures should provide the most flexibility for optimization because the helical segments can be moved in very small steps, whereas the distance between two residues in a helical conformation is comparatively long and well defined.

In this study, we have therefore inspected the possibilities of designing new reactive site geometries based on histidine pairs three positions apart in the sequence of a helix and histidine pairs where there is one His residue in each helix of a helix–loop–helix motif.

The reactivity of the $HisH^+$–His site *i, i*+3

To test the reactivity of a catalyst with a $HisH^+$–His pair where the residues are separated by three positions in the sequence within a helical segment, i.e., in positions *i, i*+3, we synthesized MNV with His-11 and His-14 in helix **I**. MNV catalyzed the hydrolysis of **I** with a second-order rate constant of 0.034 M^{-1} s^{-1} at pH 5.1 and 290 K. Previously, it was shown that MNI, with His-11 and His-15, catalyzed the hydrolysis of **I** with a second-order rate constant of 0.011 M^{-1} s^{-1} (11) (Table 1, entries h and *j*). The pK_a values of the histidine residues of MNV are 6.1 and 6.3 (17), but due to spectral overlap, they could not be unequivocally assigned by NMR spectroscopy. For MNI, the pK_a values are 6.5 and 6.1 for His-11 and His-15, respectively (Table 2, entries *f* and h).

The pK_a values of the histidine residues of MNI and MNV are similar but the reactivities differ, and the $HisH^+$–His pair *i, i*+3 is a factor of three more efficient than the *i, i*+4 pair in hydrolysis of **I** at pH 5.1 and 290 K. The kinetic solvent isotope effect for the MNV catalysed reaction has now been determined, and the ratio $k_2(H_2O)/k_2(D_2O)$ found to be 2.6. A value larger than one is indicative of strong hydrogen bonding in the transition state, and general-acid catalysis by the protonated flanking His is therefore suggested. The $HisH^+$–His pair *i, i*+3 is thus a promising template reactive site for cooperative nucleophilic and general-acid catalysis. The increased reactivity of the *i, i*+3 site over that of the *i, i*+4 can be of general use in the design of new polypeptide catalysts.

If the pK_a values of the histidine residues in MNV can be depressed, the catalysis is expected to be even more efficient in comparison with that of the 4-methylimidazole catalyzed reaction at pH 5.1. The Brønsted equations can be used to calculate that a decrease of both pK_a values by 0.5 units gives rise to a relative increase in reactivity by a factor of 1.3 for nuclophilic catalysis and by a factor of 2.1 for general-acid catalysis. The overall reactivity increase thus amounts to a factor of 2.7 in favor of the low-pK_a peptide at low pH. The reactivity of the MNI peptide was previously successfully enhanced by replacing Glu-14 by Lys-14. The resulting peptide, MNKI, had pK_a values of 5.6 for both His-11 and His-15 (Table 2, entry *j*), and k_2 for the hydrolysis of **I** was 0.041 M^{-1} s^{-1}, (Table 1, entry *l*) a factor of four larger than that of MNI (17).

To lower the pK_a of His-11 and of His-14 of MNV, we introduced Lys-8 and Lys-17 to depress the pK_a values of His-11 and His-14, respectively, and form the peptide MNKV according to the procedure outlined in ref. 16. In addition, Lys-30 and Arg-34 were added in helix **II** to provide further binding of the fumaryl anion. The pK_a values were measured and found to be 5.8 for both of the histidine residues (Table 2, entry *i*). Surprisingly, the reactivity towards **II** did not increase but remained the same (Table 1, entry *k*). The reason may be that the transition-state geometry along the most efficient pathway cannot be adopted because substituents of the substrate are too close proximity to amino acid side chains of the catalyst. For the MNKV catalyzed reactions, k_2 is 0.033 M^{-1} s^{-1} for the hydrolysis of **II** and 0.066 M^{-1} s^{-1} for the hydrolysis of **I**. A rate constant ratio of 2 due to the binding of the fumarate anion was accomplished, which is in good agreement with those observed for the catalysis by the JNII series of peptides that have basic residues in positions 11 and 15, with the ratio k_2(**I**)/k_2(**II**) in the range of 1.5–2.5. The $HisH^+$-11–His-14 site is also cooperative in both peptides.

A second *i, i*+3 site was designed with His-8 and His-11 (MNIV), and this peptide catalyzed the hydrolysis of **I** with a second-order rate constant of 0.015 M^{-1} s^{-1} (Table 1, entry *i*). The pK_a values were measured and found to be 5.5 for His-8 and 6.6 for His-11 (Table 2, entry g). In this polypeptide, the pK_a value of His-11 is somewhat elevated but it could probably be depressed by the incorporation of a Lys-10 to make a more efficient catalyst in analogy with the modifications undertaken with MNKI. Nevertheless, it too forms a cooperative site as the reactivity is higher than that calaculated from the reactivity of 4-methylimidazole. The relative reactivities of 4-methylimidazole and the peptide catalysts at that pH are calculated from the pK_a of the reference catalyst and the pK_a values of the two histidines as described above.

The reactivity of the interhelical $HisH^+$–His site

To test the possibility of obtaining a cooperative interhelical $HisH^+$–His pair, we synthesized the peptide H15,30 that contains His-15 and His-30, i.e., one His in each helix but in positions that are close in space in the four-helix bundle. We have previously shown by measurements of reactivity that residues in positions 15 and 30 are close in space as are those in positions 11 and 34 (18). The pK_a values of the histidine residues were measured and found to be 6.2 and 6.3 (Table 2, entry *k*), and the second-order rate constant for the hydrolysis of **I** was 0.018 M^{-1} s^{-1} (Table 1, entry m). Although the value is low, the rate is larger than those of two independent nucleophilic histidine residues, and there is clearly cooperativeness between His-15 and His-30. To construct a peptide with an interhelical $HisH^+$–His site with depressed pK_a values, we synthesized H11,34K (Fig. 2) that contained His-11 and His-34. Position 34 is known to be close to the hydrophobic core, and a histidine in this position has a low pK_a. Furthemore, the pK_a of His-11 of H11,34K was depressed by the introduction of a lysine residue at position 14, and the pK_a values for His-11 and His-34 were measured and found to be 5.4 and 5.5 (Table 2, entry *l*).

This reactive site of H11,34K may be directly compared to that of JNII, since the pK_a values of the two peptides are very similar. H11,34K catalyzed the hydrolysis of **II** with a second-order rate constant of 0.044 M^{-1} s^{-1} (Table 1, entry *n*), which is similar to that of the JNII catalyzed hydrolysis of **II** (k_2 = 0.048 M^{-1} s^{-1}). The rate of hydrolysis of **I** was somewhat lower. The hydrolysis of **III** (k_2 = 0.15 M^{-1} s^{-1})

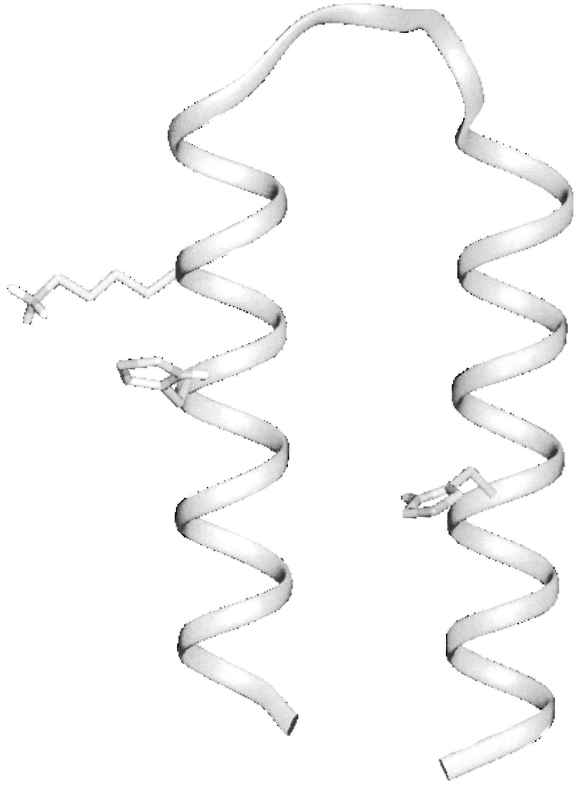
Fig. 2. The modelled structure of H11,34K showing only the sidechains of the histidine residues and Lys14. Only the monomer is shown for reasons of clarity.



shows that there is recognition of the aliphatic side chain by the hydrophobic residues of the core. The increase by a factor of 3.4 is similar to the value obtained for JNII, which is 3.9. These results show for the first time that cooperative reactive sites can be constructed in the "enzyme-like" way by introducing residues in separate secondary structures and is an important step forward towards the engineering of optimized polypeptide catalysts.

Protonated His residues provide transition state binding of oxyanions and carboxylate anions

To identify the detailed functions of His-based catalysts, it must also be clarified to what extent the protonated residues can provide transition-state binding of anionic substituents in addition to general-acid catalysis. We have therefore investigated if histidine residues can also function as hydrogen-bond donors in the transition state of the acyl transfer reaction of **I**. The "length" of the His side chain is similar to that of the ornithine although its geometry is more constrained due to its ring structure. We have previously shown that ornithine enhances the reactivity of $HisH^+$–His sites in the adjacent helix, and the idea that protonated His residues can function in the same way is therefore a reasonable one and compatible with the diverse reactivity of the imidazoyl residue.

We synthesized the peptides JNIIHR and JNIIRH with a nucleophilic histidine residue in position 34 and a proton donating histidine in position 30. For binding of the fumaryl anion, the peptides were supplemented with His-11 and Arg 15 in JNIIHR and Arg 11 and His-15 in JNIIRH. These polypeptides catalyzed the hydrolysis of **I** with second-order rate constants of 0.14 M^{-1} s^{-1} and 0.12 M^{-1} s^{-1} at pH 5.1 and 290 K (Table 1, entries *f–g*), respectively, whereas the second-order rate constant of the JNII catalyzed reaction is 0.054 M^{-1} s^{-1}. The reactivities thus increase by factors of 2.2 and 2.6, however, these enhancements are only slightly larger than what is expected from the sum of the individual $HisH^+$–His pairs in peptides such as JNII, His15,30, and His11,34. A protonated histidine residue may thus bind the fumaryl anion during the course of the reaction without giving rise to any further enhancement to binding relative to that furnished by the other basic residues. His-15 is known to have a pK_a value of approximately 5.4 in KO-42 and the MN series of peptides. Since JNIIRH has a similar rate constant as JNIIHR and other JNII derived peptides, which have been supplemented by Arg or Lys side chains in positions 11 and 15, it can be assumed that the protonated form of His-15 can also function as a binding residue in combination with histidine residues 30 and 34. However, a nucleophilic contribution from this residue probably also occurs. If this is the case, it will probably form cooperative sites with residues in positions 30 or 34, which is an efficient interhelical His–$HisH^+$ site in the catalysis of hydrolysis reactions, in comparison with other $HisH^+$ –His pairs.

Conclusions

We have shown that the $HisH^+$–His reactive sites provide efficient catalysis also in the *i, i*+3 configuration and most gratifyingly also when the site is interhelical. The residues are far from each other in the primary structure but are brought together as the helix–loop–helix is formed. This demonstration implies that reactive sites can be fine tuned also in motifs that are small in comparison with the naturally occurring ones. Yet, another function of the His residue has been identified in these motifs as it has been shown, in its protonated form, to bind anionic substituents of substrates in catalytic reactions. The *i, i*+3 site and the interhelical $HisH^+$–His pair is of general interest in the design of new polypeptide catalysts. An interhelical reactive site in a helix–loop–helix is more easily fine-tuned than an intrahelical one, since secondary structures are readily repositioned in small increments than single residues in helical segments. The reactive sites may now be introduced into cavities and crevices of natural proteins where the hydrophobic environment is expected to enhance peptide–substrate interactions and where the positioning of flanking residues is more precise and controllable.

Solvent isotope effects in the oxidation of dipeptides by aqueous chlorine

X.L. Armesto, M. Canle L., V. García, and J.A. Santaballa

Abstract: A kinetic study of the mechanism of oxidation of Ala-Gly and Pro-Gly by aqueous chlorine has been carried out. Among other experimental facts, the deuterium solvent isotope effects were used to clarify the mechanisms involved. In a first stage, *N*-chlorination takes place, and then the (*N*-Cl)-dipeptide decomposes through two possible mechanisms, depending on the acidity of the medium. The initial chlorination step shows a small isotope effect. In alkaline medium, two consecutive processes take place: first, the general base-catalyzed formation of an azomethine (β ca. 0.27), which has an inverse deuterium solvent isotope effect (k_{OH^-}/k_{OD^-} ~ 0.8). In a second step, the hydrolysis of the azomethine intermediate takes place, which is also general base-catalyzed, without deuterium solvent isotope effect, the corresponding uncatalyzed process having a normal deuterium solvent isotope effect (k_{H2O}/k_{D2O} ~ 2). In acid medium, the (*N*-Cl)-dipeptide undergoes disproportionation to a (*N*,*N*)-di-Cl-dipeptide, the very fast decomposition of the latter in deuterium oxide preventing a reliable estimation of the solvent isotope effect.

Key words: chlorination, deuterium isotope effects, fractionation factors, peptide oxidation, water treatment.

Résumé : On a effectué une étude cinétique du mécanisme d'oxydation des peptides Ala-Gly et Pro-Gly par le chlore en milieu aqueux. Parmi les résultats expérimentaux, on a utilisé les effets isotopiques du deutérium du solvant pour clarifier les mécanismes impliqués. La première étape implique une *N*-chloration qui est suivie d'une décomposition du (*N*-Cl)-dipeptide par le biais de deux mécanismes possibles suivant l'acidité du milieu. L'étape de chloration initiale ne présente qu'un faible effet isotopique. En milieu alcalin, il se produit deux processus consécutifs: le premier, la formation d'un azométhine sous catalyse basique générale (β d'environ 0,27) qui présente un effet isotopique inverse pour le deutérium du solvant (k_{OH^-}/k_{OD^-} ~ 0,8). La deuxième étape correspond à l'hydrolyse de l'intermédiaire azométhine sous catalyse basique générale, sans effet isotopique du deutérium du solvant alors que le processus non catalysé présente un effet isotopique du deutérium du solvant qui est normal (k_{H20}/k_{D2O} ~ 2). En milieu acide, le (*N*-Cl)-dipeptide subit une réaction de disproportionation conduisant à un (*N*,*N*)-di-Cl-dipeptide dont la décomposition dans l'oxyde de deutérium est tellement rapide qu'il n'est pas possible d'obtenir une évaluation fiable de l'effet isotopique du solvant.

Mots clés : chloration, effets isotopiques du deutérium, facteurs de fractionnement, oxydation de peptides, traitement des eaux.

Introduction

Although well-developed countries are looking for safe and inexpensive water and wastewater treatment methods, water halogenation, and mainly chlorination, is still nowadays a world-wide used disinfection method. During this process, the different organic compounds present in natural water undergo different chemical processes, giving rise to a number of intermediate species that are relatively unstable or reactive (1). The time of residence of such intermediates in the medium depends mainly on the structure of the compound itself and the physico-chemical conditions of the medium (2). Notwithstanding this fact, humanity is somehow indebted to chlorine, since after its adoption as a common water disinfectant, most water-transmitted diseases were beaten. The disinfection power of chlorine relies on its ability to penetrate the cell membrane and thus kill pathogens (3) (with some known exceptions, like Cryptosporidium) (4), the resulting water being suitable for drinking and domestic use.

All the mentioned facts make desirable to understand as best as possible the different reactions taking place during such industrial process.

Different studies have analyzed the risks associated to water chlorination, the main danger coming from the byproducts, some of which have been demonstrated to be carcinogenic and (or) mutagenic (5). Despite the fact that the last two decades have seen an important effort toward clarification of the pathways through which byproducts of water chlorination are generated, the topic is still far from an end (1). The oxidation of amines and amino acids by aqueous halogen solutions have been extensively studied (1). In turn,

Received November 24, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

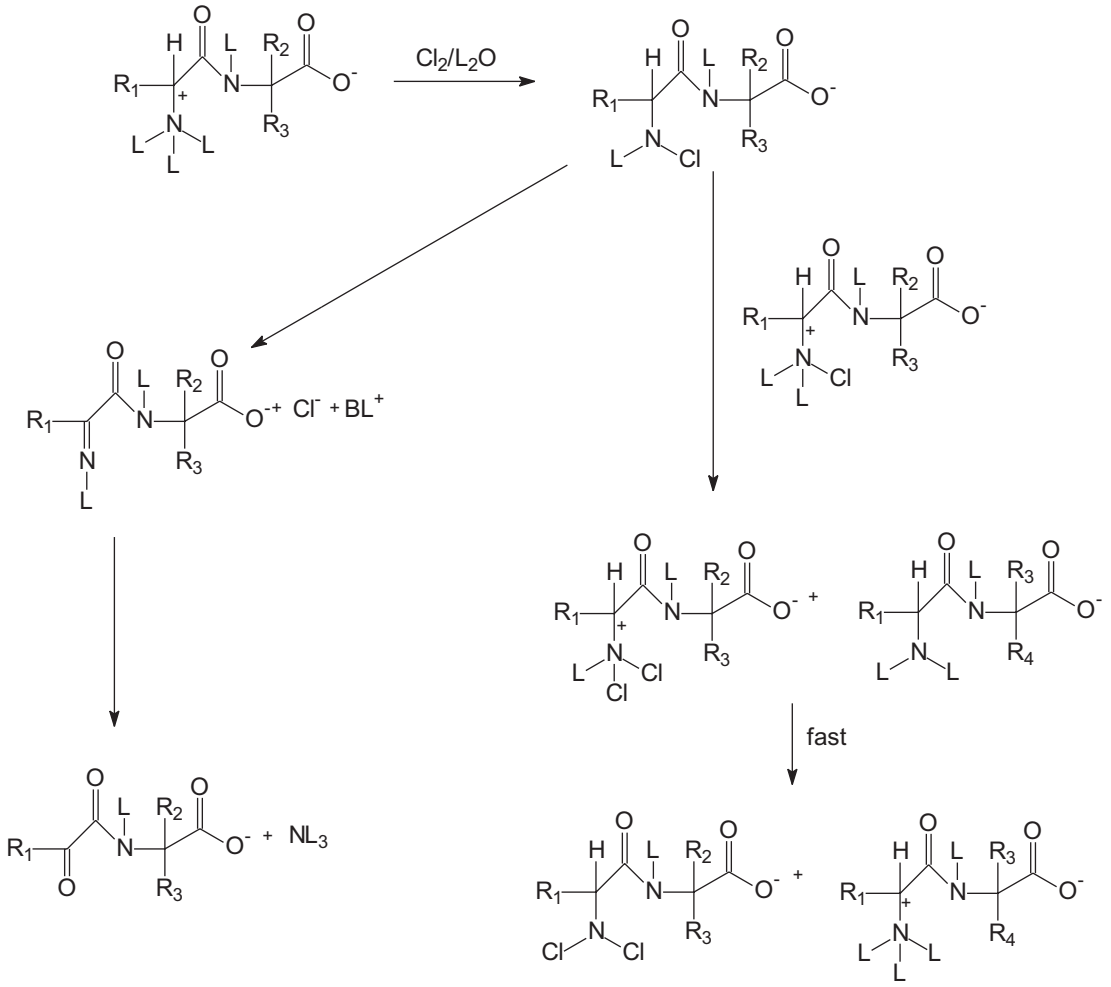
Scheme 1.



dipeptides received much less attention, assuming they had similar behaviour. Aqueous chlorine oxidants are intracellularly available by the action of the myeloperoxidase–H_2O_2–Cl^- system (6), and the action of such oxidants is of most relevance for biological phenomena like oxidative stress and aging (7).

The mechanism of chlorination of dipeptides is, therefore, of biochemical relevance and should be studied in depth.

Different authors have contributed to the application and establishment of solvent isotope effects (SIE) as a powerful tool to the elucidation of reaction mechanisms. Between his many fundamental contributions to physical organic chemistry, Kresge (8*b*) showed the way to describe the dependence of reaction rates at equilibrium with the isotopic composition of the solvent in terms of fractionation factors.

Here, we present a kinetic study of the oxidation of the dipeptides Alanyl-Glycine (Ala-Gly), **1**, and Prolyl-Glycine (Pro-Gly), **2**, by aqueous chlorine, using the D_2O SIE as a tool for the elucidation of the corresponding reaction mechanisms.

The processes under study are shown in Scheme 1 (through the paper, L is used to represent any of the used isotopic forms of hydrogen, i.e.: H or D). The generation of the corresponding (*N*-Cl)-dipeptides **3** and **4** is discussed first, and then the reactivity of such (*N*-Cl)-dipeptides under different conditions of acidity.

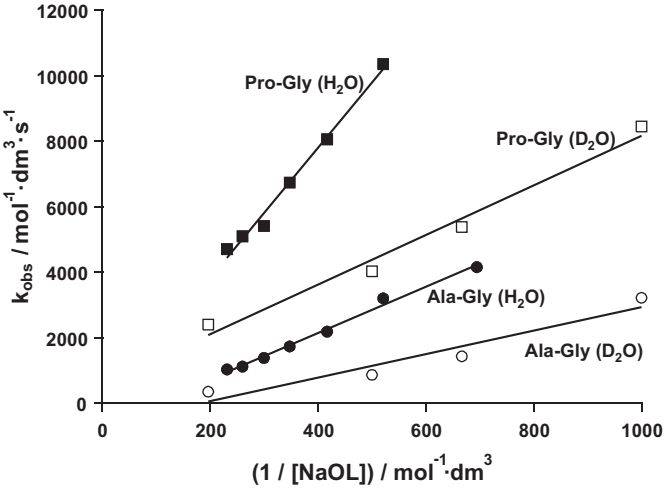
Results and discussion

(*i*) Generation of (*N*-Cl)-dipeptides

The chlorination of **1** and **2** to yield, respectively, (*N*-Cl)-Ala-Gly (**3**) and (*N*-Cl)-Pro-Gly (**4**) follows a second-order kinetic law, order one relative to both the dipeptide and the chlorinating agent. The so-obtained second-order rate constants show an inverse dependence with hydroxide ion concentration (Fig. 1).

© 1999 NRC Canada

Fig. 1. Dependence of the rate of chlorination of peptides to (*N*-Cl)-dipeptides with the acidity of the medium. $[Dipeptide]_0 = [LOCl]_0 = 5.0 \times 10^{-4}$ mol dm^{-3}; I = 1.0 mol dm^{-3}; T = 298.0 K.



The following rate equation accounts for the observed behaviour:

$$r = k_{obs}\,[\text{dipeptide}][\text{chlorinating agent}]$$

$$= \frac{a\,[\text{dipeptide}][\text{chlorinating agent}]}{OL^-}$$

Such result is consistent with the mechanism shown in Scheme 2, which has been previously proposed to explain the chlorination of amines and amino acids to, respectively, (*N*-Cl)-amines and (*N*-Cl)-amino acids (9). $R_1R_2NL_2^+/R_1R_2NL$ refers to the amino group of the peptide. Chlorination of the peptidic nitrogen linkage does not take place under the working conditions (10). From Scheme 2, the following theoretical rate equation can be obtained:

$$r = \frac{kK_{a2}[L_3O^+]}{(K_{a2} + [L_3O^+](K_c + [L_3O^+])}\,[\text{dipeptide}][LOCl]$$

Kinetic runs have been performed at pH >>11, such that $K_{a2} >> [L_3O^+]$ and $K_C >> [L_3O^+]$. Hence, the previous equation simplifies to

$$r = \frac{kK_w}{K_c[OL^-]}\,[\text{dipeptide}][LOCl]$$

This equation is formally similar to the one empirically found, where the parameter a equals (kK_w/K_C). The values for the bimolecular rate constant k are compiled in Table 1. For H_2O, we use pK_w = 13.997 and pK_C = 7.26, whereas for D_2O, pK_w = 14.873 (11) and pK_C = 7.76, the latter value being proposed assuming $\Delta pK_a \approx 0.50$ on going from H_2O to D_2O (12).

The obtained bimolecular chlorination rate constants for **1** and **2** (Table 1) are in agreement with those previously found for amines and amino acids, whose pK_{a2} is close to that of the studied dipeptides. The deuterium secondary SIE found for **1** and **2** are close to unity, which is expected in this fast process, where the transition state should be reactant-like. These values could increase by ca. 10% if $(pK_C(D_2O) - pK_C(H_2O)) > 0.50$.

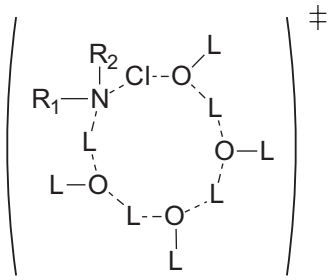
Scheme 2.

$$LOCl \rightleftharpoons ClO^- + L_3O^+ \qquad K_C$$

$$R_1R_2NL_2^+ \rightleftharpoons R_1R_2NL + L_3O^+ \qquad K_{a2}$$

$$R_1R_2NL + LOCl \longrightarrow R_1R_2NL + L_2O \qquad k$$

The magnitude of the observed SIE is in agreement with the currently accepted reaction mechanism, the slow step being the bimolecular reaction between the free amino nitrogen of the peptide and LOCl. However, the observed SIE does not allow to distinguish between direct *Cl* transfer from the *O* of LOCl to the amino *N* of the peptide and the possible involvement of a number of water molecules in the transition state (TS), like in structure (**5**) (12). In both cases, an early TS would imply a secondary SIE close to unity.



5

(*ii*) Decomposition of (*N*-X)-dipeptides in alkaline medium. Generation of *N*-(2-azomethino, 1-oxoalkyl)-amino acids

It is known from kinetic studies on the base-promoted decomposition of (*N*-X)-amines and (*N*-X)-amino acids that once the (*N*-X)-derivatives have been formed, they decompose through two consecutive processes (13): a base-promoted elimination of X^- to yield the corresponding azomethines, and a subsequent very fast hydrolysis of such azomethines to produce α-keto derivatives, chloride, and ammonia (or the corresponding amine).

For (*N*-X)-dipeptides, the intermediate azomethines lifetime is long enough to allow their observation, contrary to the case of (*N*-X)-amines. A plot of absorbance at the working wavelength (ca 237 nm) vs. time shows a maximum (14). Using Cl^- and NH_4^+ selective electrodes, it was shown that at such maximum Cl^- has been almost quantitatively released from **3** and **4**, while no NH_4^+ has been yet formed. In what follows, the mechanism of elimination to yield the azomethine intermediates is discussed.

The base-promoted elimination of X^- from (*N*-X)-dipeptides to *N*-(2-azomethino, 1-oxoalkyl)-amino acids is of first order, relative to both the (*N*-Cl)-dipeptide and the used base (Fig. 2), i.e.,

$$r = k\,[(N - X) - \text{dipeptide}][\text{base}]$$

Table 1 shows the rate constant values so-obtained, both in H_2O and D_2O. Table 1 compiles, as well, the observed values of k for the corresponding (*N*-Br)-dipeptides.

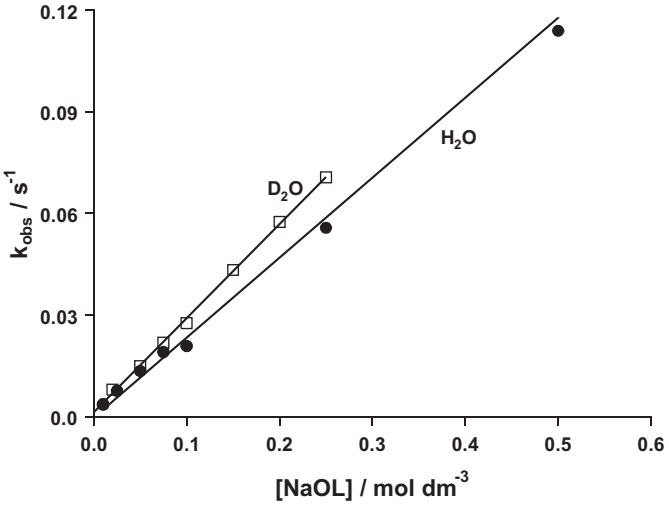
[a] Rate constant units: s^{-1}.

[b] pK_a of CF_3-CH_2OH: 12.43.

[c] Parameter *b* is given in units of mol^{-2} dm^6 s^{-1}.

Fig. 2. Influence of the concentration of sodium hydroxide on the rate of generation of *N*-(2-azomethino, 1-oxoalkyl)-amino acids during the decomposition of (*N*-X)-dipeptides. [*N*-Cl-Ala-Gly]$_0$ = 1.0×10^{-3} mol dm^{-3}; I = 1.0 mol dm^{-3}; T = 298.0 K.



Brønsted plots for **3** and **4** are linear, with slopes of, respectively, β = 0.27 (15, 16) and 0.29. Such values of β are in agreement with the magnitude of the observed deuterium isotope effect: $[k(OH^-)/k(OD^-)]$ = 0.74 for **3** and $[k(OH^-)/k(OD^-)]$ = 0.84 for **4**. These values can be explained using fractionation factors (17).

$$\frac{k_{OH^-}}{k_{OD^-}} = \frac{\Phi_{OL^-}\,\Phi_{NCIL}}{\Phi^{\pm}_{OL^-}\,\Phi^{\pm}_{NCIL}}$$

In this kind of process, the main contribution to the isotope effect is due to the transformation of OL^- into L_2O, the OL^- fractionation factor changing from 0.41 to 1.

The deuterium secondary isotope effect, due to the hydrogen attached to the nitrogen, has almost no effect. In fact, in the case of the azomethine formed from **4**, the deuterium SIE comes only from the conversion of OL^- into L_2O:

$$\frac{k_{OH^-}}{k_{OD^-}} = \frac{\Phi_{OL^-}}{\Phi^{\pm}_{OL^-}} \rightarrow \Phi^{\pm}_{OL^-} = \frac{0.41}{0.74} = 0.55$$

By definition, the fractionation factor for water is 1. This means that OL^- retains most of its character at the TS, i.e.: the TS is reactant-like and the proton is slightly transferred to OL^-. Assuming very small change in the fractionation factor of the hydrogen attached to the *N*, 0.48 is estimated for the OL^- fractionation factor at the TS in the case of **3**. Such value is close to the typical value of 0.41 for the fractionation factor of the OL^-, which, in practice, means that L^+ is less transferred when the reactant is **3**. The same conclusion is drawn from the Brønsted β values: β (**4**) >> β (**3**).

From the results with (*N*-Br)-derivatives, the influence of the nucleofuge can be expressed in terms of β_{lg} (0.33 and 0.34, respectively, for (*N*-X)-**1** and (*N*-X)-**2**).

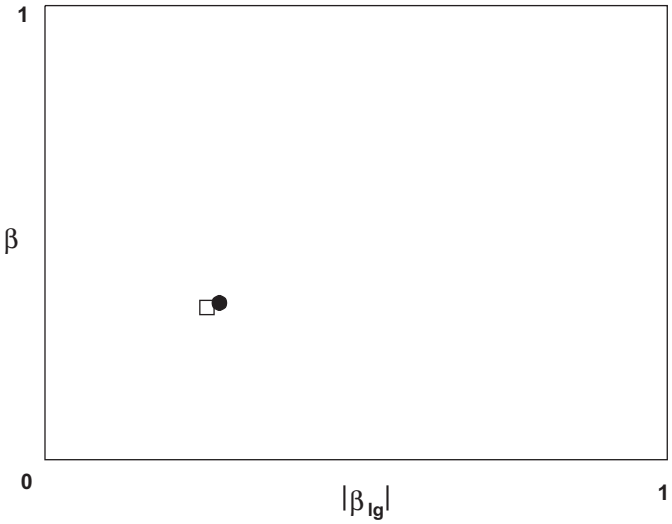
Using both parameters, it is possible to locate the TS in a More O'Ferrall – Jencks diagram (16). Figure 3 shows clearly that the process is concerted ($A_{xh}D_hD_n$), and slightly imbalanced (ca. 5%) (18), the *N—Cl* bond breaking going slightly ahead of the *C—H* bond breaking (see Scheme 3). However, no information is available about the process of carbon–nitrogen double bond formation.

(*iii*) Decomposition of (*N*-X)-dipeptides in alkaline medium: hydrolysis of *N*-(2-azomethino, 1-oxoalkyl)-amino acids to *N*-(1,2-dioxo-alkyl)-amino acids

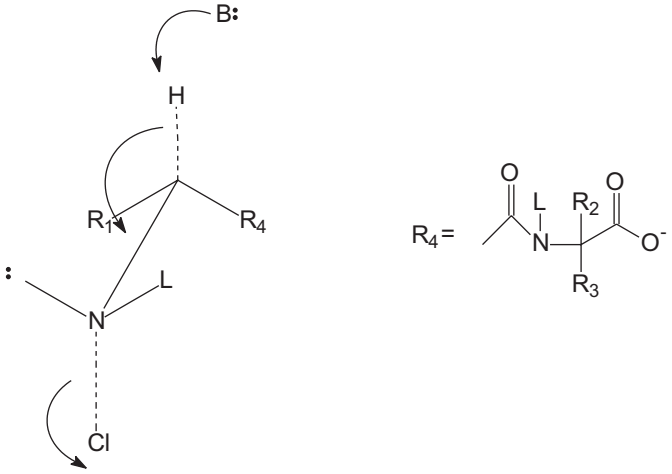
The compounds **3** and (*N*-Br)-**1** decomposed with different rates to the corresponding *N*-(2-azomethino, 1-oxoalkyl)-amino acids (vide supra), but they have the same time of decay for such intermediate. In both cases, the process was of

© 1999 NRC Canada

Fig. 3. More O'Ferrall – Jencks plot for the base-promoted decomposition of (*N*-X)-dipeptides (□, (*N*-X)-**1**; ●, (*N*-X)-**2**).



Scheme 3.



first order, relative to both the *N*-(2-azomethino, 1-oxoalkyl)-amino acid, and to OL^-. The dependence k_{obs} vs. [OL^-] was in all cases linear, showing an intercept statistically different from zero (Fig. 4).

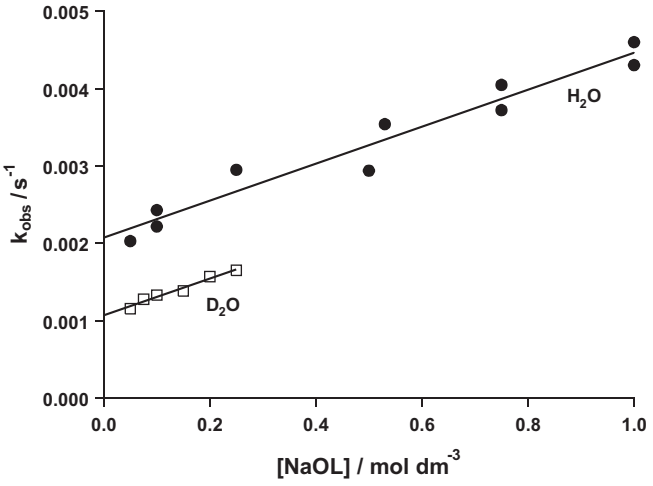
Much work has been done on the hydrolysis of imines (19), the mechanism being satisfactorily known under different conditions. In the discussion ahead, we will take the established mechanism as a starting point.

The rate equation includes a base-catalyzed pathway and an uncatalyzed one, the corresponding values of the rate constants for those routes being compiled in Table 1.

$$r = (k_0 + k_{Base}[\text{base}])[N\text{-(2-azomethino, 1-oxoalkyl)-amino acid}]$$

The rate constants obtained for the base-catalyzed azomethine hydrolysis allow to estimate a zero value for the Brønsted β. This process shows no SIE ($k_{OH}/k_{OD} \approx 1$).

Fig. 4. Decomposition of *N*-halo-dipeptides. Influence of the [OL^-] on the rate of hydrolysis of the *N*-(2-azomethino, 1-oxoalkyl)-amino acids. [*N*-Cl-Ala-Gly]$_0$ = 1.0×10^{-3} mol dm^{-3}; I = 1.0 mol dm^{-3}; T = 298.0 K.



The fact β = 0 is consistent with a mechanism in which no proton transfer takes place, but at first sight, the absence of the deuterium SIE is not easily explained. An inverse deuterium SIE would be expected for a step in which the OL^- (ϕ = 0.41) joins the azomethine to form a carbinolamine ($\phi_{COL} \approx 1$).

These results can be accounted for in terms of the reaction pathway depicted in Scheme 4: one water molecule provides assistance in the formation of the carbinolamine. In this case, there are two contributions to the isotope effect: primary and secondary deuterium isotope effects:

$$\frac{k_{OH^-}}{k_{OD^-}} = \left(\frac{k_H}{k_D}\right)_{primary} \frac{\Phi_{OL^-}\Phi_{NL}}{\Phi^{\pm}_{OL^-}\Phi^{\pm}_{NL}\Phi^{\pm}_{L_2O}}$$

The primary deuterium isotope effect is due to the proton being transferred between the water molecule and the azomethine (Scheme 4). The absence of isotope effect is explained in terms of a reactant-like TS, where the proton is only slightly transferred, so that the magnitude of the primary isotope effect cancels with the contribution of the secondary ones. The latter involves the rest of interchangeable hydrogens whose bonds are not formed or broken at the TS.

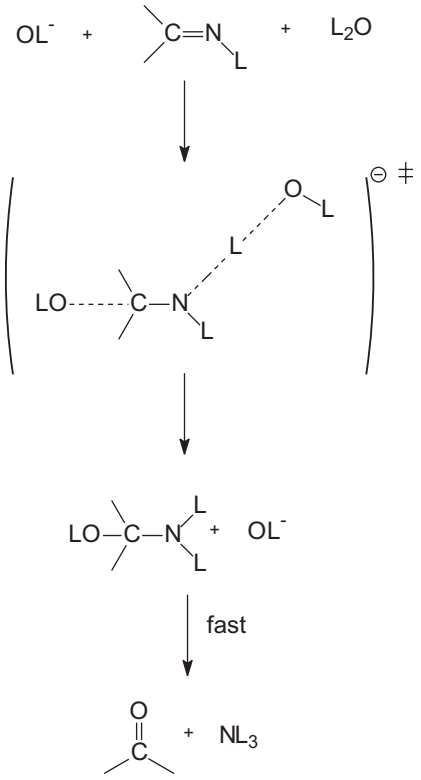
The uncatalyzed hydrolysis of the azomethine is typically explained in terms of two kinetically indistinguishable pathways: one is shown in Scheme 5, and the other consists in the attack of OL^- to the protonated azomethine (iminium ion).

As in the previous processes where a OL^- is lost, an inverse isotope effect would be expected. However, this is not the case. The value of the solvent isotope effect (k_{H2O}/k_{D2O} = 1.96) is in support of the pathway depicted in Scheme 5.

By using typical fractionation factors for the species involved in the pre-equilibrium, a minimum value of 2.1 is predicted for the deuterium SIE. Most likely, this value is an overestimation, since in addition to the formation of OL^-, the force constants for the interchangeable hydrogens are bigger for the reactants than for the products (see Scheme 5) (20).

© 1999 NRC Canada

Scheme 4.



Considering now the rate-determining step, the value of the observed deuterium SIE would imply a reactant-like TS, where the OL^- mostly retains its character.

(*iv*) Decomposition of *N*-halo-dipeptides in acid medium: disproportionation

Although (*N*-X)-dipeptides are fairly stable under mild acidic conditions, they decompose in acid medium to give the (*N*,*N*)-di-Cl-dipeptide (see Scheme 1), the process follows a second-order kinetic law, and shows a linear dependence on proton concentration (Fig. 5), i.e.,

$$r = k_{obs}[\text{N-Cl-Ala-Gly}]^2 = b[L_3O^+][\text{N-Cl-Ala-Gly}]^2$$

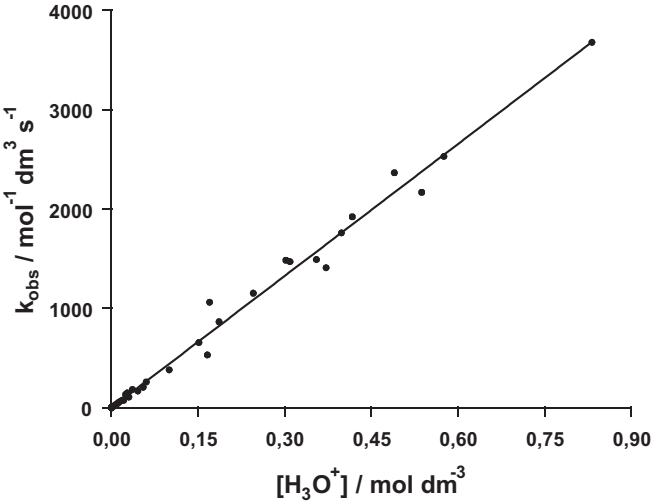
The mechanism shown in Scheme 6 has been proposed to explain the observed behaviour of *N*-Cl compounds in acid media (21).

From this mechanism, the following theoretical rate equation is derived:

$$r = \frac{kK_{aN\text{-Cl}}[L_3O^+]}{(K_{aN\text{-Cl}} + [L_3O^+])^2}[N\text{-Cl-Ala-Gly}]^2$$

The experimental rate dependence matches the theoretical one when $K_{aN\text{-Cl}} >> [L_3O^+]$, where the empirical parameter b equals $(k/K_{aN\text{-Cl}})$, the different obtained values being collected in Table 1. In a rough estimation for **3**, fitting the full equation to our kinetic data, gives $pK_{aN\text{-Cl}} = -1.42 \pm 0.70$ (see Scheme 6), which is within the order of magnitude of other values previously obtained for this type of compounds. In general, the pK_a of *N*-Cl compounds is ca. 9 units lower than that of the parent amine (22). Since $pK_a(1) = 8.27$, a value lower than zero is expected for $pK_{aN\text{-Cl}}$.

Fig. 5. Influence of the acidity in the decomposition of *N*-Cl-Ala-Gly. $[N\text{-Cl-Ala-Gly}]_0 = 5.0 \times 10^{-4}$ mol dm^{-3}; I = 1.0 mol dm^{-3}; T = 298.0 K.



Obviously, a better value of the $pK_{aN\text{-Cl}}$ could be obtained working at higher acidities, but the decomposition of the so-formed (*N*,*N*)-di-Cl-dipeptide, which is also acid catalyzed, interferes. On the other hand, the decomposition process is very fast in D_2O. As a consequence, it is very difficult to get reliable values of the rate equation parameters, and the corresponding value given in Table 1 should be taken with caution. Since this processes are not of special interest from a biochemical or environmental point of view, we do not try any discussion on the magnitude of the deuterium SIE for them.

Further work is under progress with more stable (*N*,*N*)-di-Cl-dipeptides. The interest of such experiments relies on the possibility of estimating secondary deuterium isotope effects when the species isotopically substituted is attached to a nitrogen (see Scheme 6), since commonly secondary deuterium isotope effect are measured for reactions involving carbon centers (23).

Conclusions

The deuterium solvent isotope effect has proved to be a very useful tool in the investigation of the mechanisms involved in the oxidation of dipeptides by aqueous chlorine solutions. Fractionation factors have successfully explained the observed deuterium solvent isotope effects on the different mechanisms involved in such oxidation.

Experimental section

Materials, reagents

Deuterium oxide (99.9%), Ala-Gly, and Pro-Gly were purchased from Sigma®, and used without further purification. Aqueous chlorine solutions were prepared weekly by bubbling Cl_2 (g) through NaOH (aq) and spectrophotometrically titrated daily ($\lambda_{max}(H_2O) \simeq 292$ nm, $\varepsilon \simeq 350$ mol^{-1} dm^3 s^{-1} when pH >12) (22). Aqueous bromine solutions were prepared daily by dissolving Br_2 (l) in NaOH (aq) and spectrophotometrically titrated ($\lambda_{max}(H_2O) \simeq 331$ nm, $\varepsilon \simeq 326$ mol^{-1} dm^3 s^{-1} when pH > 12) (23). (*N*-X)-compounds were

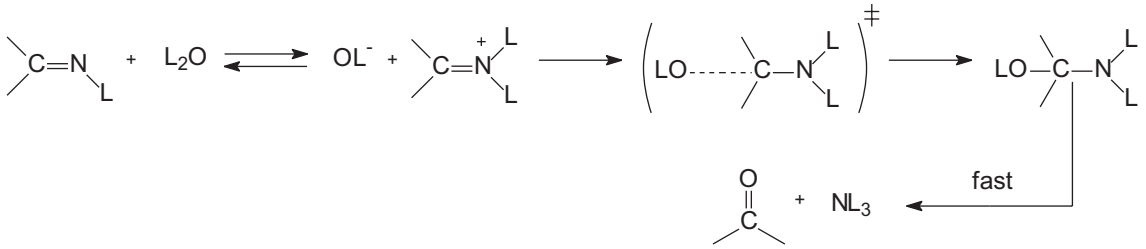
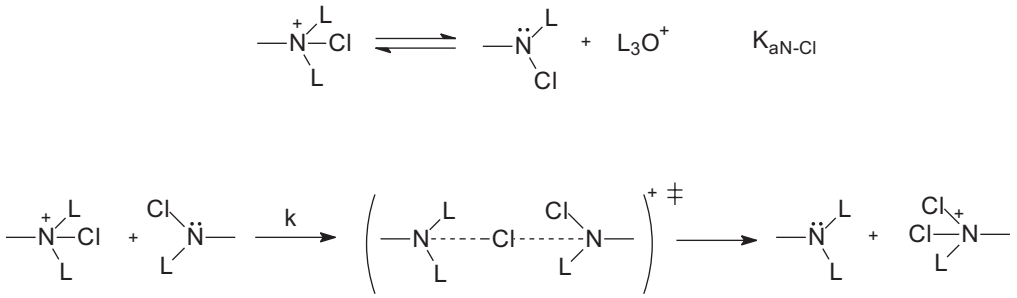


Scheme 6.



generated in the reaction cell by mixing appropriate amounts of aqueous halogen and dipeptide solutions so the ratio of the final concentrations were one. $(CF_3)_2CHOH/(CF_3)_2CHO^-$ was used as a buffer solution, HCl (aq), and NaOH (aq) were, respectively, used to get acid and alkaline media. $NaClO_4$ was used in general to control the ionic strength (I = 1 mol dm^{-3}), but KCl was used when buffering with $CF_3CH_2OH/CF_3CH_2O^-$. All other chemicals used were of the best quality commercially available.

Equipment

Conventional UV-vis (Beckman®, Cary®) and single- and multi-mixing Hi-Tech Scientific® stopped-flow spectrophotometers were used to monitor the reactions. An Ingold® Cl^- selective electrode and an Ingold® NH_3 (g) selective electrode were also used.

pH measurement and control

pH and pD measurements were carried out with combined glass electrodes. When buffer solutions of $CF_3CH_2OH/CF_3CH_2O^-$ were employed, the pH-meter was calibrated by using standardized KOH solutions, KCl being used as internal electrolyte for the reference electrode. Due to the slow response of the electrode in KOH solutions (24), ca. 5 min were allowed to elapse before any measurement.

Kinetics

Reactions were carried out at 298.0 ± 0.1 K. Reaction mixtures were prepared as described elsewhere (25). For the study on the chlorination of dipeptides to (*N*-Cl)-dipeptides, equimolar concentrations of both reagents or, at most, 1–2% excess of dipeptide were used. Unless in the study of the generation of (*N*-Cl)-dipeptides, chlorination was always carried out at a pH ca. 9, while bromination was carried out at pH ca. 11. Following this procedure, the halogenation was always finished in less than a tenth of a second (12). The solution used to achieve the acidity or basicity conditions was added only after halogenation had taken place. There was no evidence of simultaneous or partial chlorination on the nitrogen of the peptidic bond (26).

The reactions were followed at the wavelengths shown in Table 1. Kinetic data treatment was done by means of the DSC (27) or Marquardt (28) algorithms for nonlinear optimization. All reported rate constants are an average of, at least, five different runs, and their accuracy is better than 5%.

Products

The final products of the reported elimination reaction are always *N*-(2-imino-1-oxo-alkyl)-amino acids, halide, and ammonia, proofs of which have been given elsewhere (20, 29). The product of elimination reaction for *N*-Cl-Pro-Gly is *N*-[1-oxo-2-(4,5-dihydro-3H-pyrrole)]-glycine was identified using a Fisons Instruments VG quattro mass spectrometer (m/e = 171.1) (2.09%). One hundred percent chlorine loss in the reported process has been proved using a chloride selective electrode, and ammonia formation was followed using an ammonia selective electrode.

Acknowledgments

J.A. Santaballa wish to thank to Dr. R.A. McClelland for the opportunity to participate in this homage to Prof. Dr. A.J. Kresge. The research described in this paper was financed by the Xunta de Galicia (project XUGA 10307B95) and the Universidade da Coruña.

Strong Zn^{2+} and Co^{2+} catalysis of the methanolysis of acetyl imidazole and acetyl pyrazole

Ayla Khan, Alexei A. Neverov, Anatoly K. Yatsimirsky, and R.S. Brown

Abstract: The kinetics of methanolysis of acetyl imidazole (**1**) and acetyl pyrazole (**2**) have been investigated under anhydrous conditions in the presence of $Zn(ClO_4)_2$, $Co(ClO_4)_2$, and $HClO_4$ at 25°C. In all cases, the plots of the pseudo-first-order rate constant for methanolysis (k_{obs}) vs. [metal ion] or [$HClO_4$] show saturation behavior indicative of equilibrium binding of the M^{2+} or H^+ to the amide. Relative to the spontaneous methanolysis rate constant (k_o), the catalytic rate constant obtained at saturation, k_{cat}, is larger for metal-ion catalysis than for H^+ catalysis. The (k_{cat}^{H+}/k_o) ratio is 10.7 and 1.25 for **1** and **2**, respectively, while the (k_{cat}^{M2+}/k_o) for these divalent metals varies from 150-fold for **1** to between 700 and 5700-fold for **2**. By contrast, in water, proton is far more effective at promoting the hydrolysis of **1** than are metals, the aqueous (k_{cat}^{H+}/k_o) ratio being 560, while the (k_{cat}^{Zn2+}/k_o) and (k_{cat}^{Ni2+}/k_o) ratios are 15 and 3.2, respectively.

Key words: methanolysis, kinetics, metal-ion catalysis, acetyl imidazole, acetyl pyrazole.

Résumé : Opérant dans des conditions anhydres, à 25°C, en présence de $Zn(ClO_4)_2$, $Co(ClO_4)_2$ et de $HClO_4$, on a étudié la cinétique de la méthanolyse de l'acétyl imidazole (**1**) et de l'acétyl pyrazole (**2**). Les courbes de la constante de vitesse de pseudo-ordre un de la méthanolyse (k_{obs}) en fonction de [ion métallique] ou de [$HClO_4$] présentent toutes un comportement de saturation qui suggère l'implication d'une fixation en équilibre de M^{2+} ou H^+ par l'amide. Si on la compare à la constante de vitesse de méthanolyse spontanée (k_o), la constante de vitesse catalytique obtenue à saturation (k_{cat}) est supérieure pour la catalyse par les ions métalliques que pour la catalyse par les ions H^+. Le rapport k_{cat}^{H+}/k_o est égal à 10,7 et 1,25 pour les composés **1** et **2** respectivement alors que le rapport k_{cat}^{M2+}/k_o pour ces métaux bivalents varie de 150 pour **1** à 700–5700 pour **2**. En comparaison, dans l'eau, les protons sont beaucoup plus efficaces que les métaux pour favoriser l'hydrolyse de **1**; le rapport k_{cat}^{H+}/k_o est égal à 560 alors que les rapports k_{cat}^{Zn2+}/k_o et k_{cat}^{Ni2+}/k_o sont de 15 et 3,2.

Mots clés : méthanolyse, cinétiques, catalyse par les ions métalliques, acétyl imidazole, acétyl pyrazole.

[Traduit par la Rédaction]

The catalytic effect of metal ions on the hydrolyses of simple amides is usually small for the HO^- reactions (1) and generally nonexistent for the H_2O reactions. There are notable exceptions, but these involve situations where M^{2+}-ions are intramolecularly chelated to enforce proximity to the scissile C=O unit (2–5), or with ligand exchange inert Co(III) complexes (6). Some systems using M^{2+} are intermolecularly catalytic for amides not having proximal binding sites, the most important of these being Cu^{2+} complexes that probably exhibit bimodal catalysis with the Cu^{2+} acting transiently as both a Lewis acid activator of the C=O and the source of a nucleophilic Cu^{2+}-OH^- (7). Notably, M^{2+}-catalysis of the hydrolysis of simple N-acyl imidazoles devoid of a suitably positioned chelating site is, to our knowledge, relatively weak (8), and metal ions are not as good as H^+ is in promoting the hydrolysis of these, and normal, amides. As pointed out by Sigel and Martin (9), solvent H_2O provides a potent oxygen donor for binding the metal ion in competition with the weakly basic amide oxygen (or even more weakly basic N of normal amides), so the equilibrium position for binding lies well to the side of the solvated metal. Based on previous work of Deiko et al. (10) on the methanolysis of acetyl imidazole, we reasoned that metal-ion solvation in methanol might be sufficiently weakened that the equilibrium position for binding to amides might lie further to the side of the M^{2+}-amide com-

[1] 
plex (11) with concomitant catalytic enhancement of the cleavage of the N—C(O) bond. Herein, we report preliminary results of a study of the Zn^{2+}- and Co^{2+}-catalyzed methanolysis of acetyl imidazole **1** (12) and acetyl pyrazole **2** (13), indicating that there is saturation metal-ion binding and great acceleration of the methanolysis.

The plots shown in Fig. 1 illustrate that the observed pseudo-first-order rate constants for methanolysis (k_{obs}) exhibit saturation behavior at increasing [$M^{2+}(ClO_4^-)_2$], indicative of the process given in eq. [1] where P indicates the products of amine and methyl acetate, and for which can be written the kinetic expression given in eq. [2]. Given in Table 1 are the various rate (k_o, k_{cat}) and kinetic metal-dissociation (K_M) constants determined from NLLSQ fits of

[2] $$k_{obs}=(k_oK_M + (k_{cat}[M^{2+}]))/(K_M + [M^{2+}])$$

the k_{obs} vs. [$M^{2+}(ClO_4^-)_2$] data to eq. [2].[2] Also included are the rate and H^+-dissociation constants for the acid-catalyzed methanolysis of **1** and **2**, these being obtained by fits of the k_{obs} vs. [$HClO_4$] data to eq. [2] where [M^{2+}] is replaced by [$HClO_4$].

There are several features of note in the data contained in the table. First, the k_{cat}, K_M, and K_{H+} constants for metal- and acid-catalyzed methanolysis allow comparison of the relative catalytic and binding abilities of the two divalent metal ions and H^+ for each amide. The rate enhancements afforded by these, given as k_{cat}/k_o where k_o is the rate constant for the spontaneous methanolysis, are larger for the metal ions than for proton. This is unusual considering that in water, proton is far more effective at promoting the hydrolysis of **1** than are metal ions, the aqueous (k_{cat}^{H+}/k_o) ratio being 560 (12*b*), while the (k_{cat}^{Zn2+}/k_o) and (k_{cat}^{Ni2+}/k_o) ratios are 15 and 3.2.[3] Even for the exchange inert Co^{3+} complex ($(NH_3)_5Co^{3+}ImC(O)CH_3$) where the Co^{3+} is fixed at the distal N, the reaction is accelerated by only 24-fold (8). By contrast, in methanol the (k_{cat}^{H+}/k_o) ratio is 10.7 and 1.25 for **1** and **2**, respectively, while the enhancement by metals varies from 150-fold for **1** to between 700 and 5700-fold for **2**.

Second, the metal-dissociation constants (K_M) vary only by a factor of 2 in MeOH, irrespective of the amide structure and nature of the metal, and the H^+-dissociation constants vary by ~10-fold. Acetyl pyrazole, **2**, is less basic (toward H^+) than **1** by 10-fold. However, the similarity of its K_M data to those of **1**, which certainly binds the metal ion through the distal sp^2-N, indicates that association of the metal with the proximal carbonyl oxygen of the former (14) contributes to the stability of the complex in methanol to some extent. In MeOD, the Zn^{2+}-K_M values for **1** and **2** decrease by about

[2] UV kinetics were monitored under anhydrous conditions by observing in duplicate or triplicate the rate of loss of **1** and **2** at 235 and 240 nm in methanol under pseudo-first-order conditions of excess 0 < [$M^{2+}(ClO_4)_2$] < 0.01 M, [amide] = 6.7 × 10^{-5} M, ionic strength not held constant. Pseudo-first-order rate constants (k_{obs}) were evaluated by fitting the abs. vs. time traces to a standard exponential model. Values of k_{cat} and K_M given in Table 1 are derived from NLLSQ fits of the k_{obs} vs. [M^{2+}] or [H^+] plots to eq. [2].

[3] A.A. Neverov (18), reports that for the reaction of acetyl imidazole in water containing $Zn^{2+}$and Ni^{2+}, the respective k_{cat} and K_M values in the neutral hydrolysis region are (1.25 ± 0.2) × 10^{-3} s^{-1}; 3.5 × 10^{-2} M ([Zn^{2+}] = 0.1 M, $ZnCl_2$) and (2.7 ± 0.3) × 10^{-4} s^{-1}; 7.3 × 10^{-3} M ([Ni^{2+}] = 0.2 M, $NiCl_2$). These can be compared with the k_o value for water attack on the protonated species at μ = 0.2, 4.7 × 10^{-2} s^{-1}, pK_a = 3.5 (*b*). The spontaneous rate constant for neutral hydrolysis of acetyl imidazole in water is reported to be 3 × 10^{-4} s^{-1}, μ = 0 (10), 8.3 × 10^{-5} s^{-1} at μ = 0.2 (*b*), or 4.6 × 10^{-5} s^{-1} at μ = 1.0 (8*b*). For the sake of consistency, we used the available Zn^{2+}, Ni^{2+}, and H^+ data at μ = 0.2 for our comparisons.

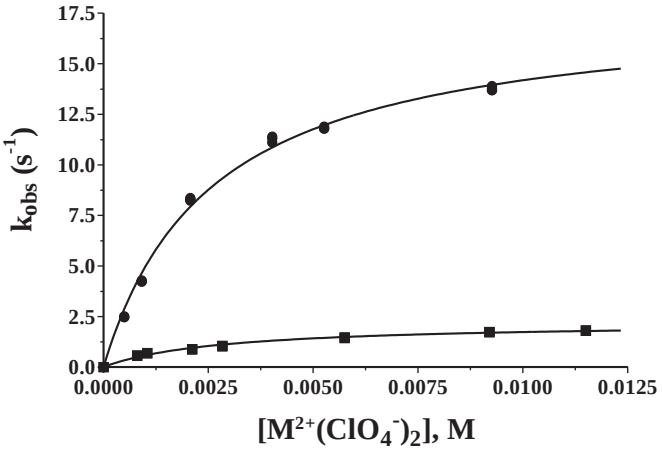
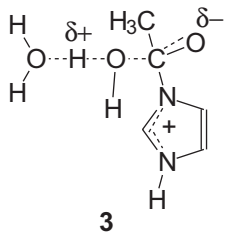
Fig. 1. Plot of pseudo-first-order rate constants for the methanolysis of acetyl pyrazole (**2**) as a function of $[M^{2+}(ClO_4^-)_2]$ at 25°C, (■) Zn^{2+}, (●) Co^{2+}. Lines are the nonlinear least-squares fits of the data to eq. [**2**].



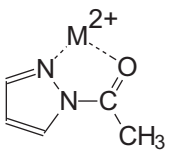
2–3-fold from their values in MeOH, perhaps suggestive of a decreased solvation of the metal ion in MeOD and (or) the possibility that the K_M value may be a more complex term involving multiple equilibria.

The solvent deuterium kinetic isotope effects for the spontaneous methanolysis (k_o) and the Zn^{2+}-reaction (k_{cat}) of **1** are 4.1 and 5.9, while those for **2** are 1.25 and 2.74, respectively. Proton inventories (15) of the Zn^{2+}-catalyzed reactions indicates that the plots of k_{cat}^{Zn2+} vs. *n*, where *n* is the atom fraction of deuterium in the solvent, are significantly bowed downwards. This is suggestive of a transition state for the metal-catalyzed reaction where there are two or more protons from multiple methanol molecules undergoing changes in bonding.

It is difficult to rationalize the unusual observation that Zn^{2+} and Co^{2+} are more effective than H^+ in catalyzing methanolysis of **1** and **2**, but the converse is true for hydrolysis. The effect is not small, since for **1**, the change in the ($k_{cat}^{H+}/k_{cat}^{Zn2+}$) ratio is roughly 500-fold. It seems reasonable that if the same acyl-transfer mechanisms and distribution of metal–H^+-bound species are operative in each solvent, then the relative greater effectiveness of the proton would be maintained. In the case of acetyl imidazole, the catalysis by proton must occur through its binding to the distal N and accelerating the rate-limiting attack of water or methanol on the remote C=O as in **3** (16). Fife and co-workers' studies (3) showed that strong acceleration of the hydrolyses of various acyl imidazoles by divalent metal ions is expected only when the metal ion can be coordinated to the C=O. In such cases, the metal ion can act as a strong electrophilic catalyst to enhance nucleophilic attack of solvent or SO^- on the polarized C=O, or to deliver a metal bound SO^-. For acyl imidazoles where there is no additional chelating group present to hold the metal ion in proximity to the C=O, modest or no catalysis of hydrolysis is observed. Chelation of the metal to the pyrazole N and C=O as in **4** can occur with acetyl pyrazole in methanol, accounting for the enhancement of methanolysis. However, metal association with the C=O cannot occur in complexes of **1** unless there is a translocation of the metal ion from the favored binding site of the distal N to the carbonyl oxygen. Subsequent to such a translocation, methanolysis would be strongly catalyzed. One might speculate that the medium effect produced by methanol alters the equilibrium between N and C=O bound metal ion to a more favourable distribution than in water with concomitant acceleration of methanolysis.



3



4

More work is necessary to clarify the factors responsible for the metal-ion catalysis and the effect of the medium. What we have shown here is that methanolysis of acetyl pyrazole is strongly accelerated by the presence of Zn^{2+} and Co^{2+} as is the methanolysis of acetyl imidazole, contrasting the poor metal-ion catalysis of its hydrolysis. It is often considered that the microenvironment existing in the active sites of enzymes more closely resemble alcohols or other reduced polarity media so the methanolysis results reported here may be relevant to the mechanism of acyl transfer mediated by metallo-proteases such as carboxypeptidase (17). The intriguing possibility that the medium alters the equilibrium distribution between solvated, N, and C=O bound metal ions begs the question of whether methanolysis of more normal amides is subject to metal-ion catalysis, a question we are actively investigating.

Reactivity in acid-catalyzed carbon–carbon heterolysis

Weiguo Cao, Ihsan Erden, Richard H. Grow, James R. Keeffe, Jiangao Song, Mary B. Trudell, Teri L. Wadsworth, Fu-Pei Xu, and Ji-Bin Zheng

Abstract: Equilibrium and rate constants have been determined for the acid-catalyzed heterolysis of two alcohols, 9-xanthydrol and *p*-anisyldiphenylmethanol, and two sulfides, (9-xanthyl) methyl sulfide and (7-tropyl) methyl sulfide. These data together with literature information are compared with rate constants for acid-catalyzed C-C heterolysis of several (9-xanthyl) compounds, (7-tropyl) compounds, a set of 3-arylcyclobutanones, and two 2-arylnitrocyclopropanes, all of which fragment to carbocations plus a carbon-centered nucleofuge. The fragmentation mechanisms are shown to be A1 or A1(ion pair) except for the 2-arylnitrocyclopropanes which cleave in trifluoroacetic acid by a concerted mechanism. Rate comparisons among several unstrained substrate sets indicate that *O*-centered nucleofuges undergo acid-catalyzed heterolysis ca. 10^3–10^4 faster than *S*-centered nucleofuges and ca. 10^9–10^{14} faster than the *C*-centered nucleofuges used here. Factors assisting C-C heterolysis (and their effectiveness) include the acidity of the medium (strong); the basicity and nucleofugality of the nucleofuge (moderate); the stability of the electrofugic carbocation (strong); and relief of ring strain (enormous). Compared with acyclic cleavages, rate accelerations worth ca. 15 kcal/mol (for cyclobutanones) and ca. 27 kcal/mol (for nitrocyclopropanes) are found. These effects are discussed in terms of transition-state structure, aided by computational evidence.

Key words: C-C heterolysis, fragmentation, acid catalysis, carbocation, ring strain.

Résumé : On a déterminé les constantes d'équilibre et les constantes de vitesse des réactions d'hétérolyse acidocatalysée de deux alcools, le 9-xynthydrol et le *p*-anisyldiphénylméthanol, et de deux sulfures, le sulfure de 9-xanthyle et de méthyle et le sulfure de 7-tropyle et de méthyle. Ces données et d'autres tirées de la littérature ont été comparées aux constantes de vitesse d'hétérolyse C-C acidocatalysée de plusieurs dérivés du 9-xanthyle, du 7-tropyle, d'un ensemble de 3-arylcylobutanones et de deux 2-arylnitrocyclopropanes qui se fragmentent tous pour donner des carbocations en plus d'un nucléofuge centré sur le carbone. On a montré que tous les mécanismes de fragmentation sont A1 ou A1(paire d'ions), à l'exception des 2-arylnitrocyclopropanes qui se clivent dans l'acide trifluoroacétique par un mécanisme concerté. Une comparaison des vitesses de plusieurs ensembles de substrats non tendus indiquent que les nucléofuges centrés sur l'oxygène subissent des hétérolyses acidocatalysées environ 10^3–10^4 fois plus rapides que celles impliquant des nucléfuges centrés sur le soufre et environ 10^9–10^{14} fois plus rapides que celles impliquant les nucléfuges centrés sur le carbone utilisés ici. Les facteurs qui favorisent l'hétérolyse C-C (et leur efficacité) incluent l'acidité du milieu (forte); la basicité et la nucléofugacité du nucléofuge (modérée); la stabilité du carbocation électrofuge (forte) et l'élimination de la contrainte de cycle (énorme). Comparés avec les clivages acycliques, les accélérations de vitesses correspondent à environ 15 kcal/mol (pour les cyclobutanones) et environ 27 kcal/mol pour les nitrocyclopropanes. On discute de ces effets en fonction de la structure de l'état de transition en s'appuyant sur des résultats de calculs théoriques.

Mots clés : hétérolyse C-C, fragmentation, catalyse acide, carbocation, tension de cycle.

[Traduit par la Rédaction]

Introduction

A large number of synthetically important reactions occur with the formation of one or more carbon–carbon bonds by polar mechanisms. Some of the more obvious of these are the aldol condensation and its large family, Michael additions, Friedel–Crafts chemistry, and acid-catalyzed polymerizations. A number of cationic cyclizations (1, 2) and cycloadditions (3, 4) also fall into this category, as does the biosynthesis of squalene (5), and the subsequent cyclization of squalene oxide to lanosterol (6). Heterolytic C-C cleavage is also well known; retroversions of some of the reactions

cited above sometimes occur. Such reactions offer, in principle, opportunities to study mechanism and structure–reactivity patterns by microscopic reversibility. Polycyclic cage compounds comprise a substantial group able to undergo rearrangement and cleavage by C-C heterolysis (7, 8). Relief of strain and enforced geometries render these transformations synthetically and mechanistically interesting.

One category of heterolytic C-C cleavages is known as β-fragmentations. Early examples include the important work of Whitmore (9) on acid-catalyzed reactions of some highly branched aliphatic systems in which substitution, elimination, rearrangement, and fragmentation competed under thermodynamic control. Shiner and Meier (10) extended this work providing rate constants and partitioning ratios for competing pathways under kinetic control. (These authors also review much of the earlier work on branched aliphatic compounds.) Meanwhile, Grob (11) had generalized cationic β-fragmentations as shown in eqs. [1] and [2]. In these systems, a-C_γ^+ is an electrofuge which, depending on its stability and reaction conditions, might depart assisted only by donor a, or might be helped to leave by a base or nucleophile. Atom or group X is a nucleofuge, i.e., an adequate electron acceptor, perhaps aided by acid. In addition to these specifications, Grob proposed that for fragmentation to be concerted, a stereochemical requirement must be met, namely that the *sigma* bond skeleton linking C_γ with X should be *anti* and coplanar, as shown in eq. [1], for optimal reactivity. This analysis is analogous to one given earlier by Nesmeyanov (12). These requirements are identical to those preferred for the E2 elimination reaction where H^+ takes the role of a-C_γ^+. Also in this category are a number of synthetically useful β-elimination reactions of silanes and stannanes in which the place of the γ-carbon is taken by Si (13) or Sn (14). Of course, whenever the fragmentation mechanism is stepwise, the stereochemical restrictions can be relaxed.

[1] 
[2] 
Grob also proposed that, in general, fragmentation of simple a-C–X systems would be faster than otherwise analogous a-C-C-C-X compounds. This prediction has been confirmed by Conrow (15) and by Shiner and Meier (10). Conrow, studying reactions [3] and [4] (among others), was able to obtain evidence that direct nucleophilic substitution at C_α is faster than fragmentation (eq. [3]), and that protonation at oxygen plus nucleophilic addition are also faster than fragmentation (eq. [4]), even with so stable an electrofuge as tropylium (Tr^+).

[3] 
[4] 
Conrow's results indicate that direct observation of a carbon-centered, cationic electrofuge should be a general result for suitable fragmentation reactions. Indeed, Fosse (16), in 1906, reported acid-promoted fragmentation of certain 9-xanthyl compounds. Deno and Sacher (17) extended these studies observing reactions [5] and [6]. Attempted cleavages of the corresponding triphenylmethyl compounds were completely unsuccessful, even in 96% H_2SO_4 at 100°C. This result indicates the powerful influence of the stability of the electrofuge in this particular case; triphenylmethyl$^+$ (pK_{R+} = –6.6) (18) is almost 10^6 less stable than xanthyl$^+$, both relative to their respective alcohols.

[5] 
[6] 
More recently, Arnett et al. (19) have determined the enthalpies of fragmentation, ΔH_{het}, for heterolytic C-C cleavage to form highly resonance stabilized carbocations and carbanions. These extensive data have allowed formulation of highly precise "master equations," which should be useful predictors of heterolysis enthalpies provided the ions formed are stabilized by resonance. Others have provided examples of measurable equilibria between covalent precursors and unusually stable, all hydrocarbon cations and anions (20). Arnett has noted that "there is increasing interest in developing low temperature processes for the cleavage of carbon–carbon bonds … especially as applied to the fossil fuel industries, where pyrolytic processes waste thermal energy and lead to tars. Heterolysis by treatment with strong acids and bases to yield ionic products are a promising alternative" (19*a*). Partly for this reason and partly because of its intrinsic interest, we set out to quantify the more general circumstances that make C-C heterolysis kinetically viable. Among these circumstances are the structures of the fragments formed in reactions [1] and [2], the efficacy of acid or base catalysis, and the influence of strain in the reactant. Also, we wished to probe for details of reaction mechanisms in the

© 1999 NRC Canada

catalyzed reactions (21, 22). Additionally, we present a useful synthetic sequence, involving regiospecific C-C cleavage in the final step, in which alkenes are acylated leading to dichloro-α,β-unsaturated ketones in two steps or to the dechlorinated analogues in three steps.

Experimental section

Materials

The following compounds were synthesized according to the literature procedures cited. NMR data are given in each case.

9-Xanthydrol (XanOH), ***1*** *(23)*: ^{1}H NMR (60 MH_3, CCl_4), δ: 7.6 (8H, m), 5.7 (1H, d, *J* = 8 Hz), 2.2 (1H, d, *J* = 8 Hz).

*9-Xanthydrol-9-*d *(XanOH-9-*d): Synthesized in the same way as **1**, but using CH_3CH_2OD in place of CH_3CH_2OH: ^{1}H NMR (60 MHz, $CDCl_3$), δ: 7.2 (8H, m), 5.2 (very low intensity), 2.2 (1H, s).

(7-Tropyl)acetone (TrAc), ***4*** *(24)*: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 6.60 (2H, t), 6.14 (2H, dt), 5.11 (2H, dd), 2.75 (2H, d), 2.20 1H, m), 2.10 (3H, s).

(9-Xanthyl)acetone (XanAc), ***6*** *(25)*: ^{1}H NMR (60 MHz, $CDCl_3$), δ: 7.13 (8H, m), 4.62 (1H, t), 2.80 (2H, d), 1.96 (3H, s).

*(9-Xanthyl)acetone-9-*d *(XanAc-9-*d): Synthesized in the same way as **6**, but using XanOH-9-*d* in place of XanOH: ^{1}H NMR (60 MHz, CDCl3), δ: 7.15 (8H, m), 2.80 (2H, s), 1.97 (3H, s).

α*-(9-Xanthyl)acetophenone (XanAp),* ***7*** *(25)*: ^{1}H NMR (60 Mhz, $CDCl_3$), δ: 7.20 (13H, m), 4.85 (1H, t), 3.35 (2H, d).

α*-(9-Xanthyl)-4-nitroacetophenone (Xan-4-*NO_2*Ap),* ***8*** *(25)*: mp 139–140°C; ^{1}H NMR (300 MHz $CDCl_3$), δ: 8.15 (2H, d), 7.85 (2H, d), 7.21 (8H, m), 4.83 (1H, t), 3.39 (2H, d); ^{13}C NMR (75 MHz, $CDCl_3$), δ: 202.1, 129.2, 128.7, 128.2, 122.5, 116.5, 44.9, 35.1.

2-Methyl-1-(9-xanthyl)-2-propanol (Xantba), ***9*** *(17)*: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 7.20 (8H, m), 4.22 (1H, t), 1.89 (2H, d), 1.65 (1H, s), 1.20 (6H, s).

*2-Methyl-1-(9-xanthyl)-2-propanol-9-*d (*Xantba-9-*d): Prepared in the same way as **9**, but using XanAc-9-*d* in place of XanAc: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 7.22 (8H, m), 1.85 (2H, s), 1.55 1H, s), 1.15 (6H, s).

(7-Tropyl)nitromethane (TrCH_2NO_2*),* ***11a*** *(24)*: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 6.68 (2H, t, *J* = 3.0 Hz), 6.31 (2H, dt, *J* = 9.6 Hz, 3.0 Hz), 5.31s (2H, dd, *J* = 9.0 Hz, 6.6 Hz), 4.46 (2H, d, *J* = 7.5 Hz), 2.98 (1H, q, 7.2 Hz).

1-(7-Tropyl)nitroethane (Tr$CH(NO_2)CH_3$*),* ***11b*** *(24)*: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 6.68 (2H, m), 6.31 (2H, m), 5.30 (2H, m), 4.67 (1H, dq, *J* = 9.6 Hz, 6.6 Hz), 2.58 (1H, dt, *J* = 9.6 Hz, 6.9 Hz), 1.58 (3H, d, *J* = 6.6 Hz).

2-(7-Tropyl)-2-nitropropane (Tr$C(CH_3)_2NO_2$*),* ***11c*** *(24)*: mp 43–44°C; ^{1}H NMR (300 MHz, $CDCl_3$), δ: 6.72 (2H, t, *J* = 3.0 Hz), 6.27 (2H, m), 5.26 (2H, dd, *J* = 9.0 Hz, 5.7 Hz), 2.05 (1H, t, *J* = 6.0 Hz), 1.73 (6H, s).

*2,2-Dichloro-3-arylcyclobutanones,****14a–g****, and 3-arylcyclobutanones,* ***15a–g***: A procedure for synthesis of cyclobutanones has been developed by Erden (27) following results reported by Krepski and Hassner (28) and Bak and Brady (29). The method requires two steps: the regio- and stereospecific cycloaddition of dichloroketene to alkenes, then dechlorination of the resultant 2,2-dichlorocyclobutanones with activated zinc. A general procedure is described here followed by ^{1}H NMR data for **14** and **15**.

Cycloaddition

A dried, nitrogen-filled, three-necked flask equipped with a reflux condenser, constant-pressure addition funnel, and nitrogen inlet is charged with 50 mmol of alkene, 75 mmol of activated zinc powder, and 100 mL of anhydrous ether, then placed in a sonication water bath. To the agitated suspension is added a solution containing 50 mmol of $POCl_3$ (distilled from anhydrous K_2CO_3), 75 mmol of trichloroacetyl chloride, and 25 mL of anhydrous ether over a 0.5 h period. The reaction mixture is maintained at 15–20°C (or refluxed) for 1–22 h. After being quenched with wet ether, the reaction mixture is filtered through Celite, and the filtrate is washed with water, sat. $NaHCO_3$, and sat. NaCl, then dried over anhydrous $MgSO_4$. Removal of ether gives a crude product that is purified by vacuum distillation (Kugelrohr) or by column chromatography or by TLC (silica gel, pet. ether/ethyl acetate, 80/20).

Dechlorination

In a flask equipped with a reflux condenser are placed a saturated methanolic NH_4Cl solution, the dichloroketene cycloadduct from the previous procedure, and an excess of activated zinc powder. The suspension is refluxed for 4–19 h, then cooled and filtered through Celite. The methanol is removed under reduced pressure, and the residue dissolved in ether. The ethereal solution is washed with water, then saturated NaCl, and dried over anhydrous $MgSO_4$. Removal of the ether gives a crude product which is purified by Kugelrohr distillation or by column and (or) thin layer chromatography (silica gel, pet. ether/ethylacetate, 80/20).

2,2-Dichloro-3-methyl-3-phenylcyclobutanone, ***14a***: ^{1}H NMR (300 MH_3, $CDCl_3$), δ: 7.46–7.26 (5H, m), 4.00 (1H, d, *J* = 17.5 Hz), 3.08 (1H, d, *J* = 17.5 Hz), 1.66 (3H, s).

*4-Hydroxy-4-(*p*-tolyl)-2-pentanone, **19** (32)*: ^{1}H NMR (300 MHz, $CDCl_3$), δ: 7.21–7.01 (4H, m), 4.38 (1H, s), 3.06 (1H, d, *J* = 18 Mz), 2.71 (1H, d, *J* = 18 Hz), 2.21 (3H, s), 1.96 (3H, s), 1.39 (3H, s).

*(9-Xanthyl)methylsufide, (XanSMe), **2***: To a prechilled roundbottom flask were added 15 mmol of 9-xanthydrol and 10 mL (0.36 mol) of methanethiol, both prechilled. The flask was kept in an ice-water bath, topped with a Dry Ice condenser, and connected to a trap containing 6 M NaOH to capture evaporated CH_3SH. To the stirred solution was added one drop of conc. H_2SO_4. After the vigorous reaction subsided, another drop of acid was added and stirring continued for 3 h. Then a final drop of acid was added. After two more hours of stirring, the ice-water bath was removed, and the excess CH_3SH allowed to evaporate into the trap. The white residue was neutralized with 6 M NaOH, then taken up in ethanol. After removal of ethanol the product was recrystallized from ethanol or hexane: yield 57%; mp 64.5–66.5°C; ^{1}H NMR (60 MHz, $CDCl_3$), δ: 7.2 (8H, m), 5.1 (1H, s), 1.7 (3H, s); ^{13}C NMR (25 MHz, $CDCl_3$); δ 129.7, 128.4, 123.5, 116.4, 42.5, 11.0. Elemental analysis (%), calcd. for $C_{14}H_{12}OS$: C 73.65, H 5.30, S 14.04; found: C,73.70, H 5.42, S 13.95.

*(7-Tropyl)methylsulfide, (TrSMe), **3** (33)*: ^{1}H NMR (60 MHz, $CDCl_3$), δ: 7.0–5.1 (6H, complex), 3.2 (1H, t), 2.0 (3H, s). The compound was not very stable and was stored under N_2 at 6°C. It was distilled before use: 74°C, 4.5 Torr. After distillation, the tropylium$^+$ content was determined by adding a weighed amount to 25 mL of 2 M H_2SO_4 and determining the apparent molar absorptivity at λ_{max} = 274 nm. This value was compared with a literature value, $\varepsilon_{273.5}$ = 4350 cm^{-1} M^{-1} (34), to establish purity.

*2-Methyl-3-(9-xanthyl)propene, (xanthylisobutylene, XanIb), **10***: Six grams of triphenylmethylphosphonium bromide (Aldrich) was slowly added to a mixture of 3 g of potassium *tert*-butoxide and 75 mL of dry benzene, refluxed under argon,, over a 1.5 h period. To this solution was added a solution of 2.45 g of (9-xanthyl)acetone (**6**). The resulting solution was refluxed for 5.5 h, then cooled and quenched with ice water. The benzene layer was washed with NH_4Cl–H_2O, then H_2O. Distillation of the benzene left a residue which was recrystallized from ethanol: yield 31%; mp 80–81°C; ^{1}H NMR (300 MHz, $CDCl_3$), δ: 7.23 (8H, m), 4.80 (1H, s), 4.40 (1H, s), 4.15 (1H, t), 2.45 (2H, d), 1.68 (3H, s); ^{13}C NMR (75 Mz, $CDCl_3$), δ: 152.5, 142.0, 128.8, 127.5, 125.4, 122.9, 116.3, 114.3, 49.6, 38.3, 22.8.

3,3-Diphenylcyclopentanone: Prepared by treatment of 3,3-diphenylcyclobutanone with diazomethane following Greene and Deprés (35): ^{1}H NMR (300 MHz, $CDCl_3$), δ 7.26 (10H, m), 3.00 (2H, s), 2.69 (2H, t, *J* = 7.5 Hz), 2.29 (2H, t, *J* = 7.5 Hz).

Reaction media for C-C heterolysis reactions

Concentrated sulfuric and perchloric acids were the best available commercial products. They were diluted with doubly distilled water and standardized by titration. Sulfuric acid-d_2 (99.5 atom% D) and perchloric acid-d_2 (99 + atom% D) were purchased as concentrated solutions from Aldrich. They were diluted with D_2O (Aldrich, 99.8 atom% D) and standardized by titration.

Trifluoroacetic acid (TFA) and trifluoroacetic anhydride (TFAA) were purchased from Aldrich. TFA was distilled before use. For determination of solvent kinetic hydrogen isotope effects, TFA and TFA-*d* were prepared in two ways. For kinetics by ^{1}H NMR, equal weights of TFAA were added to 0.98 equiv of H_2O or D_2O. NMR analysis showed the media to contain < 2% protium. Substrate concentration was 0.45 M in both isotopic media. For kinetics by UV spectroscopy equal weights of TFAA were added to 0.98 equiv. of H_2O or D_2O (as above), or to 1.02 equiv. of H_2O or D_2O in order to avoid large absorbance readings caused by TFAA. Stock solutions of substrate were made in CH_3OH or CH_3OD to be ca. 1.4–1.8 × 10^{-2} M. Reaction was initiated by addition of one drop of substrate solution to 3.0 mL of reaction medium for the UV experiments resulting in initial substrate concentrations of ca. 2.5–3.0 × 10^{-4} M. Kinetic runs were made in a pairwise fashion: TFA followed immediately by TFA-*d*, then vice versa.

Equilibrium methods

In aqueous acid media 9-xanthydrol (**1**), (9-xanthyl) methylsulfide (**2**), (7-tropyl)methylsulfide (**3**), and 4-methoxyphenyldiphenylmethanol (**5**) all undergo heterolysis to an extent governed by the acidity of the medium. The equilibrium ratios of carbocation product to starting material were determined by UV-vis spectroscopy according to eq. [7] where R^+ represents a carbocation, xanthyl$^+$ (Xan^+), or tropyl$^+$ (Tr^+), R-X is the substrate precursor, and ε_{ST} is the molar absorptivity of the equilibrium mixture in a given acidic medium.

$$[7] \qquad [R^+]/[RX] = (\varepsilon_{ST} - \varepsilon_{RX})/(\varepsilon_{R^+} - \varepsilon_{ST})$$

Absorbance measurements were made at absorbance maxima for the carbocations: 374 nm (ε = 3.97 × 10^4 cm^{-1} M^{-1}) for Xan^+ (this work), and 274 nm (ε = 4350 cm^{-1} M^{-1}) for Tr^+ (34). For compound **3**, TrSMe, it was necessary to account for substrate absorbance at 274 nm: ε = 2300 cm^{-1} M^{-1} (this work). For the two sulfides, **2** and **3**, the acid solutions used were concentrated enough that the corresponding alcohols, XanOH and TrOH, had negligible concentration. For compounds **1** and **2**, 10–15 acid concentrations were used, for **3** and **4**, 5 concentrations.

For XanSMe, measurements were made using sulfuric acid solutions, perchloric acid solutions, and more dilute perchloric acid solutions at constant ionic strength, μ = 5.00 M ($NaClO_4$). For compound **5**, measurements were made both in $HClO_4$ and H_2SO_4 solutions.

Kinetic methods

Acid-promoted heterolysis of compound **1** in $HClO_4$–H_2O solution, [H^+] = 0.12–2.66 M, was monitored by the temperature jump method. The same method was used to follow heterolysis of **2** in aq. $HClO_4$ ([H^+] = 2.18–3.29 M) and H_2SO_4 ([H_2SO_4] = 3.61–6.35 M). Likewise, the heterolysis rates of **5** were determined in $HClO_4$ ([H^+] = 2.36–4.17 M) and H_2SO_4 ([H_2SO_4] = 3.97–4.70 M) solutions. Good first-order relaxation curves were obtained and

© 1999 NRC Canada

analyzed using the "small perturbation" approximation according to Bernasconi (36). The experimental first-order rate constants found in this way are, when both reactant and products have significant equilibrium concentrations, sums of pseudo first-order forward rate constants, k_f (s^{-1}) and reverse rate constants, $k_r[R^+]$ (s^{-1}) for the alcohols and $k_r([R^+]+[CH_3SH])$ (s^{-1}) for the sulfides, where k_r is a second-order constant. Equilibrium concentration ratios, $[R^+]/[RX]$, were obtained over the same range of acidity, usually at identical acid concentrations. Since these data can be written as a function of k_f/k_r, all the information needed to evaluate k_f and k_r was available.

Compound **2** was also studied by the stopped-flow method using $HClO_4$ solutions ranging from 0.73–2.00 M. Ionic strength was held constant at 5.0 M ($NaClO_4$) in both drive syringes in order to overcome optical artifacts caused by mixing solutions of different ionic strength. Compound **3** was also examined by the stopped-flow method using H_2SO_4 solutions ($[H_2SO_4]$ = 0.0133–0.0860 M). It can be shown that when the concentration of the observed species are small, hence the change in its concentration is small, that acceptably first-order behavior is obtained even though the reverse reaction is bimolecular (36). Hence, the small perturbation analysis was used in these two instances as well. For the concentration changes observed over the number of halflives used to gather data, it can be shown that the average error in k_{exp} incurred by treating the data in the first-order fashion as no greater than 10% (36).

The cleavages of the 3-arylcyclobutanones (**14a**, **15a**, **c**, **d**, **f**, **g**) were studied in CF_3CO_2H (TFA) solvent, taking advantage of the strong UV absorbance maxima (310–325 nm) shown by the cleavage products, β-aryl-α,β-unsaturated ketones. Rate constants for **15b** and **15e** were obtained by integration of the ^1H NMR signals as a function of time in reacting solutions (CF_3CO_2H). Compound **15a** was also studied in aqueous $HClO_4$ ($[H^+]$ = 6.69–8.89 M). In aqueous acid, **15a** cleaves first to 4-phenylpent-3-en-2-one (**16a**), but this material undergoes a retroaldol condensation leading to acetone and acetophenone. For this reason, the behavior of **16a** and of the aldol addition products, **18** and **19**, were also studied. These processes were monitored at 347 nm, λ_{max} for the protonated form of enone **16a**. This form is prominent in the acid solutions used for these measurements. All the reactions in TFA gave excellent first-order kinetics. The reaction of **15a** in $HClO_4$–H_2O gave biphasic behavior, an exponential rise in absorbance followed by an overlapping exponential loss of absorbance. The latter stages of the reaction gave sequential UV spectra with excellent isosbestic points. The late-stage behavior was accurately reproduced by starting with **16a**. With the alcohols **18** and **19** acid-catalyzed dehydration to the enones, **16a** and its *p*-methyl analogue, is relatively rapid and accurately first-order, and is followed by a well-separated first-order retroaldol cleavage.

The C-C cleavages of the (7-tropyl)nitroalkanes, **11a**–**c**, were also studied by UV spectroscopy using the λ_{max} for the product tropylium ion: 272 nm in TFA and 274 nm in $HClO_4$–H_2O. These kinetics were accurately first order (37). (7-Tropyl)acetone (**4**) was studied using TFA solvent.

Carbon–carbon cleavage of the 9-xanthyl compounds, **6**–**10**, was monitored in H_2SO_4–H_2O solutions, and in the case of **6** in TFA as well, by observing the intense absorption of xanthyl cation (Xan^+) at 375 nm ($\varepsilon = 3.97 \times 10^4$, this work). The reactions in aqueous sulfuric acid were strongly acid-promoted. All reactions showed excellent first-order kinetics except that for 2-methyl-3-(9-xanthyl)propene (**10**). In this case, production of Xan^+ showed a slight induction period. The data were best fit by a double exponential equation providing first-order rate constants for the earlier and later stages of the reaction.

Finally, the ring-opening C-C cleavage reactions of 2-arylnitrocyclopropanes, **12** and **13**, were studied in TFA by ^1H NMR spectroscopy. Good first-order behavior was again observed, as previously reported (38).[2]

Computational studies

All molecular orbital calculations were performed using the SPARTAN modeling software, versions 3.0, 4.0, 5.0, and MacSpartan Plus (Wavefunction, Inc., 18401 Von Karman Ave., Suite 370, Irvine, Calif., 92612), AM1 (40) and PM3 (41) semiempirical methods were used. These showed results for *series of related compounds* that were in good agreement. However, AM1 did a better job at reproducing the heat of protonation for nitromethane, the heat of formation of cyclobutanone, and the heat of the ring-opening isomerization of cyclobutanone to but-3-en-2-one. Therefore, it is these values that are reported here. Conformational enthalpies were investigated systematically. Transition-state structures were all characterized by a single imaginary frequency corresponding to the pertinent reaction coordinate.

Ab initio calculations at the HF/3-21G and HF/6-31G* levels were carried out for several smaller model compounds. Conformational minima and maxima for rotations about specific bonds were determined by systematic variation at the 3-21G level, and these conformations were further optimized at the 6-31G* level.

Results

Product studies

The alcohols, 9-xanthydrol (XanOH, **1**) and 4-*p*-methoxyphenyldiphenylmethanol ($AnPh_2COH$, **5**), could be completely heterolyzed to the carbocations, Xan^+ and $AnPh_2C^+$, in sufficiently acidic media. The UV-vis spectra of these cations agreed well with published data (18, 42). Basification of the carbocation solutions permitted recovery of the alcohols.

The sulfides, XanSMe (**2**) and TrSMe (**3**), gave the spectra of Xan^+ and tropylium (Tr^+), respectively, in sufficiently concentrated acid. It requires significantly higher acid concentrations to effect complete formation of the cations from their sulfide precursors than from the alcohols. At acidities high enough to negate the presence of XanOH or TrOH, the sulfides produced greater or lesser conversion to Xan^+ or Tr^+ depending on the acidity. The reactions of **1**, **5**, **2**, and **3** are

[2] In our original communication, we noted that rate-determining proton transfer between heteroatoms requires a close match of pK_a values between the acid (TFA) and the protonated base (RNO_2H^+) and that this match does not appear evident at first glance. Our explanation was that ring-opening electron release from the Cl—C2 bond, concurrent with protonation, greatly increases the basicity of the oxygens at the transition state, allowing the pK_a match. We neglected to point out that this idea is an application of Jencks (38*b*) "libido rule."

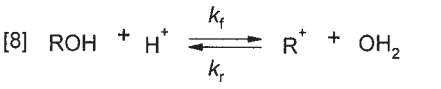
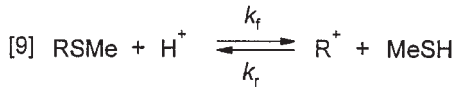
therefore formulated as reversible, acid-promoted heterolyses, eq. [8] and [9].



1: $R^+ = Xan^+$ **5**: $R^+ = AnPh_2C^+$



2: $R^+ = Xan^+$ **3**: $R^+ = Tr^+$

The acid-catalyzed carbon–carbon heterolyses of compounds **4**, **6**–**15**, **16a**, **18**, and **19** proceeded with irreversible production of an electrofugic carbocation (or a product derived therefrom) and a carbon-centered nucleofuge. For compound **4**, $TrCH_2COCH_3$, Conrow (15) showed the nucleofuge to be acetone, presumably as its enol. Deno and Sacher (17) did the same for **6**, $XanCH_2COCH_3$. The product UV spectrum of **7**, $XanCH_2COPh$, exactly matches that of an equimolar mixture of Xan^+ and acetophenone (this work). We have assumed therefore that *p*-nitroacetophenone is the nucleofugic product from **8**. Deno and Sacher (17) have shown that 2-(9-xanthyl)ethanol and 1-(9-xanthyl)-2-propanol fragment in acid solution to yield Xan^+ and either ethylene or propene. In our work, cleavage of 2-methyl-1-(9-xanthyl)-2-propanol (**9**, Xantba) as well as 2-methyl-3-(9-xanthyl)propene (**10**, $XanCH_2C(CH_3)=CH_2$, XanIb) lead quantitatively to Xan^+; we assume the nucleofuge to be isobutylene (subsequently, *tert*-butyl alcohol). In the few kinetic runs in which the "infinite time" spectrum differed from expectation by more than 2%, the runs were discarded.

Ring-opening cleavage of 3-arylcyclobutanones (**15a**–**g**) in trifluoroacetic acid (TFA) leads to β-aryl-α, β-unsaturated ketones, **16a**–**g**. These were identified by comparison with authentic samples. The cleavage products of the 2,2-dichloro-3-arylcyclobutanones were not synthesized independently, but were characterized by their ^1H NMR spectra as 1,1-dichloro-4-aryl-3-en-2-ones (**17a**, **c**, **e**, **f**), also in TFA. Yields and reaction conditions are found in Table 1.

Compound **15a**, 3-methyl-3-phenylcyclobutanone, was also studied in aqueous $HClO_4$ solution. In this medium, the initial product is **16a** (partly protonated at higher acidities). Subsequently, the characteristic UV spectrum of this compound is replaced by that of acetophenone, with acetone as the presumed byproduct. 4-Hydroxy-4-aryl-2-pentanones, **18** and **19**, also yield the UV spectrum of β-aryl-α,β-unsaturated ketones in aqueous $HClO_4$: **16a** from **18** and 4-(*p*-tolyl)pent-3-en-2-one from **19**. These spectra are eventually replaced by those of acetophenone and *p*-methylacetophenone, respectively. These changes over time are accompanied by good isosbestic points in the spectra.

The acid-catalyzed cleavages of the (7-tropyl)nitroalkanes, **11** (37) and the 2-arylnitrocyclopropanes, **12** and **13** (38*a*) have been previously characterized.

Equilibrium studies

Equilibrium production of carbocations from alcohol precursors, **1** and **5**, was analyzed as a function of acidity according to Deno's (18, 43) H_R acidity function and also using Cox and Yates (44, 45) "excess acidity" functions, X (for H_2SO_4 solutions) and X_o (for $HClO_4$ solutions), as recommended by Kresge et al. (46). Xanthydrol (**1**) was not one of the alcohols used to establish the H_R function, yet its ionization follows H_R acceptably well, giving $pK_{R+} = -0.90$ in $HClO_4$–H_2O; Deno and Evans (42) reported $pK_{R+} = -0.84$ in H_2SO_4–H_2O. The Cox and Yates correlation is given as eq. [16] (47).[3] For xanthydrol ($HClO_4$–H_2O), eq. [16] gives $pK_{R+} = -0.85 \pm 0.03$, $m^* = 2.6$ with $r^2 = 0.992$.

The other alcohol, *p*-anisyldiphenylmethanol (**5**), was one of the original H_R indicators. Deno et al. (18) reported $pK_{R+} = -3.40$ (H_2SO_4–H_2O), while we find, using the H_R function, $pK_{R+} = -3.65$ (H_2SO_4) and -3.60 ($HClO_4$). Treated according to eq. [16], $AnPh_2COH$ gives $pK_{R+} = 3.55$ in H_2SO_4

$$[16] \quad \log\left(\frac{[R^+]\, a_{OH_2}}{[ROH]\,[H^+]}\right) = m^*X + pK_{R^+}$$

[3] Values for the activity of water in H_2SO_4–H_2O solutions were taken from a compilation made by R.A. Cox (personal communication); see also ref. 47*a*. For $HClO_4$–H_2O solutions, water activities were taken from ref. 47*b*.

Table 2. Equilibrium constants for reversible ionization of alcohols **1** and **5** and concentration equilibrium quotients for sulfides **2** and **3** at 25°C.

Compound	pK_{R+} [a]	pK^s_{R+} [b]	log K_c^s [c]
1	–0.85 ± 0.03 ($HClO_4$–H_2O)		
5	–3.51 ($HClO_4$–H_2O) –3.55 (H_2SO_4–H_2O)		
2		–7.36 ± 0.14 ($HClO_4$–H_2O)	–4.67 ± 0.07 (($HClO_4$)H_2O/5.0 M ClO_4^-) ~–5.3[d] (H_2SO_4–H_2O)
3			–1.8[e] (H_2SO_4–H_2O)

[a]Obtained using eq. [16] and the X function for H_2SO_4–H_2O, the X_o function for $HClO_4$–H_2O. The standard state is 1.00 M H^+, activity coefficients unity.

[b]Obtained using eq. [17] and the X_o function.

[c]Obtained using eq. [18].

[d]The use of eq. [17] gave severe curvature. See text.

[e]Dilute H_2SO_4: 0.013 – 0.086 M. Use of an acidity function is unnecessary.

solution and –3.51 in $HClO_4$ solution, in good agreement with our H_R result and in fair agreement with Deno's original result. These and other equilibrium constants are listed in Table 2.[4] The slope parameter in eq. [16], m^*, was found for **5** to be 2.2 in H_2SO_4 and 3.3 in $HClO_4$ solution. Large values of m^* are to be expected for alcohol–carbocation equilibria (45).

Adaptation of the excess acidity correlation to the reversible heterolysis of the sulfides leads to eq. [17]. The equilibrium constant indicated as K^s_{R+} is unitless as defined here.

$$[17]\quad \log\left(\frac{[R^+]\,[MeSH]}{[RSMe]\,[H^+]}\right) = m^*X + pK^s_{R^+}\ ;\ K^s_{R^+} = \frac{a_{RSMe}\,a_{H^+}}{a_{R^+}\,a_{MeSH}}$$

In perchloric acid solution, the data for XanSMe (**2**) are fairly well behaved with some scatter but no curvature: pK^s_{R+} = –7.36 ± 0.14, m^* = 2.5, r^2 = 0.968. The difference between the ionizations of XanOH and XanSMe is very large and perhaps best revealed by the fact that whereas XanOH is half-ionized in ca. 1 M $HClO_4$, XanSMe requires over 3 M $HClO_4$ for half-ionization despite the tiny concentration of methanethiol in these solutions, ca. 10^{-5} M or less. In sulfuric acid solution, the plot of eq. [17] was badly curved. Rather than speculate about this result, we report the correlation suggested by eq. [18] where K^s_c is a concentration ratio. This plot produced $K^s_c = 5.5 \times 10^{-6}$ with r^2 = 0.970.[5]

$$[18]\quad \frac{[Xan^+]\,[MeSH]}{[XanSMe]} = K^s_c\,[H^+]$$

We also studied the fragmentation of XanSMe in perchloric acid solutions of constant ionic strength, μ = 5.00 M, maintained with $NaClO_4$. Medium effects appear to be insensitive to $[H^+]$ in these media, dominated by total $[ClO_4^-]$. The concentration quotient from eq. [18] is approximately constant against $[H^+]$, leading to a value for $K^s_c = 2.1 \times 10^{-5}$ (r^2 = 0.986) in this medium. The corresponding value in ordinary $HClO_4$–H_2O solutions obtained by the X_o function correlation is $1/K^s_{R+} = 4.3 \times 10^{-8}$, amounting to a 500-fold diminution of ionization in the standard state of 1.0 M acid, all activity coefficients at unity, compared with the 5.0 M perchlorate state. Bunton and Huang (48) found that the ionization of trianisylmethanol in dilute aqueous acid is enhanced by a number of salts, especially $LiClO_4$ and $NaClO_4$. They found further that the rate of carbocation formation is enhanced, and the rate of its reaction with water decreased by these salts. Johnston, Scaiano, and their co-workers (49) observed reduced rates of reaction of some diarylmethyl cations with azide and other anionic nucleophiles in the presence of $LiClO_4$. Bunton and Huang's analysis of activity coefficient behavior indicates that perchlorate strongly stabilizes carbocations relative to the solvated proton, and also stabilizes the fragmentation transition state though by a lesser amount. An attractive interaction between the large, nonspecifically solvated carbocation and the large, low-charge-density perchlorate ion is proposed as the cause. The overall result resembles Winstein's special salt effect on S_N1 solvolyses (50).

(7-Tropyl)methylsulfide (TrSMe, **3**) was studied in dilute H_2SO_4 solutions with poor success owing to irreproducibility of equilibrium measurements. The quantity K^s_c, defined as in eq. [18] but with tropylium$^+$ replacing xanthyl$^+$,

[4]Primary equilibrium and rate constants are available as supplemental material. Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

[5]$K^s_c(\gamma_{R+}\gamma_{MeSH}/\gamma_{RSMe}\gamma_{H+}) = 1/K^s_{R+}$. Thus, the approximate insensitivity of K^s_c to changes in sulfuric acid concentrations tells us that the ratio of activity coefficients is also approximately constant in these media. The value of this ratio is not known but is probably much less than 1, since γ_{R+}/γ_{H+} decreases with increasing acidity. Therefore, multiplication of K^s_c by the activity coefficent ratio would reduce K^s_c, bringing it closer to the value of $1/K^s_{R+}$ found in $HClO_4$ solutions.

is approximately a constant, however. Its value is ca. 1.5 × 10^{-2}. The ratio of these ionization "constants" is 2.7 × 10^3 favoring production of Tr^+ over Xan^+. Fot comparison, the ratio of the K_{R+} values derived from ionization of the corresponding alcohols is ~4 × 10^5, taking pK_{R+} = 4.75 for Tr^+ (51, 52).

We had two reasons for determining equilibrium ionization constants for compounds **1**–**3** and **5**. First, because values for **1** and **5** had already been reported (42, 18), it was important to see how well we reproduced those results. Second, we shall employ the pK_{R+} and pK^s_{R+} values in some of the analyses made of kinetic data in the next section.

Kinetic studies

*Rate constants for the reversible ionization of compounds **1**–**3** and **5***

Experimental first-order rate constants for the reversible ionization of alcohols **1** and **5** and sulfide **2** were measured as a function of acidity in aqueous acid. These could be separated into first-order constants for the fragmentation (forward) reaction, k_f, and for the recombination (reverse) direction, k_r, using the equilibrium (product/reactant) concentration ratios. The k_r values for sulfide **2** are, to a good approximation, second-order constants (see Experimental section). The k_f and k_r values depend in turn on the acidity and electrolyte properties of the media in which they were measured. Conversion of these into medium-independent second-order constants with a defined standard state required additional analysis.

We have used two methods to obtain second-order rate constants for compounds **1**, **2**, and **5**. One is the application of the excess acidity function treatment to kinetic equations developed by Cox and Yates (53). Equation [19] is the relationship to be plotted when substrate is predominately unprotonated. Equation [19*a*] is appropriate when water is used as a reactant.

$$[19]\quad \log (k_f/[H^+]) = m^{\ddagger} m^*X + \log k_f^o$$

$$[19a]\quad \log (k_f/[H^+]) - \log a_{OH_2} = m^{\ddagger} m^*X + \log k^o_f$$

The intercept provides the medium-independent second-order rate constant in the forward (fragmentation) direction for these reactions. Knowledge of K_{R+} (or K^s_{R+}) for the reaction permits calculation of $k°_r$ from the relationship $k°_r = k°_f/K_{R+}$. The slope parameters given in eq. [19] contain a factor, m^*, which is the slope of an X-plot made for *equilibrium* protonation of the substrate, similar to eq. [16]. The other factor, $m^{\neq}$, is characteristic of the way the log of the activity coefficient of the transition state behaves relative to that of the protonated substrate as X is varied.

An alternative analysis is possible for acid-catalyzed reactions for which both rate and equilibrium data are available over the same range of acid concentrations. Kresge et al. (54) proposed a linear free energy rate–equilibrium correlation for such processes. As applied to the ionization of the alcohols, the Kresge analysis uses eq. [20]; for the sulfides it is eq. [21]. In these equations, the symbols have the same

$$[20]\quad \log (k_f/[H^+]) = \alpha_K \log\left(\frac{[R^+]\, a_{OH_2}}{[ROH][H^+]}\right) + (\log k_f^o + \alpha_K \log K_{R^+})$$

© 1999 NRC Canada

$$[21]\quad \log(k_f/[H^+]) = \alpha_K \log\left(\frac{[R^+][MeSH]}{[RSMe][H^+]}\right) + (\log k^\circ_f + \alpha_K \log K^s_{R^+})$$

significance as above except that the slope coefficient, labeled α_A by Kresge (54*b*), is here denoted α_K in his honor. This coefficient relates the medium dependence of log $\gamma^{\neq}$ to that of log ($\gamma_{R+}a_{H2O}$) or log ($\gamma_{R+}\gamma_{MeSH}$). Since log γ is proportional to free energy, α_K has the significance of a normalized Brønsted coefficient, α, indicating the medium sensitivity of $G^{\ddagger}$ relative to G(products). A caveat is in order for reactions that are mechanistically general-acid or -base catalyzed, and are carried out in H_2SO_4 solutions. This is because HSO_4^- (or SO_4^{2-}) could be catalytically active, thereby having an effect on k_f (or k_r) but not on the [product]/[reactant] equilibrium ratio (53, 55).

For 9-xanthydrol (**1**) the Cox–Yates correlation was good, $r^2 = 0.990$, yielding $k^\circ_f = (1.70 \pm 0.08) \times 10^3$ M^{-1} s^{-1}. Combined with the value determined by us for K_{R+}, we obtain $k^\circ_r = (1.2 \pm 0.2) \times 10^4$ s^{-1}. This value is in reasonably good agreement with a value, $k^\circ_r = 2.3 \times 10^4$ s^{-1}, obtained by McClelland et al. (56) in 1:4 acetonitrile/water. The slope parameter, $m^{\ddagger}m^*$, is 1.9 ± 0.1. Use of the Kresge correlation also gave good linearity, $r^2 = 0.993$, with slope, $\alpha_K = 0.63 \pm 0.03$. Equation [20] (intercept) leads to $k^\circ_f = (1.9 \pm 0.2) \times 10^3$ M^{-1} s^{-1}, thence $k^\circ_r = 1.3 \times 10^4$ s^{-1}. These and other rate constants for the reversible acid-catalyzed reactions are collected in Table 3.

For $AnPh_2COH$ (**5**) in $HClO_4$ solutions, the Cox–Yates plot was accurately linear for three of the five data points only; of the other two, one was above, the other below the line. By accepting this line, we obtain $k^\circ_f = 0.42$ M^{-1} s^{-1}, $k^\circ_r = 1.5 \times 10^3$ s^{-1}, with $m^*m^{\neq} = 1.9$. The Kresge plot was excellent with $\alpha_K = 0.54 \pm 0.01$, $k^\circ_f = 0.49$ M^{-1} s^{-1}, and $k^\circ_r = 1.60 \times 10^3$ s^{-1}. The recombination rate constant for **5** has previously been measured by Diffenbach et al. (57), $k^\circ_r = (1.0 \pm 0.7) \times 10^3$ s^{-1}, and by McClelland et al. (58), in 1:2 acetonitrile/water at 20°, $k^\circ_r = 1.4 \times 10^3$ s^{-1}. In sulfuric acid, the Cox–Yates plot suffered from an insufficient range of data points though it did extrapolate to approximately the same intercept as for perchloric acid. Interestingly, a fairly good Kresge plot ($r^2 = 0.951$) could be made from the combined $HClO_4$ and H_2SO_4 data. This gave $\alpha_K = 0.56$, $k^\circ_f = 0.44$ M^{-1} s^{-1}, and $k^\circ_r = 1.5 \times 10^3$ s^{-1}. As for 9-xanthydrol, the two methods of analysis give convergent results.

For 9-xanthylmethylsulfide (**2**), the Cox–Yates plots were fairly good ($HClO_4$) and good (H_2SO_4), however, the slopes and intercepts of these plots did not agree. For $HClO_4$ solutions, $k^\circ_f = 0.35$ M^{-1} s^{-1}, the slope $m^{\neq}m^* = 1.9$, and $r^2 = 0.944$. In H_2SO_4, the same parameters were $k^o_f = 7.9 \times 10^{-2}$ M^{-1} s^{-1}, $m^{\neq}m^* = 1.1$ with $r^2 = 0.987$. A value for the recombination rate constant in $HClO_4$–H_2O is obtained using $pK^s_{R+} = -7.36$ found for that medium: $k^\circ_r = 8.1 \times 10^6$ M^{-1} s^{-1}. For H_2SO_4–H_2O, the calculation of k°_r is hampered by lack of a reliable K^s_{R+} value (see above). We report only that the experimental k_r is insensitive to [H_2SO_4] over the range 3.6–5.1 M. This suggests a value for $k^\circ_r \cong 2.5 \times 10^5$ M^{-1} s^{-1} in this medium, but it should, perhaps, not be given much quantitative weight. The Kresge plot for $HClO_4$–H_2O was accurately linear over the range 2.2–3.2 M ($r^2 = 0.999$) and led to $\alpha_K = 0.71 \pm 0.01$. This result allows from eq. [21] calculation of $k^\circ_f = 0.45 \pm 0.13$ M^{-1} s^{-1} and $k^\circ_r = (1.0 \pm 0.4) \times 10^7$ M^{-1} s^{-1}. These results are in satisfactory agreement with the Cox–Yates numbers. In H_2SO_4–H_2O, the Kresge plot was markedly curved, concave upward, allowing no further calculations. There do not appear to be any measurements of recombination rate constants for Xan^+ and neutral thiols in the literature. Ritchie and Gandler (59) report $k^\circ_r = 3.4$ M^{-1} s^{-1} for the reaction of 2-mercaptoethanol with trianisylmethyl cation, An_3C^+. The difference between that constant and the one reported here for Xan^+ plus CH_3SH is large, but is influenced by at least three factors: methanethiol is expected to be a better nucleophile than 2-mercaptoethanol; σ^* for the $-CH_2OH$ group is 0.56 (60). An_3C^+, with $pK_{R+} = 0.82$ (18, 58*a*), is almost two orders of magnitude more stable than Xan^+. Finally, triarylmethyl cations are known to combine with nucleophiles more slowly than does xanthyl$^+$. For example, An_2PhC^+, $pK_{R+} = -1.24$ (18), is less stable than Xan^+, yet reacts with water 160 times more slowly (58).

As we did with equilibrium studies, the rates of fragmentation of XanSMe (**2**) were also studied in $HClO_4$–H_2O solutions of constant ionic strength, $\mu = 5.00$ M ($NaClO_4$). Once again, medium effects appear to be dominated by the large perchlorate concentration. A simple plot of k_f vs. [H^+] was linear, $r^2 = 0.986$, giving a k^o_f value for this medium of 19.5 M^{-1} s^{-1}, which, combined with the equilibrium constant determined in this medium, provides a value for $k^\circ_r = 9.2 \times 10^5$ M^{-1} s^{-1}. Compared with the results from ordinary $HClO_4$–H_2O solutions, we see that k°_f has increased by a factor of about 50 while k°_r has decreased 10-fold. The likely cause of these effects was discussed above in the Equilibrium studies section.

(7-Tropyl)methylsulfide (TrSMe, **3**) was studied in dilute H_2SO_4 solutions, 0.013–0.086 M. A simple plot of k_f vs. [H^+] was linear, $r^2 = 0.989$, with slope = 6.6 M^{-1} s^{-1} = k°_f. Combined with the equilibrium value for dissociation, this value gives $k^\circ_r \cong 4.4 \times 10^2$ M^{-1} s^{-1}. These values are ca. 80-fold larger and 550-fold smaller, respectively, than the corresponding values for XanSMe derived from more concentrated H_2SO_4 solutions (see above). We are not aware of any previous reports of rate constants for reactions of neutral thiols with tropylium ion.

Rate constants and related data presented in this section are listed in Table 3. We estimate that for quantities without listed error limits the experimental uncertainties range from ±10 to ±20%.

*Rate constants for irreversible fragmentation of 9-xanthyl compounds **6**–**10***

Compounds **6**–**10** undergo irreversible fragmentation in acid media giving Xan^+ (xanthyl cation) and a carbon-centered nucleofuge. The tropylium compound, **4**, behaves analogously, see eq. [10]. The rates of these reactions were studied in H_2SO_4–H_2O solution. Medium-independent, second-order rate constants were obtained using the method of Cox and Yates (53) (eq. [19]) as described above. In two cases, compounds **4** and **6**, we also determined rate constants in trifluoroacetic acid. The second-order fragmentation rate constant taken from the intercept of the Cox–Yates plot has a significance that depends on the mechanism of the fragmentation reaction. If, for example, the first step is rate controlling, then one may infer that k°_f has to do with protonation of the substrate, regardless of whether or not

	ca. 80 (stage 2)	—	~1.2		~0.6

[a]Obtained using eq. [19]. The standard state is 1.00 M H^+, activity coefficients unity.

[b]Obtained as $k_{frag} = k_{rds} = k_f°/K_{eq}$ for reactions wherein unimolecular fragmentation succeeds an acid-promoted equilibrium, as assumed for compounds **6**–**9** (see text). The value of k_{frag} depends critically on K_{eq}. For **6**–**8** K_{eq} is $1/K_{BH+}$, and for **9** we take $K_{eq} = 1/K_{R+}$. Values for K_{BH+} are taken from refs. 61 (**6**, **7**) and 62 (**8**). K_{R+} for tertiary alcohol **9** is taken as ca. 10^{15} M^{-1} (see text).

[c]Determined in 7.41 M L_2SO_4 for compounds **6**–**8,** and in 5.50 M L_2SO_4 for **9** and **10**. Quoted values are averages of 3–5 ratios. Estimated uncertainty in the ratio is ±10% for **6**–**9** and ±30% for **10**.

[d]Parameters are for the two rate constants obtained by fitting the absorbance vs. time data to a double exponential expression, while k_{frag} is taken from data for **9**.

14a	Ph	CH_3	H	2.22×10^{-6}	

[a]Obtained at 25.0°C by UV spectroscopy except for compounds **15b** and **e**.

[b]These were measured at room temperature (23–24°C) by ^1H NMR spectroscopy, and compared with rates for **15g** and **f**, respectively, obtained in the same way, to estimate the rate constants listed here.

fragmentation is concerted with protonation. If the role of acid is to cause an equilibrium to be established, this followed by a rate-determining fragmentation step, i.e., the A1 mechanism, then $k°_f = K_{eq}k_{rds}$. Knowledge of the equilibrium constant enables an estimate of the rate constant for the rate-determining step, $k_{rds} = k_{frag}$. For **6** and **7**, we have used pK_{BH+} values for acetone and acetophenone, respectively (61). For **8**, a pK_{BH+} value for *p*-nitroacetophenone was used (62). For compound **9**, we required a pK_{R+} value for a 3° alcohol having assumed that fragmentation occurs from a 3° carbocation. Values for pK_{R+} ranging from –14.7 to –16.4 are found in the literature for *tert*-butyl alcohol (63, 64). The latter appears to be suitable for aqueous solution. However, the results of Arnett and Hofelich (63) for four 3° alcohols larger than *t*-BuOH show an average pK_{R+} less negative by ca. 1.5 units. We have applied this correction and estimate $pK_{R+} \approx -15$ for **9**. The Cox–Yates parameters and related quantities are collected in Table 4.

*Rate constants for ring opening isomerizations of 3-arylcyclobutanones (**15**) and 2,2-dichloro-3-arylcyclobutanones (**14**)*

In trifluoroacetic acid solutions, all the cyclobutanones studied by us undergo acid-catalyzed ring cleavage of the C2—C3 bond to yield β-aryl-α, β-unsaturated ketones, eq. [11] and [13]. Compound **15a** was also examined in $HClO_4$–H_2O solution wherein biphasic behavior is seen: ring opening isomerization is followed by a retroaldol condensation, eq. [12], and is marked by a rise in absorbance vs. time followed by an overlapping decrease. First-order rate constants for the ring opening reactions in TFA are given in Table 5. Rate constants for the reactions of **15a** in $HClO_4$–H_2O, and for the related compounds **16a**, **18a**, and **19** (see eq. [12]) are found in Table 6. These rate constants are those obtained from the Cox–Yates X_o extrapolation (eq. [19] or [19*a*]). The rate of the retroaldol reaction of compound **16a** was determined from three different sources: (*i*) from the latter stages of the ring opening reaction; (*ii*) directly from the enone, **16a**; (*iii*) from the latter stages of the dehydration of ketol, **18**. All three reactions include the retroaldol reaction of **16a**. The slope and intercept parameters of the X_o plots were in satisfactory agreement with one another, given the fact that from source (*i*), the cyclobutanone, the ring opening, and retroaldol stages were only moderately well separated. The preferred values for $k°_{retro}$ reported in Table 6 are therefore those obtained from the enone and ketol sources.

In the course of investigating the retroaldol reaction of **16a**, it was found useful to compare the rates of dehydration of ketol **18** and its *p*-methyl analog, **19**. Additional comparisons required the use of literature data for dehydration of some ring substituted α-arylacetophenones. These data are assembled in Table 7.

*Rate constants for acid-catalyzed cleavage of (7-tropyl)nitroalkanes (**11**), eq. [14], and 2-arylnitrocyclopropanes (**12**, **13**), eq. [15]*

Tropylium compounds, **11a**–**c**, fragment in TFA or in $HClO_4$–H_2O to give tropylium ion, Tr^+ (quantitatively), and products expected from reaction of the other fragment, a nitronic acid, in acid media, namely, hydroxamic acids (Victor Meyer reaction) or acetone, the Nef reaction product from **11c** (37). Rate constants and solvent isotope effects for these reactions are presented in Table 8. The data for **12** and **13** are found in Table 9.

Discussion

Synthesis of β-aryl-α,β-unsaturated ketones, 16 and 17

The sequence of reactions in which olefins (styrenes) are converted to 2,2-dichlorocyclobutanones (**14**), which are then (optionally) dechlorinated to cyclobutanones (**15**), which in turn undergo acid-catalyzed ring opening leading to enones **16** and **17**, is suggested by us to be a simple and useful preparative method for such enones. A similar sequence has also been recommended by Doyle et al. (65). A particularly useful feature of the sequence is that the final step is regiospecific and (in the cases investigated by us) stereospecific. As discussed below, ring opening occurs to produce the enol in which the double bond is more highly substituted. Ketonization then takes place so that the resulting acyl group is *trans* to the larger group on the other double bond carbon, see eqs. [11] and [13]. The ring opening step appears to be virtually quantitative, but its rate is highly dependent on the substitution pattern, especially at C3 (see Tables 1 and 5). More convenient rates in the slower cases could doubtless be achieved by using more powerfully acidic conditions, for example CF_3SO_3H–TFA or $HClO_4$–TFA. Other aspects of the electrophilic cleavage of cyclobutanones are discussed below.

Mechanisms: fragmentation of the alcohols (1, 5) and sulfides (2, 3)

In this section, we propose that hydronium ion promoted cleavage of the alcohols and sulfides occurs by the two-step

[a]4 M TFA in $CDCl_3$.

A1 mechanism in which the leaving group, water or methanethiol, is strongly hydrogen bonded to a water cluster in the rate-determining transition state. Slopes of the Kresge plots for **1**, **5**, and **2** are α_K = 0.63, 0.54, and 0.71, respectively. These results tell us that the sensitivity of the free energy of the transition states of these cleavages toward added $HClO_4$ is not as great as is the sensitivity of the free energy of the separated cleavage products. It is thus permissible to view α_K values like classic Brønsted α values. Indeed, Kresge (66) has shown that for a number of general-acid catalyzed proton transfers, experimental α and α_K values have similar magnitudes. Although providing information about the transition states, the Kresge correlations do not, unfortunately, tell us whether the reaction mechanisms are stepwise A1 processes, with equilibrium protonation followed by rate-determining fragmentation, or are concerted, with protonation accompanied by cleavage.

It has been established that nucleophilic attack by water on carbocations as unstable as 1-(*p*-anisyl)ethyl is catalyzed by general bases (67). Likewise, general base catalysis is observed for capture by water of a host of more stable carbocations including triarylmethyl, aryltropylium, and some highly stabilized xanthyl cations. Ritchie et al. (68) has argued that the reactions of water with carbocations covering the pK_{R+} range from –7 to +9.4 are all subject to general base catalysis. With the inclusion of 1-(*p*-anisyl)ethyl, $pK_{R+} \cong -8.5$, this range extends close to the limit of any carbocations capable of existence in aqueous solution. General base catalysis of attack by nucleophilic water implicates general acid catalysis for departure of nucleofugic water from the corresponding alcohols.

Catalytic assistance by general bases does not guarantee that in the absence of these bases attack of water is similarly assisted by other water molecules. Gandler (69) has given a simple but persuasive argument that, in general, the "water reaction will be stepwise, passing through the oxonium ion, ROH_2^+, rather than concerted"; (very similar arguments have been given by Jensen and Jencks (79)). In the fragmentation direction, this is the A1 mechanism. Gandler's argument compares estimated, but reasonable, values of $\Delta G°$ for the equilibrium protonation of alcohols with the overall free energies of activation for their acid-catalyzed heterolyses. Significant free energy barriers to heterolysis (8–10 kcal/mol at 25°C) remain following the protonation step. Likewise, one may estimate a residual barrier to heterolysis of at least 8 kcal/mol for $XanOH_2^+$ and a barrier of 6 kcal/mol or more even for protonated tropyl alcohol.

Gandler's conclusion does not of course negate hydrogen-bonding assistance to the departure of water by neighboring water molecules; an oxonium ion will be well hydrated. In this connection, Wolfe et al. (70) have recently reported experimental and computational results on the uncatalyzed hydration of acetone. The experimental free energy of activation is well modeled by a transition state containing four molecules of water. Further, their computations indicate that a major component of bulk water is a cyclic tetramer. Insofar as a ketone can represent a carbocation for this purpose, it seems logical that the uncatalyzed addition of water to a cationic center involves a water cluster, polarized by the cation's positive charge. The constituent water molecules in the cluster, already hydrogen-bonded in the bulk, will be even more firmly linked in the transition state and in the product oxonium ion. In the fragmentation direction, nucleofugic water is welcomed, joining, or helping to form a stable cluster.

We have observed inverse solvent isotope effects for the fragmentations of XanOH (**1**), XanSMe (**2**), and TrSMe (**3**), see Table 3. Solvent isotope effects, k_{H3O+}/k_{D3O+}, were once thought to be diagnostic for distinguishing the A1 mechanism from rate-determining protonation: the former would display an inverse rate ratio favoring reaction in D_2O by a factor of 2.5 or more, while the latter would show normal primary isotope effects being faster.

However, there now exist many examples of reactions that show both general acid catalysis *and* inverse solvent isotope effects. Just a few examples are formation of An_3C^+ from An_3COH (71), the hydrolysis of ethylorthocarbonate (72), hydrolysis of a number of acetals (73, 74), and the fragmentation of *N*-*p*-nitrophenylcarbamate (75). The magnitudes of these inverse effects range from $k_{H3O+}/k_{D3O+} \cong 0.3$ to just under unity. In such cases, the large inverse effect associated with the nonreacting hydrogens in the protonation event is more or less mitigated by a variable and normal primary effect associated with the transferred hydrogen. This partly compensating primary effect can arise if the transferred hy-

© 1999 NRC Canada

drogen is part of the reaction coordinate motion, or if for any reason, for example, strong hydrogen bonding, the zero-point vibrational energy associated with this hydrogen is reduced in the transition state relative to the reactant state (74–77).[6] It is quite conceivable that a slight variation of the A1 mechanism, one in which the transferred hydrogen remains strongly associated with the atom from which it left rather than being solvationally equilibrated, provides the necessary set of zero-point energy changes, giving rise to solvent isotope effects that are inverse, but not maximally so. Note that this variant, when employed by general acid catalysts, has the transferred proton (and (or) a geminal partner) hydrogen bonded to the conjugate base of the general acid in the rate-determining transition state. Further, in the reverse or recombination direction, one has general base catalysis by preassociation (74, 75; Wann and Kreevoy (78) present a more detailed scheme for the mechanistic possibilities of acid-catalyzed heterolyses, including diffusional events). Scheme 1 presents some of the possibilities discussed in this section.

There is much less information available about the reactions of carbocations with neutral thiols than with water. We are unaware of unequivocal evidence for general catalysis of reaction [3] or its reverse (79, 80). Perdoncin and Scorrano (81) report a pK_a = –7.0 for the conjugate acid of dimethyl sulfide. Borrowing this value for sulfides **2** and **3**, and comparing the free energy of protonation, $\Delta G°$, with the free energy of activation governing $k_f°$, $\Delta G^‡$, one finds that $\Delta G^‡$ exceeds $\Delta G°$ by 8.5–9.5 kcal/mol for XanSMe and ca. 7 kcal/mol for TrSMe. Since an error of ± 1 pK_a unit in the protonation equilibrium alters the difference between $\Delta G^‡$ and $\Delta G°$ by only ± 1.4 kcal/mol, estimates such as these leave plenty of room for the two-step A1 mechanism. Compared with alcohols **1** and **5**, the equilibrium constants for protonation of the sulfides are smaller, but so are the overall rate constants, $k_f°$.

There is no thermodynamic imperative for avoiding the conjugate acids of alcohols and sulfides in hydronium ion promoted fragmentations. Therefore, we propose the simplest mechanistic interpretation of the data: the A1 mechanism or the ion-pair variant described above.

Mechanisms: carbon–carbon cleavage of xanthyl compounds 6–10, and of (7-tropyl)acetone

The xanthylketones, **6**–**8**, and the related tropyl compound, **4**, all appear to undergo fragmentation by the classical A1 mechanism, eq. [22]. It is possible that reversible enolization of the ketones occurs prior to fragmentation, however, we have no direct evidence on the matter.

The medium-independent rate constants for the fragmentations (Table 4) are ca. 10^2 smaller than typical values (82) for acid-catalyzed enolization. However, the fragmentation rates have *much* greater dependencies on acidity than do enolizations (62, 83[7]). For the moderately concentrated acid solutions used by us, we can estimate that fragmentation rates exceed enolization rates by a factor of at least 30, thus we exclude an enolization side reaction in these media.

The evidence for the A1 mechanism is threefold. First, the thermodynamic rationale used in the previous section permits a large barrier for fragmentation of the substrate conjugate acid to be estimated, ~19–24 kcal/mol for **8**, **7**, and **6**; see listings for k_{frag} in Table 4. The solvent isotope effects, $k_f(H_2O)/k_f(D_2O)$, are about 0.55 for these substrates, allowing interpretation by the A1 mechanism. A related and important point is the solvent isotope effect measured for **6** in trifluoroacetic acid: $k_{TFA\text{-}d}$ = 0.78 ± 0.04. Acids with only one acidic hydrogen have no nonreacting hydrogens, hence any primary isotope effect will not be concealed by an inverse secondary effect. Johnson and co-workers (84) have shown that an inverse solvent isotope effect in TFA is to be expected for an A1 pathway. Less diagnostic but consistent with this assignment is the secondary isotope effect observed with compound **6** deuterated at the 9-position: k_H/k_D = 1.10 ± 0.03 in 62% H_2SO_4. This result is consistent with a rate-determining step involving a hybridization change, $sp^3 \rightarrow sp^2$ at C-9. We assume in these arguments that the reaction mechanism in TFA is the same as that in water. This seems likely; the dielectric constant of TFA is low, only 8.22 (85). The A1 (ion pair) mechanism (or conjugate acid – conjugate base pair in water) is much more likely in a medium of this sort than in water. Yet, the solvent isotope effect in TFA tells us that this does not occur. A small *normal* effect would be predicted for the ion pair mechanism (75).

Computational evidence supports the thermodynamic argument given above. The enthalpic barrier to fragmentation of the conjugate acid of **6** is calculated by the semiempirical AM1 method to be 19.3 kcal/mol, in reasonable accord with the experimentally estimated free energy barrier of 23.9 kcal/mol. For the tropyl analogue, **4**, the fragmentation barrier is computed at a healthy 14.4 kcal/mol. For this reason and because **4** fragments in TFA only 10–20 times faster than **6**, we do not imagine a different, "improved" mechanism for **4**.

For compound **9**, 2-methyl-1-(9-xanthyl)-2-propanol or Xantba, we propose that acid-promoted heterolysis to a 3° carbocation occurs reversibly and that fragmentation of this cation to xanthyl$^+$ and isobutylene is rate determining, eq. [23]. As described in Results we estimate a pK_{R+} for the intermediate 3° carbocation of ~–15. With this value, a unimolecular fragmentation constant of ca. 5×10^8 s^{-1} may be estimated for the rate-determining step. This rate is smaller than that estimated for combination of *t*-butyl$^+$ with water by about

[22] 
[6] A model for proton transfer along a hydrogen bond has the proton moving in a stable well, not part of the reaction coordinate: see ref. 76. Kreevoy and Liang (77) have presented evidence for reduced fractionation factors for protons in some hydrogen-bonded complexes.

[7] The very small dependence of k_{exp} (s^{-1}) on *X* is anticipated by the original Zucker–Hammett hypothesis that an A2 mechanism such as enolization should be correlated with [H$^+$], not requiring an excess acidity function: ref. 83*b*.

[23] 
9

5000 (64*a*) and smaller than that for reaction of 1-methycyclooctyl cation with water by a factor of ca. 12 (64*b*). Hence, we believe that the 3° cation in the present case is formed reversibly. A supporting piece of evidence is the secondary kinetic isotope effect, k_H/k_D = 1.07 ± 0.03, measured by use of Xantba-9-*d* in 50.4% H_2SO_4–H_2O, a result consistent with a hybridization change from sp^3 to sp^2 at C-9 in the rate-determining step.

Compound **10**, 2-methyl-3-(9-xanthyl)propene or XanIb, fragments quantitatively to Xan^+ and isobutylene but by a more complex mechanism than for the other xanthyl compounds. Data from biphasic time courses were fit to a double exponential equation. This allowed rate constants to be estimated for both phases (Table 4). Data from the later part of the reaction (stage 2) could be approximated by a single exponential equation, yielding a rate constant similar to that for the fragmentation of **9**. The solvent isotope effect for this stage was inverse and close to that obtained with **9**. Data from stage 1 gave a normal solvent isotope effect of approximately 6. We characterize this stage as protonation of the olefin. All results including the requirement of a double exponential fit are satisfied by mechanism [24] (86).

Trifluoroacetic acid appears to be an excellent medium for these fragmentations as well as others, see Table 10. An *X*-function value for TFA is not known, but the H_o value has been determined to be –2.71 (87). The H_o value for an H_2SO_4–H_2O medium, which would bring about fragmentation of **6** at the same rate as in TFA, is –5.2! To put it another way, the rate of fragmentation in a sulfuric acid solution of H_o = –2.71 (44% H_2SO_4) is 500 times slower than in TFA. A part of the superiority of TFA in these carbocation-forming reactions may lie in the fact that the H_R value for TFA is –11.3 (87), a value reached by H_2SO_4–H_2O solutions only at 69% H_2SO_4. Tidwell and co-workers (88) have observed that rates of protonation of a number of aliphatic olefins are slightly elevated in TFA compared with 44% H_2SO_4 and that, as a class, substituted styrenes are even more reactive in TFA. The relatively large value of $-H_R$ suggests that TFA might be particularly hospitable to delocalized carbocations (as well as to water and to other oxygen-centered leaving groups).

Mechanisms: carbon–carbon cleavage of tropylnitroalkanes, 11

In our earlier report, we identified the reaction of eq. [14] as the first example of acid-catalyzed conversion of a nitroalkane to a nitronic acid (37). The reactions differ from a tautomerization process in that instead of proton loss from the carbon next to the nitro group, we see loss of the tropylium carbocation. Not only is tropylium a superior electrofuge, its loss occurs unimolecularly with no requirement for covalent participation by a base, H_2O or TFA.

Ordinary nitroalkane-to-nitronic acid tautomerization has never been demonstrated to be acid catalyzed unlike the otherwise similar keto–enol transformations of carbonyl compounds. The extremely low basicity of nitroalkanes must be a major part of the reason for the lack of observed acid catalysis. Rather, tautomerization occurs through deprotonation by water, then reprotonation by H_3O^+. In fact, the basicity of nitroalkanes is not well quantitated, though it is known that

[24] 
© 1999 NRC Canada

nitromethane is not significantly protonated in 99–100% H_2SO_4 (89). Gillespie and Solomons (90) have reported conductometric measurements giving $K_b \cong 2.5 \times 10^{-3}$ M in H_2SO_4 solvent, and Arnett (91) provides an estimated $pK_a \cong -12$ for the conjugate acid of nitromethane. The latter value allows a calculation of $\Delta G° \cong 16$ kcal/mol for protonation of CH_3NO_2. The known rate constant for deprotonation of nitromethane by water (92) provides $\Delta G^{‡} \cong 27.5$ kcal/mol for that reaction. These results require that the tautomerization of nitromethane have a rate constant, $k \cong 5 \times 10^4$ s^{-1}, for deprotonation of $CH_3NO_2H^+$ at carbon in order for the A1 mechanism to compete with the water reaction. This does not seem an extraordinary requirement, but it must be kept in mind that the pK_a value for $CH_3NO_2H^+$ could be even more negative than assumed here.

In our original communication, we proposed that the tropylnitroalkanes fragment by the A1 mechanism (37). Since then, we have determined the solvent isotope effects, $k_{TFA}/k_{TFA\text{-}d}$, reported in Table 8. These ratios are small but normal, and stand in contrast to the inverse effect found for fragmentation of (9-xanthyl)acetone. The ratios, ranging from 1.25–1.51, are too small to represent rate-determining proton transfer, but of the right size for the A1 (ion pair) mechanism. Good precedent for this assignment comes from the studies by Ewing et al. (75) and by Johnson and Morrison (93) on the acid-catalyzed decomposition of *N*-arylcarbamates. These groups found, respectively, $k_{HCO3-}/k_{DCO3-} = 1.6$ for Ar = *p*-nitrophenyl and 1.4 for Ar = phenyl. By contrast, the lyonium-catalyzed reactions showed an inverse solvent isotope effect, 0.59 for *N*-phenylthiocarbamate and 0.67 for *N*-*p*-nitrophenylcarbamate (75). Equation [25] gives the A1 (ion pair) mechanism for tropylnitroalkane cleavage in trifluoroacetic acid. We did not determine the solvent isotope effect for H_3O^+ catalysis in water, but we speculate that the ion pair mechanism used in the low dielectric TFA medium might become the more typical A1 pathway in water.

Semiempirical (AM1 and PM3) calculations are in accord with our mechanistic assignments. Protonation of (7-tropyl)- nitromethane (**11a**) has an enthalpy change equal, within 0.25 kcal/mol, to that calculated for a model compound, 3-nitromethyl-1,4-cycloheptadiene. This result indicates that the tropyl group confers no unusual basicity upon the nitro moiety, and that the success of reactions [14] is therefore due to a subsequent step, namely, fragmentation to yield Tr^+. The computed barriers for the fragmentation of the conjugate acids are in the 11–12 kcal/mol range, smaller than that for (9-xanthyl)acetone and (7-tropyl)acetone (see above), suggesting a shorter lifetime toward fragmentation for compounds **11**-$\mathbf{H}^+$ compared with **6**-$\mathbf{H}^+$ and **4**-$\mathbf{H}^+$. This outcome permits the postulate that **11** fragments via the ion pair intermediate of eq. [25], which does not survive long enough to diffuse apart in contrast to the longer lived conjugate acids of **6** and **4**.

Computed geometries are also of interest. AM1 calculations show that ground state (7-tropyl)nitroalkanes prefer the pseudoequatorial conformation whereas their conjugate acids and fragmentation transition states are pseudoaxial: a weak preference is shown by the conjugate acids and a strong preference by the transition states. Bond lengths (C-7—C8 and C8—N) and bond orders are barely changed upon protonation. At the transition state the C7—C8 bond order has fallen to ~20% of the reactant state value while that of the C8—N bond has grown to 45–50% of the value for the product nitronic acid. Flattening at C7 has outpaced that at C8 by 52–34%. Bond order changes and flattening progress both show that cleavage of the C7—C8 bond runs ahead of the development of nitronic acid character.

Mechanisms: ring-opening addition of trifluoroacetic acid to 2-arylnitrocyclopropanes, 12 and 13

Recently, we reported that *trans*-2-phenyl- and *trans*-2-*p*-anisylnitrocyclopropanes, **12** and **13**, are easily cleaved at room temperature and below, giving rise to products derived from the intermediacy of nitronic acids, eq. [15] (38*a*). The reaction shows a strong dependence on the aryl substituent: $k_{13}/k_{12} > 2000$ in 4 M TFA/$CDCl_3$ equivalent to a reaction constant, $-\rho(\sigma^+) > 4$. Additionally, compound **12** exhibited a solvent kinetic isotope effect, $k_{TFA}/k_{TFA\text{-}d} = 2.1 \pm 0.1$. Reaction by protonation of the three-membered ring, known to occur for phenylcyclopropane, was ruled out. These pieces of evidence led us to formulate the mechanism as eq. [26] wherein the initial protonation step is concerted with cleavage of the C1—C2 bond.

This assignment is supported by several kinds of computational evidence at the AM1 level: first, the gap between the computed enthalpies of the *O*-protonated conjugate acids and the ring cleavage transition states has fallen to 3.9 kcal/mol for **12** and 2.5 kcal/mol for **13**. These numbers are significantly smaller than those found for the other C-C cleavages in this study, and make it easy to imagine that there exists no substantial barrier either to deprotonation or to cleavage. In other words, concerted proton-assisted ring opening is enforced by the vanishingly short lifetime of the conjugate acid.

In addition to the energetics, the computed geometries provide useful information. Protonation of **12** and **13** is accompanied by lengthening of the C1—C2 bond by 0.04 Å (**12**) and 0.05 Å (**13**) and reduction of the C1—N distance by 0.03 Å in each case. These changes represent at least 15–18% of the ultimate change in bond order for the C1-C2 cleavage and at least 18–24% of the increase in C1—N bond order that occurs upon completion of nitronic acid formation. These changes are much greater than those found for the tropylium series, **11**, and are made possible by an inter-

[25] $Tr\text{-}C(R)_2NO_2 \overset{TFA}{\rightleftharpoons} Tr\text{-}C(R)_2\overset{+}{N}O_2H\cdots TFA^- \xrightarrow{rds} Tr^+ + R_2C{=}NO_2H\cdots TFA^-$

esting feature of the calculated conjugate acid structures: the plane of the $-NO_2H^+$ group bisects that of the three-membered ring just as in the preferred conformation of a cyclopropylcarbinyl cation; this allows efficient electronic interaction between the two moieties.[8]

The solvent isotope effect obtained for **12** completes a spectrum of $k_{TFA}/k_{TFA\text{-}d}$ values ranging from inverse (for compound **6**) to weakly normal (for **11** and also for **15a**, see below) to a value for **12**, which we class as a small, but primary isotope effect (96).[9] Unencumbered by an inverse secondary effect of uncertain magnitude as found with k_{H3O+}/k_{D3O+} measurements, these results allow finer mechanistic distinctions to be made than would otherwise be possible. Table 11 compares calculated enthalpies of activation for fragmentation of the conjugate acids of compounds for which we have measured solvent isotope effects in TFA. The data show that with the exception of the cyclobutanone, **15a**, smaller $\Delta H^{\neq}$ values are accompanied by small, but regular increases in the isotope effect, a mechanistically useful result. A disadvantage in the use of TFA as a reaction medium is that many reactions of interest will be too fast to be studied at room temperature by conventional means. At the other end of the reactivity range, it is possible to increase the acidity of TFA solutions, thereby accelerating sluggish reactions, by including small amounts of $HClO_4$ or CF_3SO_3H in the medium ($HClO_4$/TFA and H_2SO_4/TFA: ref. 97*a*; CF_3SO_3H/TFA: ref. 97*b*). The utility of these media for solvent isotope effect determinations has yet to be established.

In closing this section, we call attention to the acid catalyzed cleavage of some cyclopropyl ketones. Equation [27] summarizes some of the experimental results with this class of compounds. The cleavage has been interpreted as occurring via protonation of the ring by D_2SO_4 (98), but a more straightforward explanation, consistent with our mechanism [26], is that first the carbonyl oxygen is protonated, then (subsequently or in concert) cleavage of C1-C2 occurs, leading to an enol which gives rise to the observed products. Ring-opening enolization of this type was first suggested by Kohler and Conant (100), and later by Deno et al. (101) and deMeijere (102). Mechanistic details such as the question of whether ring cleavage is stepwise or concerted with protonation have not been investigated.

Mechanisms: ring-opening isomerization of 3-arylcyclobutanones, 14 and 15

Ring-opening as well as ring-expansion and ring-contraction reactions of cyclobutanones have been known for some time. Many of these reactions have synthetic value and have been reviewed by Trost (103), Wong et al. (104), and by Lee-Ruff (105). The thermodynamic driving force behind such transformations is relief of ring strain. Rocek

[27] 
[28] 
[8]This geometric feature persists at the HF/6-31G* level of computation for protonated nitrocyclopropane but is *not* found, for example, in protonated 2-nitropropane or protonated nitrocyclobutane, which show a twist of 40–45°. A corollary prediction is that rotation about the exocyclic bond will be more difficult for protonated nitrocyclopropane and cyclopropylcarbinyl cation than for the other protonated nitro compounds. At HF/6-31G* dimethylcyclopropylcarbinyl$^+$ has a calculated $\Delta H^{\neq}$ = 13.9 kcal/mol, whereas the experimental value (95) for E_a is 13.7 ± 0.4 kcal/mol. Rotation is accompanied, computationally, by a lengthening of the C$^+$—C1 bond at the transition state of 0.07 Å. Similarly, but less dramatically, protonated nitrocyclopropane has a rotational barrier calculated at 5.7 kcal/mol with a C—N lengthening of 0.05 Å. By contrast, the rotational barriers and C-N distensions for protonated 2-nitropropane and nitrocyclobutane are calculated to be 1.3 kcal/mol (0.02 Å) and 1.2 kcal/mol (0.01 Å), respectively, all at the HF/6-31G* level.

[9]For example, Anderson and Fife (96) have observed $k(CH_3CO_2H)/k(CH_3CO_2D)$ = 2.1 for the general-acid catalyzed hydrolysis of diethylphenylorthoformate, a reaction for which Brønsted's α = 0.47, a value indicative of rate-determining proton transfer: ref. 96.

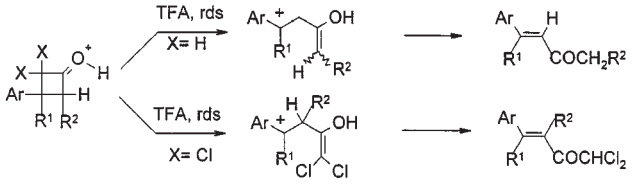
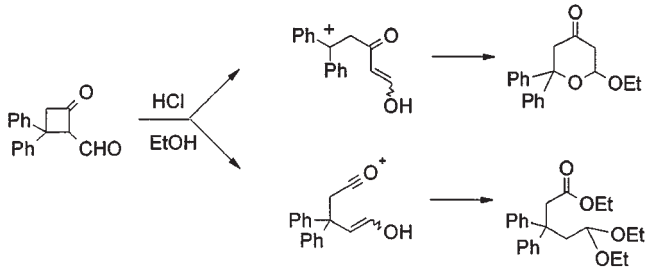
[b]Calculated as the difference, $\Delta H_f°$ (‡) – $\Delta H_f°$ (ketone). $\Delta H^{\ddagger}_{rel} = 1.37\Delta G^{\ddagger}_{exp} + 166.6$, $r^2 = 0.999$. This correlation excludes C2-substituted compounds, **15b**, **15e**, and **14a**.

[c]The difference between the bond length in the transition state and the ketone.

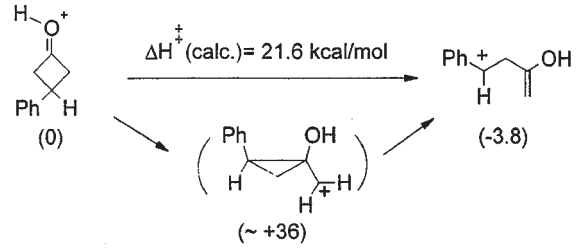
Scheme 2.



Scheme 3.



Scheme 4.



and Radkowsky (106) have estimated the strain energy for cyclobutanone at 24.5 kcal/mol. Another estimate arises from the set of homodesmotic reactions shown as eq. [28].

The average heat of reaction for these processes is 4.3 ± 0.3 kcal/mol. This indicates that cyclobutanone is less strained than cyclobutane by ca. 4.3 kcal/mol, and therefore has a strain energy of about 22 kcal/mol (107).[10]

Electrophilic activation by acids permits at least five different cleavage or rearrangement paths to occur, the result depending on the substitution pattern on the four-membered ring, the presence and location of basic sites other than the cyclobutanone oxygen, the nucleophilic properties (if any) of the medium, and the nature of the acid catalyst: strong or weak, protic or Lewis. At least four different cationic intermediates have been implicated (or merely suggested). The reactions studied by us (see eqs. [11]–[13]) are most easily understood as cleavage of the C2—C3 bond producing the most stable of the possible enols (65) along with a carbocation center at C3, see Scheme 2. This pathway is encouraged by electron donation at C3. Normally, there must be two alkyl groups at C3 (108–110), or at least one group must be aryl (110–113)[11] or vinyl (113, 114). Sufficiently good electron donors at C3 (e.g., RO, Ph; RO, RO; or R_2N) allow cleavage at moderate temperatures *without* acid catalysis (115). A relatively good nucleofuge, a conjugated enol, for example, will also help as in Scheme 3, upper path (111).[11]

A reasonable alternative to Scheme 2 is that proposed for the acetolysis of three-substituted cyclobutyl tosylates by Wiberg et al. (116). Their results were rationalized as proceeding through a bridged cyclobutyl cationic transition state to a cyclopropylcarbinyl intermediate from which the products are ultimately formed. However, this path is not tenable for our reactions, principally because the reactivity patterns for the two series are opposed. The solvolysis reactions are *retarded* by alkyl and phenyl groups at C3 in contrast to the cyclobutanone ring openings. Two phenyl groups at C3 caused further retardation of the solvolyses. All these substitutions accelerate our reaction, see Table 5. A final difference: solvolysis of the 3-aryl tosylates produced a Hammett ρ value (σ) of –1.55. From compounds **15c**, **d**, and **g**, we obtain a much larger effect, ρ = –5.5, requiring the use of σ^+ for the *p*-methyl substituent.

A further detail is revealed by the solvent isotope effect for cleavage of **15a** in trifluoroacetic acid. The rate ratio,

[10]The heat of formation of cyclobutanone was taken from Bouchoux and Houriet (107); heats of formation for the other compounds are from Pedley et al. (107); the strain energy of cyclobutane is 26.4 ± 0.2 kcal/mol: Wiberg (107).

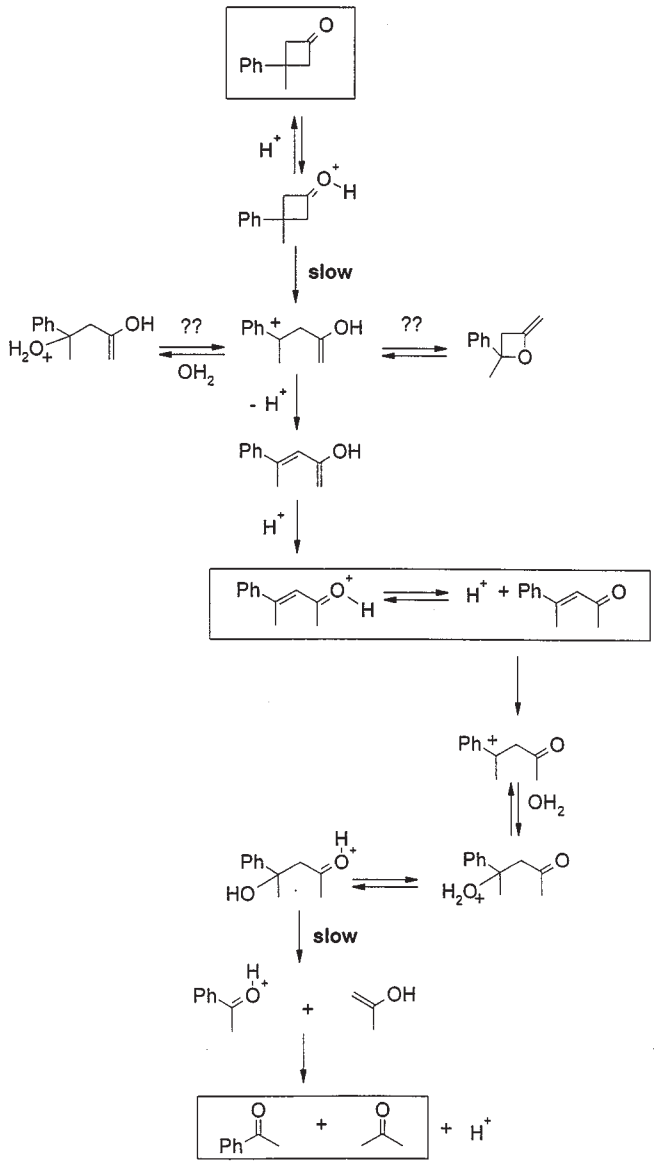
Scheme 5.



$k_{TFA}/k_{TFA\text{-}d}$ = 1.7 ± 0.1, allows placement of this reaction into the A1 (ion pair) category, although the possibility that proton transfer from TFA to substrate is at least partly rate controlling cannot be rigorously excluded.

The ring-opening isomerizations of 3-arylcyclobutanones were studied computationally using the semiempirical AM1 method, chosen because it reproduces the experimental heat of formation for cyclobutanone and its heat of isomerization to but-3-en-2-one better than do PM3 and MNDO. These calculations confirm that protonated 3-phenylcyclobutanone prefers to undergo C2-C3 cleavage forming the enolic carbocation rather than ring contraction to a cyclopropylcarbinyl cation. In fact, the ring-contracted cation is not stable toward rearrangement to the ring-opened product. This information is summarized by Scheme 4 in which relative AM1 enthalpies are given in kcal/mol.

Additionally, the computed relative enthalpies of activation for the ring-opening path, $\Delta H^{\ddagger}_{rel} = (\Delta H_f^{\ddagger} - \Delta H_f^{K})$, correlate very well with the experimental $\Delta G^{\neq}$ values for all of the ketones (K) which are unsubstituted at C2: $\Delta H^{\ddagger}_{rel}$ = 1.37 $\Delta G^{\neq}_{exp}$ + 166.6, r^2 = 0.999 (see data in Table 12). Experimentally, the replacement of H by CH_3 at C2 causes a very modest 1.5–2-fold rate enhancement (compare **15b** with **15g** and **15e** with **15f**, Table 5) even though the intramolecular regioselectivity is strong, favoring formation of the more highly substituted, more stable (82) enol intermediate. The small rate increases are likely due to a combination of opposing effects: some relief of torsional strain due to elongation of the C2—C3 bond and concomitant flattening at both termini; development of some enol character at the transition state; but both factors countered by steric inhibition of solvation. Computationally, alkylation at C2 delivers much larger rate enhancements (see Table 12), but these values are calculated for the gas phase where stabilization of a nearby positive charge by polarizable groups is an important factor, generally masked in solution.

A few calculated transition-state bond lengths are also given in Table 12 along with the differences between these lengths and those in the reactant ketone. As expected, the C2—C3 bond is considerably lengthened, while C1—C2 and C1—CO are somewhat shortened and lengthened, respectively, upon reaching the transition state. A trend can be discerned, especially for the five compounds not substituted at C2. The more reactive the ketone the less change in C2—C3 and C1—C2 lengths has occurred between the reactant and transition states — a Hammond effect. The C1—O lengthening was almost constant through the series except for the 2,2-dichloro compound, **14a**. All its bond length changes are smaller than for the other entries.

One of the cyclobutanones, 3-methyl-3-phenylcyclobutanone (**15a**), was examined in aqueous $HClO_4$ solutions. An initial ring-opening isomerization to (*E*)-4-phenylpent-3-en-2-one is overlapped in time by a retroaldol reaction leading to acetophenone and acetone: see eq. [12] and Table 6.

Taking the ring-opening reaction to have an A1 mechanism, we wished to establish the remainder of the pathway: hydration of the double bond and the final cleavage step. The hydration–dehydration equilibrium connecting enones with ketols can, in general, proceed by either of two paths: via the enol of the ketol, or by the standard carbocation mechanism. Noyce et al. (117) have shown that β-aryl-β-hydroxyketones, without sufficiently good donors at the β-carbon, use the enol mechanism. Acid-catalyzed, rate-determining enolization is followed by dehydration to the enone. With good donors at C_β, however, the mechanism passes through a carbocation at the β-carbon. The distinction is easily tested by determining the effects on the dehydration reaction rate caused by β-aryl substituents. Dehydration via the enol shows almost no substituent effect, nor does directly studied enolization. The carbocation mechanism is expected to have a large substituent effect as does the dehydration of 1-arylethanols. The relevant comparisons are found in Table 7 where it is seen that compound **18**, the ketol derived from enone **16a**, undergoes dehydration 11–12 times slower than its *p*-methyl analogue; this establishes the carbocation mechanism.

It is still possible to argue that enolization is involved for this conversion, but that enol formation is not rate determining. We argue, however, that the enol is not a competent intermediate because its rate of formation would be too

slow to account for the dehydration rate. Acid-catalyzed enolization rates are remarkably insensitive to structure (82); it is unlikely that the second-order enolization rate constant for **18** is larger than 2.5×10^{-5} M^{-1} s^{-1} (118). Additionally, the dependence of the rate of enolization upon the acidity of the medium is not great, and has been carefully investigated (83).[7] A representative example of eq. [19] quantified for acid-catalyzed enolization is log (k_{exp} (s^{-1})/[H^+]) = $0.1X$ – 4.6. With this equation, we can estimate the experimental rate constants for enolization of **18** in the $HClO_4$–H_2O media used by us for the dehydration reaction, 7.39–8.89 M $HClO_4$. Enolization is estimated to be ca. 5–40 times *slower* than the observed dehydration rates. It remains possible that at lower acidities enolization could become competitive.

Scheme 5 shows the complete mechanism for eq. [12] proposed by us. Starting from the cyclobutanone ring-opening, isomerization to the enone is the slower of the two observable stages. The retroaldol reaction then occurs, passing through the ketol. The ketol reverts to the enone faster than the retroaldol reaction, hence the rate-determining step for the latter is the C-C cleavage producing acetophenone and acetone enol. In Scheme 4, boxes enclose observable entities.

Some uncertainty remains regarding the precise state of the enone in our reaction media: how much of it is in the protonated state? In 4.30 M $HClO_4$, the UV spectrum shows λ_{max} at 283 nm. In 8.05 M $HClO_4$, this maximum shifts to 347 nm with a shoulder visible near 280 nm. We did not determine the pK_a of **16a**-H^+. Since plots of the retroaldol kinetic data using eq. [19*a*] were accurately linear over the entire acidity range used by us, we conclude that substrate protonation is a minor perturbation.

Structure and reactivity: the electrofuge

The stability of the departing electrofuge has a huge effect on the rates of C-C heterolyses; a few examples make the point clearly. As mentioned in the Introduction, neither triphenylmethylacetone nor derived alcohols cleave even in hot 100% H_2SO_4, yet the corresponding xanthyl compounds do (16, 17), see eq. [5] and [6]. Xan^+ is ca. 10^6 more stable than Ph_3C^+ in K_{R+} units. As expected, (7-tropyl)acetone (**4**) is even more reactive than (9-xanthyl)acetone (**6**), see Table 4. A second comparison involves nitroalkanes. Acid-catalyzed deprotonation at the C-N carbon is not observed, but unimolecular loss of tropylium cation from protonated (7-tropyl)nitroalkanes (**11**) is relatively facile, see Table 8.

Table 14. Comparison of fragmentation rate constants and substrate basicities for xanthyl compounds **1**, **2**, and **6**–**9** in H^+–H_2O at 25°C. See eq. [29].

Substrate	pK_{SH^+} of compound	log k_{frag} (s^{-1})[a]
1, XanOH	–3[b]	6.2
2, XanSMe	–7[b]	6.5
6, $XanCH_2COCH_3$	–3.06[c]	–4.7
7, $XanCH_2COPh$	–3.46[c]	–3.0
8, $XanCH_2COAr$[d]	–5.0[e]	–1.4
9, $XanCH_2C(CH_3)_2OH_2$	–12.5[f]	8.7

[a]Calculated as $k_{frag} = k_f°/K_{eq}$, where rate controlling fragmentation is assumed to follow equilibrium protonation of substrate (K_{eq}), except for **9**, where $K_{eq} = 1/K_{R+}$. See Table 4.

[b]Estimated using data from ref. 129.

[c]Reference 61. These are K_{BH+} values for the keto forms of the leaving groups.

[d]Ar = *p*-nitrophenyl.

[e]Reference 62. This is the K_{BH+} value for the keto form of the leaving group.

