Abstract: Five ketenes, phenyl(ethyl)ketene, phenyl(methylthio)ketene, diphenylketene, pentafluorophenylketene, and 1-naphthylketene, were generated flash photolytically and solvent isotope effects (H_2O vs. D_2O) on their hydroxide-ion-catalyzed hydration in aqueous solution were determined. The values obtained are all weakly inverse and closely similar (k_{HO}/k_{DO} = 0.76–0.97), as expected for these fast, hydroxide-ion-consuming reactions, known to proceed by nucleophilic attack of hydroxide on the ketene carbonyl group. The characteristic magnitude of these isotope effects should prove useful in identifying new examples of this reaction.

Key words: ketenes, flash photolysis, photo-Wolff reaction, solvent isotope effects on hydroxide ion consumption.

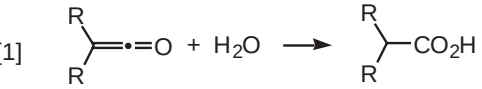
Résumé : Faisant appel à la photolyse éclair, on a généré cinq cétènes (phényl(éthyl)cétène, phényl(méthylthio)cétène, diphénylcétène, pentafluorophénylcétène et 1-naphtylcétène) et on a déterminé les effets isotopiques de solvant (H_2O vs. D_2O) sur leur hydratation catalysée par l'ion hydroxyde, en solution aqueuse. Les valeurs obtenues sont toutes semblables, faibles et inverses (k_{HO}/k_{DO} = 0,76–0,97) comme on peut s'y attendre pour ces réactions rapides utilisant l'ion hydroxyde qui se produisent par une attaque nucléophile de l'hydroxyde sur le groupe carbonyle du cétène. L'amplitude caractéristique de ces effets isotopiques devrait s'avérer utile dans l'identification de nouveaux exemples de cette réaction.

Mots clés : cétènes, photolyse éclair, réaction de photo-Wolff, effets isotopique du solvant sur la consommation de l'ion hydroxyde.

[Traduit par la Rédaction]

Introduction

Solvent isotope effects on the hydration of ketenes to form carboxylic acids, eq. [1],



catalyzed by the hydronium ion, as well as on the uncatalyzed reaction, have proved to be useful in elucidating the mechanisms of these processes, and they have also served to help identify new examples (1). The same is not true of the hydroxide-ion-catalyzed reaction: we are aware of only one published determination of this isotope effect made prior to the present work, and that was done using a rather special substrate containing a second functional group that perturbed the isotope effect and gave it an atypical value (vide infra) (2).

Received December 10, 1998.

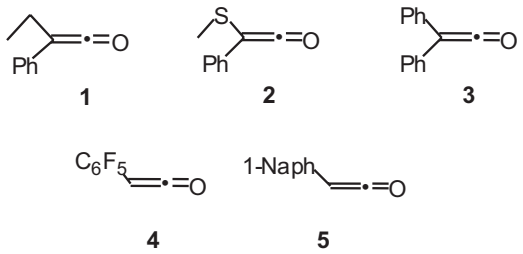
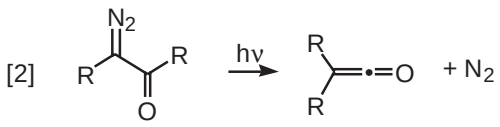
In the present paper we provide five unperturbed examples of this isotope effect, determined using the monofunctional ketene substrates phenyl(ethyl)ketene, **1**, phenyl(methylthio)-ketene, **2**, diphenylketene, **3**, pentafluorophenylketene, **4**, and 1-naphthylketene, **5**.



These ketenes were generated by photo-Wolff reactions, eq. [2],



of the corresponding diazo compounds, α-diazobutyrophenone, **6**, *S*-methyl phenyldiazothioacetate, **7**, azibenzil, **8**, penta-

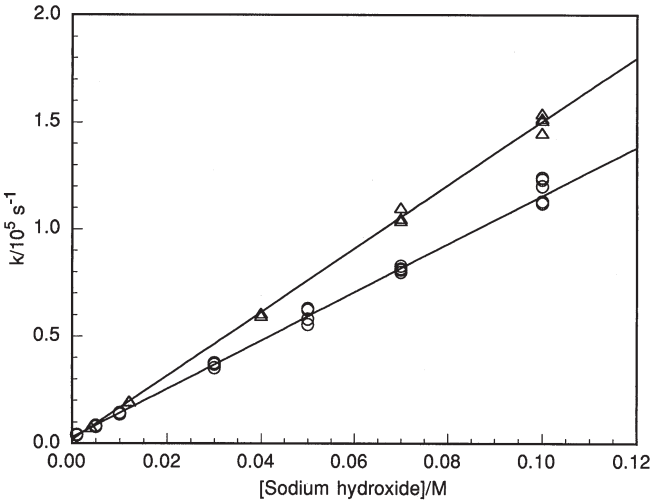
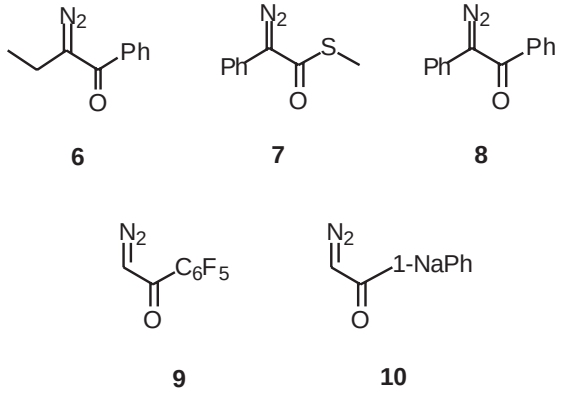
Fig. 1. Relationship between sodium hydroxide concentration and observed first-order rate constants for the hydration of pentafluorophenylketene in aqueous solution at 25°C; O: H_2O, Δ: D_2O.



fluorobenzoyldiazomethane, **9**, and 1-naphthoyldiazomethane, **10**.



Because the reactions studied were fast, flash photolytic techniques were used to carry out rate measurements.

Experimental section

Materials

α*–Diazobutyrophenone*, **6**, was prepared by diazo group transfer from *p*-toluenesulfonyl azide to butyrophenone after the latter had been activated through introduction of an α-formyl group (3). Formylation was effected using ethyl formate as the formyl source and sodium hydride as the basic catalyst. The diazo compound, a yellow oil, was purified by column chromatography on silica gel using 80% chloroform – 20% hexane as the eluent. Its spectral properties are as follows: ^{1}H NMR (200 MHz, $CDCl_3$), δ/ppm: 7.50 (m, 5H, Ar), 2.57 (q, J = 7.4 Hz, 2H, CH_2), 1.20 (t, J = 7.4 Hz, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$), δ/ppm: 189.4 (C=O), 137.8 (Ar), 131.2 (Ar), 128.4 (Ar), 127.0 (Ar), 68.3 (C=N_2), 17.0 (CH_2), 11.3 (CH_3); HRMS, M^+ for $C_{10}H_{10}N_2O$, *m/e*, calcd.: 174.0793; found: 174.0792.

Table 1. Sodium hydroxide catalytic coefficients and solvent isotope effects on ketene hydration in aqueous solution at 25°C.[a]

Substrate	k_{HO} / M^{-1} s^{-1}	k_{HO} / k_{DO}
	(6.05 ± 0.06) ×10^3	0.972 ± 0.012
	(1.89 ± 0.04) ×10^4	0.928 ± 0.026
	(4.64 ± 0.14) ×10^4	0.917 ± 0.051
	(1.13 ± 0.01) ×10^6	0.759 ± 0.009
	(1.18 ± 0.05) ×10^6	0.891 ± 0.063

[a]Ionic strength = 0.10 M.

Pentafluorobenzoyldiazomethane, **9**, has apparently been made before (4), but no details of its preparation nor of its spectral properties were given. It was synthesized here by treating pentafluorobenzoyl chloride with diazomethane. The product was a colorless crystalline solid, mp 45–46°C. Its spectral properties are as follows: IR (KBr), ν/cm^{-1} = 2123 (N≡N), 1650 (C=O); ^{1}H NMR (200 MHz, $CDCl_3$), δ/ppm: 5.71; ^{13}C NMR (50 MHz, $CDCl_3$), ^{19}F decoupled, ^{1}H not decoupled) δ/ppm: 176.8 (d, C=O), 144.3 (Ar), 142.7 (Ar), 137.6 (Ar), 113.3 (Ar), 60.1 (d, J = 204 Hz, C=N_2).

S-*Methyl phenyldiazothioacetate*, **7**, was made by diazo transfer from *p*-toluenesulfonyl azide to *S*-methyl phenylthioacetate in the presence of 1,8-diazobicyclo[5.4.0]undec-7-ene and 4-(*N,N*-dimethylamino)pyridine (5), and *azibenzil* was prepared by mercuric oxide oxidation of benzil monohydrazone (6*); 1-naphthoyldiazomethane* was a sample that had been prepared before (7). All other materials were best available commercial grades.

Kinetics

Flash photolytic generation of ketenes was performed using a conventional flash lamp system (8) and an excimer laser system (1*b*), operating at λ = 248 nm; these have already been described. With both systems, reaction mixtures were thermostatted at 25.0 ± 0.05°C. The ketene hydration reactions were followed by monitoring the decay of ketene absorbance at 250–270 nm for the phenyl-substituted substrates and at λ = 320–330 nm for the naphthyl derivative. All decays conformed well to the first-order rate law, and observed first-order rate constants were calculated by nonlinear least-squares fitting of exponential functions.

Results

Rates of hydration of the ketenes examined here were measured in dilute solutions of sodium hydroxide using H_2O and D_2O as the solvent. In all cases, a range of sodium hydroxide concentrations, usually spanning a variation of at least an order of magnitude, was employed. The ionic strength of these solutions was maintained at 0.10 M by adding sodium perchlorate as required. The data so obtained

For personal use only.

have been summarized, as supplementary material, in Table S1.[2]

As Fig. 1 illustrates, the observed first-order rate constants determined in this way are accurately proportional to sodium hydroxide concentration. Sodium hydroxide catalytic coefficients were therefore evaluated by linear least-squares analysis with proportional weighting, and solvent isotope effects were calculated as ratios of these catalytic coefficients. The results are listed in Table 1.

The sodium hydroxide catalytic coefficient for 1-naphthylketene in H_2O determined here, 1.18×10^6 M^{-1} s^{-1}, agrees well with that reported for this substrate before, 1.25×10^6 M^{-1} s^{-1} (7). The present values for diphenylketene, 4.64×10^4 M^{-1} s^{-1}, and phenyl(methylthio)ketene, 1.89×10^4 M^{-1} s^{-1}, are also consistent with previous determinations, 6.11×10^4 M^{-1} s^{-1} (9) and 3.09×10^4 M^{-1} s^{-1} (5), respectively.

Discussion

Each of the ketenes examined here reacts more rapidly in D_2O than in H_2O solutions of sodium hydroxide, and each consequently gives an inverse ($k_H/k_D < 1$) isotope effect. This is the expected direction for solvent isotope effects on hydroxide-ion-consuming reactions such as these. That follows from a model proposed by Gold and Grist (10), in which the hydroxide ion in aqueous solution is strongly solvated by three water molecules whose solvating O—H bonds are looser than the O—H bonds of bulk water. When such a hydroxide ion is consumed by reaction with a substrate, the solvating water molecules are transformed into bulk solvent, and they consequently move from a more loosely bound state to a more tightly bound state, thus producing an inverse isotope effect. This phenomenon has now been extensively documented (11).

The maximum magnitude of the solvent isotope effect on consumption of a hydroxide ion has been estimated as $k_{HO}/k_{DO} = 0.43$ (11*a*). The isotope effects observed here are much weaker than that, but they are on a rate process in whose transition state the hydroxide ion will be only partially consumed. The rates of the present reactions, moreover, are fast, and their transition states will consequently be especially reactant-like (12).

Another feature contributing to the weakness of the present isotope effects is the nucleophilic nature of the hydroxide ion plus ketene reaction (13): this generates negative charge on the ketene carbonyl oxygen atom, giving that atom alkoxide ion character, eq. [3]. Solvation of this charge, in much the same way as the hydroxide ion is solvated, then provides a normal component ($k_H/k_D > 1$) to the solvent isotope effect, which offsets the inverse factor given by hydroxide ion desolvation.

[3] 
The present inverse isotope effects are quite different from the value, $k_{HO}/k_{DO} = 1.87$, reported for the only previous example of a solvent isotope effect on a ketene plus hydroxide ion reaction (2). The substrate in that case was acetylketene, **11**, and it was argued then that the acetyl group assisted hydroxide ion attack, as evidenced by its strong rate acceleration, by allowing strong hydrogen bond formation between the hydroxyl group and the acetyl oxygen atom in the transition state of this reaction, **12**, eq. [4]:

[4] 
11 **12**

strong hydrogen bond formation is known to produce sizeable isotope effects in the normal direction (14). The inverse nature of the presently determined isotope effects reinforces this explanation.

It would seem fair to conclude, therefore, that solvent isotope effects on the reaction of hydroxide ion with simple, monofunctional, short-lived ketenes will be weakly inverse. This characteristic magnitude should be useful in identifying this reaction.

Abstract: The enantioselective oxidation of a series of heterocyclic prochiral sulfides to chiral sulfoxides has been examined using the fungal biocatalysts *Helminthosporium* species NRRL 4671 and *Mortierella isabellina* ATCC 42613. Methylthiofuranyl and -thiophenyl substrates gave (*S*)-configuration products in low to moderate enantiomeric purity on biotransformation with *H.* species, but pyridyl sulfides with the nitrogen atom located at an optimal distance of 8–10 Å from the sulfur centre gave (*S*) sulfoxides of high enantiomeric purity. The biotransformation of appropriately substituted benzothiane substrates by *M. isabellina* also gave products of high enantiomeric purity, but with (*R*) configuration at sulfur. The acceptability of the substrate and the configuration of sulfur oxidation by both *H.* species and *M. isabellina* for the range of substrates examined were found to be consistent with predictions based on cubic space models for these oxidations.

Key words: bioconversion, biotransformation, *Helminthosporium*, *Mortierella isabellina*, sulfide, sulfoxide.

Résumé : Utilisant les biocatalyseurs extraits des champignons *Helminthosporium* espèce NRRL 4671 et *Mortierella isabellina* ATCC 42613, on a étudié l'oxydation énantiosélective d'une série de sulfures hétérocycliques prochiraux en sulfoxydes chiraux. Lors des biotransformations à l'aide de l'espèce *H.* , les substrats méthylthiofuranyle et méthylthiophényle conduisent à des produits de configuration (*S*), avec des puretés énantiomériques qui vont de faibles à modérées; toutefois, les sulfures de pyridyle comportant un atome d'azote situé à une distance optimale de 8 à 10 Å du soufre conduisent à des sulfoxydes (*S*) de pureté énantiomérique élevée. La biotransformation de substrats benzothiane portant des substituants appropriés par *M. isabellina* fournit aussi des produits de pureté énantiomérique élevée; la configuration au niveau du soufre est toutefois (*R*). On a trouvé que, pour l'ensemble des produits étudiés, l'acceptabilité du substrat et la configuration du soufre oxydé par les espèces *H.* ainsi que par *M. isabellina* est en accord avec les prédictions faites sur la base de modèles spatiaux cubiques pour ces oxydations.

Mots clés : bioconversion, biotransformation, *Helminthosporium*, *Mortierella isabellina*, sulfure, sulfoxyde.

Introduction

Chiral sulfoxides have been used for many years as asymmetric starting materials for chemical synthesis (1–3). The enantioselective oxidation of prochiral sulfides by biocatalytic methods is one of the more versatile routes for the preparation of these chiral synthons (4, 5), and sulfoxides made in this way have been used in the preparation of (inter alia) chiral mevinic acid-type hypocholestemic agents (6, 7), cardiovascular agents related to the anti-anginal verapamil (8), and amino acid sulfoxides (9, 10).

We have developed the use on a synthetic scale of the fungal biocatalysts *Helminthosporium* species NRRL 4671 for the preparation of phenyl alkyl and related sulfoxides of (*S*) configuration (5), and *Mortierella isabellina* ATCC 42613 for the oxidation of similar substrates to (*R*) sulfoxides (11, 12). These reactions, catalysed by oxygenase enzymes (13), are carried out using whole-cell methodology. This requirement is dictated by the intractable nature of the membrane-bound oxygenase enzymes, and by their (presumed) extensive cofactor requirements. A further consequence of this is the limitation of structural information for these enzymes, often resulting in difficulties in the prediction of suitable substrates and reaction products for biotransformations of this type: no data are available on the nature of the sulfoxidase enzymes from *Helminthosporium* or *M. isabellina*, and all attempts to date to isolate these enzymes have failed to produce viable catalysts. To address this problem we have developed predictive models based on cubic space descriptors for the sulfoxidation reactions carried out by both *Helminthosporium* species (5) and *Mortierella isabellina* (12), shown in Figs. 1 and 2, respectively. Such "active site" mod-

els have been developed for a number of synthetically valuable enzymes, including horse liver alcohol dehydrogenase (14), lipase YS from *Pseudomonas fluorescens* (15), and *Candida rugosa* lipase (16), and have also been proposed for the analysis of whole-cell catalysed reactions for which no isolated enzymes are available, including steroid hydroxylations (17) and hydroxylations carried out by *Beauveria bassiana* (17). These models are widely used to predict and correlate substrate–product relationships for reactions catalysed by these enzymes and whole-cell biocatalysts. The model for *M. Isabellina* can also be applied to other reactions catalysed by the sulfoxidase enzyme, such as benzylic hydroxylation and epoxidation of suitable substrates (12), but the *Helminthosporium* system does not appear to possess substantial hydroxylase activity (18).

A feature of the models that we have proposed for sulfoxidations carried out by *H.* species and *M. isabellina* is the presence of a binding site for interaction with a polar site or group of the substrate. We have now specifically examined this feature of the models by the use of a range of sulfide substrates possessing heteroatom substituents at a defined distance from the site of oxidation, and present below results that confirm the location of such polar binding sites in the models for sulfoxidation by *H.* species and *M. isabellina*.

Results and discussion

The results of the biotransformations of substrates **1**–**26** are presented in Tables 1 and 2. In all cases, yields refer to isolated material and enantiomeric excesses are for homogenous product material prior to subsequent purification (e.g., crystallization) that might alter this value. The assignment of product structures relied heavily on NMR analysis, ^{1}H and ^{13}C spectral data being diagnostic of the oxidation state at sulfur. These data, together with supporting mass spectral data, are presented in the experimental section. The predominant configuration and enantiomeric excesses (e.e.) of the sulfoxide products were determined by analysis of their ^{1}H NMR spectra in the presence of the chiral shift reagents (*S*)-α-methoxyphenylacetic acid (MPAA) or (*R*)-*N*-(3,5-dinitrobenzoyl)-α-methylbenzylamine (DBMB), or by chiral stationary phase HPLC where appropriate. Use of the NMR shift reagents gave consistent, configurationally dependent shifts of signals for protons α to sulfur that have been correlated with data from sulfoxides of independently established configuration (19–21). Addition of MPAA, for example, causes the S-methyl signals of methyl sulfoxides to appear as two singlets with Δδ 0.02–0.03 ppm, cleanly resolved at 300 MHz: in over 50 such examples studied to date (5) the signal from the protons of the (*S*) enantiomer is at the higher field. The configurational assignments of Tables 1 and 2 are

[a]Data from ref. 25.

in full agreement with the complexation model proposed for interaction of (*S*)-MPAA with sulfoxides (19).

Sulfone products were also obtained from a small number of substrates. In those cases, the enantiomeric purity of sulfoxide is unlikely to be substantially affected by the formation of sulfone as (*a*) the levels of sulfone were very low (≤5%), and (*b*) control experiments in which racemic sulfoxides were incubated with *Helminthosporium* have failed to detect enantiomeric enrichment of sulfoxide or the formation of substantial amounts of sulfone. This suggests that production of sulfone from sulfide occurs by a random, non-stereoselective reoxidation of the intermediate sulfoxide without the latter leaving the active site of the enzyme. Control experiments with autoclaved (deactivated) fungal biocatalyst indicate that conversion of sulfide to sulfoxide by autooxidation under the conditions of the biotransformation accounts for <2% of the sulfoxide product.

The models for oxidation of sulfides by *Helminthosporium* sp. and *M. isabellina* are presented in simplified versions in Figs. 1 and 2. The complete three-dimensional version of the model for *H.* sp. has been discussed in detail elsewhere (5); the top view of this model, presented in Fig. 1, is sufficiently detailed for the present analysis. A full analysis of the model for *M. isabellina*, shown in Fig. 2, has also been previously discussed (12). A feature of both these models is the presence of a site, P, specific for interaction with a polar group of the substrate. These sites are located in the polar hydrophobic pocket, PHP, of the *Helminthosporium* model at an optimal distance of 8–10 Å from the site of oxidation, and in the aliphatic binding region, B, of the model for *M. isabellina*.

The biotransformation of the heterocyclic methyl sulfides **1**–**14** (Table 1) and **15**–**17** (Table 2) by *Helminthosporium* was undertaken in order to investigate (*a*) the spatial relationship between a heteroatom of the substrate and the site of oxidation, and hence (*b*) the ability of a heteroatom to interact at site P of the model for oxidation by this biocatalyst. In all cases, sulfoxides of predominantly (*S*) configuration were obtained, and the results clearly demonstrate that good yields and the highest enantiomeric purities of product are obtained for those substrates (e.g., **16** and **17**, Table 2) in which the heteroatom is located at the optimal distance from the site of oxidation. Figure 1 shows the application of the sulfoxidation model to the biotransformation of 4-methylthiomethylpyridine (**17**) and illustrates the conformations of **16** and **17** that allow the optimal distance between the heteroatom and the site of oxidation to be attained.

The importance of the 8–10 Å separation between these two sites for efficient sulfoxidation by *Helminthosporium* is confirmed by analysis of the results of Table 2. The biotransformations of the five-membered heterocycles (**5**–**8** and **10**) and that of the carbocyclic substrate **11** illustrate that the presence of the heteroatom has little or no positive effect on the outcome of the biotransformation of the former group of substrates, whereas comparison of the results from the biotransformations of the thiomethylpyridines **15**–**17** with that of the corresponding carbocyclic sulfide **18** and benzyl methyl sulfide (**19**) (Table 2) confirms the spatial significance of the heteroatom: those substrates with the optimal spatial relationship of nitrogen to sulfur (**16** and **17**) are converted to sulfoxide in highest yield and e.e. A similar relationship exists in the case of *Helminthosporium*-catalysed oxidations of *ortho*, *meta*, and *para*-substituted benzyl methyl sulfides, where only the latter two substrate groups can be converted to sulfoxide in high e.e. (22). The influence of an electronic substituent effect on the outcome of sulfoxidation is possible for substrates **1**–**4**, **9**, **12**, and **13**, but no clear trends are apparent that would suggest such an effect, and in the absence of any information on the detailed mechanism of sulfoxidation the interpretation of any such effect would be difficult.

The pyridyl substrates **15**–**17** are converted to (*R*) sulfoxides by *M. isabellina* (Table 2), and the results generally confirm the earlier finding that a polar substituent on the aromatic ring does not have a profound effect on the outcome of this biotransformation (11, 12). The importance of the aromatic ring for effective biotransformation by *M. isabellina* is, however, emphasized by a comparison of the results from

substrates **15**–**17** with that of the carbocycle **18**: the latter was converted to sulfoxide in only trace amount.

With the exception of the symmetrical sulfide **21**, the bicyclic substrates **20**–**27** were generally poor substrates for biotransformation by *Helminthosporium*, a result consistent with the model shown in Fig. 1 for oxidation by this biocatalyst: only **21** can be accommodated by the model with the aromatic ring in the PHP pocket and the sulfur atom close to the site of oxidation. Biotransformation of substrates **20**–**27** by *M. isabellina* was undertaken in order to investigate the spatial relationship between site P of the aliphatic binding region B (Fig. 2) and the site of oxidation by this biocatalyst. The positive effect of a heteroatom at position 4 of the heterocyclic ring on the stereoselectivity of sulfoxidation by *M. isabellina* is evident from a comparison of the outcome of the biotransformations of substrates **23**–**26** with those of substrates **20** and **27**. In all cases, (*R*)-configuration products of higher optical purity were obtained from the former group, and in two instances (sulfoxides from **23** and **25**) enantiopure materials could be obtained by a simple crystallization of the biotransformation products. In both **23** and **25**, the heteroatom substituent remote from sulfur is capable of acting as a hydrogen bond acceptor as shown in Fig. 2, and we postulate that this or a similar interaction with a suitable group in the enzyme's active site may be responsible for an enhancement of substrate binding, leading to an increase in the stereoselectivity of oxidation of these substrates.

Given careful choice of the nature and position of substitution present in the substrate, it is apparent that sulfoxides of high optical purity with (*R*) or (*S*) configuration may be obtained in good yield by biotransformations using *Mortierella isabellina* or *Helminthosporium* sp., respectively. This analysis facilitates the exploitation of these processes for the production of synthetically useful chiral sulfoxides.

Experimental

Materials and methods

Melting points were determined on a Kofler hot stage and are uncorrected. The ^{1}H NMR spectra were recorded on a Bruker Avance series 300 spectrometer in $CDCl_3$ using residual $CHCl_3$ as the internal standard; chemical shifts are reported in parts per million (δ) and the signals are quoted as s (singlet), d (doublet), t (triplet), q (quartet), or m (multiplet). The ^{13}C NMR spectra were recorded at 75 MHz in $CDCl_3$ solution on the above spectrometer. Mass spectra were obtained in EI mode (unless otherwise stated) using a Kratos 1S spectrometer. IR spectra were obtained using a Mattson Research Series FTIR spectrometer. Optical rotations were recorded at ambient temperature in the stated solvent using a Rudolph Autopol 3 polarimeter. Enantiomeric excess (e.e.) was determined by ^{1}H NMR analysis in the presence of three equivalents of (*S*)-(+)-α-methoxyphenylacetic acid (MPAA) (19) or two equivalents of (*R*)-(–)-*N*-(3,5-dinitrobenzoyl)-α-methylbenzylamine (DBMB) (20), or by chiral stationary phase HPLC as described below. TLC was performed on Merck silica gel F_{254} plates, 0.2 mm, and column chromatography used Merck silica gel, 230–400 mesh. *Mortierella isabellina* ATCC 42613 and *Helminthosporium* species NRRL 4671 were maintained on malt agar slopes, grown at 27°C and stored at 4°C.

Preparation of substrates

Substrates **9**, **12**, and **13** were prepared by reaction of the appropriate thiol (1 equiv.), sodium ethoxide (1 equiv.), and iodomethane (1.5 equiv.) in the standard manner (23). Compounds **5**–**8**, **10**, **11**, and **14**–**18** were prepared starting from the appropriate alcohol or chloride using sodium thiomethylate, by the general procedure described below for **15**. The following were prepared by the published procedures: **20** (24), **21** (24), **22** (25), **23** (26), **24** (27), **25** (28), and **27** (29). All substrates gave spectral (IR, NMR, and MS) data consistent with their structures.

*2-Methylthiomethyl pyridine (**15**)*

A solution of 2-pyridyl carbinol (5.0 g, 45.8 mmol) in 75 mL dry THF under argon was treated with 1.1 equiv. of triethylamine (7.03 mL, 50.5 mmol) and the mixture was cooled to 0°C. Methanesulfonyl chloride (5.51 g, 48.1 mmol) was then added dropwise with stirring and the reaction mixture allowed to warm to room temperature. Stirring was continued for a further 1.5 h, and the solid was then removed by filtration. In a separate flask, sodium metal (1.16 g, 50.4 mmol) was dissolved in 100 mL absolute ethanol, and methanethiol (2.64 g, 55.0 mmol) was passed into the ethanolic solution. The THF solution of mesylate prepared earlier was then added directly to the preformed sodium methanethiolate solution via cannula, and the reaction mixture allowed to stir overnight. Distilled water (100 mL) was added and the mixture extracted with ethyl acetate (2 × 100mL). The combined organic layers were washed with saturated sodium bicarbonate solution (2 × 50 mL) and water, and then dried. The solvent was removed in vacuo, and the product purified on silica gel (EtOAc) to give 82% isolated yield of an oil; ^{1}H NMR δ: 2.06 (3H, s), 3.80 (2H, s), 7.16 (1H, ddd,), 7.36 (1H, d), 7.66 (1H, td), and 8.53 (1H, m) ppm; ^{13}C NMR δ: 15.5, 40.4, 122.3, 123.4, 137.1, 149.5, and 158.9 ppm; MS *m*/*z* (%): 139(4), 124(4), 93(100); HRMS, M^+ calcd. for C_7H_9NS: 139.04557; found: 139.04633.

*2-Methylthiofuran (**1**)*

Furan (2.38 g, 35.0 mmol) was dissolved in dry THF (75 mL) under an argon atmosphere and the solution was cooled to 0°C. A solution of *n*-butyllithium in hexane (35.0 mmol, 14.0 mL, 2.5 M) was added dropwise with stirring, followed by the addition of dimethyldisulfide (35.0 mmol, 3.15 mL), and the reaction mixture was then stirred for 2 h at 0°C. The mixture was allowed to warm to room temperature, an equal amount of distilled water was added, the layers separated, and the aqueous layer extracted with ether (2 × 50 mL). The combined organic layers were dried and the solvent was carefully removed in vacuo to give a volatile oil (2.51 g, 63%); ^{1}H NMR δ: 2.41 (3H, s), 6.38 (1H, m), 6.44 (1H, d), and 7.48 (1H, d) ppm; ^{13}C NMR δ: 19.2, 111.8, 114.7, 145.22, and 147.8 ppm; MS *m*/*z* (%): 114(100), 99(28), 83(23), 71(23); HRMS, M^+ calcd. for C_5H_6OS: 114.01394; found: 114.01402.

*2-Methylthiothiophene (**2**)*

Thiophene (4.2 g, 50.0 mmol) was dissolved in dry THF (50 mL) under an argon atmosphere and the solution was cooled to –10°C. A solution of *n*-butyllithium in hexane (1.6 M, 45.0 mmol, 28.1 mL) was added with stirring, and the reaction was kept between –5 and 0°C for 1.5 h and then cooled to –10°C. Dimethyldisulfide (4.1 mL, 45.0 mmol) was added slowly and the reaction stirred at –10°C for a further 1 h, whereupon water was added and the reaction mixture was allowed to warm to room temperature. The two layers were separated and the aqueous layer extracted with ether (75 mL). The combined organic layers were washed with saturated sodium bicarbonate (2 × 50 mL), brine (50 mL), dried, and the solvent was removed in vacuo to give a yellow oil (3.60 g, 67%); ^{1}H NMR δ: 2.48 (3H, s), 6.94 (1H, dd), 7.06 (1H, d), and 7.28 (1H, dd) ppm; ^{13}C NMR δ: 22.6, 127.8, 128.3, 131.4, and 137.6 ppm; MS *m*/*z* (%): 130(100), 115(61), 97(2), 71(11); HRMS, M^+ calcd. for $C_5H_6S_2$: 129.99109; found: 129.99178.

*3-Methylthiofuran (**3**)*

A solution of 3,4-dibromofuran (30) (5 g) in dry ether (50 mL) was cooled to –78°C, then treated with a solution of *tert*-butyllithium (13.0 mL, 1.7 M in pentane). The reaction mixture was stirred at –78°C for a further 30 min, then dimethyldisulfide (2.08 g) was added dropwise and the mixture was stirred for 1 h before warming to room temperature, where it was then stirred for a further 2 h. The reaction mixture was cooled to 0°C, quenched with saturated ammonium chloride solution, and then extracted with ether (2 × 40 mL). The combined organic extracts were dried and the solvent was removed in vacuo to give 3-bromo-4-methylthiofuran (70%), a solution of which (3 g) in dry ether (50 mL) was treated at –78°C with a solution of *tert*-butyllithium (10. 9 mL, 1.7 M in pentane). The reaction mixture was stirred for 1 h, allowed to reach 0°C, quenched with saturated ammonium chloride solution, and the product was then extracted into ether (2 × 40 mL). The combined organic extracts were dried and the solvent was removed in vacuo to give 1.4 g (73%) of an oil; ^{1}H NMR δ: 2.38 (3H, s), 6.44 (1H, br s), 7.37 (1H, br s), and 7.47 (1H, br s) ppm; ^{13}C NMR δ: 18.8, 112.8, 141.6, 141.9, and 143.93 ppm; MS *m*/*z* (%): 114(29), 99(100), 86(30), 71(25).

*3-Methylthiothiophene (**4**)*

3-Bromothiophene (1 g, 6.13 mmol) was dissolved in dry ether (30 mL) under an argon atmosphere, and the solution cooled to –78°C. A solution of *tert*-butyllithium in pentane (3.6 mL, 1.7 M, 6.13 mmol) was added dropwise with stirring and the reaction mixture was stirred at –78°C for a further 30 min. Dimethyldisulfide (0.57 g, 6.13 mmol) was then added dropwise and the reaction mixture stirred for 1 h before warming to room temperature, where it was stirred for a further 2 h. The mixture was then cooled to 0°C, quenched with saturated ammonium chloride solution, and extracted with ether (2 × 40 mL). The combined organic extracts were dried and the solvent was removed in vacuo to give an oil; ^{1}H NMR δ: 2.50 (3H, s), 7.0 (2H, br s), and 7.33 (1H, br s) ppm; ^{13}C NMR δ: 18.1, 119.7, 126.7, 128.4, and 134.6 ppm; MS *m*/*z* (%): 130(78), 115(100); HRMS, M^+ calcd. for $C_5H_6S_2$: 129.99109; found: 129.99149.

N-*Methyl-2,3-dihydrobenzo-1,4-thiazine (**26**)*

2,3-Dihydrobenzo-1,4-thiazine (**25**) (2.5 g, 16.6 mmol) was dissolved in dichloromethane (50 mL) and 1 M aqueous sodium hydroxide (6.64 g, 0.166 mol) was added with vigorous stirring. A catalytic amount of tetra *n*-butylammonium bromide was added, followed by iodomethane (23.6 g, 0.166 mol). The reaction mixture was stirred vigorously for a further 7 days and the organic layer separated. The aqueous layer was extracted with dichloromethane (1 × 50 mL), the combined organic layers were dried, and the solvent was removed in vacuo. The resulting brown oil was purified on silica gel (5% EtOAc – 95% hexane) to give 0.68 g of a yellow oil (25%); ^{1}H NMR δ: 2.87 (3H, s), 3.00 (2H, m), 3.46 (2H, m), 6.60 (2H, m), and 6.98 (2H, m) ppm; ^{13}C NMR δ: 26.9, 40.6, 52.1, 113.0, 119.1, 119.9, 126.4, 127.9, 129.9, and 145.3 ppm; MS *m*/*z* (%): 165(100), 150(62), 136(54), 91(31); HRMS, M^+ calcd. for $C_9H_{11}NS$: 165.06122; found: 165.06143.

Preparation of racemic sulfoxides from 1–27

Racemic sulfoxide standards were prepared from sulfides **1**–**27** by oxidation using sodium *meta*-periodate: to a stirred methanolic solution (5 mL) of sulfide (1.0 mmol) at 0°C was added dropwise an aqueous solution (5 mL) of sodium *m*-periodate (1.0 mmol). The reaction mixture was stirred at 0°C for 1 h and then allowed to warm to room temperature, whereupon it was extracted with dichloromethane (3 × 15 mL), the combined organic layers were dried, and the solvent was evaporated to leave the sulfoxide, which was sufficiently pure for use as a standard for chiral shift reagent ^{1}H NMR or chiral stationary phase HPLC analysis.

Biotransformations with *Helminthosporium* sp.

Two slopes of *Helminthosporium* sp. NRRL 4671 were used to inoculate 15 1-L Erlenmeyer flasks each containing 200 mL of an autoclaved medium composed of V-8 vegetable juice (200 mL) and calcium carbonate (3 g) per litre of distilled water, adjusted to pH 7.2 prior to sterilization by the addition of 1 M sodium hydroxide. The flasks were allowed to stand overnight at 27°C, were then placed on a rotary shaker at 180 rpm, and growth continued for a further 72 h at 27°C. The fungus was then harvested by filtration and resuspended in 15 1-L Erlenmeyer flasks each containing 200 mL of distilled water. Substrate (1 g in 30 mL of 95% ethanol) was then distributed among the flasks, which were replaced on the rotary shaker at 180 rpm, 27°C, for a further 48 h. The fungus and aqueous medium were then separated by filtration as before, the aqueous medium was extracted with dichloromethane (continuous extraction, 72 h), and the fungus discarded. Concentration of the medium extract gave the crude product, which was examined by TLC, using ether or 10% methanol – ether as solvent, and then submitted to flash chromatography using a hexane – ethyl acetate or benzene–ether 10% stepwise gradient, followed by an ethyl acetate – methanol or ether–methanol 5% stepwise gradient if necessary. The yields and e.e. values quoted in the tables refer to purified, homogeneous material and, unless otherwise stated, arise from the combination of (only) homogeneous column fractions without further purification (e.g., crystallization) that could lead to changes in stereochemical enrichment values (31). Spectral and optical rotation data for products are listed below.

Biotransformations with *Mortierella isabellina*

Two slopes of *M. isabellina* ATCC 42613 were used to inoculate 15 1-L Erlenmeyer flasks each containing 200 mL of an autoclaved medium composed of glucose (40 g), yeast extract (5 g), sodium chloride (5 g), dibasic potassium phosphate (5 g), and soya flour (5 g) per litre of distilled water. Subsequent manipulations were exactly as described in the preceding paragraph except that the fungal mycelia were harvested by centrifugation rather than filtration.

Characterization of products

Spectral data for the biotransformation products are listed under the appropriate substrate heading. All products gave satisfactory HRMS data for the establishment of elemental composition. Isolated yields are listed in Tables 1 and 2.

Abstract: The absorption and emission spectra and the fluorescence lifetimes and quantum yields of alloxazine and several of its N- and C- methyl-substituted derivatives, including two isoalloxazines, have been measured in a nonpolar solvent (1,2-dichloroethane), a polar aprotic solvent (acetonitrile), and a polar protic solvent (ethanol). The excited state decays are all single exponential, suggesting that only one emitting species is present in all cases. The spectroscopic data show that the emitting species is the π,π^* electronic excited state corresponding to the ground state of the absorbing molecule; there is no evidence of excited state proton transfer for any of these solutes in any of the three solvents. The longer lifetimes and larger fluorescence quantum yields of the isoalloxazines compared with the alloxazines can be attributed exclusively to significantly slower rates of radiationless relaxation in the excited isoalloxazines. The remission and emission spectra of these same compounds adsorbed on cellulose are similar to the corresponding absorption and emission spectra in homogeneous solution, suggesting that the emitting species are the same in the adsorbed state as they are in homogeneous solution. However, the adsorbed excited species exhibit non-exponential temporal decay, attributed to inhomogeneities in the binding of the chromophore to cellulose. The emission spectra of polycrystalline samples of alloxazine and lumichrome suggest the possible occurrence of double intermolecular excited state proton transfer, but this interpretation is not supported by the further photophysical data obtained here.

Key words: photophysics, spectroscopy, alloxazine, lumiflavin, cellulose.

Résumé : Opérant dans un solvant non polaire (1,2-dichloroéthane), dans un solvant polaire non protique (acétonitrile) et dans un solvant polaire protique (éthanol), on a mesuré les spectres d'absorption et d'émission, les temps de vie de fluorescence et les rendements quantiques de l'alloxazine et de plusieurs de ses dérivés portant des substituants N- et C-méthyles. Dans tous les cas, la décroissance de l'état excité est toujours à une seule exponentielle; ceci suggère que dans tous les cas, il n'y a qu'une seule espèce qui émet. Les donnes spectroscopiques montrent que l'espèce qui émet est l'état électronique excité π,π^* correspondant à l'état fondamental de la molécule qui absorbe; pour chacun de ces solutés dans les trois solvants, il n'y a aucune indication suggérant l'existence d'un transfert de proton dans l'état excité. Les temps de vie plus longs et les rendements quantiques de fluorescence plus élevés des isoalloxazines par comparaison avec les valeurs semblables des alloxazines peuvent être attribués entièrement aux vitesses plus lentes de la relaxation sans rayonnement dans les isoalloxazines excitées. Les spectres d'émission et de réémission des même composés adsorbés sur de la cellulose sont semblables aux spectres correspondants d'absorption et d'émission de solutions homogènes; ceci suggère que les espèces qui émettent sont les mêmes dans l'état adsorbé qu'en solution homogène. Toutefois, les espèces excitées adsorbées donnent lieu à une décroissance qui n'est pas exponentielle dans le temps et ce résultat est attribué à des inhomogénéités dans la fixation du chromophore sur la cellulose. Les spectres d'émission d'échantillons polycristallins d'alloxazine et de lumichrome suggèrent laissent croire qu'il existe peut-être un double transfert de proton intermoléculaire dans l'état excité; toutefois, cette interprétation n'est pas supportée par d'autres données photophysiques obtenues dans ce travail.

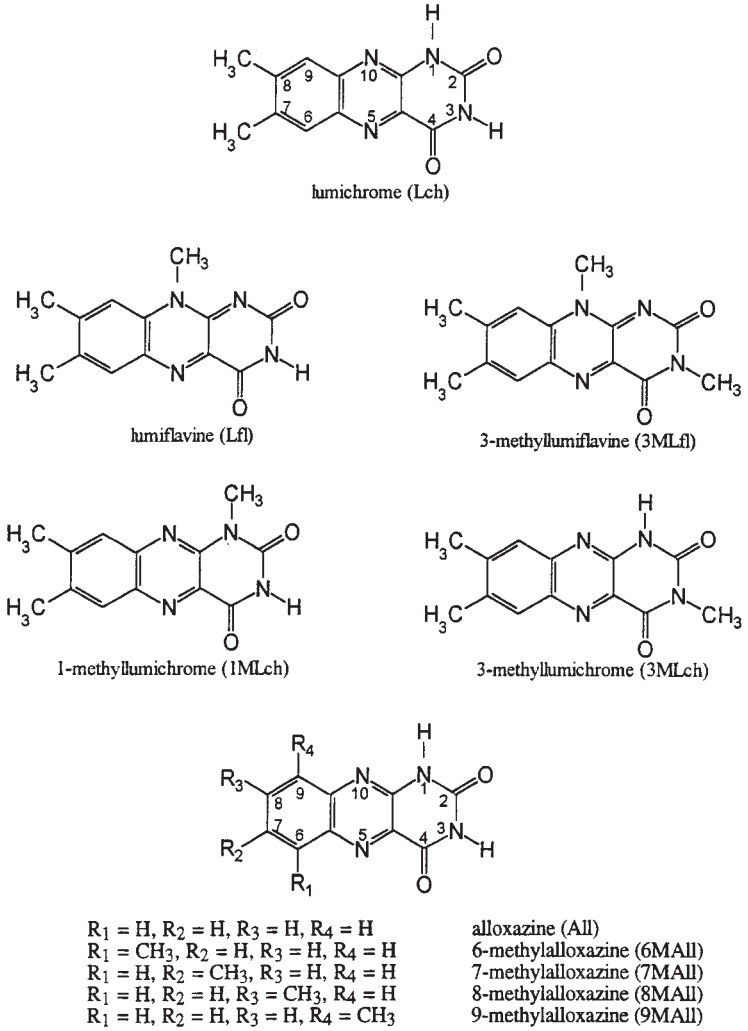
Fig. 1. Structures and abbreviations of the alloxazines and isoalloxazines employed in this study.



Introduction

Alloxazine and related compounds are numbered among an interesting group of species whose hydrogen-bonded complexes are capable of undergoing concerted intermolecular double proton transfer, and considerable work has been done to sort out the mechanism of photo-initiated double proton transfer in alloxazine – acetic acid and other complexes (1–8). The alloxazine system is a very useful one to model such processes because the isoalloxazine tautomer formed as a result of excited state proton transfer has a spectroscopically distinct emission spectrum (1, 6, 7). Recent work by one of us (1) has provided evidence that alloxazine – acetic acid complexes with appropriate structures for proton transfer can be formed in both the ground and excited states. The excited state reaction in solution is a two-step process involving, first, formation of a hydrogen-bonded structure that facilitates proton transfer, followed by proton transfer itself, with the former constituting the rate-determining step of the overall process.

The photophysics and photochemistry of alloxazine and its derivatives have been studied since 1966, when the proton transfer reactions in lumichrome and related compounds were first discovered (8). However, almost all of this previous work has been concerned with systems in homogeneous solution whereas current interests in the potential applications of photo-initiated processes are focussed largely on the solid state. Recently, Sarkar et al. (9) showed that lumichrome forms an inclusion complex with β-cyclodextrin (β-CD), and we studied the spectroscopic properties of this and several other complexes (lumichrome, Lch; 7-methylalloxazine, 7MAll; and 8-methylalloxazine, 8MAll — cf. Fig. 1) in both solution and the solid state (10). The formation of hydrogen bonds in the solid complexes was postulated to explain their ground-state absorption and steady-state fluorescence spectra, and spectroscopic evidence was found to support the existence of doubly hydrogen-bonded dimers of lumichrome capable of executing excited state double proton transfer in the solid state.

In this paper we present the results of a study of the photophysics of several alloxazines in both homogeneous solution and in the solid state, carried out with the objective of elucidating the structures and the dynamics of the excited species.

Experimental section

Materials

Alloxazine (Aldrich), lumichrome (Aldrich), and lumiflavine (Fluka) were purchased and used as received. The other

alloxazines and 3-methyllumiflavine used in this study were available from previous work, and were synthesized and purified as described in ref. 6. Cellulose (20 μm powder, Aldrich), dry acetonitrile, 1,2-dichloroethane, and absolute ethanol were used as received.

Samples of microcrystalline cellulose were placed in a vacuum oven at 70°C for at least 24 h prior to use to remove adsorbed water. Samples of the alloxazines supported on cellulose were prepared by first dissolving a weighed amount of the adsorbate in a known volume of 3:1 acetonitrile:methanol solution, then adding an aliquot of this solution to a slurry consisting of a known weight of dried cellulose powder in a known volume of the same solvent. The resulting suspension was stirred periodically and allowed to evaporate slowly. After several hours the final traces of solvent were removed by placing the sample in a vacuum oven at 40°C for about 4 h. The loading of alloxazine on cellulose was between 0.3 and 1.0 mg/g, and typically 0.8 mg/g.

Equipment and methods

Ground state diffuse reflectance absorption (remission) spectra were recorded on either a PU 8800 UV–visible spectrophotometer equipped with an integrating sphere or on a Perkin Elmer LambdaBio 40 spectrophotometer equipped with a Labsphere reflectance attachment. The methods of obtaining corrected diffuse reflectance spectra have been described elsewhere (11, 12). Steady-state fluorescence spectra were obtained with a Spex Fluoromax spectrofluorometer. UV–visible absorption spectra were recorded on an HP 8453 diode array spectrophotometer.

The fluorescence decay curves of the alloxazines in acetonitrile (except for alloxazine itself) and in 1,2-dichloroethane were measured using an IBH model 5000U spectrometer, as previously described (1). Fluorescence decay curves of all other samples were measured by exciting at 340 nm using the frequency-doubled output of a mode-locked, synchronously pumped, cavity-dumped argon-ion/DCM dye laser system, and detecting emission with a Hamamatsu microchannel plate photomultiplier coupled to a time-correlated single-photon counting system. The pulse-shape mimic technique was used to obtain the instrument response function (13), and the fluorescence lifetimes were obtained by an iterative convolution method employing a least-squares fitting procedure. This measuring system has been described in detail in refs. 13 and 14.

Fluorescence quantum yields were obtained by the standard relative method using quinine sulfate in 1 N H_2SO_4 (ϕ_f = 0.546) as a reference (15).

All measurements were performed at room temperature with air-equilibrated samples.

Results and discussion

A total of 10 alloxazines and isoalloxazines (lumiflavines) were available for study. The diffuse reflectance spectra of three representative alloxazines, 1MLch, 6MAll, and 7MAll, on cellulose are shown in Fig. 2; the absorption spectra of the same compounds in acetonitrile are presented for comparison. The diffuse reflectance spectra are plotted in terms of the remission function, $F(R)$, as a function of wavelength. $F(R)$ is proportional to absorber concentration, and is defined in the Kubelka–Munk (11, 16) theory of the interaction of light with opaque materials as

$$[1] \qquad F(R) = (1 - R)^2/2R = K/S$$

where R is the observed diffuse reflectance from the surface of the sample, K is the absorption coefficient, and S is the scattering coefficient.

The normalized emission spectra of these same three compounds, excited at 355 nm on cellulose, are presented in Fig. 3, and the emission spectra of lumichrome and alloxazine on cellulose and in the polycrystalline solid state are shown in Fig. 4. The emission spectra of the isoalloxazines, lumiflavine and 3-methyllumiflavine, on cellulose are shown in Fig. 5. The spectroscopic data for all 10 compounds on cellulose and in ethanol are collected in Table 1.

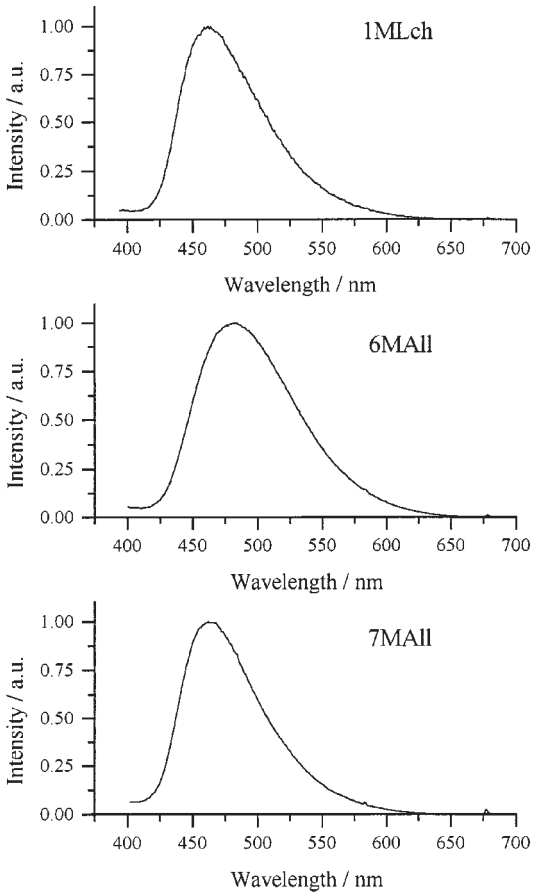
Fig. 3. Normalized fluorescence emission spectra of 1MLch, 6MAll, and 7MAll on cellulose. The loadings are the same as in Fig. 2.



The strong UV–visible absorption and emission bands of these compounds are all assignable to electric dipole allowed $\pi \rightarrow \pi^*$ transitions (17, 18). Thus, in aprotic solvents the absorption bands will be expected to undergo small red shifts with increasing solvatochromism of the medium. If the medium can form hydrogen bonds with the alloxazine, the red shifts in the absorption spectra will be even greater and the emission spectra of the alloxazinic tautomer will exhibit increasing blue shifts in more strongly hydrogen-bonded media. Taken together, the previous spectroscopic data (1, 10) and the data in Table 1 are consistent with this straightforward interpretation. Allowing for small red shifts associated with methyl substitution, the absorption and emission spectra of the alloxazines are all similar to one another, but rather different from those of the isoalloxazines, which absorb and emit much further to the red (compare, for example, 1-methyllumichrome, an alloxazine, with its structural isomer lumiflavine, an isoalloxazine). Comparing these spectroscopic data with those obtained previously for the same compounds in β-CD inclusion complexes (10) and in 1,2-dichloroethane (1), one observes that 1,2-dichloroethane and acetonitrile give similar solvent shifts, but that *on average* the alloxazine is adsorbed in a more polar environment on cellulose than in either homogeneous acetonitrile solution or in β-CD inclusion complexes.

Note also that the emission spectra of the alloxazines on cellulose (Fig. 3) are typical of the emission spectra of the

3-Methyllumiflavine	—	451	523	349	446	515

[a]The maxima of the two strong long-wavelength bands in the absorption spectra are $\lambda_{max\ 1}$, $\lambda_{max\ 2}$; the fluorescence emission maximum is λ_F.

[b]Molar absorptivities (M^{-1} cm^{-1}) are given in parentheses.

[c](s) = shoulder.

excited alloxazine in a polar environment, whereas the emission spectra of the isoalloxazines (Fig. 5) are typical of the excited isoalloxazinic forms, i.e., lying much further to the red than those of their alloxazine tautomers. Thus the alloxazines adsorbed on cellulose do not produce significant emission from the isoalloxazinic tautomer following excitation. It is then tempting to suggest that no significant excited state intermolecular proton transfer occurs in the adsorbed molecules. However, one should be cautious in drawing such a conclusion on the basis of the spectra alone, because the quantum yields of emission from species produced on excitation of alloxazines adsorbed on cellulose have not been measured and may be quite different for the excited isoalloxazinic and alloxazinic forms (10).

The emission spectra of the polycrystalline samples of lumichrome and alloxazine are very different from the spectra obtained by exciting these same compounds on cellulose. In fact the emission spectra of these polycrystalline solids (Fig. 4) might suggest that the observed fluorescence should be assigned to the excited states of their isoalloxazinic tautomers (compare Figs. 3 and 5). Excited state intramolecular proton transfer cannot occur in these molecules. Therefore if the emission from the crystalline alloxazines were assignable to the excited isoalloxazinic forms, this would provide strong evidence for the existence of doubly hydrogen-bonded dimers in the crystalline solid that undergo intermolecular double proton transfer on excitation as previously suggested for lumichrome in various solid forms (10). Note, however, that the fluorescence decay data presented below do not sustain such a simple interpretation of the spectroscopic data.

The temporal profiles of the fluorescence of the alloxazines and lumiflavine were measured in acetonitrile, ethanol, and 1,2-dichloroethane solutions at room temperature using both conventional and ps laser-excited time-correlated single-photon counting methods. Logarithmic fluorescence decay plots are given in Fig. 6 for the representative alloxazines 6MAll and 9MAll and in Fig. 7 for the isoalloxazines Lfl and 3MLfl. In all cases the fluorescence decays are well modelled by single exponential functions, as shown by the usual statistical measures of "goodness-of-fit." The lifetime, τ_f, and corresponding fluorescence quantum yield, ϕ_f, data are collected in Table 2. Note that the excited alloxazines all exhibit considerably shorter decay times than the isoalloxazines, ranging from ca. 0.5 to 1 ns for the former, and from 6 to 7 ns for the latter. The existence of excellent single exponential fits of the decay data is good evidence for the presence of a single emitting species in each case.

Given the implied presence of only a single emitting species when each of the alloxazines and isoalloxazines is excited in homogeneous solution, the rate constants for their radiative and non-radiative relaxation processes may be calculated using the following well-known relationships:

$$[2] \qquad k_r = \phi_f/\tau_f \text{ and } \sum k_{nr} = (1 - \phi_f)/\tau_f$$

Here, k_r is the rate constant for radiative decay of the excited species and $\Sigma\, k_{nr}$ is the sum of all first-order and pseudo-first-order rate constants for its non-radiative decay. The values of k_r and $\Sigma\, k_{nr}$ are also tabulated in Table 2. The sum, $\Sigma\, k_{nr}$, could in principle contain contributions from pseudo-first-order concentration and oxygen quenching of the excited species. However, the concentrations of both the ground state chromophore ($<10^{-4}$ M) and oxygen ($<10^{-3}$ M) are too small to contribute significantly to the rates of decay of the excited molecules even if the quenching were diffusion limited. Thus the measured differences in $\Sigma\, k_{nr}$ can be attributed primarily to differences in the rates of intramolecular radiationless relaxation processes in the excited states of these compounds.

Note that, with the possible exception of alloxazine itself, the values of both k_r and $\Sigma\, k_{nr}$ differ by no more than a factor of about two in the three solvents employed, as expected of systems in which the excited state decay is dominated by intramolecular processes whose rates are only weakly varying functions of solvent–solute interaction energy (see, for example, ref. 19). Note in particular that the radiative rate constants of the excited states of the alloxazines are not significantly different from that of the isoalloxazine lumiflavine, consistent with the fact that both possess similar chromophores. The longer lifetimes of the excited isoalloxazines, Lfl and 3MLfl, compared with the excited alloxazines can therefore be ascribed exclusively to the slower rates of non-radiative decay of the former. In all of the alloxazinic com-

pounds examined here, non-radiative relaxation dominates the excited state decay.

Temporal fluorescence profiles were also measured for the alloxazines and isoalloxazines on cellulose, and for the polycrystalline samples of lumichrome and the parent compound itself, alloxazine. The fluorescence data, plotted in $\log_{10} I$ (relative intensity) vs. time form, are shown in Fig. 8 for 6MAll and 7MAll on cellulose and in Fig. 9 for Lch on

cellulose and Lch crystals. None of the data are well described by single exponential fluorescence decay functions, and fits to double exponential functions of the form

$$I(t) = a_1 \exp(-t/\tau_1) + a_2 \exp(-t/\tau_2)$$

were therefore attempted. The best numerical fits of the four constants in this equation to the experimental data are shown in the figures, together with the resulting distributions of weighted residuals. The values of the lifetimes, the reduced χ^2, and the fractions of the emission attributable to each emitter, $F_i = a_i\tau_i / \Sigma\, a_j\tau_j$, are given in Tables 3 and 4.

The fits are not perfect between these experimental data and those calculated for double-exponential decay functions. However, the existence of reasonable double-exponential fits provides a rationale for seeking a mechanism in which there are two distinct emitting species. Note that for the alloxazines on cellulose the shorter-lived component has a lifetime ranging from 0.67 to 0.93 ns whereas the longer-lived component has a lifetime of from 2.0 to 3.8 ns. Since these ranges of lifetimes are not too different from the ranges of lifetimes found when the alloxazines and isoalloxazines are separately excited in liquid solvents (cf. Table 2), it might be tempting to assign the shorter-lived component to the excited alloxazine and the longer-lived component to a separate excited species, perhaps formed as the result of intermolecular proton transfer between the alloxazine and the hydroxyl groups of cellulose. However, there are a number of reasons to believe this is not the correct interpretation of these data.

First, note that double-exponential decay is observed for 1MLch on cellulose, in which the substitution of a methyl group at N(1) prevents this compound from acting as a proton donor and acceptor. Thus the longer-lived component cannot be an excited isoalloxazine in this molecule, and a

Lumichrome	525	3.87 (0.58)	0.43 (0.42)	1.24

different reason for at least its double-exponential fluorescence decay must be found. Second, for acetic acid – alloxazine complexes in which double excited state proton transfer does occur in solution, a rate of rise in the emission of the isoalloxazinic tautomer identical to the rate of decay of the excited alloxazinic form has been observed in some cases (1). No such precursor–product kinetic relationship is observed here, despite the fact that the emission was monitored at wavelengths that should have encompassed the emission of both excited tautomers, if present. Finally, the values of F_1 and F_2 (cf. Table 3) suggest that two species, if present, should contribute to the observed fluorescence with relative intensities in a range from about 2:1 to 1:2. Although the emission spectra of the alloxazines on cellulose are broad, there is no hint in these spectra that more than one species is present. If the longer-lived species are attributable to the excited isoalloxazinic tautomers, then, with up to two thirds of the total emission attributable to them, they should exhibit a second red-shifted band in the emission spectra. No such band is seen in the spectra of the alloxazines on cellulose.

We therefore seek an alternate explanation for the photophysical properties of these alloxazines and isoalloxazines adsorbed on cellulose. First, the moderately good fit of a double-exponential decay function to the decay data will not be interpreted in terms of two, and only two, emitting species. Rather, we assign the emission from the excited alloxazines on cellulose to species adsorbed in a range of environments. The values of $\Sigma\, k_{nr}$ of the methylalloxazines and Lc in ethanol are either the same or modestly smaller,

For personal use only.

compound for compound, compared with their values in 1,2-dichloroethane (cf. Table 2). We therefore tentatively conclude that polar protic environments have a stabilizing effect on the excited species. Because there is clear evidence that cellulose provides a stronger hydrogen-bonding environment than ethanol (see, for example, ref. 20), we thus assign the longer-lived species on cellulose to alloxazines, which are adsorbed at strongly hydrogen-bonding sites. The relative magnitudes of the values of F_1 and F_2 are then interpreted as indicating that cellulose provides relative numbers of highly polar and moderately polar binding sites for the alloxazines that are roughly in the ratio 1:1 to 1:2. The spectra of the ensemble of species will thus be expected to be broad, but species in different environments will have similar spectra, given that only solvatochromic shifts contribute to this breadth.

These results suggest that these heterogeneous systems would benefit from analysis using any of a number of methods for recovering underlying distributions of lifetimes from fluorescence decay data (21). To be of value, such analyses will require single-photon counting data acquired under conditions of better statistical reliability than presently available.

Finally, we note that the very different emission spectra of the polycrystalline samples of lumichrome and alloxazine, compared with their corresponding spectra in the adsorbed state (Fig. 4), might lead one to believe that these two compounds exhibit emission from their isoalloxazinic tautomers in the excited state of the crystals, or perhaps from stacked dimers. Note that their molecular structures admit the possibility of double excited state proton transfer, provided that a center of symmetry is found in the crystal structure at the geometric center of a planar arrangement of four nitrogen atoms (N(10), N(1), N′(10), N′(1)) from two adjacent molecules. However, a lack of clear confirmation from the lifetime data that the emission originates predominately from a single longer-lived species, which could be identified with the excited isoalloxazine, and our inability to date to obtain single crystals of these compounds for X-ray analysis makes such a simple interpretation problematic.

Conclusions

The absorption and emission spectra and the fluorescence lifetimes and quantum yields of alloxazine and several of its N- and C-methyl-substituted derivatives have been measured in a nonpolar solvent, a polar aprotic solvent, and a polar protic solvent. The photophysical data suggest that only one emitting species is present in all cases: the excited alloxazine when a ground state alloxazine is excited, and the excited isoalloxazine when a ground state lumiflavine is excited. There is no evidence of excited state proton transfer in any of these solutes in any of the three solvents. The longer lifetimes and larger fluorescence quantum yields of the isoalloxazines compared with the alloxazines can be attributed exclusively to significantly slower rates of radiationless relaxation in the excited isoalloxazines.

The remission and emission spectra of these same compounds adsorbed on cellulose are similar to the corresponding absorption and emission spectra in homogeneous solution, suggesting that the emitting species are the same in the adsorbed state as they are in solution. The adsorbed excited species exhibit non-exponential temporal decay. However, consistent with the spectra, this observation is attributed to inhomogeneities in the binding of the chromophore to the substrate, rather than to excited state intermolecular proton transfer.

The spectroscopic and photophysical data for polycrystalline samples of alloxazine and lumichrome do not admit a consistent interpretation of the excited state behaviour. The emission spectra suggest the possible occurrence of double intermolecular excited state proton transfer, but this interpretation is not clearly supported by the photophysical data. Further information, including crystal structures, will be necessary to advance this aspect of the work.

Determination of the configuration of ribitol in the C-polysaccharide of *Streptococcus pneumoniae* using a synthetic approach

Huiping Qin and T. Bruce Grindley

Can. J. Chem. Downloaded from www.nrcresearchpress.com by University Town Library of Shenzhen on 09/05/12
For personal use only.

Abstract: The C-polysaccharide is an antigen common to all known serotypes of *Streptococcus pneumoniae* bacteria and is a potential target for vaccine preparation. The final uncertainty in the structure of its repeating unit, a pentasaccharide phosphate containing two phosphorylcholine side chains, has been resolved by determining the configuration of ribitol. Assignment of configuration was performed by synthesis of the two trisaccharide phosphate fragments that have either D- or L-ribitol at their centers and comparison of their ^{1}H and ^{13}C NMR spectral data with that of the natural polysaccharide. The syntheses employed common synthons added in different orders to an asymmetrically substituted chiral ribitol derivative to obtain opposite chiralities in the ribitol segments. The data for the trisaccharide containing D-ribitol was almost identical to that of the natural material while that for the trisaccharide containing L-ribitol differed significantly. In particular, the chemical shift differences between the two protons of the primary carbons of ribitol units directly attached to the β-2-acetamido-2-deoxy-galactopyranosyl residue were 0.10, 0.12, and 0.33 ppm, in the natural polysaccharide, the D-ribitol-containing trisaccharide, and the L-ribitol-containing trisaccharide, respectively. The average difference between the ^{13}C NMR chemical shifts of corresponding ribitol carbons from the natural polysaccharide and the D-ribitol-containing trisaccharide phosphate was 0.034 ppm. This evidence indicates that ribitol in the C-polysaccharide has the D-configuration and that a very similar mixture of conformations in the ribitol portions is present for the natural polysaccharide and the D-ribitol-containing trisaccharide phosphate.

Key words: C-polysaccharide, *Streptococcus pneumoniae*, ribitol, dibutylstannylene acetal, determination of configuration.

Résumé : Le polysaccharide-C est un antigène commun à tous les sérotypes connus de la bactérie *Streptococcus pneumoniae* et est un objectif potentiel pour la préparation de vaccins. En déterminant la configuration du ribitol, on a levé la dernière incertitude dans la structure de son unité constitutive, un phosphate de polysaccharide contenant deux phosphorylcholine comme chaînes latérales. On a attribué la configuration en effectuant la synthèse des deux fragments de phosphate de trisaccharide comportant soit le D- soit le L-ribitol comme centres et en comparant les données de leurs spectres RMN du ^{1}H et du ^{13}C avec celles du polysaccharide naturel. On a réalisé la synthèse des trisaccharides en utilisant des synthons communs et un dérivé chiral du ribitol substitué d'une façon asymétrique qui ont été ajouté dans des ordres différents dans le but d'obtenir une chiralité différente dans ce segment. Les données obtenues avec le trisaccharide contenant du D-ribitol sont pratiquement identiques à celles du produit naturel alors que celles obtenues avec le trisaccharide contenant du L-ribitol présentent des différences significatives. En particulier, les différences de déplacements chimiques entre les deux protons des carbones primaires des unités ribitol attachées directement au résidu β-2-acétamido-2-désoxy-galactopyranosyle sont égales respectivement à 0,10, 0,12 et 0,33 ppm pour le polysaccharide naturel, le trisaccharide contenant le D-ribitol et le trisaccharide contenant le L-ribitol. La différence moyenne entre les déplacements chimiques en RMN du ^{13}C pour les carbones correspondants du ribitol du polysaccharide naturel et du trisaccharide contenant le D-ribitol sont de 0,034 ppm. Cette différence indique que le polysaccharide-C possède la configuration D et que le polysaccharide naturel et le phosphate du trisaccharide contenant le D-ribitol comportent des mélanges très semblables de conformations dans les portions du ribitol.

Mots clés : polysaccharide-C, *Streptococcus pneumoniae*, ribitol, acétal de dibutylstannylène, détermination de configuration.

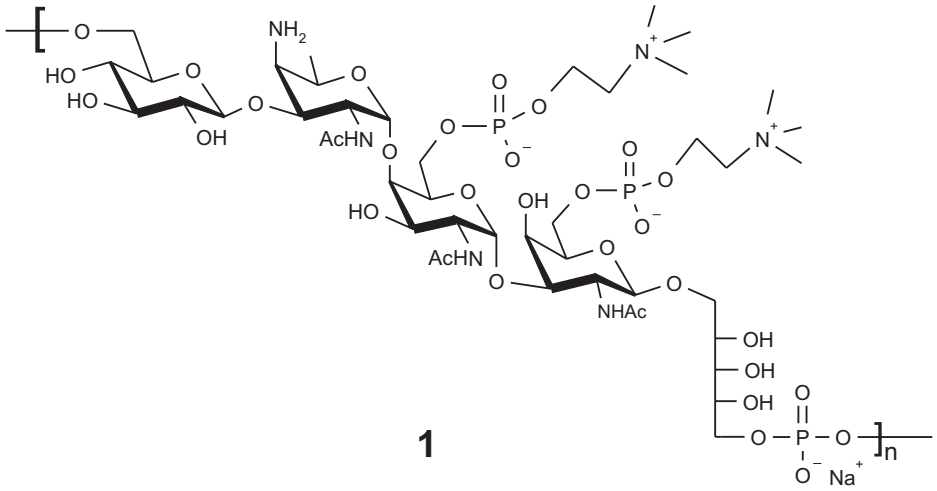
Scheme 1. The structure of the C-polysaccharide of *Streptococcus pneumoniae* with the configuration of ribitol shown as D.



1

Introduction

The Gram-positive microorganism *Streptococcus pneumoniae* induces infections such as pneumonia, bacteremia, otitis media, and meningitis in human beings (1), and resistance to drug treatment is becoming an increasing problem. Ninety serologically defined types of these capsular bacteria have been described to date (2). The capsule of each serotype is a unique polysaccharide that extends outwards from the cell wall and current vaccines against this organism contain a mixture of 23 of the capsular polysaccharides of the most common serotypes. The C-polysaccharide, a common antigen of all the known serotypes of *Streptococcus Pneumoniae*, is distributed on both the inside and outside of the cell walls (3). A polysaccharide with the same repeating unit is covalently bonded to a lipid moiety in the plasmic membrane through a phosphodiester linkage (4), in which form it is called the F antigen. Its presence in all serotypes makes it an attractive target for vaccine preparation but attempts to date have not resulted in sufficient activity to yield commercial vaccines (1*c*, 5, 6). Structural studies (7–12) showed that the polysaccharide contained the pentasaccharide repeating unit shown in Scheme 1.

The configuration of ribitol in the structure was assumed to be D, based on schemes proposed for the biosynthesis of teichoic acids where the donors of glycerol and ribitol phosphate residues are CDP-glycerol and CDP-ribitol, respectively (8, 9, 13). Teichoic acids are major constituents of Gram-positive bacterial cell walls and consist of polymers of ribitol-5-phosphate or glycerol-3-phosphate with carbohydrates and alanine as substituents (13) and the C-polysaccharide was classified as a teichoic acid (8). The experimental evidence supporting this scheme is that CDP-ribitol is incorporated in polyribitol phosphate by cell-free enzymic preparations from various Gram-positive bacteria (14). It is not certain that this scheme would apply to the ribitol phosphate in the C-polysaccharide or other polymers where ribitol phosphate constitutes a small part of the polymer.

Although the absolute configuration of glycerol has been determined a number of times (15–22), the configuration of ribitol has never been determined for any compounds derived from Gram-positive bacteria. In fact, its configuration has only been determined three times; it was demonstrated to have the D-configuration in the capsular polysaccharide from type b *Haemophilus influenzae*, a Gram-negative organism (23), in a compound isolated from a lichen (24), and in CDP-ribitol (25). Glycerol-1-phosphate normally has the D-configuration (15, 17, 19–21) in agreement with the scheme proposed for its biosynthesis, but L-glycerol-1-phosphate is also known, in the membrane-bound teichoic acid from *Streptococcus lactis* (16) and in the cell wall of *Bacillus cereus* (22). It was discovered that the biosynthetic pathway leading to L-glycerol-1-phosphate was different from that proposed for its D-analogue (26) and the question naturally arises as to whether only one biosynthetic pathway leads to ribitol-5-phosphate.

Ribitol-5-phosphate is present in several of the capsular polysaccharides of *Streptococcus pneumoniae* as well as in the C-polysaccharide, and its configuration in these compounds has also been assumed to be D (27). In this publication, we outline the determination of the configuration of ribitol in the C-polysaccharide of *Streptococcus pneumoniae* through synthesis of the two trisaccharide portions of the natural C-polysaccharide that have D- and L-ribitol at the center. A tetrasaccharide portion of the repeating unit synthesized previously had D-ribitol at the nonreducing terminus, but no attempt was made to determine whether the configuration of ribitol matched that in the natural product (28).

Results and discussion

Synthetic strategy

To simulate the environment of the ribitol unit in the C-polysaccharide, two trisaccharide phosphate targets (**18** and **24**) were designed. In **18** and **24**, instead of linking to another 2-acetamido-2-deoxy-D-galactopyranose residue as in the C-polysaccharide, the 3″ position was substituted with a methyl group. A synthetic strategy to obtain **18** and **24** was developed that made the maximum use of synthons that were common to both trisaccharides and is shown in Scheme 2.

Synthesis of trisaccharide phosphates containing the D-ribitol unit (18)

Compound **12** was obtained from the known compound, *tert*-butyldimethylsilyl 2-azido-4,6-*O*-benzylidene-2-deoxy-β-D-galactopyranoside (29), as shown in Scheme 3. The anomeric

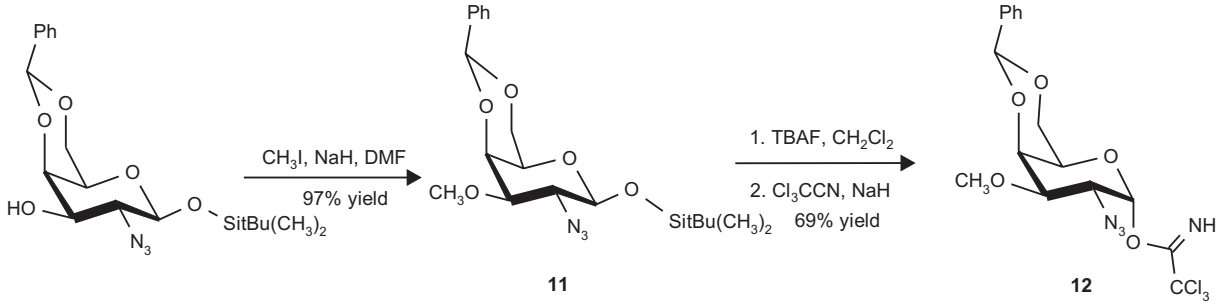
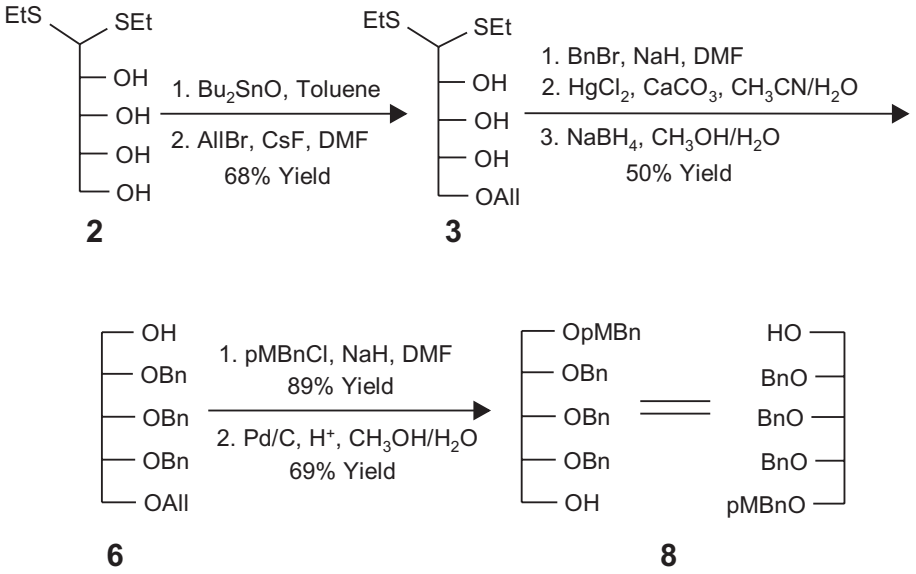
Scheme 3. Synthesis of glycosyl donor **12**.



Scheme 4. Synthesis of key ribitol-containing intermediate **8**.



tert-butyldimethylsilyl group was stable in the presence of sodium hydride, allowing O-3 to be methylated in 97% yield with methyl iodide to provide **11**. Treatment of **11** with TBAF in dichloromethane successfully afforded the desired desilylated product. Subsequent reaction with trichloroacetonitrile in the presence of sodium hydride afforded the α-trichloroacetimidate **12** selectively in a 69% yield for the two steps.

Compound **8**, the key intermediate, could be converted into either D- or L-ribitol derivatives, depending on the order in which the differentially protected primary hydroxyl groups were functionalized. Its synthesis started with D-ribose diethyl dithioacetal (**2**), which was selectively allylated at the primary position via a stannylene acetal intermediate to give **3**. This is the first time that a dialkyldithioacetal derivative has been selectively protected at the primary position via a dibutylstannylene acetal intermediate (30) and this approach replaces a four-step preparation from D-ribose (31). As shown in Scheme 4, following benzylation of the selectively allylated **3**, the diethyl dithioacetal group was removed and reduction gave **6**. Compound **6** had previously been prepared in six steps from γ-ribonolactone, a relatively expensive starting material (32). Following *p*-methoxybenzylation of the free hydroxy group and deallylation, ribitol derivative **8** was obtained. Compound **8** is an L-derivative if the free hydroxyl group is at O-1 as numbered in Scheme 4 but a D-derivative if the *p*-methoxybenzyl group is at O-1 as numbered for **6**.

The D-ribitol-containing trisaccharide phosphate **18** was synthesized by glycosylation of a phosphorus-linked disaccharide **14** with trichloroacetimidate **12**. As shown in Scheme 5, the synthesis of the disaccharide glycosyl acceptor **14** was performed by phosphitylation of L-ribitol derivative **8** with **10**. Compound **10** was made from methyl 2,3,4-tri-*O*-benzyl-6-*O*-trityl-β-D-glucopyranoside (33) by a sequence that started with detritylation in 75% yield using 30% HBr in acetic acid, an improved method. The product, methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside (**9**), was reacted with chloro 2-cyanoethyl (*N*,*N*-diisopropyl)phosphoramidite (34) in the presence of diisopropylethylamine (DIPEA) to give **10** in an 83% yield. The reaction of **10** with **8** was followed by oxidation with *m*-chloroperbenzoic acid (MCPBA) in the same pot. The *p*-methoxybenzyl group survived the acidic conditions provided by both tetrazole and MCPBA, and was removed with 2,3-dichloro-4,5-dicyanoquinone (DDQ). These two steps afforded **14** in a 57% yield. The formation of the phosphorus linkage was clearly evident in the coupling of the phosphorus to the C-4 (doublet) and C-5 (doublet) of the ribitol unit and the disappearance of isopropyl group signals (δ 24, 43) in the ^{13}C NMR spectrum. Compound **14** was a mixture of epimers at phosphorus as indicated by the two signals (δ –0.72, –0.77) in the ^{31}P NMR spectrum.

Glycosylation of the disaccharide glycosyl acceptor **14** by **12** was successfully performed in an 82% yield. As antici-

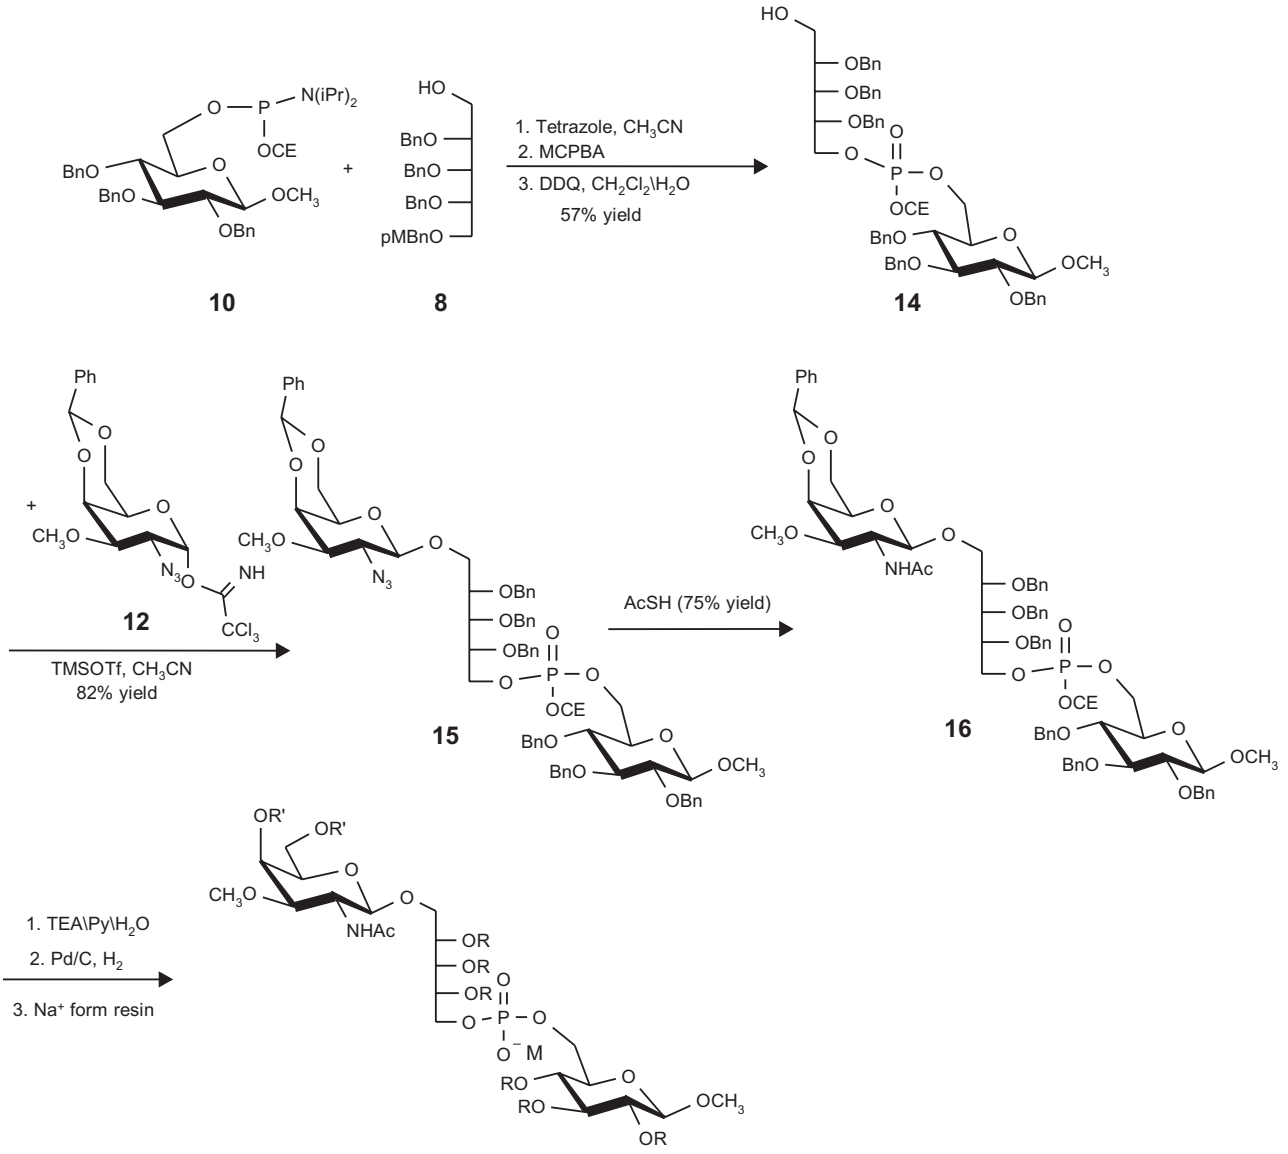
Scheme 5. Synthesis of D-ribitol-containing trisaccharide phosphate **18**.



pated, solvent participation by acetonitrile (35) caused the β-linkage to be formed selectively, which was clearly shown by the observation of a large vicinal coupling constant of 7.8 Hz between H-1 and H-2. No products having an α-linkage were observed. In the transformation of the azido group to the acetamido group, the benzylidene ring surprisingly survived overnight treatment with thiolacetic acid at room temperature to give the reduction product in 75% yield.

Due to the stereogenic centre at phosphorus, **10**, **14**, and **15** are diastereomeric mixtures, as shown by their ^{31}P NMR spectra, each of which contained two peaks. This is also reflected in the appearance of two peaks in the ^{13}C NMR spectra for most of the carbons close to the phosphorus atoms. Surprisingly, on treatment of **15** with thiolacetic acid, another pair of peaks appeared. In the ^{31}P NMR spectrum of **16**, there are two large peaks (δ –0.68, –0.96) and two small peaks (δ 0.17, –0.73). A possible explanation is that both *E* and *Z* acetamido rotamers are being observed, perhaps due to hydrogen bond formation between the amide hydrogen and a phosphate oxygen in the normally less stable conformer.