[f]Calculated from $pK_{R+} = -16.4$ for *tert*-butyl alcohol (ref. 64*a*) and log $K_{eq} = 3.9$ for the isobutylene – *tert*-butyl alcohol equilibrium: ref. 133.

Tr^+ is a more stable electrofuge than H^+ as shown by the reaction $H^+ + TrOH \rightarrow H_2O + Tr^+$, $K_{eq} = 10^{4.7}$ (51).

Less dramatic, but still large effects can be caused by tuning the stability of the carbocationic electrofuge within a series. The relative rates of cleavage of cyclobutanones **15c**, **d**, and **g** are correlated with a $\rho(\sigma^+)$ value of –5.5. Replacement at C3 of H by CH_3 or Ph produces accelerations of 180-fold and 1500-fold, respectively. The pair of 2-arylnitrocyclopropanes, **12** and **13** show that a *p*-methoxy group on the aryl ring brings about a rate enhancement greater than 2000-fold (Table 9). Other examples from cyclobutanone chemistry are found in references 110–115.

Structure and reactivity: carbon-centered nucleofuges are relatively poor

Data in Table 13 show that in general *O*-centered nucleofuges are better than *S*-centered ones, which are much better than *C*-centered nucleofuges. The entries in Table 13 are arranged in four groups; within each group the electrofuge is held constant. The basicity of the reactant is another variable that affects nucleofugality for acid-catalyzed reactions, but the effect is complex. The substrate must be protonated in order for the leaving group to depart, and this thermodynamic barrier adds to the total free energy of activation. However, the less basic the leaving group is, the greater should be its ability to leave, once protonated, other factors being equal. This reduced kinetic barrier will attenuate the thermodynamic disadvantage.

Among the first three groups in Table 13, all acid-catalyzed reactions, only in the comparison between XanOH and XanSMe does the basicity ratio, perhaps 10^4, approach or match the rate constant ratio. But if CH_3SH were a better nucleofuge than H_2O (owing to its diminished basicity), then the observed rate constant ratio favoring XanOH would be much smaller than it is. We conclude that, in this case, as in the other groups, the sulfur-centered nucleofuge is poorer than the oxygen-centered one. Further examples in support of this conclusion are given by Jensen and Jencks (79). As for the C-centered nucleophiles, it is clear from the entries that poor basicity cannot explain the greatly reduced rate constants. The final set, a group of unimolecular fragmentations, makes the same case unencumbered by the necessity to consider protonation.

Another comparison can be made using unimolecular fragmentation rate constants (calculated as described in Table 4, footnote *b*) and normalizing for substrate basicity. The process considered here is eq. [29], and the form of the comparison is a linear free energy relationship between log k_{frag} (s^{-1}) and $pK_a(SH^+)$. The data for this comparison are collected in Table 14. Although the examples are few, the data for the carbon-centered nucleofuges (compounds **6**–**9**) produce the linear correlation shown below eq. [29]. The points for the *O*-centered and *S*-centered leaving groups lie above the correlation line by 10.4 and 5.3 log *k* units, respectively. Uncertainties in the estimation of the pK_a values preclude any but a semiquantitative conclusion, but it is clear that when the basicities of the substrates are normalized, the nucleofugic reactivity order is *O*-centered > *S*-centered > *C*-centered.

[29] $$\text{Xan-XH}^+ \xrightarrow{k_{frag}} \text{Xan}^+ + \text{XH}$$

$$\log k_{frag} = 1.36\, pK_a(SH^+) - 8.30 \qquad r^2 = 0.994$$

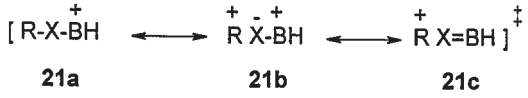
Why is C-C heterolysis intrinsically slow? Compared with C-O heterolysis, part of the disadvantage may be thermodynamic. Heats of heterolysis (in sulfolane at 25°C) measured and compiled by Arnett et al. (19*b*–*d*) show that, on average, C-O heterolysis of xanthyl substrates is 8–9 kcal/mol (ca. 6 log units) less endothermic than C-C heterolysis for leaving groups of identical basicity. The thermodynamic influence on the relative rates of C-O heterolysis may therefore be significant, although even if fully expressed at the transition state, it does not account for the observed superiority described above. The same comparison with *S*-centered leaving groups shows *no* thermodynamic advantage favoring C-S over C-C cleavage.

To address the purely kinetic factors, we adopt a simple, but useful, electrostatic point of view. We model the transition states for two processes as structures **20** and **21**. Structure **20** represents heterolysis of a neutral reactant producing carbocation R^+ and nucleofuge X^-. Structure **21** shows heterolysis of a protonated reactant in which B is a basic site and X=BH is the nucleofuge. In the first instance, **20b** will have an importance determined by the electronegativity and polarizability of X. The contribution of **20b** will be stabilizing, just as it is in strengthening a bond against homolysis. The more electronegative is X, the greater the electrostatic stabilization imparted by the contribution of **20b**. This is, of course, the idea used by Pauling (119) in establishing his electronegativity scale. Under acid catalysis, a negligible or poor leaving group can become a better one. Transition state **21** shows that the BH^+ moiety can accelerate heterolysis by increasing the importance of contributor **21b**. In addition, resonance delocalization of negativity into the BH^+ might be possible, shown by **21c**. While this effect can strongly stabi-

$$[\text{R-X} \longleftrightarrow \text{R}^+\text{X}^-]^{\ddagger}$$

20a **20b**

© 1999 NRC Canada



lize the product nuclofuge, X=H, its contribution to the transition state *diminishes* the favorable electrostatic interaction represented by **21b**. As in **20**, when X is carbon rather than oxygen, contributor **21b** will be less important, and compensation by **21c** does not, as just described, fully remedy this deficiency. This sort of argument was first made by Bell (120) in discussing proton transfer at carbon (slow) relative to that at heteroatoms. (Note that Bell's analysis offers one way of viewing the "nitroalkane anomaly" and other examples of "transition state imbalance" (see ref. 121)). The importance of electrostatic stabilization by triple-ion contributors analogous to **21b** has been predicted by computation (122) and inferred from experiment (123) for gas phase S_N2 reactions. It has also recently been confirmed by high level computations of the transition states for identity proton transfer reactions between a variety of first- and second-row nonmetal hydrides and their conjugate bases (124*a*; additional relevant calculations involving proton transfer between carbons are found in Bernasconi et al. (124*b*)).

Structure and reactivity: ring strain and stereoelectronic effects

Previous discussion has demonstrated the very large influence of acid catalysis and the stability of the electrofuge in determining the success or failure of C-C heterolysis. In this section, we address the even greater potential for reactivity made possible by relief of ring strain. First, a qualitative observation: Although 3,3-diphenylcyclobutanone (**15f**) opens at 25°C in TFA with a half life of about 1 min, 3,3-diphenylcyclopentanone remains unchanged in TFA for at least a month. This represents a rate factor of more than 50 000. Next, two quantitative comparisons are given. One is the comparison between 1-(7-tropyl)nitroethane (**11b**) and *trans*-2-phenylnitrocyclopropane (**12**). These two cleave in TFA, each yielding a monoalkylnitronic acid, $RCH{=}NO_2H$, at virtually the same rate despite the enormous difference in stability between the electrofugic moieties. Tropyl cation has pK_{R+} = 4.75 (51, 52), while $PhCHR^+$, modeled by $PHCHCH_3^+$, has $pK_R^+ \cong -15.3$ (125). The ΔpK_R^+ of approximately 20 units corresponds to 27 kcal/mol at room temperature. As noted before (38*a*), this corresponds to the strain energy of a cyclopropane ring. Fractional development of carbocation character at the transition state, a factor favoring cleavage of **11b**, is almost exactly balanced by fractional relief of ring strain! The second example compares the cleavages of (9-xanthyl) acetone (**6**) and 3-methyl-3-phenylcyclobutanone (**15a**), both of which produce an enol, $CH_2{=}C(OH)R$, and a carbocation. They do so at identical rates in H_2O and at rates differing only by a factor of 13 in TFA. The pK_{R+} of xanthyl$^+$ found in this work is –0.85, while that for $PhC(CH_3)R^+$, modeled by $PhC(CH_3)_2^+$, is estimated to be –11.8 using the correlation of Arnett and Hofelich (63). This difference amounts to almost 15 kcal/mol worth of stability in favor of xanthyl$^+$, but which is matched by relief of ring strain.

Both three- and four-membered rings provide huge rate accelerations for C-C cleavage, but the greater effect is seen with opening of cyclopropanes. Many examples of the comparative reactivity of three- and four-membered rings have been documented and discussed (126). Often, the examples are of ring-closure reactions, but since the two rings have almost the same strain energies (107),[10] the ease of closing a three-membered ring (relative to a four-membered ring) corresponds to the same relative ease of opening a three-membered ring.[12]

In the present case, we are dealing with acid-catalyzed reactions, and it is pertinent to ask whether the basicities of the nitrocyclopropane and cyclobutanone compounds are unusual enough to contribute either to the acceleration of the C-C cleavages or to the different acceleration produced by the two differently sized rings. Lacking experimental information on the basicities of nitrocompounds, we have performed semiempirical (AM1) and ab initio calculations of the proton affinities of some nitroalkanes. Compounds **11b** and **12** have, by the AM1 method, proton affinities of 189.5 and 187.1 kcal/mol, respectively. That is, the tropyl compound is the *more* basic. At the HF/6-31G* level (including corrections for zero point vibrational energy and thermal energy), we find proton affinities (298 K) for 2-nitropropane and nitrocyclopropane of 189.5 and 188.8 kcal/mol, respectively. Again, the acyclic example is more basic; that is, increased basicity for the nitrocyclopropanes is not evident and cannot, therefore, contribute to a rate acceleration. Our evidence, in fact, indicates that the protonated nitrocyclopropanes are avoided: protonation is concerted with C-C cleavage, and is accompanied by release of ring strain and an increase in basicity at the NO_2 oxygens (38*a*). All these factors combine to produce a remarkable activating effect. The story is only slightly different for the cyclobutanones. Cyclobutanone itself has an experimental proton affinity of 191.8 kcal/mol; it is 5.9 kcal/mol *less* basic than 2-butanone.[13] By the AM1 method 3-methyl-3-phenylcyclobutanone is *less* basic than (9-xanthyl)acetone by 14.9 kcal/mol. Accelerated C-C cleavage occurs despite a sizeable disadvantage in apparent basicity at the carbonyl oxygen. Again other factors, for example, relief of ring strain, more than compensate.

With regard to the comparison between the ring openings of cyclopropanes and cyclobutanes, computational evidence offers some insights. Gronert et al. (127) have reported high level calculations of nucleophilic ring closures leading to three- and four-membered rings. Cyclization to three-membered rings is characterized by unusually low enthalpies of activation — lower than for the bimolecular S_N2 analogue. Two factors were highlighted. One is that the reactant state is destabilized by a nonbonding 1,3-interaction between the nucleophilic and electrophilic centers, an interaction that has no counterpart in the intermolecular case. It is as though the reactant is already partly activated by this "proximity effect." The second factor is that the transition state comes early in the closure, before bond angle strain (the only major

[12]The homodesmotic reaction, cyclopropane + butane → cyclobutane + propane, has ΔH_{RXN} = –1 kcal/mol (107).

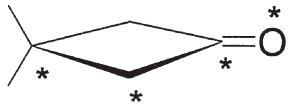
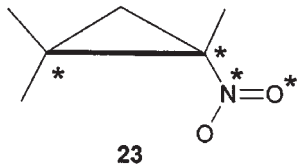
strain element at that point on the reaction coordinate) has increased very much. In terms of a ring-*opening* process, most of the ring strain has vanished at the transition state. Both effects are less important for four-membered than for three-membered rings (127*a*), and less of the ring strain energy is released at the ring-opening transition state.

There is another computational difference between the ring openings of three- and four-membered rings that we wish to note. This difference focuses on the torsional (dihedral) angle containing the breaking C—C bond, the forming C=C bond (cyclobutanone cleavages) or C=N bond (nitrocyclopropane cleavages), and the C=O (or N=O) bond of the electron-withdrawing group (see structures **22** and **23**; the starred atoms define the dihedrals). AM1 calcu-



22



23

lations on 2-phenylnitrocyclopropane (**12)** and cyclobutanones **15a** and **15g** show that the three-membered ring undergoes but a 7.5° change in this angle as the opening proceeds from reactant to protonated transition state. Moreover, the torsion occurs about an *exo*cyclic bond. The four-membered rings however must twist approximately 35° about an *endo*cyclic bond to reach the transition state. We propose that torsional stress, a costly condition in a small, relatively rigid ring, contributes significantly to the activation barrier for opening the four-membered rings, but much less for the three-membered rings. That is, we invoke the principle of least nuclear motion (128).

Conclusions

Acid-catalyzed C-C cleavages, eqs. [1] and [2], can be made conveniently fast by varying a number of structural and environmental factors. These include:

(*i*) The acidity of the medium. Enormous variation is possible, especially when nonleveling solvents are used.

(*ii*) The basicity of the nucleofuge, X, and the nucleofugality of its conjugate acid, XH, or C=C-XH. These two influences can oppose each other; the more basic is X, the less nucleofugic tends to be XH. Even substrates so weakly basic as alkenes and nitroalkanes can be induced to fragment if other factors are made favorable.

(*iii*) The stability of the electrofuge. Sufficient stability on the part of the carbocation moiety can change a failed reaction into a successful one.

(*iv*) Relief of strain. Strain release associated with opening small rings can produce spectacular rate increases. Appropriately substituted cyclopropanes can be made particularly reactive, undergoing C-C cleavage in concert with a protonation event. The cleavage of cyclobutanones, themselves easily prepared, is useful for the preparation of conjugated enones.

Additionally, we advocate the use of trifluoroacetic acid, neat or diluted with a nonbasic solvent, for the investigation of mechanistic detail through determination of solvent kinetic isotope effects on acid-catalyzed reactions. The isotope effect caused by the transferred hydrogen is uncontaminated by the inverse secondary effects which occur when H_3O^+ and D_3O^+ are used.

Acknowledgements

We are pleased to acknowledge Dr. Robert G. Bergstrom and Professor Claude Bernasconi for help with the use of the temperature-jump equipment at University of California, Santa Cruz. We also thank Professor Scott Gronert of San Francisco State University for valuable discussions. We are grateful for financial support from the NSF (no. CHE-9729001), and The Petroleum Research Fund, administered by the American Chemical Society. This research was partially supported by a Research Infrastructure in Minority Institutions award from the National Center for Research Resources with funding from the Office of Research on Minority Health, National Institutes of Health no. 5 P20RR11805.

Formation of a cyclic tetrahedral intermediate by the addition of water to 2-methyl-4H-3,1-benzoxazine followed by ring opening to 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol; pH-dependence of rate of reaction and product ratio

Wendy J. Dixon and Frank Hibbert

Abstract: Kinetic studies have shown that addition of water to protonated 2-methyl-4H-3,1-benzoxazine occurs to give a cyclic tetrahedral carbonyl addition intermediate. At pH <5, the intermediate is protonated and reacts to 2-aminobenzyl acetate, whereas at pH >7.5, the unprotonated intermediate collapses to give 2-acetylaminobenzyl alcohol. The former reaction is catalysed by buffer base but the latter is uncatalysed. At pH 9–12, reaction of hydroxide ion with protonated 2-methyl-4H-3,1-benzoxazine to give 2-acetylaminobenzyl alcohol becomes important, and at pH >12, the same product is formed by reaction of hydroxide ion with unprotonated 2-methyl-4H-3,1-benzoxazine.

Key words: mechanism, addition, tetrahedral intermediate, hydrolysis, pH profile.

Résumé : Des études cinétiques ont montré que l'addition d'eau à la 2-méthyl-4*H*-3,1-benzoxazine protonée se produit pour donner un intermédiaire d'addition au carbonyle de nature tétraédrique et cyclique. À un pH <5, l'intermédiaire est protoné et réagit vers l'acétate du 2-aminobenzyle alors qu'à pH >7,5, l'intermédiaire non protoné se décompose pour donner l'alcool 2-acétylaminobenzylique. La première réaction est catalysée par une base tampon, mais la dernière n'est pas catalysée. À des pH allant de 9–12, la réaction de l'ion hydroxyde avec la 2-méthyl-4*H*-3,1-benzoxazine protonée conduisant à l'alcool 2-acétylaminobenzylique devient important et à un pH >12, le même produit se forme par réaction de l'ion hydroxyde avec 2-méthyl-4*H*-3,1-benzoxazine non protonée.

Mots clés : mécanisme, addition, intermédiaire tétraédrique, hydrolyse, profil de pH.

[Traduit par la Rédaction]

Introduction

In the pH range 1–5, 2-methyl-4H-3,1-benzoxazine undergoes addition of water and ring opening to give 2-aminobenzyl acetate, eq. [1] (1). The form of the rate coefficient – pH profile and the observation of rectilinear plots of rate coefficient against the concentration of buffer base have identified the mechanism shown in Scheme 1. The collapse of the cyclic tetrahedral intermediate to product involves uncatalysed and buffer base (B) catalysed pathways, and the variation of the observed first-order rate coefficient with concentration of buffer base is given by eq. [2]. At low buffer concentrations, buffer base catalysed collapse of the tetrahedral intermediate to 2-aminobenzyl acetate is rate-limiting, but at high buffer concentrations, addition of water to protonated 2-methyl-4H-3,1-benzoxazine becomes rate-limiting. In previous studies, measurements were limited to pH <5, under which conditions reaction occurs to give 2-aminobenzyl acetate in greater than ca. 95% yield. At higher pH values, it was noted (1) that increasing amounts of 2-acetylaminobenzyl alcohol were formed, eq. [3]. It was also found that at fixed pH the proportion of 2-aminobenzyl ace-

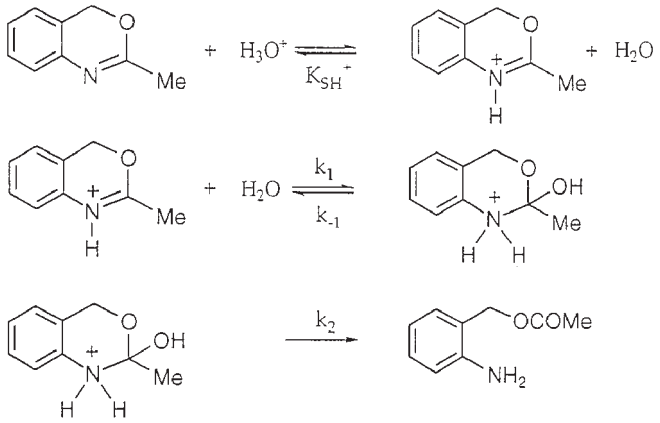
Scheme 1.



tate formed as product compared with 2-acetylaminobenzyl alcohol increased as the concentration of buffer base was increased, implying that reaction to the amide is less susceptible to buffer catalysis than formation of the ester. We have now investigated the factors influencing the formation of ester and amide and the kinetics of the formation of the amide in detail over the whole of the pH range. The reaction of acyclic imidates is known to give amides and esters depending on the reaction conditions and evidence is available to support the participation of tetrahedral carbonyl addition intermediates (2, 3). The tetrahedral carbonyl addition intermediates involved in the present work are cyclic, and their stability relative to reactants and products compared with that of acyclic intermediates is of particular interest.

Experimental

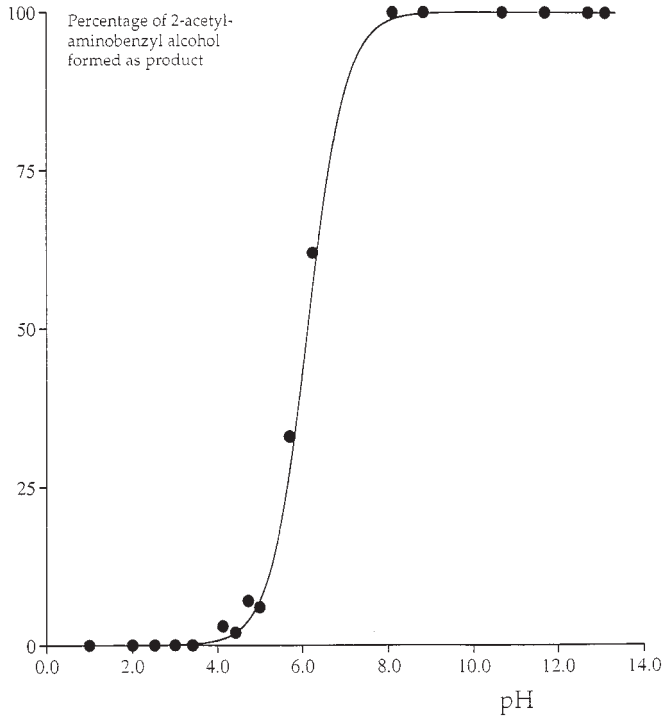
Materials

The preparations of 2-methyl-4H-3,1-benzoxazine, 2-aminobenzyl acetate, and 2-acetylaminobenzyl alcohol have been described previously (1). Carboxylic acid buffer solutions were made up by partial neutralization of a standardized solution of the carboxylic acid with a standard solution of potassium hydroxide. Buffer solutions of dihydrogen orthophosphate monoanion and monohydrogen orthophosphate dianion were made up by partial neutralization of a solution of potassium dihydrogen orthophosphate with a standard solution of potassium hydroxide. Buffer solutions of tris(hydroxymethyl)aminomethane and 2-amino-2-methyl-1,3-propanediol with the corresponding protonated amine were made up by partial neutralization of a standardized solution of the amine with standard hydrochloric acid solution. The ionic strength of all solutions was maintained at 0.25 mol dm^{-3} by addition of a weighed quantity of potassium chloride. Double distilled water was used for the preparation of solutions. Reactions under various conditions were begun by injecting 0.01 cm^3 of a concentrated solution of 2-methyl-4H-3,1-benzoxazine in Me_2SO into the reaction medium (3 cm^3).

Product analysis

The products of hydrolysis of 2-methyl-4H-3,1-benzoxazine were identified from the changes in UV spectrum accompanying the reaction. In the range pH 1–5, the final

Fig. 1. Reaction of 2-methyl-4H-3,1-benzoxazine to 2-acetylaminobenzyl alcohol and 2-aminobenzylacetate; variation with pH of the percentage of 2-acetylaminobenzyl alcohol.



spectrum following reaction was found to be quantitatively identical with the spectrum of an authentic sample of 2-aminobenzyl acetate, and at pH 7.5–13, the spectrum of the product was identical with that of 2-acetylaminobenzyl alcohol. At intermediate pH values of 5–7.5, hydrolysis of 2-methyl-4H-3,1-benzoxazine results in a mixture of 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol, depending on the pH and buffer concentration. In acetate, pivalate, and phosphate buffers, the exact composition of the product mixture was calculated from the measured absorbance at 284 nm using the known absorbance of 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol at this wavelength. Results for the variation with pH of the fraction of 2-acetylaminobenzyl alcohol compared with 2-aminobenzyl acetate formed as product are shown in Fig. 1. The results were obtained at a buffer concentration of ca. 0.01 mol dm^{-3} in the basic component of the buffer. The points in Fig. 1 are experimental values, and the solid line is a best fit predicted from the mechanism in Scheme 2 (see below). It was also found that the percentage of 2-aminobenzyl acetate formed increased with buffer base concentration, indicating that reaction to 2-aminobenzyl acetate was more susceptible to catalysis by buffer than reaction to 2-acetylaminobenzyl alcohol. This was confirmed in kinetic studies (see below).

Kinetic measurements

The methods used to study the kinetics of the ring opening of 2-methyl-4H-3,1-benzoxazine to 2-aminobenzyl acetate in the pH range 1–5 have been described previously (1). In the present work, kinetic measurements of the reaction of 2-methyl-4H-3,1-benzoxazine to 2-aminobenzyl acetate and

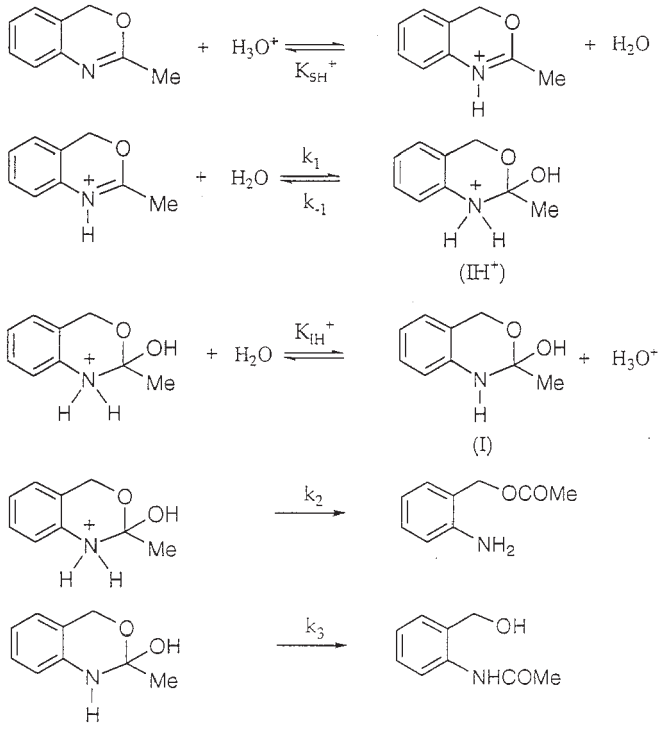
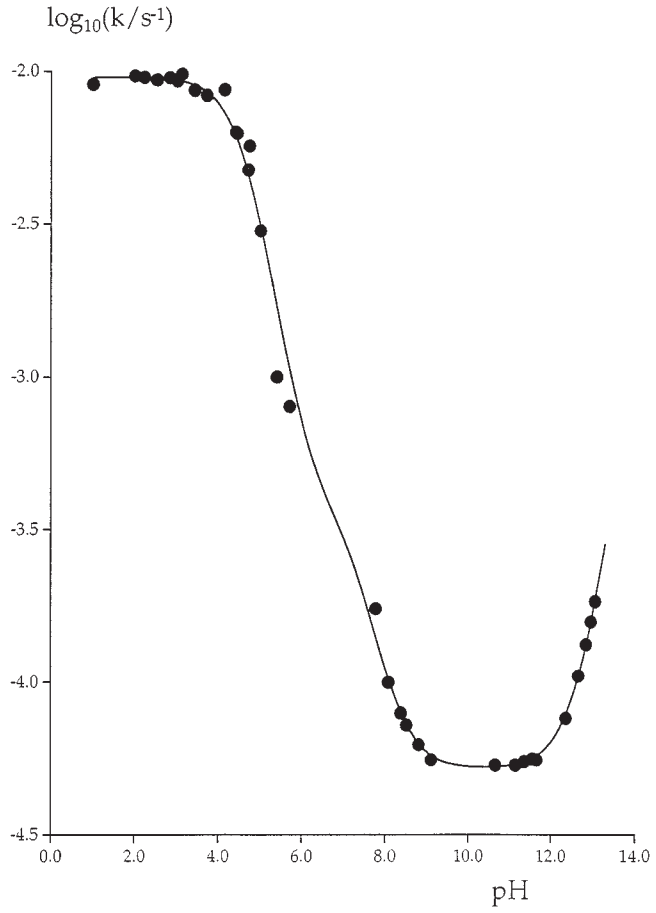
Scheme 2.



to 2-acetylaminobenzyl alcohol were made at pH values 5–13 at 298.2 K and ionic strength 0.25 mol dm^{-3}. Studies in the range pH 6–9 were made in buffers of orthophosphate monanion and dianion (pK_a 6.52) (4)[2] and of tris(hydroxymethyl)aminomethane (pK_a 8.07) (5)[3] and 2-amino-2-methyl-1,3-propanediol (pK_a 8.80) (5)[3] with the corresponding protonated amines at various buffer ratios. The dependence of the rate of reaction on buffer concentration was also investigated. Solutions of potassium hydroxide with concentrations in the range 0.001–0.25 mol dm^{-3} were used for studies at higher pH. Reactions were begun by injecting a concentrated solution of 2-methyl-4H-3,1-benzoxazine in Me_2SO into the reaction mixture to give an initial concentration of ca. 1.0×10^{-4} mol dm^{-3}. The concentration of 2-methyl-4H-3,1-benzoxazine was always kept in at least 10-fold deficit compared with buffer species or hydronium ion or hydroxide ion. Hydrolysis was followed by observing the UV spectral change with time. In a buffer of tris(hydroxymethyl)aminomethane (buffer ratio 1.0, pH 8.07 at a buffer concentration of 0.25 mol dm^{-3} in each buffer component), the spectral changes with time occurred to give clean isosbestic points at 242 and 308 nm. Reactions were usually followed by measuring the decrease in absorbance at 261 nm and were found to be accurately of first order. The value of the first-order rate coefficient (k_{obs}) was determined from an exponential fit to the variation of absorbance with time over at least three half lives. Reactions were followed for a sufficient time to allow the determination of an absorbance value corresponding to complete reaction except in the case of some of the slowest reactions. Correlation coefficients were typically 0.9999, and standard deviations of the calculated first-order rate coefficients were typically less than 1% The reactions occurred with half-lives in the range ca. 40 – 3.5×10^3 s.

Fig. 2. Dependence on pH of the rate coefficient ($\log_{10}$ k/s^{-1}) for the ring opening of 2-methyl-4H-3,1-benzoxazine in aqueous solution.



Results and discussion

Rate–pH profile

The pH dependence of the rate coefficient (k) for the hydrolysis of 2-methyl-4H-3,1-benzoxazine is shown in Fig. 2. The data were obtained from studies in solutions of hydrochloric acid and potassium hydroxide or in the presence of buffers. The value of the rate coefficient (k) given for hydrolysis in buffer solutions was obtained by extrapolation of the observed rate coefficient (k_{obs}) to zero buffer concentration and hence refers to reaction involving species derived from the solvent (water). In the range pH 1–5 the product of reaction at high buffer concentrations is exclusively 2-aminobenzyl acetate, and at pH 7.5–13, 2-acetylaminobenzyl alcohol is the sole product. In the region 5–7.5, hydrolysis of 2-methyl-4H-3,1-benzoxazine yields a mixture of 2-

[2] The pK_a value (7.20) (ref. 4) for dihydrogen orthophosphate monoanion at infinite dilution was adjusted to ionic strength (I) 0.25 mol dm^{-3} using the Debye–Huckel expression $-\log \gamma_{\pm} = 0.51 Z_i^2 \sqrt{I}/(1 + \sqrt{I})$.

[3] The value of pK_a at infinite dilution (5) was used uncorrected for the present conditions of ionic strength 0.25 mol dm^{-3}.

aminobenzyl acetate and 2-acetylaminobenzyl alcohol depending on the reaction conditions. The results in each of these pH regions will be considered in turn.

Reaction to 2-aminobenzyl acetate at pH 1–5

Data for hydrolysis in the range pH 1–5 have been published (1). Reaction occurs by addition of water to the protonated form of 2-methyl-4H-3,1-benzoxazine to give a cyclic tetrahedral addition intermediate which collapses to 2-aminobenzyl acetate, Scheme 1. Evidence for the involvement of a tetrahedral addition intermediate on the reaction pathway was provided by the observation of rectilinear plots of the observed rate coefficient against buffer base concentration as described earlier. According to the mechanism in Scheme 1, the rate coefficient for hydrolysis of 2-methyl-4H-3,1-benzoxazine extrapolated to zero buffer concentration is given by eq. [4] in which K_{SH^+} is the acid dissociation

$$[4] \qquad k = k_1k_2[H_3O^+]/(k_{-1} + k_2)(K_{SH^+} + [H_3O^+])$$

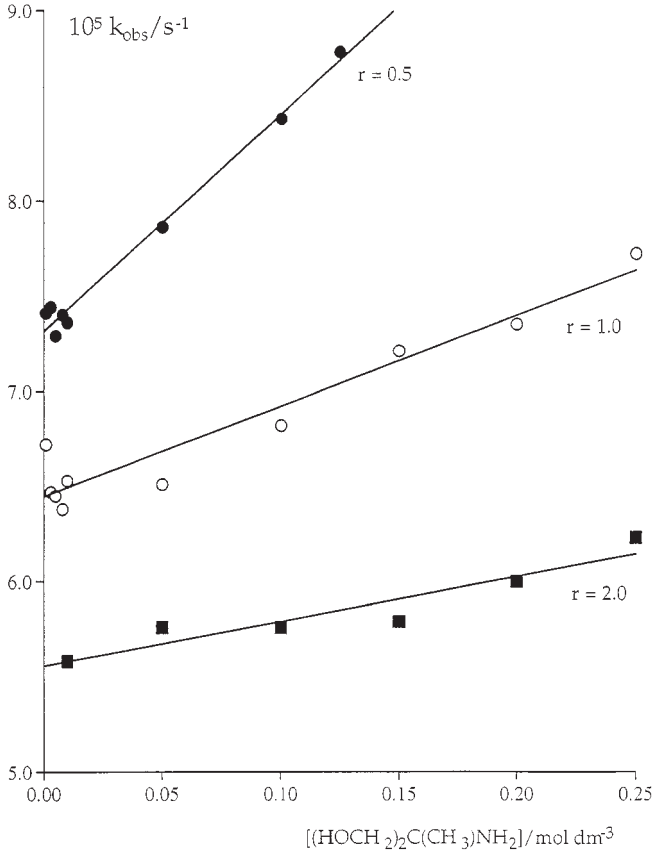
constant of protonated 2-methyl-4H-3,1-benzoxazine and the rate coefficients k_1, k_{-1}, and k_2 refer to the steps in Scheme 1. The solid line in Fig. 2 through the data points in the region pH 1–5 is a best-fit of eq. [4] to the experimental results (1) using the values shown in Table 1 for K_{SH^+}, k_1, and $k_2/(k_{-1} + k_2)$. The observed rectilinear dependence of the first-order rate coefficient (k_{obs}) on buffer concentration, eq. [2], was used to deduce values for the ratio $k_B/(k_{-1} + k_2)$ where k_B is the value of the second-order rate coefficient for catalysis of the collapse of the tetrahedral intermediate to 2-aminobenzyl acetate by chloroacetate, formate, acetate, and pivalate ions. The value of the rate coefficient ratio $k_B/(k_{-1} + k_2)$ was found to increase with increase in base strength of the catalysing buffer, giving a Brønsted plot with a value of β ca. 0.8 for the Brønsted exponent. It was also found that the value of the rate coefficient ratio $k_2/(k_{-1} + k_2)$ for spontaneous collapse of the intermediate with k_2 corrected to a second-order rate coefficient for reaction with water fitted the Brønsted plot for catalysis by buffers. This is compatible with the solvent acting as a base in catalysing the collapse of the tetrahedral intermediate.

Reaction to 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol at pH 5–9

In the present work, kinetic studies have been extended above pH 5, and the hydrolysis of 2-methyl-4H-3,1-benzoxazine gives a mixture of 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol, depending on the reaction conditions. Measurements were made in pivalate, phosphate, and in amine buffers.

In buffers of 2-amino-2-methyl-1,3-propanediol and of tris(hydroxymethyl)aminomethane (pH 7.8–9.1) where the reaction occurs to give exclusively 2-acetylaminobenzyl alcohol, there is a shallow dependence of k_{obs} on buffer concentration. Data for the reaction in buffers of 2-amino-2-methyl-1,3-propanediol buffer at different buffer ratios (r = [B]/[BH$^+$]) are shown in Fig. 3. The increase in k_{obs} with buffer concentration up to a concentration of the buffer cation of 0.125 mol dm^{-3} amounts to ca. 10, 8, and 9% at buffer ratios of r = 0.5, 1.0, and 2.0, respectively. Similar effects are observed in buffers of tris(hydroxymethyl)aminomethane. The shallow dependence on buffer concentration could be due to a salt effect as the inert salt (potassium chloride) is replaced by the buffer cation at constant ionic strength. A similar effect was previously observed in the reaction of 2-methylnaphth[1,8-de]-1,3-oxazine to 1-hydroxy-8-acetylaminonaphthalene in acetate buffers and was attributed to a salt effect (6). However, the possibility of weak buffer catalysis cannot be ruled out.

Fig. 3. Variation of the rate coefficient (k_{obs}/s^{-1}) with concentration for buffers of 2-amino-2-methyl-l,3-propanediol at different buffer ratios (r).



In the lower pH range, measurements were made in the presence of buffers of dihydrogen orthophosphate monoanion and monohydrogen orthophosphate dianion at buffer ratios r ($HPO_4^{2-}/H_2PO_4^-$) 0.5, 1.0, and 2.0, corresponding to pH values 6.22, 6.52, and 6.82. The change in k_{obs} with buffer concentration was small. For example, at a buffer ratio r = 1.0, the value of k_{obs} increased from 0.114 to 0.230 s^{-1} as the

© 1999 NRC Canada

buffer base concentration was increased from 0.001 to 0.05 mol dm^{-3}. At buffer ratios of r = 0.5 and 2.0, the values of k_{obs} increased from 0.213 to 0.447 s^{-1} and from 0.0671 to 0.107 s^{-1}, respectively. Extrapolation to zero buffer concentration gave values of k that did not fit the rate–pH profile determined in other buffers. At these pH values, the reaction of 2-methyl-4H-3,1-benzoxazine occurs to give both 2-aminobenzyl acetate and 2-acetylaminobenzyl alcohol. Although the latter reaction is not susceptible to strong catalysis by buffer, the reaction to 2-aminobenzyl acetate is catalysed by buffer. Details of the catalysis of the reaction to 2-aminobenzyl acetate by carboxylic acid buffers can be used to predict the behaviour in orthophosphate buffers. The variation of k_{obs} with buffer concentration for reaction of 2-methyl-4H-3,1-benzoxazine to 2-aminobenzyl acetate is given by eq. [2]. Extrapolation of the Brønsted plot for the variation of the value of $k_B/(k_{-1} + k_2)$ with base strength for carboxylic acid buffers (1) gives the result $k_B/(k_{-1} + k_2)$ = 1.92 × 10^3 dm^3 mol^{-1} for catalysis by monohydrogen orthophosphate dianion. This value can be used to predict that for the reaction of 2-methyl-4H-3,1-benzoxazine to 2-aminobenzyl acetate in a phosphate buffer, catalysis will be close to the upper limiting value of the rectilinear dependence of k_{obs} against buffer concentration for most of the concentrations of monohydrogen orthophosphate dianion studied. At a buffer ratio r = 1.0 and a buffer concentration of 0.001 mol dm^{-3}, catalysis will have reached ca. 66% of the limiting rate. It follows that extrapolation of values of k_{obs} obtained in the range $[HPO_4^{2-}]$ 0.001–0.05 mol dm^{-3} to zero buffer concentration is unreliable, and the results are not included in the rate–pH profile in Fig. 2.

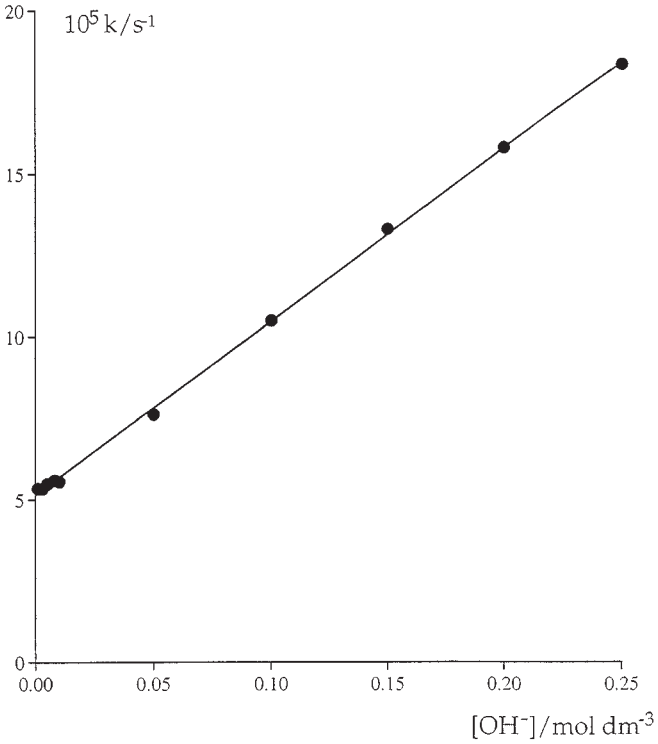
A mechanism that is compatible with the effect of pH on product ratio and with the dependence of the rate coefficient extrapolated to zero buffer concentration on pH in the range 0–9 is shown in Scheme 2. The mechanism differs from that in Scheme 1 used to explain the kinetics and formation of 2-aminobenzyl acetate in acidic solution by the inclusion of a route for collapse of an unprotonated form of the cyclic tetrahedral intermediate to 2-acetylaminobenzyl alcohol. It is assumed that collapse of the intermediate IH^+ to 2-aminobenzyl acetate is catalysed by buffer base but that collapse of the unprotonated intermediate (I) to 2-acetylaminobenzyl alcohol is uncatalysed by buffer species. If the proton transfer steps in Scheme 2 are assumed to occur rapidly and the intermediates IH^+ and I are present in low concentration, the expression in eq. [5] is obtained for the pH dependence of the rate coefficient for disappearance of 2-methyl-4H-3,1-benzoxazine.

$$[5] \qquad k = \frac{k_1[H_2O][H_3O^+](k_2[H_3O^+] + k_3K_{1H^+})}{(K_{SH^+} + [H_3O^+])\{k_3K_{1H^+} + (k_{-1} + k_2)[H_3O^+]\}}$$

$$[6] \qquad \frac{100[A]}{([E] + [A])} = \frac{100k_3K_{1H^+}}{(k_3K_{1H^+} + k_2[H_3O^+])}$$

According to the mechanism in Scheme 2, the percentage of 2-acetylaminobenzyl alcohol (A) formed as product compared with 2-aminobenzyl acetate (E) is given by the expression in eq. [6]. The results obtained for the percentage of 2-acetylaminobenzyl alcohol formed as product compared with 2-aminobenzyl acetate were plotted in the reciprocal form of eq. [6], and linear regression analysis gave a value for $k_2/k_3K_{1H^+}$ of 1.29 × 10^6 mol^{-1} dm^3. This result was used in eq. [6] to calculate the solid line in Fig. 1 for the pH dependence of the percentage of 2-acetylaminobenzyl alcohol formed as product.

Fig. 4. Variation of the rate coefficient (10^5 k/s^{-1}) for ring opening of 2-methyl-4H-3,1-benzoxazine with hydroxide ion concentration.



At pH <5 where 2-aminobenzyl acetate is the exclusive product, the terms involving k_3 can be neglected, and eq. [5] reduces to eq. [4]. In the pH region 8–9 where 2-acetylaminobenzyl alcohol is the only product, the terms involving k_2 can be neglected, and eq. [5] reduces to eq. [7]. If it is further assumed that $k_3K_{1H^+} > k_{-1}[H_3O^+]$, eq. [8] is obtained, which further reduces to eq. [9] on the assumption that $K_{SH^+} > [H_3O^+]$. Equation [9] predicts a direct dependence of k against $[H_3O^+]$. The experimental values of k in the range pH 7.8–9.1 were plotted against $[H_3O^+]$. However, a linear plot with gradient 7.1 × 10^3 dm^3 mol^{-1} s^{-1} and intercept 4.9 × 10^{-5} s^{-1} was obtained from linear regression analysis rather than the direct dependence of k against $[H_3O^+]$ predicted by eq. [9]. It was therefore necessary to modify the rate expression to include a pH-independent rate term k_0 as in eq. [10]. Thus, eq. [10] is compatible with the experimental results with values of k_1/K_{SH^+} = 7.1 × 10^3 dm^3 mol^{-1} s^{-1} and k_0 = 4.9 × 10^{-5} s^{-1}.

$$[7] \qquad k = k_1[H_2O][H_3O^+]k_3K_{1H^+}/(K_{SH^+} + [H_3O^+])(k_3K_{1H^+} + k_{-1}[H_3O^+])$$

$$[8] \qquad k = k_1[H_2O][H_3O^+]/(K_{SH^+} + [H_3O^+])$$

$$[9] \qquad k = (k_1/K_{SH^+})[H_2O][H_3O^+]$$

Reaction to 2-acetylaminobenzyl alcohol at pH 10–13

In the range pH 10–13, the product of reaction is 2-acetylaminobenzyl alcohol. Kinetic studies in this region were made in solutions of potassium hydroxide at concentrations in the range 0.001–0.25 mol dm^{-3}. The dependence of the measured first-order rate coefficient on hydroxide ion concentration is linear as shown in Fig. 4 with linear regression gradient $k_{OH} = 5.3 \times 10^{-4}$ dm^3 mol^{-1} s^{-1} and intercept $k_0 = 5.2 \times 10^{-5}$ s^{-1}. Hence, a pH-independent term and a term that is of first order in hydroxide ion contribute to the rate in this region, eq. [11]. The pH-independent term with a slightly

$$[11] \quad k = k_0 + k_{OH}[OH^-]$$

different value $k_0 = 4.9 \times 10^{-5}$ s^{-1} was also found from the variation of k with $[H_3O^+]$ in the range 7.8–9.1, eq. [10]. The average of these two values leads to k_o 5.1×10^{-5} s^{-1}.

A mechanism that is compatible with the formation of 2-acetylaminobenzyl alcohol as the sole product and with the experimentally observed dependence of k against $[OH^-]$ shown in Fig. 4 involves addition of hydroxide ion to protonated and unprotonated forms of 2-methyl-4H-3,1-benzoxazine to give a tetrahedral intermediate which collapses to product, Scheme 3.

In Scheme 3, it can be assumed that the tetrahedral intermediates are present in low concentration. The pH-independent term and the first-order term in hydroxide ion are explained by reaction of hydroxide ion with the protonated and unprotonated forms of 2-methyl-4H-3,1-benzoxazine, respectively. An alternative mechanism that will explain the pH-independent term involves reaction of the unprotonated form of 2-methyl-4H-3,1-benzoxazine with solvent. The relative importance of these two possibilities for the pH-independent term can be assessed by comparison of the value of the rate coefficient k_0 with the values of the other rate coefficients in the mechanism. If the pH-independent term arises from reaction of hydroxide ion with protonated 2-methyl-4H-3,1-benzoxazine, the result k_0 5.1×10^{-5} s^{-1} corresponds to a second-order rate coefficient for reaction with hydroxide ion of 5.7×10^4 dm^3 mol^{-1} s^{-1} using the values of K_{SH^+} 2.4×10^{-5} mol dm^{-3} for the acid dissociation constant of protonated 2-methyl-4H-3,1-benzoxazine and $K_w = 2.19 \times 10^{-14}$ mol^2 dm^{-6} for the ionic product of water under the reaction conditions. This is to be compared with the value $k_1 = 3.1 \times 10^{-3}$ dm^3 mol^{-1} s^{-1} obtained for the reaction of water with protonated 2-methyl-4H-3,1-benzoxazine. The 1.8×10^7-fold difference seems reasonable in view of the very large difference in nucleophilicity of hydroxide ion and water. If the pH-independent term arises from rate-limiting attack of water on unprotonated 2-methyl-4H-3,1-benzoxazine, the result k_0 5.1×10^{-5} s^{-1} corresponds to a second-order rate coefficient of 9.2×10^{-7} dm^3 mol^{-1} s^{-1} for reaction with water. This is to be compared with the value k_{OH} 5.3×10^{-4} dm^3 mol^{-1} s^{-1} found for reaction of hydroxide ion with unprotonated 2-methyl-4H-3,1-benzoxazine. This 600-fold difference is smaller than would have been anticipated from the very large difference in nucleophilicity of water and hydroxide ion. For this reason, the preferred explanation of the pH-independent term in the rate law, eqs. [10] and [11], is a reaction involving addition of hydroxide ion to protonated 2-methyl-4H-3,1-benzoxazine.

Dependence of *k* in the range pH 0–13

The pH dependence of the rate coefficient (k) for hydrolysis of 2-methyl-4H-3,1-benzoxazine involving species derived from the solvent over the whole of the pH range 0–13 is fitted by eq. [12], which is obtained by combining eq. [5] with eq. [11]. The solid line in Fig. 2 is a plot of eq. [12] using the values of the rate coefficients and equilibrium

$$[12] \quad k = \frac{k_1[H_2O][H_3O^+](k_2[H_3O^+] + k_3K_{1H^+})}{(K_{SH^+} + [H_3O^+])\{k_3K_{1H^+} + (k_{-1} + k_2)[H_3O^+]\}} + k_0 + k_{OH}[OH^-]$$

constants given in Table 1. At low pH, reaction of protonated 2-methyl-4H-3,1-benzoxazine with solvent occurs through a protonated tetrahedral intermediate, leading to 2-aminobenzyl acetate as product. As the pH is raised, reaction of protonated 2-methyl-4H-3,1-benzoxazine leads to 2-acetylaminobenzyl alcohol, since the tetrahedral intermediate that is common to both pathways is present in the unprotonated form. In the protonated form, the intermediate leads to 2-aminobenzyl acetate because departure of an aromatic amine as leaving group is facile. Collapse of the unprotonated intermediate to 2-aminobenzyl acetate would involve departure of an amine anion, and reaction to 2-acetylaminobenzyl alcohol involving an aliphatic alkoxide as leaving group is preferred. The change in pathway that occurs between pH ca. 6 and 7 leads to an inflexion point in the rate coefficient against pH profile. The relative amount of the two products is determined by the fraction of the tetrahedral intermediate that is protonated and the relative rates of collapse of the protonated intermediate to 2-aminobenzyl acetate and the unprotonated intermediate to 2-acetylaminobenzyl alcohol, eq. [6]. At pH 9, reaction of protonated

© 1999 NRC Canada

2-methyl-4H-3,1-benzoxazine with hydroxide ion becomes important, and above pH 12, reaction of unprotonated 2-methyl-4H-3,1-benzoxazine with hydroxide ion predominates. Both of these reactions result in the formation of 2-acetylaminobenzyl alcohol, presumably through the unprotonated form of the tetrahedral intermediate.

It was found that collapse of the protonated intermediate to 2-aminobenzyl acetate is catalysed by buffer base. This presumably occurs by assistance of removal of the hydroxy proton as the carbonyl group of the product is formed. In contrast, collapse of the unprotonated tetrahedral intermediate to 2-acetylaminobenzyl alcohol is not assisted by buffer base. The absence of catalysis in this case could indicate that addition of water to protonated 2-methyl-4H-3,1-benzoxazine is rate-limiting (that is, collapse of the intermediate to product occurs more rapidly than collapse to protonated 2-methyl-4H-3,1-benzoxazine). Alternatively, if the value of the Brønsted exponent for base catalysis of the collapse of the unprotonated tetrahedral intermediate was close to zero, buffer catalysis would be undetectible compared with solvent catalysed collapse.

Kinetic study of the reactions of various types of C-acids with amine bases in acetonitrile. An unusual effect of common BH^+ cation on the rate constants

Wlodzimierz Galezowski, Iwona Grzeskowiak, and Arnold Jarczewski

Abstract: The rates of proton transfer reactions between C-acids of different types such as 1-(4-nitrophenyl)-1-nitroalkanes, 4-nitrophenylcyanomethanes, and 2,4,6-trinitrotoluene, and organic bases such as 1,1,3,3-tetrametylguanidine, 7-methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene (MTBD), and tri-*n*-butylamine have been measured in acetonitrile at pseudo-first-order conditions. A general equation for the rates of proton transfer reactions between C-acids and bases with product existing in two forms, ions and ion pairs, has been derived and its applicability tested. The equation works well except for reactions of 1-(4-nitrophenyl)-1-nitroalkanes with guanidines for which the second-order rate constant is diminished with concentration of guanidinium cation, while tetrabutylammonium salts accelerate the reactions. Possible reasons for this are discussed.

Key words: proton transfer, kinetic study, ion pairs, C-acids, organic bases, acetonitrile, salt effect.

Résumé : Opérant dans l'acétonitrile, dans des conditions de pseudo-premier ordre, on a mesuré les vitesses des réactions de transfert de proton entre divers types d'acides-C, comme les 1-(4-nitrophényl)-1-nitroalcanes, les 4-nitrophénylcyanométhanes et le 2,4,6-trinitrotoluène, et des bases organiques, comme la 1,1,3,3-tétraméthylguanidine, le 7-méthyl-1,5,7-triazabicyclo[4.4.0]déc-5-ène (MTBD) et la tri-*n*-butylamine. On a développé une équation générale pour les vitesses de réactions de transfert de proton entre les acides-C et les bases comportant des produits existant sous deux formes, ionique et paire d'ions, et on en a vérifié le domaine d'application. L'équation donne de bons résultats, excepté pour le cas des réactions des 1-(4-nitrophényl)-1-nitroalcanes avec les guanidines pour lesquelles on observe une diminution de la constante de vitesse du deuxième ordre avec la concentration du cation guanidinium alors que les sels de tétrabutylammonium accélère les réactions. On discute des causes de ces divergences.

Mots clés : transfert de proton, étude cinétique, paire d'ions, acides-C, bases organiques, base, acétonitrile, effet de sel.

[Traduit par la Rédaction]

Introduction

The proton transfer reactions between C-acids of various structures and amine bases in solution have been extensively studied for many years (1–6). The fascination with this research results from the relative simplicity of the mechanism of the reaction even though the multistep mechanism should be considered (1).

In our previous papers, we found that the products of reactions between various C-acids and strong amine bases in acetonitrile are largely dissociated into free ions (7–9). This was evident from conductometric measurements (7, 8), but went undetected in earlier spectrophotometric equilibrium studies (10–15) in which the Benesi–Hildebrand formalism indicated an ion-pair product. Kinetics of these reactions was also consistent with the concept of associated product. The pitfall was additional amount of common BH^+ cation resulting from side reactions of acidic contaminants with amine base. The concentration of BH^+ cation appeared to be larger than that formed in deprotonation of C-acid. Therefore, the rates of proton transfer reactions from C-acids to amine bases in acetonitrile of not very large equilibrium constant should be measured in $B–BH^+$ buffer solutions to maintain reversible pseudo-first-order conditions (5, 8). However, the disadvantage of measuring in buffers is that some anions, especially nitronates, tend to show appreciable ion association at large $[BH^+]$, which is easily seen as blue shifts in electronic spectra (5). This ion association brings on undesired complexity to the supposedly simple proton transfer reactions, which makes kinetic isotope effects studies

more difficult. Another problem arising from using buffers is salt effects. Actually, in our earlier kinetic measurements in buffered media, we found an example of unexpected negative salt effect (8). Therefore, we decided to measure kinetics of reactions of various C-acids with amine bases in buffer solutions in acetonitrile to see if reliable second-order rate constants can be obtained, particularly for deprotonations of nitroalkanes where the product is split into two forms of ions and ion pairs. To avoid further complications, amine bases like tributylamine (16) and MTBD (17) that do not form homoconjugated complexes or bases characterized by low homoconjugation constant such as TMG (17) were chosen.

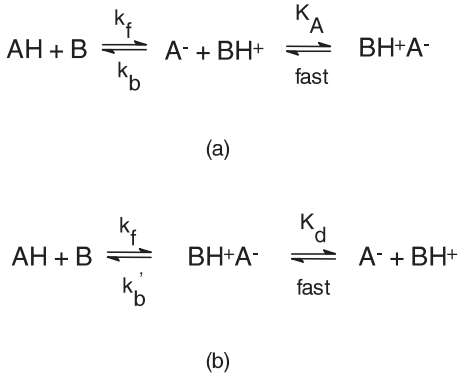
Scheme 1. The two kinetically indistinguishable mechanisms of proton transfer reactions between a C-acid and an amine base.



Results and discussion

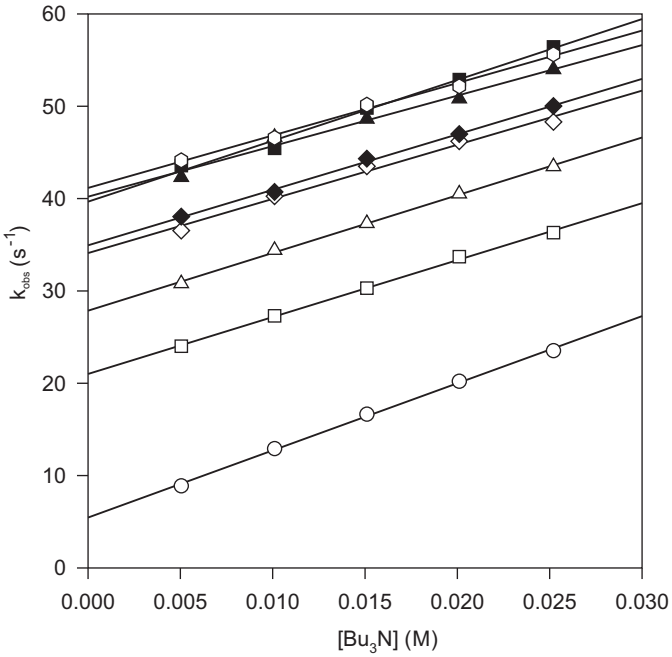
The reactions of C-acids with amine bases give colored products. With **5**, **6**, and **7**, spectra of the products are insensitive to $[BH^+]$, and the reactions were followed at λ_{max}. With nitroalkanes **1**, **2**, **3**, and **4**, a blue shift resulting from ion association is observed, and measurements were done at maximum absorbance and occasionally at λ_{max} of ion, λ_{max} of ion pair, and at isosbestic point. The observed rate constants k_{obs} were wavelength independent. For most proton transfer reactions in acetonitrile solvent, the reaction product exists predominantly as free ions (7, 8), but with alkanenitronates, ion association cannot be neglected if an amine salt is added (5).

If the equilibrium constant is not very large, the rates of proton transfer from C-acids to amine bases in acetonitrile should be measured in buffer solutions to maintain reversible pseudo-first-order conditions (8). The visible spectra of ions and ion pairs differ significantly (5), which gives an opportunity to test the assumption that ion association/dissociation is much faster than proton transfer. Inasmuch as the rates proved to be wavelength independent, the ion association/dissociation must be much faster than proton transfer, as expected. Consequently, mechanisms (*a*) and (*b*) shown in Scheme 1 could not be distinguished from our stopped-flow kinetic data. In both cases, as long as ion association/dissociation is much faster than proton transfer, eq. [1] is fulfilled.

$$[1] \qquad k_{obs} = k_f[B] + \frac{k_b f^2[BH^+]}{1 + K_A f^2[BH^+]}$$

where k_b is a second-order rate constant for proton transfer between ions at zero ionic strength (Scheme 1*a*) or is equal to a product of a first-order rate constant of proton transfer within ion pair k_b' and ion association constant K_A (Scheme 1*b*); $K_d = 1/K_A$; f is the ion activity coefficient (18). Should both mechanisms (*a*) and (*b*) operate simultaneously, then eq. [1] would retain its form with the sum of two second-order constants instead of k_f and $k_b + k_b'K_A$ instead of k_b. The second term in eq. [1] has a summation in the denominator, which is characteristic for reactions with the substrate split into two forms (19). Provided the dependence of intercept (itcp) of k_{obs} vs. [B] plot on $[BH^+]$ is known, k_b and K_A can be easily found from a double reciprocal plot:

Fig. 1. Plots of observed rate constants versus $[Bu_3N]$ for the reaction of 4-nitrophenylnitromethane with Bu_3N measured at various concentrations of Bu_3NHClO_4 in acetonitrile at 25°C. (○ 0, □ 0.0001, △ 0.0002, ◇ 0.0004, ◆ 0.001, ▲ 0.002, ■ 0.004, ⬡ 0.01 M Bu_3NHClO_4).



$$[2] \qquad 1/\text{itcp} = K_A/k_b + 1/(k_b f^2[BH^+])$$

One reason for measuring rates at constant $[BH^+]$ is to prevent changes in $[BH^+]$ during a kinetic run, thus avoiding a relatively complicated analysis. Deviations from first-order kinetics might have gone undetected in many kinetic studies performed without addition of BH^+, especially when a very strong base such as an amidine or guanidine have been used (9–13, 20, 21). Since [B] is much larger than the concentration of C-acid to ensure pseudo-first-order kinetics, some BH^+ is brought to the system with the base. The concentration of the adventitious BH^+ can be comparable to the concentration of C-acid of ca. 1×10^{-5} M. Under such conditions, a plot of k_{obs} vs. [B] may be close to a straight line, despite that initial $[BH^+]$ is unknown and it changes with base concentration, and it may give a distorted k_f and an intercept of no physical meaning. If $[BH^+]$ is kept constant by means of addition of a well-dissociated salt, the slope of the plot should give the correct value of k_f, while the second term in eq. [1] can be found as an intercept of the plot, and it has a definite physical meaning. For several reactions, all the plots of relation [1] are parallel except ones with no BH^+ salt added, some of which have markedly larger slopes (Fig. 1). However, as follows from our computer simulations of the kinetic curves, those enlarged slopes cannot be accounted for by variable concentration of BH^+ during a kinetic run.

The approach outlined above works well for many reactions of C-acids with amine bases in acetonitrile. The reaction of **1** (pK_a = 20.7) (18) with tributylamine (pK_a = 18.1) (16) is an illustrative example of a reaction of a relatively small equilibrium constant and considerable ion association

of the product. Unlike with guanidine or amidine bases, the product is roughly half-associated at $[BH^+]$ as low as 1×10^{-4} M. The distance between the parallel straight lines in Fig.1 decreases with $[BH^+]$ as the second term in eq.[1] approaches its limiting value of k_b/K_A. The dissociation constant of 9×10^{-5} M and k_b of 4.6×10^5 M^{-1} s^{-1} were obtained from the double reciprocal plot [2]. The values of k_f are independent of the concentration of tributylammonium cation (Table 1) except the one for $[BH^+] = 0$.

Equation [1] is fulfilled also for the reaction of **6** (pK_a = 19) (18) with tributylamine. The equilibrium constant is still not very large, so intercepts are significant. However, since the anions of cyano C-acids do not associate with ammonium cation as easily as nitronates do, the second term in eq. [1] can be approximated by $k_b f^2[BH^+]$, and in the ranges of $[BH^+]$, the plot [1] does not converge to the limiting straight line. The value of k_b calculated by dividing the intercepts by $f^2[BH^+]$ is (15 800 ± 1400) M^{-1} s^{-1}. The values of k_f are insensitive to the concentration of tetrabutylammonium perchlorate (Table 1). Similarly, in the reaction of **5** with TMG, the second-order rate constants do not change with $[TMGH^+]$ (Table 2). As in the preceding case, ion association constant of the product is too small to be found from eq. [2] with a reasonable accuracy; k_b is 1800 ± 200 M^{-1} s^{-1}. The reaction of **7** (pK_a = 23.2) (18) with MTBD (pK_a = 25.4) (22) has a fairly large equilibrium constant, so reverse reaction is not visible, i.e., intercepts of the plots [1] are 0 (Table 3). Again, the $MTBDH^+$ cation has no impact on k_f values (Table 3).

Quite different response of phenomenological value of k_f to increased BH^+ concentration is observed for reactions of nitroalkanes with guanidines in acetonitrile. A decrease in k_f for the reaction of **3** with TMG (Table 2), which is evident for $TMGH^+$ concentration larger than 5×10^{-3} M, could only in part be explained by a weak homoconjugation of $TMGH^+$. Our computer simulations show that at a homoconjugation constant K_{HOMO}[17] = 5 M^{-1} and in the ranges of TMG base used, a 3.7% drop in k_f value could be observed for 0.01 M BH^+ and a 7.2 % drop for 0.02 M BH^+. In fact, k_f is reduced by at least 17 and 28 % for 0.01 M and 0.02 M BH^+, respectively (Table 2). Although the equilibrium constant is not very large as indicated by intercepts increasing with $[TMGH^+]$, these intercepts do not give exact value of the second term in eq.[1].

The situation is yet clearer with MTBD base that has a negligible homoconjugation constant (17) and very large basicity (22), which allows for neglect of the second term in eq. [1]. The values of k_f for reactions of this base with **2**, **3** (pK_a = 23.9) (18), and **4** (pK_a = 25.9) (8) show considerable decrease with $MTBDH^+$ concentration (Table 3). A typical k_f at 0.01 M $MTBDH^+$ is 20–30% lower than at 0.001 M $MTBDH^+$. The extent of this reduction increases with the bulk of alkyl substituent in the C-acid. The phenomenon described above is not a typical salt effect. For a reaction with transition state more polar than substrates, one would expect rather an increase than a decrease in rates with ionic strength (23). In a relevant study of deprotonation of arylnitroalkanes by benzoate in DMSO, no salt effect was found using lithium and potassium counterions for total salt concentration up to 2×10^{-2} M (24). However, unlike with amine bases, in the reactions with anionic bases, charge separation does not take place and simple comparisons of salt effects are impossible.

The deprotonations of nitroalkanes with MTBD are in line with concept of positive salt effect. When ionic strength is increased by means of tetrabutylammonium perchlorate, k_f values actually increase with ionic strength (Table 4 and some entries in Tables 1 and 5). As already mentioned, k_f values for the reaction of MTBD with **7** are constant unless the concentration of $MTBDH^+$ is unreasonably high

(Table 3), indicating that any changes in the base such as homoconjugation cannot provide a reasonable explanation for the decrease of k_f with concentration of $MTBDH^+$. Stabilization of the nitroalkane by $MTBDH^+$ seems unlikely. Nevertheless, we studied effect of concentrated (0.1 M) $MTBDH^+$ on ^1H NMR spectra of **4** in CD_3CN, and no shifts were found.

Looking for a possible explanation of the negative salt effect, we considered that very strong amine bases such as guanidines can produce small quantities of another base, which is stronger than the guanidine, but has small steric demands. This base could deprotonate some C-acids, like sterically hindered nitroalkanes, while with others, say **7**, the other route would be unimportant. Should this be the case, the alternative deprotonation reaction could be separated by switching from constant BH^+ concentration to buffers of a constant $[B]/[BH^+]$ ratio. In such buffers, the concentration of the competing base would be kept constant, and the slopes of k_{obs} vs. [MTBD] should be parallel, giving the true k_f value. The results of such an experiment are shown in Table 5. Again, for the reaction of **7**, there is little change in k_f, but for **4** there are large variations. The smallest k_f values were found for the buffers of the lowest $[B]/[BH^+]$ ratio. Hence, this proposal had to be rejected.

Additional opportunities for explanation are open when an unstable intermediate is assumed, a natural candidate for which would be a pyramidal carbanion (Scheme 2). The lifetime of this intermediate would have to be long enough that it could not only turn into nitronate ion but also reprotonate to the nitroalkane. If the steady-state approach is applied to this mechanism, eq. [3] is derived:

$$[3]\qquad k_{obs} = \frac{k_1(k_3 f^2[BH^+] + k_2)}{(k_{-1} + k_3) f^2[BH^+] + k_2}[B] + \frac{k_{-1}(k_{-2} + k_{-3}K_A)}{(k_{-1} + k_3) f^2[BH^+] + k_2} \times \frac{f^2[BH^+]}{1 + K_A f^2[BH^+]}$$

As follows from eq. [3], the coefficient at [B] can decrease with $[BH^+]$ if only k_{-1} is not much smaller than k_3, or k_2 is not much larger than $(k_{-1} + k_3)f^2[BH^+]$ in which cases the slope would be equal k_1, and BH^+ salts would have no effect on the slope of k_{obs} vs. [B].

The existence of the intermediate, although plausible, has not been supported by independent evidence. However, the concept of the two-anion mechanism is not new. The mechanism including the carbanionic intermediate is consistent with anomalous Brönsted α values for deprotonations of nitroalkanes (25), which were explained by large electron density on the carbon atom in the transition state (26), in contrast to the nitronate ion. Formation of such a pyramidal nitro carbanion as an intermediate was postulated by Bordwell and Boyle (27). According to them, the two-anion mechanism for deprotonation of nitroalkanes could account for the kinetic isotope effects observed equally well, and perhaps better than the one-step mechanism. Probably, it would suffice to assume that the transition state has some character of a pyramidal carbanion, so our negative salt effects on rates of proton transfer could actually provide the evidence for a true carbanionic intermediate.

In conclusion, experimental evidence for fast ion association/dissociation has been provided and a general equation for the rates of proton transfer reactions with product exist-

ing in two forms, ions and ion pairs, has been derived. This equation is fulfilled except for reactions of nitroalkanes with guanidine bases. The decrease in second-order rate constant up to 30% with concentration of BH^+ is not caused by ionic strength or by a side reaction with a base produced by the buffer. The kinetic scheme involving carbanionic intermediate is a possible explanation for these salt effects.

Guanidines are very strong bases and are characterized by low homoconjugation constants, which makes them potentially suitable for kinetic studies in acetonitrile. Unfortunately, the rates of their reactions with nitroalkanes show, as described above, relatively strong dependence on guanidinium cation concentration.

Experimental

Acetonitrile

Spectroscopic grade solvent from Romil was stored over CaH_2, distilled over P_2O_5, and finally fractionally distilled from CaH_2. The middle fraction was collected and stored under nitrogen free from moisture and CO_2. Solutions of C-acids and the bases as well as B/BH^+ buffer were prepared freshly before each kinetic or equilibrium experiments.

The B/BH^+ buffer of needed concentration was made using appropriate base and its perchlorate or picrate. The picrates and perchlorates were prepared as described earlier (5, 28).

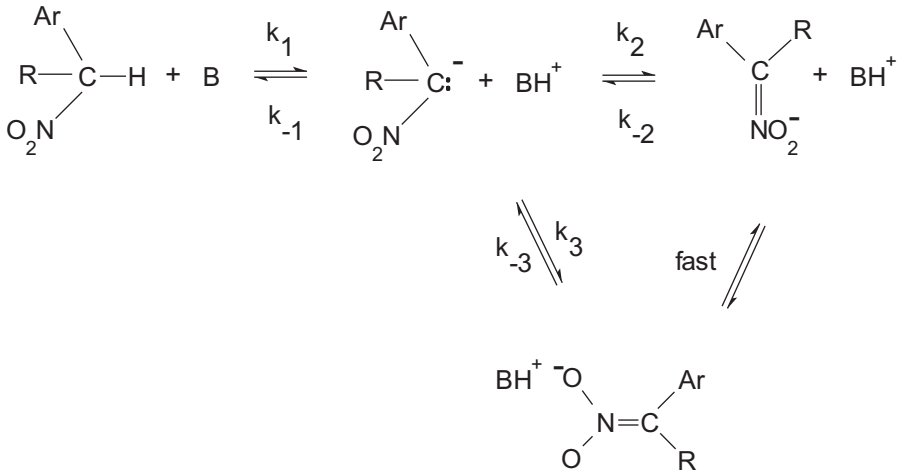
Scheme 2. Mechanism of the reaction of a nitroalkane with amine base including a carbanionic intermediate.



C-acids

4-Nitrophenylnitromethane **1** (8), 1-(4-nitrophenyl)-1-nitroethane **2** (7), 1-(4-nitrophenyl)-1-nitropropane **3** (7), 2-methyl-1-(4-nitrophenyl)-1-nitropropane **4** (7), 4-nitrophenylphenylcyanomethane **5** (29), and bis(4-nitrophenyl)cyanomethane **6** (8) were prepared according to procedures already published. The melting points and spectra after recrystallization from ethanol were in accordance with the literature. 2,4,6-Trinitrotoluene **7**, a commercial product, was purified by repeated crystallization from ethanol (mp 81°). The purity parameters were in agreement with the literature (30).

Bases

1,1,3,3-Tetramethylguanidine (TMG), commercial product from Aldrich, was stored over KOH pellets, then distilled under vacuum in an atmosphere of argon. 7-Methyl-1,5,7-triazabicyclo[4.4.0]dec-5-ene (MTBD) base, a commercial product from Aldrich, was used. The purity of the base was satisfactory as tested by NMR and titration (31). Tributylamine (Bu_3N), the commercial product from Fluka, p.a. (≥99.0% GC) was used. The purity of the sample was in agreement with FT NMR spectra published by Poucher and Behnke (32). All the operations were accomplished with protection from atmospheric carbon dioxide and moisture. The results of titration of base solutions were consistent with gravimetric concentrations within 1%. Kinetic measurements were performed with a stopped-flow spectrophotometer (Applied Photophysics) using a C-acid concentration of ca. 2.5×10^{-5} M and base concentrations shown in Tables 1–5. The values of k_{obs} were measured for typically five concentrations of base in a large excess over C-acid. Since different [BH$^+$] were used, in Tables 1–3, the ionic strength changes from one series to another and was not adjusted to a constant value with a neutral salt. In Table 5, results in buffers of a constant [B]/[BH$^+$] ratio are reported, and the ionic strength is adjusted with tetrabutylammonium perchlorate to 0.01 except for two entries where it is 0.1.

The value of spectrophotometric equilibrium constant K of 0.352 for the reaction between **4** and MTBD was calculated using the following equation: $K = f^2[BH^+][A^-]/[B][AH]$. [A$^-$] was found from the absorbance at $\lambda = 600$ nm, where the absorption of ion pair is negligible, [AH] was calculated as a difference of an analytical C-acid concentration and the sum of ([A$^-$] + [ion pair]). The K_d used for calculation of ion pair concentration is 0.0024 (5).

Hydrolysis and aminolysis of alkyl xanthate esters and cellulose analogues

Eduardo Humeres, Valdir Soldi, Marilene Klug, Mauricéa Nunes, Célia M.S. Oliveira, and Patrick J. Barrie

Abstract: The hydrolysis and aminolysis of a series of S-substituted *O*-alkylxanthate esters was studied in 20% v/v aqueous methanol at 35°C. The pH–rate profiles of the hydrolyses showed water and hydroxide-ion-catalyzed reactions. The reaction of 2,4-dinitrophenyl cellulose xanthate (CelXDNP) and *p*-nitrobenzyl cellulose xanthate (CelXNB) with polyalanine and lysozyme produced a covalent bond between the polypeptide and the cellulose matrix, as shown by solid-state ^{13}C NMR. However, the nature of the bonding could not be identified. The reaction of nucleophiles (H_2O, OH^-, RNH_2) and xanthic esters was consistent with an addition–elimination mechanism through a tetrahedral intermediate. Brønsted plots against the pK_a of the nucleophile (β_{nu}) or the nucleofuge of the substrate (β_{lg}) were used to characterize the rate-determining step. The pK_a values of the nucleophiles ranged between –1.74 and 15.74, and for the nucleofuges, they were in the range of 10.50–0.92. For nucleophiles with pK_a values up to about 10, β_{lg} was 0.10–0.15, and β_{nu} changed from 0.48 to 0.35 for the strongest electron-withdrawing nucleofuge. It was concluded that the water-catalyzed hydrolyses, and also aminolyses with moderately basic amines, occur with rate-determining formation of the tetrahedral intermediate. For strong bases such as hydroxide ion, the disappearance of the intermediate becomes the slowest step. The reaction of cellulose xanthic esters with external nucleophiles as hydroxide ion and amines shows simple first-order kinetics and is slower than alkyl or sugar xanthates, probably due to the diffusion effect through the tight cybotactic region of cellulose.

Key words: hydrolysis, aminolysis, alkyl xanthic esters, cellulose xanthic esters, sugar xanthic esters.

Résumé : Opérant à 35°C, dans un mélange à 20% v/v de méthanol aqueux, on a étudié l'hydrolyse et l'aminolyse d'une série d'esters *O*-alkylxanthiques S-substitués. Les profils pH–vitesse de réaction d'hydrolyse montrent que l'eau et l'ion hydroxyde catalysent les réactions. Les réactions du cellulose xanthate de 2,4-dinitrophényle (CeIXDNP) et du cellulose xanthate de *p*-nitrophényle (CelXNB) avec la polyalanine et la lysosyme conduisent à la formation d'une liaison covalente entre le polypeptide et la matrice de cellulose, comme on a pu le montrer par RMN du ^{13}C à l'état solide. Toutefois, il n'a pas été possible de déterminer la nature de la liaison. La réaction des nucléophiles (H_2O, OH^-, RNH_2) avec les esters xanthiques est en accord avec un mécanisme d'addition–élimination impliquant un intermédiaire tétraédrique. On a utiliser les courbes de Brønsted en fonction du pK_a du nucléophile (β_{nu}) ou du nucléofuge du substrat (β_{lg}) pour caractériser l'étape cinétiquement limitante. Les valeurs de pK_a des nucléophiles s'étalent de –1,74 et 15,74 alors que celles des nucléofuges vont de 10,50 à 0,92. Pour les nucléophiles de valeurs de pK_a allant jusqu'environ 10, les valeurs de β_{lg} va de 0,10 à 0,15 alors que pour β_{nu} elles vont de 0,48 à 0,35 pour le nucléofuge portant le groupe électroattracteur le plus fort. On en conclut que l'hydrolyse catalysée par l'eau et l'aminolyse à l'aide d'amines de basicité modérée se produisent avec formation cinétiquement limitante de l'intermédiaire tétraédrique. Pour des bases fortes, telles que l'ion hydroxyde, la disparition de l'intermédiaire devient l'étape la plus lente. La cinétique de la réaction des esters xanthiques de la cellulose avec des nucléophiles externes, tels que l'ion hydroxyde et les amines, est du premier ordre simple et ces réactions sont plus lentes que celles des xanthates d'alkyles ou de sucres; ce résultat est probablement dû à l'effet de diffusion à travers la région cybotactique compacte de la cellulose.

Mots clés : hydrolyse, aminolyse, esters xanthiques d'alkyles, esters xanthiques de la cellulose, esters xanthiques de sucres.

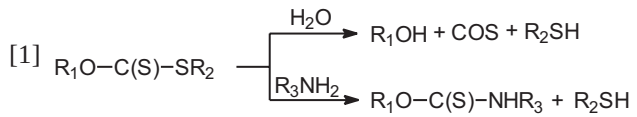
Introduction

Xanthic esters have been used in the synthesis of trithiocarbonates (1), in Friedel–Crafts reaction (2), Chugaev's reaction (3), and in the synthesis of thiols (4, 5), and also as derivatives for the isolation of carbohydrates (6). The hydrolysis of xanthic esters occurs as shown in eq. [1], and they react with amines displacing the thiol and forming a thioncarbamate ester (5). Thioncarbamates have shown high specificity as collectors in the flotation of sulfide minerals (7).



The study of the reactivity of xanthate ester moieties covalently bound to cellulose showed that the reaction of water was much faster compared to small analogue molecules (8). The water-catalyzed hydrolysis of *p*-nitrobenzyl (CelXNB) and 2,4-ditrophenyl cellulose xanthate (CelXDNP) occurs through two parallel processes (9, 10). The faster hydrolysis was ascribed to the reaction of the C-2 + C-3 isomers, whereas the slower hydrolysis corresponds to the C-6 isomer. The fast hydrolysis is due to an entropic effect of a well-oriented water molecule catalyzed by a second molecule that acts as a general base, as shown by proton inventory. Nucleophiles such as hydroxide ions and amines do not discriminate between the isomers, and the kinetics are first order (9).

In this paper, we seek to extend a previous study of the hydrolysis and aminolysis of a series of S-substituted *O*-ethylxanthate esters (11), to include sugar analogues and 2,4-dinitrophenyl cellulose xanthate, CelXDNP, a cellulose ester with a better leaving group, in order to get an insight into the mechanism of nucleophilic attack on cellulose xanthate esters and small molecule analogues.

Experimental

All reagents were of analytical grade and were used without further purification except the amines that were previously distilled in a high efficiency distilling column and kept under nitrogen atmosphere at low temperature.

The solid-state ^{13}C CP/MAS TOSS NMR measurements were performed using a Bruker MSL-300 spectrometer. All xanthate esters were identified by ^{1}H NMR and IR spectra.

S-Ethyl *O*-ethylxanthate (EXE)

Potassium *O*-ethylxanthate (EXK) was obtained using the classical procedure (12), adding carbon disulfide to a cooled solution of potassium hydroxide in ethanol. The product was recrystallized twice in ethanol; λ_{max} (ethanol) 301 nm. *S*-ethyl *O*-ethylxanthate was obtained after refluxing for 4 h, using an equimolar amount of EXK and ethyl bromide in ethanol. The product was washed with water, dried over anhydrous sodium sulfate, and distilled under vacuum: bp 76°C/10 mmHg (1 mmHg = 133.3 Pa) (lit. (13) 78°C/18 mmHg); λ_{max} 283 nm.

S-Benzyl *O*-ethylxanthate (EXB)

EXK and benzyl bromide (1:1 mol) were refluxed for 6 h in ethanol. The product was washed with water, dried over anhydrous sodium sulfate, and distilled under vacuum: bp 160°C/8 mmHg (lit. (14) 143°C/3 mmHg); λ_{max} (ethanol) 280 nm.

S-*p*-Nitrobenzyl *O*-ethylxanthate (EXNB)

EXK (2.2 g) dissolved in 10% aqueous EtOH, was allowed to react at room temperature with a solution of 2.1 g of *p*-nitrobenzyl bromide (acetone–ethanol). The reaction was followed by the appearance of the maximum at 280 nm. KBr was eliminated by filtration, and the solvent was evaporated in a rotatory evaporator. The product was recrystallized in ethanol: mp 61.6°C.

S-Phenyl *O*-ethylxanthate (EXP)

A solution of sodium ethoxide prepared from 2.3 g of sodium in 50 mL of dried ethanol was slowly added to a solution of 12 g of thiophosgene dissolved in 100 mL of chloroform at 0°C, and it was allowed to react for 3 h to obtain a solution of ethyl chlorothionoformate that was washed with water and dried over anhydrous magnesium sulfate. The solvent was stripped off in a rotatory evaporator, and the product was used without further purification (15*a*, *b*). The reaction of 1 g of sodium thiophenolate in 5 mL of dried ethanol with 1 g of ethyl chlorothionoformate produced EXP after 15 min of reaction at room temperature. Crystals of NaCl were filtered off, and the solution was treated with an aqueous solution of phosphate buffer at pH 8, the product then being extracted with diethyl ether and dried over anhydrous magnesium sulfate. Evaporation of diethyl ether left a yellow oil that was identified as EXP:TLC, alumina, hexane:ethyl acetate (1:1), one spot; λ_{max} 285 nm; after reaction with NaOH, λ_{max} 265 nm (thiophenol); after reaction with ethylamine, λ_{max} 245 nm (thioncarbamate) (15*c*).

S-*p*-Nitrophenyl *O*-ethylxanthate (EXNP)

Ethyl chlorothionoformate (3.5 g), obtained as described above, was added to 1.45 g of *p*-nitrothiophenol in 1.0 mL of pyridine, and then the temperature was raised to 60°C for 1 h. The precipitate was dissolved in 30 mL of chloroform and washed with water, subsequently being dried and then concentrated in a rotatory evaporator. Crystals were obtained after 8 h in the refrigerator: mp 51°C (lit. (16) 50°C).

S-2,4-Dinitrophenyl *O*-ethylxanthate (EXDNP)

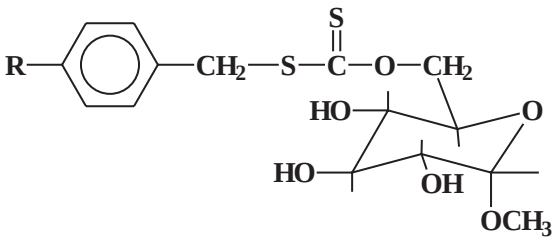
EXK (9.2 g) dissolved in 30 mL of water was mechanically shaken with a solution of 10.1 g of 1-fluoro-2,4-dinitrobenzene in 300 mL of methylene chloride, for 64 h at room temperature. The methylene chloride phase was washed with water and dried over anhydrous magnesium sulfate. The solvent was stripped off in a rotatory evaporator, and the residue was crystallized in methanol: mp 43.0°C; λ_{max} 267 nm; ms, mol. wt. 288 g mol^{-1}. Anal. (calculated values for $C_9H_8N_2O_5S_2$ in parentheses): C 37.5 (37.5), H 2.7 (2.8), N 9.7 (9.7), S 21.5 (22.0).

Methyl α-D-glucopyranoside 6-(*S*-benzyl xanthate) (MGXB)

CS_2 (2.5 mL) was added to a solution of 22.9 g of α-methyl-D-glucopyranoside in 23.6 mL of water, with magnetic stirring at room temperature, and then, slowly, 6 mL of 20 M NaOH was also added. After being allowed to react

© 1999 NRC Canada

for 5 h, the solution was neutralized with acetic acid cooled to 10°C. Benzyl bromide, 11.0 g, in 20 mL of methylene chloride, was then put in slowly, and the stirring was kept up for 2 h. The product was extracted with chloroform, and the solution was dried over anhydrous sodium sulfate. The solvent was evaporated under vacuum. The product was purified by column chromatography using alumina and eluted with hexane–CCl_4–ethanol: R_f 0.66; λ_{max} 284 nm; $[\alpha]_D^{25}$ = +80.3° (lit. +79.8°) (6).



R = H (MGXB), NO_2 (MGX–6)

The preparation of methyl α-D-glucopyranoside 6-(*S*-*p*-nitrobenzyl xanthate) (MGX-6) has been already reported (10).

2,4-Dinitrophenyl cellulose xanthate (CelXDNP) and *p*-nitrobenzyl cellulose xanthate (CelXNB) were obtained from commercial cotton tissue as described previously (9, 10), and were characterized from the degree of substitution DS (number of xanthate ester groups per 100 glucoanhydropyranose units) and the solid-state ^{13}C NMR spectra.

Reaction of CelXDNP and CelXNB with polypeptides

The reaction of cellulose esters with polyalanine (mol. wt. 1000–5000) and lysozyme was studied in dried acetone and in water saturated at pH 10, with the polypeptide at room temperature under nitrogen atmosphere. The product was exhaustively washed with water, ethanol, and diethyl ether, and finally dried under vacuum. The modified celluloses were analyzed by solid-state ^{13}C NMR.

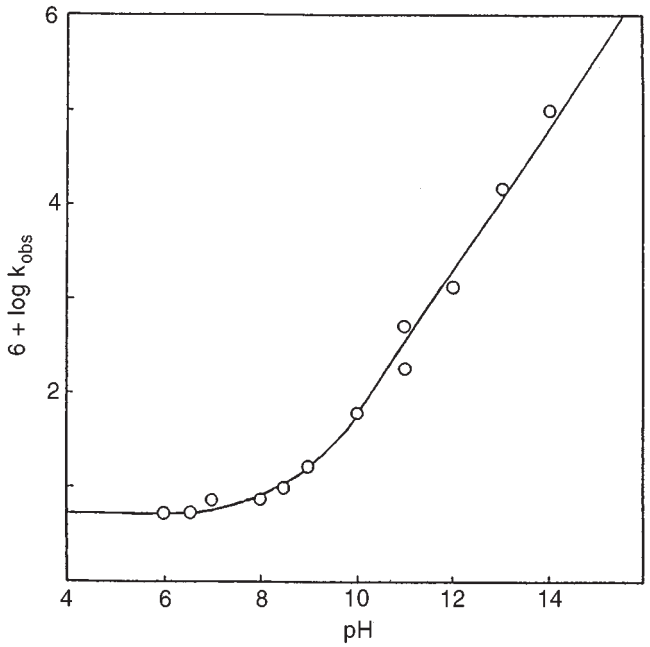
Kinetics

The hydrolyses and aminolyses were carried out in 20% v/v aqueous methanol, at 35°C. The kinetics were followed spectrophotometrically by the disappearance of the xanthate at appropriate wavelengths during at least three half-lives and were always pseudo-first order. The pH and pK_a values were corrected to the appropiate temperature (17).

In the range of pH 3–11, the hydrolyses were carried out in the presence of buffers at 10–30 mM concentrations, and the value of k_{obs} was extrapolated to zero buffer concentration.

For the aminolyses, the amine itself acted as buffer. For each ester and amine, the reaction was measured at three pH values in the range of pK_a ±1 of the amine. For each amine, the second-order rate constant k_N for the aminolysis by the free amine was obtained from a plot of k_2, the second-order rate constant at each pH, against the molar fraction of the free amine. The ester concentration was ca. 10^{-4} M, and the amine concentration was 0.03–0.1 M. The ionic strength was maintained at 0.1 (KCl).

Fig. 1. pH–rate profile of the hydrolysis of *S*-phenyl *O*-ethylxanthate at 35°C in 20% v/v aqueous methanol, μ = 0.1 (KCl).



Results

pH–rate profiles

The pH–rate profiles of the series of S-substituted *O*-ethyl xanthates were obtained in 20% v/v aqueous methanol at 35°C. They are all similar to the example shown in Fig. 1, where k_{obs} is the rate constant extrapolated to zero buffer concentration, and can be expressed by eq. [2]. There is

$$[2] \qquad k_{obs} = k_{H2O} + k_{OH}[OH^-]$$

a pH-independent region with rate constant k_{H2O} of the water-catalyzed reaction, followed at high pH by a hydroxide-catalyzed reaction with second-order rate constant k_{OH}. Table 1 shows the rate constants obtained, including those of some cellulose and sugar xanthate esters. The continuous line in Fig. 1 was drawn using the rate constant values of Table 1.

For the water-catalyzed hydrolysis of CelXNB and CelXDNP, there are two parallel reactions with rate constants k'_{H2O} for the fast hydrolysis and k''_{H2O} for the slower one. We have included these values in order to compare them with those of the series of S-substituted *O*-ethylxanthates and methylglucose xanthates analogues.

Aminolyses

The aminolyses were carried out in 20% aqueous methanol and at low ionic strength (0.1 M KCl), because the low solubility of xanthate esters produces plots of k_{obs} vs. N_T, total amine concentration, that deviate from linearity due to changes in the activity coefficients of the species involved (18).

The aminolyses were carried out with ethylenediamine (EDA, pK_1), ethanolamine (EA), and *n*-butylamine (BA).

CelXNB[h]	Lysozyme[i]	129	1.2	12.3	0.1

[a]DS = 7.9 (aminolysis); DS = 14.8 (NMR).
[b]In dried acetone, 48 h reaction.
[c]For molecular weight in the range of 5000 and 1000, respectively.
[d]Number of moles of polypeptide per 100 glucopyranoside units.
[e]DS = 15.2 (aminolysis); DS = 27.6–35.2 (NMR), DS = 29.1 (S).
[f]In aqueous saturated solution, 48 h reaction.
[g]After washing again exhaustively with water.
[h]DS = 6.76 (aminolysis); DS = 4.24 (NMR).
[i]In aqueous solution, 148 h reaction. A DS = 1.07 with lysozyme would duplicate the weight of the CelXR.

The plots of k_{obs} vs. N_T were all linear and can be represented by eq. [3],

$$[3] \qquad k_{obs} = k_o + k_N[N]$$

where k_o is the rate constant including all the terms of hydrolysis, and k_N and [N] are the second-order rate constant and the concentration of the free amine, respectively. Table 2 shows the values of k_N for the series of S-substituted *O*-ethylxanthates and some cellulose xanthate esters analogues.

The reaction of CelXNB and CelXDNP with polyalanine and lysozyme (Table 3) was followed by solid-state ^{13}C NMR, and the spectra did not change after extensive washing with water, ethanol, and diethyl ether, showing that the polypeptide was covalently bound to the cellulose matrix. The spectrum of each polypeptide was clearly superimposed on that of the cellulose. However, the signal of the expected thioncarbamate group at 190 ppm was not observed, and we are unable to come to any conclusion as to which reaction produced the bonding. The DS of the cellulose after reaction was calculated from the area of the signal of the carbonyl groups at about 177 ppm and the area of the signal due to C-1 of cellulose in the region of 90–110 ppm according to eq. [4]. In general, the DS was higher for CElXNB, probably

$$[4] \qquad DS = \frac{\text{Area(C=O)/number C=O per mol}}{\text{Area(C-1)}}$$

because the competitive hydrolysis is too fast for CelXDNP. It is important to note that a DS of about 1.0 would duplicate the weight of the cellulose ester in the reaction with lysozyme.

It is possible that the intensity of the signal of the carbon from the thiocarbonil group is too low to be detected. For the polyalanine, the ratio of the signal due to C=O per mol to one C=S should be in the range of 14–70, and for the lysozyme, this ratio is 129:1. It is also possible that the weak

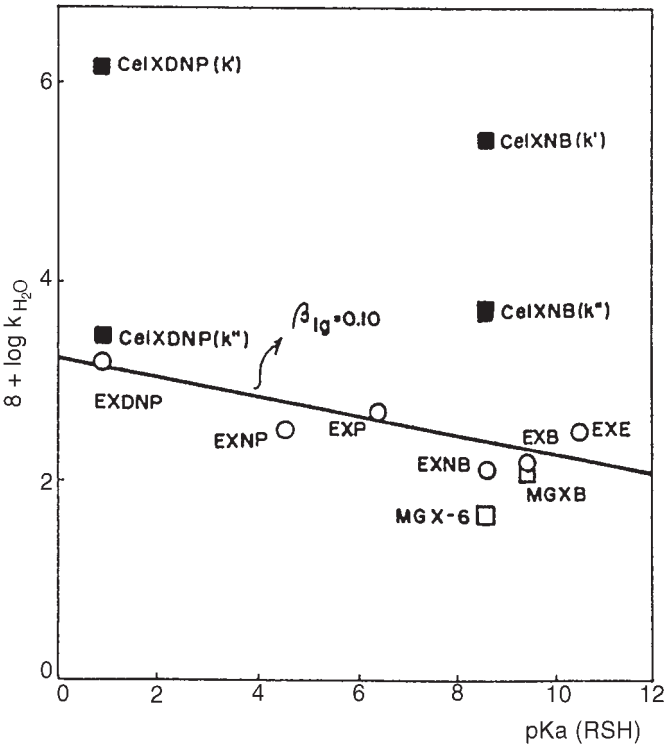
Fig. 2. Brønsted-type plot of the spontaneous hydrolysis of S-substituted ethylxanthates (○) versus the pK_a of the leaving thiol, at 35°C in 20% v/v aqueous methanol, μ = 0.1 (KCl); □, sugar xanthates in 10% aqueous ethanol; ■, cellulose esters.



C=S signal was eliminated along with the side bands when using the TOSS technique.

Discussion

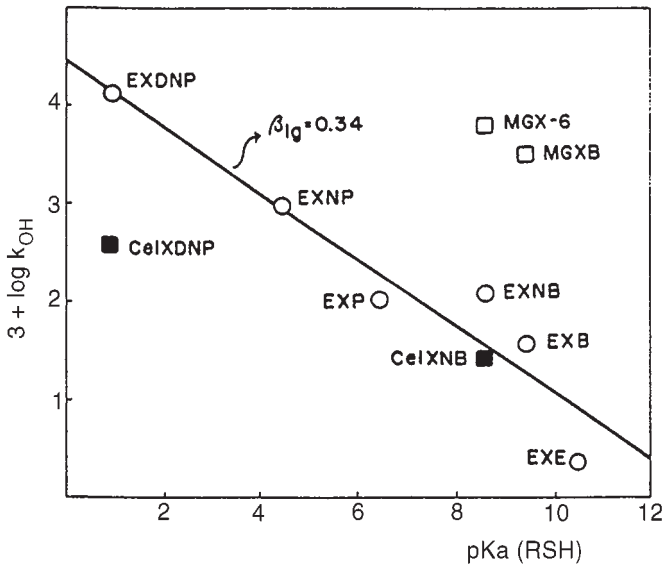
It is reasonable to assume that the reaction of xanthate esters with nucleophiles occurs, similar to the carboxylic esters, according to eq. [5] (19, 20) by an addition reaction that produces a tetrahedral intermediate followed by the elimination of the thiolate moiety.

[5] 
where

[6] $$k_{nu} = \frac{k_1}{1 + k_{-1}/k_2}$$

Brønsted plots of log k_{nu} against the pK_a of the nucleophile or the nucleofuge of the substrate, provide an insight into the rate-determining step of the reaction (21). Linear plots indicate no change in the rate-determining step, and β_{nu} and β_{lg} are related to the difference in charge between the initial and the corresponding transition state, that is, to the bond order of the Nu—C or C—S bonds.

Fig. 3. Brønsted-type plot of the hydroxide-catalyzed hydrolysis of S-substituted ethylxanthates (○) versus the pK_a of the leaving thiol, at 35°C in 20% v/v aqueous methanol, μ = 0.1 (KCl); □, sugar xanthates; ■, cellulose esters; μ = 1.0 (KCl): EXE, EXP, MGX-3, CelXNB, CelXDNP.



Hydrolyses

For the hydrolyses, Nu = H_2O, OH^-, the initial product is a thioncarbonate that decomposes rapidly to R_1OH and COS as shown in eq. [1]. The tetrahedral intermediate might be able to decompose through different pathways, but for EXE it was found that EtSH appears at the same rate of disappearance of the xanthic ester, and considering the difference of the pK_a values of ethanol and ethanethiol, the intermediate should decompose to product with C—SR_2 bond fission alone (22). This behavior should be similar when the pK_a of the nucleofuge thiol is lower.

The Brønsted-type plot of Fig. 2 for the spontaneous hydrolysis of the S-substituted *O*-ethylxanthate series is linear (the rate-determining step does not change), and β_{lg} = 0.10, suggesting that the virtual tetrahedral intermediate (23) presents a low perturbation of the C—S bond of an early transition state and that the rate-determining step must be the nucleophilic attack of the water molecule to form the intermediate. This conclusion supports the mechanism that has been postulated for cellulose xanthate esters, where a second water molecule acts as a general base catalyst for the deprotonation of the intermediate (8–10). In Fig. 2, it can be observed that small sugar xanthate molecules with hydrophilic R_1O moiety, such as MGXB and MGX-6, are somewhat less reactive than the ethyl analogue. However, the fast spontaneous hydrolysis of the cellulose esters CelXDNP and CelXNB, is 2 and 3 orders of magnitude faster than the *O*-ethylxanthate, and it has been proposed that this is a consequence of the supramolecular catalysis induced by the water molecules of the cybotactic region of the polysaccharide on the water molecule that acts as a nucleophile (9–10).

The Brønsted plot of Fig. 3 for the hydroxide-ion-catalyzed hydrolysis of the same *O*-ethylxanthate series is also linear, but β_{lg} = 0.34, indicating a later transition state

[g] Reference 9.

because of a higher activation barrier for the intermediate decomposition, and consequently, a change of rate-determining step: a fast intermediate formation is followed by a slower decomposition. These arguments will be supported by the discussion on the mechanism of aminolysis.

In this particular case, sugar xanthates are faster than the ethyl analogues, but a neighboring OH effect should be disregarded because the cellulose xanthate esters hydrolyze either at about the same rate (CelXNB) or much slower (CelXDNP) (Fig. 3). Considering the critical micelle concentration of MGXB, it is possible that the rate acceleration is due to micelle catalysis. With the present data, it is not possible to understand the slow basic hydrolysis of CelXDNP.

Aminolyses

When the nucleophile is an amine, the tetrahedral intermediate is a zwitterion that must deprotonate at a diffusion-controlled rate before forming the products (eq. [7]).

The second-order rate constants of the reaction of free amines with xanthic esters are presented in Table 2. The reaction allows the calculation of both β_{nu} and β_{lg} because the Brønsted plots are all linear. For the series of *O*-ethylxanthates, β_{nu} decreases from 0.48 for EXE to 0.35 for EXDNP (Table 4) because of the increasing electron-withdrawing effect of the nucleofuge that lowers the kinetic barrier and the transition state that occurs earlier in the reaction coordinate. On the other hand, the reaction of these amines with the xanthate series, produced low β_{lg} values. These results are consistent with a mechanism where the rate-determining step is the nucleophilic attack of the amine, and formation of the tetrahedral intermediate that disappears in a fast step because sulfur can expel the leaving group better than oxygen (19, 20). The situation is similar to that of the water-catalyzed reaction, while for the hydrolysis catalyzed by hydroxide ion the extent of the C—S bond breakage indicates that the intermediate is formed in a fast step, and the slower step is the second one. A change in the rate-determining step accompanies a significant change in the magnitude of β_{nu} and β_{lg} (19).

To compare a β-value with the calibrating equilibrium (24), the effective charge on the amine N or thiol S of the substrate has to be calculated. For primary alkyl amines, the effective charge on the N should be very close to zero, and the effective charge in the transition state should be essentially equal to β_{nu}. There is no information on the effective charge on the thiol S of xanthate esters. However, this value should be constant for the series of S-substituted esters, and $\Delta\beta_{lg}$ values for the different nucleophiles do not change, without consequences on the conclusions about the change of the rate-determining step.

Aminolyses of cellulose xanthate esters are slower than ethylxanthate analogues. Similar to the hydroxide ion-catalyzed hydrolyses, the aminolyses were strictly first-order, but the values of β_{nu} were lower than those for the *O*-ethylxanthates (Table 4). The slower attack by external nucleophiles can be interpreted as a consequence of the restricted diffusion through the tight cybotactic region. However, the lower β_{nu} values merit a more detailed study.

Cage peroxides having planar bridgehead nitrogen atoms

John T. Edward, Francis L. Chubb, Denis F.R. Gilson, Rosemary C. Hynes, Françoise Sauriol, and Alain Wiesenthal

Abstract: Three new cage peroxides, 1,6-diaza-3,4,8,9-tetraoxabicyclo[4.4.2]dodecane (**3a**),1,6-diaza-3,4,8,9-tetraoxa-11-methylbicyclo[4.4.2]dodecane (**3b**), and 1,6-diaza-3,4,8,9-tetraoxatricyclo[4.4.2.4^{11,12}]hexadecane (**4**), have been prepared by reaction of 1,2-diaminoethane, 1,2-diaminopropane, and *trans*-1,2-diaminocyclohexane, respectively, with formaldehyde and hydrogen peroxide in aqueous acidic solution. Their structures have been established by X-ray diffraction, and show the bridgehead nitrogen atoms to be predominantly sp^2 hybridized. The structures accord with ^{1}H and ^{13}C NMR spectra. Variable temperature NMR studies show that the diperoxide **3a** begins to undergo rapid inversion (on the NMR time scale) at about 303 K; up to 370 K the diperoxides **3b** and **4** show no conformational change.

Key words: cage compounds, formaldehyde, peroxides, amine nitrogen, hybridization.

Résumé : On a préparé trois nouveaux peroxydes en cage, les 1,6-diaza-3,4,8,9-tétraoxabicyclo[4.4.2]dodécane (**3a**), 1,6-diaza-3,4,8,9-tétraoxa-11-méthylbicyclo[4.4.2]dodécane (**3b**), et 1,6-diaza-3,4,8,9-tétraoxatricyclo[4.4.2.4^{11,12}]hexadécane (4) par réaction respectivement des 1,2-diaminoéthane, 1,2-diaminopropane et *trans*-1,2-diaminocyclohexane avec le formaldéhyde et le peroxyde d'hydrogène en solution aqueuse acide. On a identifié les structures par diffraction des rayons X et on a montré que les atomes d'azote en tête de pont sont hybridés principalement sous la forme sp^2. Les structures sont en accord avec les spectres RMN du ^{1}H et du ^{13}C. Des études de RMN à températures variables montrent que le diperoxyde **3a** commence à subir une inversion rapide (à l'échelle de temps de la RMN) à environ 303 K; à des températures allant jusqu'à 370 K, les composés **3b** et **4** ne présentent pas de changements conformationnels.

Mots clés : composés en cage, formaldéhyde, peroxydes, azote d'une amine, hybridation.

[Traduit par la Rédaction]

Introduction

Alder and his colleagues (1) prepared the cage compound **1** by a multistep synthesis, and the chemistry of this and other cage compounds having bridgehead nitrogen atoms has been reviewed (2). The formally similar cage triperoxide **2** (hexamethylene triperoxide diamine or HMTD), which also has bridgehead nitrogen atoms joined by three four-atom bridges, was prepared in 1900 by Baeyer and Villiger (3) in a one-pot synthesis (which must involve many steps) in which formaldehyde reacted with ammonium sulfate and hydrogen peroxide in aqueous solution.

At room temperature, Alder's cage diamine **1** exists in several conformations. In the conformation **1** represented above, the lone pairs of electrons of both tetrahedral nitrogen atoms point inwards (in–in) into the cage; in other conformations, the lone pairs are in–out and out–out. The tetrahedral nitrogen atoms of **1** are slightly flattened. In a typical tertiary amine, the nitrogen atom is 0.49 Å out of the plane of the three attached carbon atoms; in the diamine **1**, they are 0.31 Å out of this plane (4). This flattening probably takes place because of van der Waals repulsions between the two nitrogen atoms, which have van der Waals radii in the neighbourhood of 1.55 Å (5–8) and are only 2.806 Å apart in **1** (4).

1

2

On the other hand, in HMTD (2) the nitrogen atoms have been shown in crystallographic studies of Schaefer et al. (9) to be exactly planar with three-fold coordination, and with N—C distances of 1.42 Å, as compared with 1.47 Å for a

typical tertiary amine. The molecule exists as a racemic mixture of two chiral helices having C-O-O-C torsional angles of ±129.3°, and not as the achiral cylinder **2** shown above (for ease of representation) with torsional angles of zero. Schaefer et al. have shown the nonbonded N···N distance in **2** to be 3.193 Å.

The cage compound **1** has two nitrogen atoms joined by three tetramethylene bridges, the cage **2** by three -CH_2-O-O-CH_2- bridges. Is a "mixed" cage possible, having the nitrogen atoms bridged by one tetramethylene and two -CH_2-O-O-CH_2- bridges? The attempt to prepare this compound failed, the reaction of 1,4-diaminobutane with formaldehyde and hydrogen peroxide in acidic solution yielding no insoluble product. However, the reactions of some 1,2-diaminoalkanes (1,2-diaminoethane, 1,2-diaminopropane, and *trans*-1,2-diaminocyclohexane) yielded peroxidic products. The structures of these three new peroxides have been established by X-ray crystallography and two-dimensional NMR, and proved to have some of the unusual features noted in the structure of HMTD (**2**).

Experimental

General

Melting points were recorded on a Gallenkamp apparatus and are uncorrected. Combustion analyses for C, H, and N were carried out by Galbraith Laboratories, Knoxville, Tenn. Proton magnetic resonance (^{1}H NMR) spectra were recorded on a Varian Unity-500 spectrometer operating at 499.843 MHz for protons and at 125.697 MHz for carbon-13. Chloroform-*d* was used as solvent unless otherwise noted.

Various 2D experiments were carried out to assign the structures: COSY, and the two-phase sensitive experiments: HMQC and NOESY. The phase in these 2D experiments was detected using the hypercomplex mode. For COSY, the acquisition was repeated for four transients, and 256 complex increments were acquired. The data were processed using a pseudo-echo-shaped function. The final data matrix having 1K by 1K points was symmetrized (zero filling was used only in the evolution domain). For NOESY, the data were obtained using a mixing time of 0.3 s and a relaxation delay of 1 s. The acquisition was repeated for 16 transients, and 256 complex increments were acquired. The data were processed using a Gaussian apodization function. The final data matrix had 2K by 1K points (zero filling was used only in the evolution domain).

The HMQC experiment was preceded by a BIRD nulling period. The recycling delay was set to 1 s, while the nulling period (following the BIRD pulse) was set to 0.3 s. The acquisition was repeated eight times and 256 fids were acquired. During acquisition of the proton spectra, ^{13}C broadband WALTZ decoupling was applied. The data were processed with Gaussian function, with zero filling in the evolution domain (^{13}C). The final matrix size was 2K by 1K. The spectral window in the carbon domain was about 100 ppm and in the proton domain about 7 ppm.

1,6-Diaza-3,4,8,9-tetraoxabicyclo[4.4.2]dodecane, ***3a***

Aqueous formaldehyde (37%, 22 mL) was added dropwise to a stirred solution of 1,2-diaminoethane (3.0 g) in acetic acid (12 mL), followed by hydrogen peroxide (30% w/w; 30 mL), the temperature being kept below 20°C by an ice bath. The diperoxide **3a** precipitated immediately and was removed by filtration, washed copiously with water to remove acidity, and dried under reduced pressure in a desiccator: yield 8.0 g (91%), mp 79–80°C, raised to 117°C by recrystallization from ethanol.

3a : $R_1 = R_2 = H$

3b : $R_1 = CH_3$, $R_2 = H$

3c : $R_1 = R_2 = CH_3$

4

Aqueous formaldehyde (37%, 22 mL) was added dropwise to stirred 1,2-diaminopropane (3.7 g), followed by acetic acid (12 mL), and then hydrogen peroxide (30% w/w; 30 mL), the temperature being kept below 20°C by an ice bath. The diperoxide **3b** precipated and was removed by filtration and washed with water: yield 6.2 g (72%), mp 80–81°C, decomp with frothing 90°C, unchanged by recrystallization from petroleum ether.

1,6-Diaza-3,4,8,9-tetraoxatricyclo[4.4.2.4^{11,12}]hexadecane, ***4***

Aqueous formaldehyde (38%; 11 mL) was added to *trans*-1,2-diaminocyclohexane (2.82 g) in glacial acetic acid (6 mL) – water (10 mL). The solution was cooled below 20°C, and hydrogen peroxide (30%; 30 mL) was added. The peroxide precipitated immediately and was removed by filtration, washed with water, and dried: yield 4.76 g (83%), mp 115–116°C, raised to 123°C by recrystallization from ethanol. Anal. calcd. for $C_{10}H_{18}N_2O_4$: C 52.16, H 7.88, N 12.17; found: C 52.03, H 7.94, N 12.02.

1,3,5,7-Tetraazapentacyclo[3.3.2.4^{9,10}.4^{11,12}]eicosane, ***5***

Aqueous formaldehyde (36% w/w; 3.33 g) was added to a solution of 2.28 g of *trans*-1,2-diaminocyclohexane in 10 mL of ethanol. The solution became warm. It was heated to boiling, and 10 mL of water was added. The solution,

Hydrolytic yields of formaldehyde

The di- or triperoxide (about 0.2 g) was hydrolyzed in 45% sulfuric acid (5 mL) for 1 h, and then a saturated solution of dimedone in methanol (30 mL) – water (450 mL) was added. The pH was adjusted to 4.6 by addition of sodium acetate, and the solution was left overnight. The precipitate was removed on a weighed sintered glass filter, washed with water, and dried for more than 24 h in a desiccator. Yields of the formal dimedone derivative were the following: from **2**, 94 and 87%; from **3a**, 93 and 96%; from **3b**, 95% of theoretical.

Analysis for peroxide content

The triperoxide **2** (80–100 mg) and potassium iodide (1 g) were added to 2 N sulfuric acid (5 mL), and after 20 min, the yellow solution was titrated with standard sodium thiosulfate solution using a starch indicator. Active oxygen: calcd. 23.1%; found 23.0, 22.9%.

For diperoxides **3a** and **3b**, the same procedure resulted in a black precipitate and erratic results, and a different titration procedure was devised. Sulfuric acid (2 N) was added dropwise to a suspension of diperoxide (80–90 mg) in a solution of potassium iodide (1 g) and starch indicator in water (5 mL), and after each drop, standard thiosulfate solution was added to decolourize the solution. After about 1.5 mL of acid had been added, no more colour was produced. For compound **3a**, active oxygen calcd. 18.2%; found 17.7, 17.9%; for **3b**, active oxygen calcd. 16.8%; found 16.6, 16.6%.

X-ray crystallography

Crystals of the cage diperoxides were obtained from solvents noted above, **3a** and **3b** as chunky prisms, **4** as rectangular plates. Details of crystal, data collection, and refinement parameters are given in Table 1. Data were collected on a Rigaku AFC6S diffractometer controlled by TEXRAY software.[4] Molybdenum K_α radiation (λ = 0.7093 Å) was used. The structures were solved using direct methods and refined by full-matrix least squares. Hydrogen atoms were located in a difference Fourier map and refined isotropically. All non-hydrogen atoms were refined anisotropically. Data processing, structure solution, and structure refinement were all carried out using the NRCVAX system of crystallographic software (10). In the structure of **3a**, the molecule lies across a crystallographic two-fold axis that bisects the ethylene carbon–carbon bond. Table 2 contains the atomic coordinates and B_{eq} for compounds **3a** and **3b**,and Table 3 the atomic coordinates and B_{eq} for compound

[b]B_{eq} is the mean of the principal axes of the thermal ellipsoid for atoms refined anisotropically (non-hydrogens). For hydrogens, $B_{eq} = B_{iso}$.

4. Anisotropic thermal parameters, torsion angles, and least-squares planes are included as supplementary material.[5]

Results and discussion

Properties of the cage triperoxide 2 and of the cage diperoxides 3a, 3b, and 4

By analogy with the reaction of ammonia with formaldehyde and hydrogen peroxide to give **2**, we assumed that reaction of 1,2-diaminoethane would give the diperoxide **3a**, of 1,2-diaminopropane would give **3b**, and of 1,2-diaminocyclohexane would give **4.** These assumptions proved to be true.

The triperoxide **2** is a powerful explosive (11) and should be handled with extreme caution. A small amount of it on a steel plate detonates with a loud report when hit with a hammer. The diperoxide **3a** proved to be more difficult to detonate, and the diperoxide **3** even more so, as expected from their progressively less favourable oxygen balances (12).

[b]B_{eq} is the mean of the principal axes of the thermal ellipsoids for atoms refined anisotropically. For hydrogens, $B_{eq} = B_{iso}$.

The diperoxide **4** could not be detonated, and was submitted for combustion analysis in the usual way. The peroxides **3a** and **3b** were analyzed (along with **2** as a control) by decomposition of a small amount of the compound in a large excess of aqueous acid to yield formaldehyde (analyzed by formation of the derivative with dimedone (13, 14)) and hydrogen peroxide (titrated by an iodide–thiosulfate method (15)) in amounts close to theoretical. Treatment of the peroxides with aqueous picric acid did not give their picrate salts, but rather monopicrates of the diamines from which they had been made, and treatment of a very small amount of the solid peroxide with a drop of concentrated hydrochloric acid caused instantaneous decomposition to a sticky liquid. The reaction was particularly violent in the case of **2**. The solid compounds left standing on filter paper in the laboratory atmosphere eventually decomposed to a sticky mass. It seems likely that this decomposition was initiated by a trace of acid furnished by a dust or aerosol particle; the formaldehyde and hydrogen peroxide produced at the initial spot of decomposition would react to give formic acid, so that the decomposition would be autocatalytic.

Diffraction studies

The structures **3a**, **3b**, and **4** were established by X-ray diffraction.[5] ORTEP representations (16) are given in Figs. 1– 3, and in Table 4, the bond distances and angles of the three diperoxides are compared with corresponding bond distances and angles of the triperoxide **2**.

The torsional angles of the peroxide groups C-O-O-C in our three diperoxides lie between 113 and 116°, close to the equilibrium torsional angle of about 112° in hydrogen peroxide (17), while the corresponding torsional angle in HMTD is 129.3° (9). Schaefer et al. (9) point out that it takes little energy to open this angle from 112 to 129°, while closing this angle below 129° in HMTD would force nonbonded N···N atoms (3.193 Å apart) and O···O atoms (2.971 Å apart) to move closer together, with steep increases in van der Waals repulsions. Otherwise, most bond distances and an-

Fig. 1. ORTEP plot (16) of compound **3a**,showing numbering scheme. Ellipsoids are shown at 50% probability for non-hydrogen atoms.

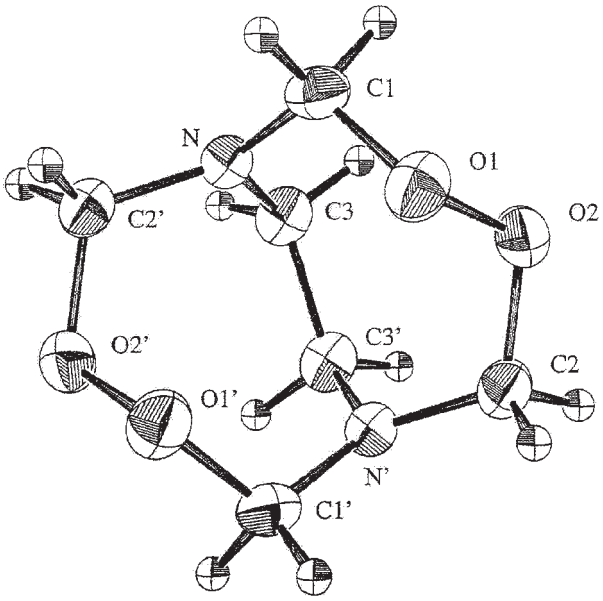

Fig. 2. ORTEP plot (16) of compound **3b**,showing numbering scheme. Ellipsoids are shown at 50% probability for non-hydrogen atoms.

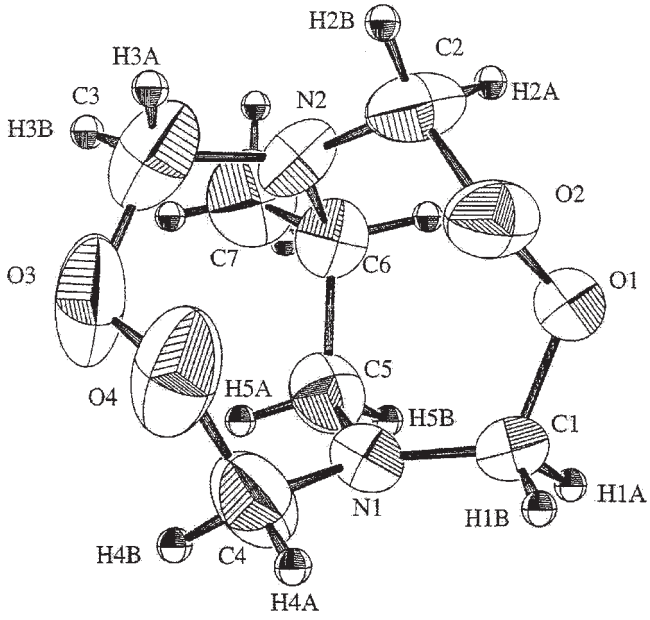
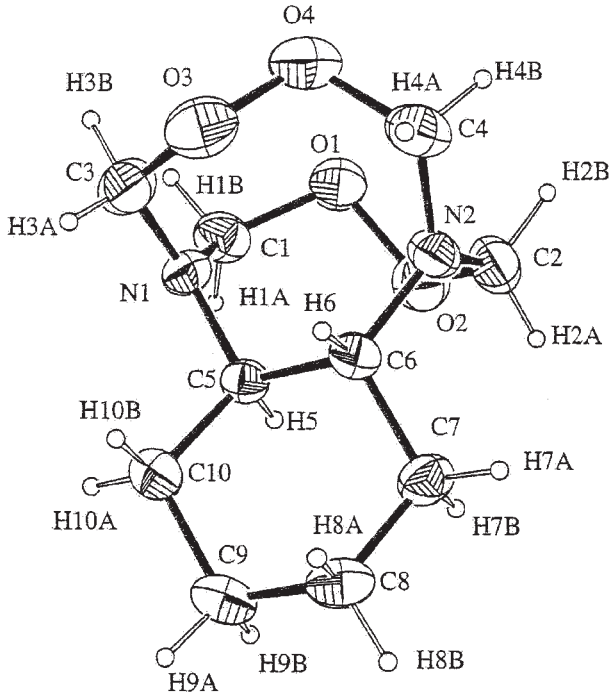


gles are fairly similar in all four compounds in Table 1. However, the bridgehead nitrogen atoms of the three new diperoxides are not completely planar, lying about 0.12–0.14 Å out of the plane of the three attached carbon atoms, while in **2** the nitrogen atoms lie exactly (within experimental limits) in this plane. Similarly, in the three new diperoxides all except one of the C-N-C angles are slightly less than 120°, whereas in **2** all are exactly 120°.

Schaefer et al. (9) suggested that the bridgehead nitrogen atoms of **2** are sp^2 hybridized because the electronegative peroxide groups withdraw electron density and lower the energy of the electron pair in the *p* orbital (the anomeric effect (19)). This hybridization explains the shortened N—C distances in **2**. Essentially, the same explanation is offered by Whittleton et al. (19) for N—C distances in the cage diperoxide formed by reaction of formaldehyde with hydrazine and hydrogen peroxide in acidic solution (20, 21). This effect would be expected to be greater in the triperoxide **2** than in the diperoxides **3a**, **3b**, and **4**, which might account for the less complete planarity of the bridgehead nitrogen atoms of the latter. Furthermore, the anomeric effect would explain why the N—C bonds of the peroxide bridges of **3a**, **3b**, and **4** are shortened, while the N—C bonds of the alkane bridges are not. It would also explain the nonbasic character of the tertiary amino groups, so that the compounds separate out of weakly acidic solutions as bases and not salts.

Fig. 3. ORTEP plot (16) of compound **4**, showing numbering scheme. Ellipsoids are shown at 50% probability for non-hydrogen atoms.



*PMR spectrum of HMTD **2***

The ^{1}H NMR spectrum of the highly symmetrical hexamethylenetetramine $(CH_2)_6N_4$ shows a sharp singlet at δ 4.64 ppm (22), and a similar spectrum would be expected for HMTD $(CH_2)_6N_2O_6$ if it had the symmetrical structure shown in **2** above, with dihedral angles of zero for the peroxide bridges CH_2-O-O-CH_2. However, the dihedral angles of ±129° of these bridges (9) result in HMTD existing as a racemic mixture of chiral helical conformers. The twist of the helix causes one hydrogen of each methylene group to point slightly inward toward the axis of the molecule, and the other slightly outward. The six methylene groups are all identical; each forms an AB system, so that the spectrum of HMTD in DMSO-d_6, shown in Fig. 4, has a pair of doublets (^2J 13.3 Hz) centered at δ 4.65 and 4.78 ppm. At higher temperatures, the helical conformers interconvert, as shown by the broadening of the NMR peaks, which eventually

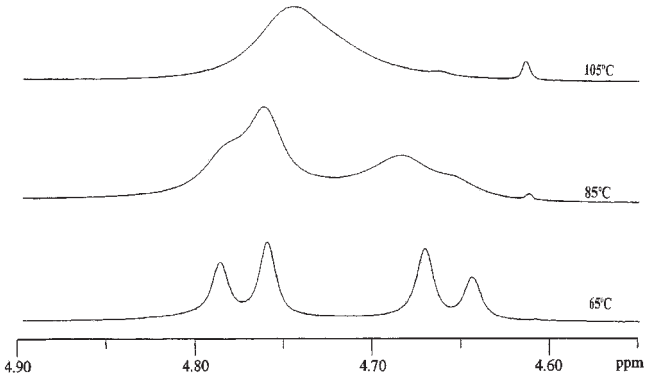
collapse into a broad singlet at about 105°C, illustrated in Fig. 4.

Fig. 4. Effect of temperature on the PMR spectrum of HMTD (**2**).



*NMR spectrum of compound **3a***

This compound, like **2**, is a racemic mixture of chiral conformers. The X-ray crystallographic studies (see Fig. 1) show that the dihedral angles of CH_2-O-O-CH_2 are not zero, as represented in **3a**, but ±115.2° (Table 4). Again, the hydrogen atoms of both N-CH_2-C and N-CH_2-O methylenes form an AB system. However, in $CDCl_3$ at 30°C, the ^{1}H NMR spectrum, shown in Fig. 5, is that of the symmetrical structure **3a**, having a doublet at δ 3.38 (4 H) for the protons of the ethylene bridge and a doublet at δ 4.83 (8 H) for the methylene protons of the peroxide bridges. The four-bond coupling is favoured by the W-configuration of the bonds between the protons of the two different types of methylenes.

Evidently, the interconversion of enantiomeric conformers of **3a**, which requires eclipsing of the bonds of two peroxide groups, takes place at a lower temperature than the interconversion of the enantiomeric conformers of **2**, which requires eclipsing of the bonds of three peroxide groups. The

© 1999 NRC Canada

Fig. 5. Effect of temperature on the PMR spectrum of **3a**.

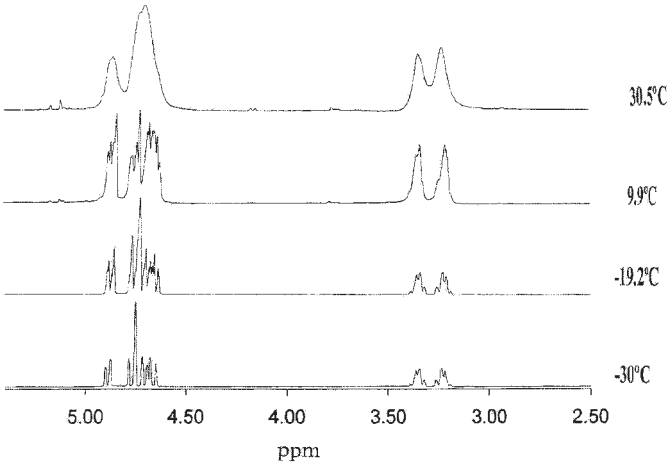


Fig. 6. The PMR spectrum of **3b**.

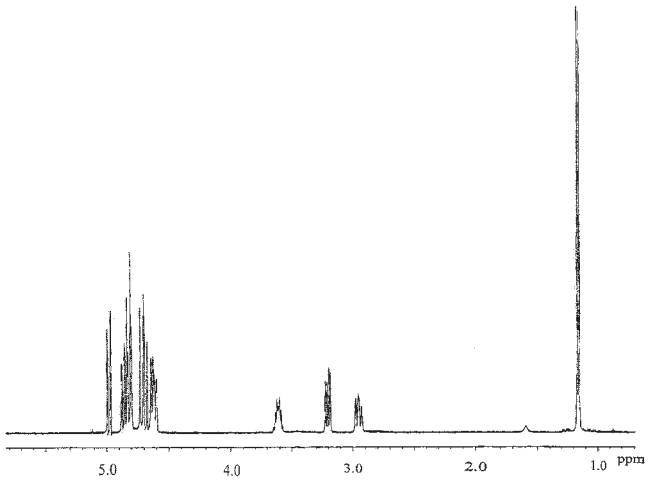

interconversion of **3a** requires also the eclipsing of the atoms of the ethylene bridge, but this is already more than half complete in the ground state of the molecule: the X-ray data (Table 4) show that the dihedral angle for N-CH_2-CH_2-N is not about 60°, as required for a staggered conformation, but 25.7° (Table 4).

At lower temperatures, the rate of interconversion drops, as evidenced by the changes in NMR spectra shown in Fig. 5. At –30°C, the ^{1}H peaks of N-CH_2-O (carbon atoms C1, C′1, C2, C′2) can be calculated as two AB quartets, one at δ = 4.66 and 4.88 ppm (^2J = 13.5 Hz), the other at δ = 4.70 and 4.77 ppm (^2J = 12.1 Hz). The high field doublet in each quartet shows a long-range splitting (^4J = 2 Hz) due to coupling to one of the ethylene protons. The spectrum for ethylene (C3 and C′3) shows symmetrical multiplets at δ = 3.347 and 3.227 ppm, and additional splitting from long-range coupling.

*NMR spectrum of compound **3b***

This compound does not show a rapid interconversion of conformers at 30°C, so that its ^{1}H NMR spectrum has a detailed structure not found in the spectrum of **3a** until the temperature of the latter has been reduced to about –20°C. The methyl group of **3b** is attached to the two-carbon bridge by a bond pointing outward; a conformational inversion would end with this bond pointing inward, into a region of steric congestion, and so is not possible. This steric effect also explains why 2-methyl-1,2-diaminopropane does not react with formaldehyde and hydrogen peroxide to form the cage diperoxide **3c**.

Table 5. NMR data for compound **3b** in $CDCl_3$.

Position	^{13}C δ (ppm)	^{1}H δ (ppm)	COSY
1	89.4	A 4.689 d of d	1A, 1B, 4B
		B 4.868 d of d	1B, 1A, 5A
2	91.5	A 4.633 d	2A, 2B, 3B, 6
		B 4.818 d	2B, 2A
3	84.3	A 4.720 d	3A, 3B
		B 4.984 d of d	3B, 3A, 2A, 6
4	91.8	A 4.824 d	4A, 4B, 5B
		B 4.616 d of d	4B, 4A, 1A
5	58.4	A 2.955 t	5A, 5B, 6, 1B
		B 3.239 m	5B, 5A, 6, 4A
6	56.3	–3.612 m	6, 5A, 5B, 7, 3A, 2A
7	15.6	–1.160 d	7, 6

The ^{1}H NMR spectrum of compound **3b** (Fig. 6; see also Table 5) corroborates the details of structure established by X-ray diffraction and shown in the ORTEP diagram of Fig 2. The signal for the three methyl protons (1.16 ppm) at position 7 is split by coupling (^3J 6.5 Hz) to the single proton at position 6 (m, 3.61 ppm). This proton in turn is coupled to the A (^3J 14 Hz) and B (^3J 7 Hz) protons at C5. The proximity of the C5 B proton to the C6 proton is shown by the NOESY spectrum.

The signals between δ 4.6 and 5.0 ppm in Fig. 6 are due to the protons at positions 1, 2, 3, and 4. The assignment of signals to positions 1–4 is possible because of their spin-coupling to the protons at positions 5, 6, and 7, as demonstrated by the COSY spectrum. The results are given in Table 5. The rigid cage structure of the molecule results in many pairs of protons being linked by four bonds in a W-configuration (see Table 5), and hence having measurable coupling constants.

The spectrum of **3b** in DMSO-d_6 has signals shifted very slightly to higher fields, but is essentially identical to the spectrum in $CDCl_3$.

NMR spectrum of compound 4

The *trans* fusion of a cyclohexane ring to the diperoxide ring of **4** results in a rigid compound incapable of any conformational change. Its ^{1}H and ^{13}C NMR (Table 6) and COSY and NOESY spectra are those expected from the structure (Fig. 3) established by X-ray diffraction, and require no comment.

Formaldehyde and cage compounds

The results reported above illustrate the proclivity of formaldehyde to form cage compounds (see also refs. 19, 20, 23–26). A further example is given by the reaction of formaldehyde with *trans*-1,2-diaminocyclohexane to give the compound **5**, analogous to cage compounds given by other 1,2-diamines (23, 24, 27). *cis*-1,2-Diaminocyclohexane does not react in this way, presumably for steric reasons. The reaction of formaldehyde with 1,2-diaminoethane gives

[c] Equatorial hydrogen.

the compound **6**, which may have the two methylenes of the ethylene bridge eclipsed (as represented in **6**) or staggered: the X-ray evidence is equivocal (28). However, the fused cyclohexane ring enforces staggering of the corresponding carbon atoms in **5**. Dreiding-type models show that only two enantiomeric forms of this compound are possible.

General conclusions

Small cycloalkane rings of 5 or 6 carbon atoms are more stable than medium-sized rings of 7–10 carbon atoms, because of steric and torsional effects. This is not true when the rings incorporate a peroxide group: medium-sized rings then become more stable than the five- or six-membered, because of the differing energies attendant on change of torsional angle for C-O-O-C and C-C-C-C chains. This fact has not often been recognized (cf. refs. 19–21, 27, 29). The structures **3a**, **3b**, and **4**, containing fused eight-membered rings, furnish further examples of this rule; alternative structures containing the peroxide groups in five-membered rings can be written for these compounds and for HMTD (20).

Spectroscopic studies on effects of triptycyl group on structures and reactivities of triplet arylcarbenes

Hideo Tomioka, Junichi Nakajima, Hidehiko Mizuno, Eiji Iiba, and Katsuyuki Hirai

Abstract: A series of triplet 9-triptycyl(aryl)carbenes, where aryl groups are phenyl, 1- and 2-naphthyl, and 9-anthryl, is generated by photolysis of the corresponding diazomethanes and observed directly by spectroscopic means. Their structures are characterized by electron spin resonance (ESR) spectroscopy in a 2-methyltetrahydrofuran matrix at 77 K, and the reactivities are investigated by laser flash photolysis in degassed benzene solution at room temperature. Comparison of the data with other arylcarbenes bearing a series of substituents, i.e., hydrogen, phenyl, naphthyl, and anthryl groups, revealed an interesting relationship between structures and reactivities of triplet arylcarbenes.

Key words: steric protection, stability of triplet carbenes, electron spin resonance, laser flash photolysis, structure–reactivity relationship.

Résumé : Utilisant la photolyse des diazométhanes correspondants, on a généré une série de 9-triptycyl(aryl)carbènes triplets dans lesquels les groupes aryles sont des groupes phényle, 1- et 2-naphtyle et 9-anthryle et on les a observés directement par des méthodes spectroscopiques. On a caractérisé leurs structures par spectroscopie RPE dans une matrice de 2-méthyltétrahydrofurane à 77 K et on a étudié leurs réactivités par photolyse éclair au laser dans une solution benzénique dégazé, à la température ambiante. Une comparaison de nos données avec celles d'arylcarbènes portant une série de substituants, comme l'hydrogène ou des groupes phényle, naphtyle et anthryle, met en évidence l'existence d'une relation intéressante entre les structures et les réactivités des arylcarbènes triplets.

Mots clés : protection stérique, stabilité des carbènes triplets, RPE, photolyse éclair au laser, relation structure–activité.

[Traduit par la Rédaction]

Introduction

Carbene chemistry has had a unique and interesting history (for a brief summary, see ref. 1). The pioneering work of Staundinger in the 1910s on the decomposition of diazo compounds and ketenes was recognized as the first independent generation of carbenes as a new reactive species. Since radicals were the intermediates "en vogue" in the following decades, they started by being generally regarded as diradicals. The subsequent work of Meerwein, Hine, and Doering contributed much to the recognition of this species as a new type of intermediate, giving characteristic reactions not encountered with radicals. Therefore, the modern history of carbene chemistry is usually considered to date from the 1950s, at a time when the chemistry of other important classes of intermediates, i.e., carbanions, carbocations, and radicals, was already relatively well classified (for reviews, see ref. 2). The complicated nature of carbene, not observed with other trivalent carbon intermediates, arises from the presence of two nonbonding electrons. Thus, carbenes can exist either as singlet or as triplet states, depending on the spins of the two nonbonding electrons. And so, probing the structural features that control the chemical properties of these intermediates always encounters the complicated issues of the relationship between reactivities, singlet–triplet energy gap (ΔG_{ST}), and structures (2, 3).

Product analysis methods have been extensively employed from the early stages of the research in this field and revealed perplexing aspects of reactions undergone by this exotic species (2). From the early 1960s, low-temperature spectroscopic techniques have enabled us to observe this ephemeral species and to understand its structural features, especially in the triplet manifolds (4). In the last two decades, laser flash photolysis has increasingly been applied to the study of carbene processes, and the dynamic properties of this highly reactive species have been investigated more quantitatively (5). Moreover, recent advances in computer technology, in both hardware and software, have dramatically increased the reliability and accuracy of computational chemistry in characterizing and predicting the reactivity–structure relationships of such computationally demanding species (for an excellent review on how to deal computationally with open-shell species, see ref. 6).

Therefore, the entire picture of this challenging species, i.e., the fourth class of carbon-based reactive intermediates in organic chemistry, begins gradually to unfold from a combination of traditional product analysis coupled with modern spectroscopic methods and high-level theoretical calculations.

More importantly, recent advances in technology make it possible for even simple experimentalists to use these state-of-the-art techniques rather routinely with great ease. Even rather challenging issues can be tackled in sophisticated ways with precursor molecules designed to generate reactive species appropriate for studying a specific issue.

The present study was undertaken in order to understand how the structure and reactivity of triplet carbenes are affected by electronic and steric effects (7). For this purpose, we designed and generated triptycyl(aryl)carbenes (**2**), where the triptycyl (Trp) group is expected to act as a kinetic protector, while aryl groups ranging from phenyl to anthryl will accept the unpaired electrons. We investigated the relationship between the structure and reactivities of **2** by ESR spectroscopy in matrices at low temperature and used time-resolved UV–vis spectroscopy in solution at room temperature. Data from these two complementary means were compared with those obtained in other arylcarbene systems, i.e., **3**–**6**, where π-conjugation effects are expected to play a more important role. The results revealed how these two factors affect the thermodynamic and kinetic stability of triplet carbenes. Preliminary reports of the present study have been published (8).

Results and discussion

Triptycyl(aryl)diazomethanes (**1**) employed in this study were prepared according to the reactions outlined in Scheme 1. When the aryl groups were phenyl (Ph) or 1- and 2-naphthyl (Np), the desired diazomethanes were obtained by the conventional hydrazonation of the corresponding ketones, followed by oxidation. This method could not be applied to the preparation of sterically more demanding diazomethane, i.e., **1d**, which was synthesized by the addition of benzyne to di(9-dianthryl)diazomethane under very mild conditions. Purification of the diazomethanes by repeated chromatography on a gel permeation column was carried out to obtain pure diazomethanes for spectroscopic studies.

ESR studies in rigid matrices at low temperatures

Irradiation of 9-triptycyl(phenyl)diazomethane (**1a**) in a 2-methyltetrahydrofuran (MTHF) glass at 77 K gave a fine-structured EPR spectrum. A lineshape characteristic of randomly oriented triplet molecules with a large *D* value attributable to a one-center $n\pi$ spin–spin interaction at the divalent carbon of arylcarbene **2a** was observed (Fig. 1*a*). The signals were analyzed in terms of *D* and *E* values and are reported in Table 1.

The *D* value is related to the separation between the unpaired electrons and the *E* value is a measure of the difference of the magnetic dipole interaction along the *x* and *y* axes. More plainly, the *D* value allows the determination of the amount of delocalization in carbenes with conjugated π-

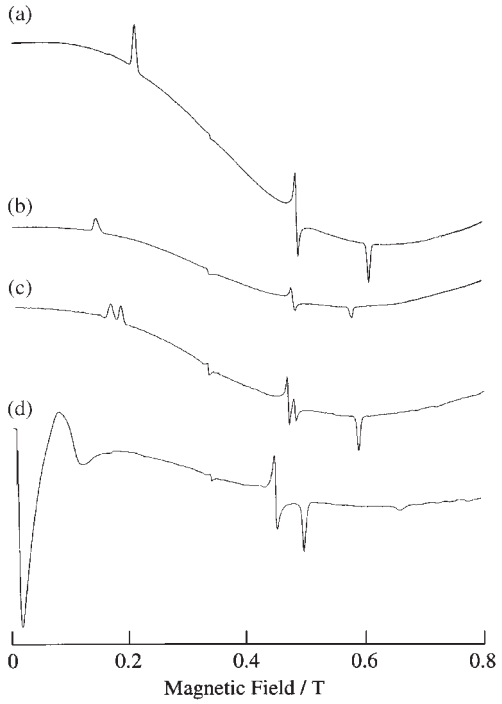
Fig. 1. ESR spectra obtained by irradiation of 9-triptycyl(aryl)diazomethanes (**1**) in MTHF matrix at 77 K, where aryl groups are (*a*) Ph, (*b*) 1-Np, (*c*) 2-Np, and (*d*) 9-An.



systems. The *D* value decreases with increasing delocalization of the unpaired electron, and the *E* value allows one to estimate the bond angles at the carbene center. For a linear carbene $E = 0$ is expected, while decreasing the bond angle leads to a larger value for *E*. The *E*/*D* ratio is frequently used to estimate the bond angle (4, 9).[2,3]

To obtain some insight into the effect of the Trp group on the structure of triplet carbene, it is useful to compare the zero-field splitting (ZFS) parameters observed for "parent" phenylcarbenes **3a** (10*a*). A very small difference in *D* values between the two is observed. This is not surprising, as little π interaction between the unpaired electrons and triptycyl phenyl rings is expected. However, a slight increase in *E* values on going from **3a** to **2a** is rather unexpected since one might expect a larger bond angle for **2a** than for **3a**, upon taking into account the large difference in steric bulkiness between H and Trp groups. A closer look at a molecular model soon reveals that steric interaction between the Ph and Trp groups in **2a** is negligible as the three phenyl rings on the tertiary carbon atom in the Trp group are held back tightly, allowing little steric interference with the phenyl ring on the carbenic carbon. In other words, the carbenic phenyl ring stays within the "spoke" region of the Trp group and hence its *ortho* hydrogens can only expand in the direction where the "peri" hydrogens on Trp cannot interact.

It is interesting to note here that a more significant decrease both in *D* and *E* values is observed on going from monophenylcarbene (**3a**) to diphenylcarbene (**3b**) than to phenyl(triptycyl)carbene (**2a**). The observation suggests that π-delocalization of the spin plays a more important role than the steric interaction in changing the structure of the triplet carbene.

Similar changes in ZFS parameters were observed for naphthylcarbene systems (Fig. 1, Table 1). The *D* and *E* values for "parent" naphthylcarbenes **4a** and **5a** decrease relative to phenylcarbene (**3a**), obviously due to extended π-delocalization (11). Again, very small changes in the *D* values and a rather slight increase in the *E* values are noted as one changes the substituent (X) from H to Trp not only in 2- but also in 1-naphthylcarbene systems. The observations suggest that the 1-Np group in **2b** is located in the cavity of triptycene moiety in order to avoid the interaction between the peri hydrogens, although the peri H on the 1-Np group can potentially interact with the peri H on the Trp group.

In the case of "parent" naphthylcarbenes, a mixture of two rotational isomers, namely s-*Z* and s-*E*, was usually found and these isomers could be readily distinguished by ESR spectroscopy (12). Assignment of ZFS parameters to a specific conformer is made possible by a point spin model as detailed by Roth and Hutton (12). Carbenes have noticeable secondary contributions to *D* due to the nearest carbons with π-electron spin densities. In the case of 2-naphthylcarbene, for instance, the π-electron density at the 1-position is twice that at the 3-position (13). This leads to a larger σ-electron–π-electron coupling for the *E* than for the *Z* isomer. Taking into account the fact that *r*, the distance between the divalent carbon and the C_1 carbon, is close to *z*, the *z* coordinate of C_1, this contribution to *D* is negative. Therefore, the *E* conformer would be expected to have the smaller *D* value.

The ESR spectrum of 9-triptycyl(2-naphthyl)carbene (**2c**) in MTHF at 77 K also consisted of two sets of triplet peaks of similar intensities, assignable to *Z* and *E* rotamers (Fig. 1*c*, Table 1). In marked contrast, only one set of triplet signals was observed in the ESR spectra of the corresponding 1-naphthylcarbene (**2b**) under the same conditions (Fig. 1*b*, Table 1). It may be that the difference in ZFS parameters between the two rotamers for **2b** is too small to be resolved by ESR under the present conditions. This is rather unlikely since the ZFS parameters between the two rotamers of parent 1-naphthylcarbene (**4a**) are well separated and no significant changes in the values are expected on going from 1-naphthylcarbene (**4a**) to triptycyl(1-naphthyl)carbene (**2b**), taking into account the small overall change in spin distribution in triplet **4a** when H is replaced with Trp.

The more likely explanation is ascribable to steric factors. It has been shown by a kinetic analysis that the *E* isomer of 1-naphthylcarbene (**4a**) is lower in energy than the *Z* isomer, probably because of steric interaction of the peri H with the hydrogen on the carbene carbon (14). In triptycyl(1-naphthyl)-carbene (**2b**), this hydrogen is replaced with the bridgehead tertiary carbon and hence steric repulsion with the peri H in

[2] A large number of triplet carbenes have been characterized by ESR spectroscopy since the pioneering work of Wasserman et al. (9).

[3] A referee has suggested that the ratio *E*/*D* is not always a reliable guide to the structure of triplet carbenes. Diphenylcarbene and fluorenylidene have very different geometries but almost exactly the same *D* and *E* values. We assume that comparison of the values observed for a series of carbenes with a similar structure would still provide some clues to the structural change of carbenes in a qualitative sense.

the *Z* isomer is expected to be much more severe than the H–H interaction in *Z*-1-naphthylcarbene. Therefore the energy difference between the two isomers becomes large enough to form the more stable isomer almost exclusively.

It should be noted here that the internal rotation of the 9-substituent around the bridgehead C—C bond in 9-substituted triptycenes is known to be hindered even at room temperature, especially when the 9-substituent is bulky (15). Since triplet triptycyl(1-naphthyl)carbene (**2c**) still has a significantly bent structure as judged from the *E* value, it is not likely that ^{3}**2c** can undergo free rotation to convert the less stable *Z* isomer into the more stable *E* isomer in matrices at low temperature. It may be, then, that the precursor diazo compound also exists predominantly as one rotamer, generating the *E* isomer.

When Trp is replaced by phenyl and naphthyl groups, i.e., on going from **2b** to **4b** and **4c** (16, 17) and from **2c** to **5b** and **5d** (16, 18), respectively, a significant decrease both in the *D* and *E* values is again observed, obviously due to extended π-delocalization. The observation again suggests that π-delocalization of the spins has more influence on the structure of triplet carbenes than do steric factors.

The effects of the Trp group on 9-anthrylcarbene (19) were somewhat different from those observed with the former two carbenes. The most notable change in this case is a rather significant decrease in the *E* value (Fig. 1*d*, Table 1). This suggests that the central bond angle undergoes significant opening as one introduces the Trp group at the 9-position. This can be easily interpreted in terms of a steric interaction between the peri H and the bridgehead carbon, as advanced above. The anthryl group has peri hydrogens both at the 1- and 8-positions and therefore cannot avoid steric interaction with the bridgehead carbon. Thus triptycyl(9-anthryl)carbene (**2d**) exhibits the smallest *E*/*D* values among triplet triptycyl(aryl)carbenes (**2**) studied in this work.

Much more significant reduction in the ZFS parameters is observed for di(9-anthryl)carbene (**6e**), which is suggested to have an almost completely linear and perpendicular geometry in which extensive delocalization of the unpaired electrons into the anthryl portions is proposed (**2a**). Since the anthryl group is planar and considerably less bulky than the triptycyl group, the fact that di(9-anthryl)carbene has a more linear and perpendicular structure than triptycyl(9-anthryl)carbene (**2d**) clearly suggests again that π-delocalization of the unpaired electrons plays a more important role in determining the structure of carbenes than do steric effects.

Laser flash photolysis studies in solution at room temperature

Irradiation of 9-triptycyl(phenyl)diazomethane (**1a**) in MTHF matrix at 77 K was monitored by UV–vis spectroscopy, which revealed the rapid appearance of new absorption bands at the expense of the original absorption due to **1a**. As shown in Fig. 2*a*, the new spectrum consists of two identifiable features, a rather sharp UV band with maximum at 314 nm and a weak broad band with an apparent maximum around 400 nm. These features are usually present in the spectra of triplet arylcarbenes in organic glasses at 77 K (4, 20). The glassy solution did not exhibit any changes for several hours when kept at 77 K. However, when it was allowed to warm to room temperature and then cooled to 77 K, the characteristic bands disappeared. On the basis of these observations, coupled with the fact that EPR signals characteristic of triplet carbene were observed under identi-

[c]Half-life ($t_{1/2}$) for carbene decaying in second order and lifetime (τ) for carbene decaying in first order.

cal conditions, the absorption spectrum is safely attributable to triplet carbene **2a**.

Laser flash photolysis (LFP) of **1a** in a degassed benzene solution at 20°C with a 10 ns, 70–90 mJ, 308 nm pulse from a XeCl excimer laser produced a transient species showing a strong absorption at 314 nm, which appeared coincident with the pulse. On the basis of the low-temperature spectrum, we assign the transient product to triplet **2a**. Support is lent to this assignment by trapping experiments using oxygen. Thus, LFP of **1a** in a non-degassed benzene solution resulted in a dramatic decrease in the lifetime of triplet **2a** and a concurrent appearance of a new absorption band at 410 nm. The rate of increase in the band at 410 nm is practically the same as that of the peak due to ^{3}**2a**, showing that triplet **2a** is quenched with oxygen to form a new species. Subsequent analysis of the spent solution showed the presence of a large amount of 9-triptycyl phenyl ketone. It is well documented that arylcarbenes with triplet ground states are readily trapped by oxygen to give the corresponding aryl ketone oxides, which usually show a rather broad band centered around 390–450 nm (21, 22). Thus, the observation can be interpreted as indicating that the triplet **2a** is trapped with oxygen to generate a carbonyl oxide, confirming that the transient absorption quenched by oxygen is due to ^{3}**2a**. A plot of the observed pseudo-first-order rate of carbonyl oxide formation versus oxygen concentration yields the quenching rate constant $k_{O2} = 1.6 \times 10^9$ M^{-1} s^{-1}.

The decay of the transient absorption due to ^{3}**2a** in the absence of oxygen was found to be first order ($k = 1.21 \times 10^3$ s^{-1}) and the lifetime is estimated to be 840 μs (Table 2). The lifetime of parent triplet phenylcarbene (**3a**) is estimated to be ~200 ns in pyridine (10*b*). Therefore, the lifetime increase of triplet phenylcarbene by addition of a Trp group is roughly estimated to be some 3 to 4 orders of magnitude. It should be noted here that this stabilization by Trp group originates mainly from kinetic factors, since no significant change in the structure of triplet carbenes is observed, at least in matrix at low temperature (vide supra). In this respect, it is very interesting to note that ^{3}**2a** is approximately 10^3 times longer lived than diphenylcarbene ^{3}**3b** (23), which must undergo significant thermodynamic stabilization as judged by considerable decrease in the ZFS parameters. Thus, kinetic stabilization is shown to play a dominant role in stabilizing triplet carbenes. Product analysis studies suggest that the Trp group is reluctant to undergo migration to the carbenic center. For instance, reactions in less reactive solvents such as benzene afforded rather complex mixtures, but no possible products arising from tribenzobicyclo[3.2.2]nonatetraene or -triene as a result of rearrangement in **2a** were detected to the limit of ^{1}H NMR detection. This is to be compared with other bicycloalkyl groups that undergo rather facile rearrangement to the carbenic center, leading to bridgehead alkenes (24). Taking into account that the [3.2.2]nonatetraene is not extremely strained, compared to other bridgehead olefins formed in the rearrangement of bicyclo(alkyl)carbenes, the slow migration of triptycyl group to the carbene center is rather puzzling. A possible explanation for the difference would appear to involve the difference in migratory aptitude between alkyl and phenyl in bicycloalkyl and triptycyl cases, respectively.

A remarkably thermal stability of triplet **2a** is also noted in monitoring the spectral changes as a function of temperature at low temperature. Thus, no appreciable changes were observed for the characteristic UV–vis spectrum of ^{3}**2a** in MTHF up to 115 K. Significant decomposition began only at 120 K. It should be noted that monophenylcarbene (^{3}**3a**) is not observable in MTHF even at 77 K since it is highly reactive under these conditions. EPR signals are observed at 77 K only when a more viscous and less reactive matrix, e.g., *p*-dichlorobenzene, is employed (see footnote 3). Moreover, diphenylcarbene (^{3}**3b**) can be observed in MTHF at 77 K but its absorption starts to disappear even below 90 K.[4]

Similar trends were observed for the naphthylcarbene systems. Triptycyl(1-naphthyl)carbene (^{3}**2b**), for instance, also decayed in first-order fashion and has a lifetime of 21 ms (Fig. 3, Table 2), which is 10^5 times longer lived than the parent 1-naphthylcarbene (^{3}**4a**) (25, 26), and 10^3 times longer lived even than di(1-naphthyl)carbene (^{3}**4c**) (17), which must undergo significant thermodynamic stabilization by the two naphthyl groups in addition to kinetic stabilization resulting from steric repulsion between the two peri hydrogens. These observations again support the idea that kinetic stabilization plays a much more important role than thermodynamic factors in increasing the lifetime of triplet carbenes.

The effect of a Trp group on the reactivity of 2-naphthylcarbene (^{3}**5a**) is rather smaller than that of the 1-isomer (^{3}**4a**). The carbene center in ^{3}**5a** is essentially the same as that in phenylcarbene with respect to steric factors and therefore the effect of steric shielding by the Trp group would be expected to be similar between the two.

9-Anthrylcarbene (**6a**) is considered to be the most stable among the monoarylcarbenes studied since the carbenic center is shielded by the two peri hydrogens and the unpaired electrons are extensively delocalized into the anthryl ring, and hence **6a** is expected to be protected quite well once the Trp group is introduced at the 9-positions. ESR data in matrix at low temperature support these ideas.

Contrary to this expectation, the lifetime of triptycyl(9-anthryl)carbene (^{3}**2d**) was found to be shorter than most of its naphthyl analogues (^{3}**2b** and ^{3}**2c**), shorter even than the phenyl derivative (^{3}**2a**); transient absorption ascribable to ^{3}**2d** decayed in second order ($2k/\varepsilon l = 2.4 \times 10^4$ s^{-1}) and the half-life was estimated to be 280 μs (Fig. 3*c*, Table 2). A possible explanation for this rather unexpected decrease in lifetime may reside in an extensive delocalization of the unpaired electrons into the anthryl ring. Then, since the carbenic center in ^{3}**2d** is effectively shielded from external reagents by the two and three peri hydrogens on the aromatic and triptycyl rings, respectively, simple reaction at the carbenic center must suffer from severe steric hindrance. The carbene is then forced to react at the aromatic rings where the unpaired electrons are delocalized. It is well known that trityl radicals undergo either "head-to-tail" (methyl–*para*) or "tail-to-tail" (*para*–*para*) coupling depending on the substitution (27). Similar reactions on the aromatic rings are also suggested for the decay pathways of triplet diphenylcarbenes bearing steric protectors at the *ortho* positions. The decay rates of triplet 2,2′,6,6′-tetrabromodiphenylcarbenes, for instance, are highly sensitive to the *para* substituents and decrease as more bulky groups are introduced at the *para* positions (28). Such reactions are expected to become more facile as the numbers of fused aromatic rings are increased; the loss of the resonance energy as a result of such a reaction on the first aromatic ring is estimated to decrease from 36 to 25 to 11 kcal/mol on going from benzene to naphthalene to anthracene (29). It should be noted here that triplet di(9-anthryl)carbene (^{3}**6e**) decays significantly faster than triplet diphenylcarbene (^{3}**3b**) (30). Since ^{3}**6e** eventually produces a carbene trimer as a result of coupling at the 10,10′-positions, while the main decay pathway for ^{3}**3b** is simple dimerization at the carbenic carbon (31), the significant difference in stabilities between the two carbenes can be interpreted in terms of the difference in the facility of the reaction at the aromatic sites. Therefore, while the carbene center of ^{3}**2** is shielded more effectively on going from ^{3}**2a** to ^{3}**2d**, the extent of π-delocalization of the unpaired electrons and the facility of the reaction at the aromatic sites are increased in the same order. The steric and electronic factors are operating in opposite directions. The lifetime data observed for ^{3}**2** reflect the overall effects of these counteracting factors.

Summary

The relationship between structure and reactivity for triplet arylcarbenes has been investigated systematically for a series of 9-triptycyl(aryl)carbenes (**2**) by using matrix isolation techniques at low temperature and time-resolved spectroscopies in solution at room temperature.

It has been revealed that π-delocalization of the spin to aromatic rings is more influential than steric factors in causing triplet arylcarbenes to assume a thermodynamically more favorable structure with respect to the corresponding singlet state, but that extensive delocalization eventually tends to decrease the kinetic stability of triplet arylcarbenes as a result of spreading the reactive centers over the π framework of the molecules. Steric protectors, on the other hand, exhibit less significant effect on the structure of triplet carbenes than aromatic groups but increase the lifetime much more significantly, obviously as a result of kinetic stabilizations. Thus, a delicate balance between these two counteracting factors determines the overall reactivities of triplet arylcarbenes.

Experimental section

General methods

IR spectra were measured on a JASCO A-100 recording spectrometer and the mass spectra were recorded on a Shimadzu QP-1000 mass spectrometer (70 eV). ^{1}H and ^{13}C NMR spectra were determined with either JEOL JNM-EX 270 or JNM-500 spectrometers. UV–vis spectra were recorded on a Hitachi 220-S spectrometer. Thin-layer chromatography was done on Merck Kieselgel 60 PF 254. Column chromatography was carried out on silica gel (ICN for dry column chromatograph). HPLC and GPC measurements were undertaken with a JASCO 800 chromatograph equipped with a UVIDEC-100-II UV–vis detector using a Fine pack C18-T5 column (4.6 × 25 cm) and a Shodex GPC H-2001 (20 mm × 50 cm) column, respectively, and GLC was carried out with a Yanagimoto G-80 gas chromatograph using an OV-17 on a Diasolid L (5.0 mm × 50 cm) column.

Preparation of 9-triptycyl(phenyl)diazomethane (1a)

To a solution of PhLi, prepared by reacting PhBr (345 mg, 2.2 mmol) and Li (38 mg, 5.5 mmol) in anhydrous Et_2O (2 mL), was added 9-(formyl)triptycene (300 mg, 1.1 mmol) (32) in anhydrous PhH (3 mL) over a period of 30 min and the mixture was stirred until all of the aldehyde was consumed. The mixture was quenched with saturated aqueous NH_4Cl solution (15 mL) and extracted with three 10 mL portions of Et_2O. The organic layer was dried over Na_2SO_4 and the ether was evaporated to dryness. The crude product was purified by preparative TLC (SiO_2), eluting with

CH_2Cl_2–*n*-hexane (1:1), to give α-*(9-triptycyl)benzyl alcohol* as a white viscous oil in 86% yield; ^{1}H NMR ($CDCl_3$) δ: 1.62 (d, *J* = 7.6 Hz, 1 H), 5.42 (s, 1 H), 6.51 (s, 1 H), 6.89–7.04 (m, 3 H), 7.07–7.24 (m, 2 H), 7.30–7.40 (m, 5 H), 7.47–7.56 (m, 3 H), 7.72 (d, *J* = 7.59 Hz, 1 H), 7.91 (d, *J* = 7.59 Hz, 1 H). To a stirred solution of the benzyl alcohol (260 mg, 0.72 mmol) in acetone (10 mL) was added a mixture of CrO_3 (111 mg), concentrated H_2SO_4 (0.06 mL), and H_2O (0.72 mL) and the mixture was stirred under reflux until the alcohol was consumed. The mixture was poured into a 5% aqueous $NaHCO_3$ solution (100 mL) and extracted with three 15 mL portions of CH_2Cl_2. The organic layer was washed with H_2O and dried over Na_2SO_4, and CH_2Cl_2 was evaporated under reduced pressure. The crude product was purified by preparative TLC (SiO_2), eluting with CH_2Cl_2–*n*-C_6H_{14} (1:1), to give *9-triptycyl phenyl ketone* as a white viscous oil in 90% yield; ^{1}H NMR ($CDCl_3$) δ: 5.40 (s, 1 H), 6.89 (t, *J* = 7.26 Hz, 3 H), 7.00 (t, *J* = 7.59 Hz, 3 H), 7.32 (t, *J* = 7.76 Hz, 3 H), 7.42 (d, *J* = 7.26 Hz, 3 H), 7.52 (d, *J* = 7.58 Hz, 3 H), 7.81 (d, *J* = 6.93 Hz, 2 H). A mixture of the ketone (200 mg, 0.56 mmol), N_2H_4·HCl (200 mg, 1.9 mmol), anhydrous N_2H_4 (10 mL), and anhydrous EtOH (5 mL) was placed in a Pyrex heavy-walled, narrow-mouthed tube. The tube was sealed and placed in an oil bath heated at 100–110°C for 24 h, after which time it was chilled in an ice bath and opened. The contents were poured into ice-water and extracted with three 10 mL portions of CH_2Cl_2. The organic layer was washed with H_2O, dried over Na_2SO_4, and evaporated to dryness. The crude material was purified by preparative TLC, eluting with CH_2Cl_2–*n*-C_6H_{14} (1:1), to leave *9-triptycyl phenyl ketone hydrazone* as a gummy yellowish solid in 48% yield; ^{1}H NMR ($CDCl_3$) δ: 5.36 (s, 1 H), 5.92 (s, 2 H), 6.83–6.89 (m, 3 H), 6.92–6.97 (m, 3 H), 7.25 (d, *J* = 5.94 Hz, 3 H), 7.32–7.41 (m, 3 H), 7.46–7.53 (m, 3 H), 7.56–7.59 (m, 2 H). A mixture of the hydrazone (100 mg, 0.28 mmol) and $Ba(MnO_4)_2$ (193 mg, 0.56 mmol) in anhydrous Et_2O (10 mL) was stirred at room temperature in the dark for 5 h. The mixture was filtered and the filtrate was evaporated to dryness under reduced pressure at room temperature. The crude product was purified by chromatography on a gel permeation column with $CHCl_3$ to afford pure *9-triptycyl(phenyl)diazomethane* (**1a**) as a reddish semisolid in 61% yield; IR (KBr) ν_{max}: 2088 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 5.44 (s, 1 H), 6.90–7.15 (m, 8 H), 7.25–7.34 (m, 6 H), 7.53 (d, *J* = 7.68, 3 H).

Preparation of 9-triptycyl(1-naphthyl)diazomethane (1b)

$SOCl_2$ (35.7 g, 0.4 mmol) was added to a solution of 9-triptycenecarboxylic acid (3.94 g, 13.2 mmol) (33) in anhydrous dioxan (25 mL) and the mixture was refluxed overnight. After evaporation of the solvent and unreacted $SOCl_2$ under reduced pressure, *9-triptycenecarboxylic chloride* was obtained as a yellowish crystal, which was used without further purification. To a solution of 1-naphthyl magnesium bromide, prepared by refluxing 1-bromonaphthalene (0.877 mg, 4.74 mmol) with Mg (113.7 mg, 4.74 mmol) in anhydrous THF (15 mL), was added the chloride (1.0 g, 3.16 mmol) in anhydrous THF (3 mL) and the mixture was stirred overnight. The mixture was quenched with saturated aqueous NH_4Cl solution and extracted with three 10 mL portions of CH_2Cl_2. After evaporation of the solvent, the crude mixture was purified by preparative TLC (SiO_2), eluting with CH_2Cl_2–*n*-C_6H_{14} (1:1), to give *9-triptycyl 1-naphthyl ketone* as a colorless solid in 30% yield; mp 112–114°C; ^{1}H NMR ($CDCl_3$) δ: 5.44 (s, 1 H), 6.90 (t, *J* = 7.59 Hz, 3 H), 7.01 (t, *J* = 7.43 Hz, 3 H), 7.20–7.26 (m, 1 H), 7.44 (d, *J* = 7.92 Hz, 6 H), 7.49–7.58 (m, 2 H), 7.62–7.68 (m, 1 H), 7.73–7.79 (m, 1 H), 7.98–8.03 (m, 1 H), 8.86 (d, *J* = 8.91 Hz, 1 H). A mixture of N_2H_4·HCl (300 mg, 2.85 mmol), anhydrous N_2H_4 (3 mL), and the ketone (200 mg, 0.49 mmol) in anhydrous PhH (1 mL) and EtOH (3 mL) was heated in a sealed tube at 100–110°C for a week. The usual work-up, followed by preparative TLC, gave *9-triptycyl 1-naphthyl ketone hydrazone* as a white semisolid in 53% yield; ^{1}H NMR ($CDCl_3$) δ: 5.38 (s, 1 H), 5.70 (s, 2 H), 6.67–6.73 (m, 3 H), 6.92–7.29 (m, 7 H), 7.34–7.48 (m, 3 H), 7.55–7.67 (m, 3 H), 7.92–8.03 (m, 2 H), 8.26–8.32 (m, 2 H). The hydrazone was oxidized and purified as described above to produce *9-triptycyl(1-naphthyl)diazomethane* (**1b**) as an orange solid in 65% yield; mp 183–184°C (dec.); IR (KBr) ν_{max}: 2040 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 5.45 (s, 1 H), 6.83–7.25 (m, 6 H), 7.28–7.54 (m, 6 H), 7.59 (d, *J* = 8.25 Hz, 1 H), 7.61 (d, *J* = 8.25 Hz, 1 H), 7.69–7.82 (m, 2 H), 7.92–7.99 (m, 1 H), 8.50 (d, *J* = 8.58 Hz, 1 H).

Preparation of 9-triptycyl(2-naphthyl)diazomethane (1c)

This compound was prepared by essentially the same procedure as reported for **1b** by way of the following compounds. *9-Triptycyl 2-naphthyl ketone*: 90% yield; a white crystal; mp 185–186°C; ^{1}H NMR ($CDCl_3$) δ: 5.46 (s, 1 H), 6.87 (t, *J* = 7.59 Hz, 3 H), 7.02 (t, *J* = 7.92 Hz, 3 H), 7.44–7.70 (m, 10 H), 7.84 (t, *J* = 6.76 Hz, 2 H), 8.54 (s, 1 H). *9-Triptycyl 2-naphthyl ketone hydrazone*: 15% yield; a white solid; mp 134–141°C; ^{1}H NMR ($CDCl_3$) δ: 5.38 (s, 1 H), 5.95 (bs, 2 H), 6.81–6.97 (m, 6 H), 7.24–7.39 (m, 6 H), 7.49–7.63 (m, 3 H), 7.82–7.97 (m, 3 H), 8.09 (s, 1 H). *9-Triptycyl(2-naphthyl)diazomethane* (**1c**): 90% yield; a red solid; mp 178°C (dec.); IR (KBr) ν_{max}: 2045 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 5.47 (s, 1 H), 6.85–7.06 (m, 6 H), 7.15 (d, *J* = 8.58 Hz, 1 H), 7.30–7.66 (m, 10 H), 7.70 (d, *J* = 8.58 Hz, 1 H), 7.75–7.80 (m, 2 H).

Preparation of 9-triptycyl(9-anthryl)diazomethane (1d)

To a stirred solution of di-(9-anthryl)diazomethane (150 mg, 0.38 mmol) (19) and phenyl[*o*-(trimethylsilyl)phenyl] iodonium triflate (1.3 g, 2.97 mmol) (34) in anhydrous THF (4 mL) at 0°C was slowly added a dry solution of tetrabutylammonium fluoride (1.5 g, 3.57 mmol) in anhydrous THF (2 mL), through a syringe in the dark. After stirring for 2 h, the mixture was poured into water and extracted with Et_2O. The usual work-up gave a crude mixture, which was purified by repeated chromatography on a gel permeation column with $CHCl_3$. The diazomethane (**1d**) was obtained as an orange solid in 18% yield; mp 69–70°C; IR (KBr) ν_{max}: 2038 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 5.47 (s, 1 H), 6.20 (dd, *J* = 7.92, 7.59 Hz, 1 H), 6.75 (dd, *J* = 7.26, 7.26 Hz), 7.12–7.55 (m, 11 H), 8.12 (d, *J* = 7.59 Hz, 2 H), 8.58 (d, *J* = 7.59 Hz, 1 H), 8.64 (s, 1 H).

ESR measurements

The diazo compound was dissolved in 2-methyltetrahydrofuran (10^{-3} M) and the solution was degassed in a quartz

© 1999 NRC Canada

cell by three freeze–degas–thaw cycles. The sample was cooled in an optical transmission ESR cavity at 77 K and irradiated with a Wacom 500 W Xe lamp using a Pyrex filter. ESR spectra were measured on a JEOL JES TE 200 spectrometer (X-band microwave unit, 100 kHz field modulation). The signal positions were read by the use of a gauss meter.

Low-temperature UV–vis spectra

Low-temperature spectra at 77 K were obtained by using an Oxford variable-temperature liquid nitrogen cryostat (DN 1704) equipped with a quartz outer window and a sapphire inner window. The sample was dissolved in dry 2-MTHF, placed in a long-necked quartz cuvette of 1 mm path length, and degassed thoroughly by repeated freeze–degas–thaw cycles at a pressure near 10^{-5} Torr (1 Torr = 133.3 Pa). The cuvette was flame-sealed under reduced pressure, placed in the cryostat, and cooled to 77 K. The sample was irradiated for several minutes in the spectrometer with a Halos 300 W high-pressure mercury lamp using a Pyrex filter, and the spectral changes were recorded at appropriate time intervals. The spectral changes upon thawing were also monitored by carefully controlling the matrix temperature with an Oxford Instrument Intelligent Temperature Controller (ITC 4).

Flash photolysis

All flash measurements were made on a Unisoku TSP-601 flash spectrometer. Three excitation light sources were used depending on the precursor absorption bands and lifetime of the transient species. They were (*i*) a cylindrical 150 W Xe flash lamp (100 J/flash with 10 μs pulse duration), (*ii*) a Quanta-Ray GCR-11 Nd:YAG laser (355 nm pulses of up to 40 mJ/pulse and 5–6 ns duration; 266 nm pulses of up to 30 mJ/pulse and 4–5 ns duration), and (*iii*) a Lamda Physik LEXTRA XeCl excimer laser (308 nm pulses of up to 200 mJ/pulse and 17 ns duration). The beam shape and size were controlled by a focal length cylindrical lens.

A Hamamatsu 150 W xenon short-arc lamp (L 2195) was used as the probe source, and the monitoring beam, guided using an optical fiber scope, was arranged in an orientation perpendicular to the excitation source. The probe beam was monitored with a Hamamatsu R2949 photomultiplier tube through a Hamamatsu S3701-512Q MOS linear image sensor (512 photodiodes used). Timing of the excitation pulse, the probe beam, and the detection system was achieved through an Iwatsu model DS-8631 digital synchroscope that was interfaced to a NEC 9801 RX2 computer. This allowed for rapid processing and storage of the data and provided printed graphic capabilities. Each trace was also displayed on a NEC CRT N5913U monitor.

Samples were placed in a long-necked Pyrex tube that had a side arm connected to a quartz fluorescence cuvette and were degassed using a minimum of four freeze–degas–thaw cycles at a pressure near 10^{-5} Torr immediately prior to being flashed. The sample system was flame-sealed under reduced pressure, and the solution was transferred to the quartz cuvette, which was placed in the sample chamber of the flash spectrometer. A cell holder block of the sample chamber was equipped with a thermostat and allowed to come to thermal equilibrium. The concentration of the sample was adjusted so that it absorbed a significant portion of the excitation light.

Spectral and cyclic voltammetric characterization of self-assembled monolayers on gold of pyrene end-labeled oligonucleotide duplexes

R. Scott Reese and Marye Anne Fox

Abstract: Self-assembled monolayers of sulfur-terminated oligonucleotide duplexes were formed on flat gold surfaces, either by exposure of a self-assembled monolayer bearing one oligonucleotide strand to the complementary strand or by preformation of a oligonucleotide duplex that was then deposited on a fresh gold surface. Virtually identical spectral behavior was observed whether the duplex was produced before deposition or by in situ complementary association. With a duplex bearing an appropriate pyrene end-label, the resulting thin film was photoresponsive. Surface emission measurements show no evidence for pyrene aggregation on the modified surfaces. The polarity of the photocurrent, reflecting photoinduced electron transfer initiated by photoexcitation of pyrene, is opposite that expected from the oligonucleotide-mediated reduction of the appended pyrene excited state.

Key words: oligonucleotide, self-assembled monolayer, duplex formation, photoelectrochemistry, surface emission.

Résumé : On a formé des monocouches autoassemblées de duplexes d'oligonucléotides se terminant avec des atomes de soufre; ces monocouches ont été formées sur des surfaces planes d'or par exposition d'une monocouche autoassemblée comportant un chaînon d'oligonucléotide vers le chaînon complémentaire ou par préformation d'un duplexe d'oligonucléotide qui est ensuite déposé sur une surface d'or fraîche. On a observé un comportement pratiquement identique quelle que soit la méthode de formation (préformation suivie d'un dépôt ou association in situ). Avec un duplexe comportant un marqueur pyrène approprié en bout de chaîne, le film mince qui en résulte est photosensible. Des mesures d'émission en surface ne fournissent aucune indication à l'effet qu'il se produirait une agrégation de pyrène sur les surfaces modifiées. La polarité du photocourant, qui est un reflet du transfert photoinduit d'électrons initié par la photoexcitation du pyrène, est de sens opposé à celui attendu sur la base d'une réduction, catalysée par l'oligonucléotide, de l'état excité du pyrène attaché.

Mots clés : oligonucléotide, monocouche autoassemblée, formation de duplexe, photoélectrochimie, émission de surface.

Introduction

Electron transfer in DNA and oligonucleotides has been studied intensely, in part because of an ongoing debate as to whether the aromatic base pairs can mediate long-range electron transfer via π-stacking interactions (1–4). Giese and co-workers (5) have recently indicated that the sequence of base pairs can strongly influence the rate and efficiency of electron migration in oligonucleotides, a conclusion supported by experiments within our own group in elaborating rates of photoinduced electron transfer in pyrene-labeled oligonucleotides (6). In that work, we showed that long-distance electron transfer may involve multiple short hops to and from guanines and that the distance dependence of the observed electron transfer rates is complicated because of a less efficient alternative quenching route by thymidine. If so, it may be possible to construct surface-anchored oligonucleotide thin films and (or) self-assembled monolayers through which directional electron flow can be achieved by controlling the sequence of component bases. Such control is important in building the framework for electronic interactions in molecular electronic devices (7–10).

There is, as well, a strong interest in developing DNA sequencing and gene mapping technologies by appending DNA or oligonucleotide segments to surfaces as thin films (11–15). A novel example (14) of this concept is demonstrated by a method in which noncomplementary oligonucleotides are bound to the surface of Au nanoparticles via a sulfur bond. Because the oligonucleotides on the particles are noncomplementary, they do not associate with each other and the particles remain dispersed in H_2O as a dark red suspension. When a solution of an oligonucleotide duplex with

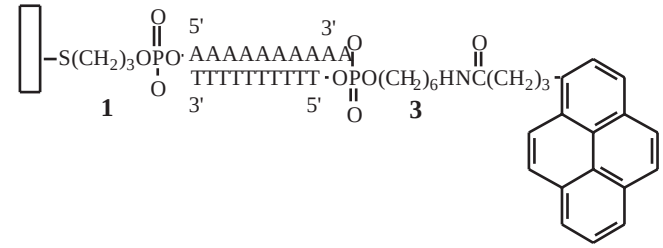
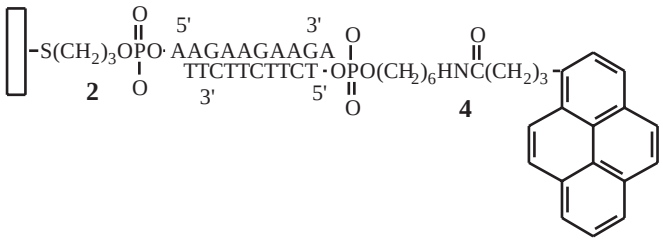
"sticky ends" that are complementary to the two surface-confined oligonucleotides is added to the solution, the nanoparticles aggregate.

For many technological applications, organic thin films (OTFs) are desirable. Because of the molecular-scale control offered by these methods, highly anisotropic films are often obtainable (8–10). This is particularly evident in self-assembled monolayers (SAMs), where surface-affinity and monolayer-packing interactions afford easy synthetic access to structurally well-defined arrays. Furthermore, if a conducting surface is used as a support for the film, the SAM may serve as an "antenna" with which to detect and harness the current generated by the electron transfer. The preparation and evaluation of such SAMs is also important from a fundamental scientific standpoint in that dimensionally controlled electron transfer is ubiquitous in the natural world and is vital in phenomena such as photosynthesis in plants and bacteria. Thus, an understanding of photoinduced electron transfer through a SAM will also play an important role in the development of systems to harness solar radiation as a source of clean, sustainable energy.

Combining our knowledge of photoinduced electron transfer in chromophore-labeled oligonucleotides with our expertise in the construction and characterization of SAMs may produce arrays that can increase our understanding of electron transfer in surface-confined architectures. In turn, this work may lead us closer to our goal of developing solid phase photosynthetic mimics, while contributing to the development of novel DNA probes based on photoactive monolayers. In this work, we describe the construction of photoactive monolayers using surface-confined oligonucleotides **1** and **2** associated with their pyrene end-labeled complements **3** and **4**. We then describe the observed photoresponsiveness of the resulting self-assembled monolayers.





Experimental

General

Unless otherwise noted, all manipulations were carried out under air. Solvents were reagent grade and, like all reagents, were used as received. Oligonucleotides **1** and **2** modified with a free thiol terminus and their oligonucleotide complements as free amines were purchased from Integrated DNA Technology, Coralville, Iowa.

Absorption spectra were acquired on a Shimadzu UV-3101PC scanning instrument, grazing angle reflectance Fourier-transform infrared (GAR-FTIR) spectra on a Nicolet 550 FTIR, circular dichroism spectra (CD) on a Jasco-600, and fluorescence spectra on a SLM Aminco SPF 500 fluorometer.

Synthesis of 3 and 4

The functionalized oligonucleotides **3** and **4** were prepared by the method described by Zahavy and Fox (6). *N*-(3-Dimethylaminopropyl)-*N*′-ethylcarbodiimide HCl (EDC), and *N*-hydroxysulfosuccinimide sodium salt (SNHS) (16, 17) were used as coupling reagents in DMSO–water to append pyrenebutanoic acid to the oligonucleotides complementary to **1** and **2** (6). The modified oligonucleotides were characterized by electrospray mass spectroscopy. Calculated mass for **3:** 3528; found for the double charged ion: 1773.2(±0.4), which is 3546(±1) (M^{2+} + H_2O). Calculated mass for **4**: 3355; found for the double charged ion: 1724.2(±0.4), which is 3448(±1) (M^{2+} + PO_4). The number of the chromophores per strand was estimated by absorption spectrometry to be 0.7 pyrene per oligonucleotide for **3**, and 0.8 pyrene per oligonucleotide for **4**, with the oligonucleotide concentration calculated from its absorption at λ = 260 nm, $\varepsilon = 1 \times 10^5$ M^{-1} cm^{-1}, and the pyrene content calculated from its absorption at λ = 342 nm, $\varepsilon = 1.4 \times 10^4$ M^{-1} cm^{-1}.

Monolayer formation

Monolayers of **1** and **2** were formed by exposing fresh Au surfaces, prepared as previously described (18), to aqueous solutions of **1** and of **2** (400 μM in 10 mM NaCl) for 3–16 h at room temperature. The modified surfaces were rinsed with copious amounts of 10 mM NaCl prior to any measurements. Longer deposition times do not affect either the observed IR spectra of the SAMs or the cyclic voltammetry of a contacting solution redox probe observed on the modified Au electrodes.

Photoelectrochemical measurements

Photoelectrochemical measurements were conducted in aqueous methyl viologen (MV^{2+}, 1 mM in 0.1 M NaCl), which had been deaerated by bubbling with Ar. The experiments were carried out in an electrochemical cell equipped with a quartz optical flat window, with Ag/AgCl as a reference electrode, and a Pt coil as the auxiliary electrode. Photocurrents were obtained by sending the output of a 150 W high-pressure Xe arc lamp through an Oriel 77250 grating monochromator set to pass 346 nm light so that only pyrene-induced effects would be observed. The resulting steady-state photocurrent was recorded under a controlled potential bias. The electrodes were located at the focus of a condensing lens (illuminated area: 0.78 cm^2) held 25 cm from the monochromator. Short-circuit photocurrents and open-circuit photovoltages were measured according to previously described procedures (18).

Fig. 1. GAR-FTIR spectra of SAMs on Au of (*a*) **1** and (*b*) **2**.

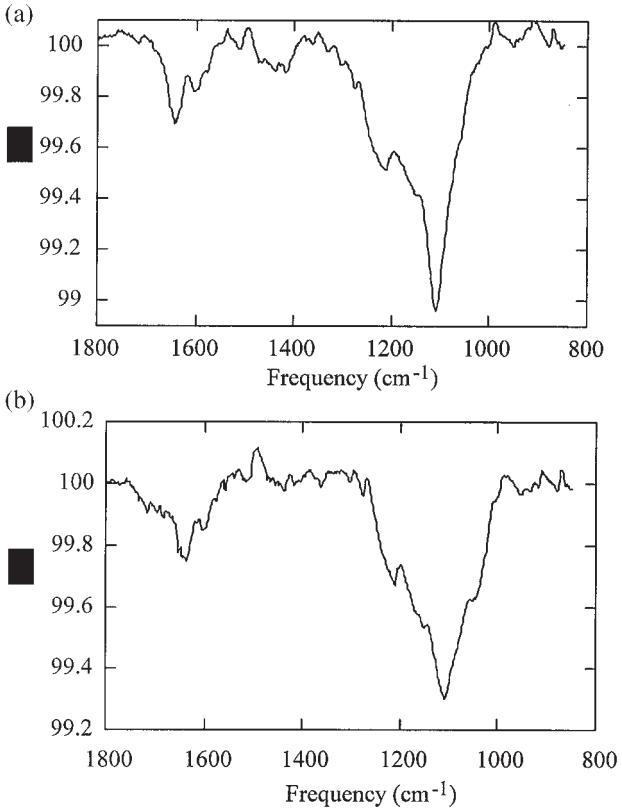

Fig. 2. Cyclic voltammetry of 0.1 M K_4 $Fe(CN)_6$ in deaerated 1 mM aqueous NaCl at bare gold (circles); Au modified with SAMs of **1** (solid line) and **1/3** (broken line). Scan rate: 100 mV/s.

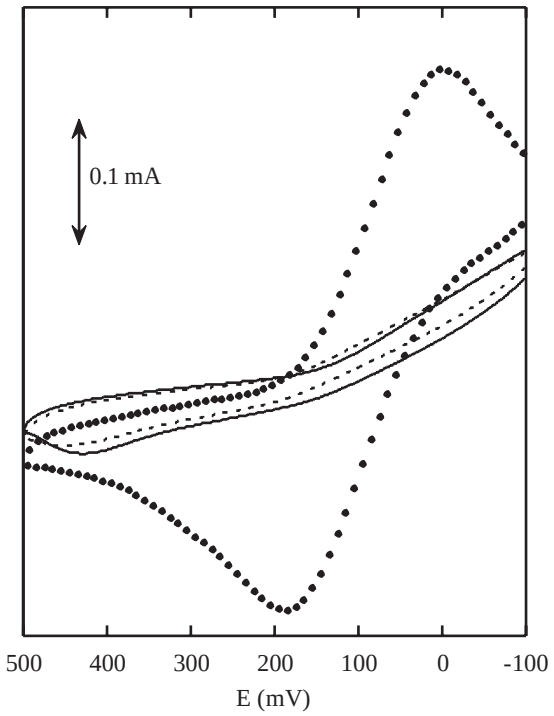

Results

SAMs of 1 and 2 on Au

GAR-FTIR spectra of the SAMs of **1** and **2** on Au exhibit absorptions characteristic of nucleotide oligomers (Fig. 1) (19–21). In the SAM of **1** on Au, a strong absorption assigned to the symmetric vibration of the phosphate group is observed at 1108 cm^{-1} and the asymmetric phosphate vibration occurs at 1213 cm^{-1}. The weak absorptions between 1380 and 1550 cm^{-1} are assigned to the in-plane ring vibrations of adenine and the stronger absorptions between 1550 and 1700 cm^{-1} to the double-bond in-plane vibrations of adenine. The spectrum of a SAM of **2** on Au closely resembles that of **1**, except that the weak absorptions between 1380 and 1550 cm^{-1} attributable to the in-plane ring vibrations of the aromatic bases are not observed.

To demonstrate oligonucleotide binding and to qualitatively evaluate packing of these films, cyclic voltammetry of a contacting 1 mM solution of $K_4Fe(CN)_6$ in 0.1 NaCl was performed at Au electrodes modified with SAMs of **1** and **2**. Although reversible curves are obtained upon repeated recycling of SAMS of either **1** or **2**, the current responses of the SAM-modified electrodes **1** and **1/3** are attenuated compared to the response at bare Au (Fig. 2). The shapes of the cyclic voltammograms are rendered less sigmoidal after exposure to the oligonucleotide, indicating that the electrodes are partially blocked by the films. The observed blocking behavior likely is dominated by electrostatic repulsion of the ferricyanide anion by the polyphosphate oligonucleotide (18).

The time course of the short-circuit current observed in an electrochemical cell employing as a working electrode an electrode modified with a SAM of **1** on Au equilibrated with an aqueous solution of MV^{2+} (1 mM in 0.1 M NaCl) at a potential of –100 mV is shown in Fig. 3. After a rapid initial drop-off of the charging current, the current approaches a limiting capacitative current. The inset is an enlarged plot of the time domain during which the electrode is alternately exposed to and shielded from illumination at 346 nm, with arrows showing when the shutter was open (on) and closed (off). No significant photoresponse beyond background can be observed. This is as expected since there is no absorptive chromophore at 346 nm in this SAM. Exactly analogous behavior was observed with an electrode modified with a SAM of **2** on Au.

SAMs of duplexes 1/3 and 2/4 on Au prepared by treatment of SAMs 1 and 2 with complements 3 and 4

Au surfaces modified with SAMs of **1** and **2** were subsequently exposed to their pyrene end-labeled complements **3** (520 μM in 10 mM NaCl) and **4** (540 μM in 10 mM NaCl), respectively, for 4–16 h. The resulting SAMs were then rinsed with 10 mM NaCl, providing GAR-FTIR spectra that are virtually identical before and after exposure to the complements, apart from weak absorptions assigned to pyrene ring C–C stretching at 1480 cm^{-1} and to C–H stretching at 2850–2975 cm^{-1} (22). The weakness of these additional bands likely reflects the small amounts of pyrene incorporated into the SAM and (or) an orientation of the appended

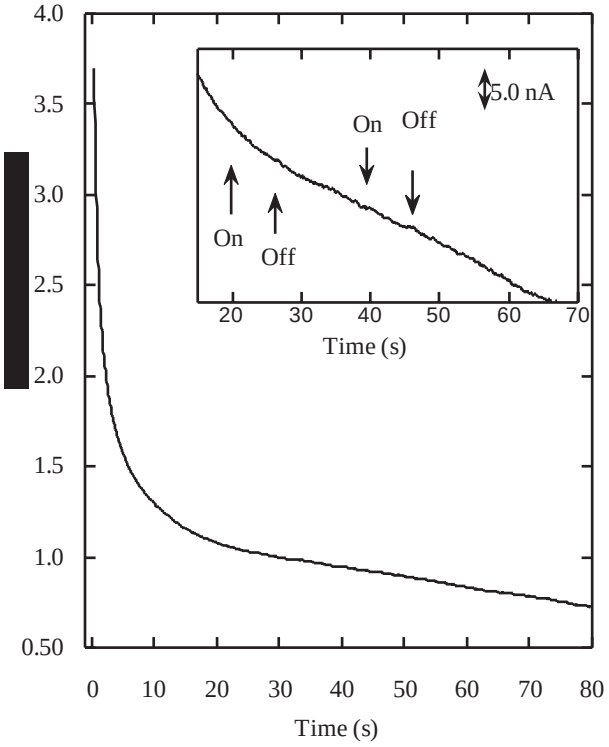
Fig. 3. Time course for the limiting current at a Au electrode modified with a SAM of **1** in a MV^{2+} solution (1 mM in 0.1 M NaCl) at an applied potential of –100 mV vs. Ag/AgCl. The inset shows the time domain in which the electrode is alternately exposed to, and shielded from, illumination at 346 nm, with arrows showing when the shutter was open (on) and closed (off).

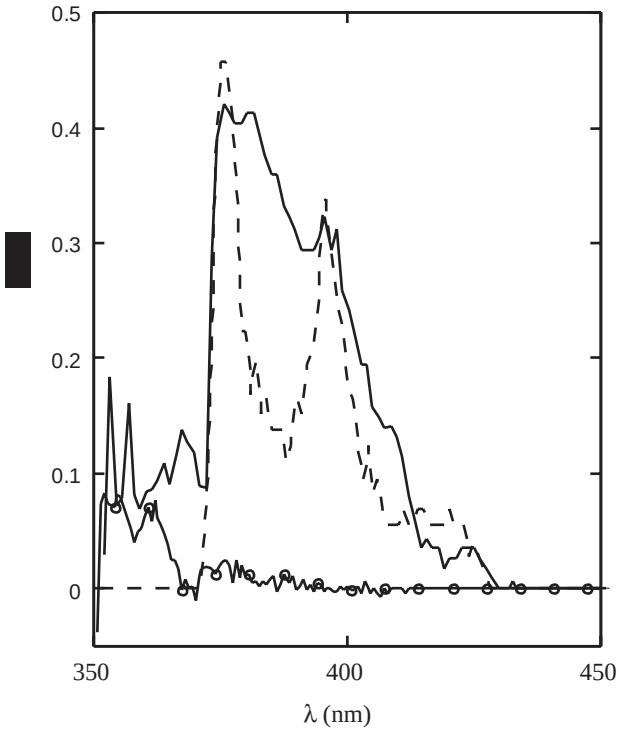


pyrene such that the IR absorptions are attenuated in the reflectance spectrum.

Figure 4 shows an emission spectrum of a film of **1** on Au before and after exposure to **3**. Although there is nearly no absorption in a SAM of **1** on Au in the region from 365 to 450 nm before exposure to the pyrene end-labeled complement, a new emission band is observed in the double-stranded complement with a maximum at 372 nm. This band is similar to the emission observed in micellar solutions incorporating very small concentrations of pyrene (23). Thus, **3** has been successfully incorporated into the **1**/**3** conjugate SAM. The absence of excimer emission at wavelengths longer than 410 nm indicates that the pyrene in this SAM does not form aggregates (23, 24) The emission from the **1**/**3** SAM is less structured than emission from **3** itself in a dilute deaerated 0.1 M KCl (OD = 0.07) solution. The emission from the film is weak and a poor signal-to-noise ratio makes complete subtraction of the scattered light from the Au background difficult. The relatively low intensity of the emission is probably caused by the low concentration of pyrene in the film but partial quenching of the pyrene emission by Au in disordered microdomains may also contribute to this effect (25). Exactly parallel emission effects are observed with a SAM of **2** on Au after exposure to **4**.

Cyclic voltammetry of a contacting 1 mM solution of $K_4Fe(CN)_6$ in 0.1 NaCl at a SAM of **2** before and after exposure to **4** is shown in Fig. 5. The magnitude of the current

Fig. 4. Emission spectra of **3** (OD = 0.7 AU) in deaerated aqueous 0.1 M KCl (broken line) and of SAMs of **1** (circles) and **1**/**3**(solid line) on contact with a deaerated 0.1 M KCl solution. Excitation at 342 nm. The emission spectra are roughly normalized to 375 nm.



passed at the electrode modified with a SAM of **2** on Au decreases so that a small limiting dark current is observed at the modified electrode after it has been exposed to its complement. This indicates fewer pinholes or defect sites that permit access of the electroactive ferricyanide to the charged SAM surface after the film has been exposed to its complement (26). This is further evidence for incorporation of **4** into the **2**/**4** duplex SAM. Analogous behavior (not shown) is observed for a SAM of **1** on Au subsequent to exposure to **3**. In both cases, exposure to the complementary oligonucleotide induces essentially complete (largely electrostatic) shielding of the surface of the electrode from the contacting electroactive solution.

The time course of the current observed with an electrode modified with a SAM of duplex **2**/**4** on Au in contact with aqueous MV^{2+} and an external bias of –100 mV is shown in Fig. 6. It shows similar capacitative behavior as the SAM of **2** but the expanded view of the time domain between 20 and 26 s reveals an anodic current of about 4 nA upon illumination compared to the background dark current. Similar results are observed with a SAM of duplex **1**/**3**, which exhibits an anodic current of about 5 nA upon illumination compared to the background dark current.

Figures 7 and 8 show the time courses of the currents at SAMs of **2**/**4** on Au at potentials of 0 mV and +100 mV, respectively. The capacitative decay current is anodic. The current under illumination is still about 4 nA more anodic than the dark current. Neither the magnitude nor the polarity of the illumination current is affected by the applied poten-

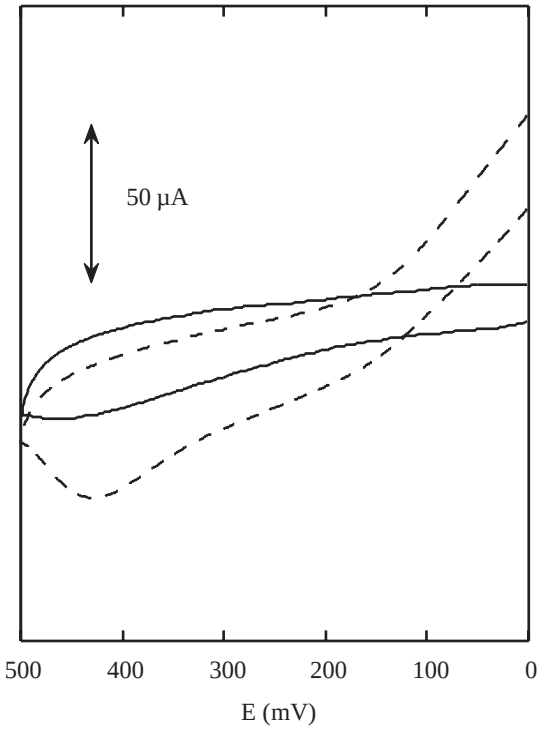
Fig. 5. Cyclic voltammetry of a contacting solution of 1 mM $K_4Fe(CN)_6$ in deaerated 0.1 M NaCl of a SAM on gold of **2** (broken line) and **2**/**4** (solid line). Scan rate: 100 mV/s.



tial bias. Similar behavior is observed for SAMs of **1**/**3** on Au at these potentials.

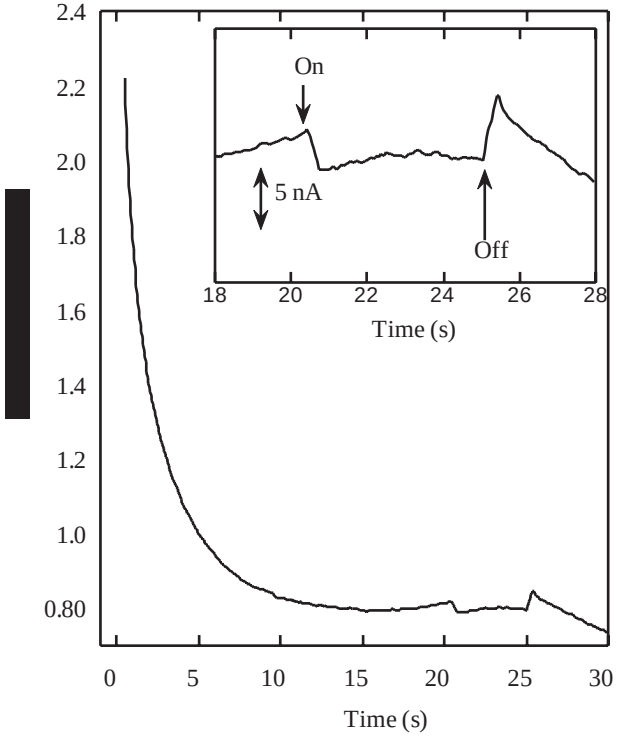
Without MV^{2+} or when hydroquinone (HQ) is substituted for MV^{2+}(10 mM in 0.1 M NaCl) in the contacting solution, no photocurrent is observed at SAMs of **1**/**3** or **2**/**4** on Au.

SAMs prepared from duplexes 1/3 and 2/4 formed in solution and subsequently deposited on Au

An alternative synthesis of SAMs **1**/**3** and **2**/**4** was undertaken in which duplexes **1**/**3** and **2**/**4** were formed in solution and then allowed to assemble on the gold substrate. This synthesis was achieved by allowing **1** and **2**, respectively, to stir gently with equimolar amounts of their complements **3** and **4**, respectively, for 16 h in NaCl (0.01 M). α-Helix formation was established by a Cotton effect in the circular dichroism spectra of the duplexes (Fig. 9) (27). No Cotton effect was observed at wavelengths longer than 320 nm, thus indicating free rotation by the appended pyrene unit.

Solutions of these duplexes were subsequently exposed to clean Au surfaces for 6–20 h. Both the surface emission spectra and the GAR-FTIR spectra of the resulting thin films closely resemble the spectra of SAMs of the surface-formed duplexes **1**/**3** and **2**/**4** discussed above. Pyrene emission at 378 nm from the SAMs prepared from the preformed duplexes confirms the presence of pyrene and, as for the in situ duplex formation technique described above, the absence of excimer emission at longer wavelengths indicates that pyrene aggregates are not formed in the films. The emission spectra of the solution-formed duplexes are virtually identical to those observed for the corresponding surface-formed duplexes. As before, cyclic voltammetry of a contacting

Fig. 6. Time course for the limiting dark current at a Au electrode modified with a SAM of **2** in a MV^{2+} solution (1 mM in 0.1 M NaCl) at an applied potential of –100 mV vs. Ag/AgCl. The inset shows the time domain in which the electrode is alternately exposed to, and shielded from, illumination at 346 nm, with arrows showing when the shutter was open (on) and closed (off).



aqueous solution of $K_4Fe(CN)_6$ at electrodes modified with the solution-formed duplexes behave as microelectrode arrays, demonstrating that the Au surface is mostly blocked by the deposited thin film.

The time course of the currents observed at electrodes modified with films of the solution-formed duplexes **1**/**3** and **2**/**4** in MV^{2+} are completely parallel to those observed with the duplexes formed on the surface, as are the effects induced by the presence and absence of MV^{2+} or HQ.

Discussion

The origin of the photocurrent observed at the SAMs of duplexes **1**/**3** and **2**/**4** on Au in contact with aqueous solutions of MV^{2+} cannot be explained by a standard charge injection mechanism, Fig. 10. The observed wavelength dependence requires that photocurrent production follow from the photoexcitation of appended pyrene, producing a highly energetic electron at the ($pyr^{-\bullet}$/pyr = –2.09 V vs. SCE) (28) energetic level and a reactive hole at the ($pyr^{+\bullet}$/pyr = +1.32 V vs. SCE) (28) level, Fig. 10*a*. One possible route for photocurrent production takes place by excited pyrene ($pyr^{-\bullet}$/pyr = –2.09 V vs. SCE) (28) donating an electron to MV^{2+} ($MV^{+\bullet}/MV^{2+}$ = –0.46 V vs. SCE, ΔG = –1.63 eV) (29) present in the contacting solution. The resulting pyrene radical cation would subsequently be reduced by the poised electrode (28), producing cathodic current

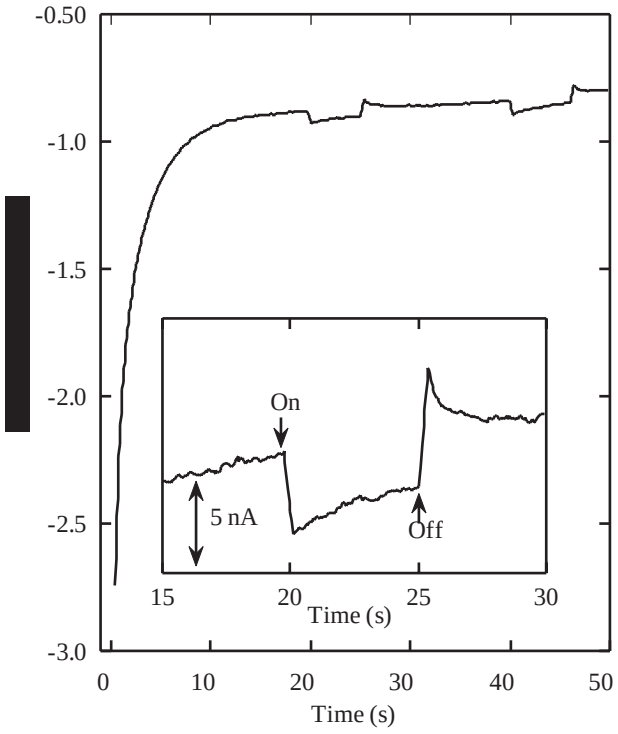

Fig. 8. Time course for the limiting current at a Au electrode modified with a SAM of **2**/**4** in a MV^{2+} solution (1 mM in 0.1 M Na Cl) at an applied potential of +100 mV vs. Ag/AgCl. The inset shows the time domain in which the electrode is alternately exposed to, and shielded from, illumination at 346 nm, with arrows showing when the shutter was open (on) and closed (off).

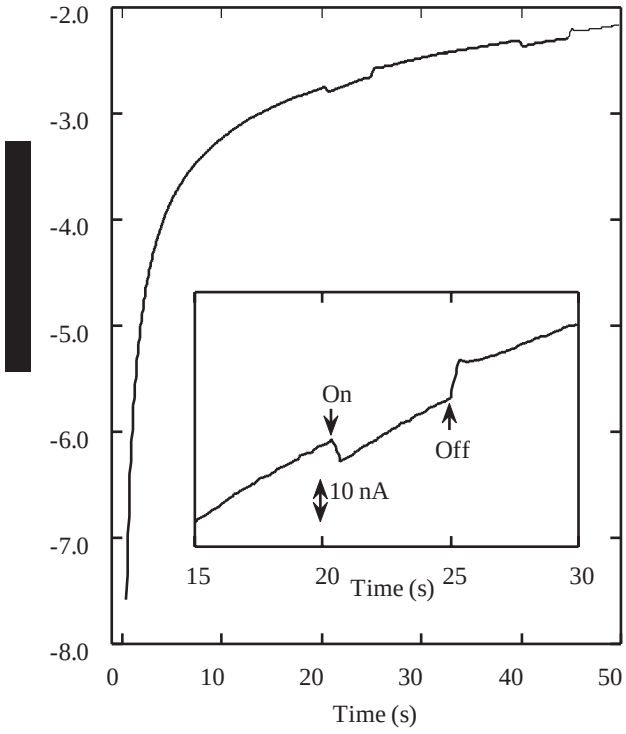

(Fig. 10*b*). In the case of duplex **2**/**4**, the intervening guanine bases ($G/G^{+\bullet}$ = +1.29 V vs. SCE) (30) may facilitate multiple electron hops between the electrode and pyrene (Fig. 10*c*). This would also result in cathodic current at the electrode under illumination. These predictions are opposite to the observed photocurrent on SAMs of **1**/**3** or **2**/**4** on Au, which are anodic.

Anodic photocurrent could be explained by direct injection of an electron from excited pyrene into the electrode. However, for a SAM of **1**/**3** or **2**/**4** on Au in contact with MV^{2+} in aqueous NaCl, there is no species present with the proper redox potential to reduce the resulting pyrene radical cation. Furthermore, when HQ ($HQ/HQ^{+\bullet}$ = +0.46 vs. SCE) (31) is substituted in the place of MV^{2+}, no photocurrent is observed. If electron injection from pyrene were responsible for the photocurrent, the response should be *enhanced*, not inhibited, by the presence of the electron donor HQ.

A conventional explanation for the sign of the observed photocurrent having been rejected, we surmise that another possible source of the observed photoeffects could be a change in the double-layer structure upon light absorption by the surface-bound pyrene. The potential at the electrode with respect to the bulk solution is known to be sensitive to double-layer structure, (32, 33) and changes in double-layer structure and capacitance have been shown to occur concomitant with a change in the redox state of surface-confined species (34, 35). In the case of the pyrene end-labeled polyphosphate duplexes **1**/**3** and **2**/**4** on Au in contact with aqueous MV^{2+}, strong electrostatic effects should produce a compact highly ordered double layer. The double-layer structure may also be affected by ground-state interactions between pyrene and MV^{2+}. Although there is no clear spectral evidence for such interactions in these thin films, ground-state complexes between MV^{2+} and pyrene have been shown to exist in aqueous solution (36) and in sodium dodecyl micelles (37). If such associations existed in the microheterogeneous environment of the thin film – electrolyte interface, they would be hard to detect directly because they would appear as small shifts in broad adsorption bands or as very low extinction charge transfer bands. The difficulty in obtaining electronic absorption spectra of SAMs on Au (by virtue of the very small amounts of absorptive chromophores present in a SAM) makes the detection of ground-state complexes in these particular experiments very difficult. If such complexes do exist and if they contribute to the equilibrium double-layer structure, such associations might be easily disrupted upon excitation of the appended pyrene. For example, charge transfer between the pyrene and MV^{2+} would result in repulsion between the pyrene radical cation and the $MV^{+\bullet}$ as well as a rearrangement of compensating ions and solvent molecules in the double-layer. Such a change in double-layer structure might be manifested as a difference in steady-state capacitative anodic current upon illumination. The possibility that changes in double-

layer structure significantly contribute to photoelectrochemical effects observed at chemically modified eletrodes bears closer scrutiny and specific consideration in future studies.

Conclusions

Sulfur-terminated oligonucleotides **1** and **2** adsorb to flat Au surfaces as self-assembled monolayers. These films partially block the cyclic voltammetric response of $K_4Fe(CN)_6$ in a contacting electrolyte solution. When these SAMs are exposed to solutions of their pyrene end-labeled complements **3** and **4**, respectively, the complements are incorporated into the film and monomeric pyrene emission is observed upon excitation at 342 nm. No substantive change is observed in the GAR-FTIR spectra of SAMs of **1**/**3** or **2**/**4** on Au compared with SAMs of **1** or **2** on Au, but the composite films are more passivating to cyclic voltammetry of a contacting electrochemical couple than are the films of their monomeric counterparts. Virtually identical SAMs can also be prepared from duplexes **1**/**3** and **2**/**4** preformed in solution and subsequently deposited on Au surfaces. The GAR-FTIR and fluorescence spectra, as well as the passivating characteristics of the solution-formed films, are completely parallel to their surface-formed counterparts.

SAMS of **1** or **2** on gold are not photoelectrochemically active themselves, but anodic photocurrent is observed at SAMs of the duplexes **1**/**3** and **2**/**4** in the presence of aqueous MV^{2+} solution. This is consistent with a photocurrent produced by interaction with the appended excited pyrene moiety. The observed photocurrent does not derive from the conventional mechanism for photosensitization by an appended pyrenyl group, which would predict a cathodic, rather than the observed anodic, photoresponse.

Proton and hydrogen atom tunnelling in hydrolytic and redox enzyme catalysis

A.M. Kuznetsov and Jens Ulstrup

Abstract: We discuss a broad theoretical frame for hydrogen transfer in chemical and biological systems. Hydrogen tunnelling, coupling between the tunnel modes and the environment, and fluctuational barrier preparation for hydrogen tunnelling are in focus and given precise analytical forms. Specific rate constants are provided for three limits, i.e., the fully diabatic, the partially adiabatic, and the fully adiabatic limits. These limits are all likely to represent real chemical or biological hydrogen transfer systems. The rate constants are referred particularly to the driving force and temperature dependence of the kinetic isotope effect (KIE). The origin of these correlations is different in the three limits. It is rooted in the tunnel factor and weak excitation of the heavier isotopes in the former two limits, giving a maximum for thermoneutral processes. A new observation is that the adiabatic limit also accords with a KIE maximum for thermoneutral processes but the KIE is here reflected solely in the activation Gibbs free energy differences, in this case rooted in the low-frequency environmental nuclear dynamics. Three systems of biological hydrogen tunnelling, viz. lipoxygenase, yeast alcohol dehydrogenase, and bovine serum amine oxygenase, offer unusual new cases for analysis and have been analysed using the theoretical frames. All the systems show large KIEs and strong indications of hydrogen tunnelling. They also represent different degrees of fluctuational barrier preparation, with lipoxygenase as the most rigid and bovine serum amine oxygenase as the softest system.

Key words: generalized Born–Oppenheimer scheme, kinetic isotope effect, gated proton transfer, partially adiabatic proton transfer, proton tunnelling in enzyme catalysis.

Résumé : On discute d'un cadre théorique général pour le transfert d'hydrogène dans des systèmes chimiques et biologiques. On s'est focalisé sur l'effet tunnel de l'hydrogène, le couplage entre les modes d'effet tunnel, l'environnement et la préparation de la barrière fluctuationnelle pour l'effet tunnel de l'hydrogène et on leur a donné des formes analytiques précises. On fournit des constantes de vitesse spécifique pour trois limites, à savoir les limites complètement diabatique, partiellement adiabatique et complètement adiabatique. Il est probable que ces limites représentent des systèmes réels de transfert de proton chimique ou biologique. Les constantes de vitesse sont reliées particulièrement à la force motrice et à la relation entre la température et l'effet isotopique cinétique (EIC). L'origine de ces corrélations est différente dans les trois limites. Dans les deux premières limites, elle est liée au facteur de l'effet tunnel et à la faible excitation des isotopes plus lourds et ceci conduit à un maximum pour les processus thermiquement neutres. Une nouvelle observation a été faite à l'effet que la limite adiabatique est aussi en accord avec un EIC maximal pour les processus thermiquement neutres; toutefois, dans ce cas, l'EIC n'est que le reflet des différences dans l'énergie libre d'activation de Gibbs qui, dans ce cas, tire son origine de la dynamique nucléaire environnementale de basse fréquence. Trois systèmes d'effet tunnel biologique de l'hydrogène, la lipoxygénase, la déshydrogénase d'alcool tirée de la levure et l'oxygénase d'amine tirée de sérum bovin, offrent des cas inusités pour l'analyse et on en a fait l'analyse dans un cadre théorique. Ils représentent aussi divers degrés de préparation de barrière fluctuationnelle alors que la lipoxygénase est la plus rigide et l'oxygénase d'amine tiré de sérum bovin est le système le plus souple.

Mots clés : schéma généralisé de Born–Oppenheimer, effet isotopique cinétique, transfert intermittent de proton, transfert de proton partiellement adiabatique, effet tunnel du proton, catalyse enzymatique.

[Traduit par la Rédaction]

1. Introduction

The ubiquity and importance of proton transfer (PT) as an "elementary" chemical and biological process is only equalled by electron transfer (ET) (1, 2). PT and ET show both mutual close physical resemblance and important differences. The most important common feature is that light particles, with conspicuous quantum mechanical character

(tunnelling), are transferred. Both particles are also strongly coupled to the environments. *Differences* are that protons are much more strongly localized than electrons. Proton tunnelling is thus only over a fraction of an angstrom while facile ET over tens of angstroms can occur. The notion of "long-range" *electron transfer* is thus well established (3–10), whereas *proton transfer* counterparts are of a quite different nature (1, 2). Proton tunnelling in chemical processes was recognised early (11–14). The view of chemical proton transfer as a quantum mechanical multiphonon electronic–vibrational transition was first introduced by Dogonadze, Kuznetsov, and Levich (15, 16). Most later achievements in quantum mechanical proton transfer theory rest in some way on the views in these reports (17–21). Condensed phase proton and hydrogen atom and hydride tunnelling are also abundantly documented experimentally (overviews in refs. 1 and 2). Along with ET, chemical PT thus offers cases for observation of room temperature nuclear tunnelling. In addition, kinetic deuterium and tritium isotope effects can be exploited, with unique prospects for characterization of proton barrier and environmental dynamics (1, 2).

Chemical proton, deuteron, and triton (overall hydron) tunnelling have been studied for several decades (22–26). Hydron tunnelling in *biological* systems is much less comprehensively characterized even though active-site structures as loci for PT in enzyme catalysis are known in detail. The reasons are associated with the multistep nature of enzyme processes, or rate-determining steps other than hydron transfer. Cases of well-characterized hydrogen atom tunnelling in enzyme processes, with large kinetic isotope effects, have, however, been reported recently, particularly by Klinman and co-workers (27–29). We shall presently address certain issues related to such new observations. In Sect. 2 we provide a formalism for hydrogen tunnelling viewed as a multiphonon quantum mechanical electronic–vibrational transition. New elements are disentanglement of *electronic* and *electron–proton* potential surfaces, kinetic isotope effects in strongly interacting proton donor–acceptor systems (the fully adiabatic limit), and ("gated") proton barrier preparation. In Sect. 3 the results are related to the Brønsted relation and kinetic isotope effects. Section 4 describes a convenient new approach to fluctuational barrier preparation ("gating") at all temperatures, important in the analysis of kinetic deuterium and tritium isotope effects. In Sect. 5 we discuss some of the recent cases of large kinetic deuterium and tritium isotope effects in redox enzyme processes, alluded to above, using the theoretical frames in Sects. 2–4. Concluding remarks are given in Sect. 6.

2. Proton tunnelling formalism in diabatic and adiabatic limits

2.1 Proton potentials and coupling to solvent and macromolecular environments

We note first two general issues (1, 2, 15, 16). One is that vibrational frequencies of C–H, N–H, and O–H stretching and bending modes, ≈3000 cm^{-1} and (or) ≈1500 cm^{-1}, respectively, are much higher than ≈200 cm^{-1}, corresponding to k_BT at room temperature. k_B is Boltzmann's constant and T the temperature. Proton dynamics in free molecules is therefore strongly quantized. This is illustrated by the harmonic potential along the proton coordinate R_p

$$[1] \qquad U_p(R_p) = \frac{1}{2} m_p \Omega_p^2 (R_p - R_{p0})^2$$

where m_p is the mass and Ω_p the vibrational frequency of the proton. R_{p0} is the equilibrium value of R_p. The full quantum mechanical bond length distribution function is given in eq. [2]:

$$[2] \qquad f_{qu}(R_p) = \left[\frac{\pi\hbar}{m_p\Omega_p \tanh(\hbar\Omega_p/2k_BT}\right]^{1/2} \times \exp\left[-\left(\frac{m_p\Omega_p}{\hbar}\right)(R_p - R_{p0})^2 \tanh\left(\frac{\hbar\Omega_p}{2k_BT}\right)\right]$$

where $2\pi\hbar$ represents Planck's constant. Equation [2] reduces to the classical Boltzmann distribution

$$[3] \qquad f_{cl}(R_p) = \left(\frac{2\pi k_BT}{m_p\Omega_p^2}\right)^{-1/2} \exp\left[-\frac{\frac{1}{2}m_p\Omega_p^2(R_p - R_{p0})^2}{k_BT}\right]$$

only when $\hbar\Omega_p << k_BT$. In the opposite limit $f_{qu}(R_p)$ is independent of T and takes the form

$$[4] \qquad f_{qu}(R_p) = \left[\frac{\pi\hbar}{m_p\Omega_p}\right]^{-1/2} \exp\left[-\left(\frac{m_p\Omega_p}{\hbar}\right)(R_p - R_{p0})^2\right]$$

Equation [4] coincides with the square of the ground state vibrational wave function, conspicuously reflecting proton tunnelling. This applies equally to other potentials such as the Morse potential (30–32). Reservations can be envisaged for strong donor–acceptor interactions (33), and for bond stretching towards dissociation, etc. (34) where barrier deformation and low frequencies may impose close to classical character. The second general observation is that proton dynamics is always strongly coupled to solvent or macromolecular environments, in the form

$$[5] \qquad V_{pol}^{prot} = -\int \vec{P}_{tot}(\vec{r})\vec{D}_s(\vec{r})(d\vec{r}); \quad S = R, P$$

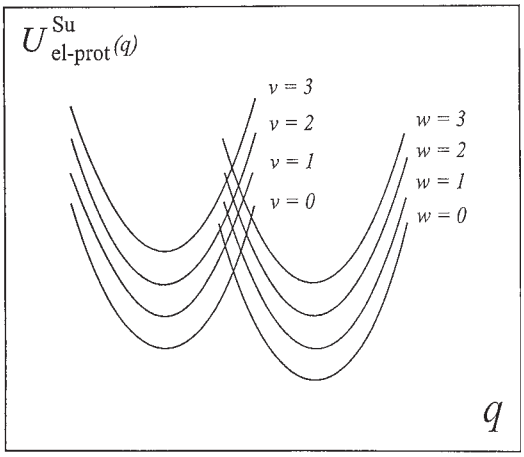
$\vec{P}_{tot}(\vec{r})$ is the environmental polarization at the point $\vec{r}$ and $\vec{D}_s(\vec{r})$ the electrostatic induction induced by the proton in the state of the reactants (R) or products (P). As proton dynamics is much faster than most solvent motion, the $\vec{D}_s(\vec{r})$ monitored by the solvent is not determined by the proton coordinate but by the quantum mechanical proton probability density (Appendix).

2.2 Born–Oppenheimer schemes and the Franck Condon principle for proton and electron–proton transfer

A generalized Born–Oppenheimer (B–O) scheme and Franck Condon (FC) principle apply to PT and hydrogen atom transfer ("combined" electron and proton transfer, or ETPT). In a first step the "usual" B–O approximation is exploited to separate electronic motion from proton and slower solvent motion. This leads to the *electronic* wave functions

© 1999 NRC Canada

Fig. 1. Diabatic electronic–proton potential Gibbs free energy surfaces spanned by the classical environmental nuclear coordinate q, for different proton vibrational states in the reactants' and products' state.



$\varphi^{el}_S(\vec{x}\,; R_p; \{q_k\})$ and *electronic* potential surfaces (S = R, P) $\varepsilon^{el}_S(R_p; \{q_k\})$. $\vec{x}$ represents the electronic coordinates. This step has an explicit perspective for hydrogen *atom* transfer (ETPT). In a *second* step the B–O approximation is used to separate the "fast" proton from the slower solvent or protein conformational motion. This step provides the *proton* wave functions, $\chi^p_{Su}(R_p; \{q_k\})$, and energies, $\varepsilon^p_{Su}(\{q_k\})$ (Sect. 2.3). Together with the pure solvent potential (Gibbs free) energy, these constitute the *electronic–proton* potential surfaces, spanned solely by the solvent/protein coordinates. The electronic potential surfaces are spanned by *all* the (fast and slow) nuclear coordinates, but the electronic–proton surfaces only by the (slow) environmental coordinates. The slower environmental, collective coordinates thus cannot depend on the much faster local, even quantum mechanical, coordinates, such as has sometimes been advanced (35).

The generalization of the B–O approximation carries over to the Franck Condon (FC) principle. The FC principle states that light particle transition only occurs near heavy nuclear configurations where the light particle energies match, i.e., at the transition configuration. The proton vibrational energies match only when environmental nuclear coordinate *fluctuations* have been taken to their transition configuration $\{q^*_k\}$, i.e., $\varepsilon^p_{Rv}(\{q^*_k\}) = \varepsilon^p_{Pw}(\{q^*_k\})$. The *proton* subsequently initiates sub-barrier tunnelling where the *electronic* levels are brought to match at the crossing along the *electronic* potential surfaces, $U^R_{el}(R^*_p; \{q^*_k\}) = U^P_{el}(R^*_p; \{q^*_k\})$, where electronic structure reorganization occurs. The proton subsequently relaxes in the products' potential $U^P_{el}(R_p; \{q_k\})$, followed by relaxation of the heavy nuclear system.

2.3 Electronic and electron–proton potential surfaces

A distinction between weakly and strongly interacting donor–acceptor systems is convenient. The former are framed by the diabatic approach (cf. above) where the reactants' and products' states constitute two different electronic states. The *electronic* potential surfaces are

$$[6] \qquad U^S_{el}(R_p; \{q_k\}) = V^S_{prot}(R_p) + \frac{1}{2}\sum_k \hbar\omega_k(q_k - q^S_{k0})^2 + U_{S0}$$

where $\{q_k\}$ and $\{\omega_k\}$ are collective solvent coordinates and vibrational frequencies, and $V^S_{prot}(R_p)$ electronically averaged bound proton potentials (= R, P). U_{S0} is the gas phase electronic energy in the equilibrium configuration and $\{q^S_{k0}\}$ the equilibrium values of $\{q_k\}$, in the states S. In the diabatic limit these quantities are averaged with respect to the electronic wave functions (Appendix). Excited proton vibrational states are, however, important and are reflected, for example, in the driving force dependence of the kinetic isotope effect. Instead of the *electronic* potential surfaces, *electron–proton* surfaces, spanned solely by the solvent coordinates, and corresponding to the vibrational proton energies ε^p_v and ε^p_w in the reactants' and products' state (v = 1, 2, ...; w = 1, 2, ...) are therefore also needed (Fig. 1). These are obtained by averaging eq. [6] with respect also to the *proton* vibrational wave functions,

$$[7] \quad U^S_{el-prot}(\{q_k\}) = \frac{1}{2}\sum_k \hbar\omega_k(q_k - q^S_{k0})^2 + \varepsilon^p_u + U_{S0}$$

S = R, P; $u = v,w$

Equations [6] and [7] are adequate in the fully *diabatic* limit. In the partially and fully *adiabatic* limits of stronger interactions, proton state averaging is no longer suitable as both the reactants' and products' states are now represented by a single adiabatic electronic state The explicit $\{q_k\}$ dependence of the proton potential is therefore left, giving the potential surface

$$[8] \qquad U^S_{pot}(R_p, \{q_k\}) = V^S_{prot}(R_p) + \frac{1}{2}\sum_k \hbar\omega_k q_k^2 - \sum_k q_k[g^S_k(R_p) + \nu^{prot}_k(R_p)]$$

S = gr, ex

These terms have been averaged with respect to the *adiabatic* electronic wave functions rather than the reactants' and products' state functions. The superscript "S" refers to the ground and first excited adiabatic electronic states. As the q_k dependence of the electronic wave functions may, further, not be negligible, the coupling factors g^S_k and $\nu^{prot}_k(R_p)$ could also depend on $\{q_k\}$, giving a nonlinear solvent coordinate dependence. Equations [6]–[8] are derived in the Appendix.

Equations [6]–[8] are the basis for most of the formalism to follow. They also apply broadly to the macromolecular protein environment where, however, the following features need attention:

(*i*) Protein environment is characterized by many local polar and charged residues. These strongly affect the transfer of localized charges such as the proton.

(*ii*) Conformational dynamics can be dominated by small configurational changes in many local groups. Motion along such collective coordinates can be equilibrated and regarded as friction free, or they can be diffusive. In either case the dynamics is not fundamentally different from other collective mode dynamics.

(*iii*) Conformational states separated by high local barriers lead to "gated" PT (Sect. 4).

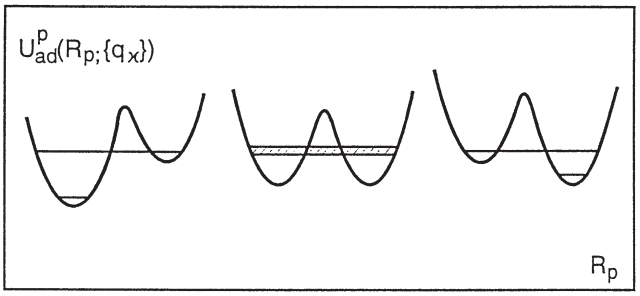
Fig. 2. Electronic double-well Gibbs free energy surface spanned by the proton coordinate R_p at different values of the slow environmental coordinate q. Left: The reactants' equilibrium configuration (q_0^R). Middle: The transition configuration (q^*). Right: The products' equilibrium configuration (q_0^p).



2.4 PT and ETPT between spatially fixed molecular fragments

We consider PT and ETPT along a linear path between two fixed molecular fragments. With a subsequent view on "gating," we introduce a general rate constant (1, 2):

$$W_{RP} = \int_{c-i\infty}^{c+i\infty} d\theta G(\theta)$$

$$G(\theta) = (\beta/i\hbar)(V_{RP}^{el})^2 \exp[-H(\theta) - \beta\theta\Delta G^0]$$

[9] $$H(\theta) = \beta\theta(1-\theta)E_R + \frac{2E_R^{prot}}{\hbar\Omega_p} \frac{\sinh\left[\frac{1}{2}\beta\hbar\Omega_p(1-\theta)\right]\sinh\frac{1}{2}\beta\hbar\Omega_p\theta}{\sinh(\frac{1}{2}\beta\hbar\Omega_p)}$$

$$\beta = (k_B T)^{-1}$$

V_{RP}^{el} is the electron exchange integral coupling the reactants' and products' states, E_R the environmental reorganization Gibbs free energy, and ΔG^0 the reaction Gibbs free energy (driving force). The contour in eq. [9] is along a line in θ-space parallel to the imaginary axis, with $0 < c < 1$. The origin and methods of treating eq. [9] are given elsewhere (1, 2, 36). As a particular note, eq. [9] also applies to the partially adiabatic limit (Sect. 2.4.2) where $\kappa(\alpha)$ is then replaced by K_{vw}^{ad}. Equation [9] gives the following other form using the saddle point method (37) in the θ-integration:

[10] $$W_{RP} = \kappa(\alpha)\frac{\omega_{eff}}{2\pi}\exp[\alpha H'(\alpha) - H(\alpha)]$$

$$\kappa(\alpha) = (V_{RP}^{el})^2\sqrt{\frac{4\pi}{H''(\alpha)\hbar\omega_{eff}^2}}$$

α is the saddle point, given by

[11] $$\Delta G^0 = -k_B T H'(\alpha)$$

$H'(\alpha)$ is the first and $H''(\alpha)$ the second derivative of $H(\alpha)$; $\kappa(\alpha)$ is the transmission coefficient, to be discussed below.

Equations [9]–[11] can be converted to the following form by available procedures (1, 2):

$$W_{RP} = Z_p^{-1}\sum_{v,w}\exp(-\varepsilon_{Rv}^p/k_B T)W_{RP}^{vw}$$

[12] $$W_{RP}^{vw} = \kappa_{vw}^p\frac{\omega_{eff}}{2\pi}\exp\left(-\frac{G_{vw}^{\neq}}{k_B T}\right)$$

$$Z_{Rp} = \sum_v \exp(-\varepsilon_{Rv}^p / K_B T)$$

This form incorporates proton mode anharmonicity, mode mixing, etc. In this sense it is more general than eqs. [9]–[11]. The quantities in eq. [12] have the following meaning:

(*a*) v and w, and ε_{Rv}^p and ε_{Pw}^p have been defined above. Z_{Rp} is the proton vibrational statistical sum in the reactants' state. In the harmonic approximation,

[13] $$\varepsilon_{Su}^p = \hbar\Omega_p^s(u + \tfrac{1}{2}); \quad S = R, P; \quad u = v, w$$

(*b*) The activation Gibbs free energy will be given the following form appropriate to a linearly responding solvent/protein environment and local harmonic modes:

[14] $$G_{vw}^{\neq} = (E_R + \Delta G^0 + \varepsilon_{Pw}^p - \varepsilon_{Rv}^p - \varepsilon_{Pw=0}^p + \varepsilon_{Rv=0}^p)^2/4E_R$$

ΔG^0 includes the zero point energy difference $\varepsilon_{Pw=0}^p - \varepsilon_{Rv=0}^p$ (cf. Sects. 3.2 and 5.1).

(*c*) The transmission coefficient κ_{vw}^p includes contributions from both "fast" systems, i.e., the *electrons* and the *proton*, and takes distinctive forms in different ranges of donor–acceptor interaction, cf. Sects. 2.4.1–2.4.3.

(*d*) ω_{eff} is the effective vibrational frequency of all modes classically reorganized (1, 2, 38).

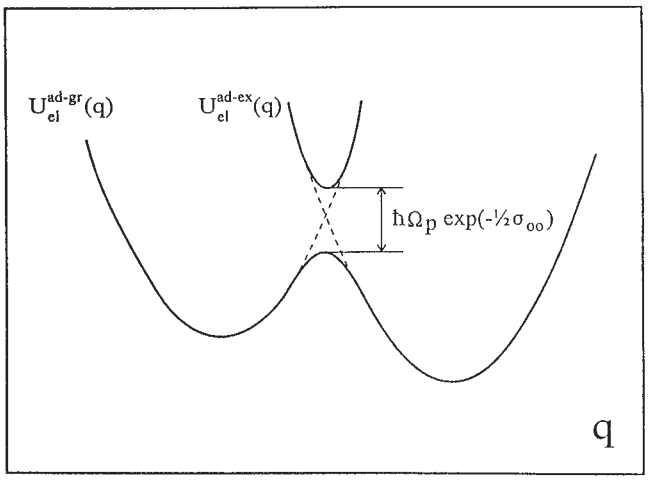
We next introduce two computational schemes (39). The *diabatic* approach applies to weak interactions, and rests on two sets of electronic and proton wave functions corresponding to electron and proton localization on the donor and acceptor. In the *adiabatic* approach, appropriate to stronger interactions, the total proton donor–acceptor system is regarded as a supermolecule where the electron adiabatically follows proton and heavy nuclear dynamics but proton tunnelling may still control the transition, and the proton double-well potential depends parametrically on the environmental coordinates. The dependence extends to the spacing between the ground and first excited proton vibrational levels. The spacing is large at the reactant environmental *equilibrium* configuration where the proton potential is strongly asymmetric (Fig. 2). The ground vibrational level here corresponds to proton/electron trapping at the donor, the first excited state to localization at the acceptor. Heavy nuclear transfer to the transition configuration brings the proton potential to a symmetric form with minimum level spacing. PT or ETPT proceeds here, followed by environmental relaxation to the products' equilibrium, proton trapping in this state, and proton double-well potential conversion to a configuration opposite the reactants' state. Three limits are now appropriate.

2.4.1 The fully diabatic limit of PT and ETPT

This limit represents weak donor–acceptor interaction, with conspicuous tunnel features. Crucial theoretical concepts are most transparent here. These concepts carry over to the partially adiabatic limit, which then follows naturally from the diabatic limit. While not likely to be encountered

© 1999 NRC Canada

Fig. 3. Adiabatic potential surface spanned by the environmental coordinate *q*. The splitting at the transition configuration is given by eq. [22].



broadly in general acid–base catalysis and proton transfer in hydrolytic enzyme catalysis, the diabatic limit is, finally, appropriate in cases of hydrogen *atom* transfer (35) and at low temperatures. The donor and acceptor groups are here frozen at relatively long distances (40–42) with concomitant, unusually large, kinetic deuterium isotope effects (41). In the fully diabatic limit *proton* tunnelling is initiated at the crossing between $U_{el-prot}^{Rv}(\{q_k\})$ and $U_{el-prot}^{Pw}(\{q_k\})$, and followed by *electron* transfer at the crossing between $U_{el}^{R}(R_p, \{q_k\})$ and $U_{el}^{p}(R_p, \{q_k\})$, i.e., at R_p, $\{q_k\} \rightarrow R_p^*$, $\{q_k^*\}$, all in the given proton vibrational states *v* and *w*. The transmission coefficient is

$$[15] \quad \kappa_{vw}^{p} = (T_{RP}^{vw})^2 \sqrt{\frac{4\pi^3}{E_R k_B T \hbar^2 \omega_{eff}^2}} << 1$$

$$[16] \quad (T_{RP}^{vw})^2 = \left| \int \varphi_{el}^{R}(\vec{x}; R_p) \chi_{Rv}^{p}(R_p) V \chi_{Pw}^{p}(R_p)\, \varphi_{el}^{p}(\vec{x}; R_p) \right|^2 d\vec{x}\, dR_p \approx (V_{RP}^{el})^2\, S_{RP}^{vw}$$

$$[17] \quad V_{RP}^{el} = \int \varphi_{el}^{R}(\vec{x}; R_p) V \varphi_{el}^{p}(\vec{x}; R_p) d\vec{x}$$
$$S_{RP}^{vw} = \left| \int \chi_{Rv}^{p}(R_p) \chi_{Pw}^{p}(R_p)\, dR_p \right|^2$$

$\varphi_{el}^{S}(\vec{x}; R_p)$ (S = R, P) is the electronic wave function in the state S, depending parametrically on R_p. $\chi_{Su}^{p}(R_p)$ is the proton wave function in the vibrational state *u* (= *v*, *w*) and electronic state S. *V* is the physical donor–acceptor interaction. V_{RP}^{el} is thus the electron exchange integral, cf. eq. [9], and S_{RP}^{vw} is the proton Franck Condon overlap factor. Equations [15]–[17] combined with eqs. [12]–[14] apply formally, subject to eq. [15]. The totally diabatic limit, with respect to *both* the electronic and proton systems, requires the stronger conditions

$$[18] \quad (V_{RP}^{el})^2\, S_{RP}^{vw} << \hbar\omega_{eff} \sqrt{\frac{k_B T E_R}{4\pi^3}}\ ;\ (V_{RP}^{el})^2 << \frac{\hbar\Omega_p E_R^{prot}}{2\pi}$$

where $E_R^{prot} = \frac{1}{2} m_p \Omega_p^2 (R_{p0}^{P} - R_{p0}^{R})^2$ is the proton reorganization energy ($\Omega_p^R \approx \Omega_p^P$).

The Franck Condon overlap factors in eq. [17] are available for harmonic, Morse, and certain other potentials (31, 32). For displaced harmonic surfaces (2)

$$[19] \quad \begin{aligned} S_{RP}^{00} &= \exp(-\tfrac{1}{2}\Delta^2);\ \tfrac{1}{2}\Delta^2 = \tfrac{1}{2}\frac{m_p\Omega_p}{\hbar}(R_{p0}^{P} - R_{p0}^{R})^2 \\ S_{RP}^{v0} &= \exp(-\tfrac{1}{2}\Delta^2)(\tfrac{1}{2}\Delta^2)^v/v! \\ S_{RP}^{0w} &= \exp(-\tfrac{1}{2}\Delta^2)(\tfrac{1}{2}\Delta^2)^w/w! \\ S_{RP}^{vw} &= \exp(-\tfrac{1}{2}\Delta^2)(\tfrac{1}{2}\Delta^2)^{|v-w|}\frac{v!}{w!}\left[L_w^{|v-w|}(\tfrac{1}{2}\Delta^2)\right]^2 \end{aligned}$$

where $L_n^{\alpha}(x)$ is the associated Laguerre polynomial (43). Subject to broadly valid conditions the WKB approximation (44) also applies in the totally diabatic and partially adiabatic limits

$$[20] \quad \begin{aligned} S_{RP}^{vw} &\approx \exp(-\sigma_{vw})\ ; \\ \sigma_{vw} &\approx \frac{2}{\hbar}\int_{a_{vw}}^{R_p^*(v,w)} \left\{ 2m_p [U_{el}^{R}(R_p, \{q_k\}) - \varepsilon_{Rv}^{p}] \right\}^{1/2} dR_p \\ &\quad + \frac{2}{\hbar}\int_{R_p^*(v,w)}^{b_{vw}} \left\{ 2m_p [U_{el}^{p}(R_p, \{q_k\}) - \varepsilon_{Pw}^{p}] \right\}^{1/2} dR_p \end{aligned}$$

where a_{vw} and b_{vw} are the left and right turning points in the tunnelling region, and $R_p^*(v,w)$ the value of R_p at the $U_{el-prot}^{Rv}$ / $U_{el-prot}^{Pw}$ crossing. In this way the proton tunnel factor can be obtained for rather arbitrary potentials. Equations [12], [14], and [17]–[20] constitute the PT and ETPT frame in the *totally* diabatic limit. As noted, this limit is most representative of ETPT and low-temperature hydron transfer. Much of the formalism, however, carries over to the *partially* adiabatic limit more representative also of PT.

2.4.2 The partially adiabatic limit

This limit accords with stronger electronic interaction but PT or ETPT is still slow due to a significant proton tunnel barrier. The first part of eq. [18] therefore remains, whereas the inverse of the second part applies. The electronic potential surfaces are modified to the *adiabatic* set:

$$[21] \quad U_{el}^{adS}(R_p; \{q_k\}) = \tfrac{1}{2}[U_{el}^{R}(R_p, \{q_k\}) + U_{el}^{p}(R_p, \{q_k\})] \pm \sqrt{[U_{el}^{R}(R_p; \{q_k\}) - U_{el}^{p}(R_p, \{q_k\})]^2 + 4(V_{Rp}^{el})^2}$$

S = gr, ex

where "–" and "+" refer to the ground (gr) and excited (ex) states (Fig. 3). The activation Gibbs free energy, $G_{vw}^{\neq}$ is still primarily determined by the reactants' and products' *electronic–proton* forms, $U_{el-prot}^{Rv}(\{q_k\})$ and $U_{el-prot}^{Pw}(\{q_k\})$, because the total electronic–proton tunnel factor, $(V_{RP}^{el})^2\, S_{RP}^{vw}$, is small. The *proton* tunnelling barrier is, however, lowered significantly due to the (large) electronic resonance splitting The transmission coefficient κ_{vw}^{ad} is suitably recast in terms of the proton energy level splitting at the transition configuration $\{q_k^*\}$:

© 1999 NRC Canada

$$[22]\quad \kappa_{vw}^{ad} = (\tfrac{1}{2}\Delta\varepsilon_{vw}^{p})^2 \sqrt{\frac{4\pi^3}{E_R k_B T \hbar\omega_{eff}^2}}$$

$$\Delta\varepsilon_{vw}^{p} \approx \hbar\Omega_p \exp(-\tfrac{1}{2}\sigma_{vw})$$

where σ_{vw} can be given a form similar to that in eq. [20] and the symmetric barrier incorporates V_{RP}^{el}.

2.4.3 The totally adiabatic limit

The inverse of both inequalities in eq. [18] apply in this limit. Electronic motion follows the proton, which again follows the environmental motion. The rate constant is

$$[23]\quad W_{RP}^{tot\text{-}ad} = \frac{\omega_{eff}}{2\pi}\exp\left[-\frac{G_{tot\text{-}ad}^{\neq}}{k_B T}\right]$$

$$[24]\quad G_{tot\text{-}ad}^{\neq} = G_{00}^{\neq} - \Delta\varepsilon_{00}^{p}\sqrt{\alpha(1-\alpha)} \approx G_{00}^{\neq} - \tfrac{1}{2}\Delta\varepsilon_{00}^{p}$$

where the transfer coefficient α was introduced in eqs. [10] and [11]. Explicit forms of α are given in eqs. [25] and [26] below. Only the proton vibrational ground state is important. $G_{00}^{\neq}$ is given by eq. [14], $\Delta\varepsilon_{00}^{\neq}$ by eqs. [20]–[22]. The quantum mechanical feature is now solely reflected in the lower activation Gibbs free energy caused by proton level splitting, again determined by the (large) electron exchange factor. The quantum mechanical feature is, however, still important and transmitted, for example, to kinetic isotope effects.

3. The Brønsted relation and kinetic isotope effects

3.1 The Brønsted relation

The Brønsted relation between the rate constant and the reaction Gibbs free energy is framed by the formalism above. The driving force dependence is referred to *environmental* nuclear dynamics rather than to the proton. When the proton modes remain in their ground states the Brønsted coefficient is (eqs. [12] and [14])

$$[25]\quad \alpha = dG_{00}^{\neq}/d\Delta G^0 \approx \frac{1}{2} + \frac{\Delta G^0}{2E_R}$$

α varies between zero and unity over the ΔG^0 ranges $|\Delta G^0| \rightarrow E_R$. This pattern is encountered for many PT reactions (21–25).

Several features modify this view. *One* is that excited hydron modes are in fact important in the diabatic and partially adiabatic limits. Equation [22] is therefore generalized:

$$[26]\quad \alpha \approx -d\ln W_{RP}/d\Delta G^0$$

$$\approx \frac{1}{2} + \frac{\Delta G^0 + w^*(\Delta G^0)\hbar\Omega_p - v^*(\Delta G^0)\hbar\Omega_p}{2E_R}$$

where $v^*(\Delta G^0)$ and $w^*(\Delta G^0)$ are the dominating values of v and w in the rate constant. Finite v^* and w^* thus gain importance as $|\Delta G^0| \rightarrow E_R$. Further, from eqs. [25] and [26], $\alpha \rightarrow 0.5$ as $|\Delta G^0| \rightarrow 0$. A *second* observation is that α can in fact be larger or smaller than 0.5 for thermoneutral processes if local solvent or intramolecular motion is subject also to vibrational *frequency* changes. A *third* observation is that both local and proton mode deformations are much stronger in PT than in ET. Anharmonic potentials are therefore needed in more precise fits to experimental data. Anharmonicity also decreases the curvature in free energy relations, giving smaller level spacing and attenuating the quantum mechanical feature (31, 32). As pointed out by Kresge (25), a *final* observation is that, in contrast to weakly hydrogen bonding C—H donors, the transfer coefficient for O and N acids and bases is often shifted between the limiting values of zero and unity within a few p*K* units. This reflects major, driving-force-independent, environmental reorganization *prior* to PT, whereas the reorganization Gibbs free energy in this step, where the driving-force dependence is focused, itself is small.

3.2 The kinetic deuterium and tritium isotope effects

The kinetic deuterium and tritium isotope effects (KIE) hold unique perspectives both for room temperature nuclear tunnelling and for environmental dynamics. The latter transfers, interestingly, from thermal activation to *environmental* nuclear tunnelling at low (cryogenic) temperatures (41). The tunnel sensitivity to the PT *distance* also holds an intriguing implication. As deuteron and triton tunnelling is less facile than proton tunnelling, deuteron and triton transfer over *smaller* distances than proton transfer is favoured, at the expense of additional activation Gibbs free energy, along the intermolecular donor–acceptor mode. Fluctuational barrier preparation (Sect. 4) is therefore more important for PT than for ET. In experimental data analysis the rate constant, k_{rC} (s^{-1} or $M^{-1}\ s^{-1}$, C = H, D, T) must therefore be given the form

$$[27]\quad k_{rC} = \Phi(R_{pC}^*)\, W_{RP}(R_{pC}^*)$$

where $W_{RP}(R_{pC}^*)$ is the rate constant (eqs. [12–17] and [22]–[24]) at the most favourable transfer distance R_{pC}^*, and $\Phi(R_{pC})$ is the distribution function along the intermolecular donor–acceptor coordinate. R_{pC}^* is in general *different* for proton, deuteron, and triton transfer.

The kinetic *deuterium* isotope effect is

$$[28]\quad KIE = \frac{k_{rH}}{k_{rD}} = \frac{\Phi(R_{pH}^*)\, W_{RP}(R_{pH}^*)}{\Phi(R_{pD}^*)\, W_{RP}(R_{pD}^*)}$$

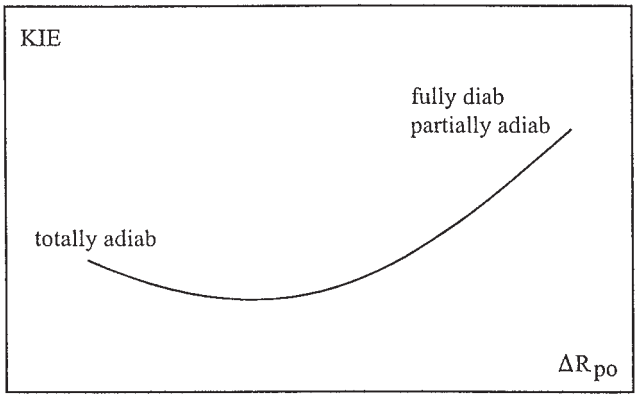
The classical Boltzmann distribution is presently an adequate representation of $\Phi(R_{pC})$:

$$[29]\quad \Phi(R_{pC}) \propto \exp\{-[w_R(R_{pC}) - w_R(R_{pC0})]/k_B T$$

where R_{pC0} is the equilibrium value of R_{pC} and $w_R(R_{pC})$ the donor–acceptor intermolecular potential, in the reactants' state. At low temperatures intermolecular donor–acceptor motion proceeds by nuclear tunnelling, and $\Phi(R_{pC})$ must be replaced by a quantum mechanical distribution function (cf. ref. 41). Quite similar considerations apply to k_{rH}/k_{rT} and k_{rD}/k_{rT} so that eqs. [28] and [29] also constitute a basis for quantum mechanical analogues of the Schaad–Swain relation (23, 45). The KIE is reflected in most of the kinetic quantities. In the activation Gibbs free energy there is KIE in the hydron vibrational frequencies; this is important when the frequencies are different in the reactants' and products' states. The dominating effect in the preexponential part is the more facile tunnelling of the lighter isotope(s). As tunnelling is from

© 1999 NRC Canada

Fig. 4. Distance dependence of the kinetic isotope effect (schematic). The declining branch for small ΔR_{p0} is representative of the totally adiabatic limit, the rising branch at larger ΔR_{p0} of the fully diabatic and partially adiabatic limits.



non-equilibrium donor–acceptor configurations, the KIE also reflects an interplay between donor–acceptor interaction and nuclear tunnelling. The effective frequency ω_{eff} could, finally, be isotope specific since ω_{eff} holds contributions from solvent librational modes.

The KIE appears rather differently in fully diabatic and partially adiabatic PT on the one hand, and in fully adiabatic PT on the other. In fully diabatic (ETPT) and partially adiabatic (PT or ETPT) processes the (deuterium) KIE is

$$[30]\qquad \frac{k_{rH}}{k_{rD}} \approx f(\Omega_{pH},\Omega_{pD}) \times \frac{\sum_{v_H,w_H} \exp\left(-\frac{v_H\hbar\Omega_{pH}}{k_BT}\right) S_{RP}^{v_H w_H} \exp\left(-\frac{G^{\neq}_{v_H,w_H}}{k_BT}\right)}{\sum_{v_D,w_D} \exp\left(-\frac{v_D\hbar\Omega_{pD}}{k_BT}\right) S_{RP}^{v_D w_D} \exp\left(-\frac{G^{\neq}_{v_D,w_D}}{k_BT}\right)}$$

$$[31]\qquad f(\Omega_{pH},\Omega_{pD}) = (\Omega_{pH}/\Omega_{pD})^2 \quad \text{in the partially adiabatic limit}$$

$$f(\Omega_{pH},\Omega_{pD}) = 1 \quad \text{in the diabatic limit}$$

with analogous equations for triton transfer. The KIE is reflected quite differently in the totally adiabatic limit, namely, in the isotope-dependent activation Gibbs free energy. This is rooted in the different electronic–proton potential surface splittings for proton, deuteron, and triton transfer. This offers an interesting parallel to classical views based on different zero point energies of the isotopes (22–24). In the present approach the origin of the activation Gibbs free energy difference is, however, quite different, and PT is also a tunnel process in the fully adiabatic limit. The kinetic deuterium isotope effect in the fully adiabatic limit is, thus, from eqs. [22]–[24] and disregarding isotope effects in ω_{eff}:

$$[32]\qquad \text{KIE} \approx \exp\{[G^{\neq}_{tot-ad}(\text{deuteron}) - G^{\neq}_{tot-ad}(\text{proton})]/k_BT\} \approx \exp\left[\{[\alpha(1-\alpha)]^{1/2}\hbar\Omega_{pH}\ \exp(-m_{pH}\Delta R_{p0}^2/4\hbar)\} \times \{1-\exp[(m_{pH}\Omega_{pH}\Delta R_{p0}^2/4\hbar)(1-\sqrt{2})/\sqrt{2})\right]/k_BT\}]$$

where $G^{\neq}_{tot-ad}$ is given by eq. [20] and ΔR_{p0} is the equilibrium hydron coordinate displacement (here taken as the same for all the isotopes). Analogous equations apply to triton KIEs.

Equations [28]–[32] hold some implications:

1. Large KIEs, for example, ≥2–3, have mostly been referred to the partially adiabatic limit (eqs. [30] and [31]) (31, 32). Significant KIEs, however, also accord with the fully adiabatic limit.

2. The KIE is *dominated* by the tunnel factor but KIE in other quantities were noted.

3. PT distances extracted from experimental data, using the partially adiabatic limit, are commonly small, i.e., 0.3–0.4 Å (see, for example, refs. 31 and 32), indicative of fluctuational effects prior to PT. This is not surprising in view of the distance sensitivity of proton tunnelling.

4. The KIE follows "normal" tunnelling distance behaviour in the totally diabatic and partially adiabatic limits in the sense of being larger the longer the PT distance. The *opposite* effect emerges in the fully adiabatic limit, i.e., the KIE is *smaller* the longer the PT distance. This is because the electronic–proton surface splitting is smaller the longer the PT distance. The *difference* between the proton and heavier isotope splittings is therefore also smaller, illustrated schematically in Fig. 4.

5. The driving-force dependence of the KIE has a maximum around thermoneutrality (2) but with different physical causes. ΔG^0-dependent slight vibrational deuteron and triton excitation is the cause in the totally diabatic and partially adiabatic limits. The maximum is shifted to finite $|\Delta G^0|$ for different reactants' and products' frequencies. In the fully adiabatic limit the ΔG^0 dependence follows the transfer coefficient, with a maximum also at $\alpha \approx 0.5$ but now dominated by low-frequency environmental dynamics.

6. The temperature dependence in the totally diabatic and partially adiabatic limits is small unless different hydron transfer distances and "soft" intermolecular donor–acceptor motion apply. Notably larger effects emerge in the fully adiabatic limit.

4. Fluctuational barrier preparation and gated proton transfer

4.1 Features of gating in proton transfer reactions

Intermolecular *donor–acceptor motion* is the basis for fluctuational tunnel barrier preparation where the proton donor and acceptor are preorganized *prior* to PT, attenuating the barrier and facilitating proton tunnelling (17–21). Proton barrier preparation accords with the notion of "gated" PT. PT is initially blocked by prohibitively long distances. Fluctuations, i.e., motion along the gating coordinate X_{gat}, opens the PT channel by lowering the PT distance, and subsequently returns to the *same* configuration as before PT.

© 1999 NRC Canada

"Gating" in this sense is a likely general feature of PT, ETPT, and hydride transfer. A specific case is proton relay in serine proteases (46) where a proton is transmitted from the donor to the acceptor via conformationally mobile His. Another example is the insertion step of olefin hydrogenation in coordination chemical catalysis where coordinated olefin is strongly shifted towards coordinated hydride and relaxed to its initial configuration subsequent to insertion (34).

In a broader sense, gating modes are also subject to reorganization. The proton or electron tunnelling factor would then compete intriguingly for the transition state configuration, which no longer coincides with the saddle point of the reactants' and product's potential surfaces.

4.2 A model for gated proton transfer

PT gating along the (dimensionless) gating coordinate X_{gat} is well illustrated by the following harmonic gating potential in the reactants' and products' state:

$$[33]\qquad U_R^{gat}(X_{gat}) = U_P^{gat}(X_{gat}) = \frac{1}{2}\hbar\omega_{gat}X_{gat}^2$$

The proton equilibrium coordinates and vibrational frequencies depend explicitly on X_{gat},

$$[34]\qquad R_{p0}^R = R_{p0}^R(X_{gat})\ ;\ R_{p0}^P = R_{p0}^P(X_{gat})\ ;\ \Omega_p = \Omega_p(X_{gat})$$

We assume that the X_{gat} dependence of Ω_p can be disregarded, and that the PT distance can be represented by the broadly appropriate linear form:

$$[35]\qquad R_{p0}^P(X_{gat}) - R_{p0}^R(X_{gat}) = \Delta R_{p0} - \gamma X_{gat}$$
$$\Delta R_{p0} = R_{p0}(X_{gat} = 0) - R_{p0}^R(X_{gat} = 0)$$

A final assumption is that relaxation along X_{gat} is fast compared to hydron tunnelling. Equilibrium along X_{gat} then prevails and the notion of a rate constant applies. Slow X_{gat} dynamics implies either that proton barrier preparation is a separate reaction step, or that PT occurs along the non-equilibrated gating coordinate. In either case composite time evolution emerges (1, 2, 47). Equations [9] and [10] are now modified to

$$[36]\qquad W_{RP} = \int_{c-i\infty}^{c+i\infty} d\theta G(\theta) S(\theta)$$

where $G(\theta)$ is given by the diabatic form in eq. [9] or [10], or the partially adiabatic form in eq. [12] combined with eq. [22], and $S(\theta)$ is the gating correction. $S(\theta)$ for the gating potential in eq. [33] is

$$[37]\qquad S(\theta) = \frac{1}{\sqrt{\pi}}\, g(\theta)\, \frac{\int dX_{gat}\, \exp[-g^2(\theta)X_{gat}^2]\exp\{-\frac{1}{2}(m_p\Omega_p/\hbar)[R_{p0}^P(X_{gat}) - R_{p0}^R(X_{gat})]^2\}}{\exp\{-\frac{1}{2}(m_p\Omega_p/\hbar)[R_{p0}^P(X_{gat} = 0) - R_{p0}^R(X_{gat} = 0)]^2\}}$$
$$g(\theta) = \frac{\sinh(\frac{1}{2}\beta\hbar\Omega_{gat})}{\{\cosh[\frac{1}{2}\beta\hbar\Omega_{gat}(1-\theta]\cosh(\frac{1}{2}\beta\hbar\Omega_{gat}\theta)\}}$$

valid at all temperatures, also when gating is by nuclear tunnelling along X_{gat}.

In the high-T limit eq. [37] takes the form

$$[38]\qquad S(\theta) = \left(\frac{\beta\hbar\Omega_{gat}}{2\pi}\right)^{1/2} \frac{\int dX_{gat}\, \exp(-\frac{1}{2}\beta\hbar\Omega_{gat}X^2{}_{gat})\, \exp\{-\frac{1}{2}(m_p\Omega_p/\hbar)[R_{p0}^R(X_{gat}) - R_{p0}^R(X_{gat})]\}}{\exp\{-\frac{1}{2}(m_p\Omega_p/\hbar[R_{p0}^R(X_{gat} = 0) - R_{p0}^R(X_{gat} = 0)]/\hbar\}}$$

Equation [38] shows that the correction involves activation energy from thermally activated motion along X_{gat} from $X_{gat} = 0$, and the *ratio* between the proton tunnel factor at the given value of X_{gat} and at equilibrium $X_{gat} = 0$. Integrating over X_{gat} in eq. [37] gives

$$[39]\qquad S(\theta) = \frac{g(\theta)}{\{[g(\theta)]^2 + (m_p\Omega_p/2\hbar)\gamma^2\}^{1/2}} \times \frac{\exp\left\{-\dfrac{[g(\theta)]^2(m_p\Omega_p/2\hbar)(\Delta R_{p0})^2}{[g(\theta)]^2 + (m_p\Omega_p/2\hbar)\gamma^2}\right\}}{\exp[-(m_p\Omega_p/2\hbar)(\Delta R_{p0})^2}$$

or, in the high-T limit

$$[40]\qquad S(\theta) = \frac{(\frac{1}{2}\beta\hbar\omega_{gat})^{1/2}}{[\frac{1}{2}\hbar\omega_{gat} + (m_p\Omega_p/2\hbar)\gamma^2]^{1/2}} \times \frac{\exp\left\{-\dfrac{\frac{1}{2}\beta\hbar\omega_{gat}(m_p\Omega_p/2\hbar)(\Delta R_{p0})^2}{\frac{1}{2}\beta\hbar\omega_{gat} + (m_p\Omega_p/2\hbar)\gamma^2}\right\}}{\exp[-(m_p\Omega_p/2\hbar)(\Delta R_{p0})^2}$$

These equations show that $S(\theta) > 1$ for finite γ while $S(\theta) \to 1$ for $\gamma \to 0$. Gating thus enhances hydron tunnelling by reducing the transfer distance.

Equation [40] can be used directly in combination with the rate constants in eqs. [12]–[15] and [22]–[24] whereas eq. [39] must be combined with the original form in eq. [9].

© 1999 NRC Canada

After insertion in eq. [36] θ-integration can be undertaken using the saddle point method (cf. Sect. 2.4).

5. Proton transfer in hydrolytic and redox enzyme catalysis

Absolute values, and the temperature and driving-force dependence of the KIE for general acid-based catalysed PT reactions, have been analysed using formalism related to the frames in Sects. 2 and 3 (1, 2, 31, 32), and the partially adiabatic limit. Maximum KIEs ≥10 only accord with the fully adiabatic limit for unphysically small PT distances. Some cases of hydrolytic enzyme processes (α-chymotrypsin (48), carboxypeptidase A (49)) have also been addressed. The smaller KIE here (1.3–2.5) can be brought in line with the fully adiabatic limit but these processes are entangled by stochastic solvent effects.

We consider here briefly some recent cases of hydrogen *atom* or *hydride* transfer in metalloenzyme kinetics, more specifically: hydroperoxidation of linoleic acid catalysed by lipoxygenase (50, 51); alcohol dehydrogenation catalysed by yeast alcohol dehydrogenase (27–29); and oxidative deamination of primary amines to aldehydes catalysed by amine oxidases (52, 53). Common denominators are the following: disentanglement of rate-determining hydrogen atom or hydride transfer; large kinetic isotope effects; temperature dependence of the KIE; and, in some cases, KIEs involving all three hydrogen isotopes. Details of the experimental investigations and mechanisms are given elsewhere (27–29, 50–55).

5.1 Lipoxygenases

Hydrogen atom transfer with radical formation is rate determining above 32°C. The kinetic deuterium isotope effect is unusually large, i.e., 56 (49, 50) while secondary isotope effects are small (<1.2). The apparent activation enthalpies are small and are almost the same for protium and deuterium transfer (5 and 7 kJ mol^{-1}, respectively).

The observed pattern accords broadly with the partially or even fully diabatic limit of hydrogen atom transfer (eqs. [12]–[17], [19], [20], and [22]), with the following notes:

1. The large isotope effects cannot be brought into accord with the fully *adiabatic* limit.

2. The insignificant KIE activation enthalpies are indicative of structurally rigid environments, i.e., similar transfer distances for the two isotopes.

3. The hydrogen transfer distance based on the data in ref. 49 can be calculated from eq. [30] combined with specific hydrogen potentials. In the harmonic approximation (eq. [19]), using $\Omega_p \approx 3000$ cm^{-1}, the transfer distance is calculated to be 0.45–0.50 Å. A Morse potential with the dissociation energy of ≈2 eV would give 0.6–0.7 Å. This is still notably smaller than common equilibrium transfer distances in hydrogen-bonded systems, indicative of fluctuational barrier preparation features for both isotopes.

4. The notion of the apparent activation enthalpy is elusive because secondary and tertiary macromolecular structures themselves depend on the temperature, implying that the kinetic parameters E_R and ΔG^0 (Sects. 2 and 3) also depend on the temperature. The small apparent activation enthalpies reflect such features, and not that the process should approach the activationless driving-force region.

5.2 Alcohol dehydrogenases

Large KIEs have been observed in both yeast and liver dehydrogenase (ADH) catalysed hydride transfer from alcohol substrates to NAD^+ (27–29). Hydride transfer is rate determining in yeast ADH action whereas liver ADH is partly controlled by product release (54). We consider briefly the former, but sophisticated investigations of liver ADH have illuminated the interplay between hydrogen transfer distance, the catalytic efficiency, and KIEs (55).

Experimental primary KIEs of yeast ADH are $k_{rH}/k_{rT} \approx 7.1$ and $k_{rD}/k_{rT} \approx 1.7$ (27, 28). The apparent activation enthalpy differences are $H_T^{\neq} - H_H^{\neq} \approx 5.1$ kJ and $H_T^{\neq} - H_D^{\neq} \approx 1.8$ kJ giving, by difference, $H_D^{\neq} - H_H^{\neq} \approx 3.3$ kJ (27). These values are significant. The detailed structural conversions are confused by coupling between primary and secondary hydrogens at the alcohol C-1 (27, 28), reflected also in the secondary isotope effects, and the overall patterns do not accord with a one-dimensional PT view. A one-dimensional frame does, however, illuminate the interplay between quantum mechanical hydride transfer and environmental dynamics. The frequency and amplitude values accord with other recent analyses of ADH and bovine serum amine oxidase based on notions quite different from the present analysis (56, 57).

According to the conditions for classical and quantum mechanical behaviour (Sect. 2.1) *all* the isotopes are dominated by quantum mechanical patterns. Approximate protium, deuterium, and tritium stretching vibrational frequencies would be ≈3000 cm^{-1}, 2100 cm^{-1}, and 1700 cm^{-1}, respectively, in accord with the condition $\hbar\Omega_p >> k_B T$. Reservations arise if the transfer mode contains conspicuous elements of hydrogen bending, or the motion is coupled to secondary hydrogen dynamics. The KIEs are large enough that the partially adiabatic limit is appropriate. Using eqs. [12]–[14] and [19], the two primary KIEs, i.e., k_{rH}/k_{rT} and k_{rD}/k_{rT}, would give the transfer distances 0.26–0.37 Å and 0.21–0.29 Å, respectively. The upper and lower limits correspond to stretching and bending. These values are small: 20–30% larger values emerge if Morse or Rosen–Morse potentials are used (31, 32) but the values are still likely to reflect an entangled hydride transfer trajectory. The two sets of values are also *different* but this could accord with different transfer distances for the isotopes and is supported by the apparent enthalpy differences. The latter then reflect motion along a "gating" coordinate up to varying reactive distances that are smaller the heavier the isotope. Distance differences of about 0.1 Å are formally needed and correspond to fluctuational gating frequencies in the appropriate range of 150–200 cm^{-1} for effective masses the size of individual residues. ADH therefore reveals a consistent pattern where hydrogen tunnelling, environmental dynamics, and fluctuational barrier preparation are all conspicuous. The present formalism, in principle, also frames these features but precise disentanglement requires a separate analysis.

5.3 Bovine serum amine oxidase

Amine oxidases catalyse the oxidation of amines to aldehydes by molecular dioxygen. Proton abstraction from the substrate to an active-site base residue is rate determining,

© 1999 NRC Canada

with little coupling to other modes. Bovine serum amine oxidase (BSAO) also shows some of the largest known KIEs in enzyme processes (27–29, 52, 53) and is therefore a very attractive target for investigations of hydrogen tunnelling in biological systems.

The KIEs for BSAO at 25°C are: $k_{rH}/k_{rT} = 35$ and $k_{rD}/k_{rT} = 3.0$ (27–29). The apparent activation enthalpies are large, i.e., 14 and 4.5 kJ, respectively, all strongly indicative of hydrogen tunnelling with significant and isotope-specific gating features. The tunnel distances calculated from the data at 25°C by eqs. [12]–[14] and [19] are 0.35–0.49 Å from k_{rH}/k_{rT} and 0.29–0.41 Å from k_{rD}/k_{rT}. The upper and lower limits are again based on hydrogen bending and stretching, respectively. If the large apparent activation enthalpies are associated solely with fluctuational barrier preparation, then the scenario is suggestive of different transfer distances for the three isotopes. The tunnel distances for protium, deuterium, and tritium transfer of ≈ 0.75 Å, ≈ 0.57 Å, and ≈ 0.5 Å, respectively, formally accord with both the absolute values and the apparent activation enthalpies of the KIEs.

6. Concluding remarks

Hydrogen transfers are basically quantum mechanical transitions. Classical hydrogen dynamics can be envisaged when the donor–acceptor interactions are strong and the hydrogen transfer barriers shallow, in which case environmental stochastic effects also become apparent (33). Chemical and biological hydron and hydride transfer are also strongly coupled to protein or solvent environments, imposing multiphonon character on the process. Hydrogen *atom* transfer (ETPT) does not arouse long-range electrostatic interactions but reorganization of short-range local group motion may still be important. The present formalism addresses both PT and ETPT as quantum mechanical (tunnel) transitions strongly coupled to the environment. Hydrogen dynamics is represented by high-frequency harmonic or anharmonic potentials. The environment is a linearly responding medium that can, however, be vibrationally or spatially dispersive (1, 2). Rate constants are derived for three limits of donor–acceptor interaction, viz. the fully diabatic, the partially adiabatic, and the totally adiabatic limits. The theory has been referred specifically to observable correlations such as the Brønsted relation and the kinetic isotope effects.

Some notions and results have been derived before (1, 2, 15–21, 31–33). A new result is, first, that the coupling features between the electronic, hydronic, and environmental systems have been precisely specified in *all* three limits (Appendix). The coupling, as appearing for example in the potential surfaces, has been recast in terms of quantum mechanical averaging with respect to either the electronic or both the electronic and hydrogen system parts, subject to choice of diabatic or adiabatic basis set. The second new result is that the rate constant has been combined with a new approach to conformational gating for hydrogen transfer. This formalism applies at all temperatures and extends to nuclear tunnelling along the gating mode. Particular attention has, further, been given to the totally adiabatic limit. The hydrogen tunnel feature is here reflected in the splitting of the adiabatic surfaces in the transition state with respect solely to the environmental nuclear coordinates. The splitting is isotope dependent and transmits to the driving-force and temperature dependence of the KIEs, with maximum at thermoneutrality. A third observation is, then, that the hydrogen transfer distance dependence of the KIE in this limit is opposite that of the fully diabatic and partially adiabatic limits.

The formalism has, finally, been used as a new frame for hydrogen transfer in three enzyme systems, all with large KIEs and strong indications of hydrogen tunnelling. One system, lipoxygenase, accords with the simplest view of H-transfer between "fixed" molecular fragments, in the sense of showing similar transfer distances for all the isotopes. Yeast ADH is indicative of conformational gating but is complicated by a composite hydrogen reaction coordinate reflected in the secondary isotope effect. BSAO finally shows straight H-transfer features but strong gating as revealed in the large apparent activation enthalpies of the KIE and the accompanying, rather different, transfer distances for the three isotopes.

Appendix

Derivation of eqs. [6]–[8]

The total system potential energy is

$$\begin{aligned}[A1]\quad \hat{U}_{pot}(\vec{x}, R_p, \{q_k\}) &= V^D_{elD}(\vec{x}) + V^D_{elA}(\vec{x}) + V^D_{elprot}(\vec{x}, R_p) + V^D_{elsolv}(\vec{x}, \{q_k\}) \\ &+ V^A_{elA}(\vec{x}) + V^A_{elD}(\vec{x}) + V^A_{elprot}(\vec{x}, R_p) + V^A_{elsolv}(\vec{x}, \{q_k\}) \\ &+ V_{protD}(R_p) + V_{protA}(R_p) + V_{protsolv}(R_p, \{q_k\}) + U^0_{solv}(\{q_k\})\end{aligned}$$

The terms in the second line denote the following: $V^D_{elD}(\vec{x})$ is the interaction between the transferring or relaxing electron(s) at the donor centre with the donor core, and $V^D_{elA}(\vec{x})$ the interaction with the acceptor core; $V^D_{elprot}(\vec{x}; R_p)$ is the electron–proton interaction when the proton is at the donor site, and $V^D_{elsolv}(\vec{x}, \{q_k\})$ the interaction between the electrons at the donor site and the solvent. The terms in the third line have an analogous meaning for the acceptor site. $V_{protD}(R_p)$ and $V_{protA}(R_p)$ are the proton potential energy at the donor and acceptor site, respectively, and $V_{prot,solv}(R_p,\{q_k\})$ the interaction between the proton and the solvent. $U^0_{solv}(\{q_k\})$ is the free solvent potential energy.

The total potential energy is suitably divided into reactants' or products' potential energies and donor–acceptor interaction terms. For the reactants' state

$$U^R = U^{0R}_{el}(\vec{x}) + V^D_{elprot}(\vec{x}, R_p) - \sum_k q_k v^{el}_k(\vec{x}) - \sum_k q_k v^{prot}_k(R_p) + U^{0R}_{prot}(R_p) + U^0_{solv}(\{q_k\})$$

$$\begin{aligned}[A2]\quad & U^{0R}_{prot}(\vec{x}) = V^D_{eD}(\vec{x}) + V^A_{eA}(\vec{x}); \\ & U^{0R}_{prot}(R_p) \rightarrow V_{protD}(R_p) \\ & -\sum_k q_k v^{el}_k(\vec{x}) = V^D_{elsolv}(\{q_k\}) + V^A_{elsolv}(\vec{x}, \{q_k\}) \\ & -\sum_k q_k v^{prot}_k(R_p) = V_{protsolv}(R_p\{q_k\})\end{aligned}$$

The terms

$$[A3]\quad V^D_{elA}(\vec{x}) + V^A_{elD}(\vec{x}) + V^A_{elprot}(\vec{x}, R_p) + V_{protA}(R_p)$$

have thus been omitted from the reactants' state potential energy in eq. [A2]. An equation equivalent to eq. [A2] applies to the products' state.

A distinction between the diabatic limit on the one hand, and the partially and fully adiabatic limits on the other hand, is now invoked. The concept of potential surfaces in the reactants' and products' states can be maintained in the diabatic limit and these are obtained by averaging eq. [A2]

© 1999 NRC Canada

or the equivalent equation for the products' state with respect to the *electronic* wave functions in the two states. For the reactants' state

$$[A4]\quad U^{R}_{pot}(R_p, \{q_k\}) = V^{R}_{pot}(R_p, \{q_k\}) - \sum_k q_k v^{prot}_k(R_p) + U^{0}_{solv}(\{q_k\})$$

where

$$[A5]\quad V^{R}_{pot}(R_p, \{q_k\}) = U^{0R}_{prot}(R_p) + \left\langle \varphi^{R}_{el}(\vec{x}; R_p, \{q_k\}) \middle| U^{0R}_{prot}(\vec{x}) + V^{R}_{prot}(\vec{x}; R_p) \right| \times \varphi^{R}_{elprot}(\vec{x}; R_p, \{q_k\}) \rangle - \sum_k q_k \left\langle \varphi^{R}_{el}(\vec{x}; R_p, \{q_k\}) \middle| v^{el}_k(\vec{x}) \middle| \varphi^{R}_{el}(\vec{x}; R_p, \{q_k\}) \right\rangle$$

Disregarding the weak dependence of the electronic wave functions $\varphi^{S}_{el}(\vec{x}; R_p, \{q_k\})$ (S = R, P) on the solvent coordinates $\{q_k\}$ (but not on the proton coordinate R_p) converts eq. [A5] to

$$[A6]\quad V^{S}_{pot}(R_p, \{q_k\}) = V^{S}_{prot}(R_p) - \sum_k q_k g^{S}_k(R_p); \qquad S = R,\ P$$

where

$$[A7]\quad V^{S}_{prot}(R_p) = U^{0S}_{prot}(R_p) + \left\langle \varphi^{S}_{el}(\vec{x}; R_p) \middle| U^{0R}_{el}(\vec{x}) + V^{S}_{elprot}(\vec{x}; R_p) \middle| \varphi^{S}_{el}(\vec{x}; R_p) \right\rangle$$
$$g^{S}_k(R_p) = \left\langle \varphi^{S}_{el}(\vec{x}; R_p) \middle| v^{el}_k(\vec{x}; R_p) \middle| \varphi^{S}_{el}(\vec{x}; R_p) \right\rangle$$

Altogether, from eqs. [A4] and [A6]

$$[A8]\quad U^{S}_{pot}(R_p, \{q_k\}) = V^{S}_{prot}(R_p) + U^{S}_{solv}(\{q_k\}) - \sum_k q_k [g^{S}_k(R_p) + V^{pot}_k(R_p)]$$

This equation coincides with eq. [8] if $U^{S}_{solv}(\{q_k\})$ is given the form $\frac{1}{2}\sum_k \hbar\omega_k q_k^2$. Averaging of the proton–solvent interaction term in eq. [A8] (the final term) with respect to the reactants' or products' (diabatic) *proton wave functions* gives the electronic potential surfaces in eq. [6]. The quantity q^{S}_{k0} is identified with

$$[A9]\quad q^{S}_{k0} = [< g^{S}_k >_s + < v^{prot}_k >_s]/\hbar\omega_k$$

$<\ldots>_S$ refers to averaging with respect to the diabatic *proton wave functions* in the states S (= R, P). The weak dependence of q^{S}_{k0} on the proton vibrational states has been disregarded.

All the steps leading to eq. [A8] also apply to the partially and fully adiabatic limits, with the following modifications:

1. The same terms as in eq. [A2] are included. The interactions in eq. [A3] are included in the V^{el}_{RP} term of eq. [18] when the partially or fully adiabatic potential surfaces are constructed.

2. Averaging with respect to the electronic states refers to the *adiabatic* electronic wave functions rather than the reactants' and products' wave functions. The Hamiltonian of the adiabatic wave functions corresponds to the full potential energy function in eq. [A1]. The superscript "S" in eqs. [A4]–[A8] then represents the ground and first excited adiabatic electronic states and not the reactants' and products' states.

3. Averaging with respect to the proton wave functions is not appropriate as the adiabatic proton wave functions do not represent proton localization solely in a given reactant's or products's well. Equations [6] and [7] therefore only apply in the *diabatic* limit whereas eq. [8] applies generally, subject to the choice of electronic basis set.

About environmental isomers and their existence in liquid water

Ernest Grunwald and Colin Steel

Abstract: Environmental isomers in a liquid are molecules of a single species that become distinguishable because they exist in distinct solvent cages. Concepts involved in environmental isomerism are defined and criteria for distinguishability derived, first by neglecting Brownian potential energy noise, then by including it. Two models are used in the simulations of a molecule jumping from a cage of one type to another. (*i*) On every Brownian "collision," the associated Schroedinger state wave is continuous, i.e., collisions and transits between cages are accompanied by zero phase change. (*ii*) On every collision and transit, there is a random phase change in the state wave. The properties of liquid water are reviewed in terms of a two-state model in which the states are environmental isomers. It is shown that (*i*) the difference in enthalpy and entropy between the isomers, (*ii*) the positions and width of their IR stretching frequencies, as well as (*iii*) dielectric constant, (*iv*) molar volume, and (*v*) O···O radial distribution data are in agreement with a model in which the more stable isomer is $H_2O\backslash 4w$ (a water molecule in a cage of four water molecules) and the less stable isomer is $H_2O\backslash 5w$. The widths of the IR bands indicate that the water–water interactions are through "linkage pairs" in which the motions of the individual molecules comprising a cage are essentially independent.

Key words: isomers, isomerism, water, liquid cages, Brownian noise, state broadening, exchange.

Résumé : Les isomères environnementaux dans un liquide sont des molécules d'une seule espèce que l'on peut différencier parce qu'elles existent dans des cages de solvant distinctes. Les concepts impliqués dans l'isomérie environnementale sont définis et on a mis au point les critères qui permettent de reconnaître les différences; ils impliquent, dans un premier temps, de négliger le bruit d'énergie du potentiel brownien et, dans un deuxième temps, de le réintroduire. On a fait appel à deux modèles de simulations pour le passage d'une molécule d'une cage à une autre. (*i*) À chaque collision brownienne, l'onde associée à l'état de Schroedinger est continue, c'est-à-dire les « collisions » et les transferts entre les cages sont accompagnés d'un changement de phase qui est égal à zéro. (*ii*) À chaque collision et transfert, il se produit un changement de phase aléatoire dans l'onde d'état. Les propriétés de l'eau liquide sont réexaminées en termes d'un modèle à deux états dans lequel les états sont des isomères environnementaux. On a montré que les données relatives à (*i*) la différence en enthalpie et en entropie entre les isomères, (*ii*) aux positions et aux largeurs de leurs fréquences d'élongation en IR, ainsi que celles relatives (*iii*) à la constante diélectrique, (*iv*) au volume molaire et (*v*) aux données de distribution radiale O···O sont toutes en accord avec un modèle dans lequel l'isomère le plus stable est $H_2O\backslash 4w$ (une molécule d'eau dans une cage de quatre molécules d'eau) et que le moins stable est l'isomère $H_2O\backslash 5w$. Les largeurs des bandes IR indiquent que les interactions eau–eau se font par des « paires de liaison » dans lesquelles les mouvements des molécules individuelles formant la cage sont essentiellement indépendants.

Mots clés : isomères, isomérie, eau cages liquides, bruit brownien, élargissement d'état, échange.

[Traduit par la Rédaction]

In a recent series of theoretical papers, we considered the conditions for distinguishability of molecular environments in liquids (1–3). In this essay, in honor of Jerry Kresge, we try to weave the strands together and amplify and develop the underlying concepts in particular as they relate to liquid water.

Some definitions

Environmental isomers are chemical species with the same molecular and structural formula that become distinguishable in a given solvent by virtue of their different solvent environments.

For a range of solvents, the phenomenon of solvent environment affecting molecular properties is familiar. For example, the fact that solvent can shift the position of the absorption spectrum of a molecule has been studied for many years (4–7). Even in a single solvent, there can be environmental effects. Thus, when a liquid phase absorption spectrum is broader than its gas-phase counterpart, we probably conclude that in the liquid, the absorbing molecules are

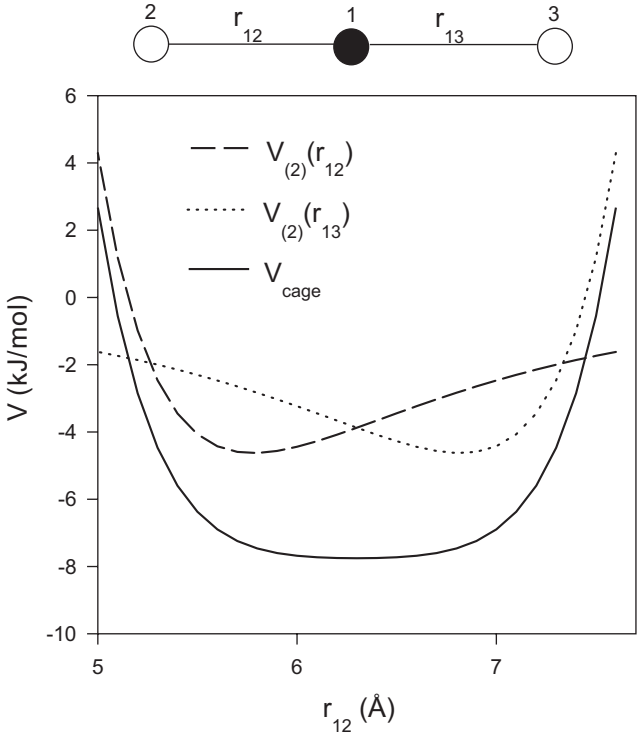
Fig. 1. Cage potential for a central molecule, 1, with two molecules, 2, 3, in its solvent cage. The cage potential is given by $V_{cage} = V_{(2)}(r_{12}) + V_{(2)}(r_{13})$, where $V_{(2)}$ is a pair potential given by $V_{(2)} = 4\varepsilon[(\sigma/r)^{12} - (\sigma/r)^6]$ with $\sigma = 5.15$ Å and $\varepsilon = 4.63$ kJ/mol.



in a range of many environments, because of their ever-varying liquid cages.

A particularly interesting case arises when a small number of environments are sufficiently different, and occur with sufficient weight, so that distinguishable species result. It is in this last and more limited case that we shall employ the term *environmental isomers*.

Material and potential energy cages

A molecule resides in a "cage" when its freedom of translation and rotation are constrained by the molecular environment. There are two common models. The first emphasizes the material cage, the second the potential energy cage. In the model of a material cage, the molecule is imprisoned by the dense packing of neighbor molecules (8) — dense enough to restrict its translation and rotation. This model is often useful. For example, it provides a basis for the analysis of geminate recombination; that is, of the recombination of reactive fragments produced from a caged molecule in a free-radical or photochemical reaction (9, 10).

In the model of a potential-energy cage, the emphasis is placed on the potential well resulting from the sum of the pairwise interactions of the molecule with its surrounding molecules. A potential energy cage is also called a "cavity." In Fig. 1, we display the cage potential for a central molecule with two identical neighbors. The two pairwise potentials add up to produce steep walls on both sides of the central molecule; that is, the central molecule exists in a potential well. In more realistic models in which there are neighbors all around, the potential well becomes a three-dimensional cage.

The potential energy cage is useful in the discussion of environmental isomerism because potential energy is basic to the definition of a molecule. As the molecule moves in isolation, its potential energy remains constant; one might say that the potential energy accompanies the molecule. In a liquid, the motion of a molecule consists of a succession of jumps, from an initial material cage to a neighboring one. As the molecule diffuses through the liquid, it leaves behind a wake of material cages through which it has passed. By contrast, the potential energy cage is not left behind. The time scales of the microscopic events are such that the potential energy cage in effect accompanies the molecule, and thus may be regarded as a fundamental property of the molecule. Briefly, in diffusion there are three critical time constants. (*i*) The transit time taken by a molecule in crossing the barrier from one cage to the next (τ_{jump}), which is of order 10^{-13} s. (*ii*) After the jump, the time taken in the new cage for the nonequilibrium energy distribution of the molecular neighbors to relax to statistical equilibrium, the correlation time (τ_{corr}), which is of order 10^{-12} s. (*iii*) The time that a molecule spends in a cage (τ_{cage}) before it jumps to the next material cage, which is of order 10^{-10}–10^{-11} s.

Although these times (whose numerical values will be examined later) are only representative and depend on the diffusing entity and the solvent, the relative values inferred by them are typical. After a diffusive jump, the molecular surroundings reach statistical equilibrium in a time that is short compared to τ_{cage}. In effect, the diffusing molecule, on passing through a succession of material cages, interacts with the medium at statistical equilibrium, except for a relatively small fraction of the time. To a good approximation, therefore, the motion of the molecule in the liquid is correlated with that of its potential energy cage. The potential energy of the cage interaction may therefore be regarded as part of the potential energy of the molecular species.

Distinguishability and cage exchange

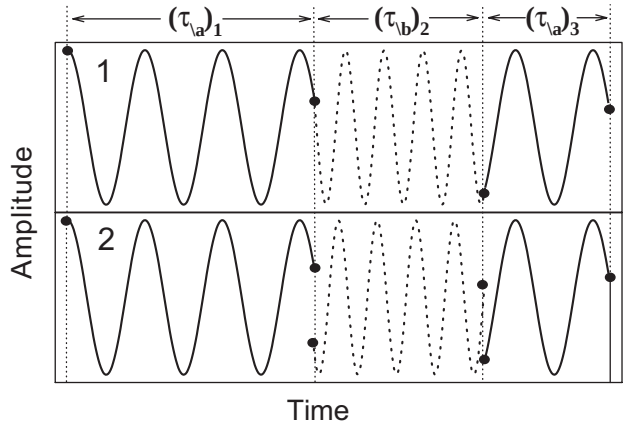
The next two sections will be theoretical. After that, we shall return to real phenomena. Theoretically, isomers are the populations of discrete minima on the potential surface for the interaction of the atoms in the molecule — minima that are linked by adiabatic motion. Note the requirement of "adiabatic." For example, in this definition ground state and triplet anthracene are not isomers because they cannot be interconverted on a single adiabatic surface. Note also that potential energy is here defined as in vibrational spectroscopy. That is, for an isolated molecule in its electronic/vibrational ground state, the potential energy V_o is equal to the state energy ε_o, minus the vibrational zero-point energy, $V_o = \varepsilon_o - \varepsilon_{vzp}$.

Suppose that the molecule is transferred to a liquid in which it can reside in alternate cages \a and \b. The substrate molecule in these two cages can then be represented by M\a and M\b. Let $V_{\backslash a}$ and $V_{\backslash b}$ denote the respective cage potentials for the molecule in cages \a and \b. Since the cage is part of the molecular entity in solution, the energies of a molecule in the cages are

$$[1a] \quad \varepsilon_{\backslash a} = V_o + \varepsilon_{vzp\backslash a} + V_{\backslash a}$$

© 1999 NRC Canada

Fig. 2. Partial wave trains when there is switching between two states \a and \b having different state frequencies or energies. In case 1, there is no phase shift accompanying the switch. In case 2, the phase shift is random.



[1*b*] $\varepsilon_{\backslash b} = V_o + \varepsilon_{vzp\backslash b} + V_{\backslash b}$

The vibrational zero-point energies $\varepsilon_{vzp\backslash a}$ and $\varepsilon_{vzp\backslash b}$ are nearly equal to each other and to ε_{vzp} for the isolated molecule. Hence, in good approximation, the energy difference between M\a and M\b is equal to the difference in cage potentials:

[2] $\varepsilon_{\backslash a} - \varepsilon_{\backslash b} = V_{\backslash a} - V_{\backslash b}$

In both environments, the atoms of the caged molecule are the same, yet the two state energies are different, and the two states exist at alternate potential energy minima connected by an adiabatic path. Since the isomerism is generated by the difference in cage potentials in the given liquid, it is reasonable to call M\a and M\b *environmental isomers*.

Since we have so far discussed environmental isomerism in terms of different state energies, it is useful to examine this concept further and to look at problems that may arise from this simple definition. We first inquire about the size of the energy difference required for distinguishability. It turns out that there are two kinds of dynamic effects that may wipe out the required distinguishability: (*a*) cage exchange and (*b*) potential energy noise due to the Brownian motion of the liquid molecules.

Cage exchange may be represented by the simple kinetic scheme

[3] $\mathrm{M\backslash a} \underset{k_{\backslash b}}{\overset{k_{\backslash a}}{\rightleftharpoons}} \mathrm{M\backslash b}$

where $k_{\backslash a}$ and $k_{\backslash b}$ are the first-order rate constants for the processes $\mathrm{M\backslash a} \rightarrow \mathrm{M\backslash b}$ and $\mathrm{M\backslash b} \rightarrow \mathrm{M\backslash a}$, respectively. Also $\tau_{\backslash a}$ ($= 1/k_{\backslash a}$) is the mean lifetime of M in cage \a before jumping to cage \b, with a similar definition for $\tau_{\backslash b}$ ($= 1/k_{\backslash b}$).

We shall define the environments \a and \b so that at equilibrium, $[\mathrm{M\backslash a}] \geq [\mathrm{M\backslash b}]$. Because at dynamic equilbrium, $k_{\backslash a}[\mathrm{M\backslash a}] = k_{\backslash b}[\mathrm{M\backslash b}]$, it follows that $k_{\backslash a} \leq k_{\backslash b}$, and $\tau_{\backslash a} \geq \tau_{\backslash b}$. In exchange kinetics, it is useful to define an exchange time by

[4] $\tau_{exch} = 1/(k_{\backslash a} + k_{\backslash b})$
$= \tau_{\backslash a}\tau_{\backslash b}/(\tau_{\backslash a} + \tau_{\backslash b})$
$= \tau_{\backslash b}[\mathrm{M\backslash a}]/([\mathrm{M\backslash a}] + [\mathrm{M\backslash b}])$

In this work, $\tau_{\backslash b}$ (potentially the smaller of $\tau_{\backslash a}$ and $\tau_{\backslash b}$) will be approximated by the time for a solvent molecule to diffuse by a length equal to a cage radius, which is given by the familiar Einstein–Smoluchowski equation,

[5] $1/k_{\backslash b} = \tau_{\backslash b} = r_{cage}^2/6D$

where D is the coefficient for self diffusion of the solvent, and r_{cage} is the cage radius. This means that any energy barrier associated with $k_{\backslash b}$ is the same as that for diffusion.

The time of the Brownian motions is governed by the Brownian correlation time τ_{corr}. The latter is roughly 100 times shorter than $\tau_{\backslash b}$, so the Brownian noise is averaged fairly well during τ_{exch}. We shall therefore treat the two dynamic effects in series. We shall first treat cage exchange in the absence of Brownian noise; in the next section, we shall add the noise.

The time-dependent Schroedinger wave equation for a quantum system in a stationary state is given by eq. [6], where $\psi(x, t)$ is the total wave function and $\phi(x)$ is its spatial part.

[6] $\psi(x, t) = \phi(x) \exp[-2\pi i(\varepsilon/h)t]$

The time-dependent part — the exponential — describes a simple harmonic circularly polarized wave of frequency $\nu = \varepsilon/h$. In cage exchange, the molecule switches between two stationary wave functions, $\psi_{\backslash a}$ and $\psi_{\backslash b}$. The ψ values can be regarded as stationary because the transit time between cages (τ_{jump}), and the time the molecule takes to come to equilibrium in the new cage (τ_{corr}) is much shorter than the time the molecule spends in a cage ($\tau_{\backslash a}$ and $\tau_{\backslash b}$). Hence, the ψ values are given by eq. [7], with $\nu_{\backslash a} = \varepsilon_{\backslash a}/h$, and $\nu_{\backslash b} = \varepsilon_{\backslash b}/h$,

[7*a*] $\psi_{\backslash a}(x, t) = \phi_{\backslash a}(x) \exp(-2\pi i \nu_{\backslash a} t)$

[7*b*] $\psi_{\backslash b}(x, t) = \phi_{\backslash b}(x) \exp(-2\pi i \nu_{\backslash b} t)$

Switching between two state frequencies $\nu_{\backslash a}$ and $\nu_{\backslash b}$ is mathematically analogous to the switching of a nucleus between two chemical shifts (2, 11, 12). Borrowing from NMR concepts, we define a dimensionless *distinguishability index* (ξ) by

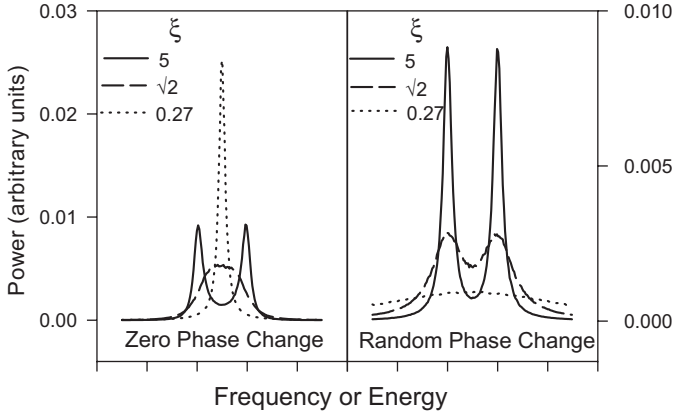
[8] $\xi = 2\pi|\nu_{\backslash a} - \nu_{\backslash b}|/(k_{\backslash a} + k_{\backslash b}) = 2\pi\,|\nu_{\backslash a} - \nu_{\backslash b}|\,\tau_{exch}$

In the case that $\varepsilon_{\backslash a} \neq \varepsilon_{\backslash b}$, the two frequencies will be different. As the caged molecule M jumps from environment \a to environment \b, the associated state wave switches from frequency $\nu_{\backslash a}$ to frequency $\nu_{\backslash b}$, and so on. This is displayed schematically in Fig. 2 for two cases. In the first, there is no phase change on switching. In the second, there is a random phase change on switching.

The fast Fourier transform (FFT) power spectra for long wave trains in these two situations are shown in Fig. 3. In each case, the individual lifetimes between switching, $(\tau_{\backslash a})_1$, $(\tau_{\backslash b})_2$, $(\tau_{\backslash a})_3$, $(\tau_{\backslash b})_4$, …., indicated in Fig. 2, are chosen stochastically to correspond to exponential lifetime distributions with mean values $\tau_{\backslash a}$ and $\tau_{\backslash b}$. In the case of zero phase change in Fig. 3, the reader will notice the similarity be-

© 1999 NRC Canada

Fig. 3. Fast Fourier transform spectra of wave trains with stochastic frequency switching between two states corresponding to two potential energy cages \a and \b. The lifetimes $\tau_{\backslash a}$ and $\tau_{\backslash b}$ are equal and have exponential distributions. In the left-hand panel, the wave train is continuous at switching (see Fig. 2, case 1). In the right-hand panel, the phase change is random (see Fig. 2, case 2).



tween the state power spectrum and NMR line shapes for exchange between two chemical shifts (11, 12). The distinguishability index ξ in eq. [8] depends only on the frequency difference $|\nu_{\backslash a} - \nu_{\backslash b}|$. That is, for a given τ_{exch}, the spectrum is the same whether the waves have frequencies $\nu_{\backslash a}$ and $\nu_{\backslash b}$, or frequencies $(X + \nu_{\backslash a})$ and $(X + \nu_{\backslash b})$, where X is any constant. The relevant variable is the *beat frequency* $|\nu_{\backslash a} - \nu_{\backslash b}|$.

However, the magnitudes of X and of $|\nu_{\backslash a} - \nu_{\backslash b}|$ are quite different in NMR and in state spectra. In NMR, X is of order 10^8 s^{-1} and $|\nu_{\backslash a} - \nu_{\backslash b}|$ is of order 10^2 s^{-1}. On the other hand, when we deal with electronic state spectra, X is of order 10^{15} s^{-1}. The value of $|\nu_{\backslash a} - \nu_{\backslash b}|$ in this situation can be estimated as follows. We begin with an estimate of τ_{exch} via eqs. [4] and [5]. We shall use $D = 2.3 \times 10^{-5}$ cm^2 s^{-1} and $r_{cage} = 6.4 \times 10^{-8}$ cm to obtain $\tau_{\backslash b} = 3 \times 10^{-11}$ s and $\tau_{exch} = 1.5 \times 10^{-11}$ s. Assuming [M\a] = [M\b] and setting $\xi = 5$ (which we designate as the margin of distinguishability, see below), eq. [8] then yields $|\nu_{\backslash a} - \nu_{\backslash b}| = 5 \times 10^{10}$ s^{-1}.

We shall now compare the two sets of parameters. The transit time between states, τ_{jump}, is similar in both examples, ca. 10^{-13} s, since its equivalent frequency, $1/\tau_{jump}$, is of order kT/h as predicted by transition state theory. Thus, in NMR, $1/\tau_{jump}$ is much greater than both X and $|\nu_{\backslash a} - \nu_{\backslash b}|$, and it is easy to agree that the phase of the NMR wave will not change during the jump. On the other hand, for Schroedinger state waves near the margin of distinguishability, $X >> 1/\tau_{jump} >> |\nu_{\backslash a} - \nu_{\backslash b}|$. If X remains irrelevant, then the phase of the wave motion will not change during τ_{jump}. If not, there could be many oscillations of the wave during τ_{jump} so that the phase change on jumping is random. Figure 3 therefore shows simulations for continuous as well as randomly discontinuous phase behavior on state switching.

When $\xi = 5$, the state waves are well resolved *in both models*. When there is zero phase change on switching, the states coalesce at $\xi = \sqrt{2}$ and the coalesced line continues to narrow for lower values of ξ. When there is random phase change on switching, there is no coalescence. Instead, the lines simply broaden until they overlap so much that only one peak can be seen. When $\xi > 5$, the state spectrum in both models consists of two distinct "lines," showing that the two states, M\a and M\b, are distinct. We shall therefore propose for distinguishability that ξ should be >5. Again using 1.5×10^{-11} s for τ_{exch}, then for distinguishability $|\varepsilon_{\backslash a} - \varepsilon_{\backslash b}|$ need only be ≥20 J/mol. This requirement is so lenient that it is usually met when the number of molecules in the cage wall changes, or when a molecule of a different species replaces a molecule in the cage wall (13).

One might therefore imagine that environmental isomerism is common. But we have not yet taken the effect of the Brownian motion of the cage molecules into account.

Effect of Brownian motion

The widespread distinguishability of liquid cage environments inferred from eq. [8] is mostly cancelled by the effect of Brownian motion. We have published a semiquantitative theory of this phenomenon (3), but the development is intricate, and it will be described here only in outline. We shall also briefly amplify some aspects of the model.

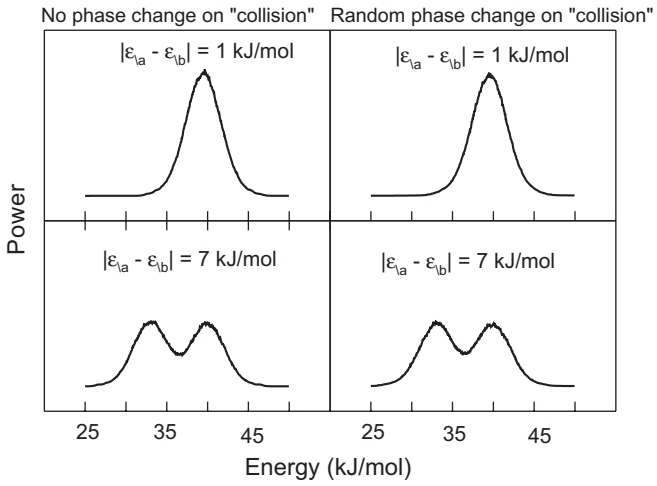
Assume that the substrate molecule M is at rest in its cage, while the neighbors of M, which we shall call N, exist in cages of their own and librate with energies governed by Boltzmann distributions. When a neighbor moves towards or away from M, the pairwise interaction energy between M and N changes. Since there are several neighbors, and the pairwise interaction energies vary, the cage potential of M fluctuates. The standard deviation of these fluctuations can be calculated if the motions of the neighbors are independent, and if the neighbor number and the pairwise interaction function are known (13). We calculated that for a hypothetical liquid consisting of spherical molecules M with an average of 10 neighbors, and in which the pairwise interactions are given by Lennard–Jones potentials with parameters appropriate for benzene, the standard deviation (σ_{cage}) is 2.6 kJ/mol. Of course, this value is not that of real benzene, but it should be close to it, and it indicates the magnitude of the phenomenon in normal non-hydrogen bonding liquids. The 2.6 kJ noise is substantial enough to obscure environmental isomerism unless $|\varepsilon_{\backslash a} - \varepsilon_{\backslash b}|$ exceeds 7 or 8 kJ/mol (see below), which is orders of magnitude greater than the 20 J/mol estimated for frequency switching without Brownian noise. For a water-like liquid with four or five neighbors and steep cage walls, a similar calculation yields Brownian noise with a standard deviation of 1.1 kJ/mol (3, 13).

Noise in the cage potential induces a corresponding noise in the Schroedinger frequencies $\nu_{\backslash a}$ and $\nu_{\backslash b}$. Exchange now is no longer purely between $\nu_{\backslash a}$ and $\nu_{\backslash b}$ but between a noisy multitude of frequencies centered, respectively, on $\nu_{\backslash a}$ and $\nu_{\backslash b}$.

The time scale of the frequency fluctuations is governed by τ_{corr}, the Brownian correlation time. This parameter represents the time for which a system retains memory of some initial configuration as it relaxes towards equilibrium. The theory of Brownian motion (14) — with reasonable assumptions — lets us estimate its magnitude. For an ensemble of molecular oscillators librating in a harmonic potential well, the theory yields eq. [9] (13).

© 1999 NRC Canada

Fig. 4. Fast Fourier transform spectra of wave trains involving switching between two states. In contrast to Fig. 3, the potential energy cages now have Brownian induced noise with standard deviation σ_{cage} = 2.6 kJ/mol and correlation time (τ_{corr}) = 8×10^{-13} s, $\tau_{\backslash a} = \tau_{\backslash b} = 3 \times 10^{-11}$ s. These parameters correspond to a benzene-like liquid.



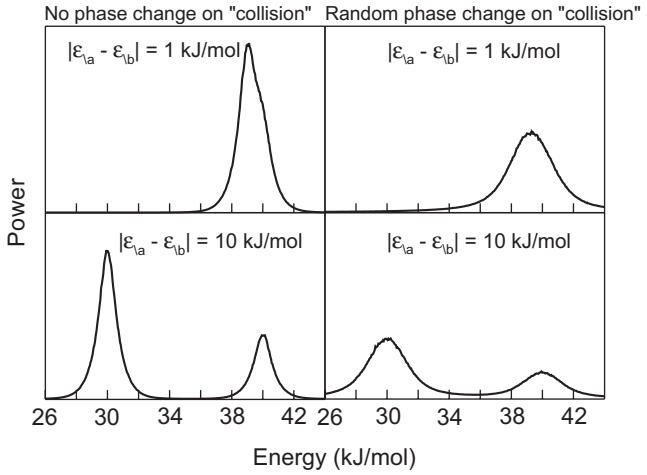
[9] $\tau_{corr} = q_{RT}^2 / 4D$

D is the macroscopic self-diffusion coefficient of the liquid, and q_{RT} is the displacement of the molecule from the cage center when the librational energy is RT. The actual cage potential is anharmonic, but for semiquantitative predictions, eq. [9] is good enough. In the following examples, D is 2.3×10^{-5} cm^2/s for benzene and 2.25×10^{-5} cm^2/s for water; q_{RT} is 8.8×10^{-9} cm for the benzene-like liquid and 2.5×10^{-9} cm for the water-like liquid. The values for τ_{corr} then are 8×10^{-13} s for the benzene-like liquid and 0.7×10^{-13} s for the water-like liquid. Notice that these correlation times are comparable to the collision times in an ideal gas at a pressure of about 1000 atm (1 atm = 101.3 kPa).

In the model (3), the potential energy is assumed to vary linearly with time until the next Brownian collision directs it towards a new value chosen at random from a Gaussian probability distribution, with standard deviation (σ_{cage}). The mean time between collisions is τ_{corr}, and the distribution of collision times about the mean is stochastic with first-order kinetics.

Figure 4 shows Fourier-transform power spectra of noisy Schroedinger wave trains for a benzene-like liquid. In the case of benzene, quantum-mechanical calculations indicate two pairwise potential minima with one 0.95 kJ/mol higher than the other (15). The simulations in Fig. 4 assume that there are two environmental isomers with [M\a] = [M\b] and with $|\varepsilon_{\backslash a} - \varepsilon_{\backslash b}|$ = 1 and 7 kJ/mol, respectively. The value of $\tau_{\backslash b}$ was estimated from eq. [5] as 3×10^{-11} s, using a cage radius of 6.4 Å, and since [M\a] = [M\b], $\tau_{\backslash a}$ was set equal to $\tau_{\backslash b}$. We considered two cases: (*i*) no phase change after a Brownian collision, (*ii*) random phase change after a collision. It is clear from Fig. 4 that $|\varepsilon_{\backslash a} - \varepsilon_{\backslash b}|$ would have to be about 7 kJ/mol or more in order for environmental isomers to be observed. Also, the difference between models (*i*) and (*ii*) is negligible. This is not surprising. In terms of the well-known gas phase spectral broadening induced by collisions

Fig. 5. Fast Fourier transform spectra of wave trains involving switching between two states. In this case, the parameters correspond to a water-like liquid with σ_{cage} = 1.05 kJ/mol, $\tau_{corr} = 0.72 \times 10^{-13}$ s, $\tau_{\backslash b} = 0.581 \times 10^{-11}$ s, $\tau_{\backslash a} = 1.36 \times 10^{-11}$ s.



(16), the spectral line is broadened to an extent $\Delta\varepsilon = h\Delta\omega/2\pi = h/(\pi\tau_{coll})$ (17). In our case, the time between dephasing events is τ_{corr}, so dephasing should introduce a broadening of only 0.16 kJ/mol (= 13 cm^{-1}).

Figure 5 shows the results of a similar simulation for a liquid with water-like properties. The value used for [M\a]/[M\b] is 0.7/0.3 (see below). Equation [5] yields a value of 0.6×10^{-11} s for $\tau_{\backslash b}$, based on $D = 2.25 \times 10^{-5}$ cm^2/s and $r_{cage} = 2.8 \times 10^{-8}$ cm. The mean correlation time (τ_{corr}), according to eq. [9], is 0.7×10^{-13} s.

Figure 5 shows the results of two sets of simulations, one with zero phase change after a Brownian collision and one with a random phase change. Each set has two values of $|\varepsilon_{\backslash a} - \varepsilon_{\backslash b}|$. The value of 1 kJ/mol is simply representative and for comparison with Fig. 4; the 10 kJ/mol value corresponds to the difference in real water (see below). In the 1 kJ/mol simulation, the two states of water overlap and are not distinguishable, although the state bands do show some asymmetry. In the 10 kJ/mol simulations, the two bands are well resolved, so that distinguishability of the corresponding states is indicated. The state widths are greater in the random phase-change model. At 10 kJ/mol, the state half-width (FWHM) is 1.3 kJ/mol for the zero phase change model, and 3.0 kJ/mol for the random phase-change model. The extra broadening, associated with the short correlation time, will be discussed in the next section.

Experimental evidence for environmental isomerism in water

We believe that water molecules in liquid water form two environmental isomers. Water is often regarded as an anomalous liquid because its properties deviate from established norms. One way to rationalize the deviations is by a two-state model in which the water molecules exist in either of two unspecified "states" that are in 1:1 equilibrium. Although the fit of this model is not always quantitative, the experimental evidence in its support is strong. In particular, the two-state model accounts for the high heat capacity of

© 1999 NRC Canada

water (18). It fits quasi-elastic neutron scattering[2] ultrasonic relaxation (19), and entropies of solution of nonpolar solutes in water (20). In these fits, and in infrared and Raman spectra described below, the difference in enthalpy between the two states is consistently 10 ± 1 kJ/mol. The most accurate two-state parameters are based on the heat capacity, which gives $\Delta H_{\a\rightarrow\b}$ = 10.5 kJ/mol, and $\Delta S_{\a\rightarrow\b}$ = 28.2 J/mol K. At 25°C, the equilibrium ratio of H_2O\a to H_2O\b is then 0.7/0.3 = 2.33.

Perhaps the best experimental evidence for a two-state model comes from the existence of accurate isosbestic points in infrared and Raman OH- and OD-stretching spectra over a range of temperatures (21–23), which shows that the bulk of liquid water consists of two, and only two, significant species. If there were more than two species contributing to the spectra, it would be extremely unlikely that there would be several sharp isosbestic points.

Water is a single species in the gas phase, so if there are two water species in the liquid, they must arise in some way from water–water interactions. Benson and Siebert (24) assumed two hydrogen-bonded complexes, which they described as tetramers and octamers. The equilibrium then proceeds with 2:1 stoichiometry: $2(H_2O)_4 = (H_2O)_8$. However, the weight of the evidence is that the two-state equilibrium proceeds with 1:1 (rather than 2:1) stoichiometry. For example, when the 2:1 model is fitted to infrared OH-stretching data, the extinction coefficient for one of the states, regardless of its nature, becomes negative (13).

If the two states are environmental isomers, most difficulties disappear. The equilibrium between H_2O in two distinct solvent cages is comparable to the transfer of H_2O between two media, such as H_2O (dilute, in benzene) = H_2O (dilute in methanol), which is 1:1. Similarly, the process H_2O\a = H_2O\b is tantamount to the distribution of H_2O between two microscopic environments, and the equilibrium constant [H_2O\a]/[H_2O\b] is analogous to a 1:1 distribution ratio.

The polarity of the two cage environments can be determined by applying Kirkwood's theory of the dielectric constant (25, 26) and assuming that liquid water consists of two isomers (27). The Kirkwood correlation factor g is defined so that $(g - 1)\mu$ gives the component of the average dipole moment of the solvent cage (or cavity) along an axis parallel to the dipole vector μ of the central caged molecule. The contribution of the solvent cage to the polarization then is proportional to $(g - 1)\mu^2$. For a normal liquid, $(g - 1)$ is close to zero. For water, the two-state model fits the dielectric constant with the following values: (H_2O\a), $(g - 1)$ = 2.01 ± 0.12; (H_2O\b), $(g - 1)$ = 0.91 ± 0.18. The 2.01 value corresponds to a highly polar cage consisting of four tetrahedrally arranged water molecules that form flexible hydrogen bonds to the central molecule. This model is essentially that argued by Bernal and Fowler (28), and elaborated by Oster and Kirkwood (26). The 0.91 value corresponds to a solvent cage that is roughly half as polar as the one with four neighbors.

The mean nearest neighbor number in liquid water has been deduced from the area of the nearest-neighbor peak in the O···O radial distribution function. X-ray diffraction data interpreted in this way lead to an average of 4.4 neighbors at room temperature (29). If the predominant, more polar, state (H_2O\a = 0.7) has 4 neighbors, and the minor less polar state (H_2O\b = 0.3) has 5 neighbors, then the average number of neighbors is 0.3 × 5 + 0.7 × 4 = 4.3, in fair agreement with the X-ray data.

There is no consensus about the arrangement of the water dipoles in the less polar state. Certainly, there are differences of description, which may be partly semantic (27, 30). One of us believes that two of the neighbors occupy hydrogen-bonded tetrahedral sites (like those in the four-cage), while three remaining neighbors form less directional electrostatic bonds (27). Because these bonds are weaker and permit greater freedom of motion than regular hydrogen bonds, the five-cage should have the higher enthalpy and the higher entropy, as is observed. With only relatively minor disruption, a fifth molecule can slip into the open ice-like structure of a four-cage (30). This picture is consistent with the anomalous ratio of the density of ice to water, which is 0.92, the ratio expected from the model being ≈ 4/(4 × 0.7 + 5 × 0.3) = 0.93.

It is interesting to note in the infrared and Raman studies on H_2O and HDO, that in all cases the absorption due to the state favored at higher temperatures occurs at higher frequencies. For example, Walrafen et al. (22) assign peak positions of 3524 and 3370 cm^{-1} to the OH stretches in the two forms of water, which we would categorize as H_2O\5w (= H_2O\b) and H_2O\4w (= H_2O\a). The difference in the positions of the maxima is 154 cm^{-1}. It has long been recognized that A-H stretching frequencies shift to higher values as the (A—H···O) hydrogen bond becomes weaker. For example, Pimentel and McClennan (31) reported that a weakening of 11 kJ/mol in the H bond of phenol and alcohols to oxygen electron donors resulted in a 100 cm^{-1} shift in frequency. This is compatible with our model in which H_2O\b lies about 10.5 kJ/mol above H_2O\a.

Given that the interactions among the water molecules involve hydrogen bonds, why do we envision cages rather than molecular complexes? Adjacent molecules in liquids can be logically classified into three categories: encounter pairs, linkage pairs, and molecular complexes. In encounter pairs, the neighbors interact through regular van der Waals interactions, which depend only on separation distance and are basically nondirectional. Each molecule in the pair is a member of the cage wall of the other, but their motions are essentially independent. In linkage pairs, the neighbors interact more strongly and probably in preferred directions (possibly through forces that are electrostatic in origin), but their motions are still independent, and each is still a member of the cage wall of the other. Finally, in molecular complexes the interaction becomes so strong that the interacting molecules lose their motional independence and become a single kinetic unit, and we can no longer regard one as being a member of the cage wall of the other.

It is not clear whether hydrogen bonds in liquid water produce linkage pairs or molecular complexes. Some authors use the term hydrogen *bonds*; others use hydrogen bond *linkages*. The average strength of a hydrogen bond in liquid

[2] G.J. Safford. Cited in ref. 22.

© 1999 NRC Canada

water is about 20 kJ/mol. Is that strong enough to make molecular complexes more favorable, i.e., to have the lower Gibbs free energy, than linkage pairs?

The problem can be formulated in terms of statistical mechanics, but the required properties are known only crudely. An order-of-magnitude calculation (13) reaches the conclusion that molecular complexes become more stable than either encounter or linkage pairs when the magnitude of the interaction energy exceeds 20–30 kJ/mol. The strength of hydrogen bonds in liquid water is near that figure.

The linkage-pair cage model described in this paper also correctly predicts spectral line widths. If there is a random phase change in the Schroedinger state wave at each Brownian collision, the mean lifetime of a quantum state in a liquid is τ_{corr}. For a vibrational transition in a liquid, the energy uncertainty in the initial state indicates the probable width of the spectral line. If the FWHM ($\Delta\nu$) of the line is given in cm^{-1} then (17),

$$[10] \quad \Delta\nu = 1/(\pi c \tau_{corr})$$

This equation is exact if the line shape is Lorentzian and incurs an 18% error if the line shape is Gaussian.

For the benzene-like liquid, $\tau_{corr} = 8 \times 10^{-13}$ s. Correspondingly, as indicated above, $\Delta\nu = 13$ cm^{-1}, a typical line width for infrared spectra in nonpolar liquids. For the water-like liquid, $\tau_{corr} = 0.7 \times 10^{-13}$ s, and $\Delta\nu$ correspondingly is 150 cm^{-1}.

The predicted $\Delta\nu$ of 150 cm^{-1} is in agreement with experiment. Walrafen et al. (22) has deconvoluted the OH-stretching band in the Raman spectrum of water and obtains 160 cm^{-1} for $\Delta\nu$ for the band due to the more populous isomer \a, and 110 cm^{-1} for the less populous isomer \b. The latter is less accurate. In the region above 7060 cm^{-1}, in the first-overtone infrared stretching band of HOD in D_2O, absorption is due almost entirely to isomer \b (13). Based on that absorption, $\Delta\nu = 186$ cm^{-1} at 17°C and 194 cm^{-1} at 61°C.

The predictions based on eq. [10] depend critically on the assumption that the molecules are moving independently, as in the model of linkage pairs. This is true not only for the Brownian motion itself, but also for the calculation of τ_{corr}, which is sensitive to this issue. We regard the agreement of eq. [10] with observed OH-band widths in water as strong supporting evidence for the model of linkage pairs.

Concluding remarks

In the above, we have shown how environmental isomerism can account for the properties of water in a straightforward fashion. Examination of the structure of water gives us clues about the conditions for environmental isomerism in other liquids. In water, the optimum hydrogen-bonded arrangement produces cages whose walls have a low molecular density. In normal liquids, the optimum neighbor number is around 10, while the optimum hydrogen-bonded water cage has a neighbor number of only 4. This facilitates the formation of a second isomer, to fill some of the available space. The introduction of an additional water molecule distorts the optimum geometry and thereby weakens the hydrogen bonds. This causes the energy to rise significantly, but it introduces no serious steric crowding. The reduced pairwise interaction in turn reduces the frequencies of the librations, and thus raises the entropy. We believe that environmental isomers will occur also in other liquids under corresponding microscopic conditions. For example, in liquid methanol, the O-H stretching spectrum measured over a wide range of temperatures shows an accurate isosbestic point at 3410 cm^{-1} (32), reminiscent of that in liquid water.

The presence of environmental isomers can have important consequences in mixed solvents as well. For example, the plots of solute enthalpies and entropies versus solvent composition in *tert*-butanol–water mixtures show puzzling maxima and minima (33). At this time, there is no obvious explanation for these anomalies. However, the facts can be interpreted, at least in principle, on the basis that there are not only the water isomers already considered, but also environmental isomers in which particular water molecules in the cage walls are being replaced by *tert*-butanol molecules. This process will generate additional environmental isomers whose population increases with the fraction of *tert*-butanol. According to Grunwald (13), the formation of two such species in addition to the two water species is sufficient to produce maxima and minima like those that are observed.

A new silicon-mediated nitrogen to oxygen rearrangement

Stefano Talami and Charles J.M. Stirling

Abstract: Migration of silicon from nitrogen to oxygen has been quantified with respect to the distance between migration termini, substituents at silicon, and substitution on the chain linking oxygen to nitrogen.

Key words: silicon migration, nitrogen to oxygen, penta coordinate intermediate.

Résumé : On a quantité la migration du silicium de l'azote à l'oxygène par rapport à la distance entre les points de migration, les substituants sur le silicium et des substituants sur la chaîne reliant l'oxygène et l'azote.

Mots clés : migration du silicium, azote à oxygène, intermédiaire pentacoordiné.

[Traduit par la Rédaction]

Rearrangements involving migration of silicon from oxygen to oxygen are familiar (1, 2), and migration between nitrogen and oxygen in *N*-silyl carboxamides has been described (3). Migration between nitrogen and oxygen has not been otherwise studied except en passant in the example mentioned below.

In an earlier study (4), we had found that 1-aminopropane reacts ca. 200 times faster with *tert*-butyldimethylsilyl chloride to give the aminosilane **la** than does ethanol to give the silyl ether **2a**. When 2-aminoethanol was used, however, the rate constant was close to that for the reaction with 1-aminopropane but *the exclusive product was the aminosilyl ether* **2b.** These results clearly suggested that the initial product of the last reaction was **lb**, which then rapidly rearranged to **2b**.

In the present work, we have shown that the rearrangement is intra- and not intermolecular. The half life of the silylamine **lc** is about 2 weeks in methanol at 60°C (4) and TBDMS–amines are stable in ethanol–hexane mixtures (5). We have now studied a series of ω-hydroxyaminosilanes **1** obtained by the general route of Scheme 1,[2] a modification of that used by Overman and his collaborators (6) in which it was found that selective *O*-deprotection of **ld** gave the rearranged product **2c**, and intermediate formation of **le** was suggested. We find that conditions of *O*-deprotection are important to ensure that the silylamino function is not also

Received December 2, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

[2]**Synthesis of *O*-trimethylsilyl-*N*-trialkylsilylamino alcohols**

Two methods were employed: (*i*) treatment of a stirred chloroform solution of amino alcohol (10 mmol) and triethylamine (80 mmol) in chloroform (100 mL) at 0°C with trimethylchlorosilane (10 mmol) gave the *O*-trimethylsilyl protected amino alcohol from which *N*-trialkylsilyl derivatives were obtained directly by addition of trialkylsilyl choride (11 mmol). Treatment of the chloroform solution with 10% aqueous NaOH or 1 M $NaHCO_3$ and subsequent distillation gave 90–99% crude yields. (*ii*) A two-step procedure was employed to obtain hindered *O*-trimethylsilyl derivatives of *N*-trialkylsilylamino alcohols or where high yields from trialkylsilylating agents were desirable. Treatment of a stirred solution of amino alcohol (12 mmol) and triethylamine (80 mmol) in THF (50 mL) at 0°C, with trimethylchlorosilane (10 mmol) and subsequent removal of the ammonium salt by filtration, gave the product which was purified by distillation under reduced pressure.

O-Trimethylsilyl-*N*-trialkylsilyl derivatives were obtained by addition of trialkylsilyl chloride (or triflate) (12 mmol) to *O*-trimethylsilylamino alcohol (10 mmol) and triethylamine (60 mmol) in THF (200 mL) at 0°C, followed by filtration and distillation.