The cyanoethyl (CE) group on phosphorus was removed by treatment with a triethylamine, pyridine, and water mixture for 2 h at room temperature and the product had only a single peak in its ^{31}P NMR spectrum (1.41 ppm), as expected for a product with no chirality at phosphorus. The disappearance of the CN (116 ppm) and two CH_2 (19 and 61 ppm) signals from the ^{13}C NMR spectrum confirmed the removal of this group. Hydrogenation removed the 4,6-*O*-benzylidene ring and all of the *O*-benzyl groups, as confirmed by disappearance of all of the signals assigned to aromatic proton and carbon signals in the ^{1}H and ^{13}C NMR

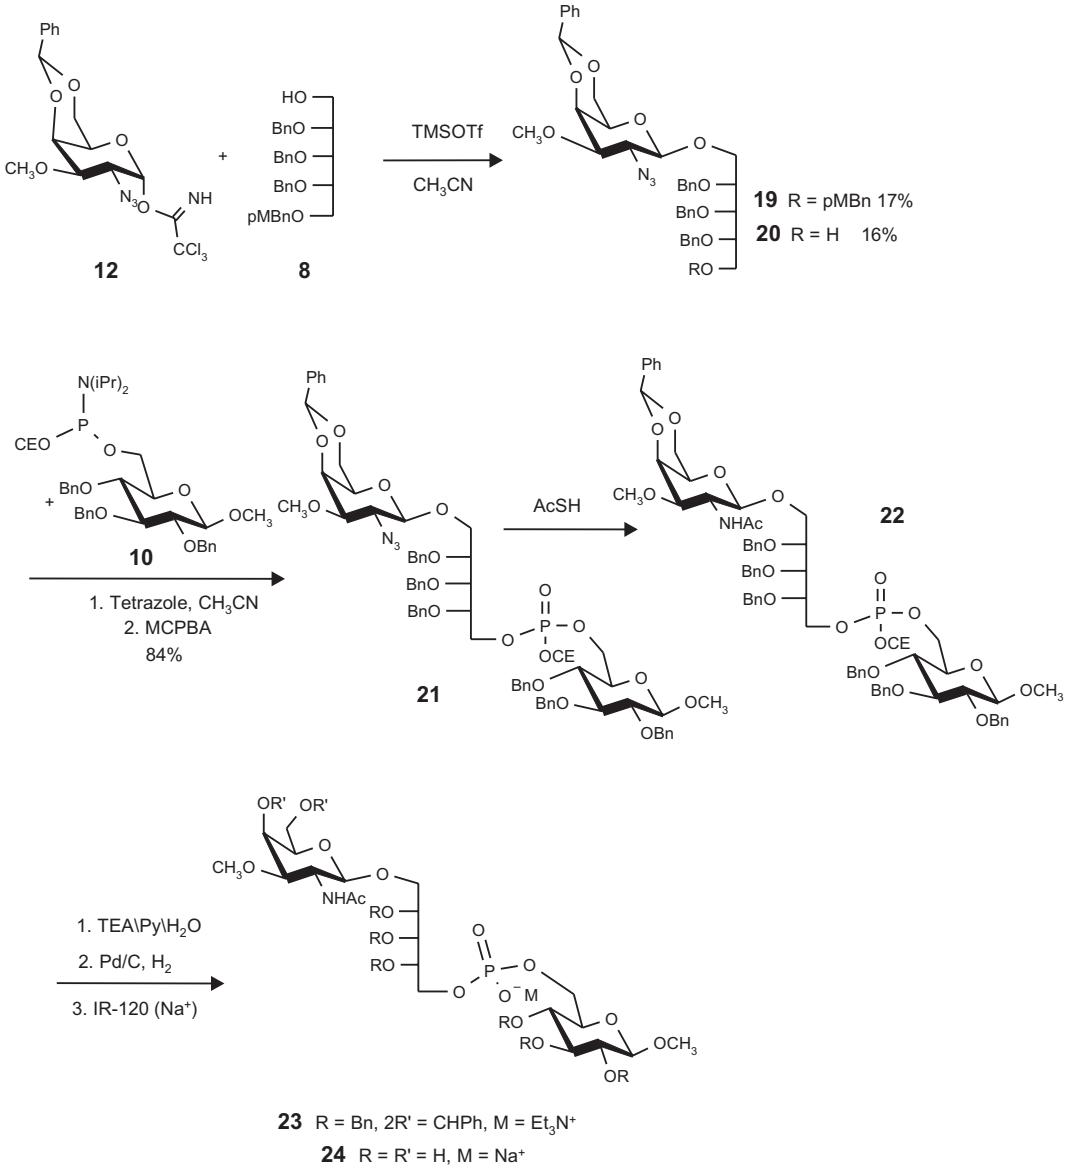
Scheme 6. Synthesis of the L-ribitol-containing trisaccharide phosphate **24**.



spectra, respectively. Treatment with Amberlite IR-120 (Na^+) resin afforded the target trisaccharide phosphate **18** in a quantitative yield. The disappearance of the signals for the ethyl group in the NMR spectra indicated the removal of the triethylammonium ion and the completion of the ion exchange reaction.

Synthesis of trisaccharide phosphate containing the L-ribitol unit (24)

The synthesis of the target trisaccharide phosphate **24** followed the reverse combination route outlined in Scheme 2. Though extra caution was exercised, coupling of **12** and **8** gave a low yield of a mixture of the expected product (**19**) and the product in which the *p*-methoxybenzyl group had been removed (**20**). Compound **19** was transformed into **20** by treatment with DDQ (63% yield) at room temperature. This observation confirms that compound **20** isolated from the coupling reaction was formed from **19** and, therefore, that formation of the glycosidic linkage was faster than the removal of the primary *p*-methoxybenzyl group under the coupling conditions. If the *p*-methoxybenzyl group had been cleaved at a rate comparable with or faster than glycoside formation, **20** and its diastereomer with the ribitol unit having the D-configuration would have been formed. The phosphotriester linkage between the disaccharide **20** and the phosphoramidite derivative **10** was formed as previously in an 84% yield. A diastereomeric mixture **21** having both configurations at phosphorus was obtained. The transformation of the azido group in **21** to an acetamido group and the subsequent transformation from **22** to **24**, as shown in Scheme 6, followed the same procedure as in Scheme 5.

Assignment of configuration

Complete assignments of all ^1H and ^{13}C NMR signals in the 500 and 125 MHz NMR spectra of the two trisaccharides **18** and **24** were made using a variety of 1D and 2D NMR

	Δδ Rib	+0.24	–0.01	+0.18	+0.21	–0.1	

[a]Δ δRib refers to the chemical shift difference of the ribitol unit between **18**, **24**, and **PnC**. Digital resolution: 0.015 ppm/point for **18**, 0.0076 ppm/point for **24**.

techniques, including JMOD, COSY, TOCSY, HMBC, and HMQC experiments.[2] In accordance with the literature report detailing the spectral data for the C-polysaccharide (11), acetone was used as an internal reference, using chemical shifts of the methyl group at δ 2.225 and δ 31.07 in the ^{1}H and ^{13}C NMR spectra, respectively, as references and sample concentrations were also the same. A detailed outline of the procedures followed for signal assignment is provided in the supplementary material. Assignments are given for the ^{1}H and ^{13}C NMR spectra of **18**, **24**, and the corresponding segments of the natural polysaccharide (**PnC**) in Tables 1 and 2, respectively.

The ^{1}H NMR spectra of the final products **18** and **24** were similar, but there were small but significant differences in the section of the spectra where the ribitol signals appear. The chemical shifts for the galactosamine (GalNAc) and glucose (Glc) parts of **18** and **24** were the same within 0.02 ppm (see Table 1), which confirmed that the careful attention given to sample preparation, data point resolution, and referencing resulted in highly reproducible chemical shifts. The largest differences were observed for the signals of H-1a and H-1b of ribitol. Most chemical shifts were obtained from first-order analysis and from 2D experiments; those for the D-ribitol segment of the 500 MHz spectrum of **18** were obtained by simulation using the program LAME8 (36), because the chemical shifts of H-1b′ and H-2′ were virtually identical. The chemical shift differences (Δδ's) between the signals of the two H-1′s from the ribitol unit in the C-polysaccharide (**PnC**) and those from **18**, the D-ribitol derivative, were small, –0.03 ppm and –0.01 ppm; in contrast, the comparable differences between the data from **PnC** and that from **24**, the L-ribitol derivative, were much larger, –0.12 ppm and +0.11 ppm. Probably the most significant observations concern the chemical shift differences between the two H-1′ signals for each compound, being 0.10 ppm for **PnC**, 0.12 ppm for the D-ribitol derivative **18**, but much larger, 0.33 ppm, for the L-derivative **24**. The chemical shift differences were also somewhat larger for the signals of H-4′ and H-5b′ for **24** with respect to **PnC** than for **18**.

These observations clearly demonstrate that the data for the D-ribitol derivative **18** was very similar to that of **PnC**, whereas that of the L-ribitol derivative **24**, while still fairly similar to that of **PnC**, was less so. In fact, the chemical shift for every proton from the ribitol part of **18** is almost identical to that of the comparable proton in the natural polysaccharide; the largest Δδ was –0.04 ppm for H-2′.

As stated above, the most significant observation is that the chemical shift differences between the two C-1′ protons

[2] Discussion of spectral assignments of **18** and **24** with some of the supporting JMOD, TOCSY, and HMQC spectra (7 pages) is available as supplementary material and can be ordered from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada.

For personal use only.

are virtually identical for **PnC** and the D-ribitol derivative **18**, being 0.10 and 0.12 ppm, respectively, whereas that for the L-ribitol derivative **24** is much larger, 0.33 ppm. This section of the spectrum of the natural polysaccharide might be different than that of the trisaccharide containing a ribitol segment of the same configuration if the size of the polysaccharide and the presence of other charged groups (phosphorylcholine groups) caused the composition of the conformational mixture for this region of the polysaccharide to be different than that present for the trisaccharide. The conformations and configuration of the ribitol segment and the conformation of the attached 2-acetamido-2-deoxy-β-D-galactopyranosyl unit will be most important in determining this chemical shift difference. The latter will be fixed in a $^4C_1$ conformation; the former, as an alditol with a β-1,3-O-O interaction in its Fischer projection, will be highly flexible (37). The ribitol segment should maintain this relative flexibility even if the remainder of the polysaccharide is less mobile. The near identity of the ^{1}H NMR chemical shifts of **PnC** and **18** supports the contention that the conformational mixtures present for both are almost identical, and the similar situation for ^{13}C chemical shifts, discussed in the following paragraph, provides further support. Therefore, the major factors influencing the H-1′ chemical shift differences will be the relative configurations at the anomeric centre of the 2-acetamido-2-deoxy-β-D-galactopyranosyl unit and those in ribitol, primarily at C-2′ but also at C-3′, and C-4′. These observations indicate that the configuration of ribitol in the natural material is D.

The ^{13}C NMR spectra of **18** and of **24** were also quite similar. The largest differences lie in the chemical shifts of C-1′ and C-4′ of the ribitol unit. The carbons of the glucopyranose units of **18** and **24** have almost the same chemical shifts, which indicates that there were no systematic shift differences between results from different samples (see Table 2). It was found that the chemical shifts of the carbons of ribitol in the synthetic D-trisaccharide phosphate **18** were almost identical to those from the corresponding part of the **PnC**; the average absolute deviation was 0.034 ppm. The chemical shifts for the same part of the L-trisaccharide phosphate **24** had an average absolute deviation of 0.15 ppm, with the largest differences at C-1 (+0.24 ppm), C-3 (+0.18 ppm), and C-4 (+0.21 ppm), respectively. All of these were less shielded than in the C-polysaccharide. ^{13}C NMR chemical shifts of carbons in acyclic systems are known (37*a*, 37*b*, 38) to be strongly dependent on the mixture of conformations present, particularly on the relative proportion of *gauche* and *anti* conformers. The close similarity of the chemical shifts of the corresponding carbons from the ribitol segments of **PnC**, **18**, and **24** to those from the first two, being identical within experimental error, strongly supports the contention that the conformational mixtures present for the ribitol segments of all three are identical. Therefore, this evidence supports the above conclusion that the ribitol unit in the C-polysaccharide of *Streptococcus pneumoniae* has the D-configuration.

Conclusions

From the differences in the NMR data of **18** and **24**, it was demonstrated that the configuration of the ribitol unit in these molecules had a significant influence on the chemical shifts of the corresponding ^{1}H and ^{13}C NMR signals. Of the two configurations, only one can be that present in the natural polysaccharide. The configuration for which the NMR data was in closer agreement to that of the corresponding part of the C-polysaccharide (**PnC**) should be the one present in the natural material as long as there is reasonable agreement. The ^{1}H and ^{13}C NMR chemical shift data for the D-ribitol derivative **18** showed remarkable agreement with that for **PnC**, with average chemical shift differences for the corresponding signals being 0.02 and 0.034 ppm, respectively; the agreement for the L-ribitol derivative **24** was significantly worse. Perhaps the most significant observation was that the chemical shift differences between the signals of the two primary hydrogens on the ribitol carbon closest to the anomeric center of the *N*-acetyl-β-D-galactopyranosyl unit were 0.10 ppm in the natural polysaccharide, 0.12 ppm in the D-ribitol derivative, but 0.33 ppm in the L-ribitol derivative. In view of the conformational flexibility of ribitol derivatives and the near identity of all ^{1}H and ^{13}C NMR chemical shifts in the D-ribitol derivative and the natural polysaccharide, it seems highly unlikely that there could be a conformational effect in the natural polysaccharide that could result in the two C-1 protons from the natural polysaccharide having a chemical shift difference markedly different than that of the trisaccharide containing ribitol with the same configuration. Thus, the ribitol unit in the C-polysaccharide of *Streptococcus pneumoniae* can now be reliably assigned the D-configuration.

Experimental section

General methods

Melting points were determined with a Fisher–Johns melting point apparatus and are uncorrected. Specific rotations were measured on Perkin–Elmer model 141 or 243 polarimeters. TLC was carried out on 0.20 mm thick Merck silica gel 60F-254 aluminum sheets cut to be approximately 7 cm long. Components were located by spraying with 2% ceric sulfate in 1 M sulfuric acid and heating on a hot plate until coloration occurred. Dry flash column chromatography was performed on silica gel 60 PF-254 for TLC. Low-pressure flash column chromatography was performed on silica gel Merck grade 9385, 230–400 mesh, 60 Å. The ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded on a Bruker AC-250 NMR spectrometer, unless otherwise noted. Some spectra were recorded on Bruker AMX-400 or AMX-500 NMR spectrometers. Solutions for NMR spectra were prepared in chloroform-*d* unless otherwise stated. Chemical shifts are reported in ppm downfield from internal TMS for ^{1}H and ^{13}C NMR spectra. The central peak for chloroform-*d*, at δ 77.0, was used as a secondary reference for ^{13}C NMR spectra. Phosphoric acid (25%) was used as an external chemical shift reference for ^{31}P NMR (δ 0.00). For **18** and **24**, acetone was used as an internal chemical shift reference for ^{1}H NMR (δ 2.225) and for ^{13}C NMR (δ 31.07). Exact masses for **3**, **5**, **6**, and **7** were measured on a JEOL AX505H mass spectrometer using fast atom bombardment (FAB) at the NRC in Ottawa. Exact masses for **10**, **11**, and **24** were measured on a Kratos IIH mass spectrometer using fast atom bombardment (FAB) at the University of Ottawa. The fast atom beam was provided by a cesium gun. Solvents for the matrix were

glycerol and (or) 3-nitrobenzyl alcohol and combinations thereof. Exact masses for **15**, **16**, **17**, **18**, **21**, and **23** were measured on a Kratos MS50 mass spectrometer using electrospray ionization (ESI) at the University of Alberta. Electrospray ionization mass spectra for **8**, **14**, and **20** were run on a VG Micromass Quattro spectrometer in acetonitrile–water (1:1) using a loop injector. The solution concentration was approximately 5.21×10^{-4} M and injection was 10 μL. The sample capillary was at 3500 V, the sample cone was at 20 V, and the source temperature was at 100°C.

D-Ribose diethyl dithioacetal, 2

To a solution of D-ribose (30.0 g, 0.20 mol) and concentrated hydrochloric acid (36 mL) was added ethanethiol (36 mL) dropwise at 0°C over 15 min and the reaction mixture was stirred for another 30 min. Then a saturated sodium bicarbonate solution was added dropwise until the solution was neutral. The resulting solution was concentrated to a residue that was extracted with ethyl acetate. The insoluble inorganic salts were removed by filtration. The ethyl acetate filtrate was concentrated to solid **2**, and recrystallized from ethanol as needles (38.61 g, 75% yield): mp 82–83°C (lit. (39) mp 82–83°C).

5-*O*-Allyl D-ribose diethyl dithioacetal, 3

Dibutyltin oxide (0.248 g, 1.0 equiv.) and compound **2** (0.256 g, 1.0 mmol) were refluxed in toluene (20 mL) for 4 h in a Dean–Stark apparatus for the azeotropic removal of water. Then the solvent was evaporated and cesium fluoride (0.222 g, 1.45 equiv.) added. After the mixture had been kept under vacuum for 1 h, a solution of allyl bromide (0.12 mL, 1.3 equiv.) in DMF solution (6 mL) was added. The reaction mixture was stirred at room temperature for 1 h when TLC showed that all starting material had been consumed. The reaction solution was concentrated to a residue that was taken up in ethyl acetate (50 mL). The solution was dried (Na_2SO_4) and concentrated to a liquid residue that was purified by dry flash column chromatography to yield the title compound (**3**): yield 0.202 g (68%); $[\alpha]_D^{24}$ –17.4 (*c* 1.16, $CHCl_3$), ^{1}H NMR, same as ref. 31; ^{13}C NMR δ: 14.4, 14.5 (2 CH_3), 25.6 (2 CH_2S), 54.4 (C-1), 71.1 (C-4), 71.5 (C-5), 72.4 (**C**$\mathbf{H_2}$-All), 72.8 (C-3), 75.0 (C-2), 117.6 (CH_2=), 133.9 (-CH=). Exact Mass (FAB) calcd. for $C_{12}H_{24}O_4S_2Na$ $[M + Na]^+$: 319.1014; found: 319.1018.

5-*O*-Allyl-2,3,4-tri-*O*-benzyl-D-ribose diethyl dithioacetal, 4

A solution of compound **3** (0.425 g, 1.44 mmol) in DMF (5 mL) was treated with excess NaH (0.42 g, 60% suspension in mineral oil, washed with hexanes 3 times before use) at 0°C. The resulting mixture was stirred for 30 min. Then a solution of benzyl bromide (1.36 mL) in DMF (2 mL) was added dropwise. The reaction solution was stirred at 0°C for 3.5 h when TLC showed that all the starting material had been consumed. Cold water was added until the total volume was about 70 mL. The water layer was extracted with pentane (5 × 40 mL). The pentane solution was dried (Na_2SO_4) and concentrated to a liquid residue that was separated with dry flash column chromatography using a gradient elution from hexane to ethyl acetate. The title compound (**4**) was obtained as a syrup (0.514 g, 63% yield); $[\alpha]_D^{23}$ 24 (*c* 6.76, $CHCl_3$); ^{1}H NMR, same as ref. 31; ^{13}C NMR δ: 14.6 (2 CH_3 SEt), 24.8, 26.1 (2 **C**H_2 SEt), 53.8 (C-1), 69.3 (C-5), 72.0, 72.4, 73.4, 74.5 (3 **C**H_2Ph, 1 **C**H_2 All), 78.9, 79.8, 82.1 (C-2, C-3, C-4), 116.4 (**C**H_2=), 134.7 (-**C**H=), 127.2-128.7, 138.2, 138.3, 138.7 (C-Ph).

5-*O*-Allyl-2,3,4-tri-*O*-benzyl-D-ribose, 5

A solution of compound **4** (0.310 g, 0.55 mmol) in aqueous acetonitrile (7.25 mL CH_3CN + 0.72 mL H_2O) was treated with mercury(II) chloride (0.604 g, 2.21 mmol) and calcium carbonate (0.229 g, 2.29 mmol). The resulting mixture was stirred at room temperature for 1 h when TLC showed that all starting material had been consumed. The reaction mixture was filtered through Celite and the filtrate was concentrated to a residue that was taken up in dichloromethane (100 mL). The solution was subsequently washed with potassium iodide solution (1 M, 3 × 100 mL) and sodium thiosulfate solution (30%, 2 × 100 mL) and then dried (Na_2SO_4) and concentrated. The title compound (**5**) was obtained as a colourless liquid (0.216 g, 86% yield); $[\alpha]_D^{23}$ 20.5 (*c* 0.48, $CHCl_3$); ^{1}H NMR δ: 3.53 (dd, 1H, H-5_a, $J_{5a,5b}$ = –10.7 Hz, $J_{5a,4}$ = 4.6 Hz), 3.67 (dd, 1H, H-5_b, $J_{5b,4}$ = 2.1 Hz), 3.87–4.01 (m, 4H, H-3, H-4, C**H**$_2$ All), 4.09 (br d, 1H, H-2), 4.47–4.82 (m, 6H, 3 C**H**$_2$Ph), 5.11–5.26 (m, 2H, C**H**$_2$=), 5.78–5.93 (m, 1H, -C**H**=), 7.22–7.33 (m, 15H, H-Ph), 9.47 (br s, 1H, -C**H**=O); ^{13}C NMR δ: 69.0 (C-5), 72.1 (**C**H_2 All), 72.5, 72.7, 79.9 (3 **C**H_2Ph), 76.5, 80.3 (2C C-3, C-4), 82.2 (C-2), 116.8 (**C**H_2=), 134.6 (-**C**H=), 127.4–128.3, 137.3, 137.5, 137.9 (C-Ph), 200.9 (C-1, H**C**=O). Exact Mass (FAB) calcd. for $C_{29}H_{32}O_5Na$ $[M + Na]^+$: 483.2148; found: 483.2195.

5-*O*-Allyl-2,3,4-tri-*O*-benzyl-D-ribitol, 6

A solution of compound **5** (0.215 g, 0.47 mmol) in aqueous methanol (methanol:water 1:1, 3 mL) was stirred with sodium borohydride (0.032 g, 0.81 mmol) for 10 h. Then water (10 mL) was added and the resulting mixture was extracted with chloroform (3 × 10 mL). The combined extracts were dried (Na_2SO_4) and concentrated to a liquid residue that was purified with dry flash column chromatography to yield the title compound (**6**) (0.194 g, 90% yield); $[\alpha]_D^{23}$ –17 (*c* 2.52, $CHCl_3$) (lit. (31) $[\alpha]_D^{23}$ –23.2; lit. (32) $[\alpha]_D$ –15.0); ^{1}H (31, 32) and ^{13}C (32) NMR spectra same as literature values. Exact Mass (FAB) calcd. for $C_{34}H_{38}O_6Na$ $[M + Na]^+$:565.2566; found: 565.2544.

5-*O*-Allyl-2,3,4-tri-*O*-benzyl-1-*O*-*p*-methoxybenzyl-D-ribitol, 7

A solution of **6** (0.150 g, 0.325 mmol) in DMF (3 mL) was stirred with sodium hydride (0.06 g, 60% suspension in mineral oil, washed with hexanes before use) at 0°C for 20 min and a solution of *p*-methoxybenzyl chloride (300 μL, 2.21 mmol) in DMF (2 mL) was added dropwise in 6 min. The resulting mixture was stirred at room temperature for 4 h when TLC showed that all starting material had been consumed. Water (15 mL) was added and the resulting mixture was extracted with pentane (6 × 20 mL). The combined extracts were dried (Na_2SO_4) and concentrated to a liquid residue that was purified with dry flash column chromatography using a gradient elution from hexane to ethyl acetate to yield **7** (0.169 g, 89% yield); $[\alpha]_D^{24}$ –0.11 (*c* 2.48,

$CHCl_3$); ^{1}H NMR δ: 3.63–3.70 (m, 4H, H-1, H-5), 3.75 (s, 3H, OC**H$_3$**), 3.85–3.95 (m, 5H, H-2, H-3, H-4, C**H$_2$** All), 4.42 (s, 2H, C**H$_2$**PhOCH$_3$-*p*), 4.57–4.72 (m, 6H, 3 **C**H$_A$H$_B$Ph, $J_{A,B}$ = –11.6 Hz, –11.9 Hz), 5.10–5.28 (m, 2H, **C**H$_2$=), 5.80–5.93 (m, 1H, -**C**H=), 6.82 (d, 2H, ½ AA′BB′ pattern, *p*MPh, *J* = 8.5 Hz), 7.18–7.25 (m, 17H, H-Ph); ^{13}C NMR δ: 55.1 (O**C**H$_3$), 69.6, 70.0 (C-1, C-5), 72.1, 72.2, 72.3, 73.7 (3 **C**H$_2$Ph, 1 **C**H$_2$ All), 72.8 (**C**H$_2$PhOCH$_3$-*p*), 78.4, 78.6 (C-2, C-3, C-4), 113.6 (2C *o*-**C**H *p*MBn), 116.6 (**C**H$_2$=), 134.8 (-**C**H=), 127.3–129.2, 130.4, 138.6, 159.0 (C-Ph). Exact Mass (FAB) calcd. for $C_{37}H_{42}O_6Na$ [M + Na]$^+$: 605.2879; found: 605.2936.

2,3,4-Tri-*O*-benzyl-5-*O*-*p*-methoxybenzyl-L-ribitol, 8

A solution of **7** (6.052 g, 10.4 mmol) in aqueous methanol (methanol:water 5:1, 55 mL) was stirred with Pd/C (10%, 0.60 g) at 60°C for 10 h. The reaction mixture was filtered through Celite and diluted with water (30 mL). The resulting mixture was extracted with dichloromethane (4 × 50 mL). The combined extracts were dried (Na_2SO_4), and concentrated to a liquid residue that was purified with dry flash column chromatography to yield **8** (3.88 g, 69% yield); $[\alpha]_D^{24}$ 11 (*c* 2.29, $CHCl_3$); ^{1}H NMR δ: 3.5–4.0 (m, 7H, H-1–H-5), 3.8 (s, 3H, OC**H$_3$**), 4.4 (s, 2H, C**H$_2$**PhOCH$_3$-*p*), 4.5–4.8 (m, 6H, 3 C**H$_2$**Ph), 6.82 (½ AA′BB′ pattern, 2H, *o*-C**H** *p*MBn, *J* = 8.5 Hz), 7.25 (m, 17H, H-Ph); ^{13}C NMR δ: 55.3 (O**C**H$_3$), 61.4 (C-1), 69.3 (C-5), 71.9, 72.4, 73.0, 74.0 (3 **C**H$_2$Ph, 1 **C**H$_2$PhOCH$_3$-*p*), 78.2, 78.9, 79.1 (3C, C-2, C-3, C-4), 113.8 (2C *o*-**C**H *p*MBn), 127.7–129.4, 130.3, 138.2, 138.3, 159.2 (C-Ph); ESI-MS (g/mol): 565 for $[C_{34}H_{38}O_6Na]^+$ [M + Na]$^+$ (100), isotopic peaks of [M + Na]$^+$: 566 (calcd. 38.6, measured 38.4), 567 (calcd. 8.5, measured 8.5), 568 (calcd. 1.3, measured 1.2); 581 for $[C_{34}H_{38}O_6K]^+$ [M + K]$^+$; calcd. mass 542.3 (M); ESI-MS (g/mol) (in the presence of trace amount of formic acid): 543 for $C_{34}H_{39}O_6$ [M + H]$^+$, 565 for $C_{34}H_{38}O_6Na$ [M + Na]$^+$, 581 for $C_{34}H_{38}O_6K$ [M + K]$^+$.

Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranoside, 9

A solution of methyl 2,3,4-tri-*O*-benzyl-6-*O*-trityl-β-D-glucopyranoside (40) (19.52 g, 27.6 mmol) in glacial acetic acid (35 mL) was treated with a solution of HBr in acetic acid (30% w/v, 7.5 mL, 1.0 equiv.) at 0°C. The resulting precipitate was removed by filtration and washed with glacial acetic acid. The combined filtrate and washings were poured onto a mixture of ice and solid sodium carbonate and the resulting mixture was extracted with dichloromethane (3 × 100 mL). The combined extracts were washed with saturated sodium hydrogen carbonate solutions (2 × 100 mL), and water (3 × 100 mL), then dried (Na_2SO_4) and concentrated to a solid that was purified by flash chromatography using hexane and ethyl acetate (2:1) as eluent. The resulting solid (9.61 g, 75% yield) was recrystallized from ether and hexane to give fine needles of **9**: mp 90–91°C; $[\alpha]_D^{20}$ +8.8 (*c* 0.34, $CHCl_3$) (lit. (40) mp 91–92°C; $[\alpha]_D^{20}$ +9.9).

(Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl (*N*,*N*-diisopropyl) phosphoramidite, 10

To a solution of **9** (3.25 g, 7.00 mmol) in dichloromethane (70 mL), stirred under argon at room temperature, were added diisopropylethylamine (DIPEA, 3.4 mL, 2.8 equiv.) and chloro 2-cyanoethyl (*N*,*N*-diisopropyl)phosphoramidite (34) (2.22 g, 1.3 equiv.). The reaction was complete in 30 min. The reaction solution was diluted with dichloromethane (30 mL), then washed with saturated sodium chloride containing 5% triethylamine (3 × 30 mL), and with tetraethylammonium bromide (TEAB, 2 M, 2 × 30 mL). The organic solution was dried ($MgSO_4$) and concentrated to a syrup that was purified with dry flash column chromatography using as eluant hexane:ethyl acetate 5:1 containing 4% triethylamine. Compound **10** was obtained as a colourless syrup (3.86 g, 83% yield); $[\alpha]_D^{20}$ 4.4 (*c* 3.03, $CHCl_3$); ^{1}H NMR δ: 1.14 (m, 12H, C**H$_3$** iPr), 2.48–2.60 (m, 2H, OCH$_2$C**H$_2$**CN), 3.36–4.05 (m, 13H, H-2–H-6, 2 C**H** iPr, OC**H$_2$**CH$_2$CN, OC**H$_3$**), 3.53 (s, OC**H$_3$**), 4.31 (d, 1H, H-1, $J_{1,2}$ = 7.6 Hz), 4.64–4.97 (m, 6H, 3 C**H$_2$**Ph), 7.15–7.37 (m, 15H, H-Ph); ^{13}C NMR δ: 19.9, 20.0 (OCH$_2$**C**H$_2$CN), 24.3, 24.4 (**C**H$_3$ *i*Pr), 42.7, 42.9, 43.1 (**C**H iPr), 56.5, 56.6 (O**C**H$_3$), 58.1, 58.4 (O**C**H$_2$CH$_2$CN), 62.2, 62.4, 62.7 (C-6), 74.3, 74.6, 75.3 (3 **C**H$_2$Ph, C-5), 77.5 (C-3), 82.1 (C-2), 84.26, 84.34 (C-4), 104.3 (C-1), 117.3, 117.5 (CN), 127.3–128.1, 137.9, 138.3 (C-Ph); ^{31}P NMR δ: 150.0, 149.4. Exact Mass (FAB) calcd. for $C_{37}H_{50}N_2O_7P$ [M + H]$^+$: 665.3356, $C_{37}H_{48}N_2O_7P$ [M – H]$^+$: 663.3199; found: 665.3323 [M + H]$^+$, 663.3210 [M – H]$^+$.

(*tert*-Butyldimethyl)silyl 2-azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranoside, 11

A solution of *tert*-butyldimethylsilyl 2-azido-4,6-*O*-benzylidene-2-deoxy-β-D-galactopyranoside (29) (3.14 g 7.71 mmol) in DMF (50 mL) was stirred with NaH (0.78 g, 60% suspension in mineral oil, washed with pentane 3 times before use) at 0°C for 0.5 h before methyl iodide (1.2 mL) was added. The reaction mixture was stirred at 0°C for 15 min, after which cold water (2 mL) was added. The resulting mixture was extracted with dichloromethane (3 × 30 mL). The combined extracts were dried (Na_2SO_4) and concentrated to a syrup that was purified by low-pressure flash column chromatography using as eluent hexane:ethyl acetate 4:1 to yield **11** as a syrup (3.14 g, 97% yield); $[\alpha]_D^{20}$ 8.5 (*c* 2.31, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 0.10, 0.12 (2 s, 6H, C**H$_3$**Si), 0.88 (s, 9H, SiC(C**H$_3$**)$_3$), 3.03 (dd, 1H, H-3, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 3.7 Hz), 3.25 (br d, 1H, H-4,), 3.41 (s, 3H, O**C**H$_3$), 3.62 (dd, 1H, H-2, $J_{1,2}$ = 7.8 Hz), 3.97 (dd, 1H, H-6a, $J_{6a,6b}$ = 12.2 Hz, $J_{6a,5}$ = 2.0 Hz), 4.13–4.20 (m, 2H, H-5, H-6b), 4.47 (d, 1H, H-1), 5.50 (s, 1H, C**H**Ph), 7.25–7.45 (m, 5H, H-Ph); ^{13}C NMR δ: –4.87, –4.14 (2 **C**H$_3$Si), 18.0 (Si**C**(CH$_3$)$_3$), 25.6 (SiC(**C**H$_3$)$_3$), 57.2 (O**C**H$_3$), 64.3 (C-2), 66.5 (C-4), 69.3 (C-6), 71.7 (C-5), 79.6 (C-3), 97.3 (C-1), 101.2 (**C**HPh), 126.4, 128.7, 129.0, 137.7 (C-Ph). Exact Mass (FAB) calcd. for $C_{20}H_{30}N_3O_5Si$ [M – H]$^+$: 420.1955; found: 420.196.

2-Azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-α-D-galactopyranosyl trichloroacetimidate, 12

A solution of **11** (1.53 g, 3.64 mmol) in dichloromethane (100 mL) was cooled to –25°C under argon and a solution of tetrabutylammonium fluoride (TBAF) in THF (1 M, 18.2 mL, 5 equiv.) was added dropwise. TLC analysis showed that all the starting material had been consumed in 10 min. The reaction mixture was poured into ice-water and the resulting mixture was extracted with dichloromethane (3 × 100 mL). The combined extracts were dried (Na_2SO_4) and concentrated to a residue, a mixture of anomers of 2-azido-

4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-D-galactopyranose. To a solution of the anomeric mixture in dichloromethane (50 mL) was added trichloroacetonitrile (4.5 mL, 45 mmol). The solution was cooled to 0°C and sodium hydride (0.19 g, 60% suspension, washed with pentane three times before use) was added. After 1 h the reaction mixture was filtered through Celite and concentrated to a foam that was purified with low-pressure flash column chromatography, using hexane:ethyl acetate 5:1 as eluent, to yield **12** as a foam (1.14 g, 69% yield); $[\alpha]_D^{24}$ 128 (*c* 0.84, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 3.56 (s, 3H, OC**H$_3$**), 3.87 (m, 2H, H-3, H-5), 4.08 (dd, 1H, H-6a, $J_{6a,6b}$ = -12.7 Hz, $J_{6a,5}$ = 1.5 Hz), 4.15 (dd, 1H, H-2, $J_{2,3}$ = 10.3 Hz), 4.32 (dd, 1H, H-6b, $J_{5,6b}$ = 1.5 Hz), 4.48 (br d, 1H, H-4, $J_{4,3}$ = 2.9 Hz), 5.59 (s, 1H, C**H**Ph), 6.51 (d, 1H, H-1, $J_{1,2}$ = 3.3 Hz), 7.34–7.53 (m, 5H, H-Ph), 8.52 (s, 1H, NH); ^{13}C NMR δ: 56.60 (O**C**H$_3$), 58.20 (C-2), 65.23(C-4), 69.04 (C-6), 71.78 (C-5), 76.26 (C-3), 95.64 (C-1), 101.1 (**C**HPh), 126.2, 128.2, 129.1, 137.4 (C-Ph), 160.59 (C=NH).

(Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 2,3,4-tri-*O*-benzyl-D-ribityl-5-phosphate, 14

To a stirred solution of **10** (0.412 g, 0.62 mmol) and **8** (0.343 g, 1.02 equiv.) in acetonitrile (10 mL) under argon was added tetrazole (77.5 mg, 1.8 equiv.). After 1 h, the reaction mixture was cooled to 0°C and a solution of *m*-chloroperbenzoic acid (MCPBA, 0.544 g, 2.6 equiv.) in dichloromethane was added dropwise. After 20 min, the reaction mixture was diluted with dichloromethane (20 mL) and the resulting solution was washed with TEAB (2 M, 1 × 20 mL) and water (1 × 30 mL). The dichloromethane solution was dried ($MgSO_4$) and concentrated to a residue that was purified by low-pressure flash column chromatography using hexane:ethyl acetate 1:1 as eluent. (Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 1-*p*-methoxybenzyl-2,3,4-tri-*O*-benzyl-D-ribityl-5-phosphate **(13)** was obtained as a colorless syrup (0.480 g, 69% yield); $[\alpha]_D^{20}$ 6.5 (*c* 3.72, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 2.41 (m, 2H, OCH_2CH_2CN), 3.30–4.12 (m, H-1–H-5, H-1′–H-6′, O**CH$_2$**CH_2CN, OC**H$_3$**), 3.49, 3.51, 3.75 (3s, OC**H$_3$**), 4.39 (d, 1H, H-1, $J_{1,2}$ = 8.3 Hz), 4.15–4.95 (m, 14H, C**H$_2$**Ph), 6.79–6.84, 7.16–7.35 (m, 34H, H-Ph); ^{13}C NMR δ: 19.00 (OCH_2**C**H_2CN), 55.14, 57.03 (2 × O**C**H$_3$), 61.64 (O**C**H_2CH_2CN), 66.57, 67.45, 67.76 (C-5, C-6′), 69.20, 69.30 (C-1), 72.38, 72.89 (**C**H_2Ph), 73.35 (C-5′), 73.60, 73.69, 74.62, 74.90, 75.48 (**C**H_2Ph), 78.03 (C-2, C-3, C-4), 77.00, 82.11, 84.26, 84.33 (C-2′, C-3′, C-4′), 104.6 (C-1′), 116.3 (CN), 113.6, 127.6-129.2, 130.2, 137.8–138.4, 159.1 (C-Ph); ^{31}P NMR δ: –0.73, –0.81.

To a solution of **13** (0.330 g, 0.294 mmol) in dichloromethane (9 mL) was added water (0.5 mL) and 2,3-dichloro-5,6-dicyanoquinone (DDQ, 0.082 g, 1.2 equiv.) and the mixture was stirred vigorously for 4 h. The organic layer was extracted with saturated sodium hydrogen carbonate (3 × 50 mL), then dried (Na_2SO_4) and concentrated to a residue that was purified with low-pressure flash column chromatography to yield **14** as a colourless syrup (0.185 g, 63% yield); $[\alpha]_D^{20}$ 5.3 (*c* 1.36, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 2.24, 2.29 (2 br t, 1H, 1-OH), 2.49 (m, 2H, OCH_2CH_2CN), 3.39 (m, 1H, H-2′), 3.45 (m, 1H, H-5′), 3.50, 3.52 (2s, 3H, OC**H$_3$**), 3.55 (br s, 1H, H-4′), 3.65 (m, 1H, H-3′), 3.86–3.95 (m, 1H, H-1), 3.99–4.05 (m, 2H, O**CH$_2$**CH_2CN), 4.18–4.50 (m, 3H, H-5, H-6′, H-1′, $J_{1',2'}$ = 7.9 Hz), 4.53–4.96 (m, 12H, C**H$_2$**Ph), 7.20–7.70 (m, 30H, H-Ph); ^{13}C NMR δ: 19.14 (OCH_2**C**H_2CN), 57.03 (O**C**H$_3$), 61.00, 61.05 (C-1), 61.62, 61.77 (O**C**H_2CH_2CN), 66.58, 67.23, 67.37 (C-5, C-6′), 72.00, 72.32, 72.43 (**C**H_2Ph), 73.30 (C-5′), 73.79, 73.90, 74.85, 74.91, 75.45 (**C**H_2Ph), 76.92 (C-4′), 77.73, 77.79, 78.03, 78.75, 78.85 (C-2, C-3, C-4), 82.06 (C-2′), 84.18, 84.25 (C-3′), 104.5 (C-1′), 116.3 (CN), 127.7–128.4, 137.6–138.3 (C-Ph); ^{31}P NMR δ: –0.72, –0.77; ESI-MS (g/mol) 1024 for $[C_{57}H_{64}O_{13}NPNa]^+$ $[M + Na]^+$ (100), isotopic peaks: 1025 (calcd. 65.2, measured 64.9), 1026 (calcd. 23.5, measured 23.5), 1027 (calcd. 5.7, measured 5.8); 1040 for $[C_{57}H_{64}O_{13}NPK]^+$ $[M + K]^+$; calcd. mass 1001.4 (M).

Following the same procedure, starting from **10** (1.389 g, 2.09 mmol) and **8** (1.133 g, 1.0 equiv.), **13** was obtained quantitatively and was treated with water and DDQ directly without further purification. Compound **14** was obtained in a 57% yield (1.190 g) based on **10**.

(Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 1-(2-azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-D-ribityl-5-phosphate, 15

A solution of **14** (0.845 g, 0.844 mmol) and **12** (0.568 g, 1.2 equiv.) in acetonitrile (30 mL) was stirred with 4 Å molecular sieves for 2 h, then cooled to -40°C and treated with TMS triflate (120 μL, 0.74 equiv.). After 30 min, pyridine (1 mL) was added and the reaction mixture was filtered through Celite. The filtrate was washed with water (3 × 80 mL), dried (Na_2SO_4), and concentrated to a syrup. The product was purified with low-pressure flash column chromatography using hexane:ethyl acetate 1:1.3 as eluent. The title compound **15** was obtained as a colourless syrup (0.892 g, 82% yield); $[\alpha]_D^{20}$ 8.2 (*c* 3.40, $CHCl_3$); ^{1}H NMR δ: 2.39 (t, 2H, OCH_2CH_2CN, *J* = 6.4 Hz), 3.13 (dd, 1H, H-3″, $J_{2'',3''}$ = 10.27 Hz, $J_{3'',4''}$ = 3.4 Hz), 3.18 (br s, 1H, H-5″), 3.38 (t, 1H, H-2, $J_{1,2}$ = 8.3, $J_{2,3}$ = 8.8 Hz), 3.45 (m, 1H, H-5), 3.48, 3.50 (2 s, 6H, 2 OC**H$_3$**), 3.51 (m, 1H, H-4), 3.63 (t, 1H, H-3, $J_{3,4}$ = 8.8 Hz), 3.77 (dd, 1H, H-2″, $J_{1'',2''}$ = 7.8 Hz), 3.87 (dd, 1H, H-1′$_A$, $J_{1'A,1'B}$ = 10.8 Hz, $J_{1'A,2'}$ = 3.7 Hz), 3.98 (m, H-2, H-3, H-4, H-6′, O**CH$_2$**CH_2CN), 4.16 (dd, 1H, H-1′b, $J_{1'b,2'}$ = 3.7 Hz), 4.21 (m, H-5′a, H-4″), 4.26 (d, H-1″), 4.29 (d, H-1), 4.30 (m, H-6a), 4.37 (m, H-5′b), 4.48 (m, H-6b), 4.55–4.95 (m, 6 C**H$_2$**Ph), 5.53 (s, 1H, C**H**Ph), 7.2–7.6 (m, 35H, H-Ph); ^{13}C NMR δ: 19.0 (OCH_2**C**H_2CN), 57.1 (2 × O**C**H$_3$), 61.6 (O**C**H_2CH_2CN), 62.2 (C-2″), 66.4 (C-5″), 66.6 (C-5′), 67.4 (C-6), 68.3 (C-1′), 69.0 (C-6″), 71.5 (C-4″), 72.2 (2 **C**H_2Ph), 73.3 (C-5), 73.6, 74.6, 74.9, 75.4 (4 **C**H_2Ph), 77.0 (C-4), 77.8 (3C, C-2′, C-3′, C-4′), 79.9 (C-3″), 82.1 (C-2), 84.3 (C-3), 101.1 (**C**HPh), 101.9 (C-1″), 104.5 (C-1), 116.3 (CN), 126.3–128.9, 137.5–138.4 (C-Ph); ^{31}P NMR δ: –0.73, –0.83. Exact Mass (ESI) calcd. for $C_{71}H_{79}N_4O_{17}PNa$ $[M + Na]^+$: 1313.5076; found: 1313.5092.

(Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 1-*O*-(2-acetamido-4,6-*O*-ben-zylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-D-ribityl-5-phosphate, 16

A solution of **15** (0.651 g, 0.505 mmol) in thiolacetic acid (4 mL) was stirred under argon at room temperature for 17 h and then was concentrated to a liquid residue. Low-pressure

For personal use only.

flash column chromatography using ethyl acetate as eluent yielded **16** as a foam (0.493 g, 75% yield); $[\alpha]_D^{20}$ +22.3 (*c* 0.35, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 1.80, 1.81 (2 s, 3H, C**H**$_3$CO), 2.32–2.36, 2.46-2.50 (m, 2H, $OCH_2C\mathbf{H}_2CN$), 3.41, 3.48, 3.51 (3 s, OC**H**$_3$), 5.527, 5.533, 5.539 (3s, C**H**Ph), 6.10, 6.38 (2 d, 1H, NH, $J_{NH,2''}$ = 6.8, 7.3 Hz), 7.20–7.48 (m, 35H, H-Ph); ^{13}C NMR δ: 18.99, 19.08, 19.15 ($OCH_2\mathbf{C}H_2CN$), 23.49 (**C**H_3CO), 54.31, 54.50, 54.62 (C-2″), 56.89, 57.06 (O**C**H_3), 61.78 (O**C**H_2CH_2CN), 66.39 (C-5″), 66.67 (C-5′), 67.60 (C-6), 68.41 (C-1′), 69.35 (C-6″), 71.89 (**C**H_2Ph), 72.36 (C-4″), 72.68 (**C**H_2Ph), 73.36 (C-5), 73.47, 74.93, 75.09, 75.49 (4 **C**H_2Ph), 77.0 (C-4), 77.61, 77.95, 78.20, 78.51, 78.66 (C-2′, C-3′, C-4′, C-3″), 82.13 (C-2), 84.27, 84.35 (C-3), 99.61, 99.89 (C-1″), 101.0 (**C**HPh), 104.6 (C-1), 116.5 (CN), 126.2–128.9, 137.8–138.4 (C-Ph), 170.9, 171.0 (CH_3**C**O); ^{31}P NMR δ: 0.17, –0.68, –0.73, –0.96. Exact Mass (ESI) calcd. for $C_{73}H_{83}N_2O_{18}PNa$ $[M + Na]^+$: 1329.5276; found: 1329.5275.

Triethylammonium (methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 1-*O*-(2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-D-ribityl-5-phosphate, 17

A solution of **16** (0.312 g, 0.239 mmol) in a mixture of triethylamine, pyridine, and water (3:1:1, 20 mL) was stirred at room temperature for 2 h. The reaction solution was concentrated to a foam of **17** (0.323 g, 99.6% yield); $[\alpha]_D^{25}$ –8.2 (*c* 0.48, CH_3OH); ^{1}H NMR (400 MHz, CD_3OD) δ: 1.22 (t, 3H, C**H**$_3CH_2$), 1.84 (s, 3H, C**H**$_3$CO), 2.95 (q, 2H, $CH_3C\mathbf{H}_2$), 3.15–3.55 (m, 12H, H-5″, H-2, H-3, H-3″, H-4, H-5, 2 OC**H**$_3$), 3.34, 3.38 (2 s, 2 × OC**H**$_3$), 3.88–4.36 (m, 14H, H-1′–H-5′, H-6″, H-6, H-2″, H-4″, H-1), 4.23 (d, H-1, $J_{1,2}$ = 7.3 Hz)), 4.05(br dd, H-2″, $J_{1'',2''}$ = 8.8 Hz, $J_{2'',3''}$ = 10.3 Hz), 4.53 (d, 1H, H-1″), 4.54–4.83 (m, 6 C**H**$_2$Ph), 5.54 (s, 1H, C**H**Ph), 7.10–7.48 (m, 35H, H-Ph); ^{13}C NMR (CD_3OD) δ: 9.31 (**C**H_3CH_2), 23.56 (**C**H_3CO), 47.72 ($CH_3\mathbf{C}H_2$), 52.77 (C-2″), 57.20, 57.52 (2 × O**C**H_3), 65.70, 66.32 (C-5′, C-6), 67.95 (C-5″), 69.81 (C-1′), 70.45 (C-6″), 72.91 (C-4″), 73.53, 74.86, 75.58 (4 **C**H_2Ph), 75.77 (C-5), 75.95, 76.48 (2 **C**H_2Ph), 79.22 (C-4), 80.10, 80.28, 80.60 (C-2′, C-3′, C-4′, C-3″), 83.47 (C-2), 85.73 (C-3), 102.2 (**C**HPh), 102.8 (C-1″), 105.9 (C-1), 127.2–129.9, 139.8–140.2 (C-Ph), 173.6 (**C** = O); ^{31}P NMR (CD_3OD) δ: 1.41. Exact Mass (ESI) calcd. for $C_{70}H_{79}NO_{18}PNa_2$ $[M - NHEt_3 + 2Na]^+$: 1298.4830; found: 1298.4814.

Sodium (methyl β-D-glucopyranosid-6-yl) 1-*O*-(2-acetamido-2-deoxy-3-*O*-methyl-β-D-galacto-pyranosyl)-D-ribityl-5-phosphate, 18

A solution of **17** (0.323 g, 0.238 mmol) in a mixture of ethyl acetate, methanol, and acetic acid (10:14.5:0.5, 25 mL) was stirred with Pd/C (10%, 0.38 g) under hydrogen (1 atm (= 101.3 kPa)) for 70 h. The reaction mixture was filtered through Celite and the filtrate was concentrated. A solution of the residue in water (3 mL) was stirred with Amberlite IR-120 (Na^+) resin overnight. The filtrate was concentrated to give **18** quantitatively; $[\alpha]_D^{20}$ –9.9 (*c* 0.68, H_2O); ^{1}H NMR (500 MHz, D_2O) δ: 2.04 (s, 3H, C**H**$_3$CO), 3.28 (m, 1H, H-2, $J_{2,3}$ = 9.4 Hz), 3.40 (s, 3H, 3″-O**C**H_3), 3.44 (dd, 1H, H-3″, $J_{2'',3''}$ = 10.9 Hz), 3.50 (m, 2H, H-3,4), 3.57 (s, 3H, 1-OC**H**$_3$), 3.58 (m, 1H, H-5), 3.66 (br dd, 1H, H-5″, $J_{5'',6a''}$ = 4.4 Hz, $J_{5'',6b''}$ = 8.1 Hz), 3.77 (dd, 1H, H-3′, $J_{2',3'}$ = 7.0 Hz, $J_{3',4'}$ = 4.8 Hz), 3.77 (dd, 1H, H-6″a, $J_{6a'',6b''}$ = 11.4 Hz), 3.83 (dd, 1H, H-2′, $J_{1',2'}$ = 6.4 Hz), 3.84 (dt, H-6″b), 3.89 (m, 1H, H-4′), 3.93 (dd, 1H, H-2″), 3.95 (d, 2H, H-1′), 3.99 (t, 1H, H-5′a, $J_{5'a,4'}$ = 6.1 Hz), 4.06 (m, 1H, H-5′b, $J_{5'b,5'a}$ = 10.4 Hz, $J_{5'b,4'}$ = 5.4 Hz), 4.07 (m, 1H, H-6a), 4.17 (dddd, 1H, H-6b, $J_{6b,6a}$ = 11.6 Hz, $J_{6b,5}$ = 5.2 Hz, $J_{6b,P}$ = 2.1 Hz), 4.22 (d, 1H, H-4″, $J_{4'',3''}$ = 3.3 Hz), 4.39 (d, 1H, H-1, $J_{1,2}$ = 8.0 Hz), 4.49 (d, 1H, H-1″, $J_{1'',2''}$ = 8.6 Hz); ^{13}C NMR (D_2O) δ: 23.94 (**C**H_3CO), 51.99 (C-2″), 57.18 (3″-O**C**H_3), 58.10 (1-O**C**H_3), 61.88 (C-6″), 64.35 (C-4″), 64.97 (d, C-6, $J_{6,P}$ = 4.8 Hz), 67.41 (d, C-5′, $J_{5',P}$ = 4.8 Hz), 69.87 (C-4), 71.34 (C-2′), 71.41 (C-1′), 71.48 (d, C-4′, $J_{4',P}$ = 7.6 Hz), 72.19, (C-3′), 73.86 (C-2), 75.38 (d, C-5, $J_{5,P}$ = 7.6 Hz), 75.78 (C-5″), 76.36 (C-3), 80.70 (C-3″), 102.67 (C-1″), 104.12 (C-1), 175.65 (**C** = O); ^{31}P NMR (D_2O) δ 1.73. 1-*O*-(2-Azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 5-*O*-*p*-methoxybenzyl-2,3,4-tri-*O*-benzyl-L-ribitol, 19, and 1-*O*-(2-azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-L-ribitol, 20

A solution of **12** (0.460 g, 1.02 mmol) and **8** (0.554 g, 1.02 mmol) in acetonitrile (20 mL) was stirred with 4 Å molecular sieves (1 g) for 1 h at room temperature. Then the solution was cooled to –50°C and trimethylsilyl trifluoromethanesulfonate (TMS triflate, 130 μL, 0.66 equiv.) was added. The reaction solution was stirred at –50°C for 40 min after which pyridine (1 mL) was added and the reaction mixture was filtered through Celite. The filtrate was washed with water (3 × 80 mL), dried (Na_2SO_4), and concentrated to a brownish syrup that was purified with low-pressure flash column chromatography using hexane:ethyl acetate 2:1 as eluent. Compound **19** was obtained as a syrup (0.145 g, 17% yield); $[\alpha]_D^{20}$ 2.2 (*c* 0.68, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 3.11 (dd, 1H, H-3′, $J_{2',3'}$ = 10.3 Hz, $J_{3',4'}$ = 3.4 Hz), 3.20 (br s, 1H, H-5′), 3.49 (s, 3H, OC**H**$_3$), 3.61–4.06 (m, 11H, H-2, H-3, H-4, H-6′a, H-1a, H-5, H-2′, OC**H**$_3$), 3.75 (s, OC**H**$_3$), 4.18–4.34 (m, 4H, H-4′, H-6′b, H-1b, H-1′, $J_{1',2'}$ = 8.3 Hz), 4.42 (t, 2H, C**H**$_2$PhOMe-*p*), 4.55–4.84 (m, 6H, 3 C**H**$_2$Ph), 5.53 (s, 1H, C**H**Ph), 6.82 (d, 2H, AA′BB′ pattern, H*o*-*p*MPh, *J* = 8.8 Hz), 7.15–7.55 (m, 22H, H-Ph); ^{13}C NMR δ: 55.12, 57.14 (2 × O**C**H_3), 62.16 (C-2′), 66.34 (C-5′), 69.07, 69.44, 70.31 (C-1, C-6′, C-5), 71.63 (C-4′), 72.34, 72.56, 72.84, 73.53 (4 **C**H_2Ph), 78.22, 78.91, 79.03 (C-2, C-3, C-4), 80.07 (C-3′), 101.1 (**C**HPh), 102.3 (C-1′), 113.7, 127.2-129.7, 130.4, 137.6–138.7, 159.1 (C-Ph).

Another product (**20**) was obtained as a syrup (0.118 g, 16% yield); $[\alpha]_D^{24}$ –3.5 (*c* 0.31, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 2.29 (br t, 5-OH), 3.14 (dd, 1H, H-3′, $J_{2',3'}$ = 10.3 Hz, $J_{3',4'}$ = 3.4 Hz), 3.26 (br s, 1H, H-5′), 3.50 (s, 3H, OC**H**$_3$), 3.65–4.07 (m, 8H, H-2, H-3, H-4, H-6′a, H-1a, H-5, H-2′), 4.18–4.34 (m, 4H, H-4′, H-6′b, H-1b, H-1′), 4.53–4.86 (m, 6H, 3 C**H**$_2$Ph), 5.58 (s, 1H, C**H**Ph), 7.15–7.55 (m, 20H, H-Ph); ^{13}C NMR δ: 57.19 (O**C**H_3), 61.25 (C-5), 62.16 (C-2′), 66.44 (C-5′), 69.45, 69.74 (C-1, C-6′), 71.63 (C-4′), 72.07, 72.70, 73.81 (3 **C**H_2Ph), 78.78, 79.09 (3C C-2, C-3,

C-4), 80.07 (C-3′), 101.2 (**C**HPh), 102.2 (C-1′), 126.3–128.3, 137.6–138.4 (C-Ph); ESI-MS (g/mol): 706 for $[M + Na - N_2]^+$, 734 for $[M + Na]^+$, 750 for $[M + K]^+$; calculated mass: 711.3 (M).

A solution of **19** (0.107 g, 0.128 mmol) in dichloromethane (5 mL) was stirred with water (0.4 mL) and 2,3-dichloro-5,6-dicyano-quinone (DDQ, 0.0327 g, 1.1 equiv.) vigorously for 4 h. The reaction mixture was extracted with saturated sodium hydrogen carbonate (3 × 20 mL), then dried (Na_2SO_4) and concentrated to a syrup that was purified with low-pressure column chromatography using ethyl acetate and hexane (1:1.2) as eluent to yield **20** as a colourless syrup (0.059 g, 63% yield). The ^{1}H and ^{13}C NMR spectra of this product were identical in all respects to that of **20** above.

(Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 1-*O*-(2-azido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-L-ribityl-5-phosphate, 21

To a solution of **10** (0.105 g, 1.1 equiv.) and **20** (0.102 g, 0.144 mmol) in acetonitrile (20 mL) was added tetrazole (23.2 mg, 2.3 equiv.). The reaction solution was stirred under argon for 40 min. The reaction mixture was cooled to 0°C and a solution of *m*-chloroperbenzoic acid (MCPBA, 0.142 g, 2.6 equiv.) in dichloromethane (5 mL) was added dropwise. The reaction was complete in 20 min. The reaction mixture was diluted with dichloromethane (30 mL) and the organic layer was washed with TEAB (2 M, 1 × 30 mL) and water (1 × 30 mL), then dried ($MgSO_4$) and concentrated. The residue was purified with low-pressure flash column chromatography using hexane:ethyl acetate 1:2 as eluent. The title compound **21** was obtained as colourless foam (0.155 g, 84% yield); $[\alpha]_D^{25}$ 6.6 (*c* 0.33, $CHCl_3$); ^{1}H NMR (400 MHz) δ: 2.42–2.46 (m, 2H, $OCH_2C\mathbf{H_2}CN$), 3.14 (m, H-3″), 3.35 (br d, 1H, H-5″), 3.37 (m, 1H, H-2), 3.49 (m, 1H, H-4), 3.50 (s, $OC\mathbf{H_3}$), 3.63 (m, 1H, H-3), 3.75–3.86 (m, 2H, H-1′a, H-2″), 3.88–4.15 (m, H-2′, H-3′, H-4′, H-6″a, $OC\mathbf{H_2}CH_2CN$), 4.16–4.53 (m, H-1′b, H-6″b, H-5′, H-4″, H-1″, H-1, H-6), 4.54–4.96 (m, 6 $C\mathbf{H_2}$Ph), 5.54 (s, 1H, C**H**Ph), 7.2–7.6 (m, 35H, H-Ph); ^{13}C NMR δ: 19.24 ($OCH_2\mathbf{C}H_2CN$), 57.11, 57.24 (2 × $O\mathbf{C}H_3$), 61.96 ($O\mathbf{C}H_2CH_2CN$), 62.15 (C-2″), 66.45 (C-5″), 66.83 (C-5′), 67.39, 67.69 (C-6), 69.08 (C-6″), 69.59 (C-1′), 71.63 (C-4″), 72.46, 72.65 (2 $\mathbf{C}H_2$Ph), 73.30 (C-5), 73.56, 74.61, 74.94, 75.49 (4 $\mathbf{C}H_2$Ph), 77.0 (C-4), 77.62, 78.18, 78.45 (C-2′, C-3′, C-4′), 80.06 (C-3"), 82.06 (C-2), 84.26 (C-3), 101.1 (**C**HPh), 102.2 (C-1″), 104.5 (C-1), 116.2, 116.4 (CN), 126.2–134.4, 137.4–138.3 (C-Ph); ^{31}P NMR δ: –0.77, –1.28. Exact Mass (ESI) calcd. for $C_{71}H_{79}N_4O_{17}PNa$ $[M + Na]^+$: 1313.5076; found: 1313.5102.

Triethylammonium (methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 1-*O*-(2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-L-ribityl-5-phosphate, 23

A solution of **21** (0.139 g, 0.108 mmol) in thiolacetic acid (2 mL) was stirred under argon at room temperature for 17 h. Then the reaction mixture was concentrated and was purified by low-pressure flash column chromatography using ethyl acetate as eluent. (Methyl 2,3,4-tri-*O*-benzyl-β-D-glucopyranosid-6-yl) 2-cyanoethyl 1-*O*-(2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-methyl-β-D-galactopyranosyl) 2,3,4-tri-*O*-benzyl-L-ribityl-5-phosphate (**22**) was obtained as a colourless foam (0.066 g, 47% yield); ^{1}H NMR (400 MHz) δ: 1.80, 1.84 (2 s, $C\mathbf{H_3}CO$), 2.34–2.46 (m, $OCH_2C\mathbf{H_2}CN$), 3.30–4.5 (m, H-1–H-6, H-1′–H-5′, H-1″–H-6″, $OC\mathbf{H_3}$, $OC\mathbf{H_2}CH_2CN$), 3.41 (s, $OC\mathbf{H_3}$), 4.52–4.96 (m, 6 $C\mathbf{H_2}$Ph), 5.54, 5.55 (2 s, C**H**Ph), 5.9, 6.2, 6.5 (2 br, NH), 7.2–7.6 (m, 35H, H-Ph); ^{13}C NMR δ: 19.13 ($OCH_2\mathbf{C}H_2CN$), 23.54 ($\mathbf{C}H_3CO$), 54.36 (C-2″), 56.88, 57.16 (2 × $O\mathbf{C}H_3$), 61.91 ($O\mathbf{C}H_2CH_2CN$), 66.46 (C-5″), 66.70, 67.30, 67.84 (C-5′, C-6), 68.63, 68.99, 69.40 (C-6″, C-1′), 72.23 (C-4″), 72.49 ($\mathbf{C}H_2$Ph), 73.32, 73.39 (C-5), 73.53, 74.59, 74.94, 75.50 (4 $\mathbf{C}H_2$Ph), 76.16, 77.00, 77.62, 78.15, 78.33, 78.49 (C-4, C-2′, C-3′, C-4′, C-3″), 82.10 (C-2), 84.28 (C-3), 99.52, 99.60 (C-1″), 100.9 (**C**HPh), 104.6 (C-1), 116.5 (CN), 126.2–128.8, 137.8–138.4 (C-Ph), 171.2 (**C**=O); ^{31}P NMR δ: –0.03, –0.58, –1.49, –1.50.

A solution of **22** (0.066 g, 0.051 mmol) in a mixture of triethylamine, pyridine, and water (3:1:1, 5 mL) was stirred at room temperature for 2 h. The solution was concentrated to a foam of **23** (0.068 g, 99.6% yield); $[\alpha]_D^{20}$ –7.9 (*c* 0.30, CH_3OH); ^{1}H NMR (400 MHz, CD_3OD) δ: 1.18 (t, 3H, $C\mathbf{H_3}CH_2$), 1.75 (s, 3H, $C\mathbf{H_3}CO$), 2.97 (q, 2H, $CH_3C\mathbf{H_2}$), 3.22 (dd, 1H, H-2, $J_{1,2}$ = 7.8 Hz, $J_{2,3}$ = 9.29 Hz), 3.35–3.45 (m, H-4,5,5″), 3.39, 3.43 (2 s, 2 × $OC\mathbf{H_3}$), 3.51 (m, H-3″,3), 3.75 (dd, 1H, H-1′, $J_{1'A,1'B}$ = –10.8 Hz, $J_{1'A,2'}$ = 6.4 Hz), 3.92 (m, H-3′,4′), 4.02 (m, H-2′,6), 4.25 (d, 1H, H-1), 4.40 (br d, 1H, H-4″, $J_{3'',4''}$ = 3.4 Hz), 4.52 (d, 1H, H-1″, $J_{1'',2''}$ = 8.8 Hz), 4.57–4.83 (m, 6 $C\mathbf{H_2}$Ph), 5.60 (s, 1H, C**H**Ph), 7.1–7.5 (m, 35H, H-Ph); ^{13}C NMR (CD_3OD) δ: 9.40 ($\mathbf{C}H_3CH_2$), 23.34 ($\mathbf{C}H_3CO$), 47.67 ($CH_3\mathbf{C}H_2$), 52.83(C-2″), 57.16, 57.57 (2 × $O\mathbf{C}H_3$), 65.85 (C-6), 66.39 (C-5′), 68.04 (C-5″), 70.54 (C-6″), 71.37 (C-1′), 72.93 (C-4″), 73.56, 73.77, 75.00, 75.50 (4 $\mathbf{C}H_2$Ph), 75.73 (C-5), 75.96, 76.41 (2 $\mathbf{C}H_2$Ph), 79.27 (C-4), 80.23 (3C C-3″, 2′, 3′, or 4′), 80.55 (C-3′ or 4′), 83.39 (C-2), 85.71 (C-3), 102.2 (**C**HPh), 103.1 (C-1″), 105.9 (C-1), 127.7–130.0, 138.5–140.5 (C-Ph), 173.5 (**C**=O); ^{31}P NMR (CD_3OD) δ: 1.22. Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support, and Dr. M.D. Lumdson and Dr. I. Burton for recording some of the NMR spectra. We also thank the National Research Council in Ottawa, the University of Ottawa, and the University of Alberta for recording high-resolution MS spectra. Special thanks go to Dr. O. Hindsgaul for arranging for the MS to be run at the University of Alberta.

Abstract: The IR and Raman spectra of two singly layered silicates, silinaite and makatite, have been investigated. The vibrational spectra were assigned based on previous studies of various silicates. The correlation between vibrational modes and the structural properties of silicates under investigation has been made. The IR and Raman spectra of silinaite are in good agreement with the known structure. However, the observed vibrational data of makatite are not completely consistent with those predicted by a factor group analysis based on the published single-crystal data.

Key words: layered silicates, silinaite, makatite, vibrational spectroscopy.

Résumé : On a déterminé les spectres IR et Raman de deux silicates en monocouches, silinaite et makatite. Les spectres vibrationnels ont été attribués en se basant sur des études antérieures sur divers silicates. On a établi une corrélation entre les modes de vibration et les propriétés structurales des silicates. Les spectres IR et Raman de la silinaite sont en bon accord avec la structure connue. Toutefois, les données vibrationnelles observées avec la makatite ne sont pas en accord complet avec ceux prédits par une analyse de groupe factoriel basée sur les donnes relatives à un cristal unique.

Mots clés : silicates en couches, silinaite, makarite, spectroscopie vibrationnelle.

[Traduit par la Rédaction]

Introduction

Makatite, kanemite, magadiite, ilerite, and kenyaite are structurally related hydrous alkali silicates (1) and silinaite, a new addition to this family of layered materials, has recently been identified (2). With the exception of ilerite, all of the above-mentioned silicates are naturally occurring minerals, but they can be readily prepared in the laboratory by hydrothermal synthesis. These hydrated layered alkali metal silicates exhibit some interesting properties, such as interlamellar sorption of water and organic molecules and ion exchange of the surface cations. These properties suggest potential practical applications as ion exchangers, adsorbents, catalysts, and molecular sieves. Recently, these layered silicates have received much attention due to their ability to transform to layered silicic acids by proton exchange. Layered silicic acids are very useful hosts in the formation of pillared materials because of the presence of reactive silanol groups in their interlayer surfaces.

The structures of these silicates have been of continuous interest in past decades because the physical and chemical properties of these materials are largely structure dependent; however, single-crystal X-ray diffraction data are only available for makatite (3) and silinaite (4). The exact structures of magadiite, ilerite, kanemite, and kenyaite are unknown. Most of the structural information has been obtained by using techniques such as solid state NMR and powder X-ray diffraction. While the X-ray diffraction method detects long-range ordering and periodicity, vibrational spectroscopy, on the other hand, can provide complementary information on short-range ordering and local structures. As part of our ongoing project of investigating structure and bonding in the above-mentioned layered silicates, we have examined the vibrational spectra of silinaite and makatite with particular attention being paid to the correlation of the vibrational properties of these materials with their structural features. The IR spectra of silinaite and makatite have previously been reported (5), but no band frequencies or detailed assignments were given. To date, no Raman study has been performed on these silicates.

Experimental

Silinaite and makatite were synthesized according to refs. 5 and 6, respectively. The purity and crystallinity were

checked by powder X-ray diffraction measurements (Philips PW 1830 powder diffractometer). The IR spectra (both 2 and 4 cm^{-1} resolution) were recorded on a Perkin–Elmer Paragon-1000 FT-IR spectrometer equipped with a DTGS detector. Samples were prepared using the standard KBr method. The Raman spectra were obtained on a Bruker RFS-100 FT-Raman spectrometer equipped with a Nd^{3+}:YAG laser (1064.1 nm) and a liquid nitrogen cooled Ge detector. The spectral resolution was 2 cm^{-1}, and 1000 scans were accumulated for the spectra. The precision for the band positions was ±1 cm^{-1}. All the measurements were performed at room temperature.

Results and discussion

1. Silinaite

The single-crystal X-ray study shows that silinaite is monoclinic with space group $A2/n$ (C_{2h}^6). There are four formula units ($NaLiSi_2O_5 \cdot 2H_2O$) per unit cell, $Z = 4$ (2, 4). The silicate consists of single layers of $[SiO_4]^{4-}$ tetrahedra. All Si sites are crystallographically equivalent and there are three different oxygen sites in the silicate layer. Each silicon atom forms three Si-O-Si bonds and only one $Si\text{-}O^{-}\text{-}M^{+}$ (M = Li or Na) bond, known as a Q^3 site. The silicate layers in silinaite are held together by $[LiO_4]$ tetrahedra in which the four terminal oxygen ions belong to four different $[SiO_4]^{4-}$ tetrahedra. The sodium ions between layers are octahedrally coordinated by interacting with four water molecules and two terminal oxygen ions that cross-link the $[LiO_4]$ tetrahedra. Each water molecule is also bonded to the silicate layer through hydrogen bonding (4).

The vibrational spectra of silinaite are shown in Fig. 1 and the corresponding IR and Raman frequencies are given in Table 1. The vibrational spectra can be divided into two regions. The first region covers the frequency range 4000–1600 cm^{-1} where stretching and bending vibrations of water molecules appear. The second region (below 1300 cm^{-1}) includes the vibrations due to the silicate layer and charge-balancing cations. Since the vibrations in these two regions are not normally coupled to one another, we shall discuss them separately.

Vibrations of silicate layer and associated cations

As mentioned earlier, the crystal structure of silinaite at ambient temperature is monoclinic with space group $A2/n$ (C_{2h}^6). One Bravais unit cell contains two formula units ($NaLiSi_2O_5 \cdot 2H_2O$). Within each Bravais unit cell, four Si atoms occupy the general positions. There are three types of crystallographically inequivalent oxygen atoms: O(1) and O(2) atoms are located at two different C_1 sites, while two O(3) atoms occupy C_i sites. Two Na and two Li ions lie on the positions with C_2 symmetry. Based on the above information, the vibrations due to the silicate layer and associated cations can be predicted by performing a factor group analysis.[4] Fifty-four vibrational bands due to the silicate layer and charge-balancing cations are expected in the IR and Raman spectra. Among them, 30 bands should be IR active while the Raman spectra should exhibit 24 bands:

$$\Gamma_{vib} = 11A_g(R) + 13B_g(R) + 14A_u(IR) + 16B_u(IR)$$

[4] Appendix 1 presents data for the factor group analysis of silinaite, while Appendix 2 gives the data for the factor group analysis of makatite. Appendices 1 and 2 are available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

where R and IR in parentheses denote Raman and IR activity, respectively. Experimentally, 13 IR bands were observed in the regions of 1300–300 cm^{-1} (Fig. 1 and Table 1). The number of observed bands is less than half of the number predicted by factor group analysis. This is due to several reasons: firstly, we were unable to obtain IR spectra below 300 cm^{-1}. In the far-IR range some silicon–oxygen bending and metal–oxygen stretching vibrations may occur (7). Secondly, accidental degeneracy and very weak intensities of certain modes may also be responsible for the observation of fewer bands. Furthermore, since IR bands are generally quite broad, it is likely that some bands are superimposed to give a broad spectral profile. The observed Raman spectrum contains 24 bands in the region of 1300–100 cm^{-1}. Some of these observed bands may be combinations or overtones.

According to the X-ray structure, the unit cell of silinaite is centrosymmetric. Therefore, the mutual exclusion rule should apply, i.e., no vibration can be active in both IR and Raman spectra. From Table 1, it is evident that all the observed IR bands indeed appear at different frequencies from those in the Raman spectrum. Therefore, the vibrational data are consistent with the X-ray result, and the unit cell of silinaite is indeed centrosymmetric.

The tentative assignments of vibrational bands in the spectra of silinaite are given in Table 1. According to previous studies (7), the various vibrations due to the silicate layer and associated cations follow the frequency order: ν_{as}SiOSi > νSiO⁻ > ν_sSiOSi > δSiO and νMO, where ν_{as}SiOSi and ν_sSiOSi refer to the asymmetric and symmetric stretching modes of Si-O-Si bridges; νSiO⁻ represents the stretch-

ing modes of terminal Si—O^- bonds; δSiO refers to the Si-O-Si and O-Si-O bending modes; and νMO represents the M–O stretching modes. There has been extensive discussion in the literature regarding the assignment of the bands of the IR and Raman spectra of various silicates (7–16). Silinaite bears some structural resemblance to sodium disilicate $Na_2Si_2O_5$ (4). Based on previous empirical assignments of the vibrational bands of α-$Na_2Si_2O_5$ and other silicates (7–16), the IR and Raman bands of silinaite can be tentatively assigned: the bands between 1300 and 950 cm^{-1} are due to the asymmetric stretching vibrations of Si-O-Si (ν_{as}SiOSi) and stretching vibrations of Si—O^- (νSiO); the bands between 780 and 600 cm^{-1} are associated with the symmetric stretching vibrations of Si-O-Si (ν_sSiOSi); the bands below 550 cm^{-1} are due to silicon–oxygen bending vibrations and the stretching vibrations arising from M—O bonds.

By studying the IR spectrum of pyrosilicates containing the Si_2O_7 group where ∠SiOSi = 180°, Lazarev has suggested that the appearance of IR bands in the frequency range between 1150 and 1200 cm^{-1} is associated with the existence of Si-O-Si bridges with an angle of 180° (or nearly so). This assumption has been extended to include other silicates with more complicated structures than pyrosilicates and has been confirmed by X-ray diffraction (7). Figure 1 shows that silinaite does exhibit two narrow intense IR bands centered at 1189 and 1159 cm^{-1}, respectively. The observation of these two bands is indicative of the existence of Si-O-Si bonds with an angle near 180°. This vibrational result is in good agreement with that obtained from the single-crystal X-ray study, which shows that the bond angle for the Si-O(3)-Si linkage is indeed 180°.

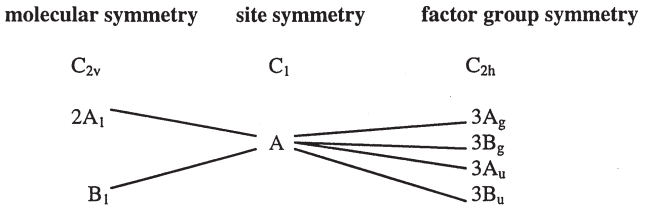
According to previous studies (7), the bands in the mid-frequency region may be assigned to the symmetric stretching vibrations, ν_sSiOSi. They are associated with the presence of bridging oxygens (Si-O-Si linkages) in the structure. For silinaite, we tentatively assign the bands between 780 and 600 cm^{-1} to ν_sSiOSi. A number of studies have shown that the band frequencies in this region are sensitive to the Si-O-Si bond angles (7, 12, 13). Lazarev (7) has pointed out that the ν_{as}SiOSi and ν_sSiOSi frequencies depend on the Si-O-Si bond angle and suggested an empirical relationship between the Si-O-Si angle and a quantity Δ, where $\Delta = (\nu_{as} - \nu_s)/(\nu_{as} + \nu_s)$. A large Si-O-Si angle corresponds to a large value of Δ. This means that an increase in the Si-O-Si angle will result in an increase in the ν_{as}SiOSi frequency and a decrease in the ν_sSiOSi frequency. It is reasonable to assume that for the linear Si-O-Si linkages the ν_sSiOSi should have a lower frequency than those of Si-O-Si units with angles less than 180°. Based upon this assumption, we assign the Raman band of silinaite at 609 cm^{-1}, which has the lowest frequency in the symmetric stretching region, to the ν_sSiOSi of linear Si-O-Si bonds.

Silinaite also contains two other inequivalent nonlinear Si-O-Si linkages. Their asymmetric vibrations (ν_{as}SiOSi) are assigned to the bands in the region 1100–950 cm^{-1}, where the Si–O^- stretching vibrations (νSiO^-) also appear. The IR spectrum of silinaite in the ν_sSiOSi frequency range has a strong band at 757 cm^{-1} and two weaker bands at lower frequency (676 and 630 cm^{-1}). They may be assigned to the symmetric stretching vibrations (ν_sSiOSi) arising from nonlinear Si-O-Si bridges.

In the Raman spectrum of silinaite, there is a very strong band located at 1068 cm^{-1}. We tentatively assign this band to the Si–O^- stretching vibration. This assignment is based on previous studies of crystalline silicates and silicate glasses containing $[SiO_4]^{4-}$ tetrahedra with one, two, three, and four nonbridging oxygens, respectively (9–13). These studies have shown that the dominant Raman bands at 1100–1050 cm^{-1}, 1000–950 cm^{-1}, near 900 cm^{-1}, and near 850 cm^{-1} are associated with the stretching vibrations (νSiO^-), due to Q^3, Q^2, Q^1 and Q^0 species, respectively. In the Raman spectrum of silinaite, only one strong band was observed at 1068 cm^{-1}, indicating that silinaite contains only Q^3 species, which is consistent with the result from single-crystal X-ray diffraction (4) and NMR studies (5) that silinaite has a single-layer structure.

Internal vibrations of water molecules

The internal vibrational modes of water molecules located between layers are worth mentioning. In addition to the molecular symmetry, the number of internal modes of water molecules in silinaite is also determined by the site (C_1) and unit cell (C_{2h}) symmetry. The scheme of correlation between the representations of the molecular, site, and factor group symmetries can be expressed as follows:



Since there are 4 water molecules per Bravais unit cell of silinaite (4), 12 crystal internal vibrations are expected:

$$\Gamma_{\text{Internal vib}} = 3A_g(R) + 3B_g(R) + 3A_u(IR) + 3B_u(IR)$$

The assignment of the fundamental vibrations of the free water molecule in the gas phase is well established. The band at 3651 cm^{-1} has been assigned to the symmetric stretching ν_1 (A_1), 1595 cm^{-1} to the bending ν_2 (A_1), and 3756 cm^{-1} to the asymmetric stretching ν_3 (B_1) (17). All three fundamentals are both Raman and IR active. From the above correlation diagram, we can see that each vibrational mode of free water molecule should split into four modes due to the correlation coupling. Among the four modes, two (A_g and B_g) are Raman active and the other two (A_u and B_u) are IR active. This factor group splitting can be clearly seen from the IR and Raman spectra of silinaite (Fig. 1). In the region of OH stretching vibrations (νOH), the IR spectrum shows four bands at 3558, 3490, 3396, and 3264 cm^{-1}, respectively. Because the frequencies of asymmetric stretching are normally higher than those of symmetric stretching, the above four bands may be assigned as follows: The bands at 3558 and 3490 cm^{-1} are due to the splitting of ν_3 (B_1 related species) and the bands at 3396 and 3265 cm^{-1} to the splitting of ν_1 (A_1 related species). In the Raman spectrum, three of the four predicted peaks were observed at 3472, 3389, and 3259 cm^{-1}. These peaks are also related to the ν_1 and ν_3 modes of free water molecules. The two bending bands, δHOH, in the IR spectrum at 1667 and 1639 cm^{-1} are corre-

lated with the splitting of the ν_2 fundamental mode for the free molecule. It is worth noting that the vibrational frequencies of IR and Raman bands of water molecules in silinaite are not coincident. This is again consistent with the fact that the unit cell of silinaite has a center of symmetry. The observed stretching frequencies in the IR and Raman spectra are lower than both ν_1 and ν_3 in free water molecules, due to the effect of hydrogen bonding between water and the silicate layer. These well-developed stretching and bending bands are sharp and intense, indicating that these vibrations are indeed due to the water molecules between layers that are part of the crystal.

In addition to the internal vibrations, factor group analysis predicts that water molecules in the crystal should also exhibit 24 external modes, including 12 rotational ($3A_g$(R) + $3B_g$(R) + $3A_u$(IR) + $3B_u$(IR)) and 12 translational ($3A_g$(R) + $3B_g$(R) + $3A_u$(IR) + $3B_u$(IR)) modes. However, we were unable to identify these lattice vibrations, since a majority of them would appear in the low-frequency region that is not accessible due to instrumental limitations.

In summary, the vibrational spectra of silinaite are consistent with the known structure obtained from the single-crystal X-ray study. IR and Raman frequencies of both the silicate layer and water molecules in silinaite are not coincident, suggesting that the unit cell is centrosymmetric. Observation of IR bands in the range 1150–1200 cm^{-1} indicates the existence of linear Si-O-Si linkages in silinaite. The strong band positioned at 1068 cm^{-1} in the Raman spectrum implies that silinaite contains Q^3 species.

Since all the above results are in good agreement with those obtained from single-crystal X-ray diffraction, we feel that the vibrational approach can now be used to probe those silicates with unknown or poorly defined structures.

2. Makatite

Makatite is also a single-layered silicate. Its composition is reported as $Na_2Si_4O_9 \cdot 5H_2O$ (18) and $Na_2Si_4O_8(OH)_2 \cdot 4H_2O$ (3). The early work by Sheppard et al. (18) suggested an orthorhombic symmetry for mineral makatite based on its powder X-ray diffraction data. A monoclinic structure with space group $P2_1/c$ (C_{2h}^5) was later proposed by Annehed et al. using the single-crystal X-ray diffraction technique (3). It seems that there is an ambiguity existing in the structure of makatite. Therefore, an IR and Raman spectroscopic study is particularly informative, since vibrational data may be used to verify the proposed structure.

According to the single-crystal data (3), makatite crystallizes in a space group of $P2_1/c$ with four units of $Na_2Si_4O_8(OH)_2 \cdot 4H_2O$ per primitive cell. Sixteen Si atoms occupy four crystallographically nonequivalent C_1 sites; Forty oxygen atoms are located at ten sets of different general positions. Four Na^+ ions lie on two different types of inversion centers and the remaining sodium ions are located in general positions. Eight hydrogen atoms in hydroxyl groups occupy C_1 sites. The contributing symmetry species of the silicon layer and charge-balancing cations at the center of the Brillouin zone are the following: $51A_g$(R) + $51B_g$(R) + $57A_u$(IR) + $57B_u$(IR). Sixteen water molecules located at eight nonequivalent C_1 sites can be treated separately. The irreducible representations including both internal and external modes are $36A_g$(R) + $36B_g$(R) + $36A_u$(IR) + $36B_u$(IR). The most important result of the factor group analysis is that the IR and Raman modes should not be coincident, since the proposed unit cell is centrosymmetric. The vibrational spectra of makatite are shown in Fig. 2 and the corresponding IR and Raman frequencies are given in Table 2. The experimentally observed frequency regions for IR and Raman spectra

are 4000–300 cm^{-1} and 3600–100 cm^{-1}, respectively. In their common region, 3600–300 cm^{-1}, 26 IR and 17 Raman bands were observed. Among them, 9 bands appear in both the IR and the Raman spectra. This means that about 35% of the IR and 54% of the Raman bands observed in the region 3600–300 cm^{-1} are coincident. The fact that many peaks have the same frequencies in both the IR and Raman spectra indicates that the unit cell of makatite may be noncentrosymmetric. If we consider the orthorhombic structure proposed by Sheppard et al. and assume the space group is noncentrosymmetric, the possible space groups may belong to *222* and *mm2* classes with factor group symmetries of D_2 and C_{2v}, respectively.

The tentative assignments for the spectra of makatite are given in Table 2. Similar to silinaite, the IR and Raman bands of makatite can be tentatively assigned as follows. The bands between 1300 and 900 cm^{-1} are assigned to the asymmetric stretching vibrations of Si-O-Si linkages and the stretching vibrations of the terminal Si—O^- bonds. The bands between 840 and 560 cm^{-1} are associated with the symmetric stretching vibrations of Si-O-Si bridges. The bands below 550 cm^{-1} are due to Si–O bending vibrations and the stretching vibrations arising from Na—O bonds.

Unlike silinaite, makatite does not have IR bands around 1150–1200 cm^{-1}. The absence of IR bands in this region suggests that makatite does not have Si-O-Si bonds with angles close to 180°.

In the Raman spectrum of makatite, two strong bands at 567 and 1025 cm^{-1} are worth mentioning. These bands can be assigned by comparison with some crystalline silicates and silicate glasses. The strongest band in the Raman spectrum is located at 567 cm^{-1}. Generally, it is believed that strong Raman bands in the 700–400 cm^{-1} region are associated with the presence of bridging oxygens in the structure

© 1999 NRC Canada

(9). They are assigned to symmetric stretching vibrations of Si-O-Si linkages (ν_sSiOSi). McMillan (9, 11) has suggested that the bands in the range 520–600 cm^{-1} are related to ν_sSiOSi due to Q^3 species. Makatite exhibits one strong Raman band at 567 cm^{-1}, indicating that Q^3 species exist in the structure. Similar to the Raman band of silinaite at 1068 cm^{-1}, we can assign the strong Raman band at 1025 cm^{-1} as νSiO^- of Q^3 species, since makatite has a single-layer structure.

The bands below 550 cm^{-1} in the IR and Raman spectra of makatite are related to the bending vibrations of silicon–oxygen and stretching vibrations of sodium–oxygen. It is not easy to make a detailed assignment in this region, since those motions are likely mixed.

The bands in the 3700–3000 cm^{-1} region represent stretching vibrations of OH groups. The IR spectrum of makatite shows two OH stretching bands: a sharp band at higher frequency (3563 cm^{-1}) and a broad one centered at lower frequency (3424 cm^{-1}). The broad low-frequency band is related to the OH groups (both hydroxyl groups in Q^3 units and those in water) involved in interlayer hydrogen bonding. The narrow band at higher frequency can be assigned to the isolated surface OH groups, suggesting that not all the hydroxyl groups in Q^3 units are involved in hydrogen bonding.

In summary, unlike silinaite, the observed vibrational data of makatite are not consistent with those predicted by a factor group analysis based on the published single-crystal data. In particular, many peaks have the same frequencies in both the IR and Raman spectra, indicating that the unit cell of makatite may be noncentrosymmetric. Analysis of the vibrational data suggests that the possible space groups of makatite may be those of the *222* and *mm2* classes in the orthorhombic crystal system. Unlike silinaite, makatite does not have strong IR bands at very high frequency (around 1150–1200 cm^{-1}), indicating that there are no Si-O-Si bonds with angles near 180° existing in makatite. The strong bands positioned at 567 and 1025 cm^{-1} in the Raman spectrum imply that makatite contains Q^3 species.