N-tert-Butyldiphenylsilyl and *N-tert*-dibutylmethylsilyl derivatives of *O*-trimethylsilyl protected amino alcohol could be purified by flash chromatography using hexane containing 5–10% of triethylamine. In the absence of triethylamine, partial hydrolysis occurs during the chromatography. Yields 60–85% of pure product were obtained.

cleaved.[3] For each of the substrates we have studied, the pure hydroxyaminosilane in a perdeuterated solvent has been allowed to rearrange, and the progress of the rearrangement has been followed by changes in the ^{1}H and ^{13}C chemical shifts in alkyl groups on silicon and in the interconnecting chain. In addition, changes in the ^{29}Si chemical shifts have also been followed in some cases. All of the end products have been fully characterized; in some cases, deprotection of the hydroxyl group has been accompanied by partial hydrolysis of the aminosilanes, which are exceptionally sensitive to cleavage.

[3] ***O*-Deprotection of *O*-trimethylsilyl-*N*-trialkylsilylamino alcohols**

Trimethylsilylethers can be solvolysed in anhydrous methanol (K_2CO_3 (0.1 equiv.), 0°C, 45 min, 100% yield) conditions in which *tert*-butyldiphenylsilylamines are stable.

In deprotecting *O*-trimethylsilyl-*N*-triisopropylsilyl-2-aminoethanol in these conditions, hydrolysis or methanolysis of triisopropylsilyl group was not detected, but a large amount of rearranged compound was obtained; better results were obtained performing the reaction at 0.1 M in methanol with 0.05 equiv. of K_2CO_3 for 10–12 min. at 0°C.

As the rearrangement is not temperature dependent but can be catalysed in methanol by K_2CO_3, *O*-deprotection of *O*-trimethylsilyl-*N*-*tert*-butyldiphenylsilyl derivatives was more effectively achieved using 0.01 equiv. of K_2CO_3 in methanol at room temperature under ultrasonication.

Acidic work-up is not advisable as the rearrangement is strongly acid catalysed. Dilution with pentane, filtration, and solvent distillation gave 99–100% recoveries.

Rearrangement of *N*-trialkylsilylamino alcohols

The *N*-silylamino alcohol was dissolved in the chosen deuterated solvent. The rearrangement was followed by ^{1}H and ^{13}C NMR. Similar rate constants were obtained using the integrals of C*H*O, C*H*N, and Si-alkyl signals. Trialkylsilylaminobutanes and trialkylsilyloxypropanes were used as reference standards.

Product identification was by comparison with ^{1}H or ^{13}C NMR spectra of pure compounds or by addition of solutions of pure *O*-alkylsilylamino alcohols.

[d]$t_{1/2}$, 480 s.

ment was observed only with two methylene groups between nitrogen and oxygen in the absence of catalysts; with 3, 4, or 5 methylene groups, i.e., with ring sizes of 6, 7, or 8 in the transition structure, the aminosilanes were inert even at 200°C. Catalysis was examined with a substrate **1f** which shows very feeble catalysis by bases (Table 1) either when these are strongly basic, e.g., Et_3N, or strongly nucleophilic, e.g., DMAP. Deprotonation of oxygen is clearly not a significant factor under these conditions and neither is external nucleophilic attack at silicon. By contrast, there is strong catalysis even by weak acids (Table 1), and enhancement of the nucleofugality of the leaving nitrogen atom is presumably involved (7).

Nucleophilic substitution at silicon is very sensitive to steric effects at silicon and in the nucleophile (4, 8). Such effects are also manifested in this rearrangement (Table 2). When the silyl group is DTBM, **1j**, rearrangement is not observable, and when it is TBDM, **1b**, the rearrangement is too fast to measure accurately. When the silyl group is TIP, **lg**, it occurs at one twentieth of the rate of TBDP, **lf**. This differential is highly sensitive to the solvent; **1g** is accelerated by a factor of 10^4 on transfer from benzene to methanol, whereas the factor for **lf** is only 7 for the same change. The reasons for this differential are not at present clear; the higher dielectric constant of methanol ($\varepsilon = 33$) over benzene ($\varepsilon = 2.3$) is not responsible, as the differential is not maintained in dimethyl sulfoxide ($\varepsilon = 47$) or in nitromethane ($\varepsilon = 36$) (Table 2). We tentatively suggest that change in a transition structure such as **3** for **1g** is less delocalized than for **lf** in which the silicon atom bears phenyl groups and that it is the hydrogen-bond donor capability of the solvent that produces greater stabilization in the transition state.

In relation to the foregoing, the effects of substituents on the chain linking oxygen and nitrogen would be expected to be considerable. When a methyl group is located α- to the hydroxyl group, as in **1e**, the reaction is inhibited (Table 2). This is consistent with the results of intermolecular reactions (4) in which propan-2-ol was found to be 154 times less reactive towards TBDMS–chloride than ethanol. Likewise, with a methyl group on the leaving nitrogen atom **1h**, rearrangement is very slow and not discernible even at 200°C, bearing in mind, however, that, vide infra, temperature coefficients in nucleophilic displacements at silicon are small

(2, 4). Clearly, the *N*-methyl group obstructs access of the distal hydroxyl group to the silicon atom. In the cases where we have been able to measure the kinetics accurately, the temperature coefficient is very small, pointing to a highly negative entropy of activation. This in turn points to what appears to be a very tight transition structure, and presumably, access of the nucleophilic oxygen is easily hindered. By contrast, when a methyl group is situated α- to nitrogen as in **1i**, the reaction is accelerated by a factor of 15. It would be reasonable to ascribe this result to the Thorpe–Ingold effect (9). In this event, the modest inhibition by a methyl group α- to oxygen appears to be a compromise between steric inhibition and Thorpe–Ingold acceleration.

The reversible enolization and hydration of pyruvate: possible roles of keto, enol, and hydrated pyruvate in lactate dehydrogenase catalysis

A. Esposito, A. Lukas, J.E. Meany, and Y. Pocker

Abstract: The reversible enolization and hydration of pyruvic acid and pyruvate anion were monitored using spectrophotometric methods at several temperatures. Widely varying values for the equilibrium constant for the enolization of pyruvic acid and pyruvate ion appear in the literature. To accurately determine the position of equilibrium for the enolization reaction, we have developed a method that gives consistent results in which purified samples of sodium pyruvate are first "titrated" with triiodide ion to remove any triiodide-scavenging impurities such as those resulting from aldol condensation reactions. After reequilibration to allow the regeneration of enol pyruvate, the addition of small quantities of triiodide result in an initial burst in the decrease of absorbance at 353 nm, followed by the much slower zero-order decrease due to the formation of new enol pyvuvate molecules. The absorbance change during the burst phase of the reaction is proportional to the enol concentration plus that of any triiodide-scavenging impurity which may be present in the original pyruvate solution. Thus, as the quantity of triiodide used in the pretreatment stage of the experiments is increased, these burst absorbance changes, ΔA, decrease until a constant value of ΔA is reached. Accordingly, this final ΔA value is proportional to enol pyruvate (or enol pyruvic acid) *in the absence of* triiodide-scavenging impurity, allowing the accurate and reproducible determinations of K_{enol}. The equilibrium constants for both pyruvate and pyruvic acid are relatively temperature insensitive and, typically, K_{enol} (pyruvate anion) = 2.6×10^{-5} and K_{enol} (pyruvic acid) = 7.8×10^{-5} at 25.0°C. The zero-order phase of the reaction of triiodide ion may be used to calculate rate constants for enolization. The hydration and dehydration of pyruvic acid were followed directly by following absorbance changes in the peak at 340 nm due to the keto group. The thermodynamic and kinetic results reported in this paper are used to help determine whether the observed "substrate" inhibition of the lactate dehydrogenase catalyzed reduction of pyruvate is actually caused by keto, hydrated, or enol pyruvate.

Key words: pyruvate, enolization, hydration, lactate dehydrogenase.

Résumé : Opérant à plusieurs températures et faisant appel à des méthodes spectrophotométriques, on a examiné l'énolisation réversible et l'hydratation de l'acide pyruvique et de l'anion pyruvate. Des valeurs très variables apparaissent dans la littérature pour la constante d'équilibre pour l'énolisation de l'acide pyruvique et de l'ion pyruvate. Dans le but de déterminer la position de l'équilibre pour la réaction d'énolisaton d'une façon précise, on a développé une méthode qui donne des résultats reproductibles; elle implique l'utilisation d'échantillons purifiés de pyruvate de sodium « prétitrés » avec l'ion triiodure pour enlever toutes les impuretés susceptibles de capter le triiodure, telles que celles résultant de réactions de condensation aldolique. Après une rééquilibration pour permettre une régénération de l'énol du pyruvate, l'addition de faibles quantités de triiodure provoque une diminution initiale rapide de l'absorbance à 353 nm, suivie d'une diminution beaucoup plus lente d'ordre zéro causée par la formation de nouvelles molécules d'énol du pyruvate. Le changement rapide d'absorbance dans la phase initiale de la réaction est proportionnel à la concentration d'énol plus celle de toute impureté susceptible de capter le triiodure qui peut encore être présente dans la solution originale de pyruvate. Donc, si l'on augmente la quantité de triiodure utilisée dans le stage de prétraitement des expériences, ces changements rapides d'absorbance, ΔA, diminuent jusqu'à l'atteinte d'une valeur de ΔA constante. Il en résulte que cette valeur finale de ΔA est proportionnelle à l'énol du pyruvate (ou à l'énol de l'acide pyruvique) *en l'absence* d'impureté susceptible de capter le triiodure et qu'elle permet d'obtenir des valeurs précises et reproductibles pour les déterminations de $K_{énol}$. Les constantes d'équilibre tant pour le pyruvate que pour l'acide pyruvique sont relativement peu sensibles à la température et les valeurs types de $K_{énol}$ (anion pyruvate) = $2{,}6 \times 10^{-5}$ et $K_{énol}$ (acide pyruvique) = $7{,}8 \times 10^{-5}$, à 25°C. On peut utiliser la phase d'ordre zéro de la réaction du

triiodure pour calculer les constantes de vitesse d'énolisation. Les réactions d'hydratation et de déshydratation de l'acide pyruvique sont suivies directement par les changements d'absorbance dans le pic à 340 nm dû au groupe cétonique. Les résultats thermodynamiques rapportés dans ce travail ont été utilisés pour déterminer si l'inhibition de « substrat » observé lors de la réduction du pyruvate catalysée par la déshydrogénase du lactate est de fait cause par le groupe cétonique, son hydrate ou l'énol du pyruvate.

Mots clés : pyruvate; énolisation; hydratation; déshydrogénase du lactate.

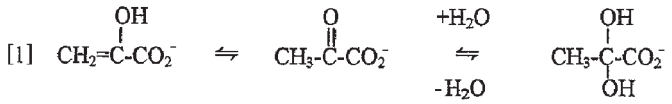
Introduction

Pyruvate is an important intermediate that is linked to many biochemical processes regulated by enzymes. In the glycolytic pathway, for example, the anaerobic regeneration of nicotinamide adenine dinucleotide (NAD^+) from its reduced form (NADH) is facilitated by the reduction of pyruvate to lactate in the presence of lactate dehydrogenase LDH (EC1.1.1.27). Under physiological conditions, pyruvate exists as an equilibrated mixture of enol, keto, and



hydrated forms (1*a*–1*f*).

Equilibrium constants have been determined in previous work for the reversible hydrations of pyruvic acid and pyruvate anion using pmr (1*a*) and spectrophotometric methods (1*f*) and the various data obtained are in relatively good agreement when due consideration is taken of the fact that the stoichiometry of the hydration of pyruvic acid involves three water molecules (1*a*). Because of the electron-withdrawing effect of the carboxyl group, pyruvic acid is considerably more hydrated in aqueous solutions than is the pyruvate ion. The hydrations of pyruvic and pyruvate ion are both known to be exothermic (1*a*, 1*d*, 1*f*).

The results of kinetic studies demonstrate that the reversible hydration of pyruvate anion is a general-acid, general-base-catalyzed process, which includes a small catalytic term for general-base catalysis by the pyruvate anion itself (2*a*, 2*b*, 2*c*). The kinetic studies also suggest that the spontaneous hydration of pyruvate anion involves the contribution of a kinetic term representing an intramolecular general-base-catalyzed path involving the neighboring carboxylate group (2*b*).

Although there is little ambiguity associated with the determination of kinetic parameters for the enolization of pyruvate and pyruvic acid (2*b*, 3, 4*a*, 4*b*), reported equilibrium constants for these reversible processes vary (1*g*, 1*h*, 2*b*, 4*b*). In the Meyer method (5) the burst of triiodide uptake, presumably by enol pyruvate (or enol pyruvic acid), is spectrophotometrically measured at 353 nm. This method generally gives unreliable values of K_{enol} because solutions of pyruvic acid or pyruvate contain a triiodide-scavenging impurity. For this reason, the classic protocol for the Meyer method (5) often gives rise to inaccurate determinations of the enol content of carbonyl compounds in solution (6*a*, 6*b*). The existence of an impurity formed in samples of pyruvic acid was reported many years ago and identified as the aldol condensation product α-keto-γ-valerolactone-γ-carboxylic acid (6*c*). One may also envisage the bimolecular aldol condensation of pyruvic acid, followed by dehydration, to form an α,β-conjugated diacid. Accordingly, apparent K_{enol} values determined by the Meyer method (5) are typically larger than the actual value. In the present work, we have circumvented this problem by utilizing purified pyruvate solutions that have been pretreated with triiodide ion to "titrate" out the I_3^- scavenging impurity. After the reequilibration between enol and keto forms we utilize a modification of the Meyer (5) method to determine K_{enol}. On the other hand, because the burst of triiodide uptake is relatively rapid, the finite time required for the complete mixing of the reaction components renders it difficult to accurately extrapolate spectrophotometric absorbances back to the kinetic zero. And since the burst absorbance changes, ΔA, typically are relatively small, the uncertainty of the absorbance at the kinetic zero can result in large deviations of the apparent K_{enol} from the actual values. In this report, we describe our solution to this problem as well.

Investigators have also attempted to approximate K_{enol} by independently determining the rates of enolization of keto pyruvate and ketonization of enol pyruvate using the relationship $K_{enol} = k_{enol} / k_{keto}$ (1*g*, 1*h*, 2*b*). Again, using this method, uncertainties may arise because of differences in the experimental conditions under which the two reactions are independently carried out (7*a*–7*c*, 8*a*, 8*b*).

It has been demonstrated that keto pyruvate serves as the preferential substrate of LDH (9, 10). This enzyme is one of many oxidoreductase enzymes that is subject to "substrate" inhibition (11). Although substrate inhibition for LDH is more pronounced for the heart than for the muscle isoenzymes (12), the physiological importance of this mode of inhibition in warm-blooded animals is controversial (13*a*–13*d*). Somero (14), however, has shown that the substrate inhibition of the enzyme in certain fishes becomes increasingly more pronounced at lower temperatures and has suggested that this phenomenon serves an important role in biological adaptation.

An earlier report by Coulson and Rabin (15*a*) suggested that enol pyruvate is a potent inhibitor of LDH and is responsible for the observed substrate inhibition of the enzyme. That original report was quoted widely in biochemistry textbooks (15*b*) and other references (15*c*) for a number of years. Although the original suggestion (15*a*) was based on reasonable experimental results, an alternative interpretation of these results is indicated by more recent, detailed studies of the kinetics and thermodynamics of the various nonenzymatic reactions of pyruvic acid and pyruvate anion in aqueous solution. Indeed, studies have since been conducted to determine the possible role of hydrated pyruvate

© 1999 NRC Canada

as well as enol pyruvate in the observed substrate inhibition of the enzyme (16, 17).

It was first proposed by Fromm (18) that the substrate inhibition of the enzyme is the result of the formation of an abortive ternary complex with the stoichiometric composition of LDH, pyruvate, and NAD^+. Two modes of LDH inhibition by pyruvate have been proposed (17, 19) involving, respectively, (*i*) the rapidly reversible formation of a ternary complex ($LDH{\cdot}NAD^+{\cdot}$pyruvate), and (*ii*) the slowly reversible formation of a binary complex between LDH and a covalently bound adduct of NAD^+ and pyruvate resulting in the formation of $LDH{\cdot}NAD^+$–pyruvate. Both hydrated pyruvate and enol pyruvate have been reported to form ternary abortive complexes with LDH and NAD^+ (16, 17).

The kinetic and thermodynamic parameters associated with the reversible hydration and enolization of pyruvate may be used to assess the likelihood of each of the different forms of pyruvate serving as potential participants either as enzyme substrates or as enzyme inhibitors. Such data provide a basis to determine whether there exists a high enough concentration of a given form of pyruvate to explain a hypothetical kinetic scheme or whether a given form of pyruvate may be formed rapidly enough to be consistent with known kinetic parameters. Over the years, two of the present authors have carried out detailed investigations of the reversible hydration and enolization of pyruvic acid and pyruvate anion (1*a*, 2*a*–2*c*, 3*a*, 3*b*, 9, 16). In the present paper, we provide selected thermodynamic and kinetic data for these reactions and show how these data can help address two questions: (*i*) which chemical form of pyruvate (enol, keto, or hydrate) is involved in the substrate inhibition of LDH? (*ii*) is the substrate inhibition recognized by Somero at lower temperatures a property of the enzyme alone, or is it also dependent on variations in the position of equilibria between enol, keto, and hydrated pyruvate as a function of temperature?

Experimental section

Materials used to prepare buffer solutions, sodium pyruvate, pyruvic acid, and all other reagents were in their commercially available reagent-grade forms. Pyruvic acid was distilled through a Vigreux column in an atmosphere of nitrogen gas, and sodium pyruvate was recrystallized using methanol–water mixtures. All solutions were prepared from distilled, deionized water. Spectrophotometric measurements were made using either a Shimadzu UV-2101PC or a Varian Cary 210 spectrophotometer. Both instruments gave rise to essentially identical kinetic and thermodynamic parameters. The temperature of the cell compartments was regulated and maintained constant by a VWR 1160 thermostated bath and circulator.

The enolization of pyruvate anion was monitored by following its iodination at 353 nm as described in earlier work (2*b*, 3, 4). Typically, 0.10 M sodium pyruvate solutions were prepared directly prior to use in 0.04 M phosphate buffers in which the ionic strength was adjusted to 0.35 M by the addition of appropriate quantities of sodium chloride. Most of the reactions were initiated by the addition of 0.05 mL of 2.05×10^{-3} M I_2 in 1.0 M KI to the 3 mL reaction cuvettes containing the buffered solutions of pyruvate. For each temperature studied, we used the appropriate value of the association constant for the reaction $I_2 + I^- \rightleftharpoons I_3^-$, $K_{I_3^-} = [I_3^-]/[I_2][I^-]$ (20*a*, 20*b*). The initiation of all kinetic runs was accomplished with the rapid mixing of the final reaction components by means of a small stirring paddle attached to the needle tip of the Hamilton microlitre syringe (21).

These reactions are known to take place in two phases (2*b*, 3, 4): a rapid burst phase in which enol pyruvate (and any unsaturated impurities inherent in the original pyruvate sample) reacts directly with the added I_3^-, followed by the zero-order reaction of I_3^- with enol pyruvate as it is formed in the rate-determining step. In attempting to employ the Meyer method (5) in which the burst phase absorbance change, ΔA, is used to determine equilibrium concentrations of enol pyruvate, $[\text{enol}] = \Delta A/\varepsilon\{1 + 1/(K_{I_3^-}[I^-])\}$, it has been found by us (2*b*) and others (4*a*) that the values obtained are usually considerably larger than those determined through other methods, suggesting the existence of an I_3^- scavenging impurity in the pyruvate samples. Even using recrystallized sodium pyruvate, the method described above gives rise to an equilibrium constant for enolization, $K_{\text{enol}} = 1 \times 10^{-4}$, which is considerably larger than that reported previously (1*g*, 1*h*, 2*b*).

We found, however, that the Meyer method could be adapted to allow the determination of valid values of K_{enol} by removing or inactivating the I_3^- scavenging impurity. Accordingly, we pretreated the buffered pyruvate solutions with small quantities of I_3^- to react with and, therefore, remove the impurity. After the pyruvate in solution reacted completely with the added I_3^- (note the pyruvate concentration was always much larger than that of iodine) it was allowed to reequilibrate with its enol form. The time allowed for reequilibration was always greater than 10 half-lives for the known rate of reequilibration between keto and enol pyruvate (2*b*). After reequilibration had taken place, we injected 0.05 mL additional I_3^- to initiate the burst uptake of I_3^- by the *equilibrium concentration of enol pyruvate*. The burst was again followed by the zero-order production of new enol pyruvate. Thus, we were able to essentially titrate out the I_3^- scavenging impurity by varying the amount of triiodide used in pretreatment.

Because the time required for complete mixing of the reaction mixtures (ca. 3–5 s) interferes with monitoring the initial stages of the burst phase, it is not possible to accurately extrapolate absorbances of the burst phase back to the kinetic zero. Thus, the actual absorbance of the I_3^- solution used to initiate the run after pretreatment must be be determined independently, using experimental conditions that simulate those used in the actual iodination experiments. Even when using 0.1 M pyruvate, the absorbance differences, ΔA, used to calculate the equilibrium concentration of enol pyruvate are relatively small (typically from ca. 0.06 to 0.07), so that the precise determination of $A_{I_3^-}$ is crucial. In these determinations, account must be taken of the residual iodide ion left over from the original I_3^- pretreatment since the added I^- increases the concentration of I_3^-, thereby increasing the spectrophotometric absorbance. In Table 1, we exemplify the absorbancies observed from solutions at various initial concentrations of I^- and I_2 at 25°C. It will be noted that our values of $A_{I_3^-(\text{obsd})}$ in Table 1 are in excellent agreement with those calculated, $A_{I_3^-(\text{calcd})}$, on the basis of published values of $K_{I_3^-}$ (20*a*, 20*b*).

[a]The data in the last two columns refer to absorbances of I_3^- in the presence of 0.01 M pyruvate anion *prior* to enolization and in the *absence* of I_3^- scavenging impurity. See text for experimental protocol.
[b]Formal concentration.
[c]Assuming: $K_{I_3^-} = [I_3^-]/[I_2][I^-] = 774$ at 25.0°C. References 20*a* and 20*b* give comparable values of $K_{I_3^-}$ over two overlapping temperature ranges.
[d]$[I_3^-] = \{774(3.36 \times 10^{-5})[I^-]\}/(1 + 774[I^-])$.
[e]Each value represents the average of 10 determinations. The average standard deviation for these values was 0.0025 absorbance units.
[f]Using the average $\varepsilon = 25\ 100\ M^{-1}\ cm^{-1}$ calculated from the data in this table.

Our observed values of the absorbance of I_3^- in the absence of pyruvate, $A_{I_3^-(obsd)}$, were compared with the extrapolated linear portion of our iodination runs, $A_{0,extrap}$ to determine ΔA for the direct and rapid reaction of triiodide with enol pyruvate. According to Davies and Gwynne (20*a*), $K_{I_3^-}$ is independent of ionic strength up to 1 M, and our own observations are in agreement with this finding. Nonetheless, the question arises whether the value of $A_{I_3^-}$ in the *absence* of pyruvate is the same as that in the *presence* of the 0.098 M pyruvate solutions used in the iodination runs. To determine this, we performed a number of very simple experiments. We first added triiodide to the buffered solution of pyruvate and when the zero-order portion of the reaction was complete, we immediately injected 0.05 mL of the triiodide solution into the same reaction mixture. This latter injection gives rise to no burst reaction whatsoever, showing that the I_3^- scavenging impurity has been deactivated and that no new enol has yet had the time to form. The *linear* extrapolation of absorbance to the endpoint of the first reaction can be made with certainty and gives yet another means of determining $A_{I_3^-}$. It will be noted, then, that this value was determined in the presence of "pure" pyruvate, but in the *absence* of triiodide-scavenging material either in the form of impurity or as enol pyruvate. The last two columns of data in Table 1 exemplify values of $A_{I_3^-}$ determined in this way. These data demonstrate that $A_{I_3^-}$ is not only insensitive to ionic strength but also independent of the presence or absence of keto pyruvate anion.

For the determination of the kinetic data for the enolization of pyruvate anion and pyruvic acid, reaction velocities were calculated from the linear portions of the spectrophotometric traces at 353 nm, $v_{enol} = \Delta A/\varepsilon\Delta t\{1 + 1/(K_{I_3^-}[I^-])\}$ and the corresponding observed pseudo-zero-order rate constants, $k_{enol} = v_{enol}/[\text{keto pyruvate}]$. The reversible enolization of pyruvate is subject to general-base catalysis (2*b*, 2*c*) so that the observed rate constants are actually a sum of kinetic terms:

$$[2] \qquad k_{enol} = k_0 + k_B[B] + k_{OH^-}[OH^-]$$

where B is the basic buffer component and k_0 is the "spontaneous" rate usually taken to be $k_0 = k_{H_2O}[H_2O]$. Rate constants for the *equilibration* between enol and keto forms, $k_{equil,\ enol} = k_{enol} + k_{keto}$, were calculated using the equilibrium constant for the reaction, $K_{enol} = [\text{enol}]/[\text{keto}]$, and the half-lives for the equilibrations from $\tau_{1/2} = 0.693/k_{equil,enol}$.

In earlier papers, we (1*a*) and others (1*b*–1*h*) reported that aqueous solutions of pyruvic acid below pH 2.2 consist predominantly of the hydrated form, while at higher values of pH the pyruvate anion is hydrated to a much lesser extent. We also demonstrated from pmr experiments the third-power dependence of the ratio of 2,2-dihydroxypropionic to pyruvic acid on the water concentration (1*a*), [hydrate]/[keto] = $K_{eq}[H_2O]^3$ (3*a*), a finding that has not always been taken into consideration in reports from other laboratories. Our spectrophotometric determinations in the present work were carried out using 0.098 M pyruvic acid and the values of χ_{hyd} = [hydrate]/([hydrate] + [keto]) and K_{hyd} = [hydrate]/[keto] given in this paper were determined at that concentration.

The largely different fractions of hydration of pyruvic acid and pyruvate anion have been utilized in a kinetic method designed to follow the dehydration of 2,2-dihydroxypropionate in aqueous buffers (2*a*, *2b*). Rate constants reported in the present work were determined from kinetic runs that were initiated by the injection of an acidic solution of pyruvic acid (with a relatively high fraction of hydrated pyruvic acid) into a neutral buffered solution along with sufficient sodium hydroxide to immediately neutralize the added acid. The essentially instantaneous deprotonation of 2,2-dihydroxypropionic acid resulted in its dehydration to keto pyruvate, a reaction that was monitored directly by the increase in absorbance at 325nm (λ_{max} = 325 nm, ε = 20 M^{-1} cm^{-1}). Typically, 0.10 mL of an acidic solution of 0.23 M pyruvic acid (pH 1.45) was injected into 3.0 mL of the buffer solution. First-order rate constants, k_{dehyd}, were determined from the linear plots of $\ln(A_\infty - A_t)$ vs. t.

Since the dehydration of 2,2-dihydroxypropionate is sensitive to catalysis both by acids and bases (2*b*, 22)

$$[3] \qquad k_{dehyd} = k_0 + k_{H_3O^+}[H_3O^+] + k_{OH^-}[OH^-] + k_{HA}[HA] + k_{A^-}[A^-]$$

where HA and A^- refer, respectively, to the acid and conjugate base of the buffer system employed. At the approximately neutral pH's used in the present work, the kinetic term in hydronium ion is negligible (2*b*). The rate of equilibration between keto and enol forms, $k_{equil,hyd} = k_{hyd} + k_{dehyd}$, may be calculated from $k_{equil,hyd} = k_{dehyd}(1 + K_{hyd})$, where K_{hyd} is the equilibrium constant for hydration, K_{hyd} = [hydrate]/{keto].

[d] Present work.
[e] This value is slightly dependent on pyruvate ion concentration (see ref. 2*b*) That reported here applies to 1×10^{-4} pyruvate so that it ccorresponds more closely to the concentration ranges used for its enzymatic reactions with LDH.
[f] Reference 2*b*.
[g] References 3*a*, 3*b*.
[h] Reference 2*a*.

Again, half-lives ($\tau_{1/2}$) were calculated from $\tau_{1/2} = 0.693/k_{equil,hyd}$.

Finally, the hydration of pyruvic acid in aqueous hydrochloric acid solutions (pH <2.2) was initiated by injecting 0.01 mL of neat pyruvic acid, or the equivalent amount diluted with acetonitrile, into 3 mL of hydrochloric acid solutions of varying concentrations. For the hydration of pyruvic acid (2*a*), $k_{hyd} = k_0 + k_{H_3O^+}[H_3O^+]$, $k_{equil,hyd} = k_{hyd}(1 + K_{hyd})/K_{hyd}$.

Results and discussion

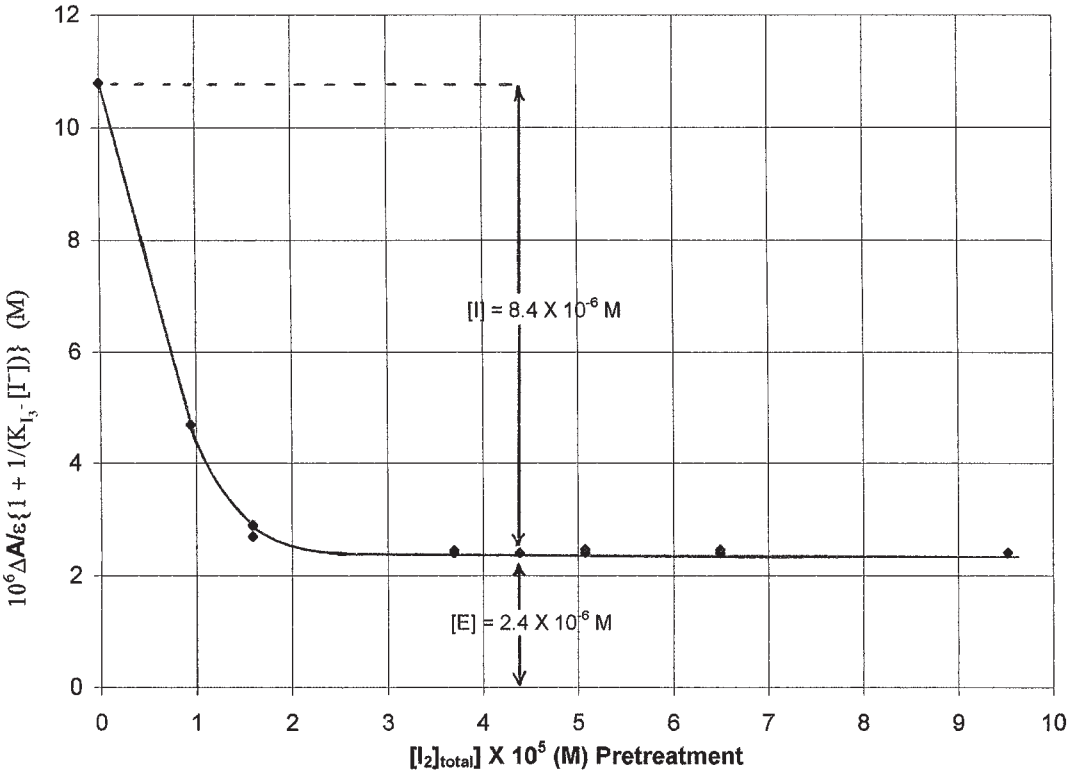
In the present investigation, we observed that the magnitude of the "burst" region resulting from the intial reaction of triiodide in solutions of pyruvate and pyruvic acid sometimes increased markedly on standing, implying that a triiodide-scavenging impurity forms over time. The rate of formation of this impurity appears to depend on the pH of the solution. In neutral phosphate buffers, the initial triiodide uptake = $\Delta A/\varepsilon\{1 + 1/(K_{I_3^-}[I^-])\}$ remains constant for up to several days, while under more acidic conditions it increases much more rapidly. For example, at pH 1.3, triiodide uptake in pyruvic acid solutions (*unpretreated* with triiodide ion) varied as follows: 1.1×10^{-5} (1 h), 1.5×10^{-5} (2 h), 3.3×10^{-5} (4 h), 6.0×10^{-5} (8 h), 9.2×10^{-5} (24 h). Consequently, when using the Meyer method to make valid determinations of K_{enol}, one must be aware of a finite "window of opportunity" for the previously described pretreatment incubation studies using triiodide. Depending on the pH and temperature for a given series of such determinations, the limits of this "window" used in the present work were such that the experiments were always carried out *after* 10 half-lives for the reequilibration between keto and enol pyruvate, but *before* the time where a measurable quantity of I_3^- scavenging impurity was known to reform in the pyruvate solutions. Table 2 lists the half-lives for the equilibration of the enolization of pyruvate anion in selected buffer solutions and for the correspondinng equilibration for pyruvic acid in 0.1 M HCl.

In developing our experimental protocol for the Meyer method (5), we found that optimal conditions for determining accurate and reproducible values of K_{enol} utilized a concentration of pyruvate around 0.1 M (actually 0.098 M). The resultant equilibrium concentration of enol pyruvate allowed an easily measured burst of triiodide uptake, $\Delta A \approx 0.06$ absorbance units, while at the same time the background absorbance due to keto pyruvate at 353 nm was maintained low enough to allow the zeroing of the instrument. However, since the burst-phase absorbance change was relatively small, determination of the actual absorbance of triiodide at the kinetic zero for the enolization of pyruvic acid and pyruvate anion is crucial to the accurate determination of K_{enol}. Since it is not possible to directly *observe* the original absorbance due to triiodide anion, it must be determined as described in the Experimental section. The close comparison of the data in the last two columns of Table 1 with the rest of the data in the table demonstrates that $A_{I_3^-}$ in the *absence* of pyruvate is the same as that in the *presence* of 0.1 M sodium pyruvate. Not only is this an important finding that confirms the validity of the value of $A_{I_3^-}$ we have used in determining $K_{enol} = \Delta A/\varepsilon\{1 + 1/(K_{I_3^-}[I^-])\}$, but it also suggests the lack of formation of a complex from the reaction of hydrated pyruvate and I_3^- as proposed earlier by Albery and Bell (4*a*).

Figure 1 shows the results of experiments in which the magnitude of the burst phase, ΔA, was measured as a function of the amount of I_3^- used in the pretreatment of pyruvate solutions. The experiments were conducted as follows. Solutions (3 mL) of buffered pyruvate (0.098 M) were pretreated with various quantities of triiodide; this phase of the iodination was allowed to go to completion and then incubated for at least 10 half-lives to allow the reequilibration between enol and keto pyruvate. After that time, 0.05 mL of a solution of 2.05×10^{-3} M I_2 in 0.10 M KI was injected

© 1999 NRC Canada

Fig. 1. Burst as a function of the total iodine concentration used in pretreating solutions of pyruvate anion.



into the incubated mixture. The plot illustrated in the figure indicates that pretreatment of the buffered pyruvate solution with triiodide effectively removes the I_3^- scavenging impurity until, at approximately a total iodine concentration of 1.5×10^{-5} M, a constant value for the "burst" is reached.

Table 3 lists values of the fraction of enolization determined as described above for pyruvate and pyruvic acid at various temperatures. It is important to note from the data in the table that the calculated fractions of the enol forms, χ_{enol}, remain relatively constant in the temperature range 11–25°C both for pyruvate anion and for pyruvic acid and, for this reason, the evaluation and interpretation of thermodynamic parameters would not be meaningful. In fact, the corresponding values of $K_{enol} = \chi_{enol}/(1 - \chi_{hydration})$ are even more similar over the pH range studied. It will be noted that the *enolization* of pyruvate anion is apparently slightly endothermic in contrast to the exothermic *hydration* of keto pyruvate. While the variation in K_{enol} for pyruvic acid is within the limits of experimental error, the corresponding hydration of pyruvic acid is clearly exothermic.

For pyruvate anion, at 25°C, χ_{enol} = [enol]/([enol] + [keto]) = 2.5×10^{-5} (Table 3). It will be noted that this value is somewhat larger than that reported by other workers (1*g*, 1*h*) using the Meyer method. Actually, our attempts at estimating, via direct *extrapolation*, the absorbance of the burst phase at the kinetic zero gave a value which was very similar to that in the literature cited above (1*g*, 1*h*). However, we observed that the mixing time interrupted the spectrophotometric monitoring of the decrease in absorbance of triiodide to the extent that the *extrapolated* triiodide absorbance at the kinetic zero was impossible to measure accurately and was, in fact, consistently lower than the *actual* values of $A_{I_3^-}$ (obsd) given in Table 1.

We note that Meyer method determinations of K_{enol} reported earlier (1*g*, 1*h*) were made using approximately 1/10 the concentration of pyruvate used in the present work. Since no mention was made in those reports concerning the use of a longer pathlength reaction cell, we assume the pathlength was the standard 1 cm. Using the value of K_{enol} and the extinction coefficient $\varepsilon = 26\,000$ cm^{-1} M^{-1} used in those earlier calculations, the absorbance change resulting from the reaction of triiodide with the equilibrium concentration of enol pyruvate would be approximately 0.004 units, a value that would be difficult to measure reproducibly. Finally, we were surprised at the relatively low value of K_{enol} reported, given the fact that no precautions were apparently taken to rid the original pyruvate solution of triiodide-scavenging material.

Burgner and Ray (*4b*), on the other hand, reported the determination of $K_{enol} = 4.1 \times 10^{-6}$ for pyruvate anion using the Meyer method at a sodium pyruvate concentration of 1.0 M. We were unable to reproduce their experiments since, at 353 nm, a 1.0 M solution of pyruvate across a pathlength of 1 cm has an absorbance much greater than 10 units. Even using their reported pathlength of 0.4375 cm would result in an absorbance due to keto pyruvate of around 5 units, making it virtually impossible to obtain accurate values of ΔA using the instrumentation they reportedly used. Again, since the work was presumably carried out using unpurified keto pyruvate and was untreated with the necessary initial aliquot of I_3^- to rid the original pyruvate solution of triiodide-scavenging impurity, the reliability of these data must be questioned.

We found values of K_{enol} for pyruvic acid to be about 3 times larger than those for pyruvate anion, perhaps partially due to the electron-withdrawing inductive effect of the carboxyl group of pyruvic acid. We must note, however, that

Table 3. Equilibria for the enolization and hydration of pyruvate anion and pyruvic acid.

Pyruvate anion			
T (°C)	11	20	25
χ_{hyd}[a,b]	0.11	0.069	0.054
K_{hyd}[a,b]	0.12	0.074	0.057
χ_{enol}	$(1.6 \pm 0.2) \times 10^{-5}$	$(1.7 \pm 0.2) \times 10^{-5}$	$(2.5 \pm 0.2) \times 10^{-5}$
K_{enol}[b,c]	$(1.9 \pm 0.2) \times 10^{-5}$	$(2.0 \pm 0.2) \times 10^{-5}$	$(2.6 \pm 0.2) \times 10^{-5}$
Pyruvic acid			
T (°C)	11	15	25
χ_{hyd}[a,b]	0.68	0.65	0.58
K_{hyd}[a,b]	2.1	1.9	1.4
χ_{enol}	$(2.2 \pm 0.2) \times 10^{-5}$	$(2.4 \pm 0.2) \times 10^{-5}$	$(2.9 \pm 0.2) \times 10^{-5}$
K_{enol}[b,c]	$(6.9 \pm 0.5) \times 10^{-5}$	$(6.8 \pm 0.5) \times 10^{-5}$	$(6.9 \pm 0.5) \times 10^{-5}$

[a]These *apparent* values of χ_{hyd} and K_{hyd} for the hydration of pyruvic acid vary with the third power of the water concentration (see ref. 1*a*). The values of K_{hyd} and χ given in this table correspond to a total pyruvate or pyruvic acid concentration of 0.098 M.

[b]Portions of these data were taken from earlier work (see ref. 1*a*).

[c]Values take into consideration the fraction of hydration, so that K_{enol} = [enol pyruvate]/[keto pyruvate].

there is not always close correlation between inductive effects of groups attached to the carbonyl of ketones and the magnitude of their values of K_{enol}. For example, although the inductive effects exerted by $-CH_3$ and $-CO_2^-$ are similar, K_{enol} for acetone (4.7×10^{-9}) (23*a*, 23*b*) is almost four orders of magnitude lower than that for keto pyruvate (2.5×10^{-5}). It is conceivable that the enol form of the pyruvate anion is stabilized, to some extent, via intramolecular hydrogen bonding between the enol hydroxy and the negatively charged carboxylate oxygens. Thus any increase in K_{enol} for pyruvic acid in comparison to pyruvate anion, caused by the electron-withdrawing inductive effect of $-CO_2H$, may be partially offset by such a mode of stabilization of the enol pyruvate anion. Unfortunately, because of the small changes in values of K_{enol} as a function of temperature in the range studied, it is not possible to calculate reliable values for the entropies of the respective enolizations of pyruvate anion and pyruvic acid.

On the other hand, the data in Table 3 indicate a very large difference in the extent to which pyruvic acid and pyruvate anion undergo hydration. It will be noted that these acyl addition reactions involve bond making between the nucleophile and the electrophilic carbonyl carbon. Accordingly, one would expect that electronic inductive effects caused by groups directly attached to the carbonyl group would be of greater importance for hydration than for the corresponding enolization reaction. Indeed, α-halogen substituents are known to greatly increase fractions of hydration of carbonyls. For example, at 25°C, whereas the fraction of hydration for pyruvate anion is ca. 0.06, that for fluoropyruvate anion is about 0.85 (9), a value that is even greater than that for the neutral pyruvic acid molecule.

For pyruvic acid, a recent report (1*g*) gives the value $K_{enol} = 6.76 \times 10^{-4}$ using the Meyer method. This larger value, almost 10 times larger than the value determined in the present investigation (Table 3), may be due to the formation of the triiodide-scavenging impurity that we observed to occur in acidic solutions of pyruvic acid as described earlier.

The method of determining K_{enol} for carbonyl compounds from the ratio of rate constants for ketonization to the corresponding quantities for enolization obviates the difficulty associated with minute levels of triiodide-scavenging impurity in solutions of the carbonyl compound to be studied. However, in the case of the pyruvic acid – pyruvate anion system, there can exist uncertainties in the calculation of K_{enol} from the ratio of rates of enolization to ketonization. In our own analysis in earlier work (2*b*), for example, we approximated $K_{enol} = k_{enol}/k_{keto} = 8.6 \times 10^{-5}$ based on accurate and reproducible values for k_{enol} but, at the same time, using values for k_{keto} (7*a*) that necessitated approximation to compensate for the different experimental conditions (e.g., ionic strength, buffer composition, temperature) under which the two reactions were independently carried out. We are also concerned that, in general, the validity of k_{enol}/k_{keto} ratios may be weakened when the determination of values of k_{keto} require complex or ambiguous kinetic methods (1*g*, 1*h*, 7*a*, 7*b*, 8*a*, 8*b*) involving reaction intermediates. For example, when attempting to determine k_{keto} for pyruvic acid by introducing solutions rich in enol content into aqueous acidic solutions, the *ketonization* of pyruvic acid enol would be paralleled by the even more rapid *hydration* of keto pyruvic acid, thereby complicating the interpretation of the ensuing decreasing absorbances.

The comparison of catalytic ratios for the ketonization and enolization of the pyruvic acid – pyruvate anion system may present additional difficulties in which the analysis of data requires certain assumptions. For example, values of $K_{enol} = k_{OH^-,\,enol}/k_{OH^-,\,keto}$ and $K_{enol,\,pyruvic\ acid} = k_{H_3O^+,enol}/k_{H_3O^+,keto}$ were evaluated in earlier work (1*g*) It must first be noted that reported values (1*g*, 2*b*) of $k_{OH^-,enol}$ vary by as much as 60%. Furthermore, it was observed that k_{keto} is nonlinear for both pyruvate anion with increasing hydroxide concentration, and for pyruvic acid with increasing hydronium ion. Thus, although the kinetic experiments themselves may be carried out carefully, calculated values of $k_{OH^-,keto}$ and $k_{H_3O^+,keto}$ at higher concentrations of OH^- and H_3O^+, respec-

tively, depend on the appropriateness of the theoretical kinetic model used in its calculation. For these reasons, the use of spontaneous rate constants for ketonization and enolization may give less ambiguous values of $K_{enol} = k_{0,enol}/k_{0,keto}$, provided, of course, that valid determinations of the spontaneous rate constants are made under identical reaction conditions. For pyruvic acid, $k_{0,enol}$ values that are in close agreement (when corrected for fractions of hydration) have been reported at 25°C (3*a*, 3*b*, 4*a*), $k_{0,enol} = 1.2 \times 10^{-6}$ s, and when this average value is compared to $k_{0,keto}$ for pyruvic acid from the work of Chiang et al. (1*g*), $k_{0,keto} = 1.06 \times 10^{-2}$ s, it follows that $K_{enol} = k_{0,enol}/k_{0,keto} = 1.2 \times 10^{-6}$ s/1.06×10^{-2} s = 1.1×10^{-4}, which is in closer agreement with the value we report in Table 3 (6.9×10^{-5}, at 25°C), allowing for differences in experimental conditions.

The kinetic and thermodynamic parameters associated with the reversible hydration and enolization of pyruvate reported in this paper may be used to access the likelihood of the keto, hydrated, and enol forms of pyruvate to serve either as enzyme substrates or as enzyme inhibitors. Specifically, the availability of these data allow a closer look at the experimental data determined by Coulson and Rabin (15*a*).

In that report, it was concluded that the substrate inhibition observed in the LDH reduction of pyruvate by NADH was actually due to a substance that can be removed from pyruvate solutions by column chromatography. It was suggested that the enzyme-inhibiting substance was enol pyruvate and *not* 2,2-dihydroxypropionate (hydrated pyruvate) because, at that time, it was believed that hydrated pyruvate could not be observed at neutral values of pH. However, according to the thermodynamic data provided in Table 3 it is now known that there exists over 2000 times more hydrated pyruvate than enol pyruvate at neutral pH at room temperature.

It is also instructive to interpret other of Coulson and Rabin's results (15*a*) in light of the kinetic data presented in Table 2. Kinetic runs were carried out in the earlier study (15*a*) using chromatographically purified solutions of pyruvic acid to oxidize NADH in the presence of LDH at room temperature. Prior to the introduction of NADH and LDH to initiate the kinetic run, the pyruvate was incubated in 0.2 M buffer solutions for 2 min. It was noted that while substrate inhibition was not observed in 0.2 M imidazole buffer, rather strong inhibition was noted in 0.2 M phosphate buffer. Because of the lack of reliable kinetic data at that time, it was tentatively concluded that the purified pyruvate enolized rapidly in the phosphate buffer, thereby forming the actual substance that inhibited LDH. It was argued that the enolization was so slow in imidazole buffer that no such inhibition was observed. The data in Table 2, however, show that the half-life for the equilibration between keto and enol pyruvate is less than a second in either 0.2 M phosphate or 0.2 M imidazole buffer. Consequently, identical (equilibrium) concentrations of enol pyruvate would have prevailed under the experimental conditions in the article cited (15*a*). It was also stated in that article that purified pyruvic acid solutions were stable at pH 1.0 for several hours at 0°C. However, according to the results we now report at the beginning of this section, we find that measurable quantities of a triiodide-scavenging impurity begin to form after about 1 h in solutions of pyruvic acid at pH 1.3. Furthermore, the data in Table 2 demonstrate that at 0°C the half-life for enolization is around 10 min and, accordingly, after even 1 h the equilibrium between keto and enol pyruvate would have been virtually complete. Thus all of the enzyme assays carried out by Coulson and Rabin (15*a*) actually involved the same fraction of enolized pyruvate and, therefore, any variations in LDH inhibition in these experiments were unrelated to the content of enol pyruvate in solution. In fact, the thermodynamic data in Table 3 indicate that the pyruvic acid solutions at pH 1.0 at 0°C utilized in that study contained mostly hydrated pyruvate.

Buffer, ionic strength, and pH effects on the magnitude of inhibition constants have been observed for LDH (16) and for other enzymes (24*a*–24*f*). For example, whereas at neutral pH a solution of 1×10^{-3} M keto pyruvate results in 27% substrate inhibition in 0.1 M phosphate buffer, the same concentration of keto pyruvate causes only 9% substrate inhibition in 0.1 M diethylmalonate buffer(16). Schwert and Winer (25) have also observed greater substrate inhibition in phosphate buffers than in other buffers. Therefore we suggest that the differences Coulson observed in the degree of substrate inhibition arising from assays in 0.2 M imidazole and 0.2 M phosphate buffers were due to specific interactions between the buffer components and the enzymes.

Somero (14*a*, 14*b*) has demonstrated that the substrate inhibition observed for muscle LDH isolated from the fish *Gillichtghys mirabilis* is much stronger at colder temperatures than at warmer temperatures. He suggested that this phenomenon is a property of the enzyme itself. In a more recent article (26), it is reported that differences in enzyme–substrate binding and thermal stabilities of Sphyraena LDH-A from various barracuda species are actually due to amino acid residues outside the active site.

However, we have been able to show that for trout muscle LDH, the increased sensitivity of substrate inhibition with decreasing temperatures is due, at least in part, to the equilibrium shift that increases the fraction of hydrated pyruvate at lower temperatures (27*a*–27*c*). Similar results were obtained using purified beef muscle and beef heart isoenzymes of LDH (16, 27*a*–27*c*) in which substrate inhibition was observed to be more severe in the case of the latter. In a typical set of experiments with beef heart LDH (16), small quantities of preincubated solutions of pyruvate (pyruvic acid) were added to reaction mixtures containing NADH and LDH to initiate kinetic runs in phosphate buffer at neutral pH at 5.0°C. The preincubated solutions of pyruvate (pyruvic acid) were as follows: (*i*) prepared in phosphate buffer and preincubated at 41°C ($\chi_{hydrate} = 0.054$); (*ii*) prepared in phosphate buffer at 5.0°C ($\chi_{hydrate} = 0.136$); (*iii*) prepared in HCl, pH 4.5, at 41°C, yielding an aqueous pyruvic acid solution ($\chi_{hydrate} = 0.412$); (*iv*) prepared in HCl, pH 4.9, at 5.0°C, yielding an aqueous pyruvic acid solution ($\chi_{hydrate} = 0.801$). The data in Table 4 show that *increasing the initial fraction of hydrated pyruvate in the assay results in increased substrate inhibition in the enzymatic reactions*. Since the four experiments illustrated in Table 4 represent kinetic runs at 5.0°C, the kinetic differences cannot be a property of the enzyme alone but must, in fact, be related to the different initial compositions of the pyruvate solutions themselves (keto

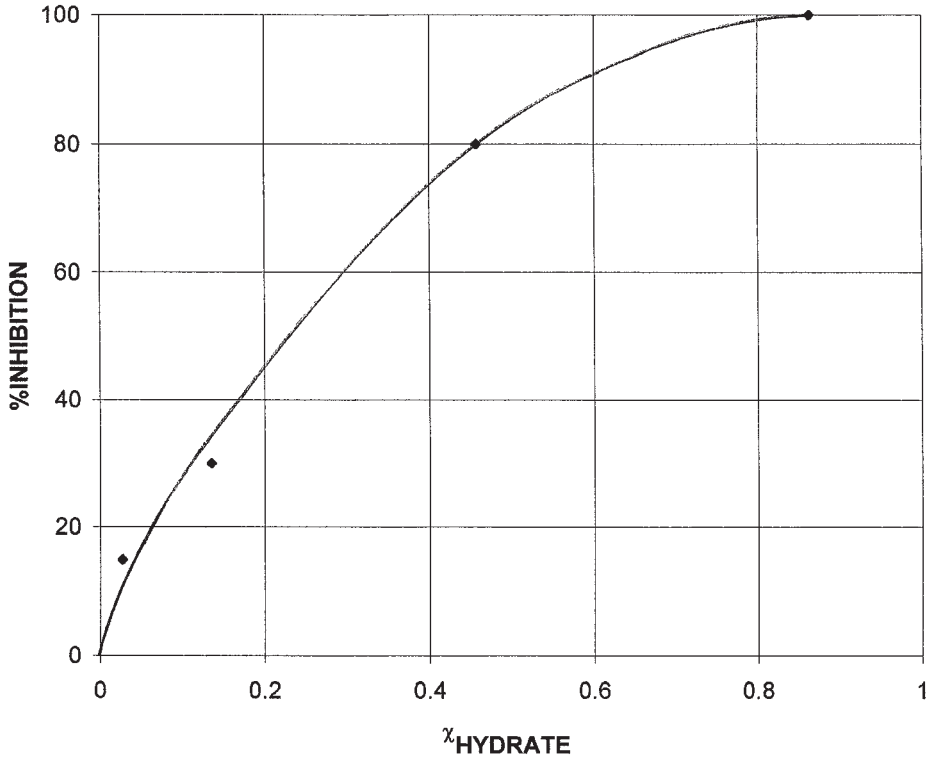
Fig. 2. Percent (%) inhibition of beef heart LDH as a function of initial fractions of hydration of pyruvate. All kinetic runs were carried out in phosphate buffer at 5.0°C.



vs. hydrated). On the other hand, the entries in Table 4 demonstrate that there is no relationship between the fraction of available enol pyruvate and the degree of substrate inhibition. Figure 2 shows that the initial fraction of hydrated pyruvate during the enzymatic reaction is directly related to the severity of substrate inhibition. Finally, we note that the kinetic experiments illustrated in Table 4 were purposely conducted at 5.0°C, where the half-life for the hydration–dehydration reequilibration (Table 2) is 100 s. Since the "initial" velocities used to generate the data in Table 4 were taken 15 s following the kinetic zero, the reequilibration between ketopyruvate and hydrated pyruvate was less than 1/10 complete when the progress of the reactions were first recorded.

Pyruvate inhibition of LDH as observed from initial velocity studies such as those represented in Table 4 has been attributed to the reversible formation of a relatively loosely bound abortive ternary complex (17) composed of LDH, NAD^+, and some form of pyruvate, which we suggest is hydrated pyruvate. Given the similarity of the shapes and structures of 2,2-dihydroxypropanoate (hydrated pyruvate) and 2-hydroxypropanoate (lactate), one would expect that the enzyme·NAD^+ complex would, indeed, accommodate hydrated pyruvate. Related experiments, involving the incubation of LDH with pyruvate solutions containing varying fractions of hydrated pyruvate (16) also have suggested that a more stable inhibitory complex is formed, again with the same stoichiometry as the rapidly formed ternary complex. In light of the kinetic and thermodynamic analysis provided in the present paper, we again suggest that hydrated pyruvate is involved in the formation of the more stable ternary complex as well.

Correlation of the rates of solvolysis of phenyl chlorothionoformate and phenyl chlorodithioformate[1,2]

Dennis N. Kevill and Malcolm J. D'Souza

Abstract: The specific rates of solvolysis of phenyl chlorothionoformate (PhOCSCl) are remarkably similar to those previously reported for phenyl chlorothioformate (PhSCOCl). When analyzed using the extended Grunwald–Winstein equation over the usual range of solvent types, these solvolyses show essentially identical divisions into the solvents favoring the addition–elimination channel and those favoring the ionization channel. The introduction of one sulfur caused a partial shift away from the addition–elimination pathway, which was dominant over the full range of solvents for phenyl chloroformate (PhOCOCl). Consistent with these results, introduction of the second sulfur within phenyl chlorodithioformate (PhSCSCl) leads to a completion of this shift, such that an extended Grunwald–Winstein treatment of the specific rates of solvolysis now shows the ionization pathway to be dominant over the full range of solvents.

Key words: Grunwald–Winstein equation, solvent nucleophilicity, solvolysis, phenyl chlorothionoformate, phenyl chlorodithioformate.

Résumé : Il existe une similitude remarquable entre les vitesses spécifiques de solvolyse du chlorothionoformate de phényle (PhOCSCl) et celle rapportée antérieurement pour le chlorothioformate de phényle (PhSCOCl). Lorsqu'on les analyse en faisant appel à l'équation étendue de Grunwald–Winstein sur la plage habituelle des types de solvant, ces solvolyses présentent des divisions essentiellement identiques entre les solvants qui favorisent la voie de l'addition–élimination et ceux qui favorisent la voie de l'ionisation. L'introduction d'un atome de soufre provoque un déplacement partiel de la voie d'addition–élimination qui était dominante pour l'ensemble des solvants dans le cas du chloroformate de phényle (PhOCOCl). En accord avec ces résultats, l'introduction d'un deuxième atome de soufre dans le chlorodithioformate de phényle (PhSCSCl) conduit à un déplacement complet, tel que le traitement étendue de Grunwald–Winstein aux vitesses spécifiques de solvolyse indique maintenant que la voie de l'ionisation est devenue dominante pour l'ensemble des solvants.

Mots clés : équation de Grundwald–Winstein, caractère nucléophile d'un solvant, solvolyse, chlorothionoformate de phényle, chlorodithioformate de phényle.

[Traduit par la Rédaction]

Introduction

It has been established (1, 2) that the solvolysis of phenyl chloroformate (PhOCOCl, **1**) follows a bimolecular addition–elimination pathway over the full range of solvents commonly employed in studies of solvent effects using either the simple (3) or extended (4) forms of the Grunwald–Winstein equation (eqs. [1] and [2], respectively).

$$[1] \qquad \log (k/k_0) = mY + c$$

$$[2] \qquad \log (k/k_0) = lN + mY + c$$

In eqs. [1] and [2], k and k_0 are the specific rates of solvolysis in a given solvent and in 80% ethanol, respectively; l is the sensitivity to changes in solvent nucleophilicity (N); m is the sensitivity to changes in ionizing power (Y); and c is a constant (residual) term.

An extension to the solvolyses of phenyl chlorothioformate (PhSCOCl, **2**), led to a different pattern of behavior (5). The addition–elimination pathway was again dominant in ethanol, methanol, aqueous ethanol, aqueous methanol, and aqueous acetone. In aqueous fluoroalcohol solvents, however, this pathway was swamped out by an alternative one with a much lower l value and a much higher m value.

Received October 14, 1998.

This paper is dedicated to Professor A. Jerry Kresge in recognition of his many contributions to physical organic chemistry.

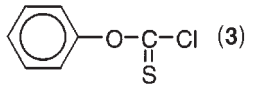
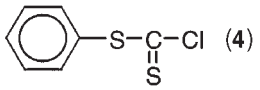
For solvolyses in 100% H_2O, Queen (6) had previously proposed an addition–elimination pathway for solvolyses of **1** and an ionization pathway for solvolyses of **2**. The magnitudes of the *l* and *m* values for the solvolyses in aqueous fluoroalcohols were considered (5) to be consistent with an ionization pathway for **2**, incorporating an appreciable solvation of the developing acylium ion (hence, the *l* value of 0.62).

In the present paper, we report concerning studies of the solvolyses of analogs of **1** and **2** in which the carbonyl oxygen has been replaced by sulfur to give phenyl chlorothionoformate (**3**) and phenyl chlorodithioformate (**4**).





Previous studies of the solvolyses of **3** in H_2O and 65% acetone have indicated a difference in mechanism. McKinnon and Queen (7) studied the hydrolyses in 100% H_2O and found increases in rate as one went from **3** to the corresponding methyl and ethyl esters. This observation, taken together with a positive entropy of activation (+13.5 cal mol^{-1} K^{-1}) for the hydrolysis of the methyl ester, was rationalized in terms of an S_N1 mechanism. It was concluded (7) that replacement of either of the oxygens of **1** by sulfur, to give **2** or **3**, was sufficient to cause a shift in the mechanism for the hydrolysis in 100% water from bimolecular to unimolecular.

Csunderlik et al. (8) studied the hydrolysis of **3** and eight ring-substituted derivatives in 65% acetone. Under their conditions, they found, for each substrate, a very negative entropy of activation (–26 to –30 cal mol^{-1} K^{-1}). A Hammett treatment, using σ° values (1, 9) gave a good linear plot with a slope (ϱ value) of 1.26, somewhat less than the 1.59 observed for the identical solvolyses of a series of aryl chloroformates (9), but consistent with a bimolecular mechanism. Also indicating a bimolecular mechanism were the solvent deuterium isotope effects, which were essentially identical to those for the corresponding solvolyses in 65% acetone of identically substituted derivatives of **1** (9).

These studies of the solvolyses of **3** suggest a similarity with the solvolyses of **2**, which were also found (5) to be bimolecular in 65% acetone but dominantly unimolecular in 100% H_2O. It will be of considerable interest to see, from application of eq. [2], just how extensive is this similarity in behavior when comparisons are made over a wider range of solvent types.

In **4**, with *both* oxygen atoms of **1** replaced by sulfur, one would expect an even stronger tendency towards an ionization pathway. A low solubility did not allow a study in 100% water and the solvolyses of chlorodithioformate esters were studied (10, 11) in 70% acetone. The relative reactivities (phenyl <methyl <ethyl <isopropyl) suggested an ionization mechanism, an assignment supported by an only slightly negative entropy of activation for the solvolysis of the methyl ester. Powerful evidence for an S_N1 pathway involving product formation at the free ion stage was provided by the observation (10, 11) for the chlorodithioformate esters of a pronounced deceleration (common-ion rate depression) in the presence of added sodium chloride, coupled with a modest acceleration in the presence of added sodium perchlorate. Despite this strong evidence for a unimolecular solvolysis (12), enormous accelerations were observed upon addition of azide ion, presumably due to a superimposed bimolecular attack (10, 11). This observation requires consideration of the possibility of a bimolecular contribution to the solvolysis in solvents of relatively high nucleophilicity and (or) relatively low ionizing power. It will be of interest to see whether any evidence can be found for an addition–elimination pathway for the solvolysis of **4**.

Results

The specific rates of solvolysis of phenyl chlorothionoformate (**3**) and phenyl chlorodithioformate (**4**), at 25.0°C, were determined in methanol, ethanol, 2,2,2-trifluoroethanol (TFE) and in binary aqueous solvents, with the other component being ethanol, acetone, or TFE. Determinations were also made in TFE–ethanol mixtures and, for **3**, in aqueous 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) mixtures. The solvolyses of **4** in aqueous HFIP were too fast to measure by the sampling technique employed. A literature value (8) was available for **3** in 65% acetone. The specific rates of solvolysis of **3** in 19 solvents and of **4** in 14 solvents are presented in Table 1, together with the N_T (13) and Y_{Cl} (14) values used in the correlation analyses.

Discussion

Solvolyses of phenyl chlorothionoformate (3)

It has been shown previously (7, 8) that chlorothionoformate esters hydrolyze rapidly to give hydrochloric acid, carbonyl sulfide, and the alcohol (7) or phenol (8), as shown in eq. [3]. In particular, it was demonstrated (8) that the hydrolysis of ring-substituted derivatives of **3** did not involve any replacement of sulfur by oxygen, so as to then give products resulting from hydrolysis of the corresponding ring-substituted derivative of **1**.

[3] 
We have previously shown (5, 15) that the extended Grunwald–Winstein equation (eq. [2]) can be a powerful tool for the investigation of solvolysis reactions in which two reaction channels operate with appreciable differences in the sensitivities to both solvent nucleophilicity and solvent ionizing power. Previous claims for an ionization mechanism in 100% water (7) and a bimolecular mechanism in 65% acetone (8) for the solvolyses of **3** suggest that a duality of mechanism will be found similar to those previously observed for **2** (5), ethyl chloroformate (15), and ethyl chlorothioformate (15).

The specific rates of solvolysis of **3** closely parallel those for solvolysis of **2**. For 11 solvents (excluding the aqueous fluroroalcohols), the $k_{(3)}/k_{(2)}$ ratios are within the narrow range of 0.35–0.58. The corresponding ratios for six aqueous

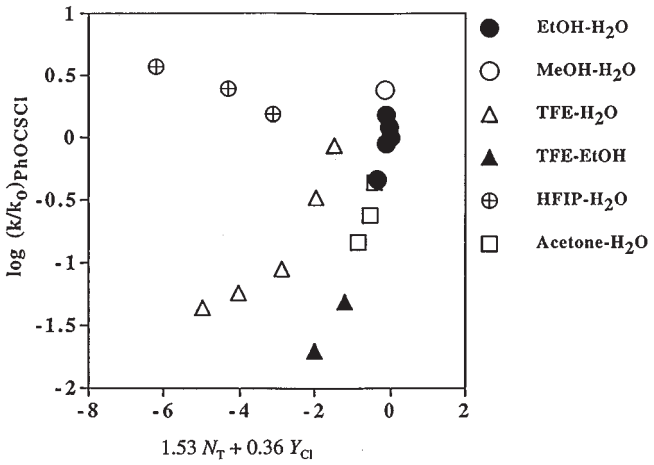
Fig. 1. Plot of log (k/k_0) for solvolyses of phenyl chlorothionoformate at 25.0°C against ($1.53N_T + 0.36Y_{Cl}$). The eight log (k/k_0) values for the TFE–H_2O and HFIP–H_2O solvents are not included in the correlation; they are added to show their considerable deviation from the correlation line.



fluoroalcohol solvents, assigned to the ionization channel in the study (5) of the solvolyses of **2**, are within a similar range of 0.97–1.14. Consistent with these values, McKinnon and Queen (7) found that, for hydrolysis in 100% water at 5°C, the ratio had a value of 0.35. This suggests a rather remarkable similarity, not only in mechanism but also in rate, between the solvolyses of **2** and **3**. Indeed, the solvolyses of **3** can be treated, in exactly the same manner as **2**, by the dual application of eq. [2]. For 11 solvents (excluding aqueous fluoroalcohols), values are obtained of $l = 1.53 \pm 0.19$, $m = 0.36 \pm 0.08$, and $c = 0.11 \pm 0.22$, with a correlation coefficient of 0.953 and an *F*-test value of 39 (Fig. 1). The *m* value is at the lower end of the range observed for addition–elimination reactions at a trigonal carbon, and this could reflect a reduced demand for solvation when, at the transition state, the negative charge is developing on a sulfur atom rather than the oxygen atom of previously reported (1, 5, 15) examples.

For solvolyses of **3** in TFE, four aqueous-TFE mixtures, and three aqueous-HFIP mixtures, values are obtained of 0.43 ± 0.06 for *l*, 1.19 ± 0.08 for *m*, and –3.14 ± 0.12 for *c*, with a correlation coefficient of 0.9905 and an *F*-test value of 130 (Fig. 2). These values are in the range previously observed for ionization reactions at an acyl carbon. A large negative *c* value is observed because the experimental k_0 value is the one applying to the other reaction channel. Indeed, the value can be used to estimate a specific rate of solvolysis in 80% ethanol by the ionization channel of 4.9 × 10^{-8} s^{-1}, some 1400 times lower than the observed value for the addition–elimination pathway.

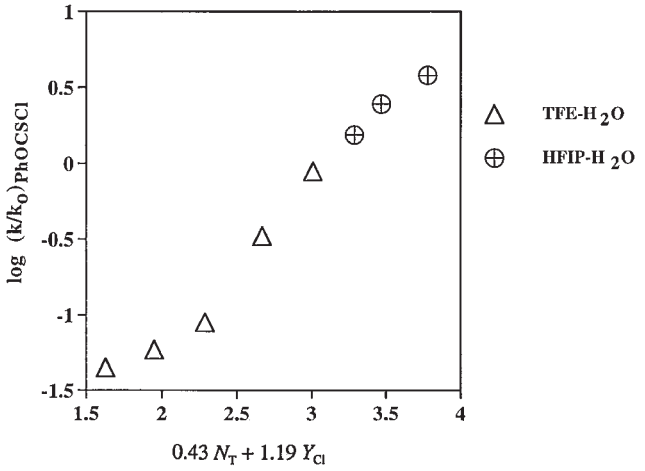

Fig. 3. Plot of log (k/k_0) for solvolyses of phenyl chlorodithioformate against ($0.55N_T + 0.84Y_{Cl}$).

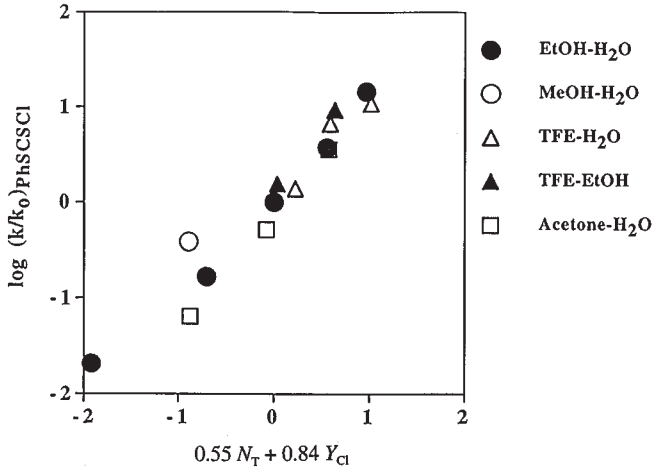

Solvolyses of phenyl chlorodithioformate (4)

McKinnon and Queen (7) found that a fairly concentrated solution of the methyl ester in 70% acetone gave dimethyl trithiocarbonate ($(MeS)_2C=S$) as the only organic product. It was postulated that the methanethiol formed initially reacted rapidly with remaining substrate (eq. [4]). In dilute solution, the ultraviolet spectrum of the product indicated an absence

[4]

of methyl trithiocarbonate, and the products were formed according to eq. [5]. Vapor phase chromatography gave no evidence for methanol formation, ruling out any reaction

[5] 
pathway involving methyl–sulfur bond fission. It is to be expected that the hydrolyses of **4** will follow a parallel pathway, but the scheme for the reaction with an alcohol (ROH) will terminate with the formation of PhSCSOR.

Since the introduction of one sulfur atom into **1** to give either **2** or **3** has been found to give an increased tendency towards ionization reaction, it is reasonable to expect that the introduction of two sulfur atoms, to give **4**, will lead to a further increase in this tendency. The observation of common-ion rate depression (11) during hydrolyses of **4** in 70% aqueous acetone (14), only a moderately ionizing solvent, indicates that this prediction is valid.

Values have been reported (11) for the solvolyses of **4** in 70% acetone at 4.94 and at 20.5°C. These values differ, however, by a factor of 25 for a 15.5°C difference in temperature and lead to an extrapolated specific rate at 25.0°C of 145×10^{-5} s^{-1}, about six times greater than our experimental value. Data simultaneously reported for the methyl ester lead to an extrapolated specific rate value at 20.5°C very close to that reported as being for **4**. One possibility is that the data at 20.5°C are for the methyl ester and not, as reported, for the phenyl ester.

The observation of one good linear extended Grunwald–Winstein plot over the full range of the 14 solvents with *l* and *m* values within the range one would expect (5, 15, 16) for the ionization mechanism suggests that this pathway now dominates over the full range of solvents. The observed sensitivity values are 0.55 ± 0.09 for *l* and 0.84 ± 0.08 for *m*; the *c* value is 0.07 ± 0.24, the correlation coefficient is 0.967, and the *F*-test value is 80 (Fig. 3). The solvent with the highest probability of an addition–elimination component is 100% ethanol, but we can calculate a value of –1.84 for log (k/k_0), in excellent agreement with the experimental value of –1.68. An analysis of the data accumulated for *tert*-butyl chloride solvolyses (17), using the identical set of solvents, leads to values for *l* of 0.37 ± 0.09 and for *m* of 0.83 ± 0.08 (correlation coefficient of 0.977), suggesting similar degrees of ionization at the transition state and with a slightly more pronounced nucleophilic solvation in the solvolyses of **4** than in those for *tert*-butyl chloride.

Conclusions

The solvolyses of **1** (PhOCOCl) and **4** (PhSCSCl) represent two extremes of solvolytic behavior. Both show a unity of mechanism over the full range of solvents commonly used in studies involving an application of the extended Grunwald–Winstein equation. The solvolyses of **1** follow an addition–elimination mechanism in which the rate-determining step involves nucleophilic addition. The solvolyses of **4** follow an ionization mechanism, with a considerable solvation of the developing carbocation. This solvation is indicated by the *l* values, from application of eq. [2], being slightly greater than for corresponding solvolyses of *tert*-butyl chloride.

In addition to being intermediate in structure, **2** (PhSCOCl) and **3** (PhOCSCl) are also intermediate in solvolytic behavior. Surprisingly, **2** and **3** behave very similarly, not only in the position of mechanistic change as the solvent is varied, but also as regards the measured specific rates of solvolysis. In ethanol, the specific rates fall when sulfur is introduced, but the fall-off from solvolysis of **2** or **3** to solvolysis of **4** is relatively small because of the change from an addition–elimination mechanism to an ionization

Table 2. Comparison of the specific rates of solvolysis, at 25.0°C, of **1**–**4** and correlations using the extended Grunwald–Winstein equation.

	Relative Rate					
Substrate	EtOH	97% TFE	n^a	l^b	m^b	R^c
1	1.00	1.00	21	1.68 ± 0.10	0.57 ± 0.06	0.973
2	0.026		16	1.74 ± 0.17	0.48 ± 0.07	0.946
2		5.9	6	0.62 ± 0.08	0.92 ± 0.11	0.983
3	0.012		11	1.53 ± 0.19	0.36 ± 0.08	0.953
3		6.9	8	0.43 ± 0.06	1.19 ± 0.08	0.991
4	0.0038	324	14	0.55 ± 0.09	0.84 ± 0.08	0.967

[a]Number of solvents.

[b]From eq. [2].

[c]Correlation coefficient.

mechanism. In 97% TFE, the opposite behavior is observed, with the initial rise from **1** to either **2** or **3** being relatively small because ionization is followed in this solvent for solvolyses of **2**–**4**, but the addition–elimination mechanism is dominant for **1**. These trends are summarized in Table 2.

The correlation analyses of the specific rates of solvolysis of **1**–**4** are also summarized in Table 2. The six entries divide into two groups of three. In one grouping, an *l* value of 1.53–1.74, coupled with an *m* value of 0.36–0.57, is considered to reflect the operation of an addition–elimination pathway. In the other grouping, *l* values of 0.43–0.62 and *m* values of 0.84–1.19 are considered as being a consequence of an ionization mechanism with appreciable nucleophilic solvation of the developing carbocation.

Experimental

Phenyl chlorothionoformate (Aldrich, 99%) and phenyl chlorodithioformate (Aldrich, 95%) were used without further purification. Solvents were purified and the kinetic runs carried out as previously described (18). The simple and multiple regression analyses were performed using the ABSTAT statistical package (Anderson–Bell, Arvada, Colorado).

Picosecond radical kinetics. Rate constants for ring openings of 2-aryl-substituted cyclopropylcarbinyl radicals

Martin Newcomb, Seung-Yong Choi, and Patrick H. Toy

Abstract: The kinetics of ring openings of a series of eight (*trans*-2-arylcyclopropyl)methyl radicals (**1**) were studied by indirect kinetic methods using Barton's PTOC esters as radical precursors and reaction with PhSeH as the competition reaction. The substituents were CF_3, F, Me, and OMe located on both the *para* and *meta* positions of the aromatic ring. Syntheses of the radical precursors and the products of the radical reactions are described. Kinetics were determined between –43 and 25°C in four cases (CF_3 and OMe substituents) and at 0 and 25°C in the other four cases. The rate constants at 25°C ranged from 1.0×10^{11} s^{-1} (*p*-CH_3) to 4.1×10^{11} s^{-1} (*p*-CF_3). The relatively large acceleration of the *p*-CF_3 group, ca. 2.5 times as fast as the parent system with Ar = Ph, correlates well with Adam's ΔD substituent parameters but not with other radical substituent parameters. These calibrated radical rearrangements provide a new set of ultrafast reactions that can be applied in mechanistic probe studies.

Key words: cyclopropylcarbinyl radical, kinetics, PTOC esters, benzeneselenol.

Résumé : On a étudié la cinétique de l'ouverture de cycle d'une série de huit radicaux (*trans*-2-arylcyclopropyl)méthyles (**1**) à l'aide de méthodes cinétiques indirectes, en utilisant les esters PTOC de Barton comme précurseurs des radicaux et la réaction avec le PhSeH comme réaction en compétition. Des substituants CF_3, F, Me et OMe ont été placés dans les positions *ortho* ainsi que *méta* du noyau aromatique. On décrit les synthèses des précurseurs de radicaux ainsi que celles des produits des réactions radicalaires. Dans quatre cas (substituants CF_3 et OMe), on a déterminé les cinétiques à des températures entre –43 à +25°C et à 0 et 25°C dans les quatre autres cas. Les constantes de vitesse à 25°C vont de $1{,}0 \times 10^{11}$ s^{-1} (*p*-CH_3) à $4{,}1 \times 10^{11}$ s^{-1} (*p*-CF_3). L'accélération relativement importante observée avec le groupe *p*-CF_3, environ 2,5 fois plus rapide que le système parent dans lequel Ar = Ph, donne une bonne corrélation avec les paramètres de substituants ΔD de Adam, mais ce n'est pas le cas avec les autres paramètres de substituants radicalaires. Ces réarrangements radicalaires calibrés fournissent un nouvel ensemble de réactions ultrarapides qui peuvent être appliquées comme sonde dans des études mécanistiques.

Mots clés : radical cyclopropylcarbinyle, cinétique, esters PTOC, benzènesélénol.

[Traduit par la Rédaction]

Rearrangements of radicals have been employed qualitatively in mechanistic probes to implicate radical intermediates and quantitatively as clocks to time radical reactions (1, 2). 2-Aryl-substituted cyclopropylcarbinyl radicals fragment quite rapidly with transient lifetimes in the picosecond range at ambient temperature (3–5), and (*trans*-2-phenylcyclopropyl)methane and related species have been applied in studies of the mechanisms of enzyme-catalyzed hydroxylation reactions (6–14). The phenyl group provides acceleration of the radical reaction, but the aromatic ring is subject to oxidation by enzymes, resulting in phenolic by-products. In addition, because the skeletal reorganization of radical and cationic intermediates is the same, such probes do not permit an inherent distinction between these two types of intermediates. In an effort to provide a wide range of fast radical probes including species that are not oxidized to phenols and that might provide information permitting distinction between radicals and cations, we have calibrated a series of 2-aryl-substituted cyclopropylcarbinyl radical ring openings. The kinetics of the rearrangements are reported here.

Received December 2, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

Precursors and products

The kinetics of ring openings for the series of radicals **1** were determined by an indirect method using Barton's PTOC esters (**2**) (15) as radical precursors and benzeneselenol trapping as the basis reaction (Scheme 1) (3, 16–18). The PTOC esters react in radical chain reactions to give acyloxyl radicals (**3**) that decarboxylate rapidly to give radicals **1**. Ring openings of radicals **1** give benzylic radicals **4** in competition with trapping by PhSeH that produces the cyclopropanes **5**. Benzylic radicals **4** also react with PhSeH

giving alkenes **6**, and the $PhSe^{\bullet}$ radical formed in these processes propagates the chain reaction.

PTOC esters are prepared from the corresponding carboxylic acids. For economy in synthesis, the sequence of reactions shown in Scheme 2 was employed. This sequence permits the preparation of the requisite carboxylic acids and the cyclic products of the radical reactions from advanced intermediates. The commercially available substituted benzaldehydes **7** were first converted to the corresponding Weinreb amides (19) **8** by Wittig olefination with *N*-methoxy-*N*-methyl-2-(triphenylphosphoranylidene)acetamide. The acrylamide derivatives **8** were cyclopropanated in reactions with the ylide from trimethylsulfoxonium iodide and sodium hydride according to the procedure developed by Rodriques (20) to afford the cyclopropylcarboxamides **9**. Hydrolysis of amides **9** by the anhydrous hydroxide procedure of Gassman et al. (21) gave acids **10,** which were homologated to the corresponding (2-arylcyclopropyl)acetic acids. For purification purposes, the homologated acids were converted to esters **11,** which were isolated and then

saponified to afford acids **12**. The requisite acids were converted to PTOC esters **2** by conventional methods.

Authentic samples of the trapped and rearranged products of the radical reactions were prepared (Scheme 3). The cyclopropanes **5** were prepared in two steps from acids **10**. Lithium aluminum hydride reduction of the acids gave alcohols **13** that were reduced to cyclopropanes **5** by conversion to the mesylate derivatives and reduction with lithium triethylborohydride (22). The acyclic products from radical ring opening (**6**) were prepared by reaction of the appropriate substituted benzylic halide with allylmagnesium chloride (23).

Kinetics

PTOC esters **2** were allowed to react in THF in the presence of PhSeH in indirect kinetic studies similar to those previously reported. Solutions were shielded from light during a thermal equilibration period. The solutions were then irradiated with visible light, which cleaves the PTOC esters and initiates the radical chain reactions. Following the radical chain reactions, the reaction mixtures were analyzed by GC. The yields of products were generally in the range of 60–80%, which is typical for this type of study. The *m*-CF_3-substituted system had yields of 40–50%. The PTOC esters are activated acyl derivatives that can react with PhSeH in polar reactions, and the intermediate acyloxyl radicals can be trapped by PhSeH in competition with decarboxylation; both side reactions reduce the overall yield but have no effect on the kinetics.

The indirect kinetic results are collected in Table 1. PhSeH is one of the fastest radical trapping agents available, but the ring-opening reactions are so fast that ring-opened products greatly predominated. Table 1 contains the ratios of rate constants for rearrangement and trapping (k_r/k_H) with errors at 1σ. For radicals **1a**,**1b**, **1g**, and **1h**, relative rate constants were determined between –43 and 25°C, and the relative Arrhenius functions for these radicals are shown graphically in Fig. 1. The log *A* terms in the relative Arrhenius functions are similar for these radicals, as expected for the case of remote substituents, giving a weighted average log *A* term of (2.4 ± 0.1) (error at 2σ).

The indirect kinetic method provides relative rate constants for rearrangement (k_r) and trapping by PhSeH (k_H). In the original calibration of the ring opening of the parent radical (**1**, Ar = Ph), the rate constants for reaction of PhSeH employed were determined by competition against ring

opening of the cyclopropylcarbinyl radical. However, a recent recalibration (18) of alkyl radical trapping by reactive H-atom donors indicated that the original rate constants for PhSeH were too large by about 30% due to an error in rate constants introduced early in the sequence of indirect kinetic studies. Accordingly, we suggested that the rate constants for reaction of PhSeH with cyclopropylcarbinyl radicals are likely to be quite similar to those for reaction of primary alkyl radicals (18).

We assume, therefore, that the rate constants for PhSeH trapping of radicals **1** are equal to those recently determined for reactions of PhSeH with a primary alkyl radical. The rate constants for PhSeH determined at ambient temperature are likely to be the most accurate, as previously discussed (18). In Table 2, we have used the rate constant for reaction of PhSeH with 1° alkyl radicals at 25°C (1.26×10^9 M^{-1} s^{-1}) (18) and the relative rate constants for ring openings and trapping of radicals **1** to calculate absolute rate constants for ring openings at 25°C. Radicals **1** are extremely short lived with lifetimes (τ = 1/k) at 25°C of only 2.4–10 ps.

In considering such reactive species, one might question whether or not the methods provide true statistical averaging. This appears to be the case for radicals **1**. In the recent study of PhSeH trapping kinetics, the radical clock used for calibration cyclized with a rate constant of 3.7×10^7 s^{-1} at 20°C and demonstrated excellent Arrhenius behavior in direct LFP kinetic studies (18). The relative rate constants and Arrhenius function for PhSeH trapping determined in that work should be quite reliable. Using the log A term for

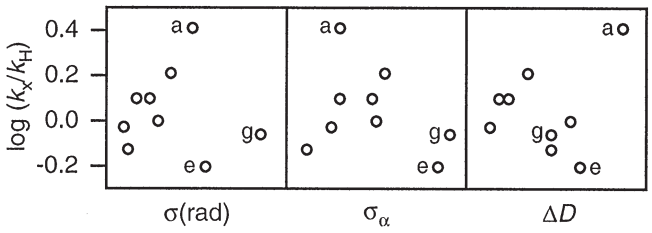
Fig. 2. Correlations of relative rate constants for ring openings of radicals **1** at 25°C with Creary's σ(rad) scale (25), Arnold's σ_α scale (26), and Adam's Δ*D* scale (27). In each plot, the points for radicals **1a**, **1e**, and **1g** are labeled with the corresponding letters.



PhSeH trapping (log *A* = 10.73 ± 0.14) (18) and the weighted average relative log *A* term for ring opening and trapping of radicals **1** noted above, the calculated log *A* term for ring openings of radicals **1** is 13.1 ± 0.2. This value is in excellent agreement that those typically found for cyclopropylcarbinyl radical ring openings including those determined with high precision in direct LFP kinetic studies of a series of cyclopropylcarbinyl radicals containing UV-detectable reporter groups (24).

On the basis of the consistent Arrhenius entropic term and its agreement with previous results, one expects that good estimates of rate constants for ring openings of radicals **1** at varying temperatures can be calculated by employing the rate constants determined at 25°C, the most reliable values, and an Arrhenius log *A* term of 13.1. Table 2 contains temperature-dependent functions for rearrangements of radicals **1** thus calculated.

Remote substituent effects in radical reactions have been considered previously. These effects are generally small, and Hammett-type treatments have large relative errors. The rate constants for ring openings of radicals **1** correlate poorly with the substituent parameters σ(rad) of Creary et al. (25), σ_α of Wayner and Arnold (26), and Δ*D* of Adam et al.(27) (Fig. 2). The fit is especially poor for the *p*-CF_3 (**1a**), *p*-Me (**1e**), and *p*-OMe (**1g**) cases using the σ(rad) and σ_α parameters. It is interesting to note, however, that the large substituent value for *p*-CF_3 in the Δ*D* scale is in good agreement with the relatively large kinetic effect found in this work.

In summary, rate constants for ring openings of a variety of *trans*-2-arylcyclopropylcarbinyl radicals are now available. The ultrafast rearrangements permit quantitation of extremely short "radical" lifetimes including lifetimes in the transition states for insertion reactions. In addition, the corresponding (arylcyclopropyl)methanes containing the *p*-CF_3 and *p*-F substituents were found to be resistant to arene oxidation (i.e., phenol production) in reactions with cytochrome P450 enzymes (13) and methane monooxygenase hydroxylase enzyme (28).

Experimental section

General methods

Commercially available reagents were purchased from the Aldrich Chemical Company and were used as received. All moisture-sensitive reactions were carried out in flame-dried glassware under a nitrogen atmosphere. Tetrahydrofuran (THF) and diethyl ether were distilled under a nitrogen atmosphere over sodium and benzophenone ketyl. Methylene chloride was distilled under a nitrogen atmosphere over phosphorus pentoxide. Dimethyl sulfoxide (DMSO) was distilled in vacuo from calcium hydride.

^{1}H and ^{13}C NMR spectra of $CDCl_3$ solutions were obtained at 300 or 500 MHz and 75 or 125 MHz, respectively. Gas chromatographic analyses were performed using flame ionization detection on a Varian 3400 chromatograph (15 m × 0.54 mm bonded phase SE-30 and Carbowax columns, Alltech). High-resolution mass spectral analyses were performed by the Central Instrumentation Facility at Wayne State University (Detroit, Mich.). Melting points were determined using a Unimelt capillary melting point apparatus (Thomas Hoover) and are uncorrected. Radial chromatography was performed on a Chromatotron model 7294T (Harrison Research Corp.) using plates coated with TLC grade silica gel (Merck) with gypsum binder and fluorescent indicator.

trans-1-Methyl-2-(4-(trifluoromethyl)phenyl)cyclopropane (5a). Procedure G

A solution of **13a** (0.28 g, 1.31 mmol) in THF (8 mL) under a nitrogen atmosphere was cooled to –30°C. To this was added sequentially via syringe triethylamine (0.45 mL, 3.23 mmol) and methanesulfonyl chloride (0.11 mL, 1.42 mmol). The mixture was stirred at –30°C for 30 min and then cooled to –78°C. A solution of $LiBEt_3H$ (1.0 M in THF, 4.0 mL, 4.0 mmol) was added via syringe. The mixture was allowed to warm slowly to room temperature and was stirred for 13 h. The reaction mixture was quenched by the addition of 30% H_2O_2 (2 mL) and 15% aqueous NaOH (2 mL). The resulting mixture was heated at reflux for 1 h and then cooled to room temperature. The organic layer was separated, and the aqueous layer was extracted with ether (3 × 25 mL). The combined organic phase was washed with brine (50 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo at 0°C. The crude product was purified by radial chromatography (pentane) to afford **5a** (0.21 g, 1.04 mmol, 79%) as a clear, colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.80–0.86 (1H, m), 0.94 (1H, dt, J_1 = 8.1 Hz, J_2 = 4.8 Hz), 1.06–1.16 (1H, m), 1.20 (3H, d, *J* = 5.7 Hz), 1.62 (1H, dt, J_1 = 8.7 Hz, J_2 = 4.5 Hz), 7.10 (2H, d, *J* = 8.4 Hz), 7.48 (2H, d, *J* = 8.4 Hz). ^{13}C NMR ($CDCl_3$) δ: 18.3, 18.9, 18.9, 24.2, 124.6 (q, J_{C-F} = 270.2 Hz), 125.1 (2C, q, J_{C-F} = 2.9 Hz), 125.6 (2C), 127.4 (q, J_{C-F} = 31.6 Hz), 148.6. 4-(4-(Trifluoromethyl)phenyl)but-1-ene (6a). Procedure H

A solution of 4-(trifluoromethyl)benzyl chloride (0.76 mL, 5.14 mmol) and allylmagnesium chloride (2.0 M in Et_2O, 5.0 mL, 10.0 mmol) in ether (20 mL) was refluxed under a nitrogen atmosphere for 16 h. This was cooled to room temperature and was quenched with saturated aqueous NH_4Cl (50 mL). The organic layer was separated, and the aqueous layer was extracted with additional ether (3 × 25 mL). The combined organic layer was washed with brine (50 mL), dried over $MgSO_4$, and concentrated in vacuo at 0°C. The crude product was purified by radial chromatography (pentane) to afford **6a** (0.90 g, 4.50 mmol, 88%) as a clear, colorless oil. ^1H NMR ($CDCl_3$) δ: 2.35–2.43 (2H, m), 2.77 (2H, t, J = 8.1 Hz), 4.97–5.08 (2H. m), 5.84 (1H, ddt, J_1 = 9.9 Hz, J_2 = 7.2 Hz, J_3 = 6.9 Hz), 7.29 (2H, d, J = 7.8 Hz), 7.53 (2H, d, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 35.0, 35.1, 115.4, 124.4 (q, J_{C-F} = 270.2 Hz), 125.2 (2C, J_{C-F} = 3.3 Hz), 128.2 (q, J_{C-F} = 32.0 Hz), 128.8 (2C), 147.7, 145.9. HRMS calcd. for $C_{11}H_{11}F_3$: 200.0813; found: 200.0810.

4-(3-(Trifluoromethyl)phenyl)but-1-ene (6b) was prepared by procedure H, from 3-(trifluoromethyl)benzyl chloride (0.80 mL, 5.16 mmol) and allylmagnesium chloride (5.0 mL, 10.0 mmol), in 85% yield (0.89 g, 4.40 mmol). ^1H NMR ($CDCl_3$) δ: 2.36–2.44 (2H, m), 2.78 (2H, dd, J_1 = 8.1 Hz, J_2 = 6.3 Hz), 4.99–5.09 (2H, m), 5.85 (1H, ddt, J_1 = 10.5 Hz, J_2 = 6.6 Hz, J_3 = 6.3 Hz), 7.35–7.47 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 35.2, 35.2, 115.4, 122.7 (q, J_{C-F} = 3.3 Hz), 124.3 (q, J_{C-F} = 270.2 Hz), 125.2 (q, J_{C-F} = 3.3 Hz), 128.6, 130.5 (q, J_{C-F} = 32.0 Hz), 131.8, 137.3, 142.6. HRMS calcd. for $C_{11}H_{11}F_3$: 200.0813; found: 200.0808.

4-(4-Fluorophenyl)but-1-ene (6c) was prepared by procedure H, from 4-fluorobenzyl bromide (1 mL, 8.04 mmol) and allylmagnesium chloride (6.0 mL, 12.0 mmol), in 79% yield (0.96 g, 6.39 mmol). ^1H NMR ($CDCl_3$) δ: 2.34–2.42 (2H, m), 2.71 (2H, dd, J_1 = 8.1 Hz, J_2 = 7.5 Hz), 4.99–5.10 (2H, m), 5.87 (1H, ddt, J_1 = 10.5 Hz, J_2 = 6.6 Hz, J_3 = 6.3 Hz), 6.95–7.03 (2H, m), 7.13–7.19 (2H, m). ^{13}C NMR ($CDCl_3$) δ: 34.5, 35.6, 114.9 (2C, d, J_{C-F} = 20.2 Hz), 115.1, 129.8 (2C, d, J_{C-F} = 7.7 Hz), 137.4 (d, J_{C-F} = 2.3 Hz), 137.8, 161.3 (d, J_{C-F} = 241.6 Hz). HRMS calcd. for $C_{10}H_{11}F$: 150.0845; found: 150.0840.

N-Methoxy-*N*-methyl-*trans*-2-(4-(trifluoromethyl)-phenyl)cyclopropanecarboxamide (9a). Procedure B

A solution of trimethylsulfoxonium iodide (24.1 g, 110 mmol) in DMSO (100 mL) under a nitrogen atmosphere was cooled with a room-temperature water bath, and NaH (2.6 g, 108 mmol) was added portionwise over 15 min. After the addition was complete, the suspension was allowed to stir for 1 h, during which time it became homogeneous. A solution of **8a** (14.1 g, 54.3 mmol) in DMSO (50 mL) was added via cannula, and the reaction mixture was stirred for 6 h. The reaction mixture was quenched by pouring it into saturated aqueous NH_4Cl solution (500 mL). The mixture was extracted with CH_2Cl_2 (3 × 250 mL). The combined organic layer was washed with brine (200 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo. The crude material was chromatographed on silica gel (40% ethyl acetate in hexanes) to afford **9a** (12.8 g, 46.8 mmol, 86%) as a clear, colorless oil. ^{1}H NMR ($CDCl_3$) δ: 1.30 (1H, ddd, J_1 = 8.4 Hz, J_2 = 6.3 Hz, J_3 = 4.5 Hz), 1.65 (1H, ddd, J_1 = 9.0 Hz, J_2 = 5.4 Hz, J_3 = 4.2 Hz), 2.38–2.46 (1H, m), 2.50 (1H, ddd, J_1 = 9.3 Hz, J_2 = 6.6 Hz, J_3 = 4.2 Hz), 3.19 (3H, s), 3.65 (3H, s), 7.18 (2H, d, J = 9.0 Hz), 7.48 (2H, d, J = 9.0 Hz). ^{13}C NMR ($CDCl_3$) δ: 16.5, 21.8, 25.2, 32.4, 61.5, 124.1 (q, $J_{C–F}$ = 270.3 Hz), 125.2 (2C, q, $J_{C–F}$ = 3.3 Hz), 126.3 (2C), 128.3 (q, $J_{C–F}$ = 32.4 Hz), 145.0, 172.2. (*trans*-2-(4-(Trifluoromethyl)phenyl)cyclopropyl)methanol (13a). Procedure D

A solution of **10a** (2.00 g, 8.69 mmol) in THF (75 mL) under a nitrogen atmosphere was cooled to 0°C, and $LiAlH_4$ (0.70 g, 18.4 mmol) was added. The mixture was stirred for 2 h, after which time the reaction mixture was quenched by the sequential addition of water (0.7 mL), 15% NaOH (0.7 mL), and water (2.1 mL). After stirring for an additional 2 h, the suspension was filtered, and the filtrate was washed with additional THF (100 mL). The combined organic solution was concentrated in vacuo, and the resulting residue was chromatographed on silica gel (40% ethyl acetate in hexanes) to afford **13a** (1.77 g, 8.17 mmol, 94%) as a white solid; mp 61°C. ^{1}H NMR ($CDCl_3$) δ: 1.01–1.06 (2H, m), 1.41 (1H, bs), 1.46–1.57 (1H, m), 1.87–1.93 (1H, m), 3.66 (2H, d, J = 6.6 Hz), 7.17 (2H, d, J = 8.4 Hz), 7.52 (2H, d, J = 8.4 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.3, 21.1, 25.9, 66.0, 124.3 (q, $J_{C–F}$ = 269.2 Hz), 125.2 (2C, q, $J_{C–F}$ = 3.5 Hz), 125.9 (2C), 127.8 (q, $J_{C–F}$ = 33.1 Hz), 146.9. HRMS calcd. for $C_{11}H_{11}F_3O$: 216.0762; found: 216.0759.

(*trans*-2-(3-(Trifluoromethyl)phenyl)cyclopropyl)methanol (13b) was prepared by procedure D, using **10b** (0.95 g, 4.13 mmol) and $LiAlH_4$ (0.30 g, 7.91 mmol), in 87% yield (0.78 g, 3.61 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.96 (2H, dd, J_1 = 7.5 Hz, J_2 = 6.9 Hz), 1.37–1.48 (1H, m), 1.85 (1H, dt, J_1 = 6.9 Hz, J_2 = 4.2 Hz), 2.96 (1H, bs), 3.54 (1H, dd, J_1 = 11.4 Hz, J_2 = 6.3 Hz), 3.63 (1H, dd, J_1 = 11.4 Hz, J_2 = 6.3 Hz), 7.19–7.41 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 13.9, 21.1, 25.4, 65.9, 122.3 (q, $J_{C–F}$ = 3.3 Hz), 122.2 (q, $J_{C–F}$ = 3.3 Hz), 124.2 (q, $J_{C–F}$ = 270.2 Hz), 128.7, 129.1, 130.5 (q, $J_{C–F}$ = 32.0 Hz), 143.7. HRMS calcd. for $C_{11}H_{11}F_3O$: 216.0762; found: 216.0766.

(*trans*-2-(4-Fluorophenyl)cyclopropyl)methanol (13c) was prepared by procedure D, using **10c** (1.95 g, 10.8 mmol) and $LiAlH_4$ (1.00 g, 26.4 mmol), in 91% yield (1.63 g, 9.81 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.86–0.93 (2H, m), 1.30–1.41 (1H, m), 1.78 (1H, ddd, J_1 = 8.4 Hz, J_2 = 6.0 Hz, J_3 = 4.5 Hz) 2.45–2.51 (1H, m), 3.57 (2H, d, J = 6.9 Hz), 6.89–7.04 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 13.5, 20.6, 25.0, 66.2, 115.0 (2C, d, $J_{C–F}$ = 20.9 Hz), 127.3 (2C, d, $J_{C–F}$ = 7.7 Hz), 138.0 (d, $J_{C–F}$ = 2.2 Hz), 161.1 (d, $J_{C–F}$ = 241.5 Hz). HRMS calcd. for $C_{10}H_{11}FO$: 166.0794; found: 166.0796.

(*trans*-2-(3-Fluorophenyl)cyclopropyl)methanol (13d) was prepared by procedure D, using **10d** (1.00 g, 5.55 mmol) and $LiAlH_4$ (0.50 g, 13.2 mmol), in 87% yield (0.80 g, 4.83 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.92 (2H, t, J = 7.2 Hz), 1.34–1.44 (1H, m), 1.76–1.82 (1H, m), 3.30 (1H, s), 3.50–3.61 (2H, m), 6.75 (1H, dt, J_1 = 8.1 Hz, J_2 = 2.4 Hz), 6.80–6.87 (2H, m), 7.18 (1H, dt, J_1 = 8.4 Hz, J_2 = 6.0 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.0, 21.1, 25.4, 65.8, 112.4 (d, $J_{C–F}$ = 20.9 Hz), 112.5 (d, $J_{C–F}$ = 20.9 Hz), 121.6 (d, $J_{C–F}$ = 2.3 Hz), 129.7 (d, $J_{C–F}$ = 8.8 Hz), 145.5 (d, $J_{C–F}$ = 7.7 Hz), 163.0 (d, $J_{C–F}$ = 243.8 Hz). HRMS calcd. for $C_{10}H_{11}FO$: 166.0794; found: 166.0796.

(*trans*-2-(4-Methylphenyl)cyclopropyl)methanol (13e) was prepared by procedure D, using **10e** (2.00 g, 11.3 mmol) and $LiAlH_4$ (1.00 g, 26.4 mmol), in 92% yield (1.68 g, 10.4 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.88–0.97 (2H, m), 1.37–1.48 (1H, m), 1.80 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.4 Hz), 2.12 (1H, s), 2.34 (3H, s), 3.55–3.66 (2H, m), 6.99 (2H, d, J = 7.8 Hz), 7.10 (2H, d, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 13.6, 21.0 (2C), 25.0, 66.5, 125.8 (2C), 129.0 (2C), 135.1, 139.4. HRMS calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1041.

(*trans*-2-(3-Methylphenyl)cyclopropyl)methanol (13f) was prepared by procedure D, using **10f** (2.00 g, 11.3 mmol) and $LiAlH_4$ (1.00 g, 26.4 mmol), in 97% yield (1.79 g, 11.0 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.92–1.03 (2H, m), 1.42–1.53 (1H, m), 1.83 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.1 Hz), 2.39 (3H, s), 2.82 (1H, s), 3.57–3.68 (2H, m), 6.92–7.24 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 13.8, 21.3, 21.5, 25.1, 66.3, 122.9, 126.4, 126.7, 128.3., 137.9, 142.6. HRMS calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1042.

(*trans*-2-(4-Methoxyphenyl)cyclopropyl)methanol (13g) was prepared by procedure D, using **10g** (0.56 g, 2.88 mmol) and $LiAlH_4$ (0.25 g, 6.59 mmol), in 95% yield (0.49 g, 2.75 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.84–0.93 (2H, m), 1.33–1.46 (1H, m), 1.44 (1H, s), 1.78 (1H, dt, J_1 = 8.4 Hz, J_2 = 4.8 Hz), 3.54–3.65 (2H, m), 3.78 (3H, s), 6.81 (2H, dt, J_1 = 8.4 Hz, J_2 = 2.1 Hz), 7.01 (2H, dt, J_1 = 8.7 Hz, J_2 = 2.4 Hz). ^{13}C NMR ($CDCl_3$) δ: 13.3, 20.6, 24.7, 55.3, 66.6, 113.8 (2C), 127.0 (2C), 134.4, 157.7. HRMS calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.0990.

(*trans*-2-(3-Methoxyphenyl)cyclopropyl)methanol (13h) was prepared by procedure D, using **10h** (1.16 g, 6.34 mmol) and $LiAlH_4$ (0.50 g, 13.2 mmol), in 78% yield (0.88 g, 4.94 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.90–1.00 (2H, m), 1.41–1.51 (1H, m). 1.43 (1H, s), 1.81 (1H, dt, J_1 = 9.0 Hz, J_2 = 4.8 Hz), 3.55–3.68 (2H, m), 3.79 (3H, s), 6.61–6.72 (3H, m), 7.18 (1H, t, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 13.9, 21.3,

25.3, 55.1, 66.2, 110.8, 111.8, 118.2, 129.3, 144.4, 160.0. HRMS calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.1001.

Methyl (*trans*-2-(4-(trifluoromethyl)phenyl)cyclopropyl)-acetate (11a). Procedure E

A solution of **10a** (1.69 g, 7.34 mmol) and DMF (2 drops) in benzene (50 mL) under a nitrogen atmosphere was cooled with a water bath as oxalyl chloride (1.3 mL, 14.9 mmol) was added. The reaction mixture was stirred for 2 h, and volatiles were removed in vacuo. The crude carbonyl chloride was dissolved in CH_2Cl_2 (25 mL), and the resulting mixture was added slowly to a solution of CH_2N_2 in ether, prepared from Diazald® (10 g, 46.7 mmol). The reaction mixture was stirred at room temperature for 16 h and then concentrated in vacuo. The resulting diazoketone was chromatographed on silica gel (20% ethyl acetate in hexanes).

The diazoketone was dissolved in dioxane (30 mL), and the solution was added portionwise to a suspension of Ag_2O (3.00 g, 12.9 mmol) and $Na_2S_2O_3$ (2.04 g, 12.9 mmol) in water (100 mL) at 75°C. The resulting suspension was stirred for 2 h and then cooled to room temperature and filtered through Celite®. The filtrate was made basic (NaOH) and washed with ether (2 × 100 mL). The aqueous layer was acidified (concentrated HCl) and extracted with ether (2 × 100 mL). The combined organic layer was washed with brine (100 mL), dried over $MgSO_4$, filtered, and concentrated in vacuo.

The resulting acid was dissolved in CH_2Cl_2 (25 mL) and added slowly to a solution of CH_2N_2 in ether, prepared from Diazald® (10 g, 46.7 mmol). The mixture was stirred at room temperature for 16 h and then concentrated in vacuo. The crude product was purified by radial chromatography (10% ethyl acetate in hexanes) to afford **11a** (1.04 g, 4.04 mmol, 55% combined yield) as a clear, colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.94 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.4 Hz), 1.05 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.4 Hz), 1.37–1.48 (1H, m), 1.81 (1H, dt, J_1 = 9.0 Hz, J_2 = 4.8 Hz), 2.42 (2H, d, J = 7.2 Hz), 3.70 (3H, s), 7.17 (2H, d, J = 8.1 Hz), 7.49 (2H, d, J = 8.1 Hz). ^{13}C NMR ($CDCl_3$) δ: 15.8, 19.1, 22.8, 38.5, 51.6, 124.3 (q, $J_{C–F}$ = 270.3 Hz), 125.1 (2C, q, $J_{C–F}$ = 3.4 Hz), 126.1 (2C), 127.8 (q, $J_{C–F}$ = 33.1 Hz), 146.8, 172.8. HRMS calcd. for $C_{13}H_{13}F_3O_2$: 258.0868; found: 258.0871.

Methyl (*trans*-2-(3-(trifluoromethyl)phenyl)cyclopropyl)-acetate (11b) was prepared by procedure E, using **10b** (1.71 g, 7.43 mmol), oxalyl chloride (1.3 mL, 14.9 mmol), and Ag_2O (3.00 g, 12.9 mmol), in 51% yield (0.98 g, 3.79 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.90 (1H, dt, J_1 = 8.7 Hz, J_2 = 5.1 Hz), 1.10 (1H, dt, J_1 = 8.7 Hz, J_2 = 5.1 Hz), 1.33–1.44 (1H, m), 1.79 (1H, dt, J_1 = 9.3 Hz, J_2 = 4.8 Hz), 2.39 (2H, d, J = 6.9 Hz), 3.67 (3H, s), 7.22–7.44 (4H, m). ^{13}C NMR ($CDCl_3$) δ: 15.3, 18.7, 22.6, 38.4, 51.5, 122.3 (q, $J_{C–F}$ = 3.3 Hz), 122.7 (q, $J_{C–F}$ = 3.3 Hz), 124.2 (q, $J_{C–F}$ = 270.8 Hz), 128.6, 129.4, 130.5 (q, $J_{C–F}$ = 32.0 Hz), 143.6, 172.7. 1-[[[(*trans*-2-(4-(Trifluoromethyl)phenyl)cyclopropyl)-methyl]carbonyl]oxy]-2(1*H*)-pyridinethione (2a)

PTOC esters were generally prepared by either the standard method (15) or the mild method (29). To a solution of acid **12a** (0.50 g, 2.05 mmol) in dry benzene at 0°C under nitrogen was added dropwise oxalyl chloride (0.45 mL, 5.1 mmol) via syringe transfer followed by one drop of DMF. The reaction mixture was stirred for 3 h at room temperature until gas evolution ceased. The excess oxalyl chloride and benzene were removed under reduced pressure. The resulting acid chloride was dissolved in dry benzene (5 mL)

© 1999 NRC Canada

and transferred by cannula into a light-shielded flask in an ice bath containing a suspension of *N*-hydroxypyridine-2-thione sodium salt (0.37 g, 2.46 mmol) and a catalytic amount of DMAP (12.2 mg, 0.1 mmol) in 10 mL of benzene. The mixture was allowed to warm to room temperature with stirring and was maintained at room temperature for 3 h. The mixture was diluted with ether (10 mL) and washed with saturated $NaHCO_3$ solution (5 mL) and saturated NaCl solution (10 mL). The organic layer was dried over $MgSO_4$ and concentrated to give crude PTOC ester **2a**, which was purified by column chromatography on silica gel (hexanes–EtOAc = 1:1, v/v) to yield 0.56 g (1.59 mmol, 78%). ^{1}H NMR ($CDCl_3$) δ: 1.08 (1H, dt, J_1 = 9.0 Hz, J_2 = 6.0 Hz), 1.15 (1H, dt, J_1 = 8.5 Hz, J_2 = 5.5 Hz), 1.51–1.57 (1H, m), 1.99 (1H, dt, J_1 = 9.5 Hz, J_2 = 5.0 Hz), 2.76–2.92 (2H, m), 6.62 (1H, dt, J_1 = 7.5 Hz, J_2 = 2.0 Hz), 7.17–7.21 (3H, m), 7.47 (2H, d, J = 8.0 Hz), 7.57 (1H, d, J = 7.0 Hz), 7.66 (1H, dd, J_1 = 8.5 Hz, J_2 = 1.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 15.6, 18.0, 22.8, 36.1, 112.7, 124.2 (q, $J_{C–F}$ = 270.5 Hz), 125.1 (2C, q, $J_{C–F}$ = 3.6 Hz), 126.2 (2C), 127.9 (q, $J_{C–F}$ = 32.3 Hz), 133.6, 137.2, 137.5, 146.1, 167.9, 175.5.

1-[[[(*trans*-2-(3-(Trifluoromethyl)phenyl)cyclopropyl)-methyl]carbonyl]oxy]-2(1*H*)-pyridinethione (2b)

To a solution of acid **12b** (146 mg, 0.60 mmol) and 2,2′-dipyridyl disulfide bis-*N*-oxide (1.1 equiv., 166 mg, 0.66 mmol) in dry CH_2Cl_2 (10 mL) in a flame-dried flask wrapped with aluminum foil was added Ph_3P (1.1 equiv., 172 mg, 0.66 mmol) at room temperature under nitrogen. The reaction mixture was stirred for 1 h and then treated with 5 mL of 10% aqueous Na_2CO_3 solution. The organic layer was separated, and the aqueous layer was extracted with 10 mL of CH_2Cl_2. The combined organic extracts were washed with saturated NaCl solution (10 mL), dried over $MgSO_4$, and concentrated under reduced pressure. Column chromatography of the residue on silica gel (hexanes–EtOAc = 1:1, v/v) under subdued light gave PTOC-ester **2b** (177 mg, 0.48 mmol, 80%).^{1}H NMR ($CDCl_3$) δ: 1.09 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.5 Hz), 1.17 (1H, dt, J_1 = 8.5 Hz, J_2 = 5.5 Hz), 1.52–1.58 (1H, m), 2.01 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.0 Hz), 2.80–2.92 (2H, m), 6.64 (1H, dt, J_1 = 6.5 Hz, J_2 = 1.5 Hz), 7.20–7.23 (1H, m), 7.31–7.42 (4H, m), 7.58 (1H, d, J = 7.0 Hz), 7.69 (1H, dd, J_1 = 9.0 Hz, J_2 = 1.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 15.3, 17.6, 22.8, 36.2, 112.6, 122.6 (q, $J_{C–F}$ = 3.8 Hz), 122.9 (q, $J_{C–F}$ = 3.6 Hz), 124.1 (q, $J_{C–F}$ = 271.4 Hz), 128.8, 129.7, 130.6 (q, $J_{C–F}$ = 32.3 Hz), 133.6, 137.3, 137.5, 142.8, 168.0, 175.7.

1-[[[(*trans*-2-(4-Fluorophenyl)cyclopropyl)methyl]carbonyl]oxy]-2(1*H*)-pyridinethione (2c)

To a solution of acid **12c** (258 mg, 1.33 mmol) and 2,2′-dipyridyl disulfide bis-*N*-oxide (1.1 equiv., 369 mg, 1.46 mmol) in dry CH_2Cl_2 (10 mL) in a flame-dried flask wrapped with aluminum foil was added *n*-Bu_3P (1.1 equiv., 361 μL, 1.46 mmol) at 0°C under nitrogen. After 2 min, the ice bath was removed. The reaction mixture was stirred for 40 min before 10% aqueous Na_2CO_3 (10 mL) was added. The organic layer was separated and the aqueous layer was extracted with 10 mL of CH_2Cl_2. The combined organic extracts were washed with saturated NaCl solution (10 mL), dried over $MgSO_4$, and concentrated under reduced pressure. Column chromatography on silica gel (hexanes–EtOAc = 1:1, v/v) under subdued light gave PTOC-ester **2c** (225 mg, 0.74 mmol, 56%). ^{1}H NMR ($CDCl_3$) δ: 0.99 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.4 Hz), 1.05 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.4 Hz), 1.39–1.50 (1H, m), 1.91 (1H, dt, J_1 = 8.7 Hz, J_2 = 5.1 Hz), 2.72–2.90 (2H, m), 6.62 (1H, dt, J_1 = 7.2 Hz, J_2 = 1.8 Hz), 6.90–6.96 (2H, m), 7.05–7.11 (2H, m), 7.17–7.22 (1H, m), 7.57 (1H, dd, J_1 = 7.2 Hz, J_2 = 1.8 Hz), 7.67 (1H, dd, J_1 = 9.0 Hz, J_2 = 1.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.7, 17.1, 22.3, 36.2, 112.5, 115.0 (2C, d, $J_{C–F}$ = 21.0 Hz), 127.7 (2C, d, $J_{C–F}$ = 7.7 Hz), 133.5, 137.3, 137.5 (d, $J_{C–F}$ = 2.2 Hz), 137.6, 161.2 (d, $J_{C–F}$ = 241.5 Hz), 168.2, 175.7.

1-[[[(*trans*-2-(3-Fluorophenyl)cyclopropyl)methyl]carbonyl]oxy]-2(1*H*)-pyridinethione (2d) was prepared by the procedure of **2c**, using acid **12d** (250 mg, 1.29 mmol), 2,2′-dipyridyl disulfide bis-*N*-oxide (358 mg, 1.42 mmol), and *n*-Bu_3P (350 μL, 1.42 mmol), in 70% yield (272 mg, 0.90 mmol). ^{1}H NMR ($CDCl_3$) δ: 1.03 (1H, dt, J_1 = 8.7 Hz, J_2 = 5.4 Hz), 1.11 (1H, dt, J_1 = 8.7 Hz, J_2 = 5.4 Hz), 1.45–1.56 (1H, m), 1.93 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.1 Hz), 2.75–2.90 (2H, m), 6.63 (1H, dt, J_1 = 7.2 Hz, J_2 = 1.8 Hz), 6.70–6.92 (3H, m), 7.16–7.24 (2H, m), 7.57 (1H, dd, J_1 = 6.9 Hz, J_2 = 1.5 Hz), 7.68 (1H, dd, J_1 = 9.0 Hz, $J2$ = 1.8 Hz). ^{13}C NMR ($CDCl_3$) δ: 15.2, 17.5, 22.7, 36.0, 112.5 (d, $J_{C–F}$ = 21.0 Hz), 112.6, 112.8 (d, $J_{C–F}$ = 22.1 Hz), 121.8 (d, $J_{C–F}$ = 3.3 Hz), 129.6 (d, $J_{C–F}$ = 8.8 Hz), 133.5, 137.0, 137.5, 144.5 (d, $J_{C–F}$ = 6.6 Hz), 162.8 (d, $J_{C–F}$ = 243.8 Hz), 167.9, 175.4.

2,2′-dipyridyl disulfide bis-*N*-oxide (269 mg, 1.07 mmol), and Ph_3P (281 mg, 1.07 mmol), in 73% yield (222 mg, 0.705 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.95 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.5 Hz), 1.04 (1H, dt, J_1 = 8.5 Hz, J_2 = 5.5 Hz), 1.41–1.46 (1H, m), 1.89 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.0 Hz), 2.77–2.86 (2H, m), 3.77 (3H, s), 6.63 (1H, dt, J_1 = 7.0 Hz, J_2 = 2.0 Hz), 6.80–6.81 (2H, m), 7.06–7.08 (2H, m), 7.19–7.22 (1H, m), 7.56 (1H, d, J = 7.0 Hz), 7.69 (1H, dd, J_1 = 9.0 Hz, J_2 = 1.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.6, 16.8, 22.3, 36.4, 55.3, 112.6, 113.7 (2C), 127.4 (2C), 133.5, 133.7, 137.3, 137.6, 157.8, 168.2, 175.7.

1-[[[(*trans*-2-(3-Methoxyphenyl)cyclopropyl)methyl]carbonyl]oxy]-2(1*H*)-pyridinethione (2h) was prepared by the procedure of **2c**, using acid **12h** (400 mg, 1.94 mmol), 2,2′-dipyridyl disulfide bis-*N*-oxide (538 mg, 2.13 mmol), and *n*-Bu_3P (531 μL, 2.13 mmol), in 78% yield (477 mg, 1.51 mmol). ^{1}H NMR ($CDCl_3$) δ: 0.98 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.1 Hz), 1.09 (1H, dt, J_1 = 8.4 Hz, J_2 = 5.4 Hz), 1.44–1.54 (1H, m), 1.89 (1H, dt, J_1 = 9.0 Hz, J_2 = 5.1 Hz), 2.80 (2H, d, J = 7.2 Hz), 3.76 (3H, s), 6.60 (1H, dt, J_1 = 6.6 Hz, J_2 = 1.8 Hz), 6.65–6.71 (3H, m), 7.13–7.20 (2H, m), 7.56 (1H, dd, J_1 = 7.2 Hz, J_2 = 1.5 Hz), 7.64 (1H, dd, J_1 = 7.2 Hz, J_2 = 1.5 Hz). ^{13}C NMR ($CDCl_3$) δ: 15.1, 17.3, 23.0, 36.2, 55.0, 111.1, 111.9, 112.4, 118.4, 129.2, 133.5, 137.0, 137.6, 143.4, 159.5, 167.9, 175.5.

Indirect kinetic studies

These studies followed the method of Newcomb et al. as previously described (4, 17). Benzeneselenol, prepared by the method of Foster (30), was distilled under subdued light. Samples were divided into 1 mL portions and sealed under vacuum in ampoules that were stored at ca. –70°C. The amount of diphenyl diselenide contaminant (typically < 4%) in each sample of PhSeH was determined by GC prior to use. In a flame-dried tube shielded from light containing a small stir bar, a mixture of radical precursors (0.04–0.05 M), PhSeH (0.5–2.0 M), and a hydrocarbon standard (octane or dodecane) in freshly distilled THF was sparged with nitrogen. The tubes were equilibrated in a temperature-regulated bath for several minutes. The shields were removed, and the stirring mixture was irradiated with a 150 W tungsten filament lamp placed 0.4 m from the tube. After 40 min, the tubes were cooled at –78°C, and the contents were analyzed by GC. All yields reported for indirect kinetic experiments were calculated from response factors determined with authentic samples.

Steady state and time-resolved spectroscopic studies of the photochemistry of 1-arylsilacyclobutanes and the chemistry of 1-arylsilenes

William J. Leigh, Rabah Boukherroub, Christine J. Bradaric, Christine C. Cserti, and Jennifer M. Schmeisser

Abstract: Direct photolysis of 1-phenylsilacyclobutane and 1-phenyl-, 1-(2-phenylethynyl)-, and 1-(4′-biphenylyl)-1-methylsilacyclobutane in hexane solution leads to the formation of ethylene and the corresponding 1-arylsilenes, which have been trapped by photolysis in the presence of methanol. Quantum yields for photolysis of the three methyl-substituted compounds have been determined to be 0.04, 0.26, and 0.29, respectively, using the photolysis of 1,1-diphenylsilacyclobutane (Φ_{silene} = 0.21) as the actinometer. The corresponding silenes have been detected by laser flash photolysis; they have lifetimes of several microseconds, exhibit UV absorption maxima ranging from 315 to 330 nm, and react with methanol with rate constants on the order of (2–5) × 10^9 M^{-1} s^{-1} in hexane. Absolute rate constants for reaction of 1-phenylsilene and 1-methyl-1-phenylsilene with water, methanol, *tert*-butanol, and acetic acid in acetonitrile solution have been determined, and are compared to those of 1,1-diphenylsilene under the same conditions. With the phenylethynyl- and biphenyl-substituted methylsilacyclobutanes, the triplet states can also be detected by laser flash photolysis, and are shown to not be involved in silene formation on the basis of triplet sensitization and (or) quenching experiments. Fluorescence emission spectra and singlet lifetimes have been determined for the three 1-aryl-1-methylsilacyclobutanes, 1,1-diphenylsilacyclobutane, and a series of acyclic arylmethylsilane model compounds. These data, along with the reaction quantum yields, allow estimates to be made of the rate constants for the excited singlet state reaction responsible for silene formation. 1-Methyl-1-phenylsilacyclobutane undergoes reaction from its lowest excited singlet state with a rate constant 10–80 times lower than those of the other three derivatives. The results are consistent with a stepwise mechanism for silene formation, involving a 1,4-biradicaloid intermediate that partitions between product and starting material.

Key words: silene, silacyclobutane, photochemistry, biradical.

Résumé : La photolyse directe du 1-phénylsilacyclobutane et des 1-phényl-, 1-(2-phényléthynyl)- et 1-(4′-biphénylyl)-1-méthylsilacyclobutane, en solution dans l'hexane, conduit à la formation d'éthylène et des 1-arylsilènes correspondants que l'on a piégés par photolyse en présence de méthanol. On a déterminé les rendements quantiques pour les photolyses des trois composés portant un groupe méthyle; si l'on utilise la photolyse du 1,1-diphénylcyclobutane ($\Phi_{silène}$ = 0,21) comme actinomètre, les valeurs sont respectivement 0,04, 0,26 et 0,29. On a détecté les silènes correspondants à l'aide de la photolyse éclair au laser; leurs temps de vie sont de plusieurs microsecondes, ils présentent des maxima d'absorption UV à des valeurs allant de 315 à 330 nm et ils réagissent avec le méthanol avec des constantes de vitesse de l'ordre de (2–5) × 10^9 M^{-1} s^{-1}, dans l'hexane. On a déterminé les constantes de vitesse absolue pour la réaction du 1-phénylsilène et du 1-méthyl-1-phénylsilène avec l'eau, le méthanol, l'alcool *tert*-butylique et l'acide acétique, en solution dans l'acétonitrile, et on les a comparées à celles du 1,1-diphénylsilène dans les mêmes conditions. Avec les méthylsilacyclobutanes substitués par des groupes phényléthynyle et biphényle, la photolyse éclair au laser permet aussi de détecter les états triplets et, en se basant sur des expériences de sensibilisation de triplets et/ou de désactivation, on a démontré qu'ils ne sont pas impliqués dans la formation du silène. On a déterminé les spectres d'émission de fluorescence et les temps de vie des singulets des trois 1-aryl-1-méthylsilacyclobutanes,du 1,1-diphénylsilacyclobutane et d'une série de composés arylméthylsilanes acycliques modèles. Ces données utilisées avec les rendements quantiques des réactions ont permis d'évaluer les constantes de vitesse de réaction de l'état singulet excité responsable de la formation du silène. La vitesse de réaction du 1-méthyl-1-phénylsilacyclobutane à partir de son

état singulet excité le plus bas est de 10 à 80 fois plus rapide que les vitesses des trois autres dérivés. Ces résultats sont en accord avec un mécanisme par lequel la formation du silène se ferait par étapes impliquant un intermédiaire 1,4-biradicaloïde qui se répartirait entre le produit de la réaction et le produit de départ.

Mots clés : silène, silacyclobutane, photochimie, biradical.

[Traduit par la Rédaction]

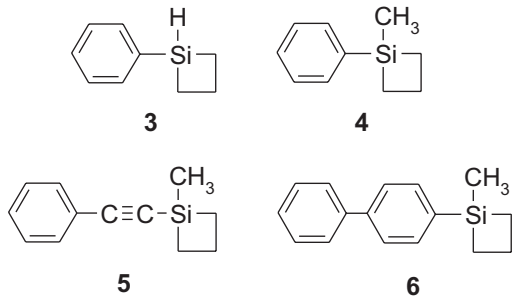
Introduction

Silacyclobutanes are well known to yield products consistent with the formation of silene-reactive intermediates upon photolysis in solution or the gas phase, or upon pyrolysis at high temperatures (1–8). These compounds have proven to be tremendously useful as photochemical precursors for transient silenes, in experiments aimed at detecting the silenes directly and studying the kinetics and mechanisms of their reactions with alcohols and other "silenophiles" (9–17). Photochemical silene formation proceeds with useful efficiencies from silacyclobutanes that bear alkyl, vinyl, ethynyl, silyl, and phenyl substituents at silicon, and possess UV absorption maxima between 190 and 250 nm (2, 4, 12, 13, 17–20). In contrast, alkoxy substitution either directly at silicon or on the aromatic rings of phenylated derivatives renders the silacyclobutane moiety inert to photocycloreversion (13, 17).

Several details of the mechanism for the photochemical cycloreversion of silacyclobutanes are known, at least for 1,1-dialkyl-substituted derivatives that absorb below ~230 nm. The reaction is initiated from the lowest (σ,σ^*) excited singlet state, by cleavage of one of the ring Si—C bonds to form a biradicaloid intermediate that cleaves to silene and alkene, recloses to starting material, and undergoes intramolecular disproportionation if an alkyl substituent is present at C2 (20). The presence of substituents at C2 of the silacyclobutane ring directs the regiochemistry of the initial cleavage toward the Si—C2 bond, leading to an intermediate whose lifetime is long enough to allow bond rotations that lead to partial scrambling of the stereochemistry at this carbon (20). This mechanism contrasts that of the thermal cleavage of silacyclobutanes, which has been shown to proceed by a stepwise mechanism involving initial C2—C3 bond cleavage (21–24).

The situation is less clear with 1-phenyl-substituted derivatives, in which the phenyl substituent is the primary chromophore. 1,1-Diphenylsilacyclobutane (**1**) affords 1,1-diphenylsilene (**2**; eq. [1]) with reasonable efficiency (Φ_2 = 0.21), and time-resolved experiments have shown that silene formation occurs on the nanosecond time scale and cannot be quenched by saturation of the solution with oxygen or other triplet quenchers (11). The reactive excited state is thus most likely the lowest excited singlet state, which in these cases is predominantly of benzenoid π,π^* character. For efficient cleavage to occur, however, the ring Si—C bonds in the reactive excited state must obviously be weakened compared to the situation in the ground state, so the lowest benzenoid excited singlet state is presumably mixed with σ,σ^*, σ,π^* or π,σ^* configurations that activate the ring toward cleavage. Whether the reaction occurs by a concerted or stepwise mechanism has not been conclusively established, although the question has in fact been addressed in two early papers on the photochemistry of 2-phenyl-substituted silacyclobutanes (4, 25).

[1] 
In this paper, we report the photochemistry of 1-phenylsilacyclobutane (**3**) and the series of 1-methyl-1-arylsilacyclobutane derivatives **4–6**, in which the aryl substituent is varied between phenyl, phenylethynyl, and biphenyl. The main goal of this work was to determine how the photophysical properties of the chromophore affect the rates and efficiencies of silene formation in arylsilacyclobutane photolysis, and hence to better define the scope and limitations of silacyclobutane photolysis as a source of reactive silenes. It seemed likely to us that the phenylacetylene and biphenyl chromophores in **5** and **6** would allow study of the photochemistry and photophysics of arylsilacyclobutanes in



much greater detail than is convenient with simple phenyl derivatives, since these chromophores generally fluoresce strongly and promote efficient intersystem crossing to the lowest triplet states, which are usually detectable by laser flash photolysis. Thus, we have studied the photochemistry of the three 1-aryl-1-methylsilacyclobutanes (**4–6**) in detail, using steady state photolysis and time-resolved UV absorption and fluorescence emission spectroscopic techniques. Photolysis of all four compounds in hydrocarbon solvents yields the corresponding silenes (**7–10**), which have been detected directly by laser flash photolysis methods and characterized on the basis of their reactivity toward methanol and *tert*-butanol. Absolute rate constants for the reactions of **7** and **8** with the two alcohols, water, and acetic acid have been determined in acetonitrile solution, and are compared to those for 1,1-diphenylsilene (**2**) under similar conditions. Fluorescence spectra and lifetimes have also been determined for **1** and the acyclic arylsilanes **11–14**, to provide a more complete framework with which to understand the

11 **12** **13** **14**

variations in photochemistry and photophysics of these arylsilacyclobutanes as a function of substituent.

Results

Silacyclobutanes **5** and **6** were prepared by reaction of 1-chloro-1-methylsilacyclobutane with phenylethynyllithium and 4-biphenylmagnesium bromide, respectively, using a procedure similar to those reported previously for the synthesis of **3** (26) and **4** (3). All four compounds were purified to >99% (GC) purity by vacuum distillation (**3–5**) or repeated recrystallization (**6**).

Photolysis (254 nm) of the four compounds as deoxygenated 0.04 M solutions in hexane containing methanol (0.05 M) led to the formation of ethylene and the methoxysilane **15** (eq. [2]). The methoxysilanes **15a–15c** were identified by GC–MS and GC coinjection with independently prepared authentic samples, while **15d** was isolated and identified on the basis of its ^{1}H NMR and mass spectra. No other products could be detected in the crude photolysates by GC analysis, up to ~20% conversion of the silacyclobutane, within the detection limits of our GC method.

a. R = H; Ar = Ph
b. R = Me; Ar = Ph
c. R = Me; Ar = C≡C-Ph
d. R = Me; Ar = 4-C_6H_4-C_6H_5

Photolysis (350 nm) of a deoxygenated 0.05 M solution of benzophenone in hexane containing 0.01 M **6** and 0.1 M MeOH led to the slow formation of benzhydrol (identified by MS), but no destruction of the silacyclobutane. Methoxysilane **15d** could not be detected in the mixture, within the limits of our GC method.

Nanosecond laser flash photolysis (λ_{ex} = 248 nm) of continuously flowing, air-saturated solutions of **3** and **4** (~0.014 M) in hexane or acetonitrile leads to weak, but readily detectable, transient absorptions in the spectral region below ≈350 nm. The absorptions decay on the microsecond time scale with mixed first- and second-order kinetics to within 10% of the prepulse level, and exhibit lifetimes in the 2–3 μs range in scrupulously dried solvent. Time-resolved UV absorption spectra were recorded for air-saturated solutions of the two compounds, 0.1–0.4 μs after the laser pulse. The spectra recorded in hexane solution are shown in Fig. 1*a*, *b* along with typical decay traces, recorded at a monitoring wavelength of 315 nm. The lifetimes and intensities of the signals are unaffected by saturation of the solutions with either nitrogen or oxygen.

Addition of water, methanol, *tert*-butanol, or acetic acid ($(0.5–5) \times 10^{-3}$ M) results in a reduction in the lifetimes of both transients and a change in decay kinetics to pseudo first order. Plots of the rate constant for decay (k_{decay}) versus concentration of added quencher according to eq. [3] (where k_0 is the first-order rate constant for the decay of the transient in the absence of added quencher and k_{ROH} is the second-order quenching rate constant) were linear in all cases. Bimolecular rate constants for reaction of **3** and **4** with the four reagents in acetonitrile solution are listed in Table 1, while those for reaction with MeOH and *t*-BuOH in hexane are listed in Table 2. Similar experiments were carried out using MeOD, *t*-BuOD, and acetic acid-*d* in MeCN solution; the k_H/k_D values calculated from these rate constants and those for reaction of the corresponding protiated reagents are included in Table 1. Previously reported rate constants for reaction of **2** with these reagents in acetonitrile are included for comparison.

[3] $$k_{decay} = k_0 + k_{ROH}[Q]$$

Laser flash photolysis of deoxygenated hexane solutions of the phenylethynyl derivative **5** (2×10^{-5} M) led to complex behavior that could be shown to result from competing formation of the silacyclobutane triplet state and silene **9**, whose absorption spectra overlap almost exactly but differ considerably in intensity. Absorptions due to the triplet dominate the transient behavior in deoxygenated hexane solution. For example, flash photolysis of a deoxygenated solution of **5** gave rise to a long-lived ($\tau \sim 5$ μs), strongly absorbing, transient with λ_{max} = 315 nm. The lifetime of the transient was reduced substantially upon addition of oxygen or 1,3-octadiene, but was apparently unaffected upon addition of 0.005 M methanol. Monitoring at 260 nm, within the long-wavelength absorption band of the silacyclobutane, gave rise to a bleaching signal that recovered almost to the prepulse level with the same lifetime as that of the transient

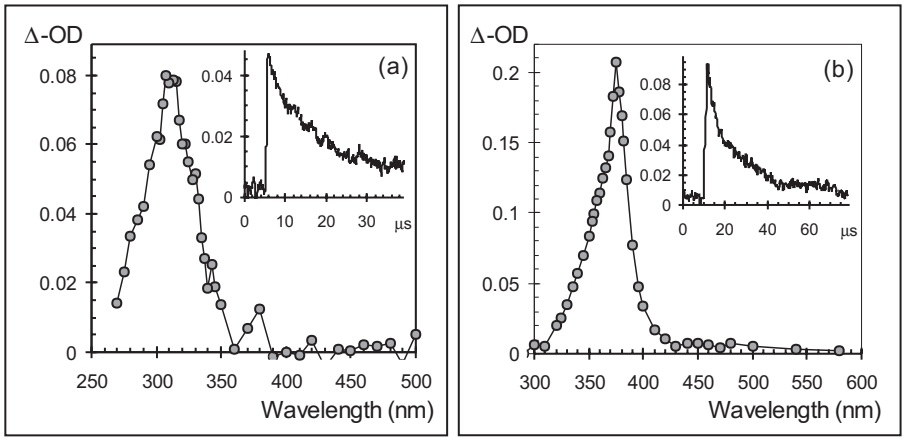
Fig. 2. Triplet–triplet absorption spectra for silacyclobutanes **5** (*a*) and **6** (*b*) in deoxygenated hexane solution containing 0.03 M methanol at 23°C.



absorption at 315 nm. The lifetimes of the absorption and bleaching signals were also identical ($\tau \sim 500$ ns) in the presence of air, but differed in oxygen-saturated solution, where the 315 nm transient decay exhibited an average lifetime of $\tau \sim 240$ ns and the bleaching signal at 260 nm recovered with a clean pseudo-first-order lifetime $\tau \sim 100$ ns. Different behavior was noted upon addition of 0.0027 M 1,3-octadiene, where the bleaching signal was unresolvable from the laser pulse and the 315 nm transient decayed with a lifetime of $\tau \sim 600$ ns, was much weaker in intensity, and was superimposed on a strong fluorescence signal.

The kinetic behavior of the bleaching signal is consistent with the formation of a transient whose decay mainly regenerates the precursor, as would be expected for a triplet state. We thus assign the transient absorption spectrum recorded under deoxygenated conditions as consisting largely of the triplet–triplet absorption spectrum of silacyclobutane **5**, superimposed on a second, more weakly absorbing, transient (assigned to the silene **9**, vide infra) that is resolvable only under conditions where the triplet is strongly quenched. The spectrum of the triplet, recorded in deoxygenated hexane solution containing 0.03 M methanol to remove contributions from the silene (Fig. 2*a*), exhibits $\lambda_{max} = 315$ nm, in the range expected for a phenylacetylene triplet (27, 28). The rate constant for quenching of the triplet by 1,3-octadiene in hexane was found to be $(9.9 \pm 0.6) \times 10^9$ M^{-1} s^{-1}, which is also consistent with its assignment. A rate constant for triplet quenching by oxygen was estimated as $k_q \sim 6 \times 10^8$ M^{-1} s^{-1} from the rates of recovery of the precursor bleaching signal in air- and oxygen-saturated solution.

In hexane solution containing 0.001 M 1,3-octadiene or saturated with oxygen, the lifetime of the residual transient absorption at 315 nm is reduced upon addition of methanol. The spectrum of the transient observed under these conditions exhibits $\lambda_{max} = 320 \pm 2$ nm (Fig. 1*c*), and can thus be most reasonably assigned to 1-methyl-1-phenylethynylsilene (**9**). The transient is quenched efficiently by MeOH, though unfortunately we were able to obtain only a qualitative estimate of the rate constant ($k_{MeOH} = (5 \pm 2) \times 10^9$ M^{-1} s^{-1}), because of interference from the triplet absorptions and sample fluorescence at higher alcohol concentrations. Experiments with solutions containing higher concentrations of diene (e.g., 0.003 M) led to no improvement in accuracy because the silene signal was weaker due to screening of the excitation light by the diene. The fact that the silene is observable under conditions where the triplet lifetime is reduced to <25 ns indicates that the silene is formed from the lowest excited singlet state of the silacyclobutane, and not from the triplet.

Similar results were obtained in laser flash photolysis experiments with the 4′-biphenyl-substituted derivative **6**. Accordingly, flash photolysis of deoxygenated 6×10^{-5} M solutions of **6** in hexane containing 0.03 M MeOH gave rise to a long-lived ($\tau = 12.5$ μs) transient that decayed with pseudo-first-order kinetics at very low laser intensities, and exhibited $\lambda_{max} = 375$ nm (Fig. 2*b*). This transient is assigned to the triplet state of **6** on the basis of the similarity of its spectrum to that of the 4-trimethylsilyl-4′-biphenyl (**13**) triplet ($\lambda_{max} = 375$ nm under similar conditions) and the fact that it is quenched by 1,3-octadiene with a rate constant $k_q = (4.9 \pm 0.5) \times 10^9$ M^{-1} s^{-1}. Alternatively, flash photolysis of air-saturated solutions of **6** in hexane containing 0.008 M 1,3-octadiene gave rise to a transient that decayed with clean pseudo-first-order kinetics ($\tau = 2.1$ μs) and exhibited $\lambda_{max} = 330$ nm. The species proved to be sensitive to the presence of methanol; a plot of k_{decay} vs. [MeOH] according to eq. [2] was linear, and afforded a slope $k_{MeOH} = (2.9 \pm 0.3) \times 10^9$ M^{-1} s^{-1}. On the basis of these data, this transient is assigned to silene **10**.

The time-resolved UV absorption spectra of silenes **9** and **10** in air-saturated hexane solution containing 0.008 M 1,3-octadiene are shown in Figs. 2*c*,*d*. The bimolecular rate constants for their reaction with MeOH under the same conditions are summarized in Table 2, along with the corresponding data for **7**, **8** and 1,1-diphenylsilene (**2**) (11). Quenching by *t*-BuOH was not investigated in these two cases.

Quantum yields for disappearance of **4–6** were determined by 254 nm merry-go-round photolysis of deoxygenated 0.03–0.04 M solutions in hexane containing methanol (0.05 M), using 1,1-diphenylsilacyclobutane (**1**) as actinometer. Photolysis of **1** in methanolic hexane solution affords ethylene and diphenylmethoxymethylsilane (**16**) as the only detectable products (2, 4, 11) — the latter due to trapping of

[a]For disappearance of substrate, from photolysis of deoxygenated 0.03–0.04 M solutions of silacyclobutane in hexane containing 0.05 M MeOH, using **1** as actinometer. Errors are listed as the standard deviation from the mean of duplicate determinations.

[b]Recorded in deoxygenated isooctane solution, at concentrations of 10^{-5}–10^{-4} M.

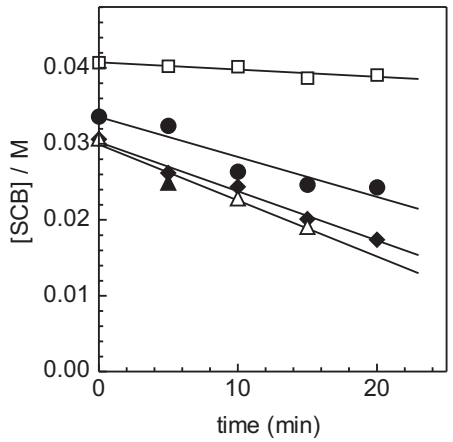
[c]Determined by time-correlated single photon counting. Errors are listed as ±2σ.

[d]Calculated from Φ_{sil} and τ_S^{SCB} (see eq. [5]).

[e]Estimated from the fluorescence lifetimes of silacyclobutane and corresponding model compounds according to eqs. [8] and [9].

[f]Calculated from Φ_{sil} and ϕ_{BIR} according to eq. [7].

Fig. 3. Concentration vs. time plots for merry-go-round photolysis of deoxygenated 0.03–0.04 M solutions of silacyclobutanes **4** (□), **5** (◆), **6** (△), and **1** (●) in hexane containing methanol (0.05 M) at 25°C.



1,1-diphenylsilene (**2**) — and is characterized by a quantum yield of Φ_2 = 0.21 ± 0.03 (11). Quantum yields were calculated from the relative slopes of plots of concentration vs. photolysis time, which are shown in Fig. 3. The results of these experiments are collected in Table 3. Qualitative observations indicated the quantum yield for photolysis of **3** to be similar to that of **4** under similar conditions.

Steady state fluorescence emission spectra of **4–6** and **1** were recorded in deoxygenated isooctane solutions at concentrations in the 10^{-5}–10^{-4} M range. The fluorescence spectra of **4–6** were slightly weaker but otherwise indistinguishable from those of the corresponding model compounds **11–13** in each case. The fluorescence spectrum of dimethyldiphenylsilane (**14**) consisted of a prominent band centered at 285 nm along with a weaker shoulder centered at ~335 nm that is tentatively attributed to intramolecular excimer formation. A similar spectrum was observed for **1**, except the long-wavelength shoulder was much weaker than in the spectrum of **14**. The fluorescence excitation spectra of the eight compounds matched the static absorption spectra (in the region above ~240 nm) in each case. Fluorescence lifetimes were determined for all eight compounds at the emission maxima by time-correlated single photon counting, under the same conditions as those employed for the determination of the steady state fluorescence spectra. In all eight cases, the fluorescence decay profiles analysed either to single exponential kinetics or to two exponentials, which consisted of a prominent (>98%) short-lived decay superimposed on a very weak (<2%) long-lived decay whose origin was not investigated. Identical fluorescence lifetimes were obtained from solutions of ca. 2-fold higher concentration in substrate, within experimental error, indicating that, at these concentrations, self-quenching of fluorescence (due to *inter*molecular excimer formation, for example) is insignificant. The fluorescence emission maxima and singlet lifetimes obtained from these experiments are listed in Table 1, along with various kinetic parameters calculated from the reaction quantum yields and singlet lifetimes (vide infra).

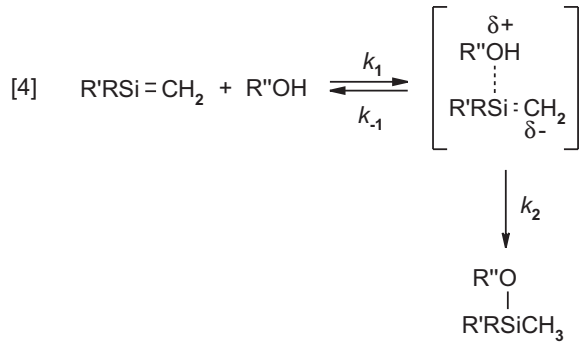
Discussion

The steady state photochemistry and time-resolved spectroscopic behavior of all four of the silacyclobutanes **3–6** are consistent with the formation of ethylene and the corresponding arylsilenes **7–10** as the exclusive products of photolysis, within the limits of our (GC and ^{1}H NMR) detection limits. The four silenes exhibit the expected trends in lifetime (τ = 2–5 μs), λ_{max} (315–330 nm), and reactivity toward alcohols (k_{MeOH} = (2–5) × 10^9 M^{-1} s^{-1} in hexane at 23°C), considering our previously reported data for 1,1-diphenylsilene (**2**) (9, 11). The steady state results reported here for photolysis of **3** in the presence of methanol are analogous to those reported previously for the photolysis of this compound in the presence of other alcohols (26).

As we reported previously for **2** (11), the reactivities of silenes **7** and **8** are significantly lower in acetonitrile solution than in hexane, probably due to weak complexation by the nitrile solvent, and in all cases the rate constants follow

© 1999 NRC Canada

the trend $k_{HOAc} \sim k_{MeOH} > k_{H_2O} > k_{t\text{-}BuOH}$. The reactivities of the three phenylsilene derivatives with each reagent are remarkably similar to one another in this solvent, probably because the small differences in rate that are expected, based on the electronic effects of the substituents (17), are offset by opposing steric and solvation effects. The three compounds show a slightly greater spread in reactivity toward methanol in hexane solution than in acetonitrile, which might reflect differences in solvation throughout the series by the nitrile solvent. As we found previously for **2** (11), the rate constants for reaction with water and the alcohols are subject to small, but clearly primary, deuterium kinetic isotope effects. This is consistent with a reaction mechanism involving initial, reversible complexation followed by rate-controlling proton transfer from oxygen to carbon (eq. [4]) (10, 11, 13, 17, 29–33).



Laser flash photolysis studies of 1,1-diphenylsilacyclobutane (**1**) in nitrogen-saturated hexane solution have shown that 1,1-diphenylsilene (**2**) is formed within the duration of the excitation pulse from a KrF excimer laser (~15 ns) (11). This establishes an upper limit (of the same value) for the lifetime of the excited state responsible for the formation of the reactive intermediate. In this case, the identification of the reactive excited state (i.e., singlet or triplet) by conventional triplet sensitization or quenching experiments is not a trivial task, and we can rule out the triplet state as the precursor only providing that its lifetime is in excess of about 10 ns. We have been unsuccessful in our attempts to detect the triplet state of **1** directly by laser flash photolysis, but this is not unexpected for a benzene derivative bearing nonconjugative substituents (27).

The results reported here for **5** and **6** provide strong evidence that the lowest triplet states of 1-arylsilacyclobutanes are not involved in silene formation. In these two cases, the triplet states are easily detectable by laser flash photolysis because intersystem crossing is more efficient in phenylalkynes and biphenyls than in simple benzene derivatives, and the triplets absorb considerably more strongly (27, 28, 34). The triplet lifetimes of these two molecules were determined to be ~14 and 12 μs, respectively, in deoxygenated hexane solution at room temperature, which should be considered to be lower limits. Quenching of the triplets by oxygen or 1,3-octadiene proceeds rapidly in both cases, but has no discernible effect on the yield of silene (as measured by the initial ΔOD of the silene absorption in the presence of oxygen or diene). In fact, the presence of diene is necessary in order to detect the corresponding silenes (**9** and **10**) cleanly by laser flash photolysis, because their spectra overlap severely with those of the triplet states of the precursors. Similarly, benzophenone-sensitization experiments with **6**, at a concentration corresponding roughly to 90% efficient triplet sensitization, failed to produce detectable amounts of the methanol trapping product of silene **10**. These experiments conclusively demonstrate that the reactive excited state of arylsilacyclobutanes, with respect to [2 + 2] photocycloreversion to the corresponding silenes, is the lowest excited singlet state.

Comparison of the singlet lifetimes of the silacyclobutanes **1** and **4–6** with those of the corresponding model compounds (**11–14**), in which the silacyclobutane ring carbons are replaced by two methyl groups, provides additional evidence for the direct involvement of the lowest excited singlet state in silene formation. Compared to the corresponding silacyclobutanes, the latter four compounds are all essentially non-photoreactive, allowing the conclusion that their singlet lifetimes are controlled mainly by *nonproductive* decay processes such as fluorescence, intersystem crossing, and internal conversion. In fact, the singlet lifetimes of the three trimethylsilyl-substituted compounds **11–13** are similar to those of the corresponding methylarenes under similar conditions (toluene, 34 ns (35); 1-phenylpropyne, 15 ns;[3] 4′-methylbiphenyl, 15.2 ns (35)), indicating that trialkylsilyl substitution has little intrinsic effect on the photophysics of the arene chromophore in each of these compounds. In contrast, the singlet lifetime of dimethyldiphenylsilane (**14**; τ_S = 3.4 ns) is substantially shorter than that of diphenylmethane (τ_S = 25.3 ns (35)). We tentatively attribute this to intramolecular excimer formation on the basis of the long-wavelength shoulder in the static fluorescence emission spectrum of the diarylsilane. This weak emission band occurs at a position characteristic of inter- and intramolecular excimer emissions in substituted benzene derivatives (36). A similar band appears in the emission spectrum of **1**, though it is weaker than in that of **14**. Diphenylmethane does not form an intramolecular excimer (35, 36), and consequently its singlet lifetime is similar to that of toluene. In any event, the singlet lifetimes of the silacyclobutane derivatives are in each case significantly shorter than those of the corresponding model compounds, which is consistent with the presence of an additional mode of excited singlet state decay due to reaction involving the four-membered ring. The alternate possibility that the shorter singlet lifetimes of the cyclics are due to an enhancement in one or more of the nonproductive decay modes cannot, however, be rigorously ruled out. Fluorescence and intersystem crossing could be quantitatively evaluated through quantum yield measurements but, even then, possible differences in the rates of nonproductive internal conversion cannot be easily evaluated.

We were surprised to discover that the quantum yield for silene formation from 1-methyl-1-phenylsilacyclobutane (**4**) is ~5 times lower than that for 1,1-diphenylsilacyclobutane (**1**), and up to ~8 times lower than those for **5** and **6**, which have lower excited singlet state energies. This must be due to a substituent effect on the rate constants for reac-

[3] In deoxygenated isooctane at 25°C. We thank T.L. Morkin for this measurement.

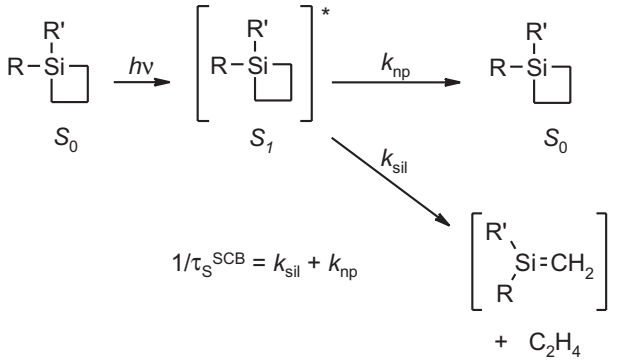
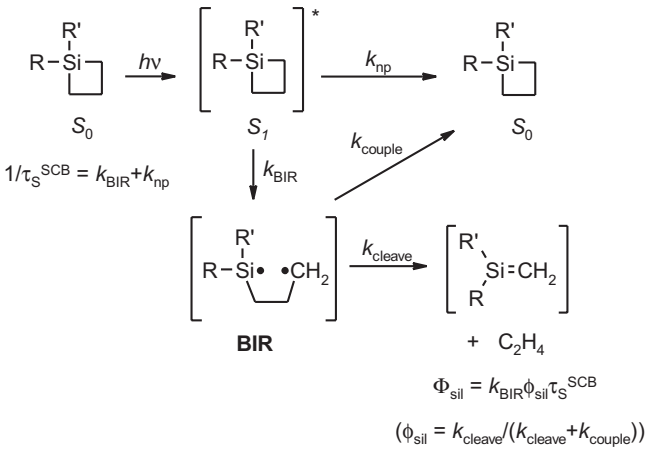
Scheme 1.



Scheme 2.



tive excited state decay and (or) (if silene formation is nonconcerted) the partitioning of the biradicaloid intermediate between silene and starting material. Scheme 1 depicts the simplest possible mechanism to account for excited state decay in these compounds, where silene formation occurs directly from the excited singlet state by concerted cycloreversion with rate constant k_{sil}, and k_{np} is the sum of the rate constants for all nonproductive pathways for excited state decay. The reaction rate constants can be calculated from the quantum yields and singlet lifetimes according to eq. [5], and are listed in Table 3. It should be noted that these are true elementary rate constants only if silene formation occurs directly from the lowest excited singlet state by a concerted mechanism.

$$[5] \qquad \Phi_{sil} = k_{sil}\,\tau_S^{SCB}$$

If silene formation occurs by a stepwise mechanism, then the k_{sil} values calculated above are a more complex function of the primary rate constant for excited state bond cleavage to form the biradicaloid intermediate (k_{BIR}) and an efficiency factor (ϕ_{sil}) that describes its partitioning between silene and the ground state of the silacyclobutane (Scheme 2 and eq. [6]). In other words, the overall quantum yield for reaction is given by the product of the state efficiencies for biradicaloid formation ($\phi_{BIR} = k_{BIR}\,\tau_S^{SCB}$) and for silene formation from the biradicaloid ($\phi_{sil} = k_{cleave}\,\tau_{BIR}$), as shown in eq. [7]. The rigorous determination of these parameters requires additional information, which could be obtained if the intermediate could be detected either directly or indirectly via chemical trapping. Unfortunately, no additional transient absorptions that might be assigned to such species have been observed on the nanosecond time scale, in these or any of the other arylsilacyclobutanes that we have studied.

$$[6] \qquad k_{sil} = k_{BIR} \cdot \phi_{sil}$$

$$[7] \qquad \Phi_{sil} = \phi_{BIR} \cdot \phi_{sil}$$

The best we can do at present is to approximate k_{BIR} values from the singlet lifetimes of the silacyclobutanes and their model compounds, making the admittedly crude assumption that the sum of the rates of the nonproductive decay processes in each of the silacyclobutanes is equal to the inverse singlet lifetime of its model compound. To the extent that this assumption is reasonable, k_{BIR} and ϕ_{BIR} can be estimated using eqs. [8] and [9], and ϕ_{sil} then follows from eq. [7]. These parameters are collected in Table 1.

$$[8] \qquad k_{BIR} \approx 1/\tau_S^{SCB} - 1/\tau_S^{mod}$$

$$[9] \qquad \phi_{BIR} = k_{BIR}\,\tau_S^{SCB} \approx 1 - (\tau_S^{SCB}/\tau_S^{mod})$$

The k_{sil} and k_{BIR} values summarized in Table 1 both indicate that the excited singlet state of 1-methyl-1-phenylsilacyclobutane (**4**) is significantly less reactive toward bond cleavage than those of **1**, **5**, and **6**. The most reasonable explanation for this is that the mixing of benzenoid π and (or) π* MOs with Si—C σ and (or) σ* MOs in the lowest excited singlet state, which is required in order to activate the silacyclobutane ring toward bond cleavage, is much less efficient in **4** than in the other three derivatives. Presumably, the more extended π-systems in **1**, **5,** and **6** assist in this mixing by perturbing the symmetries of the relevant π-type molecular orbitals.

The calculated ϕ_{BIR} and ϕ_{sil} values for the four silacyclobutanes also show some interesting trends. The data for **1** and **4** suggest that the difference in overall reaction quantum yield for these two compounds is primarily due to differences in the behavior of the biradicaloid intermediates, not to differences in the efficiencies of excited state Si—C bond cleavage. The approximately equal ϕ_{BIR} values for the two compounds result from the fact that substituent-induced perturbations that affect k_{BIR} also tend to affect the rates of the nonproductive decay processes: in spite of the fact that **4** is ~10 times less reactive than **1**, the intrinsic lifetime of its excited singlet state (as measured by τ_S^{mod}) is also ~10 times longer. In fact, the data indicate that ϕ_{BIR} varies relatively little throughout the entire series of compounds. On the other hand, ϕ_{sil} varies smoothly throughout the series, suggesting that the biradicaloid from **1** mainly cleaves ($k_{cleave} \sim 9k_{couple}$) while that from **4** mainly couples to regenerate starting material ($k_{couple} \sim 4k_{cleave}$).

Such a large variation in the relative rate constants for cleavage and coupling of the putative 1,4-biradicaloid intermediates is surprising. The two main factors that should affect the partitioning of such species between cleavage and coupling are the relative thermodynamic stabilities of the coupling and cleavage products and the conformational preferences of the 1,4-biradical as they are reflected in the relative transition state energies for cleavage and coupling (37–41). In the present cases, thermodynamics would clearly be expected to strongly favor coupling over cleavage in all

© 1999 NRC Canada

cases. Cleavage requires a colinear arrangement of the central C—C bond with the *p*-orbitals on the trivalent centers, but has little dependence on conformation about the central C—C bond. Coupling, on the other hand, can only occur from *gauche* conformers. While steric effects would clearly be predicted to lead to an increase in cleavage over coupling in the biradicaloid from **1** compared to that from **4**, it is difficult to rationalize the variation in ϕ_{sil} between **4**, **5**, and **6** on the basis of these simple arguments.

We stress again that our analysis of the data in terms of a stepwise reaction mechanism is based on the crude assumption that the singlet lifetimes of the model compounds **11–14** provide a reasonable estimate of the nonproductive contributions to the singlet lifetimes of the corresponding silacyclobutanes (i.e., $k_F + k_{IC} + k_{ISC}$). Further work will be required in order to address the validity of this assumption. To the extent that it is valid (and equally so in all cases), then the intermediacy of a 1,4-biradical en route to the corresponding silene is only really demanded for the monoaryl-substituted derivatives **4–6**, for which the k_{sil} and k_{BIR} values calculated from the lifetime data are significantly different. In the case of **1**, our data cannot rule out the possibility that silene formation occurs by a concerted $\sigma_{2s}+\sigma_{2s}$ cycloreversion mechanism.

Conclusions

The formation of 1-arylsilenes by formal $\sigma_{2s}+\sigma_{2s}$ photocycloreversion of 1-arylsilacyclobutanes is a reaction of the lowest excited singlet state, which is shown by the behavior of derivatives for which the arylsilacyclobutane triplet state can be detected directly by laser flash photolysis. Photocycloreversion proceeds with a quantum yield of only 0.04 in 1-methyl-1-phenylsilacyclobutane, which is 5 times lower than in 1,1-diphenylsilacyclobutane. The quantum yield is even higher in derivatives in which the phenyl group is replaced with 2-phenylethynyl or 4′-biphenyl substituents. The resulting silenes, 1-phenyl-, 1-methyl-1-phenyl-, 1-methyl-1-(2-phenylethynyl)-, and 1-(4′-biphenylyl)-1-methylsilene, react with aliphatic alcohols at rates on the order of (2–5) × 10^9 M^{-1} s^{-1} in hydrocarbon or acetonitrile solution at ambient temperature. Deuterium isotope and solvent effects on the rate constants are consistent with a mechanism involving reversible complexation of the silene with the alcohol, followed by rate-determining proton transfer from silicon to carbon.