Abstract: The electrochemical oxidation of gallium in a cell containing a solution of 3,5-di-*tert*-butylcatechol (H_2dbc) in a mixture of liquid ammonia and diethyl ether gives rise to the complex Ga(dbqdi)$_2$, where dbqdi is a tridentate ligand formed by the condensation of two molecules of H_2dbc and ammonia. The same paramagnetic molecule can be prepared by treating $GaCl_3$ with H_2dbc in ethanol with concentrated aqueous ammonia, with subsequent aerial oxidation. The crystal parameters are triclinic, space group $P\bar{1}$, a = 11.6140(8), b = 12.3415(9), c = 20.765(1) Å, α = 89.491(1)°, β = 74.287(1)°, γ = 75.748(1)°, Z = 2, and R = 0.0542 for 7578 unique reflections. The structure, which is based on a GaO_4N_2 kernel, is discussed on the basis of crystallographic and ESR results.

Key words: gallium, electrochemical synthesis, electron spin resonance, X-ray crystallography.

Résumé : L'oxydation électrochimique du gallium dans une cellule contenant une solution de 3,5-di-*tert*-butylcatéchol (H_2dbc), dans un mélange d'ammoniac liquide et de méthoxyméthane, conduit à un complexe de Ga(dbqdi)$_2$ dans lequel dbqdi est un ligand tridentate formé par condensation de deux molécules de H_2dbc et d'ammoniac. On peut préparer la même molécule paramagnétique en traitant du $GaCl_3$ avec H_2dbc en solution dans l'éthanol avec de l'ammoniac concentré et en le soumettent ensuite à une oxydation par de l'air. Les cristaux sont tricliniques, groupe d'espace $P\bar{1}$, a = 11,6140(8) Å, b = 12,3415(9) Å et c = 20,765(1) Å, α = 89,49(1)°, β = 74,287(1)° et γ = 75,748(1)°, Z = 2 et R = 0,0542 pour 7578 réflexions uniques. Utilisant les données cristallographiques et les résultats de la RPE, on discute de la structure, qui est basée sur un noyau GaO_4N_2.

[Traduit par la Rédaction]

Introduction

As part of a continuing programme of work on electron transfer processes in compounds of Main Group elements, we recently prepared and characterized complexes of tin and lead with a tridentate ligand obtained by condensing two molecules of 3,5-di-*tert*-butylcatechol (dbc) with ammonia (1). This condensation product is formally the 3,5-di-*tert*-butyl-1,2-quinone-1-(2-hydroxy-3,5-di-*tert*-butylphenyl) imine anion, but in fact may exist in forms that vary in charge between +1 and –3, and that may have 0, 1,or 2 unpaired electrons.

We have labeled (Scheme 1) these dbqdi-I, -II, etc. in order to identify the possible complexes which may exist; certain of these isomers (e.g,. II, IV) can have other canonical forms resulting from rearrangement of the site of the unpaired electrons within the ring. The reaction of either $SnCl_2$ or PbF_2 with the appropriate H_2dbc–ammonia mixture gave structurally similar products with $M(O_2N)_2$ kernels, but the electron spin resonance (ESR) spectra showed the tin complex to be Sn^{IV} [dbqdi-V][dbqdi-VI], whereas lead yielded the diamagnetic Pb^{II} [dbqdi-III]$_2$. These results are in general agreement with those of earlier work with M^{2+} ions (see ref. 1).

We now report the preparation and characterization of an interesting complex of gallium with this ligand system. The compound can be obtained either by a simple chemical reaction, or by the method of direct electrochemical synthesis; this latter route is analogous to that used in the synthesis of indium(III) complexes by oxidizing the metal in liquid ammonia solutions of H_2dbc (2).

Experimental

Gallium metal (99.99% purity, Aldrich), and 3,5-di-*tert*-butylcatechol (99% purity, Aldrich) were used as supplied. Organic solvents were dried and distilled before use. For the electrochemical work, ammonia, supplied as the anhydrous gas, was condensed to the liquid in ca. 30 cm^3 quantities by passing it through a flask immersed in a solid CO_2–acetone bath.

Infrared spectroscopy involved the use of samples as KBr discs, with a Nicolet 5DX instrument. Electron spin resonance (ESR) spectra were run on a Bruker ESP-300 instru-

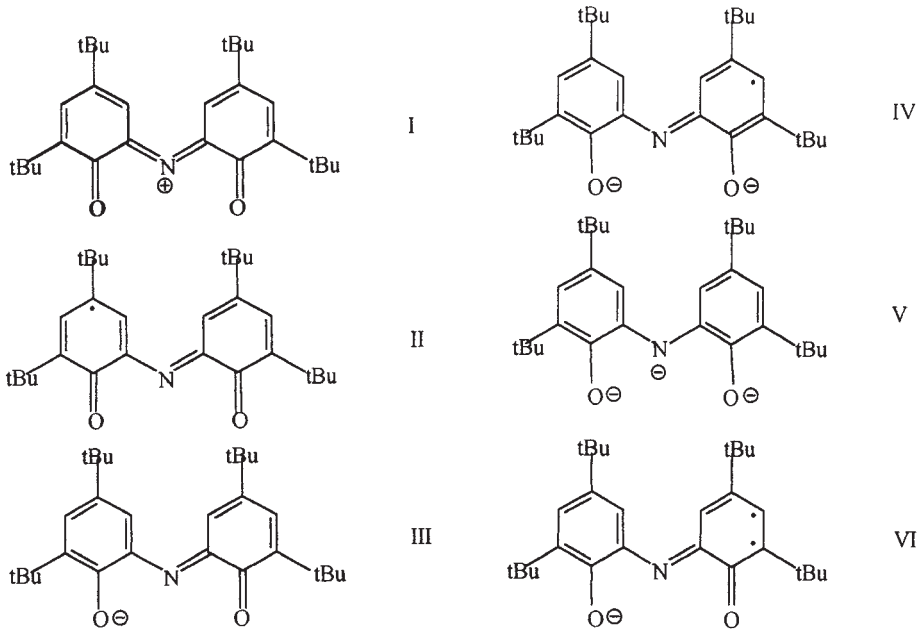
Scheme 1.



ment, using methods described previously (3). Microanalysis was performed by Canadian Microanalytical Services. Magnetic measurements were made on a VMS DMS 6000 instrument at the Universidade de Santiago de Compostela.

Electrochemical synthesis

The electrochemical cell was a round-bottomed flask (50 cm^3) with a Schlenk arm, and the anode was a gallium rod preformed onto a platinum wire, which passed through a rubber septum, while a second platinum wire formed the cathode. A solution of H_2dbc (0.5 g) in dry diethyl ether (30 cm^3) was placed in the flask, and ammonia condensed as described above. A Coutant LQ 50/50 power supply provided a current of 10–20 mA, which required an applied potential of 20–40 V. Typical current densities at the anode were in the order of 10 mA cm^{-2}. The total quantity of electricity passed through the cell during experiments, which lasted 2–4 h, was measured by means of a silver coulometer. The results of the measurement of electrochemical efficiency, derived from the measured weight loss at the anode, are discussed below. A stream of gas (dry nitrogen or air) was bubbled gently through the solution during the electrolysis.

As soon as current flowed through the cell, bubbles of gas were evolved at both anode and cathode. At the end of the experiment, the reaction mixture was evaporated to dryness, giving a mixture of crystals. Recrystallization from CH_2Cl_2 gave a dark green solid, identified as Ga(dbqdi)$_2$. (Anal. calcd. for $C_{56}H_{84}N_2O_4Ga$: C 73.2, H 9.20, N 3.05; found: C 72.2, H 9.10, N 3.23.) Yield 85%, based on quantity of gallium lost from the anode.

Chemical synthesis

Gallium metal (1.0 g, 14.3 mmol) was dissolved in 6 M aqueous hydrochloric acid (50 cm^3), and the resultant solution evaporated gently to dryness. The colourless product (hydrated $GaCl_3$) was suspended in 95% ethanol (50 cm^3), and H_2dbc (1.27 g, 5.72 mmol) in the same solvent was added, followed by concentrated aqueous ammonia (10 cm^3). A stream of air was bubbled through the stirred solution, which quickly became dark green; after 6 h, a dark green solid was collected by filtration, and further crystals were obtained by evaporating the filtrate. This product was identical to that from the electrochemical procedure (Anal. found: C 73.3, H 9.12, N 3.14). Yield 91%, based on the initial quantity of gallium.

Crystallographic analysis

Crystals of Ga(dbsqi)$_2$ prepared by the electrochemical route were recrystallized from dichloromethane. A single crystal, dimensions 0.30 × 0.30 × 0.20 mm, was attached to a quartz fiber and transferred to a Siemens SMART 3-circle diffractometer equipped with graphite monochromated Mo-Kα radiation and a CCD area detector and controlled by a Pentium-based PC running the SMART software package (4). Omega scans were used in such a way that an initial 180° scan range consisting of 0.3° intervals was followed by three further 120°, 180°, and 120° scans, with offsets of 88°, 180°, and 268°, respectively. This strategy samples the sphere of reciprocal space up to 2θ = 56.62°. Cell parameters were refined using the centroid values of 300 reflections with 2θ angles up to 56.62°. Raw frame data were integrated using the SAINT programme (5). The structure was solved by direct methods (6). An empirical absorption correction was applied to the data using the programme SADABS (7). The structure is disordered, but this was successfully modelled in terms of two equivalent *t*-C_4H_9 groups (C26–28 and C26″–28″) at C25.

Table 1 summarizes the crystal data and details of the structure refinement, Table 2 gives the atomic coordinates, and Table 3 reports the bond lengths and angles. Figure 1 shows the structure of the molecule. Tables of hydrogen atom coordinates and thermal parameters, thermal parameters

for other atoms, and least-squares planes are available as supplementary data.[3]

Results and discussion

Preparative

The complex $Ga(dbqdi)_2$ can be prepared either by direct electrochemical synthesis starting from the metal, or by the reaction of gallium(III) with an aerated mixture of H_2dbc and ammonia in aqueous ethanol. Both procedures involve strongly basic media in which H_2dbc can be assumed to dissociate, or to react directly with gallium, or to condense with ammonia to give one or more of the polydentate ligands identified in Scheme 1.

The possible reactions which can occur in a solution containing H_2dbc and ammonia have been shown to include the formation of free radical intermediates, identified by ESR spectroscopy (1). In the case of lead(II), it was suggested that the final complexation step involves the ligand (dbqdi-III) in the reaction

[1] $Pb^{II} + 2(dbdqi\text{-}III] \rightarrow Pb(dbdqi\text{-}III)_2$

to give a diamagnetic lead(II) species. With the more strongly reducing tin(II), this is followed by intramolecular electron transfer reactions

[2] $Sn^{II}(dbqdi\text{-}III)_2 \rightarrow Sn^{IV}(dbqdi\text{-}IV)_2 \rightarrow Sn^{IV}(dbqdi\text{-}IV)(dbqdi\text{-}VI)$

to produce a diradical complex. Following these arguments, we suggest that the reaction of gallium(III) chloride under identical conditions follows a similar sequence.

[3] Tables of hydrogen atom coordinates and thermal parameters and of anisotropic displacement parameters are available as supplementary material, and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada. The table of hydrogen atom coordinates has also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from: The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[3] $Ga^{3+} + Cl^- + 2(dbqdi\text{-}III)^- \rightarrow Ga(dbqdi\text{-}III)_2Cl$

[4] $Ga(dbqdi\text{-}III)_2Cl \rightarrow Ga(dbqdi\text{-}III)(dbqdi\text{-}IV) + Cl^-$

These processes lead to the formulation of the final product as a gallium(III) complex with one unpaired electron, in keeping with the structural and spectroscopic evidence discussed below.

The electrochemical procedures were similar to those described earlier (2), but with some significant detailed differences. An important parameter in such work is the electrochemical efficiency, E_F, defined as the quantity of metal dissolved from the anode per faraday of electricity flowing through the cell. When air or oxygen was bubbled through the solution phase during electrolysis, E_F was unusually low and variable from one experiment to another (~0.03–0.2 mol F^{-1}). For syntheses under nitrogen, the value of E_F was 0.31 ± 0.02 mol F^{-1}, although here again anomalous results (~0.05 mol F^{-1}) were recorded in a few experiments. In simpler solution systems, E_F can be interpreted in terms of the attack of a ligand L^{n-} on the sacrificial anode,

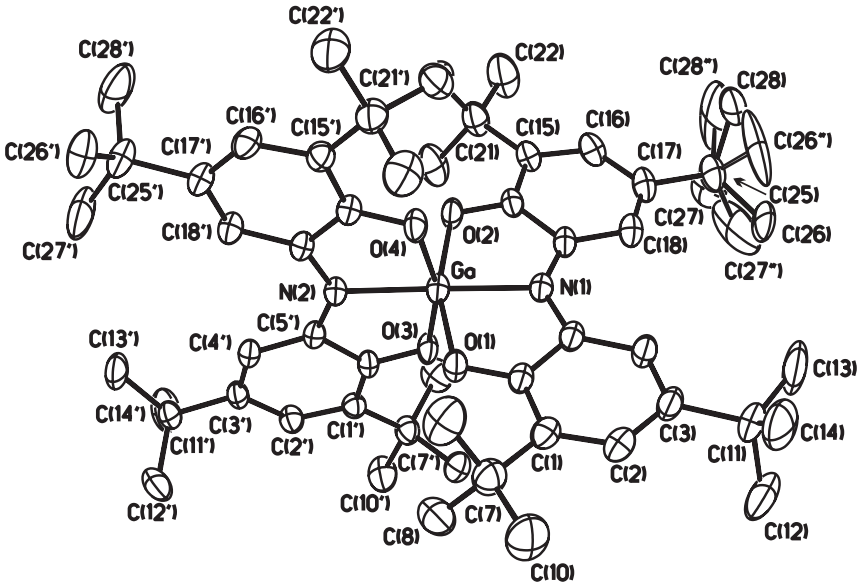
Table 4. Possible ligand combinations for gallium(I), (II), and (III) in $Ga(dbqdi)_2$.

Oxidation state	L_2	Number of unpaired electrons	Average C—O bond order	Average C—N bond order
1	II +III	1	1.75	1.5
	II + VI	3	1.75	1.5
	I + IV	1	1.5	1.75
2	I + V	0	1.5	1.5
	II + IV	2	1.5	1.5
	III + III	0	1.5	1.5
	III + VI	2	1.5	1.5
	VI + VI	4	1.5	1.5
3	III + IV	1	1.25	1.5
	II + V	1	1.5	1.25
	IV + VI	3	1.25	1.5

Fig. 1. Structure of $Ga(dbqdi)_2$, with atoms shown as 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity.



but this approach is not viable in the present case (cf. ref. 2), and the only reasonable conclusion is that the electrolysis gives rise to a gallium(III) species in the absence of oxygen.

In the earlier case of indium involving electrochemical oxidation in the presence of substituted catechols (H_2dbc; $X_4C_6(OH)_2$, X = Cl, Br), the products isolated from oxygen-free experiments were the ammonium salts of either $[In(O_2C_6X_4)_3]^{3-}$ or $[In_2(dbc)_4(NH_3)_2]^{2-}$ (2). These colourless diamagnetic complexes are air-sensitive, giving dark green paramagnetic products which were not identified, but which are presumably related to the gallium(III) complex isolated in the present work.

The structure of $Ga(dbqdi)_2$ in the solid state

To elucidate the structure of $Ga(dbqdi)_2$ in the solid state, it is necessary to consider crystallographic, magnetic, and spectroscopic results. The possible oxidation states of gallium are 1, 2, or 3, and Table 4 sets out the various combinations of dbqdi structures (Scheme 1) which can give rise to a neutral complex with each of these states. The experimental value of the magnetic moment of 1.70 B.M. establishes the presence of one unpaired electron in the molecule, and this eliminates structures based on gallium(II), and leaves two possibilities for both gallium(I) and (III).

The Ga—O bond distances to the two ligands are significantly different, with average values of 1.954(1) and 1.966(1) Å. The reason for these differences is not clear at this point, but the results are similar to those for the gallium(III) complexes $Ga(acac)_3$ (acac = 3,5-pentanedionate anion), for which *r*(Ga—O) = 1.952 Å(avg) (8), and $Ga(dbsq)_3$ (dbsq = 3,5-di-*tert*-butyl-1,2-semiquinonate) (9), where *r*(Ga—O) = 1.96(1) Å. We therefore identify **1** as a gallium(III) complex, which together with the magnetic moment implies that the ligand combinations can be either II + V or III + IV. In principle, it should be possible to distinguish between these on the basis of *r*(C—O) and *r*(C—N), and the distribution of *r*(C—C) values in the C_6 rings. The average C—O bond distance is 1.290(4) Å, with a narrow range 1.287(4)–1.294(4) Å, and this corresponds to the bond order of 1.5 found in *o*-semiquinonate complexes (10), and therefore favours the ligand combination II + V. The average *r*(C—N) is 1.350(5) Å, indicating a bond order close to that in nitrogen heterocycles, although similar distances are known (11) for

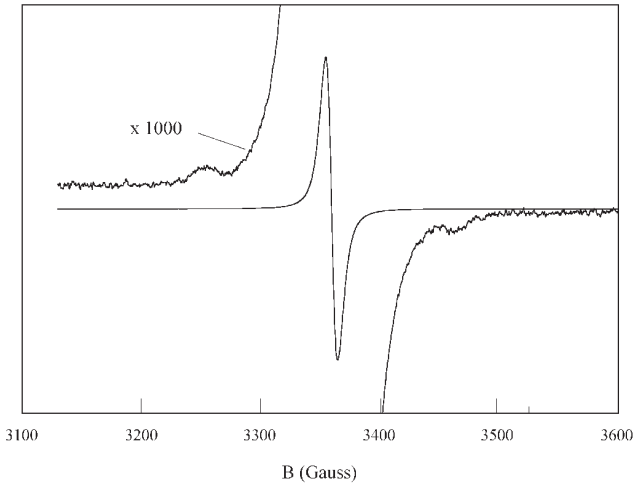
Fig. 2. EPR spectrum of crystalline $Ga(dbqdi)_2$ at 303 K.



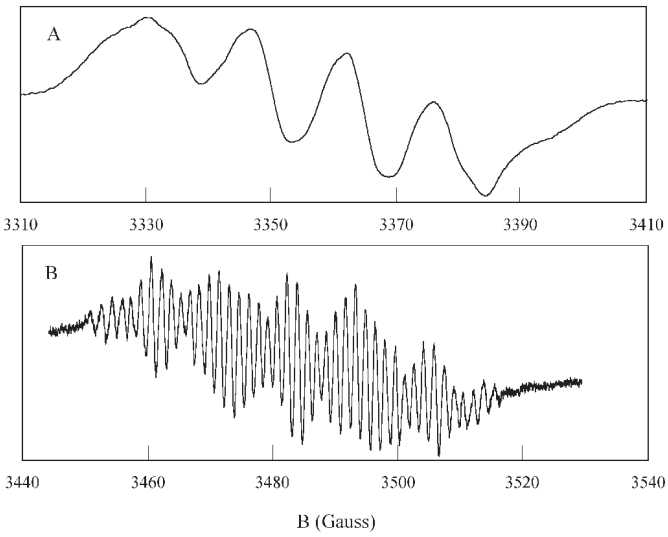
N—C=O in amides, and for H_2CN_2, so that this does not allow an unambiguous choice between the options, especially since the effects of Ga—N bonding, and of ring structure, are unknown. Equally, although a detailed analysis of the C—C bond distances predicted by III + IV or II + V reveals differences between the two, these are not sufficient to distinguish between the two possibilities. Given these uncertainties, we can only conclude that the overall evidence slightly favours the structure Ga^{III}[(dbqdi-III)(dbqdi-IV)] in the solid state, with one unpaired electron in the structure. As noted above, the preparative route in this and previous work is compatible with this formulation.

The ESR spectrum of crystalline $Ga(dbqdi)_2$ at 303 K, shown in Fig. 2, is apparently that of a monoradical species with a *g* value of 2.004 and a line width of 10 G. Figure 2 also suggests the presence of a biradical, $S = 1$, at sufficiently high gain, with two weak side resonances separated by 195 G. The presence of a biradical is confirmed by the observation of the forbidden half-field transition characteristic of $S = 1$ systems. Simulation of the spectrum in Fig. 2 indicates that the concentration of the $S = 1$ species is between 0.5% and 1% of that of the monoradical species. We have evaluated the *D* value in the spin Hamiltonian

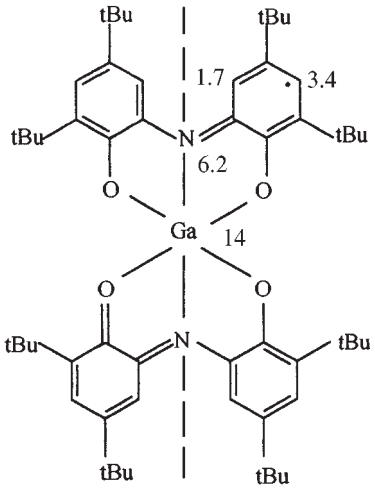
$$[5] \qquad H = gS \cdot B + D\left[S_z^2 - \frac{1}{3}S(S+1)\right] + E[S_x^2 - S_y^2]$$

from both the splitting observed in Fig. 2, and from the displacement of the half-field transition from the true half field for temperatures from 103 to 363 K. The splitting in the main spectrum yields values of $D = 195 \pm 10$ G, while the half-field transition yields values of $(D^2 + 3E^2)^{1/2} = 180 \pm 20$ G. We have also measured the intensity of the half-field transition relative to the central transition over this same temperature range, and find that it remains constant, ruling out the possibility that the $S = 1$ species is a low-energy excited triplet state. It must therefore be due to an impurity. It cannot be a solid state phenomenon, because we were also able to detect a half-field transition in a concentrated frozen solution of $Ga(dbqdi)_2$ in toluene, and the intensity ratio to the central transition was the same as that observed in the spectrum of the crystalline material.

Fig. 3. EPR spectrum of a dilute solution of $Ga(dbqdi)_2$ in toluene. *A*, 103 K; *B*, 293 K.



Scheme 2.



The monomer spectrum and the half-field spectrum in the solid state were quite narrow and showed no gallium hyperfine splitting. This has been shown to be due to exchange narrowing, because dilute and concentrated frozen solutions of $Ga(dbqdi)_2$ in toluene do show a hyperfine splitting for ^{69}Ga, ^{71}Ga of 14 G in the monomer spectrum (Fig. 3*A*). The half-field transition observed in concentrated solutions does not show a resolved hyperfine spectrum, but its increased line width, compared to the spectrum observed in the solid state, is best explained by an unresolved splitting of 14 G. The spectrum for a dilute toluene solution of $Ga(dbqdi)_2$ is given in Fig. 3*B*. Although it was not possible to get a perfect simulation, a reasonable fit was obtained with hyperfine constants for Ga splitting of 13.9 G, ^{14}N splitting of 6.2 G, and splittings of 3.4 G for two equivalent ^1H nuclei and of 1.7 G for a second pair of ^1H. This is compatible with the presence of the ligand in the form dbqdi-IV, a conclusion which agrees with the preparative and crystallographic results. The assignment of the hyperfine constants is shown in Scheme 2. The existence of pairs of H-atoms is

explicable in terms of a degeneracy equivalent to a twofold symmetry plane, indicated by the broken line.

Abstract: The voltammetric electroreduction properties of 1,2,5-thiadiazole 1,1-dioxide derivatives with different 3,4 substituents have been investigated in aprotic (mainly acetonitrile) solvent solution. The 3,4 substituents, selected according to the characteristics of their π-system, were phenanthro-9,10 (connected π-system) and acenaphtho-1,2 (fused π-system). New measurements are also presented for 3,4-diphenyl (separated π-systems). The basic properties of the substrates were investigated through voltammetry in acidic acetonitrile solutions. The substrates were more easily electroreduced (between –0.6 and –1.0 V vs. Ag/Ag^+, acetonitrile solvent) than the parent (non-1,1-dioxide) heterocycles (which are electroreduced at ca. –2.5 V). They were also more easily electroreduced (by ca. 0.4 V) than the corresponding diketones (benzil, 9,10-phenanthrenequinone, and acenaphthenequinone). The influence on voltammetric behavior of the electron-withdrawing properties of the 1,2,5-thiadiazole 1,1-dioxide ring and that of the structure of the molecules was analyzed in light of previous structural studies by X-ray crystallography and theoretical chemistry calculations. Bulk electrolysis experiments in acidic acetonitrile solutions of the phenanthro[9,10-*c*] derivative produced its previously unreported dihydrogenated derivative (thiadiazoline), which oxidizes easily. Infrared spectroscopy data suggested that the structure of this compound differs from that of 3,4-diphenyl-1,2,5-thiadiazoline 1,1-dioxide.

Key words: organic electrochemistry, 1,2,5- thiadiazoles, structure–reactivity relations.

Résumé : Opérant dans une solution dans un solvant aprotique (principalement l'acétonitrile), on a étudié les propriétés d'électroréduction voltampérométriques de dérivés du 1,1-dioxyde de 1,2,5-thiadiazole portant divers substituants dans les positions 3 et 4. Les substituants en 3,4, phénanthro-9,10 (lié à un système π) et acénaphto-1,2 (système π condensé) ont été choisis en fonction des caractéristiques de leur système π. On rapporte aussi les résultats de nouvelles mesures avec le 3,4-diphényle (systèmes π séparés). On a étudié les propriétés de base des substrats par le biais de la voltampérométrie de solutions acides dans l'acétonitrile. Les substrats sont électroréduits plus facilement (entre –0,6 et –1,0 V vs. Ag/Ag^+, acétonitrile comme solvant) que les hétérocycles parents (sans 1,1-dioxyde) qui sont électroréduits à environ –2,5 V. Ils sont aussi électroréduits plus facilement (par environ 0,4 V) que les dicétones correspondantes (benzil, 9,10-phénanthrènequinone et acénaphtènequinone). En se basant sur les résultats d'études cristallographiques et de calculs antérieurs, on a analysé l'influence des propriétés électroattractives du noyau 1,1-dioxyde de 1,2,5-thiadiazole et celle de la structure des molécules sur le comportement voltampérométrique. Des expériences d'électrolyse globale du dérivé phénanthro[9,10-*c*], en solutions acides dans l'acétonitrile, ont conduit à la formation du dérivé dihydrogéné (thiadiazoline) qui n'avait pas été rapporté antérieurement et qui s'oxyde facilement. Les données de spectroscopie infrarouge suggèrent que la structure de ce composé diffère de celle du 1,1-dioxyde de 3,4-diphényl-1,2,5-thiadiazoline.

Mots clés : électrochimie organique, 1,2,5-thiadiazoles, relations structure–réactivité.

[Traduit par la Rédaction]

Introduction

Thiadiazole derivatives have an actual or potential value as fine chemical intermediates and as molecules with pharmacological properties (1). Interest in these aspects, for the case of 1,1-dioxide derivatives, has been exemplified by recent publications on their use in β-lactams (2), in the synthesis of diaryl 1,2-diketones (3), or in their relation to potassium channel openers (4).

Our previous work (5, 6) on the electrochemical properties of 3,4-diphenyl-1,2,5- thiadiazole 1,1-dioxide (**1,** Scheme 1) in acetonitrile (ACN) solution, has shown that **1** is voltam-

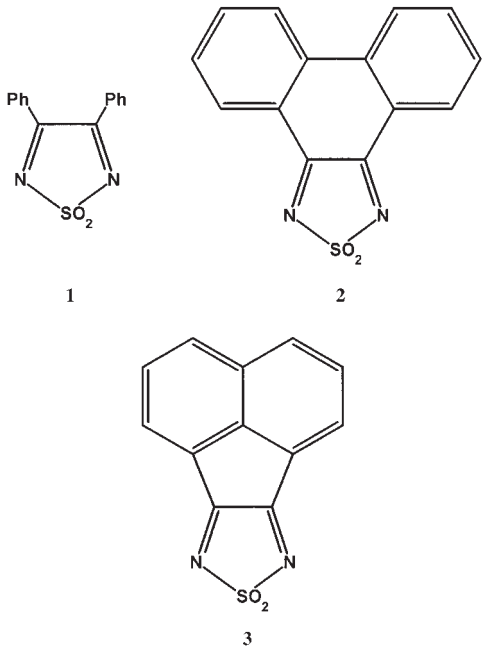
Scheme 1.



metrically reduced, in two reversible successive peaks, to the radical anion and to the dianion at ca. –0.8 and –1.6 V (vs. Ag/Ag^+, in ACN solvent, with $N(Et)_4ClO_4$ (TEAP) as supporting electrolyte). The peak potential of the second couple depends on the supporting electrolyte cation. It is shifted to higher potentials with the increasing Lewis acidity of the cation of the supporting electrolyte (6). This effect is due to stabilization of the basic dianion through complexation with the acid cations.

1 is a moderately strong base (pK_b [ACN] ≈ 12 (5)) and its electroreduction product in acidic ACN is the corresponding thiadiazoline $\mathbf{1}^{\bullet}H_2$.

The strong electron-withdrawing $>SO_2$ group of these substrates is an important factor in the voltammetric properties and the chemical reactivity for nucleophilic addition. The effect of the $>SO_2$ group can be modulated by electronic and steric effects of the substituents, such as the extent of their π-system, the degree of its conjugation with the C=N bonds of the heterocycle, and the feasibility of geometric changes upon reduction or nucleophilic addition.

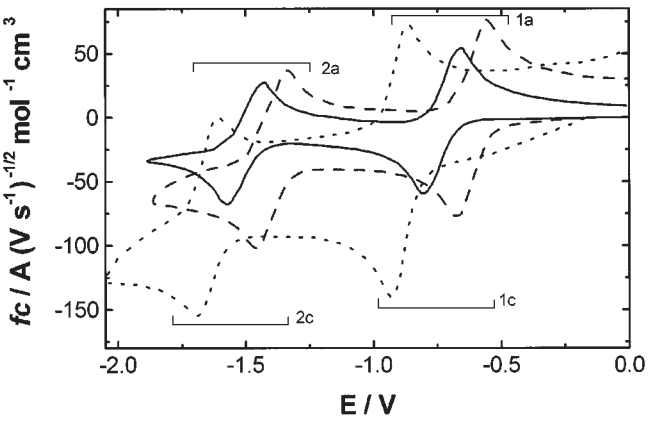
To observe these effects, we studied the voltammetric electroreduction of phenanthro[9,10-*c*]-1,2,5-thiadiazole 1,1-dioxide (**2**, Scheme 1) and acenaphtho[1,2-*c*]-1,2,5-thiadiazole 1,1-dioxide (**3**, Scheme 1) in ACN solution. These systems were compared with the previously studied 3,4-diphenyl (**1**) (5, 6) derivative.

Experiments in which selected acids of varied strength were added to the ACN solution of the substrates were also performed to obtain information about their basic properties.

Experimental

Conventional cyclic voltammetry techniques were employed. A L.Y.P. M2 potentiostat, a three-module L.Y.P. sweep generator, and a Houston Omnigraphic 2000 pen recorder were used.

Fig. 1. Cyclic voltammograms (current function vs. potential) for the substrates in ACN solution. Working electrode: vitreous carbon disk; reference electrode: Ag^+ (0.1 M, ACN) / Ag; supporting electrolyte: 0.2 M TEAP; sweep rate: 0.2 V s^{-1}. 1c, 2c, 1a, 2a : first cathodic, second cathodic, first anodic, and second anodic peak potential regions. (—) **1**, 17 mM; (– – –) **2**, 1.6 mM; (- -·-) **3**, 2.1 mM.



Experiments were performed in an undivided, gas-tight, glass cell swept by purified nitrogen and kept in a dry glove box, where all solution preparation and other experimental manipulations were made.

The reference electrode was Ag/ 0.1 M Ag^+ in ACN. It was separated from the cell solution by a porous-glass plug. A 2 cm Pt foil was the counter electrode and the working electrode was a Teflon encapsulated vitreous carbon disk of 0.074 cm^2 geometric area.

The substituted 1,1-dioxide thiadiazoles were synthesized and purified according to procedures reported by Wright (7) (**1** and **3**); and Vorreither and Ziegler (8) (**2**), respectively.

Results and discussion

General electrochemical and chemical properties

The aromatic character of the parent thiadiazole ring (9, 10), due to the contribution of one of the lone pairs of the sulfur atom to the π-system of the heterocycle, is lost in the 1,1-dioxide derivatives in which these lone pairs become bond pairs of the $>SO_2$ group. Thus, 1,1-dioxide thiadiazole derivatives have fewer delocalization possibilities than the parent ring for the extra charge of the radical anions formed by electroreduction.

However, the electroreduction of 1,2,5-thiadiazole derivatives was highly facilitated when the heterocyclic sulfur was replaced by the strongly electron-withdrawing (EWD) $>SO_2$ group, which was found to be the dominant factor determining the electroreduction potential. For example, the polarographic $E_{½}$ of the parent ring compound 1,2,5-thiadiazole is –2.52 V, and that of its 3,4-diphenyl derivative is –2.39 V (10), while the 1,1-dioxide heterocycles were typically electroreduced in the –0.6 to –1.0 V potential region (vs. 0.1 M Ag^+ (ACN)/ Ag), as shown in Fig. 1, where the cyclic voltammograms recorded in ACN solutions are presented. The voltammogram of **1** in ACN containing 0.2 M TBAP is also included for comparison (6).

The EWD character of the $>SO_2$ group causes the high electropositive character of the carbon atoms of the hetero-

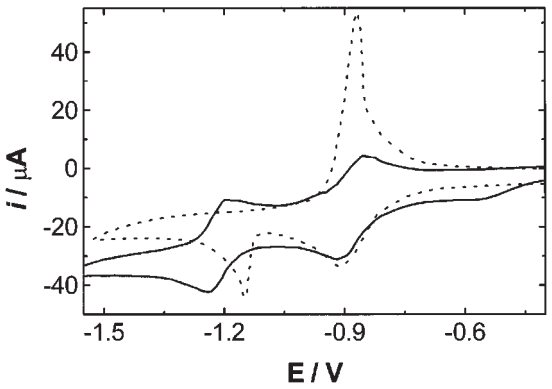
Fig. 2. Influence of the solvent in the cyclic voltammogram of **3**, when $NaClO_4$ is used as supporting electrolyte. [$NaClO_4$] = 0.25 M; working electrode: vitreous carbon disk; reference electrode: Ag^+ (0.1 M, ACN) / Ag; sweep rate 0.010 V s^{-1}. (- - -) ACN solvent; (—) mixed solvent: ACN; 30 vol.% EtOH.



cycle and, of course, also affects the chemical behavior of 3,4-disubstituted 1,2,5-thiadiazole 1,1-dioxide derivatives. A study of structural effects on the nucleophilic addition to the heterocycle C=N double bond is under way in our laboratory. As a whole, the effect of the heterocycle on its 3,4 substituents has been compared to that of an acyl-like group (1, 11).

Voltammetric behavior of 2

2 was voltammetrically reduced to its radical anion and dianion at ca. –0.6 and –1.3 V, respectively (Fig. 1), in ACN solution with TEAP as supporting electrolyte. Both processes presented typical one-electron reversible behavior. A value of 2.0×10^{-5} cm^2 s^{-1} for the diffusion coefficient of **2** was calculated from its first cathodic peak (peak 1c**2**).

The peak potential of the second couple depended on the supporting electrolyte cation. It was shifted to ca. –0.9 V with $NaClO_4$ as supporting electrolyte. The effect is similar to that reported for 1 (**6**).

Voltammetric behavior of 3

The voltammetric response of **3** showed two diffusional couples at ca. –0.9 and –1.7 V vs. 0.1 M Ag^+ (ACN)/ Ag in TEAP as supporting electrolyte (Fig. 1). As for **1** and **2**, the second couple also shifted to higher potentials (ca. –1.2 V) when $NaClO_4$ was used as supporting electrolyte. In this case, the peaks of the second couple were sharp and symmetric and the anodic peak was shifted to higher potentials and overlapped with the anodic peak of the first couple. This was especially noticeable at low sweep rates (Fig. 2, broken line). The formation and adsorption of a complex or a salt of the dianion of the substrate with Na^+ might be responsible for the effect.

The addition of 30 wt.% of EtOH to the ACN solvent changed the voltammetric aspect of the second couple, which, in this solvent mixture, presented normal diffusional behavior and shifted to lower potential by ca. 0.1 V (Fig. 2, solid line). This change is probably caused by a decrease in the effective cation acidity through its interaction with ethanol.

From the *fc* of the first cathodic peak of **3**, a diffusion coefficient of 2.2×10^{-5} cm^2 s^{-1} in ACN was calculated for a one-electron reversible charge transfer.

Comparison of the voltammetric behavior of 2, 3, and 1

The E^o values for the first reduction peak of the compounds were, in decreasing potential order, **2** (–0.592 V), **1** (–0.822 V), and **3** (–0.892 V). The position of E^o**1** between E^o**2** and E^o**3** seemed to be in disagreement with the order expected when the delocalization possibilities of the charge added to the substrates to form the radical anion were considered.

As mentioned above, **1**, **2**, and **3** can be compared with strong electron-withdrawing substituted derivatives of their 3,4 substituents, such as the corresponding diketones. Thus, the potentials for the first cathodic voltammetric peak of these diketones were measured under the same experimental conditions at 0.2 V s^{-1}. The charge transfers were found to be reversible and the peak potentials followed the expected order: –1.06 V for 9,10-phenanthrenequinone; –1.27 V for acenaphthenequinone, and –1.54 V for benzil (**Bz**).

The diketones were found to be more difficult to electroreduce than the thiadiazoles. This was expected. The azomethine (>C=N-) group is generally more easily electroreduced than the carbonyl group from which it may be considered to derive (12), and the effect of the N-bonded, electron-withdrawing, $>SO_2$ group should also facilitate the electroreduction.

The differences in electroreduction potential (ΔE_R) between thiadiazoles and quinones were similar (ΔE_R [**2** – phenanthrenequinone] ≈ 0.47 V, ΔE_R [**3** – acenaphthenequinone] ≈ 0.38 V), but ΔE_R [**1** – Bz] (0.72 V) was significatively higher. Possible structural reasons for this difference are discussed below.

It is known (13) that the first step in quinone electroreduction in aprotic media is the formation of the semiquinone radical anion. Both **2** and **3**, which have been shown by X-ray crystallography to be planar (14), can produce upon one-electron transfer a "semiquinone-like" radical anion, as shown in Scheme 2. However, the comparison between the electroreduction of **Bz** and that of **1** can not be so direct.

The phenyl groups of **1** are restricted to a *cis* orientation with respect to the heterocyclic (C3—C4) carbon–carbon bond. They are also rotated out of the plane of the heterocycle by ca. 40°, as has been shown through X-ray difractommetry and molecular orbital calculations (14). Consequently, the resonance coupling between these phenyl groups and the C=N double bond is small. In contrast, benzil has a skew structure in which the strong conjugation of the carbonyl with phenyl apparently minimizes the conjugation of the two benzoyls with each other. The two benzoyl groups are twisted with respect to each other, perhaps by as much as 90° (15).

The radical anion of **Bz** ($\mathbf{Bz}^{\bullet-}$) presumably maintains the strong phenyl–carbonyl coupling and, although the radical anion is probably less twisted than **Bz** because of the advantage in further delocalizing the added charge, it will certainly not be planar. Thus, only one benzoyl π-system (or one plus a fraction) provides resonance stabilization for $\mathbf{Bz}^{\bullet-}$. **Bz** is therefore the most difficult to reduce.

Some of the classical Lewis structures that can be written for $\mathbf{1}^{\bullet-}$ are shown in Scheme 3.

It is clear from their symmetry that both phenyl groups and both nitrogen atoms participate equally in the can-

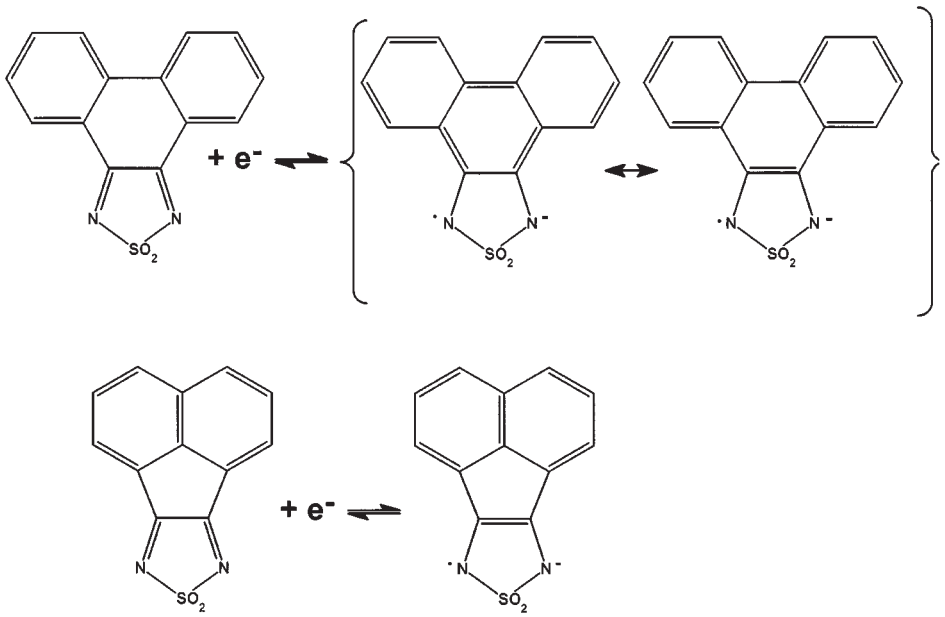
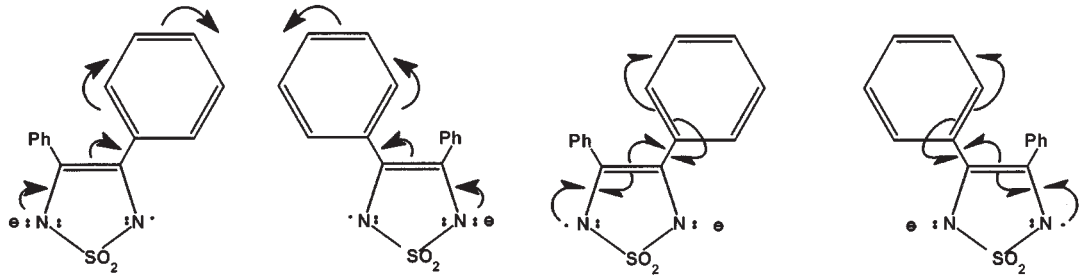
Scheme 2.



Scheme 3.



onical forms of these structures and cannot be distinguished from one another. The actual structure should contain a -NC(Ph)C(Ph)N- group sufficiently coupled (planar) to maximize the delocalization energy of the unpaired electron and sufficiently twisted to minimize repulsion, particularly between phenyl groups that are brought nearer together by the C3—C4 partial double bond character.

Thus, the free-energy difference between **1** and $\mathbf{1}^{\bullet-}$ should not be compared with that between **Bz** and $\mathbf{Bz}^{\bullet-}$, but with the free-energy difference between a hypothetical *cis*-benzil with a nearly zero carbonyl–carbonyl dihedral angle and its geometrically similar radical anion. The stabilization provided should correspond to somewhat less than two phenyl π-systems, but still more than an acenaphthene ring, thus making **1** more easily reducible than **3**.

Voltammetric results in ACN solutions with the addition of acids

The behavior of **2** and **3** in acidic ACN solution resembled that previously reported (5) for **1**. For small acid-to-substrate molar concentration ratios ([AH]/[**T**] ≤ 1, where **T** stands for any of the substrates), a prepeak at a higher potential with respect to E_p1c developed and the current intensity of peaks 1c and 2c decreased. The prepeak current intensity increased at the expense of the original substrate peaks and its peak potential shifted to higher potentials when the relative concentration of acid was increased. For molar concentration ratios of ca. 2, peaks 1c and 2c were barely detectable as shoulders of the prepeak at lower potential and the current intensity of the prepeak reached a higher limit of approximately twice that of the original peak 1c.

Voltammetric data corresponding to ca. 2×10^{-3} M ACN solutions of the substrates in the presence of several proton donors (AH) of varied strength, at a concentration ratio [AH]/[**T**] = 100 to ensure pseudo-first-order conditions, are presented in Fig. 3.

The proton donors used were phenol (PhOH, K_a (ACN) = 2.4×10^{-27}) (16), anhydrous benzoic acid (HBz, K_a (ACN) = 2×10^{-21}) (17), anhydrous trifluoracetic acid (TFA, K_a (ACN) = 4×10^{-8}) (18), and concentrated perchloric acid (K_a (ACN) = 1×10^{-2}) (16). The **1**–$HClO_4$ could not be studied because **1** reacted rapidly with the water contained in the concentrated perchloric acid added. In all cases, as expected, the cathodic peak potential increased with the strength of the added acid.

The shift to higher potentials, the doubled current intensity, and the demonstrated formation of $\mathbf{1}^{\bullet}H_2$ (5) and $\mathbf{2}^{\bullet}H_2$ (see below) indicate a 2 e, 2 H^+ process (Scheme 4), where the highly acid $\mathbf{T}H_2^{2+}$ and the highly basic $\mathbf{T}^{2-}$, which are improbable species under the conditions of these experiments, have been excluded.

The detailed analysis of Scheme 4 for each system is extremely complex. The voltammetric response depends on the equilibrium and kinetics of the charge transfers and chemical

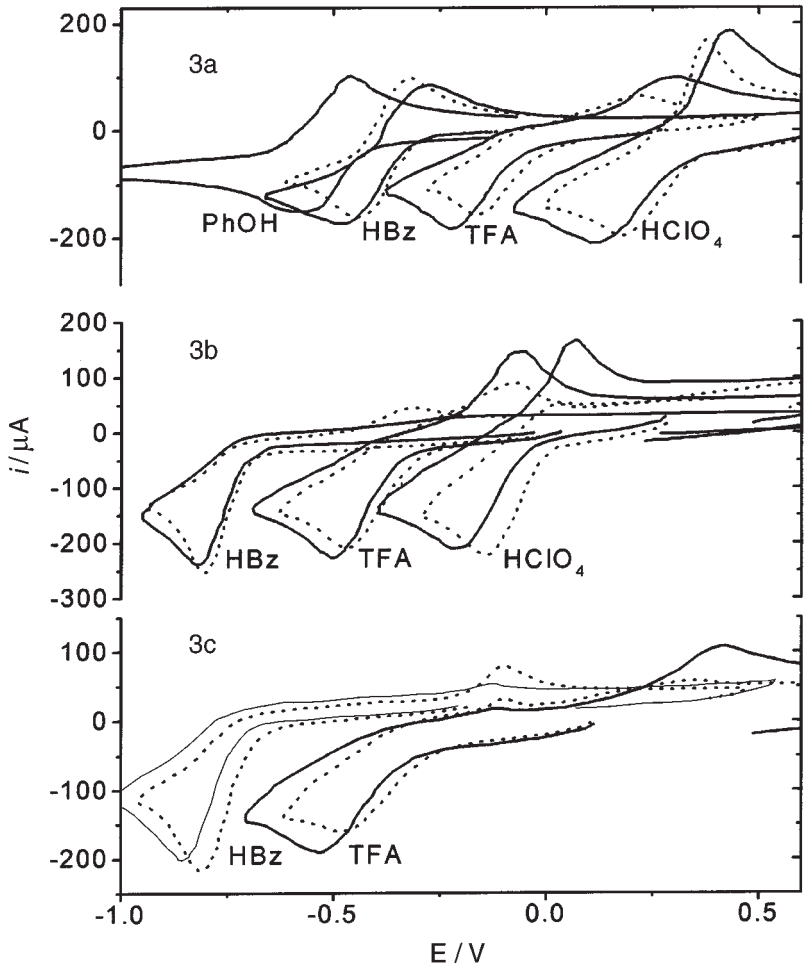
Fig. 3. Cyclic voltammograms of the substrates in ACN solution with different added acids in acid/substrate molar ratio = 100. Substrate concentration = 2 mM. Working electrode: vitreous carbon disk; reference electrode: Ag^+ (0.1 M, ACN) / Ag; supporting electrolyte: 0.2 M TEAP. Sweep rates: (—) : 0.2 V s^{-1}; (- - -): 0.02 V s^{-1}. Current values for the experiments at 0.02 V s^{-1} are multiplied by 3 to facilitate comparison. The added acid is indicated at the foot of each wave as follows: HBz: dry benzoic acid; TFA: dry trifluoracetic acid; $HClO_4$: concentrated perchloric acid. 3a: **2**; 3b: **3**; 3c: **1**.

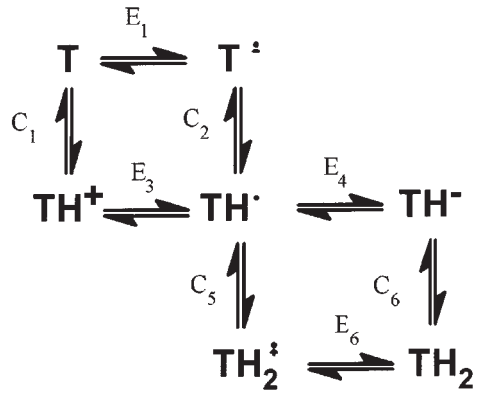


steps. It should also be noted that the deprotonation reactions indicated (with the possible exception of those in $HClO_4$ acid medium, since a high concentration of the ClO_4^- anion is provided by the supporting electrolyte) are of second kinetic order under our experimental conditions.

However, it seemed valuable to relate the observed voltammetric behavior of the **T**–HA systems to the relative acid–base properties of the species included in Scheme 4, as far as these properties can be rationalized according to the known structure of the thiadiazole substrates. Thus, **2** can efficiently stabilize the added charge in a **2**$^{\bullet}H^+$ cation through dispersal in its conjugated system. The π system available for the stabilization of a **3**$^{\bullet}H^+$ cation is less extended, while **1**$^{\bullet}H^+$ must be the strongest acid of the three since its charge can only be dispersed over one of the phenyl rings.

In the case of **1**, the minimum energy conformation postulated for its radical anion (Scheme 3), must change when **1**$^{\bullet}H^-$ is formed from it (reaction C_2**1** and charge transfer E_4**1**), since the delocalization of the added charge can only take place on one "side" of the molecule (Scheme 5). Of course, this does not apply to substrates **2** or **3**, since the structures of their monoprotonated anions can be easily de-

Scheme 4.



rived from those shown in Scheme 2 for the radical anions without structural changes.

Thus, in the **1**–HBz and the **1**–TFA systems, the reaction proceeds through a $E_1[C_2E_4]$ path to form **1**$^{\bullet}H^-$, which is further protonated to **1**$^{\bullet}H_2$.

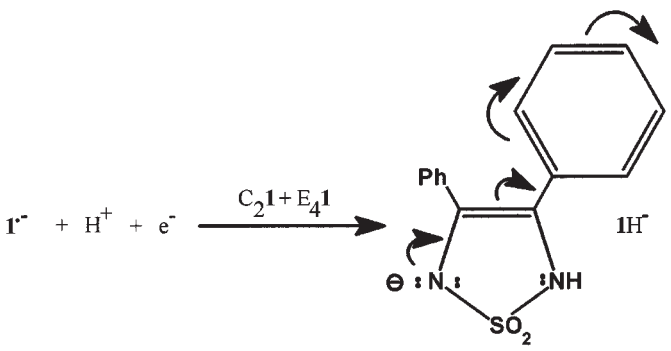
Scheme 5.

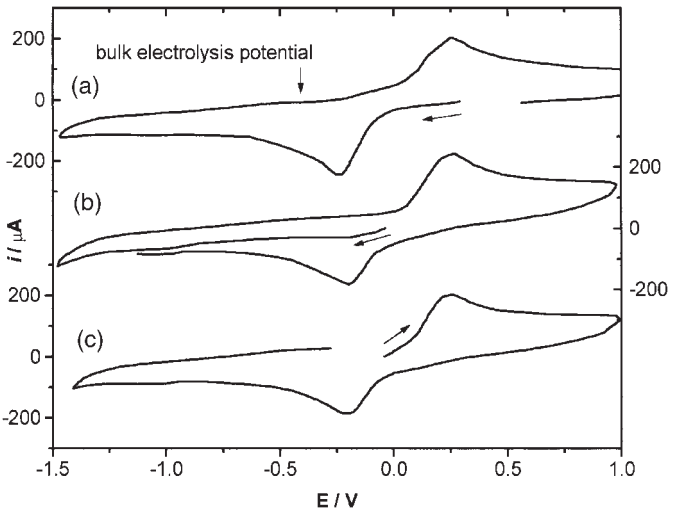


However, the anodic peak observed for the **1**–TFA system at ca. 0.4 V (Fig. 4, sweep rate: 0.2 V s^{-1}) cannot be assigned to the electrooxidation of **1**•H_2, since no anodic voltammetric signals were observed in ACN solutions of **1**•H_2 (5), with or without the addition of proton donors. Neither can this peak be caused by the electrooxidation of partially protonated species, such as **1**•H^-, which, if existent and electroxidable when TFA is added to an ACN solution of **1**, would also be present in the **1**–HBz system. It was also verified experimentally that the anodic peak did not correspond to benzil (a product of the eventual hydrolysis of **1** (19)) or its protonation products.

A controlled potential (at ca. –1.0 V) bulk electrolysis experiment of an ACN solution of **1**–TFA at a concentration ratio [TFA]/[**1**] = 50 was performed. Voltammograms scanned at selected time intervals during the electrolysis presented the same peaks shown in Fig. 3*c*. The cathodic peak continuously decreased during the electrolysis, while the anodic peak at ca. 0.4 V increased to about 60% of the initial value of the cathodic peak. Immediately after the end of the electrolysis, when the cathodic peak intensity was nearly zero, a voltammogram started in the anodic direction showed that scanning through the anodic peak caused the reappearance, in the subsequent cathodic scan, of the original cathodic peak at same potential, with about one half its initial (before electrolysis) current intensity. Neither peak could be observed in voltammograms run several hours after the electrolysis was finished. Although the electroreduction current of the acid interfered with the voltammetric observation of **1**•H_2 at ca. –1.7 V, a TLC run of the electrolyzed solution showed that **1**•H_2 was the only reaction product. The anodic peak at ca. 0.4 V must be assigned to a relatively stable intermediate in the formation of **1**•H_2 that is capable of being electrooxidized back to **1** at that potential. According to the structure assigned to **1**•H^-, the anion can be kinetically protonated in the nitrogen to give a tautomer of **1**•H_2 (**1**•H_2', Scheme 6), which would slowly transform into its stable structure[2] (**1**•H_2). The tautomer might be the species that is electrooxidable at 0.4 V.

The **2**–HA systems presented nearly reversible couples at low sweep rates in weak acids such as PhOH and HBz. A reversible $E_1\,C_2\,E_4$ might be the preferred reaction path but, in the case of the much stronger acids TFA and $HClO_4$, it is plausible that C_1**2** might precede the E_3**2** electroreduction, while the anodic process might start with the electrooxidation of **2**•H_2 (E_6**2**) at ca. 0.4 V. In the case of **3**–TFA and **3**–$HClO_4$ systems, the processes should be similar to those of **2** for the same acids. The reversibility should be decreased in the **3**–HBz system as compared with **2**–HBz, since C_2**3** should be more displaced towards the products than C_2**2** due to the higher basicity of **3**$^-$.

Fig. 4. Bulk electrolysis of the **2**–TFA system in ACN at –0.4 V. [**2**] = 2.16 mM; Electrolysis setup: divided cell; cathode: vitreous carbon rod; anode: Pt foil. Voltammetric setup (in the cathodic compartment of the electrolysis cell): working electrode: vitreous carbon disk; reference electrode: Ag^+ (0.1 M, ACN) / Ag; supporting electrolyte: 0.1 M TEAP; TFA acid = 0.1 M; sweep rate: 0.2 V s^{-1}. (*a*): Voltammogram before electrolysis; (*b*): voltammogram at the end of the electrolysis, started from the rest potential in the cathodic direction, (*c*): same in the anodic direction.



Bulk electrolysis and chemical reduction of 2: synthesis of 2•H_2

To the best of our knowledge, **2**•H_2 and **3**•H_2 have not been synthesized. The electrosynthesis of **2**•H_2 was attempted, by bulk electrolysis, on the **2**–TFA and the **2**–$HClO_4$ systems with similar results. The electrolysis was interrupted at selected time intervals to follow its course by cyclic voltammetry. The voltammograms showed that the cathodic peak current decreased, the anodic peak current increased correspondingly, and the characteristic bright red color of **2** faded as the electrolysis advanced. The initial and final voltammograms for the **2**–TFA system are shown in Fig. 4.

The electrolysis was concluded when the cathodic peak was almost undetectable in the first voltammetric sweep in the cathodic direction (Fig. 4*b*). At that time, the solution was colorless, the anodic peak had a current intensity similar to that of the original cathodic peak, and 2.05 F had been consumed per mole of **2** originally present. As shown in Fig. 4*c*, the results of a voltammetric cycle that started from the rest potential in an anodic direction indicated that the electrolysis product has been voltammetrically oxidized back to **2**.

However, only **2** and small amounts of an unidentified product could be recovered from the electrolyzed solution

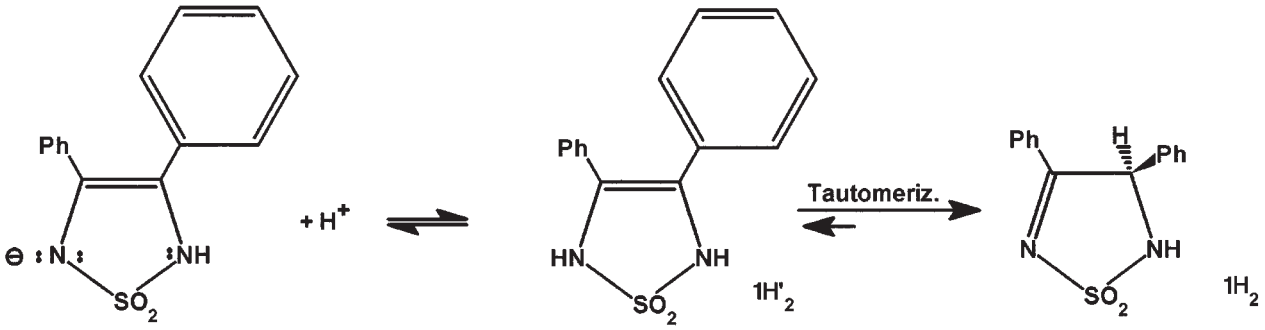
Scheme 6.



by normal work-up procedures (TLC analysis). It could be clearly observed that the chromatographic spot of the unidentified product changed from colorless to red on the layer. Bidimensional TLC analysis performed after this color change showed that the unidentified product had reverted to **2**.

It was found (TLC analysis) that **2** can be chemically reduced to the same product by metallic Zn in acidic ACN solution (obtained by the addition of dry TFA or by gaseous HCl bubbling). Vacuum evaporation of the resulting solution in the absence of air produced a white solid. An ACN solution of this white solid rapidly turned red in contact with air and, on vacuum evaporation, reverted to **2** (IR; TLC).

The IR spectrum (KBr pellet) of the white solid, which must be identified as **2**·H_2, presented an N–H IR band at 3150 cm^{-1}, along with characteristic $>SO_2$ bands at 1382 and 1172 cm^{-1}. No bands assignable to C=N (as those present at 1540 cm^{-1} in **2**, at 1560 cm^{-1} in **1**·H_2, or at 1610 and 1540 cm^{-1} in **1**) could be observed. No aliphatic C–H IR band was observed, in contrast with the IR spectrum of **1**·H_2.

The semiquinone-like structure schematized above for the radical anions $\mathbf{2}^-$ and $\mathbf{3}^-$ means that **2** and **3** can also form dianions, in which the added charges are placed on the heterocyclic nitrogen atoms, and dihydrogenated derivatives (thiadiazolines) with two N—H bonds, as suggested by the IR spectrum of **3**·H_2. In contrast, **1** is reduced to a thiadiazoline in which one of the -C=N- groups turns into a -CH-NH- group (5, 7). Thus **2**·H_2, and presumably **3**·H_2, should be considered as polycyclic derivatives of 2,1,3-benzothiadiazoline 2,2-dioxide (no C=N double bonds) while **1**·H_2 is a different thiadiazoline (one C=N double bond and one C—N single bond).

Calculation of atomic recombination in a decaying high-temperature hydrogen gas column

Jörgen Stevefelt

Abstract: The temporal evolution of the concentration of atomic radicals [H] in a high-temperature hydrogen gas column has been evaluated, assuming an exponentially decaying temperature from 5000 K to 1000 K, and for constant pressures in the range from 0.125 to 2.0 bar (1 bar = 10^5 Pa). The initial concentration $[H]_{t=0}$, assumed to correspond to thermal equilibrium, would increase with pressure, but the termolecular recombination processes also become faster with increasing pressure. As a result, high concentration of atomic radicals rapidly becomes favoured by lower gas pressure after the temperature has decayed for a certain time. Also, operation at lower pressures would make the decay of [H] radicals less dependent upon the cooling rate of the gas.

Key words: high-temperature gas, atomic recombination, hydrogen radicals.

Résumé : L'évolution au cours du temps de la concentration des radicaux atomiques [H] dans une colonne de gaz d'hydrogène chaud a été évaluée en supposant une décroissance exponentielle de la température de 5000 K à 1000 K, et pour des pressions de gaz constantes, comprises entre 0,125 et 2.0 bar (1 bar = 10^5 Pa). La concentration initiale $[H]_{t=0}$, supposée correspondre à un équilibrium thermodynamique, augmente avec la pression, mais les processus termoléculaires de recombinaison deviennent également plus rapides. Il en résulte qu'une concentration élevée des radicaux atomiques est rapidement favorisée par des pressions plus basses à partir d'un certain temps pendant la décroissance de la température. L'utilisation des basses pressions permet également de rendre la décroissance de la concentration [H] moins dépendante de la vitesse de refroidissement du gaz.

Mots clés : gaz à haute température, recombinaison atomique, radicaux d'hydrogène.

1. Introduction

Non-equilibrium gaseous media and plasmas, generally produced by various types of electrical discharges, are increasingly used as highly efficient sources of chemically active species. Of particular interest is the possibility of conducting selective chemical reactions at extremely high rates by a proper choice of experimental parameters such as pressure and temperature. The wide variety of potential applications has already stimulated much research, including experimental, theoretical, and modelling studies (1–5).

Highest energy efficiency is generally provided by pulsed discharge techniques, yielding conditions that may develop concentrations of active species which are far from thermodynamic equilibrium, at the same time as excessive gas heating is avoided. A very important property in bringing about the chemical reaction is then the lifetime of the desired active species against competing destruction processes. The rates of these processes are in general also dependent upon the average energy (the "temperature") of the active species, which decays after discharge cessation.

Reported here is a model calculation of the three-body recombination of atomic radicals in a typical environment of moderately high temperature, such as a column of hot gas at moderate pressures, created by the interruption of an electric arc discharge or by other means. Since the recombination reactions of hydrogen atoms,

[1] $$H + H + H \rightarrow H_2 + H$$

[2] $$H + H + H_2 \rightarrow H_2 + H_2$$

are well characterized in the literature, with equilibrium constants known from both spectroscopic (6) and thermochemical data (7), they were chosen for a first numerical application.

We shall first briefly discuss the values of these constants and the rate coefficients for reactions [1] and [2]. Then we shall proceed to a numerical simulation of the temporal evolution of the concentrations [H] and $[H_2]$ in a cooling gas, for several constant pressures and with gas temperature exponentially decaying from 5000 K to 1000 K in time intervals (up to a few milliseconds) that are typical in experimental situations. The concentrations will be assumed to initially correspond to themodynamic equilibrium, which may be reached by using a sufficiently long discharge pulse, with the purpose of studying how they will start deviating from equilibrium while the gas is cooling down. The results presented are of importance not only for describing hydrogen recombination, but for other gases as well. An example is fluorine atom recombination in plasma chemical cleaning

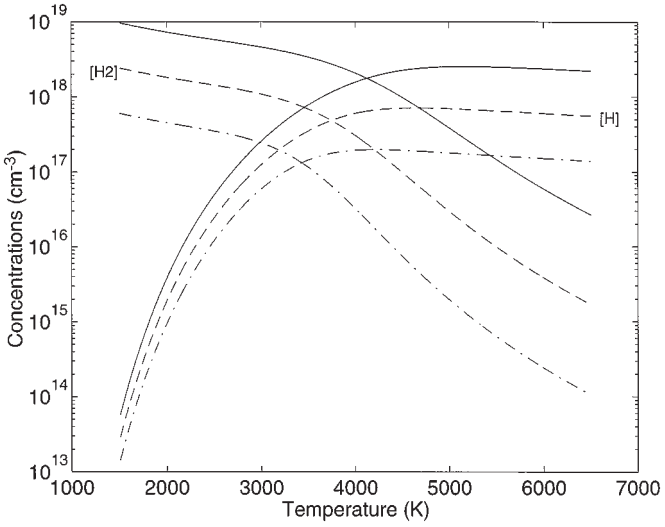
Fig. 1. Concentrations of H and H_2 in thermal equilibrium as functions of the temperature, and for three different gas pressures: 2.0 bar, (___); 0.5 bar, (— —); 0.125 bar, (— - — -).



systems for applications in electronics, using remote plasma sources.

2. Rate coefficients for recombination and dissociation in hydrogen

Hydrogen atoms in a gaseous environment recombine to form diatomic molecules H_2 exclusively through the three-body processes [1] and [2], since removal of vibrational energy by radiation is impossible for a homonuclear molecule. It is conceivable that the rates of these processes are essentially determined by the efficient relaxation of the highest vibrational states of H_2 in collisions with the third body, for which the adiabaticity parameter is of order unity. This efficient VT energy transfer would yield a "vibrational temperature" for those states being close to the gas temperature. The same efficiency might be expected for electrons acting as third bodies, but these were neglected in the present work as being considered a minority species.

Several experimental determinations of the rate coefficients for processes [1] and [2] have been reported, sometimes with rather contradictory results. We have used the values recommended by Cohen and Westberg (7), based on an extensive literature review. For reaction [1]:

[3] $k_{r1} = 8.8 \times 10^{-33}$ cm^6 s^{-1}, 50 K < T < 5000 K

and for reaction [2]:

[4] $k_{r2} = 2.7 \times 10^{-31}\ T^{-0.6}$ cm^6 s^{-1}, 50 K < T < 5000 K

A more recent review paper by Baulch et al. (8) recommends the same expression for the rate coefficient of reaction [2].

For the inverse processes, i.e., the dissociation of hydrogen molecules H_2 in collisions with H and H_2, respectively, the rate coefficients can be obtained through the known equilibrium constant K for the processes, and by applying the principle of detailed balancing:

[5] $k_{d1} = k_{r1}/K$

[6] $k_{d2} = k_{r2}/K$

Cohen and Westberg (7) give an expression for the equilibrium constant K, based on thermo-chemical data:

[7] $K = 1.96 \times 10^{-25}\ T^{0.1} \exp(52530/T)$ cm^3

For the hydrogen molecule H_2, the spectroscopic constants $\omega_e = 4395.2$ cm^{-1} and $B_e = 60.809$ cm^{-1} related to vibration and rotation are well known (6), and from them the equilibrium constant can be accurately computed by means of the relation:

$$[8] \qquad K = \frac{Q_{H_2}}{(Q_H)^2} \exp(D_0/kT)$$

where the Q's indicate total partition functions and D_0 is the dissociation energy of H_2 in its ground vibrational state. For the atoms Q_H is just the translational partition function times the multiplicity 2 of the ground electronic state ^2S,

$$[9] \qquad Q_H = 2\left(\frac{2\pi m_H kT}{h^2}\right)^{3/2}$$

In the case of the H_2 ($^1\Sigma_g^+$) molecule the total partition function will be the multiplicity (= 1) times the product of the translational, vibrational, and rotational partition functions. The vibrational partition function is given by

$$[10] \qquad Q_V = 1/[1 - \exp(-hc\omega_e/kT)]$$

whereas the rotational partition function is obtained by the state sum

$$[11] \qquad Q_R = \sum_{J=0,1,\ldots} g_J \exp[-B_e J(J+1)hc/kT]$$

with $g_J = 2J + 1$ for the even and $g_J = 3(2J + 1)$ for the odd rotational levels J. The alternating statistical weights arise from the nuclear spin ½ of the proton H. For T > 1000 K, the sum in eq. [11] can be replaced by an integral, with an error <3%:

$$[12] \qquad Q_R = 2kT/hcB_e$$

so that we obtain

$$[13] \qquad K = \left(\frac{h^2}{\pi m_H kT}\right)^{3/2} \frac{kT}{2hcB_e} \frac{\exp(D_0/kT)}{1 - \exp(-hc\omega_e/kT)}$$

for the equilibrium constant.

With the known values for B_e, D_0, and ω_e, and with temperature in K, we find

$$[14] \qquad K = 8.50 \times 10^{-23}\ T^{-0.5}\ [1 - \exp(-6323.7/T)]^{-1} \times \exp(52530/T)\ \text{cm}^3$$

Obviously, eq. [7] is a rather poor approximation for the equilibrium constant, since in particular it has the wrong temperature dependence apart from the factor $\exp(D_0/kT)$. In the following we shall use the expression [14], derived from accurate spectroscopic data.

Fig. 2. Calculated temporal evolutions of the atomic hydrogen concentration for the gas pressure 1.0 bar, and for different characteristic cooling times τ, defined by eq. [29]. T_0 = 5000 K, T_1 = 1000 K, and τ varies between 10 and 300 μs.

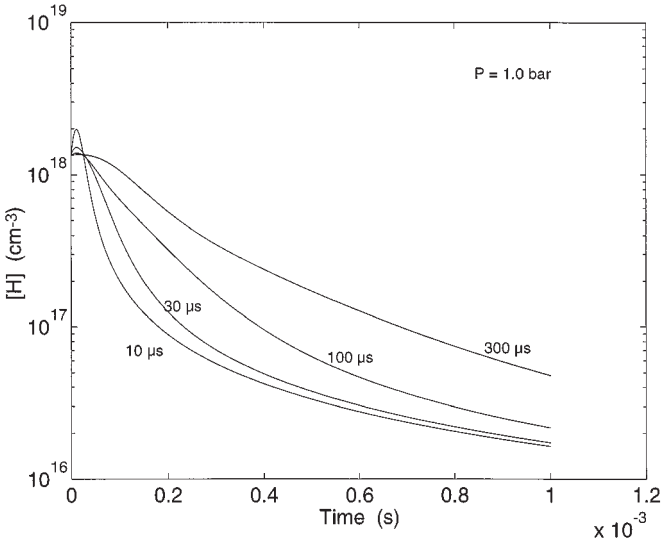

Fig. 3. Calculated temporal evolutions of the atomic hydrogen concentration for the gas pressure 0.25 bar, and for different characteristic cooling times τ, defined by eq. [29]. T_0 = 5000 K, T_1 = 1000 K, and τ varies between 10 and 300 μs.

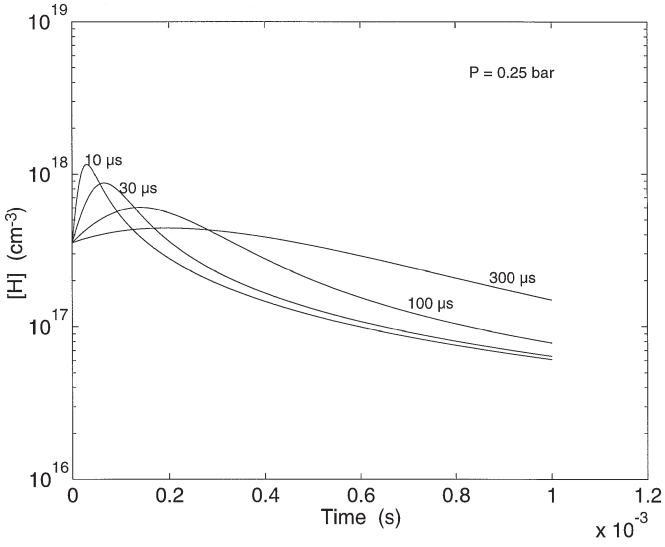

3. Temporal evolution of H and H_2 concentrations

3.1 Initial equilibrium concentrations

We have assumed that at the instant $t = 0$, the concentrations of atoms H and molecules H_2 will nearly be in thermodynamic equilibrium, such that

[15] $$[H_2]_0 / [H]_0^2 \approx K(T_0)$$

The gas pressure P at the temperature T is given by

[16] $$P = \{[H] + [H_2]\}\ kT$$

Combining eqs. [15] and [16] yields

[17] $$[H]_0 = \left\{\sqrt{1 + 4K(T_0)P/kT_0} - 1\right\}/2K(T_0)$$

[18] $$[H_2]_0 = P/kT_0 - [H]_0$$

These equilibrium concentrations are shown in Fig. 1 as functions of the temperature T_0 and for the three different gas pressures P = 0.125, 0.5, and 2.0 bar.

3.2 Theoretical formulation of the temporal evolution of atomic concentrations

For the numerical simulation of the temporal evolution of the concentrations [H] and [H_2], we considered a homogenous volume V of hydrogen gas, cooling down at constant pressure P. Then, since the total density of molecules ([H] + [H_2]) must increase with time, we had to include source terms due to the variation of the volume V in the kinetic equations for [H] and [H_2]:

[19]
$$\frac{d[H]}{dt} = -2k_{r1}[H]^3 - 2k_{r2}[H]^2[H_2] + 2k_{d1}[H][H_2] + 2k_{d2}[H_2]^2 + S_H$$
$$\frac{d[H_2]}{dt} = k_{r1}[H]^3 + k_{r2}[H]^2[H_2] - k_{d1}[H][H_2] - k_{d2}[H_2]^2 + S_{H_2}$$

If N_H and N_{H_2} are the total number of atoms and molecules in the volume V,

[20] $$[H] = N_H/V, \quad [H_2] = N_{H_2}/V$$

then

[21]
$$S_H = \frac{\partial[H]}{\partial V}\frac{dV}{dt} = -\frac{N_H}{V^2}\frac{dV}{dt} = -[H]\left(\frac{1}{V}\frac{dV}{dt}\right) \equiv s[H]$$
$$S_{H_2} = \frac{\partial[H_2]}{\partial V}\frac{dV}{dt} = -\frac{N_{H_2}}{V^2}\frac{dV}{dt} = -[H_2]\left(\frac{1}{V}\frac{dV}{dt}\right) \equiv s[H_2]$$

where

[22] $$s = -\left(\frac{1}{V}\frac{dV}{dt}\right)$$

If we further put

[23] $$C = k_{r1}[H]^3 + k_{r2}[H]^2[H_2] - k_{d1}[H][H_2] - k_{d2}[H_2]^2$$

then the eqs. [19] can be written

[24]
$$\frac{d[H]}{dt} = -2C + s[H]$$
$$\frac{d[H_2]}{dt} = C + s[H_2]$$

Adding together these two equations gives

For personal use only.

Table 1. Time elapsed in milliseconds, after which the atomic hydrogen concentration has decayed to 1/10 of its initial equilibrium value, for some gas pressures (P) and characteristic cooling times (τ).

	τ (μs)			
P (bar)	10	30	100	300
0.125	6.86	6.91	7.08	7.59
0.25	1.75	1.80	1.98	2.50
0.5	0.466	0.517	0.699	1.14
1.0	0.140	0.192	0.334	0.579
2.0	0.056	0.095	0.172	0.306

[25] $$\frac{dn}{dt} = -C + sn, \quad n = [H] + [H_2] = P/kT$$

Finally, by introducing

[26] $$[H] = xn$$
$$[H_2] = (1-x)\, n$$

we obtain the differential equation for the degree of dissociation x :

[27] $$\frac{dx}{dt} = \frac{1}{n}\frac{d[H]}{dt} - \frac{[H]}{n^2}\frac{dn}{dt} = \frac{C}{n}(x-2)$$

where the factor C can be expressed in terms of x :

[28] $$C = n^2[k_{r1}x + k_{r2}(1-x)]\left[nx^2 - \frac{1-x}{K}\right]$$

The gas density n, the reaction coefficient k_{r2}, and the equilibrium constant K are all functions of the temperature T, which in order to simulate the experimental situation of a gas column cooling by thermal conduction was modeled by the temporal evolution,

[29] $$T(t) = T_1 + (T_0 - T_1) \exp(-t/\tau)$$

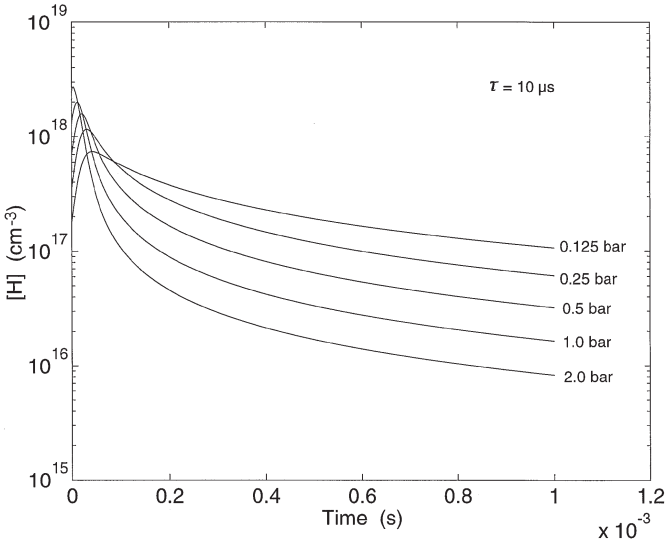
where τ was varied between 10 and 300 μs. For a very rapid cooling, the product $v_{th}\tau$, where v_{th} is the thermal velocity of the molecules H_2 (= 5.6×10^5 cm s^{-1} at T = 3000 K), will be much smaller than the characteristic dimensions of the gas column, and the assumption of constant pressure is no longer justified.

The differential equation [27], with initial densities [H] and $[H_2]$ at time t = 0 given by the equilibrium relations [17] and [18] and temperature $T(t)$ modeled by eq. [29], allowed the numerical calculation of x, and then the temporal evolution of [H] and $[H_2]$ through the relations [26].

Results

The calculated temporal evolutions of the atomic hydrogen concentration [H] are shown in Figs. 2 and 3 for the two gas pressures 1.0 bar and 0.25 bar, respectively, and for different values of the characeristic cooling time τ. For each pressure, the initial [H] concentration is given by eq. [17], with the equilibrium constant $K(T)$ calculated by eq. [14] at an initial temperature T_0 = 5000 K. The gas temperature is then assumed to decay according to eq. [29] to a final temperature T_1 = 1000 K, while pressure remains constant.

Fig. 4. Calculated temporal evolutions of the atomic hydrogen concentration for a characteristic cooling time τ = 10 μs, and for different gas pressures.



At very early times, the [H] concentration is first seen to increase. This effect is most pronounced for rapid gas cooling, and simply reflects the increasing total gas density. Rather soon, the equilibrium constant $K(T)$ increases rapidly and the recombination processes [1] and [2] will predominate over the inverse reactions. Because of their third-order character, they are most efficient at higher pressures, and at 1 bar (Fig. 2) the decay of radicals [H] depends strongly upon the cooling time τ. At first, hydrogen atoms will act as the main third body, and not until a large fraction (67–81%) of these have recombined will H_2 molecules take their place as predominant third bodies, the rate coefficient of process [2] being a factor of 4 slower than that of process [1] at $T \approx$ 3000 K. Fast atomic recombination will be accompanied by an important release of heat (4.53 eV = 7.25×10^{-19} J per recombination event) that would significantly slow down the gas cooling. However, the degree of dissociation will be far from equilibrium even at the slowest cooling time τ = 300 μs in Fig. 2: at the time t = 1 ms the gas temperature has decayed to T = 1143 K and the corresponding equilibrium concentration would be $[H]_{eq} = 1.65 \times 10^{11}$ cm^{-3}, compared to $[H] = 4.8 \times 10^{16}$ cm^{-3} obtained from the numerical calculation.

At the lower gas pressure of 0.25 bar (Fig. 3), the decay of [H] concentration is seen to be significantly slower, and to have a weaker dependence upon the cooling time τ. This can also be observed in Table 1, which shows the time θ required for the atomic hydrogen concentration to decay to 1/10 of its initial value at t = 0.

The influence of gas pressure on the decay of atomic hydrogen in the cooling gas column is further illustrated in Figs. 4 and 5 for two different characteristic times τ = 10 μs and τ = 300 μs, respectively.

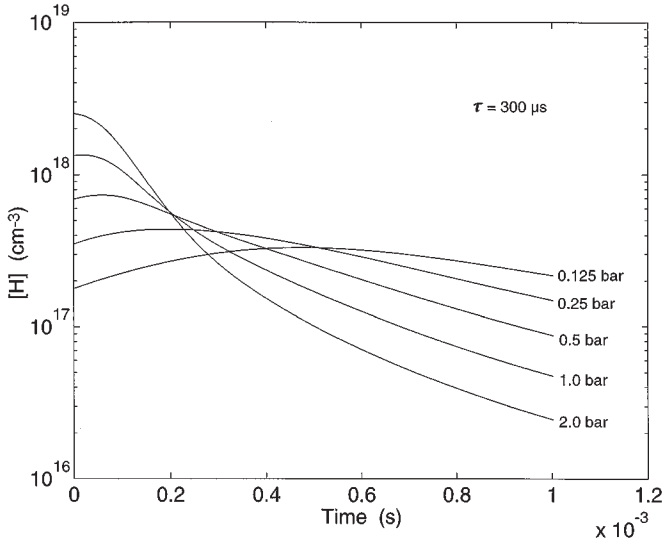
Fig. 5. Calculated temporal evolutions of the atomic hydrogen concentration for a characteristic cooling time τ = 300 μs, and for different gas pressures.



Conclusions

In summary, we have presented numerical solutions of a differential equation describing the temporal evolution of the concentration of atomic radicals [H] in a cooling hydrogen gas column. Even if the initial concentration, assumed to correspond to thermodynamic equilibrium at the temperature 5000 K, were to increase with gas pressure, this was found to be rapidly compensated by the increasing rate of three-body recombination. A further advantage of operating the chemical reactor at lower pressures was that this would make the decay of [H] radicals become less dependent upon the cooling rate of the gas.

While this study was made for a pure hydrogen gas where reaction rates for atomic recombination and molecular dissociation are well known, it is reasonable to assume that the general conclusions would also apply to other gases and gas mixtures. This would be of importance in many practical applications, where chemically active radicals are either injected into the reaction zone, or generated directly in this zone by an electrical discharge.

Preparation, ^{1}H and ^{13}C NMR, and ab initio/IGLO study of mono-*O*-protonated deltic acid and theoretical investigation of di-, tri-, and tetra-*O*-protonated deltic acids[1]

G.K. Surya Prakash, Golam Rasul, George A. Olah, Ronghua Liu, and Thomas T. Tidwell

Abstract: The hitherto elusive mono-*O*-protonated deltic acid $C_3O_3H_3^+$ was prepared by protolysis of di-*tert*-butoxy deltate in FSO_3H–SO_2ClF and in FSO_3H:SbF_5 (Magic Acid; 1:1 molar solution) in SO_2ClF as solvent at –78°C and was characterized by ^{1}H and ^{13}C NMR spectroscopy. The structure and NMR chemical shifts were also calculated by the ab initio/IGLO method. No NMR evidence was found for persistent di-*O*-protonated deltic acid under these conditions, although a limited equilibrium with the mono-*O*-protonated species can be involved. Di-, tri-, and tetra-*O*-protonated deltic acids were also studied by ab initio/IGLO method.

Key words: protonated deltic acid, aromaticity, superacids, NMR spectroscopy, ab initio and IGLO calculations.

Résumé : Procédant à –78°C, par protolyse du deltate de di-*tert*-butyle par du FSO_3H/SO_2ClF et dans FSO_3H/SbF_5 (Acide Magique; solution 1:1 molaire) dans du SO_2ClF comme solvant, on a préparé l'acide deltique mono-*O*-protoné (qui s'était avéré insaisissable jusqu'à maintenant) et on l'a caractérisé par spectroscopie RMN du ^{1}H et du ^{13}C. On a aussi calculé la structure et les déplacements chimiques en RMN à l'aide de la méthode ab initio/« IGLO ». La RMN n'a pas permis de déceler la présence soutenue d'acide deltique di-*O*-protoné même s'il est possible qu'un équilibre limité avec l'espèce mono-*O*-protonée soit possible. Faisant appel à la méthode ab initio/IGLO, on a aussi étudié les acides deltiques di-, tri- et tétra-*O*-protonés.

Mots clés : acide deltique protoné, aromaticité, superacides, spectroscopie RMN, calculs ab initio et IGLO.

[Traduit par la Rédaction]

Introduction

Although four-, five-, and six-membered cyclic protonated oxocarbons (2), di-*O*-protonated squaric acid (3,4-dihydroxy-3-cyclobutene-1,2-dione) **i**, tri-*O*-protonated croconic acid (4,5-dihydroxy-4-cyclopentene-1,2,3-trione) **ii**, and tetra-*O*-protonated rhodizonic acid (5,6-dihydroxy-5-cyclohexene-1,2,3,4-tetraone) **iii**, respectively, have been prepared and spectroscopically characterized (3) under long-lived ion conditions in solutions, the related three-membered cyclic mono-*O*-protonated deltic acid (2,3-dihydroxy-2-cyclopropenone) **iv** has never been observed. Ions **i**–**iv** are formally Hückeloid aromatic systems with significant delocalization of positive charges from the oxygen into the ring. Mono-*O*-protonated deltic **iv** acid is in fact a trihydroxy stabilized cyclopropenium ion, the smallest aromatic hydrocarbon.

Lien and Hopkinson (4) calculated the structures and energeties of mono-*O*-protonated deltic acid **iv** and its isomer trihydroxy propargyl cation **v** at the HF/6-31G*//HF/3-21G level. The OH substituents were found to be more stabilizing in the propargyl cation than in the cyclopropenium cation. This suggests that electron-donating OH substituents are relatively less effective at delocalization of the positive charge in the cyclopropenium ion (4).

We report now the preparation and ^{1}H and ^{13}C NMR spectroscopic characterization of mono-*O*-protonated deltic acid as a long-lived ion in superacid media and the study of its structure by theoretical methods.

Results and discussions

Protolytic ionization of di-*tert*-butoxy deltate (prepared as described (5)) in five-fold excess of FSO_3H:SbF_5 (magic acid; 1:1 molar solution) in SO_2ClF as solvent at –78°C resulted in the formation of mono-*O*-protonated deltic acid **1**. The 75 MHz ^{13}C NMR spectrum of the solution at –78°C

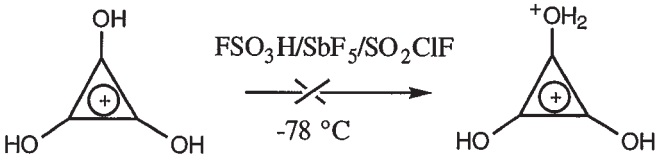
clearly showed the formation of *tert*-butyl cation $(CH_3)_3C^+$ at δ ^{13}C 334.6 (C^+, s) and 47.0 (CH_3, *q*), as well as a singlet at δ ^{13}C 128.7. We assign the peak at δ ^{13}C 128.7 to mono-*O*-protonated deltic acid. The 300 MHz ^{1}H NMR spectrum of the solution at –78°C exhibited a peak at δ ^{1}H 7.86 (*s*), besides the peaks resulting from the acid system (FSO_3H:SbF_5 (δ ^{1}H 12.91), H_3O^+ (δ ^{1}H 9.66)) and $(CH_3)_3C^+$ (δ ^{1}H 3.00). The magnetic equivalence of the three protons is in accordance with the C_{3h} symmetrical structure. When substantially less acidic FSO_3H (H_0 = –15) (6) was used in the place of Magic Acid (FSO_3H:SbF_5, H_0 = –22) (6) at –78°C with SO_2ClF as solvent, a slightly deshielded peak at δ ^{13}C 128.9 due to the mono-*O*-protonated deltic acid was observed.



No persistent static di-*O*-protonated deltic acid, however, was observed even in stronger magic acid (compared to FSO_3H). The slightly shielded (by about 0.2 ppm) carbon peak in magic acid indicates either a proton exchange process occurring at the NMR time scale between the mono-*O*-protonated deltic acid and the acid or more probably an exchange involving a small equilibrium concentration of di-*O*-protonated deltic acid (or protosolvated dication) with the monocation.

The δ ^{13}C 128.7 of mono-*O*-protonated deltic acid is about 54.7, 45.7, and 35.7 ppm, respectively, shielded compared to that of di-*O*-protonated squaric acid **i**, tri-*O*-protonated croconic acid **ii,** and tetra-*O*-protonated rhodizonic acid **iii** (3).

To substantiate the observed experimental results, we have calculated the structures and ^{13}C NMR chemical shifts of mono-*O*-protonated deltic acid. The structures were fully optimized (Fig. 1) at the ab initio correlated MP2/6-31G* level. Consistent with the experimental results, the C_{3h} symmetry structure **1**, with C—C and C—O bond lengths of 1.389 and 1.301 Å, respectively, was found to be the global minimum for mono-*O*-protonated deltic acid. For comparison, the structures of deltic acid **2** and cyclopropenium ion **3** were also calculated. A calculated C_{2v} structure for **2** has also been reported (7), and resembles our C_s structure. The C—C bond distance of **1** (1.389 Å) is 0.031 Å shorter than the average of the three C—C bond distances of **2** (1.420 Å) and is 0.020 Å longer than that of cyclopropenium ion **3** (1.369 Å). The calculated bond distance of **1** and **2** (C_s) may be compared to those of **2** (C_{2v}) obtained by X-ray analysis (8). Interestingly the structure of crystalline **2**, which is strongly hydrogen bonded, is much closer to that of **1** than of **2** (in the idealized gas phase).

The ^{13}C NMR chemical shifts of **1**–**3** were calculated by the IGLO/II method (9) using the MP2/6-31G* optimized geometries (i.e., at the IGLO/II//MP2/6-31G* level) (Table 1). The IGLO calculated δ ^{13}C shift of **1** is 133.3, deviating by only 4.6 ppm from the experimentally observed value. We have now also calculated the ^{13}C NMR chemical shifts of **i**–**iii** at the same IGLO/II//MP2/6-31G* level and plotted in Fig. 2. The IGLO calculated chemical shifts of the protonated oxocarbons, even though they refer to the idealized gas phase, are in good agreement with the experimentally obtained values.

Diprotonated deltic acid **4** was calculated at the MP2/6-31G* level. The relatively long C1—O and C2—C3 bond lengths (1.420 and 1.451 Å) (Fig. 3) and short C2—O and C3—O bond lengths (1.266 and 1.267 Å) in ion **4** compared

4 (C_s) **5** (C_s) **6** (D_{3h})

for tri- and tetra-*O*-protonated deltic acids, respectively. Protonation of **4** to form **5** and protonation of **5** to form **6** were calculated to be endothermic by 67.6 and 173.4 kcal/mol, respectively. Calculated structures of **5** and **6** are given in Fig. 1, and the calculated ^{13}C NMR chemical shift are listed in Table 1.

Experimental part

Preparation of di-*tert*-butoxy deltic acid

The di-*tert*-butoxy deltic acid was prepared according to the reported method (5).

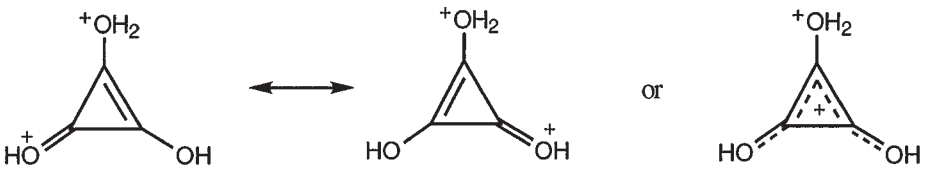
Study of protonation of di-*tert*-butoxy deltic acid

Di-*tert*-butoxy deltate (~30 mg) was dissolved in approximately 0.5 mL of SO_2ClF in a 5 mm NMR tube and cooled to –78°C in a dry ice/acetone bath. Approximately 1.5 mL of 50% v/v solution of FSO_3H:SbF_5 (1:1 molar solution), FSO_3H in SO_2ClF, was added to the solution at –78°C. The ensuing mixture was vigorously stirred (Vortex stirrer) under periodic cooling prior to transfer to a precooled NMR probe.

^1H and ^{13}C NMR spectra were obtained on Varian Associates Model Unity 300 spectrometer equipped with a 5 mm variable temperature broadband probe at 300 and 75.4 MHz, respectively. ^1H and ^{13}C NMR spectra were obtained with respect to TMS by using an acetone-d_6 capillary as external standard.

Calculational methods, basis set, and geometry

Ab initio calculations were performed with the Gaussian 94 (10*a*) package of programs. Optimized geometries were obtained at the MP2/6-31G* level (11). Improved energies were obtained by single-point energy calculations at the MP4(SDTQ)/6-311G*//MP2/6-31G* level. Vibrational fre-



© 1999 NRC Canada

quencies at the MP2/6-31G*//MP2/6-31G* level were used to characterize stationary points as minima or transition state and to evaluate zero-point vibrational energies (ZPE) which were scaled by a factor of 0.93 (10*b*). Protonation energies were calculated at the MP4(SDTQ)/6-311G*//MP2/6-31G* + ZPE level. IGLO calculations were performed according to the reported method (9) at IGLO II levels using MP2/6-31G* geometries. Huzinaga (12) Gaussian lobes were used as follows. Basis II: C or O: 9s 5p 1d contracted to [51 111, 2111, 1]; d exponent: 1.0; H: 5s 1p contracted to [311, 1]; p exponent: 0.70. The calculated ^{13}C NMR chemical shifts (δ values) are referenced to TMS.

Conclusions

Mono-*O*-protonated deltic acid was prepared by protolysis of *di-tert*-butoxy deltate in FSO_3H/SO_2ClF and in $FSO_3H:SbF_5$ (magic acid; 1:1 molar solution) in SO_2ClF as solvent at –78°C and studied by ^1H and ^{13}C NMR spectroscopy and by ab initio calculations. No NMR evidence was found for the static diprotonated deltic acid under these conditions, although in highly acidic media the exchanging system may involve the dication in some limited equilibrium. The NMR chemical shifts were evaluated using the IGLO method and are compared to the experimental values. Structures and ^{13}C NMR chemical shifts of tri- and tetra-*O*-protonated deltic acids were also calculated.

The 4,4′-dimethoxytrityl carbenium ion by ionization of 4,4′-dimethoxytrityl alcohol in acetonitrile – aqueous perchloric and nitric acids containing electrolytes: kinetics, equilibria, and ion-pair formation

Juan Crugeiras and Howard Maskill

Abstract: We have studied the equilibration shown in eq. [3] of 4,4′-dimethoxytrityl alcohol in aqueous perchloric and nitric acids containing low proportions of acetonitrile using stopped-flow kinetics techniques. The rate constants for the overall progress to equilibrium, k_{obs}, have been resolved into forward and reverse components using the equilibrium UV absorbance and a value for the molar absorptivity of the 4,4′-dimethoxytrityl carbenium ion determined in concentrated aqueous perchloric acid. The forward reaction (rate constant k_f) is first order in both the alcohol and the acid concentrations; the reverse reaction (rate constant k_r) is pseudo first order with respect to the carbocation. At constant hydronium ion concentration, the forward rate constant increases linearly with the concentration of electrolyte, whereas the reverse rate constant decreases. These effects depend upon the nature of the anion, but not the cation, and are not ionic strength effects. At constant anion concentrations, k_f in both acids, and k_r in perchloric acid, are independent of hydronium ion concentration; however, k_r decreases with increasing hydronium ion concentration at constant nitrate concentration. At nonconstant ionic strength, changes in k_f and k_r observed in increasing concentrations of perchloric acid are attributable wholly to changes in perchlorate concentration. A mechanism is proposed which involves pre-equilibrium protonation of the alcohol, heterolysis of the protonated alcohol to give a 4,4′-dimethoxytrityl carbenium ion – water ion–molecule pair, then conversion of this into a dissociated carbenium ion in equilibrium with ion pairs. To account for the strong effects of perchlorate and nitrate upon the forward rate constants, it is proposed that these anions provide additional reaction channels from the ion–molecule pair. However, we find no evidence of acid catalysis in the reaction of the ion–molecule pair (in contrast to our finding for the reaction of the corresponding ion–molecule pair formed from dimethoxytritylamine in acidic media). Some of the elementary rate and equilibrium constants of the proposed mechanism have been evaluated.

Key words: trityl, carbenium ion, stopped-flow, ion pair, ion–molecule pair.

Résumé : Faisant appel à des techniques de cinétique à flux stoppé, on a étudié l'équilibre (représenté par l'équation 3) de l'alcool 4,4′-diméthoxytritylique dans les acides perchlorique et nitrique contenant de faibles quantités d'acétonitrile. Utilisant l'absorbance UV à l'équilibre et une valeur pour l'absorptivité molaire de l'ion 4,4′-diméthoxytritylcarbénium déterminé en solution aqueuse concentrée d'acide perchlorique, on a résolu les constantes de vitesse globales de réaction pour le déplacement vers l'équilibre, k_{obs}, en deux composantes, l'une pour réaction vers l'avant et l'autre pour l'inverse. La réaction vers l'avant (constante de vitesse k_a) est du premier ordre en concentrations tant d'alcool que d'acide; la réaction inverse (constante de vitesse k_i) est de pseudo premier ordre par rapport au carbocation. À concentration d'ion hydronium constante, la constante de vitesse vers l'avant augmente d'une façon linéaire avec la concentration de l'électrolyte alors que la constante de vitesse inverse diminue. Ces effets dépendent de la nature de l'anion, mais pas de celle du cation, et elles ne sont pas des effets de la force ionique. À des concentrations d'anion constantes, les valeurs de k_a dans les deux acides et les valeurs de k_i dans l'acide perchlorique sont indépendantes de la concentration en ion hydronium; toutefois, à concentration constante de nitrate, la valeur de k_i diminue avec une augmentation de la concentration en ion hydronium. À des forces ioniques qui ne sont pas constantes, on observe des changements dans les valeurs de k_a et de k_i lorsqu'on augmente la concentration de l'acide perchlorique; ces changements sont entièrement attribués à des changements dans la concentration du

perchlorate. On propose un mécanisme qui implique un prééquilibre, protonation de l'alcool, une hétérolyse de l'alcool protoné pour donner une paire d'ion 4,4′-diméthytritycarbénium – molécule d'eau et finalement une transformation de celle-ci en un ion carbénium dissocié en équilibre avec des paires d'ions. Afin d'expliquer les effets importants des ions perchlorate et nitrate sur les constantes de vitesse vers l'avant, on suggère que ces anions fournissent des moyens additionnels de réaction pour la paire ion–molécule. Toutefois, on n'a pas mis en évidence de catalyse acide dans la réaction de la paire ion–molécule (en opposition avec les résultats que nous avons obtenus antérieurement pour la réaction de la paire ion-molécule correspondante formée à partir de la diméthoxytritylamine en milieu acide). On a évalué quelques-unes des constantes de vitesse élémentaire et d'équilibre du mécanisme proposé.

Mots clés : trityle, ion carbénium, flux stoppé, paire d'ion, paire ion–molécule.

[Traduit par la Rédaction]

Introduction

The kinetics and equilibria of ionization of substituted triphenylmethanols (substituted trityl alcohols) have been extensively studied, partly in connection with the development of the H_R acidity function (1, 2), and partly due to the importance of substituted trityl as a protecting group in organic synthesis (3). The H_R acidity function is based on the ionization equilibria of triarylmethanols, eq. [1], and equilibrium constants, K_{R^+}, for these reactions are given by eq. [2].

[1] $$Ar_3C^+ + H_2O \leftrightarrow Ar_3COH + H^+$$

[2] $$K_{R^+} = \frac{a_{Ar_3COH}\, a_{H^+}}{a_{Ar_3C^+}\, a_{H_2O}}$$

In a kinetic study of the ionization reaction of 4,4′,4′′-trimethoxytrityl alcohol (TMTOH) under acidic conditions, Postle and Wyatt (4) found that the addition of salts and nonelectrolytes has appreciable effects upon the forward and reverse rate constants of the reaction in eq. [1]. These effects were explained qualitatively in terms of the change in the activity of the water, changes in the activity coefficients of the different solutes involved in the equilibrium, and the formation of ion pairs. The effects are especially large in the case of perchlorate, an electrolyte regarded as inert in many contexts, but with an appreciable effect upon the ionization of neutral substrates where a delocalized positive charge is developed in a carbon residue in the transition state (5). Wyatt (6) proposed a value of 1.3 $dm^3\ mol^{-1}$ for the equilibrium constant for the formation of the ion pair $TMT^+ClO_4^-$ from dissociated ions in aqueous solution in order to bring the derived H_R values for aqueous perchloric acid onto the same water activity scale as that for aqueous sulfuric acid.

In other contexts, the formation of covalent organic perchlorates has been proposed in some reactions with carbocation intermediates (7). However, triarylmethyl perchlorates are fully ionic in the crystalline state and in solution in solvents of even low dielectric constant such as chloroform or dichloromethane (8).

In the investigation reported here, we have measured the overall rates of equilibration of 4,4′-dimethoxytrityl alcohol (DMTOH) in aqueous perchloric and aqueous nitric acid. From these rate constants and UV measurements at equilibrium, we have obtained experimental values for forward and reverse rate constants for the equilibrium reaction expressed as eq. [3].

[3] $$ROH + H_3O^+ \underset{k_r}{\overset{k_f}{\leftrightarrow}} R^+ + 2H_2O$$

Under the dilute acidic conditions of our investigations using the 4,4′-dimethoxytrityl system, activity coefficient effects are expected to be small and to cancel out. Consequently, thermodynamic equilibrium constants may be replaced by practical versions (9) in which activities of dilute solutes are replaced by molar concentrations, and water is referred to the mole fraction activity scale and given the value of unity.

This investigation is closely related to our prior study of the dimethoxytrityl carbenium ion generated by deamination of dimethoxytritylamine (10). In that study, we identified specific acid catalysis in the reaction of the substituted tritylammonium cation, and invoked the dimethoxytrityl carbenium ion – ammonia ion–molecule pair as a kinetically significant intermediate.

Experimental

Reagents

Aqueous solutions of nitric and perchloric acid were prepared from the commercial reagents (Merck 65 and 60%, respectively) and glass distilled water, and were titrated against solutions of sodium hydroxide previously standardized using standard solutions of potassium hydrogen phthalate. Electrolyte solutions were made from the commercial products of the highest purity available (Merck). 4,4′-Dimethoxytrityl alcohol was available from previous studies at Newcastle (10, 11).

Kinetics experiments

The rates of ionization of DMTOH were measured using an Applied Photophysics DX.17MV sequential stopped-flow spectrofluorimeter with an optical path length of 1 cm. One of the syringes of the stopped-flow device was filled with an aqueous solution of DMTOH (with 4% of CH_3CN to avoid solubility problems), and the aqueous acid ($HClO_4$ or HNO_3 with an appropriate concentration of $NaClO_4$, $Ba(ClO_4)_2$, or $NaNO_3$) was in the other syringe. The temperature of the solutions in the syringes and cell of the stopped-flow instrument was kept constant (25.0 ± 0.1°C) by circulating water from a thermostatted bath.

Spectra in Fig. 1 of the reaction mixture recorded at different times show the appearance of two absorption bands corresponding to the 4,4′-dimethoxytrityl carbocation. The reaction was studied by following the change with time in absorbance at the absorption maximum of the carbocation at 495 nm. The observed pseudo first-order rate constants (k_{obs}) were calculated by fitting the absorbance–time data to the integrated first-order rate law using a nonlinear regression

analysis program supplied by Applied Photophysics. The k_{obs} results are average values of 7–10 kinetic runs, and treatment of errors was by standard statistical procedures (12).

Results

Influence of electrolyte concentration

The influence of the electrolyte concentration upon the overall reaction rate constant (k_{obs}) was studied at 0.2 mol dm^{-3} perchloric acid by changing the concentration of sodium perchlorate, and at 0.2 mol dm^{-3} nitric acid by changing the concentration of sodium nitrate, but keeping the other reaction conditions constant in each series. We observe in Table 1 appreciable decreases in k_{obs} as the salt concentration increases for both acids. To study the effect of the charge on the cation of the electrolyte on the reaction rate, the influence of barium perchlorate concentration in perchloric acid was also investigated. These results are also included in Table 1 and show the same effect.

Influence of hydronium ion concentration

The effect of hydronium ion concentration upon the overall reaction rate constant (k_{obs}) was studied at a constant ionic strength of 1.0 mol dm^{-3} by changing the concentration of both perchloric acid (using sodium perchlorate to maintain constant ionic strength) and nitric acid (using sodium nitrate). The results obtained in these experiments are shown in Table 2. There is a distinct increase in k_{obs} with increasing perchloric acid concentration, but only a small increase for nitric acid. Analogous experiments were carried out using perchloric acid at nonconstant ionic strength; an appreciable decrease in k_{obs} with increasing acid concentration is now evident from the results in Table 3.

Kinetic analysis

The overall reaction may be described by the equilibrium in eq. [3] above where R stands for 4,4′-dimethoxytrityl, and R^+ does not imply any particular state of solvation or association. The rate equation for equilibration in terms of the changing concentration of carbenium ion is given in eq. [4].

$$[4] \qquad d[R^+]/dt = k_f[H_3O^+][ROH] - k_r[R^+]$$

Taking into account that

$$[ROH]_0 = [ROH] + [R^+]$$

where $[ROH]_0$ = the initial concentration of alcohol, and assuming that the only species absorbing at 495 nm is the carbocation ($A_{495} = [R^+]\varepsilon_{495}$ where A_{495} is the absorbance in the 1 cm cell and ε_{495} is the molar absorptivity (extinction coefficient) of the carbocation at 495 nm), then

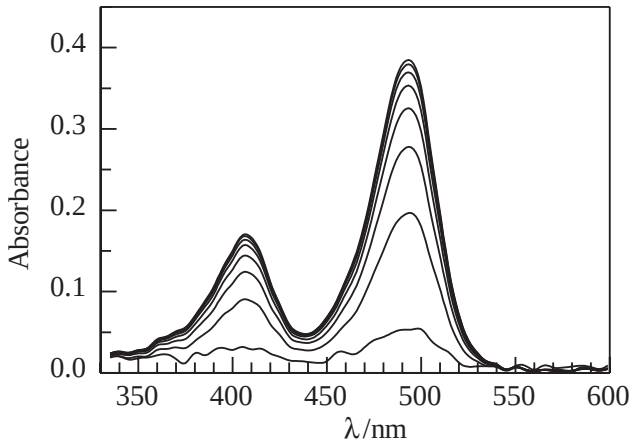
$$dA_{495}/dt = \varepsilon_{495}d[R^+]/dt$$

hence,

$$[5] \qquad dA_{495}/dt = k_f[H_3O^+][ROH]_0\varepsilon_{495} - (k_f[H_3O^+] + k_r)A_{495}$$

Solution of this differential equation gives eq. [6]:

Fig. 1. Spectra of the reaction mixture at different times. $[DMTOH]_0 = 3.3 \times 10^{-5}$ mol dm^{-3}, $[HClO_4] = 0.5$ mol dm^{-3}, ionic strength = 1.0 mol dm^{-3} ($NaClO_4$), 25°C, time intervals = 0.01 s.



$$[6] \qquad A_{495} = \frac{k_f[H_3O^+][ROH]_0\varepsilon_{495}}{k_f[H_3O^+] + k_r}[1 - e^{-(k_f[H_3O^+]+k_r)t}]$$

Comparison of eq. [6] with eq. [7], the integrated first-order rate equation used to fit the experimental absorbance–time data,

$$[7] \qquad A_{495} = A_\infty - \Delta A e^{-k_{obs}t}$$

in which $\Delta A = A_\infty - A_0$, A_∞ is the absorbance at time = infinity, and A_0 (the absorbance at time = 0) is generally zero, leads to the relationships in eqs. [8] and [9] between the single experimental rate constant for equilibration, k_{obs}, the observed overall change in absorbance associated with the attainment of equilibrium, ΔA, and the attributed forward and reverse rate constants of eq. [3].

$$[8] \qquad k_f = \frac{\Delta A k_{obs}}{[H_3O^+][ROH]_0\varepsilon_{495nm}}$$

$$[9] \qquad k_r = k_{obs} - k_f[H_3O^+]$$

Taking the value for ε_{495} of DMT^+ in 70% perchloric acid obtained in this work (10) of 7×10^4 dm^3 mol^{-1} cm^{-1}, we obtain the results for k_f and k_r at different electrolyte concentrations summarized in Table 4. Clearly, the forward reaction rate constants, k_f, increase with the increasing electrolyte concentration, whilst the reverse reaction rate constants, k_r, decrease. However, the magnitudes of these effects depend upon the nature of the anion, whereas the identity of the cation in perchloric acid seems to be irrelevant.

The influence of perchloric and nitric acid concentrations on the forward and reverse rate constants k_f and k_r at constant ionic strength (1.0 mol dm^{-3}) were also investigated using eqs. [8] and [9], and results are shown in Table 5. We observe that, within experimental error, k_f remains constant with increasing concentrations of both acids, as does k_r for perchloric acid. In contrast, k_r decreases appreciably with increasing concentrations of nitric acid. Results for perchloric acid at nonconstant ionic strength are shown in Table 6, and we observe a modest increase in k_f and a pronounced decrease in k_r as the acid concentration increases.

Discussion

By analogy with the mechanism proposed for the deamination of 4,4′-dimethoxytritylammonium ions (10, 11), we propose the mechanism shown in Scheme 1 for the reaction of DMT alcohol.

In this mechanism, step (*i*) is the reversible protonation of the alcohol. The protonated alcohol then undergoes heterolysis in step (*ii*) to yield an ion–molecule pair, i.e., a discrete intermediate comprising a carbenium ion which has a special relationship with a single water molecule. Since the single water molecule of this ion–molecule pair is identical with the water molecules of the solvent (except regarding its unique relationship with the carbenium ion), this intermediate is intrinsically different from that implicated in the corresponding deamination reaction (10). In the latter, the molecule of the ion–molecule pair (NH_3) is different from the solvent molecules. Thus, the ion–molecule pair in deamination can undergo a diffusional separation, which is followed

by protonation of the ammonia under the acidic conditions, and full solvation of both cations by water molecules. In the corresponding reaction of the ion–molecule pair in Scheme 1, i.e., step (*iii*), the change is in the number of water molecules immediately around the carbenium ion and in the nature of the relationship of each of them with the carbenium ion. This step, therefore, rather than being a dissociation or diffusion apart, will involve the loosening of one water and the addition of further loosely held solvating water molecules around the cation. Two additional steps are included in Scheme 1 to accommodate the salt effects observed experimentally. Step (*iv*) is the formation of an ion pair from the protonated alcohol and the common anion of the acid and the salt present (we denote all types of ion pairs by $R^+||X^-$), and step (*v*) is the equilibrium formation of ion pairs from dissociated anion and carbenium ion regardless of their provenance. In principle, an additional step to include collapse of the ion pair to form a covalent compound, R-X, could be added to Scheme 1 (7). However, trityl perchlorate is fully ionic in the crystal state and in solvents of low dielectric constant such as chloroform or dichloromethane (8), and we found no spectroscopic evidence (^{13}C and ^{35}Cl NMR, IR, and UV-vis) for the existence of covalent compounds DMT-X when X = $OClO_3$ or Cl (using hydrochloric acid). Consequently, we omit this extra step.

Several approximations are now required in order to relate the experimental rate constants k_f and k_r to the elementary rate constants of the mechanism in Scheme 1. First, we assume that protonation of the alcohol is rapidly reversible, i.e., step (*i*) may be treated as a pre-equilibrium with equilibrium constant K_1 (equal to k_1/k_{-1}). Secondly, we assume that the steady-state approximation may be applied to the ion–molecule pair, $R^+\cdot OH_2$, in steps (*ii*) and (*iii*). Thirdly, we assume that the molar absorptivity of the ion R^+ is the same regardless of its solvolytic environment (13), i.e., ε_{495} for R^+ = ε_{495} for $R^+||X^-$, which we denote simply by ε_{495}, and hence $A_{495} = ([R^+] + [R^+||X^-])\varepsilon_{495}$. (Although in some cases there are appreciable changes in the spectra of carbocations on increasing the concentrations of added perchlorate (14), in our reactions the position of the main absorption maximum in spectra of solutions of the carbocation is essentially the same on changing the concentration of electrolyte from 0.5 to 3.5 mol dm^{-3}.) Finally, we assume that step (*v*) of Scheme 1 constitutes a postequilibrium with equilibrium constant K_5 (equal to k_5/k_{-5}), i.e., $[R^+||X^-] = K_5[R^+][X^-]$ and that maintenance of this equilibrium does not affect the overall rate of equilibration (13). With no further assumptions, these approximations allow derivation of the following equation:

Scheme 1.

$$\text{(i)}\quad H_3O^+ + ROH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ROH_2^+ + H_2O$$

$$\text{(ii)}\quad ROH_2^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} R^+\cdot OH_2$$

$$\text{(iii)}\quad R^+\cdot OH_2 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} R^+ + H_2O$$

$$\text{(iv)}\quad ROH_2^+ + X^- \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} R^+||X^- + H_2O$$

$$\text{(v)}\quad R^+ + X^- \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} R^+||X^-$$

$$\frac{dA_{495}}{dt} = \frac{K_1(k_2k_3 + (k_{-2} + k_3)k_4[X^-])\varepsilon_{495}[ROH]_0[H_3O^+]}{(k_{-2} + k_3)(1 + K_1[H_3O^+])} - \left[\frac{K_1(k_2k_3 + (k_{-2} + k_3)k_4[X^-])[H_3O^+]}{(k_{-2} + k_3)(1 + K_1[H_3O^+])} + \frac{(k_{-2} + k_3)k_{-4}K_5[X^-] + k_{-2}k_{-3}}{(k_{-2} + k_3)(1 + K_5[X^-])}\right]A_{495}$$

Noting that K_1/dm^3 mol^{-1} will be less than 10^{-2} and possibly as low as 10^{-5} (15), $(1 + K_1[H_3O^+])$ will be approximately unity at the hydronium ion concentrations involved, so the above may be rewritten as eq. [10].

$$[10]\quad \frac{dA_{495}}{dt} = \frac{K_1(k_2k_3 + (k_{-2} + k_3)k_4[X^-])\varepsilon_{495}[ROH]_0[H_3O^+]}{(k_{-2} + k_3)} - \left[\frac{K_1(k_2k_3 + (k_{-2} + k_3)k_4[X^-])[H_3O^+]}{(k_{-2} + k_3)} + \frac{(k_{-2} + k_3)k_{-4}K_5[X^-] + k_{-2}k_{-3}}{(k_{-2} + k_3)(1 + K_5[X^-])}\right]A_{495}$$

Comparison of eq. [10] with eq. [5] now leads to eqs. [11] and [12] as the relationships for k_f and k_r in terms of the elementary rate constants in the mechanism of Scheme 1.

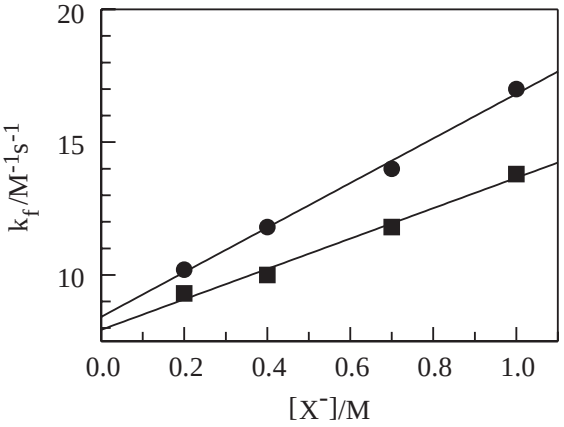
$$[11]\quad k_f = \frac{K_1k_2k_{-3}}{(k_{-2} + k_3)} + K_1k_4[X^-]$$

$$[12]\quad k_r = \frac{k_{-2}k_{-3}}{(k_{-2} + k_3)(1 + K_5[X^-])} + \frac{k_{-4}K_5[X^-]}{(1 + K_5[X^-])}$$

The linearity and finite intercept in the plot of k_f against $[X^-]$ shown in Fig. 2, using data from Table 4, provide experimental support for the validity of the mechanism in Scheme 1 and the derivations based upon it. Assuming that the collapse of the ion–molecule pair, $R^+\cdot OH_2$, back to the protonated alcohol is much faster than its further conversion to the solvated dissociated carbenium ion, i.e., $k_{-2} >> k_3$,

© 1999 NRC Canada

Fig. 2. Influence of anion concentration upon the forward reaction rate constant k_f at constant acid concentration (closed circles for perchlorate and closed squares for nitrate).



eq. [11] gives eq. [13] where $K_2 = k_2/k_{-2}$ and values for $K_1K_2k_3$ and K_1k_4 obtained by linear regression of k_f against

[13] $$k_f = K_1K_2k_3 + K_1k_4[X^-]$$

$[X^-]$ using the data of Table 4 are summarized in the columns 2 and 3 of Table 7. From column 2, we see that the product $K_1K_2k_3$ is, within experimental error, independent of the nature of the electrolyte as required by the mechanism. Furthermore, since virtually identical correlations are obtained for sodium and barium perchlorate, we conclude that k_f in these solutions is principally dependent upon concentration of perchlorate and not the ionic strength.

The same approximation ($k_{-2} >> k_3$,) applied to eq. [12] for the reverse rate constant, k_r, yields eq. [14].

[14] $$k_r = \frac{k_{-3} + k_{-4}K_5[X^-]}{(1 + K_5[X^-])}$$

Nonlinear regression analysis of k_r against $[X^-]$ using eq. [14] shows that $k_{-4}K_5$ is very much smaller than k_{-3}, so the second term of the numerator in eq. [14] may be neglected. By rearranging the simplified eq. [14], we obtain the linear relationship between $1/k_r$ and $[X^-]$ shown in eq. [15].

[15] $$\frac{1}{k_r} = \frac{1}{k_{-3}} + \frac{K_5}{k_{-3}}[X^-]$$

By plotting values of $1/k_r$ against the total concentration of the anion using data from Table 4, we get straight lines shown in Fig. 3 with a common intercept (same value of k_{-3}) but different gradients (different K_5 values according to the nature of X^-). These plots validate the approximations introduced and allow determination of k_{-3} and K_5, which are included in columns 4 and 5 of Table 7. The average value of $k_{-3} = 118\ s^{-1}$ compares with earlier results for the *overall reverse* rate constant k_r of eq. [3], i.e., the *overall forward* rate constant of eq. [1] when electrolyte effects are absent of 95 s^{-1} for reaction in water at 25°C (16), and 86 s^{-1} for reaction in 2:1 aqueous acetonitrile at 20°C (17). The average result of $K_5 = 1.45\ dm^3\ mol^{-1}$ for $X^- = ClO_4^-$ in aqueous solution compares very well with the value of 1.3 proposed by Wyatt (6) and the approximate result of 2.5 from our deamination studies (10). As expected, it is much smaller than the value of 795 $dm^3\ mol^{-1}$ reported for unsubstituted trityl perchlorate in the less polar 1,2-dichloroethane (8). The smaller value of $K_5 = 0.67\ dm^3\ mol^{-1}$ for $X^- = NO_3^-$ in water has not previously been measured as far as we are aware.

As we now have values for k_{-3} and $K_1K_2k_3$ (see Table 7), and noting that, according to the proposed mechanism of Scheme 1, $K_{R^+} = k_{-3}/K_1K_2k_3$, we can obtain practical values for the equilibrium constant K_{R^+}, which are shown in the penultimate column of Table 7. The average value of $K_{R^+} = 14.4 \pm 0.4$ ($pK_{R^+} = -1.16$) is in good agreement with literature results (1), which adds further support for the mechanism of Scheme 1 and the derivations arising from it.

Step (*iv*) of Scheme 1 could be considered either in terms of a nucleophilic attack by perchlorate anion on the protonated alcohol, water being the nucleofuge, or as a stabilization by the anion of the positive charge of the incipient carbocation in the heterolytic transition state. Sodium perchlorate is an electrolyte that has been used in kinetics and electrochemistry to control ionic strength. The term "inert electrolyte" has been used in many cases for this and other compounds used to keep ionic strength constant. But despite its low reactivity in general, there are isolated examples in the literature where perchlorate reacts with electrophiles faster than nucleophiles such as chloride (7). In such cases, and in our proposed mechanism, perchlorate acts by stabilizing the developing positive charge of nascent large nonpolarizing cations, especially those in which the positive charge is highly delocalized. From the results in column 3 of Table 7, and taking $K_1/dm^3\ mol^{-1} = 2.5 \times 10^{-3}$ (15), we calculate the values for k_4 shown in the final column of Table 7; perchlorate is more effective than nitrate. However, in spite of serious efforts, we found no spectroscopic evidence for the formation of fully covalent $DMTClO_4$ (see above).

Influence of hydronium ion concentration

As seen in Table 5, k_f is independent of the acid concentration as required by the mechanism in Scheme 1, which does not include a channel involving acid-catalyzed forward reaction of the ion–molecule pair. In this respect, therefore, the reaction of DMT alcohol is significantly different from the reaction of DMT amine (10); the latter includes a reaction channel involving acid-catalyzed separation of the cation–molecule pair. The average results obtained from Table 5 ($k_f = 17.1\ dm^3\ mol^{-1}\ s^{-1}$ for perchloric acid and 14.1 for nitric) at total electrolyte concentrations of 1 mol dm^{-3} are in excellent agreement with the ones obtained from the study of the influence of electrolyte concentration for total electrolyte concentration equal to 1.0 mol dm^{-3} and constant hydronium ion concentration (17.1 and 13.8 $dm^3\ mol^{-1}\ s^{-1}$, respectively) shown in Table 4.

The results of Table 5 also show that the concentration of perchloric acid has no effect upon k_r again as required by the mechanism. However, there is a noticeable decrease in k_r with increasing nitric acid concentration at constant total nitrate. We have no mechanistic explanation of this finding and assume, for the present, that under the particular experimental conditions of the reactions in nitric acid plus sodium nitrate, our total neglect of activity coefficient considerations is not justified.

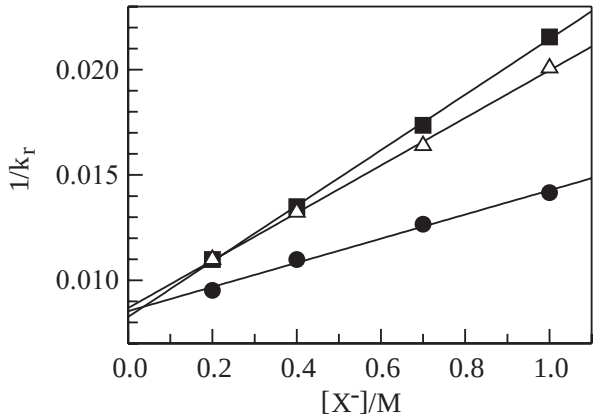
[a]From the mechanism, $K_{R^+} = k_{-3}/K_1K_2k_3$.

[b]From results in column 3 using $K_1 = 2.5 \times 10^{-3}$ dm^3 mol^{-1} (see text).

Fig. 3. Plot of the inverse of k_r against the total anion concentration (closed squares for sodium perchlorate, triangles for barium perchlorate, and closed circles for sodium nitrate).



From the results for the influence of perchloric acid on the reaction parameters at nonconstant ionic strength (Table 6), we obtain the following using eq. [13] (linear regression of k_f against $[ClO_4^-]$) and eq. [15] (linear regression of $1/k_r$ against $[ClO_4^-]$): $K_1K_2k_3 = 8.3 \pm 0.4$ dm^3 mol^{-1} s^{-1}, $K_1k_4 = 7.9 \pm 0.6$ dm^6 mol^{-2} s^{-1}, $k_{-3} = 122 \pm 3$ s^{-1}, $K_5 = 1.80 \pm 0.07$ dm^3 mol^{-1}, $K_{R^+} = 14.7 \pm 0.8$ mol dm^{-3}, and $k_4 = 3200$ dm^3 mol^{-1} s^{-1}. These results are in good agreement with the ones obtained under conditions of constant hydronium ion concentration and varying perchlorate shown in Table 7.

Strain in bicyclobutane: on the interpretation of quantitative data

Esther Rozental, Carmela Azran, Harold Basch, and Shmaryahu Hoz

Abstract: In small rings, strain energy is believed to be dominated by bond angles (Baeyer strain). However, it was found (Dill et al.) that, in bicyclobutane, bridgehead substitution effects on strain energy range from +10 to –30 kcal. Ab initio computation at the 6-31G and 6-31+G* levels have shown that the deformation caused by the bridgehead substitution is minimal and so are its energetic consequences.

Key words: bicyclobutane, strain energy, geometry distortion.

Résumé : Dans les petits cycles, on croit que l'énergie de tension est dominée par les angles de liaison (tension de Baeyer). Toutefois, il a été observé (Dill et al.) que, dans le bicyclobutane, des substitutions en tête de pont provoquent des changements dans l'énergie de tension qui vont de +10 à –30 kcal. Des calculs ab initio aux niveaux 6-1G et 6-31+G* ont permis de montrer que la déformation provoquée par une substitution au niveau de la tête de pont est minimale et qu'il en est de même pour ses conséquences énergétiques.

Mots clés : bicyclobutane, énergie de tension, distorsion de la géométrie.

[Traduit par la Rédaction]

Introduction

Mathematical formalism and intuition-based models are two approaches employed in scientific analysis. Oftentimes these two perceptions go hand in hand. However, there are cases where the mathematical formalism seems, at first sight, to contradict the intuitive understanding. An example of such a case, taken from first year chemistry course, is the pK_a of the hydronium ion H_3O^+. In aqueous solutions the proton is transferred to a water molecule leading to the identity reaction shown in eq. [1].

[1] $$H_3O^+ + H_2O \rightarrow H_2O + H_3O^+$$

This reaction is isoenthalpic and therefore should have a K = 1. However, the pK_a of H_3O^+ is –1.74, which corresponds to an equilibrium constant of 0.018 rather than to a K = 1, as expected on the basis of eq. [1]. The reason for the discrepancy between formalism and the intuitive model in this case is rather simple. In the formal language, the equilibrium constant for an acid HA is defined in eq. [2], which does not include the base (1).

[2] $$HA \rightarrow H^+ + A^-$$

For AH = H^+ = H_3O^+ where A = H_2O, this translates to K = [H_2O] = 55.5, which in turn leads into a pK_a = –1.74.

Strain energy of small ring compounds (Baeyer strain) (2) can, at the intuitive level, be pictured in simple geometrical terms such as deformation of bond lengths and bond angles. However, it also has its own formalism and definitions. In a their classical paper, Dill, Greenberg,and Liebman (DGL) (3) have shown in a variety of small ring compounds, that strain energy is affected by substitution. This point was neglected before, since the classical view "assumes electronic effects other than those resulting from angle bending to be unimportant". Because of our interest in the chemistry (4) and strain energy of bicyclobutane (5), we have examined to what extent the geometrical parameters of the bicyclobutane skeleton change due to bridgehead substitution.

Results and discussion

The list of substituents and their effect on the strain energy of bicyclobutane, as calculated by DGL (3), is given in Table 1. To see what are the structural changes caused by the substituents at the bridgehead position of bicyclobutane, we have optimized the geometries of the substituted systems at the RHF/6-31G basis set. Computations were performed with the Gaussian 94(6) package on IBM RS/6000 workstations. The energies and major geometrical parameters, defined in Fig. 1, are given in Table 2. The most important and sensitive structural parameter is the length of the central bond r1. Table 2 shows that, in general, r1 depends on the electronegativity of the atom bound to the bridgehead carbon. In the range of neutral substituents, r1 is shortest for

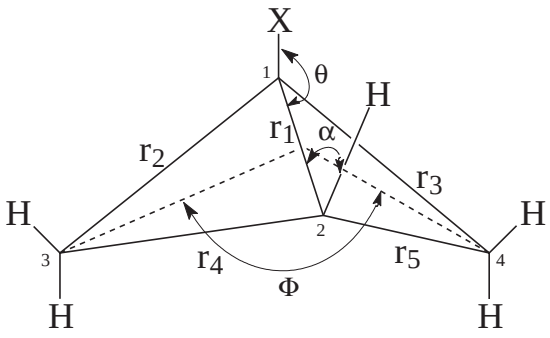
Fig. 1. Schematic drawing of bridgehead substituted bicyclobutane.



X = F (1.454 Å) and is the longest for Li (1.523 Å). This is probably due to the progressive contraction of the bonding orbitals of the substituted carbon atom, as X is more electronegative. At the bottom of the table, the average value of the geometrical parameters for X = H to X = F and the corresponding standard deviations are given. Examination of the data shows clearly that the variations in bond lengths and angles for most substituents is rather moderate. However, it is not clear what is the magnitude of the effect these changes inflict on the energy of the system. To answer this question we have performed the following calculations. The substituents were removed from the substituted bicyclobutanes, and the "distorted" geometry of the bicyclobutane moiety was kept frozen. To this geometry a hydrogen atom was added at the bridgehead position, replacing the removed substituent, and in each case, the three parameters defining the bonding of the hydrogen to the bicyclic system were fully optimized. This strategy enabled us to examine the energetic consequences of the geometrical changes induced by the various substituents. The results are given in Table 3. The data show that apart from the Li and the O^- substituents, the difference between the fully optimized bicyclobutane and the substituent – distorted systems is smaller than 1 kcal. Thus, the structural changes of the bicyclobutane system caused by the substituents are of no significant energetic consequences.

© 1999 NRC Canada

For the two negatively charged substituents O^- and BH_3^- as well as for H and Li, the computation was repeated at the RHF/ 6-31+G* level. The energies and the structural parameters are given in Table 4. The marked deviations of the structural parameters, from those of the unsubstituted system or from the averages of the data in Table 2, is largely diminished by using the 6-31+G* basis set. The energy changes after replacing the substituent by H, as described above, are also largely reduced to 2.61, 0.83, and 2.57 kcal for Li, BH_3^-, and O^-, respectively.

In conclusion, while the strain energy changes induced by bridgehead substitution covers roughly the range of +10 to –30 kcal, the energy changes associated with the net Baeyer strain (2) as conceived the intuitive way is negligible (with the exception of X = O^-, Li). The change in the strain energy observed by DGL indeed results from the electronic interaction of the substituent with the carbon framework of bicyclobutane. The distortion of the latter has a minimal effect on the energy of the system. The aforementioned enhanced interaction becomes possible due to the resemblance of the central bond to a π bond in olefin (4).

Facile formation of azines from reactions of singlet methylene and dimethylcarbene with precursor diazirines: theoretical explorations

Gennady V. Shustov, Michael T.H. Liu, and K.N. Houk

Abstract: The reactions of the singlet methylene (**1a**) and dimethylcarbene (**1b**), with their diazirine precursors, diazirine (**2a**), and dimethyldiazirine (**2b**), have been studied theoretically using ab initio and density functional theory. The reaction has no activation barriers for the parent system (**1a** + **2a**) and proceeds via a reactive complex and a transition state with a small negative enthalpy of activation ($\Delta H^{\neq}_{298}$ = –1.1 kcal mol^{-1}, $\Delta S^{\neq}_{298}$ = –34.4 cal mol^{-1} K^{-1}, ΔG°_{298} = 9.2 kcal mol^{-1}) for the dimethyl derivatives (**1b** + **2b**). The formation of *N*-methylene diazirinium ylides (**3a,b**) is exothermic by 64–80 kcal mol^{-1}. The isomer, 1,3-diazabicyclo[1.1.0]butane (**4a**), is more stable (5–12 kcal mol^{-1}) than isomer **3a**, but can neither be formed by direct thermal reaction of **1a** with **2a** nor undergo the direct rearrangement into formaldazine (**5a**). The rearrangement of ylides **3a,b** into azines **5a,b** proceeds by conrotatory C_3-N_1 ring opening. The predicted activation barrier of ca. 15 kcal mol^{-1} for the ring opening in ylide **3b** is in excellent agreement with experimental data. The formation of pyridinium ylides from carbenes and pyridine is also studied.

Key words: diazirinium ylide, ab initio MO (molecular orbital) theory, density functional theory, pyridinium ylide, CIS (singles configuration interaction) transition energies.

Résumé : Faisant appel à des calculs théoriques ab initio et à la théorie de la densité fonctionnelle, on a étudié sur une base théorique les réactions du méthylène singulet (**1a**) et du diméthylcarbène (**1b**) avec leurs précurseurs, la diazirine (**2a**) et la diméthyldiazirine (**2b**). Dans le cas du système parent (**1a** + **2a**), la réaction ne présente pas de barrières d'activation et elle se produit par le biais d'un complexe réactif alors que, pour les dérivés diméthylés (**1b** + **2b**), elle se produit par le biais d'un état de transition comportant une faible enthalpie d'activation négative ($\Delta H^{\neq}_{298}$ = –1,1 kcal mol^{-1}; $\Delta S^{\neq}_{298}$ = –34,4 cal mol^{-1}; ΔG° = 9,2 kcal mol^{-1}). La formation d'ylures de *N*-méthylène diazirinium (**3a,b**) est exothermique (64 à 80 kcal mol^{-1}). L'isomère **4a**, 1,3-diazabicyclo[1.1.0]butane, est plus stable que l'isomère **3a** par environ 5 à 12 kcal mol^{-1}; toutefois il ne peut être formé par réaction thermique directe de **1a** avec **2a** et il ne peut pas subir un réarrangement direct conduisant à la formaldazine (**5a**). Le réarrangement des ylures **3a,b** en azines **5a,b** se produit par une ouverture conrotatoire du cycle C_3-N_1. La barrière d'activation calculée, environ 15 kcal mol^{-1}, pour l'ouverture du cycle de l'ylure **3b** est en excellent accord avec les données expérimentales. On a aussi étudié la formation d'ylures de pyridinium à partir de carbènes et de pyridine.

Mots clés : ylure de diazirinium, théorie des orbitales moléculaires ab initio, théorie de la densité fonctionnelle, ylure de pyridinium, énergies de transition CIS.

Introduction

The generation of carbenes by thermolysis or photolysis of diazirines and diazoalkane precursors is a powerful method for preparative and mechanistic study. In the absence of alkenes, photolysis or thermolysis of diazirines (**2**) often results in the formation of azines (**5**) (1). Even in the presence of alkenes, this reaction may compete substantially with reactions of carbenes (1*a–c*); this side reaction can interfere with kinetic measurements on rates of carbene reactions (1*d*, *e*). The detailed mechanism of the reaction of carbenes with diazirines remains largely unknown. It has been suggested (1*a–c*) that an intermediate in the reaction can have a structure of diazirinium ylide (**3**) or 1,3-diazabicyclo[1.1.0]butane (**4**) (Scheme 1).

The measured rate constants for the reaction of singlet dialkyl- (2) and chlorosubstituted carbenes (3) with the corresponding diazirines lie within the range 10^5–10^8 M^{-1} s^{-1}.

[a]Number of imaginary frequencies in parentheses.

These values approximate those measured for reactions of the singlet carbenes with alkenes (1*b*), which in the absence of stabilizing substitutes lack an enthalpic barrier (4).

We have employed theoretical calculations at a high level of theory to answer the following questions.

(*i*) What are the activation energies for the reactions of the singlet carbenes with diazirines?

(*ii*) What intermediates are formed in these reactions?

(*iii*) What are the fates of intermediates formed in this reaction? Is the dissociation of intermediates possible? Can the intermediate be detected?

Our work represents the first attempt to address these questions of the mechanism of the reaction of carbenes with diazirines. We have studied theoretically the reactions of the singlet methylene (**1a**, R = H) and dimethylcarbene (**1b**, R = Me) with their diazirine precursors **2a** (R = H) and **2b** (R = Me), respectively, (Scheme 1), using both density functional and ab initio theory.

Computational methods

All calculations presented here were performed with Gaussian 94 (5). Geometry optimizations and frequency calculations were carried out at the B3LYP/6-31+G(d) theoretical level. For the parent system (**1a**–**5a**), MP2/6-311+G(d,p) (frozen core approximation) and standard G2 level calculations (5) were also performed. The G2 level (6) corresponds effectively to calculations at the QCISD(T)/6-311+G(3df,2p) //MP2(full)/6-31G(d) level with the incorporation of HF/6-31G(d) scaled zero-point vibrational energies (ZPE) and several higher level corrections. The harmonic frequency analysis verified the nature of the stationary points as minima (all real frequencies) or as transition structures (one imaginary frequency) and was used to provide an estimate of the ZPE values. Tables 1 and 2 show the total energies of reactants, products, and transition states along with the ZPE values. Schematic representations of the relative energies of the $C_2H_4N_2$ and $C_6H_{12}N_2$ isomers are drawn in Figs. 1 and 2.

Heat capacities and entropy corrections were made using scaled frequencies and standard statistical procedures (7) to determine enthalpies and free energies at 298 K. Zero-point

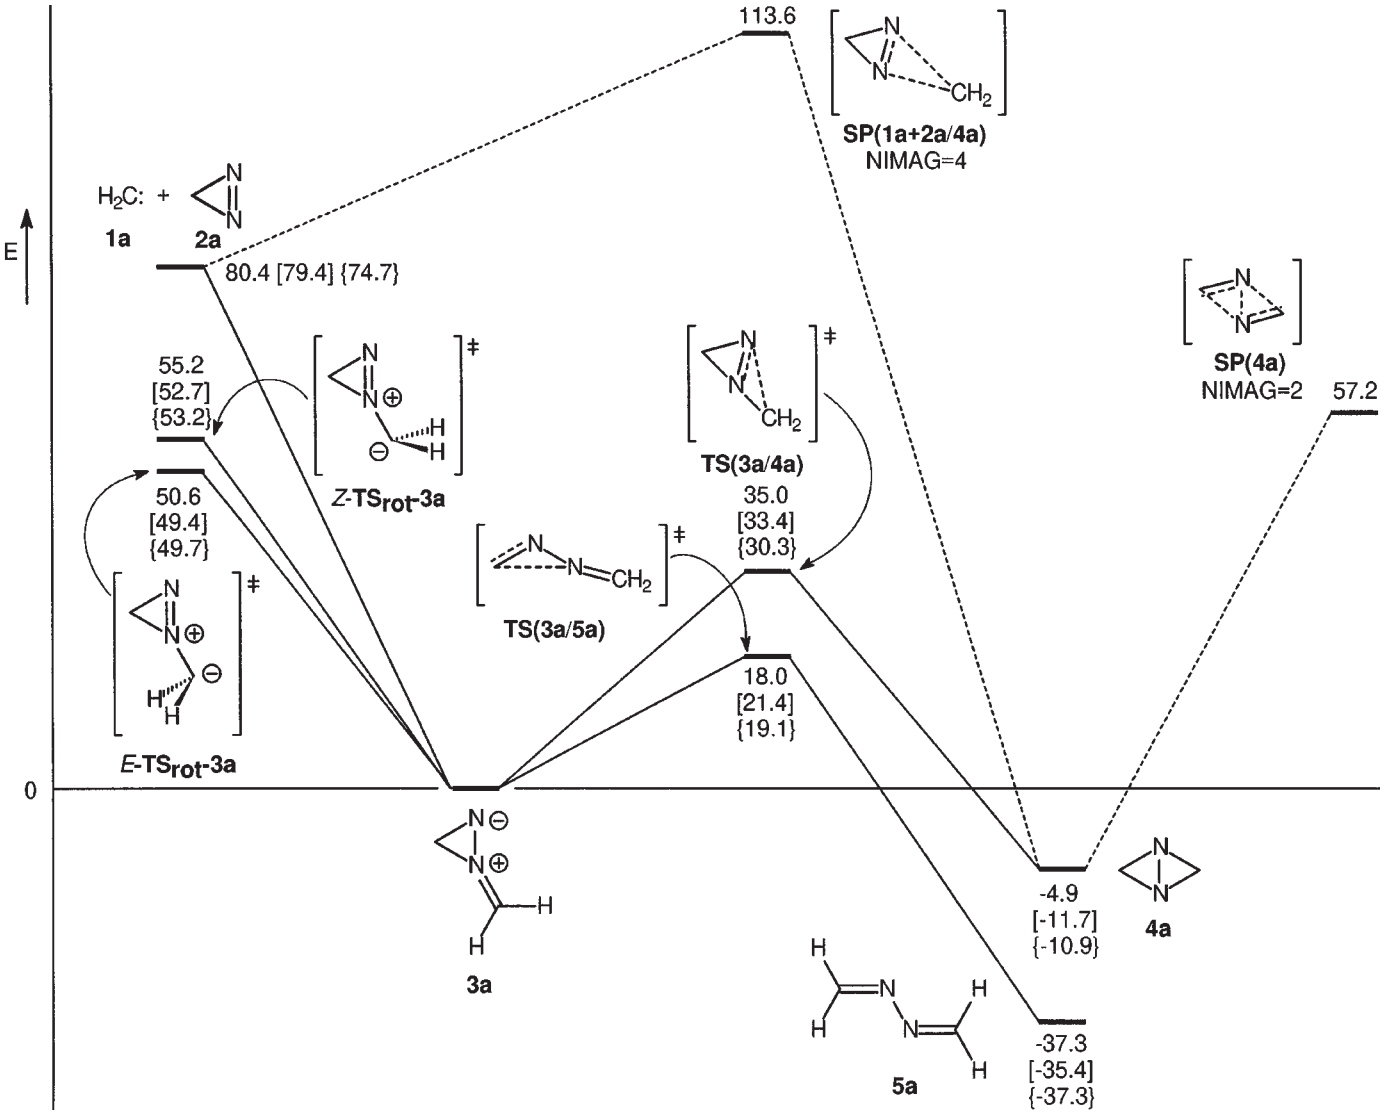
Fig. 1. Schematic presentation of the relative energies (in kcal mol^{-1}) of the $C_2H_4N_2$ isomers, considered in the present work, at B3LYP/6-31+G(d) + ΔZPE, MP2(fc)/6-311+G(d,p) + ΔZPVE (in square brackets), and G2 (in braces); NIMAG = number of imaginary frequencies.



corrections (ΔZPE) and the frequencies were scaled by a 0.95 factor for the B3LYP/6-31+G(d) and MP2(fc)/6-311+G(d,p) levels and by a 0.89 factor for the G2 level.

A profile of the potential energy surface of the C_1 methylene–diazirine reaction to give ylide was calculated at the B3LYP/6-31+G(d) level by freezing the CN distance and optimizing all other geometrical parameters for each point. The CN distance was varied from 3.699 to 1.599 Å with a 0.3 Å step.

Charge distributions in ylide **3a** and its rotational transition states were computed based on HF/6-311+G(d,p)//MP2 (fc)/6-311+G(d,p) wave functions using the natural bond orbital (NBO) (5, 8)[2] analysis.

The intrinsic reaction coordinate (IRC) (9) connecting transition state **TS(3a/4a)** to the two associated minima **3a** and **4a** was computed at the B3LYP/6-31+G(d) level.

The energies of singlet excited states of diazirines **2a,b**, ylides **3a,b**, and azines **5a,b** were calculated by single point all singles configuration interaction (CIS) calculations (5) with the 6-311+G(d,p) basis set at the MP2/6-311+G(d,p) (for **2a**, **3a**, and **5a**) and B3LYP/6-31+G(d) optimized geometries (for **2b**, **3b**, and **5b**).

Results and discussion

Carbene–diazirine reaction

There are at least two probable approaches of carbenes **1a,b** to diazirines **2a,b**: the C_1 symmetrical approach leading to ylides **3a,b** and the C_s symmetrical one, which can afford in bicyclo[1.1.0] species, **4a,b**.

The C_s approach is an orbital symmetry forbidden reaction. Indeed, a saddle point **SP(1a+2a/4a)** (Figs. 1, 3) was

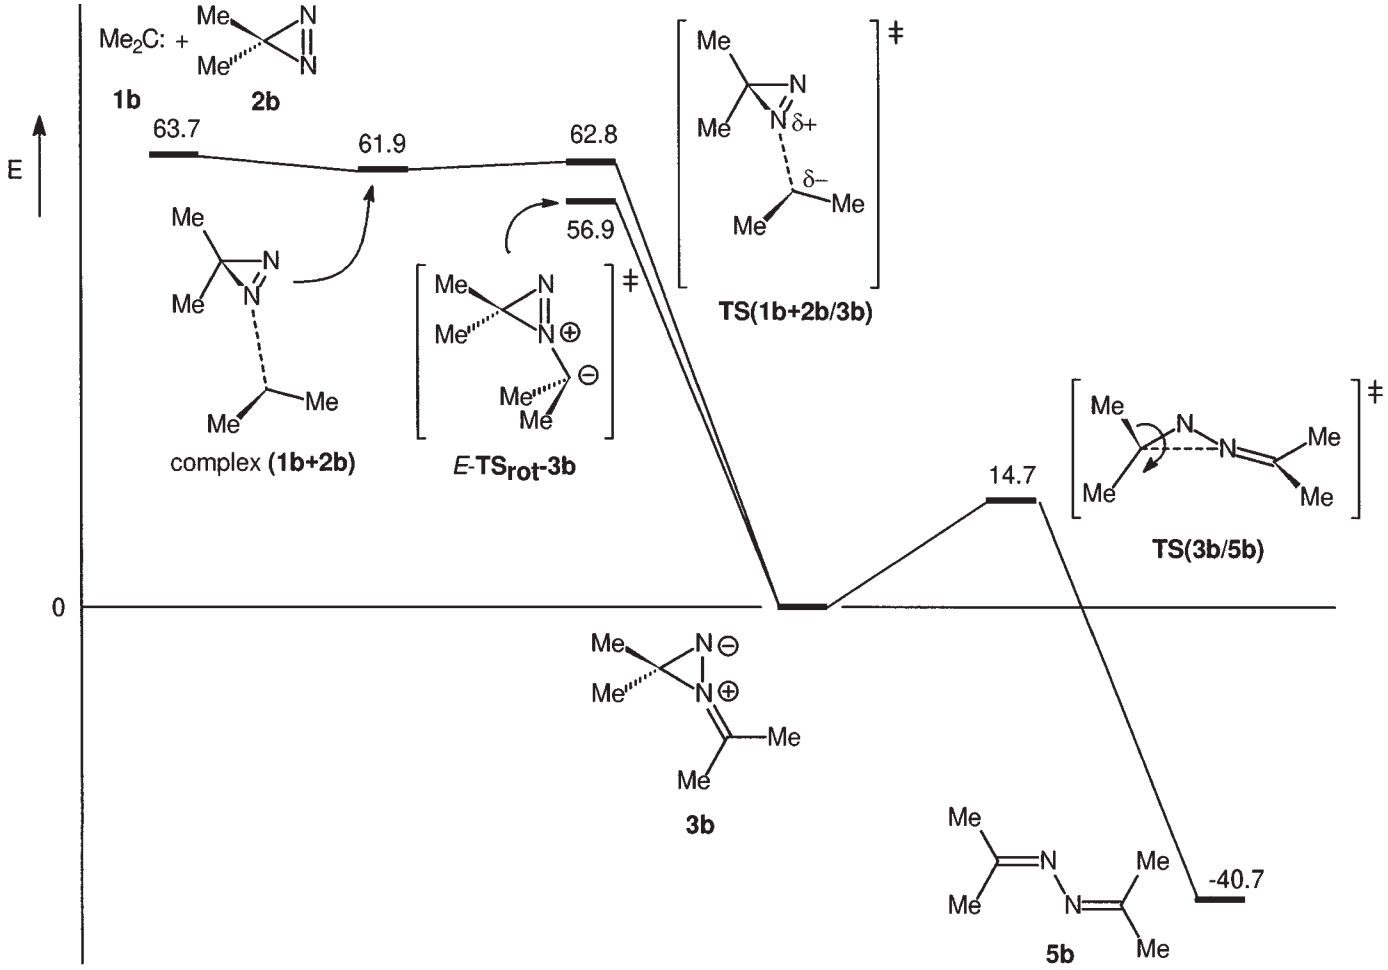
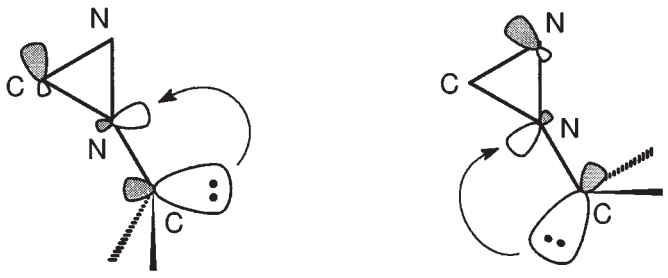
Fig. 2. Schematic presentation of the relative energies of the $C_6H_{12}N_2$ isomers, considered in the present work, at B3LYP/6-31+G(d) + ΔZPE in kcal mol^{-1}.



Scheme 2.



found on this pathway under a C_s symmetry constraint; it has *four* imaginary frequencies and is 33.5 kcal mol^{-1} higher in energy than the reactants. Any deviation from the C_s symmetrical approach of carbene **1a** to diazirine **2a** leads not to bicyclic product but to ylide **3a**. The formation of diazirinium ylide **3a** was simulated using the distance from the carbon atom of **1a** and one nitrogen of **2a** as a reaction coordinate. No local maxima and minima were found when the reaction coordinate was changed from 3.699 to 1.599 Å (Fig. 4).

The C_1 approach of carbene **1b** to diazirine **2b** proceeds via the formation of reaction complex **(1b+2b)**, which is a shallow minimum on the $C_6H_{12}N_2$ potential energy surface at 0 K (Table 2, Fig. 2). The transition state, **TS(1b+2b/3b)**, for conversion of complex to ylide product has an activation energy of only 0.9 kcal/mol, and a negative energy with respect to the reagents ($\Delta H^{\neq}_{298}$ = –1.1 kcal mol^{-1}). A substantial decrease of entropy upon formation of the reactive complex **(1b+2b)** ($\Delta S^{\neq}_{298}$ = –24.0 eu) and transition state **TS(1b+2b/3b)** ($\Delta S^{\neq}_{298}$ = –34.4 eu) leads to a free energy of formation ($\Delta G°_{298}$ = 5.9 kcal mol^{-1}) for the complex and a free energy of activation for the reaction of 9.2 kcal mol^{-1} at 298 K.

As shown in Fig. 3, carbenes **1a,b** attack diazirines **2a,b** from a direction which is substantially out of the plane of the diazirine ring. The empty *p* orbital of the carbenes interacts with the π orbital of the N=N bond and the out-of-phase combination of the nitrogen nonbonding orbitals as it approaches.

Structures and reactivities of diazirine ylide intermediate

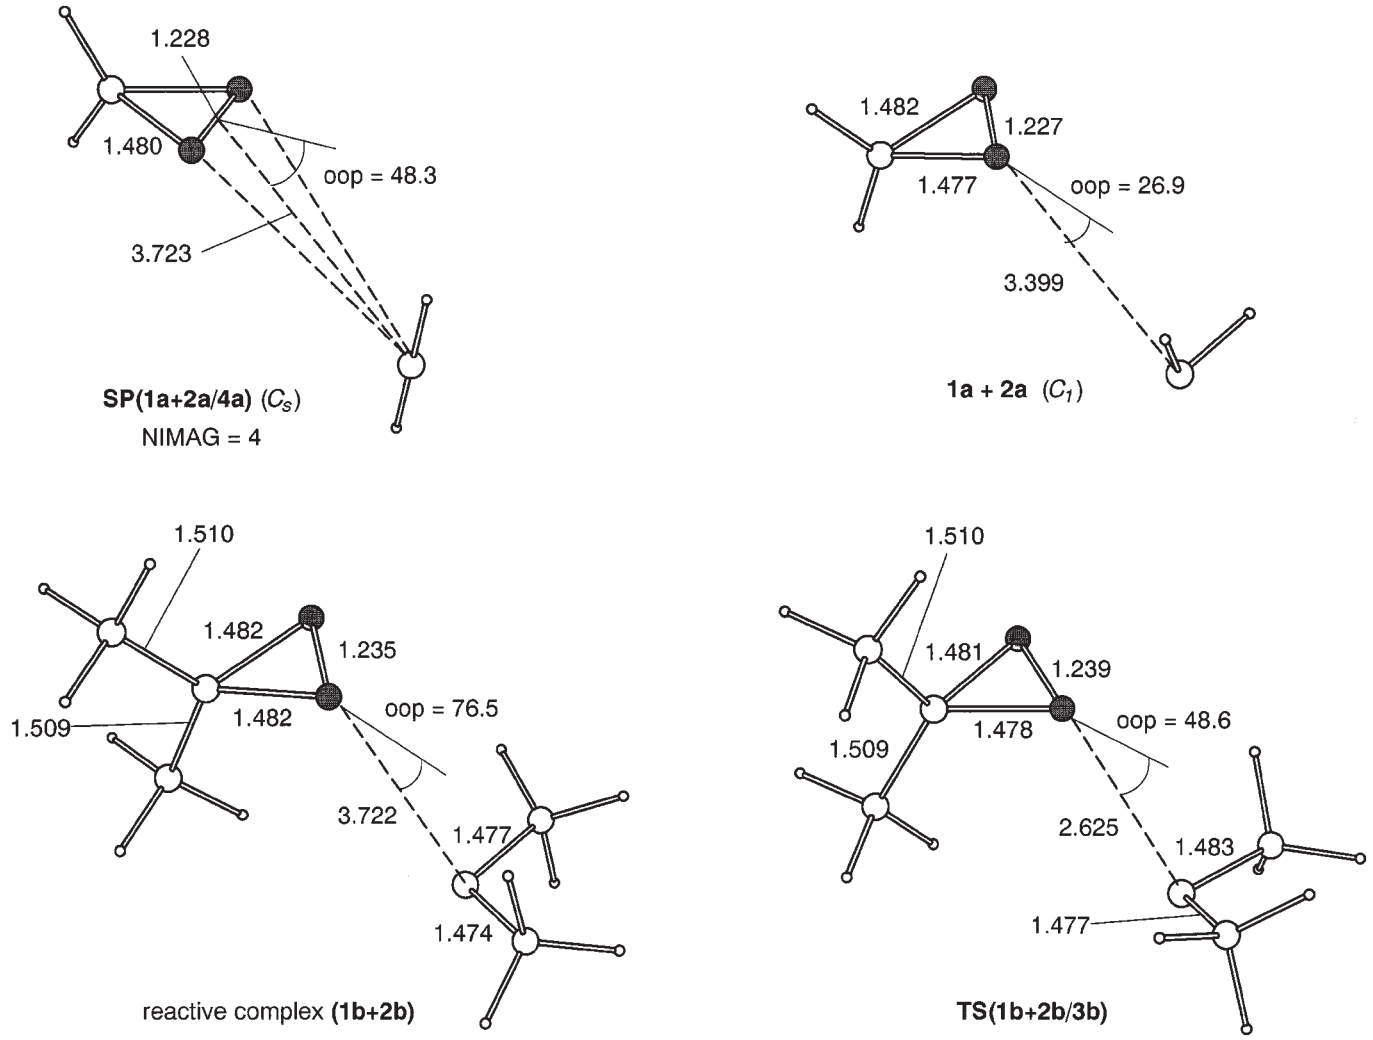
Fig. 3. B3LYP/6-31+G(d) geometries of the symmetrical (C_s, a saddle point of fourth order) and asymmetrical (C_1, an intermediate point) approaches of **1a** to **2a** and of reactive complex **(1b+2b)** and transition state **TS(1b+2b/3b)**; oop = out-of-plane angle; NIMAG = number of imaginary frequencies. The closed circles stand for nitrogen atoms. Distances in angstroms, angles in degrees.



surfaces. The formation of ylides **3a,b** is very exothermic from carbenes **1a,b** and diazirines **2a,b** (Figs. 1, 2).

The planar configuration at N_1 and C_4, the N_1C_4 distance of ca. 1.3 Å (Fig. 5) indicates nearly complete double character of the C_4—N_1 exocyclic bond in ylides **3a,b**. High barriers to rotation about this bond, ca. 50 kcal mol^{-1} (Fig. 1, 2), confirms this double bonding.

Two isomers, *E*-$\mathbf{TS_{rot}}$-**3a** and *Z*-$\mathbf{TS_{rot}}$-**3a** (Fig. 5), of the rotational transition state of ylide **3a** were found. The lower energy of *E*-$\mathbf{TS_{rot}}$-**3a** in comparison to *Z*-$\mathbf{TS_{rot}}$-**3a** apparently caused by the interaction of the nonbonding (*n*) orbital of the C_4 atom with the anti-periplanar antibonding σ*-like orbital of the C_3—N_1 bond of the three-membered ring. In *Z*-$\mathbf{TS_{rot}}$-**3a**, the *n* orbital of the C_4 atom interacts with the σ*-like orbital of the N=N bond, which is a weaker internal σ acceptor due to its double-bond character (Scheme 2).

This is manifested by the shortening of the C_4—N_1 bond in *E*-$\mathbf{TS_{rot}}$-**3a** in comparison with *Z*-$\mathbf{TS_{rot}}$-**3b** (Fig. 5). In the case of ylide **3b**, only the *E*-isomer of the rotational transition state (Figs. 2, 5) was calculated.

The NBO analysis of **3a** confirms the presence of the C_4—N_1 double bond and the N—N double bonding in transition states *E*- and *Z*-$\mathbf{TS_{rot}}$-**3a**. Also, according to this analysis, a maximum negative charge is localized on the N_2 atom in the ground state **3a** and on the C_4 atom in the rotational transition states (Scheme 3).

It is of interest to compare the diazirinium ylide **3a** with the pyridinium ylide **7**.

calculations, pyridinium ylide **7** is characterized by a stabilization energy of 69.7 kcal mol^{-1} with respect to carbene **1a** and pyridine **6**. Our B3LYP/6-31+G(d) calculations of pyridine and its ylide **6** yielded a similar value of the stabilization energy –66.1 kcal mol^{-1} (including ΔZPE). We also calculated a transition state (**TS$_{rot}$-7**, C_s symmetry) for rotation of the methylene group in ylide **7**.

The standard thermodynamic parameters of formation of the diazirinium ylide **3a** and the pyridinium ylide **7** are shown in Scheme 4. Both reactions are highly exothermic, but will be less so with carbene stabilizing substituents.

The exocyclic CN bond (1.342 Å) in pyridinium ylide **7** is appreciably longer, and the barrier to rotation (27.1 kcal mol^{-1}) is considerably lower than it is in the diazirinium ylides **3a,b** (1.30 Å, >50 kcal mol^{-1}) (Figs. 1, 2, 5). The localization of negative charge on the electronegative N_2 atom in diazirinium ylides **3a,b** substantially promotes double bonding.

For the parent system, we have also optimized an isomer of ylide **3a**–1,3-diazabicyclo[1.1.0]butane (**4a**) (Table 1, Figs. 1, 6). Compound **4a** is a true minimum on the $C_2H_4N_2$ potential energy surface. All three methods predict that **4a** is more stable then ylide **3a** (Table 1, Fig. 1). As shown above, bicycle **4a** is not be formed in the direct thermal reaction of carbene **1a** with diazirine **2a**. Moreover, the thermal rearrangement of **4a** into azine **5a** is also a forbidden reaction: a second-order saddle point **SP(4a)** (Figs. 1, 6) was found at an attempt to locate a transition state of the double ring opening in **4a** under C_2 symmetry constraint. Therefore, 1,3-diazabicyclo[1.1.0]butanes **4** are not likely intermediates in the thermal reactions of singlet carbenes with diazirines.

The cyclization of ylide **3a** into **4a**, **3**, was also studied. A transition state **TS(3a/4a)** (Fig. 6) is characterized by a high

relative energy (>30 kcal mol^{-1}, Fig. 1) and cannot compete with a transition state **TS(3a/5a)** (ca. 20 kcal mol^{-1}) for the rearrangement of ylide **3a** to formaldazine (**5a**).

The rearrangements of ylides **3a,b** into azines **5a,b** are exothermic conrotatory C_3-N_1 ring opening reactions (see the geometries of **TS(3a/5a)** and **TS(3b/5b)**, Fig. 6). With an activation barrier of ca. 15 kcal mol^{-1}, rearrangement of methylene diazirinium ylides like **3b** should proceed rapidly at temperatures >25°C. However, at low temperatures, a tetraalkyl ylide **3** can be detected by means of UV spectroscopy.

For comparison with experiment, the first two electronic transition energies of diazirines **2a,b**, ylides **3a,b**, and azines **5a,b**, calculated by the CIS method, are given in Table 3. The CIS method generally exaggerates the energies of electronic transitions, and the corresponding calculated wavelengths of these transitions are shorter than the experimental ones. In the case of diazirines **2a,b**, an average difference between the predicted wavelengths of the first transition and the experimental ones is ca. 23 nm, and for azines **5a,b**, this difference amounts to ca. 65 nm (Table 3). Taking into account these differences, the first electronic absorption bands of methylene diazirinium ylides **3** are expected to occur at 250–294 nm.

Recent experimental data on laser flash photolysis of adamantylidene diazirine confirm our predictions. Bonneau et al. (15) observed a transient absorption with λ_{max} = 290 nm,

which may be attributed to the formation of an ylide from the reaction of adamantylidene with the diazirine. The decay of this transient obeyed a first-order rate law with lifetime >150 ms in either air-saturated or nitrogen-flushed isooctane at room temperature. An activation energy of 15.5 kcal mol^{-1} and a pre-exponential factor of $10^{12.3}$ were obtained from the temperature dependence of the lifetime.

Conclusions

(*i*) The reactions of singlet methylene and dimethylcarbene with diazirines have no enthalpic barriers; the free energies of activation for these reactions of singlet carbenes with their diazirine precursors, like the reactions of singlet carbenes with alkenes, have mainly entropic origins.

(*ii*) *N*-Methylene diazirinium ylides (**3**) are the intermediates in the reactions of singlet carbenes (**1**) with their precursors diazirines (**2**). These ylides have a planar (C_s) equilibrium geometry with an exocyclic double CN bond and localization of the negative charge on the two-coordinated nitrogen atom of the ring. Although 1,3-diazabicyclo [1.1.0]butanes (**4**) are more stable than the corresponding methylene diazirinium ylides (**3**), they are not be formed by the direct reaction of carbene **1** with diazirine **2**.

(*iii*) *N*-Methylene diazirinium ylides (**3**) are much more stable than the reactants **1** and **2**, excluding the possibility of dissociation. The relatively high barrier (ca. 15–20 kcal mol^{-1}) for the rearrangement of ylides (**3**) to azines (**5**) offers an opportunity to detect these ylides through spectroscopic methods, or trapping by dipolarophiles.

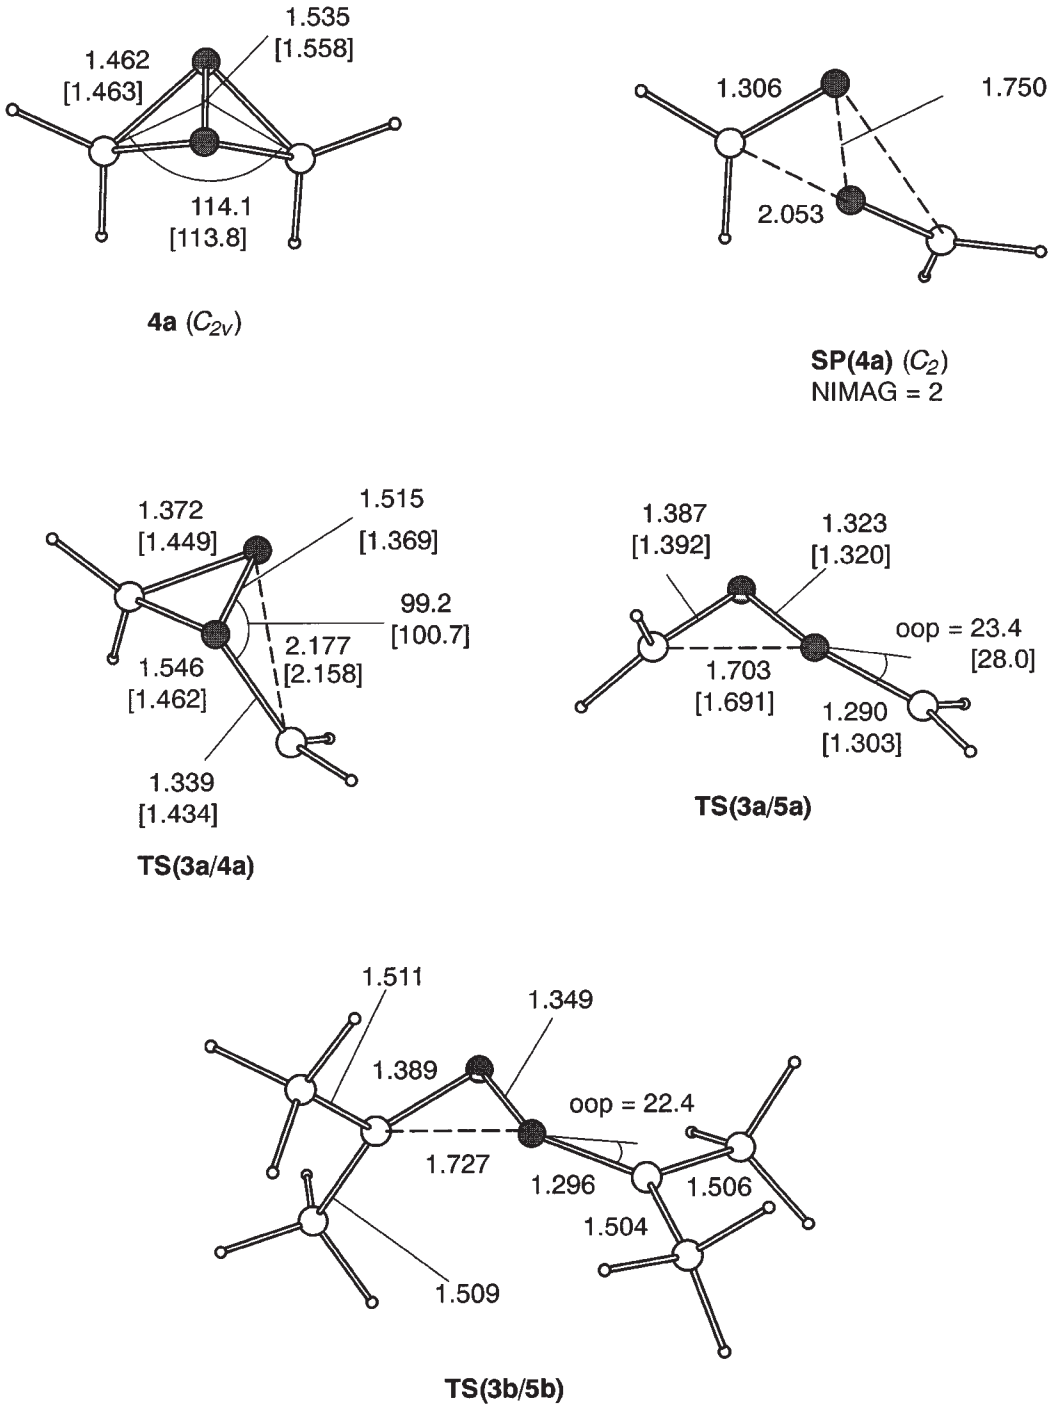
The closed circles stand for nitrogen atoms. Distances in angstroms, angles in degrees.



Since the reactions of carbons with diazirines is so facile, we assume that the low yields of the azines in carbene photolysis are due to secondary reactions. It has been reported (14) that the azines are unstable to photolysis. Also, the reactions of azines with carbenes may serve as an additional channel for azine disappearance. We simulated the reaction of the singlet methylene (**1a**) with formaldazine (**5a**) at the B3LYP/6-31+G(d) level of theory and found no enthalpic activation barrier.

Synthesis and kinetics of decomposition of some novel *S*-nitrosothiols

Andrew P. Munro and D. Lyn H. Williams

Abstract: The *S*-nitrosothiols 2-acetamido-2-deoxy-*S*-nitroso-1-thio-β-D-glucopyranose 3,4,6-triacetate (GPSNO) and *S*-nitroso-*N*-carbamyl-D,L-penicillamine (SNCP) were synthesized by *S*-nitrosation of the corresponding thiols, isolated, and fully characterized. The nitrosothiol (TGSNO) from 1-thioglycerol was obtained as a red gelatinous liquid, which decomposed rapidly at room temperature and so was not characterized. The kinetics of decomposition of GPSNO showed that there is a surprisingly large thermal pathway overlaid with a Cu^{2+}/RS^{-} catalyzed reaction. The results strongly suggest that the product disulfide complexes Cu^{2+} (for which there is some spectral evidence), leading to incomplete conversion by that route. Ascorbate also acts as a Cu^{2+} reductant. Another *S*-nitroso sugar, *S*-nitroso-1-thio-β-D-glucose (SNTG), behaved very similarly from solutions generated and used in situ. The decomposition of TGSNO shows induction periods suggesting that slow initial generation of Cu^{+} (the true catalyst) is taking place. There appears to be also a significant alternative pathway (analogous to that found for GPSNO), where the rate appears to be independent of $[Cu^{2+}]$, but very unusually this pathway is effectively halted by addition of EDTA either at the start of the reaction or at a later time. Reaction schemes are put forward to account for these unusual reaction characteristics.

Key words: *S*-nitrosothiols, nitric oxide, ascorbate, copper catalysis.

Résumé : On a synthétisé les *S*-nitrosothiols, 3,4,6-triacétane de 2-acétamido-2-désoxy-*S*-nitroso-1-thio-β-D-glucopyranose (GPSNO) et *S*-nitroso-*N*-carbamyl-D,L-pénicillamine (SNCP), en procédant à la *S*-nitrosation des thiols correspondants, on les a isolés et caractérisés complètement. Le nitrosothiol (TGSNO) obtenu à partir du 1-thioglycérol est un liquide gélatineux rouge qui se décompose rapidement à la température ambiante et il n'a pas été caractérisé. La cinétique de décomposition du GPSNO montre qu'il existe une voie réactionnelle thermique importante qui est recouverte par une réaction catalysée par Cu^{2+}/RS^{-}. Les résultats suggèrent fortement que le disulfure formé se complexe avec le Cu^{2+} (quelques données spectrales supportent ces hypothèses); cette interaction provoque une conversion incomplète par cette voie. L'ion ascorbate agit aussi comme réducteur du Cu^{2+}. Un autre *S*-nitrososucre généré en solution et utilisé in situ, le *S*-nitroso-1-thio-β-D-glucose (SNTG), se comporte d'une façon très semblable. La décomposition du TGSNO présente des périodes d'induction qui suggèrent une génération initiale lente du Cu^{+} (le vrai catalyseur). Il semble exister une voie de réaction alternative importante (analogue à celle observée pour le GPSNO) dans laquelle la vitesse semble indépendante de $[Cu^{2+}]$; il est toutefois surprenant de réaliser que cette voie est effectivement interrompue par l'addition d'EDTA soit au début de la réaction soit plus tard. Des schémas réactionnels sont proposés pour expliquer ces caractéristiques réactionnelles inusitées.

Mots clés : *S*-nitrosothiols, oxyde nitrique, ascorbate, catalyse par le cuivre.

[Traduit par la Rédaction]

Introduction

One aspect of the continuing intense and widespread interest in the "nitric oxide story" concerns the chemistry of *S*-nitrosothiols, RSNO. Not only are these compounds under active consideration as possible nitric oxide donors for medical therapeutic use, but also currently there is much interest in establishing the part played by them in vivo, possibly in the storage and transport of NO in the body. *S*-Nitrosoglutathione GSNO (1), *S*-nitrosoproteins (2), and the *S*-nitroso derivative of hemoglobin (3) have been identified as naturally occurring compounds, and there are literature hypotheses regarding their role in the storage and transport of NO around the body (2, 4). A recent suggestion that the interconversion between the Fe-NO and side chain S-NO forms in nitrosated hemoglobin, in some way controls blood pressure (3), has attracted much interest. The biological (5) and chemical (6) properties of *S*-nitrosothiols have recently been reviewed.