Comparison of the singlet lifetimes of the three 1-aryl-1-methylsilacyclobutanes and the corresponding aryltrimethylsilane suggests that cycloreversion proceeds by cleavage of one of the ring Si—C bonds to yield a 1,4-biradicaloid that partitions between silene and starting material. A similar analysis for 1,1-diphenylsilacyclobutane is consistent with either concerted or stepwise mechanisms for silene formation. The lifetime data allow calculation of rate constants for the primary excited state ring cleavage process and state efficiencies for formation of the intermediate and its collapse to silene, assuming that the singlet lifetimes of the model compounds approximate the rates of the nonproductive contributions to excited state decay in the corresponding silacyclobutane. Variations in the rate constant for excited state cleavage throughout the series are tentatively attributed to the effects of substituents on the degree of mixing of the benzenoid π-type molecular orbitals of the chromophore with σ-type molecular orbitals localized in the silacyclobutane ring. Modest variations in excited singlet state energy have no discernible effect on the rate constant, within this limited series of compounds. The relative rates of cleavage and coupling in the putative 1,4-biradicaloid intermediate are very sensitive to substitution at the silicon center; coupling predominates in the biradical from 1-methyl-1-phenylsilacyclobutane, while cleavage predominates in that from 1,1-diphenylsilacyclobutane.

Future work in this area will be directed at developing a better understanding of the various factors that contribute to the efficient formation of reactive silenes from photolysis of arylsilacyclobutanes, and exploiting this reaction for potentially useful applications.

Experimental

Ultraviolet absorption spectra were recorded on a Perkin Elmer Lambda 9 spectrometer interfaced to a Pentium microcomputer. Fluorescence emission spectra and lifetimes were determined using a Photon Technologies Inc. LS-100 spectrofluorimeter, which also enables lifetime determinations by the time-correlated single-photon counting technique. Gas chromatographic (GC) analyses were carried out using a Hewlett–Packard 5890II + gas chromatograph equipped with a conventional heated injector, a flame ionization detector, a Hewlett–Packard 3396A integrator, and a DB1 megabore capillary column (15 m × 0.53 mm; Chromatographic Specialties, Inc.). Mass spectra and GC–MS analyses were recorded on a Hewlett–Packard 5890II gas chromatograph equipped with an HP-5971A mass selective detector and a DB5 fused silica capillary column (30 m × 0.25 mm; Chromatographic Specialties, Inc.). Semipreparative gas chromatographic separations were carried out using a Varian 3300 gas chromatograph equipped with a thermal conductivity detector and a 3.8% UCW982 on 80/100 Supelcoport (24 ft × 0.25 in.; Supelco, Inc.) stainless steel column. Elemental analyses were performed by Guelph Chemical Laboratories, Inc.

2,2,4-Trimethylpentane (isooctane) and hexane were BDH Omnisolv grade and were used as received from the supplier. Acetonitrile (BDH Omnisolv) was distilled from calcium hydride and then further dried by several passages through activated alumina. Methanol, methanol-*O*-*d*, *tert*-butanol, *tert*-butanol-*O*-*d*, glacial acetic acid, acetic acid-*d*, trimethylphenylsilane (**11**), and phenyl(trimethylsilyl)acetylene (**12**) were of the highest purity available, and were used as received from Aldrich Chemical Co. 4′-Trimethylsilylbiphenyl (**13**; mp 49–50°C) (42) and dimethyldiphenylsilane (**14**; bp 99°C (0.75 Torr; 1 Torr = 133.3 Pa) (43)) were prepared by the reported procedures, and purified by recrystallization or vacuum distillation to purities in excess of 99%, as estimated by capillary GC.

1-Phenylsilacyclobutane (**3**) was prepared by lithium aluminum hydride reduction of 1-phenyl-1-chloro-1-silacyclobutane as reported by Bertrand et al. (26). The compound was purified by vacuum distillation (bp 97–100°C/20 Torr (26)), and exhibited the following spectroscopic properties. IR: 2963.0 (m), 2924.0 (s), 2854.2 (s), 2122.6 (m), 1731.4

1-Methyl-1-phenylsilacyclobutane (**4**) was prepared by the method of Auner and Grobe (3), and purified by column chromatography on silica gel using hexane as eluant. The compound was characterized on the basis of the following spectroscopic data. IR: 2963.8 (s), 2856.5 (m), 1428.2 (s), 1396.3 (s), 1249.9 (s), 1115.5 (s), 867.2 (s), 772.1 (s), 732.5 (s), 697.6 (s), 427.7 (s); ^{1}H NMR, δ (ppm): 0.55 (s, 3H), 1.26 (m, 4H), 2.19 (p, 2H), 7.40 (m, 3H), 7.64 (m, 2H); ^{13}C NMR, δ (ppm): –1.8, 14.3, 18.2, 127.9, 129.4, 133.5; MS, *m*/*z* (*I*): 162 (10), 134 (100), 119 (45), 105 (20), 93 (7), 79 (5), 53 (10), 43 (13).

1-Methyl-1-phenylethynylsilacyclobutane (5)

To a cooled (–78°C) solution of phenylacetylene (0.55 mL, 5.0 mmol) in anhydrous ether (20 mL) was added a 1.6 M hexane solution of *n*-butyllithium (3.1 mL, 5.0 mmol). The solution was allowed to warm to room temperature and stirred for an additional 2 h. The solution was recooled to –78°C, and a solution of 1-chloro-1-methylsilacyclobutane (0.48 g, 4 mmol) in dry diethyl ether (10 mL) was added dropwise over ~10 min with stirring. The solution was allowed to warm to room temperature over 12 h, and then hydrolyzed with water (20 mL). The aqueous layer was extracted with ether (3 × 10 mL). The ether extracts were combined and dried over anhydrous magnesium sulfate, filtered, and stripped of solvent to yield a colorless liquid that was purified by silica gel column chromatography using hexane as eluant. The product (0.63 g, 3.4 mmol, 85%) was obtained as a colorless liquid and identified as 1-methyl-1-phenylethynylsilacyclobutane (**3**) on the basis of the following data: IR (neat): 3096 (w), 2970 (m), 2928 (m), 2156 (s), 1488 (s), 1251 (m), 1220 (m), 1121 (s), 879 (s); UV, λ_{max}: 247-nm, $\varepsilon_{248\ nm}$: 78 990 ± 1200 M^{-1} cm^{-1}; ^{1}H NMR, δ: 0.5 (s, 3H), 1.12 (m, 2H), 1.28 (m, 2H), 2.15 (m, 2H), 7.32 (m, 3H), 7.48 (m, 2H); ^{13}C NMR, δ: –0.1, 15.4, 18.4, 92.4, 107.1, 122.8, 128.3, 128.8, 132.0; MS, *m*/*z*: 186 (20), 158 (67), 143 (100), 129 (20), 117 (11), 103 (10), 77 (8), 53 (15), 43 (25); HRMS, calcd. for $C_{12}H_{14}Si$: 186.08647; found: 186.08633.

1-(4′-Biphenylyl)-1-methylsilacyclobutane (6)

Magnesium turnings (6.0 g, 0.25 g-at.) were placed in a 250 mL 2-necked round-bottom flask fitted with a condenser, addition funnel, magnetic stirrer, and gas inlet, and covered with anhydrous ether. A solution of 4-bromobiphenyl (6.38 g, 0.027 mol) in anhydrous ether (100 mL) was then added dropwise, at a rate sufficient to sustain reflux of the reaction mixture (~1 mL/min). To the resulting dark gray reaction mixture was added, dropwise with stirring over 15 min, a solution of 1-chloro-1-methylsilacyclobutane (3.0 g, 0.025 mol) in anhydrous ether (20 mL). The mixture was stirred for a further 16 h at room temperature, the stirrer was removed, and the resulting grey-brown solution was decanted from the suspended magnesium salts into a 500 mL Erlenmeyer flask. Water (200 mL) was added; the mixture was stirred vigorously for 10 min and then placed in a separatory funnel to separate the aqueous and organic layers. The yellow ether solution was washed with water (3 × 25 mL) and dried over anhydrous magnesium sulfate. Evaporation of the solvent on the rotary evaporator afforded an oily yellow solid (5.1 g), whose ^{1}H NMR spectrum was consistent with the desired product **6**. The solid was recrystallized twice from 95% ethanol to yield the product as slightly yellow plates (2.5 g, 0.0105 mol, 42%). A portion of the material (0.2 g) was further purified by column chromatography on silica gel using hexane as the eluant. Three more recrystallizations from 95% ethanol afforded the product as colourless plates (mp 41–41.5°C), which were identified as 1-(4-biphenylyl)-1-methylsilacyclobutane (**6**) on the basis of the following data: IR (neat): 3068.7 (w), 3021.8 (w), 2960.8 (m), 2926.0 (m), 1382.8 (m), 1249.7 (m), 1116.1 (s), 863.2 (s), 757.4 (s), 723.2 (s), 695.9 (s), 653.5 (s); UV, λ_{max}: 257 nm, $\varepsilon_{248\ nm}$: 24 000 ± 2000 M^{-1} cm^{-1}; ^{1}H NMR, δ: 0.58 (s, 3H), 1.22 (m, 2H), 1.29 (m, 2H), 2.17 (m, 2H), 7.53 (m, 3H), 7.65 (m, 6H); ^{13}C NMR, δ: –1.81, 14.37, 18.25, 92.4, 126.58, 127.08, 127.37, 128.71, 133.94, 137.24, 140.93, 142.08; MS, *m*/*z*: 238 (17), 211 (22), 210 (100), 195 (49), 167 (18), 165 (22), 152 (10), 53 (25), 43 (67). Anal. calcd. for $C_{16}H_{18}Si$: C 80.63, H 7.62; found: C 80.60, H 7.80.

Methoxymethylphenylsilane (**15a**) and methoxydimethylphenylsilane (**15b**) were prepared by reaction of methylphenylchlorosilane and dimethylphenylchlorosilane, respectively, with methanol in ether in the presence of trimethylamine (43, 44).

Methoxydimethyl(phenylethynyl)silane (**15c**) was prepared by the method of Corriu et al. (45), and exhibited analytical and spectroscopic data similar to those reported. 4-Methoxydimethylsilyl-4′-biphenyl (**15d**) was identified after isolation from a semipreparative scale photolysis of a deoxygenated solution of **6** (0.24 g, 1 mmol) and methanol (0.4 mL, 10 mmol) in hexane (10 mL), in a quartz photolysis tube with 8 RPR-2537 low-pressure mercury vapor lamps. The photolysis was carried out to ca. 70% conversion of **6** (ca. 5 h). The resulting bright yellow photolysate was stripped of solvent to yield a yellow oil, which was chromatographed on a Florisil column using hexane–dichloromethane mixtures. The product, which was isolated in modest purity (ca. 95% by GC) as a light yellow oil (0.05 g, 0.2 mmol, 20%), exhibited ^{1}H NMR and mass spectral data consistent with its proposed structure: ^{1}H NMR, δ: 0.06 (s, 6H), 3.48 (s, 3H), 7.34–7.53 (m, 9H); MS, *m*/*z*: 243 (5), 242 (27), 228 (21), 227 (100), 197 (31), 181 (8), 167 (9), 165 (11), 152 (10), 59 (21).

Analytical-scale photolyses were carried out using a Rayonet reactor fitted with 4–8 RPR-2537 lamps and a merry-go-round apparatus. Aliquots of hexane or cyclohexane-d_{12} solutions containing **3–6** (0.03–0.04 M) and methanol (0.05 M) were placed in Suprasil quartz cuvettes (3 mm × 10 mm), sealed with rubber septums, and saturated with dry argon. Hexadecane (0.01 M) was included as an internal GC standard for the runs carried out in hexane. The only products detected in these photolyses were ethylene, the corresponding methoxysilane (**15a–15d**), and small amounts of products identified as the corresponding hydroxysilanes on the basis of GC–MS analysis, presumably due to the presence of small amounts of water. The alkoxysilanes were

© 1999 NRC Canada

identified by GC–MS and GC coinjection with the authentic samples. Quantum yield experiments were carried out in similar fashion, simultaneously irradiating solutions of **1** and **4–6** in hexane containing 0.05 M methanol.

Fluorescence emission spectra and lifetimes were recorded on argon-saturated isooctane solutions, whose concentrations were adjusted to yield an absorbance of 0.1–0.2 at the excitation wavelength (245–260 nm). In each case, the fluorescence excitation spectrum matched the UV absorption spectrum in the region above ~240 nm.

Nanosecond laser flash photolysis experiments employed the pulses (248 nm; ca.15–25 ns; 70–150 mJ) from Lumonics 510 or Lambda Physik Compex 120 excimer lasers filled with F_2–Kr mixtures in helium or neon, and a microcomputer-controlled detection system (46). The intensity of the beam was reduced to <10 mJ at the cell using a series of stainless steel wire meshes as neutral density filters. Solutions were prepared at concentrations such that the absorbance at the excitation wavelength was ca. 0.7 (~8×10^{-4} M), and were flowed continuously through a 3 × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir. Nitrogen or oxygen was bubbled continuously through the reservoir throughout the experiments. Solution temperatures were controlled to within 0.1°C with a VWR 1166 constant temperature circulating bath plumbed to a brass sample holder, and measured with a Teflon-coated copper–constantan thermocouple which was inserted directly into the flow cell. Quenchers were added directly to the reservoir by microlitre syringe as aliquots of standard solutions. Rate constants were calculated by linear least-squares analysis of decay rate vs. concentration data (six or more points) that spanned at least one order of magnitude in the transient decay rate. Errors are quoted as twice the standard deviation obtained from the least-squares analysis in each case.

Acknowledgments

We wish to thank the McMaster Regional Centre for Mass Spectrometry for high-resolution mass spectra and exact mass determinations, Tracy Morkin and Nicholas Toltl for technical assistance, and the Natural Sciences and Engineering Research Council of Canada for financial support.

Formation and nucleophilic capture of *N*-nitrosiminium ions

Latifa Chahoua, Alain Vigroux, Yvonne Chiang, and James C. Fishbein

Abstract: A study of the solvolysis of a series of (*N*-nitrosomethylamino)arylmethyl esters and azides and the products of nucleophilic trapping of the corresponding *N*-nitrosiminium ion intermediates in aqueous media, 25°C, ionic strength 1 M is reported. Structure–reactivity data for the forward and reverse reactions have been obtained. In three cases, the rate constants for reactions of the cations with nucleophiles have been measured directly by laser flash photolysis. The data allow a comparison of the degree to which the *N*-methyl-*N*-nitroso functionality enhances cation stability from a thermodynamic and kinetic perspective. It has been possible to deduce that the carbon basicity of azide ion is less than 1 kcal/mol greater than that of acetate ion.

Key words: nitrosiminium ions, α-acetoxynitrosamines, carbocations, iminium ions, nucleophilicity.

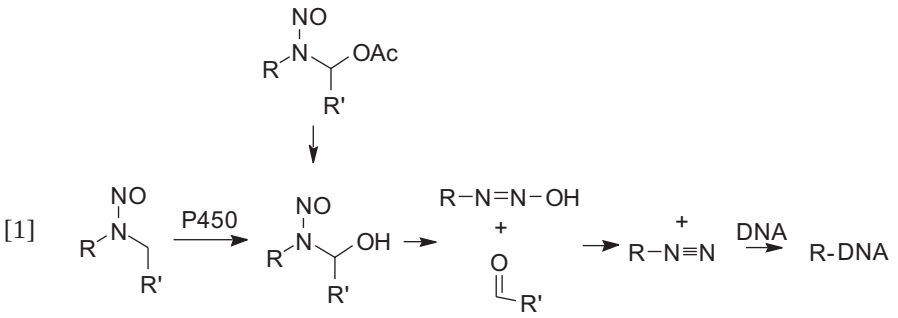
Résumé : On a effectué une étude, en milieu aqueux, à 25°C et à une force ionique de 1 M, sur la solvolyse d'une série d'esters (*N*-nitrosométhylamino)arylméthyles et d'azotures apparentés et sur la nature des produits du piégeage nucléophile des ions intermédiaires *N*-nitrosiminium correspondants. On a obtenu des données relatives de structure–réactivité pour les réactions normales et inverses. Dans trois cas, faisant appel à la photolyse éclair au laser, on a pu mesurer directement les constantes de vitesse des réactions des cations avec les nucléophiles. Les données permettent de comparer à quel degré la fonction *N*-méthyl-*N*-nitroso accroît la stabilité du cation de points de vue tant thermodynamique que cinétique. On a pu déduire que la basicité du carbone de l'ion azoture n'est plus grande que celle de l'ion acétate que par moins de 1 kcal/mol.

Mots clés : ions nitrosiminium, α-acétoxynitrosamines, carbocations, ions iminium, nucléophilicité.

[Traduit par la Rédaction]

Introduction

α-Acetoxydialkylnitrosamines are important in understanding the mechanisms of mutagenesis and carcinogenesis of dialkylnitrosamines (1, 2). They serve as precursors to α-hydroxydialkynitrosmaines that are formed in the activation of dialkylnitrosamines by P-450 enzymes, as illustrated in eq. [1]. Evidence has been summarized that indicates that in the case of most α-acetoxydialkylnitrosamines, formation of the α-hydroxy intermediate occurs by formation of an *N*-nitrosiminium ion that is subsequently hydrated by solvent water, as in eq. [2] (3–6). Some characterization of the kinetic stability of certain of these intermediates has been reported (7), including the photochemical generation and direct determination of reactivity in one case (8). α-Substituted benzylic cations have been relatively well characterized with regard to the effects of substituents on cation stability and selectivity, and it is of interest to understand how the *N*-nitrosomethylamino group compares to others as a cation stabilizing substituent. The present study was undertaken to quantitatively elucidate this cation stabilizing ability in a



Received November 17, 1998.

This paper is dedicated to Jerry Kresge, an outstanding chemist, collaborator, and friend, in recognition of his many achievements in chemistry.

[2] 
benzylic system. In summary, the *N*-nitrosomethylamino group stabilizes the adjacent benzyl cation both kinetically and thermodynamically to an extent that is similar to the stabilization that is provided by an α-azido group. In addition, it has been possible to compare the cation generating reactions involving the acetate and azide precursors and the cation capture reactions by acetate and azide ions, two nucleophiles of very similar proton basicity. An upper limit, of 1 kcal/mol, on the difference in carbon basicity of these two nucleophiles has been derived.

Experimental

Warning! Most α-acyloxynitrosamines are powerful direct acting carcinogens. Manipulations were carried out using frequently changed double pairs of disposable gloves and in the well-ventilated hood. Contaminated, and potentially contaminated, materials were treated with 50% aqueous sulfuric acid containing the commercially available oxidant "No Chromix" (Aldrich Chemical).

Materials

Organic solvents were dried and purified by distillation before use. Organic and inorganic chemicals for synthesis were ACS grade or better. Inorganic chemicals were used without further purification. Organic chemicals were typically purified prior to use in synthesis or kinetic experiments. Water was distilled in glass.

Methods

Kinetics

The kinetics of decomposition were observed using either a Hewlett Packard 8452A diode array spectrophotometer, or an Applied Photophysics DX 17MV stopped-flow spectrophotometer. For compounds **3k** and **4k**, rate constants for the addition of water and azide ion to the nitrosiminium ions generated by KrF laser flash photolysis were measured as described for the unsubstituted compound earlier (8). In all cases, temperature was maintained at 25°C by means of attached recirculating water baths.

The buffer solution in each reaction cell was made up by diluting a concentrated stock buffer solution. Ionic strength of reaction solutions was maintained at 1 M with $NaClO_4$. A stock solution of $NaClO_4$ was added to the cuvette to maintain the ionic strength of 1 M. The buffers that were used include phosphate, MOPS, MES, CHES, acetic acid, cyanoacetic acid, methoxyacetic acid, cacodylic acid, and morpholine.

The stock solution of the nitrosamine was made up in freshly distilled dry CH_3CN. Reactions performed in the stopped-flow spectrophotometer were carried out by mixing 25 parts of the aqueous buffer with 1 part of the nitrosoamine in CH_3CN solution using 2.5 and 0.1 mL syringes, respectively. Final concentration of the nitrosamine in the reactions was ~10^{-4} M.

The pH values were obtained after the kinetic run using an Orion model SA 720 pH meter equipped with a Corning combination electrode. Two point calibrations were done prior to recording pH values. Calibration of the meter was performed using commercially available standards or those prescribed by the *Merck Index* (9).

Product analysis

The products of decomposition under various conditions, vide infra, were quantitated after 10 halflives of reaction of the starting materials. Product quantitation involved either ^{1}H-NMR or HPLC. In the former case, the reactant concentrations were on the order of 0.01 M. In the latter case, concentrations were typically in the range of 10^{-4}–10^{-5} M and utilized a Waters chromatography system with Axxiom data system and Waters Wisp-Ultra autoinjector attached. Separations were carried out with 6:4 acetonitrile/water as eluent over a 15 cm waters C18 column. Quantitation of the products was accomplished using standard curves containing at least two points that were generated from products that were synthesized independently.

A series of experiments were carried out to examine the partitioning of the nitrosiminium ion intermediates between capture by water and alcohols. Reactions were carried out by dissolution of the starting ester in buffer solution that was, by volume, 1% ethanol, 9% other added alcohol, and 90% H_2O, ionic strength 1 M with $NaClO_4$.

Synthesis

Esters, azide ion adducts, and ethers, products of nitrosiminium ion trapping by alcohols, were synthesized and are listed and correspondingly numbered in Table 1.

The α-acyloxynitrosamines **1a**–**7a** and **1b**–**8b** were synthesized using previously published methods (3, 4). Physical data for **2a** and **2b** were reported previously (6). ^{1}H NMR ($CDCl_3$) δ (ppm): **1a**: (*E*) isomer (98%): 8.26 (1H, s), 7.32 (2H, s), 7.01 (2H, s), 3.83 (3H, s), 2.82 (3H, s), 2.24 (3H, s); (*Z*) isomer (2%): 3.57 (3H, s); 2.18 (3H, s); Anal. calcd.: C 55.46, H 5.88, N 11.76; found: C 56.96, H 5.82, N 10.86; **3a**:(*E*) isomer (86%): 8.28 (1H, s), 7.37 (4H, m), 2.8 (3H, s), 2.25 (3H, s); (*Z*) isomer (14%): 3.57 (3H, s), 2.18 (3H, s); **4a**: (*E*) isomer (96%): 8.28 (1H, s), 7.38 (4H, m), 2.80 (3H, s), 2.26 (3H,s); (*Z*) isomer (4%): 3.57 (3H, s), 2.2 (3H, s); **5a**: (*E*) isomer (96%): 8.34 (1H, s), 7.76 (2H, d), 7.53 (2H, d), 2.81 (3H, s), 2.28 (3H, s); **6a**: (*E*) isomer (96%): 8.38 (1H, s), 8.32 (2H, d), 7.61 (2H, d), 2.83 (3H, s), 2.30 (3H, s); (*Z*) isomer (4%): 3.60 (3H, s), 2.24 (3H, s). Anal. calcd.: C 43.32, H 3.61, N 10.11; found: C 43.60, H 3.85, N 9.84; **5b**: δ (*E*) isomer (96%): 8.45 (1H, s), 8.35 (2H, d), 7.65 (2H, d), 4.28 (2H, s), 2.84 (3H, s); (*Z*) isomer (4%): 3.62 (3H, s); **6b**: (*E*) isomer (96%): 8.45 (1H, s), 8.35 (2H, d), 7.65 (2H, d), 4.28 (32H, s), 2.84 (3H, s); (*Z*) isomer (4%): 3.62 (3H, s); **8b**: (*E*) isomer (94%): 8.41 (1H, s), 7.8 (2H, d), 7.6 (2H, d), 4.25 (2H, d), 2.84 (3H, s); (*Z*) isomer (6%): 3.63 (3H, s).

*(*N-*Methyl*-N-*nitroso)arylmethyl azides **1c**–**3c***

α-Chloroacetoxy-*N*-nitrosamine ester (2.4 mmol) was dissolved in a solution (35 mL H_2O/25 mL methanol) containing 1.0 M NaN_3. The solution was stirred at room temperature overnight (for **3c**, we stirred at –10°C for 2 h). A large amount of water was added to precipitate the product. The product was extracted with methylene chloride. The organic layer was dried over $MgSO_4$ and was filtered. Methylene chloride was then evaporated off using a flow of Argon and a warm water bath. Compound **1c** was purified by preparative TLC using 1:7 ether:pentane as the eluting solvent. The crude material of **2c** was washed with pentane to get rid of aldehyde. The purification of **3c** was hampered by the presence of aldehyde, the mixture of crude material was treated with bisulfite in methanol and subsequently purified by preparative TLC using 1:9 ethyl acetate/pentane. ^{1}H NMR ($CDCl_3$) δ (ppm): **1c**: (*E*) isomer (100%): 7.42 (1H, s), 7.33 (2H, d), 6.93 (2H, d), 3.83 (3H, s), 2.82 (3H, s). Anal. calcd.: C 48.84, H 5.01, N 31.7; found: C 49.1, H 5.05, N 31.43; **2c**: (*E*) isomer (94%): 7.44 (1H, s), 7.42 (5H, s), 2.82 (3H, s); (*Z*) isomer (6%): 3.51 (3H, s); **3c**: (*E*) isomer (93%): 7.4 (1H, s), 7.37 (5H, 2d), 2.8 (3H, s); (*Z*) isomer (7%): 3.5 (3H, s). Anal. calcd.: C 42.58, H 3.57, N 31.04; found: C 42.64, H 3.60, N 30.92.

The synthesis of **4c** and **5c** was accomplish using Wiessler's procedure (10), since the method above was not successful. The imines (11) (6.5 mmol) were dissolved in 10 mL of dry methylene chloride and added slowly to NOCl (6.5 mmol) in 20 mL of dry methylene chloride at –30°C. Sodium azide (6.5 mmol), dissolved in 5 mL of DMSO, was added dropwise to the previous mixture. After 5 min, the product was washed with water and extracted with methylene chloride. The organic layer was dried over $MgSO_4$ and was filtered. The methylenechloride was then evaporated off using a flow of Argon. The product was purified by preparative TLC using 0.5:9.5 ether/pentane.^{1}H NMR ($CDCl_3$) δ (ppm): **4c**: (*E*) isomer (91%): 7.4 (5H, m), 7.27 (1H, s), 2.82 (3H, s); (*Z*) isomer (9%): 3.53 (3H, s); **5c**: (*E*) isomer (87%): 7.63 (5H, 2d), 7.5 (1H, s), 2.82 (3H, s); (*Z*) isomer (13%): 3.53 (3H, s). ^{13}C NMR ($CDCl_3$) δ **4c**: 135.5–124.6 (6 pics, Ar), 79.0 (*C*H-N), 27.18 (*C*H_3-N).

The ethers were synthesized by decomposition of an ester in the neat alcohol. Thus, in a typical procedure, the acetoxy or chloroacetoxy compound (1.0 mmol) was dissolved in dry alcohol (4 mL) and allowed to reflux for 16 h. A large amount of water was then added, the product was extracted with methylene chloride, the organic layer was dried over $MgSO_4$, and the solvent was removed under a stream of argon. The crude material was purified by preparative TLC using 1:20 ether/petroleum ether. ^{1}H NMR ($CDCl_3$) δ (ppm): **2d**: (*E*) isomer (96%): 7.34 (5H, m), 6.78 (1H, s), 3.57 (2H, m), 2.68 (3H, s), 1.25 (3H, t); (*Z*) isomer (4%): 3.4 (3H, s). Results

The decay of (*N*-methyl-*N*-nitroso)arylmethyl acetates, chloroacetates, and azides exhibited good first-order kinetics of absorbance decay in the range of conditions studied for 4–6 halflives of reaction. In the case of the azides, the reactions were carried out only in acidic solutions containing 0.01–0.1 M $HClO_4$ in order to prevent nonsimple kinetics of decay due to the formation of azide ion product that could inhibit decay of the starting material due to common ion inhibition. The rate constants k_{obsd} in these cases were independent of the acid concentration, agreeing within experimental error for at least two different acid concentrations that differed by at least a factor of two. In the cases of the esters, the values of k_{obsd} were determined typically at three buffer concentrations for a given buffer ratio and a concentration range between 0.05 and 0.3 M. The values of k_{obsd} in all cases increased less than 10% from low to high buffer concentration, and extrapolation of the plot of k_{obsd} against buffer concentration to the *y*-axis yielded to value of k_1, the buffer-independent, pH-independent rate constant. Determinations of k_1 were carried out in a minimum of two different buffers, typically acetic and cacodylic acids, and the values generally agreed within 10%. The mean values of k_1 for all compounds are reported in Table 2.

For a number of α-acetoxydialkylnitrosamines, the effect on k_{obsd} of increasing acetate ion concentration, while maintaining constant ionic strength (1 M) with $NaClO_4$, was determined. A plot illustrating the effect for a number of compounds is indicated in Fig. 1. The value of k_{obsd} decreases, in all cases measured, to less than 25% the value of k_{obsd} in the absence of added acetate ion. Specific salt effects, due to replacement of sodium perchlorate by sodium trifluoroacetate, have been shown to decrease the value of k_{obsd} by less than 10% at comparable concentrations (6).

To clarify the nature of the reaction that appeared to be acetate independent at very high acetate ion concentrations, a single experiment was run with compound **2a** in which the effect of acetate concentrations up to 1.35 M was determined at an ionic strength of 3 M ($NaClO_4$) in D_2O. The data are plotted in Fig. 2. Product analysis by ^{1}H-NMR of a reaction at completion that originally contained 1.35 M ace-

tate ion in D_2O showed a 12% yield of methylammonium ion. The analysis of these experiments are discussed in more detail later.

The rate constants for reactions of two *N*-nitrosiminium ions with water and azide ion were measured by laser flash photolysis using the *p*-cyanophenyl ethers, as described earlier (8). The decay of absorbance of the cations exhibited clean first-order kinetics for five halflives of decay. Rate constants for decay of the cation were measured in 0.01 and 0.02 M cacodylic acid buffer (50% anion), and the two values of k_{obsd} agreed within 5%. The rate constant for decay of **3k** in aqueous media containing 0.01 M cacodylic acid buffer (50% anion) and 10% by volume trifluoroethanol was identical with that in buffered water within experimental error. The second-order rate constants for reaction of azide ion were taken as the slopes of plots of k_{obsd} against azide ion concentration that contained three points. The rate constants for addition of water to the cations derived from **3k** and **4k** are 1.15 (± 0.1) × 10^6 s^{-1} and 1.35 (± 0.1) × 10^6 s^{-1}, respectively. The rate constants for the addition of azide ion are 2.4 (± 0.2) × 10^9 M^{-1} s^{-1} and 2.8 (± 0.2) × 10^9 M^{-1} s^{-1}, respectively.

Characterization of products and yields were initally performed under various conditions to check the generality of what has previously been reported — these are summarized in Table 3. Decay of the esters gives quantitative yields of the aryl moiety. Analysis by ^{1}H-NMR gives less than quantitative yields of the methyl fragment, likely due to proton exchange of the methyl diazonium ion intermediate that gives rise to the alcohol product (12). An experiment was carried out to quantitate the extent of acetate ion stimulated denitrosation of a nitrosiminium ion; this is discussed later.

A series of experiments was carried out to determine the partitioning of the nitrosiminium ions, derived from chloroacetate esters, between capture by water, ethanol, and a second alcohol, as indicated in eq. [3]. The observed product ratios were corrected for the differences in nucleophile

[3] 
concentrations to give ratios of second-order rate constants, and these are summarized in Table 4.

Studies were carried out to trap the similarly generated nitrosiminium ions by azide ion. A plot of the fraction of azide ion adduct as a function of azide ion concentration is illustrated in Fig. 3. Control experiments establish that there is no measurable effect on the rate constant, k_{obsd}, for the decay of the esters with increasing concentrations of azide ion up to 0.01 M. Plots of k_{obsd} against azide ion concentration containing 4–5 azide ion concentrations between 0.001 and 0.01 M indicate that the value of k_{obsd} at 0.01 M azide ion is less than 10% larger than the intercept extrapolated to 0 M azide ion.

Discussion

Cation formation

Rate constants for the pH independent solvolysis of α-acetoxy, α-chloracetoxy, and α-azido (*N*-nitrosomethylamino)arylmethane amines were measured at 25°C, in aqueous media of ionic strength 1 M ($NaClO_4$) that contained 4%

[a]Rate constants as in eq. [3].

Fig. 3. Plot of the fractional yield of azide ion adduct against azide ion concentration for the reaction of **1b** (squares), **2b** (triangles), **3b** (diamonds), **4b** (circles), and **8b** (inverted triangles) at 25°C, ionic strength 1 M ($NaClO_4$).

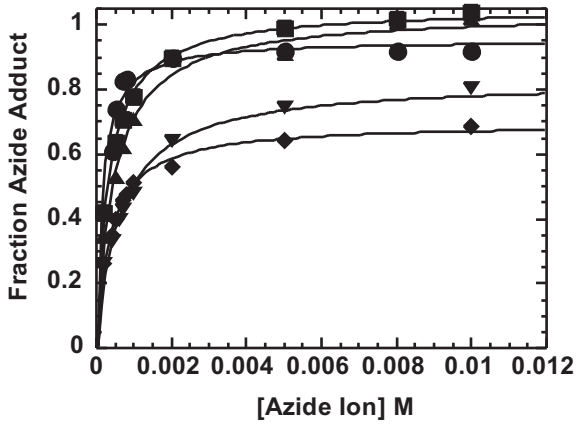

Fig. 4. Plot of log k_1 against σ^+ for the solvolysis of acetates, chloroacetates, and azides at 25°C, ionic strength 1 M ($NaClO_4$).

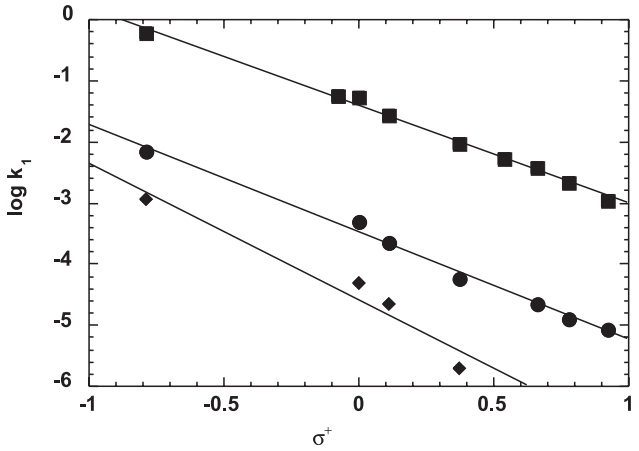

by volume acetonitrile. Figure 4 is a plot of the log k_1 against σ^+. The slopes of the plots are –2.23 (r^2 = 0.949), –1.76 (r^2 = 0.993), and –1.61 (r^2 = 0.994) for the azides, acetates, and chloroacetates, respectively. The uncertainty in the value for the azides is greatest due to the fewer data points, but the slope is likely greater than for the other systems. Inspection of the plot shows that the deviations of the four points in the azide correlation are similar in the esters. A plot of the log k_1 values for the azide (*y*-axis) against those for the same substituents in the acetate series (*x*-axis) is linear with a slope of 1.31 (r^2 = 0.998). Plots of log k_1 against σ give slightly larger slopes of –3.53 (r^2 = 0.834), –1.98 (r^2 = 0.978), and –1.90 (r^2 = 0.988) for the azides, acetates, and chloroacetates, respectively, when the point for the *para*-methoxy substituent is excluded. This point deviates positively from all three such correlations, by 0.3, 0.56, and 0.46 log units for the azides, acetates, and chloroacetates, respectively.

The negative values of the slopes are consistent with positive charge buildup in the transition state for formation of nitrosiminium ion intermediates, as in eq. [2]. These values are considerably smaller than the values of ρ^+ ~–5 for the solvolysis of simple benzylic and phenethyl substrates (13). This is expected due to the substantial resonance stabilizing effect of the *N*-nitrosomethylamino substituent that can donate electrons to the developing electron deficient center in the transition state. Similar smaller values of ρ and ρ^+ have been reported for systems in which there are additional substituents in the α-position that are capable of stablization by resonance electron donation (14).

Cation capture

There have been numerous reports indicating that the dominant reaction of nitrosiminium ions with alcohol, carboxylic acid, and water solvents involves carbon–oxygen bond formation to give α-oxy substituted nitrosamines (3–8, 15–17). That this is the dominant reaction here, at neutral

© 1999 NRC Canada

pH, is confirmed by the data in Table 3. It was recently reported that nitrosiminium ions can undergo denitrosation (7), in particular in the presence of azide ion and a thiolate ion. The last two experiments in Table 3 were carried out as a check on the extent of this reaction with solvent water and dilute (0.05 M) buffer. The yields of methylammonium ion of 7% confirm that there is denitrosation of the nitrosiminium ion in weakly buffered solvent, although it is clearly a minor pathway. The dominant pathway involves the production of methanol by formation of the α-hydroxynitrosamine, which decomposes to the methanediazonium ion that yields methanol. The less than quantitative yield is almost certainly accounted for by proton exchange involving the diazonium ion that occurs to an appreciable extent at this pH in the presence of low buffer concentrations (12). It must be noted that the literature does contain a single report of what appears to extensive denitrosation of a nitrosiminium ion intermediate by solvent (18). Decomposition of the cyclic α-acetoxynitrosamine, eq. [4], in aqueous media gives a 54% yield of myosmine that presumably arises by denitrosation that is competitive with α-carbon–oxygen bond formation.

[4] 
myosmine

The common ion rate depression illustrated in Fig. 1 indicates that acetate ion acts predominantly as a nucleophile at the α-carbon to yield the starting α-acetoxynitrosamine. The effect of acetate appears to diminish at high acetate concentrations such that there is remnant of reaction that is not further inhibited by the addition of acetate ion. This has been reported previously (6) and was analyzed according to the mechanism of eq. [5] in which acetate can react to either

[5] 
regenerate starting material, by k_{-1}^{ac}, or assist formation of the α-hydroxynitrosamine by general base catalyzed addition of water, k_b. An alternative to this scheme would be either nucleophilic attack, or general base catalyzed attack of water, by acetate ion, on the nitrogen of the nitrosiminium ion to yield the imine which subsequently hydrolyzes. This is illustrated in the mechanism of eq. [6].

[6] 
An experiment comparing common ion rate depression in D_2O with the yield of methylammonium ion at high acetate ion concentration indicates that denitrosation of the nitrosiminium ion is a minor pathway. The common ion rate depression of **2a** in D_2O was determined at 3 M ionic strength ($NaClO_4$) at acetate concentrations up to 1.35 M, the data are shown in Fig. 2. The most general mechanism, eq. [6], includes both general base catalyzed addition of water attack at carbon, k_b, and

[a]Values determined from common ion inhibition experiments, constants defined in eq. [5]. Standard errors in parentheses.
[b]$k_{ACO-}/k_{H2O} = k_{-1}^{ac}/k_{H2O} + k_b/k_{H2O}$.

denitrosation via k_n, by whatever mechanism. The rate equation for this mechanism is shown in eq. [7]. The best fit of the data to this equation is shown as the solid line in Fig. 2 for which the following values are used for the given parameters:

$$[7] \qquad k_{obsd} = \frac{k_1}{\left[\dfrac{1}{\dfrac{k_{H_2O}}{k_c[AcO^-]} + \dfrac{k_n + k_b}{k_c}}\right] + 1}$$

k_1 = 0.00051 (± 0.00002), k_{H2O}/k_c = 0.054 (± 0.006), and $(k_n + k_b)/k_{-1}$ = 0.077 (± 0.008). At 1.35 M acetate ion, based on these parameters, 68% of the remaining reaction entails acetate assisted product formation, by $k_b + k_n$. The yield of methylammonium ion at 1.35 M acetate ion was determined by ^{1}H-NMR to be 12%. This represents an upper limit of the part of the acetate ion assisted product formation that involves denitrosation. This 12% is an upper limit because it is assumed that no methylammonium ion is formed in the remaining 38% of the reaction that involves product formation through pathways that are not assisted by acetate ion. Based on this analysis then, less than 18% (= 100 × 12%/68%) of the acetate assisted product formation involves denitrosation, and the remaining 82% must involve general base catalyzed attack of water on the cation, consistent with our original notion eq. [6].

The data on common ion inhibition at 1 M ionic strength in Fig. 1, and that not shown for compound **4a**, were treated according to the mechanism of eq. [6], which ignores the minor denitrosation pathway. The appropriate expression for k_{obsd} is indicated in eq. [8] and best fits to the data in Fig. 1, solid lines were drawn using the values for the parameters indicated in Table 5.

$$[8] \qquad k_{obsd} = \frac{k_1}{\left[\dfrac{1}{\dfrac{k_{H_2O}}{k_c[AcO^-]} + \dfrac{k_b}{k_c}}\right] + 1}$$

The reactivity of azide ion with several cations was also investigated. One method involved the azide ion trapping studies, for which the data are included in Fig. 3. Azide ion proves to be quite effective, with limiting amounts of the azide ion product being reached in the millimolar concentration range. Figure 3 indicates that in two cases the upper limit of the trappable fraction of cation falls well below 1.0. This has been observed previously and ascribed to azide ion stimulated denitrosation that competes with N—C bond formation, as illustrated in the mechanism of eq. [9] (7). There is no clear correlation of substituents with the

limiting fraction of azide adduct. The two substituents with the smallest limiting fractions, the *p*-Cl and *p*-CF_3, are electron withdrawing, but the *m*-Cl substituent of intermediate character between the two gives azide adduct in excess of 90%. The appropriate expression for the fraction of azide adduct (F_{az}) as a function of azide ion concentration is given in eq. [10]. Best fits to the data are indicated by the solid

$$[10] \qquad F_{az} = \frac{1}{1 + \dfrac{k_n^{az}}{k_c^{az}} + \dfrac{k_{H_2O}}{k_c^{az}[N_{3^-}]}}$$

lines in Fig. 3 using values for the parameters that are included in Table 6. The data for k_{N3}/k_{H2O} ($= (k_n^{az} + k_c^{az})/k_{H2O}$) are in reasonable agreement with the ratios obtained from the rate constants that were directly measured for three of the compounds using laser flash photolysis (see Results). The values of k_{N3}/k_{H2O} show a small decrease with increasing electron-withdrawing character of the substituent, the plot of log k_{N3}/k_{H2O} against σ^+ has a slope of –0.44 (r^2 = 0.961, maximum deviation in y = 0.1 log unit).

Based on the quantitative relationships established in Tables 5 and 6 and the directly measured rate constants for reactions of azide and water with the cations, microscopic constants can be calculated that allow a clearer view of the cation stabilizing characteristics of the *N*-methyl-*N*-nitroso moiety. The equilibria of interest appear in eqs. [11] and [12]. A summary of the relevant rate and equilibrium constants appears in Table 7. Rate constants, k_c^{az}, for reaction of azide ion at the α-carbon of the cations with H, *p*-Cl, and *m*-Cl substituents were determined from the rate constants for disappearance of the cations measured by laser flash

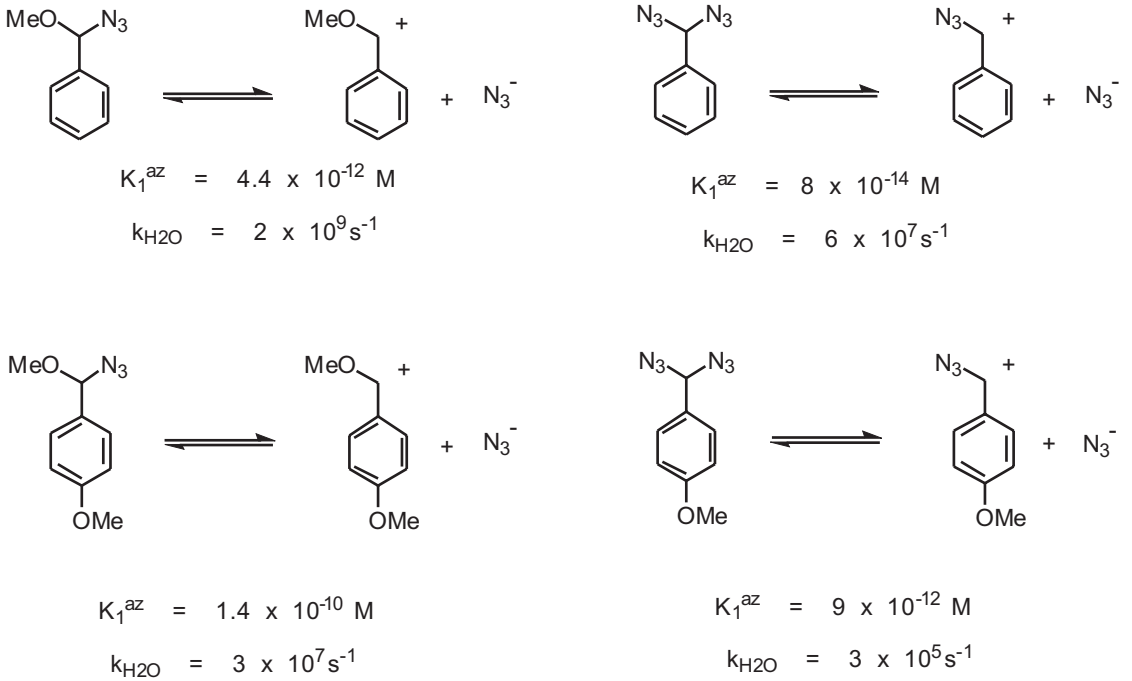
[11] 
[12] 
photolysis and the ratio k_n^{az}/k_c^{az} in Table 6 that were determined from the azide ion trapping analysis. No correction for the reaction of water at nitrogen was made, as this appears to be minimal (vide supra). For the *p*-methoxyphenyl cation, the value for k_c^{az} was calculated from linear extrapolation of the plot of log k_c^{az} against σ^+ for the unsubstituted, *p*-Cl and *m*-Cl compounds. The value of k_{H2O} was calculated from the value k_c^{az} and the appropriate combination of ratios in Table 6. Values for the reaction at carbon by acetate ion, k_c^{ac}, were then determined from the values of k_{H2O} and the values of k_c^{ac}/k_{H2O} in Table 5. The values of k_c^{az} and k_c^{ac} can then be combined with values of k_1 (Table 2) for the decomposition of the azide and acetate adducts, respectively, to give the equilibrium constants for cation formation.

The equilibrium constants for cation formation from the acetates exceed those for formation from the azide, for a given substituent, by a factor of ~1000.

Comparison of some of the values in Table 7 with some previously reported similar numbers for other α-substituted arylmethyl cations is instructive relative to the cation stabilizing ability of the *N*-methyl-*N*-nitroso group. Scheme 1 illustrates the relevant cations and their equilibrium and rate constants for reaction with solvent water (19). As can be

© 1999 NRC Canada

Scheme 1.



seen for both the benzylic and *p*-methoxybenzyl systems, the equilibrium constants for formation of the α-nitrosomethylamino cations are slightly smaller than those for formation of the analogous α-azido cations, right pair in Scheme 1, by less than 1.1 kcal/mol. The equilibrium constants for α-nitrosomethylamino cations are smaller by 3 and 2.7 kcal/mol than the corresponding α-methoxy-benzyl and *p*-methoxybenzyl cations, respectively. Thus, regarding equilibrium stablization, the α-nitrosomethylamino group is the least effective. In contrast, the α-nitrosomethylamino cations are the most kinetically stable of the cations. They react with water with rate constants that are a factor of 80 and 2 slower than the corresponding α-azido-benzyl and *p*-methoxybenzyl cations, respectively; and factors of 10^3 and 40 slower than the corresponding α-methoxybenzyl and *p*-methoxybenzyl cations, respectively.

Amyes and Richard (19) rationalized the contrasting kinetic and thermodynamic effects in Scheme 1 — the smaller rate constants for cation capture of the thermodynamically less stable α-azido cations — as being due to a larger intrinsic barrier for cation capture in the case of the α-azido cations due to loss of more extensive resonance delocalization compared to the α-methoxy cations. The more extensive loss of resonance contributes to a larger intrinsic barrier (20*a*). This explanation appears applicable to the present case. Resonance in the α-nitrosomethylamino cations is similarly more extensive than in the case of the α-methoxy cations, and so, the intrisic barrier for capture may be larger despite the lesser thermodynamic stability of the former cations. It should be noted that not only is there a more extensive loss of resonance stablization in the case of the α-azido and α-nitrosmethylamino compared to α-methoxy cations, but additionally, there is likely the contribution of *re-establishment of resonance delocalization* in the product cation-hydrates that may contribute to the larger intrinsic barriers for capture of the α-azido and α-nitrosomethylamino cations. There is no resonance delocalization involving the α-methoxy group *in the product* of water attack on the α-methoxy cation.

It is surprising that despite the slightly greater stability of the α-azido cations compared to the α-nitrosomethylamino cations, the $\rho_{eq} = -3.8$ for formation of the α-azido cations is more negative than $\rho_{eq} = -2.7$ for the α-nitrosomethylamino cations.[2] These values suggest greater delocalization into the benzene ring in the case of the α-azido system than for the α-nitrosomethylamino system. It is possible that some of the carbocation stabilization in the case of the α-azido cations may arise from the relatively strong N≡N triple bond in the imino-diazonium ion character of one of the resonance forms.[3]

It is notable that the values of k_{H2O} are similar for the comparable α-azido and α-nitroamino cations, given the differences in the functionalities involved. A range of Lewis structures that need to be considered is illustrated in Scheme 2 and highlights important uncertainties suggested by the present results. It is the shift, in going from the cation to the transition state, in the dominance of the various Lewis forms, and the consequent changes in bond lengths and angles, that contributes to the larger intrinsic barrier for capture of the α-azido and α-nitrosmethylamino cations compared to the α-methoxy cations. The structure of the transition state is a weighted average of reactant and product, and probably other, structures. The larger values of k_{H2O} for the α-azido cations than for the α-nitrosmethylamino cations may be due to less resonance delocalization in the α-

[2] We had not initially noted this but it was kindly pointed out by a referee (see ref. 20*b*).
[3] Prof. J. Richard (SUNY, Buffalo) suggested this possibility.

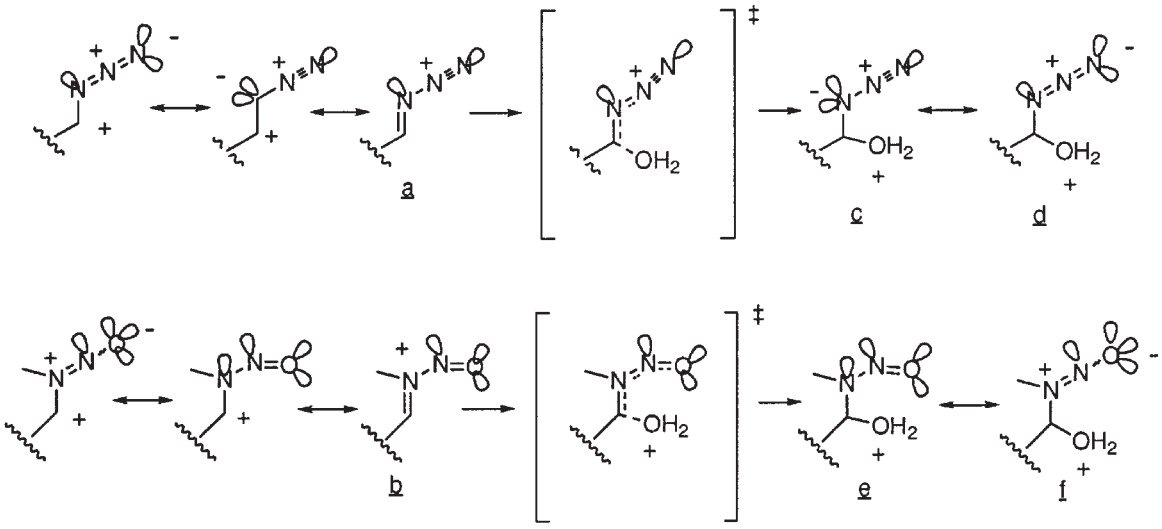
Scheme 2.



azido cation than in the α-nitsosomethylamino cation. This would be consistent with what is expected on the basis of the electron-withdrawing abilities of the diazonium ion and nitroso groups. The value of σ^- is σ^- = 1.46 for the nitroso group, while σ^- = 3–3.4 for the diazonium ion (21). Thus, structure **a** (Scheme 2) should be relatively less important to the total structure of the α-azido cation than structure **b** is to the nitrosomethylamino cation. The smaller resonance stabilization by the α-azido group should give rise to a smaller intrinsic barrier — consistent with the larger rate constants k_{H2O} for capture of these cations by water.

Of the product structures, the contribution of **d** to the total structure of α-azido compound is likely significantly greater than that of **c**; and this difference is likely larger than the difference in contribution of **f** compared to **e** in the α-nitrosamino compound. This deduction is based on the relatively energetically unfavorable unpaired electrons on the anionic nitrogen in **c** compared to those on the amino nitrogen in **e** and on the differences in σ^-, mentioned above. All things being equal, this would suggest more bond length and angle reorganization in going to the transition state for capture of the α-azido cation. This would lead to the expectation of larger barriers for capture of the α-azido cations — opposite the experimental observation. But Scheme 2 shows that the comparison is not simple: the relevant resonance forms have different bond multiplicities and orbital structures in the α-azido compared to the α-nitrosaminomethyl system, and these differences likely impact on the extent of structural reorganization in ground and transition states and in the degree to which this is manifest in the intrinsic barriers. An alternative explanation is that there is relatively little contribution to the transition state of the product-like resonance forms, but this seems unlikely. It is the change from the dominant resonance forms of the cations to the different dominant product-like resonance forms in the transition state that contributes to the larger intrinsic barrier for capture of the α-azido cations compared to the α-methoxycarbocations.

The equilibrium constants for cation formation show only small changes as a function of the substituent on the benzene ring. The values of ρ^+ are –2.41 (r^2 = 0.993) and 2.67 (r^2 = 0.948) for the acetates and azides, respectively. This is considerably smaller than the value of ρ^+ = –9 for the equilibrium formation of 1-phenethyl cations from the chlorides (13, 22). The smaller values of ρ^+ are consistent with considerable resonance donation by the nitrosomethylamino group in the cation that lessens the demand for stabilization of the cation by substituents in the benzene ring. Similar smaller values of ρ^+ are seen in the acid catalyzed formation of oxocarbocations from substituted benzaldehyde diethyl acetals for which ρ^+ = –3.3 (14).

Comparison of the equilibrium constants for the azide and acetate adducts with identical substituents yields information on the differences in carbon basicity between acetate and azide ions. This is because the reaction of azide ion, as well as acetate, with the unsubstituted nitrosomethylamino benzyl cation appears to be significantly activation limited, not simply diffusion controlled. The rate constant for the azide ion reaction was measured directly by laser flash photolysis (8) and the increase in the rate constant for azide ion capture of the *m*-chloro compound shows that the reaction with the unsubstituted compound cannot be diffusion limited. In addition, it was shown (8) that a thiolate nucleophile reacts with the nitrosomethylamino benzyl cation with a rate constant of 2.8×10^9 M^{-1} s^{-1} that is larger than that for azide ion. Further, the rate constant for reaction with azide ion is significantly smaller than the values of $5–7 \times 10^9$ M^{-1} s^{-1} that have been directly measured for the reaction of azide ion with diaryl- and triarylmethyl cations that do not appear to be appreciably less hindered than the nitrosiminium ions studied here (23). The smaller rate constant for the reaction of acetate ion is also smaller than the value of $\sim 5 \times 10^8$ s^{-1}, which represents the upper limit for encounter-controlled capture of cations by acetate ion (24). Thus, the differences, between the acetate and azide adducts, in the equilibrium constants for cation formation reflect the balance of differences in intrinsic carbon basicity and (or) other properties between the two nucleophiles.

The observed differences in equilibrium constants can almost entirely be accounted for by differences in solvation of the acetate and azide anions. This indicates, surprisingly,

© 1999 NRC Canada

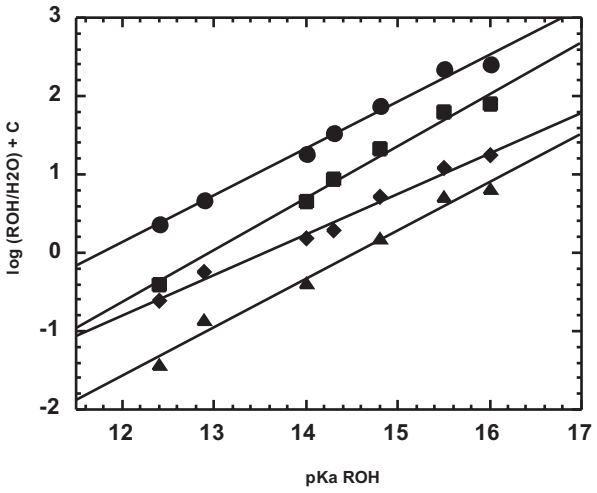
that there is little difference between the carbon basicity of acetate and azide ions. This is most easily understood by combination of the two equilibria for cation formation to give eq. [13] below.

[13] 
Appropriate combination of the two equilibrium constants gives the value of K_{tx} = 1300 for transfer of the carbon fragment between the two nucleophiles, 4.3 kcal/mol in favor of the azide adduct. This preference is a combination of the differences in intrinsic carbon affinity of the two nucleophiles as well as the differences in the strength of solvation of the two anions, and the two neutral species as well. The free energy of transfer from the gas phase to water is larger for acetate ion than azide ion by 6.6 kcal/mol (25). The free energy of transfer from the gas phase to water is larger for acetic acid than hydrazoic acid by 3.3 kcal/mol (25). If is is assumed that there is a similar difference for the acetate adduct compared to the azide adduct in eq. [13], then 3.3 (= 6.6 – 3.3) kcal/mol of the 4.3 kcal/mol for the equilibrium in eq. [13] is due to the stronger solvation of acetate ion than azide ion. This means that the difference between azide ion and acetate ion in intrinsic carbon basicity is on the order of 1 kcal/mol in favor of azide ion. The assumption that the difference in solvation of the neutral species is the same as that for the corresponding neutral acids may be incorrect if some of the difference in the case of the acids is due to stronger hydrogen bond donation by acetic acid than by HN_3. This would make the difference in free energy of transfer of the neutral species in eq. [13] less than 3.3 kcal/mol, which would indicate that a larger fraction of the observed 4.3 kcal/mol for the equilibrium in eq. [13] would be accounted for simply by differences in the solvation of the anions. This makes the calculated difference of 1 kcal/mol between the carbon basicities of azide and acetate ions an upper limit.

The recognition of the important contribution of solvation to the equilibrium in eq. [13] may also account for the unexpected observation that the difference, between acetate and azide ion, in the rate constants for the highly exoergic capture of the cations is larger than the difference, between azide and acetate adducts, in the rate constants for the highly endoergic formation of the cations. Table 7 shows that the ratio, k_c^{az}/k_c^{ac}, is a factor of ~100, whereas Table 2 indicates that the values of k_1 for the azides is only a factor of 10 smaller than the acetates. The requirement for extensive desolvation prior to the small amount of bond formation that likely exists in the transition state for the highly exothermic cation capture reaction could explain the larger difference in reactivity between the two nucleophiles, given the stronger solvation of the acetate ion that exists (vide supra). More facile desolvation of azide ion has been invoked previously to account for the larger limiting rate constants for reaction of azide ion compared to carboxylate ions and amines with carbocations (24, 26).

The reactivities of a series of alcohols with four of the cations was determined in 90% H_2O/1% EtOH/9% ROH solutions, ionic strength 1 M ($NaClO_4$), and show that there is little change in selectivity as a function of the aryl group substituent. This is illustrated in Fig. 5, which plots the alcohol water selectivity as a function of alcohol pK_a. For the *p*-H, *p*-Cl, and *p*-CF_3 substituents, the slopes of the least-squares correlations are 0.62 (r^2 = 0.983), 0.66 (r^2 = 0.989), 0.60 (r^2 = 0.989), respectively. The *m*-Cl substituent, of intermediate electron-withdrawing power, gives the smallest slope, β = 0.52 (r^2 = 0.989). The reason for this apparent anomaly is not understood. The intermediate values of β suggest there is considerable charge buildup on the attacking alcohol, and significant bond formation in the transition state for cation capture by these weak nucleophiles.

Fig. 5. Plot of log (ROH/H_2O) against pK_a ROH for the alcohol–water selectivity of cations from chloroacetates **2b** (circles, C = 1.5), **3b** (triangles, C = 1), **4b** (diamonds, C = 0.5), **8b** (triangles, C=0) at 25°C, ionic strength 1 M ($NaClO_4$), solvent H_2O/EtOH/ROH = 90/1/9.



Notably, Fig. 5 indicates that trifluoroethanol (pK_a = 12.4) behaves as a normal nucleophile for its pK_a, and this contrasts with previous reports. In the capture of 1-phenylethyl cations (24) and oxocarbocations (27), trifluoroethanol is a significantly poorer nucleophile than expected for its pK_a. The reason for the different, "normal" behavior in comparison with other alcohols in the present case is unclear.

1998 Alcan Award Lecture
Surface electrochemistry — surface science with a joy stick[1]

Jacek Lipkowski

Abstract: This lecture gives a review of thermodynamic, spectroscopic, STM and AFM imaging, and X-ray diffraction studies of molecular and ionic adsorption at Au(111) electrodes. In the first part, thermodynamics of adsorption of simple ions such as sulfate, chloride, bromide, and iodide will be discussed. At high coverages, anions adsorbed at a single crystal surface form ordered 2D adlayers. We show that the structure of these adlayers can be studied by STM and surface X-ray diffraction techniques. Next, the information concerning adsorption of simple ions is used to describe mixed adlayers formed by coadsorption of anions and metal adatoms. We demonstrate how to combine electrochemical experiments with in situ polarization-dependent Cu K-edge X-ray absorption spectroscopy to determine the composition and the structure of mixed films formed by deposition of Cu on Au(111) in the presence of SO_4^{2-}. In the last part we review our efforts to describe coordination of organic molecules to gold electrodes. First, we will discuss adsorption of benzonitrile at the Au(111) electrode surface. We combine electrochemical methods with in situ infrared spectroscopy to describe (*i*) the energetics of molecular adsorption at the gold electrode surface, (*ii*) the character of the interaction of the adsorbed molecule with the metal substrate, and (*iii*) the influence of the electric field on the orientation of the adsorbed molecule. In the last section we describe surface aggregation phenomena. We apply AFM and STM to determine the structure of hemimicelles formed at the Au(111) electrode surface by adsorbed molecules of sodium dodecyl sulfate and we discuss the potential-controlled transformation of these hemimicelles into a condensed monolayer.

Key words: surface electrochemistry, electrosorption, surface aggregation, gold electrodes, molecular adsorption, ionic adsorption.

Résumé : Ce travail passe en revue les données thermodynamiques, spectroscopiques, d'imagerie « STM » et « AFM » ainsi que les études de diffraction des rayons X relatives à l'adsorption moléculaire et ionique sur des électrodes d'Au(111). Dans la première partie de ce travail, on discute de la thermodynamique d'adsorption d'ions simples, tels les ions sulfate, chlorure, bromure et iodure. À des couvertures élevées, les anions adsorbés sur une seule surface cristalline forment des couches d'adsorption 2D bien ordonnées. On démontre que la structure de ces couches d'adsorption peut être étudiée par les techniques d'imagerie STM et par diffraction des rayons X par la surface. Ensuite, on utilise l'information relative à l'adsorption d'ions simples pour décrire des couches d'adsorption mixtes formées par coadsorption d'anions et d'atomes métalliques adsorbés. On montre comment on peut combiner des expériences électrochimiques avec la spectroscopie in situ d'adsorption des rayons X Cu à la limite du K dépendante de la polarisation pour déterminer la composition et la structure de films mixtes formés par le dépôt de Cu sur Au(111), en présence de SO_4^{2-}. Dans la dernière partie, on passe en revue les efforts que nous avons faits pour décrire la coordination de molécules organiques sur les électrodes d'or. Nous discuterons en premier lieu de l'adsorption du benzonitrile sur la surface de l'électrode Au(111). On combine les méthodes électrochimiques avec la spectroscopie infrarouge in situ pour décrire : (*i*) les énergies impliquées dans l'adsorption moléculaire au niveau de la surface d'une électrode d'or; (*ii*) le caractère de l'interaction de la molécule adsorbée avec le substrat métallique et (*iii*) l'influence du champ électrique sur l'orientation de la molécule adsorbée. Dans la dernière section, on décrit le phénomène d'agrégation à la surface. On applique les méthodes AFM et STM pour déterminer la structure des hémimicelles qui se forment au niveau de la surface de l'électrode d'Au(111) par les molécules de dodécylsulfate de sodium adsorbées et on discute de la transformation, à potentiel contrôlé, de ces hémimicelles en une monocouche condensée.

Mots clés : électrochimie de surface, électroabsorption, agrégation en surface, électrodes d'or, adsorption moléculaire, adsorption ionique.

1. Introduction

In classical surface science one works in ultra high vacuum (UHV) where the residual pressure is on the order of 10^{-10} Torr (1 Torr = 133.3 Pa). Under that condition, a plethora of photon and electron spectroscopies, electron diffraction, and atom and ion scattering techniques may be employed to study the coordination of atoms and molecules to solid surfaces. The character of adsorbate–substrate and adsorbate–adsorbate interaction can then be investigated in great detail. The two-dimensional ordering in adlayers of adsorbed atoms and molecules may also be interrogated with the help of these techniques. However, systems investigated in UHV conditions are out of equilibrium and the adsorbates have to interact very strongly with the solid surface or the experiments have to be performed at very low temperatures to prevent their desorption into vacuum.

Surface electrochemistry describes phenomena at the electrified solid–liquid interface. The presence of the solvent restricts the number of techniques that may be employed to study surface coordination at electrode surfaces. For years these processes were investigated chiefly with the use of traditional electrochemical methods that measured only macroscopic quantities such as charge, surface concentrations, or surface energies. Surface electrochemistry has gone through a period of scientific and technological revolution in the last decade. New spectroscopic techniques were developed and applied to study interfacial phenomena at the molecular level. Thus infrared reflection spectroscopy may be employed today to study the attachment of ions and molecules to electrode surfaces (1–4). Synchrotron-based X-ray diffraction and X-ray absorption techniques are used to determine long-range and short-range order at the interface (5–8). Electroreflectance (9), second harmonic generation (10, 11), and sum frequency generation (12) spectroscopies are applied to probe the electronic structure of the electrode surface and the molecular dynamics of interfacial phenomena. Finally, last but not least, scanning probe microscopies such as atomic force and scanning tunneling microscopy provide real-time and real-space images of the interface with atomic resolution (13–16). In electrochemistry, these spectroscopic, diffraction, and surface imaging methods are frequently referred to as nontraditional. Today, by a careful combination of traditional and nontraditional methods, one can provide an atomistic picture of interfacial phenomena that does not differ in detail from the picture of surface processes observed in the UHV environment. In contrast to vacuum, surface electrochemistry may be employed to study processes at equilibrium and under ambient conditions. The knowledge gained from these studies is relevant to many other disciplines such as energy storage and conversion, corrosion protection, electroplating and electrolytic production of metals, and biomimetic research, to give a few examples.

In an electrochemical experiment one applies a potential to the electrode and measures the charge flowing to the electrode surface. This charge generates a field on the order of 10^7–10^8 V/m that drives ions and dipolar molecules. By turning a dial on a control instrument one can manipulate the ions and molecules present at the interface. Therefore, electrochemistry provides surface science with a "joy stick" that can be used to force ions and molecules to adsorb or desorb, to form ordered or disordered adlayers, change their surface orientation, spread them into a uniform film, or group them together into surface aggregates.

This review describes our efforts to determine the structure of the electrified solid–solution interface by a combination of electrochemical, spectroscopic, diffraction, and surface imaging techniques. We will present results acquired chiefly with the Au(111) electrode. At the interface with an electrolyte solution, this gold single-crystal plane behaves as a nearly ideal capacitor over a range of potentials exceeding 1 V and the adsorption processes may be investigated over a range of charge densities that spans almost 100 μC cm^{-2}. For other metals, the metal dissolution and hydrogen adsorption/evolution processes restrict this range of potentials and charges significantly. That range of potentials and charges constitutes a tremendous force to control the interfacial phenomena. We will show how to use the "joy stick" to study adsorption of ions, coordination of small aromatic molecules, and surface aggregation of long-chain surfactant molecules. The objective of this review is to show a cross section of our research. Therefore, we will present our own results without giving exhaustive coverage of the literature. This paper is based on a plenary lecture and is addressed to a general reader; a specialist should look to the original literature for technical details.

2. Ionic adsorption and coadsorption at electrode surfaces

2.1 Energetics

We will begin by describing the energetics of ionic adsorption with the help of electrochemical techniques. We have developed an original method based on the measurement of charge at the solid electrode surface (capacitive chronocoulometry) to determine thermodynamic data such as surface concentrations (Gibbs excesses) and Gibbs energies of adsorption. Capacitive chronocoulometry has been applied to study ionic adsorption and coadsorption at gold electrode surfaces. Details of these investigations are described in three recent review articles (17–19). Figure 1 shows representative results of these studies. As an example, the adsorption of sulfate and halides illustrates how the surface concentration of an anion, its Gibbs energy of adsorption, and the charge on the metal vary as a function of applied potential.

The top panel shows changes in the surface concentration of the four anions. The middle panel shows the corresponding changes in the charge density at the metal surface. The data in the middle panel may be used to correlate changes in the surface concentration of anion to the charge density on the metal. The adsorption of anions starts at a negatively charged surface. When the metal surface is negatively charged, the surface concentration of the anion changes slowly with potential so that a long "foot" is seen on the Γ versus E plot. When the charge on the metal approaches zero, the surface concentration of the anion rises steeply. At more positive charge densities changes in the surface concentration of the anion are slow again. We will refer to this section as the quasi-plateau. For halides, the maximum surface concentrations observed at the most positive potentials

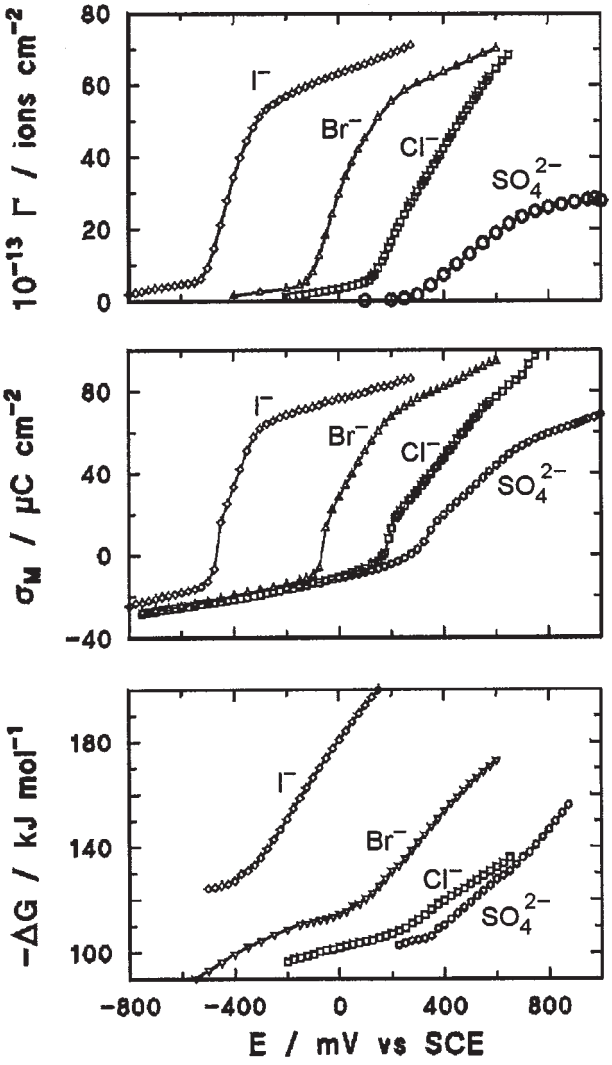
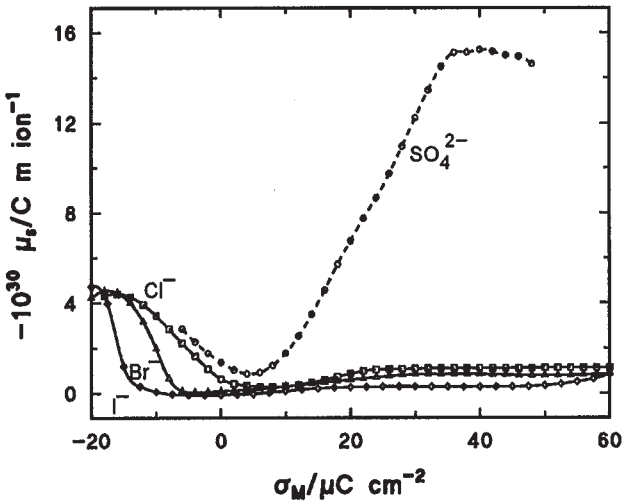
Fig. 1. Comparison of SO_4^{2-}, Cl^-, Br^-, and I^- adsorption at the Au(111) electrode surface from 0.1 M $HClO_4$ + 10^{-3} M K_2SO_4 and 0.1 M $KClO_4$ + 10^{-3} M KCl, KBr, and KI solutions. Top panel, surface concentration versus potential plots. Middle panel, charge density curves. Bottom panel, Gibbs enegry of adsorption. Standard state is an "ideal" Γ = 1 ion cm^{-2} for the surface species and an "ideal" c = 1 mol dm^{-3} for the bulk species (taken from ref. 19).



agree within a few percent with the packing densities, estimated from the van der Waals radii to be 6.3 × 10^{14} ions/cm^2 for iodide, 8 × 10^{14} ions/cm^2 for bromide, 9 × 10^{14} ions/cm^2 for chloride. In contrast to the halides, the maximum measured concentration of sulfate is only about one third of the maximum packing density, estimated on the basis of crystallographic data, to be 6.6 × 10^{14} ions/cm^2. This result indicates that adsorption of sulfate and halide ions has somewhat different character. Within the plateau region, the surface concentrations of anion vary smoothly and do not display discontinuities, indicating that close to saturation the monolayer of adsorbed anion is compressible. We will show later that anions form ordered adlayers at surface concentrations close to saturation. The bottom panel in Fig. 1 shows the Gibbs energy plots. These data demonstrate that the

Fig. 2. Plots of the surface dipole moment of adsorbed anion at the Au(111) surface for (○) SO_4^{2-}; Cl^- (□); Br^- (Δ) (taken from ref. 17).



strength of ionic adsorption increases by moving from sulfate to iodide. The Gibbs energy plots are nonlinear and this nonlinearity suggests that ionic adsorption has a multiple state character and that the nature of the surface coordination changes with potential or with the charge on the metal.

Electrochemical data may be used to calculate the surface dipole (μ_s), which represents a dipole formed by an adsorbed anion and its image charge in the metal. The surface dipole is a good measure of the polarity of the chemisorption bond (20). The dipole moments calculated for sulfate, chloride, and bromide at the Au(111) surface are plotted against the charge on the metal in Fig. 2. The dipole moments for adsorbed anions have negative sign; however, in the following we will discuss their absolute values only. Overall, the values of the dipole moment increase in the order $Br^- < Cl^- < SO_4^{2-}$, indicating that the polarity of the chemisorption bond increases by moving from Br^- to SO_4^{2-}. Apparently, the polarity of the electrosorption bond is a strong function of the charge on the metal. For adsorbed Br^- and Cl^-, the polarity is large at the negatively charged surface, but decreases significantly at positive charges. The very small dipole moment for halides may be a result of charge redistribution due to the mixing of electronic states of the adsorbed anion with electronic states of the metal. In contrast, for adsorbed SO_4^{2-} the polarity of the bond becomes quite large at positive charges. These results confirm that there are significant differences between the adsorption behavior of simple halide ions and this polyatomic oxy-anion.

The electrochemical measurements described in this section provide fundamental knowledge concerning the surface concentration of adsorbed anions, its dependence on charge and potential, the energetics of ionic adsorption, and the polarity of the chemisorption bond. These macroscopic data have to be acquired before imaging, diffraction, or spectroscopic experiments are performed to probe the structure of the interface at the molecular level. Numerous examples in the literature show that without the availability of such macroscopic data the interpretation of experiments performed

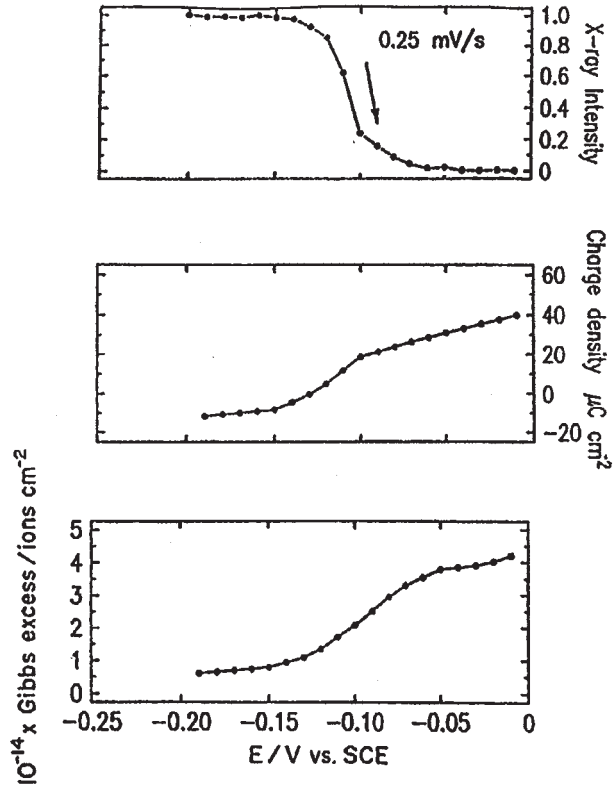
with these advanced techniques may be erroneous, as emphasized by Weaver and co-workers in ref. 21.

2.2 Surface reconstruction phenomena

We will now present structural data to complement the thermodynamic description of ionic adsorption given in the preceding section. Adsorbed anions have a significant impact on the crystallography of the Au(111) electrode surface. The Au(111) electrode surface is known to be reconstructed if it is negatively charged, and the reconstruction is lifted when the metal is charged positively (22, 23). The reconstructed surface has a 4% higher atom density than the unreconstructed surface. The gold atoms in the top reconstructed layer of gold are driven out of registry with respect to the position of atoms in the bulk of the crystal. As a result, the reconstructed surface has a characteristic stripe-like appearance shown in the STM image in the top panel of Fig. 3. When the surface is positively charged, the reconstruction is lifted and the gold atoms relax back into the positions on the

Fig. 4. Potential dependence of: (top panel) integrated scattered X-ray intensity in the vicinity of (–0.044, 1.022, 0.2); (middle panel) charge density at the metal surface; (bottom panel) surface concentration of adsorbed Br^- for Au(111) electrode in 0.1 M $KClO_4$ + 0.01 M KBr (adapted from ref. 24).



truncated 3D lattice, to form a hexagonal structure as shown in the bottom panel of Fig. 3.

The impact of ionic adsorption on the surface reconstruction phenomenon may be conveniently studied with the use of the surface X-ray scattering technique (SXS). In this technique, the gold electrode is pressed against a thin polypropylene foil so that a thin layer of electrolyte (a few micrometers thick) is trapped between the film and the electrode surface. An intense X-ray beam from a synchrotron penetrates the foil and the electrolyte and the X-ray photons diffracted from the surface are detected (6, 19). To determine the charge densities and the surface concentrations of the adsorbed anion at which the reconstruction is lifted, one has to combine the results of SXS experiments with the knowledge of surface charges and coverages determined by electrochemical techniques. This point is illustrated with an example from a collaborative work between groups at Guelph and Brookhaven (24) in which surface X-ray scattering and chronocoulometric techniques were applied to study the lifting of the reconstruction of the Au(111) electrode in the presence of adsorbed Br^- ions.

Figure 4 summarizes the main results of these experiments. The three panels show the potential dependence of (*i*) the integrated intensity of the X ray scattered by the reconstructed surface (top panel), (*ii*) the charge density at the metal (middle panel), and (*iii*) the surface concentration of adsorbed Br (bottom panel). The intensity of the X-ray scattered from the reconstructed surface is a good measure of

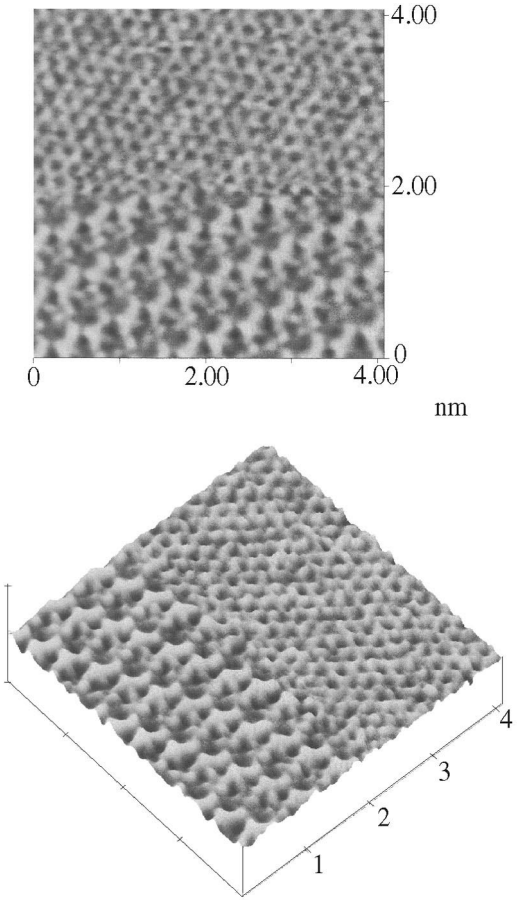
Fig. 5. STM images of the ordered adlayer formed by sulfate adsorbed at the Au(111) electrode surface. Top picture: top view; bottom picture: side view. The image was acquired by recording the bottom part at potential E = 0.9 V vs. SCE, where the ($\sqrt{3} \times \sqrt{7}$) structure is formed, and the top part at potential E = 0.3 V vs. SCE, where sulfate is desorbed and the Au(111) surface is seen. The potential was stepped from E = 0.9 V to E = 0.3 V vs. SCE during the acquisition of the image. 0.5 M H_2SO_4 solution.



the extent of the reconstruction. Below E = –0.15 V the surface is reconstructed and the intensity has a maximum value. This region corresponds to charge densities lower than –8 μC/cm^2 and a surface concentration of Br^- lower than 8 × 10^{13} ions/cm^2. This latter value corresponds to about 10% of the saturated bromide surface concentration of 8 × 10^{14} ions/cm^2. At E = –0.15 V the X-ray intensity begins to drop and by E = –0.095 V it has only 20% of its original value. In this range, the charge density has increased to +20 μC/cm^2 and the surface concentration has risen to 2 × 10^{14} ions/cm^2. This latter value corresponds to one quarter of the saturated bromide surface concentration. Apparently, the lifting of the reconstruction spans a potential range of about 60 mV, where the surface charge changes from –10 to 20 μC/cm^2 and bromide coverage increases from 10 to 25% of its saturation value. Since the changes of charge are paralleled by a significant increase in the surface coverage by adsorbed bromide, it is difficult to establish whether the reconstruction is lifted by surface charge or by bromide adsorption.

The above studies demonstrate that the structure of the Au(111) surface changes with potential, charge, and coverage. At negative charge densities and low surface coverages, ions are adsorbed at the reconstructed surface, while at positive charges and high coverages the data represent adsorption at the unreconstructed (1 × 1) substrate. The structural transformation takes place around the potential of zero charge (pzc) at the metal. The pzc is located at the fast rising section of the surface coverage versus potential plot shown in Fig. 1. This behavior is representative for all anions. In general, the adsorption of anions (particularly halides) assists in lifting the reconstruction of the Au(111) surface.

2.3 Structure of the ordered adlayers

It is now well established that adlayers of adsorbed anions are disordered (mobile) up to coverages of about 94% of the saturated value (25). At higher coverages, the formation of ordered two-dimensional structures is observed. These ordered adlayers are formed at the unreconstructed (1 × 1) gold surface. All three halides form uniaxial-incommensurate $c(p \times \sqrt{3})$ structures, which in the case of iodide is transformed into the rotated-hexagonal structure at higher coverages (25). These structures are electrocompressible and the spacing between the adsorbed species decreases continuously with the electrode potential. The electrocompressibility of these adlayers is responsible for the linear variation of the coverage with potential, seen earlier in Fig. 1, in the upper portion of the surface–concentration plots. The incommensurate character of the overlayer structure indicates that the halide–gold bond does not have a well-defined directionality and can not be described in terms of singular values of bond length, bond angle, and coordination number.

An interesting case that has been debated extensively in the literature is the structure of the ordered adlayer formed by adsorbed sulfate ions. Figure 5 shows an STM image of the ordered sulfate ions adsorbed at the Au(111) surface at the positive end of potentials, near the onset of gold oxidation. The top image shows the top view while the bottom image shows the side view of the superstructure. Similar structures were observed at Pt(111) (26, 27), Ru(111) (28), and Cu(111) (29) electrodes. The model of this structure and the interpretation of the STM images evolved with time. The first STM images for the ordered sulfate adlayer, reported by Magnussen et al. (30), were interpreted as images of hydrogen-bound bisulfate corresponding to a total coverage of 0.4 ML (where 1 ML coverage (ML = monolayer) corresponds to the surface concentration of gold atoms at an ideal Au(111) surface, 1.39 × 10^{15} atoms/cm^2). However, chronocoulometric measurements performed at Guelph and radiochemical experiments at Urbana, Ill. (31), subsequently demonstrated that the adsorbed species is sulfate, not bisulfate, and that the limiting sulfate coverage amounts to only 0.2 ML. Weaver and co-workers (32) performed additional STM and FTIR studies of this system and, to reconcile the results of the chronocoulometric and STM measurements, proposed a model in which hydronium ions are incorporated into the ($\sqrt{3} \times \sqrt{7}$) network. This model was further developed by Itaya and co-workers (28), who incorporated hydrogen-bonded water chains into the ($\sqrt{3} \times \sqrt{7}$) network of adsorbed sulfate. The Itaya model was recently refined by Ataka and Osawa (33) with the help of additional information extracted from IR spectroscopic experiments. This is therefore a case where the availability of precise

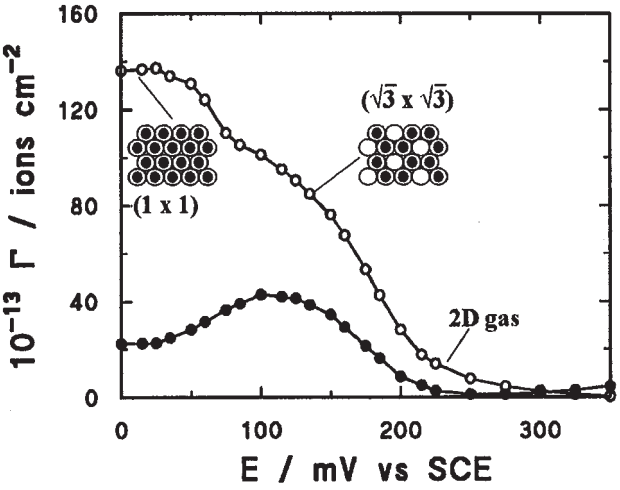
Fig. 6. Surface concentration of copper and sulfate at the Au(111) electrode surface from 0.1 M $KClO_4$ + 10^{-3} M $Cu(ClO_4)_2$ + 10^{-3} M K_2SO_4 + 10^{-3} M $HClO_4$ solution. Open points: surface concentration of copper; solid points: surface concentration of sulfate. The cartoons show schematically the structure of Cu adlayer (taken from ref. 34).



electrochemical data forced the reinterpretation of structural information obtained by STM. It elegantly illustrates the point that a modern description of the solid–solution interface requires concerted use of both electrochemical and nonelectrochemical (imaging, diffraction, spectroscopic) techniques.

2.4 Mixed adlayers form by anions coadsorbed with copper adatoms

Anions are known to form mixed overlayers with copper adatoms, electrodeposited from a solution onto a surface of a foreign substrate. The two-dimensional ordering of copper adatoms is significantly affected by the presence of coadsorbed anions. Our major contribution to this field has been to develop a method of measuring the surface composition of these mixed adlayers (34–36). Knowing the surface concentrations of copper and anion, we were able to give a new interpretation to the STM data published in the literature. We will illustrate this point with the example of coadsorption of sulfate and copper at the Au(111) electrode surface. This system has been investigated by so many surface-specific techniques that it may be considered as the touchstone of surface electrochemistry.

The surface composition of this mixed adlayer is shown in Fig 6. In the presence of SO_4^{2-}, the copper deposition starts at potentials where the initial surface concentration of the anion is very small. The surface concentration of sulfate increases quickly with the copper coverage until a maximum is reached at a potential where the copper coverage is 2/3 ML. The maximum sulfate concentration corresponds to 1/3 ML. At that point the sum of the surface concentrations of copper and sulfate is equal to 1 ML. When the copper coverage increases above 2/3 ML the surface concentration of sulfate decreases to reach a limiting value of 1/6 ML at a copper coverage of 1 ML. At the same time the surface concentration of adsorbed copper becomes equal to the surface concentration of gold atoms. It is now well established that this adlayer consists of an epitaxial (1 × 1) monoalyer of Cu atoms and that the sulfate ions are adsorbed on top of the copper layer (37).

The structure corresponding to the surface concentration of copper 2/3ML and sulfate concentration 1/3 ML has been the subject of a major controversy. The STM image of the long-range structure of this adlayer is shown in Fig. 7. Similar STM images of this structure have been published before (37–42). Anions were believed to be invisible to STM and hence the images were interpreted as showing copper adatoms. This interpretation implies that copper coverage is 1/3 ML. In contrast, surface concentrations determined by electrochemical techniques and shown in Fig. 6 gave the copper coverage 2/3ML. To explain these discrepancies, we proposed (34) that, in agreement with the statistical model by Hackaby and Blum (43), the structure of the mixed overlayer corresponds to a honeycomb ($\sqrt{3} \times \sqrt{3}$)R30° lattice of Cu atoms, as shown schematically in Fig 6. We have also suggested that the STM/AFM images are images of sulfate rather than copper atoms.

To determine the location of the sulfate ions in the mixed adlayers we performed complementary X-ray absorption experiments at the Cornell High Energy Synchrotron Source (CHESS) (18, 44, 45). This was a collaborative work with T. Tyliszczak and A. Hitchcock from McMaster University. For the X-ray absorption spectrum of the mixed 2/3ML copper and 1/3ML sulfate adlayer, we performed FEFF 6.01 multiple scattering calculations using different models of the mixed adlayers. The calculations were carried out assuming a constant framework of Cu adatoms arranged in a ($\sqrt{3} \times \sqrt{3}$)R30° lattice and various positions of the sulfate ions. The spectra were calculated for sulfate ions turned either with one oxygen atom toward the centers of the honeycombs and the three other oxygens toward the solution or with three oxygens toward the honeycombs and one oxygen toward the solution. The calculations were carried out by positioning the sulfate ion in front of the honeycomb center and moving it in and out of the plane of copper atoms, in the direction normal to the surface. The experimental and calculated extended X-ray absorption fine structures (EXAFS) of these spectra are compared in Fig. 8. Here, the EXAFS spectra plot the normalized modulation of the absorption coefficient for copper atoms on the surface versus the wave vector defined as $k = \sqrt{[2m(h\nu - E_0)]}/h$, where $h\nu$ is the photon energy, E_0 is the energy of the absorption edge, and m is the electron mass. The characteristic oscillations of the normalized modulation of the absorption coefficient are caused by the scattering of photoelectrons emitted by the absorber (copper atom) from atoms present in its coordination shell. A good match between the measured and simulated spectra was observed only when (*i*) the three oxygens of the sulfate ion were directed towards the empty center of the honeycomb; (*ii*) the sulfate ion was moved above the plane of copper adatoms so that the bond angle between the oxygen and copper atoms is equal to 45°; (*iii*) each of the three oxygen atoms of the sulfate ion were coordinated to two copper atoms of the honeycomb. This model is presented in Fig. 9 (18, 44). Independently, the IBM group (46) proposed an essentially identical model on the basis of surface X-ray scattering experiments. Therefore, the XAS and SXS studies confirmed that STM and AFM images determined for this system are images of sulfate ions rather than copper atoms.

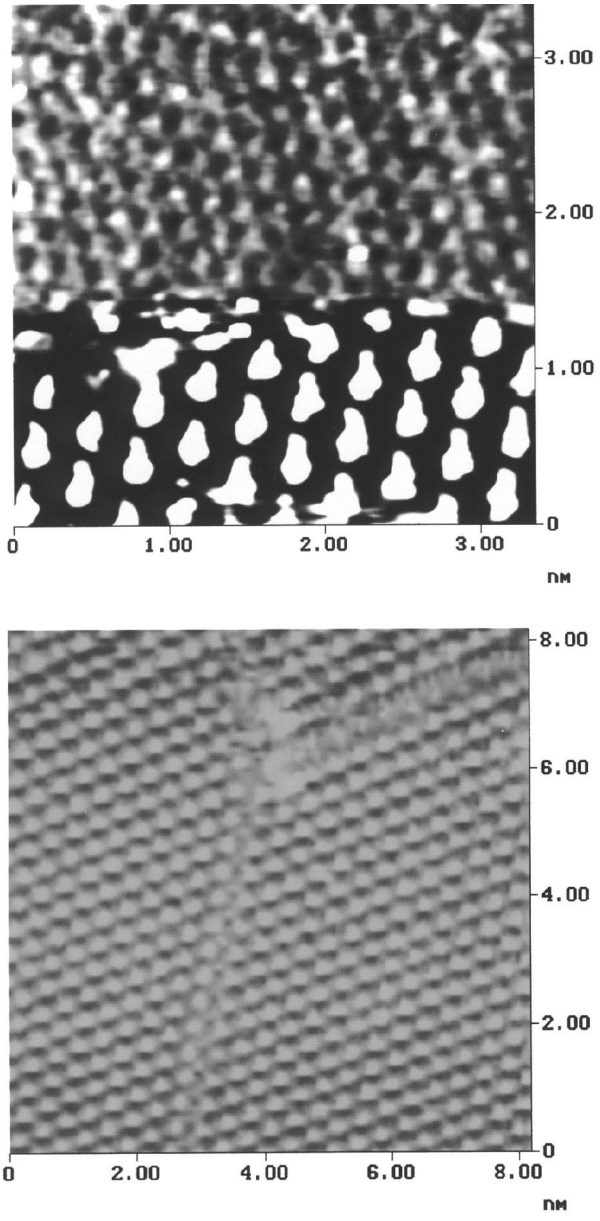
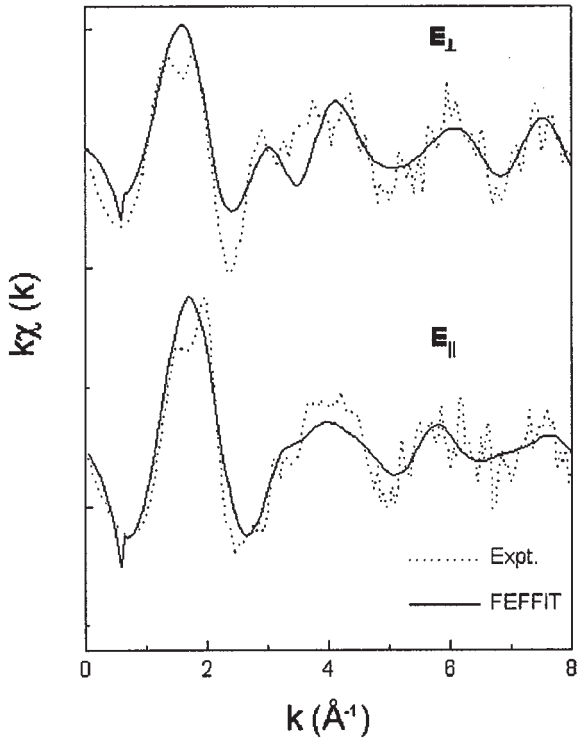
Fig. 7. STM images of the mixed adlayer formed by copper atoms (2/3 ML) coadsorbed with sulfate (1/3 ML) at the Au(111) electrode surface. The top image was acquired by recording the bottom part at potential E = 0.1 V vs. SCE, where the ($\sqrt{3} \times \sqrt{3}$)R30° structure is formed, and the top part at potential E = 0.3 V vs. SCE where copper and sulfate are desorbed from the electrode surface. That section of the image reveals the hexagonal structure of the unreconstructed Au(111) surface. The potential was stepped from E = 0.3 V to E = 0.1 V vs. SCE during the acquisition of the image. 0.1 M $KClO_4$ + 10^{-3} M $HClO_4$ + 10^{-3} M K_2SO_4 + 10^{-3} M $Cu(ClO_4)_2$ solution. The bottom image shows a long-range order for the ($\sqrt{3} \times \sqrt{3}$)R30° structure formed at E = 0.1 V vs. SCE.



3. Surface coordination of organic molecules

A significant fraction of our efforts has been directed to the study of the coordination of organic molecules to metal electrode surfaces. Similar to the case of ionic adsorption, our strategy involved a concerted use of electrochemical methods to provide a macroscopic description of organic molecules at metal surfaces in terms of surface concentrations and Gibbs energies of adsorption, in addition to the use of spectroscopic and diffraction techniques to probe the nature of the surface coordination bond and the effect of adsorbed molecules on the electronic and crystallographic structure of the metal. Our research has focused chiefly on adsorption at gold electrodes. The results of the thermodynamic studies were described in two reviews (47, 48). Investigations of the effect of molecular adsorption on the electronic and crystallographic structure of gold single crystal electrodes by second harmonics generation are published in refs. 49–51, and by UV–visible electroreflectance are described in refs. 52 and 53. Recent surface X-ray scattering studies of the impact of organic molecules on the reconstruction of the Au(111) surface are presented therein (54, 55). Finally, we employed external reflection Fourier transform infrared (FTIR) spectroscopy to study the orientation of organic molecules at the Au(111) electrode surface (56, 57).

Fig. 8. Comparison of the experimental k weighted EXAFS $k\chi(k)$ (dotted line) with the calculated EXAFS (solid line), for the honeycomb ($\sqrt{3} \times \sqrt{3}$)R30° structure of copper and sulfate coadsorbed on the Au(111) surface (taken from ref. 18).



We have learned that FTIR spectroscopy is perhaps the most useful non-electrochemical method for studying the coordination of organic molecules to the surface of a metal electrode. The adsorption of organic molecules frequently has a dissociative character. The dissociation of the molecule at the electrode surface may be assisted either by the formation of the surface coordination bond or by the high electric field present at the interface. The dissociative or non-dissociative character of molecular adsorption can easily be determined with the help of the FTIR technique. We would

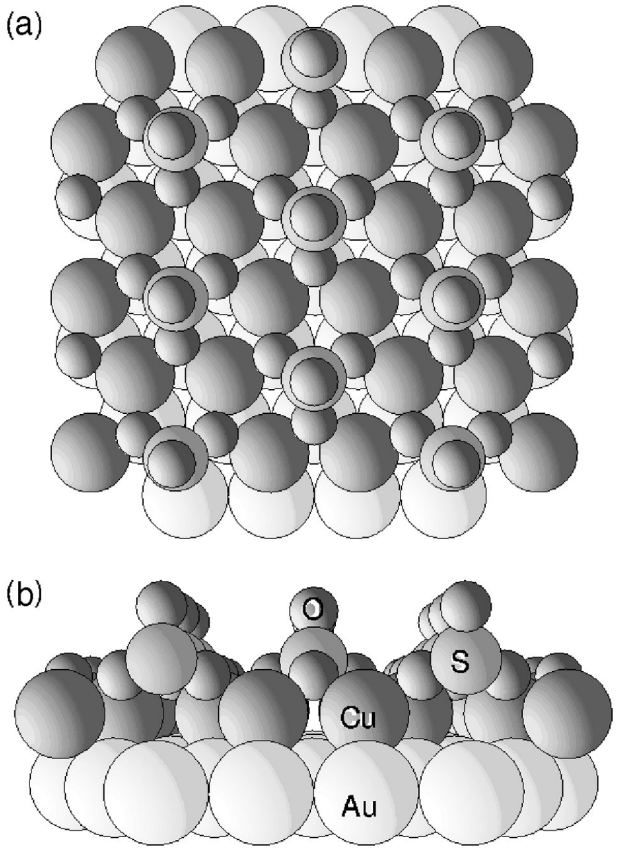
Fig. 9. Model for the honeycomb ($\sqrt{3} \times \sqrt{3}$)R30° structure of copper and sulfate coadsorbed on the Au(111) surface: (*a*) top view, (*b*) side view(taken from ref. 44).

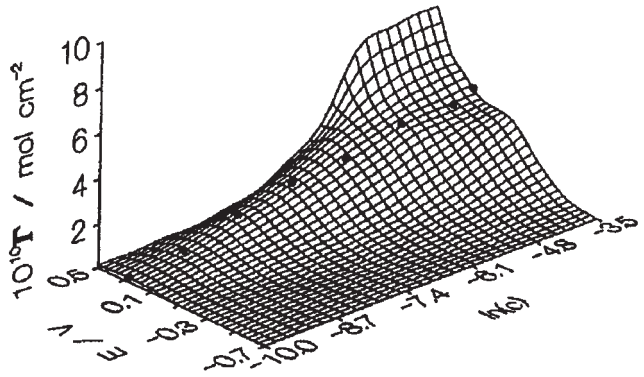


like to illustrate this point with the example of benzonitrile (BN) adsorption at the Au(111) surface. In the preceding sections, we have presented a few cases where the availability of quantitative thermodynamic data caused a reinterpretation of the results of spectroscopic or surface imaging experiments. The adsorption of BN at gold is an opposite example. FTIR studies of this system changed the interpretation of the thermodynamic data (57).

Figure 10 shows the surface concentration of BN at the Au(111) electrode surface plotted as a function of electrode potential and bulk BN concentration in 3D coordinates. The black points overlaid on these plots show the position of the pzc over the range of BN concentration studied. The adsorption isotherm displays a well-defined plateau at potentials around the pzc. The surface concentration corresponding to the plateau region is very close to the maximum packing density for adsorbed flat (π-bonded) molecules estimated to be 0.35 nmol cm^{-2}. At potentials higher than the pzc and bulk BN concentrations higher than 10^{-3} M the surface concentration increases above the plateau value. We initially interpreted this increase of the surface concentration as a potential-induced reorientation of adsorbed BN molecules from the π-bonded to the vertical N-bonded surface coordination (58).

More recently, we employed external reflection FTIR spectroscopy to verify this interpretation (57). Figure 11 compares the transmission spectrum of pure BN with the reflection spectrum recorded for the bulk BN concentration

Fig. 10. Three-dimensional plot representing the adsorption isotherms determined as a function of the electrode potential for BN adsorbed on the Au(111) electrode surface. The dots shown on the plots correspond to the position of the potential of zero charge (taken from ref. 58).



and the electrode potential corresponding to the far right corner of the isotherm in Fig 10. In reflection FTIR spectroscopy one measures electrode reflectivity at the potential at which the molecules are adsorbed at the electrode surface (E_2) and at the potential at which the molecules are desorbed from the electrode surface into the thin-layer cavity (E_1). The spectrum that is plotted is then the normalized difference between the reflectivities at E_2 and E_1. This technique is known as subtractively normalized interfacial Fourier transform infrared spectroscopy (SNIFTIRS). The SNFTIRS shows the difference between the IR spectra for molecules in solution and at the electrode surface. For these reasons the SNIFTIRS spectrum in Fig. 11 displays bipolar features. The bands that are directed below the background line (negative bands) correspond to IR absorption by adsorbed molecules, and the bands that are directed above the background (positive bands) correspond to IR absorption by molecules desorbed into the thin-layer cavity. Apparently, the bands in the SNIFTIRS do not match the bands in the transmission spectrum of pure BN. That behavior suggests that adsorption of BN has a dissociative character at positive potentials. It is well known that nitriles may be easily hydrolyzed to amides according to the reaction scheme shown at the bottom of Fig. 11. It is therefore likely that at positive potentials BN molecules are converted into benzamide (BA) as a result of a surface-catalyzed reaction.

To test this hypothesis, Fig. 12 compares transmission spectrum for pure BA with the SNIFTIR spectra for 0.03 M solutions of BA and BN, respectively. This time the fingerprint of the SNFTIR spectrum for BA matches the transmission spectrum for pure benzamide. Significantly, the shape of the SNIFTIR spectrum for benzonitrile resembles the spectrum for benzamide. This result confirms that at positive potentials and higher bulk concentrations, the adsorption of benzonitrile at the Au(111) electrode surface has a dissociative character. By careful analysis of the evolution of the SNIFTIR spectra with the electrode potential we were able to demonstrate that, at the negatively charged surface, BN adsorption has a nondissociative character. At negative charge densities, the adsorbed molecules are adsorbed flat, π-bonded to the metal. When the potential and charge are moved in the positive direction (the potential approaches the

pzc) the BN molecules progressively reorient to assume a tilted N-bonded coordination and the tilt angle increases. At the positively charged surface the hydrolysis of benzonitrile begins and benzamide is formed. In this case, by a combination of thermodynamic and spectroscopic techniques, we were able to determine not only the composition of the interface but also the changes in the character of surface coordination of BN caused by a change of the electrode potential.

4. Surface aggregation phenomena

Investigations of the adsorption of amphiphilic and ionic surfactants at electrode surfaces constitute another important direction of our research. Surfactants are ubiquitous in our daily activities and find use in a host of technologies. Knowledge of the forces that control the assembly of surfactant molecules at the solid–liquid interface is vital for such traditional fields as detergency, flotation, oil recovery, and tribology (59). Thin organic films deposited at solid surfaces also find application in the fabrication of optoelectronic devices, sensors, biosensors, and chemically modified electrodes (60). Monolayers and bilayers of phospholipids deposited at solid supports are used as models of biological membranes in biomimetic research (61, 62).

Electrochemistry provides a unique opportunity to study the assembly of amphiphilic and ionic surfactants at electrode surfaces and to investigate the influence on surface aggregation phenomena of the charge at the metal. We have extensively studied the mechanism by which the long-chain surfactant molecules that are spread at the gas–solution (GS) interface in a Langmuir trough can be transferred onto the solid–solution interface of a metal electrode (metal–solution interface (MS)). We have developed an original technique in which a Wilhelmy plate (WP) is used to measure the film pressure of surfactant spread at the GS interface while the film pressure at the MS interface is simultaneously determined using in situ electrochemical methods (63–65). Using this technique, we have demonstrated that the transfer of the insoluble monolayer from the GS onto the MS interface can be investigated quantitatively. We have also employed elastic light scattering experiments and UV-visible and fluorescence spectroscopies to study how the film of surfactant molecules behaves over a wide range of potentials and charge densities applied to the metal side of the interface (66–69).

Figure 13 summarizes the main results of our research on the adsorption of 4-pentadecyl-pyridine (C_{15}-4-Py) at the Au(111) electrode surface. The metal–electrolyte interface behaves as a capacitor. Adsorption of an organic molecule

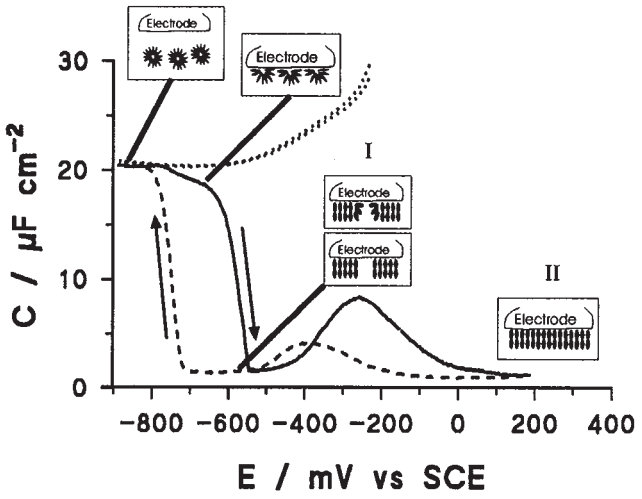
Fig. 13. A schematic of the proposed mechanism for the adsorption/desorption of a flm of insoluble surfactants from/to the Au electrode (taken from ref. 68).



decreases the interfacial capacity. In Fig. 13, the change in the differential capacity is used to show how the structure of the film changes with the electrode potential. The cartoons depict the various states of the surfactant molecules. The dotted line represents the differential capacity of the film-free electrode. At potentials near the pzc (E = 270 mV), the surfactant spreads to form a condensed film. This could be seen as a significant decrease of the capacity. When the potential becomes more negative the capacity increases somewhat. Here, the film becomes less ordered and the organic layer is either porated or surface aggregates are formed, a prelude to desorption that occurs at the most negative potential. When the organic molecules desorb from the surface, the capacity of the electrode initially covered by the film becomes equal to the capacity of the film-free interface. Light scattering and fluorescence quenching experiments demonstrated that, at this potential, the surfactant exists as an organized structure (micelles) near the electrode surface. Interestingly, these organizations do not diffuse away from the interface and are easily readsorbed when the potential is made less negative.

When the direction of the change of potential is reversed, re-spreading of the aggregates occurs. Initially, the micelles adhere to the metal surface and form hemimicelles. The shape of the hemimicelles is controlled by the magnitude of the contact angle. The contact angle changes from 90° to 0° as the electrode potential becomes more positive and the film pressure increases. This progressive change in the contact angle explains a progressive quenching of light scattering and fluorescence within the potential range in which hemimicelles are formed (66–68). When the contact angle is large, the hemimicelle-covered electrode surface is rough and scatters electromagnetic radiation. In addition, a significant fraction of the surfactant molecules contained in a hemimicelle is sufficiently far from the metal surface so that their fluorescence is not quenched. When the contact angle decreases, the surface becomes smoother and the surfactant molecules come closer to the electrode surface. The light scattering decreases and the fluorescence is quenched. At potentials close to the pzc, the hemimicelles spread onto the metal surface to form initially a loose, and later a more ordered, film. The desorption/spreading of surfactants has similarities to the potential-dependent spreading of oil droplets onto the Hg electrode surface described recently by Zutic and co-workers (70–72). In addition, it has also been demonstrated that the so-called reductive desorption of self-assembled monolayers of thiols involves formation of micelles in the subsurface region (73, 74). It appears that all these phenomena may be described by a common model.

We provided a very convincing argument in support of the above mechanism when we succeeded in imaging hemimicelles of sodium dodecyl sulfate (SDS) and in spreading these hemimicelles into a condensed film with the help of AFM and STM microscopies (75). The adsorption of SDS at solid surfaces has long attracted the attention of the surface science community. Direct atomic force microscopy images of surface aggregates of SDS at graphite (76–79) and gold (80) surfaces have recently been published. These images were acquired without any potential control. The coupling of electrochemistry with AFM and STM imaging was accomplished in our laboratory and we have succeeded in providing the first direct visualization of the potential-controlled transformation of hemimicellar aggregates of SDS into a condensed film at the Au(111) electrode surface. Figure 14 shows an STM image of the SDS covered gold surface at a potential close to the pzc of the Au(111) electrode surface. The image shows a characteristic pattern of stripes arranged in domains rotated by 60° or 120°. The stripes have a periodicity of 4.5 ± 0.5 nm, which is close to the dimensions of a micelle of SDS in the bulk of the solution. The image shows that the gold surface is covered by a number of gold islands of monoatomic height. The adsorbed SDS molecules form the stripe-like aggregates on the top of these islands as well. They are not visible in the black and white image shown in Fig. 14, but they can be seen in color images available in the electronic version of ref. 75.

Figure 14*b* shows a high-resolution image of the stripes. This image reveals an ordered array of individual SDS molecules at the edge of the stripes and a frizzy interior of the stripes. Apparently, the surfactant molecules are immobilized at the edge of the stripe while they are relatively mobile in the stripe interior. The molecules belonging to the edges of two neighboring stripes are apparently correlated so that the border between the two stripes has a characteristic zipper-like appearance. The distance between the spots on the rim of a stripe amounts to 5 ± 0.5 Å and the distance between spots belonging to the nearest rims of the zipper amounts to 7 ± 0.5 Å. These dimensions correspond well to the size of the so called ($\sqrt{3} \times \sqrt{7}$) structure formed by sulfate adsorbed at the Au(111) electrode surface and shown earlier in Fig. 5. In fact, one can easily see that the positions of SDS molecules belonging to different zippers are also correlated to the extent that the adsorbed molecules form a long-range two-dimensional lattice. A unit cell of this lattice consists of two vectors that are 4.4 and 0.5 nm long and are oriented at an angle of 70°. We used this lattice to build a model of the hemimicelle, shown in Fig. 15. In each unit cell, we placed two flat-lying SDS molecules that are stretched out along the longer axis of the cell and are directed with the hydrocarbon tails towards the interior of the cell. In this packing the sulfate groups from four adjacent

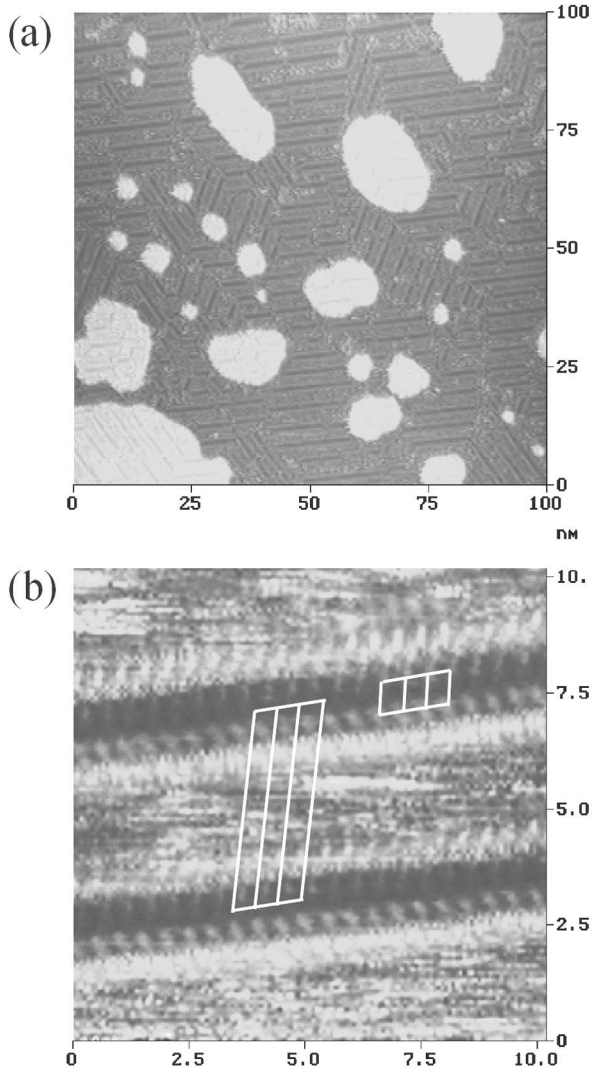
Fig. 14. STM images of hemicylindrical SDS aggregates formed at the Au(111) electrode surface at E = 300 mV (SCE) from 16 mM SDS solution. The images were acquired with a constant tunneling current 0.2 nA and the tip voltage –200 mV; (*a*) image of a 100 × 100 nm section of the electrode area; (*b*) unfiltered high-resolution image showing individual SDS molecules at the edge of hemicylindrical aggregates (taken from ref. 75).



cells are arranged into the characteristic (√3 × √7) structure. We demonstrated earlier that adsorbed sulfate ions form the (√3 × √7) ordered adlayers at (111) surfaces of many metals and that this particular structure is stabilized by water molecules bridging neighboring sulfate ions through hydrogen bonding. We propose that the same interaction stabilizes the sulfate groups of the flat adsorbed SDS molecules. We also propose that the characteristic pattern of long stripe-like surface aggregates of SDS results from the interaction between the sulfate groups from adjacent hemicelles. The sulfate groups are ordered in an array of (√3 × √7) cells forming a "zipper" that cements the large unit cells of the SDS aggregates. The remaining molecules in the hemimicelle aggregate on the top of the flat adsorbed molecules to form a hemicylindrical shape as proposed by Manne (77) and Wanless and Ducker (78). The cross section of the hemimicelle along the direction of the longer vector of the unit cell is schematically shown in Fig. 14*b*. Following Wanless and Ducker (78), we have assumed that seven SDS molecules may be accommodated in the hemimicelle. The resolution of STM images is much better than the resolution of images acquired by AFM. Consequently, STM images provide details of the molecular structure of the hemimicellar aggregates formed by SDS unknown to the previous AFM studies of this system.

We have also investigated the effect of the electrode potential (charge) on the structure of the SDS aggregates (75). We have provided the first direct visualization of the potential-controlled transformation of hemimicellar aggregates of SDS into a condensed film, most likely a monolayer. Our data show that the hemimicellar aggregates are formed at small or moderate absolute charge densities and that the condensed film is formed when the amount of positive charge on the metal is either equal or superequivalent with respect to the charge of the adsorbed surfactant. These results demonstrate a tremendous potential of electrochemistry to study the influence of the charge on the solid upon the surface aggregation of surfactants. Electrochemistry provides a unique opportunity to study continuously the different stages involved in the interaction of surfactants with solid surfaces, such as adsorption of micelles, formation of hemimicelles, and spreading of hemimicelles into a condensed monolayer.

5. Summary and outlook

We have attempted to demonstrate the benefits of a concerted use of traditional (electrochemical) and nontraditional (spectroscopic, diffraction, imaging) techniques in studying the structure and composition of the solid–solution interface. The traditional methods provide fundamental information concerning the composition of the interface. They allow the measurement of the charge density at the solid surface and the characterization of the energetics of the interfacial phenomena in terms of Gibbs energies. In addition, if temperature-dependent experiments are performed, the enthalpies and entropies of the systems can be obtained (81, 82). However, if electrochemical methods are to contribute to surface science, they have to be applied to perform quantitative measurements that can be rigorously processed using the Gibbs–Duhem (electrocapillary) equation of the interface (83). Too often, however, electrochemical measurements are restricted to recording a cyclic voltammogram. The information provided by such measurements is then of a qualitative nature and attempts to estimate surface coverages from these data are based on extra-thermodynamic assumptions that are frequently erroneous.

Today, surface electrochemistry is equipped with almost all the tools that are needed for both macroscopic and microscopic description of interfacial phenomena. Many issues that were unresolved in the past may be addressed again today. The revival of electrocatalysis is perhaps the best example (84). The methodological progress has spawned new disciplines such as electrochemical nano-technology (16). Surface electrochemistry is making significant inroads into other disciplines such as materials science (85) and it is my personal opinion that, in the near future, surface electrochemistry will play a significant role in biomimetic research. Electron and ion transfer are fundamental processes in the

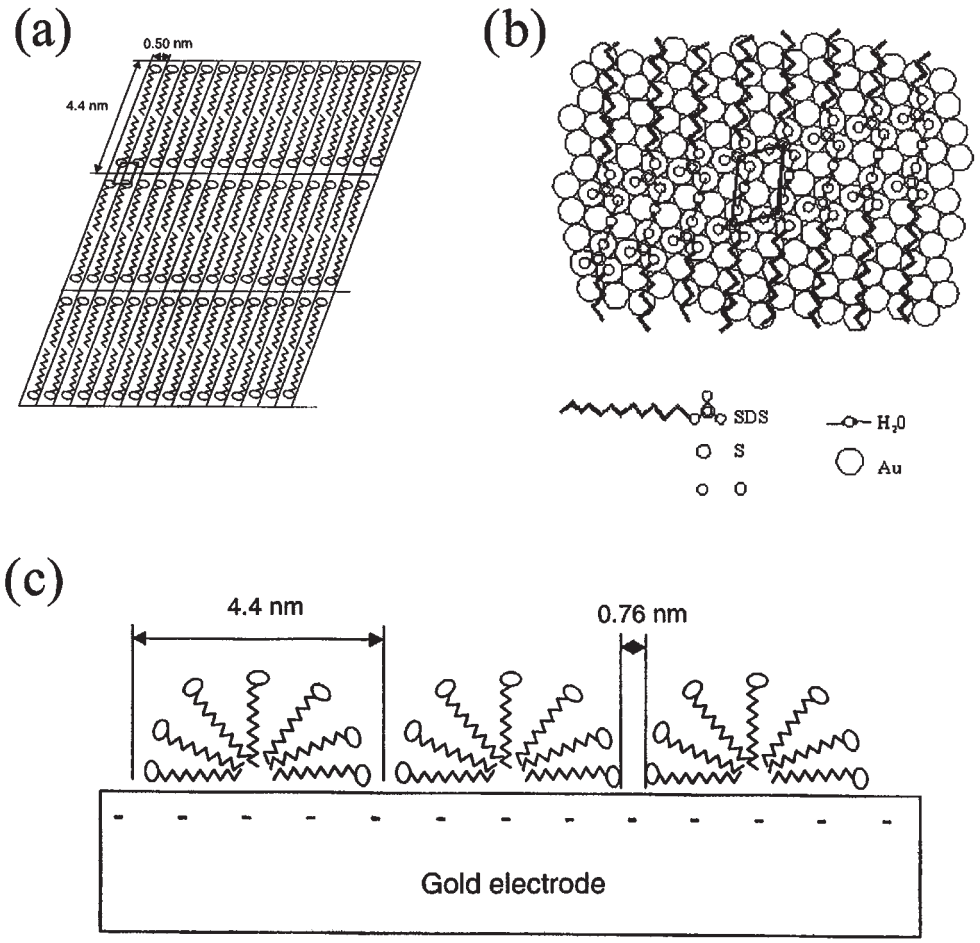
Model of the structure of SDS aggregates built around the ($\sqrt{3} \times \sqrt{7}$) lattice: (*a*) long-range stracture; (*b*) packing of SDS molecules around the ($\sqrt{3} \times \sqrt{7}$) lattice formed by sulfate head groups hydrogen bonded through water; (*c*) side view of the hemimicellar structure(taken from ref. 75).



activity of biological membranes. These processes also play a central role in electrochemical science. Fortunately, electrochemistry is well equipped to study these reactions. It is already known that phospholipid bilayers may be deposited onto nonconductive solids and we have just learned that they may also be coated onto a metal electrode surface (61, 62). The macroscopic and microscopic techniques of surface electrochemistry may therefore be employed to study membrane processes. This will certainly constitute an important thrust in our research.

Acknowledgements

I would like to acknowledge the work of my students. The studies of ionic adsorption were carried out by Z. Shi, S. Wu, A. Chen, W. Savich, X. Cai, and N. Li. The coordination of organic molecules was investigated by J. Richer, L. Stolberg, A. Iannelli, S. Morin, A. Chen, and H.-Q. Li. The work on Langmuir–Blodgett films was the effort of D. Bizzotto, J. Noel, V. Zamlynny, H. -Q. Li, and J. Rubinstein. The surface aggregation phenomena were investigated by I. Burgess, C. Jeffrey, and X. Cai. The help of Dr. G. Szymanski was invaluable for many of these projects. Our work involved many national and international collaborations. X-ray absorption experiments were carried out in collaboration with A. Hitchcock and T. Tyliszczak from McMaster University. Surface X-ray scattering involved collaboration with B.M. Ocko, O.M. Magnussen, and Th. Wandlowski from Brookhaven National Laboratory. I would like also to acknowledge many years of collaboration with D.M. Kolb of the University of Ulm, B. Pettinger of the Fritz Haber Institute in Berlin, Z. Galus of the University of Warsaw, S.-G. Sun of Xiamen University, D.E. Irish of the University of Waterloo, and S. Roscoe of Acadia University. This research was supported by grants from the Natural Sciences and Engineering Research Council of Canada.

Étude expérimentale et modélisation des réactions d'oxydation du néopentane et de l'isopentane

S. Taconnet, Y. Simon, G. Scacchi et F. Baronnet

Résumé : Les phénomènes responsables de la différence de comportement des hydrocarbures vis à vis de l'autoinflammation sont encore, à ce jour, très mal connus. Nous avons donc tenté de déterminer les processus qui sont à l'origine du phénomène de cliquetis dans les moteurs à allumage commandé à partir de l'étude des mécanismes réactionnels d'hydrocarbures d'indice d'octane différents : le néopentane et l'isopentane. Cette étude a été réalisée à 873 K, en utilisant un réacteur continu auto-agité par jets gazeux. Les résultats expérimentaux ont été modélisés à l'aide du logiciel de simulation de mécanismes réactionnels CHEMKIN. Ces mécanismes ont alors été comparés à ceux du *n*-pentane, du cyclopentane, du *n*-heptane et de l'isooctane déterminés, dans des conditions expérimentales identiques, lors d'études que nous avons effectuées antérieurement. Cette comparaison montre que l'on peut expliquer, au moins en partie, la sensibilité d'un hydrocarbure à l'autoinflammation par la présence, dans le milieu réactionnel, de radicaux stabilisés par résonance.

Mots clés : oxydation, néopentane, isopentane, autoinflammation, modélisation.

Abstract: The different behaviour of hydrocarbons with respect to autoignition phenomena is, at present, not yet fully explained. We have therefore investigated the oxidation of two alkanes that have different octane numbers: neopentane (85.5) and isopentane (92.3), to obtain a better understanding of their reaction mechanisms, in particular, those reactions that are responsible for the onset of knock in spark ignition engines. The experimental study was performed at 873 K in a jet-stirred flow reaction vessel. The oxidation mechanisms were simplified by using the CHEMKIN programme of simulation of reaction mechanisms. These mechanisms were compared to those accounting for the oxidation of *n*-pentane, cyclopentane, *n*-heptane, and isooctane that we have previously studied. This comparison shows that the different behaviour of these hydrocarbons can be explained, at least in part, by the presence, in the reaction medium, of resonance-stabilized radicals.

Key words: oxidation, neopentane, isopentane, autoignition, modelling.

Introduction

Dès 1921, T. Midgley et T.A. Boyd, chercheurs des laboratoires de la société « General Motors », découvrirent que l'on pouvait limiter les phénomènes de cliquetis en ajoutant aux essences de petites quantités d'organométalliques. Parmi ces additifs, permettant l'utilisation de taux de compression élevés dans les moteurs, les plus efficaces sont les alkyles de plomb. Le plomb tétraéthyle puis le plomb tétraméthyle furent utilisés comme additifs antidétonants pendant plus de 50 ans, jusqu'à ce que de nouvelles normes antipollution apparaissent aux États Unis dans les années 70 puis en Europe dans les années 80 et imposent la suppression de ces dérivés du plomb dans les essences, incompatibles avec l'utilisation de pots catalytiques.

Le développement de l'essence sans plomb a relancé, ces dernières années, l'intérêt pour les recherches sur les mécanismes d'oxydation des hydrocarbures (1–4). En effet, l'abandon des additifs et la recherche de carburants d'indice d'octane élevé nécessitent une meilleure compréhension du mécanisme de combustion.

Dans cette optique, nous avons tenté d'élucider les mécanismes d'oxydation de deux hydrocarbures (5) : l'isopentane (méthyl-2 butane) d'indice d'octane recherche (RON) : 92,3 et le néopentane (diméthyl-2,2 propane) d'indice d'octane recherche : 85,5.

Ces recherches entrent dans le cadre d'une étude générale sur la compréhension des mécanismes chimiques à l'origine des phénomènes d'autoinflammation et font suite aux recherches déjà effectuées sur les mécanismes d'oxydation du *n*-pentane, du cyclopentane (6), du *n*-heptane et de l'isooctane (7). En particulier, cette étude permettra d'examiner l'influence de la structure sur le comportement de quatre hydrocarbures saturés en C5.

Dans cet article nous présentons une étude expérimentale des réactions d'oxydation de l'isopentane et du néopentane

mises en oeuvre dans un réacteur continu auto-agité par jets gazeux. Ces résultats expérimentaux ont permis, grâce à une simulation, de présenter les mécanismes réactionnels simplifiés de l'oxydation de ces deux hydrocarbures.

Technique expérimentale

L'étude expérimentale de l'oxydation de l'isopentane et du néopentane est réalisée à 873 K en utilisant un réacteur continu auto-agité par jets gazeux dont le chauffage est assuré par des résistances électriques isolées de marque Thermocoax.

L'alimentation du réacteur se fait grâce à trois voies d'alimentation en réactifs (fig. 1) : (*i*) une voie d'introduction des hydrocarbures gazeux (néopentane), préchauffée à 723 K; (*ii*) une voie d'introduction des hydrocarbures liquides (isopentane); et (*iii*) une voie d'alimentation en air, préchauffée à 823 K.

Les débits d'air et d'hydrocarbure gazeux sont régulés et mesurés par les débitmètres massiques (RDM 280 de la société Air Liquide) D_1 et D_2.

Le débit d'hydrocarbure liquide est régulé, quant à lui, grâce à un pousse-seringue (Precidor 5003).

La prise d'échantillon s'effectue à l'aide de deux ampoules de chromatographie A_1 et A_2 montées en série et encadrées par deux vannes électromagnétiques qui se ferment successivement (V_2 puis V_1) pour isoler le flux gazeux sortant du réacteur. La pression totale dans les ampoules est mesurée par un capteur de pression C_2. Les produits de réaction sont analysés par chromatographie en phase gazeuse.

Enfin, le circuit se termine par une vanne pointeau VP qui permet de régler le débit total des gaz sortant du réacteur et ainsi modifier le temps de passage tout en gardant une pression totale constante dans le réacteur (mesurée par le capteur C_1). La circulation des gaz est assurée par une pompe à palettes.

Afin d'éviter des problèmes de vaporisation de l'isopentane liquide au niveau du système d'injection, la pression totale au sein du réacteur a été fixée à 630 torr (1 torr = 133,3 Pa), valeur supérieure à la pression de vapeur saturante de ce composé. Les pressions partielles d'oxygène et d'hydrocarbure ont été choisies de façon à obtenir un rapport hydrocarbure/O_2 de 1/4 (richesse 2). Des conditions expérimentales identiques ont été utilisées lors de l'étude de l'oxydation du néopentane.

Résultats expérimentaux

Les réactions d'oxydation de l'isopentane et du néopentane ont été étudiées pour des temps de passage, dans le réacteur, variant entre 0,4 et 1,2 s. Les réactifs et produits de réaction ont été dosés par chromatographie en phase gazeuse. La majorité des produits (hydrocarbures) a été analysée sur un chromatographe Shimadzu Mini 3 équipé d'un détecteur à ionisation de flamme. La colonne utilisée a une longueur de 5 m et un diamètre de 1/4 de pouce; elle est remplie de squalane et est maintenue à une température constante de 60°C. Les bilans effectués sur les éléments C, H et O (proches de 100 % pour les temps de passage les plus faibles) montrent qu'aucun produit primaire[3] important n'a été omis.

Oxydation du néopentane

L'étude a été menée pour des avancements de réaction, par rapport au néopentane, variant entre 10 % (pour un temps de passage : τ = 0,4 s) et 17 % (τ = 1,2 s). La consommation en O_2 est de seulement 2 % pour un temps de passage, dans le réacteur, de 1,2 s.

Dans le cas de l'oxydation du néopentane, les produits identifiés et dosés sont les suivants : hydrogène, méthane, éthylène, éthane, propène, isobutène, dioxyde de carbone et eau. Les courbes de formation de ces composés sont représentées sur les figures 2, 3 et 4. On peut noter l'allure inhabituelle de la courbe de formation de l'hydrogène dont nous reparlerons par la suite.

[3] Un produit de réaction est dit « primaire » lorsqu'il est formé à partir des réactifs ou des radicaux libres uniquement. Il est dit « secondaire » lorsqu'il est formé à partir des produits primaires. Un produit primaire se caractérise par une vitesse de formation initiale non nulle, alors qu'un produit secondaire possède une vitesse de formation initiale nulle.

Fig. 2. Oxydation du néopentane à 873 K. Courbes de formation de CH_4 et $isoC_4H_8$.

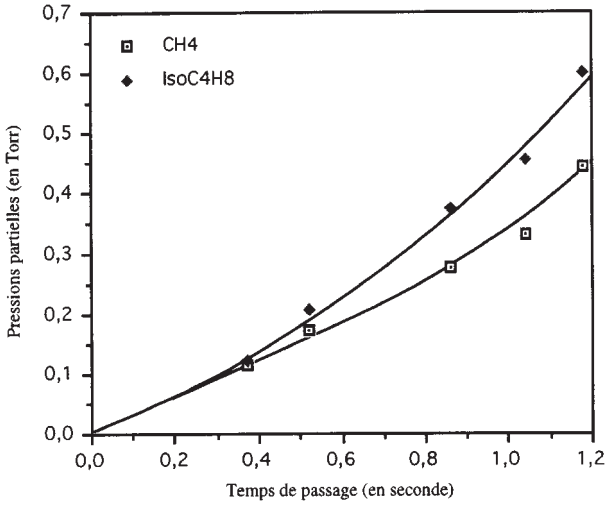

Fig. 3. Oxydation du néopentane à 873 K. Courbes de formation de C_2H_4, C_2H_6 et C_3H_6.

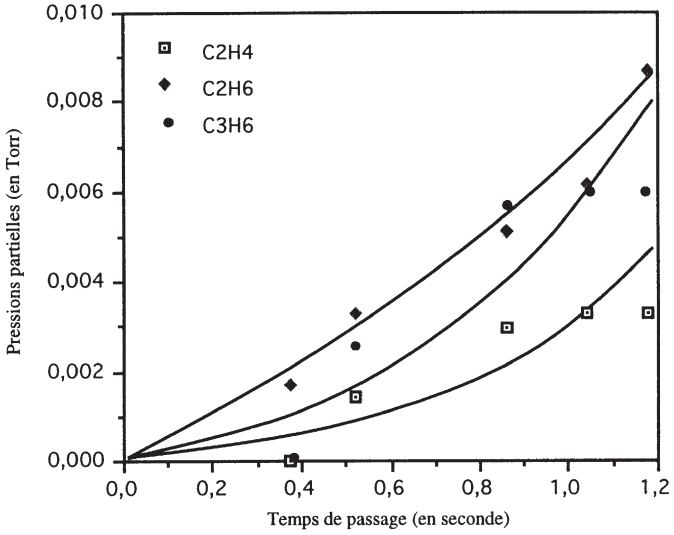

Le caractère primaire ou secondaire des produits de réaction a été déterminé en traçant les diagrammes « horizontaux » correspondants (figs. 5, 6 et 7). Ces diagrammes sont tracés en portant le pourcentage molaire du produit considéré par rapport à l'ensemble des produits dosés (réactifs non compris) en fonction du temps de passage. Sur ces diagrammes, le caractère primaire d'un composé est caractérisé par une courbe ne passant pas par l'origine, alors que, au contraire, le caractère secondaire se distingue par une courbe passant par l'origine. En effet, un produit secondaire (vitesse initiale nulle) est absent du milieu réactionnel pour des avancements très faibles; la limite du pourcentage molaire de ce composé par rapport à l'ensemble des produits formés tend vers 0 quand le temps de passage tend vers 0. Par contre, un produit primaire (vitesse initiale non nulle) est déjà présent dès les premiers instants de la réaction, le pourcentage considéré plus haut aura donc une limite différente de 0 quand le temps de passage tend vers 0. Les diagrammes « horizontaux » (figs. 5, 6 et 7) montrent que l'isobutène, le

Fig. 4. Oxydation du néopentane à 873 K. Courbes de formation de H_2, CO_2 et H_2O.

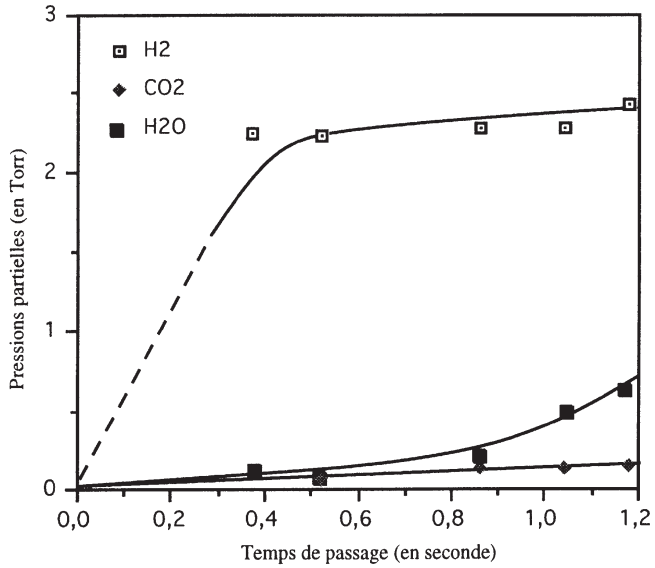

Fig. 5. Oxydation du néopentane à 873 K. Répartition des produits de la réaction en fonction du temps de passage pour CH_4 et $isoC_4H_8$.

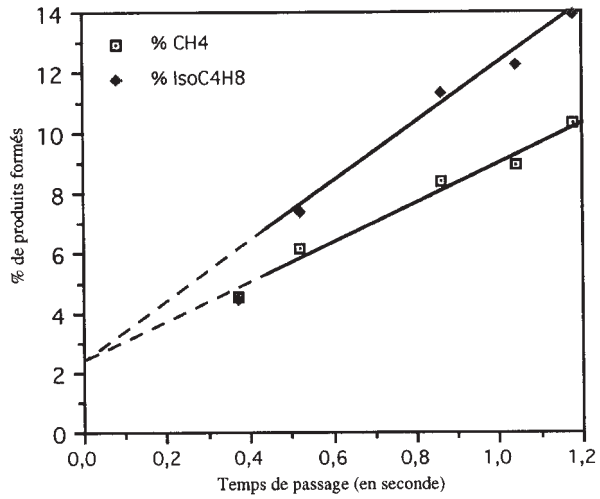

méthane et l'hydrogène sont des produits primaires, alors que l'éthylène, le propène et le dioxyde de carbone sont secondaires. Il subsiste cependant un doute quant au caractère primaire ou secondaire de l'eau et de l'éthane.

Oxydation de l'isopentane

La réaction d'oxydation de l'isopentane a été étudiée pour des avancements, par rapport à l'hydrocarbure, variant de quelques % (non mesurables) à 0,4 s jusqu'à 37 % à 1,2 s. La consommation d'oxygène atteint, quant à elle, 7 % pour le temps de passage le plus élevé.

Cette étude a permis d'identifier 15 produits d'oxydation différents : hydrogène, méthane, éthylène, propène, allène, butène-1, isobutène, butadiène-1,3, butènes-2 *cis* et *trans*, méthyl-3 butène-1, méthyl-2 butène-1, méthyl-2 butène-2, dioxyde de carbone et eau.

L'allène a été identifié mais est présent en quantité trop faible pour pouvoir être dosé. Les courbes de formation des

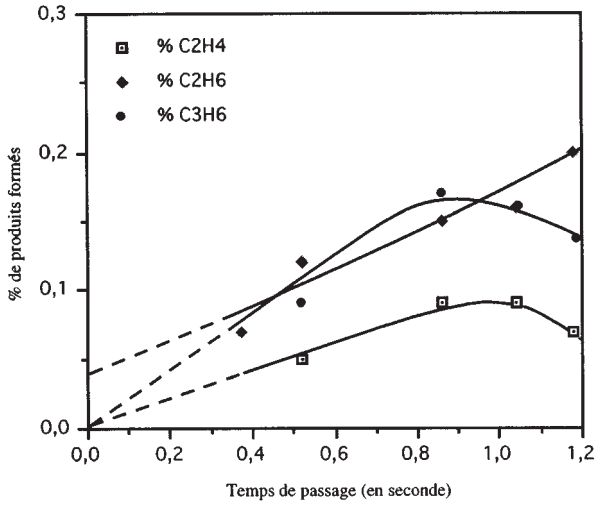

Fig. 7. Oxydation du néopentane à 873 K Répartition des produits de la réaction en fonction du temps de passage pour H_2, CO_2 et H_2O.

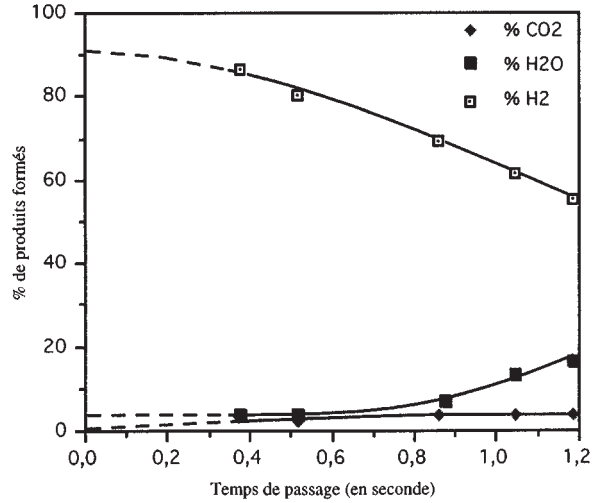

produits de réaction sont représentées sur les figures 8, 9 et 10.

L'analyse des diagrammes « horizontaux » (figs. 11, 12 et 13) montre que tous les produits dosés sont primaires, sauf le butadiène-1,3 et peut-être le méthyl-3 butène-1. Dans le cas de CO_2 et H_2O, la dispersion des points expérimentaux est telle que l'on ne peut déterminer si la courbe passe ou non par l'origine. Comme dans le cas du néopentane, l'allure de la courbe de formation de l'hydrogène sera discutée par la suite.

Interprétation des résultats expérimentaux

Les réactions d'oxydation des hydrocarbures peuvent évoluer suivant deux voies très différentes en fonction du domaine de température exploré. Cette caractéristique provient

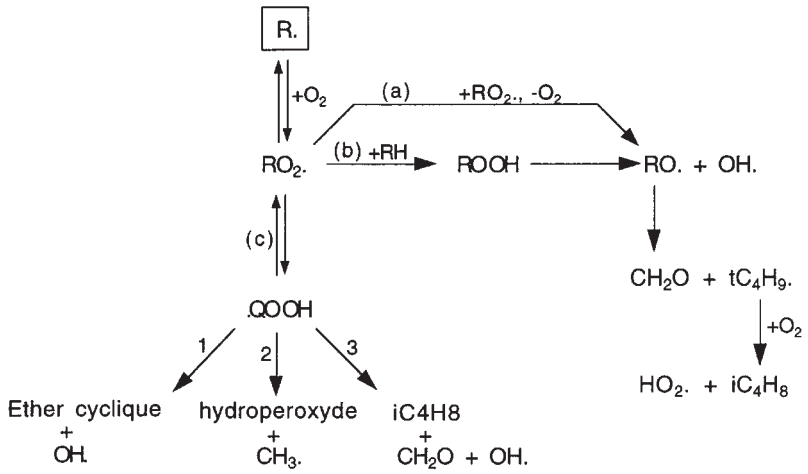
Schéma 1. Mécanisme « basse température » de l'oxydation du néopentane.



de la réversibilité de la réaction d'addition d'une molécule d'oxygène sur le radical alcoyle R$^\bullet$ formé par l'amorçage :

$$R^\bullet + O_2 \underset{2}{\overset{1}{\rightleftharpoons}} RO_2^\bullet$$

Pour des températures modérées (inférieures à 800 K), cette réaction est fortement déplacée dans le sens 1 de la formation du radical peroxyalcoyle $RO_2^\bullet$ qui s'isomérise en radical hydroperoxyalcoyle $^\bullet$QOOH et conduit, finalement, à des composés oxygénés (éthers cycliques, aldéhydes, cétones, alcools). Ce mécanisme est appelé mécanisme de « basse température » (8–13).

Pour des températures plus élevées (supérieures à 1000 K), la réaction précédente est déplacée dans le sens 2. Les radicaux R$^\bullet$ ne s'oxydent plus mais se décomposent par rupture de liaisons C—C en petits radicaux ($CH_3^\bullet$, $C_2H_5^\bullet$) qui seuls s'oxydent. C'est alors un mécanisme dit de « haute température » (14–27).

Le radical alcoyle R$^\bullet$ peut également réagir avec O_2 pour former l'alcène conjugué correspondant :

$$R^\bullet + O_2 \rightarrow \text{alcène conjugué} + HO_2^\bullet$$

Cette réaction est effectivement importante à une température que l'on peut qualifier d'intermédiaire, entre 800 et 1000 K (28).

Oxydation du néopentane

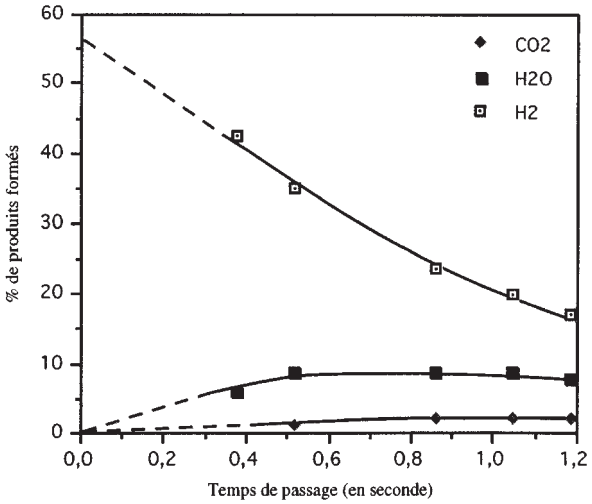
L'amorçage de la réaction d'oxydation du néopentane conduit à la formation d'un seul radical alcoyle R$^\bullet$, le radical : $(CH_3)_3CCH_2^\bullet$. Le mécanisme général de l'oxydation du néopentane à « basse température » peut être schématisé de la façon suivante (voir Schéma 1).

La voie réactionnelle (b) conduit à la formation d'isobutène secondaire, par décomposition d'une molécule d'hydroperoxyde ROOH. Expérimentalement, nous avons montré que l'isobutène formé par l'oxydation du néopentane est primaire (fig. 5) et ne peut donc pas être formé de façon prépondérante par la voie (b).

La voie réactionnelle (c) correspond à l'isomérisation du radical $RO_2^\bullet$ [$(CH_3)_3CCH_2OO^\bullet$] en radical $^\bullet$QOOH [$(CH_3)_2(CH_2OOH)CCH_2^\bullet$] qui se décompose pour former de l'isobutène ou des composés oxygénés (éthers cycliques ou hydroperoxydes insaturés). Les constantes de vitesse des processus 1 et 3 sont respectivement : $k_1 = 10^7$ s^{-1}, et k_3 =

© 1999 CNRC Canada

Fig. 13. Oxydation de l'isopentane à 873 K. Répartition des produits de la réaction en fonction du temps de passage pour H_2, CO_2 et H_2O.



$8{,}4 \times 10^5\ s^{-1}$ (29). Les éthers formés par cette séquence réactionnelle devraient donc être présents en quantité au moins égale voire plus importante que l'isobutène, ce qui n'est pas le cas puisque ces composés oxygénés n'ont même pas été détectés. Cette voie réactionnelle (c) est donc probablement négligeable dans le mécanisme d'oxydation du néopentane.

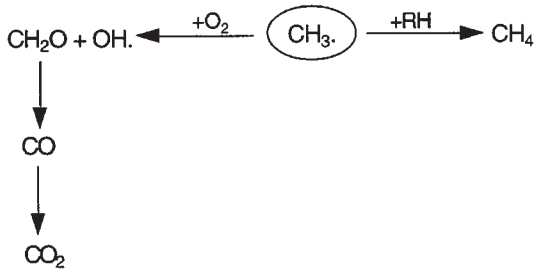
La voie réactionnelle (a) conduit, quant à elle, à la formation d'isobutène primaire et les résultats expérimentaux ne permettent pas d'évaluer son importance relative dans le mécanisme général car l'isobutène peut provenir du mécanisme de « haute température ».

La décomposition du radical alcoyle $R^{\bullet}$ suivant le mécanisme de « haute température » conduit à la formation du radical $CH_3^{\bullet}$ et de l'isobutène :

$$R^{\bullet} \rightarrow CH_3^{\bullet} + \text{isobutène}$$

Le radical $CH_3^{\bullet}$ peut ensuite réagir de la façon suivante (voir Schéma 2) :

Schéma 2. Mécanisme « haute température » de l'oxydation du néopentane.



Ce mécanisme concorde avec le fait que l'isobutène est formé en quantité plus importante que le méthane et plus particulièrement avec la relation entre les concentrations : (isobutène) ≈ (CH_4) + (CO_2) que l'on observe expérimentalement.

En conclusion, le mécanisme d'oxydation du néopentane à 873 K est probablement, presque exclusivement, un mécanisme de « haute température ». La modélisation, présentée dans le paragraphe suivant, nous permettra de vérifier cette hypothèse.

Revenons sur le mécanisme de formation de l'hydrogène. La figure 4 montre que la quantité d'hydrogène formée à faible temps de passage est anormalement élevée. Nous avons, de plus, observé à faible temps de passage, la formation d'un dépôt de produits lourds à la sortie du réacteur. Ces produits n'ont pas été dosés puisqu'ils se condensent dans l'appareillage expérimental.

Des réactions de combinaisons, de déshydrogénations et de condensations pourraient expliquer ces deux observations, mais leur importance à faible temps de passage, alors que seules des réactions primaires devraient se produire, ne peut s'expliquer que par un mauvais fonctionnement hydrodynamique du réacteur pour les forts débits.

Il pourrait se former, dans le réacteur, des zones de faible agitation et donc de fort temps de passage où se produiraient ces réactions de polymérisation; puis on retrouverait, en diminuant le débit, une agitation correcte et donc une formation normale d'hydrogène dans ces conditions, ceci bien que le réacteur soit, en théorie, agité à partir d'un temps de passage de 0,05 s.

Oxydation de l'isopentane

Contrairement à l'oxydation du néopentane, l'amorçage de la réaction d'oxydation de l'isopentane conduit à quatre radicaux alcoyles différents : CH_3-CH_2-$CH(CH_3)(CH_2^{\bullet})$; CH_3-CH_2-$C^{\bullet}(CH_3)_2$; CH_3-$CH^{\bullet}$-$CH(CH_3)_2$; $CH_2^{\bullet}$-CH_2-$CH(CH_3)_2$.

Le mécanisme d'oxydation de l'isopentane à « basse température » étant beaucoup plus complexe que celui du néopentane, il est très difficile de conclure quant à l'importance relative des différentes voies réactionnelles à partir des seuls résultats expérimentaux.

Dans ce mécanisme, la seule voie négligeable est la décomposition de l'hydroperoxyde ROOH:

$$RO_2^{\bullet} \rightleftarrows ROOH \rightarrow OH^{\bullet} + RO^{\bullet}$$

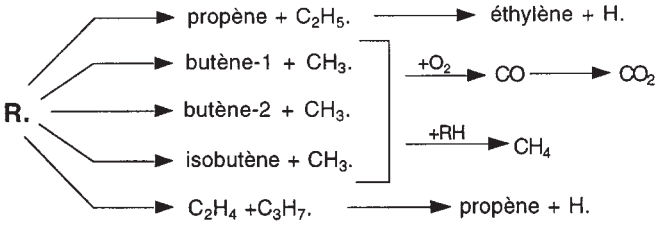
$$\rightarrow \text{aldéhyde ou cétone} + \text{radical alcoyle}$$

$$\xrightarrow{+O_2} \text{alcène} + HO_2^{\bullet}$$

En effet, cette séquence réactionnelle conduit à la formation d'alcènes secondaires, alors que tous les alcènes dosés dans l'oxydation de l'isopentane sont primaires (figs. 11 et 12).

Pour le mécanisme de « haute température », la décomposition des quatre radicaux isopentyle formés par l'amorçage conduit à la formation d'alcènes : éthylène, propène, butènes 1 et 2, isobutène (Schéma 3) :

Schéma 3. Mécanisme « haute température » de l'oxydation de l'isopentane.



© 1999 CNRC Canada

Si le mécanisme « haute température » est prépondérant dans la formation des alcènes, les concentrations de ces composés doivent être compatibles, à l'instant initial, avec les relations :

$$(C_3H_6) = (C_2H_4)$$

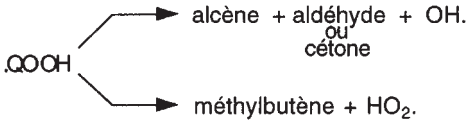
et

$$(1\text{-}C_4H_8) + (2\text{-}C_4H_8) + (iC_4H_8) = (CH_4) + (CO) + (CO_2)$$

Or, expérimentalement, on trouve à l'instant initial :

$(C_3H_6)_0$	= 9,5 %	$(iC_4H_8)_0$	= 5 %
$(C_2H_4)_0$	= 9,5 %	$(CH_4)_0$	= 9,5 %
$(1\text{-}C_4H_8)_0$	= 0,5 %	$(CO)_0$	= 0
$(2\text{-}C_4H_8)_0$	= 4 %	$(CO_2)_0$	= 0

Les relations précédentes sont tout à fait vérifiées à très faible avancement. Il semblerait, finalement, que le mécanisme de « haute température » soit majoritaire dans la formation des alcènes non conjugués (autres que les méthylbutènes). Les seuls composés formés, essentiellement, par le mécanisme de « basse température » sont les méthylbutènes et les aldéhydes ou cétones (non dosés) qui sont vraisemblablement formés par les processus :



Modélisation des réactions d'oxydation du néopentane et de l'isopentane

Les mécanismes réactionnels utilisés pour la simulation des réactions d'oxydation du néopentane et de l'isopentane ont été générés par le logiciel EXGAS, mis au point au laboratoire, qui permet une écriture systématique des mécanismes réactionnels en phase gazeuse (30, 31).

Ce logiciel est composé de trois parties :

(*i*) une base de données C_0–C_2 comprenant tous les processus uni et bimoléculaires mettant en jeu des réactifs et des produits qui contiennent au plus deux atomes de carbone (32). Les grandeurs cinétiques utilisées pour les réactions de cette base (781 processus) sont principalement extraites de la littérature (réfs. 33 et 34);

(*ii*) un générateur de mécanisme primaire pour lequel les seules espèces moléculaires pouvant réagir sont l'hydrocarbure et l'oxygène;

(*iii*) un générateur de mécanisme secondaire qui permet de faire réagir les produits issus du mécanisme primaire.

Pour garder un fichier de taille raisonnable, la génération du mécanisme secondaire ne se fait pas de la même façon que celle du mécanisme primaire. Dans le but de faciliter la génération du mécanisme secondaire, toutes les espèces moléculaires contenant plus de deux atomes de carbone, ayant la même formule brute et le même groupement fonctionnel, sont regroupées sous le même nom sans distinction des différents isomères. Une telle opération est appelée le « lumping » des molécules.

Les paramètres cinétiques relatifs aux processus issus des mécanismes générés sont calculés par le logiciel KINGAS (31, 35) à partir de grandeurs thermodynamiques fournies par le logiciel THERGAS (36). Ces deux logiciels ont été développés au DCPR, à partir des méthodes de Benson (37).

Finalement, le mécanisme réactionnel servant à la simulation est constitué de la base C_0–C_2 à laquelle est ajouté le mécanisme issu du générateur en respectant les règles suivantes :

(*i*) aucune des réactions écrites dans la base n'est réécrite dans le mécanisme généré;

(ii) doivent être générées : les métathèses impliquant des radicaux de la base, les réactions de terminaison entre radicaux de la base et ceux issus du générateur, les réactions impliquant des réactifs de la base mais conduisant à des produits contenant plus de deux atomes de carbone.

Les réactions d'oxydation du néopentane et de l'isopentane sont alors simulées en utilisant le logiciel CHEMKIN développé par Sandia National Laboratories (Livermore, Calif., U.S.A.).

Simulation de l'oxydation du néopentane

La réaction d'oxydation du néopentane a été simulée en utilisant un mécanisme généré suivant les règles exposées précédemment. Les tentatives de simulation utilisant un mécanisme « primaire + secondaire » n'ayant pas abouti pour des raisons numériques (divergence), le mécanisme de départ est donc un mécanisme primaire qui comprend 106 espèces et 888 réactions.

Les constantes de vitesse des réactions de ce mécanisme ont été modifiées de façon à obtenir des courbes de formation des produits de réaction aussi proches que possible des courbes expérimentales. Cette modification ne porte que sur le facteur préexponentiel *A* et ceci dans des limites raisonnables compte tenu de l'incertitude que nous avons sur ces paramètres (au maximum un facteur 10).

Afin d'améliorer cet ajustement entre courbes théoriques et expérimentales, nous avons ajouté au mécanisme primaire précédent des réactions secondaires de l'isobutène (Tableau 1 : réactions 27 et 29) qui est le produit primaire majoritaire dans cette réaction d'oxydation (hormis H_2 non simulé). On a tenu compte également de la réaction de branchement : $C_5H_{10}(OOH)OO^{\bullet} \rightarrow CH_3^{\bullet} + 2\ OH^{\bullet} + 2\ CH_2O + C_2H_2$ (Tableau 1 : réaction 26) qui accélère très fortement la production d'eau, ainsi que des réactions de métathèse et de terminaison utilisant des radicaux secondaires (Tableau 1 : réactions 28 et 30).

Enfin, nous avons effectué une analyse de sensibilité des différentes réactions de ce mécanisme, dont le but est de déterminer les réactions négligeables. Ces réactions peuvent être éliminées du mécanisme sans que cela modifie les courbes de formation des produits de la réaction d'oxydation.

Ces simplifications conduisent à un mécanisme final qui ne comporte plus que 53 espèces et 243 réactions (Tableau 1 + base C_0–C_2 non représentée). Les résultats de ces simulations sont représentés, pour les produits les plus importants, sur les figures 14–17.

Fig. 14. Oxydation du néopentane à 873 K. Courbes de formation simulées de CH_4 et $isoC_4H_8$.

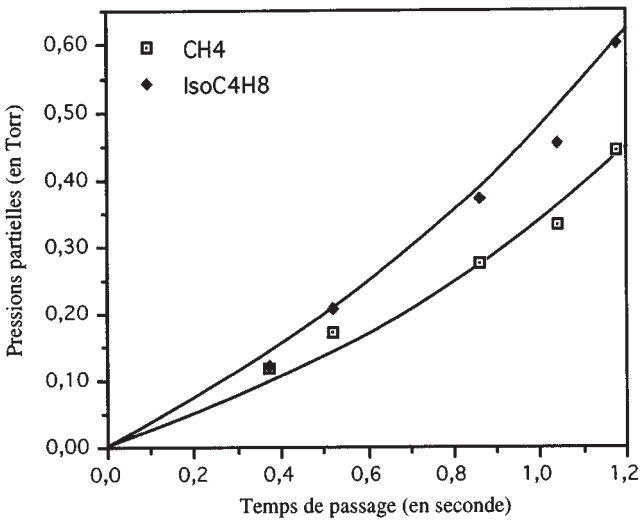

Fig. 15. Oxydation du néopentane à 873 K. Courbes de formation simulées de C_2H_4 et C_2H_6.

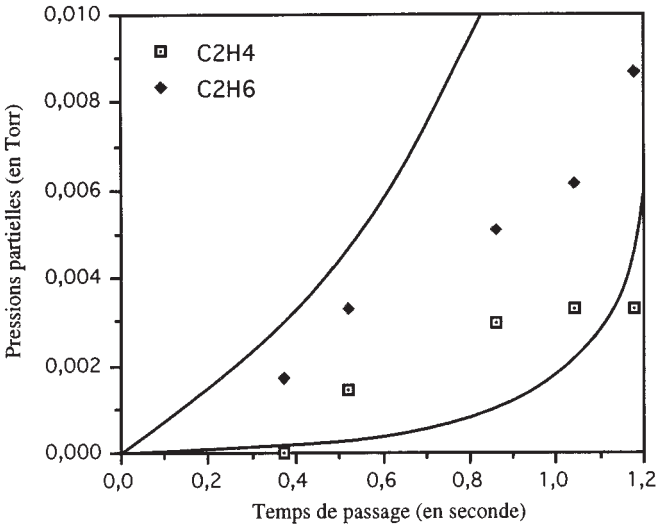

L'ajustement entre courbes théoriques et expérimentales obtenu est très bon pour les hydrocarbures principaux (CH_4 et iC_4H_8) et convenable pour les autres (C_2H_4, C_2H_6 et C_3H_6). Cependant, les points expérimentaux concernant les deux alcènes montrent que ces espèces sont consommées. Comme les réactions correspondantes n'ont pas été écrites dans notre mécanisme, il est normal que les courbes simulées s'écartent des points expérimentaux lorsque le temps de passage augmente. De plus, ces alcènes sont présents en petites quantités et la mesure de faibles pressions partielles est

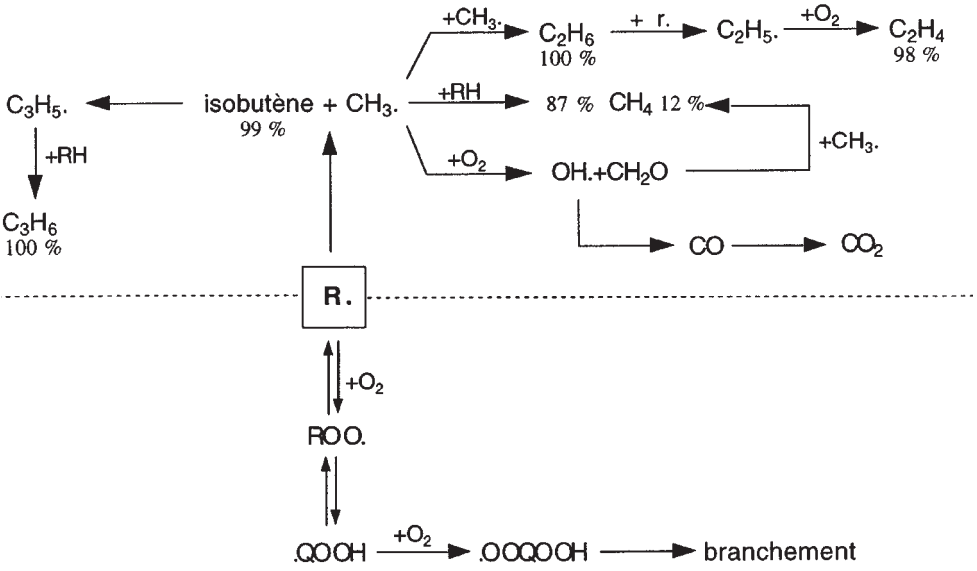
Schéma 4. Mécanisme final de l'oxydation du néopentane.



très délicate. On peut estimer la précision de ces mesures à ±0,001 torr, ce qui inclut la reproductibilité, les erreurs d'échantillonnage et les erreurs d'analyse. Par contre il n'a pas été possible de simuler quantitativement la formation des produits oxygénés H_2O et CO_2. En effet, la production de CO_2 et H_2O est contrôlée, principalement, par la réaction de branchement à partir du radical HOOQOO•, mais nous n'avons pas pu augmenter la constante de vitesse de cette réaction plus que nous ne l'avons fait sans faire diverger le système. La production de H_2 n'a pas été simulée pour les raisons évoquées précédemment.

Finalement, le mécanisme d'oxydation du néopentane peut être schématisé (voir Schéma 4) où R• représente le radical néopentyle (les % correspondent au pourcentage de formation du produit par la voie indiquée).

Le mécanisme d'oxydation du néopentane est donc essentiellement un mécanisme de « haute température », c'est à dire un mécanisme dans lequel le radical alcoyle R• se décompose jusqu'à l'obtention de petits radicaux (CH_3•, C_2H_5•) qui seuls s'oxydent. L'accélération de la réaction par rapport à une réaction de pyrolyse s'explique par la présence, dans le mécanisme d'oxydation, de réactions de branchement.

Simulation de l'oxydation de l'isopentane

Comme dans le cas de l'oxydation du néopentane, le mécanisme de départ ayant servi à la simulation de l'oxydation de l'isopentane est constitué de la base C_0–C_2 et du mécanisme primaire généré par le système. Ce mécanisme comprend 365 espèces et 1498 réactions. Afin d'améliorer l'ajustement entre courbes expérimentales et théoriques, nous avons rajouté à ce mécanisme des réactions secondaires de métathèse des pentènes (Tableau 2 : réactions 56–66) et des réactions de terminaisons des radicaux secondaires (Tableau 2 : réactions 67–69). Les pentènes sont regroupés

[a] *A* en $cm^3\ mol^{-1}\ s^{-1}$; *E* en cal mol^{-1}; $k = AT^b \exp(-E/RT)$.
Nota : Ce tableau présente les paramètres cinétiques moyens des différents types de processus du mécanisme de « basse température ». La simulation a, quant à elle, été effectuée en différenciant les isomères possibles; ceci engendre un nombre très important de processus (405) que nous ne pouvons présenter ici.

(sans distinction d'isomères) car la simulation s'effectue, pour les réactions secondaires, en utilisant la technique du « lumping ».

Les modifications apportées aux constantes de vitesse portent uniquement sur le facteur préexponentiel *A* qui n'a pas été modifié de plus d'un facteur 10.

L'analyse de sensibilité effectuée sur ce mécanisme a permis de le simplifier en portant le nombre de réactions à 606 (base C_0–C_2 comprise mais non représentée) et le nombre d'espèces à 299 (Tableaux 2 et 2bis). La comparaison entre les courbes de formation des produits de réaction simulées et expérimentales est représentée sur les figures 18–22. Les courbes simulées sont en accord avec les résultats expérimentaux. L'ajustement est très bon dans le cas des hydrocarbures et un peu moins en ce qui concerne CO_2 et H_2O. Comme dans le cas du néopentane, l'hydrogène n'a pas été simulé.

Finalement, le mécanisme d'oxydation de l'isopentane peut être schématisé de la façon suivante (Schéma 5) :

Fig. 18. Oxydation de l'isopentane à 873 K. Courbes de formation simulées de CH_4, $isoC_4H_8$ et méthyl-2 butène-2.

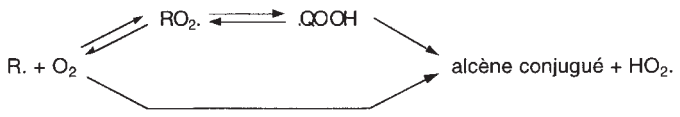
Discussion et conclusion

La comparaison des mécanismes d'oxydation du néopentane et de l'isopentane montre que ces deux réactions évoluent de façon assez différente. En effet, l'oxydation de l'isopentane est partagée entre les deux mécanismes de « haute et basse températures », alors que l'oxydation du néopentane évolue uniquement suivant la voie de « haute température ».

Cette différence peut s'expliquer en considérant les deux voies possibles de formation de l'alcène conjugué et du radical $HO_2^{\bullet}$:



Dans le cas de l'isopentane, l'alcène conjugué existe (méthylbutènes) et le radical associé $HO_2^{\bullet}$ participe à la réaction de terminaison la plus rapide : $2\ HO_2^{\bullet} \rightarrow H_2O_2 + O_2$ conduisant à l'agent de branchement dégénéré H_2O_2 qui se décompose ensuite en deux radicaux $OH^{\bullet}$ très réactifs. Cette terminaison principale n'est, en réalité, pas une « vraie » terminaison puisqu'elle revient à remplacer des radicaux peu réactifs $HO_2^{\bullet}$ par des radicaux $OH^{\bullet}$ très réactifs.

En revanche, dans le cas du néopentane, l'alcène conjugué n'existe pas et il ne se forme donc pas de radicaux $HO_2^{\bullet}$ par les deux voies ci-dessus. La terminaison principale est : $2\ CH_3^{\bullet} \rightarrow C_2H_6$ qui ne conduit pas à un agent de branchement dégénéré.

La molécule de néopentane aurait donc tendance à s'oxyder plus difficilement que celle de l'isopentane, comme l'a confirmé l'étude expérimentale dans laquelle nous avons pu noter un avancement de réaction, par rapport à l'hydrocarbure, beaucoup plus élevé pour l'oxydation de l'isopentane que pour l'oxydation du néopentane (les expériences étant réalisées dans les mêmes conditions).

Tableau 3. Répartition (en %) des alcènes précurseurs de radicaux stabilisés par résonance, à 20 % d'avancement, dans l'oxydation de 6 hydrocarbures saturés.

	Hydrocarbure (RON)					
Alcène (BRON)	nC_7H_{16} (0)	nC_5H_{12} (61,7)	**neoC_5H12 (85,8)**	**isoC_5H_{12} (92,3)**	isoC_8H_{18} (100)	cyC_5H_{10} (102)
C_3H_6 (–)	9	7,5	—	**13**	7,5	—
1-C_4H_8 (144)	—	3,5	—	**1**	—	—
Met2-But1 (146)	—	—	—	**5,5**	—	—
2-C_4H_8 (155)	—	—	—	**7**	—	—
isoC_4H_8 (170)	—	—	**14**	**6,5**	26	—
cyC_5H_8 (171)	—	—	—	—	—	33
Met2-But2 (176)	—	—	—	**2,5**	—	—
cyC_5H_6 (218)	—	—	—	—	—	2,5
Total %	9	11	**14**	**35,5**	33,5	35,5

Cependant, cette constatation est en contradiction avec les valeurs d'indice d'octane recherche de ces deux composés. En effet, l'indice d'octane de l'isopentane (92,3) est plus élevé que celui du néopentane (85,5).

Les mécanismes primaires d'oxydation ne permettent donc pas d'interpréter la différence d'indice d'octane existant entre ces deux hydrocarbures et il semble donc nécessaire de faire intervenir un mécanisme secondaire plus complet de la réaction.

Considérons la nature et la répartition des produits primaires formés par ces deux réactions d'oxydation et plus particulièrement celle des alcènes. Les alcènes formés (sauf C_2H_4) sont en majorité des composés précurseurs de radicaux allyliques stabilisés par résonance. Ces radicaux, très peu réactifs, peuvent inhiber la réaction d'oxydation en participant à de nouvelles terminaisons. Ceci pourrait expliquer l'indice d'octane élevé de ces deux hydrocarbures.

D'autre part, la comparaison des quantités d'alcènes formés par ces réactions (Tableau 3) pour un avancement identique de 20 % montre que le pourcentage d'alcènes précurseurs de radicaux stabilisés par résonance est plus important dans le cas de l'isopentane que dans le cas du néopentane, ce qui expliquerait que l'indice d'octane du néopentane soit inférieur à celui de l'isopentane.

Cette constatation a, par ailleurs, déjà été faite lors de l'étude des réactions d'oxydation du *n*-heptane et de l'isooctane (7), ainsi que celles du *n*-pentane et du cyclopentane (6) pour lesquels la différence d'indice d'octane avait pu être interprétée par la présence ou l'absence de radicaux stabilisés par résonance.

Le tableau 3 résume la répartition des alcènes précurseurs de radicaux stabilisés par résonance formés lors des réactions d'oxydation des six hydrocarbures étudiés, pour un avancement de réaction identique de 20 %. L'analyse de ce tableau montre que la quantité totale d'alcènes formés augmente avec l'indice d'octane de l'hydrocarbure. La différence d'indice d'octane existant entre ces différents hydrocarbures pourrait donc s'expliquer par la présence plus ou moins importante d'alcènes d'indice d'octane de mélange élevé (BRON, Blending Research Octane Number) (38) qui réagiraient suivant un mécanisme secondaire pour former des radicaux stabilisés par résonance. Cette corrélation qualitative entre la quantité d'alcènes formés et l'indice d'octane de l'hydrocarbure n'est cependant qu'une première approche qui pourrait être affinée en tenant compte de

© 1999 CNRC Canada

l'efficacité de chacun des alcènes formés en tant que précurseur de radicaux stabilisés.

Hypervalent iodine oxidation of α-substituted 2,4-dihydroxyacetophenones: synthesis of novel *o*-iodophenoxy ethers via rearrangement of iodonium ylides

Om Prakash, Vijay Sharma, and Madan P. Tanwar

Abstract: α-Substituted 2,4-dihydroxyacetophenones (**1a–1i**) have been oxidized with phenyliodonium diacetate (PIDA) under three conditions (*i*) PIDA–KOH–MeOH (basic) at 0°C, (*ii*) PIDA–MeOH (neutral) at reflux temperature, and (*iii*) PIDA–AcOH (acidic) at reflux temperature, to afford novel *o*-iodophenoxy ethers (**4a–4i**) via rearrangement of respective iodonium ylides (**5a–5i**).

Key words: hypervalent iodine reagents, phenyliodonium diacetate, α-substituted 2,4-dihydroxyacetophenones, α-substituted 2-hydroxy-3-iodo-4-phenoxyacetophenones, iodonium ylides rearrangement.

Résumé : On a oxydé des 2,4-dihydroxyacétophénones α-substituées (**1a–1i**) à l'aide du diacétate de phényliodonium (« PIDA ») dans trois conditions : (*i*) PIDA–KOH–MeOH (basique), à 0°C; (*ii*) PIDA–MeOH (neutre), à la température de reflux et (*iii*) PIDA–AcOH (acide), à la température de reflux; ces oxydations conduisent à de nouveaux éthers *o*-iodophénoy (**4a–4i**) par le biais d'un réarrangement des ylures d'iodonium respectifs (**5a–5i**).

Mots clés : réactifs hypervalents de l'iode, diacétate de phényliodonium, 2,4-dihydroxyacétophénones α-substituées, 2-hydroxy-3-iodo-4-phénoxyacétophénones α-substituées, réarrangement d'ylures d'iodonium.

[Traduit par la Rédaction]

Introduction

A surge of interest in the use of hypervalent iodine reagents in organic synthesis has been witnessed by its explosive growth during few last decades (1–5). Major areas of interest are hypervalent iodine oxidation of carbonyl compounds (4), phenolic oxidations (2*a*, 5), oxidative rearrangements (1*e*), etc. These studies have provided a large number of new and convenient methods for the synthesis of a wide variety of organic compounds, including various heterocyclic compounds and bridgehead compounds (3, 6).

A notable hypervalent iodine oxidation of enolizable ketones with PIDA and potassium hydroxide in methanol leads to the formation of α-dimethylacetals (7, 8) (eq. [1]). However, the presence of a phenolic group at the *ortho* position of ketones such as acetophenone, etc. affords coumaran-3-ones by intramolecular participation in this oxidation (9, 10) (eq. [2]). On the other hand, hypervalent iodine oxidation of various phenols has provided attractive routes for the synthesis of valuable *p*-quinones, *o*-quinones, quinone acetals, etc., which are otherwise difficult to obtain (eq. [3]) (11, 12).

[1] 
[2] 
[3] 
Results and discussion

Based upon these observations, we became interested in oxidizing those compounds containing *ortho* and *para* phenolic groups and an enolizable ketonic moiety, for example, 5-acetyl-2,4-dihydroxyacetophenone (**1a**), with phenyliodonium diacetate (PIDA) and KOH in MeOH. The attempted reaction yielded a yellow crystalline solid (mp 143–145°C; yield 75%), which separated out during the stirring of the reaction mixture. Instead of obtaining bis-coumaranones **2** (via a route analogous to eq. [2]) or compound **3** (via a route analogous to eq. [3]), interestingly, a novel formation of 5-

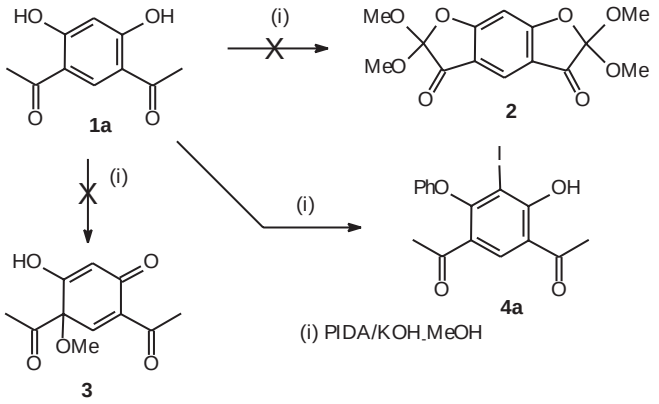
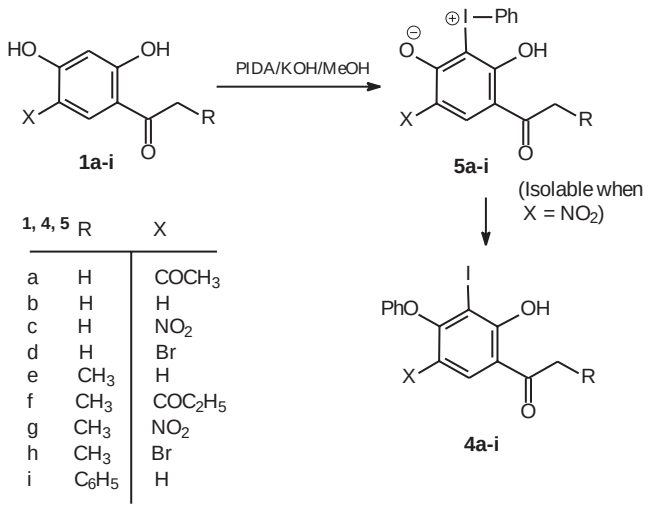
Scheme 1.



Scheme 2.



acetyl-2-hydroxy-3-iodo-4-phenoxyacetophenone (**4a**) was observed (Scheme 1).

A preliminary account of this study was reported earlier (13). This observation, coupled with the fact that the rearranged products from this reaction i.e., *o*-iodo ethers, are potential precursors for the synthesis of a variety of interesting compounds such as dibenzofurans, which are associated with diverse physiological activities (14), prompted us to study the scope of this novel route.

In the present study, a full account of our detailed investigations on the oxidation of α-substituted 2,4-dihydroxyacetophenones (**4a–4i**) with phenyliodonium diacetate under different conditions is described.

Accordingly, we first carried out oxidation of 2,4-dihydroxyacetophenones (**1b–1d**) with PIDA – KOH in MeOH, to afford the corresponding rearranged *o*-iodo ethers (**4b–4d**). This rearrangement occurred via the intermediacy of iodonium ylides of the type **5b–5d** as evidenced by the isolation of ylide **5c** as a high-melting yellow solid, from the oxidation of ketone **1c**. Acidification of **5c** with hydrochloric acid, followed by refluxing the methanolic solution of the resultant solid (mp 153–154°C), afforded a rearranged product **4c** (mp 190–191°C; yield 77%). However, our attempt to isolate similar intermediates **5a**, **5b**, **5d** in other cases ended up with no success, as only the rearranged products **4a**, **4b**, **4d** were obtained from these reactions. The physical data for the products **4a–4d** are listed in Table 1.

Similarly, oxidation of 2,4-dihydroxy-5-nitropropiophenone (**1g**) with PIDA with KOH in MeOH at 0°C (condition (i)) afforded iodonium ylide **5g** as a yellow crystalline solid (based on ^{1}H NMR and mp). This ylide, on acidification with hydrochloric acid followed by refluxing, gave 2-hydroxy-3-iodo-4-phenoxy-5-nitroacetophenone (**4g**) in 48% yield.

2,4-dihydroxypropiophenone (**1e**), 2,4-dihydroxy-5-propionylpropiophenone (**1f**), 5-bromo-2,4-dihydroxypropiophenone (**1h**), and 2,4-dihydroxydeoxybenzoin (**1i**) also underwent smooth transformation to 2-hydroxy-3-iodo-4-phenoxypropiophenone (**4e**) 2-hydroxy-3-iodo-4-phenoxy-5-propionylpropiophenone (**4f**), 5-bromo-2-hydroxy-3-iodo-4-phenoxypropiophenone (**4h**), and 2-hydroxy-3-iodo-4-phenoxydeoxybenzoin (**4i**), respectively. The intermediates, iodonium ylides **5e**, **5f**, **5h**, and **5i**, could not be isolated.

In view of the marked effect of conditions on the course of various hypervalent iodine-mediated transformations, it was considered worthwhile to investigate the role of other reaction conditions on the oxidation of compounds **1a–1i**.

i	C_6H_5	H

Thus substrate **1a** was also oxidized with PIDA under condition (ii), viz. PIDA in methanol (neutral) at reflux temperature, and under condition (iii), PIDA in acetic acid (acidic) at reflux temperature (Scheme 3). The product, obtained after the usual work-up under these conditions, was characterized as **4a,** which was found to be identical to that prepared under reaction condition (i). However, yields of the products were found to be lower in conditions (ii) and (iii) than in condition (i).

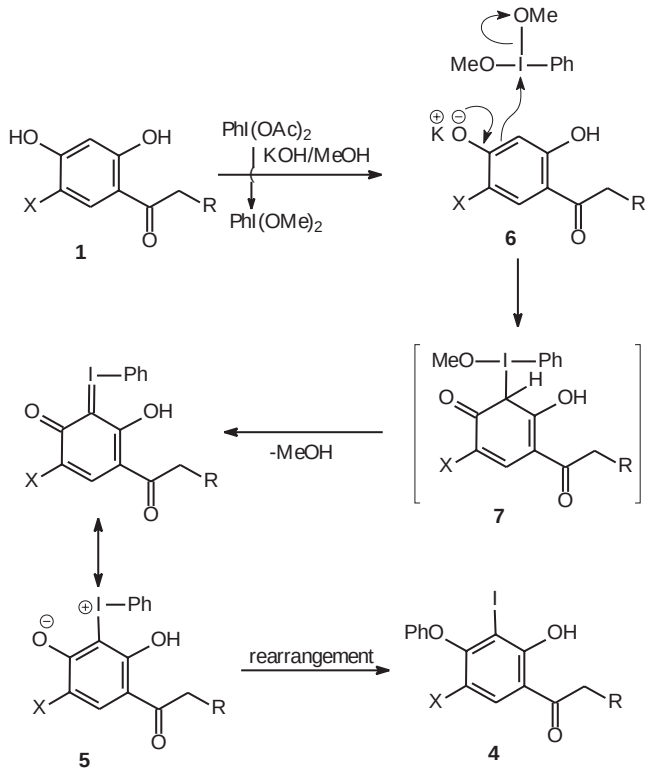
Similarly, applying conditions (ii) and (iii), other phenolic ketones **1b–1i** were oxidatively rearranged to the corresponding *o*-iodophenoxy ethers **4b**–**4i**. The physical data for the products (% yields and melting points under different conditions) are given in Table 1.

A plausible mechanistic pathway for **1**→**4** via rearrangement of iodonium ylide (15, 16) of type **5** is outlined in Scheme 4. Under strong basic conditions (KOH in MeOH) PIDA is converted into dimethoxyiodobenzene (17), ($PhI(OMe)_2$), while substrate **1** changes in situ into the corresponding potassium phenolate **6**. Dimethoxyiodobenzene attacks at position 3 of phenolate **6** to form intermediate **7**, which loses methanol to produce iodonium ylide **5**. The iodonium ylide **5** finally rearranges to product **4**. It is to be noted that under conditions (ii) and (iii) the electrophilic attack of PIDA itself takes place, on substrate **1** (in place of dimethoxyiodobenzene), to afford the final product via intermediates of type **5** and **7**. Since PIDA in acetic acid gives the products in lower yields (5–18%), basic conditions presumably assist the removal of a proton from intermediate **7**. Thus $PhI(OMe)_2$ may not be an obligatory reagent for the products **4** and **5**.

It is relevant to mention that while our detailed investigation of this rearrangement was in progress and a preliminary communication had also appeared (13), Mallik and Mallik reported the oxidation of 2,4-dihydroxyacetophenone and other phenolic ketones with PIDA–MeOH at reflux temperature to afford *o*-iodophenoxy ethers (18). Although these reaction conditions also afforded the same *o*-iodo ethers **4**, PIDA – KOH in MeOH (our condition i) gave better results in terms of yields and isolation of products.

Finally, the formation and rearrangement of phenolic iodonium ylides containing an enolizable ketone moiety offers a novel route for the synthesis of new *o*-iodophenoxy ethers that are otherwise difficult to prepare using conventional methods. The most striking feature of this approach is that the enolizable ketonic group present in compounds **1a–1i** remains unaffected under these reaction conditions, which normally oxidize the α-position of the enolizable ketones (7, 8). Another noteworthy feature of this oxidative rearrangement is that phenolic ketones having electron-withdrawing substituents ($COCH_2R$ and NO_2) at the 5-position yield better results. The products obtained from this study are potential precursors of various organic compounds, especially heterocyclic compounds. For example, *o*-iododiaryl ethers are useful intermediates for dibenzofuran synthesis as they could be readily cyclized either photochemically (15) or chemically through the use of Ph(II) salts(16), *n*-Bu_3SnH–AIBN (19), etc.

Scheme 4.



Experimental

Melting points were measured in open capillaries in a sulfuric acid bath and are uncorrected. IR spectra were recorded on a Beckmann IR-20 spectrophotometer. ^1H NMR spectra were taken on a Perkin Elmer (90 MHz) instrument. EI mass spectra were recorded on a mass spectrophotometer operating at 70 eV. 2,4-Dihydroxyacetophenone (**1b**) (20) and its analogues (5-bromo-2,4-dihydroxyacetophenone (**1d**) (21), 2,4-dihydroxy-5-nitroacetophenone (**1c**) (22), 5-acetyl-2,4-dihydroxyacetophenone (**1a**) (20, 21)), 2,4-dihydroxypropiophenone (**1e**) (20) and its analogues 5-bromo-2,4-dihydroxypropiophenone (**1h**) (23), 2,4-dihydroxy-5-nitropropiophenone (**1g**) (22*a*), 5-propionyl-2,4-dihydroxypropiophenone) (**1f**) (21), and 2,4-dihydroxydeoxybenzoin (**1i**) (24) were prepared according to literature procedure.

© 1999 NRC Canada

Oxidation of 5-substituted 2,4-dihydroxyacetophenones (1a–1d), 5-substituted 2,4-dihydroxypropiophenones (1e–1h), and 2,4-dihydroxydeoxybenzoin (1i) with phenyliodonium diacetate – potassium hydroxide in methanol (condition i). General procedure

To a stirred solution of potassium hydroxide (0.03 mol) in methanol (20 mL) at 0°C in a conical flask placed in an ice bath was added 5-substituted 2,4-dihydroxyacetophenone, 5-substituted 2,4-dihydroxypropiophenone, or 2,4-dihydroxydeoxybenzoin (**1**) (0.01 mol). PIDA (0.011 mol) was slowly added to the resulting solution and the stirring was continued overnight. Water was added to the resulting reaction mixture followed by dilute HCl. Subsequently, the mixture was extracted with dichloromethane (3 × 50 mL). The combined organic phases were washed with water and dried over anhydrous sodium sulphate. The solvent was distilled off at reduced pressure. The crude product, so obtained, was purified by passing through a column using silica gel (60–120 mesh size) and ethyl acetate – petroleum ether (1:10) as eluent to afford pure product **4**.

The yields and melting points of products **4a**–**4i** are given in Table 1.

*Isolation of iodonium ylides **5c** and **5g***

To a stirred solution of potassium hydroxide (1.680 g, 0.03 mol) in methanol (20 mL) at 0°C in a conical flask placed in an ice bath was added 2,4-dihydroxy-5-nitroacetophenone (**1c**, 1.970 g, 0.01 mol) or 2,4-dihydroxy-5-nitropropiophenone (**1g**, 2.110 g, 0.01 mol). The reaction mixture was stirred for 10 min. PIDA (3.542 g, 0.011 mol) was added slowly to the resulting solution and the stirring was continued for half an hour. A yellow crystalline solid (separated out of the solution) was isolated by filtration, followed by washing with methanol. **5c**: yield, 3.272 g, 82%, mp >200°C. **5g**: yield 2.312 g, 56%, mp 196–198°C; ^{1}H NMR (DMSO) δ 1.2 (t, 3H, C_1-$COCH_2C\mathbf{H}_3$), 2.97(q, 2H, C_1-$COC\mathbf{H}_2CH_3$), 6.70–7.25(m, 5H, C_4-I-$C_6\mathbf{H}_5$), 8.6(s, 1H, C_6-**H**).

Oxidation of 5-substituted 2,4-dihydroxyacetophenones (1a–1d), 5-substituted 2,4-dihydroxypropiophenones (1e–1h), and 2,4-dihydroxydeoxybenzoin (1i) with phenyliodonium diacetate in methanol (condition ii). General procedure

PIDA (0.01 mol) was added to a solution of 5-substituted 2,4-dihydroxyacetophenone, 5-substituted 2,4-dihydroxypropiophenone, or 2,4-dihydroxydeoxybenzoin **1** (0.01 mol) in methanol (20 mL) and the reaction mixture was refluxed. The progress of the reaction was monitored by TLC. After about 12 h the solvent was removed in vacuo To the resulting mixture was added water, followed by extraction with dichloromethane (3 × 50 mL). The combined organic phases were washed with water and dried over anhydrous sodium sulphate. The solvent was distilled at reduced pressure to obtain the crude product, which was purified by passing through a column using silica gel (60–120 mesh size) and petroleum ether – ethyl acetate (10:1) as an eluent to afford pure product **4.**

The physical data of the pure products are listed in Table 1.

Oxidation of 5-substituted 2,4-dihydroxyacetophenones (1a–1d), 5-substituted 2,4-dihydroxypropiophenones (1e–1h), and 2,4-dihydroxydeoxybenzoin (1i) with phenyliodonium diacetate in acetic acid (condition iii). General procedure

PIDA (0.01 mol) was added to a solution of 5-substituted 2,4-dihydroxyacetophenone, 5-substituted 2,4-dihydroxypropiophenone, or 2,4-dihydroxydeoxybenzoin **1** (0.01 mol) in acetic acid (20 mL) and the reaction mixture was refluxed. The progress of the reaction was monitored by TLC. After about 8 h the solvent was removed in vacuo. To the resulting mixture was added water, followed by extraction with dichloromethane (3 × 50 mL). The combined organic extracts were washed with water and dried over anhydrous sodium sulphate. The solvent was distilled at reduced pressure to obtain the crude product, which was purified by passing through a column using silica gel (60–120 mesh size) and petroleum ether – ethyl acetate (10:1) as an eluent to afford pure product **4**.

The physical data of the pure products are listed in Table 1.

Spectral and analytical data of products 4a–4i

*5-Acetyl-2-hydroxy-3-iodo-4-phenoxyacetophenone (**4a**)*: IR (Nujol, cm^{-1}): 1630, 1670 (C=O). ^{1}H NMR ($CDCl_3$) δ: 2.47 (s, 3H, C_1-$COC\mathbf{H}_3$), 2.72 (s, 3H, C_5-$COC\mathbf{H}_3$), 6.80–7.42 (m, 5H, C_4-$OC_6\mathbf{H}_5$), 8.45 (s, 1H, C_6-**H**). Reactions of aminoboron compounds with palladium and platinum complexes

Christopher M. Vogels, Heather L. Wellwood, Kumar Biradha, Michael J. Zaworotko, and Stephen A. Westcott

Abstract: Reactions of 3-$NH_2C_6H_4B(OH)_2$ (**1**, APBA) with $[MCl_4]^{2-}$ (M = Pd, Pt) give the boronic acid-containing complexes, $MCl_2(APBA)_2$ (M = Pd, **2**; M = Pt, **3**). Addition of **1** to $[PdCl_2(COE)]_2$ (COE = η^2-C_8H_{14}) ultimately led to $PdCl_2(APBA)_2$ (**2**). The pinacol derivative $PdCl_2(APBpin)_2$ (**5,** pin = $O_2C_2Me_4$) was characterized by an X-ray diffraction study. Crystals of **5** were monoclinic, a = 13.836(5), b = 14.937(5), c = 11.287(5) Å, β = 99.042(9)°, Z = 2, with space group $P2_1/c$. Monoalkene complexes $PtCl_2(COE)(APBA)$ (**8**) and $PtCl_2(COE)(APBpin)$ (**9**) were generated from the addition of APBA and APBpin, respectively, to $[PtCl_2(COE)]_2$. Reactions of 2-$NMe_2CH_2C_6H_4B(OH)_2$ (**10**) with palladium complex $[PdCl_2(COE)]_2$ proceed via selective B—C bond cleavage to give the cyclopalladated dimer $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$ as the major amine-containing product. Likewise, reactions with borinic esters $H_2NCH_2CH_2OBR_2$ (R = Bu, **14**; R = Ph, **15**) give products derived from cleavage of the B—O bond. The unique palladium complex $PdCl_2[3\text{-}NC_5H_4B(OH)_2]_2$ (**19**) was prepared by addition of $(3\text{-}NC_5H_4BEt_2)_4$ (**18**) to $[PdCl_2(COE)]_2$ in wet methylene chloride, where adventitious water was used to convert the organoborane product into the corresponding boronic acid moiety.

Key words: aminoboronic acids, platinum, palladium, cyclometallation.

Résumé : Le 3-$NH_2C_6H_4B(OH)_2$ (**1**, APBA) réagit avec les ions $[MCl_4]^{2-}$ (M = Pd, Pt) pour donner des complexes contenant de l'acide boronique, $MCl_2(APBA)_2$ (M = Pd, **2**; M = Pt, **3**). L'addition de **1** au $[PdCl_2(COE)]_2$ (COE = η^2-C_8H_{14}) conduit finalement au $PdCl_2(APBA)_2$ (**2**). Le dérivé du pinacol, $PdCl_2(APBpin)_2$ (**5**, pin = $O_2C_2Me_4$) a été caractérisé par une étude de diffraction des rayons X. Les cristaux du produit **5** sont monocliniques, groupe d'espace $P2_1/c$, avec a = 13,836(5), b = 14,937(5) et c = 11,287(5) Å, β = 99,042(9)° et Z = 2. On a généré des complexes monoalcéniques, $PtCl_2(COE)(APBA)$ (8) et $PtCl_2(COE)(APBpin)$ (**9**), par addition respectivement de APBA et de APBpin sur le $[PtCl_2(COE)]_2$. Les réactions du 2-$NMe_2CH_2C_6H_4B(OH)_2$ (**1**0) avec le complexe de palladium $[PdCl_2(COE)]_2$ se font avec un clivage sélectif de la liaison B—C et la formation du dimère cyclopalladié $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$ comme principal produit contenant de l'amine. De la même manière, les réactions avec des esters de l'acide boronique, $H_2NCH_2CH_2OBR_2$ (R = Bu, **14**; R = Ph, **15**), conduisent à la formation de produits dérivés du clivage de la liaison B—O. On a préparé le complexe de palladium unique, $PdCl_2[3\text{-}NC_5H_4B(OH)_2]_2$ (**19**) par addition de $(3\text{-}NC_5H_4BEt_2)_4$ (**18**) sur du $[PdCl_2(COE)]_2$ dans du chlorure de méthylène humide dont l'eau accidentelle est utilisée sert à transformer le produit organoborane en portion acide boronique correspondante.

Mots clés : acides aminoboroniques, platine, palladium, cyclométallation.

[Traduit par la Rédaction]

Introduction

The bioinorganic chemistry of compounds containing boronic acid groups, $B(OH)_2$, is an area of growing interest and has recently expanded to include boron-containing purine nucleosides (1), psuedocryptands (2) (which mimic the naturally occurring antibiotics boromycin and aplasmomycin), steroids (3), calixarenes (4), carbohydrates (5), fatty acids (6), porphyrins (7), and amino acids (8). Interestingly, boronic acids have been found to facilitate the transport of various ribonucleosides in and out of liposomes (9). Recent interest in compounds containing boronic acid groups arises from the ability of the boron atom to coordinate (via an empty *p*-orbital) with certain atoms, such as nitrogen and oxygen, of biomolecules. As a result, compounds containing boronic acids are able to act as selective targets for specific

binding sites. For example, aromatic boronic acids have been shown to inhibit the serine proteases chymotrypsin and subtilisin (10). Serine proteases are a diverse group of proteolytic enzymes whose physiological functions include digestion of proteins, blood clotting, and cell lysis in the immune response. The crystal structure of subtilisin complexed with either phenylboronic acid or phenylethaneboronic acid (11) shows that the boron moiety exists as a tetrahedral adduct with the active hydroxyl site of the serine protease.

Work by Matteson et al. (12*d*) has shown that (*R*)-acetamido-2-phenylethaneboronic acid, a boron analogue of *N*-acetyl-phenylalanine, also acts as an effective and reversible inhibitor of serine proteases. Indeed, this compound is several orders of magnitude more effective than the corresponding aromatic boronic acids for the inhibition of chymotrypsin even in the micromolar concentration range. Since this discovery, much effort has focused on the synthesis of related boron-containing amino acid and peptide derivatives for possible applications as enzyme inhibitors (12, 13).

The observed biochemical activities and ability of boronic acids to facilitate the transport of molecules intracellularly prompted us to investigate the use of aminoboron compounds as ligands for biologically active transition metals. For instance, while both *cis* and *trans* amine complexes of platinum display anticancer properties, the overall efficacy of these chemotherapeutic compounds is limited by their numerous toxicities and poor cellular-uptake rates (arising from low solubility in water). As a result, a great deal of research has focused on improving aminoplatinum-based drugs for use in cancer therapy (14). With this in mind, we have begun to examine the possibility of generating new complexes of platinum and palladium containing aminoboron appendages. The results of our initial investigations are described herein.

Experimental

General procedures

Reagents and solvents used were obtained from Aldrich Chemicals. Palladium chloride and potassium tetrachloroplatinate were obtained from Strem. NMR spectra were recorded on a JEOL JNM-GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 270.05 MHz. ^{11}B{^{1}H} NMR chemical shifts are referenced to external $F_3B{\cdot}OEt_2$ at 86.55 MHz. ^{13}C{^{1}H} NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 67.80 MHz. Multiplicities are reported as (s) singlet, (d) doublet, (t) triplet, (q) quartet, (quint) quintet, (m) multiplet, (br) broad, and (ov) overlapping. Infrared spectra were obtained using a Mattson Polaris FT-IR spectrometer and reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Desert Analytics (Tucson, Ariz.).

μ-[Dichloro(*cis*-cyclooctene)palladium(II)]

μ-[Dichloro(*cis*-cyclooctene)palladium(II)], $[PdCl_2(COE)]_2$, was prepared by modification of a known synthesis (15*a*). Sodium chloride (363 mg, 6.21 mmol) was added as a solid to an isopropanol–water suspension (11:16 mL ratio by volume) of palladium chloride (500 mg, 2.82 mmol). After 1 h of stirring, cyclooctene (3 mL, 23.03 mmol) and a catalytic amount of tin(II) chloride (27 mg, 0.14 mmol) were added. After 20 h, solvent was removed under vacuum to afford a dark orange solid. $[PdCl_2(COE)]_2$ was extracted with methylene chloride, filtered to remove impurities, and collected following the removal of methylene chloride under vacuum. Yield: 620 mg (77%) of an orange solid; mp 164°C (decomposition). NMR spectroscopic data (in $CDCl_3$): ^{1}H δ: 6.20 (m, 4H, =C*H*R), 2.33 (s, 8H), 1.67 (s, 8H), 1.40 (s, 8H); ^{13}C{^{1}H} δ: 109.5 (br, =*C*HR), 29.1, 28.8, 26.3.

$PdCl_2(APBA)_2$ (2)

Method A

Sodium chloride (36 mg, 0.62 mmol) was added in small portions as a solid to a 25 mL methanol suspension of palladium chloride (50 mg, 0.28 mmol) to generate the methanol soluble species, sodium tetrachloropalladate. After 1 h of stirring, a 5 mL methanol solution of 3-aminophenylboronic acid (87 mg, 0.56 mmol) was added dropwise to the clear amber solution. Within 2 h, an isomeric mixture of *cis* and *trans* **2** precipitated and was collected by filtration and washed with methanol (3 × 5 mL) and methylene chloride (3 × 5 mL). Yield: 110 mg (81%) of a yellow solid.

Method B

In another reaction, 3-aminophenylboronic acid (91 mg, 0.58 mmol) was added in small portions as a solid to a stirred 25 mL methylene chloride solution of $[PdCl_2(COE)]_2$ (75 mg, 0.13 mmol). After 20 h, the reaction was filtered and a yellow solid was collected. The solid was washed three times with 10 mL portions of hexane and methylene chloride. Complex **2** was crystallized from a tetrahydrofuran–hexane solution. Yield: 50 mg (39%) of a yellow solid; mp 276°C (decomposition). IR (nujol): 3233 (m), 3125 (m), 2946 (s), 1582 (m), 1462 (m), 1377 (m). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 8.14 (s, 4H, B(O*H*)$_2$), 7.63 (s, 2H), 7.33 (ov, 4H), 6.86 (s, 2H), 6.07 (s, 4H, N*H*$_2$); ^{11}B{^{1}H} δ 35.1 (br); ^{13}C{^{1}H} δ 147.6, 135.2 (br, *C*-B), 130.6, 125.0, 122.4, 120.4. Anal. calcd. for $PdCl_2C_{12}H_{16}N_2B_2O_4$: C 31.94, H 3.58, N 6.21; found: C 32.04, H 3.66, N 5.90.

$PtCl_2(APBA)_2$ (3)

A 25 mL aqueous solution of 3-aminophenylboronic acid (224 mg, 1.45 mmol) was added dropwise to a 25 mL water solution of potassium tetrachloroplatinate (300 mg, 0.72 mmol). Within 4 h, the solution became yellow, and a fine brown–yellow precipitate was collected by filtration and discarded. The clear yellow filtrate was chilled to 0°C, and after 24 h, **3** precipitated and was collected by filtration. Yield: 230 mg (55%) of a yellow solid; mp 267°C (decomposition). IR (nujol): 3266 (w), 3186 (w), 2885 (s), 1582 (m), 1461 (s), 1377 (s). NMR spectroscopic data (in acetone-d_6): ^{1}H δ: 7.88 (s, 2H), 7.72 (d, J_{H-H} = 5 Hz, 2H), 7.45 (m, 2H), 7.24 (t, J_{H-H} = 5 Hz, 2H), 6.74 (s, 4H, N*H*$_2$); ^{11}B{^{1}H} δ 30.9 (br); ^{13}C{^{1}H} δ: 141.5, 136.3 (br, *C*-B), 132.6, 129.5, 129.4, 124.0. APBpin (4)

3-Aminophenylboronic acid (250 mg, 1.61 mmol) and 10 g of activated molecular sieves (BDH 4A) were added to a 25 mL methylene chloride solution of pinacol (190 mg, 1.61 mmol). After 5 days, the sieves were removed by filtration, and methylene chloride was removed under vacuum to give **4**. Yield: 350 mg (95%) of a light yellow solid; mp 93°C. IR (nujol): 3465 (w), 3375 (w), 3125 (s), 1628 (m), 1578 (m), 1452 (s), 1376 (s), 1145 (m). NMR spectroscopic data (in $CDCl_3$): ^{1}H δ: 7.20 (m, 2H), 7.14 (s, 1H), 6.80 (m, 1H), 3.63 (s, 2H, N*H*$_2$), 1.31 (s, 12H, BO_2C_2*Me*$_4$); ^{11}B{^{1}H} δ 31.8 (br); ^{13}C{^{1}H} δ: 145.9, 129.2 (br, *C*-B), 128.4, 124.9, 121.2, 118.1, 83.7 (BO_2*C*$_2$Me$_4$), 24.9 (BO_2C_2*Me*$_4$). $PdCl_2$(APBpin)$_2$ (5)

Method A

Complex **2** (250 mg, 0.51 mmol) was added slowly as a solid to a tetrahydrofuran solution of pinacol (140 mg, 1.20 mmol) and 10 g of activated molecular sieves (BDH 4A). After 3 days, the sieves and unreacted **2** were removed by filtration, and the filtrate was collected. Complex **5** was collected following the removal of tetrahydrofuran under vacuum. Yield: 50 mg (16%) of an orange solid.

Method B

To a 50 mL methylene chloride solution of $[PdCl_2(COE)]_2$ (200 mg, 0.35 mmol), a 15 mL methylene chloride solution of **4** (305 mg, 1.39 mmol) was added dropwise. The reaction was allowed to proceed for 2 h before the solvent was removed under vacuum. Complex **5** was crystallized from a tetrahydrofuran–hexane solution. Yield: 300 mg (70%) of an orange solid; mp 152°C (decomposition). IR (nujol): 3187 (w), 3121 (w), 2968 (s), 2891 (s), 1583 (w), 1461 (s), 1377 (s), 1148 (m), 722 (w). NMR spectroscopic data (in $CDCl_3$): ^{1}H δ 7.67 (s, 4H), 7.57 (s, 2H), 7.32 (s, 2H), 5.06 (br s, 4H, N*H*$_2$), 1.33 (s, 24H, BO_2C_2*Me*$_4$); ^{11}B{^{1}H} δ: 31.5 (br); ^{13}C{^{1}H} δ: 139.3, 132.7, 130.8 (br, *C*-B), 129.0, 127.7, 125.5, 84.2 (BO_2*C*$_2$Me$_4$), 25.1 (BO_2C_2*Me*$_4$). $PtCl_2$(APBpin)$_2$ (6)

Complex **3** (360 mg, 0.63 mmol) and 10 g of activated molecular sieves (BDH 4A) were added to a tetrahydrofuran solution of pinacol (163 mg, 1.34 mmol). The mixture was allowed to stand for 3 days before the sieves and unreacted **3** were removed by filtration. Complex **6** was isolated following removal of solvent under vacuum. Yield: 40 mg (9%) of a yellow solid; mp 224°C. IR (nujol): 1591 (m), 1400 (m), 1359 (m), 1332 (w), 1145 (m), 853 (w). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 7.63 (s, 2H), 7.49 (m, 4H), 7.30 (m, 4H), 1.36 (s, 24H), ^{11}B{^{1}H} δ: 32.6 (br); ^{13}C{^{1}H} δ: 148.0, 141 (br, *C*-B), 128.3, 121.8, 120.1, 116.8, 67.0, 21.7. Anal. calcd. for $PtCl_2C_{24}H_{36}N_2B_2O_4$: C 40.93, H 5.16, N 3.98; found: C 40.63, H 5.31, N 4.02.

Reaction of $[PdCl_2(COE)]_2$ and 4

A 20 mL methylene chloride solution of **4** (114 mg, 0.52 mmol) was added dropwise to a stirred 50 mL methylene chloride solution of $[PdCl_2(COE)]_2$ (150 mg, 0.26 mmol). After 30 min, the clear orange solution became clear red, at which point methylene chloride was removed under vacuum to afford complex **7**, which was washed with hexane (3 × 5 mL). Yield: 120 mg (91%) of a red–orange solid; mp 138°C (decomposition). IR (nujol): 3194 (m), 3123 (m), 2973 (s), 2885 (s), 2842 (s), 1583 (m), 1461 (s), 1364 (s), 1146 (m), 695 (m). NMR spectroscopic data of **7** (in $CDCl_3$): ^{1}H δ: 7.65 (s, 2H), 7.56 (s, 1H), 7.29 (s, 1H), 6.03 (m, 2H, =CHR), 5.24 (s, 2H, N*H*$_2$), 2.31 (br s, 4H), 1.60 (br s, 4H), 1.45 (br s, 4H), 1.34 (s, 12H, BO_2C_2*Me*$_4$); ^{11}B{^{1}H} δ: 32.1 (br); ^{13}C{^{1}H} δ 139.0, 132.8, 131.0 (br, *C*-B), 129.1, 127.7, 125.5, 117.3 (br, =*C*HR), 84.2 (BO_2*C*$_2$Me$_4$), 29.3, 27.8, 26.3, 25.1 (BO_2C_2*Me*$_4$). Reactions gave minor amounts of the diamine complex, which complicated elemental analyses.

Reaction of 7 and PPh_3

Complex **7** (44 mg, 0.09 mmol) was dissolved in 10 mL of methylene chloride, and a 10 mL methylene chloride solution of triphenylphosphine (25 mg, 0.09 mmol) was added dropwise to the clear red solution. Within 1 h, a yellow precipitate formed and was collected by filtration. Yield: 25 mg of a yellow solid. Selected NMR data (in $CDCl_3$): ^{1}H δ: 7.70 (m, *Ar*, 2H), 7.41 (m, *Ar*, 3H); $PdCl_2(PPh_3)_2$.

$PtCl_2$(COE)(APBA) (8)

To a stirred 50 mL methylene chloride solution of $[PtCl_2(COE)]_2$ (100 mg, 0.13 mmol), 3-aminophenylboronic acid (41 mg, 0.26 mmol) was added in small portions as a solid. The cloudy, yellow mixture was filtered after 2 days, and the clear yellow filtrate was stored under dinitrogen at 0°C. Within 48 h, **8** precipitated and was collected by filtration. The yellow solid was washed with ether (3 × 10 mL), hexane (3 × 10 mL), and cold methylene chloride (1 × 2 mL). Yield: 80 mg (29%) of a yellow solid; mp 169°C. IR (nujol): 3186 (w), 3116 (w), 2965 (s), 2890 (s), 1584 (m), 1462 (s), 1377 (s), 723 (m). NMR spectroscopic data (in acetone-d_6): ^{1}H δ: 7.95 (s, 1H), 7.77 (s, 1H), 7.54 (m, 2H), 5.95 (s, J_{H-Pt} = 27 Hz, 2H, =C*H*R), 2.46 (s, 4H), 2.14 (s, 4H), 1.81 (s, 4H); ^{11}B{^{1}H} δ 29.6 (br); ^{13}C{^{1}H} δ: 146.9, 136.4 (br, *C*-B), 133.6, 129.3, 128.9, 126.4, 93.3 (s, J_{C-Pt} = 80 Hz, =*C*HR), 28.4, 26.8, 26.1.

$PtCl_2$(COE)(APBpin) (9)

To a 50 mL methylene chloride solution of $[PtCl_2(COE)]_2$ (145 mg, 0.19 mmol), a 10 mL methylene chloride solution of **4** (89 mg, 0.41 mmol) was added dropwise. After 5 h, methylene chloride was removed under vacuum to afford a yellow solid. Complex **9** was crystallized from a methylene chloride – hexane solution. Yield: 150 mg (66%) of a yellow powder; mp 236°C (decomposition). IR (nujol): 3116 (w), 2935 (s), 1578 (w), 1461 (s), 1377 (s), 1145 (m), 726 (m). NMR spectroscopic data (in $CDCl_3$): ^{1}H δ: 7.70 (s, 2H), 7.61 (s, 1H), 7.36 (s, 1H), 5.91 (br s, 2H, =C*H*R), 5.35 (s, J_{H-Pt} = 32 Hz, 2H, N*H*$_2$), 2.36 (br s, 2H), 2.25 (br s, 2H), 1.74 (br s, 2H), 1.41 (br s, 6H), 1.34 (s, 12H, BO_2*Me*$_4$); ^{11}B{^{1}H} δ 32.2 (br); ^{13}C{^{1}H} δ: 139.4, 131.7, 131.0 (br, *C*-B), 129.2, 126.7,

124.1, 93.1 (J_{C-Pt} = 164 Hz, =*C*HR), 84.3 ($BO_2C_2Me_4$), 29.3, 28.2, 26.3, 25.1 ($BO_2C_2Me_4$). Anal. calcd. for $PtCl_2C_{20}H_{32}NBO_2$: C 40.35, H 5.43, N 2.35; found: C 41.08, H 5.68, N 2.46.

2-$NMe_2CH_2C_6H_4B(OH)_2$ (10)

Compound **10** was prepared by modification of a known procedure (16). To a 20 mL ether solution of *N*,*N*-dimethylbenzylamine (10.0 g, 74 mmol), a 10.0 M solution of *n*-butyllithium in hexanes (8.2 mL, 82 mmol) was added dropwise under an atmosphere of dinitrogen. The lithiation of *N*,*N*-dimethylbenzylamine was allowed to proceed at room temperature for 18 h. Trimethylborate (10.0 mL, 88 mmol) was added at 0 °C, and the reaction mixture was allowed to warm to room temperature. After 4 h, 10 mL of water was added and the aqueous phase separated. The addition of 20 mL of isopropanol and subsequent cooling of the mixture to 0 °C resulted in the precipitation of lithium borate, which was removed by filtration. Complex **10** was isolated upon removal of water under vacuum. Yield: 3.25 g (25%) of an off-white powder. NMR spectroscopic data (in D_2O): ^{1}H δ: 7.41 (m, 1H), 7.20 (m, 2H), 7.08 (m, 1H), 3.81 (s, 2H, Ar-CH_2-N), 2.34 (s, 6H, NMe_2); ^{11}B{^{1}H} δ: 8.9 (br); ^{13}C{^{1}H} δ: 150 (br, *C*-B), 145.5, 135.0, 132.9, 132.4, 128.6, 69.6 (Ar-*C*H_2-N), 49.4 (NMe_2).

Reaction of Na_2PdCl_4 + 10

A fresh solution of sodium tetrachloropalladate was prepared by the addition of sodium chloride (36 mg, 0.62 mmol) to a 30 mL methanol suspension of palladium chloride (50 mg, 0.28 mmol). After 1 h of stirring, a 10 mL methanol solution of **10** (111 mg, 0.62 mmol) was added dropwise. The yellow precipitate that formed over 1 h was collected by filtration and washed with water (3 × 5 mL). Selected NMR data (in $CDCl_3$): ^{1}H δ: 7.16 (m, 2H), 6.97 (m, 2H), 6.87 (m, 4H), 3.93 (s, 4H, Ar-CH_2-N), 2.86 (s, 12H, NMe_2); $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$.

Reaction of $[PtCl_2(COE)]_2$ + 10

To a stirred 35 mL methylene chloride solution of $[PtCl_2(COE)]_2$ (150 mg, 0.20 mmol), compound **10** (75 mg, 0.42 mmol) was added in small portions as a solid. After 20 h, the reaction was filtered and methylene chloride removed under vacuum. Complex **13** was extracted from the resulting brown–orange solid with hexane (10 × 10 mL). Attempts at isolating compound **13** were complicated by the ubiquitous presence of a minor amount of an unidentified compound. IR (nujol): 3060 (w), 3001 (w), 2927 (s), 2854 (s), 1586 (w), 1471 (m), 717 (s), 651 (s). Selected NMR data (crude) for **13** (in $CDCl_3$): ^{1}H δ: 7.03 (m, 3H), 6.57 (s, J_{H-Pt} = 43 Hz, 1H), 4.84 (s, J_{H-Pt} = 68 Hz, 2H, =C*H*R), 4.05 (s, J_{H-Pt} = 38 Hz, 2H, Ar-CH_2-N), 2.99 (s, J_{H-Pt} = 32 Hz, 6H, NMe_2), 2.73 (br s, 4H), 2.28 (br s, 4H), 1.81 (br s, 4H); ^{13}C{^{1}H} δ: 147.3, 133.1, 127.4 (J_{C-Pt} = 43 Hz, *C*-Pt), 126.2, 124.9, 122.1, 87.7 (s, J_{C-Pt} = 191 Hz, =*C*HR), 74.8 (s, J_{C-Pt} = 44 Hz, Ar-*C*H_2-N), 51.8 (NMe_2), 30.0, 28.5, 26.5.

2-$NMe_2CH_2C_6H_4Bpin$ (11)

A 10 mL methylene chloride solution of pinacol (330 mg, 2.79 mmol) was added dropwise to a 35 mL methylene chloride suspension of **10** (600 mg, 3.35 mmol). Ten grams of activated molecular sieves (BDH 4A) were added to the mixture to facilitate the formation of **11**. The reaction was allowed to stand for 5 days at which point the sieves and unreacted **10** were removed by filtration. Compound **11** was isolated following removal of methylene chloride under vacuum. Yield: 0.52 g (72%) of an off-white solid; mp 75°C. IR (nujol): 3150 (s), 1476 (w), 1348 (m), 1151 (s), 1107 (s), 1043 (s), 748 (m). NMR spectroscopic data (in $CDCl_3$): ^{1}H δ: 7.55 (d, J_{H-H} = 5 Hz, 1H), 7.19 (app. quint, J_{H-H} = 8 Hz, 2H), 7.01 (d, J_{H-H} = 8 Hz, 1H), 3.86 (s, 2H, Ar-CH_2-N), 2.57 (s, 6H, NMe_2), 1.31 (s, 12 H, $BO_2C_2Me_4$); ^{11}B{^{1}H} δ: 15.3 (br); ^{13}C{^{1}H} δ: 143.9 (br, *C*-B), 139.8, 131.6, 127.6, 127.5, 123.1, 80.5 ($BO_2C_2Me_4$), 65.6 (Ar-*C*H_2-N), 45.9 (NMe_2), 26.8 ($BO_2C_2Me_4$). Reaction of Na_2PdCl_4 + 11

A fresh solution of sodium tetrachloropalladate was generated by the addition of sodium chloride (22 mg, 0.37 mmol) to a stirred 15 mL methanol suspension of palladium chloride (30 mg, 0.17 mmol). After 1 h of stirring, a 10 mL methanol solution of **11** (88 mg, 0.338 mmol) was added dropwise. After 3 h, a yellow precipitate had formed and was collected by filtration. Yield: 35 mg (75%) of a yellow solid. NMR spectroscopic data (in $CDCl_3$): ^{1}H δ: 7.16 (m, 1H), 6.97 (m, 2H), 6.87 (m, 4H), 3.93 (s, 4H, CH_2N(Me)$_2$), 2.86 (s, 12H, $CH_2N(Me)_2$), $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$.

Reaction of $[PdCl_2(COE)]_2$ + 11

A 10 mL methylene chloride solution of **11** (182 mg, 0.70 mmol) was added dropwise to a stirred 25 mL methylene chloride solution of $[PdCl_2(COE)]_2$ (100 mg, 0.17 mmol). After 6 h, solvent was removed under vacuum to yield an orange–brown oil. Selected NMR data (in $CDCl_3$): ^{1}H δ: 7.16 (m, 2H), 6.97 (m, 2H), 6.87 (m, 4H), 3.93 (s, 4H, CH_2N(Me)$_2$), 2.86 (s, 12H, $CH_2N(Me)_2$) $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$; 9.19 (br), 8.06 (m), 7.92 (m), 7.60 (m), 7.42 (m), 4.72 (m), 2.98 (s) [2-$HNMe_2CH_2C_6H_4Bpin]_2[PdCl_4]$; 1.38 (s) $(Bpin)_2O$. ^{11}B{^{1}H} δ: 31.9 (br, $[2\text{-}HNMe_2CH_2C_6H_4Bpin]_2[PdCl_4]$), 23.1 (br, $(Bpin)_2O$).

$PtCl_2(COE)(2\text{-}Me_2NCH_2C_6H_4Bpin)$ (12)

The addition of a 0.5 mL deuterated chloroform solution of **11** (24 mg, 0.09 mmol) to a 0.5 mL deuterated chloroform solution of $[PtCl_2(COE)]_2$ (35 mg, 0.05 mmol) was performed under an atmosphere of dinitrogen. The reaction was allowed to proceed for 4 h before characterization by NMR spectroscopy was performed. IR ($CHCl_3$): 2981 (m), 2929 (s), 2854 (m), 1600 (w), 1471 (m), 1346 (s), 1145 (m), 906 (s), 745 (s), 651 (s). Reaction of Na_2PdCl_4 + 14

Sodium chloride (18 mg, 0.31 mmol) was added to a stirred 15 mL methanol suspension of palladium chloride (25 mg, 0.14 mmol) to produce sodium tetrachloropalladate. A 5 mL methanol solution of dibutylborinic acid, ethanolamine ester (57 mg, 0.31 mmol) was added dropwise to the solution, and the reaction was allowed to proceed for 45 h. The product was obtained upon removal of methanol under vacuum. NMR spectroscopic data (in D_2O): ^1H δ: 3.76 (m, 4H), 3.44 (br, 4H, N*H*$_2$), 2.68 (m, 4H); $PdCl_2(NH_2CH_2CH_2OH)_2$.

Reaction of K_2PtCl_4 + 14

Dibutylborinic acid, ethanolamine ester (29 mg, 0.16 mmol) was added as a solid to a stirred 20 mL aqueous solution of potassium tetrachloroplatinate (30 mg, 0.07 mmol). The reaction was allowed to proceed for 18 h. A yellow solid was isolated following the removal of water under vacuum. Selected NMR data (in D_2O): ^1H δ: 3.79 (m, 4H), 3.08 (m, 4H), 2.82 (br, 4H, N*H*$_2$), $PtCl_2(NH_2CH_2CH_2OH)_2$; $^{11}B\{^1H\}$ δ: 19.9 (s, $B(OH)_3$).

Reaction of Na_2PdCl_4 + 15

Sodium chloride (22 mg, 0.38 mmol) was added as a solid to a stirred 15 mL methanol suspension of palladium chloride (30 mg, 0.17 mmol) to produce the methanol soluble species, sodium tetrachloropalladate. After 1 h of stirring, a 10 mL methanol solution of diphenylborinic acid, ethanolamine ester (80 mg, 0.36 mmol) was added dropwise, and the clear amber solution became black immediately. Methanol was removed under vacuum, and the aqueous and organic soluble species were characterized by NMR spectroscopy. For the water soluble phase, NMR data (in D_2O): ^1H δ: 3.76 (m, 4H), 3.44 (m, 4H), 2.68 (m, 4H); $PdCl_2(NH_2CH_2CH_2OH)_2$. $^{11}B\{^1H\}$ δ: 19.9 (s, $B(OH)_3$). For the organic soluble phase, NMR data (in $CDCl_3$): ^1H δ: 8.22 (m), 7.57 (m), 7.45 (ov); $^{11}B\{^1H\}$ δ: 29.6 (br, $PhB(OH)_2$).

Reaction of K_2PtCl_4 + 15

Diphenylborinic acid, ethanolamine ester (29 mg, 0.13 mmol) was added in small portions as a solid to a stirred 20 mL aqueous solution of potassium tetrachloroplatinate (25 mg, 0.06 mmol). Water was removed under vacuum after 10 h, and the aqueous and organic soluble products were characterized by NMR spectroscopy. NMR data (in D_2O): ^1H δ: 3.79 (m, 4H), 3.08 (m, 4H), 2.82 (m, 4H); $PtCl_2(NH_2CH_2CH_2OH)_2$. $^{11}B\{^1H\}$ δ: 19.9 (s, $B(OH)_3$). For the organic soluble phase, NMR data (in $CDCl_3$): ^1H δ: 8.22 (m), 7.57 (ov) 7.45 (ov); $^{11}B\{^1H\}$ δ: 29.6 (br, $PhB(OH)_2$).

Reaction of $[PdCl_2(COE)]_2$ + 14

Under an atmosphere of dinitrogen using an MBraun glovebox, a 2 mL THF solution of dibutylborinic acid, ethanolamine ester (39 mg, 0.21 mmol) was added dropwise to a stirred 5 mL THF solution of $[PdCl_2(COE)]_2$ (30 mg, 0.05 mmol). The reaction was allowed to proceed for 1.5 h before solvent was removed under vacuum. The resulting yellow solid was washed with hexane (2 × 3 mL) to remove cyclooctene. The solid was dried under vacuum, and the product was extracted with 1 mL of deuterated chloroform. Selected NMR data (in $CDCl_3$): ^1H δ 4.12, (s), 3.24 (br), 2.84 (s), 1.31 (s), 0.89 (s); $^{11}B\{^1H\}$ δ 60.5 (br). The product decomposed (1 h) in solution to give palladium metal.

Reaction of $[PtCl_2(COE)]_2$ + 14

Under an atmosphere of dinitrogen using an MBraun glovebox, a 0.5 mL deuterated chloroform solution of dibutylborinic acid, ethanolamine ester (12 mg, 0.07 mmol) was added dropwise to a 0.5 mL deuterated chloroform solution of $[PtCl_2(COE)]_2$ (25 mg, 0.03 mmol). The reaction was allowed to proceed for 3 h before the product was characterized by IR and NMR spectroscopy. IR ($CHCl_3$): 3319 (w), 2930 (m), 1571 (w), 1468 (w), 1330 (w), 901 (s), 726 (s), 651 (s). Selected NMR data for $PtCl_2(COE)(NH_2CH_2CH_2OBBu_2)$ **16** (in $CDCl_3$): ^1H δ: 5.61 (br, 2H, C=C*H*R), 5.29 (br, J_{H-Pt} = 68 Hz, 2H, N*H*$_2$), 4.10, (br), 3.22 (br), 2.38 (br), 2.27 (br) 2.12, (br) 1.78, (br) 1.47 (br), 1.30 (br), 0.87 (br); $^{11}B\{^1H\}$ δ: 56.1 (br). The product decomposed (1 h) in solution to give platinum metal.

Reaction of $[PtCl_2(COE)]_2$ + 15

Under an atmosphere of dinitrogen using an MBraun glovebox, a 0.5 mL deuterated chloroform solution of diphenylborinic acid, ethanolamine ester (15 mg, 0.07 mmol) was added dropwise to a 0.5 mL deuterated chloroform solution of $[PtCl_2(COE)]_2$ (25 mg, 0.03 mmol). The reaction was allowed to proceed for 3 h before the clear yellow solution was characterized by NMR and IR spectroscopy. NMR data for $PtCl_2(COE)(NH_2CH_2CH_2OBPh_2)$ (**17**) (in $CDCl_3$): ^1H δ: 7.63 (m, 4H), 7.43 (m, 6H), 5.62 (br s, 2H, C=C*H*R), 5.30 (br s, J_{H-Pt} = 62 Hz, 2H, N*H*$_2$), 4.17 (s, 2H), 3.33 (s, 2H), 2.36 (br, 4H), 2.14 (br, 4H), 1.76 (br s, 4H); $^{11}B\{^1H\}$ δ: 47.8 (br); $^{13}C\{^1H\}$ δ 136.6 (br, *C*-B), 134.4, 131.7, 130.5, 130.1, 127.7, 93.7 (s, J_{C-Pt} = 165 Hz, *C*=*C*HR), 63.5, 46.6, 29.4, 28.0, 26.3. IR ($CHCl_3$): 2929 (w), 2853 (w), 1576 (w), 1470 (w), 1438 (w), 1322 (w), 905 (s), 727 (s), 851 (s).

$PdCl_2(3\text{-}NC_5H_4B(OH)_2)_2$ (19)

A 10 mL methylene chloride solution of 3-(diethylboryl)pyridine (102 mg, 0.69 mmol) was added dropwise to a stirred 30 mL methylene chloride solution of $[PdCl_2(COE)]_2$ (100 mg, 0.17 mmol). After 48 h, an orange precipitate was collected by filtration and washed with methylene chloride (3 × 5 mL). Yield: 60 mg (42%) of an orange solid; mp 234°C. IR (nujol): 3197 (w), 2923 (s), 2856 (s), 1576 (w), 1462 (m), 1377 (m). Selected NMR data (in acetone-d_6): ^1H δ: 9.24 (s, 4H, B(O*H*)$_2$), 8.94 (m, 2H), 8.41 (m, 4H), 7.61 (m, 2H); $^{11}B\{^1H\}$ δ: 29.2 (br). Solubility problems precluded $^{13}C\{^1H\}$ NMR data collection.

$PdCl_2(3\text{-}NC_5H_4Bpin)_2$ (20)

To a 40 mL methylene chloride suspension of **19** (134 mg, 0.32 mmol), pinacol (45 mg, 0.38 mmol) and 10 g of activated molecular sieves (BDH 4A) were added. The mixture was allowed to stand for 7 days before the sieves and unreacted **19** were removed by filtration. The filtrate was collected, and methylene chloride removed under vacuum to afford a yellow solid, which was washed with hexane (3 × 10 mL) to remove excess pinacol. The product was crystallized from a CH_2Cl_2–hexane solution. Yield: 160 mg (86%)

X-ray crystallographic data for 5

Crystals of **5** suitable for X-ray diffraction studies were obtained by recrystallization from a THF–hexane mixture at 5°C. A summary of the crystal data and parameters for data collection is given in Table 1. Data were collected at 203 K on a Siemens SMART/CCD diffractometer equipped with an LT-II low-temperature device. Diffracted data were corrected for absorption using the SADABS[3] program. SHELXTL was used for structure solution, and refinement was based on F^2.[4] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were fixed at calculated positions. Selected bond distances and angles are given in Table 2 and final atomic coordinates in Table 3. Complete tables of bond distances and angles, final atomic coordinates, and anisotropic displacement parameters have been deposited as supporting material.[5]

Results and discussion

1. Reactions with 3-aminophenylboronic acid

The synthesis of amines containing boronic acid groups is often a complicated procedure requiring several complex organic transformations (12*d*). As a result, the range of compounds containing both an amine and a boronic acid functionality is surprisingly small. Indeed, the use of aminoboronic acids as ligands for transition metals has not yet been explored. As part of our initial investigation into this area, we set out to prepare palladium and platinum complexes containing commercially available 3-aminophenylboronic acid (3-$NH_2C_6H_4B(OH)_2$, APBA, **1**). We have found that addition of **1** to aqueous solutions of $[MCl_4]^{2-}$ (M = Pd, Pt) gives the corresponding boronic acid-containing complexes $MCl_2(APBA)_2$ (M = Pd, **2**; M = Pt, **3**). These complexes are insoluble in most common organic solvents, and attempts to dissolve them in coordinating solvents such as DMSO led to decomposition where the solvent was clearly displacing the weakly bound aminoboron group. Although aniline derivatives are known to coordinate to palladium and platinum (17), the addition of an electron-withdrawing boronic acid group to the phenyl moiety, not surprisingly, severely reduces the nucleophilicity of the already weak aniline group (pK_a = 4.6 for conjugate acid, anilinium ion). Attempts to generate diaqua complexes $[M(OH_2)_2(APBA)_2](NO_3)_2$ by addition of $AgNO_3$ to **2** and **3** in water gave rapid degradation to the corresponding metals along with the formation of boric acid.

Compounds containing boronic acids are extremely difficult to characterize in terms of elemental composition, owing to the ease with which they partially dehydrate to the corresponding trimeric or oligomeric anhydrides (12*a*). To alleviate this complication, as well as to increase solubilities in organic solvents, we replaced the hydroxyl groups on **1** with the more electron donating pinacol-derived group (pin = $O_2C_2Me_4$) (18) to give 3-$NH_2C_6H_4$Bpin (**4**, APBpin). Unfortunately, substitution reactions in water involving **4** and the tetrachloro salts suffered from competing cleavage of the pinacol groups to give complicated mixtures of products. However, transesterification of the boronic acid derivatives **2** and **3** with pinacol ultimately generated the corresponding complexes $MCl_2(APBpin)_2$ (M = Pd, **5**; M = Pt, **6**) in low yields (9–16%).

The molecular structure of diamine complex **5**, which crystallizes with four molecules of tetrahydrofuran per complex, is shown in Fig. 1, and selected bond distances and angles provided in Table 2. The aminoboron ligands lie in a *trans* configuration with Pd—N bond distances of 2.047(3) Å being similar to that observed for the analogous

Table 2 (*concluded*).

bonds in *trans*-$PdCl_2(NH_2CH_2Ph)_2$ (19). The boronate ester functionality (BO_2R_2) lies in the plane of the arene ring and has two short B—O bonds (1.354(5) and 1.372(5) Å). These results indicate that "dative" bonding is significant for both the aromatic ring π-electrons and oxygen atoms with boron. The slight difference in the two B—O bond lengths has been observed previously in chelate complexes of phenylboronic acid (20). To the best of our knowledge, this is the first structurally characterized example of an aminoboronate–metal complex.

To avoid problems arising from reactions carried out in aqueous solutions, we decided to examine the reactivities of both APBA and APBpin with $PtCl_2(COD)$ (COD = 1,5-cyclooctadiene) in organic solvents. Unfortunately, no reaction, or decomposition, was observed when this platinum complex was treated with either aminoboron species at room or elevated temperatures. We then decided to prepare the analogous *trans* amine complexes from the monoalkene metal compounds $[MCl_2(COE)]_2$ (M = Pd, Pt; COE = η^2-C_8H_{14}) (Scheme 1), as both *cis* and *trans* platinum amine complexes are known to be biologically active (14). The starting organometallic dimers, which are soluble in common organic solvents, were prepared by the addition of *cis*-cyclooctene to aqueous solutions of the corresponding metal tetrachloride salts (15). Diamine complex $PdCl_2(APBA)_2$ (**2**) was obtained in moderate yields (39%) from reactions of boronic acid **1** with $[PdCl_2(COE)]_2$. Interestingly, dropwise addition of 1 equiv. of pinacol derivative **4** to the palladium dimer gave rapid formation of the novel air-stable organometallic complex $PdCl_2(COE)(APBpin)$ (**7**). Attempts to generate the corresponding boronic acid derivative via this route afforded equal amounts of disubstituted amine **2** along with starting alkene complex $[PdCl_2(COE)]_2$. The difficulty in generating the boronic acid analogue of **7** presumably arises from the insoluble nature of the amine starting material in organic solvents. In an attempt to generate a mixed phosphine-amine complex, we have found that addition of 1 equiv. of PPh_3 to **7**, however, afforded $PdCl_2(PPh_3)_2$ where the phosphines have displaced both the weakly bound cyclooctene and aminoboron ligands. Interestingly, subsequent addition of a second equivalent of

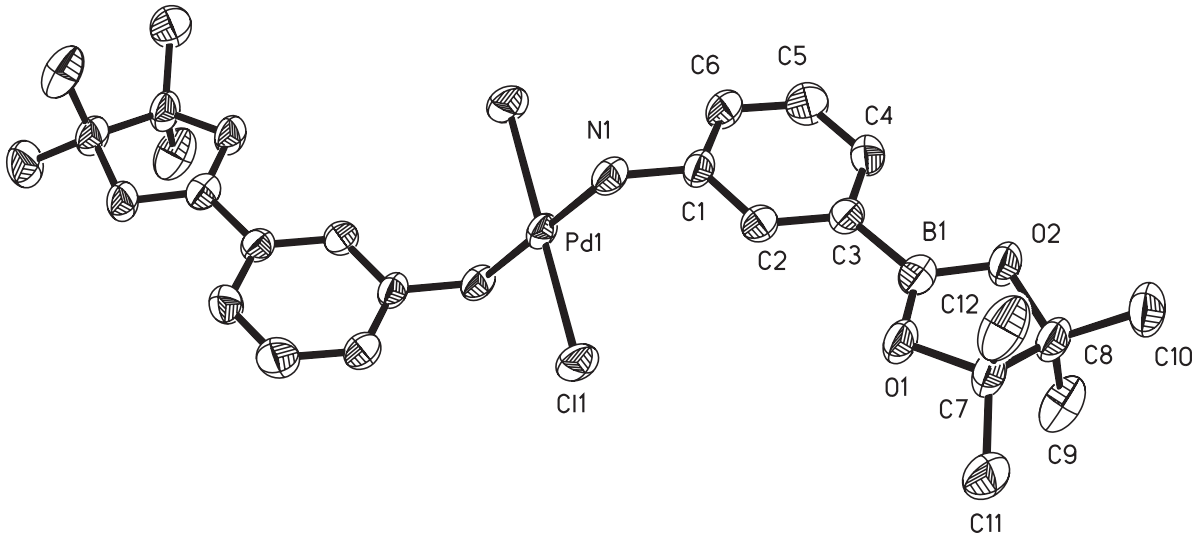
Fig 1. Molecular structure of $PdCl_2(APBpin)_2$ (**5**, pin = $O_2C_2Me_4$) with hydrogen atoms and molecules of THF omitted for clarity.



aminoboronic ester to **7** resulted in facile loss of the labile cyclooctene ligand with concomitant formation of $PdCl_2(APBpin)_2$ (**5**). Similar studies on the addition of pyridines to palladium monoalkene complexes have been reported previously (21).

Unlike reactions with palladium, only monoalkene complexes $PtCl_2(COE)(APBA)$ (**8**) and $PtCl_2(COE)(APBpin)$ (**9**) were generated from the addition of the corresponding aminoboron derivatives to $[PtCl_2(COE)]_2$. Attempts to displace the alkene proved unsuccessful, even with addition of

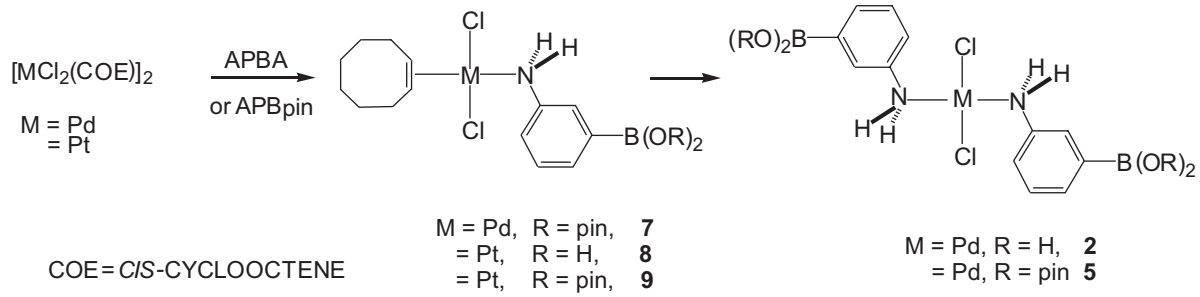
Scheme 1.



excess aminoboron ligand at elevated temperatures.[6] This observation is consistent with the known ability of platinum to form stronger M–alkene bonds than palladium, owing to an increase in the amount of π-backbonding (22). Spectroscopic and X-ray diffraction studies of similar *trans*-$PtCl_2(\eta^2$-alkene)(L) (L = nitrogen-containing ligand) complexes have been reported previously (23).

2. Reactions with *N*,*N*-dimethylbenzylamineboronic acid

Boron derivatives of *N*,*N*-dimethylbenzylamine, 2-$NMe_2CH_2C_6H_4B(OH)_2$ (**10**) and 2-$NMe_2CH_2C_6H_4$Bpin (**11**), were prepared by established procedures (16). Significant intramolecular interaction exists between the nitrogen atom and the boron atom in solution as evidenced by $^{11}B\{^1H\}$ NMR spectroscopy (24). Peaks at δ 8.9 and 15.3 ppm observed for **10** and **11**, respectively, are shifted considerably upfield from phenylboronic acid (δ 29.6 ppm), indicating that the boron atom is four coordinate. Not surprisingly, a distinct solvent effect is observed on the rates of N—B bond dissociation in these systems, as shown previously using NMR spectroscopy (25).

Reactions of **10** or **11** with Na_2PdCl_4 in water or methanol gave the known cyclopalladated dimer $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$ (26) as the major amine-containing product (identified using ^1H NMR spectroscopy and mp) along with formation of boric acid; this latter species presumably arising from the addition of water to liberated "Cl-$B(OH)_2$". The cyclopalladated compound has been prepared previously from the addition of *N*,*N*-dimethylbenzylamine to Na_2PdCl_4, along with concomitant formation of HCl, where the *ortho* C(sp^2)—H bond of the phenyl group is broken as a new C(sp^2)—Pd bond forms (26). Our observation is intriguing in that it shows a preference for activation of the C(sp^2)—B bond over the conventional C(sp^2)—H bond. This selectivity suggests that intramolecular coordination of the nitrogen atom to boron severely weakens the corresponding C—B bond. A strong base (typically NaOH or TlOH) is usually required to facilitate cleavage of the C—B in the Suzuki–Muyari cross-coupling reactions of organic halides with organoboronic acids (27). No reaction was observed in analogous reactions with the platinum salt, K_2PtCl_4, and either **10** or **11**.

The cyclometallated dimer $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$ was also obtained from reactions of alkene complex $[PdCl_2(COE)]_2$ with **10** in reactions carried out in wet CH_2Cl_2. This reaction probably proceeds via initial coordination of the aminoboron ligand followed by loss of cyclooctene to provide a 14-electron intermediate "$PdCl_2L$" (where L = aminoboron ligand) (28). Addition of water or an extra equivalent of amine may coordinate putatively to the boron atom and facilitate rapid B—C bond cleavage to give the desired cyclopalladated fragment, which will subsequently dimerize to give $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$. No reaction was observed when $[PdCl_2(COE)]_2$ was treated with **10** in dry solvent under an inert atmosphere. Reactions of $[PdCl_2(COE)]_2$ with 2-$NMe_2CH_2C_6H_4$Bpin **11** in wet methylene chloride also generated the cyclopalladated dimer $[PdCl(2\text{-}NMe_2CH_2C_6H_4)]_2$ along with pinB-O-Bpin and the ammonium salt $[2\text{-}HNMe_2CH_2C_6H_4Bpin]_2[PdCl_4]$, where an extra equivalent of the aminoboron ligand has been used to mop up the liberated Cl-Bpin. Addition of Cl-Bpin to **11** would result in initial formation of $[2\text{-}pinBNMe_2CH_2C_6H_4Bpin]^+Cl^-$, which would rapidly degrade with addition of adventitious water to the protonated ammonium salt along with "HO-Bpin," the latter of which will further degrade to give pinB-O-Bpin (similar nucleophilic degradation reactions have been reported previously for catechol derivatives, see ref. 29).

Consistent with this proposed pathway, the pinacol derivative **11** reacts initially with $[PtCl_2(COE)]_2$ to give an air-sensitive species, which we have tentatively assigned as the coordination complex $PtCl_2(COE)(\eta^1\text{-}2\text{-}NMe_2CH_2C_6H_4Bpin)$ (**12**). The proton NMR spectrum of **12** indicates that one C(sp^2)-H is significantly deshielded (δ 8.87 ppm) with respect to starting aminoboron compound (δ 7.55 ppm), which we postulate may lie over the metal square plane, as noted previously for the bisamine adduct $PdCl_2$(1-tetralone oxime)$_2$ (30). Attempts to grow crystals of this coordination complex suitable for X-ray diffraction studies were unsuccessful, as compound **12** decomposes to give a number of unidentified products (by NMR spectroscopy) along with the cycloplatinated monomer $PtCl(COE)(2\text{-}NMe_2CH_2C_6H_4)$ (**13**) (Scheme 2).

Initial loss of cyclooctene followed by oxidative addition of the B—C bond with subsequent reductive elimination of the Cl-Bpin fragment and recoordination of the alkene moiety would give the cycloplatinated product (28, 31). Formation of this cycloplatinated species was also observed in analogous reactions with the boronic acid **10**. Interestingly, no reaction was observed between alkene complex

[6] A minor amount (<5%) of the diamine complex *trans*-$PtCl_2(APBpin)_2$ was generated upon heating for prolonged periods (days). An X-ray diffraction study on this compound was carried out, and the platinum analogue proved to be isostructural with complex **5**. Complete details of this study are provided in the supplementary data.

3. Reactions with borinic esters

Reactions of dibutylborinic acid, ethanolamine ester, $H_2NCH_2CH_2OBBu_2$ (**14**), or diphenylborinic acid, ethanolamine ester, $H_2NCH_2CH_2OBPh_2$ (**15**), with the tetrachloro salts, $[MCl_4]^{2-}$, in aqueous solvents proceed via cleavage of the B—O bond to give a mixture of metal–ethanolamine complexes (32). Formation of these degradation products was confirmed by independently adding commercially available ethanolamine to the corresponding metal salts. Reactions with **14** gave boric acid, and presumably butane, while phenylboronic acid, $PhB(OH)_2$, was generated as the major boron-containing product in reactions using **15**. Although the boron atom is initially stabilized by intramolecular coordination of the amine nitrogen atom in the free ligand, nucleophilic degradation of the borinic group appears to be rapid once the B←N bond is broken and the amine coordinates to the metal centre. Cleavage of the B—O bond in these ligands has been observed previously (33). Likewise, similar degradation products were observed with reactions of **14** and **15** with $[PdCl_2(COE)]_2$. Reactions with $[PtCl_2(COE)]_2$, however, gave the corresponding monoamine complexes $PtCl_2(COE)(NH_2CH_2CH_2OBBu_2)$ (**16**) (^{11}B NMR δ 56.1 ppm) and $PtCl_2(COE)(NH_2CH_2CH_2OBPh_2)$ (**17**) (^{11}B NMR δ 47.8 ppm), respectively, both of which rapidly decompose in air to give a number of unidentified ethanolamine-derived products (Scheme 3).

4. Reactions with 3-(diethylboryl)pyridine

3-(Diethylboryl)pyridine (**18**) was originally prepared in 1983 (34) and its use in coupling reactions is well established (35). The remarkable stability of this compound under ambient conditions is due to its cyclic-tetrameric nature in the solid state and in solution. Four molecules of **18** are bound together through intermolecular nitrogen–boron bonds (36). We hypothesized that reactions of **18** with either $[MCl_4]^{2-}$ or $[MCl_2(COE)]_2$ (M = Pd, Pt) would result in the formation of metal–pyridine complexes by breaking the N→B bonds. Nucleophilic attack by water on the boron atom should therefore result in breaking the B—C_{Et} bonds and concomitantly generating the corresponding pyridine – boronic acid metal complexes. Interestingly, although no product formation was observed using the metal chloride salts, reactions with $[PdCl_2(COE)]_2$ in wet methylene chloride gave modest yields (42%) of the desired boronic acid complex $PdCl_2[NC_5H_4B(OH)_2]_2$ (**19**) (Scheme 4). This result implies that coupling reactions carried out in an aqueous or basic environment may initially transform tetrameric **18** to the corresponding boronic acid analogue in the presence of a palladium catalyst (35). We are presently investigating coupling reactions using aminoboronic acid derivatives and

© 1999 NRC Canada

will report our findings in due course. Complex $PdCl_2(NC_5H_4Bpin)_2$ (**20**) was prepared by transesterification of **19** with pinacol. Not surprisingly, no reaction was observed using the less reactive platinum complex $[PtCl_2(COE)]_2$.

Conclusions

We have investigated the reactivity of several aminoboron compounds with $[MCl_4]^{2-}$ salts and monoalkene dimers $[MCl_2(COE)]_2$ (M = Pd, Pt). Addition of 3-aminophenylboronic acid (APBA) to $[MCl_4]^{2-}$ (M = Pd, Pt) gave the corresponding metal derivatives $MCl_2(APBA)_2$. Diamine complexes were also generated by addition of APBA and APBpin (pin = $O_2C_2Me_4$) to the palladium alkene dimer $[PdCl_2(COE)]_2$. The aminoboron ligands were ineffective in displacing the coordinated cyclooctene group in analogous reactions with the platinum dimer. Interestingly, cleavage of the B—C and B—O bonds dominated reactions involving aminoboron ligands, $2\text{-}NMe_2CH_2C_6H_4B(OR)_2$ and $H_2NCH_2CH_2OBR_2$, respectively. Although 3-(diethylboryl)pyridine is stabilized by intramolecular N→B interactions, the novel boronic acid-containing complex $PdCl_2[NC_5H_4B(OH)_2]_2$ was prepared by addition of this aminoboron ligand to the palladium alkene dimer. We are presently investigating the biological activities of several of these new platinum derivatives, the results of which will be published in due course.

Acknowledgements

Thanks are gratefully extended to the Natural Sciences and Engineering Research Council of Canada, Mount Allison University, St. Mary's University for financial support, as well as Johnson Matthey Ltd. for the generous supplies of platinum salts. We also thank Dan Durant, Roger and Marilyn Smith, and John Marcone (DuPont) for their expert technical assistance, Dr. H. Jenkins (S.M.U.) for assistance with the X-ray data, and anonymous reviewers for helpful comments.

Surface tension studies of lauryl sulfobetaine – β-cyclodextrin and dodecyltrimethylammonium bromide – β-cyclodextrin inclusion complexes in aqueous solution

S. Göktürk, M. Mahramanlıoğlu, and M. Tunçay

Abstract: β-Cyclodextrin (β-CD) is a cyclic oligosaccaride with an apolar cavity that shows a certain degree of selectivity in binding organic and inorganic compounds. Lauryl sulfobetaine (LSB) and dodecyltrimethylammonium bromide (DTAB), having the same hydrophobic and different polar groups are used in order to compare the influence of the polar group on complex formation with β-CD. The surface tension increased as β-CD is added to premicellar region of amphoteric (LSB) and cationic surfactant (DTAB) solutions. The relation between the surface tension and surfactant concentration can be expressed by the Szyszkowski equation, which combines the Langmuir adsorption model and the Gibbs equation. Binding constants were determined from the effect of added β-CD on the surface tension vs. concentration curves for LSB and DTAB aqueous solutions.

Key words: β-cyclodextrin, surfactant, surface tension method, complex formation, binding constant.

Résumé : La β-cyclodextrine (β-CD) est un oligosaccharide cyclique comportant une cavité apolaire qui présente une certaine sélectivité pour fixer des composés organiques et inorganiques. Dans le but de comparer l'influence du groupe polaire sur la formation d'un complexe avec une β-CD, on a utilisé la sulfobétaïne de lauryle (SBL) et le bromure de dodécyltriméthylammonium (BDTA) qui ont le même caractère hydrophobe et des groupes polaires différents. La tension superficielle augmente lorsqu'on ajoute de la β-CD à la région prémicellaire des solutions des agents de surface amphothère (SBL) et cationique (BDTA). La relation entre la tension superficielle et la concentration d'agent de surface peut être exprimée par l'équation de Szyskowski qui combine le modèle d'adsorption de Langmuir et l'équation de Gibbs. On a déterminé les constantes de fixation à partir de l'effet produit par l'addition de la β-CD sur la tension superficielle en fonction des courbes de concentration de solutions aqueuses de SBL et de BDTA.

Mots clés : β-cyclodextrine, agent de surface, méthode de la tension superficielle, formation de complexe, constante de fixation.

[Traduit par la Rédaction]

1. Introduction

The host–guest chemistry of inclusion complexes of the α- and β-cyclodextrins has been widely studied in relation to the general problem of understanding structural and ligand binding effects (1–5). Cyclodextrins (CDs) are shaped like a truncated cone with relatively hydrophobic hollow cylindrical cavities, and show a certain degree of selectivity in binding organic and inorganic compounds (6). β-Cyclodextrin (β-CD) shows amphiphilic character due to an apolar cavity and a hydrophilic annulus consisting of a number of hydroxyl groups. Surfactants that contain both hydrophobic and hydrophilic moieties are ideal guests for studying complexation with cyclodextrins. It is known that there are several types of inclusion complexes of β-CD in solutions. Inclusion complexes with a 1:1 host–guest ratio are commonly known (2). In some cases, when the hydrophobicity of the guest molecules increases, it may complex with two β-CD molecules to form a 2:1 inclusion compounds (7).

The ability of a cyclodextrin molecule to form an inclusion complex with a solute is dependent on (among other things) the diameter of the cyclodextrin cavity, the size, and geometry of the solute (3).

The difference among the cyclodextrins is in the number of glucopyranose units: six in α-CD, seven in β-CD, and eight in γ-CD, and also in the size of the cavity: α-CD (internal diameter = 5 Å), β-CD (internal diameter = 6.9 Å), γ-CD (internal diameter = 8.5 Å). The cavity of β-CD is of a hydrophobic character and has a diameter of 6.9 Å, which is ideally suited to accommodate the hydrophobic, i.e.,

Fig. 1. Surface tension results for 5 mM (■) and 8 mM DTAB (+) solutions as a function of the concentration of added β-CD. The symbols represent experimental data, and the solid lines represent the best fit.

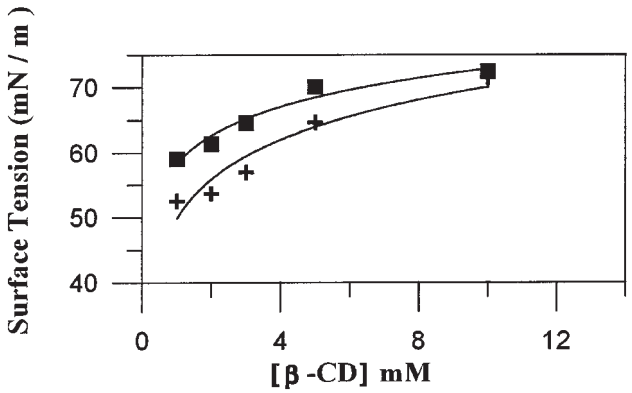

Fig. 2. Surface tension results for 1 mM (◆), 2 mM (✳), and 4 mM (●) LSB solutions as a function of the concentration of added β-CD. The symbols represent experimental data, and the solid lines represent the best fit.

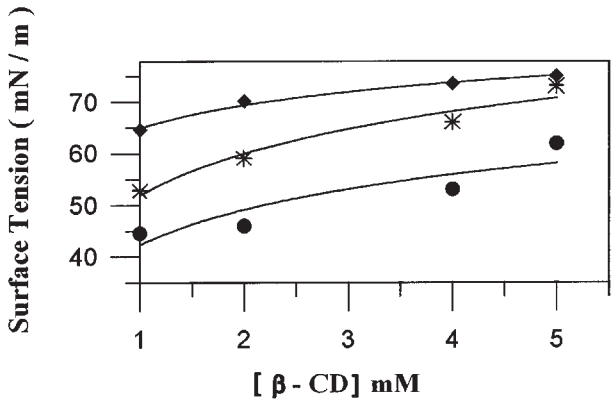

aliphatic part of the chosen surfactant that has a diameter of about 5 Å. Since the interior wall of the CD cavity is hydrophobic in nature, a hydrophobic alkyl group of the aliphatic part of surfactant molecules enters the cavity. Moreover, the rims of the CD cavity are lined with OH groups, which can form hydrogen bonds with the hydrophilic part of the surfactant molecule and thus add to the stability of the complexes formed (8).

Association constants for such complexes have been determined using various physical methods (9), including UV and visible spectroscopy (10, 11), calorimetry (12, 13), conductivity (14), NMR spectroscopy (15, 16), vapor pressure (17), and surface tension measurement (18). Each method has advantages and disadvantages, as well as limitations. Of the methods mentioned for studying complexation of CD with aqueous solutes, surface tension experiments appear to be the most suitable for inferring accurate values of binding constants between surfactants and β-CD (18). This method is based on the use of surface tension measurements to infer changes in the thermodynamic activity of the surfactant. The technique requires measuring the change in surface tension by addition of a solute to aqueous solutions of the surfactants, but it is necessary to ensure that both the solute and the complex are nonsurface active.

Binding constants of β-CD with surface active agents (S) were determined from the change of surface tension of solutions of the surface active agents in the presence of β-CD. The effect of β-CD on the surface tension and on the critical micelle concentration (CMC) of the different surfactants studied here can be explained by the formation of inclusion complexes. The correlation of surface activities with surface tension values in the β-CD–S solutions were made using the Szyszkowski equation, which combines the Langmuir adsorption model and the Gibbs equation.

In this work, the binding between β-CD and two surfactants having the same alkyl chain but different polar head group, i.e., lauryl sulfobetaine (LSB) and dodecyltrimethylammonium bromide (DTAB) was studied to gain further insight into the relative roles of the hydrophobic effect vs. interactions between the annular hydroxyl groups of β-CD and the surfactant head group in the complexes.

2. Experimental

a. Materials

The surfactants used in this study were DTAB, obtained from Aldrich Chemical Co., and LSB, obtained from Sigma Chemical Co. The β-CD was obtained from Aldrich Chemical Co., and all of these compounds were used as received. The water was distilled twice and deionized.

b. Surface tension method

The surface tension of the aqueous solutions was determined by stalagmometry in bidistilled water. The weight of 30 drops of the respective solution was determined, and the mean weight of 1 drop calculated (19).

The surface tension was then computed according to the equation

$$\gamma = \frac{m_{sol}}{m_{H_2O}} \gamma_{H_2O}$$

where γ = surface tension of respective solution, m_{sol} = mean weight of one drop of the solution, m_{H_2O} = mean weight of one drop of water, γ_{H_2O} = surface tension of water at 20°C (72, 77 mN m^{-1}). About 6–8 measurements were made for each solution, and the standard deviation of the surface tension from the mean value was found to be less than ±0.2 mN m^{-1}. All surface tension measurements were made at 20 (±0.2)°C. Surface tension versus concentration measurements were made for DTAB and LSB. All experiments were repeated under the same conditions in the presence of fixed β-CD concentrations.

3. Results and discussion

The surface tension of the system DTAB and LSB, with and without various amounts of added β-CD, were measured at 20°C as a function of surfactant concentration.

Preliminary surface tension measurements indicated that both β-CD–LSB and β-CD–DTAB complexes are nonsurface active. Surface tension values of the surfactant solutions approached the surface tension of pure water when sufficient β-CD was present to complex virtually all of the LSB and DTAB. Figures 1 and 2 show the influence of added β-CD

Fig. 3. Surface tension versus the logarithm of the molar concentration of DTAB in aqueous solution at 20°C in the absence (+) and presence of 2 mM (▲), 5 mM (■), and 10 mM (●) β-CD.

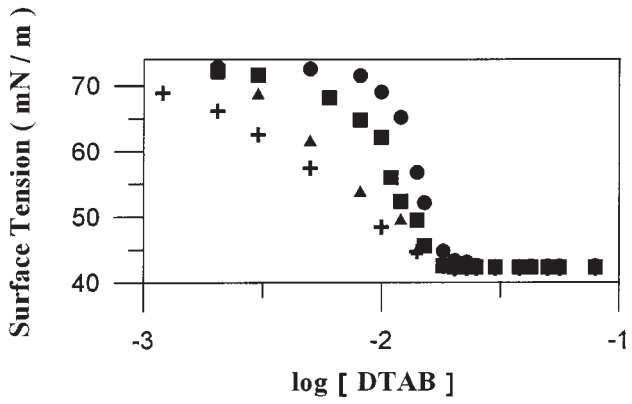

Fig. 4. Surface tension versus the logarithm of the molar concentration of LSB in aqueous solution at 20°C in the absence (+) and presence of 2 mM (◆), 5 mM (✳) β-CD.

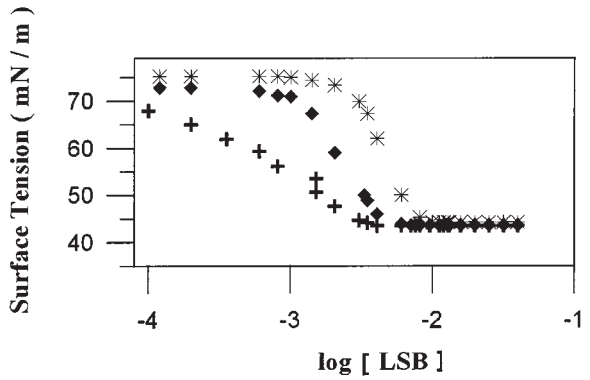

on the surface tension of the solutions containing fixed concentrations of DTAB (5 and 8 mM) and LSB (1, 2, and 4 mM), respectively. A mean least-squares computer fitting program was applied to experimental surface tension data in order to find the best fit. The curves drawn in Figs. 1 and 2 represent the surface tension values predicted by curve fitting.

The surface tension values obtained were plotted versus the logarithms of the surfactant concentration to derive the CMC of DTAB and LSB in the presence and absence of β-CD (Figs. 3 and 4). For both surfactants, the addition of β-CD shifted the CMC to higher concentrations. As seen in Figs. 3 and 4, addition of β-CD invariably increases the concentration of both DTAB and LSB required to attain a given degree of surface tension lowering and to reach the critical micelle concentration (CMC), reflecting the fact that the thermodynamic activity of the surfactants is decreased by the formation of inclusion complexes with β-CD. The increase in the CMC values was found to be proportional to the β-CD concentration. The dependence of the CMC of DTAB and LSB on the β-CD concentration are shown in Figs. 5 and 6, respectively. The experimental data for premicellar solutions of DTAB and LSB, with and without

Fig. 5. Dependence of the critical micelle concentration of aqueous solutions of DTAB on the concentration of β-CD at 20°C.

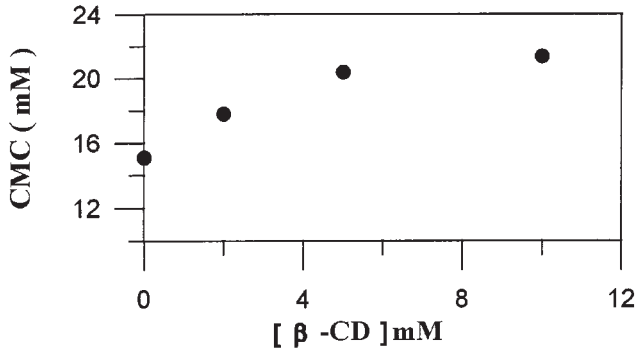

Fig. 6. Dependence of the critical micelle concentration of aqueous solutions of LSB on the concentration of β-CD at 20°C.

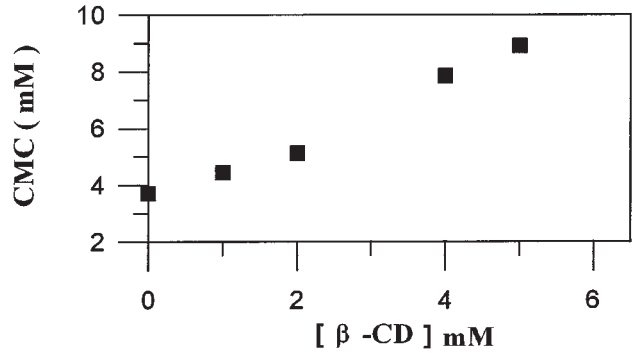

the presence of a fixed β-CD concentration, are shown in Figs. 7*a–c* and 8*a*, *b*, respectively.

By analyzing all of the surface tension vs. concentration data for systems below and above the CMC, for solutions with and without added β-CD, it was possible to infer the best values of the β-CD–S association constant as well as some of the parameters in the mass action model for micelle formation (20–22). The solid curves in Figs. 7*a–c* and 8*a*, *b* correspond to regions in which the surface tension of surfactant solutions (in the absence of β-CD) varies nearly linearly with the logarithm of the surfactant concentration; the condition of semi-log linearity seems to apply to most of the surface tension results obtained between about 45 and 65 mN m^{-1}. Equations for the lines were calculated by fitting surface tension vs. log [DTAB] and log [LSB] data using least-squares analysis.

To interpret the surface tension data, two binding reactions were considered:

$$S + CD \overset{K_1}{\rightleftharpoons} S(CD)$$

$$S + CD + CD \overset{K_2}{\rightleftharpoons} S(CD)_2$$

The surface tension data are modelled by assuming that the total concentration of β-CD and surfactant are given by

$$[S]_{total} = C_s + K_1 C_{\beta\text{-}CD} C_s + K_1 K_2 C^2_{\beta\text{-}CD} C_s$$

$$[\beta\text{-}CD]_{total} = C_{\beta\text{-}CD} + K_1 C_{\beta\text{-}CD} C_s + 2K_1 K_2 C^2_{\beta\text{-}CD} C_s$$

where K_1 represents the binding constants for the 1:1 β-CD surfactant complex, and K_2 is the equilibrium constant for binding an additional β-CD molecule to the 1:1 complex. C_s and $C_{\beta\text{-CD}}$ are the concentrations of free surfactant and β-CD, respectively.

The effect of DTAB and LSB on the surface tension curves was used to infer values of binding constant for 1:1 and 1:2 complexes for each of the five systems, utilizing the data analysis method described previously (23). It was tested whether the complexation between DTAB, LSB, and β-CD only result in a 1:1 complex. Results indicated that only 1:1 complexes and not 2:1 complexes formed for both surfactants at least in the concentration range studied. This suggests that in the case of β-CD–DTAB and β-CD–LSB, steric and dipolar repulsive forces dominate to an extent that 2:1 complex is unfavourable. Nonexistence of a 2:1 complex between both DTAB, LSB, and β-CD agree with the conclusion obtained previously for dimethyldodecylammonium oxide (DDAO) (18) and (DTAB) (24).

The Γ*RT* values inferred from the Gibbs equation (where Γ is the Gibbs surface excess quantity) were calculated from the slopes of the semi-log curves presented in Figs. 7*a–c* and 8*a*, *b*. Surface tension data presented in Figs. 7*a–c* and 8*a*, *b* were also fitted to the Szyszkowski equation, which combines the Langmuir adsorption model for surface adsorption and the Gibbs equation.

$$\gamma = \gamma_0 - t_d \ln (1 + BC_s)$$

where $t_d = \Gamma^{\infty}RT$, Γ^{∞} is the value of the surface excess of the surfactant when a complete monolayer is present, and B is related to the equilibrium constant in the Langmuir equation for adsorption of the surfactant at the liquid–gas interface.

The least-squares analysis of data for two surfactants in the absence of β-CD indicated that a good correlation can be obtained by using the Szyszkowski equation. In fitting the surface tension data for solutions containing β-CD in the

© 1999 NRC Canada

Table 1. Szyszkowski parameters and 1:1 binding constant obtained by least-squares regression analysis.

	DTAB	LSB
B (M^{-2})	1650 ± 200	281 ± 50
t_D (mN m^{-1})	6 ± 0.8	22 ± 0.7
K_1 (mol^{-1} dm^3)	1900 ± 400	2900 ± 350

premicellar region, a good correlation was obtained for the inclusion of 1:1 complex in the model.

The derived K_1 values for DTAB–β-CD systems are somewhat smaller than those inferred from other methods (K_1 = 18 100 mol^{-1} dm^3) (24). It was previously found that the surface tension method yields lower value of the binding constant than those of other methods (18, 23).

4. Conclusions

For both DTAB and LSB, the addition of β-CD shifts the CMC to higher concentrations and also shifts the surface tension to higher values.

The effects of β-CD on the surface tension and on the CMC of the DTAB and LSB can be explained by the formation of inclusion complexes. It is known that inclusion complexation makes surfactant molecules more hydrophilic and causes transport from the micelles or from the surface into the bulk.

For the addition of the same concentration of β-CD, the change in surface tension is less for DTAB than for LSB. For 2 mM LSB and 8 mM DTAB, the addition of 5 mM β-CD shifts the surface tension from 47.6 to 72 mN m^{-1} and from 51.6 to 64.6 mN m^{-1}, respectively. The addition of 5 mM β-CD also shifts the CMC of DTAB from 1.51×10^{-2} to 2.04×10^{-2} mol dm^{-3} and the CMC of LSB from 3.71×10^{-3} to 8.91×10^{-3} mol dm^{-3}.

The ΓRT values inferred from the Gibbs equation are not constant for both surfactants; this can be explained by the change of ionic strength with concentration, since the activity of the surfactant does not vary in direct proportion to its molar concentration. As seen in Table 1, the influence of ionic strength on ΓRT is more pronounced for LSB.

The results suggest that the complex-forming ability of the β-CD is greater for LSB than for DTAB. The 1:1 binding model applied here to fit surface tension results for both DTAB–β-CD and LSB–β-CD solutions provides a good correlation of data obtained throughout a relatively large range of concentrations of both surfactants.

The 1:2 binding constants are calculated as zero, which is reasonable, since the C_{12} hydrocarbon chain is not long enough to accommodate more than one β-CD molecule. Also, steric and dipolar repulsive forces are dominant to an extent that 2:1 complex formation is unfavourable in case of DTAB and LSB.

The values determined here for the 1:1 binding constant are lower than those reported in literature for most compounds containing a C_{12} group. Previous work shows that the binding constant depends on the nature of the surfactant head group and its ability to interact with water and with β-CD in the 1:1 complex. The value of K_1 (1900 ± 400 mol^{-1} dm^3) obtained for DTAB is found to be in quite good agreement with the K_1 constant previously obtained for the cationic form of DDAO (1800 ± 300 mol^{-1} dm^3) (18).

Comparison of the binding constants indicate that the β-CD cavity has a preferential affinity for the amphoteric form of $C_{12}H_{25}$, that is, LSB is more strongly bound than DTAB. This result is not surprising, since binding tendency is expected to vary with the nature of the head group (25). Additional head groups (SO_3) may change the degree of polar–apolar and apolar–apolar interaction that results in changes in the value of binding constant. Therefore, higher value of K_1 obtained for LSB can be explained by the formation of hydrogen bonds between the SO_3 group of this molecule and hydroxyl groups on the rims of the β-CD cavity. We have to infer that the complex formation between LSB and β-CD is of a more complicated nature than that of inclusion complexes. Consequently, in addition to the inclusion complex, an interfacial complex may also be formed between the annular hydroxyl group and the SO_3 group.

Solubility of diphenyl sulfone in organic nonelectrolyte solvents. Comparison of observed versus predicted values based upon the general solvation model

Kristin A. Fletcher, Carmen E. Hernández, Lindsay E. Roy, Karen S. Coym, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported for diphenyl sulfone dissolved in 8 alkane, 10 alcohol, and in aqueous solvent media at 25°C. Results of these measurements are used to test the predictive ability of the general solvation model

$$\log C^{sat}_{A,org}/C^{sat}_{A,aq} = c + rR_2 + s\pi^H_2 + a\sum\alpha^H_2 + b\sum\beta^H_2 + vV_x$$

where $C^{sat}_{A,org}$ and $C^{sat}_{A,aq}$ refer to the solute solubility in the organic solvent and in water, respectively, R_2 is the solute's excess molar refraction, V_x is the McGowan characteristic volume of the solute, π^H_2 denotes the solute's dipolarity/polarizability, and $\Sigma\alpha^H_2$ and $\Sigma\beta^H_2$ are the overall hydrogen-bond acidity and basicity descriptors for the solute. The remaining symbols in the above expression are known solvent coefficients, which have been determined previously through regressional analysis of published organic solvent – water partition coefficient and vapor–liquid equilibrium data. Computations show that the general solvation model predicts the solubility behavior of diphenyl sulfone in the 11 organic solvents for which predictions could be made to within an overall average absolute deviation of about ±20%.

Key words: diphenyl sulfone solubilities, organic solvents, solubility predictions, general solvation model.

Résumé : On a déterminé les solubilités expérimentales de la diphénylsulfone dans 8 alcanes, 10 alcools et dans un milieu aqueux à 25°C. Les résultats de ces mesures ont été utilisés pour vérifier les capacités de prédiction du modèle général de solvatation

$$\log C^{sat}_{A,org}/C^{sat}_{A,aq} = c + rR_2 + s\pi^H_2 + a\sum\alpha^H_2 + b\sum\beta^H_2 + vV_x$$

dans lequel $C^{sat}_{A,org}$ et $C^{sat}_{A,aq}$ se réfèrent à la solubilité du soluté dans le solvant organique et dans l'eau, respectivement, R_2 est la réfraction molaire en excès du soluté, V_x est le volume caractéristique de McGowan du soluté, π^H_2 spécifie le caractère dipolaire et la polarisabilité du soluté alors que $\Sigma\alpha^H_2$ et $\Sigma\beta^H_2$ sont les descripteurs d'acidité et de basicité globale du pont hydrogène du soluté. Les symboles résiduels de l'équation sont des coefficients de solvant connus qui ont été déterminés antérieurement par le biais dune analyse régressionnelle de coefficients de partage eau – solvant organique et de données d'équilibre vapeur–liquide publiés. Les calculs montrent que le modèle général de solvatation permet de prédire le comportement de la solubilité de la diphénylsulfone dans les 11 solvants organiques pour lesquels on a pu faire des prédictions à l'intérieur dune déviation absolue moyenne globale d'environ ±20%.

Mots clés : solubilités de la diphénylsulfone, solvants organiques, prédictions de la solubilité, modèle général de solvatation.

[Traduit par la Rédaction]

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity/mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and hetero-atom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated

[a]Calculated as log $[C_{A,org}^{sat}/C_{A,aq}^{sat}]$, where $C_{A,org}^{sat}$ and $C_{A,aq}^{sat}$ refer to the molar solubility of the solute in the organic solvent and in water, respectively.
[b]% dev. = $100[(C_{A,org}^{sat})^{pred} - (C_{A,org}^{sat})^{exp}]/(C_{A,org}^{sat})^{exp}$.

data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application, though, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the database contain as many different functional groups as possible, preferably with adequate representation from both mono- and multifunctional solute/solvent molecules to permit evaluation of potential synergistic effects. The database should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions. For this reason, we have measured diphenyl sulfone solubilities in both water and in 18 different organic solvents. These measurements will be used to further test the applications and limitations of correlational expressions derived from the general solvation model.

Materials and methods

Diphenyl sulfone (Aldrich, 97%) was recrystallized several times from methanol. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), 2,2,4-trimethylpentane (Aldrich, HPLC), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Co., absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), and 1-octanol (Aldrich, 99+%, anhydrous) were stored over molecular sieves before use. Gas chromatographic analysis showed the organic solvent purities to be 99.7 mol% or better. Water (Aldrich HPLC grade) was used as received.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least 3 days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated diphenyl sulfone solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with methanol for spectrophotometric analysis at 267 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance versus concentration working curve for nine standard solutions. The concentration of diphenyl sulfone in the standard solutions varied from 2.08×10^{-4} to 9.35×10^{-4} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\varepsilon \approx 1850$ L mol^{-1} cm^{-1} (2.08×10^{-4} M) to $\varepsilon \approx 1750$ L mol^{-1} cm^{-1} (9.35×10^{-4} M).

Identical molar absorptivities were obtained for select diphenyl sulfone solutions that contained up to 5 vol.% of the neat organic solvents. All solvents studied were optically transparent at the analysis wavelength of 267 nm.

Experimental molar solubilities of diphenyl sulfone, C_A^{sat}, in water and in the 18 organic solvents studied are listed in the second column of Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%. We were unable to find any experimental diphenyl sulfone solubility data in the published chemical literature for these solvent systems to compare our measured values against.

Results and discussion

Solvents studied include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory (12–19) and the general solvation model (20, 21) are perhaps the only ones that are capable of describing solute behavior in such a wide range of solvent mixtures. Lack of enthalpy of fusion data for diphenyl sulfone eliminates Mobile Order theory from consideration. The enthalpy of fusion is required in Mobile Order theory predictions to calculate the fluidization term that describes the breaking of solute–solute interactions in the crystalline lattice.

The general solvation model, on the other hand, correlates gas/solvent partition coefficients (as log *L*)

$$[1] \qquad \log L = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + d \log L^{16}$$

and water/solvent partition coefficients (as log *P*)

$$[2] \qquad \log P = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + vV_x$$

where R_2 and V_x refer to the molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, and $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity. For any given solvent, numerical values of the six curve-fit coefficients (*c*, *r*, *s*, *a*, *d*, *b*, and *v*) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. Neither equation requires knowledge of the solute's enthalpy of fusion.

Previous papers have documented the ability of eq. [1] to describe processes that occur in condensed phases. Processes that have been successfully described include water – organic solvent partitions (22), water–micelle partitions (23), water–skin permeation (24), blood–brain distribution (25), and high-performance liquid chromatographic retention behavior (26). The alternative eq. [2] is generally used for systems that involve both a gas and a condensed phase, examples of which would include the solubility of gases (21, 27, 28), and retention times for gas–liquid and gas–solid chromatography (29, 30). Abraham et al. (31) recently proposed a computational method for determining the numerical values of the three solute descriptors (π_2^H, $\Sigma\alpha_2^H$, and $\Sigma\beta_2^H$) from measured saturation solubilities of the solute in different solvents as the prime experimental observation. The partition coefficient *P* was calculated as the molar solubility ratio for the solute dissolved in the organic solvent and in water, i.e., $P = C_{A,org}^{sat}/C_{A,aq}^{sat}$. In closing, the authors noted that by reversing the computational procedure, one could use the general solvation model to predict the solubility behavior of a solute dissolved in different organic solvents. Such predictions would require knowledge of the solute's aqueous solubility, numerical values of all five solute descriptors, and the regression coefficients for the solvents under consideration.

Three specific conditions must be met in order to use eqs. [1] and [2] to predict the solubility of a crystalline solute. First, the same solid phase must be in equilibrium with the saturated solutions in the organic solvent and in water. This requires that there should be no solvate or hydrate formation. Second, the secondary activity coefficient of the solute in the saturated solutions must be unity (or near unity). This particular condition may restrict the general solvation model to solids having only limited solubility in water and nonaqueous solvents. Finally, for solutes that ionize in aqueous solution, C_A^{sat} is the molar solubility of the molecular form.

Table 1 summarizes the predictive ability of eq. [2] for the 11 different organic solvents for which regressional coefficients could be found (31). For convenience, we have listed the regressional coefficients in Table 2. As a point of information, the coefficients refer to "dry" solvents not in actual contact with water. Abraham et al. (20) have reported numerical values for several additional alcohol solvents, but unfortunately their regressional analyses used experimentally determined partition coefficients. Water is fairly soluble

© 1999 NRC Canada

in alcohols such as 1-butanol through 1-octanol. Dissolved water alters the solvent's polarizability and hydrogen-bonding character, which is reflected in the numerical values of the regressional coefficients. Predictions were thus limited to the eight saturated hydrocarbons, methanol, ethanol, and 1-octanol. Numerical values of the solute descriptors (R_2 = 1.570; π_2^H = 2.15; $\Sigma\alpha_2^H$ = 0; $\Sigma\beta_2^H$ = 0.70 and V_x = 1.605) were taken from a published compilation (22) containing over 700 different solutes.

Examination of the numerical entries in Table 1 reveals that eq. [2] does provide fairly reasonable (though by no means perfect) estimates for the solubility behavior of diphenyl sulfone in both alkane and alcohol solvents. The average absolute deviation between the predicted and observed partition coefficients is 0.094 log units, which is comparable in magnitude to the standard deviations associated with the regressional analysis for *c*, *r*, *s*, *a*, *b*, and *v* coefficients for the individual solvent systems. A deviation of 0.094 log units in the water – organic solvent partition coefficient corresponds to approximately a ± 20% error in the predicted molar solubility. Readers are reminded that in evaluating the predictive applicability of the general solvation model that several of these systems are highly nonideal, and that the molar solubility covers up to 35-fold range. Our past experience in using solution models has been that the better models will generally give predicted values that fall within ±40% or so of the observed solute solubility. For example, this was the case in using Mobile Order theory to predict the solubility behavior of *trans*-stilbene (32), benzil (33), pyrene (34), fluoranthene (35), anthracene (36), and thioxanthen-9-one (37) in a wide range of organic nonelectrolyte solvents. The computations performed in the present study suggest that expressions derived from the general solvation model can be used to predict solute solubilities. The general solvation model is limited in application at the present time, however, to the 25 or so organic solvents for which regressional coefficients have been evaluated.

Chiral recognition in solution. Interactions of α-amino acids in concentrated aqueous solutions of urea or ethanol

Giuseppina Castronuovo, Vittorio Elia, Anna Pierro, and Filomena Velleca

Abstract: Enthalpies of dilution of the L and D forms of glutamine, citrulline, and phenylalanine in concentrated aqueous solutions of urea or ethanol were measured calorimetrically at 298 K. Glycine, urea, formamide, and phenol were also studied under the same experimental conditions, to get information about the behaviour of the zwitterion and of the functional group in the side chain of the cited amino acids when the concentration of the cosolvent changes. The derived pairwise enthalpic interaction coefficients for the three amino acids were rationalized according to the preferential configuration model. Indications are that, in concentrated urea, the coefficients for citrulline and glutamine are determined mainly by the interactions between the cosolvent and the hydrophilic groups in the molecule of the amino acids. For phenylalanine, coefficients are less positive than in water, because the presence of urea, which solvates preferentially the zwitterions, attenuates hydrophobic interactions between the benzene rings. In ethanol, coefficients for the three amino acid become negative or more negative than in water, because in this medium hydrophilic interactions are enhanced. Chiral recognition, namely the difference in the values of homo- and heterochiral interaction coefficients, was detected only for phenylalanine in urea. Hence, the nature of the cosolvent, influencing differently hydrophilic and hydrophobic interactions, can lead to the detection of chiral recognition also for those systems that, as phenylalanine, do not present this effect in pure water.

Key words: α-amino acids, excess functions, molecular interactions, preferential configuration.

Résumé : Faisant appel à la calorimétrie et opérant à 298 K, on a mesuré les enthalpies de dilution des formes D et L de la glutamine, de la citrulline et de la phénylalanine dans des solutions concentrées aqueuses d'urée ou d'éthanol. Utilisant les mêmes conditions, on a aussi étudié la glycine, l'urée, le formamide et le phénol pour tirer des informations concernant le comportement du zwitterion et du groupe fonctionnel de la chaîne latérale des acides aminés cités lorsqu'on modifie les concentrations de cosolvant. Les coefficients d'interaction enthalpiques par paires qu'on en a dérivé pour les trois acides aminés sont rationalisés en fonction du modèle configurationnel préférentiel. On a recueilli des indications à l'effet que, dans l'urée concentrée, les coefficients de la citrulline et de la glutamine sont déterminés principalement par les interactions entre le cosolvant et les groupes hydrophiles des molécules d'acides aminés. Pour la phénylalanine, les coefficients sont moins positifs que dans l'eau à cause de la présence de l'urée qui solvate les zwitterions de façon préférentielle et qui atténue les interactions hydrophobes entre les noyaux benzéniques. Dans l'éthanol, les coefficients des trois acides aminés deviennent négatifs (ou plus négatifs) que dans l'eau parce que, dans ce milieu, il y a augmentation des interactions hydrophiles. On n'a détecté de reconnaissance chirale, à savoir, une différence dans les valeurs des coefficients d'interaction homo- et hétérochirales, que pour la phénylalanine dans l'urée. En conséquence, la nature du cosolvant, qui influence de façons différentes les interactions hydrophile et hydrophobe, peut aussi conduire à la détection d'une reconnaissance chirale pour des systèmes qui, comme la phénylalanine, ne donnent pas lieu à cet effet dans l'eau pure.

Mots clés : acides α-aminés, fonctions d'excès, interactions moléculaires, configuration préférentielle.

[Traduit par la Rédaction]

Introduction

Nonbonding interactions in aqueous solutions of nonelectrolytes have reached a good qualitative understanding from the analysis of the excess thermodynamic properties using a group additivity approach (1). The results of this approach for the excess Gibbs free energies have shown that interactions between domains having the same effect on water structure (hydrophilic–hydrophilic or hydrophobic–hydrophobic) are favourable, while interactions between domains having contrasting effects (hydrophilic–hydrophobic) are unfavourable (2). On these bases, calorimetric and spectroscopic data col-

lected in our laboratory in the last years have been rationalized through a qualitative model that hypothesizes the occurrence of more probable configurations in solution. Two hydrated, interacting molecules bearing hydrophilic and hydrophobic domains interact through a preferential configuration which maximizes favorable interactions between similar domains (i.e., hydrophilic–hydrophilic or hydrophobic–hydrophobic or in general like–like domains), while minimizing unfavorable interactions between unlike domains (i.e., hydrophilic–hydrophobic or like–unlike domains) (3, 4).

The "preferential configuration" model was successfully employed to explain chiral recognition occurring in aqueous solutions of α-amino acids (5–9). Coulombic forces acting in the aqueous solutions of free α-amino acids, where dipolar ions predominate, were long thought to screen the subtle differences in the interactions between molecules of the same or different chirality (10, 11). For these reasons, attention was mainly focused on nonionic α-amino acid derivatives, obtaining encouraging results (12–14). To the contrary, systematic studies from this laboratory, concerning the investigation of the homologous series of α-amino acids bearing unsubstituted alkyl chains, have shown that the presence of dipolar ions is the main factor that determines chiral recogniton, namely, the difference in the energetics of homo- and heterochiral interactions (5, 6). In fact, electrostatic interactions between the opposite charges of the zwitterions determine two different preferential configurations, depending on the chirality of the molecules (5, 6, 8, 9). When chirality is the same, the two interacting molecules have the side chains in the same half-space determined by the imaginary plane containing the charged groups. In contrast, for molecules of different chirality, the alkyl groups lie in two different half-spaces. These two different configurations, enhancing the steric differences of the two interacting solutes, lead to rather large differences in the interactions between the side chains, thus making chiral recognition to be detected. The preferential configuration sustained by the interactions between the four charges of zwitterions must be regarded as one of the possible configurations of two interacting molecules, but it is the only one able to differentiate interactions between the alkyl chains. Other configurations exist in solution: among them, the most important is the side-by-side juxtaposing only two of the oppositely charged groups of zwitterions (15). This configuration maximizes the juxtaposition of hydrophilic and hydrophobic domains, but is inactive toward chiral recognition. Hence, the absence of this last effect in 1 M HCl, where dipolar ions disappear (16), is probably due to a side-by-side prevailing configuration, determined by the simultaneous juxtaposition of the alkyl and carboxyl groups, with the charged amino groups occupying remote positions.

To gain a further understanding of the interaction mechanism in the aqueous solutions of α-amino acids, we are carrying out a research program on the physical chemical properties of these solutes in mixed solvents. The second coefficient of the virial expansion of the excess enthalpy as a function of molalities is the quantity considered, because it has revealed particularly useful to get information about the interaction mechanism. Here, we examine the enthalpies of dilution of the L and D forms of citrulline, phenylalanine, and glutamine in concentrated aqueous solutions of urea or ethanol, two solutes often employed as denaturing agents for polypeptides, proteins, and other biopolymers. The delicate balance of intra- and intermolecular interactions responsible for the only biologically active conformation of proteins in water is greatly modified at high urea or ethanol concentrations, provoking denaturation. In such situations, the mixed solvent has properties quite different from those of pure water. For the α-amino acids here reported, the presence of urea or ethanol causes variations in the relative intensities of the interactions between different domains. That could change the prevailing mechanism of interaction acting in pure water. That allows to gain information about the factors responsible of this interaction mechanism and of the presence or absence of chiral recognition in water. To that, glutamine and citrulline were chosen because they behave as prevailingly hydrophilic solutes in water, being negative the enthalpic interaction coefficient characterizing their binary solutions. Phenylalanine, instead, is a prevailingly hydrophobic solute, being positive its enthalpic coefficient in water. Glycine, urea, formamide and phenol have also been studied in the same experimental conditions, in that they mimic the behaviour of the functional groups of the investigated α-amino acids when the structure of the medium changes. Hence, through the analysis of homo- and heterochiral enthalpic interaction coefficients, we aim to ascertain whether the hypothesis of preferential configurations holds in these systems, and what are the various contributions acting in the interaction.

Experimental

Solutes employed were Sigma–Aldrich products. Their purity was assessed by the company to be greater than 98–99%. They were used without further purification. Measurements of the heats of dilution were carried out using an LKB flow microcalorimeter and a thermal activity monitor from Thermometric. Calorimeters were equipped with a GP 10 gradient programmer, a 500 μL mixing chamber, a PSV 50 electrovalve, and a P3 peristaltic pump (all from Pharmacia) for the automatic preparation and the pumping of solutions into the cells of the calorimeters. The method has been tested through known systems. Enthalpies of dilution in water of urea and hexane-1,2-diol have been determined, and the evaluated pairwise enthalpic interaction coefficients (h_{xx} = –331 ± 3 J kg mol^{-2} for urea and h_{xx} = 2999 ± 46 J kg mol^{-2} for hexane-1,2-diol) were in good agreement with the literature value (h_{xx} = –350 ± 13 J kg mol^{-2} for urea (1) and h_{xx} = 2955 ± 55J kg mol^{-2} for hexane-1,2-diol (3)). The values of the dilution enthalpies, ΔH_{dil}, were obtained from

$$\Delta H_{dil}(m_x^{i} \rightarrow m_x^{f}) = -(dQ/dt)/P_S$$

where (dQ/dt) is the heat evolved per unit time, P_S is the total mass flow rate of mixed solvent for unit time, and m_x^{i} and m_x^{f} are the initial and final molalities, respectively. ΔH_{dil} is given in J kg^{-1} of solvent in the final solution.

Results

An excess function is defined as the difference between the values of that function referred to a real and an ideal solution. Then, the excess enthalpy is obtained by

© 1999 NRC Canada

$$[1] \qquad H^E = H(m) - H^{id} = H(m) - (H^\circ_S - \Sigma m_x \bar{H}^\circ_x)$$

where $H(m)$ and H^E, the absolute and the excess enthalpy, respectively, both refer to 1 kg of solvent and m_x moles of each solute; H^{id} is the enthalpy of the ideal solution; $\bar{H}^\circ_s$ is the enthalpy of 1 kg of solvent, and $\bar{H}^\circ_x$ is the limiting partial molal enthalpy of each solute. According to the treatment of solution properties originally proposed by McMillan and Mayer (17) and specifically applied to those of aqueous solutions of nonelectrolytes by Kauzmann and co-workers (18) and other authors (19, 21), an excess thermodynamic property, of a solution containing n solutes, J^E, can be expressed as a virial expansion of molalities of pair and higher order interaction coefficients, j, as follows

$$[2] \qquad J^E = \sum_{i=1}^{n} \sum_{k=1}^{n} j_{ik} m_i m_k + \text{higher terms}$$

For ternary solutions containing the solutes x and y, virial coefficients of the power series of the excess enthalpies, h_{xy}, as a function of molalities can be derived from the enthalpies of dilution, ΔH_{dil}, as follows

$$[3] \qquad \Delta H_{dil}(m_x^i, m_y^i \rightarrow m_x^f, m_y^f)$$
$$= H^E(m_x^f, m_y^f) - m_x^f/m_x^i \, H^E(m_x^i, m_y^i)$$
$$= h_{xx} m_x^f (m_x^f - m_x^i) + h_{yy} m_y^f (m_y^f - m_y^i)$$
$$+ 2h_{xy} m_x^f (m_y^f - m_y^i) + \text{higher terms}$$

where m_x^i, m_y^i, m_x^f, m_y^f are the molalities of the x and y solutes before and after the dilution process, respectively. According to the Mc Millan–Mayer approach (17), the h coefficients appearing in eq. [3] represent the enthalpic contributions to the Gibbs free energy coefficients characterizing the interaction between pairs, triplets, or higher order interactions. They implicitly account also for all variations of solvent–solvent and solute–solvent interactions. Considering as solvent the mixture of ethanol–water or urea–water, a solution of the solute x can be regarded as a binary one and then eq. [3] reduces to

$$[4] \qquad \Delta H_{dil}(m_x^i \rightarrow m_x^f)$$
$$= h_{xx} \, m_x^f \, (m_x^f - m_x^i) + \text{higher terms}$$

where ΔH_{dil} is expressed in J kg^{-1} of mixed solvent, and the molalities are calculated as moles per kg of mixed solvent.

Two-solute solutions, as the D and L forms of an amino acid, are, instead, ternary solutions which are characterized by cross-coefficients evaluated by means of an auxiliary function ΔH^{**}:

$$[5] \qquad \Delta H^{**} = \Delta H_{dil}(m_D^i, m_L^i \rightarrow m_D^f, m_L^f)$$
$$- \Delta H_{dil}(m_D^i \rightarrow m_D^f) - \Delta H_{dil}(m_L^i \rightarrow m_L^f)$$
$$= 2h_{DL} m_D^f (m_L^f - m_L^i) + \text{higher terms}$$
$$= 2h_{DL} m_L^f (m_D^f - m_D^i) + \text{higher terms}$$

where $h_{DD} \equiv h_{LL}$ and h_{DL} are the homochiral and heterochiral pairwise enthalpic interaction coefficients, respectively, in the mixed solvent used. The values of the coefficients of the excess enthalpies were obtained by fitting ΔH_{dil} or ΔH^{**} by a least-squares method. The fitting was tried with polynomials of increasing degree, choosing finally the one of the highest degree for which all the coefficients are significant with respect to their own 95% confidence limits. For most of the examined systems, the concentration ranges studied are limited, so that only the second homochiral or heterochiral coefficients, h_{LL} and h_{DL}, are to be determined.

To examine the role of urea or ethanol in affecting like solute – like solute interactions, the present data could be treated differently to evaluate the triplet term h_{xxy}, where y is urea or ethanol. In this case, we refer to a process through which a ternary solution of the x and y solutes in water is diluted by a binary solution containing the cosolute y at the same concentration (m_y) as that in the ternary solution. It can be demonstrated that in this case h_{xy} and h_{xyy} cannot be evaluated, and the dilution enthalpy, expressed in J kg^{-1} of water, is

$$[6] \qquad \Delta H_{dil} = (h_{xx}^w + 3h_{xxy}^w m_y) m_x^f (m_x^f - m_x^i)$$
$$+ \text{higher terms}$$

where w stands for water. Fitting ΔH_{dil} as a function of the abscissa m_x^f $(m_x^f - m_x^i)$ and knowing h_{xx}^w, it is possible to derive h_{xxy}^w.

However, the parameter we will employ in the following is h_{xx} determined in the mixed solvent: two reasons urge us to do that. Firstly, like solute – unlike solute interactions are certainly significant in a denaturation process, which actually requires high concentrations of the cosolute: the properties of this mixed solvent are different from those of water and modify like solute – like solute interactions. We want to explore just how this mixed solvent acts on the pair interactions in the same experimental conditions as those acting in the denaturation process. Besides, using such high concentrations of urea or ethanol is not suitable to evaluate the triplet term: coefficient for like solute – unlike solute interactions in water are better obtained using comparable concentrations of both solutes. Calculations performed for glycine in concentrated urea prove that. The derived triplet coefficient does not remain constant at increasing urea concentration, an indication that, in such conditions, water changes its properties depending on cosolute concentration.

Enthalpic pair interaction coefficients for glycine, urea, formamide, and phenol in concentrated aqueous solutions of urea or ethanol are reported in Tables 1–3. For urea in solutions of urea as cosolvent, the coefficients increase toward less negative values at increasing cosolvent concentration; for glycine and formamide, they even change sign, passing from negative to positive. In ethanol as cosolvent, glycine exhibits a very pronounced variation towards large negative values, while urea and formamide show a flat minimum. For phenol, the decrease towards negative values is very steep.

In Tables 4–6, homo- and heterochiral pairwise enthalpic interaction coefficients are summarized for the aqueous solutions of citrulline, glutamine, and phenylalanine containing urea or ethanol. Glutamine and citrulline present a behaviour very similar to that of glycine, formamide, and urea in urea or ethanol: their homo- and heterochiral coefficients go toward positive or less negative values at increasing urea concentration, and toward highly negative values at increasing ethanol concentrations. Chiral recognition is detected for both amino acids only at the highest ethanol concentration.

7.00	53 ± 8[f]	–165 ± 11	41 ± 16	28	0.55–0.31

[a]mol/kg.
[b]J kg mol^{-2}. Errors reported are the 95% confidence limits.
[c]J kg^2 mol^{-3}.
[d]Number of experimental data.
[e]Concentration range, mol/kg.
[f]Reference 24. That reference reports also a value at 9.0 m urea, namely 109 ± 3 J kg mol^{-2}.
[g]Reference 1.
[h]Only the second coefficient was needed to best fit the experimental data. The enthalpic coefficient for formamide in water is –115 ± 1 J kg mol^{-2} (ref. 25), and it is 32 ± 4 J kg mol^{-2} in 8 m urea (ref. 21).

For phenylalanine in urea, coefficients are positive and become smaller at increasing concentration of the cosolvent. Chiral recognition is not detected for this amino acid in water, but it is very large in urea, disappearing only at the highest concentration of the cosolvent. In ethanol solutions, a very rapid decrease from positive to negative values is exhibited by both homochiral and heterochiral coefficients, repeating the behaviour of phenol. A small chiral recognition is detected only at the highest ethanol concentration.

Discussion

The results presented in this work aim to give an indirect contribution to the understanding of the phenomenon occurring upon the denaturation of proteins by high concentrations of urea or ethanol. Comparison between the properties of solutes in water and in water–cosolvent mixtures is useful for obtaining a deeper insight into the factors promoting the unfolding of biopolymers in such solutions (21). It must be underlined that the conclusions which will be drawn about the systems presently investigated, containing concentrated urea or ethanol, are based only on enthalpic data; however, Gibbs energy data would be necessary for a more satisfactory interpretation.

The enthalpic interaction coefficients for citrulline and glutamine in water are negative, thus indicating a typical behaviour of prevailingly hydrophilic solutes. Probably, hydrophobic interactions are shielded, attenuated by the bulky hydrophilic groups. In concentrated urea, coefficients become positive for citrulline and less negative for glutamine (see Tables 4 and 5). That reproduces the behaviour shown by glycine, formamide, and urea, prevailingly hydrophilic solutes, whose pair enthalpic interaction coefficients become positive or less negative at increasing urea, as reported in Table 1. The transition to a thermochemically unfavourable behaviour at increasing concentration of cosolvent can probably be ascribed to the increased dielectric constant of the medium; that reduces polar hydrophilic interactions. In addition, given that hydrophilic–hydrophilic interactions are favoured for a negative contribution to the excess free energy, it seems reasonable to hypothesize that the cosolvent urea interacts mainly with the hydrophilic groups, whose increased hindrance contributes to the attenuation of the interactions. To that, it is useful to remember that also other authors report that energetically favourable interactions exist between the polar peptide groups and zwitterionic groups (22), or that urea molecules preferentially adsorb onto charged hydrophilic residues on the surface of globular proteins (23). Phenylalanine, instead, shows coefficients becoming less positive at increasing urea for the attenuated ability of the zwitterions to force interactions between the benzene rings. The behaviour shown by phenylalanine is similar to that found in a preceding study on α-amino acids bearing unsubstituted alkyl chains in concentrated aqueous solutions of urea. There, evidence was given that, at increasing urea concentration, the contribution of the zwitterionic group to the pairwise enthalpic interaction coefficient varies from a negative to an almost null value, underlining a transition towards a thermochemically unfavorable behavior (24). At the same time, hydrophobic contributions decrease linearly at increasing urea concentration: the coupled effects should lessen the value of the coefficients. On the other hand, being the final state (bulk) less structured than pure water for the presence of urea, water released to the bulk should undergo a larger enthalpic and entropic change, making larger the value of the coefficient. The attenuation of hydrophobic interactions in urea, as respect to water, is found to be the prevailing effect, as in the case of alkan-1-ols (27), alkan-*m*,*n*-diols (28), *N*-acetylamides of α-amino acids in 7 M (29) or

8 M urea (30), and amides in 6 M guanidinium chloride (31).

The preferential configuration model accounts for the enhanced cooperativity of hydrophobic interactions when sustained by hydrophilic interactions. The presence of a hydrophilic domain on the side chain of an α-amino acid determines an enthalpic, favorable contribution to the interaction between the hydrophobic domains in the homochiral configuration. Sometimes, the failure of this interaction in the heterochiral configuration is the origin of chiral recognition, larger than that detected in the presence of unsubstituted side chains (7, 9). Citrulline and glutamine do not exhibit chiral recognition in pure water, or for the shortness of the side chain or, alternatively, because the two different preferential configurations cannot exist. Probably, the comparable strength of the interactions between the residues in the alkyl chain and between zwitterions can impose a unique, side-by-side configuration for both homo- and heterochiral systems. Urea, formamide, and glycine, whose residues represent the functional groups of the two amino acids, are characterized by similar enthalpic coefficients in water. The hypothesis that the two functional groups concur in imposing a side-by-side configuration in water is supported by the negative values of the coefficients for citrulline and glutamine, which are clearly determined by the hydrophilic functional groups. At increasing urea concentration, glycine, urea, and formamide transit to a thermochemically unfavourable behaviour, losing rapidly their capability to explicate the interaction responsible for chiral recognition in α-amino acids. Then, citrulline and glutamine do not exhibit this last effect, nor in water, nor varying urea concentration (Table 4 and 5).

Phenylalanine does not exhibit chiral recognition in water, too. Coefficients, however, are positive, probably because

they are determined by the presence of a preferential configuration imposed by the interaction between the two rings and sustained by the hydrophobic interaction between the methylene groups (7). The very high and negative value of the volume pairwise coefficient in water for this amino acid, $v_{LL} = -8 \pm 4$ cm^3 kg mol^{-2}, is an important indication of the hydrophobic structure-maker nature of benzene rings (32). The interaction between these hydrophobic domains could concur with the one between zwitterions, imposing a unique, side-by-side configuration in the homo- and heterochiral systems that does not allow chiral recognition to be observed in water. In concentrated urea, instead, phenylalanine exhibits a large chiral recognition (Table 6). In fact, while the homochiral coefficient presents a sudden decrease between 0 and 1 m urea, varying slightly thereafter, the heterochiral coefficient maintains almost the same value as in water up to 7 m urea. The presence of urea influences differently hydrophobic and hydrophilic interactions. Therefore, the almost invariant value of the heterochiral coefficient means that the induced variations balance, leaving the coefficients to the same value as in water. The rapid decrease of the homochiral coefficient indicates that the prevailing effect is the attenuation of hydrophobic interactions. At 9 m urea, the decreased interactions between zwitterions implies the impossibility of determining the configuration leading to chiral recognition and, consequently, the disappearance of the last effect. It must be underlined that while zwitterions become "inactive," hydrophobic interactions are still effective, thus determining identical and positive values for both homo- and heterochiral coefficients. This behaviour

© 1999 NRC Canada

resembles that shown by another prevailingly hydrophobic amino acid, namely norleucine, in concentrated urea (24).

In aqueous solutions containing ethanol as cosolvent, the behaviour of the substances employed is evidence that the nature of the medium greatly influences the strength of nonbonding interactions. Urea, glycine, formamide, and phenol are characterized by enthalpic interaction coefficients which, independently of their sign in water, go toward negative values in ethanol. That is in agreement with the decrease of the dielectric constant of the medium, favouring hydrophilic interactions. The coefficients for urea and formamide approach slowly more negative values, while those for glycine and phenol change rapidly toward highly negative values (Tables 2 and 3). Then, glycine and phenol, more markedly than urea and formamide, show an increased ability in imposing preferential configurations for thermochemically favourable contributions. At increasing ethanol concentration, citrulline and glutamine behave similarly to glycine, urea, and formamide with a rapid decrease toward highly negative values of both homo- and heterochiral coefficients. For both amino acids, a small chiral recognition is detected only at the highest cosolvent concentrations, where interactions between zwitterions become highly predominant, allowing preferential configurations, responsible of chiral recognition, to be present. Phenylalanine shows a monotonous and similar trend for both homo- and heterochiral coefficients, which invert sign at about 5 m ethanol. Then, they attain a large negative value (about –3000 J kg mol^{-2}) at 9 m ethanol, similar to that found for phenol. The change in the structure of the solvent and the decrease of the dielectric constant determine two opposite effects. Hydrophilic interactions are improved, and consequently, the cooperativity of hydrophobic interactions between the side chains increases. On the other hand, the presence of ethanol as cosolvent improves the number of hydrogen bonds in the bulk solution, thus lowering its energetic level. At increasing concentrations of ethanol, that leads both coefficients to be smaller than those obtained in water, and determines the inversion of their sign at m_{EtOH} >3 (see Table 6). Only at the highest ethanol concentration a small chiral recognition is detected, whose origin is probably the same as that found for citrulline and glutamine.

To conclude, the presence of urea or ethanol influences differently the very complex and delicate balance of hydrophilic and hydrophobic interactions. Because of that, chiral recognition can be detected also for those amino acids that do not present this effect in water. However, that occurs only when the side-by-side configuration prevailing in water is stabilized simultaneously by hydrophobic and hydrophilic interactions, as in the case of phenylalanine. On the contrary, when the side-by-side in water is stabilized prevailingly by hydrophilic interactions, as for citrulline and glutamine, chiral recognition cannot be detected. Then, the study in mixed solvents confirms the validity of the preferential configuration model used to explain the results obtained in water.

Electrocatalytic hydrogenation of 4-phenoxyphenol on active powders highly dispersed in a reticulated vitreous carbon electrode

Pierre Dabo, André Cyr, Jean Lessard, Louis Brossard, and Hugues Ménard

Abstract: Electrodes consisting of particles of a transition metal entrapped and dispersed in a reticulated vitreous carbon (RVC) matrix were prepared in situ by stirring the particles in the presence of an RVC cathode. Such electrodes were used for the electrocatalytic hydrogenolysis (ECHsis) of 4-phenoxyphenol, a compound representative of the 4-O-5 type linkage in lignins. The electrolyses were carried out under galvanostatic control in aqueous 1 M NaOH. Raney nickel, nickel boride, and transition metals supported on activated charcoal or alumina were used as catalytic powders. The extent and efficiency of the ECHsis of 4-phenoxyphenol was found to depend on the catalyst and on the temperature.

Key words: electrocatalytic hydrogenation, electrocatalytic hydrogenolysis, 4-phenoxyphenol, Raney nickel, palladium on charcoal, palladium on alumina.

Résumé : Des électrodes constituées de particules d'un métal de transition incorporées et dispersées dans une matrice de carbone vitreux réticulé ont été préparées in situ en agitant les particules en présence d'une cathode de carbone vitreux. Ces électrodes se sont avérées actives pour l'hydrogénolyse électrocatalytique du 4-phénoxyphénol, un composé représentatif des liaisons de type 4-O-5 des lignines. Les électrolyses ont été effectuées à courant constant en milieu aqueux NaOH 1 M. Les poudres catalytiques étudiées et évaluées sont le nickel de Raney, le borure de nickel et des métaux de transition déposés sur charbon activé ou sur alumine. Les résultats montrent que l'efficacité de l'électrohydrogénolyse dépend de la nature de la poudre catalytique et de la température.

Mots clés : hydrogénation électrocatalytique, hydrogénolyse électrocatalytique, 4-phénoxyphénol, nickel de Raney, palladium sur charbon, palladium sur alumine.

Introduction

It is now recognized that the electrocatalytic hydrogenation (ECH) of organic compounds (1, 2), a process in which chemisorbed hydrogen is first generated at the electrode surface by electrolysis of water and then reacts with the adsorbed organic substrate, offers several advantages over both catalytic hydrogenation and direct electrochemical reduction. One of the main advantages over catalytic hydrogenation is the lower temperature and pressure needed. With respect to direct electrochemical reduction, ECH usually requires less energy (a less negative potential) and, furthermore, secondary reactions involving radical anions (and (or) radicals) are avoided. Among the parameters affecting the ECH efficiency, the nature of the electrode material and the electrode surface, the latter related to the technique of electrode preparation, are of prime importance (1, 3, 4). Most of the electrodes used so far for ECH consist of a coating of a catalytic material such as Raney nickel (R-Ni) or a transition metal (Pt, Pd, Rh) on a metal support (5), the coating being formed by electrodeposition, plasma spraying, sputtering, thermal decomposition, etc. Such electrodes usually have a relatively large surface area. Alternatively, in the case of R-Ni, the particles, which are characterized by a large surface area, have been used directly as the electrocatalyst, either by depositing them on a horizontal metallic plate (6–9), by using them in a flow-through packed bed reactor (10, 11), or by stirring the powder in the presence of a gold cathode (gold having a high hydrogen overvoltage), in which case the particles are charged with chemisorbed hydrogen when in contact with the cathode (12). Agglomeration of the R-Ni particles leading to a loss of activity (10–12) represents a possible drawback for the use of R-Ni powders in ECH.

Depolymerization of renewable biomass compounds such as coal, peat, or lignin is arousing much interest today. For example, many studies have been devoted to coal liquefac-

tion (13) or to the degradation of lignin into valuable products (14). Ether linkage cleavage appears to be of prime importance for the success of these degradations (15) and various diaryl model compounds containing C—O bonds have been extensively investigated (16–18). Recently it has been shown that the C—O bond of α and β aryl ethers, model dimers representative of the α-O-4 and β-O-4 bonds of lignin (19), can be successfully cleaved by electrocatalytic hydrogenolysis (ECHsis) (20). However, little attention has been paid to diphenyl ethers, dimers that model the 4-O-5 bonds of lignin (19). This type of C—O bond is stronger than the α-O-4 and even the β-O-4 bonds, and thermal cracking or catalytic hydrogenation of diphenyl ethers usually gives low conversion rates (13, 21). Thus, the ECHsis of a diphenyl ether constitutes a stringent test for the effectiveness of ECH as a method for the hydrogenolysis of C—O bonds of aryl ethers and for the activity of various electrocatalysts.

This paper reports the results of an investigation of the ECH of 4-phenoxyphenol on an in situ built-up electrode consisting of a transition metal powder embedded in the open-pore structure of a piece of reticulated vitreous carbon (RVC). Upon stirring the catholyte, the catalyst powder is forced inside the pores by convection and remains in the pores throughout the electrolysis. Such a technique has the advantage of allowing any type of catalyst to be easily tested in a powdery form. Thus, catalysts commonly used for catalytic hydrogenation of organic compounds such as R-Ni, nickel boride (Ni_2B), transition metals dispersed on activated charcoal (M/C) and on alumina (M/Al_2O_3), and other catalysts such as fractal nickel (Ni) and palladium deposited on nickel particles (Pd/Ni) were tested for the ECH of 4-phenoxyphenol. ECH efficiency was also investigated with special attention paid to the effect of temperature and the type of carbon onto which the metal is dispersed.

Experimental

Electrolyses

The electrolyses were carried out at constant current using an Electrosynthesis Company (ESC) 410 potentiostat connected to an ECS 640 digital coulometer and an ECS 2830 digital multimeter. A two-compartment jacketed glass H-cell (volume of each compartment: 50 mL) having a Nafion-324 (E.I. duPont de Nemours & Co.) membrane (1.8 cm^2) as separator and equipped with a condenser, was connected to a constant-temperature circulating bath (Haake 1). The cathode was a piece of reticulated vitreous carbon (from ECS, $2.5 \times 2 \times 0.6$ cm^3, 100 ppi) to which a nickel stripe for electrical contact was fixed and into which the catalyst powder was embedded in the following way: (*i*) the powder was introduced into the cathodic compartment containing the solvent and supporting electrolyte (30 mL); (*ii*) the anodic compartment was filled with a 1 M NaOH solution (30 mL); and (*iii*) the catholyte was stirred (magnetic bar) prior to the application of a constant current. The counter electrode was a graphite rod. After less than 30 min of polarization, almost all the particles were entrapped in the RVC matrix and 4-phenoxyphenol (140 mg, 2.5×10^{-4} mol, 8.3×10^{-3} M solution) was then added to the catholyte.

Electrocatalysts

For each of the following electrocatalysts, the amount of powder added to the catholyte for the entrapment of the particles was adjusted to optimize the rate of ECH. (*i*) Fractal nickel (Ni): 0.5 g (Inco 255) used without any further treatment. (*ii*) Crystalline nickel boride (Ni_2B): 0.5 g (Aldrich) used without further treatment. (*iii*) Amorphous Ni_2B: 0.5 g, prepared according to the procedure described by Brown (22). (*iv*) Raney nickel (R-Ni): 1.0 g of Raney alloy (Ni/Al 50/50 w/w, Fluka) was treated with 10% aqueous NaOH at 50°C for 1 h. After decanting the solution, the powder was stirred for 2 h in an aqueous solution of cinnamic acid (500 mg in 50 mL) in order to remove the chemisorbed H resulting from the leaching of aluminum. Cinnamic acid was chosen because it has an activated double bond that is easily hydrogenated over R-Ni. The solution was decanted and the resulting R-Ni powder was thoroughly rinsed with 1 M aqueous NaOH and immediately transferred into the cathodic compartment. (*v*) Activated charcoal (C) and metals deposited on activated charcoal (M/C): 0.2 g of C, of Pd/C (5 and 10% w/w), of Ru/C (5% w/w), and of Pt/C (5% w/w) purchased from Aldrich; 0.2 g of Rh/C (5% w/w; Fluka). (*vi*) Metals deposited on alumina (M/Al_2O_3): 0.2 g of Pd/Al_2O_3 (5% w/w) and Rh/Al_2O_3 (5% w/w) used without further treatment. (*vii*) Palladium deposited on fractal nickel (Pd/Ni): 0.5 g prepared according to a procedure previously described (23).

Products analysis

After the electrolysis, the reticulated vitreous carbon electrode was thoroughly rinsed successively with 1 M NaOH and distilled ethanol. The solution was filtered, saturated with NaCl, acidified to pH ≈ 1 with 5 M HCl, and extracted with ethyl acetate. The products were analyzed by gas–liquid chromatography (GLC) and (or) high-pressure liquid chromatography (HPLC) and identified by comparing their retention times with those of authentic samples. The progress of the electrolysis was followed by GLC and (or) HPLC from aliquots (0.5 mL) treated as above. The GLC analyses were carried out on a Hewlett Packard (HP) 5790a chromatograph equipped with a FID detector using a 30 m long DB-5 fused silica column, and the HPLC analyses were carried out on a system composed of a C_{18} column packing, Beckmann 100A pumps, a Beckmann 420 controller, a Hitachi 100-40 spectrometer at $\lambda = 272$ nm, and a HP3390A integrator.

General considerations

The ECHsis of the carbon–oxygen bond of 4-phenoxyphenol was studied in a 1 M aqueous NaOH solution (the phenol, $pK_a \approx 10$, is converted to the phenolate salt, which is soluble in water) under constant current conditions. The charge passed corresponded to six electrons per molecule of phenoxyphenol (6 F/mol), which is three times the charge required for complete hydrogenolysis of a C—O bond. Phenol was the main product. In some cases, cyclohexanone and cyclohexanol were also formed in small amounts. The formation of phenol, cyclohexanone, and cyclohexanol is readily explained by the classical ECH mechanism, i.e., by reactions [1]–[6]. First, chemisorbed hy-

[a]Electrolysis conditions: 0.75 mmol of substrate, 1 M NaOH, I = 5 mA, Q = 6 F/mol, T = 50°C.

[b]Electrolysis performed on the reticulated vitreous carbon matrix without active powder.

[c]Electrolysis performed on R-Ni treated with cinnamic acid (see text).

[d]Electrolysis performed on R-Ni not treated in an aqueous cinnamic solution. Cyclohexanol (15%) was formed.

[e]No potential was applied. Cyclohexanol (5%) was formed.

drogen is formed at the surface of the cathode by reduction of water (reaction [1])

[1] $$2H_2O + 2M \xrightarrow{2e^-} 2M(H) + 2OH^-$$

where M is the metallic surface and (H)M chemisorbed hydrogen. Hydrogenolysis of the C—O bond then proceeds as in catalytic hydrogenation, i.e., by reaction of the adsorbed substrate (adsorption step shown in reaction [2]) with chemisorbed hydrogen (reaction [3]) followed by desorption of the product (reaction [4]).

[2] 
[3] 
[4] 
Phenol may then be hydrogenated further to cyclohexanone and cyclohexanol (reactions [5] and [6]).

It is important to point out that the efficiency of the ECH of a given organic compound depends on the relative rates of the hydrogenation step [3] (i.e., hydrogenolysis) and of hydrogen desorption (reactions [7] and (or) [8]) (1, 3). If reaction [3] is too slow with respect to reactions [7] or [8], only hydrogen evolution occurs and no formation of hydrogenation products (through reactions [2]–[4], then [5] and [6]) is observed.

[5] 
[6] 
[7] $$M(H) + H_2O + e^- \rightarrow H_2 + OH^- + M$$

[8] $$2M(H) \rightarrow H_2 + 2M$$

Results and discussion

The data on the effect of the electrocatalyst and temperature upon the efficiency of the ECHsis of 4-phenoxyphenol in 1 M aqueous NaOH as measured by the yield of phenol formed (determined by HPLC) are summarized in Tables 1 and 2. Cyclohexanone and cyclohexanol were formed in small amounts only in the case of high conversion of the substrate, i.e., with the most active catalysts (see Table 1, entries 6 and 7, and Table 2, entry 3). Thus the hydrogenation of phenol is slower than the hydrogenolysis of the C—O bond. It is noteworthy that hydroquinone (1,4-dihydroxybenzene) and benzene were not detected, which shows that the C—O bond attached to the 4-hydroxyphenyl ring is cleaved with a high selectivity and must be weaker than the other C—O bond. Also, no aromatic ring hydrogenation prior to the cleavage of the C—O bond was observed. As well, no aromatic ring hydrogenation prior to the C—O

[b]Cyclohexanone (4%) and cyclohexanol (4%) were formed.

bond cleavage was observed despite the fact that the C—O bonds of phenoxyphenol are expected to be stronger than those of the previous model compounds studied (20).