Formerly, it was believed that most RSNO compounds (with a few exceptions, notably GSNO and *S*-nitroso-*N*-acetyl penicillamine, SNAP) were too unstable in the pure state to allow their isolation and characterization, but in recent years an increasing number have been shown to be stable at room temperatures, although others decompose during extraction. In general, the corresponding *O*-nitroso compounds, the alkyl nitrites, are much more widely stable and of course

well known. Fairly dilute (1×10^{-3} to 1×10^{-4} M) solutions of all RSNO are easily generated from thiols and nitrous acid in an equilibrium process, which lies very much on the side of RSNO, and are usually sufficiently stable (even for those examples which cannot be obtained in the pure state) to allow experiments to be successfully carried out in situ.

For most RSNO compounds that have been studied, the thermal decomposition reaction is rather slow at room temperature, with half lives of many tens of hours. However, we have shown (7, 8) that in solution, in phosphate buffer at pH 7.4, RSNO species decompose giving NO and RSSR, in a copper-catalyzed process. The effective reagent is Cu^+, generated in situ by thiolate reduction of Cu^{2+} (eqs. [1]–[3]), which in many cases occurs when both RS^- and Cu^{2+} are present only at the trace impurity level. In contrast to the corresponding photochemical reaction, there is no EPR evidence for intermediate thiyl radical formation. There is a large reactivity range that results from the presence or otherwise of suitable substituents (e.g., $-NH_2$) which will allow bidentate binding by Cu^+ to occur. If the reactions are carried out aerobically then the ultimate fate of NO is NO_2^- after initial oxidation of NO, although at very low NO concentrations, such as those encountered in vivo, oxidation of NO by oxygen is very slow and probably will not compete with other NO reactions.

[1] $2Cu^{2+} + 2RS^- = 2Cu^+ + RSSR$

[2] $RSNO + Cu^+ = RS^- + Cu^{2+} + NO$

[3] $4NO + 4OH^- + O_2 = 4NO_2^- + 2H_2O$

[4] $RSNO + R'SH = R'SNO + RSH$

Added thiols can produce a variety of effects. If the thiol is structurally different from that from which RSNO is derived, then transnitrosation (eq. [4]) can occur, leading to the formation of a new R′SNO (9). If the added thiol is the same as that from which RSNO is derived, then at low concentration of added thiol, catalysis can occur (increasing the rate of Cu^+ formation), whereas at higher concentrations, thiol complexation of Cu^{2+} can occur, often resulting in the appearance of substantial induction periods, during which Cu^+ is being generated from very low concentrations of free Cu^{2+} (8, 10). The relative importance of each reaction (reduction and complexation) is governed by the thiol concentration and structure. At very much higher added thiol concentrations, a quite different reaction or series of reactions occurs, leading principally to ammonia formation, together with some nitrous oxide (11, 12).

Recently, we have shown that ascorbate ion can bring about two reactions with *S*-nitrosothiols (13): (*i*) at low ascorbate concentration, the copper catalyzed reaction is dominant in which ascorbate takes over the role of the thiolate and acts as a reducing agent for Cu^{2+} (this reaction can be completely halted by EDTA addition), and (*ii*) at much higher ascorbate concentration, a different reaction occurs, unaffected by the presence of Cu^{2+} or EDTA, and which leads to NO and *thiol* (and not diulfide) formation; under these conditions, all the evidence suggests that ascorbate acts as a nucleophile and undergoes electrophilic nitrosation in the same way as do nitrous acid and alkyl nitrites — the former being a very well known reaction.

In this paper we describe the synthesis and characterization of a *S*-nitrosothiol derived from a thio sugar and examine its decomposition together with that of the *S*-nitroso derivative of 1-thioglycerol (prepared in solution) to nitric oxide, both of which turn out to show some unusual features.

Experimental section

Materials

An aqueous solution of sodium nitrite (0.11 g in 1.65 cm^3) was added dropwise over 2 min with vigorous stirring to a solution of a commercial sample of 2-acetamido-2-deoxy-1-thio-β-D-glucopyranose 3,4,6-triacetate (0.30 g in 1:1 methanol: 1 M HCl, 3.3 cm^3, and containing concentrated sulfuric acid 0.17 cm^3). The mixture became pale red almost immediately, was stirred for 1 h, and the precipitate collected by filtration. The pink solid was washed with ice-cold water and air-dried for 24 h. (65% yield). The solid was stable at room temperature but decomposed on heating, so no melting point could be recorded. Elemental analysis calcd. for $C_{14}H_{20}N_2O_9S$: C 42.9, H 5.15, N 7.1%; found: C 43.0, H 5.03, N, 6.6%. The UV-visible spectrum showed λ_{max} (H_2O) 343 and 557 nm, ε 450 and 17 $dm^3\ mol^{-1}\ cm^{-1}$ respectively. The infrared spectrum included bands at 1572 cm^{-1} (NO stretch) and 654 cm^{-1} (CS stretch). The complex ^1H NMR spectrum was consistent with the expected structure **1**.

Attempts to prepare the *S*-nitroso derivative of 1-thioglycerol (3-mercapto-1,2-propanediol) TGSNO (structure **2**) resulted in the formation of a red gelatinous liquid, which decomposed rapidly at room temperature, but which could be kept for a short while below 4° in the dark. It was, however, too unstable to purify and characterize. However, a solution prepared from equimolar quantities of 1-thioglycerol and sodium nitrite gave a UV-visible spectrum with λ_{max} 333 and 544 nm, ε 881 and 21 $dm^3\ mol^{-1}\ cm^{-1}$, respectively. Similarly, the *S*-nitroso derivative of 1-thio-β-D-glucose SNTG (structure **4**) was too unstable to isolate, but we obtained the characteristic UV-visible spectrum with λ_{max} 342 and 557 nm with ε 436 and 14 $dm^3\ mol^{-1}\ cm^{-1}$, respectively. These spectral characteristics are very similar to those found for GPSNO.

The same synthetic procedure gave a 54% yield of the *S*-nitroso derivative SNCP (structure **3**) of *N*-carbamyl penicillamine (provided as a gift by the former Wellcome company). This was a stable green solid with red reflections, very similar in appearence to the closely related and very well known *S*-nitroso-*N*-acetyl penicillamine (SNAP). Elemental analysis calcd. for $C_6H_{11}N_3O_4S$: C 32.6, H 4.98, N 19.0%; found: C 32.3, H 4.86, N 18.4%. The UV-visible spectrum showed λ_{max} (H_2O) 340 and 590 nm, ε 853 and 20 $dm^3\ mol^{-1}\ cm^{-1}$. The infrared spectrum included bands at 1494 cm^{-1} (NO stretch) and 661 cm^{-1} (CS stretch). The ^1H NMR spectrum was in accord with the expected structure and included the characteristic (14) downfield shift of the proton signals in the vicinity of the sulfur atom upon nitrosation.

All other materials were commercial samples of the highest available purity grade.

Spectral measurements

These were all carried out in aqueous phosphate buffer, pH 7.4, at 25° in a conventional spectrophotometer operating in the time-drive mode at around 340 nm or in the spectral scan mode. Typical concentrations of GPSNO were ~1×10^{-3} mol dm^{-3}. Solutions of TGSNO and SNTG were prepared at the same concentration by reaction of equimolar amounts of 1-thioglycerol or 1-thio-β-D-glucose and sodium nitrite in mildly acidic solution, immediately prior to investigations of the decomposition characteristics at pH 7.4.

Nitric oxide and nitrite ion analysis

Nitric oxide was determined in the reaction solutions, under nitrogen, using a commercial World-Precision ISO-NO specific electrode, calibrated with standard ascorbic acid-sodium nitrite solutions. Nitrite ion was determined by a modification of the Griess method (8).

Results

2-Acetamido-2-deoxy-*S*-nitroso-1-thio-β-D-glucopyranose 3,4,6-triacetate (GPSNO), 1

We have prepared GPSNO by direct *S*-nitrosation of the corresponding thiol, using a modification of the method used by Field et al. (15) for the first synthesis of SNAP. It was characterized by satisfactory elemental analyses and by the observation of the NO and CS stretching frequencies in the infrared spectrum and also by observation of the characteristic UV-visible absorbances at 343 and 557 nm. The pink solid is quite stable at room temperature. Analysis of an aqueous solution of GPSNO by Ellman's method (16) showed that the thiol level resulting from the equilibration of GPSNO in solution was 1.9% when the total GPSNO concentration was ~5×10^{-3} mol dm^{-3}.

In solution at pH 7.4, the decomposition of GPSNO showed the rather unusual absorbance–time plots shown in Fig. 1 for a series of solutions containing different concentrations of added Cu^{2+}. To separate any metal ion catalyzed process from any other reaction, we carried out two experiments with and without the addition of the general metal ion chelator EDTA, and these traces are given in Fig. 2. The faster reacting component of the reaction (which is Cu^{2+} catalyzed) is completely attenuated, leaving the other component unchanged. Addition of the specific Cu^{+} chelator neocuproine generated the same pattern of behaviour (not shown).

The effect of ascorbate in low concentration was also investigated, and the results are presented graphically in Fig. 3. Clearly ascorbate catalyzes the reaction, and also results in the quantitative decomposition of GPSNO observed now as a single process.

Repeat scans of the decomposition (shown in Fig. 4) at high concentration of added Cu^{2+} (5×10^{-5} mol dm^{-3}) showed the clear development of a small absorbance at around 280 nm, which can be interpreted as the Cu^{2+} complex of the

Fig. 2. Absorbance–time plots for the decomposition of GPSNO (1×10^{-3} M) in the presence of Cu^{2+} (1×10^{-5} M) (*a*) without EDTA, (*b*) with EDTA (1×10^{-3} M).

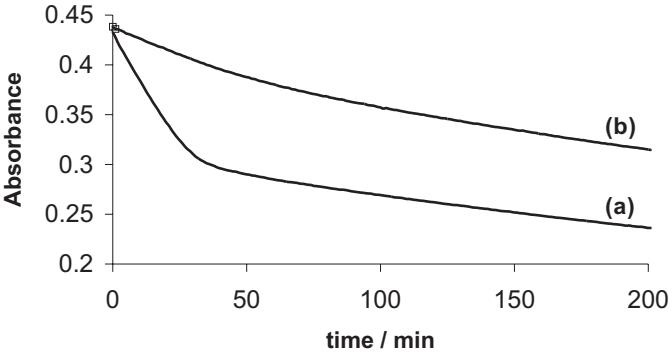

Fig. 3. Absorbance–time plots for the decomposition of GPSNO (1×10^{-3} M) in the presence of Cu^{2+} (1×10^{-5} M) with (*a*) no ascorbate, (*b*) ascorbate (5.0×10^{-5} M), (*c*) ascorbate (1.0×10^{-4} M).

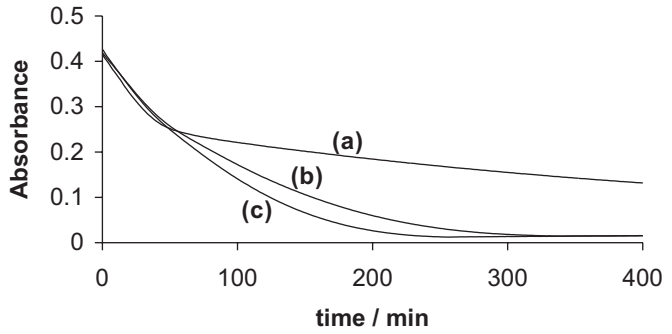


disulfide derived from GPSNO. When the reaction was carried out anaerobically, NO was detected using the NO–electrode system in the solution at ~30%. The same experiment carried out aerobically gave a value of 51% of the theoretical maximum of nitrite anion.

There was a very rapid reaction between GPSNO and sulfite ion at pH 7.4 in the presence of added EDTA, yielding a second-order rate constant of 8630 M^{-1} s^{-1}. No nitric oxide or nitrite ion were detected in these reaction products.

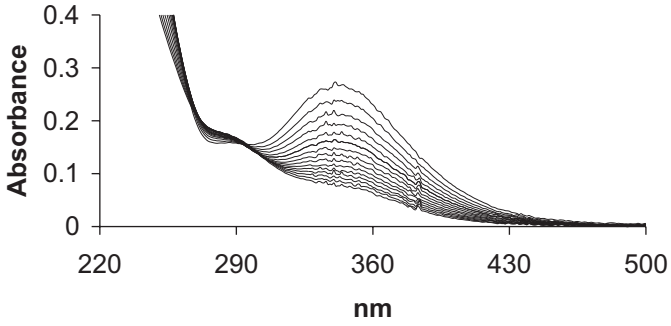
Attempts to isolate the *S*-nitroso derivative of 1-thio-β-D-glucose were unsuccessful, even though it was clear from the development of a red colour that *S*-nitrosation had occurred. The decomposition of solutions generated from the thiol and nitrous acid were examined spectrophotometrically at pH 7.4 and showed very similar behaviour to that shown in Fig. 1 for GPSNO. In the same way, the addition of EDTA completely suppressed the Cu^{2+}-catalyzed reaction leaving a significant thermal reaction.

S-Nitroso 1-thioglycerol (TGSNO), 2

All attempts to effect the nitrosation of 1-thioglycerol (3-mercapto-1,2-propanediol) using the known procedures generated an unstable red gelatinous liquid. It is almost certain that this is the *S*-nitroso derivative of 1-thioglycerol and solutions prepared from equimolar amounts of 1-thioglycerol and nitrous acid gave the expected UV-visible spectrum so characteristic of *S*-nitrosothiols.

The decomposition behaviour is shown in Fig. 5 and reveals a similar pattern of behaviour to that found earlier for

Fig. 4. Repeat scans (4 min intervals) for the decomposition of GPSNO (1×10^{-3} M) with added Cu^{2+} (5×10^{-5} M). Absorbance increases at 280 nm and decreases at 350 nm.



GPSNO in that it appears that there are two reactions: one catalyzed by added [Cu^{2+}] and the other not. In contrast, however, to the results for GPSNO, the spectral traces of the Cu^{2+}-dependent reaction show evidence of induction periods which are shorter as the [Cu^{2+}] and the concentration of the added 1-thioglycerol (not shown) is increased. In marked contrast to the behaviour of GPSNO, however, the effect of added metal ion chelator EDTA to solutions of TGSNO (Fig. 6) progressively halted *both* components of the reaction (the Cu^{2+}-dependent and Cu^{2+}-independent pathways), leaving a virtually stable solution of TGSNO over at least 12 h. Addition of neocuproine produced the same effect. When EDTA was added at various time points after the start of the reaction, decomposition was immediately halted at those time points. The NO-probe gave a value of ~45% for NO production and the nitrite analysis, and when the reaction was carried out aerobically, gave a figure of 97% of the theoretical maximum.

Ascorbic acid, added in low concentration (1×10^{-5} to 1×10^{-4} M) also catalyzed the decomposition of TGSNO and resulted in quantitative reaction, just as in the case of GPSNO. At much higher ascorbate concentration (0.04–0.24 M) and in the presence of EDTA, the reaction was fully first order in TGSNO concentration, and there was an excellent linear relationship between the observed first-order rate constant and ascorbate concentration, yielding a value of 1.59×10^{-3} M^{-1} s^{-1} for the second-order rate constant. Under these conditions NO (or NO_2^- if aerobic) is formed, together with the thiol product.

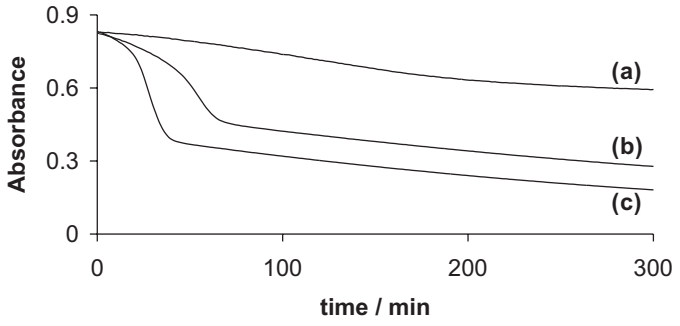
Repeat scans (not shown) of the reaction carried out in the presence of added Cu^{2+} (5×10^{-5} M) clearly showed the disappearence of the absorbance at around 340 nm, and there was some evidence of the development of a small absorbance in the 260 nm region, which disappeared during the course of the reaction.

S-Nitroso-*N*-carbamyl penicillamine (SNCP), 3

The *S*-nitroso derivative of *N*-carbamyl penicillamine (SNCP) was synthesized, fully characterized, and shown to be a stable solid at room temperature. In aqueous solution, 1.5% free thiol was determined by Ellman's method, reflecting again the equilibration in solution. The thiol was a gift from the former Wellcome company, and the quantity of SNCP synthesized did not allow enough material for the study of its decomposition characteristics. However, some rate measurements were carried out on the decomposition of

© 1999 NRC Canada

Fig. 5. Absorbance–time plots for the decomposition of TGSNO (1×10^{-3} M) with (*a*) no added Cu^{2+}, (*b*) Cu^{2+} (0.5×10^{-5} M), (*c*) Cu^2 (1×10^{-5} M).



SNCP generated and used in situ from equimolar quantities of the thiol and nitrous acid. Good first-order plots were obtained for experiments with added Cu^{2+} in the range 0.3–1.0 $\times 10^{-5}$ M, and the measured first-order rate constants were linearly dependent on [Cu^{2+}].

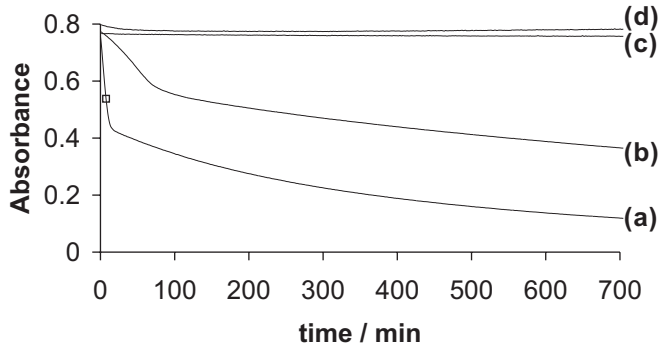
Discussion

GPSNO (1)

The successful synthesis of GPSNO and and of SNCP together with the demonstration of their apparent indefinite stability in the solid state has added further examples to the small list of stable *S*-nitrosothiols. It is likely that it, along with all RSNO species tested, will show the general characteristics of vasodilation and inhibition of platelet aggregation in vivo. Testing is underway. It is possible that this sugar derivative may have significant advantages (e.g., of solubility in water) over SNAP and GSNO for in vivo administration in order to effect these properties. A related sugar derivative, which does not have the stability of GPSNO in the pure state, has been shown (17) to have vasodilatory properties, including when the application is made transdermally to human cutaneous vascular smooth muscle.

The characteristics of in vitro decomposition and NO release of GPSNO are somewhat unusual compared with those of other *S*-nitrosothiols, particularly those derived from cysteine and related compunds. Figure 1 shows the pattern. It is clear that there are two reactions here, an initial faster reaction which is Cu^{2+}-catalyzed (and which does not go to completion unless the [Cu^{2+}] is relatively high –5×10^{-5} M in this case), and a slower reaction which is unaffected by the [Cu^{2+}], shows no signs of stopping at incomplete conversion, and which appears to be a thermal reaction. This interpretation is supported by the evidence in Fig. 2 which shows the disappearance of the copper-promoted reaction when EDTA is present (7), leaving the thermal reaction unaffected. The same result was obtained (not shown) when the specific Cu^{+} chelator neocuproine was added, at the same concentration, instead of EDTA, confirming our earlier suggestions that in these copper ion catalyzed reactions, the true catalyst is Cu^{+} (8), generated by thiolate ion reduction of Cu^{2+}. Thiolate ion is likely to be present in all RSNO solutions because of the reversibility of the *S*-nitrosation process (18). In this case we have measured a thiol level of ~2% in a solution of GPSNO (~5×10^{-3} M), which is a fairly typical figure, and which is high enough to effect Cu^{2+} reduction.

Fig. 6. Absorbance–time plots for the decomposition of TGSNO (1×10^{-3} M) with added Cu^{2+} (1×10^{-5} M) (*a*) without EDTA, (*b*) with EDTA (1×10^{-5} M), (*c*) with EDTA (2×10^{-5} M), (*d*) with EDTA (5×10^{-5} M).



We estimate the first-order rate constant (assuming the decomposition to be a first-order process) for the decomposition of GPSNO by the thermal route to be ~3×10^{-5} s^{-1}, i.e., with a half life of about 6–7 h. This compares with a value for the half life for the thermal decomposition of *S*-nitroso cysteine (one of the more unstable nitrosothiols in the pure state) of ~55 h at the same temperature (8). Other related structures e.g., SNAP, behave similarly.

The copper-catalyzed part of the reaction shows an interesting feature in that reaction without added Cu^{2+} appears to cease after only less than 30% conversion. As the added Cu^{2+} increased so does the % conversion, until at 5×10^{-5} M added Cu^{2+} reaction is essentially quantitative and is so rapid as to effectively swamp the thermal reaction. We have not observed this pattern of behaviour with other *S*-nitrosothiols. Incomplete conversion, however, has been noted earlier in the glutathione (GSH)/Cu^{2+} promoted decomposition of GSNO, in the presence of added oxidized glutathione, GSSG (19), which was interpreted in terms of complexation of Cu^{2+} by the added GSSG. For the GSNO reaction, there was spectroscopic evidence of such a complex with a shoulder at 250 nm and at higher concentration, a peak of low extinction at 620 nm, characteristic of a Cu^{2+} complex, for which a 1:1 structure has been proposed (20). Here with GPSNO decomposition we find (Fig. 4) the development of a small absorbance at around 280 nm which could reasonably be ascribed to the formation of the Cu^{2+} complex of the disulfide.

The derivative from 1-thio-β-D-glucose (generated in situ) behaved in a very similar manner, suggesting that the basic sugar unit provides sites which are available in the product disulfides for coordination of Cu^{2+}, and which allows a significantly larger rate of thermal decomposition of *S*-nitroso sugars generally when compared with simpler cysteine derivatives.

We detected nitric oxide in the decomposition reaction when it was carried out anaerobically. With relatively long reaction times it is extremely difficult to determine NO quantitatively, because of its reactivity, particularly towards traces of oxygen. Under these circumstances a measured yield of ~30% NO is not unusual. A little more difficult to explain is the relatively low yield of nitrite anion (51%)

© 1999 NRC Canada

determined when the reaction was carried out aerobically. We have no obvious explanation at this stage.

When ascorbic acid was added at 5×10^{-5} and 1×10^{-4} M, reaction proceeds to completion, implying that Cu^{2+} bound to the disulfide product is accessible for reduction by ascorbate but not by thiolate.

As part of another study which is looking at reactions involving nucleophilic attack at the nitroso nitrogen atom,[2] we discovered that sulfite ion is generally very reactive towards *S*-nitrosothiols, bringing about complete decomposition in seconds or fractions of seconds in most cases. The reaction forms the thiol and not the disulfide product, and does not generate nitric oxide (or nitrite ion in the presence of air), and by analogy with the corresponding reaction of nitrous acid (21), probably forms hydroxylamine disulfonate.

GPSNO shows the same characteristics in reaction with sulfite ion with a second-order rate consant of 8630 M^{-1} s^{-1}, which means that for reaction of GPSNO (1×10^{-3} M) and sulfite (2×10^{-2} M), the half life of reaction is only 4×10^{-3} s. Since reaction is so rapid and thiol products are readily analysed by the Ellman procedure, this reaction could be the basis for a quantitative analytical procedure for the determination of *S*-nitrosothiols.

TGSNO (2)

Unfortunately, it appears that TGSNO is not sufficiently stable at room temperature to enable a complete characterization and to allow standard solutions to be prepared from it. The red liquid, which could be kept at 0° for some weeks, is almost certainly the *S*-nitroso compound, and the UV-visible spectrum supports this. TGSNO was chosen for this study because preliminary in vivo testing experiments with solutions generated and used in situ had shown some unusual results which could result in some beneficial therapeutic properties.[3]

The decomposition features shown in Fig. 5 are in some ways similar to those found for GPSNO, in that there appear to be two reactions, one copper ion catalyzed and the other not. The copper-catalyzed reaction, however, does show induction periods, not evident in the reactions of GPSNO. Induction periods of this kind have been observed on a number of previous occasions (8, 10), and have been interpreted as the relatively slow initial formation of Cu^{+} (from Cu^{2+} and RS^{-}) with the regeneration of both reactants (eq. [2]). As expected, the induction period is reduced as the $[Cu^{2+}]$ is increased. It is also effectively removed by addition of thioglycerol (RS^{-}), not shown. Nitrite ion was formed quantitatively when reactions were carried out aerobically, and a substantial amount of NO (45%) was measured when oxygen was excluded.

One major difference between the reactions of TGSNO and GPSNO is shown in Fig. 6, where it can be seen that the addition of EDTA effectively stops *both* reactions. Reaction can also be halted when the EDTA is added during the course of the reaction, rather than at the beginning. The non-Cu^{2+}-catalyzed reaction cannot therefore, for TGSNO, be a thermal reaction, if it is halted by the addition of EDTA. It is not immediately obvious what is going on here. There are clearly two reactions taking place, one catalyzed by "free" Cu^{2+} and the other not, yet both are stopped by EDTA addition. A possible explanation is that the slower reaction *is* a copper-promoted reaction, but the effective catalyst, Cu^{+}, is obtained by thiolate reduction of the RSSR–Cu^{2+} complex, which would be expected to be a slower process than the thiolate reduction of free Cu^{2+}, and which would lead to complete, rather than partial decomposition of TGSNO. Further work is needed to clarify this point.

Some evidence of RSSR–Cu^{2+} complex formation is evident from the repeat scan experiments (not shown), but the complex does not appear to be as stable as that generated from GPSNO. Ascorbate also acts as a reducing agent at low concentration, resulting in complete decomposition of TGSNO, implying that, as for GPSNO, Cu^{2+} bound to the disulfide product is accessible for reduction by ascorbate.

At higher concentrations of addded ascorbate, the role of ascorbate changes from that of a reducing agent to that of a nucleophile, which undergoes electrophilic nitrosation by TGSNO, resulting in the formation of NO (becoming NO_2^{-} if aerobic) and the thiol 1-thioglycerol (cf. the reaction of nitrous acid with ascorbic acid (22)). Its reactivity is comparable to that of SNAP and *S*-nitroso-*N*-acetylcysteine.[4] A similar reaction has been reported (13) for the reaction of TGSNO with 1-thioglycerol at high [1-thioglycerol], where RS^{-} now acts as a nucleophile, leading to ammonia formation.

SNCP (3)

Because of a shortage of material, we were unable to carry out a full kinetic analysis on the decomposition of SNCP. However, we found good first-order behaviour over a range of $[Cu^{2+}]$ and obtained a value of 780 dm^3 mol^{-1} s^{-1} for the second-order rate constant k_2 (defined by rate = $k_2[RSNO][Cu^{2+}]$), which compares with a value of 20 dm^3 mol^{-1} s^{-1} for the closely structurally related SNAP. It is tempting to account for the reactivity difference in terms of the relative abilities of the *N*-$COCH_3$ and *N*-$CONH_2$ groups to bind Cu^{+} in an intermediate leading to NO formation, but this does not take account of the relative thiolate concentrations in both cases, which can dramatically affect reactivity in the ability to generate Cu^{+} from Cu^{2+} (10).

Conclusions

We have prepared and characterized two new stable *S*-nitrosothiols, GPSNO and SNCP, and have examined the decomposition in aqueous buffer (pH 7.4) of GPSNO, TGSNO, and SNTG (the latter two generated and used in situ). All reactants decomposed by two pathways, (*i*) GPSNO by a significant thermal pathway in parallel with a Cu^{2+}-catalyzed reaction, which tends to stop at incomplete conversion, as the Cu^{2+} catalyst is tied up by complexation with the disulfide product, and (*ii*) TGSNO by a Cu^{2+} pathway, which also stops at incomplete conversion probably for the same reason, together with a component which may arise by copper

catalysis where the true catalyst Cu^{+} is generated from the product disulfide–Cu^{2+} complex. Both compounds showed the "normal" reactivity with relatively high concentrations of reactive nucleophiles such as ascorbate and sulfite.

The secondary α-deuterium isotope effect at the site of the enzyme-catalyzed *cis-trans* isomerization of maleylacetone. Mechanistic implications

Michael S. Finnin and Stanley Seltzer

Abstract: An equal mixture of monodeuterated isotopomers of maleylacetone, viz., 4-hydroxy-6-oxo-2,4-heptadienoic-2-d_1 acid (**1**) and 4-hydroxy-6-oxo-2,4-heptadienoic-3-d_1 acid (**2**) was synthesized and subjected to catalyzed *cis-trans* isomerization by the maleylacetoacetate *cis-trans* isomerase–glutathione system. These studies were designed to probe the detailed mechanism of enzyme-catalyzed *cis-trans* isomerization about the C-2—C-3 bond of the substrate. In the competitive reaction, **2** accumulates with respect to **1** at high extent of reaction. ^{1}H NMR analysis indicates that **1** reacts 15% faster than **2** in line with a nucleophilic addition mechanism at C-2 rather than a conjugate addition mechanism at C-2 and C-3, to convert the C-2—C-3 double bond to a single bond to allow facile internal rotation.

Key words: enzyme-catalyzed *cis-trans* isomerization, secondary α-deuterium isotope effect, maleylacetoacetate *cis-trans* isomerase, *cis-trans* isomerization mechanism.

Résumé : On a synthétisé un mélange égal des isotopomères monodeutérés de la maléylacétone, soit l'acide 4-hydroxy-6-oxohepta-2,4-diénoïque-2-d_1 (**1**) et l'acide 4-hydroxy-6-oxohepta-2,4-diénoïque-3-d_1 (**2**) et on l'a soumis à une isomérisation *cis-trans* catalysée par le système glutathion–isomérase *cis-trans* du maléylacétoacétate. Ces études avaient pour but d'étudier en détail le mécanisme de l'isomérisation *cis-trans*, catalysée par les enzymes, autour de la liaison C-2—C-3 du substrat. Lors de réactions compétitives au cours desquelles on laisse aller la réaction pendant longtemps, le produit **2** s'accumule par rapport à **1**. Une analyse des spectres RMN du ^{1}H indique que le composé **1** réagit à une vitesse qui est de 15% supérieure à celle du composé **2**; ces résultats suggèrent que la conversion de la double liaison C-2—C-3 en liaison simple, qui permet une rotation interne facile, se fait par un mécanisme d'addition nucléophile en C-2 plutôt que par un mécanisme d'addition conjuguée en C-2 et en C-3.

Mots clés : isomérisation *cis-trans* catalysée par les enzymes, effet isotopique secondaire d'un deutérium en α, isomérase *cis-trans* de la maléylacétoacétonate, mécanisme de l'isomérisation *cis-trans*.

[Traduit par la Rédaction]

Introduction

The process of *cis-trans* isomerization about double bonds is an important reaction in biochemistry. Most notable is the visual process where light catalyzes the isomerization of opsin-bound 11-*cis*-retinal to the all-*trans* form thereby triggering, in a complex set of reactions, the transmission of the visual signal (1). While this reaction is photocatalytic, the regeneration of the 11-*cis*-retinal from the all-*trans*-isomer occurs in a series of dark reactions (2).

A similar reaction is found in the photocycle of the purple membrane which *Halobacteria salinarium* uses to capture and utilize sunlight as a source of energy (3). All-*trans*-retinal bound to the protein, bacterioopsin, is photoisomerized to the bound 13-*cis*-retinal, initiating structural changes which result in the active transport of a proton across the membrane. As part of the cycle, the 13-*cis*-bound retinal is reconverted to the bound all-*trans*-isomer in a dark reaction catalyzed by the protein in order to retrigger the system for the next cycle.

Another example of a biologically important *cis-trans* isomerization, and which this report is concerned with, is found in one of the enzymatic reactions necessary for the metabolic degradation of aromatic amino acids (4). Phenylalanine, for example,

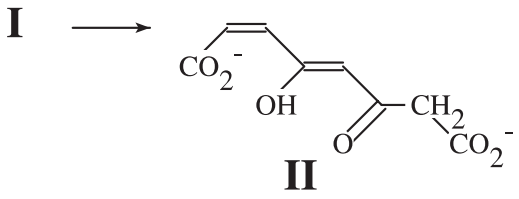
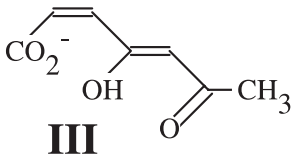
I

is converted through oxidation, deamination, and decarboxylation to homogentisic acid (**I**). The aromatic ring is then oxidatively cleaved to form maleylacetoacetate (**II**). This intermediate must first be *cis-trans* isomerized before the next enzyme can hydrolytically cleave it to fumarate and acetoacetate. The latter two compounds are then metabolized in the usual way.



II

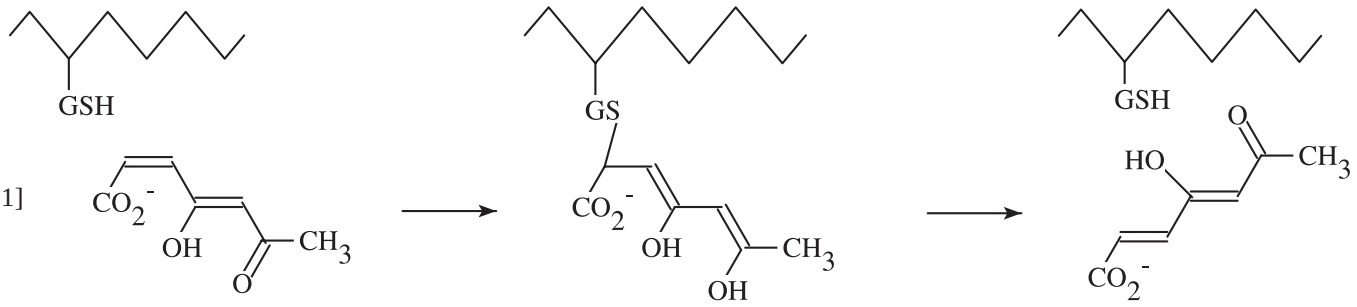
The mechanism of enzyme-catalyzed *cis-trans* isomerization of maleylacetoacetate has been the subject of continual research in our laboratory (5). Maleylacetoacetate, up to now, has been synthesized only through enzymatic oxidation of homogentisate, and it is formed in impure state. Early on we prepared maleylacetone (**III**), an analogue of **II**, with parallel functionality. The analogue can be prepared in pure state, and the enzyme, maleylacetoacetate *cis-trans* isomerase, readily catalyzes its *cis-trans* isomerization.



III

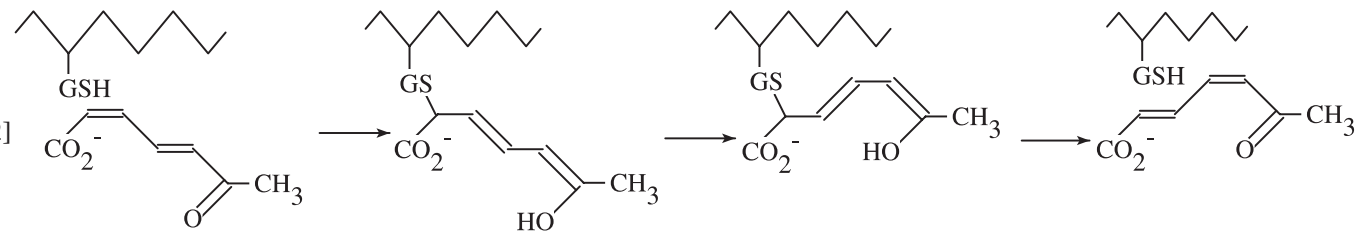
The enzymatic reaction requires a coenzyme, glutathione, a tripeptide of γ-glutamic–cysteine–glycine. It has been shown that the free sulfhydryl of cysteine is the catalytic site of the coenzyme in this reaction. Both the substrate and the coenzyme bind to the enzyme, and it is there where nucleophilic catalyzed isomerization takes place (6). Previous studies support the mechanism represented by eq. [1].

[1]



Recent studies with other analogues of maleylacetone, lacking the enolic hydroxyl have uncovered a concerted double *cis-trans* isomerization, presumably by a bicycle-pedal motion, catalyzed by the same enzyme system and proposed to follow the same mechanism (see eq. [2]) (7).

[2]

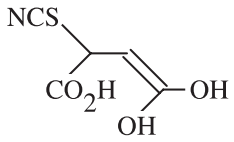


cis,trans ***trans,cis***

© 1999 NRC Canada

In this mechanism the reader should note that conjugate addition at C-2 and C-3 of the substrate is proposed not to take place. Instead, nucleophilic addition at C-2 with double bond migration is proposed, as supported by the lack of proton exchange at C-3 when the reaction is carried out in D_2O (8). This report is concerned with further evidence for nucleophilic addition at C-2 without concerted addition at C-3.

Several years ago the inverse secondary α-deuterium isotope effect in the thiocyanate-catalyzed *cis-trans* isomerization of maleic acid was reported (k_D/k_H = 1.16) (see ref. 9 in which the isotope effect given is for 40° but was measured from 15 to 80°). The isotope effect is consistent with the formation of an intermediate where one of the vinyl carbons becomes tetracoordinate while the other remains tricoordinate, allowing internal rotation about the central C—C bond. (Here, too, vinyl hydrogens do not exchange when the reaction is carried out in D_2O) (9). After rotation, loss of thiocyanate results in the formation of fumaric acid. A related α-deuterium isotope effect study in the enzyme-catalyzed *cis-trans* isomerization of maleylacetone is reported here, and the results are consistent with nucleophilic addition at C-2 of the substrate.



Results

Two deuterium-labeled isomers of maleylacetone (**1** and **2**) were prepared as a mixture. Monodeuterated maleic anhydride was first prepared by electrolytic reduction of monobromomaleic acid in D_2O, as described previously (10). The maleic-d_1 acid-d_2 was converted to its anhydride-d_1 and treated with isopropenyl acetate (11) to form the two deuterium-labeled butenolide isomers (**3** and **4**). Hydrolysis of the purified butenolides, as previously described (11), yielded a mixture of maleylacetone isotopomers. Mass spectral analysis of maleic-d_1 anhydride exhibits the following ion masses with their normalized intensities: 55(100.0), 98(1.18), 99(31.47), and 100(4.60). These data when compared with the data from the NBS library for maleic anhydride: 54(100.0), 98(50.4), and 99(2.4) suggest that there is 8.9% dideuterated maleic anhydride, and the remainder is the mono deuterated compound. Mass spectral analysis of the isotopically labeled butenolides exhibits the following important peaks: 96(44.31), 97(5.97), 123(4.65), 124(100.0), 125(13.88), 138(1.63), 139(21.36), and 140(4.10). The previously reported partial mass spectrum for the nondeuterated butenolide is 69(30), 95(31), 123(100), 138(33) (11). Correction for the ^{13}C and ^{17}O abundances to the 96–97 and the 123–125 mass regions result in an average content of 6.8% of dideuterated butenolide with the remainder represented by the monodeuterated species. We consider the content of the dideuterated maleylacetone to amount to between 6.8 and 8.9%.

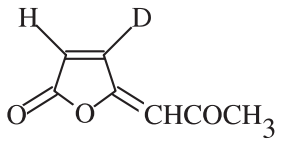
3



4

Quantitation of the isotope effect to be described below was accomplished by prolonged ^1H NMR signal acquisition. Consequently thermal isomerization of the unreacted labile substrate presented a problem. It was found, however, that conversion of the maleylacetone to its methyl ester with the Meerwein reagent, followed by extraction with chloroform and transfer to benzene-d_6 for ^1H NMR determination, resulted in a stable product with well-separated vinyl resonances.

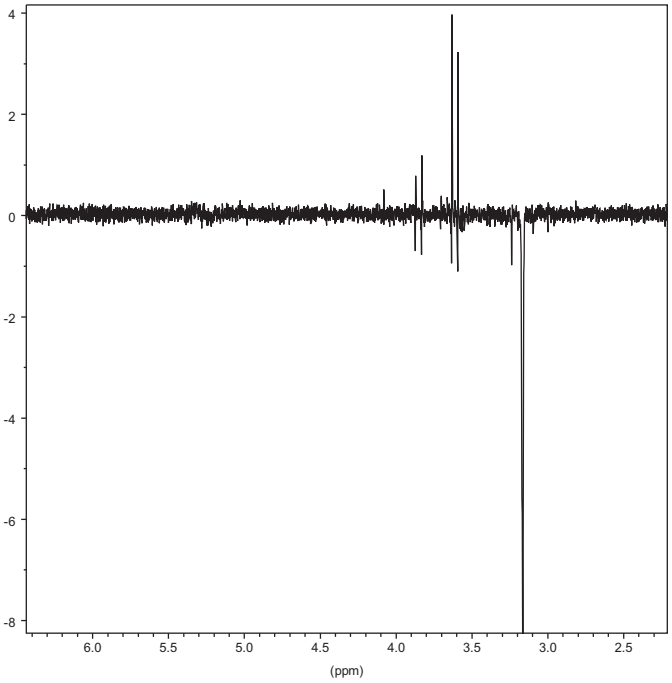
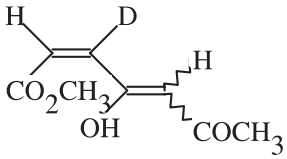
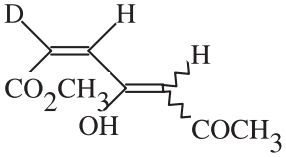
Fig 2. NOE-difference spectrum for methyl maleylacetone of natural isotopic abundance. The FID, obtained from off-resonance irradiation, was subtracted from the FID, obtained from irradiation of H-5 at δ 5.03 with a decoupler power of 50 L. The FID difference was then Fourier transformed and phased.



The C-2-C-3 vinyl region of the corresponding methyl ester of maleylacetone is shown in Fig 1. Any dideuterated species would, of course, be silent in this region. The major resonances at δ 5.72 and 5.48 each have a triplet in the approximate center of a doublet. The doublets each have a J = 12.2 Hz, representing an AB-quartet for nondeuterated maleylacetone methyl ester. The presence of the precursors of these isotopomers, viz., maleic anhydride-d_0 or the butenolide-d_0, was not obvious by mass spectrometry. The large triplets are expected for vinyl-H spin coupled to vinyl-D at the adjacent carbon. Each triplet represents one of the two following compounds.

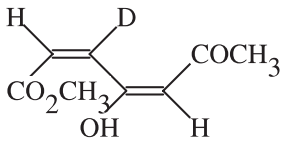


5

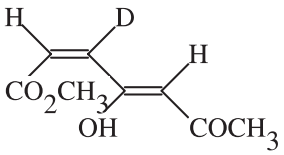


6

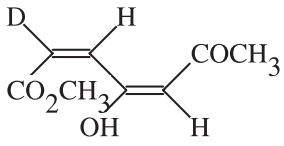
NOE-difference experiments were performed on the nondeuterated methyl ester. Irradiation of the methyl groups of the ester and of the acetyl groups produced no demonstrable changes in the intensity of the C-2-C-3 vinyl hydrogens. However, irradiation of H5 at δ 5.03 produced a small positive intensity difference in the downfield vinyl-H and a larger positive difference in the upfield vinyl-H (see Fig 2). Thus H-2 is the downfield vinyl-H, and H-3 is the upfield



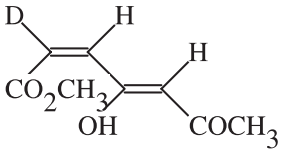
7 cis,cis-3-d$_1$



8 cis,trans-3-d$_1$



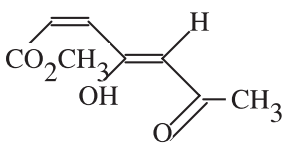
9 cis,cis-2-d$_1$



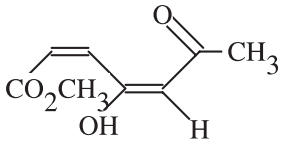
10 cis,trans-2-d$_1$

vinyl-H. Consequently, the area of the downfield vinyl triplet measures the amount of **5** present, while the area of the upfield vinyl triplet measures the amount of **6** present.

There are two smaller triplets centered in doublets at about δ 5.93 and 5.46. The low field doublet also has a J = 12.2 Hz; the low field peak of the minor high field doublet is under the major resonance and so its coupling constant was not determined. There are therefore four monodeuterated *cis*-2 isomers present which can be represented as **7**–**10**. As pointed out above the AB-quartets represent nondeuterated methyl ester isomers of maleylacetone: one being *cis,trans*, the other *cis,cis*. The major isomer has its C-5-vinyl proton at δ 5.03, while the corresponding C-5-vinyl proton of the minor isomer is at δ 6.12. Based on this the major isomer is tentatively assigned to the *cis,trans* structure. H-5 in the *cis,trans* structure is closer to the C-2—C-3 double bond and should feel its diamagnetic effect more strongly than H5 in the *cis,cis* structure. The diamagnetic effect of the ester carbonyl is at longer distance and consid-



cis,trans



cis,cis

ered here to be smaller. Which is the minor and which is the major isomer, however, is of no consequence to the determination of the isotope effect (vide infra).

The individual resonances were deconvoluted and the areas measured to separate monodeuterated from nondeuterated species. The sum of the nondeuterated species is estimated to amount to about 9%. The areas of the separated minor and major low field triplets were summed and compared to the area of the high field sum of the major and coalesced minor triplet. As seen in Fig 1, half of the high field AB doublet of the minor nondeuterated species is under the coalesced high field triplet. It is assumed that the area of the half of the minor AB doublet under the triplet is equal to the half that is visible at δ 5.44. These peaks are

[d]High field multiplet representing two monodeuterated isomers plus half of an AB-doublet due to a nondeuterated species; see text.

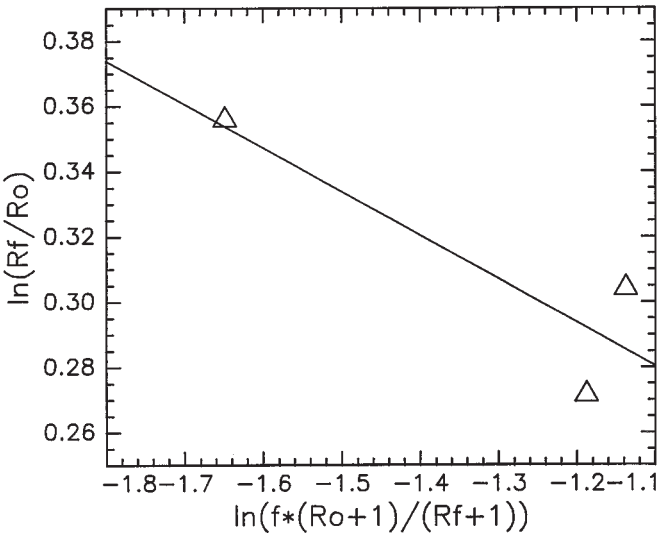
[e]Upfield half of the separated AB-doublet due to a nondeuterated species; see text.

[f]The fraction of maleylacetone remaining.

[g]The ratio of maleylacetone isotopomers obtained from NMR integration after partial enzymatic reaction (VLF-D + LF-D)/(HF-D – UF-D), and designated as R_f.

[h]This is the initial ratio of maleylacetone isotopomers and designated as R_0.

Fig 3. Plot of ln (R_f/R_0) vs. ln $(f(R_0 + 1)/(R_f + 1))$. The least squares slope is equal to –0.133.



quite small, and any difference between the low and high field halves of this doublet will be quite small. Thus the area of the peak at δ 5.44 was subtracted from the sum of the major and minor coalesced triplets at high field.

Since these studies are highly dependent on the integrated areas of vinyl peaks, obtained from sequential pulsing, it is important to have fully relaxed protons from the previous pulse before a new pulse is applied. The T_1 values of the vinyls of the monodeuterated maleylacetone methyl ester were measured. They are 7.2 and 6.4 s for the protons at δ 5.72 and 5.48, respectively. The nondeuterated methyl ester exhibits T_1 values for the corresponding resonances of 3.9 and 2.2 s, respectively.

A relaxation delay of 60 s between pulses was chosen. Pulsing was generally for about 10 hs and was carried out in blocks of 64. Between each block the NMR was programmed to automatically reshim the Z and Z^2 coils to improve and maintain high resolution. The integrated areas of the peaks due to the vinyl proton of unreacted monodeuterated maleylacetone methyl ester together with the fraction of reaction are shown in Table 1.

The ratios of the vinyl ^{1}H NMR peak areas (see Fig. 1) of methyl ester isotopomers of maleylacetone, obtained from the four terms, viz., (VLH-D + LF-D)/(HF-D – UF-H), and defined as the areas of (*i*) the very low field monodeuterated species, (*ii*) the low field monodeuterated species, (*iii*) the highfield multiplet representing two monodeuterated isomers plus half of a nondeuterated isomer, and (*iv*) half of an AB-doublet representing half of the resonance due to the presence of a nondeuterated maleylacetone methyl ester species, respectively, are given in Table 1. These ratios are, in effect, the ratios of the amounts of **5** to **6**, remaining after enzymatic reaction where the quantity, f, refers to the fraction of initial reactant remaining after reaction and referred to as R_f. The initial ratio (no enzymatic reaction) of **5** to **6** is referred to as R_0 (see Table 1).

The relationship of the isotope effect to R_f, R_0, and f is given in Appendix as [A-10] and is previously derived in slightly different form in ref. 12. A plot of ln (R_f/R_0) vs. ln $(f(R_0 + 1)/(R_f + 1))$ is shown in Fig. 3. The slope, equivalent to $k_1/k_2 - 1$, is –0.133, leading to an inverse isotope effect, $k_D/k_H = 1.15$ at C-2.

Discussion

The *cis-trans* isomerization about a nonactivated carbon–carbon double bond, as in ethylene, requires an activation energy of about 60 kcal/mol (13). The energy can be reduced by formation of an intermediate where the double bond is converted to a single bond, thereby allowing facile rotation. This can be accomplished by addition of a nucleophile, an electrophile, or a radical to one of the sp^2 carbons of the double bond. In the case of nucleophilic addition, the negative charge generated in the intermediate can be delocalized in electron sinks if they are present in the molecule, thereby lowering the activation energy. If there are no groups available to stabilize a charged or a radical center, an alternative mechanism might be for the reactant to undergo conjugate addition at that carbon–carbon double bond to form a single bond to allow rotation after which the conjugate is expelled. To differentiate between the two types of mechanisms, a secondary α-deuterium isotope effect test can be applied.

The secondary α-deuterium isotope effect was first mechanistically rationalized by Streitwieser et al. (14) and later

© 1999 NRC Canada

theoretically justified by Wolfsberg and Stern (15). In simplest terms, a reaction at thermal equilibrium, involving a unimolecular conversion of a tetracoordinate carbon to a trigonal carbon will proceed approximately 15% more slowly when a deuterium atom is substituted for protium at that carbon atom. Many examples of this exist in the solvolysis literature. Conversely, conversion of a trigonal carbon to a tetracoordinate carbon will proceed at a comparable faster rate when a deuterium atom is substituted for protium at that carbon atom.

Maleylacetoacetate *cis-trans* isomerase requires the coenzyme, glutathione (GSH), for activity. The sulfhydryl group is the active site of the coenzyme, as shown by inhibition studies with *S*-methyl glutathione (6). Binding and affinity studies with glutathione analogues show that GSH binds to the enzyme along the backbone of the tripeptide, steering the sulfhydryl group away from the surface of the enzyme so that it is available to react with the maleylacetoacetate or maleylacetone substrate (6). GSH is itself a very good nucleophile (16), and judging from the model reaction of thiocyanate with maleic acid, a most reasonable mechanism would be for enzyme-bound GSH to add to the carbon–carbon double bond of the enzyme substrate. In fact in the absence of the enzyme, a conjugate addition product of GSH to maleylacetone has been identified where the sulfur has added to C-2 and a proton to C-3 (8). The question here is whether addition to only one carbon or concerted addition to both carbons, i.e., sulfur to C-2 and a proton to C-3, takes place in the enzymatic reaction in order to form an intermediate capable of facile internal rotation.

In previous studies it was shown that the enzymatic reaction when carried out in D_2O does not lead to D-exchange at C-3 of fumarylacetone, the product of maleylacetone *cis-trans* isomerization (8). Is it possible for the enzyme to catalyze concerted conjugate addition by putting a proton (deuteron) at C-3 and stereospecifically remove the same proton (deuteron) after rotation, masking this test for conjugate addition? To answer this question a secondary α-deuterium isotope effect at the carbon–carbon double bond undergoing rotation has been measured.

A mixture of equal amounts of isotopomers, **1** and **2**, and their minor isomers (vide supra), of maleylacetone has been synthesized and subjected to enzyme-catalyzed *cis-trans* isomerization. Substrate **1** has a deuterium label at C-2, while **2** has the label at C-3. If nucleophilic addition takes place at C-2 with double bond migration to form the intermediate shown in eq. [1] then one would expect **1** to react faster than **2**. That is to say that after a substantial extent of reaction an excess of **2** over **1** would be found in the remaining unreacted substrate. Only one of the two sp^2 carbons is converted to a tetracoordinate carbon. If, however, concerted conjugate addition takes place, both sp^2 carbons are converted to tetracoordinate carbons, and one would expect approximately equal isotope effects at each carbon, and the amounts of **1** and **2** in the remaining unreacted substrate would be expected to be equal.

The structures **1** and **2** and their minor isomers were converted to surrogates **6** and **5**, respectively, in order to stabilize maleylacetone against isomerization during the long periods necessary for NMR analysis. NOE experiments were performed on the undeuterated methyl ester of maleylacetone. These included irradiation of the OCH_3, and CH_3CO groups, and the vinyl proton at C-5, as well as off-resonance irradiation, under otherwise identical conditions. Figure 2 shows the difference spectrum for irradiation at H-5 minus that for off-resonance where the upfield vinyl doublet is enhanced relative to its partner at lower field. NOE enhancements are inversely proportional to the sixth power of the distance between two nuclei. Using standard bond angles and lengths, the distances between H-3 and H-5 in the *cis,cis* and *cis,trans* isomers are calculated to be 2.50 and 3.76 Å, respectively, while the distances between H-2 and H-5 for these isomers are 4.67 and 5.47 Å, respectively. While we have assigned the *cis,trans* conformation to the major isomer, H-3 is clearly closer to H-5 in either *cis,trans* or *cis,cis* isomers than is H-2 to H-5. Since the larger NOE enhancement is seen at the higher field vinyl doublet (δ 5.48), it is this doublet which represents H-3 and the lower field doublet at δ 5.72 which represents H-2. Thus the large triplet at δ 5.72 was assigned to compound **5** and the large triplet at δ 5.48 assigned to compound **6**. The assignment of which ^1H resonance is due to H-2 and which to H-3 is independent of the assignment of which conformational isomer, *cis,cis* or *cis,trans,* is the major isomer.

As shown in Fig. 1 and Table 1, the minor isotopomers with vinyl resonances at about δ 5.93 and δ 5.46 are low in concentration, relative to the major isomers in both the starting material and in the remaining substrate after extensive enzymatic reaction. While the interconversion of these *cis,cis* and *cis,trans* conformations is slow on the NMR time scale, the similar relative concentrations in starting material and remaining substrate indicates that either the enzyme is equally efficient in isomerizing minor and major conformations, the enzyme catalyzes interconversion of conformations, or that a nonenzymatic equilibration of conformations, slow on the NMR time scale but rapid before observation, occurs.

Secondary deuterium isotope effects, as the name implies, are considered to be small in magnitude, and one would hope that the precision in their measurements would be sufficient to demonstrate the absence or the presence of an isotope effect. In this study we examine the relative rates of isomerization of isotopomers in a competitive experiment by NMR integration. NMR allows one to study the relative rates of reaction of a mixture of isotopomers without prior separation of the individual components even if that were possible. Mass spectrometry, which is usually used in such studies, would likely be of little use in this competitive study unless the individual isotopomers were synthesized and isolated and their rates were measured against the natural compounds in separate experiments. In the past, NMR integration was considered to be a somewhat imprecise method to measure concentrations of solutes but the use of digital analysis instead of analog analysis has improved the precision of measurement. In this study we also resort to deconvolution of minor components of the spectrum. Because these are minor components and because this, too, is now done by digital analysis, the precision of deconvolution has also improved. This study, however, has less of a dependence on precision than most studies of secondary deuterium isotope effects. First, the reaction is taken to large extents of reaction so that an effect of 15% is magnified to

© 1999 NRC Canada

30–40% (see R_f and R_0 in Table 1). There is little doubt that **1** reacts faster than **2**. Second, as pertains to the mechanistic question posed in this study, this is essentially an all-or-none type of study. Either **1** or **2** reacts with equal rates, or one isotopomer reacts faster than the other. The results shown in Table 1 clearly show the latter. As for precision of the effect, which we determine to be $k_D/k_H = 1.15$ from Fig. 1, each R_f and R_0 are the averages of three determinations, each with an average deviation of ±0.7%. Using these apparent deviations and assuming a relative error of ±5% in f, an error analysis (17) of eq. [A-10] leads to a predicted relative error of 5% in $k_1/k_2 - 1$.

In conclusion, there is little doubt that **1** reacts faster than **2** by some 15%, inconsistent with an enzyme-catalyzed concerted conjugate addition but in line with a mechanism that proposes that rate-controlling addition at C-2 with double bond migration towards the acetyl group takes place. The results support the mechansism depicted in eqs. [1] and [2].

Experimental

General information

^{1}H NMR spectra were obtained with a Bruker AM-300 spectrometer. The vinyl region was deconvoluted and integrated using the Bruker WINNMR software package on a 486 PC. During data acquisition a relaxation delay of 60 s was used between 90° pulses. Data acquisition (4.2 s/fid) was generally carried out for about 10 hs for each kinetic isotope effect run. After each group of 64 fids was acquired, the NMR spectrometer, by previous programming, reshimed its Z and Z^2 coils to improve and maintain high resolution.

Enzyme preparation

Maleylacetoacetate *cis-trans* isomerase was obtained from *Vibrio O1* bacteria and purified as described previously (4*b*, 6). Isolation and purification included the following steps: (*i*) sonication of bacteria and centrifugation, (*ii*) protamine sulfate treatment, (*iii*) salt precipitation, (*iv*) hydroxyapatite chromatography, and (*v*) affinity chromatography on a GS-agarose column. The measured specific activity of the enzyme at this point was 13.4 μmol/min mg of protein (corrected for GSH and substrate saturation).

Maleylacetone-2 or -3-d_1 (4-hydroxy-6-oxo-2,4-heptadienoic-2 or-3-d_1 acid)

Maleic-d_1 acid-d_2 was prepared electrolytically from monobromomaleic acid (Aldrich) in D_2O as described previously (10). Maleic-d_1 acid-d_2 was converted to maleic anhydride-d_1 by distillation from P_2O_5 as previously described (see Results for mass spectrum) (10). Reaction of the anhydride with isopropenyl acetate in the presence of aluminum chloride, as previously described (11), yielded 4-acetonylidenebutenolide (Z) (see Results for its mass spectrum), which was hydrolyzed in H_2O (11), as previously described (11), to yield a mixture of maleylacetone isotopomers.

Methyl ester of maleylacetone-d_1 (methyl 4-hydroxy-6-oxo-2,4-heptadienoate-2 or -3-d_1)

Trimethyloxonium fluoroborate, obtained from Aldrich, was used to convert maleylacetone-d_1 in aqueous solution to its methyl ester with modification of the procedure previously published (5*a*). The enzyme reaction mixture was frozen in a dry ice – acetone bath and the solid lyophilized. The solid residue was taken up in 1 mL of water and transferred to a 10 mL beaker to which was added 170 mg of sodium bicarbonate and 550 mg of trimethyloxonium fluoroborate. Reaction was allowed to proceed for about 30 min while it was cooled in ice water. The ester was extracted into chloroform (4 × 0.5 mL) and the layers separated. The combined chloroform layers were dried over a few crystals of sodium sulfate, decanted, and evaporated. The residue was dissolved in benzene-d_6 for ^{1}H NMR analysis (see Fig. 1 for ^{1}H NMR of its C-2/C-3 vinyl region).

Kinetic isotope effect experiments

A computer program was written which used previously published rate constants (6, 8) for enzymatic and nonenzymatic reactions to calculate, by numerical integration, the instantaneous concentrations of substrate, GSH, and product to help predict the extent of reaction for given initial concentrations of reactants at various reaction times. GSH is not consumed in the enzymatic reaction, however, it is consumed in a nonenzymatic conjugate addition reaction with the isomerization product, which is 50 times faster than GSH conjugate addition with the starting material. As the GSH concentration is depleted through these nonenzymatic reactions, the enzymatic reaction is retarded, since the enzyme requires GSH for its action. The computer calculation proved to be a good predictor of the extent of reaction for a given specified time and specified initial concentration of reactants. Kinetic isotope effect experiments were carried out at ambient temperature.

Acknowledgments

This research was carried out under contract DE-AC02-76CH00016 with the U.S. Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Science. The authors thank Charles Hoogstraten for the preparation of maleic-d_1 acid-d_2 and Ms. Elinor Norton for mass spectral analysis.

Appendix

In a competitive reaction of two isotopic molecular species, A_1 and A_2, with nonisotopic reactants, B, C, etc., occurring with rate constants, k_1 and k_2, respectively, and which is unimolecular in A, the ratio of rate constants is given by[3]

[A-1] $k_1/k_2 = [\ln (a_1/a_1^0)]/[\ln (a_2/a_2^0)]$

where a_1 and a_2 are the amounts of remaining A_1 and A_2 reactants after a substantial amount of reaction, and a_1^0 and a_2^0 are the initial amounts of these reactants. The ratio, a_1/a_2, will differ more substantially from a_1^0/a_2^0 at high extents of reaction. The ratio, a_1^0/a_2^0 (= R_0), refers to the initial ratio of concentrations of malelyacetone-3-d_1 to maleylacetone-2-d_1 methyl esters. The ratio, a_1/a_2 (= R_f), refers to the corresponding ratio of unreacted species when the reaction is halted at fraction of substrate remaining, f, and defined as

[A-2] $f = (a_1 + a_2)/(a_1^0 + a_2^0)$

The fraction of substrate remaining is measured spectrophotometrically and consequently includes all maleylacetone species. This includes nondeuterated, monodeuterated, and dideuterated. Nondeuterated and dideuterated species are present in small concentrations. While eq. [A-2] is not exact, it is close to being exact in this system. From eq. [A-1] we get

$$[\text{A-3}] \quad \frac{a_1}{a_1^0} = \left(\frac{a_2}{a_2^0}\right)^{(k_1/k_2)}$$

and dividing by a_2/a_2^0, we get

$$[\text{A-4}] \quad \frac{\frac{a_1}{a_1^0}}{\frac{a_2}{a_2^0}} = \left(\frac{a_2}{a_2^0}\right)^{(k_1/k_2)-1}$$

But

$$[\text{A-5}] \quad \frac{R_f}{R_0} = \frac{\frac{a_1}{a_1^0}}{\frac{a_2}{a_2^0}}$$

Therefore,

$$[\text{A-6}] \quad \frac{R_f}{R_0} = \left(\frac{a_2}{a_2^0}\right)^{(k_1/k_2)-1}$$

Since

$$[\text{A-7}] \quad f = \frac{a_1 + a_2}{a_1^0 + a_2^0} = \frac{a_2 R_f + a_2}{a_2^0 R_0 + a_2^0} = \frac{a_2}{a_2^0} \times \frac{R_f + 1}{R_0 + 1}$$

and

$$[\text{A-8}] \quad \frac{a_2}{a_2^0} = f \times \frac{(R_0 + 1)}{(R_f + 1)}$$

Thus from eq. [A-6]

$$[\text{A-9}] \quad \frac{R_f}{R_0} = \left[\frac{f(R_0 + 1)}{(R_f + 1)}\right]^{(k_1/k_2)-1}$$

Therefore,

$$[\text{A-10}] \quad \frac{k_1}{k_2} - 1 = \frac{\ln\left(\frac{R_f}{R_0}\right)}{\ln f\frac{(R_0 + 1)}{(R_f + 1)}}$$

The problem of distinguishability of rate constants in the two-step consecutive sequence A → B → C

John Andraos

Abstract: A detailed analysis of the absorbance versus time functional forms of the chemical species in the consecutive two-step unimolecular reaction scheme is presented. Distinguishability of rate constants is discussed with respect to the characterization of growth–decay and decay–growth curves and the rate constant – reaction step ambiguity. A new method based on the functional form of the absorption extremum involving the intermediate B with catalyst concentration is proposed to overcome the problem of rate constant assignments.

Key words: reaction mechanism, kinetics analysis, physical organic chemistry.

Résumé : On présente une analyse détaillée de l'absorption en fonction du temps des formes fonctionnelles des espèces chimiques dans deux étapes consécutives d'une réaction unimoléculaire. On discute de la différentiation des constantes de vitesse par rapport à la caractérisation des courbes de croissance–décroissance et décroissance–croissance et de la difficulté d'identifier l'étape déterminante de la constante de vitesse de la réaction. On propose une nouvelle méthode basée sur la forme fonctionnelle de l'extremum d'absorption impliquant l'intermédiaire B avec une concentration du catalyseur pour surmonter le problème d'attribution des constantes de vitesse.

Mots clés : mécanisme réactionnel, analyse cinétique, chimie organique physique.

[Traduit par la Rédaction]

Introduction

The determination of rate laws and reaction mechanisms is of fundamental importance in chemistry. Indeed, the discipline of physical organic chemistry was born with these concepts at its centre and continues to be rich in this tradition in current pure and applied organic chemistry research. Most notably, the area of kinetic and spectroscopic characterization of reaction intermediates has benefitted greatly from reaction mechanism analysis. There exist cornerstone references on the subject of solution-phase chemical kinetics which describe in detail various kinetic systems and the time-dependent behaviour of their component chemical species (1–6).

One such reaction scheme is the two-step consecutive unimolecular transformation given in eq. [1] with associated rate constants k_1 and k_2. Note that the subscript labels for the rate constants, 1 and 2, refer to step 1 and step 2, respectively, in the sequence.

$$[1] \qquad A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

This particular kinetic system is well known with several examples cited in the literature (1–14). The time-dependent absorbance functions of each of the chemical species, A, B, and C are given in eqs. [2*a*]–[2*c*] with initial conditions $A_A(0) = A_A^0$, $A_B(0) = 0$, and $A_C(0) = 0$ at time zero (1–6).

$$[2a] \qquad A_A = A_A^0 \exp[-k_1 t]$$

$$[2b] \qquad A_B = A_A^0 \left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)\{\exp[-k_2 t] - \exp[-k_1 t]\}$$

$$[2c] \qquad A_C = A_A^0 \left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left\{1 - \frac{1}{k_1 - k_2}(k_1 \exp[-k_2 t] - k_2 \exp[-k_1 t])\right\}$$

where A_A^0 represents the initial absorbance of A at time zero, and ε_A, ε_B, and ε_C represent the absorption coefficients of A, B, and C, respectively.

This paper presents a new detailed analysis of this kinetic system encompassing that found in the traditional works cited above. More importantly, the less well-documented experimental problem of assigning calculated rate constants, k_1 and k_2, obtained from nonlinear regression analysis to the appropriate steps in the reaction sequence is addressed. This problem has been documented by a few authors, and essentially two methods have been described which deal with the ambiguity of rate constant assignments (7–15). These methods rely either on inclusion of additional chemical knowledge or on analysis of the variation of absorption coefficients to remove the ambiguity. A method based only on the behaviour of the extremum absorption of the intermediate B is presented here. This method is universal and is particularly advantageous for cases where required additional

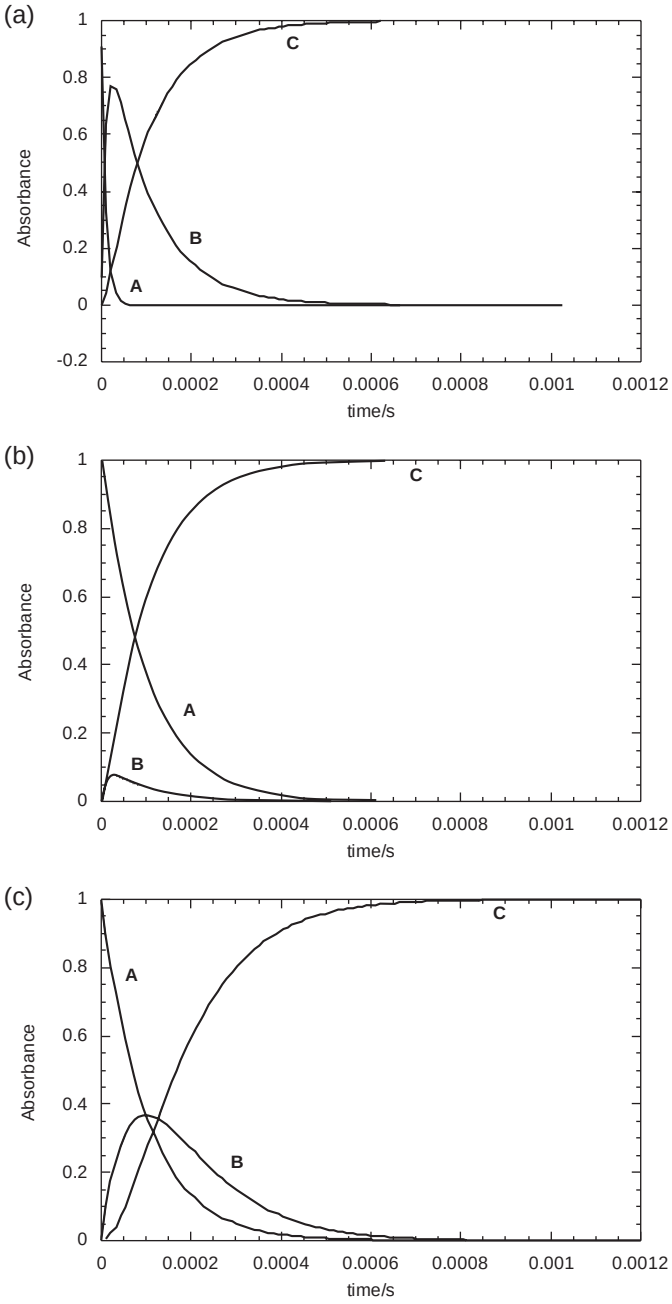
Fig. 1. Absorbance–time functions for species A, B, and C fitted according to eqs. [2*a*]–[2*c*]: (*a*) $k_1 = 10^5$ s^{-1}, $k_2 = 10^4$ s^{-1}, $A_A^0 = 1$, $\varepsilon_B/\varepsilon_A = 1$, $\varepsilon_C/\varepsilon_A = 1$; (*b*) $k_1 = 10^4$ s^{-1}, $k_2 = 10^5$ s^{-1}, $A_A^0 = 1$, $\varepsilon_B/\varepsilon_A = 1$, $\varepsilon_C/\varepsilon_A = 1$; and (*c*) fitted according to eqs. [5*a*]–[5*c*]: $k_1 = 10^4$ s^{-1}, $k_2 = 10^4$ s^{-1}, $A_A^0 = 1$, $\varepsilon_B/\varepsilon_A = 1$, $\varepsilon_C/\varepsilon_A = 1$.



experimental information to overcome the problem may be difficult to obtain.

Explanations given in the literature of the apparent mathematical ambiguity in this kinetic scheme vary depending on the author and are either incomplete or somewhat cloaked in confusing language. In addition to presenting a new method, it is intended to also provide a unified analysis of the problem which ties all ideas together in a concise and clear fashion without sacrificing rigour.

Properties of the two-step consecutive sequence

We begin by reviewing the properties of the absorbance–time functions pertaining to eq. [1]. It is instructive to examine the following three cases: (*i*) $k_1 > k_2$, (*ii*) $k_2 > k_1$, and (*iii*) $k_1 = k_2 = k$. For case (*i*), eqs. [2*a*]–[2*c*] apply as written. For case (*ii*), eqs. [3*a*]–[3*c*] given below apply.

$$[3a] \quad A_A = A_A^0 \exp[-k_1 t]$$

$$[3b] \quad A_B = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_2 - k_1}\right)\{\exp[-k_1 t] - \exp[-k_2 t]\}$$

$$[3c] \quad A_C = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left\{1 - \frac{1}{k_2 - k_1}(k_2 \exp[-k_1 t] - k_1 \exp[-k_2 t])\right\}$$

It should be noted that the sets of eqs. [2*a*]–[2*c*] and [3*a*]–[3*c*] are identical. Multiplication of the numerator and denominator by –1 in the terms $k_1/(k_1 - k_2)$ and $1/(k_1 - k_2)$ in eqs. [2*b*] and [2*c*], respectively, leads immediately to eqs. [3*b*] and [3*c*]. For case (*iii*), setting $k_1 = k_2 = k$ in eqs. [2*a*]–[2*c*] results in indeterminate forms for A_B and A_C. A mathematical manipulation employed to overcome this problem is to express one rate constant as a multiple of the other and then to find the limiting expressions as this factor approaches unity. Hence, setting $k_2 = nk_1$ where $0 < n < \infty$ leads to the set of eqs. [4*a*]–[4*c*].

$$[4a] \quad A_A = A_A^0 \exp[-k_1 t]$$

$$[4b] \quad A_B = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{1}{n-1}\right)\{\exp[-k_1 t] - \exp[-nk_1 t]\}$$

$$[4c] \quad A_C = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left\{1 - \frac{1}{n-1}(n \exp[-k_1 t] - \exp[-nk_1 t])\right\}$$

Taking the limit of eqs. [4*a*]–[4*c*] as $n \rightarrow 1$ and using l'Hôpital's rule (16) results in eqs. [5*a*]–[5*c*].

$$[5a] \quad A_A = A_A^0 \exp[-kt]$$

$$[5b] \quad A_B = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)kt \exp[-kt]$$

$$[5c] \quad A_C = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\{1 - (1 + kt)\exp[-kt]\}$$

As is readily apparent, the set of eqs. [4*a*]–[4*c*] conveniently describes all three cases: case (*i*) occurs when $0 < n < 1$, case (*ii*) occurs when $1 < n < \infty$, and case (*iii*) occurs when $n = 1$. This manipulation of representing one rate constant as a multiple of the other is very useful and will become important in later analyses.

A detailed analysis of the forms of the functions describing the time-dependent absorbances of species A, B, and C reveals a number of important characteristics. Figs. 1*a–c* illustrate graphically the three absorbance–time functions for each of the cases given above. The absorbance–time func-

1	3	A or B or C
2	3	A and B, or A and C, or B and C
3	1	A, B, and C

tion for species A is simply a first-order decay with an initial absorbance equal to A_A^0 and a limiting final absorbance ($t \to \infty$) equal to zero. The absorbance–time function for species B is characterized as concave down with a single maximum. The initial and limiting final absorbances are both equal to zero. The maximum point in the absorbance–time function for B has a value given by

$$[6a] \qquad A_B^{max} = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{1}{n-1}\right)[n^{-1/(n-1)} - n^{-n/(n-1)}]$$

occurring at

$$[6b] \qquad t_m = \frac{1}{k_1}\left(\frac{\ln n}{n-1}\right)$$

where $k_2 = nk_1$, $0 < n < \infty$. Note that the co-ordinates of the maximum for each of the cases given above are

$$t_m = \frac{1}{k_1 - k_2}\ln\left(\frac{k_1}{k_2}\right)$$

and

$$A_B^{max} = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)\left[\left(\frac{k_1}{k_2}\right)^{-k_2/(k_1-k_2)} - \left(\frac{k_1}{k_2}\right)^{-k_1/(k_1-k_2)}\right]$$

when $k_1 > k_2$ ($0 < n < 1$) or $k_1 < k_2$ ($1 < n < \infty$), and $t_m = 1/k$ and $A_B^{max} = A_A^0(\varepsilon_B/\varepsilon_A)\exp(-1)$ when $k_1 = k_2$ ($n = 1$). It may be verified that the function in n in eq. [6*a*] approaches a limiting value of exp (–1) = 0.3679 as n approaches 1 (see Appendix A). Finally, the absorbance–time function for species C is a sigmoidal growth and is characterized as having an inflection point dividing the curve into a concave up portion before the inflection point and a concave down portion after it. The value of t corresponding to the inflection point is commonly referred to as the induction period. From eq. [4*c*] this inflection point occurs exactly at the value of t corresponding to the maximum of the absorbance–time function of B (see eq. [6*b*]), and has a corresponding absorbance value given by

$$[7] \qquad A_C^{inf} = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left\{1 - \frac{1}{n-1}(n^{(n-2)/(n-1)} - n^{-n/(n-1)})\right\}$$

The initial and limiting final absorbances are equal to zero and $A_A^0(\varepsilon_C/\varepsilon_A)$, respectively. The point (0, 0) corresponds to a minimum; whereas, the limiting absorbance of $A_A^0(\varepsilon_C/\varepsilon_A)$ corresponds to a maximum. Note also that the absorbance curve for C is invariant to the transposition of values for k_1 and k_2 (see Fig. 1).

Possible experimental outcomes

If a chemical system is described by the reaction mechanism of eq. [1], then there are several experimental possibilities for observing the chemical species depending on the number of species observed at any one time according to a particular property. For example, in the case of a kinetics experiment conducted using UV-vis spectrophotometry, if each chemical species has a characteristic monitoring wavelength unique to that species, then it is possible to observe the absorbance–time evolution of each component separately. In practice such an ideal situation is rarely encountered, and hence usually several combinations of species may be observed at once. Table 1 summarizes the various possible experimental situations, and Tables 2–4 list the possible absorbance–time functions for observing one, two, and three chemical species at a given monitoring wavelength, respectively. Note that the entries in Table 2 correspond to the equations and properties given in the previous section.

At this point it is important to examine the general case of observing three chemical species (A, B, and C) with respect to isobestic points. There are three cases of isobestic points to consider: (*i*) $\varepsilon_A = \varepsilon_B$, (*ii*) $\varepsilon_A = \varepsilon_C$, and (*iii*) $\varepsilon_B = \varepsilon_C$. The expression in Table 4 is simplified under these conditions and the possible functional outcomes are greatly reduced as is shown by the entries in Table 5.

Properties of growth–decay and decay–growth curves

Suppose that a kinetics experiment is performed in which the appearance and disappearance of B is monitored directly as a function of time. Typically, the array of data points (t_i, $A_{B,i}$) is fitted by means of a nonlinear regression algorithm to a model given by

$$[8] \qquad y = a[\exp(-bt) - \exp(-ct)]$$

where a, b, and c are parameters to be determined. Parameters b and c refer to the two rate constants and are thus always positively valued; whereas, parameter a is a pre-exponential factor that can be positively or negatively valued. Note that eq. [8] is the general form of eqs. [2*b*], [3*b*], and [4*b*]. It is worth examining in detail the functional behaviour of eq. [8] which will reveal information about the location of extrema (maxima, minima, and inflection points) and the directions of concavity of the curve between extrema.

Let us consider all parameters to be positively valued. We begin by taking first and second derivatives of y with respect to t

$$[9a] \qquad \frac{dy}{dt} = a[-b\exp(-bt) + c\exp(-ct)]$$

Table 2. Absorbance–time functions for observing one chemical species in eq. [1].

Case	Absorbance–time function and boundary conditions	Function type
A	$A_A(t) = A_A^0 e^{-k_1 t}$ $A_A(0) = A_A^0$ $A_A(\infty) = 0$	Decay
B	$A_B(t) = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t} - A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_1 t}$ $A_B(0) = 0$ $A_B(\infty) = 0$	Growth–decay if $k_1 > k_2$ or $k_2 > k_1$
C	$A_C(t) = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right) - A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t} + A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left(\frac{k_2}{k_1 - k_2}\right)e^{-k_1 t}$ $A_C(0) = 0$ $A_C(\infty) = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	Sigmoidal growth if $k_1 > k_2$ or $k_2 > k_1$

[9*b*] $$\frac{d^2y}{dt^2} = a[b^2 \exp(-bt) - c^2 \exp(-ct)]$$

and find that an extremum occurs at

[10] $$t = \frac{1}{c-b}\ln\left(\frac{c}{b}\right)$$

when $dy/dt = 0$. The value of y at this extremum is

$$y_m = a\left[\left(\frac{c}{b}\right)^{-b/(c-b)} - \left(\frac{c}{b}\right)^{-c/(c-b)}\right]$$

The identity of the extremum and the direction of concavity at this point are then found by substituting eq. [10] into the expression for the second derivative (eq. [9*b*]) and determining the sign of the value (16). Hence, eq. [8] exhibits a *minimum* (concave up) when $b > c$ and a *maximum* (concave down) when $c > b$. Figs. 2*a* and 2*b* illustrate the two possible curves: a positively valued growth–decay curve when $c > b$, and a negatively valued decay–growth curve when $b > c$. Note that if the pre-exponential factor a is negatively valued, the above analysis results only in the transposition of b and c in all equations; however, the conclusions of Theorems 1–3 (vide infra) remain unchanged. Table 6 summarizes the important conclusions of the above functional analysis on eq. [8].

From the above analysis we may then establish a simple inspection method to identify which rate constant corresponds to which part of the curve:

> *Theorem 1.* Given a growth–decay or decay–growth function of the form of eq. [8] with positively valued parameters a, b, and c, the rate constant corresponding to the growth part of the curve is the one associated with a minus sign preceding the exponential factor containing that rate constant.

Furthermore, from Table 6 we can also draw the following conclusions regarding the correspondence between the rate constant for the growth and its relative magnitude.

> *Theorem 2.* For a growth–decay function of the form of eq. [8] with positively valued parameters a, b, and c, the growth part of the curve corresponds to the larger rate constant; whereas, the decay part of the curve corresponds to the smaller rate constant.
>
> *Theorem 3.* For a decay–growth function of the form of eq. [8] with positively valued parameters a, b, and c, the growth part of the curve corresponds to the smaller rate constant; whereas, the decay part of the curve corresponds to the larger rate constant.

A similar analysis of the general expression in eq. [11] applicable to any

[11] $$y = a \exp(-\alpha t) - b \exp(-\beta t) + c$$

of the possible experimental growth–decay and decay–growth curves listed in Tables 3 and 4 reveals the same functional properties as summarized in Table 7.

The problem of distinguishability of rate constants

Consider the growth–decay curves for the intermediate B shown in Figs. 1*b* and 1*c*. Both curves are fitted to the expression given in eq. [2*b*] where the values $k_1 = 10^5$ s^{-1}and $k_2 = 10^4$ s^{-1} are applicable to Fig. 1*b*, and the values $k_1 = 10^4$ s^{-1}and $k_2 = 10^5$ s^{-1} are applicable to Fig. 1*c*. The subscripts 1 and 2 in the rate constant descriptors strictly refer to steps 1 and 2, respectively, in the reaction sequence. Comparison of the forms of these two growth–decay curves indicates that they have identical functional behaviours, *except that their amplitudes differ.* More precisely, the similarities are that the growth part in each curve corresponds to the faster rate, 10^5 s^{-1} (see Theorem 2), the decay part of each curve corresponds to the slower rate, 10^4 s^{-1} (see Theorem 2), and the occurrence of the maximum in each case is at $t = 2.56 \times 10^{-5}$ s (using eq. [6*b*]). The difference is that the amplitude of the maximum absorbance given by eq. [6*a*] is 0.77 for $k_2/k_1 = n = 0.1$ (Fig. 1*b*) and 0.077 for $k_2/k_1 = n = 10$ (Fig. 1*c*). From this example, it is evident that the faster rate constant associated with the growth in each curve corresponds to either the first *or* second steps in the reaction sequence. Likewise, the slower rate constant associated with the decay in each curve corresponds to either the first *or* second steps in the reaction sequence. The conclusion is that one cannot assign the two rate constants to their respective

Case	Absorbance–time function and boundary conditions	Function type
A and B	$A(t) = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t}$	Sum of two decays if $\frac{\varepsilon_B}{\varepsilon_A} < \frac{k_1 - k_2}{k_1}$ and $k_1 > k_2$
	$+A_A^0\left[1 - \left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)\right]e^{-k_1 t}$	Growth–decay if $\frac{\varepsilon_B}{\varepsilon_A} > \frac{k_1 - k_2}{k_1}$ and $k_1 > k_2$
	$A(0) = A_A^0$	N.B.: It is impossible to have a sum of two growths or a decay–growth curve.
	$A(\infty) = 0$	
A and C	$A(t) = A_A^0\left[1 + \left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left(\frac{k_2}{k_1 - k_2}\right)\right]e^{-k_1 t}$	Sum of two decays if $\frac{\varepsilon_C}{\varepsilon_A} < \frac{k_2 - k_1}{k_2}$ and $k_2 > k_1$
	$-A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t} + A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	Decay–growth if $\frac{\varepsilon_C}{\varepsilon_A} > \frac{k_2 - k_1}{k_2}$ and $k_2 > k_1$
	$A(0) = A_A^0$	N.B.: It is impossible to have a sum of two growths or a growth–decay curve.
	$A(\infty) = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	
B and C	$A(t) = A_A^0\left(\frac{k_2\varepsilon_C - k_1\varepsilon_B}{\varepsilon_A}\right)\left(\frac{1}{k_1 - k_2}\right)e^{-k_1 t}$	Sum of two growths if $\varepsilon_B > \varepsilon_C$, $k_2 > k_1$, and $\frac{k_2}{k_1} > \frac{\varepsilon_B}{\varepsilon_C}$
	$+ A_A^0\left(\frac{\varepsilon_B - \varepsilon_C}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t} + A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	Growth–decay if $\varepsilon_B > \varepsilon_C$, $k_2 > k_1$, and $\frac{k_2}{k_1} < \frac{\varepsilon_B}{\varepsilon_C}$ or if $\varepsilon_B > \varepsilon_C$, $k_1 > k_2$, and $\frac{k_2}{k_1} < \frac{\varepsilon_B}{\varepsilon_C}$
	$A(0) = 0$	Sigmoidal growth if $\varepsilon_B < \varepsilon_C$, $k_1 > k_2$, and $\frac{k_2}{k_1} > \frac{\varepsilon_B}{\varepsilon_C}$ or if $\varepsilon_B < \varepsilon_C$, $k_1 < k_2$, and $\frac{k_2}{k_1} > \frac{\varepsilon_B}{\varepsilon_C}$
	$A(\infty) = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	N.B.: It is impossible to have a sum of two decays.

steps in the reaction sequence for either of these growth–decay curves when these curves are treated separately by data fits. The assignments can be made only when the results of the two data fits are compared. This apparent ambiguity has been stated by others (6, 14) in terms of two solutions satisfying an equation of the form of eq. [2*b*] and interchanging the values of the rate constants in eq. [2*b*]. It should be made clear that the operation of transposing k_1 and k_2 in eq. [2*b*] is different from and not to be confused with the functional analysis given previously in which the ratio of k_2 to k_1 in eq. [2*b*] is varied. In chemical terms, a given growth–decay kinetic curve may correspond to either of two situations: (*i*) a fast formation of a strongly absorbing intermediate in the first step followed by its slow decomposition in the second step, or (*ii*) a slow formation of a weakly absorbing intermediate in the first step followed by its rapid decomposition in the second step.