Effect of the electrocatalyst

The electrocatalysts considered in Table 1 can be arbitrarily divided into four classes: nickel-type catalysts (entries 2–7), which are known to be efficient for the ECH of organic molecules (24); transition metals supported on active carbon (M/C) (entries 9–13); transition metals supported on alumina (M/Al_2O_3) (entries 14 and 15); and palladium supported on various substrates (entries 16 and 17). To the authors' knowledge, this is the first time that transition metals supported on alumina are reported to be employed as electrocatalysts for ECH, despite the fact that they are extensively used as catalysts for the catalytic hydrogenation of organic compounds (25).

The high hydrogen overvoltage on vitreous carbon (26) contributes to rendering the vitreous carbon an inert cathode material (i.e., no chemisorption or weak chemisorption of hydrogen) in the presence of a transition metal catalyst, as in the case of a gold cathode in the presence of R-Ni (12). As anticipated from the fact that there is little or no chemisorption of hydrogen on vitreous carbon, only hydrogen evolution occurred at the RVC electrode in the absence of a catalyst (see entry 1).

For fractal nickel (Ni, entry 2) and crystalline Ni_2B (entry 3), the rate of desorption of chemisorbed hydrogen (reactions [7] and (or) [8]) is much faster than the rate of C—O bond hydrogenolysis (reaction [3]) as evidenced by the absence of phenol and by the nearly quantitative recovery of the starting phenoxyphenol after the electrolysis. The two latter electrocatalysts are inactive for the ECHsis of an aryl–O–aryl bond. However, amorphous Ni_2B is active, as seen in entry 4 where 30% of phenoxyphenol was hydrogenolysed to phenol (mass balance of 100%). For the catalytic hydrogenation of olefins, it has been observed before that crystalline Ni_2B is a less active catalyst than amorphous Ni_2B (27). The factors responsible for this difference have not yet been clearly identified: they might consist of electronic effects and (or) surface effects.

Based on entries 4 and 5, it can be seen that R-Ni (49% of phenol, entry 5) is a more efficient electrocatalyst than amorphous Ni_2B (30% of phenol, entry 4). For the ECH of phenanthrene, it has been reported that the two latter catalysts have the same intrinsic activity (3). They have also approximately the same activity in catalytic hydrogenation of unsaturated hydrocarbons (22, 28). Thus, the relative activity of R-Ni and Ni_2B as catalytic hydrogenation catalysts depends on the type of bond hydrogenated, such as polar C—O σ-bonds compared to nonpolar π-bonds. In the electrolysis of entry 5, the hydrogen present on the R-Ni catalyst after leaching of the alloy was removed by stirring the particles in an aqueous solution of cinnamic acid, the double bond of which is easily hydrogenated by catalytic hydrogenation. When the electrolysis was carried out with freshly leached R-Ni not treated with cinnamic acid (entry 6), phenoxyphenol was completely hydrogenolysed to phenol, about 15% of which was hydrogenated further to cyclohexanol (mass balance of 98%: 83% of phenol and 15% of cyclohexanol). Similar results were obtained under open circuit conditions (entry 7), after the same time as that used for the electrolysis of entry 6: complete conversion of phenoxyphenol with a 95% mass balance (90% of phenol and 5% of cyclohexanol). The experiments of entries 6 and 7 show that (*i*) with the relative quantities of substrate and R-Ni used, there was enough chemisorbed hydrogen on the R-Ni particles after leaching to completely hydrogenolyse 4-phenoxyphenol; (*ii*) most of the current passed in the electrolysis of entry 6 was used to generate molecular hydrogen (hydrogen evolution), and (*iii*) the R-Ni catalyst treated with cinnamic acid appears less active than the freshly prepared R-Ni catalyst that has retained the chemisorbed hydrogen formed in the leaching process.

Data for entries 9–13 are related to noble metals dispersed on activated charcoal (M/C catalysts). Activated charcoal is inactive for the electrohydrogenolysis of 4-phenoxyphenol (entry 8) as anticipated from the fact that there is little or no hydrogen chemisorption on carbon, as already pointed out. The mass balances of 68–83% for entries 8–13 are due to the loss of phenol and phenoxyphenol remaining strongly adsorbed on the charcoal particles. It should be noted that even after a 24 h reflux in ethanol, it was not possible to desorb the products (phenol and 4-phenoxyphenol) from the active powder. Indeed, the weight ratio of charcoal powder to phenoxyphenol was about 1.7 and activated charcoal is well known to strongly adsorb organic compounds. This is why only small quantities of activated charcoal are used to remove colored impurities from organic solutions. The results of entries 9–12 indicate that the nature of the noble metal dispersed onto the active carbon has a determining effect on the efficiency of the electrohydrogenolysis of 4-phenoxyphenol. On the one hand, with the Rh/C, Pt/C, and Ru/C catalysts (entries 9–11), the rate of hydrogen desorption (reaction [7] and (or) [8]) is much faster than that for hydrogenolysis of 4-phenoxyphenol, which results in a very poor efficiency of electrohydrogenolysis (0–7%) for the three catalysts. On the other hand, for the Pd/C catalysts, hydrogenolysis and hydrogen desorption have comparable rates, resulting in fair to good electrogenolysis efficiencies (38–55%, entries 12 and 13). The concentration of dispersed palladium on the active carbon is a key parameter since 38%

© 1999 NRC Canada

of phenol is generated with Pd(5%)/C compared to 55% for Pd(10%)/C, the other experimental parameters being the same. It should be added that a twofold increase of the amount of Pd(5%)/C catalyst did not lead to a higher conversion rate. It is relevant to note that for catalytic hydrogenolysis of C—O bonds, Pd/C powder is a commonly used catalyst (24), Rh/C and Pt/C catalysts being also efficient, and Ru/C being totally inefficient (29).

The electrohydrogenolysis of 4-phenoxyphenol is efficient when alumina is used as support for palladium (entry 14: 62% yield of phenol). A great advantage of alumina over activated charcoal as support material is that phenol and phenoxyphenol are not retained on the alumina particles after rinsing the electrode, leading to a higher mass balance (89% in entry 14) than when activated charcoal is the support (71% in entry 12). The use of Rh for the electrohydrogenolysis of 4-phenoxyphenol remains deceptive even with alumina as a support material, as illustrated by the data of entry 15.

Based on entries 14, 12, 16, and 17, it is shown that 62, 38, 7, and 3% of phenol is formed when Pd is supported on alumina, active carbon, barium sulfate, and fractal nickel, respectively. The higher conversion rate obtained with Pd/C and Pd/Al $_2O_3$ may tentatively be ascribed to the higher adsorption capacity of active carbon and alumina towards organic compounds compared to nickel, as the mechanism of ECH involves the adsorption of the organic compound (reaction [2]). Further, it must be stressed that, when dealing with dispersed catalysts, the crystallite size effect and the interaction of the metal support play a very important role (30).

Effect of temperature

The data related to the electrolysis of 4-phenoxyphenol at 25°C, 50°C, and 75 °C with Pd(5%)/C and Pd(5%)/Al_2O_3 as catalysts are given in Table 2. As far as Pd(5%)/C electrocatalyst is concerned, the higher the temperature, the higher the amount of phenol. In addition, small amounts of both cyclohexanone and cyclohexanol were detected at 75°C (entry 3). By contrast, with Pd(5%)/Al_2O_3, an increase of the temperature had little effect on the extent of electrohydrogenolysis (compare entries 4 and 5).

Conclusions

A new device, with which a powdered catalyst active for catalytic hydrogenation of organic compounds can be used as electrode material, has been designed and tested for the ECHsis of 4-phenoxyphenol. High efficiencies (50–60%) of electrohydrogenolysis to phenol have been obtained with Pd/Al_2O_3, Pd/C, and R-Ni catalysts and the efficiency was found to decrease in the following order: Pd/Al_2O_3 ≥ Pd/C ≥ R-Ni >Ni_2B (amorphous) >> (Rh/Al_2O_3 ≈ Pt/C ≈ Pd/$BaSO_4$) > (Ru/C ≈ Pd/Ni) > (Rh/C ≈ Ni ≈ Ni_2B (crystalline)). The cleavage of a diphenyl ether bond is very promising for the recovery of biomass compounds, as these types of bonds are often found in Kraft lignin.

Normal acid/base behaviour in proton transfer reactions to alkoxy substituted carbenes: estimates for intrinsic barriers to reaction and pK_a values

John Paul Pezacki

Abstract: Theoretical Eigen curves can be drawn through Brønsted data for dimethoxycarbene (**1**), phenyltrimethylsiloxycarbene (**3a**), 4-methylphenyl(trimethylsiloxy)carbene (**3b**), 4-methoxyphenyl(trimethylsiloxy)carbene (**3c**), and β-naphthyl(trimethylsiloxy)carbene (**3d**). The Brønsted plots for these data are clearly curved with α values near 1 when proton transfer is thermodynamically unfavourable and α values near 0 when proton transfer is thermodynamically favourable, suggesting that these carbenes behave as "normal" Brønsted bases. Estimates of the intrinsic barriers ($\Delta G_0^{\ddagger}$) for proton transfer reactions and of the pK_a values for the conjugate acids of the carbenes, extracted from these theoretical curves, have been made. The magnitudes of the intrinsic barriers ($\Delta G_0^{\ddagger}$) for these proton transfer reactions determined by Eigen and Marcus theories are all 1–5 kcal mol^{-1}, suggesting that these reactions are intrinsically fast. Small intrinsic barriers also imply "normal" acid/base behaviour. Extrapolated pK_a values are also the first estimates for the pK_a values of the conjugate acids of carbenes **1** and **3a–3d**.

Key words: carbenes, proton transfer reactions, carbocations, Marcus theory, Brønsted plots.

Résumé : On peut tracer des courbes théoriques de Eigen à partir de données de Brønsted pour les diméthoxycarbène (**1**), phényltriméthylsiloxycarbène (**3a**), 4-méthylphényl(triméthylsiloxy)carbène (**3b**), 4-méthoxyphényl(triméthylsiloxy)-carbène (**3c**) et β-naphtyl(triméthylsiloxy)carbène (**3d**). Les courbes de Brønsted pour ces données sont vraiment incurvées, avec des valeurs de α près de 1 quand le transfert de proton est thermodynamiquement défavorisé et des valeurs de α près de 0 quand le transfert de proton est thermodynamiquement favorisé; ceci suggère que ces carbènes se comportent comme des bases de Brønsted « normales ». On a évalué les barrières intrinsèques ($\Delta G_0^{\ddagger}$) pour les réactions de transfert de proton et les valeurs de pK_a pour les acides conjugués des carbènes à partir de ces courbes théoriques. Les amplitudes des barrières intrinsèques ($\Delta G_0^{\ddagger}$) pour les réactions de transfert de proton déterminées par les théories de Eigen et Marcus sont toutes de l'ordre de 1 à 5 kcal mol^{-1}, ce qui suggère que ces réactions sont intrinsèquement rapides. Des barrières intrinsèques faibles impliquent aussi un comportement acide/base « normal ». Les valeurs de pK_a extrapolées correspondent aussi aux premières estimations de valeurs de pK_a d'acides conjugués des carbènes **1** et **3a–3d**.

Mots clés : carbènes, réactions de transfert de proton, carbocations, théorie de Marcus, courbes de Brønsted.

[Traduit par la Rédaction]

Introduction

Proton transfer reactions to and from carbon atoms are usually quite different from those to and from heteroatoms (commonly referred to as "normal" Brønsted acids and bases) (for some reviews, see ref. 1). Carbon-centered acids and bases usually undergo proton transfer reactions more slowly than do their heteroatom counterparts and are believed to do so directly rather than through a solvent molecule in aqueous solvents. Normal Brønsted acids and bases are thought to donate or accept a proton through one or more water molecules, according to the Swain–Grunwald mechanism (2, 3), as well as directly from acid to base. Furthermore, Brønsted plots for proton transfer reactions between normal acids and bases follow *Eigen curves* with slopes (α) equal to zero when proton transfer is thermodynamically favourable, with rate constants for proton transfer being at or near the diffusion-controlled limit. When proton transfer is thermodynamically unfavourable, diffusion-controlled separation of the products is rate limiting (4) and the slopes (α)

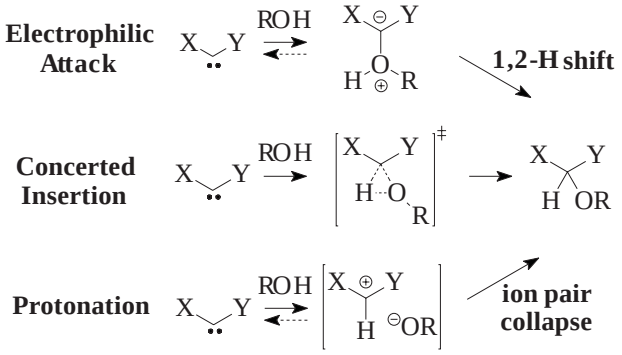
Scheme 1.



equal one. There is only a small region near $\Delta pK = 0$ where proton transfer is partially rate limiting and deuterium isotope effects are observed. Carbon-centered acids and bases generally give Brønsted plots that, by comparison, are not as sharply curved, if they show curvature at all. This lack of curvature in Brønsted plots for carbon acids and bases is presumably the result of changes in hybridization, changes in heavy-atom bond lengths and angles, desolvation in the rate-limiting transition state, differences in hydrogen-bonding ability, and changes in delocalization of charge. Any or all of these effects are believed to result in higher activation barriers, even when proton transfer is thermodynamically favourable (i.e., higher intrinsic barriers), and therefore smaller changes in transition state position (and in slope α) as a function of ΔpK for the reaction (1). However, nearly all of the studies related to the acid/base chemistry at carbon atoms have been restricted to carbanions and their conjugate acids; by comparison, the acid/base chemistry of divalent carbon atoms, carbenes, and their conjugate acids is not well established.

The formal insertions of carbene intermediates into O—H bonds are well-known processes and can occur by different mechanisms depending on the nature of the carbene intermediate (5). Carbenes may insert into O—H bonds from the singlet spin state by a concerted mechanism, or by initial formation of an oxonium ylide intermediate followed by a 1,2-hydrogen shift, or by proton transfer (Scheme 1).

The proton transfer mechanism leads to the formation of a carbocation – alkoxy anion pair, which can collapse to form formal O—H insertion products. The observation of carbocationic intermediates after the photochemical generation of carbenes in solutions containing hydroxylic reactants, in laser flash photolysis (LFP) experiments, has shown that several carbenes of different structure undergo O—H insertion into alcohols via this mechanism. For example, diphenyl and diarylcarbenes have been shown to insert into the OH bonds of alcohols by a proton transfer mechanism, by direct observation of the resulting carbocationic intermediates by LFP, eq. [1] (6).

[1] 
In other cases, proton transfers to carbenes have been implied, based on product distributions. An example is the trapping of cycloheptatrienylidene with deuterated alcohols, which leads to mixtures of products with deuterium and the alkoxy substituent located at different positions in the cycloheptatriene products (eq. [2]) (7). Deuterium scrambling implicates a mechanism involving initial proton transfer to the carbene center, which leads to the formation of the aromatic tropylium cation and an alkoxide ion. Ion pair collapse occurs at any of the ring carbons of the tropylium ion, which results in a mixture of products. Benzotropylium cations have also been implicated in reactions of benzoannelated cycloheptatrienylidenes with alcohols (7*b*).

[2] 
In general, the stepwise mechanism for O—H insertion of carbenes into hydroxyl groups involving initial proton transfer to the carbene carbon is favoured when the conjugate acid of the carbene is a relatively stable and persistent carbocationic intermediate. Even highly electrophilic carbenes can undergo OH insertions via a proton transfer mechanism. For example, tight ion pairs have been implicated in OH insertion reactions by highly electrophilic 2-bicyclo[2.1.1]hexylidene, suggesting a proton transfer mechanism (8). For carbenes whose conjugate acids are highly unstable species, a concerted mechanism is *enforced* by the lack of a significant lifetime of the resulting carbocation – alkoxy anion pair in solution. However, predicting which mechanistic pathway in Scheme 1 will dominate for a given carbene is difficult since more *electrophilic* carbenes may also attack at oxygen, even when proton transfer leads to the formation of stable carbocationic intermediates.

The proton transfer mechanism has been implicated in several systems based on direct observations of resulting carbocations, or on product distributions, or on slopes of Brønsted plots. Non-zero slopes in Brønsted plots suggest that the reactions depend on the acidity of the O—H containing substrate with the rate constants for O—H insertion (assuming that proton transfer is rate limiting) and are proportional to the pK_a's of the protonating acid. Often overlooked is the fact that such rate constants will also depend on the thermodynamics of the overall reaction, according to the Hammond postulate, and the pK_a's of the conjugate acids of carbene intermediates are also important in determining how fast a given proton transfer event will occur. Unfortunately, for most carbenes such thermodynamic parameters are unknown and virtually impossible to measure directly with present-day equipment. However, in some cases, when the conjugate acids of carbenes are stable and unreactive, it is possible to gain information about their pK_a values.

Many nucleophilic nitrogen-substituted carbenes have been generated by deprotonation of conjugate acid iminium ions. Examples include the C-2 deprotonation of imidazolinium salts (9*a*) (eq. [3]) and of thiazolium salts (10) including

[3] 
[4] 
thiamin **C_2-ylide of thiamin** **C_2-ylidene of thiamin**

thiamin[3] (11) (eq. [4]. A pK_a value of ca. 16 has been estimated for thiamin (eq. [4]) (12), and those for thiazolium ions fall between ca. 16 and 22 (13). Also, "normal" acid/base behaviour has been implicated in proton transfer reactions of thiazolium ions including thiamin (12–14). More recently, a pK_a of 24 for the conjugate acid of the stable carbene 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene (eq. [5]) has been measured by ^{1}H NMR in DMSO solvent by monitoring hydrocarbon acids (such as 2,3-benzofluorene, eq. [5]) and their conjugate bases (15). Alder et al. also noted that while the carbon acids and their conjugate bases were distinguishable by ^{1}H NMR, suggesting that proton transfer is slow compared to the NMR time scale, proton transfer between 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene and its conjugate acid is fast as evidenced by the fact that the carbene and its conjugate acid appear as an averaged spectrum in the presence of base (15).

[5] 
The reported acid/base reactivity of diamino and aminothiocarbenes suggests that other π-donor-substituted carbenes may also behave as normal Brønsted bases and that equilibria between carbenes and their conjugate acids may be established in solution. The evaluation of the acid/base chemistry of dimethoxycarbene and four aryltrimethylsiloxycarbenes, as well as the first estimates of the pK_a values for their conjugate acids, is presented here.

1. Brønsted relations and Eigen curves

1.a Proton transfer to dimethoxycarbene

Like diamino and aminothiocarbenes, dimethoxycarbene (**1**) is considered to be a *nucleophilic* carbene due to conjugative stabilization through donation by the lone pairs on the oxygen atoms of the methoxy substituents to the formally vacant virtual *p*-orbital at the carbene carbon (16, 17). Conjugative donation to the carbene carbon gives dimethoxycarbene (**1**) dipolar character and also strongly stabilizes the singlet state. The singlet–triplet energy gap ($\Delta\epsilon_{ST}$) of **1** has been calculated to be ~ 76 kcal mol^{-1} (17). The inductively electron-withdrawing methoxy substituents also interact with the filled sp^2 orbital (the lone pair on the carbene carbon), which results in extra stabilization of **1**.

[6] 
1

Dimethoxycarbene (**1**) has been generated from 7,7-dimethoxynorbornadienes (18), an oxadiazoline (19), dimethoxydiazirine (20), and hexamethoxycyclopropane (21), and its preference for reaction with electron-deficient olefins, for reaction with carbonyl groups at carbon (19), and for displacing leaving groups (chlorine) via S_N2 type reactions in solutions of benzene (22) supports the premise that carbene **1** is *nucleophilic* in character.

It is thought that dimethoxycarbene behaves as a nucleophile because of its dipolar character and because of the resonance stabilization of positive charge at the carbene carbon in the transition states and intermediates of reactions involving attack of the carbene carbon lone pair onto its reaction partner (23). Resonance stabilization in the ground state of **1**, in the transition states and in carbocationic intermediates, makes proton transfer to dimethoxycarbene (**l**) the most likely mechanism for formal OH insertion reactions. Such a proton transfer mechanism is supported by observed kinetic isotope effects (20*e*).

In a previous investigation (20*c*), rate constants for the reactions of dimethoxycarbene with a series of oxygen-centered acids were measured by LFP in acetonitrile, and a Brønsted plot, based on the linear free energy relationship in eq. [7] or its differential form in eq. [8], was constructed based on the data for **1** in Table 1.

[3] Although some C-2 anions of thiazolium and imidazolium ions are considered to be more ylide-like than carbene-like, recent crystal structures of stable compounds have shown that the carbon heteroatom bonds are more like single bonds than double bonds and that the carbene carbons in these structures are very nearly neutral in charge, suggesting that they are better represented as carbenes rather than ylides (9*a*, 9*b*) although these views have been challenged (9*c*).

[a]Reference 20*c*.
[b]Rate constants from ref. 35*b*.
[c]pK_a values in water (24).
[d]Quenching plots for dimethoxycarbene by $ClCH_2CH_2OH$, FCH_2CH_2OH, and 2,2,2-trifluoroethanol (TFE) were found to be concave upward due to the contribution of oligomeric alcohol to the rate constants for the decay of this carbene. The rate constants for these acidic species therefore represent upper limits for the rate constants for reaction with the monomeric form.
[e]k_a values are approximations based on low concentration ranges of curved quenching plots where the plots are approximately linear.

A slope of $\alpha \sim 0.66$ was determined by Du et al. (20*c*). The pK_a values used by Du et al. (20*c*) and for all Brønsted correlations reported here are those determined in water (24) (see Table 1) as a result of a lack of appropriate thermodynamic data for these acids in acetonitrile solvent (the pK_a values of various acids in acetonitrile have been compiled by K. Izutsu, see ref. 25). Therefore correlations of the data should be considered to be *semi-quantitative*, although the pK_a values for phenols and carboxylic acids in acetonitrile and in water may be approximated by eq. [9] (1*a*), which is assumed to be valid for the acidic species in Table 1. Knowledge of the pK_a's in acetonitrile would make the interpretation of these data quantitative.

$$[7] \quad \log(k_a) = \alpha \cdot \log(K_a) + \text{constant}$$

$$[8] \quad \delta \log(k_a) = \alpha \cdot \delta \log(K_a)$$

$$[9] \quad pK_a^{MeCN} - pK_a^{H_2O} \approx 14.0$$

Slopes of Brønsted plots (α) are considered to be a measure of the extent of proton transfer at the transition state for the reaction, with $\alpha = 0$ representing the structure of the reactants and $\alpha = 1$ representing that of the products, respectively. An α value of 0.66 suggests that the transition state for proton transfer to dimethoxycarbene is more product-like than reactant-like over the pK_a range studied. However, the structure of the transition state may change with pK_a, following the thermodynamics of the reaction, according to the Hammond postulate (26). Reactions that are exothermic have transition states that are more reactant-like and those that are endothermic have transition states that are more product-like. Such changes in transition state structure lead to curvature in Brønsted plots. Curvature in Brønsted plots can be evaluated with Marcus rate theory (27)[4] and such evaluations follow.

When proton transfer reactions are fast, as in those to and from electronegative atoms ("normal" Brønsted acids and bases), then diffusion becomes a limiting factor except for small values of ΔpK when proton transfer is, at least, partially rate determining. Curvature in Brønsted plots for proton transfers to and from normal Brønsted acids and bases then arises from changes in the rate-determining step. When proton transfer is thermodynamically unfavourable, diffusional separation of the products is rate limiting (α approaches 1), and when proton transfer is thermodynamically favourable then diffusional encounter becomes rate limiting (α approaches 0). In such cases, the rate-determining proton transfer step can itself be divided into three steps as described by Eigen (4).

The reactions of dimethoxycarbene (**1**) with oxygen-centered acids (the forward reaction in eq. [10]) appear to be at least partially diffusion controlled when proton transfer is thermodynamically favourable, given that the observed rate constants for proton transfer to these carbenes reach a maximum at values greater than 10^9 M^{-1} s^{-1}. If dimethoxycarbene behaves as a normal Brønsted base, then it should be possible to draw an Eigen curve (4) through the data points in the Brønsted plot, based on the three-step mechanism for proton transfer in eq. [10], where k_d is the rate constant for diffusion together of the reactants, k_{-d} is the rate constant for diffusional separation of the products, and k_p and k_{-p} are the rate constants for proton transfer within the encounter complex.

The steady-state solution to eq. [10], where k_a (eq. [11]) is the observed bimolecular rate constant for proton transfer to

[4]For examples of the use of quadratic Brønsted correlations to solve for Marcus theory parameters, see ref. 28.

[10] 
1 by the oxygen-centered acids, is given in eq. [12]. The values for k_p and k_{-p} are defined in eqs. [13] and [14], respectively (13, 29).

[11] 
$$[12] \quad k_a = \frac{k_d k_p k_{-d}}{k_p k_{-d} + k_{-d} k_{-d} + k_{-d} k_{-p}}$$

$$[13] \quad k_p = k_{p\,(\Delta pK=0)} \cdot 10^{0.5(\Delta pK)}$$

$$[14] \quad k_{-p} = k_{p\,(\Delta pK=0)} / 10^{0.5(\Delta pK)}$$

The values for ΔpK are defined by the relation in eq. [15], where pK_a^{AH} are the pK_a's of the oxygen acids, pK_a^{CH+} is the pK_a for the conjugate acid of the carbene, and α for the proton transfer step is assumed to be 0.5 at $\Delta pK = 0$.

$$[15] \quad \Delta pK = pK_a^{AH} - pK_a^{CH+}$$

[16] 
[17] 
After statistical correction for the number of equivalent acidic sites on the protonating species (p), and substituting values of $k_d = 3.2 \times 10^9$ M^{-1} s^{-1} and $k_{-d} = 1 \times 10^{10}$ s^{-1}, least-squares fitting of the expression in eq. [18] to the data for **1** in Table 1 yielded a smooth Eigen curve (middle curve in Fig. 1) with coefficients of $pK_a^{CH+} = 11.0 \pm 0.1$ (water, ~25 in MeCN) and $\log k_{p\,(\Delta pK\,=\,0)} = 8.92 \pm 0.23$ M^{-1} s^{-1}.

$$[18] \quad \log k_a = \log \left(\frac{k_d \cdot k_p \cdot k_{-d}}{k_p \cdot k_{-d} + k_{-d} k_{-d} + k_{-d} \cdot k_{-p}} \right)$$

where

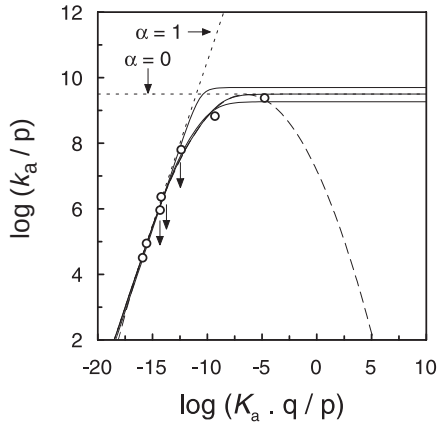
$$k_p + k_{p(\Delta pK=0)} \cdot 10^{0.5(pK_a^{AH} - pK_a^{CH+})}$$

and

$$k_{-p} = \frac{k_{p\Delta pK=0}}{10^{0.5(pK_a^{AH} - pK_a^{CH+})}}$$

Similar least-squares fitting of the expression in eq. [18] to the data for **1** in Table 1, with $k_{-d} = 1 \times 10^{10}$ s^{-1} and k_d determined by the fit, yielded a different Eigen curve (lower curve in Fig. 1) with computed values of $pK_a^{CH+} = 11.2 \pm 0.2$ (water, ~25 in MeCN), $\log k_d = 9.27 \pm 0.16$ M^{-1} s^{-1}, and $\log k_{p\,(\Delta pK\,=\,0)} = 9.18 \pm 0.31$ M^{-1} s^{-1} from the fit. Analogous least-squares fitting (upper curve in Fig. 1), with $k_d = 5 \times 10^9$ M^{-1} s^{-1}, $k_{-d} = 1 \times 10^{11}$ s^{-1}, and $k_{p\,(\Delta pK\,=\,0)} = 10^{12}$ M^{-1} s^{-1} (essentially no intrinsic barrier) defined, yielded a value for pK_a^{CH+} of 10.6 ± 0.2 (water, ~25 in MeCN) with a much poorer fit through the data. Since the actual rate constants for diffusional encounter of carbenes with alcohols and diffusional separation of conjugate acids – alkoxide ion pairs are not known, a variety of different values were chosen in a series of fits. A summary of these results obtained from all the least-squares fits is presented in Table 2. Interestingly, all least-squares fits yielded similar pK_a values for the conjugate acid of dimethoxycarbene (1) despite widely different values for k_d and k_{-d}.

Fig. 1. Brønsted plot for the protonation of dimethoxycarbene in acetonitrile at 20°C. Arrows indicate that the corresponding data points are upper limits for the log k_a values (see text). The solid lines are theoretical Eigen curves (see text), the dotted lines are extrapolated from the portions of the middle Eigen curve where $\alpha_{obs} = 0$ and $\alpha_{obs} = 1$. These dotted lines cross at $pK_a^{AH} = pK_a^{CH+}$ ($\Delta pK = 0$) (4). The broken line is the Marcus curve through the data.



Kirmse et al. (35*b*) have suggested that proton transfers to aryltriphenylsiloxycarbenes occur via a preassociation mechanism. Such proton transfers would obey the relation in eq. [19], where K_{ass} is the association constant.[5]

$$[19] \quad k_a = \left(\frac{K_{ass} k_d k_p k_{-d}}{k_p k_{-d} + k_{-d} k_{-d} + k_{-d} k_{-p}} \right)$$

The least-squares fitting of the logarithmic form of the expression in eq. [19] to the data for **1** in Table 1, assuming $k_d = 4 \times 10^{10}$ M^{-1} s^{-1} and $k_{-d} = 4 \times 10^{10}$ s^{-1}, yielded a smooth Eigen curve through the data with coefficients yielding values of $pK_a^{CH+} = 11.2 \pm 0.2$ (water, ~25 in MeCN), $\log k_{p\,(\Delta pK\,=\,0)} = 9.78 \pm 0.32$ M^{-1} s^{-1}, and $K_{ass} = 4.6 \times 10^{-2}$.

In all cases, least-squares fitting of the data, using the Eigen model with reasonable assumptions regarding rate constants for diffusional encounter and separation (29), yields reasonable curves through the data and computed values of

[5] For eq. [19] to hold, K_{ass} must be dimensionless. K_{ass} will be dimensionless when ROH (the proton donor) is in large excess and when [ROH] remains constant over the course of the reaction.

[a]These Eigen curves are identical graphically. See ref. 30 for discussions on the coupling of diffusion and apparent intrinsic barriers to reaction.
[b]These values were defined and are not results from curve fitting of the data.
[c]These curves clearly do not go through the data points.

~11 (water, ~25 in MeCN) for the pK_a of the conjugate acid of dimethoxycarbene, and computed intrinsic barriers[6] (the barrier to reaction at $\Delta pK = 0$) of 2.4–3.7 kcal mol^{-1}. The small variation within each theoretical model then depends on what values of k_d and k_{-d} are used (30). The magnitude of the "apparent" intrinsic barrier (larger than 1 kcal mol^{-1}) suggests that the proton transfer step (k_b) may be coupled with other molecular events that contribute to this barrier and that are not accounted for by this model (4). The fact that reasonable Eigen curves can be drawn through the Brønsted data suggests that dimethoxycarbene is a "normal" Brønsted base and that the pK_a of its conjugate acid lies between those of 2,2,2-trifluoroethanol (TFE) and 1,1,1,3,3,3-hexafluoroisopropanol (HFIP) in acetonitrile. Thiazolium ions and thiamin (which itself is a thiazolium cation) have pK_a'*s* of ~14–20 in aqueous solution (12–14). As well, the pK_a of a conjugate acid of a diaminocarbene has been measured to be 24 in DMSO (15). Since the conjugate bases of these cations may be written as carbenes, they are good model systems for comparison. The cations are stable species and the carbene–ylide conjugate bases would be more stable/less reactive than oxygen-substituted carbenes. The computed pK_a of the conjugate acid of **1** suggests that it is more acidic than thiazolium ions, which is expected as a result of the increased electronegativity of oxygen as compared with nitrogen and sulfur. Oxazolium ions are known to be more acidic than their imidazolium and thiazolium ion counterparts (31). Interestingly, the pK_a's of the electron-deficient 4-biphenylnitrenium ion and 4-aminobiphenyl dication in 20% aqueous acetonitrile have been estimated as 16 and 0.1 (32), respectively, suggesting that the conjugate acid of 4-biphenylnitrenium ion is much more acidic than the conjugate acid of **1.**[7]

Curvature in Brønsted plots can also be evaluated with Marcus rate theory (27, 28) by taking advantage of the relation in eq. [20], where w^r is the work required to bring the reactants into a reaction complex, $\Delta G_0^{\ddagger}$ is the intrinsic reaction barrier, $\Delta G^{\ddagger}$ is the overall free energy of activation, and ΔG^0 is the difference in free energy between the reactants and the products (28). The slope parameter α is defined by the differential in eq. [8], and differentiation of $\Delta G^{\ddagger}$ with respect to ΔG^0 in eq. [20] gives an alternative mathematical representation for α in eq. [21]. The second derivative in eq. [22] reflects the change in α as a function of the intrinsic

[6]There are many potential factors that may influence the magnitudes of apparent intrinsic barriers to reaction (1, 3, 30) so that interpretation of the computed values for the intrinsic barriers should be made with caution.
[7]Nitrenium ions are isoelectronic with carbenes.

barrier for reaction ($\Delta G_0^{\ddagger}$), implying that intrinsically fast reactions will show more distinct curvature in Brønsted plots than will those with large intrinsic barriers.

$$[20] \quad \Delta G^{\ddagger} = w^{r} + \left(1 + \frac{\Delta G^0}{4\Delta G_0^{\ddagger}}\right)^2 \Delta G_0^{\ddagger}$$

$$[21] \quad \alpha = \frac{\partial \Delta G^{\ddagger}}{\partial \Delta G^0} = \left(1 + \frac{\Delta G^0}{4\Delta G_0^{\ddagger}}\right) / 2$$

$$[22] \quad \frac{\partial \alpha}{\partial \Delta G^0} = \frac{1}{8\Delta G_0^{\ddagger}}$$

After statistical correction for the number of equivalent acidic sites on the protonating species (q), least-squares fitting of the quadratic expression in eq. [23], which is a form of eq. [20] (28), to the data for **1** in Table 1 yielded a smooth curve (Fig. 1) with the following coefficients: a = 7.17, b = –0.715, c = –0.0552. The correlation coefficient (R) is 0.996, which is statistically a better fit than that to a straight line (R = 0.929).

$$[23] \quad \log(k_a/p) = a + b\,\log(K_a q/p) + c\,\log(K_a q/p)^2$$

After substitution and rearrangement in eqs. [20] and [23], coefficients a, b, and c yielded values of the Marcus theory parameters (27, 28) for the work required to bring the reactants into a reaction complex, $w^r \approx 4.5$ kcal mol^{-1}, and for the intrinsic reaction barrier, $\Delta G_0^{\ddagger} \approx 1.5$ kcal mol^{-1}. The calculated value for the intrinsic barrier to proton transfer to dimethoxycarbene, although semiquantitative due to the lack of thermodynamic data for the protonating acids in acetonitrile solutions, indicates that proton transfer to the carbene carbon is an intrinsically fast reaction akin to those of normal acids/bases. The value of the intrinsic barrier computed here may in fact be too low as the influence of diffusion may not be accounted for properly in the Marcus model (30). In fact, proton transfer may never be completely rate determining. When this is the case then the Eigen model is preferred.

One can determine the tangents to the curve in the Brønsted plot in Fig. 1 by determining the first derivative of the quadratic expression in eq. [23] (eq. [24]). Coefficients b and c come from the least-squares fitting of the data to eq. [23], and substituting those values and values for log ($K_a q/p$) into eq. [24] yields values for α (the slope of the tangent at a point on the graph). Likewise, one may substitute values for b, c, and α into eq. [24] and determine which point on the curve corresponds to a particular value of α.

$$[24] \quad \alpha = \frac{\partial[\log(k_a/p)]}{\partial[\log(K_a q/p)]} = b + 2c[\log(K_a q/p)]$$

In this manner log ($K_a q/p$) values where α equals 0, 0.5, and 1 were computed using the quadratic expression (eq. [23]) for the Brønsted curve for the protonation of dimethoxycarbene. These values of α are the slopes of the tangent lines to the curve at points (log K_a, log k_a) = (–6.48, 9.49), (–11.0, 8.34), and (–15.5, 4.99), respectively. Since α can be considered to be a measure of transition state structure, a reasonable approximation for the point on the Brønsted curve where the acid/base reaction is thermoneutral (i.e., $\Delta G^0 = 0$) is the point where the transition state lies exactly halfway between reactants and products (α = 0.5).[8] If the proton transfer reaction between an oxygen-centered Brønsted acid and dimethoxycarbene reaction is to be considered thermoneutral then $K_{C:}$ in eq. [25] must equal unity, and K_a^{AH} (eq. [16]) must equal the acid dissociation constant for the conjugate acid of dimethoxycarbene, K_a^{CH+} (eq. [17]). The tangent to the curve with slope of α = 0.5 at the point (–11.0, 8.34) therefore suggests that the log K_a^{CH+} for the conjugate acid of dimethoxycarbene is approximately –11.0 (water) and that the pK_a for dimethoxymethyl cation is ~ 11.0 (water, ~ 25 in acetonitrile). In fact, substituting the calculated values for the intrinsic barrier and work term for proton transfer to dimethoxycarbene into eq. [20], with $\Delta G^0 = 0$, gives a value of ~ 6 kcal mol^{-1} for the free energy of activation ($\Delta G^{\ddagger}$) when the reaction is thermoneutral. This value corresponds to a bimolecular rate constant of $k_a \approx 2.0 \times 10^8$ M^{-1} s^{-1} (log k_a = 8.30), which corresponds to the point (–11.1, 8.30) on the Brønsted curve (by solving the quadratic expression in eq. [23]) indicating that the interpretations here are, at least, self-consistent. Although the Eigen model more accurately accounts for the contributions of diffusional rate constants to the overall reactions when the transfer step is not fully rate determining, both the Eigen and the Marcus models predict similar pK_a values for the conjugate acid of dimethoxycarbene.

[25] 
$$[26] \quad K_{C:} = \frac{K_a^{AH}}{K_a^{CH+}}$$

1.b Proton transfer to aryltrimethylsiloxycarbenes

Aryltrimethylsiloxycarbenes (**3**) have been generated from the corresponding acylsilanes (**2**) both thermally and photochemically (for a review of α-siloxy carbenes generated from acylsilanes see ref. 34). Rate constants for the protonation of **3a–3d** by hydroxylic acids in organic media have been measured by LFP (35). The direct observation of carbocationic intermediates **4a–4d** unambiguously proves that proton transfer to arylsiloxycarbenes **3a–3d** is the initial step in formal OH insertion reactions of these carbenes.

[27] 
2 **3** **4**

2a: Ar = Ph;
2b: Ar = 4-methylphenyl;
2c: Ar = 4-methoxyphenyl;
2d: Ar = β-Naphthyl.

[8] It has been shown that the slope of a Brønsted plot can be influenced by pre-equilibrium desolvation. Thus, the magnitude of the obtained coefficient alone may not exactly reflect the thermodynamics of the reaction. See Murray et al. (33).

© 1999 NRC Canada

Arylsiloxycarbenes are expected to be *nucleophilic* in character. Evidence for this comes from addition reactions with carbonyl compounds (presumably at carbon) (36). Conjugative stabilization occurs in carbenes **3a–3d** through donation from the aryl substituents and by the lone pairs on the oxygen atoms of the trimethylsiloxy substituents to the formally vacant *p*-orbital at the carbene carbon. Additional stabilization of carbenes **3a–3d** and cations **4a–4d** results from hyperconjugation of the trimethylsilyl group, with resulting positive charge on silicon and negative charge at the carbene carbon.

[28]

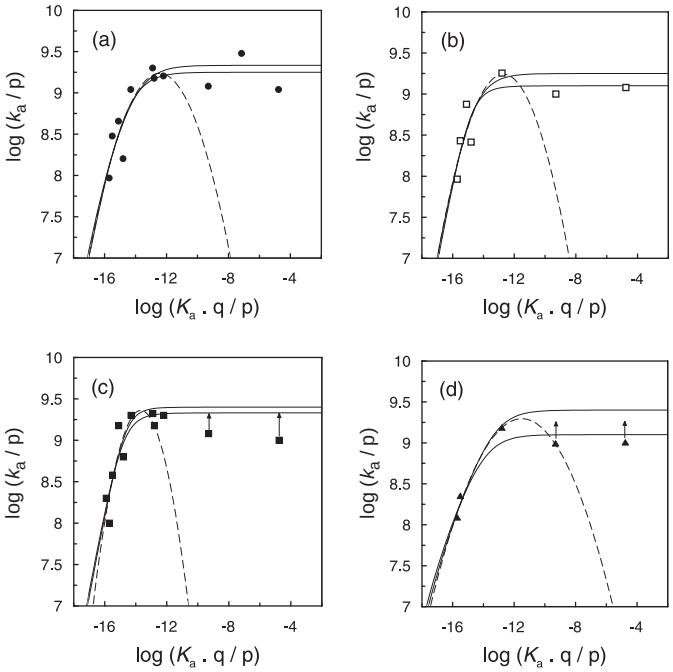
The analysis of the kinetic data for proton transfer to aryltrimethylsiloxycarbenes **3a**–**3d**, obtained by Kirmse et al. (35*b*), according to Eigen theory and to Marcus theory (27, 28) are presented here. The relevant kinetic data may be found in Table 1.[9]

From the data in Table 1, Brønsted plots for the proton transfer reactions to aryltrimethylsiloxycarbenes **3a**–**3d** by oxygen acids were constructed by plotting log (k_a/p) vs. log ($K_a^{AH}q/p$) (Fig. 2) for each carbene, where q and p are statistical factors for the number of equivalent basic sites on the carbene (always 1) and the number of equivalent acidic sites on the protonating acid. Linear least-squares fitting of these data to eqs. [18] and [19] was performed in a fashion analogous to that for the data for dimethoxycarbene protonation. The results are summarized in Table 2.

Although Kirmse, Guth, and Steenken (35*b*) have suggested that the proton transfer reactions to carbenes **3a**–**3d** are probably not diffusion controlled because the largest rate constants measured are at least an order of magnitude lower than that of diffusion in acetonitrile ((2–4) × 10^{10} M^{-1} s^{-1}), according to the Eigen model, these proton transfers can be diffusion controlled even when the rate constants are far below the diffusion-controlled limit provided that the reactions are reversible. In fact, the actual proton transfer step may never be fully rate determining, even at small values of ΔpK, provided that the reactions are intrinsically fast. Normal acid/base behaviour in these carbenes and their conjugate acids also explains the lack of significant isotope effects.[10]

For carbenes **3a–3d**, the computed intrinsic barriers were 1–3.7 kcal mol^{-1}. The pre-equilibrium model predicted lower values for the intrinsic barriers to proton transfer (1–2.4 kcal mol^{-1}) as compared to those predicted by the three-step model. Within experimental error, the pK_a's for the conjugate acids of carbenes **3a**–**3d** were all ~15 (water, ~ 29 in acetonitrile), regardless of which values of k_d and k_{-d} were used, suggesting that there is not a significant substituent effect on the acid dissociation constant for phenyl(trimethylsiloxy)carbenium ion (the conjugate acid of phenyltrimethylsiloxycarbene). This is not surprising since π-donor substituents interact favourably with both the empty *p*-orbital of the carbene and the conjugate acid carbenium

Fig. 2. Brønsted plot for the protonation of (*a*) Ph(Me_3SiO)C: (●); (*b*) 4-MeC_6H_4(Me_3SiO)C: (□); (*c*) 4-$MeOC_6H_4$(Me_3SiO)C: (■); (*d*) β-$C_{10}H_7$(Me_3SiO)C: (▲), all in acetonitrile at 20°C. The upper solid lines are theoretical Eigen curves (see text) where k_d = 3.2 × 10^9 M^{-1} s^{-1} and k_{-d} = 1 × 10^{10} s^{-1} (see Table 2); the lower solid lines are theoretical Eigen curves where k_d values were defined by least-squares fits and k_{-d} = 1 × 10^{10} M^{-1} s^{-1} (see Table 2), and the broken line is the Marcus curve through the data.



[9] Many of the plots of k_{obs} vs. [ROH] obtained by Kirmse et al. (35*b*) were curved; however, the rate constants in Table 2 are all bimolecular. Those that are approximations of bimolecular rate constants, obtained at low [ROH], are marked as such. Curved plots of k_{obs} vs. [ROH] are the consequence of a second competing (faster) reaction of carbene with ROH that is second order with respect to [ROH] at higher [ROH]: $k_{obs} = k_o + k_a[ROH] + k_a'[ROH]^2$. The rate constants associated with the higher order term in the quadratic expression of k_{obs} (k_a') in these instances can be considered as "pseudo bimolecular" because [ROH] is high and essentially constant over the course of the reaction. The higher order term starts to dominate k_{obs} when the [ROH] is sufficiently large to allow for a preassociation step prior to proton transfer (or in self-association of ROH when the carbene reacts with ROH dimers).

[10] Kirmse et al. (35*b*) measured rate constants for the protonation of α- and β-naphtholate anions by $HClO_4$ in acetonitrile (k_{H+} ~ 4 × 10^{10} M^{-1} s^{-1}). Larger intrinsic barriers for proton transfers to carbenes **3a–3d**, compared with those for the protonation of α- and β-naphtholate anions, combined with preassociation mechanisms for carbenes **3a–3d** would explain the apparent discrepancy. The preassociation mechanism proposed by Kirmse et al. involves proton transfer through a second molecule of alcohol. This type of mechanism is analogous to the Swain–Grunwald mechanism for "normal" acids/bases in water (2, 3). Such mechanisms do not display detectable kinetic isotope effects. However, at low concentrations of alcohol, the preassociation mechanism probably does not occur in favour of a direct mechanism since the carbenes have a finite lifetime (~100–200 ns) in solution. A preassociation mechanism, where the acid is not bulk solvent, requires two molecules of acid and two diffusional steps prior to proton transfer.

ion, resulting in ground state stabilization of both the reactant and the product and a small change in $\Delta\Delta G^{o}$. Conversely, π-acceptor substituents should cause ground state destabilization of both carbene and conjugate acid carbenium ion. In both cases the bond order between the carbene carbon and the attached group (aryl in this case) bearing the substituent does not change dramatically after proton transfer. The situation is quite different from that of the acid dissociation constants for benzoic acids or phenols where the stabilities of the protonated forms are not dramatically affected by the presence of substituents. Since the carbenes (**1**, **3a–3d**) have finite lifetimes in solution, the reactions may not be reversible (i.e., no internal return). For such cases Marcus theory can be used to explain curvature in Brønsted plots.

[29] 
Marcus rate theory (27, 28) was also applied to the data in Table 1 for **3a–3d** in a fashion analogous to that applied to the data for dimethoxycarbene protonation. In each case, the rate constants for proton transfer by acids with pK_a's of 12 and higher (in water) were essentially the same; this is the portion of the Brønsted plots where $\alpha \approx 0$ and diffusion is at least partially rate determining. Therefore, data for only those acids with p$K_a \leq 12$ were fitted to the quadratic expression in eq. [24]. Least-squares fitting of the data to the quadratic expression in eq. [24] gave coefficients *a*, *b*, and *c* that yielded values of the Marcus theory parameters of 0.8, 0.7, 0.3, and 1 kcal mol^{-1} for the intrinsic reaction barriers ($\Delta G_0^{\ddagger}$), and 4.9, 4.8, 4.7, and 7 kcal mol^{-1} for the work terms (w^r), for phenyltrimethylsiloxycarbene (**3a**), 4-methylphenyl-(trimethylsiloxy)-carbene (**3b**), 4-methoxyphenyl(trimethylsiloxy)carbene (**3c**), and β-naphthyl(trimethylsiloxy)carbene (**3d**), respectively. Again, the pK_a values for the conjugate acids (pK_a^{CH+}) of carbenes **3a–3d** computed from Marcus parabolas were very similar to those predicted by Eigen theory.

1.c Variation in transition state structure

Substitution of the intrinsic barriers determined for dimethoxycarbene and aryltrimethylsiloxycarbenes **3a–3d**, from the coefficients of quadratic Brønsted correlations, into the partial derivative in eq. [22] allows for the evaluation of the change in α as a function of the change in ΔG^{o} for proton transfer reactions to these carbenes. For dimethoxycarbene, α is predicted to change from a value of 1 to a value of 0 over a $\Delta\Delta G^{o}$ range (12 kcal mol^{-1}) that corresponds to a range of ~9 pK_a units for the protonating acids. This change in α corresponds to a change in transition state structure, from very product-like (α = 1) to essentially reactant-like (α = 0). Similarly, α values for arylsiloxycarbenes **3a–3d** are predicted to change from $\alpha \approx 1$ to $\alpha \approx 0$ over pK_a ranges of ~5, ~4, ~2, and ~6, respectively. Such dramatic changes in the slope parameter α and in transition state structure are typical for "normal" acids and bases where α changes from near 0 to near 1 over a $\Delta\Delta G^{o}$ range that corresponds to ~4 pK_a units (4), but are rarely observed in carbon acids and bases.

2. "Normal" acid/base behaviour

The fact that the Brønsted plots for carbenes **1** and **3a–3d** are all curved and that theoretical Eigen curves or Marcus parabolas can be drawn through these data provides strong evidence that these π-donor-substituted carbenes behave as "normal" Brønsted bases. The dramatic change in the slope parameter α (and in transition state structure) over a narrow range of Δp*K* of the protonating acids for these carbenes is also consistent with normal acid/base behaviour. Brønsted plots for the protonation of normal bases typically change slope from unity to zero over a ΔpK_a range of ~4 units (1, 4).

Small intrinsic barriers to proton transfer are also common for "normal" acids and bases and intrinsic barriers of 1–5 kcal mol^{-1}, computed for carbenes **1** and **3a–3d**, are consistent with their normal acid/base behaviour. Examples of other carbon bases, which have small intrinsic barriers to proton transfer reactions and show some "normal" acid/base behaviour, include cyanide (29*c*, 37), acetylide (38), C-2 thiazolium ions (12–14), the C-2 ylide of thiamin (14), and C-2α anions of covalent intermediates of thiamin (39). The small intrinsic barriers determined here for dimethoxycarbene and carbenes **3a–3d** support the idea that electron delocalization, rehybridization (carbenes do not undergo a change in hybridization either during or after proton transfer), changes in bond lengths and angles of heavy atoms, and changes in solvation do not significantly affect the barriers to proton transfer to these π-donor-substituted carbon bases as is the case for other carbon acids and bases with larger intrinsic barriers to proton transfer. Presumably the most stable ground state conformations of these carbenes are those where the π-donor substituents (methoxy and aryl) are already aligned with, and are already donating electron density to, the vacant *p*-orbital at the carbene carbon so that bond angles, lengths,[11] and electron delocalization do not change dramatically at the transition state for proton transfer.

Other criteria for evaluating "normal" acid/base behaviour such as acid inhibition cannot be evaluated in acetonitrile solvent because of the increased rate constants for reaction by oligomeric acids at higher concentrations of acid, and clearly the Swain–Grunwald mechanism does not apply in this solvent system although the participation of a second molecule of acid in a reaction complex has been proposed previously (35*b*). It is evident that oxygen-substituted carbenes behave very much like "normal" Brønsted bases.

3. Conclusions

Brønsted plots for proton transfer data for dimethoxycarbene and for aryltrimethylsiloxycarbenes **3a–3d** show distinct Eigen curvature that is characteristic of reactions between "normal" acids and bases. Values of α that are near 1 when proton transfer is thermodynamically unfavourable and near 0 when proton transfer is thermodynamically

[11]Professor Denk et al. have found only small differences (~0.3 Å) in C—N bond lengths in stable diaminocarbenes compared with those in their conjugate acids from X-ray crystallographic data (M.K. Denk, S. Gupta, and A.J. Lough, personal communication).

© 1999 NRC Canada

favourable, combined with rate constants of ~10^9 M^{-1} s^{-1} for thermodynamically favourable proton transfer reactions, support the notion that these carbenes behave as "normal" Brønsted bases. Values for intrinsic barriers ($\Delta G_0^{\ddagger}$) calculated from Eigen curves and using the Marcus theory formalism indicate that these reactions are intrinsically fast, which provides further support for normal acid/base behaviour. A consequence of normal acid/base behaviour is that proton transfer in the thermodynamically favourable direction proceeds with maximum rate constants of ~10^9 M^{-1} s^{-1}, and that proton transfer may be reversible depending on the lifetimes of the carbenes and their conjugate acids (carbocations) in solution. Ultimately, curvature in the Brønsted plots for dimethoxycarbene and for aryltrimethylsiloxycarbenes **3a**–**3d** can be explained by changes in the rate-determining step for proton transfer as a function of the pK_a for the protonating acid and (or) by variation in transition state structure, near pK = 0, according to the Hammond postulate. These observations bring to light the fact that caution must be taken in making mechanistic claims (i.e., ruling out proton transfer mechanisms) for reactions of carbenes with normal Brønsted acids based solely on negligible (or 0) Brønsted slopes. *For carbenes that behave as "normal" Brønsted bases, near-zero Brønsted slopes may simply reflect the fact that proton transfer is thermodynamically favourable over the p*K_a *range of acids that is studied and that diffusion is at least partly rate limiting.* Estimates for pK_a values of the conjugate acids of carbenes **1** and **3a**–**3d** have been computed directly from Eigen curves and from tangents to Marcus parabolas (α values at individual points on the curves). The pK_a values computed by both methods are roughly the same for each carbene. These pK_a values are ~11 (water, ~25 MeCN) for dimethoxymethyl cation and ~15 (water, ~29 in MeCN) for aryltrimethylsiloxymethyl cations **4a**–**4d**. These pK_a values should be viewed as very rough "ballpark" first estimates because the analyses that yielded them are *semi-quantitative or qualitative*.

Acknowledgments

J.P.P. would like to thank the Natural Sciences and Engineering Research Council of Canada for continued financial support in the form of a post-graduate scholarship, and Professor Wolfgang Kirmse (Ruhr – Universität Bochum) for useful discussions and advice.

A 2-D NMR investigation of the micellar solubilization site in ionic micellar solutions

Brent E. Hawrylak and D. Gerrard Marangoni

Abstract: Two-dimensional NOE spectroscopy (NOESY) experiments have been used to examine the dissolution of two typical solubilizates (1-butanol and benzene) in anionic sodium dodecyl sulfate (SDS) micelles and of benzene in cationic dodecyltrimethyammonium (DTAB) micelles. In all cases, significant, positive NOESY cross peaks were obtained that appeared to correlate well with the expected locus of solubilization of these solubilizates in these surfactant systems. The NOESY technique, which is a noninvasive experiment, is found to provide significant insight in terms of the solubilization of these molecules in the interior of ionic micelles.

Key words: solubilization, surfactants, NMR spectroscopy, 2-D NOESY experiments.

Résumé : On a fait appel à des expériences de spectroscopie EON bidimensionnelle (« NOESY ») pour étudier la dissolution de solubilisats typiques de butan-1-ol + benzène dans des micelles anioniques de dodécylsulfate de sodium et de benzène dans des micelles cationiques de dodécyltriméthylammonium. Dans tous les cas, on a obtenu des pics NOESY croisés qui semblaient donnés une bonne corrélation avec le locus de solubilisation attendu pour des solubilisats dans ces systèmes d'agents de surface. On a observé que la technique de NOESY, qui n'est pas invasive, fournit des informations significatives en termes de solubilisation de ces molécules à l'intérieur de ces micelles ioniques.

Mots clés : solubilisation, agents de surface, spectroscopie RMN, expériences de spectroscopie EON bidimensionnelle.

[Traduit par la Rédaction]

Introduction

The solubilization of substances inside micelles and bilayers that are otherwise insoluble in an aqueous medium has received considerable academic and industrial attention. Much of the literature has focused on the determination of the partition constant (the *p*-values) of the solubilizates in micelles. There have been, by comparison, relatively few investigations of the location of solubilizates inside micelles (1).

In water – nonaqueous solvent systems, a significant factor in the determination of the micellar properties (i.e., cmc values, aggregation numbers, degrees of counterion binding) is the degree to which the nonelectrolyte penetrates into the micellar phase (1–4). The mole fraction of solubilizate in the micellar phase, *p*, is defined as

$$[1] \qquad p = \frac{c_{s,mic}}{c_{s,t}}$$

Here, $c_{s,mic}$ is the concentration of solubilizate in the micellar phase and $c_{s,t}$ is the total concentration of solubilizate. The *p*-values of solubilizates have been measured by a number of different techniques (1). NMR determinations of the *p*-values of solubilizates are accomplished by the application of the Fourier transform pulsed-gradient spin echo (FT-PGSE) experiment as described by Stilbs (5–7), or by the NMR – paramagnetic relaxation enhancement experiment (the NMR–PRE) (8–11). This method is based on the changes in the relaxation rate of the solubilizate in surfactant and surfactant-free solutions, in the presence of paramagnetic ions, and has been successfully applied in a number of surfactant–solubilizate systems (8–12).

In recent years, however, there has been a significant amount of interest in the location of solubilizates in the micellar interior. One of the most widely used experiments for examining the location of a solubilizate in the micellar phase has been to determine the aromatic ring current induced shifts of aromatic solubilizates on surfactant chain protons (13–15). Paramagnetic relaxation enhancement experiments have also been used to determine the average location of the solubilizate in the micellar interior (16–18). Fluorescence probing experiments have yielded significant information on the location of certain molecules in the micellar interior (19). However, the NMR aromatic solute induced shift experiments (ASIS experiments) and the fluorescence probing experiments are limited to specific classes of molecules. The NMR paramagnetic relaxation enhancement experiments are more general in their implementation; however, these experiments rely on the presence of a small amount of a paramagnetic probe on the surface of the micelles. Although extreme care is taken to insure that the ratio of paramagnetic probe to surfactant is kept small, perturbations of the micellar structure are unavoidable.

Two-dimensional nuclear Overhauser enhancement experiments (NOESY) have been shown to provide significant information on the intra- and intermolecular proximity of

protons (20). In the case of macromolecules such as proteins, the 2-D NOESY experiment has been shown to provide valuable information in the determination of the conformation and dynamics of these large molecules (21). If the motions of the respective protons undergoing cross-relaxation are in the extreme narrowing region, then the cross peaks of the 2-D NOESY spectrum will be of opposite sign to those of the diagonal (a small-molecule NOESY results). In the case of large molecules like proteins, the motions of these molecules are outside of the extreme narrowing limit; hence, the nOe is negative and the cross peaks of these large molecules in the NOESY spectrum are of the same sign as the diagonal peaks (i.e., a large-molecule NOESY results). For a micellar solution, it is well known that there are two motions that are fairly well separated in time (22). Firstly, a slow motion that is ascribed to the translation diffusion of the surfactant molecule across the micellar surface, or to the rotational tumbling of the whole micelle, occurs in the nanosecond range (out of the extreme narrowing region). However, the reorientational motions of the chains inside the micellar interior are in the picosecond range, i.e., well inside the extreme narrowing limit. Hence, for a surfactant–solubilizate system, the motions of the molecules inside the micelles are in the extreme narrowing region (22), and a small-molecule NOESY may be expected.

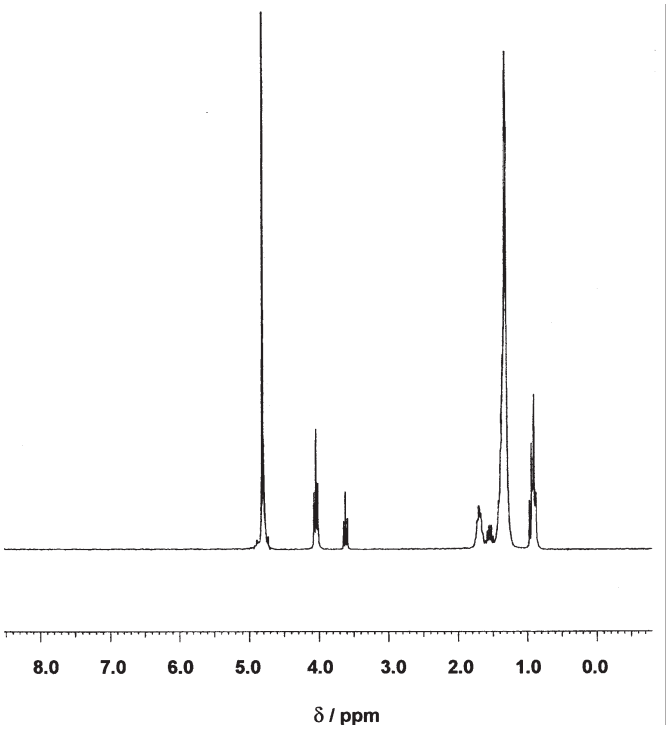
There are a few papers in the literature dealing with the application of the 2-D NOESY technique to probe micellar solubilization (23, 24). However, a detailed study on well-characterized mixed micellar systems is lacking. In this paper, we report our results on the determination of the NOESY contour plots for two typical solubilizates (1-butanol and benzene) in a micellar solution of SDS and for benzene in a micellar solution of DTAB. In all cases, we observe positive cross peaks between the solubilizate and the surfactant protons in the NOESY contour plots. These cross peaks appear to be consistent with the known locus of solubilization of these molecules in the micellar interior. It is demonstrated that the NOESY technique may provide a relatively straightforward and noninvasive way of determining the solubilization site of a number of different molecules in various micellar systems.

Experimental

Sodium dodecyl sulfate (SDS) was purchased from BDH (specially pure). Repeated recrystallizations from methanol and Soxhlet extraction from diethyl ether were used to purify the surfactant. Dodecyltrimethylammonium bromide (DTAB) was obtained from the Sigma Chemical Company, and it was purified by at least three recrystallizations from an acetone–ethanol mixture. The solubilizates (1-butanol and benzene) were all high-purity reagent from the Aldrich Chemical Company and were used as received. D_2O (99.8%) was purchased from Aldrich or CDN Isotopes.

The 1-D NMR spectra (^1H) for the surfactant–solubilizate systems were obtained on a Bruker AC-200 at St. Francis Xavier University operating at 200.13 MHz for protons and on a Bruker AC-250 at the Atlantic Region Magnetic Resonance Centre (ARMRC) at Dalhousie University. A typical ^1H spectrum for the SDS–1-butanol system is given in Fig. 1. D_2O was used as solvent for all the NMR experiments. The ^1H spectra were referenced to the HOD peak, which was assigned a value of $\delta = 4.810$ ppm. 2-D NOESY experiments were performed on the Bruker AC-250 NMR spectrometer at the ARMRC. The mixing times and the delay times for the NOESY experiments were estimated from the spin-lattice relaxation times of the surfactant–solubilizate systems. In all cases, we used an acquisition delay of $\approx 3 \times T_1$ and a mixing time of $\approx 1 \times T_1$ to obtain the NOESY spectra. This corresponded to a mixing time of 1.0 s for the SDS–1-butanol system and ≈ 3.5 s for both the SDS–benzene and the DTAB–benzene surfactant–solubilizate systems. Solutions of 70 mg/mL of SDS (243 mM) or 50 mg/mL of DTAB (0.162 M) were prepared directly in small sample vials. The appropriate quantity of the SDS or DTAB stock solution was transferred to an NMR tube and 8–10 μL of the solubilizate was added directly to the NMR tube with a Hamilton syringe.

Fig. 1. Proton NMR spectrum for the system SDS–1-butanol.



Results and discussion

The NOESY contour plots for each of the solubilizate–surfactant systems are given in Figs. 2–4. In all cases, it is clear that significant cross peaks occur in the NOESY experiments that would indicate the proximity of the protons between the solubilizate and the surfactants. For each of the surfactant–solubilizate systems, we observed positive cross peaks in the NOESY experiments between the protons on the solubilizates and the surfactant protons, indicating that the motions of the protons on both the surfactants and solubilizates are in the extreme narrowing range. It is clear then from Figs. 2–4 that despite the dynamic nature of the surfactant–solubilizate systems (i.e., a wide range of motions well separated in time), the nOe's have not been reduced in magnitude to near-zero values. The presence of

Fig. 2. Contour plots for the 2-D NOESY experiment on the system SDS–1-butanol at 293 K.

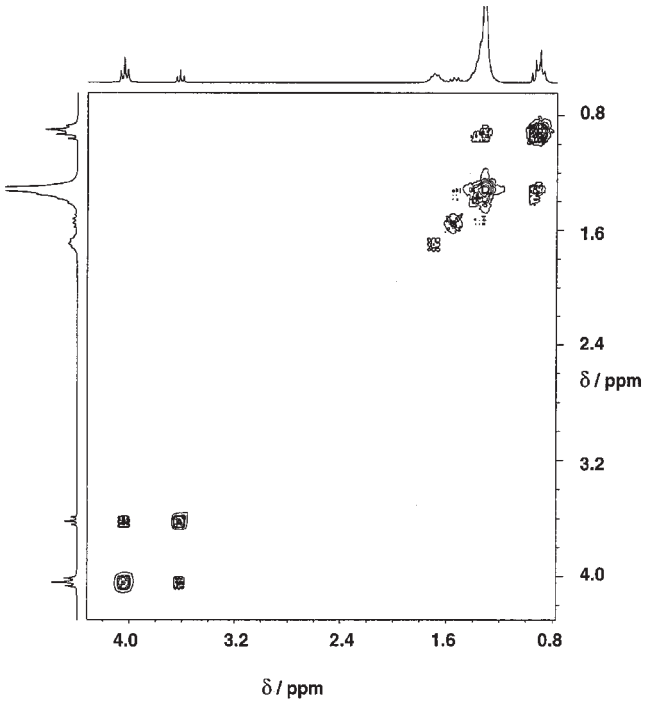

Fig. 3. Contour plots for the 2-D NOESY experiment on the system SDS–Bz at 293 K.

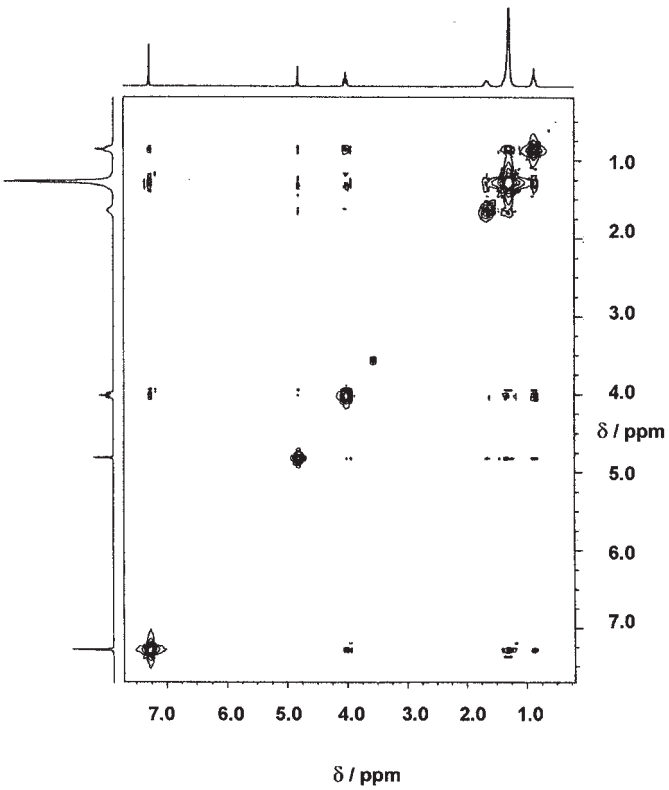

these cross peaks must then indicate the presence of significant intermolecular dipolar interactions between the surfactant and the solubilizate (i.e., generally representing a spatial proximity of <0.50 nm).

The NOESY spectrum for the system SDS–1-butanol is given in Fig. 2. From the spectrum, we observe strong correlations between the α-protons of the SDS (δ ≈ 4.0 ppm) and the 1-butanol (δ ≈ 3.8 ppm). We also observe a strong correlation between the methyl protons of the butanol (δ ≈ 0.9 ppm) and the SDS chain protons (δ ≈ 1.4 ppm). A number of other correlations exist in the region around 1 ppm that are likely cross peaks between the -CH_3 peak and the C-11 protons of the SDS, as well as cross peaks between the methyl protons and the C-3 protons of 1-butanol. These cross peaks may be due to the folding of the carbon chains of SDS and 1-butanol occurring in the micellar interior. This is consistent with the literature explanation for the location of the solubilizate in the SDS micelles, i.e., the alcohol is located in the micelle with its headgroup in intimate contact with the SDS micellar headgroups, while the hydrocarbon chain is pointed inwards towards the centre of the micelle.

While the NOESY spectrum for 1-butanol in the SDS micellar system indicates that the alcohol molecules are confined primarily to the headgroup region of the SDS micelles, the NOESY contour plot for the SDS–benzene system (Fig. 3) is significantly different. In this case, we observe positive cross peaks between the benzene protons (δ ≈ 7.2 ppm) and all the SDS surfactant protons. This is consistent with the benzene molecules being able to sample the entire micellar interior, with no particular region of the micelle being a favoured locus of solubilization for benzene. This is in excellent agreement with the NMR paramagnetic relaxation experiments and ASIS experiments of Wasylishen et al. for benzene in SDS micelles (16). These authors concluded that benzene molecules are distributed rather uniformly throughout the interior of the SDS micelles. In our NOESY experiments, since we observe no particular difference in the magnitude of the benzene cross peaks, we can conclude that the benzene molecules have no real preference for one part of the micellar interior over another.

The NOESY spectrum for the system DTAB/benzene is given in Fig. 4. It is clear from Fig. 4 that this NOESY spectrum is remarkably different than the SDS–benzene NOESY contour plot (Fig. 3). In this spectrum, the correlations between the benzene protons (δ ≈ 7.2 ppm) and the DTAB headgroup protons (3.0–3.2 ppm) are strong, while somewhat weaker correlations exist between benzene protons and the chain protons of the DTAB molecules inside the micelles. The presence of the large cross peak between the benzene and the headgroup protons indicates a preferential interaction between the benzene molecule and the headgroup region of the micelle. This is in excellent agreement with the well-known locus of solubilization of benzene in DTAB micelles (16). This localization of the benzene molecules in the DTAB headgroup region may be due to the hydrophobic nature of the DTAB headgroup (three methyl groups attached to the quatenary nitrogen), which may lead to significant hydration differences in the headgroup of the positively charged surfactant micelle. It may also be that the presence of the aromatic π-electrons will electrostatically attract the benzene molecules towards the headgroup region of the cationic micelles.

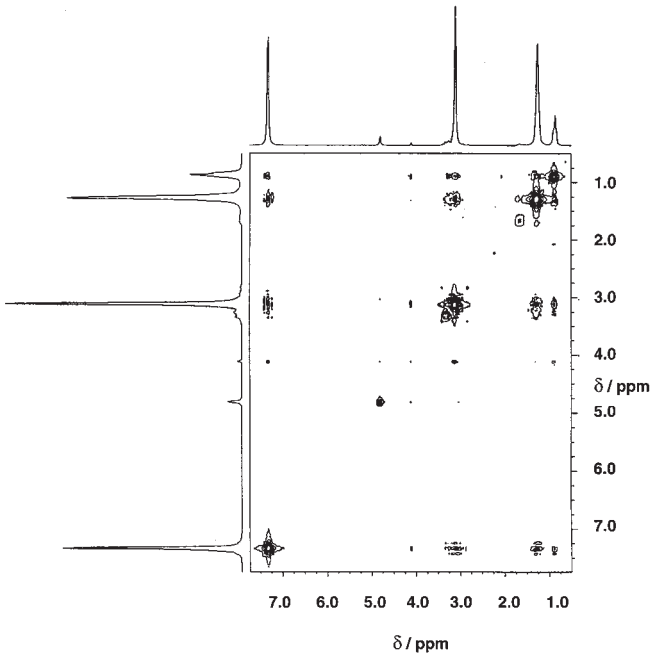
Fig. 4. Contour plots for the 2-D NOESY experiment on the system DTAB–Bz at 293 K.



Summary and conclusions

The NOESY spectra for 1-butanol–SDS, benzene–SDS, and benzene–DTAB indicate that the locus of solubilization of these typical solubilizates can be reliably determined by analysing the cross peaks in the NOESY spectrum of the surfactant–solubilizate system. In the case of the 1-butanol–SDS system, the NOESY spectrum indicates that the alcohol is solubilized with the alcohol headgroups in intimate contact with the surfactant headgroups. In addition, the manner in which the alcohol chain is buried in the micelle can be obtained from the NOESY spectra. For benzene, the NOESY spectra indicate a rather even distribution of benzene molecules throughout the SDS micellar interior, whereas for the DTAB–benzene system, the NOESY spectra indicate the preference of benzene molecules for the micellar headgroup region. It should be noted that when we examine the 2-D COSY experiments for these systems, there is a complete lack of any cross peaks in the regions where we observe dipolar correlations in the NOESY contour plots.

The main advantage of the 2-D NOESY experiment lies in the noninvasive nature of the technique; the locus of solubilization is determined without the need of solubilized aromatic molecules or added paramagnetic agents, which can perturb the micellar structure. We are currently examining the locus of solubilization via the NOESY technique for a wide variety of surfactant–solubilizate combinations. These will be the subjects of future publications.

Photocycloelimination of α,α-dichlorocyclobutanones

Jailall Ramnauth and Edward Lee-Ruff

Abstract: Direct irradiation of a series of α,α-dichlorocyclobutanones in benzene solutions results in photocycloelimination to give 1,1-dichloroalkenes in yields ranging from 30–65%. The α,α-dichlorocyclobutanones were formed in good yields from the [2+2] cycloaddition of the terminal olefins with dichloroketene. This two-step sequence formally represents a "metathesis" of two olefinic functions and provides an easy access to functionalized 1,1-dichloroalkenes. Irradiation of the dichlorocyclobutanones in the solid state led to poor yields of 1,1-dichloroalkenes and polymeric mixtures, however, photoreactions performed in zeolites gave similar yields as those run in benzene solutions.

Key words: dichlorocyclobutanones, dichloroalkenes, olefin metathesis, photocycloelimination.

Résumé : L'irradiation directe d'une série de α,α-dichlorocyclobutanones, en solutions benzéniques, provoque une photocycloélémination qui conduit à la formation de 1,1-dichloroalcènes, avec des rendements allant de 30 à 65%. Les α,α-dichlorocyclobutanones se formes avec de bons rendements par la cycloaddition [2+2] d'oléfines thermiques avec le dichlorocétène. Cette séquence en deux étapes correspond à une "métathèse" de deux fonctions oléfiniques et elle fournit une voie d'accès facile aux 1,1-dichloroalcènes fonctionnalisés. L'irradiation des dichlorocyclobutanones à l'état solide conduit, avec de mauvais rendements, aux 1,1-dichloroalcènes avec des mélanges de polymères; toutefois, les photoréactions effectuées dans des zéolites donnent des rendements semblables à ceux obtenus en solution dans le benzène.

Mots clés : dichlorocyclobutanones, dichloroalcènes, métathèse d'oléfine, photocycloélimination.

[Traduit par la Rédaction]

Introduction

Photocycloelimination is one of three principal reaction channels from electronically excited cyclobutanones, which also include decarbonylation and ring expansion (1). If the photocycloelimination process occurs in an orthogonal fashion with respect to the ketene–olefin cycloaddition to form cyclobutanones, such a two-step sequence formally represents a metathesis of two olefinic groups (2). Furthermore, since a large number of functionalized terminal olefins are commercially available and dichloroketene adds easily to terminal olefins (3), such a scheme would constitute a convenient route to substituted 1,1-dichloroalkenes.

1,1-Dichloroalkenes are important synthetic intermediates, especially for the synthesis of arylacetic acids (4) and various alkynes (5). The commonly used methods for the preparation of 1,1-dichloroalkenes include the dichloromethylenation of carbon–oxygen double bond of carbonyl compounds with Wittig-type reagents obtained from organophosphines and carbon tetrachloride, and Horner–Emmons reagent generated from cathodic reduction of diethyl trichloromethyl phosphonate (6).

Previously, we reported the photocycloelimination of bicyclic cyclobutanones in nonpolar aprotic solvents containing a minimal amount of an alcohol to quench the intermediate ketene produced, generating substituted terminally functionalized carboxylic esters (7). Although the yields are excellent, the complete elimination of the ring expansion pathway could not be achieved in some cases. Also, the [2+2] cycloaddition with ketenes requires activated olefins such as enol ethers and conjugated dienes.

Herein, we report the direct irradiation of a series of α,α-dichlorocyclobutanones generated from the [2+2] cycloaddition of dichloroketene to the corresponding terminal olefins, giving 1,1-dichloroalkenes. Such a reaction can be formally represented by Scheme 1 in which terminal chlorination of a terminal alkene is the net conversion. Such direct chlorination reactions cannot be effectively performed on terminal alkenes.

Scheme 1.

Results and discussion

The dichlorocyclobutanone derivatives **2**(a) and **2**(b) were prepared according to literature methods (8, 9) from the commercially available alkenes **1**(a) and (b), respectively. Irradiation of a 6×10^{-3} M solutions of **2**(a) and **2**(b) in

benzene for 2 h using a medium pressure mercury lamp with a pyrex filter went to ca. 70% conversion to give the known compounds **3**(a) (10) and **3**(b) (11) in 30 and 40% isolated yields, respectively, with trace amounts (<1%) of starting olefins **1**(*a*) and **1**(b) (see Scheme 2). The structures of **3**(a) and **3**(b) were based on ^{1}H-NMR spectra and comparison with literature data. Compound **3**(a) exhibited a single proton singlet at δ 6.86 ppm assigned to the vinylic proton, while **3**(b) showed only aromatic signals. It was somewhat surprising to detect the presence of trace amounts of starting olefins **1**(*a*) and (b), indicating that the photocyclo eliminations also occurred on the less substituted side, however, only to a minor extent. The low yields of these derivatives could be attributed to some polymerization of the 1,1-dichloroalkenes.

The dichloroketene adducts **2**(c)–**2**(f) were prepared from the cycloaddition of dichloroketene (generated in situ from trichloroacetyl chloride and activated zinc) to the corresponding olefins **1**(c)–**1**(f) in the presence of 1,2-dimethoxyethane (DME) (12) as cosolvent in yields ranging from 74 to 85% after purification. The structures of these compounds were fully characterized by spectral and analytical data. The olefins **1**(c)–**1**(f) were prepared from the benzoylation of the commercially available alcohols in excellent yields (90–96%). The dichlorocyclobutanones **2**(c)–**2**(f) were irradiated as before (ca. 80% conversions) to give exclusively the dichloroalkenes **3**(c)–**3**(f) in yields ranging form 54 to 65% after chromatography. The structures of these alkenes were confirmed by spectral data. The ^{1}H-NMR data of **3**(c) exhibited a one proton triplet (J = 6.7 Hz) at δ 6.21 ppm assigned to the vinylic proton. This proton appeared at δ 5.9 ppm in the original olefin. The ^{13}C-NMR spectrum showed the eight unique carbon signals. For compound **3**(d),the ^{1}H-NMR spectrum showed a single triplet (J = 7.1 Hz) at 6.00 ppm associated with the vinylic proton, and the ^{13}C-NMR spectrum revealed the nine signals one would expect for this compound. The ^{13}C-NMR spectrum revealed the nine unique carbons of compound **3**(e), and the ^{1}H-NMR spectrum showed sharp singlets at δ 5.01 and δ 2.00 corresponding to the methylene and methyl protons, respectively. Olefin **3**(f) showed two triplets at δ 4.45 (J = 6.6 Hz) and δ 2.77 (J = 6.4 Hz) associated with a substituted ethyl group and a sharp methyl singlet at δ 2.10 in its ^{1}H-NMR spectrum. The ^{13}C-NMR spectrum showed 10 signals in accordance with the assigned structure for **3**(f).

In the continuation of our work on the triplet photosensitized reaction of cyclobutanones to form cyclopropanes (13), we were interested in the possibility of preparing dichlorocyclopropanes via the photodecarbonylation of dichlorocyclobutanones. Some dichlorocyclopropanes have been shown to exhibit insecticidal properties (14). Under triplet sensitized conditions, using acetone as both the sensitizer and solvent, the dichlorocyclobutanone **2**(c) and **2**(d) gave olefins **3**(c) and **3**(d), respectively, as the major nonpolar products. These results were somewhat surprising and contrary to the behaviour of alkyl substituted cyclobutanones. To rationalize these results, one must consider the mechanism of cyclobutanone photochemistry. It has been shown that cycloelimination can occur form a vibrationally excited ground state of cyclobutanone formed from internal conversion (15). This is based on observations of cycloeliminations occurring in the thermal reactions of cyclobutanones (16). The triplet state of cyclobutanone has been implicated in the decarbonylation process (17). The fact that decarbonylation does not occur in these α,α-dichlorocyclobutanones can be explained by a simple but very reasonable model proposed by Moule (18). The triplet state may be too short-lived due to efficient intersystem crossing to $S°$ in the presence of a heavy atom (19). This deactivation process would compete with decarbonylation and form a hot ground state resulting in cycloelimination.

Another rationalization for the lack of decarbonylation in these systems is the increase of the triplet state energy level brought about by an electron-withdrawing substituent. Ketones possessing an electron-withdrawing α-substituent such as oxygen and chlorine show a hypsochromic shift of the $n\rightarrow\pi^*$ absorption band (20). This electronic effect would also be expected to increase the triplet energy level, which may result in inefficient triplet sensitization by acetone (E_T = 78 kcal), resulting in an endothermic process. Thus, direct excitation of cyclobutanone might be expected to give only cycloelimination products.

Radicals and diradicals that are produced in solution suffer a different fate from those produced in the solid state. To explore the possibility that the 1,4-acyl-alkyl diradical might undergo decarbonylation in the solid state, we explored the photochemistry of **2** in the crystal lattice.

© 1999 NRC Canada

Solid state photolysis often differs from solution photochemistry due to the rigidity associated with the crystal lattice and has received a great deal of attention recently (21). The solid state photolyses of **2**(a)–**2**(c) and **2**(e) were done according to a modified literature procedure (22). After the usual work-up and chromatography, poor yields of the 1,1-dichloroalkenes were obtained but no cyclopropanes were detected. The photolysate consisted primarily of intractable polymeric materials. This problem did not occur to any great extent in the solution state photolyses due to the dilute conditions under which these reactions were conducted.

To minimize the extent of polymerization due to radical processes, we explored these photochemical reactions in zeolites (23). For this work, incorporation of the dichlorocyclobutanones within the supercages was accomplished by stirring hexane solutions in the presence of anhydrous Na-Y zeolite, followed by thorough washings with hexane. Analysis of the hexane washings revealed no residual starting materials, indicating complete incorporation of the substrate within the zeolite cages. The vacuum-dried complexes were photolyzed as hexane slurries for 2 h with stirring. After work-up, which involved extraction with ether and then chromatography, the yields were about the same as those in the solution phase. However, the conversions were on average 10% lower than those in the solution phase.

It has been shown that the photocycloelimination of α,α-dichlorocyclobutanones can provide an easy route to 1,1-dichloroalkenes. This method formally represents a metathesis of two olefinic groups. With the limited number of methods available for the synthesis of these derivatives, this method provides an easy two-step alternative. What is attractive is the generality in terms of the wide range of functionalized terminal olefins that can add to dichloroketene.

Experimental

Melting points (mp) were determined on a Reichert melting point apparatus and are uncorrected. NMR spectra were recorded on a Bruker ARX 400 spectrometer in $CDCl_3$ containing 1% TMS or unless otherwise noted. Fourier Transform Infrared (FT-IR) spectra were recorded on a Pye Unicam SP3-200 spectrometer as thin films or as KBr pellets. Photolyses were carried out using a Hanovia 450W medium-pressure mercury arc lamp in a water-cooled quartz immersion well. Pyrex tubes containing the samples were strapped around this well and the assembly immersed in an ice-water bath. The samples were degassed for 30 min prior to irradiation. All solvents used in these reactions were dried and distilled. Analytical thin layer chromatography (TLC) was done using commercially prepared silica gel 60F 254 plastic sheets (E. Merck & Co.). Preparative TLC was carried out with Aldrich silica gel 60F 254 precoated glass plates. Elemental analyses were performed by Guelph Chemical Laboratories Limited. All reactions were performed under inert atmosphere conditions. All precursor chemicals were purchased from the Aldrich chemical company. Olefins **1**(c)–**1**(f) were prepared from benzoylation of the corresponding alcohol using benzoyl chloride in pyridine. The cyclobutanones **2**(a) and **2**(b) were prepared according to literature methods (8, 9).

General photolysis procedures

A solution of dichlorocyclobutanones **2**(a)–**2**(e) (0.4 mmol) in 70 mL of benzene was degassed with argon for 30 min and then irradiated for 2 h. The solvent was removed under reduced pressure, and the residue was chromatographed on TLC plates (hexane:ethyl acetate, 90:10). The conversions were ca. 70–80%. The yields reported are the isolated yields based on starting materials. Solid-phase photolyses were done by sandwiching the solids between two pyrex microscope slides. The slides were secured with tape and placed in a quartz tube. After the irradiation, the slides were rinsed with CH_2Cl_2, the solvent removed under reduced pressure, and the residue was chromatographed as before. For the zeolite work, 1 g of Na-Y zeolite was added to the dichlorocyclobutanone (0.4 mmol) in 50 mL hexane. This suspension was stirred overnight at room temperature. After this time, the suspension was filtered, and the solid washed with 4 × 100 mL hexane. Evaporation of the hexane washings revealed no starting materials. The vacuum dried solids were suspended in 70 mL of hexane and photolyzed for 2 h with constant stirring. After this time, the solid was filtered and subjected to a soxhlet extraction overnight. Conversions were ca. 60–70%.

General procedure for the preparation of dichlorocyclobutanones 2(c)–2(e)

A two-neck round-bottom flask, equipped with a magnetic stirrer, dropping funnel, and argon inlet was charged with activated zinc (9) (4 equiv.) and the olefin (1 equiv.) in anhydrous ether (2 mL/mmol of olefin). To this vigorously stirred suspension was added dropwise a mixture of trichloroacetyl chloride (2 equiv.), 1,2-dimethoxyethane (DME) (2 equiv.), and anhydrous ether (1 mL/mmol) over a period of about 30 min. This mixture was stirred at room temperature overnight. After this time, hexane was added (~50 mL) and the suspension stirred for 5 min to precipitate the zinc salts. The solution was then decanted and treated sequentially with 100 mL H_2O, 3 × 100 mL saturated $NaHCO_3$, 100 mL saturated NaCl and then dried over Na_2SO_4.

*3-(Benzoyloxy)methyl-2,2-dichlorocyclobutanone (**2**(c))*: Prepared in 85% yield from olefin **1**(c). The crude product was recrystallized from hexane to give a white solid; mp 71–72°C; ^{1}H-NMR δ: 8.04–7.26 (m, 5H), 4.71–4.64 (m, 2H), 3.57–3.50 (dd, 1H, J = 9.9, 7.7 Hz), 3.44–3.41 (m, 1H), 3.27–3.21 (dd, 1H, J = 7.7, 9.8 Hz); FT-IR (KBr): 1809, 1713, 1599 cm^{-1}; ^{13}C-NMR δ: 191.1, 166.0, 133.5, 129.7, 129.4, 128.6, 87.4, 63.3, 45.2, 44.3. Anal. calcd. for $C_{12}H_{10}O_3Cl_2$: C 52.77, H 3.69; found: C 52.69, H 3.64.

*3-[2-(Benzoyloxy)ethyl]-2,2-dichlorocyclobutanone (**2**(d))*: Prepared in 80% yield from olefin **1**(d). The crude product was passed through a short plug of silica gel to give a colourless oil. ^{1}H-NMR δ: 8.06–7.44 (m, 5H), 4.51–4.46 (m, 2H), 3.47–3.39 (m, 1H), 3.17–3.06 (m, 2H), 2.47–2.38 (m, 1H), 2.16–2.04 (m, 1H); FT-IR(neat): 1812, 1718 cm^{-1}; ^{13}C-NMR δ: 192.4, 166.4, 133.2, 129.8, 129.6, 128.5, 88.8, 62.5, 48.0, 43.5, 30.4. Anal. calcd. for $C_{13}H_{12}O_3Cl_2$: C 54.38, H 4.21; found: C 54.33, H 4.30.

*3-(Benzoyloxy)methyl-2,2-dichloro-3-methylcyclobutanone (**2**(e))*: Prepared in 84% yield from the olefin **1**(e). The crude product was chromatographed through a short plug of silica gel to give a viscous oil, which solidified on standing at –10°C overnight; mp 48–49°C. ^{1}H-NMR δ: 8.02–7.46 (m, 5H), 4.59 (s, 2H), 3.34–3.39 (d, 1H, *J* = 17.0 Hz), 3.16–3.11 (d, 1H, *J* = 17.6 Hz); FT-IR (KBr): 1811, 1732 cm^{-1}; ^{13}C-NMR δ: 191.4, 165.9, 133.5, 129.7, 129.3, 128.6, 91.0, 68.1, 51.6. 44.9, 20.6. Anal. calcd. for $C_{13}H_{12}O_3Cl_2$: C 54.38, H 4.21; found: C 54.37, H 4.07.

*3-[2-(Benzoyloxy)ethyl]-2,2-dichloro-3-methylcyclobutanone (**2**(d))*: Prepared in 75% yield from olefin **1**(f). The crude product was passed through a short plug of silica gel to give a colourless oil. ^{1}H-NMR δ: 8.05–7.44 (m, 5H), 4.55–4.50 (m, 2H), 3.41–3.36 (d, 1H, *J* = 16.8 Hz), 2.93–2.89 (d, 1H, *J* = 15.8 Hz), 2.41–2.30 (m, 2H), 1.48 (s, 3H); FT-IR (KBr): 1811, 1732 cm^{-1}; ^{13}C-NMR δ: 192.5, 166.3, 133.2, 129.9, 129.6, 128.5 92.7, 61.5, 54.7. 43.8, 35.3, 22.7. Anal. calcd. for $C_{14}H_{14}O_3Cl_2$: C 55.83, H 4.69; found: C 55.48, H 4.41.

*1,1-Dichloro-2-phenylethene (**3**(a)) (10)*: Yield: 30%; ^{1}H-NMR δ: 7.54–7.31 (m, 5H), 6.26 (s, 1H).

*1,1-Dichloro-2,2-diphenylethene (**3**(b)) (11)*: Yield: 40%; ^{1}H-NMR δ: 7.33–7.29 (m).

*3-Benzoyloxy-1,1-dichloro-1-propene (**3**(c))*: Yield: 65%; ^{1}H-NMR δ: 8.06–7.43 (m, 5H), 6.21–6.18 (t, 1H, *J* = 6.7 Hz), 4.93–4.91 (d, 2H, *J* = 6.8 Hz); ^{13}C-NMR (acetone-d_6) δ: 166.4, 134.2, 130.6, 130.3, 129.5, 126.3, 125.1, 61.9. Anal. calcd. for $C_{10}H_8O_2Cl_2$: C 51.89, H 3.49; found: C 51.12, H 3.53.

*4-Benzoyloxy-1,1-dichloro-1-butene (**3**(d))*: Yield: 58%; ^{1}H-NMR δ: 8.05–7.43 (m, 5H), 6.00–5.96 (t, 1H, *J* = 7.1 Hz), 4.39–4.36 (t, 2H, *J* = 6.2 Hz), 2.69–2.64 (m, 2H); ^{13}C-NMR (acetone-d_6) δ: 166.6, 133.9, 131.1, 130.2, 129.4, 127.9, 121.9, 63.2, 30.2. Anal. calcd. for $C_{11}H_{10}O_2Cl_2$: C 53.90, H 4.11; found: C 53.77, H 3.90.

*3-Benzoyloxy-1,1-dichloro-2-methyl-1-propene (**3**(e))*: Yield: 54%; ^{1}H-NMR δ: 8.06–7.44 (m, 5H), 5.01 (s, 2H), 2.00 (s, 3H); ^{13}C-NMR (acetone-d_6) δ: 166.4, 133.9, 132.3, 130.5, 130.3, 129.5, 119.2, 65.5, 18.1. Anal. calcd. for $C_{11}H_{10}O_2Cl_2$: C 53.90, H 4.11; found: C 55.14, H 4.60.

*4-Benzoyloxy-1,1-dichloro-2-methyl-1-butene (**3**(e))*: Yield: 60%; ^{1}H-NMR δ: 8.05–7.44 (m, 5H), 4.45–4.42 (t, 2H, *J* = 6.6 Hz), 2.77–2.74 (t, 2H, *J* = 6.4 Hz), 1.98 (s, 3H); ^{13}C-NMR δ: 166.5, 133.1, 131.4, 130.0, 129.6, 128.4, 116.9, 61.9, 34.7, 20.3.

Synthesis, characterization, and biological relevance of hydroxypyrone and hydroxypyridinone complexes of molybdenum

Sarah J. Lord, Noah A. Epstein, Robert L. Paddock, Christopher M. Vogels, Tracy L. Hennigar, Michael J. Zaworotko, Nicholas J. Taylor, William R. Driedzic, Tom L. Broderick, and Stephen A. Westcott

Abstract: We have prepared a number of complexes of the type *cis*-MoO_2L_2 where L represents a hydroxypyronato or hydroxypyridinonato ligand. Both the maltol (3-hydroxy-2-methyl-4-pyrone, Hma) and kojic acid (5-hydroxy-2-hydroxymethyl-4-pyrone, Hka) complexes, *cis*-$MoO_2(ma)_2$ (**1**) and *cis*-$MoO_2(ka)_2$ (**2**), have been characterized by X-ray diffraction studies. The pyrone ligands are bound to molybdenum in a *cis* bidentate fashion via the deprotonated hydroxyl groups and the ketone moieties. Crystals of **1** are orthorhombic, a = 12.107 (1), b = 8.6169 (8), c = 16.472 (1) Å, Z = 4, space group $Pca2_1$, and those of **2** are monoclinic, a = 8.4591 (5), b = 16.3453 (10), c = 10.2954 (7) Å, β = 103.0320 (10)°, Z = 4, space group $P2_1/c$. Hydroxypyridinone molybdenum complexes have been prepared for both maltol and kojic acid derivatives with the substituents Me, *n*-Pr, CH_2Ph, Ph at the ring nitrogen. Crystals of the 3-hydroxy-2-methyl-1-phenyl-4-pyridinone (Hppp) derivative, $MoO_2(ppp)_2$ (**9**), are monoclinic, a = 10.9476 (6), b = 13.5353 (9), c = 17.4877 (10) Å, β = 93.465 (4)°, Z = 4, space group $P2_1/n$. Initial investigations into the effects molybdenum compounds have on diabetic hearts are presented. Both Na_2MoO_4 (used as a control) and **1** were effective in lowering blood glucose and free fatty acid levels. Diabetic rats treated with molybdate showed significant improvements in postischemic cardiac function.

Key words: molybdenum, hydroxypyrones, hydroxypyridinones, heart function.

Résumé : On a préparé un certain nombre de complexes du type *cis*-MoO_2L_2 dans lesquels L est un ligand hydroxypyronato ou hydroxypyridinonato. On a caractérisé ces complexes avec le maltol (3-hydroxy-2-méthyl-4-pyrone, Hma) et l'acide kojique (5-hydroxy-2-hydroxyméthyl-4-pyrone, Hka), *cis*-$Mo(ma)_2L_2$ (**1**) et *cis*-$MoO_2(ka)_2$ (**2**) par diffraction des rayons X. Les ligands pyrone sont liés au molybdène d'une façon bidentate *cis* par le biais des groupes hydroxyméthyles déprotonés et des portions cétoniques. Les cristaux de **1** sont orthorhombiques, groupe d'espace $Pca2_1$, avec a = 12,107 (1), b = 8,6159 (8) et c = 16,472 (1) Å et Z = 4 alors que ceux de **2** sont monocliniques, groupe d'espace $P2_1/c$, avec a = 8,4591 (5), b = 16,3453 (10) et c = 10,2954 (7) Å, β = 103,0320 (10)° et Z = 4. Les complexes du molybdène et de l'hydroxypyrone ont été préparés avec des dérivés du maltol et de l'acide kojique portant des substituants Me, Pr, CH_2Ph et Ph sur l'azote du cycle. Les cristaux du dérivé 3-hydroxy-2-méthyl-1-phényl-4-pyridone (Hppp), $MoO_2(ppp)_2$ (**9**), sont monocliniques, groupe d'espace $P2_1/n$, avec a = 10,9476 (6), b = 13,5353 (9) et c = 17,4877 (10) Å, β = 93,465 (4)° et Z = 4. On présente les résultats d'études préliminaires relatives à l'effet des composés du molybdène sur des coeurs diabétiques. Le Na_2MoO_4 (utilisé comme contrôle) ainsi que le composé **1** sont tous les deux efficaces pour diminuer les niveaux de glucose et des acides gras libres dans le sang. Des rats diabétiques traités au molybdate ont montré des améliorations significatives dans la fonction cardiaque postischémique.

Mots clés : molybdène, hydroxypyrones, hydroxypyridinones, fonction cardiaque.

Introduction

Maltol (3-hydroxy-2-methyl-4-pyrone, Hma) and kojic acid (5-hydroxy-2-hydroxymethyl-4-pyrone, Hka) are naturally occurring nontoxic compounds that have found recent applications in bioinorganic chemistry (1). Interest in maltol and kojic acid arises from their ability to deprotonate readily (pK_a for Hma = 8.38, pK_a for Hka = 7.72) and act as anionic chelating, bidentate O,O′ ligands towards a number of biologically active metals. For instance, iron–maltol complexes have found some potential in the treatment of iron-deficiency anaemia (2) and maltol has been examined as a possible chelating agent for lowering aluminum levels in the body (3).

Although metal complexes containing maltol (4) and kojic acid (5) groups are well known, the most significant and well-studied example is the vanadium complex, $VO(ma)_2$ (BMOV) (4*h*). This remarkable compound displays potent insulinomimetic properties and has been the subject of numerous chemical and physiological studies (6). Indeed, Orvig, McNeill and co-workers have shown that BMOV is effective in lowering blood glucose levels in diabetic rats and is relatively nontoxic over a six month administration period (6*b*). BMOV also facilitates the prevention of long-term diabetes-induced pathology and attenuation of hyperinsulinemia and hypertension in genetically hypertensive rats (6*a*). Prevention of cardiac dysfunction in diabetic rats treated with BMOV is of singular importance as Type I (Insulin-Dependent Diabetes Mellitus – IDDM) diabetics are particularly susceptible to heart failure (7). With the advent of insulin therapy, deaths arising from cardiovascular complications associated with diabetes mellitus have risen from 20% to 80% (7). Attempts to develop new compounds for the oral treatment of diabetes should, therefore, have potent insulinomimetic properties as well as show improvement in cardiac pump function over conventional insulin therapy.

Much effort has focused on generating new vanadium compounds to meet these requirements (8). Vanadium complexes containing 3-hydroxy-2-methyl-pyridinone ligands, derived from the addition of primary amines to maltol, have been reported (8*c*, 8*d*). Variation of the amine substituent allows for fine tuning of the hydrophilic/lipophilic balance of the ligands and, therefore, of the corresponding metal complexes (2*b*). The ability to tailor the physical properties of pyridinone ligands has also been utilized to transport metal ions across biological membranes (9).

Recent studies have shown that other transition metals also display certain insulinomimetic properties (10). For example, insulin-like effects on blood lipids have been reported recently in diabetic rats treated with sodium molybdate, Na_2MoO_4 (10*b*). With this in mind, we postulated that oxomolybdenum complexes containing organic ligands may also prove effective for the oral treatment of diabetes. As part of our initial investigation, we have prepared a number of hydroxypyrone and hydroxypyridinone molybdenum complexes and report herein on the amelioration of heart function defects in diabetic rats treated with Na_2MoO_4 and the molybdenum analogue of BMOV, *cis*-bis(maltolato)dioxomolybdenum(VI) (**1**).

Experimental

Materials and methods

Chemicals used were of reagent grade. Maltol, kojic acid, amines, and 3-hydroxy-1,2-dimethyl-4-pyridinone were obtained from Aldrich Chemicals and molybdic acid was purchased from Strem. NMR spectra were recorded on a JEOL JNM-GSX270 FT-NMR spectrometer. ^1H NMR chemical shifts are reported in ppm and referenced to residual protons in $CDCl_3$, D_2O, and DMSO-d_6 at 270.05 MHz. $^{13}C\{^1H\}$ NMR chemical shifts are referenced to internal solvent peaks at 67.80 MHz. Multiplicities are reported as (s) singlet, (d) doublet, (t) triplet, (q) quartet, (m) multiplet, (br) broad, and (ov) overlapping. Infrared spectra were obtained with Nujol on KBr/NaCl plates using a Perkin–Elmer 710B and a Mattson Polaris spectrometer and are reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, N, and H were carried out at Desert Analytics (Tucson, Ariz.).

Complex **1** (4*a*) and complex **3** (11*g*) were prepared by established methods using molybdic acid. Compounds Hhmp (5*d*), Hhnp (5*d*), Hbpp (5*d*), Hnpp (9*a*), and Hppp (12*b*) were all prepared by previously reported methods with slight modifications. Selected spectroscopic data for these ligands are reported as follows.

3-Hydroxy-6-hydroxymethyl-1-methyl-4-pyridinone, (Hhmp): mp 204°C (dec.); IR (Nujol): 870 (m), 1079 (w), 1129 (m), 1225 (w), 1268 (w), 1310 (m), 1454 (s), 1480 (m), 1552 (s), 1627 (m), 2964 (s), 3310 (br); $^{13}C\{^1H\}$ (in D_2O), δ: 43.2, 62.1, 116.5, 131.3, 148.4, 150.6, 173.3.

3-Hydroxy-6-hydroxymethyl-1-propyl-4-pyridinone, (Hhnp): mp 186°C (dec.); IR (Nujol): 722 (m), 859 (s), 972 (s), 1083 (s), 1131 (s), 1217 (s), 1270 (m), 1454 (s), 1463 (m), 1564 (m), 1643 (m), 2722 (m), 3178 (br); $^{13}C\{^1H\}$ (in D_2O), δ: 12.5, 26.3, 57.3, 62.0, 116.9, 130.1, 148.5, 150.1, 173.3.

Benzyl-3-hydroxy-2-methyl-4-pyridinone, (Hbpp): mp 204°C (dec.); IR (KBr): 855 (m), 1455 (m), 1500 (m), 1570 (s), 1620 (s), 3152 (m); $^{13}C\{^1H\}$ (in $CDCl_3$), δ: 12.2, 57.4, 111.3, 126.0, 128.5, 128.6, 129.5, 135.4, 137.8, 146.6, 170.0; ^1H δ: 2.27 (s, 3H), 4.72 (br s, 1H), 5.09 (s, 2H), 6.45 (d, J = 7 Hz, 1H), 7.01 (br d, J = 7 Hz, 2H), 7.31 (m, 4H).

3-Hydroxy-2-methyl-1-propyl-4-pyridinone, (Hnpp): mp 161°C (dec.); IR (Nujol): 844 (s), 1033 (m), 1223 (s), 1349 (m), 1462 (s), 1504 (m), 1571 (s), 1625 (s), 2971 (s), 3145 (br); $^{13}C\{^1H\}$ (in D_2O), δ: 12.5, 14.0, 25.9, 58.6, 114.8, 137.1, 141.0, 147.3, 171.1.

3-Hydroxy-2-methyl-1-phenyl-4-pyridinone, (Hppp): $^{13}C\{^1H\}$ (in $CDCl_3$), δ: 13.8, 111.2, 126.9, 128.9, 129.7, 130.1, 137.5, 141.9, 145.9, 170.4.

Preparation of *cis*-bis(5-hydroxy-2-hydroxymethyl-4-pyronato)dioxomolybdenum(VI), $MoO_2(ka)_2$, 2

To a stirred suspension of molybdic acid (0.25 g, 0.74 mmol) in 10 mL of water, a 10 mL aqueous solution of kojic acid (0.42 g, 2.96 mmol) was added dropwise. The addition of isopropanol to the solution resulted in the crystallization of white starting material. The yellow product was crystallized following further addition of isopropanol and was collected by suction filtration. The product was washed with ether (2 × 50 mL) and dried under vacuum. Yield: 0.22 g (36%) of a light yellow powder; mp 170°C (dec.). IR

Preparation of *cis*-bis(3-hydroxy-2-methyl-1-propyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(npp)_2$, 5

A 10 mL water solution of molybdic acid (0.16 g, 0.47 mmol) was cooled to 0°C in an ice–water bath. To this chilled solution, Hnpp (0.35 g, 2.10 mmol) was added in small portions as a solid. After 18 h of stirring, the solution was allowed to return to room temperature and the yellow precipitate collected by vacuum filtration. Complex **5** was recrystallized from a methylene chloride – hexane solution and collected by suction filtration. Yield: 0.33 g (76%) of a yellow solid; mp 283°C (dec.). IR (Nujol): 721 (w), 818 (w), 890 (w), 1268 (m), 1377 (m), 1462 (s), 1496 (m), 1551 (m), 1612 (w), 2940 (s). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 0.89 (t, $J_{H–H}$ = 5 Hz, 6H), 1.73 (m, $J_{H–H}$ = 5 Hz, 4H), 2.50 (s, 6H), 4.08 (t, $J_{H–H}$ = 5 Hz, 4H), 6.47 (d, $J_{H–H}$ = 5 Hz, 2H), 7.87 (d, $J_{H–H}$ = 5 Hz, 2H); ^{13}C{^{1}H} δ: 10.4, 11.6, 23.3, 54.8, 108.3, 133.0, 137.7, 154.4, 169.6. Anal. calcd. for $MoO_6C_{18}H_{24}N_2$: C 46.95, H 5.25, N 6.09; found: C 46.60, H 5.35, N 5.95.

Preparation of *cis*-bis(3-hydroxy-6-hydroxymethyl-1-propyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(hnp)_2$, 6

Solid Hhnp (0.12 g, 0.65 mmol) was added in small portions to a stirred 15 mL aqueous solution of molybdic acid (0.05 g, 0.15 mmol). After 18 h, a yellow precipitate was collected by vacuum filtration and washed with water (3 × 10 mL) and diethyl ether (3 × 10 mL). Yield: 0.07 g (47%) of a yellow solid; mp 238°C (dec.). IR (Nujol): 722 (s), 863 (m), 927 (m), 1106 (s), 1244 (s), 1290 (m), 1454 (s), 1537 (m), 1620 (m), 2883 (s). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 0.92 (t, $J_{H–H}$ = 8 Hz, 6H), 1.77 (d, $J_{H–H}$ = 5 Hz, 4H), 4.02 (s, 4H), 4.50 (s, 4H), 5.76 (br s, 2H), 6.54 (s, 2H), 7.75 (s, 2H); ^{13}C{^{1}H} δ: 10.7, 23.9, 54.4, 59.2, 109.3, 125.3, 148.5, 155.8, 171.9. Anal. calcd. for $MoO_8C_{18}H_{24}N_2 \cdot 3H_2O$: C 39.56, H 5.53, N 5.13; found: C 40.04, H 5.63, N 5.19.

Preparation of *cis*-bis(1-benzyl-3-hydroxy-2-methyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(bpp)_2$, 7

To a 25 mL aqueous solution of molybdic acid (0.14 g, 0.41 mmol), 1-benzyl-3-hydroxy-2-methyl-4-pyridinone (0.39 g, 1.81 mmol) was added as a solid in small portions. After 24 h, a yellow precipitate was collected by vacuum filtration and washed with water (2 × 10 mL) and methanol (3 × 10 mL). Yield: 0.38 g (83%) of a yellow solid; mp 295°C (dec.). IR (KBr): 830 (w), 895 (s), 930 (m), 1270 (s), 1360 (m), 1490 (s), 1550 (s), 1615 (m), 3170 (w). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 2.27 (s, 6H), 5.46 (s, 4H), 6.58 (d, $J_{H–H}$ = 8 Hz, 2H), 7.12–7.44 (ov m, 10H), 8.06 (d, $J_{H–H}$ = 8 Hz, 2H). ^{13}C{^{1}H} δ: 12.2, 57.4, 108.9, 126.6, 128.2, 129.2, 133.6, 135.9, 139.0, 154.9, 170.3. Anal. calcd. for $MoO_6C_{26}H_{24}N_2$: C 56.12, H 4.35, N 5.03; found: C 56.06, H 4.40, N 5.00.

Synthesis of 1-benzyl-3-hydroxy-6-hydroxymethyl- 4-pyridinone, (Hhbp)

1-Benzyl-3-hydroxy-6-hydroxymethyl-4-pyridinone was prepared by modification of a known procedure (5*d*). Kojic acid (1.40 g, 9.85 mmol) was dissolved in a 3:1 mixture of water:ethanol (40 mL) whereupon benzylamine (1.50 g, 14.00 mmol) was added dropwise. The reaction mixture was heated to reflux under an atmosphere of dinitrogen for 12 h and then cooled to 5°C. After 3 h, a dark brown precipitate was collected by vacuum filtration and washed with water (2 × 10 mL) and methanol (3 × 10 mL). Yield: 0.24 g (11%) of light brown crystals; mp 258°C. IR (Nujol): 879 (m), 1124 (m), 1245 (m), 1377 (m), 1462 (s), 1518 (w), 1563 (m), 1643 (m), 2930 (s), 3196 (br). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 4.28 (s, 2H), 5.19 (s, 2H), 6.29 (s, 1H), 7.13 (d, $J_{H–H}$ = 5 Hz, 2H), 7.35 (m, 3H), 7.48 (s, 1H); ^{13}C{^{1}H} δ: 54.2, 59.2, 112.2, 123.9, 126.3, 127.6, 128.8, 136.9, 146.8, 147.6, 170.8.

Preparation of *cis*-bis(1-benzyl-3-hydroxy-6-hydroxymethyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(hbp)_2$, 8

1-Benzyl-3-hydroxy-6-hydroxymethyl-4-pyridinone (0.40 g, 1.73 mmol) was added in small portions to a stirred 15 mL aqueous solution of molybdic acid (0.13 g, 0.38 mmol). After 24 h, complex **8** had precipitated from solution and was collected by filtration and washed with water (3 × 10 mL) and methanol (2 × 15 mL). Yield: 0.40 g (89%) of a yellow solid; mp 240°C (dec.). IR (KBr): 895 (m), 924 (m), 1172 (m), 1248 (s), 1313 (m), 1468 (s), 1522 (s), 1563 (s), 1614 (s), 1642 (m), 3219 (br). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 4.44 (t, $J_{H–H}$ = 16 Hz, 4H), 5.41 (s, 4H), 5.84 (br s, 2H), 6.66 (s, 2H), 7.18–7.42 (m, 10H), 7.85 (s, 2H); ^{13}C{^{1}H} δ: 55.7, 58.9, 109.9, 125.9, 126.6, 128.0, 128.7, 135.6, 149.2, 155.6, 172.2. Anal. calcd. for $MoO_8C_{26}H_{24}N_2 \cdot H_2O$: C 51.49, H 4.32, N 4.62; found: C 51.73, H 4.26, N 4.67.

Preparation of *cis*-bis(3-hydroxy-2-methyl-1-phenyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(ppp)_2$, 9

To a stirred 30 mL aqueous solution of molybdic acid (0.20 g, 0.59 mmol), 3-hydroxy-2-methyl-1-phenyl-4-pyridinone (0.59 g, 2.93 mmol) was added in small portions as a solid. After 18 h, **9** precipitated from solution and was

© 1999 NRC Canada

collected by vacuum filtration. The resulting solid was washed with water (5 × 25 mL) and methanol (3 × 5 mL). Yield: 0.51 g (82%) of a yellow powder; mp 272°C. IR (Nujol): 895 (s), 1298 (s), 1365 (s), 1480 (s), 1515 (w), 1543 (s), 1610 (m), 2925 (s), 3058 (br). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 2.09 (s, 6H), 6.64 (s, 2H), 7.61 (m, 10H), 7.90 (s, 2H); ^{13}C{^{1}H} δ: 13.8, 108.6, 126.7, 129.9, 133.3, 138.6, 141.2, 154.1, 170.9. Anal. calcd. for $MoO_6C_{24}H_{20}N_2$: C 54.55, H 3.82, N 5.30; found: C 54.11, H 4.02, N 5.21.

Synthesis of 3-hydroxy-6-hydroxymethyl-1-phenyl-4-pyridinone, (Hhpp)

Aniline was added dropwise (1.38 g, 14.82 mmol) to a 25 mL aqueous solution of kojic acid (1.00 g, 7.04 mmol). The reaction was heated to reflux for 96 h and was filtered hot to remove a black oil. After the mixture was allowed to stand for 18 h at 0°C a dark precipitate was collected and dissolved in 5 mL of methanol. Following the addition of 25 mL of water, a brown solid precipitated and was discarded. The filtrate was collected and solvent removed under vacuum to afford a red oil and dark solid. This mixture was dissolved in a minimum of hot methanol and cooled to 2°C. Within 18 h, Hhpp precipitated and was collected by suction filtration. Yield: 0.11 g (7%) of a light brown solid; mp 224°C. IR (Nujol): 703 (m), 854(m), 1152 (m), 1314 (m), 1488 (m), 1515 (m), 1573 (s), 1644 (s), 3057 (br), 3219 (br). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 4.02 (s, 2H), 5.91 (br s, 1H), 6.47 (s, 1H), 7.32 (s, 1H), 7.48 (s, 2H), 7.53 (s, 3H); ^{13}C{^{1}H} δ: 59.2, 111.1, 123.6, 126.9, 129.3, 129.7, 140.7, 146.3, 148.2, 171.4. Isolation of Hhpp was problematic. This is presumably due to a significant amount of hydrogen bonding between aniline and the resulting pyridinone compound. Indeed, a pyridinone–aniline adduct (Hhpp·H_2NPh) could be isolated in certain instances from solutions of hot methanol. IR (Nujol): 700 (m), 745 (m), 863 (m), 1210 (m), 1307 (m), 1487 (m), 1515 (m), 1573 (s), 1640 (m), 3068 (br). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 3.87 (d, J_{H-H} = 5 Hz, 2H), 6.25 (s, 1H), 6.34 (s, 1H), 6.52 (d, J_{H-H} = 8 Hz, 2H), 6.62 (t, J_{H-H} = 8 Hz, 1H), 7.12 (t, J_{H-H} = 8 Hz, 2H), 7.41 (s, 1H), 7.65 (s, 5H); ^{13}C{^{1}H} δ: 43.7, 111.0, 112.1, 116.5, 123.7, 127.0, 129.0, 129.4, 130.0, 140.8, 146.0, 146.3, 147.5, 171.0.

Preparation of *cis*-bis(3-hydroxy-6-hydroxymethyl-1-phenyl-4-pyridinonato)dioxomolybdenum(VI), $MoO_2(hpp)_2$, 10

To a stirred 10 mL aqueous solution of molybdic acid (0.02 g, 0.06 mmol), 3-hydroxy-6-hydroxymethyl-1-phenyl-4-pyridinone (0.06 g, 0.28 mmol) was added in small portions as a solid. After 18 h, **10** precipitated from solution and was collected by vacuum filtration. The solid was washed with water (5 × 25 mL) and methanol (3 × 5 mL). Yield: 0.03 g (45%) of a yellow solid; mp 261°C. IR (Nujol): 771 (m), 853 (m), 902 (m), 935 (m), 1163 (m), 1305 (s), 1523 (s), 1552 (s), 1590 (m), 1611 (m), 3205 (w). NMR spectroscopic data (in DMSO-d_6): ^{1}H δ: 4.09 (s, 4H), 5.68 (s, 2H), 6.73 (s, 2H), 7.60 (s, 8H), 7.72 (s, 2H); ^{13}C{^{1}H} δ: 59.2, 108.0, 125.7, 126.6, 129.8, 130.0, 140.2, 150.0, 155.1, 173.1. Anal. calcd. for $MoO_8C_{24}H_{20}N_2$: C 51.44, H 3.60, N 5.00; found: C 51.24, H 3.51, N 4.80.

X-ray crystallography

Crystal data for complexes **1**, **2**, and **9** are provided in Table 1. Data for **1** and **9** were collected on a Nicolet LT2 equipped Siemens P4 diffractometer using the ω method ($4° \leq 2\theta \leq 60°$). Data for **2** were collected on a Siemens SMART/CCD diffractometer equipped with an LT-II low-temperature device. The data were corrected for absorption by a faced-indexed analytical method. Three standard reflections every 100 showed no significant decay. The structures were solved by Patterson and Fourier methods, and refined by full-matrix least squares (SHELXTL IRIS). For complex **1**, the alternate polarity cell gave R and wR values of 0.0221 and 0.0251. A weighting scheme of $w^{-1} = \sigma^2(F)$ was used in the last cycles of refinement. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined using a riding model. Atomic coordinates, thermal parameters, bond lengths and angles, and alternate views of the complexes have been deposited as supplementary material.[4]

Animal model and induction of diabetes

Male Sprague–Dawley rats with an initial body weight of 200 g were used in this study. Diabetes was induced in ether-anesthetized rats by an intravenous injection of 60 mg/kg of streptozotocin freshly dissolved in 50 mM sodium citrate buffer, pH 4.5. Control animals received citrate buffer only. After 48 h, the induction of diabetes was confirmed by glucose testing in the urine using Keto-diastix (Ames). Animals were caged in groups of two and provided with food and water ad libitum until the time of experimentation. Animals used in this study were cared for according to the recommendations in the Canadian Council on Animal Care's Guide to the Care and Use of Experimental Animals.

Treatment protocol

After confirmation of diabetes, treatment was initiated by adding $MoO_2(ma)_2$ and sodium molybdate to the drinking water. Intake of compounds was determined on a molar basis adjusted for body weight over a 24 h period. During the 6 week treatment period, the average daily intake of $MoO_2(ma)_2$ by diabetic animals was 0.15 mmol/kg per 24 h and that of molybdate-treated diabetic animals was 0.13 mmol/kg per 24 h. Analytically pure $MoO_2(ma)_2$ was used in this study (Anal. calcd. for $MoO_8C_{12}H_{10}$: C 38.12, H 2.67; found: C 38.08, H 2.66). The pH of the drinking water was adjusted to 7.4 with sodium hydroxide. Under these conditions complex **1** formed a salt that could be recovered by titration with HCl (as ascertained by ^{1}H NMR spectroscopy). Treatment was initiated immediately following the

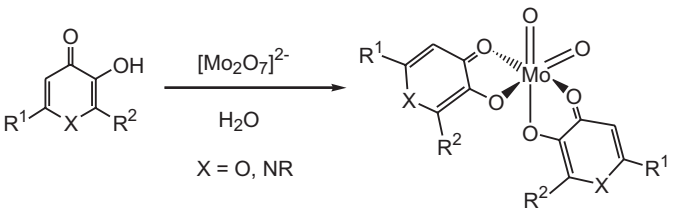
confirmation of diabetes for a 6 week period. Control animals received water only.

Heart perfusions

Following treatment, hearts from sodium pentobarbital-anesthetized rats were quickly excised, placed in ice-cold buffer and immediately perfused retrogradely via the aorta with Krebs–Henseleit buffer containing 11 mM glucose and 1.75 mM Ca^{2+} (pH 7.4, gassed with 95% O_2 – 5% CO_2). During this perfusion, the hearts were trimmed of excess tissue, the pulmonary arteries were cut, and the openings of the left atria were cannulated. Hearts were then switched to the working mode and perfused at a 15 cm H_2O left atrial filling pressure and 100 cm H_2O hydrostatic aortic afterload in a recirculating buffer system containing 11 mM glucose and 1.2 mM palmitate prebound to 3% bovine serum albumin. Hearts were initially perfused under aerobic conditions for a 15 min period. Global ischemia was induced by clamping off both aortic and preload lines for a period of 25 min. Following ischemia, flow was restored and hearts were allowed to recover for a further 30 min period. Throughout the perfusion, heart rate and aortic pressure development were recorded using a Biotronix pressure recorder (model BL630) interfaced with a Biotronix chart recording system (model BL882). Aortic flow was measured by timed collections. At the end of the reperfusion period, hearts were rapidly frozen with clamps cooled to the temperature of liquid nitrogen, and stored at –80°C.

Fig. 1. Synthesis of molybdenum hydroxypyrone and hydroxypyridinone complexes.



Statistical analysis

A one-way analysis of variance, followed by the Newman–Keuls test, was used to determine statistical significance for comparisons between group means. A value of $p < 0.05$ was considered significant. All data are reported as mean ± S.E.M.

Results and discussion

Hydroxypyrone complexes

$MoO_2(ma)_2$ (**1**, ma = maltolato) is readily prepared in high yield (87%) from addition of maltol to molybdic acid, $(NH_4)_2Mo_2O_7$, in aqueous solutions at neutral pH (Fig. 1, ref. 4*a*). IR and NMR spectroscopic data are consistent with a *cis*-dioxo complex containing two chelating maltolato ligands. Analogous reactions with kojic acid afford the corresponding complex, $MoO_2(ka)_2$ (**2**), in much lower yields (36%). Both **1** and **2** are yellow crystalline complexes, stable indefinitely in the solid state and relatively soluble in water.

Increased solubility observed for **2** in aqueous solutions presumably arises due to the pendant CH_2OH group on the pyrone ring. Unlike the maltol derivative, however, **2** decomposes in water at elevated temperatures to give a mixture of molybdates.

As with **1** (4*a*), the IR spectrum for **2** shows that the strong band at 1660 cm^{-1}, assigned as mainly ν(C=O) in kojic acid, decreases in intensity and shifts to a lower wavenumber (1647 cm^{-1}) upon coordination to the d^0 metal centre. Likewise, the bands at 1611 cm^{-1} (strong) and 1578 cm^{-1} (medium), belonging to the strongly mixed ν(C=C) and ν(C=O) modes in pyrones (3*a*, 4*a*), also shift to lower energies upon complexation and are observed at 1574 cm^{-1} and 1520 cm^{-1}, respectively. The band at

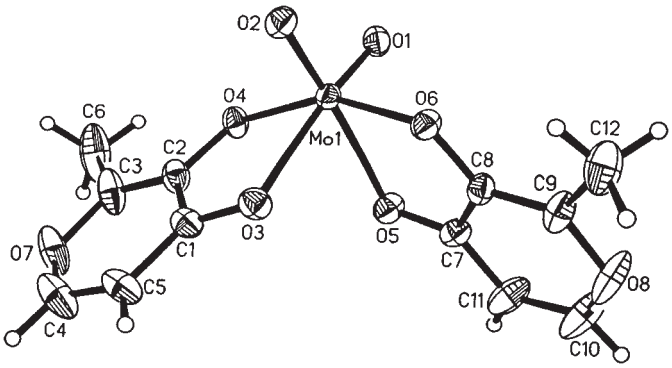

Fig. 3. The molecular structure of $MoO_2(ka)_2$, **2**.

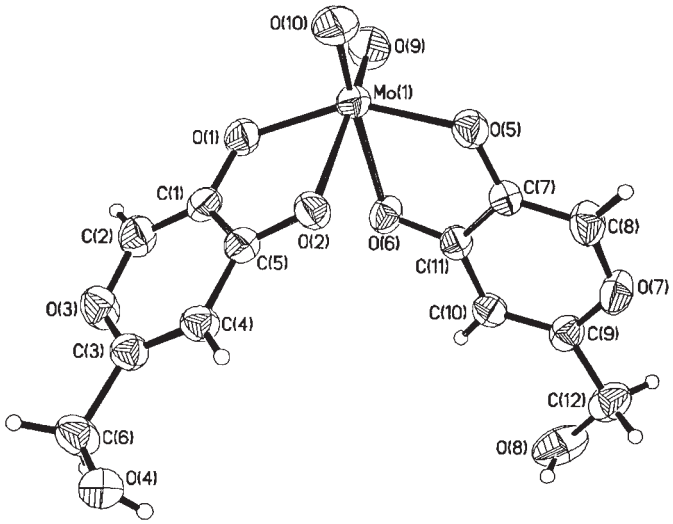

3168 cm^{-1} for the OH stretches of kojic acid is observed at 3122 cm^{-1} for **2**. The two strong IR bands present at 919 and 890 cm^{-1} assigned to ν_s (Mo=O) and ν_{as}(Mo=O) are similar to those reported previously for **1** and for the tropolone complex, *cis*-$MoO_2(trop)_2$ (12). The wavenumbers observed in kojic acid and its metal derivatives are lower than those for the maltol derivatives, presumably because of the electron-withdrawing nature of the hydroxymethyl group as opposed to the electron-donating ability of the methyl group in maltol (5*b*).

The proton NMR spectra of **2** in D_2O indicates a pair of broad singlets at δ 6.67 and 7.87 due to the ring CH protons. The singlet at 6.67 ppm is shifted downfield by 0.23 ppm in comparison with kojic acid while the other ring proton is shifted upfield by 0.06 ppm. The exocyclic methylene protons of the hydroxymethyl group appear as a singlet at δ 4.42 in **2** while the chemical shift of the analogous protons in starting pyrone appear at δ 4.73.

Single crystals of **1** were grown from a wet methylene chloride solution cooled to 5°C and those for **2** grown from a H_2O–i-PrOH mixture. An X-ray diffraction study of **1** was carried out to determine unequivocally the nature of the compound about to undergo biological testing. The molecular structures of $MoO_2(ma)_2$ and $MoO_2(ka)_2$ are depicted in Figs. 2 and 3, respectively, and crystallographic data for both compounds are given in Table 1. Atomic coordinates and displacement parameters for **1** and **2** are given in Table 2. Selected bond distances and angles for **1** and **2** are provided in Tables 3 and 4, respectively. The coordination sphere about the molybdenum atoms in both cases consists of six oxygen atoms arranged in a distorted octahedral geometry. The molecular structures confirm a *cis* arrangement of dioxo

ligands as predicted by extended spectroscopic data and Hückel calculations (13). The Mo=O bond lengths (avg. = 1.701 (2) Å, **1**; avg. = 1.695 (2) Å, **2**) are comparable to those found in other oxomolybdenum(VI) complexes (14). The two ketonic oxygen atoms of the pyrone moieties are *trans* to the oxo ligands and the stronger field hydroxyl oxygens are *trans* to one another. Similar coordination environments have been observed previously in analogous vanadium–maltol (15) and iron – kojic acid complexes (5*d*).

As expected, a slight lengthening of the ketone C=O bond is observed upon complexation, with a mean distance of 1.268 (4) Å in **1** and 1.275 (3) Å in **2** compared with 1.244 Å found in free kojic acid (16). The molybdenum–oxygen (ketone) bond in this case is somewhat longer (avg. = 2.225 (2) Å, **1**; avg. = 2.261 (2) Å, **2**) than the Mo – deprotonated oxygen distance, the average being only 1.992 (2) Å in **1** and 1.989 (2) Å in **2**. This observation provides a distinction between Lewis acid–base versus covalent bonding for these two types of oxygen atoms. It is interesting to note that the ketone oxygen–molybdenum bond length is slightly longer in **2** than in **1**, indicating weaker bonding interaction for this hydroxypyrone. Low metal-binding constants have been reported previously for kojic acid derivatives (5*c*). Interestingly, average C(6)—O(4) bond lengths of 1.384 (5) Å observed for the hydroxymethyl groups in **2** are somewhat shorter than those seen in kojic acid (1.406 Å), presumably due to a slight reduction in the degree of intermolecular hydrogen bonding for the molybdenum complex. Indeed, O–H···O interactions in **2** occur at 2.887 and 3.069 Å, while distances of 1.87 and 2.08 Å are reported for kojic acid.

Hydroxypyridinone complexes

A series of *N*-substituted 3-hydroxy-4-pyridinones were readily prepared (Fig. 4) from the addition of primary amine ($MeNH_2$, *n*-$PrNH_2$, $PhCH_2NH_2$, and $PhNH_2$) and either maltol (9) or kojic acid (5*d*). Functionalization of the ring

nitrogen in the hydroxypyridinones allows for fine tuning of physical properties such as water solubility, hydrolytic stability, and lipophilicity without compromising thermodynamic binding constants (9*b*). Indeed, the corresponding pyridinone complexes are somewhat less water soluble and slightly more lipophilic than the pyrone complexes **1** and **2**. For instance, although the N–Me complex $MoO_2(dpp)_2$ **3** is only sparingly soluble in dimethyl sulfoxide, the kojic acid – aniline derivative **10** is readily soluble in methylene chloride. While metal complexes containing *N*-substituted 3-hydroxy-4-pyridinones are well known (2*b*, 8*c*–8*d*, 9, 11), the only molybdenum complex reported containing these biologically relevant ligands is the 3-hydroxy-1,2-dimethyl- 4-pyridinone (Hdpp) derivative, $MoO_2(dpp)_2$ **3** (11*g*).

Upon complexation with molybdenum, the four-band infrared spectral pattern between 1400 and 1610 cm^{-1}, characteristic of pyrone and pyridinone ligands (4*a*, 17), is also observed, along with an expected bathochromatic shift. These four bands are assigned collectively as ν(C=C) and ν(C=O). Of the four possible isomers for complexes of the type *cis*-MoO_2L_2 (18), the most likely isomer is the one in which both ketone oxygens of the pyridinone ligands are *trans* to the molybdenum oxo groups (13). A single-crystal X-ray diffraction study was carried out on the 3-hydroxy- 2-methyl-1-phenyl-pyridinone derivative **9** to confirm this assignment.

The molecular structure of **9** is shown in Fig. 5, atomic coordinates and displacement parameters in Table 5, and

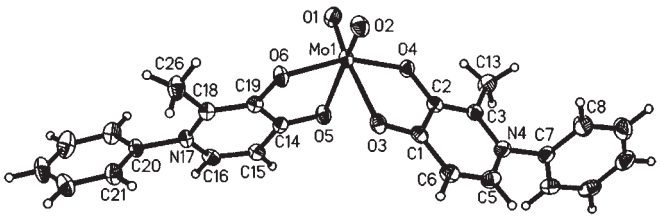
Fig. 5. The molecular structure of $MoO_2(ppp)_2$, **9**.



bond distances and angles are provided in Table 6. Similar Mo—O bond distances are observed in **9** and the parent pyrone complex **1**. The bond distances within the pyridinone ring also display trends similar to those described for **1** and other metal–pyridinone complexes (11). A pronounced localization of the formal double bonds in the ring, albeit to a lesser extent than that observed for the pyrone systems, is clearly indicated by the short C(2)—C(3), C(5)—C(6), and ketone C(1)—O(3) bonds. Resonance forms for pyridinone ligands have been described in detail elsewhere (11, 19). A N(4)—C(7) bond distance of 1.458 (3) Å, however, is slightly shorter than that reported for the free ligands 3-hydroxy-1-*p*-methoxyphenyl-2-methyl-4-pyridinone (cf. 1.474 (1) Å) (19) and 3-hydroxy-1,2-dimethyl-4-pyridinone (cf. 1.482 (4) Å) (20). Average C-N-C angles of 120.0° are similar to those reported earlier (11, 19, 20).

Biological relevance

We have begun our investigation into the effect of molybdenum complexes on heart function in diabetic rats and report our findings herein. Initial work was conducted using **1**, the molybdenum analogue of BMOV, because of the efficacy of this latter compound as an insulin mimic, along with the control (10) sodium molybdate, Na_2MoO_4. Confirming the diabetic state, plasma glucose and free fatty acid levels

© 1999 NRC Canada

Table 7. Physical characteristics and blood profile of control and diabetic rats.

Group	Glucose (mM)	Free fatty acids (mM)	Body weight (g)	Fluid intake (mL/kg per 24 h)
Control	6.1 ± 0.1	0.37 ± 0.04	492 ± 8	43 ± 2
Diabetic	23.2 + 1.5[a,c]	0.51 + 0.09[a,c]	291 + 19[a]	163 + 22[a,c]
+ molybdate	13.2 + 1.4[a,b]	0.17 + 0.02[a,b]	286 + 12[a]	90 + 12[a,b]
+ $MoO_2(ma)_2$	16.3 + 1.3[a,b]	0.13 + 0.02[a,b]	328 + 17[a]	115 + 13[a,b]

Values are presented as mean ± S.E.M. for six to eight animals in each group. Average daily intake of $MoO_2(ma)_2$ by diabetic animals was 0.15 mmol/kg per 24 h, whereas that of molybdate was 0.13 mmol/kg per 24 h.

[a]Significant vs. control.

[b]Significant vs. diabetic.

Table 8. Effects of $MoO_2(ma)_2$ and sodium molybdate treatment on heart function.

Perfusion condition	HR (beats/min)	PSP (mmHg)	RPP (beats mmHg $min^{-1)}$	DP (mmHg)	AF (mL/min)
Aerobic perfusion					
Control	250 ± 8	92 ± 5	23 ± 1	59 ± 2	42 ± 4
Diabetic	200 ± 13[a]	94 ± 4	19 ± 1[a]	63 ± 2	20 ± 3[a]
+ molybdate	243 ± 20	97 ± 3	23 ± 2	62 ± 3	36 ± 4[b]
+$MoO_2(ma)_2$	214 ± 12	87 ± 5	18 ± 1	63 ± 4	17 ± 3[a,c]
Reperfusion following ischemia					
Control	190 ± 21	87 ± 9	16 ± 2	57 ± 5	16 ± 6
Diabetic	164 ± 25	74 ± 11	14 ± 2	61 ± 9	6 ± 2[a]
+ molybdate	235 ± 11	94 ± 3	22 ± 1	64 ± 2	25 ± 3[b]
+ $MoO_2(ma)_2$	114 ± 14[c]	45 ± 16[c]	9 ± 3[c]	35 ± 12	3 ± 2[ac]

Values are presented as mean ± S.E.M. for six to eight animals in each group. HR, heart rate; PSP, peak systolic pressure; RPP, heart rate pressure product; DP, diastolic pressure; AF, aortic flow. Hearts were perfused under aerobic conditions for 15 min, then subjected to 25 min of global ischemia followed by 30 min of aerobic reperfusion. Reperfusion data obtained at the end of the 30 min.

[a]Significant vs. control.

[b]Significant vs. diabetic.

[c]Significant vs. diabetic treated with molybdate.

were markedly elevated in the diabetic rats (Table 7). Body weight, as expected, was lower in diabetic rats than in the controls. Food and fluid intake was maintained during the 6 week period. Treatment of diabetic animals with either sodium molybdate or $MoO_2(ma)_2$ (**1**) significantly reduced levels of plasma glucose but proved to have weaker insulin-like effects when compared to BMOV (4*h*, 5, 6). It is interesting to observe that treatment with $MoO_2(ma)_2$ and sodium molybdate also reduced plasma glucose and free fatty acid levels in diabetic rats. Rats treated with both molybdenum complexes suffered from initial weight loss although those given complex **1** gained weight at the end of the treatment. No animals suffered from diarrhea and all survived treatment with these molybdenum complexes.

The 6 week period of diabetes was selected because alterations in heart function occur within this period (21–23). As shown in Table 8, if hearts from diabetic rats are perfused under aerobic conditions, significant differences in function are noted. Diabetic rat hearts show a significant depression in rate–pressure product as a result of a decrease in heart rate. Aortic flow in these rats is also depressed compared to that in control hearts. Treatment of diabetic rats with sodium molybdate, however, prevented this depression in aortic flow from occurring, an effect not observed in diabetic rats treated with $MoO_2(ma)_2$. During reperfusion of previously ischemic hearts, the benefits of sodium molybdate on mechanical function of diabetic rat hearts are also clearly observed. These are associated with significant and dramatic increases in aortic flow. No benefits of $MoO_2(ma)_2$ treatment on reperfusion recovery of diabetic hearts were seen.

Preventing the diabetes-induced depressions in heart function can be accomplished with agents that decrease circulating levels of lipids and glucose (21–24), which could possibly explain the benefits of molybdate on reperfusion on recovery of diabetic hearts. Diabetic hearts exposed to low levels of fatty acids can oxidize glucose as an additional substrate (24) since the poorly controlled state is characterized by energy requirements met primarily from the oxidation of fatty acids (25). Although conjectural, the possibility exists that molybdate-treated diabetic hearts oxidized more glucose during reperfusion, allowing them to be less sensitive to ischemia (26).

Conclusions

A series of hydroxypyrone and hydroxypyridinone complexes of molybdenum have been prepared and were characterized by a number of physical methods including X-ray diffraction studies. Initial biological data demonstrate that treatment of diabetic animals with sodium molybdate not only reduces plasma levels of glucose and fatty acids, but also prevents the depression in cardiac function from occur-

© 1999 NRC Canada

ring in diabetic hearts. The maltolato complex, $MoO_2(ma)_2$, also showed some improvement in blood glucose and free fatty acid levels but had no effect on heart function. We are currently investigating the physical properties necessary to generate a more active molybdenum complex for the treatment of cardiac dysfunction associated with diabetes.

Dimethyltellurium(IV) derivatives with mixed 1,1-dithio ligands. Crystal structures of $Me_2Te[S_2CNMe_2][S_2COEt]$ and $Me_2Te[S_2CNEt_2][S_2COMe]$

John E. Drake, Layla N. Khasrou, Anil G. Mislankar, and Raju Ratnani

Abstract: Mixed ligand derivatives of $Me_2TeLL'_2$, where L = *N*,*N*-dialkyl dithiocarbamate or *O*,*O*-alkylene dithiophosphate and L′ = *O*-alkyl dithiocarbonate, have been synthesized and characterized by elemental analysis, ^1H, ^{13}C, ^{31}P, and ^{125}Te NMR spectroscopy and infrared and Raman spectroscopy, and X-ray crystallography. $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**: $P\bar{1}$ (no. 2), with cell parameters a = 10.073(3) Å, b = 10.139(2) Å, c = 9.108(2) Å, α = 92.36(2)°, β = 115.55(2)°, γ = 111.19(2)°, V = 760.7(4) Å^3, Z = 2, R = 0.0343, R_w = 0.0296. $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**: $P2_1/c$ (no. 14) with cell parameters a = 9.881(4) Å, b = 17.671(3) Å, c = 10.149(4) Å, β = 113.65(3)°, V = 1623.3(10) Å^3, Z = 4, R = 0.0567, R_w = 0.0514. The immediate environment about tellurium in both molecules is essentially that of a saw-horse structure in which the lone pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid. The S-Te-S angles in the two molecules are 166.87(6)° and 162.0(1)° for **8** and **9**, respectively. In both molecules, the Te—S bonds to the dithiocarbamate groups are slightly shorter than those to dithiocarbonates. The dithiocarbamate groups are oriented to give secondary interactions involving the apparently terminal sulfur atoms resulting in Te—S distances of 3.205(2) and 3.277(4) Å, respectively, in **8** and **9**. However, only in **9** is there a similar Te—S distance of 3.346(5) Å involving the S_2COMe group because in **8**, the OEt group of S_2COEt, rather than the terminal S atom, is oriented toward Te.

Key words: structure, tellurium, methyl, dithiocarbamates, dithiocarbonates, dithiophosphates.

Résumé : On a synthétisé des dérivés à ligands mixtes du $Me_2TeLL'_2$ dans lesquels L = dithiocarbamate de *N*,*N*-dialkyle ou dithiophosphate de *O*,*O*-alkylène et L′ = dithiocarbonate de *O*-alkyle et on les a caractérisés par analyse élémentaire, spectroscopie RMN du ^1H, ^{13}C, ^{31}P et ^{125}Te, spectroscopie infrarouge et Raman et par diffraction des rayons X. $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, $P\bar{1}$ (no. 2), avec a = 10,073(3), b = 10,139(2) et c = 9,108(2) Å, α = 92,36(2), β = 115,55(2) et γ = 111,19(2)°, V = 760,7(4) Å^3, Z = 2, R = 0,0343, R_w = 0,0296. $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, $P2_1/c$ (no. 14), avec a = 9,881(4), b = 17,671(3) et c = 10,149(4) Å, β = 113,65(3)°, V = 1623,3(10) Å^3, Z = 4, R = 0,0567, R_w = 0,0514. Dans les deux molécules, l'environnement immédiat autour du tellure est essentiellement celui d'une structure cavalière dans laquelle la paire d'électrons libres est apparemment stéréochimiquement active et elle occupe une position équatoriale dans une bipyramide trigonale déformée. Dans les deux molécules, les angles S-Te-S sont de 166,87(6) et 162,0(1)° pour les molécules **8** et **9** respectivement. Dans chacune des molécules, les liaisons Te—S vers les groupes dithiocarbamates sont légèrement plus courtes que celles dans les dithiocarbonates. Les groupes dithiocarbonates sont orientés de façon à donner des interactions secondaires impliquant les atomes de soufre apparemment terminaux; il en résulte des distances Te—S de 3,205(2) et 3,277(4) Å pour les composés **8** et **9** respectivement. Toutefois, seul le composé **9** donne lieu à une distance Te—S semblable, 3,346(5) Å, impliquant le groupe S_2COMe; cette situation résulte du fait que, dans le composé **8**, c'est le groupe OEt du S_2COEt qui est orienté vers le Te et non l'atome S terminal.

Mots clés : structure, tellure, méthyle, dithiocarbamates, dithiocarbamates, dithiophosphonates.

[Traduit par la Rédaction]

Introduction

Several reports have appeared on organotellurium(IV) compounds with a variety of 1,1-dithio ligands including *O*-alkyl dithiocarbonates (1–6), *N*,*N*-dialkyl dithiocarbamates (5–14), and *O*,*O*-dialkyl (alkylene) dithiophosphates (4–6, 13–20), but relatively few refer to the formation of mixed ligand moieties, such as those of the general type

$RTeL_2L'$ (14) or R_2TeLL' (21). We report on the synthesis of nine dimethyltellurium(IV) compounds with mixed 1,1-dithio ligands along with their characterization by ^1H, ^{13}C, ^{31}P, and ^{125}Te NMR spectroscopy, infrared and Raman spectroscopy, and elemental analysis. X-ray crystal structures of $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, and $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, confirm that these are mixed ligand species and not 1:1 mixtures of the bis derivatives.

Experimental

Materials

$TeCl_4$, Me_4Sn, NaS_2CNMe_2, and NaS_2CNEt_2 were obtained from Aldrich, and the latter two were dried in vacuo for 4–5 days prior to use. Me_2TeCl_2 was prepared by the reaction of $TeCl_4$ and Me_4Sn in toluene at 60°C under reflux for 4 h by adaptation of the method used for the preparation of Ph_2TeCl_2 (22). $Me_2TeCl[S_2CNMe_2]$ and $Me_2TeCl[S_2CNEt_2]$ were prepared as described in the literature (12) as were the sodium and ammonium salts of *O,O*-alkylene dithiophosphatic acids and the potassium salts of *O*-alkyl dithiocarbonic acids (23, 24). All solvents were dried and distilled prior to use, and all reactions carried out under anhydrous conditions.

Preparation of dimethyl(*N,N*-alkyl dithiocarbamato)(*O,O*-alkylene dithiophosphato)tellurium(IV) compounds

Typically, $NaS_2POCMe_2CMe_2O$ (ca. 1.4 mmol) was added to a solution of an equimolar amount of Me_2TeCl_2 in dried dichloromethane (20 mL). The mixture was stirred for 2 h and then filtered to remove NaCl and unreacted dithiophosphate salt. The solvent was reduced to 5 mL under vacuum, *n*-hexane (5 mL) was added, and the solution left overnight in the refrigerator at –6°C. The resulting crystals were washed with *n*-hexane and dried in vacuum to give $Me_2TeCl[S_2POCMe_2CMe_2O]$ as white crystals. $Me_2TeCl[S_2POCMe_2CMe_2O]$ (0.470 g, 1.16 mmol) was then dissolved in dichloromethane (20 mL), NaS_2CNMe_2 (0.168 g, 1.17 mmol) added with constant stirring, and the colorless solution turned yellow. The mixture was stirred for 2 h at ambient temperature and then filtered to remove NaCl or any unreacted dithiocarbamate salt. The volume of the solvent was reduced to 5 mL, *n*-hexane (5 mL) was added, and the solution was left overnight in the refrigerator at –6°C. The solvent was decanted off the crystals, which were then pumped on to dryness on the vacuum line to give $Me_2Te[S_2CNMe_2][S_2POCMe_2CMe_2O]$, **1**, as yellow crystals (0.459 g, yield 81%; mp 129°C). Anal. calcd. for $C_{11}H_{24}NO_2PS_4Te$: C 27.01, H 4.95; found: C 26.85, H 4.75. Similarly, using NaS_2CNEt_2 was formed $Me_2Te[S_2CNEt_2][S_2POCMe_2CMe_2O]$, **2**, as yellow crystals (yield 86%, mp 127–128°C). Anal. calcd. for $C_{13}H_{28}NO_2PS_4Te$: C 30.20, H 5.46; found: C 29.74, H 5.28. Similarly, starting with $Me_2TeCl[S_2POCH_2CMe_2CH_2O]$ was formed $Me_2Te[S_2CNMe_2][S_2POCH_2CMe_2CH_2O]$, **3**, as yellow crystals (yield 83%, mp 114–115°C). Anal. calcd. for $C_{10}H_{22}NO_2PS_4Te$: C 25.28, H 4.67; found: C 25.58, H 4.54. $Me_2Te[S_2CNEt_2][S_2POCH_2CMe_2CH_2O]$, **4**, as yellow crystals (yield 87%, mp 88–89°C). Anal. calcd. for $C_{12}H_{26}NO_2PS_4Te$: C 28.64, H 5.21; found: C 28.43, H 5.27. Unfortunately, no crystals suitable for X-ray diffraction studies were obtained for compounds **1**–**4** despite extensive efforts at recrystallization.

Preparation of dimethyl(*O*-alkyl dithiocarbonato)(*O,O*-alkylene dithiophosphato)tellurium(IV) compounds

In a manner essentially the same as described above, the reaction of $Me_2TeCl[S_2POCMe_2CMe_2O]$ (0.234 g, 0.58 mmol) in dichloromethane (20 mL) with KS_2COMe (0.087 g, 0.59 mmol) gave $Me_2Te[S_2COMe][S_2POCMe_2CMe_2O]$, **5**, as pale-yellow crystalline material: 0.223 g, yield 81%, mp 87–88°C. Anal. calcd. for $C_{10}H_{21}O_3PS_4Te$: C 25.23, H 4.45; found: C 25.30, H 4.85. Similarly, using KS_2COEt was formed $Me_2Te[S_2COEt][S_2POCMe_2CMe_2O]$, **6**, as pale-yellow crystals: yield 83%, mp 72°C. Anal. calcd. for $C_{11}H_{23}O_3PS_4Te$: C 26.96, H 4.73; found: C 27.07, H 4.83. Unfortunately, attempts to grow X-ray quality crystals of **5** and **6** were not successful.

Preparation of dimethyl(*N,N*-dialkyl dithiocarbamato)(*O*-alkyl dithiocarbonato)tellurium(IV) compounds

Typically, KS_2COMe (0.154 g, 1.05 mmol) was added, with constant stirring, to a solution of $Me_2TeCl[S_2CNMe_2]$ (0.324 g. 1.03 mmol) in dichloromethane (20 mL). The colorless reaction mixture changed to yellow after a few minutes. The stirring was continued for 1 h after which KCl and unreacted dithiocarbonate salt were filtered off before the solvent was pumped off under vacuum to yield a yellow powder. The crude product was recrystallized from dichloromethane–*n*-hexane to give $Me_2Te[S_2CNMe_2][S_2COMe]$, **7**, as yellow crystals: 0.176 g, yield 88%, mp 95–97°C. Anal. calcd. for $C_7H_{15}NOS_4Te$: C 21.84, H 3.93; found: C 22.22, H 3.85. Similarly were obtained $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, as yellow crystals: yield 88%, mp 106–108°C. Anal. calcd. for $C_8H_{17}NOS_4Te$: C 24.08, H 4.29; found: C 24.15, H 4.18. $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, as yellow crystals: yield 89%, mp 75–77°C. Anal. calcd. for $C_9H_{19}NOS_4Te$: C 26.17, H 4.62; found: C 25.56, H 4.71. X-ray quality crystals were obtained for compounds **8** and **9**, but not for **7** despite extensive attempts at recrystallization.

Alternative synthesis of $Me_2Te[S_2CNMe_2][S_2POCMe_2CMe_2O]$, 1, and compounds 2–6

In essentially the same manner as described above, $NH_4S_2POCMe_2CMe_2O$ (0.124 g, 0.54 mmol) was added, with constant stirring, to a solution of $Me_2TeCl[S_2CNMe_2]$ (0.165 g, 0.53 mmol) in dichloromethane (20 mL). The colorless reaction mixture immediately changed to yellow. The reaction mixture was stirred for 2 h, filtered to remove NH_4Cl or any unreacted dithiophosphate salt, and then *n*-hexane (approximately 5 mL) was added after the solvent had been reduced to 5 mL by pumping. Crystals were formed when the solution was left overnight in the refrigerator at –6°C. The solvent was decanted and the crystals pumped to dryness to give $Me_2Te[S_2CNMe_2][S_2POCMe_2CMe_2O]$, **1**, as yellow crystals: 0.218 g, yield 85%, mp 129°C. Similarly were formed compounds **2**–**6**.

Alternative in situ preparation of $Me_2Te[S_2CNMe_2][S_2COMe]$, 7

Typically, NaS_2CNMe_2 (0.147 g, 1 mmol) was added to a solution of Me_2TeCl_2 (0.228 g, 1 mmol) in dried carbon

disulfide or dichloromethane (20 mL). The reaction mixture was stirred for 2 h, and then KS_2COMe (0.146 g, 1 mmol) was added before the mixture was stirred for a further 2 h. The resulting mixture was filtered to remove NaCl, KCl, and unreacted materials, and the solvent reduced to 5 mL under vacuum before *n*-hexane (5 mL) was added. A yellow powder resulted, which was dried under vacuum after the solvent was decanted. The compound was recrystallized from dichoromethane–*n*-hexane to give $Me_2Te[S_2CNMe_2][S_2COMe]$, **7**, as yellow crystals: 0.280 g, yield 72%, mp 95–97°C. All of the compounds **1**–**9** were also prepared in this manner.

Physical measurements

Elemental analyses were performed at Guelph Chemical Laboratories, Guelph, Ontario. The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker 300 FT/NMR spectrometer in $CDCl_3$ using Me_4Si as internal standard. The ^{31}P and ^{125}Te NMR spectra were recorded on a Bruker 200 FT/NMR spectrometer in $CDCl_3$ using 85% H_3PO_4 andMe_2Te, respectively, as external standard. The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as KBr pellets and far infrared spectra on a Bomem IR spectrometer between polyethylene films as Nujol mulls. Raman spectra were recorded using samples in sealed capillary tubes on a Spectra-Physics 164 spectrometer using the 5145 Å exciting line of an argon ion laser. The melting points were determined on a Fisher–Johns apparatus.

X-ray crystallographic analysis

Pale yellow block-shaped crystals of $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, and $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, were sealed in thin-walled glass capillaries and mounted on a Rigaku AFC6S diffractometer, with graphite-monochromated MoKα radiation.

Cell constants corresponded to triclinic and monoclinic cell for **8** and **9**, respectively, whose dimensions are given in Table 1, along with other experimental parameters. Based on the appropriate systematic absences for **9**, statistical analyses of intensity distributions, and the successful solution and refinement of the structures, the space groups were determined to be $P\bar{1}$ (no. 2) for **8** and $P2_1/c$ (no. 14) for **9**. The data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied.

The structures were solved by direct methods (25), and all calculations were performed using the TEXSAN (26) crystallographic software package of Molecular Structure Corp.[2]

[2] Least-squares function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/(\mathrm{Lp})^2$, S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, Lp = Lorentz-polarization factor, and p = p factor.

© 1999 NRC Canada

The non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were included in their idealized positions with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached.

The weighted and unweighted agreement factors and standard deviation of an observation of unit weight[3] are given in Table 1. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, sin θ/λ, and various classes of indices showed no unusual trends. Interatomic distances and bond angles are given in Table 2, and the molecular structures of the two compounds are displayed as ORTEP diagrams in Figs. 1–4. The final atomic coordinates and equivalent isotropic thermal parameters for the non-hydrogen atoms, anisotropic thermal parameters for non-hydrogen atoms, and final fractional coordinates and thermal parameters for hydrogen atoms, have been deposited.[4]

Calculation of Pauling partial bond order

The formula proposed by Pauling (27) for calculating the bond orders of partial bonds is given by $d_n - d = -0.60 \log n$, where d_n is the bond length for bond number, n, and d is the length of the single bond of the same type. Based on the C—C single bond of 1.54 Å, Pauling's formula gives bond lengths of 1.36 Å for $n = 2$; 1.72 Å for $n = 0.5$; and 1.90 Å for $n = 0.25$. These give percentage increases in bond length for the partial bonds of approximately 12 and 23%, respectively, for $n = 0.5$ and 0.25. It is reasonable to assume that similar relationships relating bond order to interatomic distances for the much longer secondary interactions or partial bonds involving Te and S should utilize percentage differences "normalized" to 1.54 as follows rather than absolute differences.

Pauling's relationship, which can be written as $n = 10^X$, where $X = (d - d_n)/0.6$, can be modified to allow for percentage differences normalized to 1.54 to give $X = [1.54(d - d_n)/d]/0.6$ or $X = 2.5(d - d_n)/d$. Based on a Te—S single bond length of 2.63 Å, typical calculated values of the lengths of partial bonds for various values of n are as follows: 1.0, 2.63; 0.75, 2.76; 0.50, 2.95; 0.25, 3.26; 0.10, 3.68; n, bond length (Å). This scale appears to be compatible with the sum of the van der Waals radii of 3.86 Å for Te and S (28).

Results and discussion

The preparation of a variety of dimethyltellurium(IV) compounds with two different 1,1 dithio ligands is achieved in 80–90% yield by the action of approximately equimolar amounts of the sodium or potassium salt of a dithiocarbamic or dithiocarbonic acid with an *O,O*-alkylene dithiophosphate or *N,N*-dialkyl dithiocarbamate derivative of chlorodimethyltellurium(IV) such as $Me_2TeCl[S_2POCMe_2CMe_2O]$, $Me_2TeCl[S_2POCH_2CMe_2CH_2O]$, or $Me_2TeCl[S_2CNMe_2]$ in dichloromethane, in accord with the eqs. [1]–[3]:

[1] $Me_2TeCl[S_2\overline{POGO}] + NaS_2CNR_2 \rightarrow Me_2Te[S_2CNR_2][S_2\overline{POGO}]$

[2] $Me_2TeCl[S_2\overline{POCMe_2CMe_2O}] + KS_2COR' \rightarrow Me_2Te[S_2COR'][S_2\overline{POCMe_2CMe_2O}]$

[3] $Me_2TeCl[S_2CNR_2] + KS_2COR' \rightarrow Me_2Te[S_2CNR_2][S_2COR']$

(G = -CMe_2CMe_2-, -$CH_2CMe_2CH_2$-; R = Me, Et; R′ = Me, Et)

These mixed ligand dimethyltellurium(IV) compounds can also be formed in similar yields by the addition of the ammonium salt of the dithiophosphoric acid to chlorodimethyl (*N,N*-dialkyl dithiocarbamato)tellurium(IV) as exemplified by eq. [4]:

[4] $Me_2TeCl[S_2CNMe_2] + NH_4S_2\overline{POCMe_2CMe_2O} \rightarrow Me_2Te[S_2CNMe_2][S_2\overline{POCMe_2CMe_2O}]$

The Me_2TeClL species can also be prepared in situ in which case the reaction involves the complete addition of an equimolar amount of the salt of one 1,1-dithio acid to dimethyltellurium dichloride, the removal of insoluble salts, and the addition of an equimolar amount of the salt of a different 1,1-dithio acid, as exemplified by eqs. [5] and [6]. The overall yield based on Me_2TeCl_2 is close to 70%

[5] $Me_2TeCl_2 + KS_2COR' \rightarrow Me_2TeCl[S_2COR'] + KCl$

[6] $Me_2TeCl[S_2COR'] + NaS_2CNR_2 \rightarrow Me_2Te[S_2CNR_2][S_2COR'] + NaCl$

Solid samples of compounds **1**–**9** are stable over extended periods, particularly when stored in the refrigerator, as can be confirmed by the fact that NMR spectra recorded after several months show no changes from the spectra recorded immediately after the formation of the compounds. All of the compounds are soluble in common organic solvents such as benzene, toluene, carbon disulfide, dichloromethane, and chloroform, the later being used as the solvent for spectroscopic studies. The vibrational spectra as well as the NMR spectra of the freshly prepared samples provide definitive evidence that these compounds are indeed the mixed ligand species, Me_2TeLL', and not 1:1 mixtures of the bis species Me_2TeL_2 and $Me_2TeL'_2$. This is of course further confirmed by the X-ray structures of **8** and **9**. The NMR spectra recorded over time also indicate that eventually all derivatives, Me_2TeLL', slowly disproportionate to the two bis derivatives, Me_2TeL_2 and $Me_2TeL'_2$. The three species appear to be in equilibrium because the addition of more Me_2TeL_2 to a solution brings about the expected changes in the relative

[3] Standard deviation of an observation of unit weight: $\Sigma w(|F_o| - |F_c|)^2/(N_o - N_v)^{1/2}$, where N_o = number of observations and N_v = number of variables.

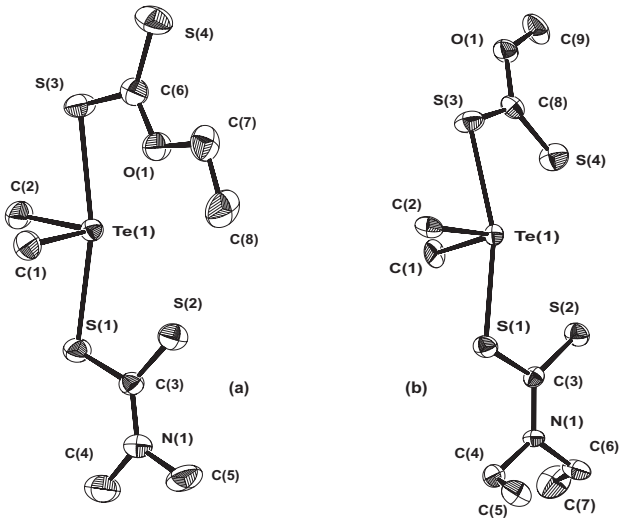
Fig. 1. ORTEP plots of the molecules (*a*) $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, and (*b*) $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**. Atoms are drawn with 30% probability ellipsoids and spheres with hydrogen atoms omitted for clarity.

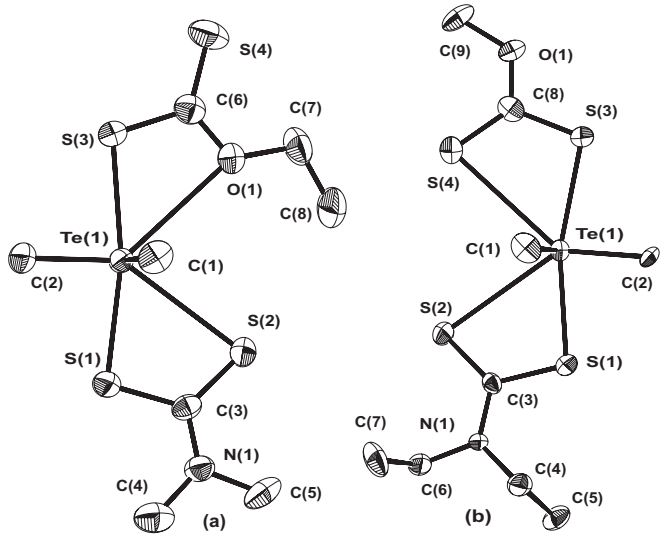


amounts of Me_2TeLL' and $Me_2TeL'_2$. However, all three species, simultaneously also undergo reductive elimination to Me_2Te and the diligands, so that the spectra become very complicated. Qualitatively, the reductive elimination does not appear to be a reversible process so eventually the solution becomes depleted of tellurium(IV) species. Qualitatively, the disproportionation and reductive elimination appear to be most evident for derivatives containing dithiocarbonate ligands and least evident for those containing the cyclic dithiophosphate ligands.

Crystal structures of $Me_2Te[S_2CNMe_2][S_2COEt]$, 8, and $Me_2Te[S_2CNEt_2][S_2COMe]$, 9

$Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, crystallizes in the space group $P\bar{1}$ and $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, in $P2_1/c$. The ORTEP diagrams in Fig. 1*a* and 1*b* illustrate that in both compounds the immediate environment about tellurium is that of the sawhorse structure typical of tellurium(IV) compounds in which the lone pair is assumed to be active stereochemically and occupying an equatorial position in a distorted trigonal bipyramid, approximately in the position of the Te(1) label. The two methyl groups occupy the other two equatorial positions; the C-Te-C bond angles of 95.3(3)° and 96.4(7)° in **8** and **9**, respectively, being close to the value of 96(1)° in $Me_2Te[S_2CN(CH_2)_3CH_2][S_2CN(CH_2)_4CH_2]$ (21), and similar to those of 93.9(2)°, 96.6(2)°, and 96.2(2)° in related bis derivatives, $Me_2Te[S_2CNMe_2]_2$ (12), $Me_2Te[S_2COMe]_2$ (1),and $Me_2Te[S_2COEt]_2$ (2), respectively. The average Te—C bond length of 2.12(1) Å in **8** and **9** is essentially the same as that in $Me_2Te[S_2NCMe_2]_2$ and the two $Me_2Te[S_2COR]_2$ species. The S-Te-S bond angle of 166.87(6)° for the axial sulfur atoms in **8** is close to that in the mixed species, $Me_2Te[S_2CN(CH_2)_3CH_2][S_2CN(CH_2)_4CH_2]$ (166.1(2)°), as well as in $Me_2Te[S_2NCMe_2]_2$ and $Me_2Te[S_2COR]_2$ (167.58(7)° and166.2(2)° avg., respectively). By contrast, the value of 162.0(1)° in **9** is the same as in $Me_2Te[S_2CN(CH_2)_3CH_2]_2$ (21), so it is difficult to detect an obvious pattern or trend. The two Te—S bonds in the

Fig. 2. ORTEP plots of the molecules (*a*) $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, and (*b*) $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, showing the stereochemistry about tellurium when the intramolecular interactions leading to unsymmetrical ligands are included. The atoms are drawn with 30% probability ellipsoids and spheres. Hydrogen atoms are omitted for clarity.



bis species $Me_2Te[S_2NCMe_2]_2$, $Me_2Te[S_2COMe]_2$, and $Me_2Te[S_2COEt]_2$ have an average value of 2.63(1) Å, even though in all three cases the two Te—S bonds have quite different lengths ranging from 2.566(1) to 2.680(1) Å. In **8** and **9**, the Te—S bonds to the S_2CNR_2 groups, 2.620(2) in **8** and 2.608(5) Å in **9**, are shorter than those to the S_2COR groups, 2.650(2) in **8** and 2.620(5) Å in **9**. In the absence of any Te--S associations involving the bonded S atom at contact distances less than the sum of the van der Waals radii of 3.86 Å (28), bonding to dithiocarbamates is apparently slightly favored.

The pendant sulfur atoms in the dithiocarbamate groups are oriented toward the tellurium center to give Te—S anisobonds of 3.205(1) in **8** and 3.277(4) Å in **9** (see Fig. 2*a* and 2*b*). These values are typical for analogous dithiocarbamates and correspond to normalized Pauling partial bond orders of about 0.25, which is compatible with their being part of the coordination sphere. Similar Te—S anisobonds, varying from 3.274(2) to 3.521(1) Å, occur in $Me_2Te[S_2COMe]_2$ and $Me_2Te[S_2COEt]_2$ (2) as well as in the two independent molecules of $Me_2TeCl[S_2COEt]$ with values of 3.210(3) and 3.292(3) Å (29). Similarly, in $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, there is an anisobond between Te(1)—S(4) of 3.346(5) Å involving the S_2COMe group (see Fig. 2*b*). Surprisingly, the orientation of the S_2COEt group in $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, is such that the second sulfur atom is turned away from tellurium so that Te(1)—S(4) is 5.085(2) Å and so clearly not bonded (see Fig. 2*a*). The intramolecular association now involves the oxygen of the OEt group with a Te(1)—O(1) distance of 3.145(5) Å. In a study of analogous monothiocarbonates (30), the terminal oxygen atom is oriented toward the tellurium center in $Me_2Te[SCO_2(i\text{-}Pr)]_2$ and $Me_2TeCl[SCO_2Me]$, with Te—O (terminal) distances averaging 3.05(8) Å in the former and 2.948(8) Å in the latter. However, in $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, one of the $SCO_2(i\text{-}Pr)$ groups has a Te—O

Fig. 3. Plot of the molecule $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, showing the intermolecular interactions involving the anisobonded sulfur atoms leading to a dimer. Hydrogen atoms and the carbon atoms of the phenyl rings other than those attached to phosphorus are omitted for clarity.

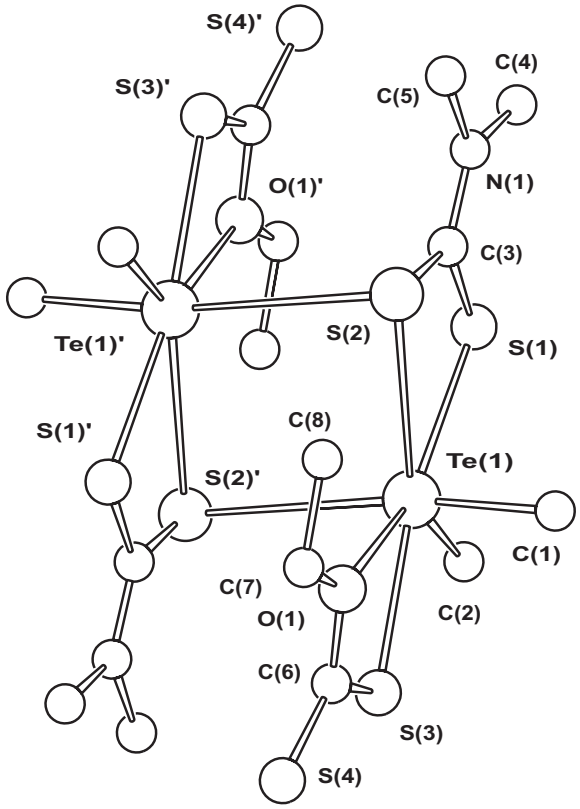

Fig. 4. Plot of the molecule $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, showing the intermolecular interactions involving the anisobonded sulfur atoms leading to a dimer. Hydrogen atoms and the carbon atoms of the phenyl rings other than those attached to phosphorus are omitted for clarity.

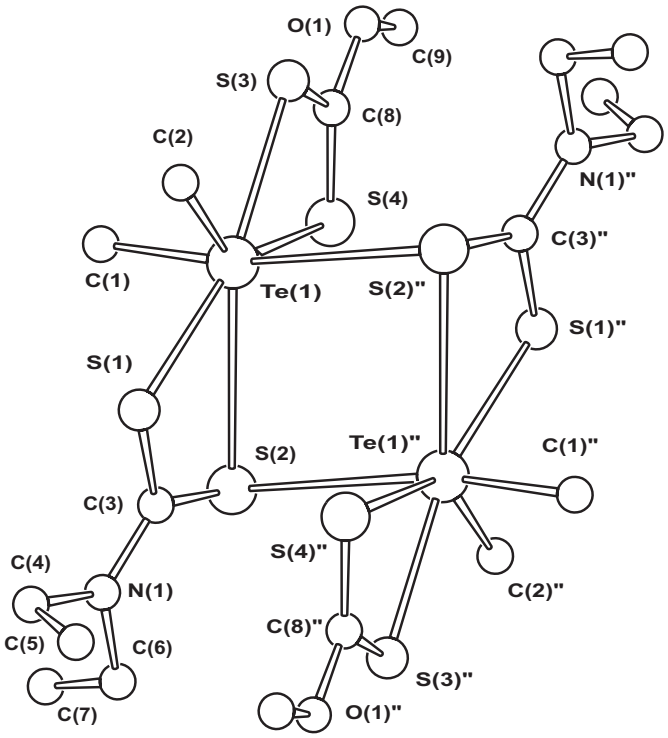

(terminal) distance of 3.050(5) Å, but the other is oriented so that the Te—O(i-Pr) distance is 3.150(5) Å. This orientation is repeated in $Me_2TeBr[SCO_2(i\text{-}Pr)]$ where the Te—O(i-Pr) distance is 2.930(6) Å. Thus, again it is difficult to detect a consistent trend.

In $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, the orientations of the dithiocarbamate and dithiocarbonate groups result in the five atoms, S(1), S(2), S(3), S(4), and C(2), as well as Te(1) forming an approximate plane (mean deviation from plane of 0.1164 Å) with C(1) above the plane (2.06(1) Å) to give an approximate pentagonal pyramidal arrangement about Te(1) or a pentagonal bipyramidal arrangement if the lone pair is assumed to be occupying the axial position *trans* to C(1) (see Fig. 2*b*). The two planar S_2CN and S_2CO cores of the dithio groups have a dihedral angle of 10.4(1)°. By contrast, in $Me_2Te[S_2CN(CH_2)_3CH_2][S_2CN(CH_2)_4CH_2]$, the dihedral angle between the two different dithiocarbamate groups is only 1.4(1)°. Despite the fact that the oxygen atom of the OEt group is turned toward tellurium in $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, rather than the terminal sulfur atom as can be seen from Fig. 2*a*, there is still an approximate plane (mean deviation from plane of 0.0946 Å) around tellurium with the five atoms, S(1), S(2), S(3), C(2), and now O(1) as well as Te(1) forming the plane with C(1) above the plane (2.08(1) Å). The two planar S_2CN and S_2CO cores of the dithio groups have a dihedral angle of only 3.9(1)°. Similar pentagonal planes appear to be a common feature for dimethyltellurium derivatives with sulfur ligands having been reported for $Me_2Te[S_2COR]_2$ (1, 2), $Me_2Te[SCO_2R]_2$ (30), $Me_2Te[SCONR_2]_2$ (31), and $Me_2Te[S_2CN(CH_2)_3CH_2]_2$ (21), where the two dithio groups have small dihedral angles. However, by contrast, in $Me_2Te[S_2CN(CH_2)_4CH_2]_2$, the orientation of the two dithiocarbamates results in a dihedral angle between the two planar S_2CN cores being 69.6(2)° so that the arrangement about tellurium is better described as a distorted octahedral with the lone pair apparently inactive (21). A similar arrangement is found in $Ph_2Te[S_2COEt]_2$ so again it is difficult to identify factors that determine these orientations.

An examination of possible intermolecular associations reveals that both **8** and **9** have similar Te--S′ interactions involving only the anisobonded sulfur atoms of the dithiocarbamate groups as is illustrated by Figs. 3 and 4. The Te(1)—S(2)′ distances are 3.567(2) and 3.585(5) Å for **8** and **9**, respectively, which correspond to bond orders close to 0.15, leading to pseudo-dimers. Thus, despite the different orientations of the dithiocarbonate groups in **8** and **9**, neither of which show any intermolecular distances indicative of associations, similar dimeric units are formed in **8** and **9** by bridges in which the Te(1)-S(2)--Te′(1) and S(2)-Te(1)--S′(2) angles are 72.72(4)° and 107.28(4)°, respectively, for **8** (see Fig. 3) and 72.63(9)° and 107.37(9)°, respectively, for **9** (see Fig. 4). A similar bridging system is found in $Me_2TeI[S_2CN(CH_2)_3CH_2]$, where, in contrast with the $Me_2TeX[S_2CN(CH_2)_4CH_2]$ analogues which all have the halogen atoms acting as bridges, a rectangular bridge again

© 1999 NRC Canada

leads to pseudo-dimers with Te(1)-S(2)--Te′(1) and S(2)-Te(1)--S′(2) angles of 76.19(9)° and 103.8(1)°, respectively (21). Surprisingly, there are no comparable Te--S--Te bridges in the bis-$Me_2Te[S_2CN(CH_2)_nCH_2]_2$ species. In general, dithiocarbonates apparently do not tend to form intermolecular interactions through the sulfur atoms.

As with other dithiocarbamates, the (Te)S-C-N angles are all less than 120°, at 117.0(5)° and 114(1)° for **8** and **9**, respectively, whereas the (Te)S-C-S and S-C-N angles are all over 120°, averaging 122(1)°, which is consistent with the π-bond delocalization within the S_2CN planar moiety being of greater importance in the S_2C—N and TeS(N)C—S bonds. The (Te)S—C bonds (1.756(9) Å avg.) are typical of an S—C bond attached to the stronger Te—S bond in anisobidentate di- and monothiocarbamate derivatives (31) and also shorter than the sum of the covalent radii of C and S of 1.81 Å, suggesting a small degree of participation in the delocalized π-bonding. The C—S bond involving the anisobonded sulfur atom is shorter, with an average length of 1.676(9) Å. This is still considerably longer than a C=S bond (ca. 1.56 Å in CS_2, COS, or CSTe (32)) but similar to that observed in species such as $(NH_2)_2CS$ and thus consistent with a considerable degree of partial π-bond character as well as an anisobidentate link. Not only are the dithiocarbonate groups planar in terms of the sulfur and oxygen atoms about the central carbon, with a mean deviation of 0.003 Å in **8** and 0.004 Å in **9**, but so to a first approximation are the ethyl and methyl groups; C(7) and C(8) being out of plane by only 0.050 and 0.068 Å, respectively, in **8** and C(9) only 0.018 Å out of the plane in **9**. The terminal C=S bond in **8** (1.633(7) Å) is apparently shorter than the anisobonded C=S(--Te) bond in **9** (1.66(2) Å), and conversely, the C—STe bond in **8** (1.74(2) Å) is longer than in **9** (1.729(7) Å). The bond lengths and angles within the S_2CO moiety are in the same range as those reported for $Me_2Te[S_2COEt]_2$ (2), $Me_2Te[S_2COMe]_2$ (1), and $Me_2TeCl[S_2COEt]_2$ (29), which emphasizes the rigidity of the ligand regardless of its orientation about tellurium or whether it is in a mixed ligand species, bis compound, or haloderivative.

The S(1)-Te(1)-S(2) bite angles of the two dithiocarbamate groups are 60.89(2)° and 59.7(1)° with "bites" of 2.994(3) and 2.987(6) Å in **8** and **9**, respectively, which are typical of anisobidentate dithiocarbamates. Similarly, the S(3)--S(4) bite angle in **9** of 59.1(1)° in the dithiocarbonate is close to the average of the two angles in $Me_2Te[S_2COEt]_2$ (2). In view of the rigidity of the planar groups, not surprisingly, the S(3)—S(4) distances in **8** and **9** are similar.

Infrared and Raman spectra

Selected features in the infrared and Raman spectra and their assignments are given in Table 3. In considering these mixed species, it is useful to establish those features among the plethora of peaks, especially those associated with the presence of the CH_3 and CH_2 groups, that most clearly identify the presence of the particular dithiocarbamate, dithiocarbonate, or alkylene dithiophosphate group. In tellurium dithiocarbamate species, a distinctive peak in the infrared spectrum between 1484 and 1508 cm^{-1} corresponds to the ν(C-NR_2) stretching vibration, and one generally of medium intensity in both effects between 963 and 985 cm^{-1} corresponds to the ν(C-S) stretch of the terminal or aniso sulfur atom (7, 8, 12). In tellurium dithiocarbonates, three strong features define the presence of stretching modes involving the stretching of the CO and CS bonds within the moiety S_2COC. As was confirmed by normal coordinates analyses, there is considerable mixing amongst these modes that are seen at ca. 1200, 1120, and 1040 cm^{-1}, and hence, they are assigned as $\nu(S_2COC)_a$, $\nu(S_2COC)_b$, and $\nu(S_2COC)_c$, respectively (29). Strong bands in the infrared spectra in the region 995–900 cm^{-1} provide characteristic features indicative of the presence of the alkylene dithiophosphate group in $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$, which are attributable to ring vibrations that are probably coupled with C-C stretching vibrations (20, 30, 31). In compounds **1**–**9**, the above features are seen for the appropriate groups at similar, but not identical positions, to the corresponding bis compounds. Thus, for example, for $Me_2Te[S_2CNMe_2][S_2POCH_2CMe_2CH_2O]$ (**3**), ν(C-NR_2) and ν(C-S) are seen at 1517 and 968 cm^{-1}, respectively, in the infrared and Raman spectra, compared to 1491 and 973 cm^{-1} in $Me_2Te[S_2CNMe_2]_2$ (12), and the most distinct ring vibration in $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$ at 994 cm^{-1} is seen at 985 cm^{-1} in **3**. All of this data is indicative of the presence of a mixed species rather than a mixture of two bis compounds.

The characteristic peaks corresponding to the Te-C asymmetric and symmetric stretches are prominent in all of the Raman spectra of **1**–**9**, in general having values for ν(Te-C)asym (531–541 cm^{-1}) that are closer to those found in $Me_2Te[S_2COR]_2$ or $Me_2TeCl[S_2COR]$ (533–544 cm^{-1}) than to $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$ (ca. 529 cm^{-1}) (20). In $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, whose structure has been described above, the two Te-S stretches are assigned to 359 and 317 cm^{-1}, compared to the asymmetric and symmetric stretches in $Me_2Te[S_2CNMe_2]_2$ (362 and 349 cm^{-1}) and $Me_2Te[S_2COEt]_2$ (382 and 301 cm^{-1}), which is of course consistent with the mixed compound rather than a mixture, as can be illustrated for all nine compounds. While the mixing between the two Te-S modes is going to still be significant in **1**–**9**, the groups are not equivalent as in bis compounds. The Te—S bond to the dithiocarbamate is slightly shorter, so the band at 359 cm^{-1} probably has a greater contribution from Te-S(CNR_2) and that at 317 cm^{-1} a corresponding contribution from Te-S(COR). Both bands are seen at slightly higher wave number in $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**, at 369 and 328 cm^{-1}, which is at least consistent with both bonds being slightly shorter in **9** than in **8**. For the compounds containing a dithiophosphate group, **1**–**6**, it is reasonable to assign the band at higher wave number as having more contribution from Te-S(CNR_2) or Te-S(COR), because in the bis compounds, $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$, the Te-S stretches were assigned at lower wave number than in the bis dithiocarbamates and -carbonates (20).

NMR spectra

The $^{13}C\{^1H\}$ NMR spectral data for compounds **1**–**9** are presented in Table 4. Although the peaks corresponding to the S_2CN and S_2CO carbon atom are the weakest in every spectrum, they provide definitive evidence for the formation

of the mixed ligand Me_2TeLL' species. Thus, for example, in the spectrum of $Me_2Te[S_2CNMe_2][S_2COMe]$, **9**, for which we have the solid state structure, two peaks are seen at 198.9 and 222.2 ppm which correspond to the S_2CN and S_2CO peaks, respectively. These are shifted slightly but definitively from those of the corresponding bis species, $Me_2Te[S_2CNMe_2]_2$ at 200.0 and $Me_2Te[S_2COMe]_2$ at 220.9 ppm (12, 2). When the spectra are rerecorded after 24 h, two additional peaks corresponding to the two bis species are present. Identical features are seen in the spectra of compounds **7** and **8**. In compounds **1**–**4**, which contain a cyclic dithiophosphate instead of a dithiocarbonate, the shift of the S_2CN carbon is more marked.

The peak attributed to the $TeCH_3$ carbon is at 17.32 ppm in $Me_2Te[S_2CNMe_2][S_2POCMe_2CMe_2O]$, **1**, which is slightly less than the average value of the chemical shift for their bis analogues $Me_2Te[S_2POCMe_2CMe_2O]_2$ and $Me_2Te[S_2CNMe_2]_2$, which are at 19.2 and 16.6 ppm, respectively (12, 20). The chemical shifts in **2**–**4** range from 17.29 to 17.55 ppm but in compounds **5** and **6** are at ca. 16.9 ppm, which is closer to the value of ca. 15.6 ppm found in the bis dithiocarbonates (2). In the mixed ligand compounds that contain dithiocarbamate and -carbonate, **7**–**9**, the $TeCH_3$ shifts are essentially the average of the bis species, so the contributions appear to be additive. All of the carbon atoms in the ligands have very similar, though not identical, chemical shifts to those observed in the analogous bis compounds (2, 12, 20). The doublets arising from P-C coupling and the values of the J^{PC} coupling constants are as observed for the bis compounds and (or) related cyclic dithiophosphate derivatives (20, 33).

The $^{31}P\{H\}$ NMR spectra of fresh samples show single peaks (see Table 4) in the region 107.5–110.0 ppm for compounds **1**, **2**, **5**, and **6**, relative to a peak at 105.0 ppm in $Me_2Te[S_2POCMe_2CMe_2O]_2$, and at 97.6 and 98.1 ppm for compounds **3** and **4**, respectively, relative to 92.0 ppm in $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$ (20). These constitute downfield shifts relative to the free cyclic dithiophosphoric acids of the order of 15.1–17.6 ppm when a dithiocarbamate is present with the dithiophosphate and of the order of 20.5–21.0 ppm when a dithiocarbonate is present. These shifts appear to favor the concept that the dithiophosphates are essentially bidentate in solution (34), presumably through rapid exchange. When the spectra were recorded again after the solutions had been left standing, peaks at 105 or 92 ppm were observed arising from the formation of $Me_2Te[S_2POCMe_2CMe_2O]_2$ or $Me_2Te[S_2POCH_2CMe_2CH_2O]_2$, respectively, as the result of disproportionation and grew over several days to be approximately equal in height with that of the Me_2TeLL' species.

The ^{125}Te NMR spectra of freshly prepared solutions (Table 4) show a single peak whose chemical shift is reasonably close to the average value for the related bis compounds and hence in the range 519–528 ppm for compounds **1**–**4**, 539 and 536 ppm for **5** and **6**, and 474–491 ppm for **7**–**9**. The spectra of compounds **7**–**9** show evidence of the presence of the bis species, indicating that disproportionation is already significant in the time taken to run a ^{125}Te NMR spectrum in species that do not contain a cyclic dithiophosphate. Over a period of approximately three days, the relative peak heights of the bis species increase, although all are decreasing in intensity. The peak due to $Me_2Te[S_2COR]_2$ dies away more rapidly, presumably reflecting the fact that the dithiocarbonate derivatives more readily undergo reductive elimination to Me_2Te and diligand.

The ^1H NMR spectral data for compounds **1**–**9** are summarized in Table 5. The splitting patterns and intensities of peaks in the ^1H NMR spectra of all of these compounds are found to be consistent with the structures of **7** and **8**, and by extension to all of the other derivatives. All compounds, **1**–**9**, show a sharp singlet assignable to the CH_3 groups attached to tellurium in the range 2.45–2.54 ppm. The CH_3Te chemical shifts are close to but not quite additive for compounds **1**–**6** and essentially additive for **7**–**9** in that they all lie close to the average value of the two analogous bis derivatives. As was the case for the ^{13}C NMR spectra, the chemical shifts of protons within the ligands are close to but not identical to those of the bis ligand species. In all derivatives containing a dithiocarbamate group, compounds **1**–**4** and **7**–**9**, the two CH_3 or CH_3CH_2 groups show no signs of nonequivalence despite the fact that the nitrogen atom is clearly planar in the solid state structures of **8** and **9**. There is still no sign of coalescence in low-temperature runs. Similarly, in the compounds containing the dithiophosphate groups, **1**–**6**, only single peaks are seen for the CH_3 protons of the dithiophosphate groups even though they have the potential to be in nonequivalent positions. This is the same as was observed for the corresponding bis species, where nonequivalent positions were seen in solid state structures (20). Compounds **3** and **4** have hydrogen atoms attached to the α-carbon atom of the glycoxy groups, which display geminal coupling with phosphorus with $^J(PH)$ values of 15.5 Hz that are the same as in the bis species and appear to be more typical of bidentate than monodentate linkages.

Concluding comments

The study demonstrates that, despite the well-known propensity of Me_2TeL_2 species, where L is a dithio ligand, to undergo exchange and reductive elimination, mixed ligand species of the type Me_2TeLL', are formed in both stepwise and in situ reactions and are not just fortuitous 1:1 mixtures of Me_2TeL_2 and $Me_2TeL'_2$ derivatives. Surprisingly, the orientations of the dithiocarbonate groups differ in $Me_2Te[S_2CNMe_2][S_2COEt]$, **8**, and $Me_2Te[S_2CNEt_2][S_2COMe]$, **9**; having the pendant sulfur atom turned toward tellurium in **9** as has been found for the corresponding bis dithiocarbonate species, $Me_2Te[S_2COEt]_2$ and $Me_2Te[S_2COMe]_2$, but away from tellurium in **8**. This suggests that the difference in energy when aniso bonds are formed between OR groups or terminal S atoms, must be very small and easily overridden by other effects. Despite the difference in the intramolecular associations in **8** and **9**, the intermolecular association to make pseudo dimers is identical in both resulting in Te–S–Te–S rectangular bridges involving the pendant sulfur atom of the dithiocarbamate groups.

Stereospecific thionation of 2-ethoxy-1,2-oxaphosphorinane 2-oxide and its derivatives with Lawesson's reagent

Alexandre M. Polozov, Sheldon E. Cremer, and Phillip E. Fanwick

Abstract: The parent phostone, 2-ethoxy-1,2-oxaphosphorinane 2-oxide **1**, and derivatives with substituents at the 3-position (methyl, phenyl, and benzyl; compounds **2**–**4**) were converted with Lawesson's reagent to provide the corresponding sulfide analogues **5**–**8** in moderate yields. The conversion of **2**–**4** occurred with retention of configuration at the phosphorus center. This was implied from the relative R_f values and ^{13}C and ^{31}P NMR chemical shifts of the individual isomers and confirmed for the transformation of **3b** to **7b** by X-ray structures of each of these. Oxidation of **7b**, **8a**, and **8b** with *m*-chloroperoxybenzoic acid alone led to the corresponding oxides **3b**, **4a**, and **4b** with retention. The presence of trifluoroacetic acid during this oxidation process led to varying degrees of epimerization about phosphorus and was dependent on the relative molar equivalents of this acid.

Key words: 2-ethoxy-1,2-oxaphosphorinane 2-oxide, 2-ethoxy-1,2-oxaphosphorinane 2-sulfide, phostone, thiophostone, Lawesson's reagent, stereoselective synthesis, X-ray diffraction.

Résumé : Utilisant le réactif de Lawesson, on a transformé la phostone fondamentale, la 2-oxyde de 2-éthoxy-1,2-oxaphophorinane (**1**), et ses dérivés portant des substituants en position 3 (méthyle, phényle et benzyle, composés **2**–**4**) en analogues sulfurés correspondants (**5**–**8**) avec des rendements modérés. La conversion des composés **2**–**4** se fait avec rétention de configuration au niveau du centre phosphoré. On a déduit cette conclusion sur la base des les valeurs relatives des R_f et des déplacements chimiques en RMN du ^{13}C et du ^{31}P des isomères individuels et elle est confirmée, pour la conversion de **3b** en **7b**, par les structures de chacun telles que déterminées par diffraction des rayons X. L'oxydation des composés **7b**, **8a** et **8b** à l'aide de l'acide *m*-chloroperbenzoïque seul conduit aux oxydes correspondants **3b**, **4a** et **4b** avec rétention de configuration. Lors de ces oxydations, l'addition d'acide trifluoroacétique au milieu réactionnel conduit à divers degrés d'épimérisation autour du phosphore et celui-ci dépend des quantités molaires relatives de cet acide.

Mots clés : 2-oxyde de 2-éthoxy-1,2-oxaphophorinane, 2-sulfure de 2-éthoxy-1,2-oxaphophorinane, phostone, réactif de Lawesson, synthèse stéréosélective, diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

The thionation of the phosphoryl group (P=O) is a fundamental reaction in organophosphorus chemistry. In recent years, Lawesson's Reagent (LR) has become a reagent of choice for this transformation due to improved yields of thiophosphoryl products and milder reaction conditions (1–7) compared to the conventional use of P_2S_5 (8–10). Another advantage of LR over P_2S_5 was its stereochemical predictability. Whereas chiral phosphorus compounds led to predominant retention of configuration (1, 5, 6) with this reagent, reports using P_2S_5 were sometimes variable (predominant retention (8–10) or racemization (9, 10)). In the present study, a careful investigation of the stereochemistry of thionation of 2-ethoxy-1,2-oxaphosphorinane 2-oxides (phostones) with LR was undertaken, including an analysis of the reaction products and correlation of their stereochemical configuration with the starting materials.

Stereochemical research in organophosphorus chemistry is often based on phosphorinane systems (11), because of their relevance to biologically important substances. For example, 1,2-oxaphosphorinane derivatives were recently studied as analogs of natural carbohydrates with emphasis on a potential medical application (12–17). Thus, we selected the phostone series **1**–**4** (Scheme 1) for thionation, since these materials were previously studied in our laboratory (18–22).

To our knowledge, no attempts have been made to prepare the thio analogs **5**–**8**. Herein, we describe the stereochemical results of the reactions of 2-ethoxy-3-alkyl-1,2-oxaphosphorinane 2-oxides **2** and **4** as well as the 3-phenyl derivative **3** with LR. The stereospecific course for **3b** to **7b** was confirmed by X-ray crystal structure studies; the relative R_f values and relative nmr spectral data enabled tentative isomer assignments for compounds **2**, **4**, **6**, and **8**.

Results and discussion

1. Optimization of the reaction conditions of the thionation reaction

Thionation of phosphoryl compounds has been carried out in benzene or toluene solutions up to reflux temperatures and with 1/0.5 ratio of reactant/reagent (1–3). Similar reaction conditions were employed in subsequent papers (4–7). The distillation or chromatography of the resultant reaction mixture with or without water work-up gave products in moderate yields.

Heating the parent oxaphosphorinane **1** at reflux temperatures with 0.55 equiv. of LR in toluene for 1.5 h and subsequent distillation resulted in a 52% yield of the 1,2-oxaphosphorinane 2-sulfide **5**. The yield was lower upon water work-up followed by silica gel chromatography (47%). Utilization of other solvents at reflux (benzene for 22 h; acetonitrile for 27 h) gave only 31 and 29% yields, respectively. The yield of **5** was improved through multiple extraction of the original reaction mixture (nonaqueous work-up) with EtOAc/hexane (15:85) under ultrasound irradiation followed by distillation (64%). GC–MS spectra of the extract showed less impurities than the original reaction mixture; impurities made the purification of the product by any method more difficult.

2. Synthesis of thionophosphorinates 6–8. Sterochemistry of the thionation reaction

Synthesis of starting materials and separation of the individual isomers followed previous methods (20–22). Furthermore, isomer **3b** was separated from the isomeric mixture **3a**,**b** by fractional recrystallization to provide a single crystal for X-ray structural analysis.

The optimized reaction conditions found during the synthesis of **5** were applied to the thionation of isomeric compounds **2**–**4**. Moreover, a 1:0.75 equivalent ratio of **2**–**4** to LR was used to accelerate the slower reactions; in addition, the reactions were allowed to proceed for a longer time. The slower reactions were possibly due to greater steric demands in **2**–**4** than in the unsubstituted oxaphosphorinane **1**.

The reactions were conducted with highly enriched isomers of **3b**, **4a**, and **4b** and on isomer mixtures of **2a**,**b** and **3a**,**b**; in all cases, the isomers were racemic mixtures. The reactions products were then analyzed by GS–MS and ^{31}P nmr spectroscopy. Separation and purification was readily achieved by flash chromatography of the individual isomers (large R_f difference). Although the yields were only moderate, each reaction occurred in a stereospecific fashion. (Table 1).

The reaction rates of the *cis* versus the *trans* isomers of **2**–**4** with LR were very similar. This was determined by monitoring their ratio in the GC as the reaction progressed. The ratio was constant throughout the reaction. Since the rates of reaction with LR were reported to increase with an increase in the nucleophilicity of phosphoryl oxygen (3, 4), the nucleophility of the P=O in the individual isomers of **2**–**4** is concluded to be comparable.

A single crystal X-ray study of both **3b** and the 2-ethoxy-1,2-oxaphosphorinane 2-sulfide **7b** revealed these to be *cis* isomers (vide infra). This established that this reaction proceeded with retention of configuration about phosphorus. A relative comparison of R_f values, GC retention times, and ^{31}P nmr chemical shift data of *cis*-**7b**, enabled the isomers **6b**, **7b**, and **8b** to be assigned to the *cis* configuration. The *cis* isomers (**6b**, **7b**, and **8b**) had smaller R_f values (more polar) on silica gel TLC plates and longer GC retention times. Likewise, the corresponding ^{31}P NMR shifts of the *cis* iso-

mers were upfield from the *trans* isomers. These assignments were supported by the relative consistency of their ^{13}C NMR spectra (Table 2). The chemical shifts of endocyclic C-3 and C-6 of the *cis* isomers (**b**) are downfield, and the ^{31}P-$^{13}C(5)$ coupling constants are somewhat larger than those in the *trans* isomers (**a**); moreover, C-7 for the *cis* isomers are slightly upfield from the *trans* isomers.

3. Stereochemistry of the oxidation reactions

The *m*-chloroperoxybenzoic acid (MCPB) oxidation of menthyl phenylphosphinothiolates compounds is known to proceed with predominant retention of configuration at phosphorus (23). However, the addition of trifluoroacetic acid (CF_3CO_2H) resulted in partial to predominant inversion of configuration at the phosphorus centre, and depended upon the molar equivalents of added acid (23).

The pure isomers **7b**, **8a**, and **8b** were stereospecifically oxidized to **3b**, **4a**, and **4b** respectively with *m*-CPBA in CH_2Cl_2 at 0°C. When 1 and 5 equiv. of CF_3CO_2H were added to the oxidation of **7b**, the resultant ratio of **3a**/**3b** was 1:24 and 1:1.4, respectively (Scheme 2). However, no isomerization was observed when single isomers **7b** or **3b** were subjected to CF_3CO_2H alone under the same reaction conditions (concentrations and temperature). Thus, the mechanism of the oxidation itself must be altered by the presence of CF_3CO_2H.

Structural study

Upon evaporation from CH_2Cl_2–cyclohexane solutions, single crystals of **3b** and **7b** suitable for X-ray studies were prepared. Figures 1 and 2 display the ORTEP structures along with a list of selected geometrical parameters.[2]

The X-ray crystal study of the racemic molecules **3b** and **7b** revealed no unusual features of the molecular structures. The molecules adopted chair conformations, with both the phosphoryl (thiophosphoryl) and phenyl groups in equatorial positions. The structural parameters (bond length and angles) in **3b** were close to those measured in **7b**. In both molecules, the phosphorus end of the molecule is flatter than the hydrocarbon end of the ring. The flattening around the phosphorus site in **3b** is greater than in **7b**, which is evident from the smaller torsional angles of 50.15(0.19)° for C(4)-P(1)-O(1)-C(1) and –47.23(0.17)° for O(1)-P(1)-C(4)-C(3) in **3b** compared to the analogous torsional angles of –53.08(0.31)°

[2]Tables of crystallographic data, structure solution and refinement, positional parameters, bond distances and angles, torsion angles, and anisotropic temperature factors have been deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. With the exception of bond and torsion angles and anisotropic temperature factors, these have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

for C(4)-P(1)-O(1)-C(1) and 49.84(0.31)° for O(1)-P(1)-C(4)-C(3) in **7b.** The phenyl ring in both molecules is close to perpendicular to the plane of the phosphorinane ring plane as defined by the dihedral angle formed from the two planes in **3b**: C(10)C(5)C(6)/C(2)O(1)C(4) of –76.30°; and the two planes in **7b**: C(10)C(5)C(6)/ C(2)O(1)C(4) of –71.63°.

Additional selected geometrical bond lengths (Å), bond angles, and torsional angles for **3b** are the following: P(1)—O(3) 1.4576(15), P(1)—O(2) 1.5769(14), P(1)—O(1) 1.5828(15), P(1)—C(4) 1.798(2); O(1)-P(1)-C(4) 104.27(9)°, O(3)-P(1)-O(1) 110.44(8)°; C(1)-C(2)-C(3)-C(4) –60.99(0.28)°, O(1)-C(1)-C(2)-C(3) 59.09(0.28)°. Likewise selected geometrical parameters for **7b** are the following: P(1)—S(1) 1.9208(13), P(1)—O(2) 1.583(2), P(1)—O(1) 1.587(2), P(1)—C(4) 1.818(3); O(1)-P(1)-C(4) 102.24(14)°, S(1)-P(1)-O(1) 110.71(10)°; C(4)-C(3)-C(2)-C(1) 60.78(0.51)°, C(3)-C(2)-C(1)-O(1) –58.70(0.51)°.

Experimental

General

All reactions with LR were carried out in flame-dried glassware under a nitrogen atmosphere. NMR spectra were recorded on a GE OMEGA 300 NMR spectrometer (300 MHz). $CDCl_3$ was used as the solvent in all cases unless stated otherwise. Chemical shifts for ^1H, ^{13}C (75 MHz), and ^{31}P (121 MHz) NMR were reported in ppm relative to TMS, $CHCl_3$, and 85% H_3PO_4, respectively. Coupling constants, *J*, are given in Hz. GC–MS data were obtained on a Hewlett–Packard 5890A Gas Chromatograph-5970 series mass selective detector: capillary column DB-1, 0.25 mm id × 30 m; inj. temp. 260°C; det. temp. 265°C; init. temp. 70°C for 5 min then 10°C min^{-1}; final temp. 250°C. Elemental analyses were performed by Quantitative Technologies Inc., N.J.. HRMS were performed at the Washington University Resource for Biomedical and Bio-organic Mass Spectrometry in St. Louis, Mo. Melting points were determined with Thomas–Hoover capillary melting point apparatus and are uncorrected. TLC (Aldrich) plates were developed by iodine. All chemicals were purchased from the Aldrich Chemical Co. and used without further purification. Preparative flash chromatography was performed with Acros silica gel (0.035–0.075 mm).

X-ray diffraction

The crystals were mounted on a glass fiber in a random orientation in an Enraf–Nonius CAD-4 computer controlled κ axis diffractometer equipped with a graphite crystal, incident beam monochromator, using Mo K_α radiation (λ = 0.71073 Å). Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $20 < \theta < 23°$. The data were collected at a temperature of 296 ± 1 K using the ω-2θ scan technique. For **3b**, a total of 3344 reflections were collected of which 2986 were unique; for **7b**, a total of 2061 reflections were collected of which 1973 were unique. Lorentz and polarization corrections were applied to the data. No absorption correction was made. The structures were solved by direct methods using SIR92 (24). The remaining atoms were located in succeeding difference Fourier syntheses. Hydrogen atoms were included in the refinement but restrained to ride on the atom to which they are bonded. Refinement was performed on an AlphaServer 2100 using SHELX-93 (25). Final R = 0.043 (**3b**), 0.043 (**7b**); R_w = 0.125 (**3b**), 0.123(**7b**). Crystallographic drawings were constructed using programs ORTEP (26).

Isolation of crystalline *cis*-2-ethoxy-3-phenyl-1,2-oxaphosphorinane 2-oxide 3b

A solution of a mixture of isomers **3a**,**b** (3.2 g, **3a**:**3b** ratio 1.3:1) in CH_2Cl_2–cyclohexane (1:1) was allowed to slowly evaporate at room temperature. A single isomer **3b** (0.70 g, mp 79–81°C) was filtered out as colorless crystals: R_f 0.43 (EtOAc); ^{1}H NMR δ: 7.39–7.22 (m, 5H), 4.42–4.18 (m, 2H), 4.06–3.82 (m, 2H), 3.26–3.13 (m, 1H), 2.39–2.12 (m, 2H), 2.07–1.83 (m, 2H), 1.17 (dt, 3H, $^3J_{HH}$ = 7.0 Hz); *m*/*z*: 240 (M^+, 24%), 184 (11), 130 (100), 115 (20), 104 (40), 91 (45), and 77 (17). ^{13}C NMR δ: 135.62 ($^2J_{CP}$ = 8.5), 128.47, 128.42, 127.18 (d, $^3J_{CP}$ = 2.4), 69.99 (d, $^2J_{CP}$ = 7.4), 62.01 (d, $^2J_{CP}$ = 7.3), 42.96 ($^1J_{CP}$ = 124.5), 28.85 ($^3J_{CP}$ = 6.1), 27.19 ($^2J_{CP}$ = 4.9), 16.26 ($^3J_{CP}$ = 6.1 Hz); ^{31}P NMR δ: 22.4 ppm. HREI–MS calcd. for $C_{12}H_{17}O_3P$: 240.0915; found: 240.0919; R_f 0.33 (EtOAc); *m*/*z*: 240 (M^+, 26%), 184 (21), 130 (100), 115 (23), 104 (53), 91 (47), and 77 (19). By comparison, the *trans* isomer **3a** had an R_f value of 0.33 (EtOAc) and a ^{31}P NMR shift at 26.5 ppm.

2-Ethoxy-1,2-oxaphosphorinane 2-sulfide 5

The preparation and properties of compound **1** have been reported (21, 22, 27–32). A solution of **1** (0.5 g, 3 mmol) and LR (0.68 g, 1.7 mmol) in toluene (3 mL) was stirred and heated at reflux for 1.5 h. Three variants of the work-up were used:

(*i*) The reaction mixture was washed by water (3 mL) and extracted with toluene (3 × 3 mL). The combined extracts were dried over anhydrous $MgSO_4$, filtered, the solvent was removed in vacuum, and the residue was purified by flash column chromatography on SiO_2 (EtOAc/hexane, 1:9) to give **5** (0.26 g, 47% yield) as a colorless liquid.

(*ii*) The reaction mixture was distilled in vacuum (bp 79–81°C/0.45 mmHg) (1 mmHg = 133.3 Pa) to give **5** (0.29 g, 52% yield).

(*iii*) The toluene was removed in vacuum, and the oily residue was extracted with EtOAc/hexane, 15:85 (4 × 10 mL) under ultrasound radiation (5 min for each extraction). Then, the solvent was removed in vacuum, and the residue was distilled in vacuum (bp 79–81°C/0.45 mmHg) to give **5** (0.35 g, 64% yield).

^{1}H NMR δ: 4.34–4.09 (m, 4H), 2.21–2.06 (m, 4H), 1.86–1.63 (m, 2H), 1.35 (t, 3H, $^3J_{HH}$ = 9.0 Hz); *m*/*z*: 180 (M^+, 60%), 136 (39), 119 (19), 103 (18), 93 (17), 65 (22), 55 (100), and 41(26). Anal. calcd. for $C_6H_{13}O_2PS$: C 40.00, H 7.27; found: C 39.71, H 7.06.

2-Ethoxy-3-methyl-1,2-oxaphosphorinane 2-sulfide 6

A solution of **2** (0.67 g, 3.76 mmol; **2a**:**2b**, 1.3:1) and LR(1.14 g, 2.11 mmol) in toluene (4 mL) was stirred and heated at reflux for 3.0 h. A mixture of **6a**:**6b** (1.2:1) was obtained. The toluene was removed in vacuum, and the oily residue was extracted with EtOAc/hexane, 15:85 (3 × 25 mL) under ultrasonic radiation. The solvent was removed in vacuum, and the residue was purified by flash column chromatography on SiO_2 (60 g, EtOAc/hexane, 5:95, then 7:93) to give **6a** (0.26 g, 36% yield) and **6b** (0.17g, 23% yield) as clear oils. HREI–MS calcd. for $C_7H_{15}O_2PS$ (mixture of isomers): 194.0530, found: 194.0524. This compound, prepared by a different method, has been reported previously (33).

***trans*-2-Ethoxy-3-methyl-1,2-oxaphosphorinane 2-sulfide 6a**

^{1}H NMR δ: 4.33–4.08 (m, 4H), 2.10–1.61 (m, 5H), 1.30 (t, 3H, $^3J_{HH}$ = 7.1 Hz), 1.13 (dd, 3H, $^3J_{HH}$ = 6.5, $^3J_{HP}$ = 21.7 Hz); *m*/*z*: 194 (M^+, 42%), 166 (4), 150 (18), 133 (10), 93 (18), 69 (77), and 41 (100).

***cis*-2-Ethoxy-3-methyl-1,2-oxaphosphorinane 2-sulfide 6b**

^{1}H NMR δ: 4.29–4.05 (m, 4H), 2.10–1.61 (m, 5H), 1.33 (t, 3H, $^3J_{HH}$ = 7.1 Hz), 1.20 (dd, 3H, $^3J_{HH}$ = 6.8, $^3J_{HP}$ = 20.5 Hz); *m*/*z*: 194 (M^+, 50%), 166(5), 150(24), 133 (14), 93(13), 69(84), and 41(100).

2-Ethoxy-3-phenyl-1,2-oxaphosphorinane 2-sulfide 7

A solution of **3** (0.9 g, 3.75 mmol; **3a**:**3b**, 3.2:1) and LR (1.14 g, 2.8 mmol) in toluene (4 mL) was stirred and heated at reflux for 3.0 h. A mixture of **7a**:**7b** (3.2:1) was obtained. The toluene was removed in vacuum, and the oily residue was extracted with EtOAc/hexane, 15:85 (3 × 30 mL) under ultrasonic radiation. The solvent was removed in vacuum, and the residue was purified by flash column chromatography on SiO_2 (EtOAc/hexane, 5:95, then 15:85) to give **7a** (0.19 g, 20%) as a clear oil and **7b** (0.17 g, 17% yield) as colorless crystals; mp 84–86°C (CH_2Cl_2–cyclohexane).

A similar protocol was applied to the pure isomer **3b** (0.14 g, 5.83 mmol). After work-up and flash chromatography, pure **7b** (0.07 g, 47%) was isolated.

yield) as a clear oil. ^{1}H NMR δ: 7.32–7.19 (m, 5H), 4.39–3.95 (m, 4H), 3.08–3.03 (ddd, 1H, $^2J_{HH}$ = 14.0, $^3J_{HH}$ = 6.1 Hz, $^3J_{HP}$ = 11.0 Hz), 2.62 (ddd, 1H, $^2J_{HH}$ = 14.0, $^3J_{HH}$ = 9.2 Hz, $^3J_{HP}$ = 18.2 Hz), 2.30–2.14 (m, 1H), 1.88–1.64 (m, 4H), 1.20 (t, 3H, $^3J_{HH}$ = 7.0 Hz); *m*/*z*: 270 (M^+, 100%), 195 (10), 179 (18), 144 (62), 129 (45), 115 (25), 91 (77), 65 (30), and 41 (24). Anal. calcd. for $C_{13}H_{19}O_2PS$ (mixture of 95% **8a** and 5% **8b**) (%): C 57.76, H 7.08; found: C 57.89, H 7.17.

cis-2-Ethoxy-3-benzyl-1,2-oxaphosphorinane 2-sulfide 8b

A solution of **4b** (0.039 g, 0.015 mmol; 96% isomer purity) and LR (0.046 g, 0.012 mmol) in toluene (0.5 mL) was stirred and heated at reflux for 3.0 h. Toluene was removed in vacuum, and the oily residue was extracted with EtOAc/hexane, 15:85 (3 × 3 mL) under ultrasonic radiation. Solvent was removed in vacuum, and the residue was purified by flash column chromatography on SiO_2 (EtOAc/hexane, 10:90) to give **8b** (0.018 g, 44% yield; 96% isomer purity) as a clear oil.

^{1}H NMR δ: 7.33–7.17 (m, 5H), 4.35–4.01 (m, 4H), 3.36 (ddd, 1H, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 0.8, $^3J_{HP}$ = 2.3 Hz), 2.41 (ddd, 1H, $^2J_{HH}$ = 13.6, $^3J_{HH}$ = 5.5, $^3J_{HP}$ 11.5 Hz), 2.23 –2.02 (m, 1H), 1.79–1.61 (m, 4H), 1.37 (t, 3H, $^3J_{HH}$ = 7.1 Hz); *m*/*z*: 270 (M^+, 100%), 195 (9), 179 (17), 151 (15), 144 (72), 129 (45), 115 (26), 91 (85), 65 (33), and 41(25).

Oxidation of _cis_-2-ethoxy-3-phenyl-1,2-oxaphosphorinane 2-sulfide 7b with _m_-CPBA

A solution of *m*-CPBA (26 mg; 0.086 mmol, based on 57% content) in CH_2Cl_2 (0.5 mL) was added over 1 min to a stirred solution of **7b** (20 mg, 0.078 mmol, 100% isomeric purity) in CH_2Cl_2 (4 mL) at 0°C. Stirring was continued for 5 min and then the mixture was treated with aq. Na_2CO_3 sat. (3 mL) and extracted by CH_2Cl_2 (3 × 3 mL). The combined extracts were dried over anhydrous $MgSO_4$, filtered, and analyzed by GC–MS and ^{31}P NMR. Only **3b** was detected. Evaporation of solvent gave **3b** (17 mg, 91%).

Oxidation of _cis_-2-ethoxy-3-phenyl-1,2-oxaphosphorinane 2 sulfide 7b with _m_-CPBA in the presence of CF_3CO_2H

A solution of *m*-CPBA (26 mg; 0.086 mmol, based on 57% content) in CH_2Cl_2 (0.5 mL) was added over 1 min to a stirred solution of **7b** (20 mg, 0.078 mmol, 100% isomeric purity) and 1 equiv. of CF_3CO_2H (8.9 mg, 0.78 mmol) in CH_2Cl_2 (4 mL) at 0°C. Stirring was continued for 5 min, and the mixture was then treated with aq. Na_2CO_3 sat. (3 mL) and extracted with CH_2Cl_2 (3 × 3 mL). The combined extracts were dried over anhydrous $MgSO_4$, filtered, and analyzed by GC–MS and ^{31}P NMR. A mixture of **3b** (96%) and **3a** (4%) was detected by ^{31}P NMR and GC–MS.

The identical procedure using 5 equiv. of CF_3CO_2H (45 mg, 3.9 mmol) gave a mixture of **3b** (42%) and **3a** (58%).

Oxidation of _cis_-2-ethoxy-3-benzyl-1,2-oxaphosphorinane 2-sulfide 8b with _m_-CPBA

A solution of *m*-CPBA (27 mg; 0.089 mmol, based on 57% content) in CH_2Cl_2 (0.5 mL) was added over 1 min to a stirred solution of **8b** (22 mg, 0.081 mmol, 100% isomeric purity) in CH_2Cl_2 (4 mL) at 0°C. Stirring was continued for 5 min and then the reaction worked up as before (see oxidation of **7b**). Only **4b** was detected by ^{31}P NMR and GC–MS. Evaporation of the solvent gave **4b** (18 mg, 86%). ^{31}P NMR δ: 26.8 ppm; R_f 0.34 (EtOAc); *m*/*z*: 254 (M^+, 44%), 163 (72), 144 (29), 135 (65), 129 (49), 117 (42), 91 (100), and 65 (39).

Oxidation of _trans_-2-ethoxy-3-benzyl-1,2-oxaphosphorinane 2-sulfide 8a with _m_-CPBA

A solution of *m*-CPBA (27 mg; 0.089 mmol, based on 57% content) in CH_2Cl_2 (0.5 mL) was added over 1 min to a stirred solution of **8a** (22 mg, 0.081 mmol, 100% isomeric purity) in CH_2Cl_2 (4 mL) at 0°C and then stirred for an additional 5 min and worked up as before (supra infra). Only **4a** was detected in the ^{31}P NMR spectrum and by GC–MS. Evaporation of the solvent gave **4a** (19 mg, 93%). ^{31}P NMR δ: 29.6 ppm; R_f 0.26 (EtOAc); *m*/*z*: 254 (M^+, 75%), 163 (14), 144 (45), 135 (28), 129 (66), 117 (53), 91 (100), and 65 (43).

Electrochemical reduction and oxidation of DDT

Simona G. Merica, Wojceich Jędral, Susan Lait, Peter Keech, and Nigel J. Bunce

Abstract: Electrolysis has been studied as a possible method to treat DDT wastes. In methanol, the major process was dehydrochlorination to DDE followed by further reduction. In an aqueous emulsion containing 1% heptane and 0.1% Triton SP-175®, DDT was reduced at a deposited lead electrode with sodium sulphate as the supporting electrolyte by sequential hydrodechlorination of the aliphatic chlorine atoms. An excellent material balance was achieved, but the current efficiency was poor, even at low current densities. Electrooxidation of DDT was also investigated; in aqueous solutions or emulsion, little oxidation occurred because of competing oxidation of water at the highly positive potentials needed to oxidize DDT. In acetonitrile, electrooxidation occurred with high current efficiency by way of "electrochemical combustion" of DDT and its intermediate oxidation products to CO_2. We conclude that development of an electrolytic technology for destroying DDT wastes is unlikely.

Key words: electroreduction, electrooxidation, voltammetry, surfactant media.

Résumé : On a évalué l'utilité potentielle de l'électrolyse comme méthode de se débarrasser de résidus de DDT. Dans le méthanol, le processus majeur est une déhydrochloruration en DDE qui est suivie d'une réduction ultérieure. Dans une émulsion aqueuse contenant 1% d'heptane et 0,1% de Triton SP-175®, en présence de sulfate de sodium comme électrolyte de support, le DDT peut être réduit au niveau d'une électrode de plomb, par hydrodéchlorurations successives des atomes de chlore aliphatiques. On a pu établir une excellente balance des produits, mais l'efficacité de courant est mauvaise, même à de faibles densités de courant. On a aussi étudié l'électrooxydation du DDT; en solution aqueuse ou à l'état d'émulsion, il se produit peu d'oxydation à cause d'une oxydation compétitive de l'eau aux potentiels hautement positifs requis pour oxyder le DDT. Dans l'acétonitrile, l'électrooxydation se produit avec de très bonnes efficacités de courant par le biais d'une "combustion électrochimique" du DDT et de son produit d'oxydation intermédiaire en CO_2. On conclut que le développement d'une technologie électrolytique d'élimination des résidus du DDT est peu probable.

Mots clés : électroréduction, électrooxydation, voltampérométrie, milieu d'agents de surface.

[Traduit par la Rédaction]

Introduction

Although the use of DDT (1,1-bis(*p*-chlorophenyl)-2,2,2-trichloroethane) was discontinued in North America in the early 1970s, it remains a significant environmental problem, both because of leaching from abandoned waste dumps and because it is still used for mosquito control elsewhere. DDT is persistent in the environment due to its resistance to biodegradation (1). Along with previous authors, we have been studying electrolysis as a possible method for converting DDT to more biodegradable compounds. Figure 1 shows the structures and common abbreviations of DDT and its derivatives.

Fukami and Nakajima in 1953 (2) electrolysed DDT at a dropping mercury electrode at –1.6 V vs. a saturated calomel electrode (SCE) and obtained DDD in 80% yield together with a small amount of yellow resinous substance (this may have been DDMS, which is a pale yellow oil). Reddy and Reddy (3) showed the reduction of DDT to DDD to be an irreversible two-electron reaction. They proposed, following the work of Lambert and Ingall (4), that two electrons were added to DDT, to produce Cl^- + DDD^- which then protonated. (Unlike aryl chlorides (5), the electroreduction of alkyl chlorides does not afford radical anions as discrete intermediates).

Rosenthal and Lacoste (6) observed three two-electron reductions in 90% ethanol:10% 1.0 M aqueous methyltributylammonium chloride. These were attributed to successive hydrodechlorination of DDT's three aliphatic chlorines, on the evidence that DDD showed reduction waves at the same potentials as the second and third reduction waves for DDT. Tandon et al. (7), who worked in 4% DMF:50% ethanol:46% aqueous tetramethylammonium bromide, noted three well-defined reduction waves at –0.370 to –0.430 V, –0.795 to –0.955 V, and –1.110 to –1.225 V vs. SCE, and observed the three stepwise reductions, ultimately to DDO,

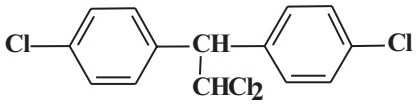
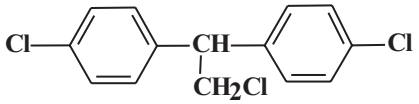
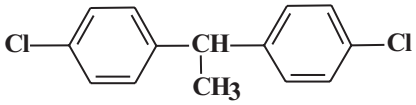
1,1'-(2,2,2-trichloroethylidene)bis(4-chlorobenzene) ("DichloroDiphenylTrichloroethane" = DDT)



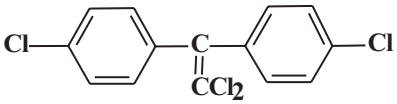
1,1'-(2,2-dichloroethylidene)bis(4-chlorobenzene) ("DichloroDiphenylDichloroethane" = DDD)



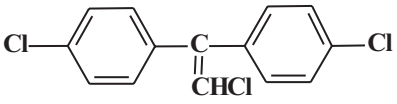
1,1'-(2-chloroethylidene)bis(4-chlorobenzene) ("DichloroDiphenylMonochloroethane, Saturated" = DDMS)



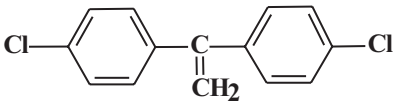
1,1'-ethylidenebis(4-chlorobenzene) ("DichloroDiphenylethane, 0 aliphatic chlorines" = DDO)



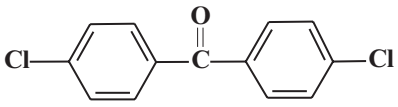
1,1'-(2,2-dichloroethenylidene)bis(4-chlorobenzene) ("DichloroDiphenyldichloroEtylene" = DDE)



1,1'-(2-chloroethenylidene)bis(4-chlorobenzene) ("DichloroDiphenylMonochloroethylene, Unsaturated" = DDMU)



1,1'-(ethenylidene)bis(4-chlorobenzene) ("DichloroDiphenylethylene, No aliphatic chlorines, Unsaturated" = DDNU)



4,4'-dichlorobenzophenone (DBP)

at these respective potentials. They proposed a mechanism in which each dechlorination step involves a fast electron transfer and proton addition to give the alkyl radical, followed by a second, rate-limiting, electron transfer and proton addition to complete the replacement of -Cl by -H. This mechanism is consistent with the localization of 98% of the electron density in the LUMO of DDT in aliphatic C-Cl σ^* antibonding orbitals (8). Four irreversible reduction steps were also observed by cyclic voltammetry in carefully dried acetonitrile (ACN) and DMF using tetraethylammonium phosphate as the supporting electrolyte (9), also suggesting consecutive ECE mechanisms (10).

Electrochemical oxidation of DDT has been studied less extensively than reduction. Keenan and Stuart (11) oxidized DDT at +2.10 V vs. SCE in 5% aq 0.1 M tetraethylammonium perchlorate:95% ACN solution at a Pt anode, and obtained 4,4′-dichlorobenzophenone (DBP), 1,1,1-trichloro-2-(4-chlorophenyl)-2-(4-chloro-2,5-benzoquinone)ethane and a small amount of 2,2,2-trichloro-1,1-bis-(4-chlorophenyl) ethanol (Kelthane). The low yield of Kelthane was not surprising given that its oxidation peak is only 0.02 V more positive than that of DDT. Cyclic voltammetry indicated that all of the oxidation steps were irreversible; the peak potentials for DDT were at +2.3 and +2.6 V vs. SCE.

The ability to remove all three aliphatic chlorines from DDT by electrolysis suggested that it might be possible to develop a technology in which DDT could be transformed electrochemically into less toxic, more biodegradable products, provided that the reaction could be achieved with high chemical and electrical efficiency under "environmentally friendly" conditions. An ideal situation would be a sequence in which "side chain" reduction of DDT to DDO at the cathode would be followed by anodic oxidation of DDO to products that might be compatible with a subsequent biological treatment.

Experimental

DDT, DDD, DDE, 4,4′-dichlorobenzophenone (DBP), and tetraethylammonium chloride (TEACl) were obtained from

© 1999 NRC Canada

Aldrich; a standard solution of DDMU in methanol was obtained from AccuStandard. DDNU, DDO, and DDMS were synthesized as described below. All compounds were assayed by HPLC and (or) GC–MS. Sodium sulfate supporting electrolyte and HPLC grade solvents were obtained from Fisher. Triton SP-175® was generously supplied by Union Carbide Canada.

DDNU

The method employed was part of a longer synthesis by Grummitt et al. (12). 2,2,2-Trichloro-1,1-bis-(4-chlorophenyl) ethanol (1.0474 g, 3.92 mmol) was heated under reflux in an oil bath at 210–220°C for 15 min. After cooling to 80°C and addition of 1.0 mL of 20% aq H_2SO_4, the mixture was stirred at reflux at 140–150°C for 1 h. Cooling and two recrystallizations from ethanol (10 mL) gave pale yellow needles of DDNU (0.4884 g, 1.96 mmol, 50.0%, mp 83–84°C, lit. (12) 84–86°C); ^{1}H NMR ($CDCl_3$) δ (ppm): 5.45 (s), 7.3 (m).

DDO

DDNU (0.3639 g, 1.461 mmol), $AlCl_3$ (10 mg), 5% Pd–C (77.1 mg), and cyclohexene (4.0 mL) were stirred for 5 days under dry argon. Filtration and removal of solvent gave a yellow oil, which was chromatographed over silica gel (60–200 mesh, 22 g) and eluted with hexane (5 mL fractions). Fractions were checked for composition by TLC, and the presence of DDO was verified by GC–MS. The DDO-rich fractions were pooled, evaporated, and crystallized from 95% ethanol (1 mL) to give white fluffy needles of DDO (40.6 mg, 0.162 mmol, 11.1%, mp 44–45°C); ^{1}H NMR ($CDCl_3$) δ (ppm): 1.6 (d), 4.1 (q), 7.3 (m). The literature melting point for DDO is 54–55°C (4); however, GC–MS and HPLC analysis showed contamination by traces of DDNU even after purification.

DDMS

2,2-Bis-(4-chlorophenyl)ethanol (201.6 mg, 0.755 mmol) and $SOCl_2$ (0.500 mL, 7.15 mmol) were refluxed for 2 h with stirring under dry air. The reflux condenser was removed, allowing most of the $SOCl_2$ to evaporate while the solution boiled for a further 15 min, then the residue was stirred for 1 h and the remaining $SOCl_2$ allowed to evaporate overnight. The gummy yellow product (121.4 mg, 0.425 mmol, 56.3%) was dissolved in hexane (1 mL), chromatographed over silica gel (60–200 mesh, 20 g), and eluted with hexane (10 mL fractions). The composition of fractions was checked by TLC and GC–MS. The fractions containing DDMS with no significant contaminants were pooled to give a very pale yellow oil, DDMS (27.4 mg, 0.0959 mmol, 12.7%); ^{1}H NMR ($CDCl_3$) δ (ppm): 4.0 (d), 4.3 (t), 7.3 (m).

HPLC

The system comprised a Waters U6K injector, Waters 600E system controller, and Model 486 tuneable absorbance detector set to λ = 240 nm (electroreduction) and 227 nm (electrooxidation). The system was connected to a PC controlled by Millennium 2010 chromatographic software. Analytical separations were performed on a Waters μBondapack C_{18}, 3.9 × 300 mm column. The column was eluted with 55/45 ACN/water at 2.5 mL/min, for electroreduction experiments, while for electrooxidation a 90/10 MeOH/water mixture at 2 mL/min was employed. All solvents were HPLC grade and filtered using 0.45 μm Nylon 66 membranes.

GC–MS

The instrument was a Hewlett Packard 5971 Series mass selective detector interfaced to a Hewlett Packard 5890 Series II gas chromatograph equipped with a J&W DB5 capillary column (0.25 mm i.d. × 30 m, 0.25 μm thick film) using helium as the carrier gas. The temperature program used for identification of electroreduction products was 100°C (3 min); 100–180°C at 12°/min; 180–300°C at 7°/min, 300°C (5 min). In the case of electrooxidation, the following program was employed: 70°C (3 min); 70–200°C at 20°/min; 200–300°C at 15°/min.

Electrolyses

The solvents used in exhaustive electrolyses were HPLC grade methanol, HPLC grade acetonitrile, reagent grade *t*-BuOH (which was purified by successive recrystallization), and Triton SP-175 emulsion (surfactant:heptane:water = 0.1:1:98.9 v/v). The latter contained 0.05 M Na_2SO_4 as supporting electrolyte; it was prepared by sonication and was indefinitely stable at neutral pH.

Continuous flow electroreductions

These experiments were performed using a sandwich-type flow-through cell previously described (13). Current-controlled electroreduction at a Hg pool cathode (A = 6 cm^2) was performed using a Ti/IrO_2 anode (A = 20 cm^2) and saturated Ag/AgCl reference electrode. Prior to electrolysis, the catholyte was purged with argon for 20 min, and a slow argon flow was maintained throughout the experiment. A 25.0 mL sample of 1 mM, DDT 0.05 M TEACl in methanol was circulated through the cathodic compartment at 2.5 mL/min using a peristaltic pump, and 25 mL of TEACl–methanol was pumped through the anodic compartment. Samples (0.1 mL) were taken at intervals during the electrolysis. Extraction of the electrolyzed solution with CH_2Cl_2 allowed for product analysis by GC–MS.

Current-controlled electroreductions were also performed using a cathode of deposited lead (A = 40 cm^2) and an anode of Ti/IrO_2 (A = 20 cm^2). Deposition on a lead wire frame was accomplished by circulating 50 mL of 10 mM $Pb(NO_3)_2$ + 125 mM disodium citrate through the cathodic compartment while applying a current of 20 mA for 45 min. A 25.0 mL sample of 0.1 mM, DDT in Triton SP-175 emulsion was circulated through the cathodic compartment at 5 mL/min, and 25 mL emulsion was circulated through the anodic compartment. The reservoir of the cathodic emulsion was stirred magnetically, and heptane was added periodically to maintain the emulsion. Samples (0.5 mL) taken at intervals during electrolysis were treated with 5 M H_2SO_4 (50 μL) and heptane (0.25 mL) to destroy the emulsion and to extract DDT and reduction products. Reaction rates were corrected for the consequent change in the volume of the solution.

Current-controlled electroreductions were also performed using a cathode of deposited nickel (from a 1:1 $NiSO_4$:$NiCl_2$ solution, A = 40 cm^2) on a nickel wire frame. Experimental conditions were comparable as for current-controlled electroreduction on deposited lead.

© 1999 NRC Canada

Single-flow electroreductions

A peristaltic pump passed 0.1 mM DDT in emulsion from a 500 mL container through the cathodic compartment at 0.4 mL/min and circulated 25 mL emulsion through the anodic compartment. Unlike the continuous flow electrolyses, the output from the cathodic compartment was directed to waste. Samples were taken from the cathodic compartment output and treated with H_2SO_4 and heptane as in continuous flow experiments. To achieve a steady state, current was applied for 30 min before sampling.

Anodic voltammetry

The electrochemical cell was a glass container with a Teflon lid which had four openings for electrodes and an argon purging tube. The anode was a Pt wire (0.20 cm^2); an external reference Ag/AgCl electrode was used, with a bridge filled with two solutions. The part that was in contact with the Ag/AgCl electrode contained saturated aqueous KCl solution, while the part that was in contact with the analyzed solution was filled with 0.1 M $LiClO_4$ – acetonitrile. The counter electrode was a Pt foil with area of 5 cm^2. The solutions were deaerated prior to electrolysis. The cell was controlled by a EG&G, model 273, potentiostat–galvanostat interfaced with a PC and operated by M270 electrochemical software. The following parameters were used: pulse height, 100 mV; pulse width, 50 ms; scan rate, 2 mV s^{-1}. The solutions were purged with argon for 15 min before taking measurements. All potential data were reported using SHE as common point of reference, and the anodic current was reported as positive.

Electrooxidations

These experiments used the same type of cells as used for electroreductions. For the electrolyses performed in acetonitrile and in 1:1 *t*-BuOH:H_2O, the cell was made of high-density polypropylene, while for the experiments performed in emulsion, the cell was made of Plexiglas. Care was taken to select appropriate solvent-resistant tubing for the peristaltic pump. The working electrode had an area of 25 cm^2 and was either a Pt foil or a Ti/IrO_2 plate. The counter electrode was a glassy carbon electrode. The cell was controlled amperostatically by means of a EG&G, model 173, potentiostat–galvanostat. In continuous flow experiments, a 25.0 mL sample of DDT solution (1 mM DDT – 0.1 M $LiClO_4$ – acetonitrile; 0.2 mM DDT in 50/50 *t*-BuOH/H_2O – 0.05 M Na_2SO_4; or 0.1 mM DDT – emulsion – 0.05 M Na_2SO_4) was continuously recirculated through the anodic compartment using a peristaltic pump (flow rate = 5 mL min^{-1}), and 25.0 mL of electrolyte was pumped through the cathodic compartment. The electrolysis was monitored by HPLC by removing samples from the bulk solution; for product identification, the electrolyzed solution was extracted in dichloromethane and analyzed by GC–MS. In single-flow experiments, a solution of 0.1 mM DDT in 0.1 M $LiClO_4$ – acetonitrile was pumped from a 0.25 L container through the anodic compartment at 1 mL/min, and the output from the anode was directed to waste. Approximately 25 mL of electrolyte solution was recirculated through the cathodic compartment, as in continuous flow experiments. Both solutions were purged with argon for ~30 min before electrolysis to remove dissolved CO_2. After current was applied, an equilibration time of 10 min was allowed before samples were collected.

Carbon dioxide was quantitated using the single-flow procedure, by directing the output from the cell to a closed container connected to a methanol trap (3 mL) followed by a $Ba(OH)_2$ trap (25 mL of 3 mM). During the sample collection period (10 min), Ar was flushed through the sample. The $Ba(OH)_2$ solution was allowed to stand for few hours to clear, and the residual hydroxide ion was then titrated against 10 mM HNO_3.

Results and discussion

Electroreductions

We first performed continuous flow electrolysis of 1 mM DDT in methanol with TEACl as the supporting electrolyte using an Hg pool cathode, to allow product identification corresponding to the reduction waves observed polarographically. Methanol was chosen because it is inexpensive, miscible with water, and not toxic to microorganisms. Although TEACl is too expensive an electrolyte for use on an industrial scale, tetraalkylammonium salts have been used in most of the published voltammetric studies involving DDT (1, 5–7, 10, 13).

After 20 min of amperostatic electrolysis at 2 mA cm^{-2}, most of the DDT had reacted. DDE was the major product; DDD, DDMU, and a small amount of DDMS were minor products. After 60 min, DDE was still the major product; the concentration of DDT was not greatly altered, but the relative amounts of DDMU and DDMS had increased, and DDNU and DDO became detectable. Similar products were obtained by Schweizer et al. (1) who electrolyzed 10 mM DDT in a bicontinuous emulsion of dodecane, didodecyldimethylammonium bromide (DDAB), and water. They observed two reduction waves at –1.4 and –2.0 V vs. Ag/AgBr. Potentiostatic electrolysis at –1.4 V under deoxygenated conditions gave DDE (31%) and DDD (10%) at 51% conversion of DDT, with minor amounts of DDO, DDMU, and DDMS. Electrolysis at –2.0 V to 100% conversion gave more extensive reduction to DDO (55%), DDMS (27%), and traces of 1,1-diphenylethane. Under aerated conditions, the yield of 1,1-diphenylethane increased to 34%, and 1-(4-chlorophenyl)-1-phenylethane (22%) and DDO (37%) were also formed.

The formation of DDE and its further reduction products DDMU and DDNU is not compatible with DDT → DDD → DDMS → DDO as the proposed pathway for electroreduction (2, 6, 7, 10). One possible mechanism is an initial reduction to $DDT^{\cdot -}$ and loss of Cl^-, giving $Ar_2CH\text{-}CCl_2^{\cdot}$ radicals, which can disproportionate into DDD and DDE. Another is base-catalyzed elimination of HCl from DDT, in which the base is formed in situ at the cathode as the by-product of reduction of other DDT molecules.

$$DDT + 2e^- + MeOH \rightarrow DDD + Cl^- + MeO^-$$

Experimental evidence in favour of the second option was obtained by allowing DDT (10^{-3} mol L^{-1} in methanol) to react with different concentrations of methanolic sodium methoxide for time periods up to 140 min. After 50 min, for example, the fraction of DDT converted to DDE was 0.0022 (10^{-4} mol L^{-1} NaOMe), 0.015 (10^{-3} mol L^{-1} NaOMe), and

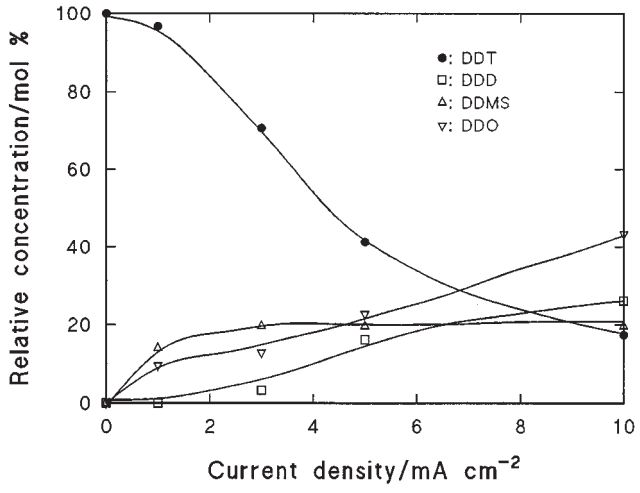
0.14 (10^{-2} mol L^{-1} NaOMe). Detectable amounts of DDE were even obtained at time zero (immediate quench of the solution). Direct comparison with the electrolytic experiments is not possible because the local concentration of MeO^- in the vicinity of the cathode is unknown.

The bicontinuous emulsion used by Schweizer et al. (1) employs large volumes of surfactant and organic solvent and is only 22% water. We showed previously (14) that aqueous emulsions of 1% heptane, 0.1% Triton SP-175 were stable for hours of electrolysis when stirred. We therefore investigated the use of this medium for the electroreduction of 0.1 mM DDT. Lead was selected as a cathode based on our previous work (14), and nickel was selected based on the work of Liu et al. (15) involving electroreduction of carbon tetrachloride. Both metals were freshly deposited prior to electrolysis of DDT. Small amounts of heptane had to be added periodically when the current density was greater than 3 mA cm^{-2} to replace heptane lost through ohmic heating of the solution and through entrainment by the H_2 evolved. Sodium sulphate was selected as an inexpensive, nontoxic electrolyte. The electrolyses were performed in the same way as those in methanol except that a two-electrode system was used. The loss of DDT followed first-order kinetics in all cases: see Table 1.

In the Triton SP-175 emulsion, the products were consistent with the pathway DDT → DDD → DDMS → DDO.

Fig. 3. Electroreduction of 0.1 mM DDT in 0.5 M Na_2SO_4 – emulsion at a Pb cathode (A = 40 cm^2, single flow, F = 0.4 mL min^{-1}).



DDE was not formed, consistent with the concentration of base (OH^- in this case) being low in the emulsion phase. Figure 2 shows the progress of the reaction at Pb using a current density of 5 mA cm^{-2}. No more than traces of DDD were present at any stage of the reaction, indicating that this intermediate was immediately reduced to DDMS before reentering the bulk solution. Mass balances at the Pb cathode were at least 97% at current densities ≤3 mA cm^{-2}; at higher current densities, loss of heptane caused by H_2 evolution led to deposition of products from the solution.

The electroreductions at Ni also followed pseudo-first-order kinetics, but gave poorer mass balances (typically ~80% after 3 h electrolysis). HPLC analysis showed an unidentified peak with a retention time more than twice as long (less polar) than any of the standard DDT derivatives. The identified reduction products were also counter-intuitive. At 0.5 mA cm^{-2}, the major product was DDO, corresponding to complete dechlorination of the side chain; DDMS was the major product at 3 mA cm^{-2} and was formed exclusively at 5 mA cm^{-2}. We anticipated that increasing the current density, and hence the polarization of the cathode, would increase the extent of dechlorination, not the reverse. A possible explanation is competing reduction by chemisorbed H_2, given that nickel is well known as a hydrogenation catalyst.

Single-flow electrolyses (i = 0.1–10 mA cm^{-2}) were performed at Pb in order to determine the current efficiency in the emulsion medium. There was no significant disappearance of DDT at current densities <1 mA cm^{-2}; at these low current densities, the polarization of the cathode was insufficient for efficient electron transfer. The yield of DDMS was nearly constant at $i \geq 1$ mA cm^{-2}, while the yields of DDD and DDO increased with current (Fig. 3). At 10 mA cm^{-2}, 84% of the DDT was reduced to DDD (24%), DDMS (19%), and DDO (41%). The current efficiency was greatest at i = 1 mA cm^{-2} but, even so, was only 0.2%.

Schweizer et al. (1) also studied "mediated" (16) electrochemical reduction in the bicontinuous emulsions, using $Co(bipy)_3^{2+}$ as a mediator. Significant electrolysis occurred at the relatively positive potential of –1.0 V, consistent with $Co(bipy)_3^{+}$, formed by reduction of $Co(bipy)_3^{2+}$, acting as

the reducing agent for DDT. After 3 h, the major products were DDE (24%), DDMU (17%), DDD (17%), DDMS (12%) and DDO (24%). Further electrolysis increased the yield of DDMU at the expense of DDD and DDMS.

Electrooxidations

Voltammetry of DDT at a Pt anode in ACN – 0.1 M $LiClO_4$ revealed half-wave potentials at +2.29 and +2.58 V vs. SHE (cf. ref. 11). Oxidation at +2.29 V involves conversion of DDT to 4,4′-dichlorobenzophenone (DBP), demonstrated by showing that the second oxidation corresponded to the oxidation potential of DBP. Differential pulse voltammograms of 1 mM DDT, DBP, and hydroquinone (HQ, which is known to undergo a 2e$^-$ oxidation (17)) in 0.1 M $LiClO_4$ – ACN at a Pt anode (Fig. 4) were obtained. The relative heights of these voltammetric peaks show that both DDT and DBP undergo 4e$^-$ oxidations.

Continuous flow electrolyses were performed in various solvents: 0.1 M $LiClO_4$ – acetonitrile, 0.05 M Na_2SO_4 in 50/50 t-BuOH/H_2O, and 0.05 M Na_2SO_4 – Triton SP-175 emulsion. The disappearance of starting material and appearance of products were monitored by removing samples from bulk solution and analyzing them by HPLC. Pt and Ti/IrO_2 were used as anodes; Ti/IrO_2 is an example of a "dimensionally stable anode," the mechanism of action of which has been proposed to involve surface-generated hydroxyl radicals as the reactive oxidant. This type of anode was of interest in that the hydroxyl radicals might be able to attack DDT (or its reduction products) at potentials less positive than those needed for direct oxidation of the substrate. This is an important consideration for substances like DDT that are resistant to oxidation, because it is impossible to avoid concurrent, parasitic oxidation of water.

Using Triton SP-175 emulsion as the reaction medium, no loss of DDT was observed at either Pt or Ti/IrO_2, using various current densities 0.2–20 mA cm^{-2}. In both acetonitrile and 50/50 t-BuOH/H_2O, the starting material was observed to disappear but the mass balance of organic products was very poor. Using a Pt anode and current density i = 5 mA cm^{-2}, DDT disappeared more than 10 times faster in 0.1 M $LiClO_4$ – ACN ($k = 6.5 \times 10^{-4}$ s^{-1}) than in 50/50 t-BuOH/H_2O ($k = 5.3 \times 10^{-5}$ s^{-1}). In the former case, the only product detected was DBP (Fig. 5), but in t-BuOH/H_2O, DBP was accompanied by traces of 2,2,2-trichloro-1-(4-chlorophenyl)ethanone. In 0.1 M $LiClO_4$ – acetonitrile, the rate of disappearance of DDT at a Ti/IrO_2 anode (i = 5 mA cm^{-2}) was slower ($k = 5.8 \times 10^{-4}$ s^{-1}) than at Pt; DBP was again the major organic product, along with traces of chlorophenol and 2,2,2-trichloro-1-(4-chlorophenyl)ethanone. A rationalization of these products involves proton loss from $DDT^{\cdot+}$ to give $Ar_2C^{\cdot}$-CCl_3, followed by either attack of O_2 (from the atmosphere) at the radical centre or a second oxidation to Ar_2C^+-CCl_3 and nucleophilic attack by water.

We considered that the poor mass balance of organic products might result from "electrochemical combustion" (18) of DDT and intermediate products at the anode. We therefore modified the apparatus to trap any CO_2 formed during electrooxidation in ACN – 0.1 M $LiClO_4$ in $Ba(OH)_2$ solution. The residual amount of HO^- was determined by titration. Experiments were performed at both Pt and Ti/IrO_2 using various current densities. Once CO_2 was included,

© 1999 NRC Canada

mass balances improved to ≥92%; current efficiencies ranged up to >30% (Table 2), with the highest current efficiencies being achieved by operating at the smallest practical current densities. The first step in the oxidation yields DBP; however, at the potential required to oxidize DDT, DBP is further oxidized at the electrode surface.

Conclusions

At a Pb cathode, DDT is sequentially reduced to less chlorinated derivatives, particularly DDMS and DDO. No loss of chlorine is observed from the phenyl rings, consistent with our earlier experiments with polychlorinated benzenes (13, 14). Reduction takes place in an almost entirely aqueous medium, based on the new surfactant Triton SP-175, using sodium sulfate as an environmentally friendly supporting electrolyte. Mass balances are excellent at all stages of the reaction, but the current efficiency of the process (0.2%) is completely unacceptable for any practical technology to be contemplated.

Conversely, in the case of electrooxidations, high current efficiencies (>30%) were obtained, but only in a nonaqueous solvent; this time, it is the solvent that is technologically impractical. The potential required to oxidize DDT is sufficiently positive that neither an aqueous cosolvent (*t*-BuOH) nor an aqueous surfactant allowed oxidation of DDT to compete successfully with oxidation of water. In acetonitrile, the highly positive potential required to oxidize DDT leads to concurrent oxidation of all reaction intermediates, and "electrochemical combustion" gives CO_2 as a major product.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support, Union Carbide for providing Triton SP-175 surfactant, and a referee for suggesting base-catalyzed elimination from DDT.

Apparent molar volume of some ω-amino acids in aqueous electrolyte systems

D. Kumar

Abstract: Apparent molar volumes (V_ϕ) of some ω-amino acids have been determined in aqueous guanidine hydrochloride (6 *m* GuHCl) and sodium sulphate (2 *m* Na_2SO_4) solutions at 288.15 and 298.15 K using a vibrating tube digital densimeter. The transfer volumes of amino acids from water to aqueous electrolyte systems have been reported. The transfer properties are interpreted in terms of strong interactions, based on a cosphere overlap model of guanidine hydrochloride/sodium sulphate molecules with the charged centers of the zwitterions (amino acid molecules), as compared to ion – nonpolar group interactions.

Key words: amino acids, denaturation, guanidine hydrochloride, sodium sulphate, apparent molar volume, zwitterions, limiting apparent molar volume.

Résumé : Faisant appel à un densimètre digital à tube vibrant et opérant à 288,15 et 298,15 K, en solutions aqueuses de chlorhydrate de guanidine (6 *m* GuHCl) et de sulfate de sodium (2 *m* Na_2SO_4), on a déterminé les volumes molaires apparents (V_ϕ) de quelques acides ω-aminés. On a calculé les volumes de transfert des acides aminés de l'eau aux systèmes aqueux d'électrolyte. On interprète les propriétés de transfert en fonction de fortes interactions, découlant d'un modèle de recouvrement de cosphères des molécules de chlorhydrate de guanidine/sulfate de sodium avec les centres chargés des zwitterions (molécules d'acides aminés) par opposition aux interactions ion – groupe non polaire.

Mots clés : acides aminés, dénaturation, chlorhydrate de guanidine, sulfate de sodium, volumes molaires apparents, zwitterions, volume molaire apparent limite.

[Traduit par la Rédaction]

Introduction

Investigations on the volumetric properties of model compounds such as amino acids provide valuable information that ultimately leads to a better understanding of the behavior of biological macromolecules or proteins. A small change in water structure can greatly inhibit the physiological reactions in tissues or cells, which are made up of biological macromolecules. The change in water structure can be brought about by the presence of electrolytes. Sometimes, these changes are helpful in controlling undesired physiological reactions (1–4) occurring in living organisms. In view of the above, the study of the effect of electrolytes on model compounds of biological macromolecules is of fundamental importance.

Volumetric studies on amino acids in aqueous electrolyte systems reflect the combined effect of various hydrophilic and hydrophobic interactions in these systems. It was observed that concentrated salt solutions have large effects on the structure and properties of proteins, including solubility, denaturation, and the activity of enzymes. Nandi and Robinson (5) studied the *salting in* or *salting out* effects of several salts on macromolecules or proteins, and suggested that the salts interact directly with the peptide group. Denaturation of proteins in the presence of urea and guanidine hydrochloride has been studied extensively (6, 7).

In this paper, the limiting apparent molar volumes of five ω-amino acids in aqueous guanidine hydrochloride and sodium sulphate solutions over the concentration range 0.05–0.70 mol kg^{-1} have been presented, with the aim of deducing possible correlations between structural interactions of amino acids in aqueous salt solutions and the effects of salt on proteins.

Materials and methods

Five ω-amino acids chosen for the study were glycine (**Gly**), β-alanine (**β-Ala**), γ-aminobutyric acid (**γ-Aba**), δ-aminovaleric acid (**δ-Amv**), and ε-aminocaproic acid (**ε-Ahx**). All amino acids and guanidine hydrochloride were procured from Sigma Chemical Company, St. Louis, Mo., U.S.A. Anhydrous sodium sulphate (G.R.) was obtained from Sarabhai M. Chemicals, India. Guanidine hydrochloride, sodium sulphate, and all the amino acids except δ-aminovaleric acid were used after drying at 373.15 K for 10 h in a vacuum oven and were stored in a desiccator over P_2O_5. δ-Aminovaleric acid was dried in vacuo over P_2O_5 at 277.15 K before use. Doubly distilled water was deionized by passing it through two Cole–Parmer mixed-bed ion-exchange columns and degassed by boiling it before use in preparation of solutions. Solutions were prepared by mass using a Mettler AE-163 electronic balance. All density measurements were carried out only on freshly prepared solutions.

An Anton Paar high-precision vibrating tube digital densimeter (model DMA 60/601) with precision of $\pm 3 \times 10^{-3}$ kg m^{-3}

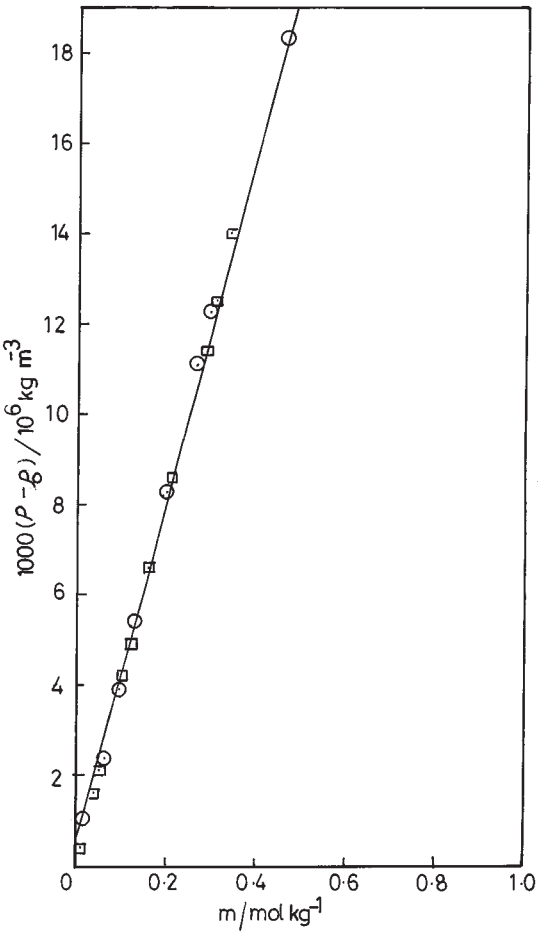
Fig. 1. Plot of $1000(\rho - \rho_0)$ versus molality of NaCl. Present work (○); ref. 10 (□).

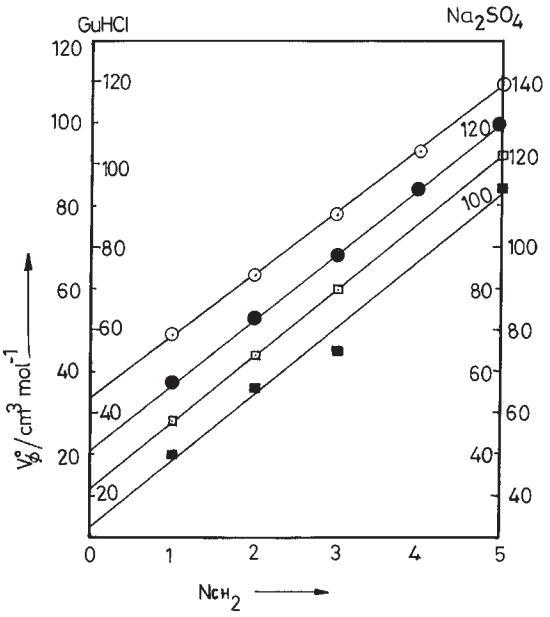


was used for the density measurements of the solutions. The temperature in the measuring cell was controlled to ±0.01 K and monitored with a Paar model DT-100-20 digital thermometer. The densimeter was calibrated using the literature data for densities of dry air (8) and pure water (9) at 288.15 and 298.15 K. The densities of pure water at 288.15 and 298.15 K are 0.999 098 and 0.997 048 (10^3 kg m^{-3}) and of air at the same two temperatures are taken as 0.001 161 and 0.001 122 (10^3 kg m^{-3}), respectively. The density and apparent molar volume data of aqueous sodium chloride from this study are compared (Appendix A) with the literature values (10). The data were plotted as $1000(\rho - \rho_0)$ against molality of sodium chloride (Fig. 1). The apparent molar volume at infinite dilution from the present study (16.50 cm^3 mol^{-1}) has been compared with the literature value (16.62 cm^3 mol^{-1}), which is in fairly good agreement.

Results and discussion

The results of density measurements on aqueous solutions of guanidine hydrochloride, sodium sulphate, and solutions of ω-amino acids in 6 *m* guanidine hydrochloride and 2 *m* sodium sulphate at 288.15 and 298.15 K were used to determine the apparent molar volumes (Appendix B). The apparent molar volumes (V_ϕ) of amino acids in 6 *m* GuHCl and 2 *m* Na_2SO_4 solutions at two temperatures were calculated using the relation

Fig. 2. Plot of V_ϕ^0 versus N_{CH_2}. GuHCl at 288.15 K (○); GuHCl at 298.15 K (●); Na_2SO_4 at 288.15 K (□); Na_2SO_4 at 298.15 K (■).



$$[1] \qquad V_\phi = 1000(\rho_0 - \rho)/\ m\ \rho\ \rho_0 + M/\rho$$

where *m* is the molality, *M* is the molar mass of the solute, ρ is the measured density of solution, and ρ_0 the density of the 6 *m* GuHCl / 2 *m* Na_2SO_4 solution at 288.15 and 298.15 K. Since the apparent molar volumes (V_ϕ) were found to vary linearly with molality, the limiting apparent molar volumes have been calculated by using the equation

$$[2] \qquad V_\phi = V_\phi^0 + b_V\ m$$

where V_ϕ^0 is the limiting apparent molar volume and b_V is an experimental slope. The values of apparent molar volumes at infinite dilution (V_ϕ^0) and experimental slope (b_V) are presented in Table 1.

The limiting apparent molar volumes of the amino acids in aqueous guanidine hydrochloride and sodium sulphate at each temperature are larger than the corresponding values in water (7). It is also noted that the limiting apparent molar volumes of the amino acids in aqueous guanidine hydrochloride at 298.15 K are larger than at 288.15 K, except for glycine. However, for aqueous sodium sulphate, V_ϕ^0 shows an increase with temperature, except in the case of γ-Aba. The V_ϕ^0 values plotted against N_{CH_2}, the number of CH_2 groups (Fig. 2) in the backbone chain, yielded straight lines at 288.15 and 298.15 K. The V_ϕ^0 vs. N_{CH_2} data could, therefore, be regressed by

$$[3] \qquad V_\phi^0 = V_\phi^0\ (NH_3^+,\ COO^-) + \sum_{n=1}^{N_{CH_2}} n\ V_\phi^0\ (CH_2)$$

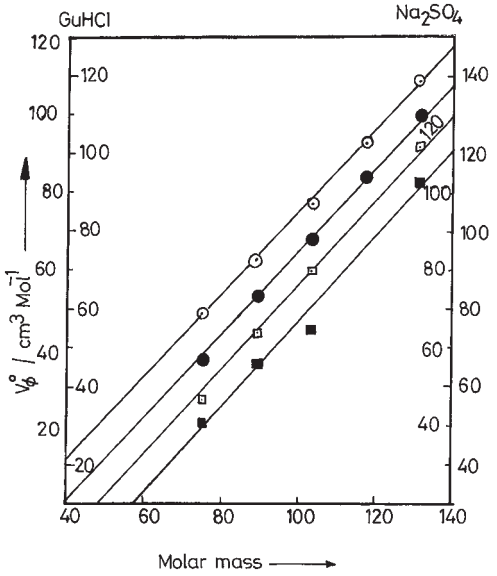
Fig. 3. Plot of V_ϕ^0 versus molar mass of amino acids. GuHCl at 288.15 K (○); GuHCl at 298.15 K (●); Na_2SO_4 at 288.15 K (□); Na_2SO_4 at 298.15 K (■).



where V_ϕ^0 (CH_2) is the volume contribution of the CH_2 group in appropriate units and V_ϕ^0 (NH_3^+, COO^-) is identified as the contribution due to polar end groups, NH_3^+ and COO^-. The average values of V_ϕ^0 (CH_2) in aqueous guanidine hydrochloride solutions are found to be 15.15 and 15.78 cm^3 mol^{-1}, while in aqueous sodium sulphate solutions the values are 16.04 and 16.25 cm^3 mol^{-1} at 288.15 and 298.15 K, respectively. These calculated values are compared with literature values (11), 15.3–15.8 cm^3 mol^{-1} in aqueous KSCN solutions at the two temperatures, and this value approaches 15.8–16.0 cm^3 mol^{-1} as the KSCN concentration increases at 298.15 K.

It has been found that the apparent molar volume, in general, increases with the increasing molar mass and size of the amino acids (Fig. 3). These results indicate that the volume contribution of the hydrocarbon portion of the amino acid is proportional to the molecular weight (similar to other organic solutes) and the volume contribution due to $^+H_3N(CH_2)_nCOO^-$ ($1 \le n \le 5$) is not strongly affected by the hydrocarbon groups. The trend of the limiting apparent molar volume V_ϕ^0 is found to be Gly < β-Ala < γ-Aba < δ-Amv < ε-Ahx.

The limiting apparent molar volumes of transfer were calculated by subtracting the limiting apparent molar volumes of amino acids in water from the limiting apparent molar volumes in aqueous electrolyte solutions. The limiting apparent molar volume of transfer, ΔV_{tr}^0, for amino acids studied in going from water to aqueous electrolyte systems, is calculated using the relation

$$[4] \qquad \Delta V_{tr}^0 = V_\phi^0 \text{ (aq. electrolyte)} - V_\phi^0 \text{ (water)}$$

where the limiting apparent molar volumes for ω-amino acids in water are taken from the author's work reported elsewhere (7).

The limiting apparent molar volumes of transfer, ΔV_{tr}^0, for transfer of amino acids from water to aqueous guanidine hydrochloride and sodium sulphate systems are presented in Table 2. An examination of the ΔV_{tr}^0 values indicates that the ΔV_{tr}^0 is highest for γ-Aba at 288.15 K and for ε-Ahx at 298.15 K. The ΔV_{tr}^0 for Gly is lower than that for β-Ala at 288.15 and 298.15 K for both GuHCl and Na_2SO_4 (except 6 *m* GuHCl at 288.15 K). However, the variation of ΔV_{tr}^0 in GuHCl and Na_2SO_4 with the number of carbon atoms N_{CH_2} in the backbone chain is not so regular for ω-amino acids at 288.15 and 298.15 K. The fact is that, with the increase in N_{CH_2}, the charge separation increases and hence the NH_3^+ and COO^- cosphere overlap decreases, leading to an in-

crease in salt – polar group interactions. Thus, the decrease in the number of electrostricted water molecules results in an increase in volume (12). Also, when cosolute, i.e., GuHCl/Na_2SO_4 molecules, interact with the charged centers of amino acids, some of the previously electrostricted water molecules around these centers return to their normal structure due to the hydration cosphere overlap effect, causing a net decrease in electrostriction that ultimately gives rise to an increase in transfer volume. The variation of ΔV_{tr}^0 with the number of CH_2 groups for ω-amino acids gives volume contributions for different groups. The intercepts give the volume contributions of the charged end or head groups (NH_3^+, COO^-), while the slopes give the volume contribution of the methylene (-CH_2) groups.

As the hydrophobic hydration of the -CH_2 groups in ω-amino acids is suppressed by overlap of the hydration cospheres of the polar end groups and in the presence of electrolyte, strong polar–polar group (=NH_2^+--COO^- and Cl^---NH_3^+ or Na^+--COO^- and SO_4^{2-}--NH_3^+) interactions enhance the hydrophobic hydration, thereby resulting in the positive transfer volume contribution of the -CH_2 groups. The resulting positive transfer volumes, ΔV_{tr}^0, for the transfer of amino acids from water to aqueous guanidine hydrochloride and sodium sulphate can be explained by assuming a decreased electrostriction of the solvent around the charged groups on the amino acid due to strong interactions between these groups and the $(H_2N)_2C{=}NH_2^+$ and Cl^- ions. The reduced structure-breaking tendency of $(H_2N)_2C{=}NH_2^+$ and Cl^- ions, due to their interactions with the amino acid, also contributes to the positive transfer volumes. However, Belibagli and Ayranci (13) proposed that the positive transfer volume ΔV_{tr}^0 is due to the solute–cosolute–solvent interactions. The discrepancy between their result with the present work on glycine is explained on the basis of the difference in the instrument used for density measurements. Belibagli and Ayranci conducted the density measurements using the buoyancy balance method, which is not capable of the high precision offered by the Anton Paar high-precision vibrating tube digital densimeter. The present work also supports a similar variation of ΔV_{tr}^0 with the number of CH_2 groups observed in water + KSCN + amino acid and water + NH_4Cl + amino acid systems (11, 14).

Conclusions

The present work, which is confined to volumetric studies of ω-amino acids in aqueous electrolyte systems, reflects the combined effect of various hydrophilic and hydrophobic interactions in these systems. It is concluded that the limiting apparent molar volume increases with increase in temperature as well as with a -CH_2 group increment in the backbone of the amino acids. Positive transfer volumes, ΔV_{tr}^0, for the transfer of amino acids from water to aqueous GuHCl and Na_2SO_4 systems, have been observed. The results reveal that guanidine hydrochloride is a water-structure breaker and interacts with charged end groups of the zwitterionic amino acids, causing a net decrease in electrostriction of the solvent, while sodium sulphate is a water-structure maker.

The structure and some molecular properties of acetone-picrylhydrazone

K.C. Brown, B.R. Nelson, J.W. Quail, B.E. Robertson, J.A. Weil, and Z. Zimpel

Abstract: Various physical measurements and quantum-mechanical computations to characterize molecular 2-propanone(2,4,6-trinitrophenyl)hydrazone, alias acetone-picrylhydrazine (AH), are reported, including an X-ray diffraction structural determination, an ^{1}H and ^{13}C NMR study of its internal hindered reorientation, and a theoretical (SCF-MO) interpretation of these observations. The structure of AH was determined by X-ray crystallography. The space group is $P\bar{1}$, with a = 10.1768(9) Å, b = 7.7968(18) Å, c = 8.0018(5) Å, α = 92.102(6)°, β = 99.919(7)°, γ = 105.926(6)°, Z = 2, $wR2(F^2)$ = 0.1995 based on all 2748 unique reflections. The (picryl) proton NMR thermal work yielded a Gibbs activation energy $\Delta G^{\ddagger}$ = 46.9 ± 0.4 kJ mol^{-1} in acetone-d_6 and 48.1 ± 0.2 kJ mol^{-1} in chloroform-d, whereas ^{13}C NMR (two pairs in the picryl ring) yielded 46.6 ± 1.0 and 46.4 ± 1.0 kJ mol^{-1} in acetone-d_6. The SCF-MO computations yielded a detailed model of the conformerization path. Various model conformations and tautomers of AH have been considered, as has removal of H^+ or of H^0 from its hydrazinic linkage.

Key words: dynamic NMR, picrylhydrazone, hindered rotation, activation parameters, SCF-MO model.

Résumé : On a caractérisé 2,4,6-trinitrophénylhydrazone de la propan-2-one (AH, obtenue à partir de l'acétone et de la picrylhydrazine) par des mesures physiques et des calculs de mécanique quantique, comportant une détermination de structure par diffraction des rayons X, une étude de la réorientation interne empêchée par examen des spectres RMN du ^{1}H et du ^{13}C et une interprétation théorique (SCF-MO) de ces observations. On a déterminé la structure de AH par diffraction des rayons X: groupe d'espace $P\bar{1}$, avec a = 10,1768(9), b = 7,7968(18) et c = 8,0018(5) Å, α = 92,102(6)°, β = 99,919(7)° et γ = 105,926(6)°, Z = 2, $wR2(F^2)$ = 0,1995 sur la base des 2748 réflexions uniques. Le travail thermique en RMN du proton (picryle) permet de tirer une énergie d'activation de Gibbs de $\Delta G^{\ddagger}$ = 46,9 ± 0,4 kJ mol^{-1} dans l'acétone-d_6 et de 48,1 ± 0,2 kJ mol^{-1} dans le chloroforme-d; par ailleurs, la RMN du ^{13}C (deux paires dans le noyau picryle) conduit à des valeurs de 46,6 ± 1,0 et de 46,4 ± 1,0 kJ mol^{-1} dans l'acétone-d_6. Les calculs SCF-MO ont permis de tirer un modèle détaillé de la voie conformationnelle. On a considéré divers modèles de conformations et de tautomères pour AH et pour ses dérivés obtenus par enlèvement de H^+ ou de H^0 de sa liaison hydrazinique.

Mots clés : RMN dynamique, 2,4,6-trinitrophénylhydrazone de l'acétone, rotation empêchée, paramètres d'activation, modèle SCF-MO.

[Traduit par la Rédaction]

Introduction

The present paper presents our recent study of 2-propanone(2,4,6-trinitrophenyl)hydrazone (alias: acetone-picrylhydrazine ≡ AH), a molecule that presents much of interest for structural studies (Fig. 1). We include an X-ray diffraction single-crystal determination of the molecular structure, a detailed nuclear magnetic resonance (NMR) study of internal molecular motions, and a molecular-orbital (self-consistent-field Hartree–Fock) examination of its energetics and geometric configuration. Certain aspects of its acidity and oxidizability will also be discussed. With regard to the former, our interest in AH stems in part from its ability to form stable alkali salts (1) and its reaction to form picryl-ring addition compounds with the enolate of acetone (2).

General reviews dealing with hydrazones are available (3, 4). However, relatively little information dealing specifically with AH is to be found, but the recent literature does contain a preparative recipe (5), slightly modified herein, and also describes some polarographic reduction work (6).

Preparation and characterization of AH

A solution containing 10 g of 2,4,6-trinitrophenylhydrazine[2] in 300 mL of acetone, after adding one drop of 6 M aqueous HCl, was refluxed for 30 min. The solvent was then

[2]This compound, picrylhydrazine, was prepared by reaction of picrylchloride (10 g in 160 mL methanol) with hydrazine hydrochloride (8.5 g in 20 mL water), followed by treatment with aqueous Na_2CO_3 (8.5 g in 40 mL water, added in batches). Addition of aqueous HCl (60 mL of 2 M acid) then yielded the solid yellow product.

removed by rotary evaporation. The impure hydrazone was crystallized from 95% EtOH to give bright yellow crystals: mp 129.5–130.5°C. FT IR (cm^{-1}): 3280 (N–H), 3108–3075 (C–H, ar), 2944–2918 (C–H, al). ^{1}H NMR δ (300.13 MHz, 280 K, acetone-d_6) (ppm): 11.06 (1 H, s), 8.98 (2 H, s), 2.14 (3 H, s), 2.04 (3 H, s). ^{1}H NMR δ (300.13 MHz, 290 K, chloroform-*d*) (ppm): 11.12 (1 H, s), 8.91 (2 H, s), 2.08 (6 H, s). See Fig. 2. ^{13}C NMR δ (75.47 MHz, 330 K, acetone-d_6) (ppm): 159.33 (C7), 138.15 (C1), 136.56 (C2, C6), 136.04 (C4), 125.82 (C3, C5), 24.01 and 16.50 (C71 and C72). See Fig. 3. Anal. calcd. for $C_9H_9N_5O_6$: C 38.17, H 3.20, N 24.73; found: C 38.62, H 3.24, N 24.88.

X-ray diffraction structural study of AH

A yellow plate-shaped crystal was mounted on a glass fibre on a Picker FACS-1 diffractometer, equipped with graphite-monochromated Mo-K_α radiation (λ = 0.71073 Å). Data collection and initial data processing were carried out using the NRCC diffractometer control system (7). Data processing and structure solution used XTAL3.4 (8). SHELXL-97 (9) was used for refinement of the structure. Cell constants and orientation matrices were obtained from least-squares refinement, using 32 reflections and their Friedel mates in the range $45° < 2\theta < 55°$. Details of the structure determination results are given in Table 1. The intensities of three representative reflections were measured after data for sets of 47 reflections had been obtained. Over the course of data collection, the standards decreased by 3.5%, and a linear correction factor was applied to the data. No correction was made for absorption. Lorentz and polarization corrections were applied to the data. The structure was solved by direct methods in space group *P*1 and then converted into space group $P\bar{1}$. The non-hydrogen atoms were refined anisotropically; hydrogen atoms were located on Δ*F* maps and then adjusted to ideal positions and not refined. The final cycle of full-matrix least-squares refinement was based on all 2748 reflections and 181 parameters, refining the parameter $wR2 = [\Sigma\, w(F_o^2 - F_c^2)^2 / \Sigma\, w\, F_o^4]^{1/2}$. The refinement converged to a value of $wR2(F^2) = 0.1995$ on all data. A final Fourier difference map calculation showed no peaks of chemical significance. The atomic coordinates are given in Table 2, and various interatomic distances and angles of interest are set out in Table 3. Tables of thermal parameters, anisotropic thermal parameters, atomic coordinates and bond lengths involving hydrogen atoms, torsion angles, and contact distances are available as supplementary data.[3]

When positional restraints on H1 were removed, followed by eight cycles of refinement, the H1 position was found to be consistent with sp^2 hybridization of N1 and within 3σ of the idealized position.

The standard unit cell contains two conformeric molecules (Fig. 1) related by a center of inversion. There is no crystal mirror plane, but in fact the two isomers are nonsuperposable mirror-image conformers (enantiomers). They differ primarily in the relative orientations of the nitro groups *ortho* to the hydrazine linkage at carbon C1.

NMR experimental

The solvents used were acetone-d_6 and chloroform-*d*, in order to be able to reach down to ca. 200 K and also because they differ appreciably in H-bonding capability (10). Tetramethylsilane was used as the line-position standard. The ^{1}H and ^{13}C NMR experiments were performed on a Bruker AMX-300 spectrometer at 300.13 and 75.47 MHz,

[3] These data can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada. Tables of hydrogen atom coordinates and of bond lengths involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, England.

[a] U(eq) is defined as one third of the trace of the orthogonalized U^{ij} tensor.

respectively. Temperature control on the AMX-300 was provided by a B-VT-1000 variable-temperature unit. Temperature calibration was performed using the chemical shift difference between the methyl and hydroxy peaks of neat methanol, at and below room temperature.

Nuclear magnetic resonance spectroscopic study of AH

The proton spectrum of AH (Fig. 2) is well suited to a study of the internal dynamics of the molecule. In the past, we have performed similar studies on 2,2-diphenyl-1-picrylhydrazine (≡ DH) (10, 11).

The picryl protons are convenient probes of the interchange process, which transforms one conformer into the other (Fig. 1). These protons experience different magnetic environments primarily because the two *ortho*-nitro groups, on carbons 2 and 6 of the picryl ring, are at different orientations relative to the ring, largely due to hydrogen bonding to the hydrazinic hydrogen in AH. In this compound the picryl protons therefore have a non-zero chemical shift difference Δ_{H3-H5} (61.6 Hz in acetone-d_6 (T = 210 K), and 209.5 Hz in chloroform-d (T = 210 K; Fig. 2, lower)). Also, an electron-coupled scalar interaction (J) between them is observed in the very slow exchange spectrum as a small line splitting, e.g., 2.7 Hz at 183 ± 1 K in acetone-d_6 and 2.5 Hz at 210 ± 1 K in chloroform-d.

[a]The proton position was fixed by the geometric configuration of the neighbor atoms.

[b]Not a bond torsion angle.

The ^{13}C nuclei also can be used to give information about the internal dynamics. At low temperature (210 K) there are nine distinct peaks in the ^{13}C NMR spectrum, six of which correspond to nonequivalent carbons in the picryl ring Here $\Delta_{C2–C6}$ = 491.5 Hz and $\Delta_{C3–C5}$ = 127.1 Hz (Fig. 3, lower). As the temperature is raised, these pairs of peaks coalesce and there are only seven peaks observed at 330 K (Fig. 3, upper). One can use the peaks due to carbons 2 and 6 (which are interchanging) and carbons 3 and 5 (which are interchanging) for lineshape analysis. In practice, however, there is a large difference in the signal strengths for these pairs of carbons, the latter pair having the larger signal-to-noise ratio. This presumably is due to the nuclear Overhauser effect on carbons 3 and 5 resulting from the decoupling radiation applied to the protons attached to these carbons. Sufficient acquisition time, especially near the peak-coalescence temperature, overcame this problem. Thus carbons 2 and 6 as well as carbons 3 and 5 were used for the rate study. To our knowledge, this is the first case in which two sets of peaks in the same NMR spectrum have been used to investigate the same conformational interchange phenomenon. The assignment of resonances in the ^{13}C spectrum for carbons 3 and 5 was verified using a *J*-modulation experiment (12).

It was thought at first that the two methyl groups might potentially be useful as another probe into the reorientation

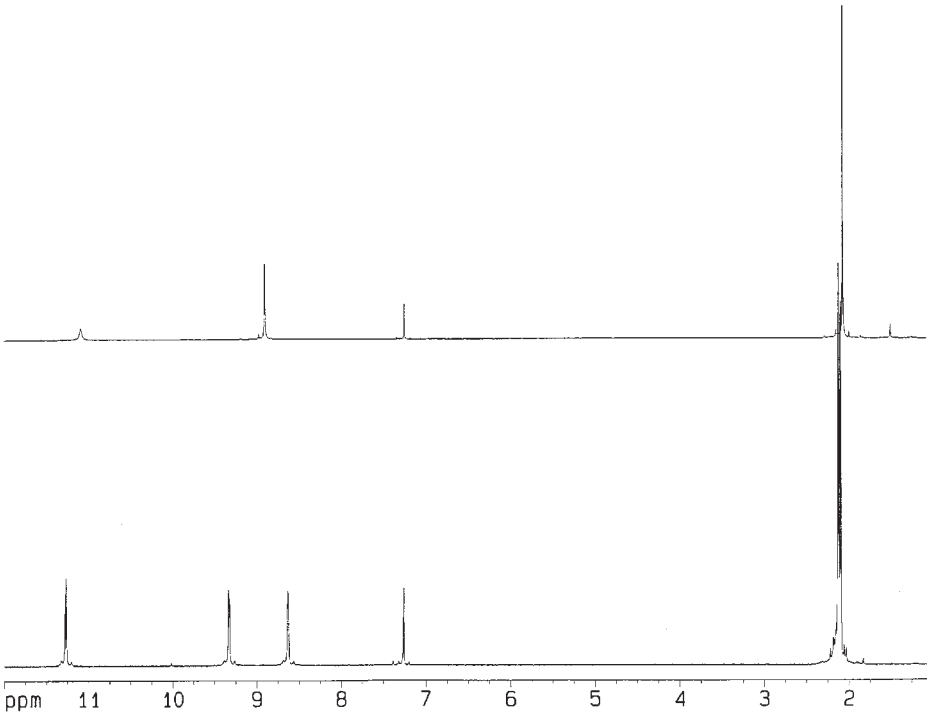

Fig. 3. The ^{13}C NMR spectrum of AH taken at 75.47 MHz in acetone-d_6 at 210 K (lower) and 330 K (upper).

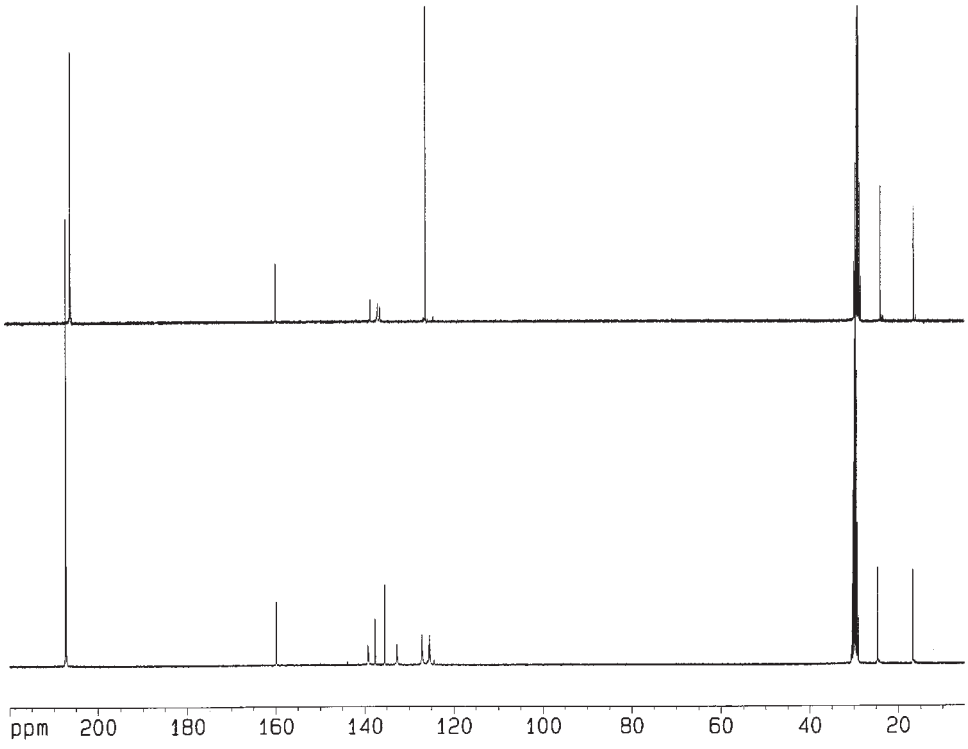

process. At low temperature (210 K), two distinct ^{1}H NMR peaks are observed, since the protons in each methyl group act as equivalent; the peaks are separated by 30.8 Hz in acetone-d_6 and by 8.1 Hz in chloroform-*d*. However, there is little or no change in either peak shape or separation as the temperature is raised. On heating from 183 to 240 K in acetone-d_6, the methyl ^{1}H peak separation increases slightly. It then decreases slowly on going to higher temperatures. In

Table 4. Activation energy E_a, natural logarithm of the frequency factor k_∞, the standard molar activation enthalpy change $\Delta H^\ddagger$, entropy change $\Delta S^\ddagger$, and Gibbs free-energy change $\Delta G^\ddagger$, all at 298.15 K, as a function of the nuclide and the solvent. The number n_T of temperatures at which lineshapes were measured, respectively, was 13, 9, 10, 14. The observed low-temperature relaxation times T_2 used to give the basic line widths for the fittings were (in Hz) 0.20, 0.159, 0.076, 0.21 taken at temperatures 183 K for the first value, 190 K for the middle pair, and 210 K for the fourth. Estimated errors (in parentheses) were calculated according to the procedure given in Sandström (ref. 14, Chap. 7).

Nuclide	Solvent	E_a (kJ mol^{-1})	ln k_∞ (k_∞ in s^{-1})	$\Delta H^\ddagger$ (kJ mol^{-1})	$\Delta S^\ddagger$ (J mol^{-1} K^{-1})	$\Delta G^\ddagger$ (kJ mol^{-1})
^{1}H3,5	Acetone-d_6	40.1 (4)	26.7 (4)	37.6 (4)	–31.2 (2)	46.9 (4)
^{13}C2,6	Acetone-d_6	44.1 (8)	28.5 (4)	41.7 (8)	–16.4 (3)	46.6 (1.0)
^{13}C3,5	Acetone-d_6	44.6 (8)	28.7 (4)	42.1 (8)	–14.5 (3)	46.4 (1.0)
^{1}H3,5	Chloroform-*d*	55.3 (5)	32.4 (4)	52.9 (5)	15.9 (9)	48.1 (2)

the same solvent, the ^{13}C peak separation decreases slowly from 183 to 330 K at a rate of –0.2 Hz K^{-1}. In $CDCl_3$, the ^{1}H peak separation of the methyl peaks decreases at a rate of approximately –0.06 Hz K^{-1}. Here, on heating, the peaks merge at approximately 300 K and then reappear at 320 K. In summary, kinetic broadening and coalescence of the methyl doublets was not observed.

For the ^{1}H NMR (acetone-d_6) experiments, spectra at n_T = 13 different temperatures between 183 and 280 K were obtained, at approximately 10 K intervals. The NMR samples were allowed to equilibrate at each new temperature for 20 min. With chloroform-*d*, n_T was 14, for temperatures between 210 and 340 K. For the ^{13}C NMR work (C2,6 and C3,5 in the acetone), n_T was 9, within the range 210–330 K.

The temperature dependences of the chemical shift differences at the lower temperatures (183–240 K) below onset of conformerization effects were investigated. The slopes with increasing temperature were estimated to be (Hz K^{-1}) 1.89 (H3,5), 0.44 (C2,6), and 0.00 (C3,5) in acetone-d_6 and 0.15 (H3,5) for chloroform-*d*. These data were used to extrapolate the appropriate chemical shift differences for the lineshape fitting. It proved to be important for accuracy to use line widths (i.e., T_2 values; see Table 4) obtained at the lowest temperatures attainable.

Spectral analyses were performed using the Maple symbolic computation program (13). Input consisted of the chemical shifts of the resonances, line-width parameter, rate parameter, and the lineshape equations (14). It was assumed that the lineshapes are Lorentzian, that the reorientation time is small compared to the mean lifetime of the two configurations (Fig. 1) of the AH molecules in solution, and that the reorientation process is mutual.

The Arrhenius model (15)

$$[1] \qquad \ln(k_T) = \ln(k_\infty) - E_a/(RT)$$

for an isothermal process was used to determine the molar activation energy E_a, where R is the ideal gas constant and T is the temperature in degrees kelvin. The pseudo-thermodynamic activation parameters (see ref. 14) were calculated via the equations

$$[2] \qquad \Delta H^\ddagger = E_a - RT$$

$$[3] \qquad \Delta S^\ddagger = R[\ln(k_\infty hN_A/(eRT))]$$

$$[4a] \qquad \Delta G^\ddagger = \Delta H^\ddagger - T\Delta S^\ddagger$$

$$[4b] \qquad = RT\,[\ln(RT/(k_T hN_A))]$$

where h is Planck's constant, N_A is Avogadro's number, and e is the base of the natural logarithm.

Lineshape analysis of the picryl ^{1}H and ^{13}C NMR spectra gave a set of synthesized shapes corresponding nicely to the experimental shapes, yielding values of the rate constant k_T, in s^{-1}, for each temperature T. The Arrhenius plots obtained from the k_T versus T data yielded values of E_a as presented in Table 4. Application of eqs. [2]–[4] then yielded the molar pseudo-thermodynamic parameters $\Delta H^\ddagger$, $\Delta S^\ddagger$, and $\Delta G^\ddagger$ at 298.15 K, also given in Table 4. Of these, $\Delta G^\ddagger$ is thought to yield the most reliable numbers, due to statistical cancellation of certain errors (10, 14). It is evident then from the NMR data that there is a mechanism (hindered reorientation of the nitro groups at C2 and C6, and of H1) via which the hydrogen bond can be temporarily broken.

We have also investigated the oxidizability of AH, in part using ^{1}H NMR spectroscopy. For comparison, acetone (and also chloroform) solutions of 2,2-diphenyl-1-picrylhydrazine (DH) were run in tandem with these. The oxidants PbO_2(s) and $KMnO_4$(s) were used, both of which are well known (16) to rapidly generate the stable free radical 2,2-diphenyl-1-picrylhydrazyl (≡ D, alias DPPH) from DH at room temperature, with resulting purple color and immediate EPR signal.[4] No color change or EPR signal was detected on such treatment of AH. The room-temperature 300 MHz ^{1}H NMR spectrum of AH showed virtually no change after 4 h of exposure to oxidant, but did show some new peaks, both in the methyl and phenyl regions, after 24 contact hours. The NMR line widths continued to be narrow, and were unshifted. By contrast, the ^{1}H spectrum of DH after contact with oxidant immediately yielded much broadened lines of DH, and no new lines developed. We conclude that AH is much more inert to oxidation than is DH, despite their various structural similarities.

Molecular orbital study of AH

Ab initio restricted Hartree–Fock calculations for the isolated AH model molecule were performed using Gaussian 92 with an Alpha DEC 5000 computer. Several optimum nu-

[4] One condition for stability of a hydrazyl free radical has been stated (17) to be equality of the electron spin population on the two hydrazinic nitrogens, as is the case with radical D (DPPH) derived from DH.

© 1999 NRC Canada

clear configurations (minima on the potential energy surface) of the AH molecule were found using the split-valence 3-21G basis set of atomic orbitals. The use of an even higher basis set was made impossible by the size of our molecule (29 atoms, 146 electrons); such a project would require prohibitively more computer time to finalize the calculations. On the other hand, the set 3-21G of atomic orbitals is relatively inexpensive but works well with hydrogen, carbon, nitrogen, and oxygen atoms (18).

The set of optimized variables (set I) found for the electronic ground state of AH is to be compared with the crystallographic data.[5] One can see that, with a few interesting exceptions, our computational results agree well with the X-ray diffraction data (Table 3). The carbon–hydrogen and nitrogen–hydrogen bond lengths always tend to be overestimated by the relatively low level (small basis set of atomic orbitals, Hartree–Fock approximation) of our ab initio computations. Therefore such consistent differences between these pairs of bond lengths should not raise major concerns. The lengths of bonds C1—N1, N1—N7, and N7—C7 demonstrate the double-bond character of the N7—C7 bond and the mixed character of the C1—N1 bond, which is in agreement with how we represent this molecule using resonance structure formulas. This is also in agreement with the carbon–carbon distances in the picryl ring: the bonds C1—C2 and C1—C6 (of length ca. 1.43 Å) are appreciably longer than the other ring C—C bonds (of length close to 1.37 Å).

The picryl ring, as revealed both by the experiment and by theory, is almost perfectly planar. The six ring carbons have a root-mean-square deviation of 0.013 Å from such an ideal plane, with maximal displacements (Å) between +0.018(2) (C6) and –0.015(3) (C4) from the plane.

The computational results are consistent with the existence of a hydrogen bond between H1 and O21: the O21—H1 distance of 1.8 Å (Table 3) is typical for the hydrogen bond, and the atoms N1, H1, O21, and N2 are in the picryl-ring plane. The intramolecular hydrogen-bond energy is difficult to define, since the breaking of such a hydrogen bond involves a change of the nuclear configuration in the molecule. We note that there is a tautomer of our model molecule, with "H1" attached to N7 (see below). In this configuration there is no intramolecular hydrogen bond. The energy difference between these two tautomers is about 53 kJ mol^{-1}, which is within the energy range of typical hydrogen bonds.

One way to quantify the nonequivalence of the two methyl groups in the isolated ground-state molecule is to calculate the electron density at each of these. We find that the Mulliken charge numbers are –0.6233 and –0.6827 at the carbon atoms, for C71 and C72, and 0.1029 and 0.0660 when the hydrogens are included. This suggests that methyl C71 is less screened than C72, with its ^{1}H and ^{13}C NMR peaks thus occurring further from the TMS signal.

There are two appreciable differences between the computational results and the X-ray diffraction measurements:

1. The X-ray data revealed a torsion angle C2-C1-N1-N7 of –177.3° (Table 3) while the calculation of this angle gave –156.8°. Thus in the crystal, utilizing the values of two other torsion angles, C1-N1-N7-C7 and C71-C7-N7-N1 or C72-C7-N7-N1 (Table 3), one finds that the plane defined by atoms N1, N7, and C7 is nearly identical with the picryl ring, yielding an extended π-electron system. However, in our optimized structure these two planes form an angle of ca. 20°. We ascribe this difference (which is not energetically very sensitive) to the influence of neighbouring molecules. The trend towards planarity of the molecules influenes the manner in which they stack within the crystal.

2. The second difference is in the rotational position (e.g., see torsion angle C1-C6-N6-O62 in Table 3) of the nitro group at carbon C6: –85.1° (measured) versus –144.7° (calculated). Thus, while in the crystal the plane of the NO_2 group is almost perpendicular to the picryl ring, the computations show that in the model it is rotated by only ca. 35° with respect to this ring. We think that here, too, the most probable reason for this difference is that there are intermolecular interactions in the crystal that favor the observed configuration. Moreover, the distortion discussed in paragraph 1 above can contribute to this effect: the electrons on nitrogen atom N7 (having an atomic charge number of –0.36) can interfere with the electrons on oxygen O61. This conclusion is also supported by the fact that nitrogen N6 of the rotated nitro group does not lie exactly in the picryl-ring plane, as is demonstrated by the C1-C5-C6-N6 angle of 174.5° (Table 3).

In addition to the minima in the total (Born–Oppenheimer) electronic energy discussed above for the two equivalent conformers (Fig. 1), we have found several other unconstrained minima. The configuration of the model molecule in a second (and higher) minimum in the energy, with parameters referred to as set II of nuclear coordinates, is characterized by a C1-N1-N7-C7 torsion angle of 79.2°. This is saying that the plane containing the atoms N1, N7, and C7 is almost perpendicular to the plane defined by atoms C1, N1, and N7, which are close to coplanar with the picryl-ring plane. The rotational position of the nitro group attached to C6, as measured by the torsion angle C1-C6-N6-O62, is ca. –126.1°. The nitro group attached to C2 and H1 remain in the plane, with the H-bond intact.

There also are two other "tautomers", with the hydrogen atom "H1" at N7 (set III) and at C7 (set IV). The energies of the four stable configurations II, III, and IV relative to the energy of set I were found to be 36.2, 53.3, and 149.1 kJ mol^{-1}. Clearly these energies are very large relative to the thermal energy (ca. 2.5 kJ mol^{-1}) of AH molecules at room temperature, so that the thermal populations of the conformational states defined by sets II, III, and IV are expected to be very small compared to the population of the lowest-energy conformation (set I).

Calculations were also performed to investigate the intermediate states for conformerization of AH to depict the journey of H1 from its location in one ground-state (GS) conformer to that in the other. For this, it was convenient to study a series of model molecules with the (only) constraint imposed that the torsion angle $\Omega_2 \equiv$ C2-C1-N1-H1 be equal to selected angles ranging from 0° to 180°; the range 0° to –180° is obtained by symmetry. The choice of angle Ω_2

[5] There is a second such state, with equal energy, featuring the opposite sign of all torsion angles. The chiral nature of our molecule thus leads to existence of pairs of conformers.

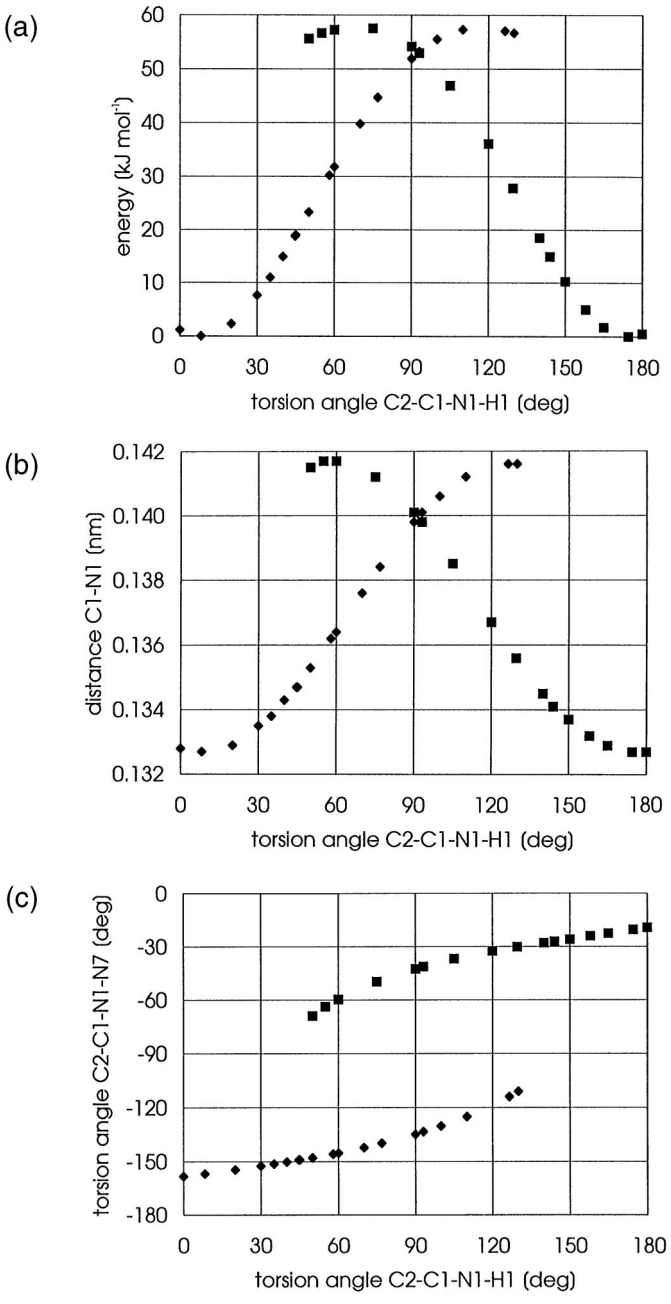
Fig. 4. Plot of the SCF-MO model of molecule AH: (*a*) minimized energy, (*b*) bond length C1—N1, and (*c*) torsion angle C2-C1-N1-N7, all versus the constraining torsion angle Ω_2 = C2-C1-N1-H1.



rather than $\Omega_6 \equiv$ C6-C1-N1-H1 is arbitrary. We note that the relationship between Ω_2 and Ω_6 is not a simple analytical one; Ω_2 is equal to $\Omega_6 - 180°$ only when atoms C1, C2, C6, and N1 all occur in one plane.

The conformations at Ω_2 = 8.2° and at 174.6° (Fig. 4*a*), attained without imposing any constraint, correspond to the minimum energy (ground state GS, as shown in Fig. 1 left model and right model, and discussed above; also see Table 3). These angles correspond to Ω_6 = –174.6° and –8.2°, respectively. The curves of the electronic energy, of the distance C1—N1, and of torsion angle C2-C1-N1-N7 in the model molecule in the optimized configurations are plotted as functions of Ω_2 in Figs. 4*a*–4*c*, respectively. It is evident from Fig. 4*a* that two values of the energy are obtainable from our calculation, within an extensive Ω_2 region (ca. 50°–130°). It was not possible for us to obtain energy-minima solutions beyond the ones plotted in the upper regions, i.e., outside the angle range indicated. It may well be that here we have a relatively rare example of a mathematical "catastrophe" event (unstable critical point) occurring within a single molecule, as discussed (with focus on charge density) in a review by Bader et al. (19). As such, it may be worthy of a detailed analysis not appropriate herein. A description of the two states encountered within the ca. 80° range of Ω_2 where duplicity occurs will be furnished below.

Further discussion and summary

We now examine some details of the internal electronic structure and bonding in ground-state AH. The bond angle C1-N1-N7 is 121.6(2)° (expt.) and 119.1° (theor.), as seen in Table 3. This suggests that, to good approximation, the electron hybridization at N1 for the three bonds is sp^2, and that there is a well-defined lone pair in a pure *z* orbital (oriented normal to the picryl ring). This is very similar to the situation in 2,2-diphenyl-1-picrylhydrazine (≡ DH), where the angle is ca. 121° (20). The bond lengths at N1 are C1—N1 = 1.339(2) Å (1.355 in DH) and N1—N7 = 1.384(2) Å (1.381 in DH).

In AH, the lone-pair orbitals in the hydrazinic nitrogens are literally orthogonal to each other. The one on N1 is a pure *p* orbital while the other (on N7) is a member of an sp^2 hybrid set. By contrast, in DH they are both pure *p* orbitals, close to parallel, as well as normal to the picryl ring, so as to form an extended π system; the π-electron orbitals of the two phenyl rings in DH are tilted away from this.

It is clear that $\Delta G^{\ddagger}$ is smaller (ca. 47 as compared to ca. 63 kJ mol^{-1}, in acetone-d_6) for AH than for DH. One may question whether bond C1—N1 might have less π character in the former; the bond lengths observed (in the solid) are inconsistent with this notion. Perhaps the smaller bulk and mass (~3×) of the dimethylmethanimino (DMMI) group in AH is easier to reorient than the diphenylamino (DPA) group in DH. More particularly, one needs to consider the impedance (e.g., hydrogen bonding) created by the solvent surroundings. Thus the N7-DMMI group in AH may be easier to reorient than the picryl ring, whereas in DH the latter may be easier to rotate than the DPA group.

The differences found with the two solvents show the same trends for AH (Table 4) and for DH (Table 9 of ref. 10). Thus the values of $\Delta G^{\ddagger}$ are slightly higher in chloroform than in acetone, correlatable with the trend in the solvent hydrogen-bonding characteristics (Taft β parameter). The values of $\Delta S^{\ddagger}$ are of opposite sign for the two solvents, for both AH and DH. Perhaps, in the future, this phenomenon can be linked to the reorganization of the solvent molecules during the reorientation process.

We turn now to further discussion of the modeled conformerization process and to detailed consideration of

© 1999 NRC Canada

Figs. 4*a*–4c. We shall consider the path from the ground-state $\Omega_2 = 8.2°$ with increase in Ω_2, but could equivalently have started at $\Omega_2 = 174.6°$ with decrease in Ω_2.

Use of the Cahn–Ingold–Prelog chirality rule yields that the computed configuration at atom N1 for the $\Omega_2 = 8.2°$ ground state is *S*, that the three atoms bonded to N1 then go through a planar configuration at ca. 25°, and thereafter have the *R* configuration as Ω_2 increases, with the N1 moiety becoming more and more tetrahedral. The opposite chirality event occurs for the other curve, departing from the 174.6° ground state (chirality *R*) towards smaller Ω_2. In the duplicity range, transfer from one state to the other (at fixed Ω_2) implies a change in chirality.

We see that the energies of the two configurations become equal at $\Omega_2 \sim 92.5°$. We call this the crossing angle Ω_2^x. One major effect in going from 8.2° (GS) towards Ω_2^x (and beyond) is that C1—N1 becomes substantially longer, going from 1.327 to 1.416 Å at $\Omega_2 = 130°$, as seen in the plot of this bond distance versus Ω_2 (Fig. 4*b*). We note that the angle C1-N1-N7 is 119.1° at GS, going to 110.9° at Ω_2^x (almost tetrahedral) and on to 106.9° at 130° (upper-energy state). These results indicate that a major aspect of this excitation is the loss of the double-bond character of C1—N1. Simultaneously the hydrogen bonding involving H1 disappears on going from $\Omega_2 = 8.2°$ towards Ω_2^x. The N7-DMMI group, which remains basically intact, rotates about C1—N1, with torsion angle C2-C1-N1-N7 (Fig. 4*c*) moving from –156.8° at $\Omega_2 = 8.2°$ to –133.7° at Ω_2^x, and to –111.1° at 130° (upper-energy state). Note the dramatic jump in this angle when switching configurations, maximal at Ω_2^x.

The picryl ring, in the Ω_2 range 50°–130°, is close to having a reflection plane $\sigma_\perp$ through C1 and C4, perpendicular to the ring. For instance, at Ω_2^x, the nitro groups at C2 and C6 occur rotated by similar torsional angles (the NO_2 planes lie at about 33° from the picryl plane). Hence there is no hydrogen bond between H1 and O21 (or O61), as is also evident from the large H1—O21 distances (2.781 and 2.618 Å), in the two Ω_2^x configurations. It is worth pointing out that the complete molecule is far from having $\sigma_\perp$ as a symmetry plane, anywhere in the Ω_2 range, due to the two methyl groups. These are inequivalent (at Ω_2^x, the Mulliken charge numbers are –0.6213 for C71 and –0.6751 for C72, when excluding the hydrogens). We note that they do not appear to interchange surroundings during the conformerization.

What now can one deduce about the transition process, going from the minimum at $\Omega_2 = 8.2°$ to the other minimum at $\Omega_2 = 174.6°$? If molecule AH follows the lower-energy curve from the ground state upward to Ω_2^x, there is an energy requirement of 53 kJ mol^{-1}.[6] This compares very satisfactorily with the measured values of E_a given in Table 4, especially so since all solvent molecules had to be ignored in our modeling. At Ω_2^x, C1—N1 = 1.400 Å and C1-N1-N7 = 110.9° for both states. One must note, however, that switching configurations at this point is not isoenergetic, in that rotating the DMMI group appropriately might well require substantially more energy. One low-energy mechanism that comes to mind for switching configurations is intra-atomic transfer of proton H1 from its bond to the lone-pair orbital on N1, which has almost tetrahedral (*R*) configuration at Ω_2^x. This would leave the molecule with an effective Ω_2 of ca. 210° and an *S* configuration at N1, and its energy could then readily descend from there to that at the $\Omega_2 = 174.6°$ minimum. There then would be no need to rotate the DMMI group, which is consistent with the absence of a major solvent effect. More detailed study of this type of internal proton-transfer process is called for. Note that, conceivably, proton H1 at (near) Ω_2^x could also transfer temporarily to either of the *ortho* NO_2 groups. Finally, we note that, of course, transition between the two curves (Fig. 4*a*) could take place anywhere within a wide range of Ω_2; it is relevant that the upper energy is almost constant from 50° to 130°.

One can now turn briefly to some chemical comparisons of AH and DH. The hydrazinic proton is acidic in both. The alkali salts of both seem quite similar (21)[7]. On the other hand, as seen above, AH and DH differ greatly in oxidizability.

One might rationalize the difficulty in oxidizing AH as compared to DH by invoking the need of the MnO_4^- ion (or PbO_2) to react at a linkage with appreciable double-bond character (C1—N1 in the present case), i.e., initial complexation might be needed, as seems to be the case with oxidation of carbon–carbon double bonds by chromyl chloride (22). Perhaps attachment to double bond C7—N7 present in AH prevents such attack at C1—N1. In general, the mechanisms for the transition-ion/oxide-mediated reaction with double bonds are still in need of clarification (e.g., the oxidation of such bonds by OsO_4 (23)).

Furthermore, of course, radical A may well be quite unstable relative to D (DPPH) due to relatively attenuated unpaired-electron delocalization in the former, and considerable difference in hybridization at N7. More work on this question is planned. UHF/3-21 calculations on the unreported radical A suggest that its energy is higher than that of the molecule AH in its ground state: the sum of the energies of A and the free hydrogen atom H (derived with the 3-21 basis of atomic orbitals) is 6.3 kJ mol^{-1} higher than the ground-state energy (UHF/3-21) of AH. The model radical has an almost planar picryl ring, with approximately a mirror symmetry plane $\sigma_\perp$ through C1 and C4, perpendicular to the ring. The two *ortho* nitro groups are rotated by about 30° about their C—N bonds, away from the picryl-ring plane. The computed central bond lengths are C1—N1, 1.357; N1—N7, 1.396; C7—N7, 1.300 Å; the hydrazine bond angles are: C1-N1-N7 116.5°, N1-N7-C7 114.0°. The DMMI group in A is much like the one in AH.

Thermodynamics of substituted pyrazolone. V: Potentiometric and conductometric studies of complexes of some transition metals with 4-(4-acetophenyl)hydrazono-3-methyl-2-pyrazolin-5-one

Ashraf A. El-Bindary, Adel Z. El-Sonbati, and Hanan M. Kera

Abstract: Proton-ligand dissociation constants of 4-(4-acetophenyl)hydrazono-3-methyl-2-pyrazolin-5-one (AHMP) and metal-ligand stability constants of its complexes with some transition metal ions were calculated potentiometrically in 0.1 M KCl and 50% (v/v) ethanol–water mixture. The order of stability constants was found to be $Th^{4+} > UO_2^{2+} > Ce^{3+} > La^{3+} > Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$. The dissociation constant, pK_1^H, of AHMP and the stability constants, log *K*, of their complexes were determined at different temperatures (298, 308, and 318 K). The corresponding thermodynamic parameters (ΔG, ΔH, and ΔS) were derived and discussed. The dissociation process is nonspontaneous, endothermic, and entropically unfavourable. The formation of the metal complexes has been found to be spontaneous, exothermic, or endothermic (depending the metal), and entropically favourable. The stoichiometries of these complexes were determined conductometrically and indicated the formation of 1:1 and 1:2 (metal:ligand) complexes.

Key words: 4-(4-acetophenyl)hydrazono-3-methyl-2-pyrazolin-5-one, dissociation and stability constants, thermodynamic parameters, stoichiometries.

Résumé : Faisant appel à une méthode potentiométrique et opérant dans des solutions 0,1 M de KCl dans un mélange à 50% (v/v) d'éthanol–eau, on a déterminé les constantes de dissociation proton-ligand de la 4-(4-acétophényl)hydrazono-3-méthyl-2-pyrazolin-5-one (AHMP) et les constantes de stabilité métal-ligand de ses complexes avec des ions de quelques métaux de transition. On a trouvé que l'ordre de stabilité est $Th^{4+} > UO_2^{2+} > Ce^{3+} > La^{3+} > Mn^{2+} > Co^{2+} > Ni^{2+} > Cu^{2+} > Zn^{2+}$. La constante de dissociation, pK_1^H, de l'AHMP et les constantes de stabilité des complexes ont été déterminées à diverses températures (298, 308 et 318 K). On en a tiré les paramètres thermodynamiques correspondants (ΔG, ΔH et ΔS) et on en discute. Le processus de dissociation non pas spontané, il est endothermique et défavorisé d'un point de vue entropique. On a trouvé que la formation de complexes métalliques est spontanée, exothermique ou endothermique (suivant le métal) et favorisée d'un point de vue entropique. On a déterminé les stoechiométries de ces complexes par conductimétrie et elles indiquent qu'il y a formation de complexes 1:1 et 1:2 (métal:ligand).

Mots clés : 4-(4-acétophényl)hydrazono-3-méthyl-2-pyrazolin-5-one, constantes de dissociation et de stabilité, paramètres thermodynamiques, stoechiométries.

[Traduit par la Rédaction]

Introduction

In recent years, there has been considerable interest in the coordination chemistry of the azo pyrazolone donor. In part, this interest has arisen because of the biological importance of this donor system (1). A number of metal complexes containing azo pyrazolone donors have been characterized (2–4). In continuation of our earlier work (5–8) on metal complexes, we report herein the dissociation constant of AHMP, and the stability constants for its compelexes with Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+} at different temperatures, determined potentiometrically. The corresponding thermodynamic parameters are derived and discussed. Moreover, the stoichiometeries of these complexes are determined conductometrically at 298 K.

Experimental

Preparation of the ligand

AHMP (Fig. 1) was prepared by gradual addition of an aqueous solution of 0.01 mol (0.69 g) of sodium nitrite to a concentrated hydrochloric acid solution of 0.01 mol (1.35 g) of *p*-aminoacetophenone with stirring and kept for about

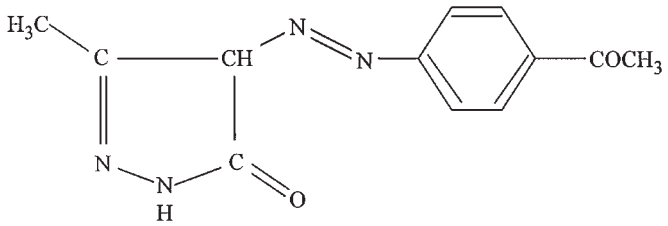

Fig. 2.

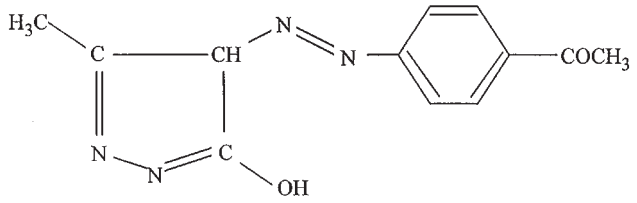

20 min in the ice bath. The formed diazonium chloride solution was added gradually with stirring to a 0.01 mol (0.98 g) cold solution of pyrazolinone in 50 mL ethyl alcohol containing 5 g sodium acetate. After diluation, the azo pyrazolone compound formed was filtered off and was washed with ethyl alcohol. The crude material was recrystallized from ethyl alcohol and then dried in a vacuum desiccator over anhydrous calcium chloride. The purity (mp 138°C) was checked by elemental analysis (found: C 59.20, H 5.00, N 23.01; calcd.: C 59.01, H 4.95, N 22.93).

The IR spectrum of AHMP was recorded on a Perkin–Elmer 883 spectrophotometer using KBr discs (4000–400 cm^{-1}). The IR spectrum show a strong band at 3276 cm^{-1} assigned to the ν(NH) of the pyrazolone ring. The strong band at 1670 and a medium one at 1600 cm^{-1} are both assigned to the carbonyl oxygen of the side chain and pyrazolone ring, respectively. The bands corresponding to the ν(N=N) symmetric stretching vibration appears at 1570 and 1500 cm^{-1}.

The ^{1}H NMR spectrum of AHMP was recorded on a EM-390 MHz spectrophotometer using d_6-DMSO as solvent with TMS as the internal standard. The ^{1}H NMR spectrum exhibited a signal at 5.2 ppm, assigned to the NH proton of pyrazolone ring (9). The δ CH_3 signal appeared at 2.6 ppm (10). The protons of the aromatic ring resonate downfield in the δ 7.2–8.5 ppm range (11).

Reagents and materials

Metal ion solutions (0.001 M) were prepared from AnalaR metal salt samples (BDH) in doubly distilled water and standardized with EDTA (12). The ligand solution (0.01 M) was prepared by dissolving the accurate weight of the solid in ethanol (AnalaR). Solutions of 0.005 M HCl and 1 M KCl were also prepared in doubly distilled water. A carbonate-free sodium hydroxide solution in 50% (v/v) ethanol–water mixture was used as titrant and standardized against AnalaR oxalic acid.

Potentiometric measurements

The apparatus, general conditions, and methods of calculation were the same as in the previous work (13, 14). The following mixtures were prepared and titrated potentiometrically at 298 K against standard 0.02 M NaOH in 50% (v/v) ethanol–water mixture:

(*i*) 5 mL 0.005 M HCl + 5 mL 1 M KCl + 25 mL ethanol;
(*ii*) 5 mL 0.005 M HCl + 5 mL 1 M KCl + 20 mL ethanol + 5 mL 0.01 M ligand;
(*iii*) 5 mL 0.005 M HCl + 5 mL 1 M KCl + 20 mL ethanol + 5 mL 0.01 M ligand + 10 mL 0.001 M metal salt.

For each mixture, the volume was made up to 50 mL with doubly distilled water before the titration. These titrations were repeated for temperatures of 308 and 318 K. A constant temperature was maintained to ±0.05 K by using an ultrathermostat (Gallenkamp thermo stirrer 85). The pH-meter readings in 50% (v/v) ethanol–water mixture are corrected according to the Van Uitert and Hass relation (15).

Conductometeric measurements

Solutions of 10^{-4} M of metal ions were titrated with 10^{-3} M of AHMP. These titrations were performed using a YSI model 32 conductance meter and carried out at 298 K.

Results and discussion

Potentiometric studies

Proton-ligand stability constants

The average number of protons associated with the AHMP at different pH values, $\bar{n}_A$, was calculated from the titration curves of the acid in the absence and presence of AHMP. Thus, the formation curves ($\bar{n}_A$ vs. pH) for the proton-ligand systems were constructed and found to extend between 0 and 1 in the $\bar{n}_A$ scale. This means that AHMP has one ionizable proton (the enolized hydrogen ion of the carbonyl oxygen in the pyrazolone moiety). Different computational methods (16) were applied to evaluate the dissociation constant. The number of replicates is five, and the average values obtained are listed in Table 1.

The AHMP has a lower acidic character (higher pK_1^H value than 4-(4-acetophenyl)hydrazono-1-phenyl-3-methyl-2-pyrazolin-5-one).[2] This is quite reasonable because the presence of the NH group (pyrazolone moiety) will enhance the amidic form, whereby a stronger O—H bond is formed. Therefore, the amidic nature of the molecule retards the re-

moval of the ligand proton and hence increases the basicity of the ligand (Fig. 2).

Metal-ligand stability constants

The formation curves for the metal complexes were obtained by plotting the average number of ligands attached per metal ion ($\bar{n}$) versus the free ligand exponent (pL), according to Irving and Rossotti (17). These curves were analyzed, and the successive stability constants were determined using different computational methods (18, 19). The values of the stability constants (log K_1, log K_2, and log β), as well as the ratio log K_1/log K_2, are given in Table 2. The following general remarks can be made:

(*i*) The maximum $\bar{n}$ values in all cases were found to be ≅2, revealing that both ML and ML_2 types of complexes are formed in solution.

(*ii*) No precipitate was observed in the titration vessel, indicating that the possibility of formation of metal hydroxide can be excluded.

(*iii*) For all complexes, the tendency of a metal ion to coordinate with ligand is proportional to the number of vacant sites. The ratio between consecutive stability constants, is to certain extent, statistically determined (20).

(*iv*) The order of stability constants of the metal complexes of AHMP was found to be

$$Th^{4+} > UO_2^{2+} > Ce^{3+} > La^{3+} > Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$$

The sequence of stability ($Mn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$) of the complexes of AHMP reflects the changes in the heat of complex formation across the series and arises from a combination of the influence of both polarizing ability of the metal ion (21) and crystal-field stabilization energies (22). The greater stability of Cu^{2+} complexes is produced by the well-known Jahn–Teller effect. The stability constant of the divalent oxygenated cation complex (UO_2^{2+}) has a higher value than the other divalent cation complexes (Table 2). This may be attributed to the bonded oxygen atoms, which may increase the electrostatic attraction between the metal ion and the coordinated ligands and overcome any steric hindrance offered by the oxygen of the oxygenated cation (23). The higher values of the stability constants of the Th^{4+} complexes compared to that of the other divalent metal complexes is expected on the basis of the charge and ionization potential of Th^{4+} ion.

Effect of temperature

The dissociation constant (pK_1^H) for AHMP, as well as the stability constants of its complexes with Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+}, have been evaluated at 298, 308, and 318 K, and are given in Tables 1 and 2. The slope of the plot (pK_1^H or log K vs. 1/T) was utilized to evaluate the enthalpy change (ΔH) for the dissociation or complexation process, respectively. From the free energy change (ΔG) and (ΔH) values, one can deduce the entropy change (ΔS), using the well-known relationships [1] and [2]:

$$[1] \qquad \Delta G = -2.303RT \log K = 2.303RT\ pK$$

$$[2] \qquad \Delta S = (\Delta H - \Delta G)/T$$

All thermodynamic parameters of the dissociation process of AHMP are recorded in Table 1. Inspection of these values reveals that

(*i*) The pK_1^H value decreases with increasing temperature, revealing that its acidity increases with increasing temperature.

(*ii*) A positive value of ΔH indicates that its dissociation is accompanied by adsorption of heat and the process is endothermic.

(*iii*) A large positive value of ΔG indicates that the dissociation process is not spontaneous.

(*iv*) A negative value of ΔS is obtained, due to extensive solvation of metal chelates in ethanol–water mixture.

All the thermodynamic parameters of the stepwise stability constants of AHMP complexes are recorded in Table 3. It is known that the divalent metal ions exist in solution as octahedrally hydrated species, and the obtained values of ΔH and ΔS can then be considered as the sum of two contributions: (*i*) release of H_2O molecules, and (*ii*) metal-ligand bond formation.

It was suggested (24) that the ions in aqueous solution order the water molecules around them and, during complex formation between oppositely charged ions (ligand L^- and M^{n+}), will lead to the breakdown of the metal–water arrangement, resulting in positive entropy and enthalpy changes. Examination of these values shows that

(*i*) The stepwise stability constants (log K_1 and log K_2) for AHMP complexes decreases with increasing temperature in the case of Mn^{2+}, Cu^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+}, whereas in the case of Co^{2+}, Ni^{2+}, and Zn^{2+}, the reverse happens, i.e., the stability constants increase with increasing temperature.

(*ii*) The negative values of ΔG for the complexation process of Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+} with AHMP suggest a spontaneous nature of this process.

(*iii*) The ΔH values are positive in the case of Co^{2+}, Ni^{2+}, and Zn^{2+}, whereas in the case of Mn^{2+}, Cu^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+}, these are negative. This means that these processes are endothermic and favourable at higher temperatures for Co^{2+}, Ni^{2+}, and Zn^{2+} complexes, while in the case of Mn^{2+}, Cu^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+} complexes, the process are exothermic and favourable at lower temperature.

(*iv*) The positive values of ΔS for the complexation process of AHMP with Mn^{2+}, Cu^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, UO_2^{2+}, and Th^{4+} confirm that complex formation is entropically favourable. In contrast, the La^{3+} and Ce^{3+} complexes have negative ΔS values (8). Such negative entropy changes can be attributed to the extensive solvation of metal chelates in the aqueous–ethanol medium. This may be due to the exposure of the polar oxygen, nitrogen, and metal ion of the chelate to the solvent molecules (25).

Conductometric studies

Stoichiometries

Stoichiometries of the complexes of AHMP with Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, La^{3+}, Ce^{3+}, UO_2^{2+}, and Th^{4+} are obtained from the conductometric measurements. These studies were carried out to investigate the stoichiometries of the formed complexes by breaks in the titration curves denoting the formation of 1:1 and 1:2 (metal:ligand) complexes. Therefore, the reaction between the metal ions and AHMP occurs via the formation of a covalent linkage with the oxygen of the OH group (pyrazolone moiety) and the nitrogen

© 1999 NRC Canada

of the azo group. The increase in conductance upon titrating metal ions by AHMP is probably due to the liberation of the hydrogen ions from the OH during the complex formation (5). The decrease of the conductance value occurs due to (*i*) the increase of the volume of the metal ion chelate formation, which is accompanied by a decrease in the value of the diffusion coefficient of the particle, and (*ii*) the lowering of the charge on the metal ion through covalent bond formation with AHMP.