It can be shown that the same ambiguity holds true for decay–growth curves, and hence we are lead to the statement given in Theorem 4.

> *Theorem 4.* For growth–decay and decay–growth functions of the forms of eqs. [8] and [11] it is impossible to assign unambiguously the rate constant parameters to the particular steps in the reaction sequence solely on the basis of the results of a single data fit according to these equations.

Determining the rate constant – reaction step correspondence

External chemical information

An obvious method to relieve the ambiguity stated in Theorem 4 is to obtain one of the rate constants in eq. [1], either k_1 or k_2, from a separate experiment. The easier rate constant to obtain is k_1, since this is immediately derived from the single exponential decay of species A. However, as already noted, the methodology of conducting the time-resolved experiment may preclude such a solution. If all species in a given chemical system have overlapping absorptions, then it would be difficult to obtain unique absorbance–time functions for species A and B. This is especially true if species A and B either have similar structures so that they are not distinguishable by different monitoring absorption bands or have weak chromophores altogether. Only a fortuitous situation in which species A and B have unique UV-vis absorption bands will permit this method to work. Detection by infrared absorption spectroscopy, on the other hand, is more powerful in this regard, as it is more likely to distinguish chemical species from unique IR absorption bands than it is from UV-vis ones, particularly in solution-phase experiments.

Yamasaki et al. (7, 8) recently proposed a new integrated profiles method to handle simultaneous analysis of the absorbance–time functions for species A and B given in eq. [1],

	$A(\infty) = A_A^0\left(\frac{\varepsilon_C}{\varepsilon_A}\right)$	
$\varepsilon_A = \varepsilon_C$	$A(t) = A_A^0\left[1 + \left(\frac{k_2\varepsilon_C - k_1\varepsilon_B}{\varepsilon_C}\right)\left(\frac{1}{k_1 - k_2}\right)\right]e^{-k_1 t}$	Growth–decay if $\varepsilon_B > \varepsilon_C$ and $k_1 > k_2$ or if $\varepsilon_B > \varepsilon_C$ and $k_1 < k_2$
	$+ A_A^0\left(\frac{\varepsilon_B - \varepsilon_C}{\varepsilon_C}\right)\left(\frac{k_1}{k_1 - k_2}\right)e^{-k_2 t} + A_A^0$	Decay–growth if $\varepsilon_B < \varepsilon_C$ and $k_1 > k_2$ or if $\varepsilon_B < \varepsilon_C$ and $k_1 < k_2$
	$A(0) = A_A^0$	
	$A(\infty) = A_A^0$	
$\varepsilon_B = \varepsilon_C$	$A(t) = A_A^0\left[1 - \frac{\varepsilon_B}{\varepsilon_A}\right]e^{-k_1 t} + A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)$	Growth if $\varepsilon_B > \varepsilon_C$ Decay if $\varepsilon_B < \varepsilon_C$
	$A(0) = A_A^0$	
	$A(\infty) = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)$	

provided that the condition of unique detection of the species is met. The strength of the method is that it is able to resolve nearly equally valued rate constants even when kinetic data may contain significant instrumentation noise.

Absorption coefficient method

A method based on the magnitude and variation of the absorption coefficient of intermediate B has been reported as a way of deciding which rate constant corresponds to which step in the reaction sequence (14). It is based on comparing the set of pre-exponential factors in an equation of the form of eq. [11] with that obtained when k_1 and k_2 are transposed. Taking the general case of observing all three species simultaneously, we have two forms of the absorbance–time equation given in Table 4. Equation [12] applies when k_1 is assigned to step 1 and k_2 is assigned to step 2.

[12] $A(t) = ae^{-k_1 t} + be^{-k_2 t} + c$

where $a = A_A^0[1 + (k_2\varepsilon_C - k_1\varepsilon_B)/\varepsilon_A(k_1 - k_2)]$, $b = A_A^0 k_1(\varepsilon_B - \varepsilon_C)/\varepsilon_A(k_1 - k_2)$, and $c = A_A^0(\varepsilon_C/\varepsilon_A)$. Equation [13] applies when k_1 is assigned to step 2 and k_2 is assigned to step 1.

[13] $A(t) = a' e^{-k_2 t} + b' e^{-k_1 t} + c'$

where $a' = A_A^0[1 + (k_1\varepsilon_C' - k_2\varepsilon_B')/\varepsilon_A'(k_2 - k_1)]$, $b' = A_A^0 k_2(\varepsilon_B' - \varepsilon_C')/\varepsilon_A'(k_2 - k_1)$, and $c' = A_A^0(\varepsilon_C'/\varepsilon_A')$. Since either of these expressions may describe a given experimental kinetic trace, the value of the absorbance, A(t), is the same in each case. Hence, equating eqs. [12] and [13] results in

[14a] $a = b'$

[14b] $b = a'$

[14c] $c = c'$

From eqs. [14a]–[14c] we have the following equalities relating absorption coefficients:

[15a] $\varepsilon_A' = \varepsilon_A$

[15b] $\varepsilon_B' = \varepsilon_A + \frac{k_1}{k_2}(\varepsilon_B - \varepsilon_A)$

[15c] $\varepsilon_C' = \varepsilon_C$

With prior knowledge of the values of the absorption coefficients of reactant A and product C, two possible values for the absorption coefficient of intermediate B, ε_B and ε_B', may be obtained corresponding to the two sets of rate constant assignments. As noted previously (6, 14), the "correct" value of the absorption coefficient for B may be decided immediately on the basis of structural assignments if a stable analogue of B is known. Otherwise, the assignment will be based on whether or not the absorption coefficient varies with the ratio k_1/k_2 as given by eq. [15b]. This necessarily means examining other kinetic traces of the form of eq. [11] recorded at different values of k_1/k_2. A correct value of the absorption coefficient is one that is independent of k_1/k_2 or k_2/k_1. As written, eq. [15b] implies that ε_B is the correct value, since it is independent of k_1/k_2; whereas ε_B' is the incorrect value, since it is linearly dependent on this ratio. The reverse statement is true if eq. [15b] is solved in terms of ε_B as the dependent variable so that in this case ε_B is linearly

dependent on k_2/k_1 and ε_B' is not. An alternative formalism of distinguishing ε_B and ε_B', which is more practical, is to express each in terms of the pre-exponential coefficients *a*, *b*, and *c* that would be obtained from nonlinear least-squares analysis. The relationships are given by eqs. [16*a*] and [16*b*].

$$[16a] \quad \varepsilon_B = \frac{\varepsilon_A}{A_A^0}\left[b\left(1 - \frac{k_2}{k_1}\right) + c\right]$$

$$[16b] \quad \varepsilon_B' = \frac{\varepsilon_A}{A_A^0}\left[a\left(1 - \frac{k_1}{k_2}\right) + c\right]$$

It may be verified that eq. [16*a*] is invariant to the ratio of rate constants whereas eq. [16*b*] is not when ε_B is the correct absorption coefficient, and that the reverse is true when ε_B' is the correct absorption coefficient (see Appendix B).

Absorbance extremum method

If the transformations A to B and B to C in eq. [1] are catalyzed by some species Q such that the concentration of catalyst, [Q], is invariant with time during the course of the kinetic experiment, then the absorption–time functions for A, B, and C given by eqs. [4*a*]–[4*c*] still apply. Such an experimental constraint represents the well-documented pseudo-first-order condition. In general, the rate constants k_1 and k_2 will be some functions of the concentration of catalyst; for example, $k_1 = f([Q])$ and $k_2 = g([Q])$. The subscripts 1 and 2 refer to the first and second steps, respectively, so that the first step is associated with *f* and the second step is associated with *g*. Conversely, the functional assignments to the rate constants may be reversed so that $k_2 = f([Q])$ and $k_1 = g([Q])$. To resolve which assignment pertains to an experimental situation, the absorbance extremum is monitored as a function of catalyst concentration [Q]. The functional behaviour of the extremum with catalyst concentration will be

© 1999 NRC Canada

different for the two possible rate constant assignments. In the case of growth–decay curves the absorbance extremum is a maximum, and in the case of decay–growth curves it is a minimum. An important experimental criterion that must be met for this method to work is that the initial absorbance of species A must be kept constant in all experiments constituting the range of catalyst concentrations examined. This ensures that the correct values of the absorption maxima or minima are recorded from the collected growth–decay or decay–growth curves, respectively. Any artifacts or detractions from this criterion will result in spoiled data. Since growth–decay curves are more often encountered experimentally, we will now illustrate the method for these functions obtained under various experimental situations involving species B.

The case when B is observed uniquely

From eq. [6*a*], the absorption maximum of species B takes the form

$$[17] \qquad A_B^{max} = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{f}{g-f}\right)\left[\left(\frac{g}{f}\right)^{-f/(g-f)} - \left(\frac{g}{f}\right)^{-g/(g-f)}\right]$$

where A_B^{max} is a function of [Q], when the assignments $k_1 = f([Q])$ and $k_2 = g([Q])$ are made. If the functional assignments of k_1 and k_2 are transposed so that $k_2 = f([Q])$ and $k_1 = g([Q])$, then the resultant analagous expression is given by

$$[18] \qquad A_B^{max} = A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{g}{f-g}\right)\left[\left(\frac{f}{g}\right)^{-g/(f-g)} - \left(\frac{f}{g}\right)^{-f/(f-g)}\right]$$

$$= A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{g}{g-f}\right)\left[\left(\frac{g}{f}\right)^{-f/(g-f)} - \left(\frac{g}{f}\right)^{-g/(g-f)}\right]$$

where the second step is associated with f and the first step is associated with g. A closer examination of eqs. [17] and [18] indicates that the expressions are distinguishable by the factors $f/(g-f)$ and $g/(g-f)$. Hence, it is possible to assign a rate constant to a particular step in the sequence on the basis of its functional dependence on catalyst concentration. This does *not* imply that the calculated rate constant parameters obtained from a *single* growth–decay curve may be assigned to a specific reaction step (see Theorem 4). To distinguish which rate constant is associated with which step in the reaction sequence, a *collective* analysis must be performed on all growth–decay curves obtained over the catalyst concentration range examined. The methodology is as follows. The $(t_i, A_{B,i})$ data points from a kinetic trace obtained at a given catalyst concentration are first fitted to the model eq. [8] using a nonlinear least-squares algorithm. Then, the absorption maximum of this trace is determined from the calculated parameters at $t = (1/(c-b))\ln(c/b)$ according to $y_m = a[(c/b)^{-b/(c-b)} - (c/b)^{-c/(c-b)}]$. Note that $y_m > 0$ when $a > 0$ and $c > b$, or when $a < 0$ and $b > c$. The process is repeated for other kinetic traces recorded at several catalyst concentrations until a set of data points $([Q]_i, y_{m,i})$ is obtained. The functions given by eqs. [17] and [18] can be constructed once the functional forms for f and g are known. The data points $([Q]_i, y_{m,i})$ are then plotted and matched with the appropriate curve. A match with eq. [17], for example, indicates that the first step in the reaction is associated with the rate constant having a catalyst dependence given by $f([Q])$, and the second step is associated with the rate constant having a catalyst dependence given by $g([Q])$.

We illustrate the method with two numerical examples. Suppose we have a chemical system described by eq. [1] such that the first step is invariant to catalyst concentration while the second step obeys a linear relationship with catalyst concentration. From our growth–decay curves for species B we obtain parameters b and c but cannot assign these to the particular steps in the reaction scheme on the basis of any one curve. Hence, we have either case (*i*) $b = f([Q]) = D_1$ and $c = g([Q]) = D_2 + D_3[Q]$ or case (*ii*) $c = f([Q]) = D_1$ and $b = f([Q]) = D_2 + D_3[Q]$, where the constants D_1, D_2, and D_3 would be known from separate experiments. To overcome the ambiguity, plots according to the forms of eqs. [17] and [18] are made and compared with the actual $y_{m,i}$ versus $[Q]_i$ plot to determine which of the above cases is applicable. Figures 3*a* and 3*b* illustrate the functions given by eqs. [17] and [18] using the definitions of f and g given in cases (*i*) and (*ii*). The method also works when the rate constants b and c are independent of catalyst concentration; i.e., we have either case (*iii*) $b = f([Q]) = D_1$ and $c = g([Q]) = D_2$ or case (*iv*) $c = f([Q]) = D_1$ and $b = g([Q]) = D_2$. Figures 4*a* and 4*b* illustrate the functions given by eqs. [17] and [18] using the definitions of f and g given in cases (*iii*) and (*iv*).

Cases when B and A, B, and C, and B, C, and A are observed together

From Tables 3 and 4 the functions describing growth–decay curves for these three cases may be conveniently described by the relation

$$[19] \qquad y = a\exp(-k_1 t) - b\exp(-k_2 t) + c$$

where

$$a = A_A^0\left[1 - \left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)\right]$$

$$b = -A_A^0\left(\frac{\varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)$$

and $c = 0$ apply to observing B and A together;

$$a = A_A^0\left[\left(\frac{k_2\varepsilon_C - k_1\varepsilon_B}{\varepsilon_A}\right)\left(\frac{1}{k_1 - k_2}\right)\right]$$

$$b = A_A^0\left(\frac{\varepsilon_C - \varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)$$

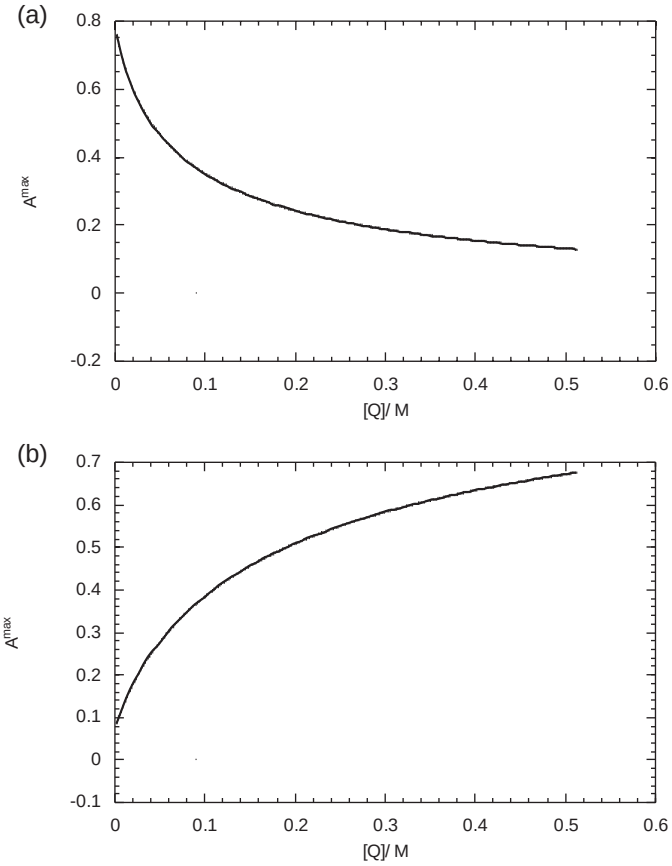
and $c = A_A^0(\varepsilon_C/\varepsilon_A)$ apply to observing B and C together; and

$$a = A_A^0\left[1 + \left(\frac{k_2\varepsilon_C - k_1\varepsilon_B}{\varepsilon_A}\right)\left(\frac{1}{k_1 - k_2}\right)\right]$$

$$b = A_A^0\left(\frac{\varepsilon_C - \varepsilon_B}{\varepsilon_A}\right)\left(\frac{k_1}{k_1 - k_2}\right)$$

© 1999 NRC Canada

Fig. 3. Plot of (*a*) eq. [17] and (*b*) eq. [18] with $f([Q]) = D_1 = 10$, $g([Q]) = D_2 + D_3[Q] = 1 + 100[Q]$, and $A_A^0(\varepsilon_B/\varepsilon_A) = 1$. If the data fit this equation then (*a*) the function *f* corresponds to the first step, and the function *g* corresponds to the second step; (*b*) the function *g* corresponds to the first step, and the function *f* corresponds to the second step.



and $c = A_A^0(\varepsilon_C/\varepsilon_A)$ apply to observing B, C, and A together. The absorbance maximum occurs at

$$[20] \quad t = \frac{1}{k_2 - k_1} \ln\left(\frac{bk_2}{ak_1}\right)$$

and has a value given by

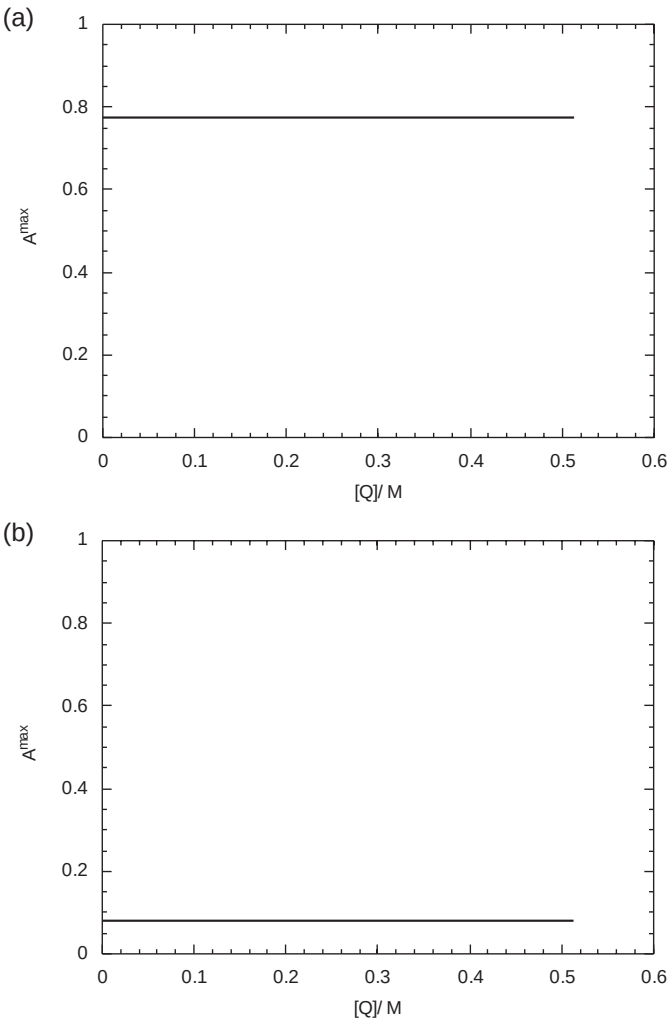
$$[21] \quad y_m = a\left(\frac{bk_2}{ak_1}\right)^{-k_1/(k_2-k_1)} - b\left(\frac{bk_2}{ak_1}\right)^{-k_2/(k_2-k_1)} + c$$

where the coefficients *a* and *b* are also functions of k_1 and k_2, as given by the relationships defined above depending on what chemical species are observed. The functional form of the absorbance maximum with catalyst concentration is given by

$$[22] \quad A^{max} = a\left(\frac{bg}{af}\right)^{-f/(g-f)} - b\left(\frac{bg}{af}\right)^{-g/(g-f)} + c$$

with the assignment $k_1 = f([Q])$ and $k_2 = g([Q])$ made in the appropriate expressions for the pre-exponential parameters; and by

Fig. 4. Plot of (*a*) eq. [17] and (*b*) eq. [18] with $f([Q]) = D_1 = 10$, $g([Q]) = D_2 = 1$, and $A_A^0(\varepsilon_B/\varepsilon_A) = 1$. If the data fit this equation then (*a*) the function *f* corresponds to the first step, and the function *g* corresponds to the second step; (*b*) the function *g* corresponds to the first step, and the function *f* corresponds to the second step.



$$[23] \quad A^{max} = a\left(\frac{bf}{ag}\right)^{-g/(f-g)} - b\left(\frac{bf}{ag}\right)^{-f/(f-g)} + c$$

with the assignment $k_1 = g([Q])$ and $k_2 = f([Q])$.

Summary

A detailed account of the forms of the absorbance–time functions of the unimolecular consecutive two-step reaction sequence is given. The problem of distinguishability of rate constants is discussed with particular emphasis on the rate constant – reaction step ambiguity. A general method based on the functional form of the absorption extremum with catalyst concentration is proposed as a means to overcome this ambiguity in rate constant assignments. Of particular interest to biochemists, enzymologists, and medicinal chemists is the

© 1999 NRC Canada

application of this new method to the resolution of consecutive pseudo-first-order rate constants which are functions of pH. Chemical reactions obeying mechanisms of this type will then be described by simultaneous pH–rate profiles. Work is currently in progress on the theoretical and experimental verification of this new method for such chemical systems.

Appendix A

In this appendix a proof is given for the relationship

$$[A1] \quad \lim_{n\to 1}\left\{\frac{1}{n-1}\left[n^{-1/(n-1)} - n^{-n/(n-1)}\right]\right\} = e^{-1}$$

Proof: Since substitution of $n = 1$ leads to an indeterminate form, the expression is rewritten as a rational function and l'Hôpital's rule (16) is applied as shown by the sequence of steps below.

$$[A2] \quad \lim_{n\to 1}\left\{\frac{1}{n-1}\left[n^{-1/(n-1)} - n^{-n/(n-1)}\right]\right\}$$

$$= \lim_{n\to 1}\left\{\frac{\left(\frac{1}{n}\right)^{-1/(n-1)} - \left(\frac{1}{n}\right)^{-n/(n-1)}}{n-1}\right\}$$

$$= \lim_{n\to 1}\left\{\frac{\left(\frac{1}{n}\right)^{-1/(n-1)}\left[\frac{\ln n + \frac{1}{n} - 1}{(n-1)^2}\right] - \left(\frac{1}{n}\right)^{-n/(n-1)}\left[\frac{\ln n + 1 - n}{(n-1)^2}\right]}{1}\right\}$$

$$= \lim_{n\to 1}\left\{\left(\frac{1}{n}\right)^{1/(n-1)}\left[\frac{\ln n}{n(n-1)}\right]\right\}$$

$$= \lim_{n\to 1}\left\{\left(\frac{1}{n}\right)^{1/(n-1)}\right\} \lim_{n\to 1}\left\{\frac{\ln n}{n(n-1)}\right\}$$

Each of the limits above is then evaluated separately. The left-hand limit is evaluated as follows. Letting $z = n^{-1/(n-1)}$ and taking natural logarithms of both sides leads to

$$\ln z = -\frac{\ln n}{n-1}$$

Then,

$$[A3] \quad \lim_{n\to 1} \ln z = -\lim_{n\to 1}\left\{\frac{\ln n}{n-1}\right\} = -\lim_{n\to 1}\left\{\frac{\frac{1}{n}}{1}\right\} = -1$$

after again applying l'Hôpital's rule, since substitution of $n = 1$ leads to an indeterminate form. Hence,

$$[A4] \quad \lim_{n\to 1} z = \lim_{n\to 1}\{n^{-1/(n-1)}\} = e^{-1}$$

The right-hand limit of eq. [A2] is evaluated with a final application of l'Hôpital's rule to yield

$$[A5] \quad \lim_{n\to 1}\left\{\frac{\ln n}{n(n-1)}\right\} = \lim_{n\to 1}\left\{\frac{\frac{1}{n}}{2n-1}\right\} = 1$$

Substitution of these results into eq. [A2] completes the proof.[2]

[2] A referee has suggested an alternative solution which involves substituting $n = 1 + \varepsilon$ in eq. [A1] and evaluating the limit as $\varepsilon \to 0$. The resultant limit is $\lim_{\varepsilon\to 0}(1+\varepsilon)^{-(1+\varepsilon)/\varepsilon}$ which can be evaluated to give e^{-1} using the same sequence of steps in arriving at eq. [A4] from eq. [A3].

© 1999 NRC Canada

Appendix B

Equations [16*a*]–[16*b*] are obtained by first rearranging the expressions for the pre-exponential factors *b* and *b*′, respectively, and then substituting *a* for *b*′ in the case of eq. [16*b*]. If ε_B is the correct absorption coefficient for the intermediate B then eq. [16*a*] becomes an identity upon substitution of the expression for *b*, thus making ε_B independent of k_1/k_2. On the other hand, eq. [16*b*] reduces to

$$[B1] \quad \varepsilon_B' = \varepsilon_A + (\varepsilon_B - \varepsilon_A)\frac{k_1}{k_2}$$

upon substitution of the expression for *a*, thus making ε_B' linearly dependent on k_1/k_2. Note that eq. [B1] is identical to eq. [15*b*]. An assignment of the absorption coefficient of B to ε_B implies that the first step in the sequential mechanism corresponds to rate constant k_1 and that the second step corresponds to rate constant k_2. If ε_B' is the correct absorption coefficient for the intermediate B, then eq. [16*a*] reduces to

$$[B2] \quad \varepsilon_B = \varepsilon_A + (\varepsilon_B' - \varepsilon_A)\frac{k_2}{k_1}$$

upon substitution of *b* with the expression for *a*′, thus making ε_B linearly dependent on k_2/k_1. On the other hand, eq. [16*b*] becomes an identity upon substitution of *a* with the expression for *b*′, thus making ε_B' independent of k_2/k_1. An assignment of the absorption coefficient of B to ε_B' implies that the first step in the sequential mechanism corresponds to rate constant k_2 and that the second step corresponds to rate constant k_1. It should be noted that eqs. [B1] and [B2] are identical upon rearrangement. Equation [B1] is written with ε_B' as the dependent variable while eq. [B2] is written with ε_B as the dependent variable.

In practice kinetic traces recorded at various k_1/k_2 ratios are fit to an expression of the form of eq. [11]. At this stage the rate constant subscript labels 1 and 2 are arbitrary. Having obtained the five parameters from nonlinear least-squares analysis, plots of $b(1 - k_2/k_1) + c$ versus k_1/k_2 and $a(1 - k_1/k_2) + c$ versus k_1/k_2 are then made. If the former plot shows no dependence on k_1/k_2 and the latter plot shows a linear dependence on k_1/k_2, then the absorption coefficient of B is ε_B and k_1 and k_2 are assigned to the first and second steps, respectively. If, on the other hand, the former plot shows a hyperbolic dependence on k_1/k_2 (linear dependence on k_2/k_1) and the latter plot shows no dependence on k_1/k_2, then the absorption coefficient of B is ε_B', and k_1 and k_2 are assigned to the second and first steps, respectively.

A theoretical study on the reactivity of vinyl iodonium ions

Tadashi Okuyama and Hiroshi Yamataka

Abstract: Reactions of methyl(vinyl)iodonium ion and the β-substituted derivatives as well as divinyliodonium ion with chloride ion were examined theoretically by ab initio MO (MP2) calculations at the double-zeta (DZ) + d level. Interaction of the iodonium ion **1** with Cl^- leads to chloro-λ^3-iodane **2**. Transition states for the S_N2, ligand-coupling substitution (LC), and β-elimination (βE) are found for reactions at the vinyl group. The barrier to LC is usually the lowest in the gas phase, but relative barriers to S_N2 and to βE change with the substituents. Effects of solvent were evaluated by a dielectric continuum model and found to be large on S_N2 but small on LC. The experimental observations in solution that the S_N2 is the most facile for the β-methyl-substituted **1** while it is retarded by the β-*tert*-butyl and β-chloro substitutions are reproduced by the calculations that take medium effects into account.

Key words: vinyliodonium salt, polyvalent iodine, vinylic S_N2 reaction, ligand coupling, ab initio MO calculation.

Résumé : Faisant appel à des calculs théoriques ab initio MO(MP2) au niveau DZ + d, on a étudié les réactions de l'ion chlorure avec l'ion méthyl(vinyl)iodonium, ses dérivés β-substitués ainsi que l'ion divinyliodonium. L'interaction de l'ion iodonium (**1**) avec Cl^- conduit au chloro-λ^3-iodane (**2**). Pour les réactions au niveau du groupe vinyle, on a trouvé des états de transition pour la réaction S_N2, la substitution de couplage du ligand (CL) et l'élimination β (Eβ). La barrière au CL est généralement la plus basse pour les réactions en phase gazeuse, mais les barrières relatives pour les réactions S_N2 et d'Eβ varient avec les substituants. On a évalué les effets de solvant par un modèle diélectrique continue et on a trouvé qu'ils sont importants pour les réactions S_N2, mais faibles pour le CL. Les calculs qui tiennent compte des effets de milieu permettent de reproduire les observations expérimentales pour les réactions en solution dans lesquelles les réactions S_N2 de l'ion **1** substitué par un groupe méthyle en β sont plus facilitées alors qu'elles sont ralenties par des substituants *tert*-butyle ou chloro.

Mots clés : sel vinyliodonium, iode polyvalent, réaction S_N2 vinylique, couplage de ligand, calculs d'OM ab initio.

[Traduit par la Rédaction]

Polyvalent organoiodine compounds have attracted the interest of organic chemists because of their diversity in reactivities, offering powerful synthetic tools as well as mechanistic challenges (1–4). Vinyl iodonium salts among others exhibit an intriguing mechanistic spectrum in the reaction with nucleophiles/bases.

First of all, vinyl iodonium salts are good precursors of vinyl cations. Simple α-alkyl substituted vinyliodonium salts cannot be isolated probably due to the ease of formation of the stable secondary vinyl cations. A 1-cyclohexenyliodonium salt is only moderately stable due to the angle strain in a 1-cyclohexenyl cation intermediate (5), and readily undergoes solvolysis (6). A styryliodonium salt gives a vinylenebenzenium intermediate in ionizing solvolytic media (7). A β,β-dialkylvinyliodonium salt also undergoes ionization to the secondary vinyl cation in polar solvents via participation of the β-alkyl group (8). By contrast, simple 1-alkenyliodonium salts do not show any sign of ionization even in a powerfully ionizing solvent like trifluoroacetic acid (9). Primary vinyl cation must be too unstable to be formed under these normal conditions.

A second easily occurring reaction when a hydrogen is present at the α position is α-elimination leading to alkylidenecarbene, eq. [1] (10, 11). Very weak bases like dichloroacetate can induce this reaction of 1-alkenyliodonium salts, and in neutral alcohols like methanol or ethanol, both substitution and α-elimination of these salts can compete with each other.[3]

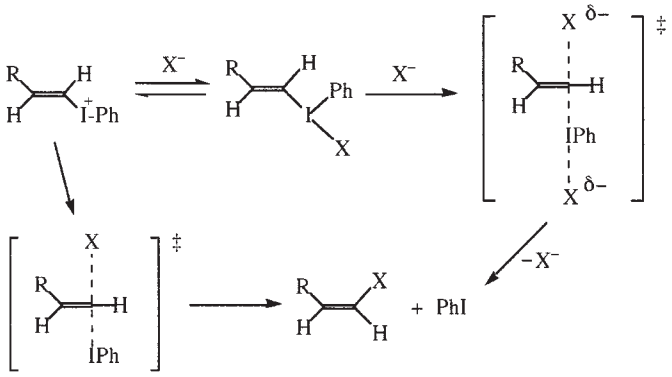
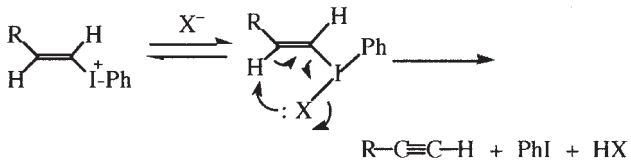
Scheme 1.



Reactions of 1-alkenyliodonium salts with nucleophiles like chloride, bromide, and iodide ions with extremely weak basicity lead to the in-plane vinylic S_N2 substitution with complete inversion of configuration, Scheme 1 (9, 11, 12). This is the first and definitive example of this kind of reaction, vinylic S_N2,[4] that has long been neglected as a possible mechanism (15). This reaction occurs both directly and via preequilibrium formation of halo-λ^3-iodane (Scheme 1). The accompanying reaction is intramolecular *syn* β-elimination (βE) within the λ^3-iodane intermediate, eq. [2]. The β-tertiary alkyl substitution seems to inhibit the S_N2 reaction of the vinyliodonium salts and leads exclusively to βE (12).

[2]



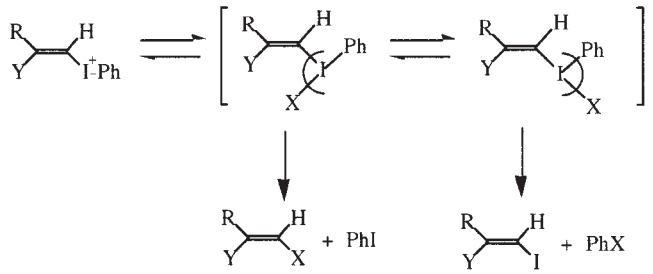
The β-alkyl,β-halogeno disubstitution retards the S_N2 substitution, while the β-elimination is impossible, and an alternative substitution reaction with complete retention of configuration was observed (16). This is concluded to occur through a ligand coupling (LC) within the halo-λ^3-iodane intermediate via an out-of-plane arrangement of the nucleophile. The accompanying formation of 1-iodo-1-alkene and halobenzene is consistent with this mechanism, Scheme 2. This reaction can show up even in the reaction of a simple 1-alkenyliodonium salt with halide ions when both the nucleophilic and basic reactions at the carbon (Scheme 1 and eq. [2]) are retarded in acidic media like trifluoroacetic acid (9).

To understand the variations of the closely related reactions of vinyl iodonium salts and the effects of β-substitution on these reactivities, theoretical investigations were carried out on the reactions of a series of β-substituted vinyliodonium ions with chloride ion by means of ab initio molecular orbital calculations. The results are summarized in this paper.

Calculation method

All calculations were carried out at the second-order Møller-Plesset perturbation (MP2) level (17) by using the

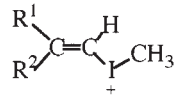
Scheme 2.

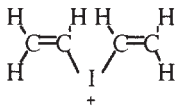


Gaussian 94 program (18). For carbon and hydrogen atoms, 6-31G(d) and 6-31G basis sets were used, respectively, while for other atoms the double-zeta (DZ) basis sets of Dunning and Hay (19) and effective core potentials (ECP) developed by Wadt and Hay (20) were employed. The DZ basis sets were augmented by a set of six *d*-type polarization functions for Cl and I (*d* exponents 0.75 (Cl) and 0.226 (I)) as well as a diffusion function for Cl. Reactants, complexes, and transition structures were fully optimized and were identified by means of a full analysis of the vibrational modes at those stationary points. Effects of solvation (acetonitrile, dielectric constant = 37.5) were evaluated by a dielectric continuum model using a self-consistent reaction field approximation (SCRF) (21). Free energy at 298 K was obtained on the basis of numerically calculated frequencies in the gas phase.

Results

We have chosen methyl(vinyl)iodonium ion, **1a**, as a model compound for phenyl(vinyl)iodonium ion, which is actually employed for reactions in solution, and studied the reaction at the vinyl group with the chloride ion as a reference reaction. Then, the effects of β-substitution on the structure and its reactivity were investigated for β-Me (**1b**), β-*t*-Bu (**1c**),





1a, $R^1 = R^2 = H$

b, $R^1 = CH_3$, $R^2 = H$

c, $R^1 = (CH_3)_3C$, $R^2 = H$

d, $R^1 = CH_3$, $R^2 = Cl$

1e

and β-Cl-β-Me (**1d**) derivatives.

The calculated geometry of **1a** is shown in Fig. 1. The interaction of **1a** with Cl^- leads to the formation of two complexes, **2a** and **3a** (Fig. 1). The location of the chloride ion in **2a** is characteristic of a hypervalent bonding of C_α-I-Cl with an angle of 170.3° and an elongated C_α—I bond (2.114 to 2.155 Å), while in **3a** Cl^- is located on the vinylic plane and is hydrogen-bonded to the α-hydrogen (2.202 Å). In **3a**, both C—H and C—I bonds at the α-position become longer than those in **1a** (Fig. 1). That is, **2a** is taken as a

[4] There are some experimental implications that the vinylic S_N2 reaction is possible (13), and some theoretical calculations on this subject have recently appeared (14).

[b]The divinyl model.

[c]Relative energy to **1e** + Cl^-.

hypervalent 10-I-3 species, chloro-λ^3-iodane, and **3a** is a hydrogen-bond complex. An alternative conformation of the λ^3-iodane **2a** with the apical methyl group could not be found as an energy-minimum species. The more electronegative vinyl group is favored in the apical position rather than methyl, as is generally referred to as apicophilicity (22). The β-substituted derivatives show similar behavior. In fact, the geometrical features of **1a–d** and of **2a–d** are essentially the same within each sets, irrespective of the β-substituents.

The total electronic energies of the iodonium ions **1a–d** and chloro-λ^3-iodanes **2a–d** are summarized in Table 1, together with the stabilization energies ($-\Delta E$) for formation of **2**. The energy levels for the low-lying vacant orbitals are given in Table 2. The formation of the hypervalent bond brings about stabilization of more than 100 kcal mol^{-1} in the gas phase. In contrast, the hydrogen bonding stabilization for **3a** is smaller (96.0 kcal mol^{-1}). The stability of λ^3-iodane decreases in the order, **2d** > **2a** > **2b** > **2c**. Clearly, the electronegative substituent on the apical ligand (vinyl group) stabilizes the λ^3-iodane (**2b** vs. **2d**), while the electron-donating β-alkyl group reduces this stability (22). The stability of λ^3-iodane **2** relative to iodonium ion **1** is similar both in terms of electronic energy and free energy.

Transition states (TS) for the substitutions with both inversion (**4a–d**) and retention (**5a–d**) of configuration were determined, and structures of those for the reference compound (**4a** and **5a**) are shown in Fig. 1. In TS **4**, the incoming chloride ion is located in a plane of the vinyl group and this is the TS for the in-plane vinylic S_N2 reaction of the iodonium ion **1**. In TS **5**, the chloride ion is located out-of-plane of the vinyl group and has interactions with both the α-carbon and iodine. The bond angle of Cl-C_α-I (81.3°) is smaller than that of Cl-C_α-H (93.2°), and TS **5** leads to substitution with retention of configuration. This retention TS may be regarded as the TS for LC within a halo-λ^3-iodane.

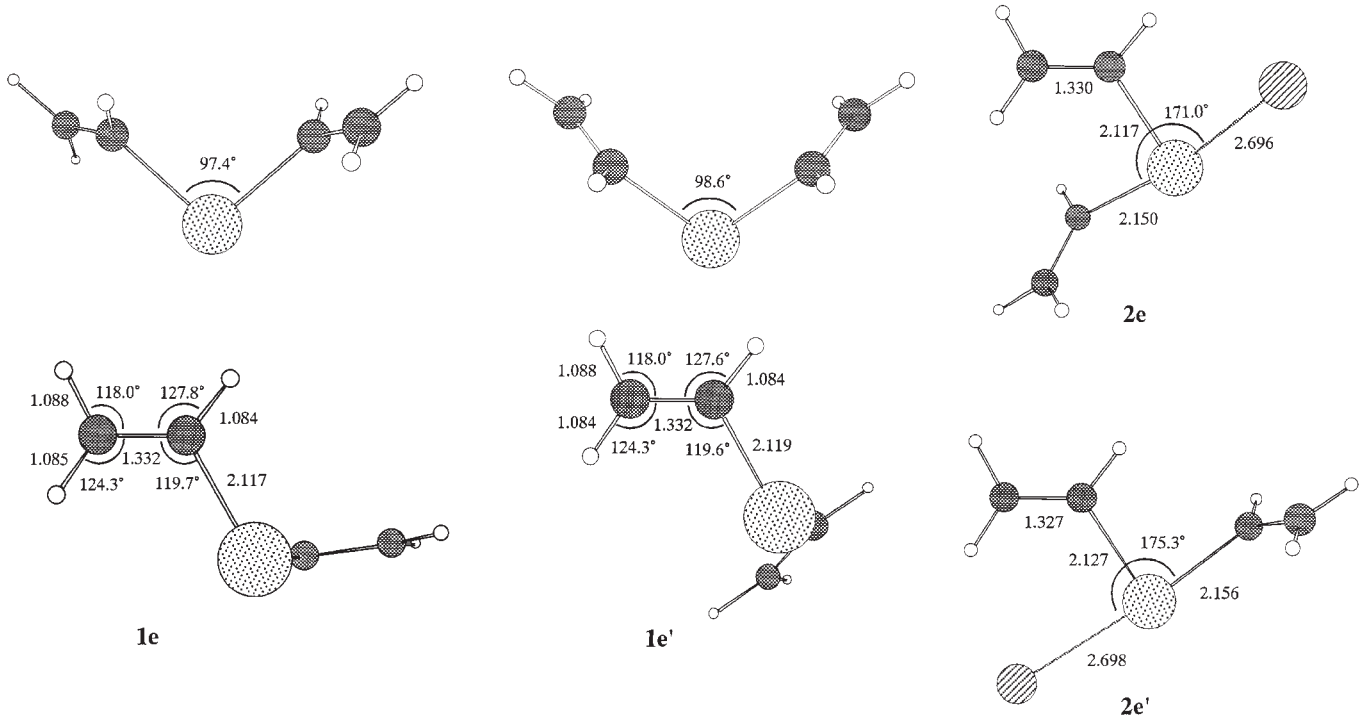
[a]Energies are given in eV. Symbols in parentheses signify the symmetry of the orbital: σ^*_M, anti-bonding orbital of I-CH_3; σ^*_V, anti-bonding orbital of I-C_α; π^*, orbital of the vinyl group.

[b]Orbital localized on the apical vinyl group.

[c]Orbital localized on the equatorial vinyl group.

Fig. 2. Optimized geometries of **1e** and **2e** and their conformers.



The TS values for βE (**6a–c**) were also determined (**6a** in Fig. 1). Here, the bond angle C_β-C_α-H becomes larger, and the C—C bond length shortens as compared to those in **2a**, exhibiting partial triple-bond nature. It is noted that the C_β—H—Cl bond is nearly linear (178.8°) in **6a**.

We have postulated previously that the LC substitution and βE occur both from the chloro-λ^3-iodane, which has a conformation with the vinyl group in an equatorial position (and the chlorine in the apical position) (9, 12). Since such a conformation could not be obtained as an energy minimum for the methyl(vinyl)iodonium model because of apicophilicity reasons (22), another model system closer to the actual phenyl(vinyl)iodonium ion was examined, i.e., the divinyliodonium ion (**1e**) and the species resulting from complexation with the chloride ion. We obtained two conformations of the ion; one with C_2 (**1e**) and one with C_s symmetry (**1e′**) as shown in Fig. 2. The former is only 0.42 kcal mol^{-1} more stable than the latter (Table 1). Figure 2 shows two views of each conformer with selected geometrical parameters. Interaction of **1e** (or **1e′**) with Cl^- results in the hypervalent intermediate of two different conformations, **2e** and **2e′**, with the former being more stable than the latter by 0.97 kcal mol^{-1} (Fig. 2 and Table 1). In **2e**, Cl is located near the α-hydrogen of the equatorial vinyl group, while Cl is near the β-hydrogen in **2e′**. The angles of the apical bonds are 171.0 and 175.3° for **2e** and **2e′**, respectively. It is also noted that the apical C_α—I bond length is 2.150–2.156 Å, while the equatorial bond length is 2.117–2.127 Å. The close similarity in Cl^- complexation energies of **2e** and **2a** shows that the difference in an equatorial ligand (i.e., methyl vs. vinyl) has little influence on the stability of the λ^3-iodane.

Optimized geometries of the TS values for the S_N2, LC, and βE obtained for **1e** + Cl^- are illustrated in Fig. 3. Geometrical features of these TS values **4e–6e** are similar to those obtained for the methyl vinyl species (**4a–6a**). The two views of **4e** and **5e** are shown to illustrate the stereochemistry of the substitutions in Fig. 3. The TS for βE, **6e**, is essentially in a plane except for the vinyl group of the nucleofuge.

The electronic and free energy of transition states **4–6** with respect to the stable iodane **2** are given in Table 3. Effects of solvation on these energies were evaluated for

acetonitrile solution by a dielectric continuum model using an SCRF approximation (21) at the gas phase geometries, and the results are included in Table 3.

Discussion

As described in the introduction section, the experimental results can be summarized as follows. (*i*) For simple 1-alkenyliodonium ions (modeled by **1a**, **1b**, or **1e**), S_N2 and βE are the competing reactions with LC being less favored. (*ii*) The β-*tert*-butyl substitution (modeled by **1c**) completely inhibits the S_N2 pathway, and the only reaction observed is βE. (*iii*) The 2-chloro substitution of 1-alkenyliodonium ion (modeled by **1d**) retards S_N2, makes βE impossible, and makes LC the only reaction observed (12). We will examine how the experimental observations of relative ease of the three reactions can be reproduced by the calculations.

Calculations in the gas phase

LUMO

Let us first examine what are the low-lying vacant orbitals of the vinyliodonium ion **1** and the λ^3-iodane **2** and how these orbitals are related to the reactivities toward nucleophiles. In Table 2 are summarized the lowest three vacant orbitals. For all the methyl iodonium salts (**1a**–**d**) and their λ^3-iodanes (**2a**–**d**), the LUMO is the anti-bonding orbital (σ^*_M) localized on the I—CH_3 bond even though this bond is in the equatorial position of **2**. This suggests that the most facile reaction to occur would be the S_N2 reaction at the methyl group; this is quite reasonable, although we do not examine reactions at this site. In the vinyl group portion of our interest, the σ* orbital (σ^*_V) for the C_α—I bond is lower than the π* orbital both for **1** and **2**. This feature that the σ* is lower than the π* orbital was recently pointed out by Modena and co-workers (14*b*) to suggest preference of

© 1999 NRC Canada

the in-plane vinylic S_N2 reaction of the methyl(vinyl)iodonium ion. In divinyl-λ^3-iodane **2e** the σ^* for the apical bonding is the LUMO, and the π^* orbital of the apical vinyl group is the third lowest vacant orbital (LUMO + 2); that is, the apical vinyl group would be a more reactive site than the equatorial one toward nucleophiles. The low-lying σ^* orbitals are characteristic of the vinyl iodonium ion and λ^3-iodane derivatives and contribute to make the in-plane nucleophilic attack at the vinyl group a facile pathway of these substrates.

S_N2 vs. LC

The calculated TS energies for the reactions of the vinyliodonium ions (Table 3) indicate that in the gas phase the in-plane S_N2 (**4**) is less favorable than the out-of-plane substitution (**5**) for all the compounds examined (**1a**–**1e**) both in terms of electronic energy and free energy. These results point out that the LUMO energy level is not the determining factor of the reactivity of the methyl(vinyl)iodonium ion (14*b*).

The above energetic order that predicts more favorable LC than S_N2 process is in marked contrast to arguments recently presented by Glukhovtsev et al. (14*a*), who carried out ab initio MO calculations on the reaction of vinyl chloride with chloride ion with the G2 procedure and found that the barrier to the in-plane S_N2 of inversion of configuration is lower (32.7 kcal mol^{-1}) than that to the out-of-plane substitution of retention of configuration (42.8 kcal mol^{-1}). The apparent discrepancy between the two computations are very likely due to the presence of a facile ligand coupling pathway for the iodonium salts (interaction of Cl with I at the transition state), which is absent in the reaction of vinyl chloride. Clearly the results on the reaction of vinyl chloride cannot be extrapolated to the vinyliodonium system.

Inclusion of the entropy term makes the energy difference between the S_N2 TS (**4**) and LC TS (**5**) smaller, as evident from $\Delta G^{\ddagger}$, but TS **4** is still consistently higher in energy than TS **5**. Thus, the gas-phase results differ from those observed experimentally in solution. Substituent effects on the barrier to LC (**5**) in the gas phase are rather small, but the β-chloro group raises the TS for S_N2 considerably (Table 3, **4d** vs. **4b**).

S_N2 vs. βE

The transition state for βE (**6a**), for the methyl(vinyl)iodonium system, does not seem to be a good model for the βE TS of the phenyl iodonium derivative (used in the actual reactions), because the chloride ion has a hydrogen-bonding interaction with the methyl hydrogen. By contrast, the chlorine keeps the interaction with the iodine in the divinyl system, **6e**, showing intramolecular reaction behavior within the hypervalent intermediate **2e′**. The TS values for S_N2 (**4a**) and βE (**6a**) were calculated to be similar in energy for the methyl(vinyl)iodonium system, while the former is considerably higher in energy than the latter for the divinyl system in the gas phase (cf. **4e** and **6e**, Table 3). Thus, the energetics obtained by the gas-phase calculations is again different from that deduced from the solution reactions (more facile S_N2 over βE).

Effects of the β-*tert*-butyl substitution are rather unexpected. The calculation results in the gas phase do not show appreciable retardation of S_N2 expected from the steric effect due to β-*tert*-butyl (**4c** vs. **4a**/**4b** in Table 3) either in terms of $\Delta E^{\ddagger}$ or $\Delta G^{\ddagger}$. Comparison of the S_N2 TS **4c** with **4b** (or more markedly with **4a**) shows that the angle C_β-C_α-Cl becomes larger from 110.3° to 115.0°, while the bond length C_α—Cl is shortened from 2.652 to 2.494 Å on going from **4b** to **4c**. That is, TS becomes considerably late by changing the β-methyl to the β-*tert*-butyl group. The steric bulk of the *tert*-butyl group is avoided by the wider angle of C_β-C_α-Cl. The late TS of **4c** results in its low polarity or a small TS dipole moment.

Medium effects

The calculations suggest that gas-phase reactivities, though the experimental data are not available, differ much from the trends observed on solution reactions. That is, medium effects are important in determining the reactivity of the iodonium/iodane substrates. Calculated dipole moments, μ, of the iodanes **2** and TS **4**–**6** are summarized in Table 4. The variation of μ is not uniform particularly in the case of S_N2 TS (**4**). All the μ of TS for LC (**5**) and βE (**6**) are somewhat smaller than those of the corresponding iodanes (**2**), and variation by the structure (**a**–**e**) is rather small. By contrast, the μ of **4** changes greatly with substituent: that for the β-*tert*-butyl derivative (**4c**) is much smaller than that of the iodane **2c**, while that of the unsubstituted vinyl system (**4a** or still markedly **4e**) is greater than that of **2a** (or **2e**). From these results we can expect different medium effects on different reactions, and thus we evaluated the medium effects by the SCRF calculations to examine how much those dipole moment variations affect the energetics in solution, even though the method is the simplest scheme that takes the effect of the dielectric constant of solvent into account and admittedly crude for quantitative energy evaluations.

The results listed in Table 3 in fact demonstrate that the medium effects dramatically change the energetics, and are as expected from the dipole moment differences, compared with the gas-phase results. First, the S_N2 TS is now lower in energy than the LC TS for **1a**, **1b**, and **1e**. It is also apparent that incorporation of medium effects results in a large stabilization of the TS for S_N2 (**4e**) but a small change in the energy barrier to βE (**6e**) for the divinyl system. The βE barriers for the other methyl systems are raised. Hence, the S_N2 reaction is now predicted to be the most facile reaction for **1a**, **1b**, and **1e**.

© 1999 NRC Canada

Second, although the gas-phase calculations do not show any appreciable adverse effects of the β-*tert*-butyl group on the S_N2 TS, the medium effect is large, and the free-energy difference for **4c** becomes greater than that for **4a** by 13.0 kcal mol^{-1}. This trend arises from a smaller μ of the late TS, **4c**, as discussed above. The S_N2 process is totally inhibited, and βE becomes the most feasible process of **1c** in solution. Finally, it is obvious that the S_N2 process is retarded by the β-chloro substitution, and LC becomes a more facile reaction for **1d**. In this case, the medium effects are rather small, and the observed effects of β-chloro substitution are intrinsic as reproduced by the gas-phase calculations (Table 3). Taking the medium effects into consideration, though crude, all the calculation results are consistent with the experimental observations in solution.

In summary, the major experimental preferences for the three product formation processes, namely, substitution with inversion of configuration (S_N2), substitution with retention of configuration (LC), and β-elimination (βE), are possible reaction pathways in the gas phase, but the relative ease of the three pathways can only be reproduced by the calculations with medium effects; that is, (*i*) the vinylic in-plane S_N2 reaction is demonstrated as a possible substitution pathway, and it is a more feasible pathway than LC, for **1a** and **1b** as well as **1e**; (*ii*) S_N2 is inhibited by the β-*tert*-butyl substitution (**1c**), and βE becomes the predominant pathway; (*iii*) S_N2 is disfavored, and LC is the predominant process for the β-Me–β-Cl system (**1d**); (*iv*) the experimental variation in the reactivity of a series of vinyliodonium salts are not only due to the intrinsic character of these species, but are modified by the medium effects. Finally, the present results fully support the previous idea that the substitution with inversion of configuration occurs via in-plane S_N2 TS, while that with retention and β-elimination occurs via the halo-λ^3-iodane intermediate.

Acknowledgments

The authors are grateful to Professor Shigeru Nagase for some preliminary calculations and advice and to Professor Masahito Ochiai for invaluable suggestions. Numerical calculations were in part carried out at the Computer Center of the Institute for Molecular Science, Okazaki, Japan.

Detection and kinetic characterization of S_NV intermediates. Reactions of thiomethoxybenzylidene Meldrum's acid with thiolate ions, alkoxide ions, OH^-, and water in aqueous DMSO

Claude F. Bernasconi, Rodney J. Ketner, Xin Chen, and Zvi Rappoport

Abstract: The reaction of thiomethoxybenzylidene Meldrum's acid (**5-SMe**) with thiolate and alkoxide ion nucleophiles is shown to proceed by the two-step addition–elimination S_NV mechanism in which the tetrahedral intermediate accumulates to detectable levels. For the reactions with thiolate ions, rate constants for nucleophilic addition (k_1^{RX}), its reverse (k_{-1}^{RX}), and for conversion of the intermediate to products (k_2^{RX}) were determined. For the reactions with alkoxide ions, only k_1^{RX} and k_{-1}^{RX} could be obtained; the intermediate in these reactions did not yield the expected substitution products, and hence no k_2^{RX} values could be determined. The reaction with OH^- and water are believed to follow the same mechanism, but the respective intermediates remain at steady-state levels, and only k_1^{OH} and $k_1^{H_2O}$ for nucleophilic attack on **5-SMe** were measurable. New insights regarding structure–reactivity behavior in S_NV reactions are gained from comparisons of rate and equilibrium constants in the reactions of **5-SMe** with the corresponding parameters in the reactions of methoxybenzylidene Meldrum's acid (**5-OMe**) and benzylidene Meldrum's acid (**5-H**). In particular, the relative importance of steric and π-donor effects of the MeS vs. MeO group in **5-SMe** and **5-OMe**, respectively, and their role in affecting the intrinsic rate constants for nucleophilic addition, has been clarified by these comparisons. Our results also add support to a previous suggestion that soft–soft type interactions tend to increase intrinsic rate constants for thiolate ion addition to vinylic substrates, especially **5-SMe** with the soft MeS group.

Key words: nucleophilic vinylic substitution, intrinsic rate constants, transition state imbalances, steric/π-donor/anomeric effects.

Résumé : On a démontré que la réaction du thiométhoxybenzylidène de l'acide de Meldrum (**5-SMe**) avec des nucléophiles comme les ions thiolate et alcoolate se produit par un mécanisme d'addition–élimination en deux étapes, S_NV, au cours duquel l'accumulation de l'intermédiaire tétraédrique est telle qu'il est possible de le détecter. Pour les réactions avec les ions thiolates, on a déterminé les constantes de vitesse de l'addition nucléophile (k_1^{RX}), de la réaction inverse (k_{-1}^{RX}) ainsi que celle de la conversion de l'intermédiaire en produits (k_2^{RX}). Pour les réactions avec les ions alcoolates, on n'a pu déterminer que les valeurs de k_1^{RX} et de k_{-1}^{RX}; dans ce cas, l'intermédiaire ne conduit pas aux produits de substitution attendus et on n'a donc pas pu déterminer les valeurs de k_2^{RX}. On suppose que les réactions avec l'eau et avec l'ion OH^- se produisent par le même mécanisme; toutefois, les intermédiaires respectifs se maintiennent aux niveaux de l'état stationnaire et, pour les réactions nucléophiles avec le **5-SMe** on ne peut mesurer que les valeurs de k_1^{OH} et $k_1^{H_2O}$. On a développé une meilleure compréhension du comportement structure–réactivité dans les réactions S_NV en procédant à des comparaisons des constantes de vitesse de réaction et d'équilibre dans les réactions du **5-SMe** avec les paramètres correspondants dans les réactions du méthoxybenzylidène de l'acide de Meldrum (**5-OMe**) et du benzylidène de l'acide de Meldrum (**5-H**). Ces comparaisons ont permis, en particulier, de clarifier l'importance des effets stériques et donneurs π des groupes MeS par rapport à MeO respectivement dans les composés **5-SMe** et **5-OMe** et de leur rôle sur les valeurs intrinsèques des constantes de vitesse de réaction de l'addition nucléophile. Nos résultats confirment une suggestion faite antérieurement à l'effet que les interactions de type mou-mou tendent à augmenter les constantes intrinsèques des vitesses de réactions pour les réactions d'addition de l'ion thiolate sur des substrats vinyliques, particulièrement le **5-SMe** comportant le groupe mou MeS.

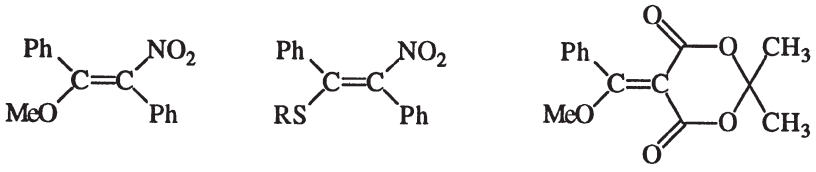
[Traduit par la Rédaction]

Nucleophilic substitution at vinylic carbon (S_NV) is an important reaction that may proceed by a variety of different mechanisms (1–7). With substrates (**1**) moderately or strongly activated by electron withdrawing substituents (Y,Y′), the preferred mechanism involves two steps as shown in eq. [1] where Nu^- is an anionic nucleophile, and LG is the anionic leaving group.

[1] 
1 **2** **3**

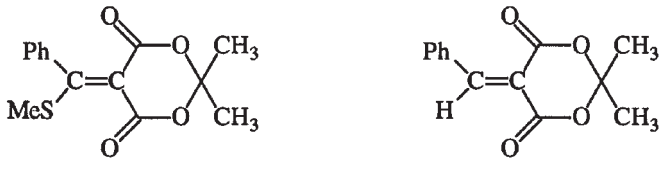
Recent research in our laboratory has focused on reactions of strong nucleophiles with highly activated substrates that have a sluggish leaving group where the intermediate accumulates to detectable levels. Early examples include the reactions of β-methoxy-α-nitrostilbene, **4-OMe**, and β-thioalkoxy-α-nitrostilbene, **4-SR**, with thiolate ions (8, 9); for other examples see refs. 10–13. Recently, we have reported that in the reactions of thiolate and alkoxide ions with methoxybenzylidene Meldrum's acid, **5-OMe**, the respective intermediates are also directly observable (14).



4-OMe **4-SR** **5-OMe**

Our main motivation in searching for systems that allow direct observation of the intermediate is that all rate constants in eq. [1] (k_1, k_{-1}, and k_2) can be determined. A systematic study of how these rate constants depend on the Nu^-, LG, and Y,Y′ is expected to help unravel the complex interplay of the various factors that affect reactivity in S_NV reactions. Apart from the basicities of nucleophile and leaving group, these factors include π-donor effects of the leaving group as well as the nucleophile (once attached to the substrate), anomeric, steric, polarizability, inductive/field, and resonance effects of the activating groups, and possibly others.

In the present paper we report on our study of the reactions of thiomethoxybenzylidene Meldrum's acid, **5-SMe**, with thiolate and alkoxide ions as well as OH^- and water in 50% Me_2SO – 50% water (v/v). Just as with **5-OMe**, the respective intermediates in the reactions of **5-SMe** with thiolate and alkoxide ions (but not with OH^-) were directly observable. However, the reactivity patterns with **5-SMe** show some important differences compared to those with **5-OMe**. Of particular interest are the insights gained not only from comparisons between **5-SMe** and **5-OMe** but also from those between **5-SMe** and the unsubstituted benzylidene Meldrum's acid, **5-H** (15), and especially from comparison of *intrinsic* rate constants[2] for the various compounds.



5-SMe **5-H**

Results

Reaction of 5-SMe with OH^- and water

The rate of hydrolysis of **5-SMe** conforms to eq. [2], as for the hydrolysis of **5-OMe** (14). The organic product is the same as in the hydrolysis of **5-OMe**, i.e., **5-OH**,[3] which under most conditions is present in the form of its anion

[2] The intrinsic rate constant of a reaction with a forward rate constant k_1 and a reverse rate constant k_{-1} is defined as $k_o = k_1 = k_{-1}$ when the equilibrium constant $K_1 = 1$ ($\Delta G° = 0$).

[3] The identification of **5-OH** has been described elsewhere (14).

Fig. 1. Reaction of **5-SMe** with $HOCH_2CH_2S^-$ at pH 10.58 in 50% DMSO – 50% water at 20°C. Pseudo-first-order rate constants of the second (slow) process according to eq. [6].

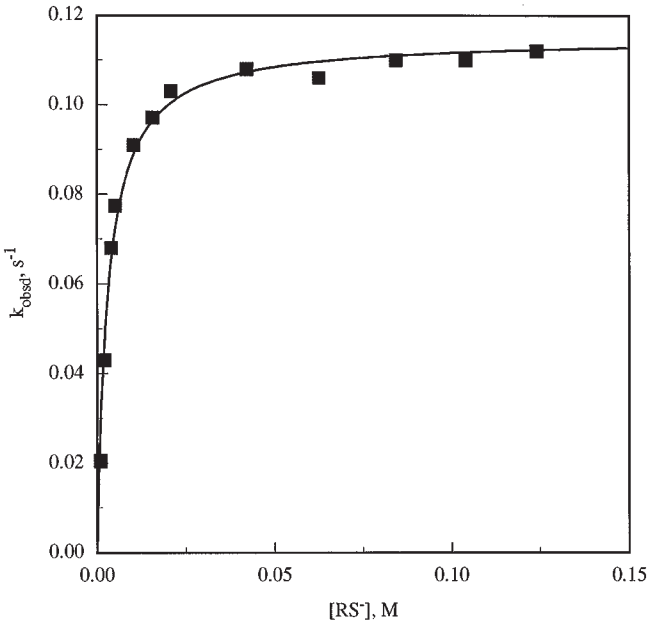

Fig. 2. Reaction of **5-SMe** with $CF_3CH_2O^-$ at pH 14.00 in 50% DMSO – 50% water at 20°C, $[\mathbf{5\text{-}SMe}]_o = 8.0 \times 10^{-5}$ M. Spectrum *a* represents **5-SMe** taken in a neutral solution in the absence of $CF_3CH_2O^-$; all other spectra are at pH 14.00 in the presence of 0.15 M $CF_3CH_2O^-$. Spectrum *b* taken approximately 5 s after mixing, spectrum *c* taken 5 s after *b*, and all other spectra taken at additional 5 s intervals for 120 s.

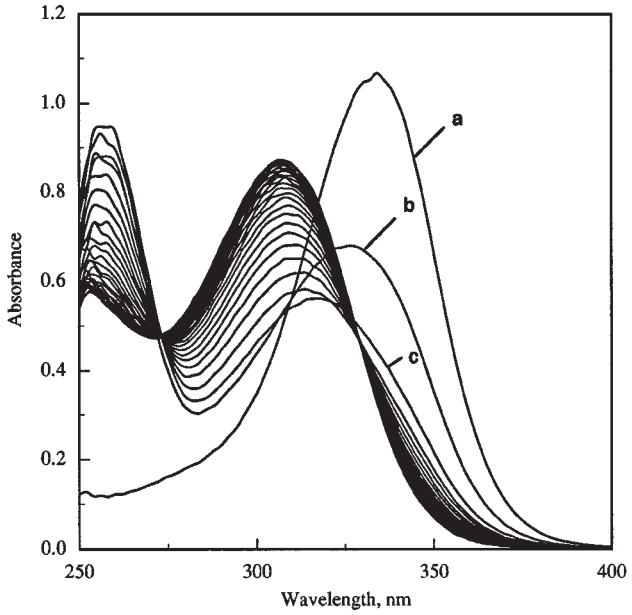
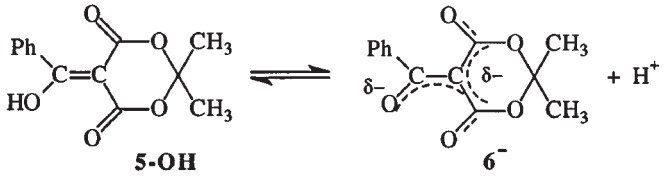


$\mathbf{6}^-$ (pK_a(**5-OH**) = 1.06) (14). The main difference between the hydrolysis of **5-SMe** and **5-OMe** is that the reaction of **5-SMe** is several orders of magnitude slower.

[2] $$k_{obsd} = k_{H_2O} + k_{OH}[OH^-]$$

Reaction of 5-SMe with thiolate ions

When **5-SMe** is mixed with a thiolate buffer two kinetic processes are observed. The first is on the stopped-flow time scale and leads to a loss of absorption at 335 nm, which is the λ_{max} of **5-SMe**. This is consistent with addition of RS^- to **5-SMe** according to eq. [3]. The spectrum of the intermediate, **5-(SMe,SR)**$^-$, which is expected to be similar to that of intermediates derived from the addition of thiolate or alkoxide ions to **5-OMe** (14) and **5-H** (15) or alkoxide in addition to **5-SMe** ($\lambda_{max} \approx 260$ nm, see below), could not be recorded. This is because at the relatively high thiolate ion concentrations (>10^{-2} M) required to push the equilibrium of eq. [3] to the right there is strong interference by the absorbance of RS^-. (In the reactions of **5-OMe** or **5-H** with thiolate ions, the spectra of the corresponding intermediates were easily obtained (14, 15) because the equilibrium constants for thiolate ion addition are much higher, so that much lower [RS^-] could be used.)



5-OH **6**$^-$

[3] 
5-(SMe,SR)$^-$

The kinetic data conform to eq. [4]. Some of the plots of k_{obsd} vs. [RS^-] have measurable intercepts that yield an approximate value for k_{-1}^{RS}; k_1^{RS} and k_{-1}^{RS} values are reported in Table 1.

[4] $$k_{obsd} = k_1^{RS}[RS^-] + k_{-1}^{RS}$$

The second process is much slower, with k_{obsd} showing a nonlinear dependence on [RS^-] (Fig. 1). This is consistent with conversion of **5-(SMe,SR)**$^-$ to **5-SR** according to eq. [5].

[b] Calculated as $k_{-1}^{RX} = k_1^{RX}/K_1^{RX}$ with K_1^{RX} from eq. [6]; the k_{-1}^{RX} values based on eq. [4] are 0.48, 2.96, 26.4, and 0.041 s^{-1} for *n*-BuS^-, $HOCH_2CH_2S^-$, $MeO_2CCH_2S^-$, and $CF_3CH_2O^-$, respectively; the former values are considered more accurate.

[c] Average value based on determinations at 260 and 335 nm.

[d] Reference 14.

[e] In units of s^{-1}.

[f] The value 2.30×10^{-2} refers to k_u in eq. [9]; depending on which explanation holds for the reaction of **5-(SMe,OCH_2CF_3)$^-$**, k_2^{RX} is either k_u or $<k_u$, see text.

© 1999 NRC Canada

In this case, the nucleophilic addition step acts as a fast preequilibrium, and k_{obsd} is given by eq. [6].

$$[6] \qquad k_{obsd} = \frac{K_1^{RS} k_2^{RS}[RS^-]}{1 + K_1^{RS}[RS^-]}$$

K_1^{RS} and k_2^{RS} values determined by nonlinear squares fit to eq. [6] are summarized in Table 1.

The observed spectral changes call for comment. At low $[RS^-]$ ($K_1^{RS}[RS^-] << 1$) the change in absorbance at 355 nm (λ_{max} of **5-SMe**) is small. This is because the reaction represents conversion of **5-SMe** into **5-SR** with **5-(SMe,SR)**$^-$ acting as a steady-state intermediate, and the spectra of **5-SR** are similar to that of **5-SMe**. At intermediate $[RS^-]$ ($K_1[RS^-] \geq 1$), the changes in absorbance are large because the reaction refers mainly to conversion of **5-(SMe,SR)**$^-$ to **5-SR**, and **5-(SMe,SR)**$^-$ absorbs very little at 335 nm. As $[RS^-]$ is increased further, the observed changes in absorbance decrease again. This is because the product is a mixture of **5-SR** and the symmetrical adduct **5-(SR,SR)**$^-$ that is rapidly formed by addition of RS^- to **5-SR**. This adduct has a similar absorption spectrum as **5-(SMe,SR)**$^-$, which is the "reactant" under these conditions.

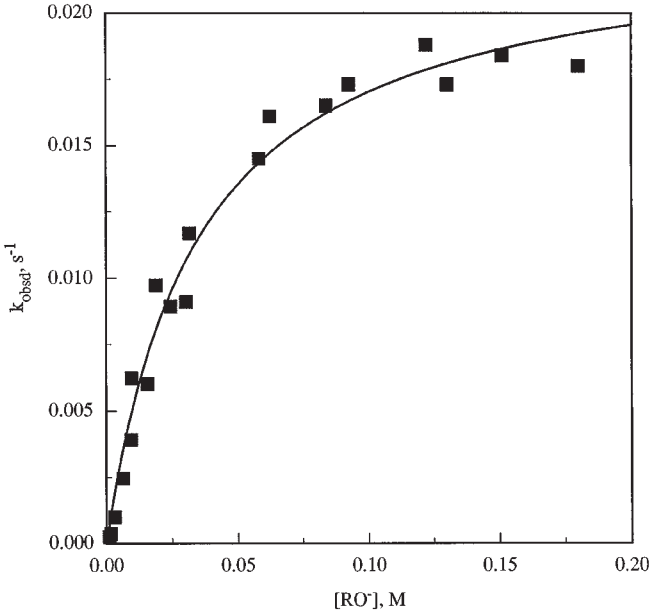
Reaction of 5-SMe with alkoxide ions

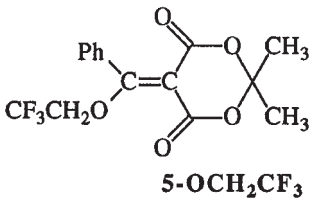
The reaction of **5-SMe** with a $CF_3CH_2O^-$ buffer at high $[CF_3CH_2O^-]$ is characterized by three kinetic processes. The fastest one leads to a rapid loss of **5-SMe**; it is accompanied by the formation of a new species at 260 nm. The spectrum of the latter is characteristic of a tetrahedral intermediate,[4] consistent with the formation of **5-(SMe,OR)**$^-$ (R = CF_3CH_2), eq. [7]. The spectral changes are shown in Fig. 2.

[7] **5-SMe** + RO^- $\underset{k_{-1}^{RO}}{\overset{k_1^{RO}}{\rightleftharpoons}}$ 
5-(SMe,OR)$^-$

The second process leads to a product with a λ_{max} = 306 nm (Fig. 2). It is unclear what this product is. It cannot be the substitution product **5-OCH$_2$CF$_3$** because its rate of hydrolysis is expected to be much faster than the rate of the transformation of **5-(SMe,OR)**$^-$ into the new species at 306 nm. (The hydrolysis of **5-OCH$_2$CF$_3$** can be expected to be at least as fast as hydrolysis of **5-OMe**. At pH 14.59 and 14.01, the conditions under which the second process was measured kinetically, k_{obsd}, for the hydrolysis of **5-OMe** is 27 and 7.2 s^{-1}, respectively, while the k_{obsd} values for the second process range from 1.06×10^{-3} to 1.80×10^{-2} s^{-1}, depending on $[CF_3CH_2O^-]$.) The spectrum of the new species is indeed inconsistent with **5-OCH$_2$CF$_3$** whose spectrum should be similar to that of **5-OMe** (λ_{max} = 278 nm) (14). But the spectrum is also inconsistent with the hydrolysis product **6**$^-$ (λ_{max} = 284 nm) (14); **6**$^-$ is eventually formed, but on a much slower time scale which corresponds to the third kinetic process mentioned earlier. Our results require one of two possible interpretations. (*i*) The intermediate, **5-(SMe,OCH$_2$CF$_3$)**$^-$, undergoes a reaction other than loss of MeS^-, leading to an unidentified product that eventually hydrolyzes to **6**$^-$. (*ii*) **5-(SMe,OCH$_2$CF$_3$)**$^-$ *is* converted to **5-OCH$_2$CF$_3$** but then rapidly reacts and forms an unidentified product that is eventually converted to **6**$^-$.

Fig. 3. Reaction of **5-SMe** with $CF_3CH_2O^-$ at pH 14.59 monitored at 260 nm or 335 nm in 50% DMSO – 50% water at 20°C. Pseudo-first-order rate constants of the second (slow) process according to eq. [9].





5-OCH$_2$CF$_3$

With respect to the kinetic determinations, the rates for the first process were measured at pH 14.59 by monitoring the reaction at 335 and 260 nm. The data are consistent with eq. [8].

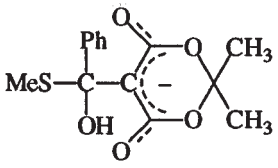
$$[8] \qquad k_{obsd} = k_1^{RO}[RO^-] + k_{OH}[OH^-]$$

There is a contribution by the hydrolysis reaction ($k_{OH}[OH^-]$ term) that becomes significant at low $[RO^-]$; k_1^{RO} was determined from the slope of plots of $k_{obsd} - k_{OH}[OH^-]$ vs. $[RO^-]$ (not shown). ($[RO^-]$ was corrected for the homoassociation constant (K_{assoc} = 1.8 M^{-1}) (10) of $CF_3CH_2O^-$ with CF_3CH_2OH.) The reported k_1^{RO} value in Table 1 is the average of k_1^{RO} = 1.53 ± 0.04 M^{-1} s^{-1} at 335 nm and 1.28 ± 0.02 at 260 nm; k_{-1}^{RO} is too small to be obtained from these experiments.

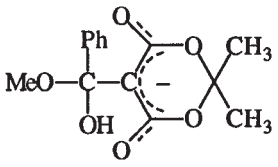
The rates of the second process were measured at pH 14.59 (λ = 260 nm) and pH 14.01 (λ = 300 nm). A plot

[4] It is virtually identical to the spectra of **5-(OMe,SR)**$^-$ generated by the reaction of **5-OMe** with RS^- (14).

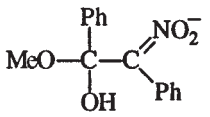
© 1999 NRC Canada



5-(SMe,OH)$^-$



5-(OMe,OH)



4-(OMe,OH)$^-$

of k_{obsd} vs. [RO$^-$] is shown in Fig. 3. It is consistent with eq. [9],

$$[9] \qquad k_{obsd} = \frac{K_1^{RO}[RO^-]}{1 + K_1^{RO}[RO^-]} k_u$$

with K_1^{RO} being the equilibrium constant for eq. [7], and k_u referring to the unknown reaction that depletes the intermediate. Least-squares analysis of the data according to eq. [9] yields $K_1^{RO} = (2.86 \pm 0.35) \times 10^1$ M^{-1} and $k_u = (2.30 \pm 0.10) \times 10^{-2}$ s^{-1}.

The kinetic behavior of the reaction of **5-SR** with HC≡CCH$_2$O$^-$ is similar to that for the reaction with CF$_3$CH$_2$O$^-$. However, the rate measurements for the second process gave irreproducible results which are not reported, and hence only k_1^{RO} could be determined.

Discussion

Detection of the intermediate

As is the case for **5-OMe**, the respective intermediates **5-(SMe,SR)**$^-$ in the reactions of **5-SMe** with *n*-BuS$^-$, HOCH$_2$CH$_2$S$^-$, and MeO$_2$CCH$_2$S$^-$, and the intermediates **5-(SMe,OR)**$^-$ in the reactions with HC≡CCH$_2$O$^-$ and CF$_3$CH$_2$O$^-$ all accumulate to detectable levels under the appropriate conditions. As has been discussed in detail elsewhere (8–13), the requirements for the intermediate to be detectable are that the equilibrium of the first step is favorable (k_1^{RX}[RX$^-$] > k_{-1}^{RX} or K_1^{RX}[RX$^-$] > 1) and that the rate of formation of the intermediate is faster than its rate of conversion to products (k_1^{RX}[RX] > k_2^{RX}). These conditions are evidently met in the reactions of **5-SMe** with RS$^-$ and RO$^-$.

The only intermediate that has remained elusive under all conditions is **5-(SMe,OH)**$^-$ in the hydrolysis reaction. The reasons for this are the same as why the corresponding intermediates such as **5-(OMe,OH)**$^-$ (14) and **4-(OMe,OH)**$^-$ (16) have not been detectable: their conversion to products via two pathways not available to intermediates lacking the OH group is faster than their formation and turns them into steady-state intermediates. One of these additional pathways is intramolecular acid catalysis of leaving-group departure by the OH group (10, 11, 16). The other involves rapid deprotonation of the OH group, generating the dianionic form of the intermediate which expels the leaving group much more rapidly than the monoanionic form (10, 11, 16). Note that the rapid conversion of **5-(SMe,OH)**$^-$ to products implies that attack by water and OH$^-$ is rate limiting in the hydrolysis reaction, i.e., $k_{H_2O} = k_1^{H_2O}$ and $k_{OH} = k_1^{OH}$, respectively (eq. [2]).

Structure–reactivity relationships

A. Equilibrium constants for nucleophilic addition

It is instructive to compare the equilibrium constants for nucleophilic addition to **5-SMe** with those for addition to **5-H** and **5-OMe**, which are included in Table 1. Irrespective of the nucleophile, the relative magnitude of these equilibrium constants follows the order K_1^{RX} (**5-SMe**) << K_1^{RX}(**5-OMe**) << K_1^{RX}(**5-H**). For example, for HOCH$_2$CH$_2$S$^-$ as the nucleophile, the ratios K_1^{RS}(**5-SMe**):K_1^{RS}(**5-OMe**):K_1^{RS}(**5-H**) are 6.2×10^{-9}:4.8×10^{-7}:1; for the other thiolate ions, these ratios are quite similar. For CF$_3$CH$_2$O$^-$ as the nucleophile, the ratios K_1^{RO}(**5-SMe**):K_1^{RO}(**5-OMe**): K_1^{RO}(**5-H**) are 4.5×10^{-6}:1.7×10^{-2}:1.

These trends result from an interplay of differences in steric, inductive/field, π-donor, and anomeric effects on the three reaction systems. These factors affect the K_1^{RX} values in the following way. (*i*) The increasing size in the order H << OMe << SMe leads to increasing steric crowding in the adduct and hence lowers K_1^{RX} for both **5-OMe** and **5-SMe** relative to **5-H**, and more so for **5-SMe**.[5] (*ii*) The electron-withdrawing inductive/field effect should enhance both K_1^{RX}(**5-OMe**) and K_1^{RX}(**5-SMe**) relative to K_1^{RX} (**5-H**), and somewhat more so for **5-OMe**.[6] (*iii*) The π-donor effect of the MeO and MeS groups that leads to resonance stabilization of **5-XMe** (see **5-XMe** $^{\pm}$) reduces K_1^{RX} for **5-OMe** and **5-SMe** relative to **5-H**, with the effect on K_1^{RX}(**5-OMe**) being the strongest.[7] (*iv*) The anomeric effect is an adduct stabilizing factor that mainly affects the dialkoxy intermediates in the reactions of **5-OMe** with RO$^-$ [8] and enhances K_1^{RO}(**5-OMe**) relative to K_1^{RO}(**5-SMe**) and K_1^{RO}(**5-H**).

For the thiolate ion reactions, the steric and π-donor effects appear to be the dominant factors, dramatically reducing K_1^{RS}(**5-OMe**) and K_1^{RS}(**5-SMe**) relative to K_1^{RS}(**5-H**), greatly offsetting the inductive/field effect. The fact that K_1^{RS}(**5-SMe**) is smaller than K_1^{RS}(**5-OMe**) indicates that the greater steric effect of the MeS group combined with the somewhat weaker inductive/field effect are dominant in this comparison and more than offset the weaker π-donor effect of the MeS group. Overall, when comparing the K_1^{RS} values of the three substrates, the steric effect emerges as the most important factor.

For the alkoxide ion reactions the K_1^{RO} values for **5-SMe** and **5-OMe** are not as strongly depressed relative to K_1^{RO} for

[5] Taft's steric substituent constants, E_s, are –0.55 for MeO and –1.07 for MeS, respectively (17), while Charton's (18) ν_{ef} values are 0.36 for MeO and 0.64 for MeS, respectively.
[6] σ_F = 0.30 and 0.20 for MeO and MeS, respectively (19).
[7] σ_R = –0.43 and –0.15 for MeO and MeS, respectively (19).
[8] In the present context, the anomeric effect (20, 21) refers to the stabilization exerted by geminal oxygen atoms (22–25), e.g., in dialkoxy adducts such as **5-(OMe,OR)**$^-$.

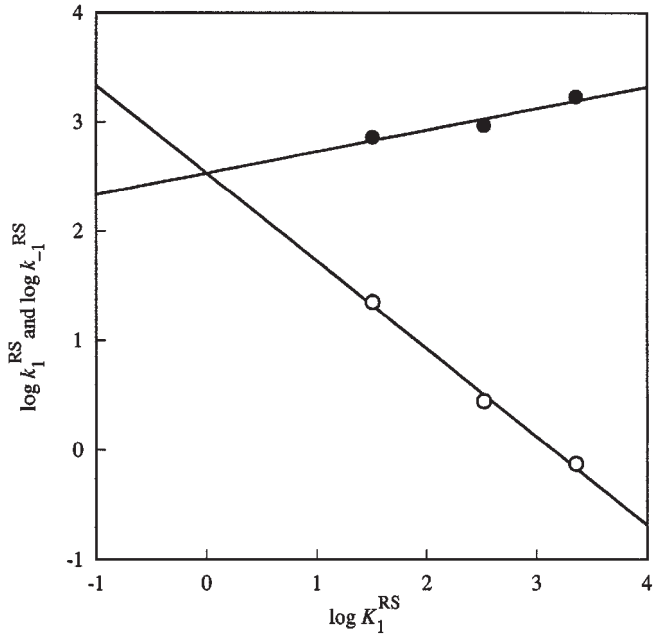
5-XMe± (X = O or S)

5-H as for the thiolate ion reactions. Here, the smaller size of the alkoxide ion nucleophiles reduces the steric crowding in the respective intermediates. On the other hand, K_1^{RO} (**5-OMe**) appears to be much more enhanced relative to K_1^{RO} (**5-SMe**) than is the case with thiolate ion nucleophiles. This demonstrates the importance of the anomeric effect, which stabilizes the dialkoxy but not the alkoxy–thioalkoxy complexes.

With respect to their absolute magnitude, the K_1^{RS} values are significantly larger than the K_1^{RO} for addition of alkoxide ion of comparable pK_a. For example, K_1^{RS} for *n*-BuS^- addition to **5-SMe** (2.26×10^3 M^{-1}) is 79-fold larger than K_1^{RO} = 28.6 M^{-1} for $CF_3CH_2O^-$ addition to the same substrate, even though the pK_a^{RSH} of *n*-BuSH is only 11.40, while that of $CF_3CH_2O^-$ is 14.0. The enhanced carbon basicity of sulfur

Fig. 4. Reaction of **5-SMe** with *n*-BuS^-, $HOCH_2CH_2S^-$, and $MeO_2CCH_2S^-$. Plots of log k_1^{RS} (●) and log k_{-1}^{RS} (○) vs. log K_1^{RS}. The point where the two lines intersect corresponds to log k_o^{RS}, see text.



compared to oxygen nucleophiles manifests itself even more dramatically in the reactions of **5-H** where steric hindrance is less important: $K_1^{RS} = 5.89 \times 10^{11}$ M for *n*-BuS^- vs. $K_1^{RO} = 6.43 \times 10^6$ M^{-1} for $CF_3CH_2O^-$. On the other hand, in the reaction of **5-OMe** with alkoxide ions the anomeric effect reduces the advantage of the sulfur bases: $K_1^{RS} = 1.70 \times 10^5$ M (*n*-BuS^-) vs. $K_1^{RO} = 6.81 \times 10^4$ M ($CF_3CH_2O^-$).

The higher carbon basicity of sulfur compared to oxygen bases has been commonly attributed to stronger polarizability (26–28) or "softness" (29, 30) of the sulfur compounds, i.e., in the reaction of RS^- with polarizable electrophiles such as **5-H**, **5-OMe**, **5-SMe**, and other alkenes there is a favorable soft–soft interaction, while in the reactions of RO^- with the same electrophiles there is a less favorable hard–soft interaction. An additional factor, particularly important in aqueous media, is the weaker solvation of thiolate compared to that of alkoxide ions (31–33).

B. Rate constants for nucleophilic addition by RS^- and RO^-

The rate constants for nucleophilic attack on **5-SMe**, **5-OMe**, and **5-H** follow the same qualitative pattern as the equilibrium constants, i.e., k_1^{RX}(**5-SMe**) << k_1^{RX}(**5-OMe**) << k_1^{RX}(**5-H**). Specifically, the ratios k_1^{RS}(**5-SMe**):k_1^{RS}(**5-OMe**):k_1^{RS}(**5-H**) are 6.4×10^{-5}:3.1×10^{-3}:1 for $HOCH_2CH_2S^-$, which is representative for all thiolate ion nucleophiles. For the $CF_3CH_2O^-$ reaction the ratios k_1^{RO}(**5-SMe**):k_1^{RO}(**5-OMe**):k_1^{RO}(**5-H**) are 6.8×10^{-5}:5.3×10^{-2}:1. For the thiolate ion reactions the rate constant ratios are substantially smaller than the equilibrium constant ratios, consistent with the notion that the electronic and steric factors discussed above are only partially expressed at the transition state. On the other hand, for the alkoxide ion reactions the rate constant ratios are quite comparable to the equilibrium constant ratios, sug-

© 1999 NRC Canada

gesting that in moving from the reactants to the transition state, some or all the factors are nearly as strongly expressed as in moving from the reactants to the adducts. These results indicate that there must be significant differences in the *intrinsic* rate constants[2] of the various reactions.

The intrinsic rate constants are reported in Table 2. For the thiolate ion reactions they were obtained by suitable extrapolation of plots of log k_1^{RX} or log k_{-1}^{RX} vs. log K_1^{RX} (Fig. 4); they also yield the normalized Brønsted coefficients β_{nuc}^{n} and β_{lg}^{n}. For the alkoxide ion reactions, log k_o^{RX} was estimated as log k_1^{RO} – 0.5 log K_1^{RO} with k_1^{RO} and K_1^{RO} for $CF_3CH_2O^-$. (This is equivalent to applying the simplest version of the Marcus equation (34), $\Delta G^{\ddagger} = \Delta G_o^{\ddagger} + 0.5\Delta G° + (\Delta G°)^2/16\Delta G_o^{\ddagger}$ and neglecting the third term, which should be very small in our case. The factor 0.5 in front of $\Delta G°$ implies $\beta_n^{nuc} \approx 0.5$, which is a reasonable value in view of the trend in β_n^{nuc} for RO^- addition to **5-H** and **5-OMe** discussed below.)

There are large differences in the k_o^{RX} values for the various reactions. For a given type of nucleophile k_o^{RX}(**5-SMe**) << k_o^{RX}(**5-OMe**) << k_o^{RX}(**5-H**), while for a given substrate the intrinsic rate constant for the thiolate ion reactions is much higher than for the alkoxide ion reactions. To understand why such large differences in the k_o^{RX} values exist, we need to remind ourselves that intrinsic rate constants are purely kinetic quantities that have been corrected for differences in the equilibrium constants that arise from different degrees of steric, inductive/field, π-donor, anomeric, solvation, and polarizability effects. This means that if at the transition state these factors were being developed or lost in proportion to the degree of bond formation ("balanced" transition state), the k_o^{RX} values should be the same for all the reactions. The fact that they are different means that the transition states are imbalanced in several respects.

The rules of the principle of nonperfect synchronization (PNS) allow us to describe these effects as follows. (The PNS (35–37) states that if the development of a product stabilizing factor lags behind bond changes or charge transfer at the transition state, k_o is reduced. The same is true if the loss of a reactant stabilizing factor runs ahead of bond changes or charge transfer. For product stabilizing factors that develop early or reactant stabilizing factors that are lost late, k_o is enhanced. For product or reactant *de*stabilizing factors, the opposite relationships hold.)

(*i*) The π-donor resonance stabilization of **5-SMe** and **5-OMe** is expected to follow the generally observed pattern of resonance effects (35–37), and hence its loss should be more advanced than bond formation. This results in a reduction of the intrinsic rate constants and must be part of the reason why k_o^{RX} for both **5-OMe** and **5-SMe** are lower than for **5-H**.

(*ii*) The observation that the k_o^{RX}(**5-SMe**) values are more strongly reduced than the k_o^{RX}(**5-OMe**) values, despite the smaller π-donor effect of the MeS group compared to that of the MeO group, implies that an additional PNS effect is operative. We propose that this additional effect is the early development of the steric factor. (In the context of the PNS (35–37), steric crowding is a product destabilizing factor which depresses k_o if it is more advanced than bond formation.) This factor is stronger for the reactions with **5-SMe** than with **5-OMe** and should therefore depress k_o^{RX}(**5-SMe**) more than k_o^{RX}(**5-OMe**). This is a particularly significant conclusion because predictions as to whether development of steric effects is generally ahead of bond formation or lags behind it have been difficult to make (37). Specifically, in our earlier study (14) where only data on **5-OMe** and **5-H** were available, no definite conclusion regarding steric effects on the intrinsic rate constants could be drawn.

(*iii*) Following generally observed behavior (37–39), the partial desolvation of the nucleophiles that occurs as they enter the transition state should be more advanced than bond formation. This has the effect of reducing the intrinsic rate constant. Because the solvation of highly basic alkoxide ions is stronger than that of thiolate ions (31–33), k_o^{RO} decreases more than k_o^{RS}, which explains, at least in part, why k_o^{RS} >> k_o^{RO} for all substrates.

(*iv*) An additional PNS effect contributing to the high k_o^{RS} values in the thiolate ion reactions may come from the soft–soft interactions if these interactions developed ahead of bond formation. As has been discussed in more detail elsewhere (40), this is a reasonable possibility.

(*v*) The question whether the anomeric effect in the reactions of **5-OMe** with alkoxide ions develops early (increase in k_o^{RO}(**5-OMe**)) or late (decrease in k_o^{RO}(**5-OMe**)) is an interesting one. From the fact that for the alkoxide ion reactions log k_o^{RO}(**5-OMe**) – log k_o^{RO}(**5-SMe**) is large (≈2.39), while for the thiolate ion reactions log k_o^{RS}(**5-OMe**) – log k_o^{RS}(**5-SMe**) is small (1.13), one might conclude that the anomeric effect enhances log k_o^{RO}(**5-OMe**), implying that its development is ahead of bond formation of the transition state. However, an alternative interpretation of these differences is that it is log k_o^{RS}(**5-SMe**) for the thiolate ion reactions which is unusually large, making the difference log k_o^{RS}(**5-OMe**) – log k_o^{RS}(**5-SMe**) look small. An enhanced log k_o^{RS}(**5-SMe**) value could be the result of the MeS group making **5-SMe** softer than **5-OMe**, which would increase the soft–soft interactions and its k_o^{RS}(**5-SMe**) increasing PNS effect. (This may be similar to findings Bunnett has described 40 years ago (41).) Comparisons between **5-OMe** and **5-H** render this alternative interpretation more plausible: the difference log k_o^{RO}(**5-OMe**) – log k_o^{RO}(**5-H**) = –1.37 is, within experimental error, indistinguishable from log k_o^{RS}(**5-OMe**) – log k_o^{RS}(**5-H**) = –1.51, i.e., there is no enhancement of log k_o^{RO}(**5-OMe**) that could be attributed to early development of the anomeric effect.

C. Rate constants for the reactions with OH^- and water

The reactivity ratios for the OH^- reaction are k_1^{OH}(**5-SMe**):k_1^{OH}(**5-OMe**):k_1^{OH}(**5-H**) = 3.6 × 10^{-4}:0.3:1, which compares with k_1^{RO}(**5-SMe**):k_1^{RO}(**5-OMe**):k_1^{RO}(**5-H**) = 6.8 × 10^{-5}:5.3 × 10^{-2}:1 for the $CF_3CH_2O^-$ reactions. The smaller reductions in k_1^{OH} for the reactions with **5-SMe** and **5-OMe** relative to **5-H** must be the result of the smaller size of OH^- compared to $CF_3CH_2O^-$, which reduces the steric effect in the reactions with **5-SMe** and **5-OMe**. The fact that the absolute values of k_1^{OH} are all lower than for the corresponding alkoxide ion reactions can be attributed to the even stronger solvation of OH^- than that of the alkoxide ions (38, 39, 42), which reduces the intrinsic rate constant for OH^- addition (PNS effect) even more than for alkoxide ion addition.

For the water reaction only data for **5-SMe** and **5-OMe** are available; they yield $k_1^{H_2O}$(**5-SMe**)/$k_1^{H_2O}$(**5-OMe**) = 9.4 × 10^{-5}, which compares with k_1^{OH}(**5-SMe**)/k_1^{OH}(**5-OMe**) = 1.2

© 1999 NRC Canada

$\times 10^{-3}$ for the OH^- reaction. The greater selectivity in the water reaction may reflect a more intermediate-like transition state because the reaction is thermodynamically less favorable. As a result, $k_1^{H_2O}$(**5-SMe**) is more strongly reduced by the steric effect, and $k_1^{H_2O}$(**5-OMe**) is more strongly enhanced by the anomeric effect, consistent with the Hammond postulate (43–45).

D. Brønsted coefficients

Table 2 reports a variety of Brønsted coefficients such as β_{nuc}, β_{lg}, β_{eq}, β^n_{nuc}, and β^n_{lg}. For the thiolate ion reactions, β_{nuc} and β^n_{nuc} follow the well-known pattern of being very small (10, 11, 38, 40, 46–48) and $|\beta_{lg}|$ or $|\beta^n_{lg}|$ being quite large, implying little bond formation at the transition state. (This is the traditional view (43, 44, 49), although this view has been challenged (50–52) as well as defended (45).) It has been argued previously (15, 40) that the small β_{nuc} (β^n_{nuc}) values are not necessarily the result of a Hammond–Leffler effect (43, 44) arising from very large equilibrium constants for thiolate ion additions. Our results with **5-SMe** for which the K_1^{RS} values are much smaller than for **5-OMe** and particularly **5-H** support this view.

The finding that β_{eq} for the reaction of thiolate ions with **5-SMe** is smaller than 1 is again consistent with the results of **5-OMe** (14) and **5-H** (15) as well as with other examples (40, 46).

In contrast to the thiolate ion reactions β_{nuc} (β^n_{nuc}), alkoxide ion addition appears to follow the Hammond–Leffler (43, 44) trend towards larger values for thermodynamically less favored reactions. This is confirmed by the results for **5-SMe**. The unusually large β_{eq} value for alkoxide ion addition to **5-OMe** has been discussed elsewhere and attributed to the anomeric effect (14).

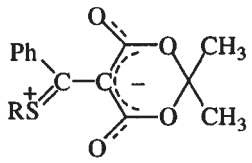
E. Rate constants for leaving group expulsion

Our data set for the k_2^{RX} process is not as complete as for the nucleophilic addition step. However, by including k_{-1}^{RX}, which also represents leaving group expulsion, into the discussion, several insights emerge.

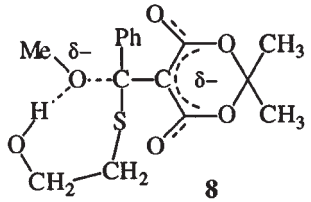
(*i*) The k_{-1}^{RX} values indicate that there is moderate to strong inverse correlation between leaving group departure rate constants and the proton basicity of the leaving group. This is reflected in the relatively large β_{lg} values which range from –0.57 to –0.97 (Table 2).

(*ii*) The k_2^{RS} values for the reactions of thiolate ions with **5-SMe** and **5-OMe** increase significantly with increasing pK_a^{RSH}, indicating a substantial electronic push by the RS group left behind. This is reflected in the $\beta_{push} = d\log k_2^{RX}/dpK_a^{RXH}$ values of 0.44 (**5-SMe**) and 0.75 (**5-OMe**), respectively (Table 2). This push is the result of the developing resonance effect in the product **(5-SR)**$^{\pm}$.

(*iii*) Because a decrease in pK_a^{RSH} enhances k_{-1}^{RS} but lowers k_2^{RS}, the k_2^{RS}/k_{-1}^{RS} ratios in the reactions with thiolate ions increase strongly with decreasing pK_a^{RSH}($d(\log k_2^{RS}/k_{-1}^{RS})/dpK_a^{RSH}$ = 1.01 for **5-SMe** and 1.34 for **5-OMe**). ($d(\log k_2^{RS}/k_{-1}^{RS})/dpK_a^{RSH} = \beta_{push} - \beta_{lg}$, with β_{lg} referring to the k_{-1}^{RS} step.) For the reaction of *n*-BuS^- with **5-SMe**, the k_2^{RS}/k_{-1}^{RS} ratio is close to unity (0.55), reflecting the fact that $pK_a^{RSH} \approx pK_a^{MeSH}$.



(5-SR)$^{\pm}$



8

(*iv*) The k_2^{RS} value for the reaction of $HOCH_2CH_2S^-$ with **5-OMe** does not fit the correlation of log k_2^{RS} with the pK_a^{RSH} defined by *n*-BuS^- and $MeO_2CCH_2CH_2S^-$; it shows a strong positive deviation (14). This contrasts with k_2^{RS} for the reaction of $HOCH_2CH_2S^-$ with **5-SMe** which shows no deviation. The exalted k_2^{RS} value for **5-OMe** has been attributed to intramolecular hydrogen bonding assistance of methoxide ion departure by the OH group as shown in **8** (14). The absence of such assistance in the reaction of **5-SMe** is consistent with the weaker susceptibility to acid catalysis of thiolate ion departure compared to alkoxide ion departure (12, 13).

(*v*) The k_2^{RS} values for MeS^- departure from **5-(SMe,SR)**$^-$ are much higher than for MeO^- departure from **5-(OMe,SR)**$^-$. For example, k_2^{RS}(**5-SMe**)/k_2^{RS}(**5-OMe**) = 3.6×10^3 in the reaction with *n*-BuS^-. (The k_2^{RS}(**5-SMe**)/k_2^{RS}(**5-OMe**) ratio in the reaction with $HOCH_2CH_2S^-$ is approximately 5×10^3. This ratio is only approximate because for k_2^{RS}(**5-OMe**) the reaction with $MeO_2CCH_2CH_2S^-$ whose pK_a^{RSH} is very close to that of $HOCH_2CH_2S^-$ is used instead of the reaction with $HOCH_2CH_2S^-$; the reaction of **5-OMe** with $HOCH_2CH_2S^-$ is subject to intramolecular hydrogen bonding catalysis and has an exalted k_2^{RS} value (see (*iv*) above).) This is mainly the result of two factors. One is the superior leaving group ability of MeS^- compared to MeO^-, which is related to the lower proton basicity of the sulfur base ($pK_a^{MeSH} \approx 11.1$[9] vs. $pK_a^{MeOH} \approx 17.2$ (10)) but probably attenuated by its stronger carbon basicity. The other is the greater steric crowding in **5-(SMe,SR)**$^-$ compared to **5-(SMe,OR)**$^-$, which should enhance the k_2^{RS}(**5-SMe**)/k_2^{RS}(**5-OMe**) ratio. The steric effect on leaving group departure is also seen in the fact that k_2^{RS} for MeS^- departure from the more crowded **5-(SMe,SR)**$^-$ in the reaction of *n*-BuS^- with **5-SMe** is much larger than k_2^{RS} for MeS^- departure from the less crowded **5-(SMe,OR)**$^-$ in the reaction of $CF_3CH_2O^-$ with **5-SMe**. Without the steric effect, the expected stronger electronic push by the CF_3CH_2O group compared to that of the *n*-BuS group should render k_2^{RO} larger than k_2^{RS}. The same comments apply to the comparison of k_2^{RS} with k_2^{RO} in the reactions of **5-OMe** with *n*-BuS^- and $CF_3CH_2O^-$.

Experimental section

Materials

Thiomethoxybenzylidene Meldrum's acid, **5-SMe**, was synthesized as described by Huang and Chen (54); mp 160–162°C (lit. (54) 164°C). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 1.77

[9] Estimated as 0.3 units lower than pK_a^{n-BuSH}, based on the fact that in pure water the pK_a difference between MeSH and *n*-BuSH is 0.3 units (53).

© 1999 NRC Canada

(s, 6H), 1.90 (s, 3H), 7.43–7.48 (m, 5H). All reagents were purified as described earlier (14).

Methodology

Preparation of solutions, pH measurements, in situ generation of intermediates, recording of spectra, and kinetic measurements were performed as described before (14).

Conclusions

(*i*) The conditions necessary for the direct observation of the S_NV intermediate, i.e., $K_1^{RX}[RX^-] > 1$ and $k_1^{RX}[RX^-] > k_2^{RX}$, are easily met for the reactions of **5-SMe** with all nucleophiles except for OH^-. In this latter reaction the acidic nature of the OH group in **5-(SMe,OH)**$^-$ leads to additional pathways that accelerate the conversion of the intermediate to products to the point of turning **5-(SMe,OH)**$^-$ into an undetectable steady state intermediate.

(*ii*) The ratios of the equilibrium constants for $HOCH_2CH_2S^-$ addition to **5-SMe**, **5-OMe**, and **5-H** are 6.2×10^{-9}:4.8×10^{-7}:1; they are representative for all thiolate ion reactions of this study. The strong reduction in K_1^{RS}(**5-SMe**) and K_1^{RS}(**5-OMe**) compared to K_1^{RS}(**5-H**) is mainly the result of the steric and π-donor effects. The fact that K_1^{RS}(**5-SMe**) < K_1^{RS}(**5-OMe**) indicates that the steric effect is, overall, the dominant factor. The corresponding ratios for $CF_3CH_2O^-$ addition are 4.5×10^{-6}:1.1×10^{-2}:1. They indicate less severe crowding in the intermediates derived from **5-SMe** and **5-OMe**. The smaller K_1^{RO}(**5-SMe**)/K_1^{RO}(**5-OMe**) ratio for the alkoxide ion reactions compared to the K_1^{RS}(**5-SMe**)/K_1^{RS}(**5-OMe**) ratio for the thiolate ion reactions shows the importance of the anomeric effect in **5-(OMe,OR)**$^-$.

(*iii*) Because of the greater polarizability and weaker solvation of thiolate compared to alkoxide ions, the equilibrium constants for thiolate addition to all substrates are much higher than for addition of alkoxide ions of the same proton basicity.

(*iv*) The rate constants for nucleophilic addition to **5-SMe**, **5-OMe**, and **5-H** are affected by the same factors as the equilibrium constants, but the relative importance of these factors is different because of multiple transition state imbalances that affect the intrinsic rate constants. For a given type of nucleophile the k_0^{RX} values follow the order **5-SMe** << **5-OMe** << **5-H**, which is mainly the result of early loss of the π-donor stabilization of **5-SMe** and **5-OMe** and early development of the steric effect at the transition state. For a given substrate, k_0^{RS} >> k_0^{RO}; this is a consequence of early desolvation of the nucleophile, probably combined with early development of the soft–soft interactions in the reactions with thiolate ions. These soft–soft interactions appear to be particularly beneficial in the reaction of **5-SMe** due to the softness of the MeS group.

(*v*) The fact that β_{nuc} is very low for thiolate ion addition to **5-SMe**, despite the relatively small equilibrium constants, confirms previous conclusions that in thiolate additions to electrophiles the generally observed low β_{nuc} values are not the result of a Hammond effect.

(*vi*) The leaving group departure rate constants depend on the following factors: the pK_a of the leaving group (increased rate with decreasing pK_a, moderate to large negative β_{lg} values), the pK_a of the remaining group (increased rate with increasing pK_a, moderate to large β_{push} values), leaving group atom (higher rate with S than with O), and steric effects (increased rate with bulkier leaving and (or) remaining groups).

(*vii*) In the reaction of **5-OMe** with $HOCH_2CH_2S^-$, the k_2^{RS} value is abnormally high because of intramolecular hydrogen bonding assistance of MeO^- departure by the OH group. In contrast, the k_2^{RS} value for the reaction of **5-SMe** with the same nucleophile is not enhanced, indicating that intermolecular assistance of MeS^- departure is not important.

Formation and behavior of intramolecular *N*-(styrylalkyl)aniline exciplexes

Frederick D. Lewis, Jill M. Wagner-Brennan, and Alan M. Miller

Abstract: The photophysical and photochemical behavior of several aniline spacer – styrene molecules in which the spacer is a short polymethylene chain has been investigated. Long wavelength excitation selectively excites the aniline chromophore which undergoes intramolecular quenching by the styrene to yield an intramolecular exciplex. Exciplex fluorescence is observed for both of the tertiary anilines investigated and for one of the three secondary anilines. More rapid exciplex formation in nonpolar vs. polar solvents is attributed to the necessity of desolvating the polar aniline singlet in polar solvents. Intramolecular adduct formation is the major photochemical process for the secondary anilines, but is highly inefficient for the tertiary anilines. The behavior of the intramolecular aniline–styrene exciplexes is compared to that of the styrene-amine exciplexes previously investigated in this laboratory.

Key words: intramolecular exciplex, fluorescence, aniline, styrene.

Résumé : On a étudié le comportement photophysique et photochimique de plusieurs molécules de type aniline écarteur – styrène dans lesquelles l'écarteur est une courte chaîne de polyméthylène. Une excitation de grande longueur d'onde excite sélectivement le chromophore aniline qui subit une désactivation intramoléculaire par le styrène pour donner un exciplexe intramoléculaire. On observe la fluorescence d'exciplexe dans les deux anilines tertiaires étudiées et dans l'une des trois anilines secondaires. La formation plus rapide de l'exciplexe dans les solvants non polaires par rapport aux solvants polaires est attribuée à la nécessité de désolvatation du singulet polaire de l'aniline dans les solvants polaires. La formation d'adduit intramoléculaire est le principal processus photochimique dans le cas des anilines secondaires, mais ce processus à toutes fins pratiques ne se produit pas dans le cas des amines tertiaires. On compare le comportement des exciplexes intramoléculaires aniline–styrène aux exciplexes styrène–amine étudiés antérieurement dans ce laboratoire.

Mots clés : exciplexe intramoléculaire, fluorescence, aniline, styrène.

[Traduit par la Rédaction]

N,*N*-Dialkylanilines are good electron donors and have been widely employed in studies of photoinduced electron transfer (1). Inter- and intramolecular quenching of singlet arenes by dialkylanilines in nonpolar solvents can result in the formation of charge-transfer stabilized fluorescent exciplexes (2–8). Increasing solvent polarity causes a red shift in the exciplex fluorescence and, in most cases, a decrease in fluorescence intensity. Complete electron transfer in polar solvents leads to the formation of the arene anion radical and aniline cation radical. Secondary *N*-alkylanilines are also good electron donors, however, exciplex fluorescence is generally not observed upon quenching of arenes by secondary anilines (9, 10). The absence of exciplex fluorescence has been attributed to rapid intersystem crossing or N-H proton transfer within the exciplex.

Quenching of singlet anilines by ground-state acceptors should also result in electron transfer. In comparison to quenching of singlet acceptors by ground-state anilines, quenching of singlet anilines by ground-state acceptors remains largely univestigated. The weak long-wavelength absorption and relatively short singlet lifetimes of the anilines restricts the choice of ground-state acceptors. Beens and Weller (2*a*) noted the failure of dimethylaniline and benzene to form an exciplex and suggested that the small extent of orbital overlap might be responsible. Fluorescence quenching of singlet anilines by chloromethanes (11) and chlorobenzenes (12) has been reported; however, exciplex fluorescence is not observed. Hansen and co-workers (13) reported that primary and secondary (but not tertiary) *o*-allylanilines undergo intramolecular addition reactions to yield indole derivatives. Electron transfer from the singlet aniline to the allyl group followed by proton transfer and radical pair combination was proposed as the mechanism for this reaction. Red-shifted fluorescence was observed for the secondary *o*-allylanilines compared to a saturated model compound; however, no exciplex fluorescence was observed for the tertiary *o*-allylanilines.

We previously observed that both secondary and tertiary (aminoalkyl)styrenes undergo intramolecular addition reactions (14). The observation of exciplex fluorescence supported the occurrence of electron transfer from ground-state tertiary alkyl amines to singlet styrene. We report here an in-

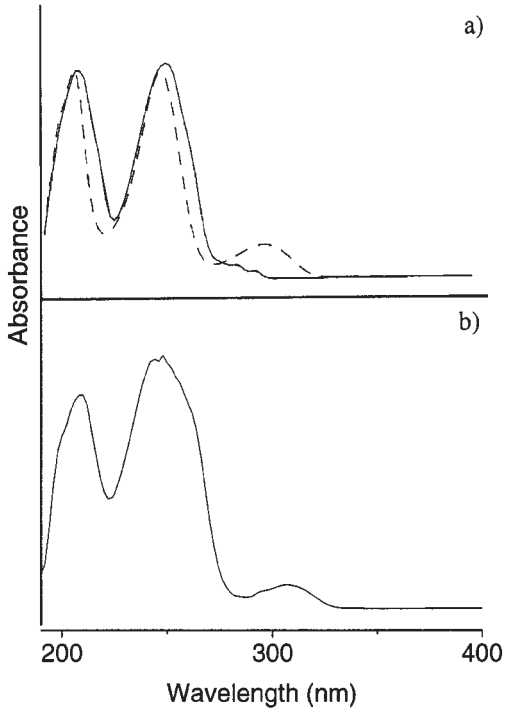
vestigation of the photochemical behavior of the covalently linked *N*-(styrylalkyl)anilines **1**–**5** and the *N*-alkenylanilines **6** and **7** (Chart 1). The lower singlet energy of the aniline vs. styrene chromophore permits investigation of electron transfer from the singlet aniline to the ground-state styrene in **1**–**5**. Intramolecular quenching of tertiary anilines by styrene in nonpolar solvent results in a single fluorescence band attributed to an intramolecular aniline–styrene exciplex. In moderately and highly polar solvents two fluorescence bands are observed and attributed to locally excited aniline and exciplex fluorescence. Exciplex fluorescence is also observed for the secondary styrylaniline **3**, but not its homologues **4** or **5**. Intramolecular adduct formation is observed for the secondary styrylanilines **3**–**5** and for the linked acrylate **6**, but not for tertiary styrylanilines **1** and **2** or for the linked alkene **7**. The pronounced differences in the behavior of arene–aniline and arene–alkylamine exciplexes are discussed.

Results

The *N*-alkenylanilines **1**–**7** were prepared by standard procedures, purified by column chromatography, and characterized by ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry as well as by absorption and fluorescence spectroscopy (see Experimental). The alkenes in **1**–**6** possess the *E*-configuration, as determined by NMR, and contain <2% of the *Z*-isomer, as determined by gas chromatography.

The absorption spectrum of *N*,*N*-dimethylaniline (DMA) in hexane solution consists of a weak band at 296 nm (f = 0.04) and a stronger band at 250 nm (f = 0.28) (15). The

Fig. 1. Absorption spectra in acetonitrile solution. (*a*) *N*-Methylaniline (----) and β-methylstyrene (—); (*b*) styrylaniline **4**.



maxima for *N*-methylaniline (MA) are at slightly shorter wavelengths (294 and 243 nm). Increasing solvent polarity results in only small shifts in the band maxima. The absorption spectrum of β-methylstryene (β-MS) in hexane solution consists of a weak, structured band at long wavelength (284 nm, f = 0.008) and a stronger band at shorter wavelength (250 nm, f = 0.70) (15). The maxima change only slightly in more polar aprotic solvents. The spectra of MA and β-MS in acetonitrile solution are shown in Fig. 1*a*. The absorption spectra of the linked styrylanilines **1**–**5** are similar to the sum of the absorption spectra of DMA or MA and β-MS, as shown for **3** in Fig. 1b. Similarly, the spectra of **6** and **7** are similar to the sum of the spectra of the aniline and acrylate or alkene chromophores, respectively. At wavelengths >295 nm, the aniline chromophore in **1**–**7** absorbs essentially all of the incident light.

DMA, MA (16), and β-MS (17) are fluorescent in both polar and nonpolar solvents. Selected literature data for fluo-

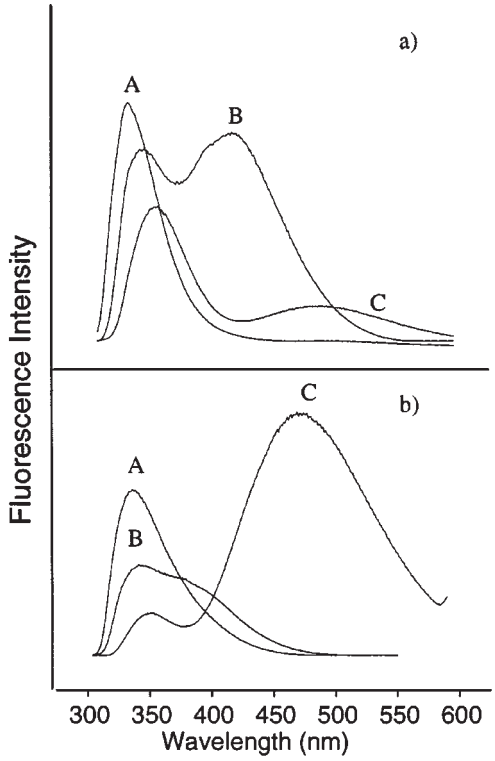
rescence maxima, lifetimes, and quantum yields are summarized in Table 1. The fluorescence maxima of DMA and MA display large solvent-induced shifts, whereas the maximum for β-MS is independent of solvent polarity. Spectra of MA in hexane and acetonitrile are shown in Fig. 2 along with the spectrum of β-MS in acetonitrile. The spectrum of DMA at 77 K in a methyltetrahydrofuran (MTHF) glass displays both fluorescence (λ_{max} = 336 nm) and phosphorescence (λ_{max} = 435 nm) with a ratio of ca. 1:10. Only fluorescence is observed under these conditions for β-MS.

The tertiary styrylanilines **1** and **2** and the secondary styrylaniline **3** display solvent-dependent dual emission (Fig. 3). In hexane solution only a single maximum is observed, however, it is red shifted and broadened with respect to the fluorescence of DMA or MA. In more polar solvents, dual emission is observed. For purposes of discussion, the single band observed in hexane and the shorter wavelength band in more polar solvents is designated F_1 and the longer wavelength band designated F_2. The alkenylanilines **4**–**7** display a single maximum designated F_1 in both nonpolar and polar solvents. The emission maxima, decay times, and fluorescence quantum yields for the F_1 and F_2 bands of **1**–**7** in several solvents are reported in Table 2. At 77 K in a MTHF glass, **1** and **2** display emission similar in appearance to the fluorescence of DMA with band maxima at 336 nm. No styrene-like fluorescence, aniline-like phosphorescence, or F_2 fluorescence is observed under these conditions.

Irradiation of the tertiary anilines **1** and **2** in acetonitrile solution results in rapid conversion to a 1:1 photostationary state of *trans* and *cis* styrene isomers which were isolated and characterized. Prolonged irradiation results in slow formation of other products which were not characterized. Product formation is more rapid in benzene vs. acetonitrile solution. The products were not isolated, however, GC–MS analysis of irradiated solutions is consistent with the formation of intramolecular adducts similar to those formed upon irradiation of tertiary (aminoalkyl)styrenes (14*b*).

Irradiation of the secondary anilines **3**–**6** in hexane or acetonitrile solution leads to the formation of products which

Fig. 3. Fluorescence spectra of styrylanilines in hexane (*A*), diethyl ether (*B*), and acetonitrile (*C*) solution. (*a*) Secondary styrylaniline **3**; (*b*) tertiary styrylaniline **2**.



result from addition of the aniline N-H to the styrene or acrylate double bond (Chart 2). Formation of the *cis* isomers is also observed, but is a relatively minor photoprocess. Adducts **3a** and **4a** were obtained in 50 and 33% isolated yield, respectively, and were characterized as the pyrrolidine and piperidine derivatives by NMR and mass spectral fragmentation. The adducts are not stable under the conditions of irradiation, limiting the preparative yields. GC–MS analysis of the irradiated mixtures indicated that the regioisomeric adducts **3b** and **4b** were formed as minor products in acetonitrile solution. The acrylate **6** also forms mainly the pyrrolidine adduct **6a**. In the case of **5** the major product is piperidine derivative **5b**, rather than the azepine **5a**. Thus, the regioselectivity of adduct formation for **3**–**5** is analogous to that for the corresponding (aminoalkyl)styrenes (14*a*). No photoproducts are formed upon prolonged irradiation of the alkenylaniline **7**.

Discussion

The formation and behavior of intramolecular arene spacer – tertiary aniline exciplexes in which the spacer is a flexible polymethylene chain have been extensively investigated (5–9). The tertiary aniline chromophore has been connected to the spacer either at the para position (**8**, Ar = 9-anthryl or 1-pyrenyl) or via nitrogen (**9**, Ar = 9-anthryl) (Chart 3). Intramolecular quenching of the singlet arene by ground-state tertiary aniline in nonpolar solvents results in the formation of fluorescent exciplexes, which are proposed to have sandwich-type geometries. For exciplexes of largely charge-transfer character, Weller (2*c*, *d*) found the enthalpy

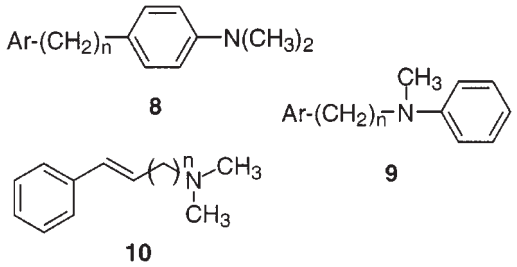
Chart 3.



of exciplex formation could be related to the singlet energy of the excited molecule, E_S, and the reduction and oxidation potentials of the acceptor and donor, respectively, measured in acetonitrile solution, by the empirical relationship given in eq. [1],

$$[1] \qquad -\Delta H_{ex} = E_S + E_{red}(A) - E_{ox}(D) + C$$

where the constant term is the solvent-dependent Coulomb attraction energy. In polar solvents, arene spacer – aniline exciplexes are proposed to adopt "looser" or more extended geometries and fluoresce at longer wavelengths with diminished quantum yield or become totally nonfluorescent. We have observed similar solvent-dependent photophysical behavior for the tertiary (aminoalkyl)styrenes **10** (Chart 3), which also undergo intramolecular addition reactions via singlet exciplex intermediates (14).

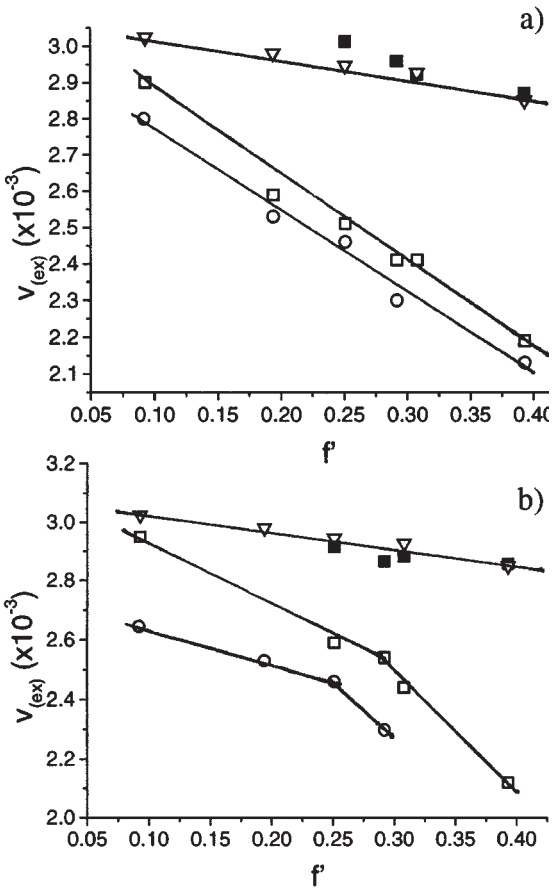
The aniline spacer – styrene systems **1**–**5** differ from previously investigated systems such as **8** and **9** or the (aminoalkyl)styrenes **10** in that the singlet energy of the aniline chromophore is lower than that of the appended alkene. As seen in Fig. 1, MA and β-MS have similar absorption spectra, the lower energy band in MA extending to longer wavelength than that of β-MS. Thus the aniline chromophore in **1**–**5** can be selectively excited at wavelengths >290 nm. It is not possible to investigate bimolecular quenching of singlet anilines by ground-state styrenes due to competitive absorption by styrene at the higher concentrations needed in these experiments. The absorption spectra of **1**–**5** are similar to the sum of the spectra of the two chromophores. Thus, there appears to be no strong ground-state interaction between the two chromophores.

Behavior of tertiary anilines

The arene spacer – aniline systems **8** and **9** and the (aminoalkyl)styrenes **10** display both locally excited and exciplex fluorescence in hexane and moderately polar solvents. In contrast, the fluorescence spectra of the aniline spacer – styrene systems **1** and **2** in hexane consist of a single band, F_1, which is broadened and red-shifted by ca. 7 nm with respect to the fluorescence of DMA (Tables 1, 2). Identical spectra are obtained when the excitation is absorbed predominantly by aniline (294 nm) or equally by aniline and styrene (275 nm). The fluorescence of **1** and **2** (Fig. 3*b*) in

© 1999 NRC Canada

Fig. 4. Solvent polarity dependence of the emission maxima of *N*,*N*-dimethylaniline (▽), the styrylaniline locally excited aniline fluorescence in polar solvents (■), the styrylaniline exciplex fluorescence (□), and the exciplex fluorescence of ((*N*,*N*-dimethylamino)alkyl)styrenes (○). (*a*) Compounds with dimethylene linkers **1** and **10** (n = 2); (*b*) compounds with trimethylene linkers **2** and **10** (n = 3).



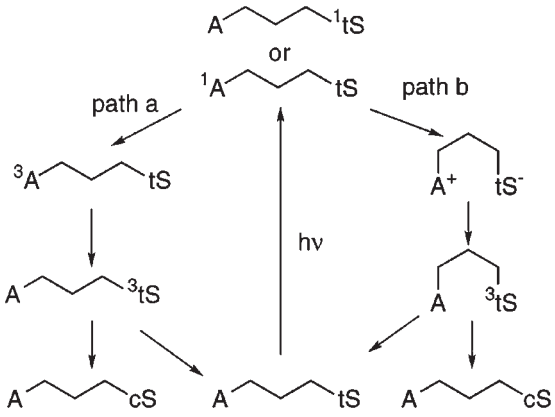
ethers and more polar solvents consists of two bands, F_1 and F_2. The higher energy F_1 band has similar maxima and band shape to that of DMA or MA in these solvents and is assigned to the locally excited aniline singlet. The lower energy F_2 band displays larger solvent-induced shifts and is assigned to the singlet aniline–styrene exciplex. The intensity of exciplex fluorescence for **1** and **2** increases with increasing solvent polarity, unlike the arene linker – aniline and (aminoalkyl)styrenes **8**–**10** for which the exciplex fluorescence intensity decreases in polar solvents. This difference suggests that the exciplexes from **1** and **2** retain a folded geometry even in acetonitrile solution.

Lippert–Mataga plots (18) of the fluorescence maxima for both the locally excited and exciplex bands of **1** and **2** vs. the solvent polarity parameter f', eq [2],

$$[2] \qquad f' = (\varepsilon - 1)/(2\varepsilon + 1) - (n^2 - 1)/(4n^2 + 2)$$

are shown in Fig. 4*a*, *b*, along with the data for DMA and the (aminoethyl)styrenes **10** (n = 2 and n = 3) (14*a*). The maxima for the F_1 bands of **1** and **2** in diethyl ether and more polar solvents are similar to those of DMA (Tables 1 and 2). However, the maximum for the single fluorescence

Scheme 1.



A: aniline, tS: *trans*-styrene, cS: *cis*-styrene

band F_1 observed for **1** and **2** in hexane solution lies below the maximum for DMA. In the case of **1**, inclusion of the hexane F_1 maximum with the exciplex maxima in more polar solvents provides a good fit to a straight line, which parallels the published data for **10** (n = 2) (Fig. 4*a*). The data for **2** and **10** (n = 3) is more limited, and there is an apparent change in slope for the Lippert–Mataga plot between solvents of moderate and high polarity (Fig. 4*b*).

Further evidence for the assignment of the single fluorescence band F_1 of **1** and **2** in hexane solution to an exciplex is provided by comparison of room temperature spectra with those obtained in frozen glasses at 77 K. In the moderately polar solvent MTHF, both locally excited and exciplex fluorescence are observed at room temperature in fluid solution. Cooling to 77 K results in disappearance of the exciplex fluorescence and a small shift in the locally excited fluorescence from 335 to 331 nm. The absence of exciplex fluorescence in 77 K glasses is commonly observed for donor spacer – acceptor systems with flexible polymethylene spacers and is attributed to their inability to adopt sandwich-type geometries in rigid media (6*b*, 19). The fluorescence spectrum of **2** at 77 K in a methylcyclohexane glass is similar to the fluorescence of DMA under the same conditions, however, the strong phosphorescence observed from DMA (20) is absent in the spectrum of **2**. Furthermore, no styrene-like fluorescence is observed upon excitation of **2** at 275 nm, at which the styrene and aniline chromophores have similar absorbance. The complete absence of both styrene fluorescence and aniline phosphorescence in the 77 K spectrum of **2** is indicative of efficient singlet–singlet energy transfer from styrene to aniline and triplet–triplet energy transfer from aniline to styrene, which does not phosphoresce. This singlet–singlet, triplet–triplet relay (Scheme 1, path a) is reminiscent of the benzophenone linker – naphthalene system investigated by Lamola et al. (21).

It is interesting to note that the emission maxima for the intramolecular exciplexes **1** and **2** lie at higher energy than those of the corresponding (aminoalkyl)styrenes (Fig. 4). The oxidation potential of DMA is lower than that of triethylamine, TEA, (0.78 vs. 0.98 V vs. SCE) (4*b*), and thus DMA would be expected to form a more stable exciplex with styrene. Since the singlet energy of DMA is lower than

© 1999 NRC Canada

that of β-MS (4.08 vs. 4.25 eV), similar enthalpies of exciplex formation are calculated using eq. [2] for the intermolecular quenching of singlet DMA by β-MS (E_{red} = –2.54 V (22), ΔH_{ex} = –0.61 eV) and for quenching of singlet β-MS by TEA (ΔH_{ex} = –0.58 eV). According to Weller (2), the exciplex emission maximum in hexane solution can be related to the donor and acceptor redox potentials by the empirical relationship given in eq. [3].

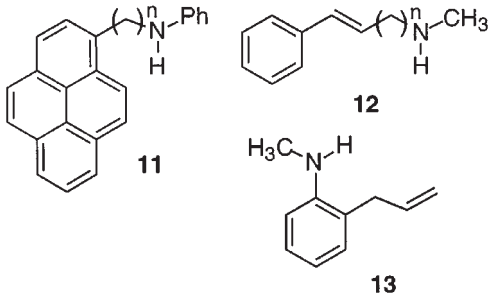
$$[3] \qquad h\nu_{ex} = E_{ox}(D) - E_{red}(A) - 0.15 \pm 0.10 \text{ eV}$$

Thus the emission maximum of the aniline exciplex should be lower than that of the corresponding (dimethylaminoalkyl)styrene by ca. 0.2 eV. However, the emission maxima of **2** and **10** (*n* = 3) in hexane solution are at 338 and 378 nm, respectively (14*b*). A similar difference is found upon comparison of the data of Yang et al. (8) for the intramolecular pyrene–aniline system **9** (*n* = 3) with the data of Swinnen et al. (23) for the analogous (dimethylaminopropyl) pyrene. A part of this difference can be accounted for by the larger ground-state repulsion energy for TEA vs. DMA intermolecular exciplexes, which has previously been noted by Knibbe et al. (2*b*), and recently examined in detail by Vauthey and Henseler (4*c*). An additional factor may be poor orbital overlap in the intramolecular arene–aniline exciplexes. While we do not have data for intermolecular aniline–styrene exciplexes, published data for pyrene–aniline exciplexes establish that the intermolecular exciplex (3) fluorescence maximum is at substantially lower energy than the intramolecular exciplex (8) with a trimethylene linker (460 vs. 430 nm). Much smaller differences in $h\nu_{ex}$ are observed for inter- vs. intramolecular arene–trialkylamine exciplexes (14*a*, 24).

The fluorescence quantum yields and decay times for the F_1 and F_2 fluorescence from **1** and **2** are reported in Table 2. The absence of locally excited fluorescence or dual exponential fluorescence decay in hexane solution indicates that exciplex formation is rapid ($>10^{10}$ s^{-1}) in this solvent. The exciplex fluorescence rate constants ($k_{fex} = \Phi_{fex}\tau_{ex}^{-1}$) for **1** and **2** are larger than that for DMA (Table 1), providing further support for the assignment of the F_1 emission in hexane to the intramolecular exciplex. The decay times of the locally excited fluorescence of **1** and **2** in ether and acetonitrile solution are between 0.1 and 0.6 ns, indicating that intramolecular quenching is slower in these solvents than in hexane solution. Desolvation of the moderately polar aniline chromophore must accompany formation of a sandwich-type exciplex and could account for the slower rates in more polar solvents. The decay times of the exciplexes in ether and acetonitrile are longer than those of the locally excited state, indicating that exciplex formation is irreversible. The exciplex fluorescence rate constants all are in the range 2.0–3.7 × 10^7 s^{-1}, similar to the values for (aminoalkyl)styrene exciplexes in nonpolar solvents (14).

The only photochemical reaction observed for **1** and **2** in acetonitrile solution is photoisomerization, which leads to a ca. 1:1 mixture of *trans* and *cis* isomers. Triplet sensitized irradiation of β-MS also yields a 1:1 photostationary state (25). Formation of the styrene triplet in **1** and **2** could occur either via intersystem crossing of the aniline chromophore followed by intramolecular triplet–triplet energy transfer from aniline to *trans*-styrene (Scheme 1, path a) or via intersystem crossing of the singlet exciplex to yield the locally excited *trans*-styrene triplet (Scheme 1, path b). In benzene solution, additional products are formed in low yield and tentatively identified as intramolecular stilbene–aniline adducts on the basis of their mass spectral fragmentation. In the case of the tertiary ((dimethylamino)ethyl)styrene **10** (*n* = 2), intramolecular addition is more efficient than isomerization (14*b*). The kinetic acidity of the more stable, delocalized, tertiary aniline cation radical is expected to be lower than that of a trialkylamine cation radical (26). Thus, it is not surprising that exciplex proton transfer is less efficient for the exciplex of **2** vs. **10** (*n* = 2).

Chart 4.



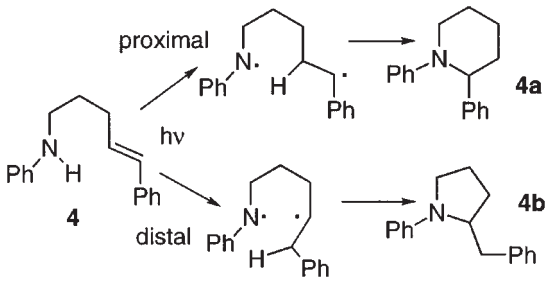
Behavior of secondary anilines

The behavior of arene spacer – secondary aniline systems has received relatively little attention. Okada et al. (9) reported that bimolecular quenching of singlet pyrene by MA results in the formation of a nonfluorescent exciplex that decays via both proton transfer and intersystem crossing processes. Proton transfer was not observed for the linked pyrene spacer – aniline systems **11** (*n* = 1–3) (Chart 4). Its absence was attributed to the high energy of conformations appropriate for its occurrence (10). Fast intersystem crossing was observed for **11** (*n* = 1) but not for *n* = 2 or 3, which were reported to have long exciplex lifetimes in ethyl ether solution. We have observed that the secondary (aminoalkyl) styrenes **12** (*n* = 1–5) form nonfluorescent exciplexes which undergo proton transfer, resulting in the formation of intramolecular adducts (14).

Dual fluorescence is observed for **3** in both ether and acetonitrile solution (Fig. 3*b*) and is attributed to locally excited aniline and intramolecular exciplex fluorescence. To our knowledge, this is the first reported observation of intramolecular exciplex fluorescence involving a secondary aniline. The exciplex emission maxima for **3** are essentially the same as those for **1**. In view of the higher oxidation potential of MA vs. DMA (1.03 vs. 0.79 V vs. SCE (4*b*)), the emission maximum for **3** would have been expected to be at higher energy than that of **1** (eq. [3]). Extra stabilization of the exciplex via intramolecular hydrogen bonding could account for this seeming anomaly. Exciplex stabilization could also account for the common observation of similar efficiencies of inter- and intramolecular quenching of singlet arenes by secondary and tertiary amines (1*c*, 14, 19). The exciplex fluorescence quantum yields and lifetimes for **3** are smaller or shorter than those of **1**, especially in acetonitrile solution (Table 2). The occurrence of proton transfer for **3** but not for

© 1999 NRC Canada

Scheme 2.



1 in polar solvents can account, at least in part, for this difference.

A single fluorescence band is observed for **4** and **5** in both nonpolar and polar solvents (Table 2). Their band maxima are red-shifted with respect to that of MA by 2–7 nm in hexane solution, and the fluorescence rate constants are larger than that of MA. These observations may reflect either perturbation (e.g., internal solvation) of the aniline locally excited state or the formation of an exciplex in nonpolar solvents. The band maxima and fluorescence rate constants in ether and acetonitrile are similar to those of MA, and thus these bands are assigned to locally excited aniline fluorescence. The decay times for the locally excited fluorescence of the secondary anilines **3** and **4** in ether and acetonitrile are similar to those of the tertiary anilines **1** and **2**. The longer singlet decay time for **5** is consistent with slower folding of the longer polymethylene spacer (14).

The photochemical behavior of **3**–**5** is qualitatively similar to that of the secondary (aminoalkyl)styrenes **12**. The formation of **3a**, **4a**, and **5b** as the major adducts is indicative of regioselective N-H transfer to the proximal end of the styrene double bond in **3** and **4** (Scheme 2) and the distal end in **5**. A similar pattern of regioselectivity was attributed in the case of **12** (n = 2–4) to least motion pathways for exciplex proton transfer (14*a*). The failure of styrene *trans*→*cis* isomerization to compete effectively with adduct formation for **3**–**5** indicates that neither aniline nor exciplex intersystem crossing (Scheme 1) competes effectively with proton transfer (Scheme 2). This result is consistent with the observation of slow intersystem crossing for the pyrene – secondary aniline exciplexes **11** (n = 2 or 3) (10).

The linked acrylate **6** and alkene **7** were investigated in order to determine the effect of changing the alkene acceptor upon exciplex formation and behavior. The reduction potential of methyl crotonate (–2.51 V vs. SCE) in acetonitrile solution (27) is similar to that of β-MS (–2.54 V vs. SCE) (22), and thus similar behavior might be anticipated. The photochemical behavior of the acrylate **6** is analogous to that of **3**, yielding an adduct tentatively identified as the pyrrolidine **6a** as the major product (Chart 2). The fluorescence parameters of **6** are also similar to those of **3** in nonpolar solvents (Table 2). However, no exciplex fluorescence is observed for **6** in ether or acetonitrile solution, and the lifetime of the locally excited aniline fluorescence from **6** in acetonitrile is much longer than that of **3**. These observations suggest that the more extensive π-orbital overlap for styrene vs. acrylate may result in the formation of a more stable exciplex.

The unactivated alkene **7** is a weaker electron acceptor than either the styrene or acrylate. Thus, it is not surprising that the aniline-like F_1 fluorescence maximum and lifetime of **7** are similar to those for MA in both hexane and aceonitrile solution (Tables 1, 2). The absence of intramolecular quenching of aniline by the terminal alkene is consistent with the observed absence of adduct formation. This result stands in contrast to the observation of red-shifted aniline fluorescence and intramolecular adduct formation reported by Hansen and co-workers (13) for the *o*-allylaniline **13**. The secondary anilines **7** and **13** differ both in the point of attachment of the alkene and the length of the spacer connecting the alkene to the aniline. We suspect the latter factor is most important, as much stronger through-bond coupling is expected for a single methylene vs. trimethylene spacer (10, 28).

Concluding remarks

In previous studies of arene linker – amine exciplex formation, the electronically excited arene interacts with a ground-state amine (5–10, 14, 19). The roles of the arene and amine have been reversed in the present investigation in which the singlet aniline interacts with a ground-state styrene. The styrylanilines **1**–**5** display photochemical behavior that differs in several important respects from that previously reported for the tertiary and secondary (aminoalkyl) styrenes **10** and **12** (14).

In the case of the tertiary anilines **1** and **2**, an increase in solvent polarity results in a decrease in the rate constant for intramolecular exciplex formation and an increase in the intensity of exciplex formation, precisely the opposite of the solvent effects observed for **10**. Since singlet aniline is much more polar than singlet styrene, the solvent reorganization energy for exciplex formation from singlet aniline but not singlet styrene is expected to increase with increasing solvent polarity. Once formed, the styrene–amine exciplexes undergo relaxation to a nonfluorescent extended geometry in polar solvents whereas the aniline–styrene exciplexes do not. Evidently, the localized alkylamine cation radical is more strongly solvated than is the delocalized aniline cation radical. The difference in charge delocalization can also explain the observation of more efficient proton transfer in the styrene–amine vs. aniline–styrene exciplexes in nonpolar solvents.

The photochemical behavior of the secondary anilines **3**–**5** (Scheme 2) is qualitatively similar to that of the analogous styrene–amines **12**. However, **3** provides the first example of exciplex fluorescence from an intramolecular arene–amine exciplex. The emission maxima of **3** is similar to that of **1** even though it should be less stable, based on the higher oxidation potential of MA vs. DMA. Similarly, the tertiary styrene–amine exciplexes have lower energy emission maxima than those of **1** or **2** in spite of the higher oxidation potential of trialkylamines vs. DMA. Clearly, factors other than amine oxidation potential influence the stability of the arene–amine intramolecular exciplexes.

Experimental

General methods

^{1}H NMR spectra were recorded on Varian VXR-300 and Varian Gemini 300 MHz spectrometers in $CDCl_3$ and methyl sulfoxide-d_6 solvents with TMS as an internal standard. In-

© 1999 NRC Canada

frared spectra of 0.005–0.02 M solutions of amines in dichloromethane or chloroform were recorded in 1 mm path-length NaCl cells using a Biorad FTS60 spectrometer. Mass spectra were obtained using a Hewlett–Packard 5985 GC/VG70-250E MS system using an ionizing voltage of 70 eV. UV-visible absorption spectra were measured with a Hewlett–Packard model 8452A diode array spectrophotometer in 1 cm path-length quartz cuvettes. Room temperature fluorescence emission and excitation spectra were recorded using a SPEX Fluoromax spectrophotometer. Solutions were approximately 10^{-4} M and were purged with nitrogen in a 1 cm path-length quartz cuvette fitted with a white rubber septum (Aldrich). Fluorescence quantum yields were determined using *trans*-1-phenylpropene (Φ_f = 0.35) (29) as a reference standard. Fluorescence decays were measured using a Photon Technology International LS-1 single photon counting apparatus with a gated hydrogen arc lamp using a scatter solution to obtain the lamp decay profile. The decays were analyzed using deconvolution and single or multiplex exponential least-squares fitting as described by James et al. (30). The reduced χ^2 values, randomness of residuals, and autocorrelation functions were used to determine the goodness of the fit.

Preparative scale irradiations were carried out under nitrogen in Pyrex test tubes using a Rayonet reactor fitted with RPR 3000 lamps. Acetonitrile solutions (0.01 M alkylstyrylaniline) were irradiated to >90% conversion of starting material, while monitoring the progress of the reaction by GC. The *cis* isomers of **1**–**6** have slightly shorter GC retention times than the *trans* isomers. Products were isolated by column chromatography. Product yields are based on either isolated yields or GC integration. Irradiations in hexane or benzene were done on a small scale and monitored by GC. The products from the small-scale photoreactions were characterized by mass spectral fragmentation.

Materials

All solvents used were spectral grade. Benzene (Aldrich) was refluxed over sodium metal and distilled prior to use. Acetonitrile (Fisher) was distilled over CaH_2 prior to use. Hexane (Aldrich), anhydrous diethyl ether (Fisher), acetonitrile (Aldrich), methanol (Fisher), chloroform (Fisher), and ethyl acetate (Fisher) were used without further purification. Aniline (Aldrich) was distilled over zinc powder prior to use.

trans-N-*Phenyl*-N-*methyl-4-phenyl-3-buten-1-amine (*trans-***1***)*

trans-Styrylacetic acid (Aldrich) was converted to the acid chloride by reaction with thionyl chloride followed by removal of excess thionyl chloride under reduced pressure. To a solution of the acid chloride in benzene was added a mixture of aniline, sodium methoxide, benzene, and ether. The resulting amide was isolated and purified by silica-gel chromatography (1:1 hexane/ether). Reduction of the amide with $LiAlH_4$ followed by silica-gel chromatography (1:3 hexane/dichloromethane) afforded *trans*-**1** (60%) as a colorless oil. ^{1}H NMR δ: 7.25–7.40 (m, 7H), 6.73–6.80 (m, 3H), 6.47–6.52 (d, 1H, *J* = 15.9 Hz), 6.23–6.31 (m, 1H), 3.49–3.54 (t, 2H, *J* = 7.4 Hz), 3.01 (s, 3H), 2.49–2.57 (q, 2H). ^{13}C NMR δ: 149.1, 137.6, 131.7, 129.3, 128.6, 127.8, 127.2, 126.1, 116.2, 112.3, 52.8, 38.6, 30.5. MS (*m*/*e*): 237 (M+), 120 (100). HRMS: 237.1517 (calcd.) and 237.1515 (obs.). Preparative irradiation of a 0.01 M solution of *trans*-**1** in acetonitrile followed by chromatography provided *cis*-**1** in an isolated yield of ca. 50%. ^{1}H NMR δ: 7.35–6.66 (m, 10H), 6.50–6.42 (d, 1H), 5.71–5.62 (m, 1H), 3.41–3.50 (m, 2H), 2.52–2.45 (m, 2H), 2.96 (s, 3H). ^{13}C NMR δ 149.03, 137.40, 130.78, 129.27, 128.60, 128.28, 127.74, 126.79, 116.17, 112.25, 52.78, 38.55, 26.04.

trans-N-*Phenyl*-N-*methyl-5-phenyl-4-penten-1-amine (*trans-***2***)*

Reaction of the lithium salt of phenylacetylene (Aldrich) with 1-bromo-3-chloropropane yielded 1-chloro-5-phenyl-4-pentyne, which was purified by vacuum distillation. Reaction of this chloroalkyne with *N*-methylaniline afforded the product of *N*-alkylation, which was purified by silica-gel chromatography (4:1 hexane/chloroform). Reduction with $LiAlH_4$ followed by purified by silica-gel chromatography (1:3 hexane/chloroform) afforded **2** as a colorless oil. ^{1}H NMR δ: 7.19–7.35 (m, 7H), 6.68–6.72 (m, 3H), 6.38–6.43 (d, *J* = 15.8 Hz, 1H), 6.19–6.25 (m, 1H), 3.34–3.39 (t, *J* = 7.4 Hz, 2H), 2.93 (s, 3H), 2.21–2.26 (q, *J* = 7.0 Hz, 2H), 1.73–1.78 (quintet, *J* = 7.4 Hz, 2H). ^{13}C NMR δ 149.3, 137.7, 130.4, 130.1, 129.3, 128.6, 127.0, 126.0, 116.0, 112.2, 52.3, 38.4, 30.6, 26.4. MS (*m*/*e*): 251 (M+), 120 (100). HRMS: 251.1674 (calcd.) and 251.1652 (obs.). Preparative irradiation of a 0.01 M solution of *trans*-**2** in acetonitrile followed by chromatography provided *cis*-**2** in an isolated yield of ca. 45%: ^{1}H NMR δ: 7.41–6.73 (m, 10H), 6.54–6.50 (d, 1H), 5.76–5.71 (m, 1H), 3.45–3.36 (m, 2H), 2.94 (s, 3H), 2.45–2.41 (q, 2H), 1.84–1.76 (m, 2H). ^{13}C NMR δ: 149.25, 137.61, 130.48, 129.56, 128.86, 128.28, 127.07, 126.71, 116.06, 112.21, 52.32, 38.49, 26.29, 26.97.

trans-N-*Phenyl-4-phenyl-3-buten-1-amine (**3**)*

Modification of the procedure used for the preparation of **1** by using aniline in place of *N*-methylaniline afforded **3** as a colorless oil. ^{1}H NMR ($CDCl_3$) δ: 7.19–7.41 (m, 7H), 6.64–6.76 (m, 3H), 6.50–6.55 (d, *J* = 16 Hz, 1H), 6.22–6.28 (m, 1H), 3.75 (bs, 1H), 3.27–3.32 (t, *J* = 6.7 Hz, 2H), 2.56–2.60 (q, *J* = 6.9 Hz, 2H). ^{13}C NMR δ: 148.2, 137.3, 132.3, 129.3, 128.6, 127.4, 127.3, 126.1, 117.5, 113.0, 43.3, 33.0. HRMS: 223.1361 (calcd.) and 223.1374 (obs.).

trans-N-*Phenyl-5-phenyl-4-penten-1-amine (**4**)*

Modification of the procedure used for the preparation of **2** by using aniline in place of *N*-methylaniline provided **3** as a colorless oil. ^{1}H NMR δ: 7.14–7.36 (m, 7H), 6.59–6.72 (m, 3H), 6.40–6.45 (d, *J* = 15.9 Hz, 1H), 6.20–6.28 (m, 1H), 3.65 (bs, 1H), 3.15–3.19 (t, *J* = 7.0 Hz, 2H), 2.29–2.36 (q, 2H), 1.76–1.84 (quintet, 2H). ^{13}C NMR δ: 148.4, 137.6, 130.6, 130.0, 129.3, 128.6, 127.1, 126.0, 117.3, 112.8, 43.5, 30.7, 29.2. MS (*m*/*e*): 237 (M+), 106 (100). HRMS: 237.1517 (calcd.) and 237.1518 (obs.).

trans-N-*Phenyl-6-phenyl-5-hexen-1-amine (**5**)*

Modification of the procedure used for the preparation of **4** by using 1-bromo-4-chlorobutane in place of 1-bromo-3-chloropropane provided **3** as a colorless oil in 15% overall yield. ^{1}H NMR δ: 7.19 (m, 3H), 6.97 (m, 2H), 6.47 (m, 2H), 5.80 (d, 2H), 3.68 (m, 2H), 3.25 (m, 2H), 2.50 (m, 2H). ^{13}C

NMR δ: 145.50, 129.67, 128.98, 125.49, 117.17, 112.70, 112.47, 26.88. HRMS: 251.1679 (calcd.) and 251.1674 (obs.).

*Ethyl-(*E*)-5-anilino-2-pentenoate (**6**)*

Ethyl-(*E*)-5-bromo-2-pentenoate was synthesized according to the procedure reported by Bunce and Irwin (31). Stirring at room temperature for 24 h with aniline afforded compound **6** as an oil (59%). ^{1}H NMR δ: 7.26 (t, 2H), 6.95 (m, 1H), 6.75 (t, 2H), 6.65 (d, 2H), 5.90 (m, 1H), 3.74 (s, 3H), 3.32 (t, 2H), 2.55 (m, 2H). ^{13} C NMR δ: 166.70, 147.26, 146.44, 145.64, 134.60, 132.44, 131.31, 129.79, 128.94, 113.51, 51.07, 42.51, 30.21. HRMS: 205.110 28 (calcd.) and 205.110 30 (obs.).

trans-N-*Phenyl-5-hexen-1-amine (**7**)*

Following the procedure of Ohsawa et al. (32), **7** was obtained as a colorless oil. ^{1}H NMR δ 7.27(m, 2H), 6.84 (m, 3H), 5.85 (m, 1H), 5.5 (bs, 1H), 5.11 (m, 2H), 3.20 (t, 2H), 2.17 (m, 2H), 1.81 (m, 2H). HRMS: 251.1674 (calcd.) and 251.1674 (obs.).

N-*Phenyl-2-phenylpyrrolidine (**3a**)*

A solution of compound **3** (0.1 g) in acetonitrile (36 mL) was bubbled with dry N_2 for 10–15 min in a Pyrex test tube and irradiated using a Rayonet reactor fitted with RPR 3000 lamps. The reaction was monitored by gas chromatography until >90% of starting material was converted to products (3 h). Evaporation of the solvent under reduced pressure and column chromatography (silica gel, 50% hexane in dichloromethane) yielded 0.05 g **3a**. ^{1}H NMR δ: 7.14–7.34 (m, 7H), 6.63–6.67 (dd, *J* = 7.3 Hz, 1H), 6.49–6.52 (d, *J* = 6.6 Hz, 2H), 4.72–4.76 (dd, J = 8.7 Hz, 1H), 3.69–3.74 (m, 1H), 3.38–3.46 (m, 1HO, 2.36–2.43 (m, 1H), 1.92–2.04 (m, 3H). ^{13}C NMR δ: 147.2, 144.6, 129.0, 128.5, 126.7, 126.0, 115.8, 112.3, 62.9, 49.1, 36.1, 23.1. HRMS: 223.1361 (calcd.) 223.1373 (obs.).

N-*Phenyl-2-phenylpiperdine (**4a**)*

Irradiation of **4** (0.15 g) in acetonitrile (60 mL) using the conditions described for **3** afforded 0.05 g **4a**: ^{1}H NMR δ: 6.72–7.28 (m, 10H), 4.48–4.52 (dd, *J* = 6.3 Hz, 1H), 3.36–3.42 (m, 1H), 3.23–3.29 (m, 1H), 1.92–2.00 (m, 2H), 1.52–1.73 (m, 2H); ^{13}C NMR δ: 151.9, 143.6, 128.8, 128.3, 127.3, 126.3, 119.6, 118.8, 61.0, 50.6, 33.5, 25.7, 22.1; HRMS: 237.1517 (calcd.) and 237.1500 (obs.). Small-scale irradiation **4** in hexane afforded **4a** as the major product and a second product tentatively identified as **4b**: MS-EI (*m*/*z*): 237, 222, 208, 194, 180, 167, 160 (100), 152, 146, 139, 132, 126, 117, 104, 97, 91, 83, 77, 65, 51.

5b

Small-scale irradiation of **5** in hexane or acetonitrile solution afforded a major product tentatively identified as **5b**. MS-EI (*m*/*z*): 251, 222, 208, 160, 146, 132, 119 (100), 106, 91, 77, 65, 51.

6a** and **6b

Small-scale irradiation of **6** in benzene solution afforded a major product tentatively identified as **6a**: MS-EI (*m*/*e*): 205, 146 (100), 130, 117, 104, 91, 77, 65, 51. Also detected was a minor product tentatively identified as **6b**: MS-EI (*m*/*e*): 205, 177, 144, 132 (100), 117, 104, 91, 77, 59, 51.

Ketonization equilibria of phenol in aqueous solution[1]

Marco Capponi, Ivo G. Gut, Bruno Hellrung, Gaby Persy, and Jakob Wirz

Abstract: The two keto tautomers of phenol (**1**), cyclohexa-2,4-dienone (**2**) and cyclohexa-2,5-dienone (**3**), were generated by flash photolysis of appropriate precursors in aqueous solution, and the pH–rate profiles of their enolization reactions, **2** → **1** and **3** → **1**, were measured. The rates of the reverse reactions, **1** → **2** and **1** → **3**, were determined from the rates of acid-catalyzed hydron exchange at the *ortho*- and *para*-positions of **1**; the magnitude of the kinetic isotope effect was assessed by comparing the rates of hydrogenation of phenol-2*t* and -2*d*. The ratios of the enolization and ketonization rate constants provide the equilibrium constants of enolization, pK_E(**2**, aq, 25°C) = –12.73 ± 0.12 and pK_E(**3**, aq, 25°C) = –10.98 ± 0.15. Combination with the acidity constant of phenol also defines the acidity constants of **2** and **3** through a thermodynamic cycle. These ketones are remarkably strong carbon acids: pK_a(**2**) = –2.89 ± 0.12 and pK_a(**3**) = –1.14 ± 0.15. They disappear by proton transfer to the solvent with lifetimes, τ(**2**) = 260 μs and τ(**3**) = 13 ms, that are insensitive to pH in the range from 3–10.

Key words: proton transfer, tautomers, flash photolysis, kinetic isotope effect, pH–rate profiles.

Résumé : Opérant en solution aqueuse, on a généré les deux tautomères cétoniques du phénol (**1**), la cyclohexa-2,4-diénone (**2**) et la cyclohexa-2,5-diénone (**3**), par photolyse éclair de précurseurs appropriés et on a mesuré les profils pH de la vitesse pour leurs réactions d'énolisation, **2** → **1** et **3** → **1**. On a déterminé les vitesses des réactions inverses **1** → **2** et **1** → **3** à partir des vitesses d'échange d'hydron acidocatalysées dans les positions *ortho*- et *para*- de **1**; on a évalué l'amplitude de l'effet isotopique cinétique en comparant les vitesses d'hydrogénation du phénol-2*t* et -2*d*. Les rapports des constantes de vitesse d'énolisation et de cétonisation permettent d'arriver aux constantes d'équilibre d'énolisation, pK_E(**2**, aq, 25°C) = –12,73 ± 0,12 et pK_E(**3**, aq, 25°C) = –10,98 ± 0,15. Une combinaison avec la constante d'acidité du phénol permet de définir aussi les constantes d'acidité de **2** et de **3** à travers un cycle thermodynamique. Ces cétones sont des acides carbonés relativement forts: pK_a(**2**) = –2,89 ± 0,12 et pK_a(**3**) = –1,14 ± 0,15. Elles disparaissent par transfert de proton vers le solvant avec des temps de vie, τ(**2**) = 260 μs et τ(**3**) = 13 μs qui sont insensibles au pH entre 3 et 10.

Mots clés : transfert de proton, tautomères, photolyse éclair, effet isotopique cinétique, profils pH–vitesse.

[Traduit par la Rédaction]

Introduction

Twenty years ago, we reported on the observation of acetophenone enol by flash photolysis and determined the acidity constant of the enol from the pH–rate profile of its ketonization in aqueous solution (1). That work was a sideline of studies aimed primarily at the characterization of diradical intermediates in Norrish Type 2 reactions, and would not have been pursued, had Prof. A.J. Kresge not visited Basel and convinced us that the photochemical approach to study enol kinetics should be further exploited. Thus began a growing friendship and continued collaboration with the unbeatable research team of Jerry Kresge and his wife, Yvonne Chiang. On the scientific side, we were rewarded by participating in the kinetic and thermodynamic characterization of the enolization equilibria of a representative selection of carbonyl compounds over the last two decades (2).

The protomeric equilibria of thermodynamically stable enols have received less attention. Phenol (**1**) is much more stable than its keto tautomers cyclohexa-2,4-dienone (**2**) and cyclohexa-2,5-dienone (**3**), because proton transfer from oxygen to carbon disrupts π-conjugation of the phenyl ring. Nevertheless, keto tautomers of phenols are frequently invoked as reactive intermediates, e.g., in the Photo–Fries rearrangement, the Kolbe–Schmitt and Reimer–Tiemann reactions, in electrophilic substitutions of phenols, and in the oxidative metabolism of aromatic compounds ("NIH-shift"). In preliminary work (3), we generated cyclohexa-2,4-dienone (**2**) by flash photolysis and observed the kinetics of its enolization, **2** → **1**, in acidic and neutral aqueous solutions. The rate constant of ketonization, k^K(**1** → **2**), was estimated from the rate of deuteration of **1** in 1 N D_2SO_4 at 80°C. Combination with the rate constant of enolization, k^E(**2** → **1**), provided a preliminary estimate of the equilibrium constant of enolization of **2** in aqueous solution, $K_E \equiv [\mathbf{1}]/[\mathbf{2}] = k^E(\mathbf{2} \rightarrow \mathbf{1})/k^K(\mathbf{1} \rightarrow \mathbf{2}) \approx 10^{(13 \pm 1)}$. We now report the

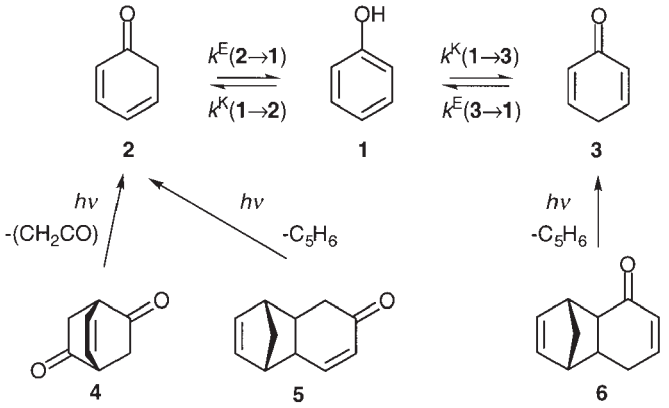
Scheme 1.



complete pH–rate profile of the enolization reaction **2** → **1** in aqueous solution and an accurate value for K_E. A brief study of the other keto tautomer of **1**, cyclohexa-2,5-dienone (**3**), is included. The photoreactions that were used to generate dienones **2** and **3** are shown in Scheme 1.

Results

Continuous irradiation of compounds 4–6

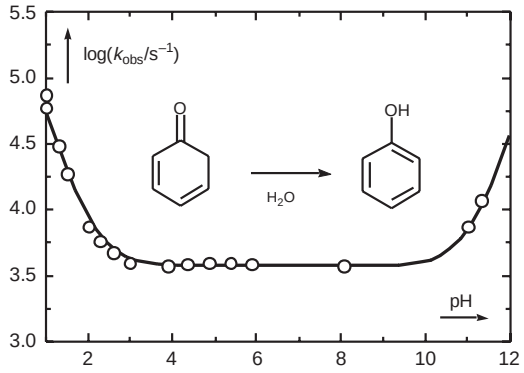
Direct irradiation of bicyclo[2.2.2]oct-2-ene-5,7-dione (**4**) eliminates ketene to yield **2** as a primary product that tautomerizes to phenol (3). Oxadi-π-methane rearrangement is the predominant reaction initiated by triplet sensitization of **4** (4). Irradiation of tricyclo[6.2.1.0^{2,7}]undeca-5,9-dien-4-one (**5**) or tricyclo[6.2.1.0^{2,7}]undeca-4,9-dien-3-one (**6**) also gave phenol as a major photoproduct that was identified by GC–MS analysis. The flash photolysis experiments described below provided direct evidence that phenol is formed via the primary photoproducts **2** and **3** after light-induced cycloelimination of cyclopentadiene from **5** and **6**, respectively, as indicated in Scheme 1.

Flash photolysis; rates of enolization of the keto tautomers 2 and 3

Aqueous solutions of compounds **4**–**6** were flashed with 25 ns pulses from an excimer laser operated on XeCl (200 mJ per pulse, 308 nm), or 20 μs pulses from a conventional electric discharge flashlamp of up to 1000 J electrical energy. The cycloadducts **4** and **5**, presumed to be photochemical precursors of **2**, both gave rise to weak transient absorption in the range of 280–330 nm. The decays of these transients obeyed first-order kinetics with rate constants depending on pH and buffer concentrations. Degassing had no influence on the yield or lifetime of the transient intermediates. Ketones **4** and **5** are sensitive to base, but decomposition was sufficiently slow to permit measurements in freshly prepared, weakly basic solutions. The decay rates of the 300 nm transients produced from **4** and **5** were equal, within the limits of error, in neutral water (k_{obs} = 3800 ± 300 s^{-1}) and faster, but again equal, in 2.0 mM aqueous KOH (7600 ± 800 s^{-1}).

Because **4** gave somewhat stronger transient signals and was available in larger quantity, this precursor was used to collect a more extensive set of data at various pH (25°C, ionic strength I = 0.1 M, Table 1). The resulting pH–rate profile of the enolization reaction **2** → **1** is shown in Fig. 1. As is well known from many studies of ketone enolization (2), the rate of enolization is accelerated by acid and by base, but, unlike the behavior of simple ketones, the pH-independent contribution dominates the overall reaction over a large range, 3 ≤ pH ≤ 10. The solid line corresponds to function [1], which was fitted to the observed rates of enolization by nonlinear least-squares adjustment of the parameters $k^E_{H^+}$ and $k^E_{OH^-}$, the rate coefficients for acid and base catalysis, and k^E_0 for the reaction catalyzed by the solvent (Table 2). The dissociation constant of water at ionic strength I = 0.1 M was taken as $K_w = 1.59 \times 10^{-14}$ M^2 (5). Weighting of the data was not required, because the relative errors of the observed rate constants, and hence, standard errors of log (k_{obs}) values, were approximately constant.

Fig. 1. pH–rate profile for the enolization of 2,4-cyclohexadienone (**2**) in aqueous solution at 25.0°C and I = 0.10 M.



$$[1] \qquad \log (k^E_{obs}/s^{-1}) = \log \{(k^E_0 + k^E_{H^+}[H^+] + k^E_{OH^-}K_w/[H^+])/s^{-1}\}$$

Acetate and tris(hydroxymethyl)methyl amine (Tris) buffers were used to determine some rate constants at pH values around 5 and 8. The decay rates increased linearly with buffer concentration, and the intercepts obtained by least-squares fitting of these individual plots are given in Table 1. From the slopes of the buffer dilution plots only general base catalysis is detectable, $k_{Ac} = (9.5 \pm 0.4) \times 10^3$ M^{-1} s^{-1}, $k_{Tris} = (1.8 \pm 0.2) \times 10^5$ M^{-1} s^{-1}. Solvent isotope effects (Table 2) were found to be in the normal direction ($k_H > k_D$) for the decay rate constants k^E_0 of cyclohexa-2,4-dienone and of its 6,6-dideuterated derivative **2**-d_2, but strongly inverse on the coefficient $k^E_{H^+}$ of the acid-catalyzed reaction.

Flash photolysis of **6** gave very weak transient absorption around 250 nm, which is the wavelength expected for the absorption of 2,5-cyclohexadienone (**3**) (6). Eight traces were averaged for each measurement to improve the signal-to-noise ratio. Due to the instability of **6** to base, experiments were limited to acidic and neutral solution. The decay rates of **3** were more than an order of magnitude slower than those of **2** (Table 1). The rate coefficients k^E_0 and $k^E_{H^+}$ for **3** were determined by nonlinear least-squares fitting of eq. [1] (omitting the last term for base catalysis), and are also given in Table 2.

Isotope exchange kinetics; rates of ketonization

At room temperature the exchange of the aromatic hydrogen atoms of **1** is slow. Solutions of phenol-2*d* and phenol-2*t* in 0.1 N $HClO_4$ were kept at 80.0 ± 0.5°C, and the loss of their deuterium or tritium label to the solvent was monitored by 400 MHz ^{2}H NMR and by scintillation counting, respectively (Table 3). Details of the procedures are given in the experimental section. The analysis of these data to determine the isotope effect and to extrapolate to the rate constant $k^K_{H^+}$ for the acid-catalyzed ketonization reaction **1** → **2** is now described.

Acid-catalyzed exchange of aromatic hydrogen proceeds by a two-step reaction mechanism with a C-protonated intermediate (7), Scheme 2. Solutions of the substrate **2**-L in H_2O are assumed to be dilute, such that that the second step, **2**-L$^+$ → **1** + L$^+$, is practically irreversible. Following the notation

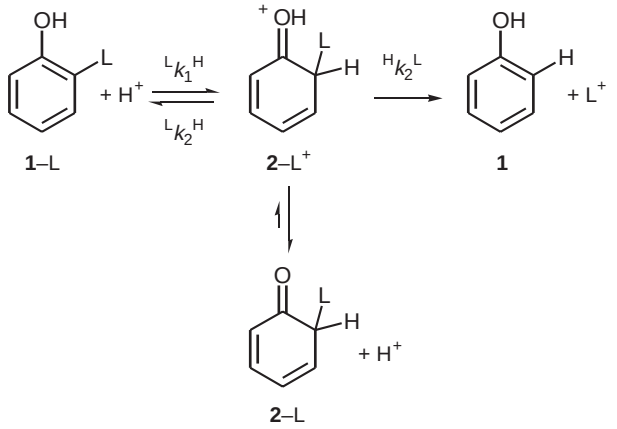
Scheme 2.



used by Kresge and Chiang (7), the rate coefficients shown in Scheme 2 carry two superscripts to facilitate the bookkeeping of isotope effects. The *right-hand superscript* designates the isotope involved in the hydron transfer reaction between C2 and the solvent (*primary isotope effect*). The *left-hand superscript* designates the spectator isotope remaining on C2 during this reaction (*secondary isotope effect*).

Dissociation equilibria of oxygen acids are, in general, established more rapidly than those of carbon acids (8). Accordingly, we assume that OH dissociation of **2**-L$^+$ (the vertical reaction shown in Scheme 2) is faster than hydron dissociation from carbon to form **1** or **1**-L (horizontal reactions). This assumption conforms to the accepted mechanism for hydronium-ion-catalyzed enolization of simple carbonyl compounds, which consists of rapid and reversible hydronation of the substrate on oxygen followed by rate-determining removal of a carbon-bound hydron by a molecule of water (9). Application to the present case might be questioned on the grounds that CH dissociation of **2**-L$^+$ is thermodynamically favored over OH dissociation by 2.3*RT* × pK_E which, as we shall see below, amounts to 72.6 ± 0.7 kJ mol^{-1}. However, we have recently shown that even larger thermodynamic bias is insufficient to overcome the kinetic preference for OH dissociation (10). Moreover, the inverse solvent isotope effect observed on the acid-catalyzed enolization of **2** (k_H/k_D = 0.5, Table 2, row 3) is strong evidence for pre-equilibrium protonation on oxygen.

If OH dissociation of **2**-L$^+$ is faster than CH dissociation, then carbon protonation is the rate-determining step in acid-catalyzed ketonization of **1** → **2**, and the rate constant of this process is given by eq. [2]. The statistical factor of 2 arises because the ketonization rate constant $k^K_{H^+}$ refers to protonation at either of the *ortho* positions C2 or C6, whereas $^{H}k_1^{H}$ refers to protonation at C2 only.

$$[2] \qquad k^K_{H^+} = 2\,{}^{H}k_1^{H}$$

Carbon protonation does, however, not fully determine the rate of isotopic exchange, because only a fraction of the protonated intermediate **2**-L$^+$ eventually loses the label by dissociating to **1** + L$^+$. The rates of the forward reaction (loss of label) and backward reaction (retention of label) are of the same order of magnitude, $^{H}k_2^{L} \approx {}^{L}k_2^{H}$. Since protonation of **1**–L is much slower than the subsequent steps, $^{L}k_1^{H}[H^+] << {}^{H}k_2^{L} + {}^{L}k_2^{H}$, the steady-state (Bodenstein) approximation is applicable to **2**-L$^+$, and the observed rate constant for acid-catalyzed loss of label L may be expressed as the product of the rate constant of C-protonation of **1**-L, the proton concentration, and the partitioning ratio of intermediate **2**-L$^+$, eq. [3].

$$[3] \qquad k^{-L}_{obs} = {}^{L}k_1^{H}[H^+]\frac{{}^{H}k_2^{L}}{{}^{H}k_2^{L} + {}^{L}k_2^{H}}$$

The ratio of the experimental rate constants of detritiation and dedeuteration in aqueous acid of a given concentration is then given by eq. [4].

$$[4] \qquad \frac{k^{-T}_{obs}}{k^{-D}_{obs}} = \frac{{}^{T}k_1^{H}}{{}^{D}k_1^{H}}\frac{{}^{H}k_2^{T}}{{}^{H}k_2^{T} + {}^{T}k_2^{H}}\frac{{}^{H}k_2^{D} + {}^{D}k_2^{H}}{{}^{H}k_2^{D}}$$
$$= \frac{{}^{T}k_1^{H}}{{}^{D}k_1^{H}}\frac{1 + {}^{D}k_2^{H}/{}^{H}k_2^{D}}{1 + {}^{T}k_2^{H}/{}^{H}k_2^{T}}$$

Our goal is to calculate the rate constant for acid-catalyzed ketonization of **1**, $k^K_{H^+}$, from the observed rates of dedeuteration and detritiation, k^{-D}_{obs} and k^{-T}_{obs}. Extrapolation from observed isotope exchange rates k_T and k_D to k_H is commonly done on the basis of the Swain relation (eq. [5]) (11). However, eq. [4] contains contributions from both primary and secondary kinetic isotope effects. In a detailed study of acid-catalyzed hydron exchange in 1,3,5-trimethoxybenzene, Kresge and Chiang (7) have established that the Swain relation gives reliable results when it is applied individually to primary and secondary isotope effects.

$$[5] \qquad (k_H/k_D)^{1.442} = k_H/k_T$$

The first factor on the right-hand side of eq. [4], $^{T}k_1^{H}/{}^{D}k_1^{H}$, is a purely secondary isotope effect: hybridization of carbon atom 2 changes from sp^2 to sp^3 upon protonation (step 1 in Scheme 2), which influences bonding to the isoto-

5.59 ± 0.02	79.0 ± 0.3

pic label L. Such secondary isotope effects are known to be inverse, and to have a relatively constant value of about 12% per deuterium atom, i.e., ${}^{H}k_1^{H}/{}^{D}k_1^{H}$ = 0.88 ± 0.04 (7, 12). The factor ${}^{T}k_1^{H}/{}^{D}k_1^{H}$ can then be estimated using the Swain relation

$$[6]\qquad \frac{{}^{T}k_1^{H}}{{}^{D}k_1^{H}} = \frac{{}^{T}k_1^{H}}{{}^{H}k_1^{H}}\frac{{}^{H}k_1^{H}}{{}^{D}k_1^{H}} = \left(\frac{{}^{D}k_1^{H}}{{}^{H}k_1^{H}}\right)^{(1.442-1)}$$

$$= (0.88 \pm 0.04)^{-0.442} = 1.06 \pm 0.02$$

The fractions appearing in the second term of eq. [4] are a product of primary and secondary isotope effects. In the numerator we have ${}^{D}k_2^{H}/{}^{H}k_2^{D} \equiv x$. By application of the Swain relation we obtain ${}^{T}k_2^{H}/{}^{H}k_2^{T} = x^{1.442}$, and eq. [4] is replaced by eq. [7].

$$[7]\qquad \frac{k^{-T}_{obs}}{k^{-D}_{obs}} = (1.06 \pm 0.02)\frac{1+x}{1+x^{1.442}}$$

The experimental rate constants for detritiation and dedeuteration of **1**-2*l* at 80°C in 0.1 N $HClO_4$ are given in Table 3. Equation [7] can be solved for x by iterative approximation to give x = 4.1 ± 0.5. Insertion of x into eq. [3] (L = D) gives ${}^{D}k_1^{H} = k^{-D}_{obs}(1 + x)/[H^+]$ and using ${}^{H}k_1^{H} = {}^{D}k_1^{H}(0.88 \pm 0.04)$, we can replace eq. [2] by eq. [8], in which the desired rate constant of ketonization is expressed fully in terms of experimentally determined quantities

$$[8]\qquad k^{K}_{H^+} = 2k^{-D}_{obs}(x+1)(0.88 \pm 0.04)/[H^+]$$

We obtain $k^{K}_{H^+}$(353 K) = (8.1 ± 1.3)10^{-5} M^{-1} s^{-1} for the rate constant of acid-catalyzed ketonization, **1** → **2**. The error limits were determined by propagation of the standard errors of the experimental data and of the assumed range for the secondary isotope effect, taking account of the high covariance between x and k^{-D}_{obs} through eq. [7].

Temperature dependence of the kinetic data

Flash photolysis of **4** in 0.1 N aqueous $HClO_4$ was done at various temperatures from 25 to 80°C (Table 4). The rate constants accurately obeyed the Arrhenius equation, $k = A\exp(-E_a/RT)$, and linear regression of log (k^E_{obs}/s^{-1}) vs. 1/T gave the Arrhenius parameters log (A/s^{-1}) = 9.58 ± 0.11 and E_a = 27.0 ± 0.7 kJ mol^{-1}. The rate coefficient for the acid-catalyzed enolization of **2** at 80°C is calculated as $k^{E}_{H^+} = k^{E}_{obs}/[H^+]$ = (3.94 ± 0.06)10^6 M^{-1} s^{-1} from this regression. Combination with the rate constant of ketonization provides the equilibrium constant of enolization of **2** at this temperature, K_E(353 K) = $k^{E}_{H^+}/k^{K}_{H^+}$ = (3.94 ± 0.06)10^6/(8.1 ± 1.3)10^{-5} = (4.9 ± 0.8)10^{10}, pK_E(353 K) = –10.69 ± 0.07.

The temperature dependence of the isotopic exchange rates was determined by monitoring the deuteration of phenol in 1 N DCl/D_2O at 60.0, 70.0, and 80.0 ± 0.5°C by 300 MHz ^{1}H NMR. This was easier than repeating the dedeuteration of phenol-2*d* at several temperatures, and at the same time, provided exchange rates at C4 of phenol. Secondary isotope effects from isotopic substitution at positions remote from the site of protonation (C4 and C6 for deuteration at C2) have been demonstrated to be negligible (7). The resulting exchange rate constants k^{D_2} and k^{D_4} are given in Table 3. These values are two to three times higher than those obtained in preliminary work by deuteration of phenol in 1 N D_2SO_4 at the same temperature (3). The discrepancy may in part be attributed to incomplete dissociation of D_2SO_4 in 1 N solution. Linear least-squares regression of log (k/s^{-1}) vs. 1/T gave the Arrhenius parameters log (A/s^{-1}) = 11.61 ± 0.13 and E_a = 109 ± 1 kJ mol^{-1} for *ortho*-deuteration, and log (A/s^{-1}) = 10.47 ± 0.32 and E_a = 100 ± 2 kJ mol^{-1} for *para*-deuteration. The rate constants calculated for 25°C from these regressions are k^{D_2} = (3.47 ± 0.16)10^{-8} M^{-1} s^{-1} and k^{D_4} = (1.02 ± 0.12)10^{-7} M^{-1} s^{-1}.

The ratio between the rate constant of ketonization **1** → **2**, eq. [8], and the observed rate constant of *ortho*-deuteration amounts to $k^{K}_{H^+}/k^{D_2}$ = (8.1 ± 1.3)10^{-5}/(3.22 ± 0.03)10^{-5} = 2.5 ± 0.4 at 80°C. This factor is a compound of primary and secondary isotope effects of the substrate as well as ionic strength and isotope effects of the solvent. The temperature dependence of this factor is estimated from the formula $k^{K}_{H^+}/k^{D_2} = \exp(-\Delta E_0/RT)$, assuming that it may be attributed to a single dominant zero-point vibrational energy difference ΔE_0. That is an overly crude assumption, but the correction of +0.4 for extrapolation to room temperature is small; the ratio resulting for 25°C is $k^{K}_{H^+}/k^{D_2}$ = 2.9 ± 0.8 (the error margin was increased by 0.4, the amount of the above correction), and the rate constant for acid-catalyzed ketonization **1** → **2** at 25°C is then calculated as $k^{K}_{H^+}$ = (2.9 ± 0.8)(3.47 ± 0.16)10^{-8} = (1.01 ± 0.28)10^{-7} M^{-1} s^{-1}. The same factor was used to calculate the acid-catalyzed rate constant of ketonization **1** → **3**, $k^{K}_{H^+}$ = (2.9 ± 0.8)k^{D_4} = (2.96 ± 0.27)10^{-7} M^{-1} s^{-1}.

Discussion

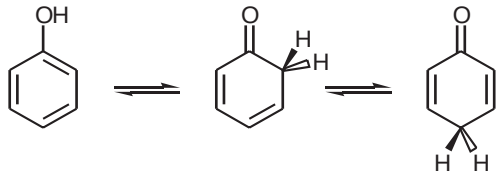
Evidence for keto tautomers of phenol

In a review article on the theory of unsaturated and aromatic compounds, published in 1899, Thiele (13) speculated that the propensity of phenol (**1**) and its anion to undergo substitution and oxidation reactions might be attributed to rapid equilibration of **1** with the transient keto forms **2** and **3**. At that time, the concepts of protomerism, as in Scheme 3, and mesomerism, Scheme 4, were not clearly distinguished. From the present viewpoint, it is clear that the ketonization of phenol, Scheme 3, is much too slow to explain the reactivity of phenol towards, e.g., bromine, but mesomeric charge delocalization, as shown in Scheme 4, is still used to explain the enhanced reactivity of phenolate at the *ortho* and *para* positions.

Only 2 years later, Lapworth (14) put forth the hypothesis that bromocyclohexadienones are the primary products formed in the aqueous bromination of phenol to rationalize the exclusive bromination of **1** at the *o*- and *p*-positions.

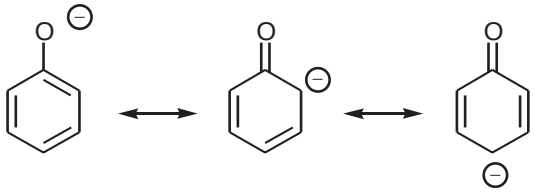
© 1999 NRC Canada

Scheme 3.



1 **2** **3**

Scheme 4.



These bromocyclohexadienone intermediates were detected 15 years ago by Tee et al. (15) using the stopped-flow technique. Cyclohexadienones were also proposed (16) and later characterized (17, 18) as intermediates in the Photo–Fries rearrangement of aryl esters. 4-Benzylcyclohexa-2,5-dienone was identified by CIDNP as a transient intermediate in the photorearrangement of benzyl phenyl ether; it had a half-life of about 4 s in cyclohexane (19).

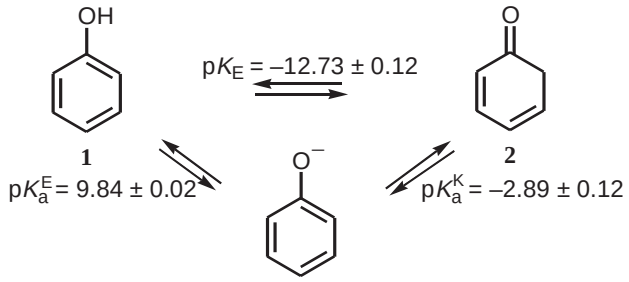
4*H*-Keto tautomers of heavily substituted phenols have been isolated in crystalline form (20). The tautomers of parent phenol, cyclohexa-2,4-dienone (**2**), and cyclohexa-2,5-dienone (**3**), were generated by flash vacuum pyrolysis of suitable Diels–Alder adducts, trapped at 77 K, and characterized by their IR and UV spectra (21). Pentaammineosmium complexes of **1**–**3** have been identified, and it was shown that all three tautomeric complexes are of comparable thermodynamic stability (22).

In the present work, cyclohexadienones **2** and **3** were formed by flash photolysis of suitable precursors (**4**–**6**, Scheme 1) in aqueous solution, which allowed their enolization rates to be measured directly. The transient formed by flash photolysis of **4** has previously been identified as cyclohexa-2,4-dienone (**2**) based on the observed decay kinetics, the position of its absorption (the first π,π^* absorption band of stable cyclohexa-2,4-dienones is around 300 nm, log $\epsilon \approx 3.7$ (6)), the identification of phenol as the final product, and the formation of 1,3,5-hexatrienone upon irradiation of **4** in a glassy matrix (3). The present finding that precursor **5** gives the same transient intermediate (absorption and pH-dependent decay rate) confirms that assignment. Formation of cyclohexa-2,5-dienone (**3**) from precursor **6** was assumed by analogy, and that is supported by the observed transient kinetics and the identification of phenol as the final product.

Thermochemistry of cyclohexadienone–phenol tautomerization

Several thermochemical estimates have been reported for the protomeric equilibria of phenol (**1**) with ketones **2** and **3** (Scheme 3): $\Delta_{(\mathbf{2}\text{ or }\mathbf{3})\rightarrow\mathbf{1}}G^{\ominus}$ (g, 298 K) = –18.6 kcal mol^{-1} was obtained from a bond additivity scheme (23), and $\Delta_{\mathbf{2}\rightarrow\mathbf{1}}G^{\ominus}$(aq, 298 K) = –13 ± 3 kcal mol^{-1} from estimates of the aqueous protonation equilibria for each tautomer to the common cation (24). $\Delta_{\mathbf{2}\rightarrow\mathbf{1}}H^{\ominus}$(g, 298 K) = –15.2 kcal mol^{-1} is obtained using Benson's group increments (25). Tee and Iyengar (15) predicted $\Delta_{\mathbf{3}\rightarrow\mathbf{1}}G^{\ominus}$(aq, 298 K) = –15 kcal mol^{-1} based on an earlier estimate of the p*K* for C-protonated phenol. Shiner et al. (26) generated the cyclohexadienones **2** and **3** by pyrolytic cycloreversion of their formal Diels–Alder adducts with cyclopentadiene, compounds **5** and **6**, and measured their gas phase acidities by the flowing afterglow technique. The derived heats of tautomerization, $\Delta_{\mathbf{2}\rightarrow\mathbf{1}}H^{\ominus}$ = – 6 ± 3 and $\Delta_{\mathbf{3}\rightarrow\mathbf{1}}H^{\ominus}$ = –10 ± 3 kcal mol^{-1} are, however, not compatible with present data.

Scheme 5.



From the present data, the enolization constant of **2** at 25°C is determined as the ratio of the enolization and ketonization rate constants given in Table 2, K_E(**2**, aq, 298 K) = $k^E_{H^+}/k^K_{H^+}$ = (5.4 ± 0.3)10^5/(1.01 ± 0.28)10^{-7} = (5.4 ± 1.5)10^{12}, pK_E = –12.73 ± 0.12. This value, and the acidity constant of phenol, pK_a^E(**1**, 298 K) = 9.84 ± 0.02 (expt. sect.), form two legs of a thermodynamic cycle, from which the C–H acidity constant of ketone **2** can be calculated, pK_a^K = pK_E + pK_a^E = –2.89 ± 0.12 (Scheme 5). It turns out that ketone **2** is one of the strongest carbon acids known (27).

The enthalpy of enolization can be calculated by the second-law method from the temperature dependence of the enolization constant, d ln K_E/dT = $\Delta_E H^{\ominus}/RT^2$, $\Delta_E H^{\ominus}$ = 2.303R[pK_E(T_2 = 353 K) – pK_E(T_1 = 298 K)]/(1/T_2 – 1/T_1) = –74.8 ± 5.1 kJ mol^{-1}. The standard free energies of enolization are $\Delta_E G^{\ominus}$(aq) = 2.303RT × pK_E(353 K) = –72.3 ± 0.5 kJ mol^{-1} at 353 K and –72.7 ± 0.7 kJ mol^{-1} at 298 K. The entropy of enolization, $\Delta_E S^{\ominus}$(aq, 298 K) = –7 ± 16 J K^{-1} mol^{-1}, is very small, too small to be reliably determined from these values. In our preliminary communication (3), we had estimated the temperature dependence of the enolization constant by neglecting the temperature dependence of the free energy of enolization $\Delta_E G^{\ominus}$, i.e., by assuming $\Delta_E S^{\ominus} \approx 0$.

The enolization constant of 2,5-cyclohexadienone **3** is similarly obtained as the ratio of the corresponding acid-catalyzed rate constants of enolization and ketonization (Table 2), K_E(298 K) = $k^E_{H^+}/k^K_{H^+}$ = (9.5 ± 3.2)10^{10}, pK_E = –10.98 ± 0.15 (Scheme 6).

The thermochemical data obtained in this work are summarized in Table 5. Note that the acidity constants pK_a^E and pK_a^K reported here are concentration quotients determined at ionic strength I = 0.1 M. The experimental enolization constants are in reasonable, though not perfect, agreement with the results of density functional calculations given in Table 6. The (gas phase) enolization constants predicted by these calculations are pK_E(**2**) = –10.4 and pK_E(**3**) = –9.8.

Exchange kinetics and kinetic isotope effects

Isotope exchange rates of phenol in aqueous sodium hydroxyde were already determined in 1936 by Ingold et al. (28). These authors used 2.2 M solutions of phenol and found that the exchange rate reached a maximum when the concentration of NaOH was about half that of phenol. Hydron transfer from phenol as a general oxygen acid to phenolate as a carbon base was identified as the dominant mechanism for exchange under these conditions. In the present work, hydron exchange experiments were done with dilute solutions and under acid catalysis. Note that, from the data given in Tables 2 and 5, base is predicted to *reduce* the rate of hydron exchange in dilute aqueous solutions. The rate of hydrogen exchange at carbon 2 of phenol in strong base, pH >> pK_a^E(**1**), is given by $k_0'^K = k_{OH}^E \cdot K_w / K_a^K = 4 \times 10^{-11}$ s^{-1} at 25°C. This is more than an order of magnitude less than the rate calculated for the same process in neutral solution, $k_0^K = k_0^E K_a^E / K_a^K = 7 \times 10^{-10}$ s^{-1}, because the reaction of protons with phenolate accelerates ketonization at pH < 12 until proton catalysis saturates at pH ≈ pK_a^E = 9.84.

The method used to assess the magnitude of the kinetic isotope effects and to determine the rate constants of ketonization from the observed rates of hydron exchange of phenol in aqueous acid closely follows previous work of Kresge and Chiang (7) and was described in the results section. Some of the observed kinetic isotope effects deserve mention. The four decay rates determined for **2** and **2**-d_2 in H_2O and D_2O (Table 2) give two closely similar values for the predominantly primary kinetic isotope effect, k(**2**-h_2)/k(**2**-d_2) = 6.6 ± 0.2, and for the compound (secondary and medium) solvent isotope effect, $k(H_2O)/k(D_2O)$ = 1.44 ± 0.03. Both of these values are consistent with the mechanism assigned to the pH-independent enolization of ketone **2**: rate-determining hydron transfer from carbon to solvent water. A crude a priori estimate for the solvent isotope effect, $k(H_2O)/k(D_2O) \approx 1.5$, is obtained by assuming $K_a^K(H_2O)/K_a^K(D_2O) \approx 1/l^3 = 3$ (l = 0.69 is the fractionation factor for the hydronium ion (29)) and application of the Brønsted equation $k(H_2O)/k(D_2O) = [K_a^K(H_2O)/K_a^K(D_2O)]^\alpha$ with $\alpha \approx 0.35$ (2*b*). Finally, the inverse isotope effect observed on the acid-catalyzed enolization of **2**-L (Table 2, row 3), shows that OH fission of **2**-L$^+$ (vertical reaction in Scheme 2) is faster than CH or CL fission, in spite of a strong thermodynamic bias for the latter.

The range covered by experimental data on keto–enol protomeric equilibria is nearly doubled by the present measurements of phenol ketonization: enolization constants now extend over a range of about 30 orders of magnitude, and the corresponding rate constants vary by about 20 orders of magnitude. The free-energy relationship between these quantities is clearly curved, and the curvature defines the intrinsic barrier of proton transfer to the β-carbon atom of enols $\Delta G_0^\ddagger$ = 57 kJ mol^{-1} (2*b*). Similar values have been determined previously from curvature in Brønsted plots (30, 31). The pH-independent, spontaneous dissociation of **2** as a carbon acid, $k_0^E = 3.8 \times 10^3$ s^{-1}, dominates the pH–rate profile of **2** (Fig. 1) from pH 3 to 10. On the other hand, the contribution of this mechanism to the pH–rate profiles for the enolization of simple ketones such as acetophenone is barely noticeable (31), because carbon protonation of enolates is so highly exergonic that these rates approach the diffusional limit.

Experimental

General

All concentrations are nominal values referring to 25°C. No corrections were applied for volume expansion at higher

© 1999 NRC Canada

temperatures. The required, small corrections would affect acid-catalyzed rate constants of enolization and ketonization by the same factor that would cancel in their ratio, the enolization constant.

Materials

Samples of tricyclo[6.2.1.$0^{2,7}$]undeca-5,9-dien-4-one (**5**) and tricyclo[6.2.1.$0^{2,7}$]undeca-4,9-dien-3-one (**6**) were obtained as a gift from Dr. C. Shiner, University of Colorado, Boulder (23), and samples of 5,7-dioxobicyclo[2.2.2]octane-2,3-dicarboxylic acid from Profs. M. Demuth, MPI Göttingen, and C.A. Grob, University of Basel.

Phenol-2*d* was synthesized from 2-bromophenol as described by Tashiro et al. (32). ^{1}H NMR indicated >90% deuteration at the 2-position. The same procedure was used to synthesize phenol-2*t*: NaOH (500 mg) was dissolved in 1 mL of tritium-enriched water and 520 mg of 2-bromophenolate (2.7 mmol) was added. CuAl catalyst (125 mg, Ventron, Karlsruhe) was added. The solution was stirred vigorously for 30 min. The catalyst was removed by filtration. The solution was acidified with 2 N HCl whereupon phenol precipitated. The aqueous solution was extracted with 10 mL of ether. The organic extract was dried with Na_2SO_4, and the solvent was evaporated at room temperature under a stream of N_2. The residue was sublimed in vacuo (<1 Pa) at room temperature. A sample containing 0.6 mg (6.4 μmol) of phenol-2*t* had an activity of 1750 Bq on a calibrated scintillation counter which corresponds to a tritium content of 0.25 ppm.

Bicyclo[2.2.2]oct-7-ene-2,5-dione (**4**) was prepared by oxidative bisdecarboxylation of 5,7-dioxobicyclo[2.2.2]octane-2,3-dicarboxylic acid, samples of which were obtained as gifts from Profs. Grob (33) and Demuth (5). The following, improved method was taken from the thesis of Weitemeyer (34). $Pb(OAc)_4$ (18 g) was added to a stirred solution of the diacid (4.48 g) in pyridine (60 mL) which was immersed in a water bath at 20°C. The yellow solution slowly turned orange to deep red under evolution of CO_2. After an hour, the solution was gently warmed to 40°C until the gas evolution ceased after 90 min. $CHCl_3$ (200 mL) was added and the mixture shaken with 40 mL of cold 20% HCl. The precipitate was removed and washed with $CHCl_3$. The combined organic phases were washed four times with 40 mL of 20% HCl until the color was removed, neutralized with $NaHCO_3$, and dried. Evaporation of the solvent left a brown–red solid residue which was chromatographed on silica with an 80:20 mixture of hexane and diethyl ether and sublimed at 90°C in vacuo to give 560 mg (20.6%) of **4** as colorless crystals.

A sample of **4** (50 mg) was deuterated in 2 mL of D_2O containing 0.1 g of NaOD. The solution turned yellow. After 10 min the diketone was extracted with ether. The organic phase was washed with D_2O, evaporated to dryness, and sublimed at 80°C in vacuo, giving off-white crystals of **4**-6,6,8,8-d_4 (40 mg). ^{1}H NMR (D_2O) δ: 2.8 (m, <0.01 H), 3.8 (m, 1 H, > CH-), 6.8 ppm (m, 1 H, -CH=); solvent peak (HDO) δ: 5.0 ppm. MS: 141 (8.8), 140 (100, M^+), 139 (9.1).

Isotopic exchange experiments

The samples of phenol-2*d* (7 NMR tubes containing 0.5 mL, 0.04 M) and phenol-2*t* (20 mL, 0.007 M) in 0.1 N $HClO_4$ were heated simultaneously in a thermostat bath that was kept at 80.0 ± 0.1°C. Deuterium loss from phenol-2*d* in samples removed periodically from the bath was determined by integration of the two peaks observed in the ^{2}H NMR spectra, at δ 1.13 (HDO) and at 1.28 ppm (phenol-2*d*). The first six samples covered two half-lives, the last was drawn after seven half-lives.

Deuteration rates of phenol in 1.0 N DCl in D_2O were determined by 300 MHz ^{1}H NMR. The NMR tubes (10 for each temperature) were heated in a water bath which was held at 80.0, 70.0, or 60.0 ± 0.1°C, removed at appropriate time intervals, and stored at in a refrigerator until all samples had been collected. The signal of the *meta* hydrogens (δ = 7.4 ppm; dd, $J_{2,3} = J_{3,4}$ = 7 Hz, 2H) was used as an internal standard. First-order exponential decays were fitted to the integrated signal intensities of the *ortho* (δ = 6.9 ppm; d, $J_{2,3}$ = 7 Hz, 2H) and *para* (δ = 7.1 ppm; t, $J_{3,4}$ = 7 Hz, 1H) hydrogens (Table 3).

The contents of phenol-2*t* were determined by liquid scintillation counting of 31 aliquots of 0.5 mL containing 7 mM of phenol which were drawn periodically over three half-lives of the exchange reaction. A final sample was measured after 10 half-lives. The aliquots were extracted with 4 mL of diethyl ether to separate the tritiated phenol from the tritium that had exchanged into water. To correct for variations (±10%) in the efficiency of the extraction, the absorbance of each extract was measured at 274 and 281 nm, and the radioactivity of the samples were normalized by these absorbances. In this way, the standard error of single measurements was reduced to about 3%. The activity of the samples was determined by scintillation counting on a Packard scintillation analyzer CA 2000 using 1,4-bis(5-phenyl-2-oxazolyl)benzene (POPOP) and Packard emulsifier 299 as scintillation reagents. Prior to the measurements, the instrument was calibrated with a standard of known activity.

Flash photolysis

All kinetic measurement were done with water-jacketed quartz cells which were kept at 25.0 ± 0.1°C unless stated otherwise. Temperature readings were taken from a thermoelement that was dipped into the sample solutions. Acid and base strength was adjusted with HCl in the range of 0.1 to 0.001 N or KOH in the range of 0.01 to 0.001 N. Values from buffered solutions quoted in this paper were obtained by extrapolation to zero buffer concentration and thus refer to wholly aqueous solutions. All solutions were adjusted to ionic strength I = 0.1 M by the addition of NaCl. Kinetic data determined by different persons using different experimental setups differed by up to 20%, much more than the standard error of sample means determined by a single person in a series of experiments (cf., e.g., the first two entries of Table 1).

Spectrophotometric titration of phenol

A 0.3 mM solution of phenol in water (3 mL) containing 0.010 M NH_4Cl and 0.09 M NaCl was titrated with 30 μL portions of 0.1 N NaOH in a quartz cell which was left untouched in the thermostatted (25 ± 0.1°C) sample holder of a Perkin–Elmer Lambda 9 UV spectrophotometer. The UV spectra were recorded and digitized (250–310 nm, 120 absorbance readings per spectrum, 16 spectra per titration) after each addition and the acid concentration was measured

© 1999 NRC Canada

with a calibrated (35) Metrohm 6.0236.100 micro glass electrode using a digital Metrohm pH meter 654. The spectra were analyzed using the program SPECFIT of Zuberbühler and co-workers (36). The original spectra were reproduced with a standard error of <0.002 absorbance units using the two dominant eigenvectors of the factor analysis. The loading coefficients fitted well to a titration curve (standard errors of single runs were <0.001 p*K* units). Three independent runs gave an average dissociation quotient of phenol, $pK_{a,c} = 9.84 \pm 0.02$ (ionic strength $I = 0.1$ M). Using activity coefficients for $I = 0.1$ M ($\gamma_{H^+} = 0.83$ and $\gamma_{\mathbf{1}^-} = 0.76$ (7)), the thermodynamic acidity constant of phenol is estimated as $pK_a^{\ominus} = 10.04 \pm 0.03$. This is about 0.05 units higher than the literature values commonly quoted (37).

Synthesis, characterization, and Cu(II) solution chemistry of dioxotetraazamacrocycles

Ramunas J. Motekaitis, Yizhen Sun, Arthur E. Martell, and Michael J. Welch

Abstract: The synthesis and characterization of four new dioxotetraazamacrocycles: 1,4,8,11-tetraazacyclotetradecane-3,9-dione; 1,4,7,10-tetraazacyclotridecane-2,9-dione; 1,4,7,10-tetraazacyclotridecane-3,8-dione; and 1,4,7,10-tetraazacyclododecane-2,9-dione are described. Two related, previously prepared macrocycles, are included in this study: 1,4,8,11-tetraazacyclotetradecane-5,7-dione and 1,4,7,10-tetraazacyclotridecane-11,13-dione. The protonation constants, stability constants with Cu^{2+} ions, as well as electronic spectra of the di-deprotonated copper(II) complexes are also reported. These results are discussed in terms of the suitability of this new class of ^{62}Cu, ^{64}Cu, ^{67}Cu complexes in PET imaging or radiotherapeutic applications. The synthetic schemes outlined provide a study of the relative Cu^{2+} behavior with a family of positional isomers of unsubstituted dioxotetraazamacrocycles.

Key words: multidentate ligand, tetraazamacrocyclic compound, dioxopolyaza macrocycles, cyclic amides, copper(II) complexes.

Résumé : On décrit la synthèse et la caractérisation de quatre nouveaux dioxotétraazamacrocycles: 1,4,8,11-tétraazacyclotétradécane-3,9-dione; 1,4,7,10-tétraazacyclotridécane-2,9-dione; 1,4,7,10-tétraazacyclotridécane-3,8-dione et 1,4,7,10-tétraazacyclododécane-2,9-dione. Dans cette étude, on a inclus deux macrocycles apparentés, préparés antérieurement: 1,4,8,11-tétraazacyclotétradécane-5,7-dione et 1,4,7,10-tétraazacyclotridécane-11,13-dione. On a déterminé les constantes de protonation, les constantes de stabilité avec les ions Cu^{2+} ainsi que les spectres électroniques des complexes diprotonés du cuivre(II). On discute de ces résultats en fonction de la possibilité d'utiliser cette nouvelle classe de complexes du ^{62}Cu, du ^{64}Cu et du ^{67}Cu dans l'imagerie PET ou dans des applications radiothérapeutiques. Les schémas de synthèse proposés permettent d'examiner le comportement relatif du Cu^{2+} avec celui d'une famille d'isomères de position de dioxotétraazamacrocyles non substitués.

Mots clés : ligand multidentate, composé tétraazamacrocyclique, dioxopolyazamacrocyles, amides cycliques, complexes du cuivre(II).

[Traduit par la Rédaction]

Introduction

Macrocyclic oxo polyamines are unique metal chelators, their structure bearing the dual features of macrocyclic polyamines and oligopeptides (1–5). They are capable of coordinating to certain transition metal ions, such as Cu^{2+}, Ni^{2+}, Co^{2+}, and Pd^{2+}, with simultaneous displacement of hydrogen ions from the amido groups. The imide anions may also stabilize the trivalent ions of Cu(III) and Ni(III) (6).

Our ultimate interest in macrocyclic oxo polyamines is the preparation and characterization of low molecular weight copper chelates possessing –2 to +2 net charge as potential radiopharmaceuticals and PET imagining candidates. Thus, depending on the ratio of amide groups to ligand, such a study is possible. Our initial focus, the subject of this research, is the study of six unsubstituted macrocyclic dioxotetraamines. To this end, two previously reported and four new macrocyclic ligands were synthesized with new and improved synthetic schemes. Previous studies were limited to compounds that may be obtained by direct methods. Herein are developed new schemes which will be helpful in the future synthesis of structural variants of these ligands.

Divalent transition metal ion complexes of macrocyclic dioxotetraamines have shown some interesting properties and important biological functions: copper(II) complexes have been used to model superoxide dismutase (7); cobalt(II) complexes to model methane monooxygenase (8*a*); and to carry oxygen reversibly (8*b*, *c*); nickel(II) complexes to oxidize olefins to cyclic alkoxyl compounds (9, 10) and to model methyl coenzyme-*M*-reductase (11). A novel application is the preparation of a chelating resin for copper based on the incorporation of a cyclic tetraazadione into a cross-linked polymer (12).

While more than thirty substituted macrocyclic dioxotetraamines have been synthesized, only a few methods have been used to prepare them. These methods are limited to the use of malonates (13) and other esters (14), diacid dichlorides under high-dilution conditions (15–17), and bis(α-chloroamides)

Received October 30, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

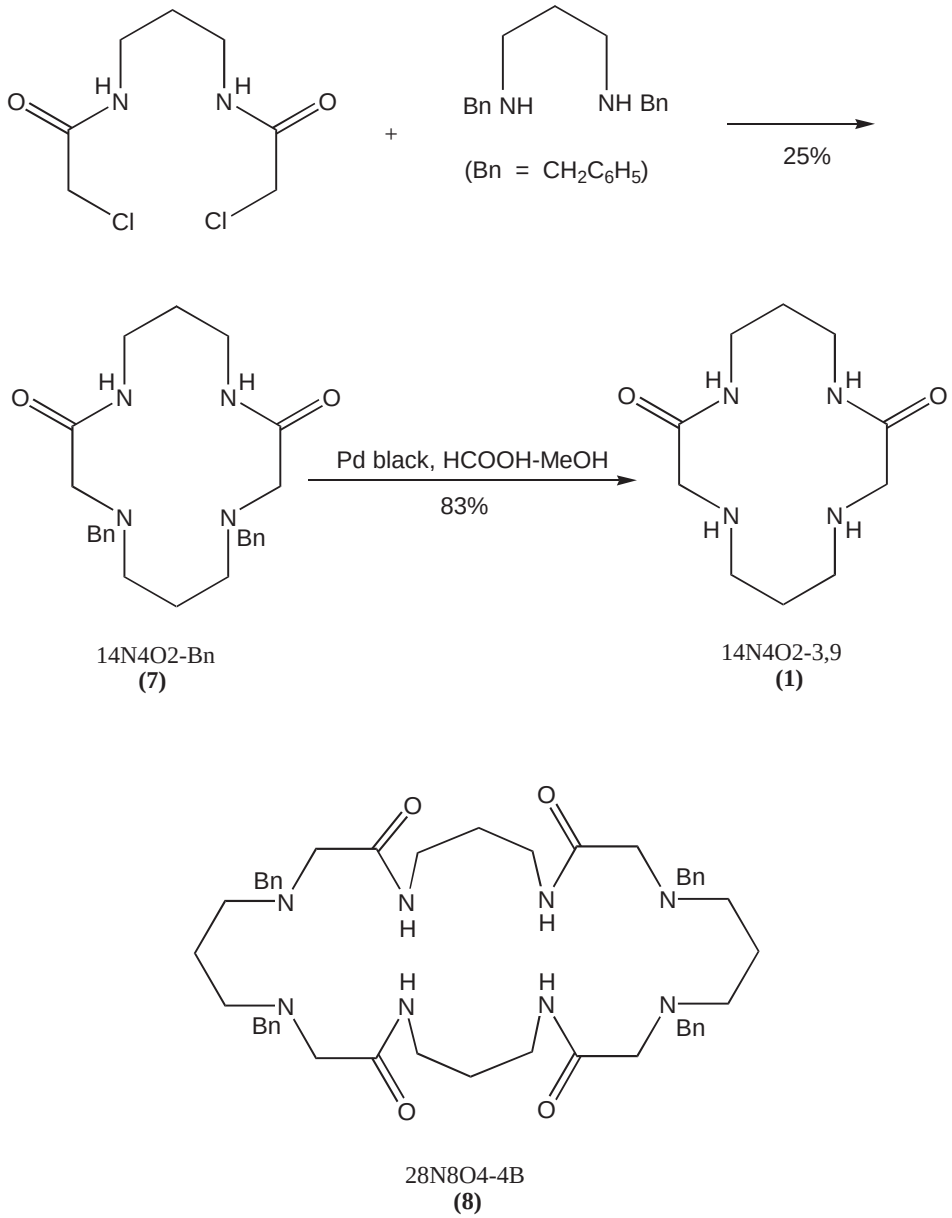
Scheme 1.



(18–20), which are reacted with various polyamines to form macrocyclic diamides from 1:1 cyclization reactions or macrocyclic tetraamides by 2:2 cyclization reactions.

Although the Richman–Atkins tosylamide procedure (21, 22) has been widely used for the preparation of polyaza macrocycles and crown ethers, it has not yet been exploited in the synthesis of macrocyclic dioxotetraamines. After trying the conventional methods (13–20), we found that the Richman–Atkins method is indeed superior to the others, and the fear that the amide bond would not survive the rather drastic detosylation conditions did not materialize. We now report the synthesis of four new dioxotetraamine macrocycles with this tosylation–detosylation procedure.

While many macrocyclic dioxotetraamines have been reported, only three unsubstituted dioxotetraazamacrocycles have been investigated potentiometrically for Cu^{2+} affinity. In this paper we report the protonation constants and stability constants with Cu^{2+} for all of the new ligands and compare these results with other polyaza oxo macrocycles studied with Cu^{2+}.

Results and discussion

Synthesis

Tabushi et al. (14) reported a convenient and general method for the synthesis of dioxopolyamine macrocycles through the cyclization of diamines and diesters of α,ω-dicarboxylic acids. Since then, most of the dioxotetraazamacrocycles were prepared by this method. This procedure requires neither high dilution nor nitrogen protection. However, the drawbacks of this method are that tedious chromatographic purification is needed, and the yield is usually very low. For the preparation of the four dioxotetraazamacrocycles mentioned in this paper, the Tabushi method is limited due to the different dioxo positions in these macrocyclic rings.

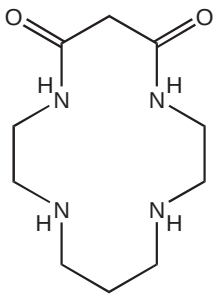
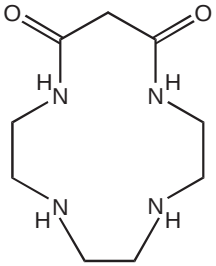
1,4,7,10-tetraazacyclododecane-2,9-dione

12N4O2-2,9 **(4)**



1,4,8,11-tetraazacyclotetradecane-5,7-dione

14N4O2-5,7 **(5)**



1,4,7,10-tetraazacyclotridecane-11,13-dione

13N4O2-11,13 **(6)**

Several *N*-substituted 1,4,8,11-tetraazacyclotetradecane-3,9-dione, 14N4O2-3,9 (1), were described by Bradshaw et al. (20). A bis(α-chloroamide) was used as starting material to react with a *N*,*N*′-dialkylated diamine to form the macrocyclic diamide. High-dilution conditions were not necessary, and the yields of the cyclization were about 40–50%. Adapted from this work, Scheme 1 was designed for the preparation of compound 1,4,8,11-tetraazacyclotetradecane-3,9-dione, 14N4O2–3,9 (**1**). The cyclization reaction was performed in refluxing acetonitrile, and the initial concentration of the reactants is 0.04 M. After chromatographic purification, an impure 14N4O2–3,9-Bn (**7**) and a nearly pure 28N8O4-Bn (**8**),which is the 2:2 condensation product, were obtained. The R_f values of compound **7** is 0.57 and of compound **8** is 0.48 (developed by CH_2Cl_2:MeOH = 9:1). After a second chromatographic purification, the yield of isolated 14N4O2–3,9-Bn (**7**) is 21%; and 7% of the 28-membered ring (28N8O4-Bn) (**8**) was also obtained. When the reaction was performed at the initial concentration of 0.007 M, the 2:2 cyclization reaction was nearly eliminated, and the yield of the 1:1 condensation product is about 25%. Another drawback of this synthetic route is the last step: debenzylation reaction. The activity of the catalyst, freshly prepared Pd black, is difficult to control, so that a good steady yield is difficult to obtain.

In Scheme 2, the Richman–Atkins tosylamide procedure was adopted. The initial concentrations of the reactants in the cyclization reaction are about 0.1 M, no 2:2 condensation product was found; thus chromatographic purification is unnecessary. Yield of the recrystallized products (tosylated) are about 40–50%. In the detosylation steps, the yields of 1,4,7,10-tetraazacyclotridecane-2,9-dione, 13N4O2–2,9 (**2**),

and 1,4,7,10-tetraazacyclotridecane-3,8-dione, 13N4O2–3,8 (**3**), are 47 and 87%, respectively; for the 12-membered ring 1,4,7,10-tetraazacyclododecane-2,9-dione, 12N4O2–2,9 (**4**), the isolated yield is 23%, probably due to the higher solubility of this compound in the reaction mixture.

Reactions of ligands in aqueous solution

Protonation constants

Each of the six macrocycles studied possesses two amino groups and two endocyclic amide groups. The amide group becomes a powerful coordinating group only upon loss of the nitrogen-bound proton. This has been discovered originally with various di-, tri-, and tetrapeptides (23) as well as with compounds such as diglycylethylenediamine (24) and its derivatives. The most notable metal ions found to participate in this kind of bonding in aqueous solution are Cu^{2+} and Ni^{2+}, but others are also possible. However, this deprotonation is always metal-ion assisted, and OH^- itself is too weak a base to remove this amidic proton.

The log protonation constants found for each ligand are listed in Table 1. In each case, the first protonation constant may be used to infer the relative basicity of its amino groups. Thus, depending on the ring size and isomer considered, the range of this basicity is from 6.98 to 9.53 log units. The ligands **5** and **6** possess the most basic amino groups, while the [12]aneN_4 ligand **4** is the weakest base. In compound **1**, the electropositive ends of the two keto groups are closer to the amino groups compared to its isomer **5**, and this proximity reduces the basicity from 9.52 to 7.88. A large reduction in basicity is observed in the comparison of isomeric ligands **6** and **2**: 9.05 to 7.21. As expected, the removal of a methylene between the amido nitrogens has very little effect on the basicities of the distal trimethylene diamine moieties in compounds **1** and **3**: 7.88 vs. 7.69. The basicity of the ethylenediamine moiety in ligand **4** is the lowest, since the two keto groups are closest and the ring size of the macrocycle is the smallest.

The relative magnitude of the second protonation constant is a measure of the difficulty of protonating near a protonated center. Thus, the tendency in the $\Delta \log K_{1-2}$ values is to be larger for the trimethylendiamine containing ligands and smaller for the ethylenediamine bridged compounds.

[f]Literature: 7.73 (NIST Database 46)[2].

The very small Δ log K_{1-2} value of ligand **3** of 1.79 points to the existence of electronic independence of the two protonation steps, while the very large Δ log K_{1-2} value of 5.36 in ligand **6** is probably the highest difference observed in any ethylenediamine derivative and can be interpreted to mean that a second protonation requires a breakup of a favorably chelated single proton shared between the two amino nitrogens.

Several acyclic model compounds listed in Table 2 may be employed upon for assessing the absolute values of the protonation constants found in the macrocycles. Four rules may be derived from this list in Table 2:

(*i*) The first log protonation constant of ethylenediamine is ~9.9.

(*ii*) The first log protonation constant of a trimethylenediamine is ~10.5.

(*iii*) The second log protonation constant is <~2.0 units lower than the first, unless electrostatic interaction is a factor.

(*iv*) The presence of an amide group lowers the amino log protonation constant by >1 unit if the carbonyl side is closer to the amino group.

These rules, derived from the sterically free alicyclic compounds, suggest that when ΔpK values greater than 2 units are encountered in Table 1, the macrocyclic effects are such that the basic nitrogen groups are "forced" to be close to each other so that an H^+, initially chelated to two amino nitrogens, is actually displaced with difficulty to form a coulombic repulsive pair of contiguous N^+ species. The compounds containing a basic ethylenediamine moiety are **2**, **4**, and **6**. Rule 1 applies to **6** and Rule 4 applies to **2** and **4**. On the other hand, the compounds containing a basic trimethylenediamine moiety are **1**, **3**, and **5**. Rule 2 applies to **5** and Rule 4 applies to **1** and **3**. According to Rule 3, the second protonation constants imply that the nitrogens are very independent in **1** and **3** but a little more restricted in **5**.

Equilibrium constants of Cu^{2+} complexes

The expression of formation constants for systems that lose protons while forming the predominant complex in solution can be problematic with these H_2L^{2+} type ligands. The normal species ML^{2+} does not necessarily form. The convention used here uses the H_{-1} and H_{-2} notation to indicate that one and two protons were released, respectively, into solution during the formation of the metal complex. The negative subscripts –1 and –2 represent proton displacement from an amide, while any additional protons "lost" indicated by –3 imply a loss of one proton from a coordinated water molecule and 2 protons from amide groups. In this work, one or more of the following overall reactions were found to occur for Cu^{2+} with ligands **1**– **6**. These concentration constants are listed in Table 3.

[1] $Cu^{2+} + L \rightleftarrows CuH_{-2}L + 2\ H^+$ log $\beta_{CuH_{-2}L}$

[2] $Cu^{2+} + L \rightleftarrows CuH_{-1}L^+ + H^+$ log $\beta_{CuH_{-1}L}$

[3] $Cu^{2+} + L \rightleftarrows CuL^{2+}$ log β_{CuL}

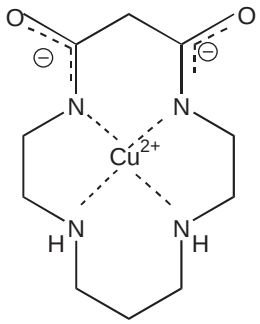
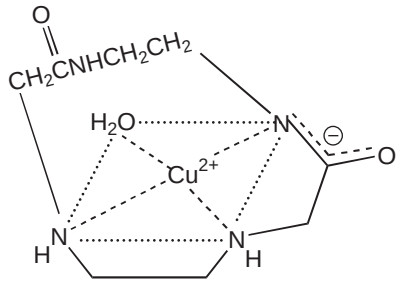
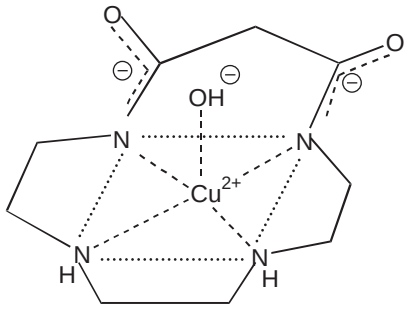
12 $CuH_{-2}L$ (L = 1)



13 $CuH_{-2}L$ (L = 5)

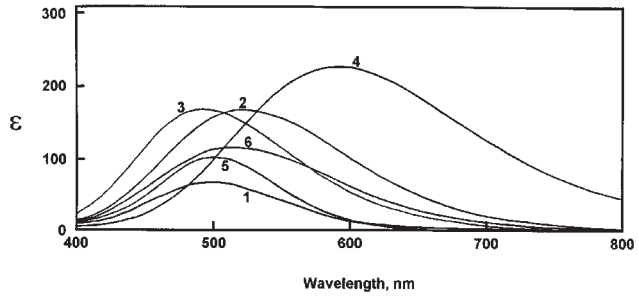


14



15

Fig. 1. Visible spectra of $CuH_{-2}L$ species where L = compounds **1** to **6**.



[4] $Cu^{2+} + L + H^+ \rightleftarrows CuHL^{3+}$ $\log \beta_{CuHL}$

[5] $Cu^{2+} + L \rightleftarrows CuH_{-3}L^- + 3\ H^+$ $\log \beta_{CuH_{-3}L}$

The most important species in all systems is $CuH_{-2}L$ in which Cu^{2+} is reasonably assumed to be tetracoordinated to four N donors as shown in **12** and **13**. The $CuH_{-2}L$ complexes of ligands **2**, **3**, **4**, and **6** would be similarly formulated. The normal chelate CuL^{2+} was found in five of the species, but in most cases it is not very important. The intermediate species $CuH_{-1}L^+$ was found only in two ligands, but is very important in the complexes found from compound **4**. It forms only to the extent of ~10% with ligand **6**. Drawing **14** illustrates the probable bonding arrangement in $CuH_{-1}L^+$. The proximity of the remaining amido N makes it statistically favorable to complete this reaction to give $CuH_{-2}L$. There probably is a very marked cavity size to metal ion diameter mismatch to make compound **4** the weakest ligand tested. The pentacoordinate axial hydroxo $CuH_{-3}L^{-1}$ species forms only at high p[H] and is of no interest at intermediate p[H] values. It is not surprising that for compound **4** this species is favored at lower p[H] than for the other compounds. The high p[H] pentacoordinate species for ligand **6** was previously not identified. Its suggested bonding is shown in drawing **15**. The other pentacoordinate complexes are probably similar.

Ligand **4** is somewhat special in its marked low affinity for Cu(II), since there was a tendency in 1:1 systems for $Cu(OH)_2$ precipitation just after initial formation of this complex. To prevent the onset of precipitation, advantage was taken of the larger than usual formation of the ML^{2+} type complex. Therefore, it was assumed that 1:2 Cu^{2+}/L complexes could form. The titration of a 1:2 ratio worked very well. The additional constants obtained are listed on the bottom of Table 3. This 1:2 M/L complex probably binds as indicated schematically by **16**.

One analog of **4** is found in the literature.[2] Perhaps not surprisingly 2,6-dioxo-1,4,7,10-tetraazacyclododecane, **17**, also exhibits unusual Cu^{2+} formation equilibria. It has similar protonation constants, 7.48 and 4.22, and forms stepwise amide complexes. Its formation constants[2] are lower than those of the Cu(II) complexes of **4**.

Visible spectra

During solution studies, distinct color development was noted as the titrations progressed. To compare these results, the visible spectra were obtained at p[H] values corresponding to the maximum concentration of species $CuH_{-2}L$ and

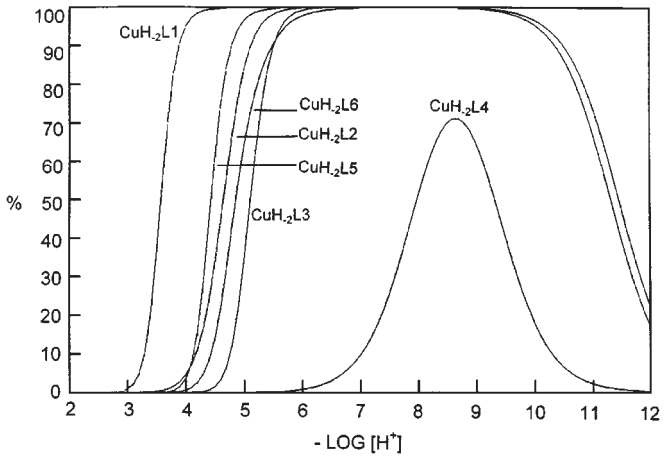
Fig. 2. Relative stability of the $CuH_{-2}Lx$ species where x = compounds **1** to **6**. All other species were omitted from the drawing to focus on the main species $CuH_{-2}L$.



were normalized for concentration. From plots of the extinction coefficients vs. wavelength in Fig. 1, it becomes obvious that the solution structure of the copper complex with ligand **4** is fundamentally different from that of the remaining complexes. In fact, it is proposed that if the $CuH_{-2}L$ geometries are generally planar, then when L is **4**, the metal must be out of the plane. Support for this speculation can be gleaned from the spectrum of $CuH_{-2}L$ when L is the open-chain structural analog DGEN (*N*,*N*′-diglycylethylenediamine): $NH_2CH_2CH_2C(O)NH\text{-}CH_2CH_2\text{-}NHC(O)CH_2CH_2NH_2$ (24). Because there are no geometric restrictions, this species (DGEN-Cu) is planar as implied from its spectrum: λ_{max} 520, ε 170 $M^{-1}cm^{-1}$.

Suitability of Cu^{2+} complexes for applications

The pM values shown in Table 3 indicate that the copper complex with ligand **1** is the strongest from the concentration perspective. However, a deeper understanding may be seen in Fig. 2, which shows the relative behavior of all six Cu–L systems studied herein. By far the best ligand is **1**, both because it has the highest pM value and because it forms at the lowest pH as seen from the comparison in Fig. 2. It is noteworthy that **1** is an isomer of ligand **5** with a characteristic malonodiamide moiety that apparently is too restrictive for the best fit of a Cu^{2+} ion. A similar isomer pair may be found by comparison of compounds **2** and **6** of the [13] macrocycles. Apparently, by moving away from malonodiamide in the [13] macrocycles the ligand **2** is also somewhat better than ligand **6**.

Shrinking the macrocycle **1** by the removal of a methylene group produces ligand **3** or ligand **2**. Although both of these ligands have lower affinity for Cu(II), **2** gives the more stable complex.

However, one neutral complex studied here is found to be particularly ill-suited for in vivo application. Ligand **4** is so sterically unsuitable that it is reluctant to form its $CuH_{-2}L$ complex until above p[H] 7. The best candidate found is ligand **1**.

While there are several other ways of arranging two dioxo groups in the cyclam framework to form diamides, it is not known at this time whether they would outperform ligand **1**.

Experimental

Materials and methods

N,*N*′-Dibenzyl-1,3-diaminopropane (19), *N*,*N*′-bischloroacetyl-1,3-diaminopropane (25), *N*,*N*′-bischloroacetyl-1,2-

© 1999 NRC Canada

diaminoethane (25), *N,N′*-ditoluenesulfonyl-1,2-diaminoethane, and *N,N′*-ditoluenesulfonyl-1,3-diaminopropane were prepared by previously reported procedures (26). Hydrogen bromide, 30 wt.% in acetic acid and the ligand 1,4,8,11-tetraazacyclotetradecane-5,7-dione (**5**) were purchased from the Aldrich Chemical Company.

The ligand 1,4,7,10-tetraazacyclotridecane-11,13-dione (**6**) was kindly supplied by Dr. Ichiro Murase of Dojindo Chemical Company and prepared by Dr. Hidefumi Kato of Kurume Technical College. Although its direct synthesis had been published by Kimura and Machida (8*a*), the modification herein consists of refluxing a 1 L absolute ethanol solution of 16 g (0.1 mol) diethyl malonate and 14.6 g (0.1 mol) triethylenetetraamine for 72 h. It is important to reduce the volume substantially but not to remove the solvent completely. A few seeds were then added, and the crystallization was allowed to continue for 48 h at 25°C. The crystals collected were recrystallized from absolute ethanol for an overall yield of 6.4 g (~30%); mp 185–186°C. IR (KBr) 1660 cm^{-1} (strong, amide absorption). Mass (EI+) = 214 (calcd. 214.3).

The proton and carbon-13 NMR were recorded on a Varian XL-200 spectrometer operating at 200 MHz, and the chemical shifts are reported in ppm relative to tetramethylsilane. The mass spectra were obtained with the departmental VG analytical 70S high-resolution double focusing magnetic sector spectrometer with an attached VG analytical 11/250J data system. Measurements were made by the departmental mass spectrometry specialist, Dr. Lloyd W. Sumner. The C, H, N analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn.

Synthetic routes and procedures

The route used for the synthesis of 14N4O2–3,9 (**1**) is shown in Scheme 1.

*1,11-Dibenzyl-1,4,8,11-tetraazacyclotetradecane-3,9-dione (**7**)*

N,N′-Dibenzyl-1,3-diaminopropane, 2.54 g (0.01 mol), *N,N′*-bischloroacetyl-1,3-diaminopropane, 2.27 g (0.01 mol), and powdered K_2CO_3, 25 g (0.18 mol) were added to 250 mL of acetonitrile, and this reaction mixture was heated to reflux for 20 h. It was filtered and washed with CH_3CN; from the filtrate 4.1 g of white residue was obtained. After chromatographic purification, 0.87 g of product was collected from an eluant of CH_2Cl_2:MeOH = 98:2. Another 0.57 g sample was also obtained (eluted by CH_2Cl_2:MeOH = 98:2). A pure sample of 0.71 g was obtained after a second flash chromatography from the 0.87 sample. ^{1}H NMR ($CDCl_3$): 7.29–7.14 (m, 12H, NH and arom.), 3.505 (s, 4H, -CH_2- of benzyl), 3.302–3.250 (m, 4H, -CH_2- of 5 and 7 position), 3.027 (s, 4H, -CH_2- of 2 and 10 position), 2.451 (t, 4H, -CH_2- of 12 and 14 position), 1.756 (quin. 2H, -CH_2- of 6 position), 1.641 (quin. 2H, -CH_2- of 13 position). ^{13}C NMR (in $CDCl_3$): 171.387 (-CO- of amido); 137.397 (C-1 of arom.); 128.984, 128.463, 127.508 (C-2,3,4 of arom.); 59.974 (-CH_2- of benzyl); 58.388 (-CH_2- of 5 and 7 positions); 52.845 (-CH_2- of 2 and 10 positions); 40.104 (-CH_2- of 12 and 14 positions); 28.432 (-CH_2- of 6 position); 27.277 (-CH_2- of 13 position). FABMS: [M + H^+] = 409. Anal. calcd. for $C_{24}H_{32}N_4O_2 \cdot 1/2H_2O$: C 69.06, H 7.91, N 13.43; found: C 69.28, H 7.87, N 13.31. R_f = 0.57 (developed by CH_2Cl_2:MeOH = 98:2); and the R_f value of the 28-membered ring (compound **6**) is about 0.48, developed by the same mixed solvents.

*1,4,8,11-Tetraazacyclotetradecane-3,9-dione (**1**)*

Compound **7**, 0.20 g (0.5 mmol), was dissolved in 12 mL of 4.4% HCOOH–CH_3OH solution containing about 0.2 g of freshly prepared palladium black catalyst (27). The mixture was stirred at room temperature under Ar atmosphere for 24 h. The crude product was recrystallized from 10:1 (v/v) of abs. EtOH:conc. HCl; 0.10 g of pure product was obtained, yield 83%. ^{1}H NMR (in D_2O *t*-BuOH as internal standard = 1.29 ppm): 3.711 (s, 4H, -CH_2- of 2 and 10 positions), 3.277 (t, 4H, -CH_2- of 5 and 7 positions), 3.063 (t, 4H, -CH_2- of 12 and 14 positions), 1.72 (m, 4H, -CH_2- of 6 and 13 positions). ^{13}C NMR (in D_2O; *p*-dioxane as internal standard: 67.400 ppm): 166.714 (-CO- of the amido), 47.577 (C-2 and C-10), 42.213 (C-5 and C-7), 40.480 (C-12 and C-14), 27.271 (C-6), 20.173 (C-13). FABMS: [M + H^+] = 229. Anal. calcd. for $C_{10}H_{20}N_4O_2 \cdot 2HCl$: C 39.88, H 7.31, N 18.60; found: C 39.70, H 7.42, N 18.41.

General procedure for the preparation of ditoluenesulfonyl dioxotetraazamacrocycles 9, 10, 11 (Scheme 2)

To a 500 mL three-necked flask, 120 mL of DMF, 4.5 g of K_2CO_3, 1.2 g of NaH (60% dispersion in mineral oil), and 0.015 mol of *N,N′*-ditoluenesulfonyl-1,2-diaminoethane or *N,N′*-ditoluenesulfonyl-1,3-diaminopropane were added in sequence. This reaction mixture was heated to 60°C to which a solution of 0.015 mol of *N,N′*-bischloroacetyl-1,3-diaminopropane or *N,N′*-bischloroacetyl-1,2-diaminoethane in 80 mL of DMF was added in about 15 min. The reaction mixture was then heated to 90–95°C for 18 h. The inorganic salts were removed by filtration, and the solvents were removed by vacuum distillation. The crude product was first boiled with 200 mL of 95% ethanol and then recrystallized in boiling glacial acetic acid; pure crystalline product was obtained.

*4,7-Ditoluenesulfonyl-1,4,7,10-tetraazacyclotridecane-2,9-dione (**9**)*

Compound **9** was obtained in 41% yield. ^{1}H NMR (in $CDCl_3$): 7.65 and 7.36 (d, 8H, arom.), 6.9 (b, 2H, -CONH-), 3.73 (s, 4H, -CH_2- 3 and 8 positions), 3.48 (t, 4H, -CH_2- 11 and 13 positions), 3.30 (s, 4H, ethylene), 2.46 (s, 6H, -CH_3), 1.8 (b, 2H, -CH_2- 12 position). ^{13}C NMR (in DMSO): 166.61 (-*C*ONH-); 134.63, 135.45, 129.94, 127.21, (arom.); 51.834 (-CH_2- of 3 and 8 positions); 45.941 (-CH_2- 11 and 13 positions); 33.382 (ethylene); 26.108 (-CH_2- 12 positions); 21.081 (-CH_3). FABMS: [M + Na^+] = 523. Anal. calcd. for $C_{23}H_{30}N_4O_6S_2 \cdot CH_3COOH$: C 51.55, H 5.84, N 9.62; found: C 51.55, H 6.01, N 9.65.

*1,10-Ditoluenesulfonyl-1,4,7,10-tetraazacyclotridecane-3,8-dione (**10**)*

Compound **8** was obtained in 36% yield. ^{1}H NMR (in DMSO-d_6): 7.69 and 7.38 (d, 8H, arom.), 3.52 (s, 4H, ethylene), 3.22 (t, 4H, -CH_2- 2 and 9 positions), 2.95 (t, 4H, -CH_2- 11 and 13 positions), 2.37 (s, 6H, -CH_3), 1.7 (b, 2H,

-CH_2- 12 position). FABMS: [M + Na^+] = 545 and [M + H^+] = 523. Anal. calcd. for $C_{23}H_{30}N_4O_6S_2$: C 52.87, H 5.75, N 10.73; found: C 52.80, H 5.93, N 10.49.

*4,7-Ditoluenesulfonyl-1,4,7,10-tetraazacyclododecane-2,9-dione (**11**)*

Compound **11** was obtained in 53% yield. ^{1}H NMR (in DMSO-d_6): 8.285 (b, 2H, -CONH-), 7.65 and 7.46 (d, 8H, arom.), 3.56 (s, 4H, -CH_2- 3 and 8 positions), 3.21 (s, 4H, -CH_2- 5 and 6 positions), 2.96 (s, 4H, -CH_2- 11 and 12 positions), 2.416 (s, 6H, -CH_3). FABMS: [M + Na^+] = 531. Anal. calcd. for $C_{22}H_{28}N_4O_6S_2 \cdot H_2O$: C 50.19, H 5.70, N 10.65; found: C 50.32, H 5.783, N 10.04.

General procedure for the preparation of dioxotetraazamacrocycles 2, 3, 4 (Scheme 2)

Compound **9**, **10**, or **11** (2 mmol) and 1.2 g of phenol were dissolved in 20 mL of 30% HBr–CH_3COOH (30%), and this reaction solution was heated in a 90–95°C bath for 20 h. The solution became brown, and a large amount of white precipitate separated. It was cooled to room temperature. and was filtered, the crude product was washed with ether; a white precipitate was obtained. This crude product was dissolved in 12 mL of water and was extracted with 12 mL portions of ether. The separated ether phase was decolorized with charcoal. The colorless aqueous solution was evaporated to nearly dryness. The white residue was dissolved in 1 mL of water, then diluted with 25 mL of MeOH; after cooling at –10°C for 16 h, a pure product gradually crystallized.

*1,4,7,10-Tetraazacyclotridecane-2,9-dione (**2**)*

Compound **2** was obtained in 47% yield. ^{1}H NMR (in D_2O, MeOH as internal standard: 3.35 ppm): 3.925 (s, 4H, -CH_2- of 3 and 8 positions), 3.513 (s, 4H, ethylene), 3.454 (t, 4H, -CH_2- of 11 and 13 positions), 1.917 (quin. 2H, -CH_2- of 12 position). ^{13}C NMR (in D_2O, MeOH as internal standard: 49.00 ppm): 165.947 (-CONH-), 49.596 (-CH_2- of 11 and 13 positions), 42.458 (ethylene), 40.120 (-CH_2- of 11 and 13 positions), 27.167 (-CH_2- of 12 position). FABMS: [M + H] = 215. Anal. calcd. for $C_9H_{18}N_4O_2 \cdot 2HBr$: C 28.72, H 5.32, N 14.89; found: C 28.69, H 5.51, N 14.83.

*1,4,7,10-Tetraazacyclotridecane-3,8-dione (**3**)*

Compound **3** was obtained in 87% yield. ^{1}H NMR (in D_2O, MeOH as internal standard: 3.35 ppm): 3.882 (s, 4H, -CH_2- of 2 and 9 positions), 3.530 (s, 4H, ethylene), 3269 (t, 4H, -CH_2- of 11 and 13 positions), 2.05 (quin. 2H, -CH_2- of 12 position). ^{13}C NMR (in D_2O, MeOH as internal standard: 49.00 ppm): 167.757 (-CONH-), 47.688 (-CH_2- of 2 and 9 positions), 45.022 (ethylene), 39.005 (-CH_2- of 11 and 13 positions), 20.239 (-CH_2- of 12 position). FABMS: [M + H] = 215. Anal. calcd. for $C_9H_{18}N_4O_2 \cdot 2HBr$: C 28.72, H 5.32, N 14.89; found: C 28.71, H 5.70, N 14.66.

*1,4,7,10-Tetraazacyclododecane-2,9-dione (**4**)*

Compound **4** was obtained in 23% yield. ^{1}H NMR (in D_2O, *p*-dioxane as internal standard: 3.56 ppm): 3.739 (s, 4H, -CH_2- of 3 and 8 positions), 3.346 (s, 4H, -CH_2- of 11 and 12 positions), 3.306 (s, 4H, -CH_2- of 5 and 6 positions). ^{13}C NMR (in D_2O, *p*-dioxane as internal standard: 67.40 ppm): 166.38 (-CONH-), 48.22 (-CH_2- of 3 and 8 positions), 40.81 (-CH_2- of 11 and 12 positions), 39.543 (-CH_2- of 5 and 6 positions). FABMS: [M + Na^+] = 223. Anal. calcd. for $C_8H_{16}N_4O_2 \cdot 2HBr$: C 26.52, H 4.97, N 15.47; found: C 26.59, H 5.11, N 15.59.

Solution potentiometry

Standard solution

Carbon-dioxide-free, 0.10 M potassium hydroxide solution was prepared from Dilut-it® (Baker) Ampoules with doubly distilled water and standardized against KHP (potassium acid phthalate) to the phenolphthalein endpoint. Standard copper chloride solution 0.02 M was prepared from $CuCl_2$ (Fisher) and standardized by ion exchange methods (Dowex 50W X-8, strong acid resin).

Apparatus

The potentiometric apparatus consisted of a 100 mL capacity jacketed and capped glass cell provided with a magnetic stirrer, protective Ar inlets and outlets, a Metrohm 10 mL capacity incremental burette, and fitted with separate extension glass and reference (saturated calomel) electrodes for maximum accuracy and stability, connected to a Corning Model 150 pH meter.

Calibration

A small, known aliquot of standard 0.10 M HCl and a 5.000 mL aliquot of 1.000 M KCl were diluted to 50.00 mL with doubly distilled water in the thermostated (25.00 ± 0.05°C) titration cell. The p[H] ([H] = mol protons/L solution) was set on the meter to the calculated –log of the nominal H^+ molarity, and the standard KOH solution was added portionwise up to p[H] 11.0. Gran's plot showed the concentration of CO_2 to be <2.0% of KOH. From this it was also found that log K_w ($[H^+][OH^-]$) = –13.78 is suitable for reproducing the basic titration points.

Protonation constants

For each ligand studied, 0.1–0.2 mmol ligand was directly weighed and dissolved to make a 50.00 mL test solution at 25.0°C and μ = 0.100 (KCl). Usually, 0.050–0.100 mL aliquots of standard 0.10 M KOH were added to the test solution while the p[H] was noted. Generally, 10–20 points of data were collected for each *a* value (*a* = mol KOH added/mol of ligand present). The data collection was stopped at p[H] 11. The computation of the protonation constants was effected with Program BEST (28). The refinement process also yielded an exact molecular weight for each ligand (see Table 4).

© 1999 NRC Canada

Stability constants

To conserve ligand, each completed protonation titration solution was neutralized with standard 0.1 M HCl for reuse in copper determinations. A 1:1 molar ratio of copper to ligand was added, and a calculated portion of 1.000 M KCl was added to readjust the ionic strength back to 0.100. Usually, the copper-containing solution was treated with successive 0.100 mL aliquots of standard base until the recorded p[H] was near 11.0. The computations were made with the PC program BEST (28). The log β model developed for each Cu–ligand system was discovered by the systematic addition of required species until the titration curve was reproduced exactly. The initial species $MH_{-2}L$ was always the dominant form for most of the copper complexes, although, depending on the particular ligand, other species were also found, but in much lower concentrations. The computations on ligand **4** were carried out on three experiments, while all others were carried out on single experiments.

Electronic spectra

The UV-vis spectra of the complexes were obtained on a Perkin–Elmer Fast Scan model 553 spectrophotometer fitted with 1.000 cm matched cells and approximately 1.0 mM solution at p[H] corresponding to complete formation of $CuH_{-2}L$.

Organic reaction in water. Part 2[1]: Michael addition in water without phase transfer agents

Flavia Martins da Silva, Adriana Kniaseff Gomes, and Joel Jones, Jr.

Abstract: The Michael additions of dicarbonyl compounds, nitroalkanes, and thiols to 2-cyclohexen-1-one can be accomplished in water without phase transfer agents. The reaction is extremely sensitive to the pH of the reaction media, and therefore, the methodology can be optimized with the control of this variable. The best pH depends on the used nucleophile.

Key words: Michael addition, aqueous media, water, 2-cyclohexen-1-one, ketone.

Résumé : Les additions de Michael de composés dicarbonylés, de nitroalcanes et de thiols sur la cyclohexèn-2-one-1 peuvent être réalisées dans l'eau sans agents de transfert de charge. La réaction est extrêmement sensible au pH du milieu réactionnel et, en conséquence, la méthodologie peut être optimisée par le contrôle de cette variable. Le meilleur pH dépend du nucléophile utilisé.

Mots clés : addition de Michael, milieu aqueux, eau, cyclohexèn-2-one-1, cétone.

[Traduit par la Rédaction]

The use of water as the solvent in organic reactions has been uncommon for several reasons, among them the insolubility of the reactant (2), the incompatibility of the intermediates with water (2), and the competition of the desired reaction with hydrolysis (3). However, one of the main problems in the chemical industry is related with the use of organic solvents in its processes. The manufacture, transport, stock, handling, and disposal of solvents are aspects that demand great care and expense. For these reasons, the substitution of organic solvent as reaction media by water has great interest to organic synthesis because this minimizes the environmental impact, besides lowering the cost and decreasing operational danger.

In addition to the economic and human aspects, water presents many physical–chemical properties that can be useful in the reactions, such as high polarity, ion solvating capacity, and the ability to form hydrogen bonds, to form a structured liquid (4), and to aggregate apolar molecules dissolved in the water (hydrophobic effect) (2, 5–7).

Since 1980, when Breslow published his studies showing the importance of the use of water as solvent in Diels–Alder reactions (5), some studies have been made in this solvent in the sub- (2–31, 34–37) and superheated (31, 32) states. In the literature are examples of reactions such as hetero Diels–Alder (8, 9), dipolar cycloadditions (10), Claisen rearrangements (11), nucleophilic additions (12–23), and substitutions (3), Barbier reactions (24–31), autocatalytic cleavages (32, 33), oxidations (34, 35), reductions (36), photoreactions (37), among others.

The Michael addition reaction (38) is commonly applied in organic synthesis, and it has great importance in the formation of a new carbon–carbon bond and in the synthesis of polyfunctional compounds. Recently, examples of Michael reactions in aqueous media have appeared. Keller and Feringa (13) studied the 1,4-addition of several ketoesters with α,β-unsaturated aldehydes and ketones, and of α-nitroesters with methyl vinyl ketone (14). These reactions occur in aqueous media catalysed by ytterbium triflate.

Nitroalkanes give the same type reaction in aqueous media, catalyzed by sodium hydroxide in the presence of a phase transfer agent, as shown by Ballini and Bosica (15). Lubineaou and Augé (16) published the first example of Michael addition of nitroalkanes in water without catalyst. However, the method seems to be only effective when nitromethane and nitroethane are used as nucleophiles, and methyl vinyl ketone as electrophile.

The 1,4-addition of water-soluble phosphines (17, 18) and pyridines (19) were also studied in an aqueous media. Also in water or in double solvents systems, alkyl halides, in presence of zinc and copper, react with α,β-unsaturated ketones and aldehydes, leading to the addition products (20–23).

We have studied this reaction type in aqueous media, with basic catalysis, without phase transfer agents, to examine its

utility in organic synthesis and for preparation of polyfunctional intermediates.

Experimental

Materials

2-Cyclohexenen-1-one and thiophenol were purchased from Aldrich, nitromethane and 1-propanethiol from Merck, acetylacetone from Sigma, and diethyl malonate and nitroethane from Carlo Erba. The reagents were used as received. Reaction products were purified by radial chromatography in a Harrison Research Chromatotron. High-resolution gas chromatograph (HRGC) analyses were performed on a HP-5890-II gas chromatograph with FID by using a 30 m (length), 0.25 mm (i.d.), and 0.5 μm (phase thickness) RTX-5 silica capillary column; H_2 as gas carrier; and flow division of 1/20. NMR analyses were performed on a Brucker (300 or 200 MHz) in $CDCl_3$ solution with TMS as internal pattern. The FT-IR spectra were recorded on a Nicolet Magna-IR-FT (NaCl film).

Typical procedure

To 5 mmol of the nucleophile was added to a 10 mL of 0.5 M aqueous NaOH solution. Soon after, 5 mmol of 2-cyclohexenen-1-one were added. The reaction mixture was then stirred vigorously for the time indicated in the Table 1. Then the reaction mixture was neutralized with concentrated hydrochloric acid and extracted with chloroform. The organic extract was dried (anhydrous Na_2SO_4), and the solvent was evaporated under reduced pressure.

Products analysis

Results

In our experiments, we studied in aqueous media the Michael addition of dicarbonyl compounds, nitro compounds, and thiols to 2-cyclohexenen-1-one, without a phase transfer agent. As we know that in nucleophilic reactions in water one of the main problems is related to the competition with the hydrolysis process of the electrophile (3), we studied the reaction under three different conditions, where the main variant is the pH of the reaction media. The reaction was catalyzed by NaOH (pH 14), Na_2CO_3 (pH 10), or $NaHCO_3$ (pH 7.5). Yields of purified products obtained are reported in Table 1.

For the reactions of the dicarbonyl compounds, diethyl malonate, and acetylacetone, the best yields were reached in pH 10, leading to 30 and 35% yields, respectively.

In the case of the nitro compounds, the Michael addition of nitromethane leads to the product **2a** with 65% yield when the pH is 14. On the other hand, nitroethane leads to several products in this reaction condition. However, 1,4-addition products of the nitroethane to the 2-cyclohexenen-1-one can be obtained in pH 7.5 or 10 in 25 and 20% yields, respectively.

The tested thiols were 1-propanethiol and thiophenol. The best pH for the reaction is 7.5, leading to 70 and 95% yields, respectively.

Discussion

We verified that the Michael addition of dicarbonyl compounds, nitroalkanes, and thiols to the 2-cyclohexen-1-one can be carried in water without phase transfer agent. The reaction is sensitive to the pH of the reaction media, and therefore, the methodology can be optimized with this variable control. The best pH depends on the nucleophile used.

An important study for the understanding of the influence of pH in nucleophilic reactions is reported by King et al. (3), where it is shown that several nucleophilic reactions can be optimized with the pH control according to the equation: $pH_{max} = 1/2[\log (k_w/k_{OH}) + pK_w + pK_a]$, where k_w and k_{OH} are the hydrolysis rate of eletrophile promoted by the water and hydroxide, respectively, K_w is the autoprotolysis constant of water, and K_a is the acid dissociation constant of the nucleophile. However, this relationship has only been established in dilute solutions (10^{-4}–10^{-5} M).

As our work involves heterogeneous solutions, this equation does not apply to our system. This can be seen by comparison of the reactions of 1-propanethiol and nitromethane with 2-cyclohexen-1-one. In spite of using the same eletrophile and nucleophiles of similar pK_a, the best pH are very different.

In our opinion, the studied system is very complex. Several parallel reaction paths can occur depending on the nucleophile, the electrophile, and the used reaction media. The reaction can occur in solution where, probably, the hydrophobic effect will have an important weight, or in the interface of the aqueous solution with the organic reagents; besides, in some cases, retro-Michael is a possibility. For the mechanistic study, the dilute system seems to be less complex, since it is ideal solutions, presenting therefore fewer variables. However, in synthetic terms, the reaction in a heterogeneous media, even if it is of difficult understanding, it is more appropriate since it facilitates the scale-up because that would not have problems with a bigger reaction volume.

Conclusions

We believe that the present work contributes to the field of organic reactions in aqueous solution, demonstrating that Michael addition can be made in this solvent without phase transfer agents. The advantage of not using phase transfer agents is the emulsion absence in the extraction process. This simple fact is of extreme importance in wide scale (industrial production), reducing production costs and environmental pollution.

Regioselective protonation of ferrocene in superacid and formation of a C—H—Fe bond. An experimental and theoretical study of the structure and dynamics of the ferrocenonium ion

Annika Karlsson, Anders Broo, and Per Ahlberg

Abstract: Protonation of ferrocene has been suggested to take place on carbon (*exo*-protonation) or iron (*endo*-protonation). However, experiments have not been conclusive because of interfering exchange reactions. Now low-temperature protonation of ferrocene and [$^2H_{10}$]-ferrocene in superacid and direct observation of the carbocation by ^1H NMR at low temperature shows only primary protonation and that it exclusively takes place in an *endo*-fashion. Studies by DFT calculations using B3LYP hybrid functional indicate the presence of an intramolecular nonlinear C—H—Fe bond and that the proton might be delocalized between carbon and iron. Potential energy barriers for degenerate rearrangements of the hydride bridged carbocation are low, suggesting that the proton might be delocalized between all 10 carbons and iron. The NMR results are consistent with such an interpretation.

Key words: regioselective, protonation, superacid, ferrocenonium ion.

Résumé : Il a été suggéré que la protonation du ferrocène puisse se faire sur le carbone (protonation-*exo*) ou sur le fer (protonation-*endo*). Toutefois, les expériences ne permettaient pas de tirer des conclusions à cause de réactions d'échange qui causaient des interférences. Il est maintenant possible d'opérer à basse température, dans un superacide, pour effectuer la protonation du ferrocène et du [$^2H_{10}$]-ferrocène; la RMN du ^1H à basse température permet d'observer le carbocation directement et de montrer que la protonation primaire se fait exclusivement de façon *endo*. Des calculs « DFT » à l'aide d'une fonction hybride B3LYP montrent qu'il existe une liaison intramoléculaire non linéaire C—H—Fe et que le proton pourrait être délocalisé entre le carbone et le fer. Les barrières d'énergie de potentiel pour les réarrangements dégénérés du carbocation ponté par un hydrure sont faibles; ceci suggère que le proton puisse être délocalisé entre les dix atomes de carbone et le fer. Les résultats de la RMN sont en accord avec une telle interprétation.

Mots clés : régiosélectif, protonation, superacide, ion ferrocénonium.

[Traduit par la Rédaction]

Introduction

Low-temperature protonation of ferrocene (**1**) and [$^2H_{10}$]-ferrocene ([$^2H_{10}$]-**1**) in superacid and direct observation of the carbocations formed by ^1H NMR at low temperature show that primary protonation in an *endo*-fashion exclusively takes place. Density functional theory (DFT) calculations using the B3LYP functional indicate that the proton is in a novel type of bond — an intramolecular nonlinear C—H—Fe bond.

The protonation and, more generally, the electrophilic substitution of the iron group metallocenes has been investigated many times. A focus has been the primary step in this reaction and whether or not the electrophile would first coordinate to the metal (*endo*-path in Fig. 1) or attach itself to one of the rings (*exo*-path in Fig. 1)(1).

Recent publications have adressed the protonation of **1** from the experimental and theoretical side (1*n*–*p*). These latest results again do not agree on the pathway. In this report, we present our results of a combined experimental and theoretical investigation that show that in superacid the primary process is exclusively *endo*-protonation and reveals the structure and dynamics of the protonated species, i.e., the ferrocenonium ion (**2**) which contains a C—H—Fe bond.

Fig. 1. The *endo*- and *exo*-pathways for electrophilic substitution of ferrocene (**1**).

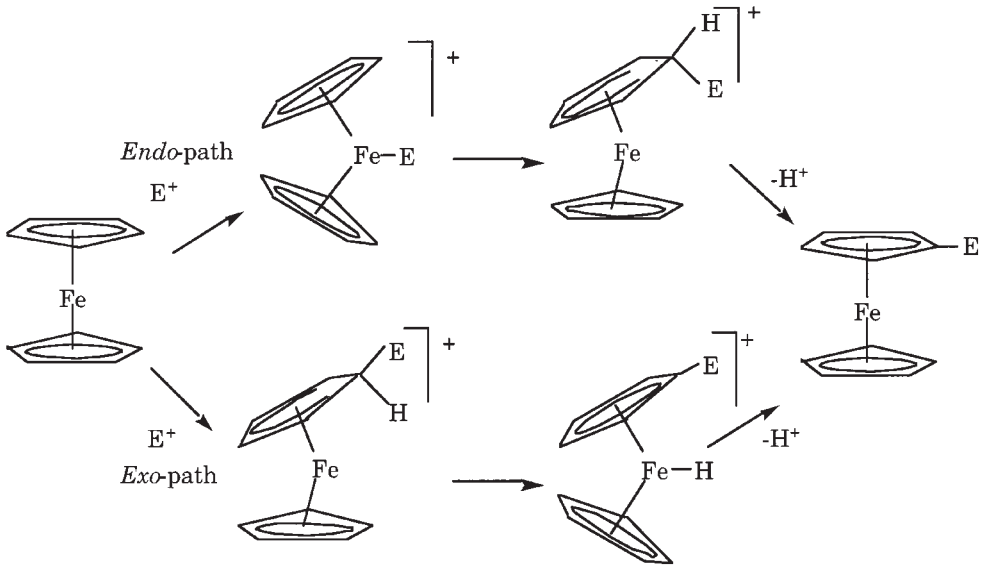

Fig. 2. (*a*) ^{1}H NMR spectrum at –122°C of ion **2** obtained by protonation of **1** in HSO_3F:SO_2ClF (1:10, v:v) at –125°C. (*b*) ^{1}H NMR spectrum at –109°C of deuterium labelled ion **2** obtained by protonation of [$^2H_{10}$-**1**] in HSO_3F:SO_2ClF:SO_2F_2 (1:6:1, v:v:v) at –115°C, showing that no protons have substituted ring-deuterons, i.e., that the protonation exclusively takes place in an *endo*-fashion. Chemical shifts are referenced to $CHDCl_2$ δ 5.32.

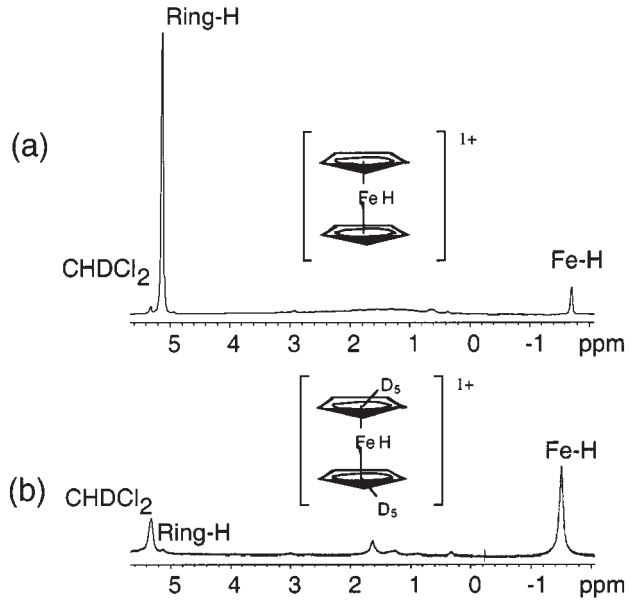

Previously, monoacylferrocenes have been protonated in superacid, yielding carbonyl oxygen protonation (2). Upon increasing the acidity of the superacid, both carbonyl oxygen and iron protonation have been reported to take place (3). However, there is no report on superacid protonation of the parent ferrocene **1** — an easily oxidized compound.

Results and discussion

Protonations of **1** and [$^2H_{10}$]-**1** in superacid were performed directly in NMR tubes using a special ion generation technique (4). A degassed solution of compound **1** (5 mg in 150 μL CD_2Cl_2) was mixed into a 0.5 mL degassed superacid solution with the composition HSO_3F:SO_2ClF (1:10, v:v) at –125°C, yielding a blue–green solution of ion **2** (0.025 M). The NMR tube was sealed and stored in liquid N_2 before spectroscopic investigation. The ^{1}H NMR spectrum of ion **2** at –122°C is shown in Fig. 2*a*.

The two singletts at δ 5.12 and δ –1.67 with the relative intensity 10:1 were assigned using ^{1}H,^{1}H NOESY to the ring C-H protons and the Fe-H proton, respectively. No spin–spin coupling between the ring hydrogens and Fe-H were resolved. That only two singletts were observed indicate that the ferrocenonium ion undergoes extensive fast degenerate rearrangements. The ^{1}H decoupled ^{13}C NMR spectrum showed only one signal at δ 77.82 ($CHDCl_2$ δ 54.00) ascribed to the ring carbons.

There are a number of previous reports on NMR studies of the ferrocenonium ion (**2**) in H_2O saturated with BF_3 (1). Compound **1** has been dissolved in H_2OBF_3 under anaerobic conditions. The ^{1}H NMR chemical shifts for ion **2** were similar to those obtained in superacid, i.e., δ 5.06 and δ –1.88 (relative to the acid peak set to δ 8.30) (1*p*).

When similarly compound **1** was dissolved in D_2O saturated with BF_3 and studied by NMR, it was found that the ferrocenonium ion formed contained essentially no protium. All protons had been exchanged for deuteriums. From this result it was concluded that ion **2** is formed by *exo*-protonation rather than *endo*-protonation. From the reaction mixture, compound [$^2H_{10}$]-**1** has been isolated (1*p*).

Compound [$^2H_{10}$]-**1** has been used in this work as a precursor for the preparation of deuterium labelled **2** in superacid. A degassed solution of compound [$^2H_{10}$]-**1** (5 mg in 150 μL CD_2Cl_2) was mixed into a 0.5 mL degassed superacid solution with the composition HSO_3F:SO_2ClF:SO_2F_2 (1:6:1, v:v:v) at –115°C, yielding a blue–green solution of deuterium labelled ion **2** (0.025 M). The NMR tube was sealed, and the ^{1}H NMR spectrum shown in Fig. 2*b* was obtained at –109°C. The singlett at δ –1.51 was ascribed to the Fe-H protons. Only traces (0.1 atom% ^{1}H) of ring hydrogens at δ 5.11

© 1999 NRC Canada

were observed. These results clearly show that the primary protonation is not *exo*-protonation, since such a protonation in Fig. 1 should have given a one proton signal at about δ 5.11 and no ^1H signal at δ –1.51 because in this mechanism deuterium ends up on iron. Rather, the results show that the protonation is highly regioselective in an exclusive *endo*-fashion, i.e., the protonation occurs directly on iron or *endo* on carbon.

Interestingly, the results in superacid also show that no $^1H/^2H$ exchange of the ferrocenonium ion takes place under these conditions. Obviously, the conjugate base of the superacid is too weak to yield reversible protonation. Thus, this irreversible protonation allowed for the resolution of the primary protonation step.

The previously reported extensive ring proton exchange observed in D_2OBF_3, which formed the basis for the conclusion that the primary protonation is *exo*-protonation, is presumably caused by reversible hydronation of compound **1**. The conjugate base of D_2OBF_3 is much stronger than the corresponding one for a superacid. As a consequence, D_2OBF_3 therefore yields protonation which is less complete and reversible. This makes it possible for a slower reaction with the *exo*-protonation mechanism to operate in combination with the faster reaction with the reversible *endo*-protonation mechanism, resulting in extensive exchange of the ring protons for deuteriums.

The "hydridic" shift of the *endo*-proton in the ferrocenonium ion has been assumed to indicate that the proton is bonded to iron (Fe-H) rather than to carbon (C-H). However, Mueller-Westerhoff et al. (1*p*) have recently resolved coupling between the *endo*-proton and all 10 ring protons. Furthermore, their results indicate the presence of an iron–proton coupling. These results have been interpreted as being due to the presence of both carbon protonated ferrocenonium ions and iron protonated ferrocenonium ions that are in rapid equilibrium with each other.

Computations

With the aim to further clarify the nature of **2**, we have carried out extensive calculations using density functional theory (DFT) with the B3LYP hybrid functional (5, 6). All DFT calculations were done with the Gaussian 94 program (7). The build in basis sets 6-311G(f), 6-311G(f,d,p), and 6-31G were used. Broo[2] has recently shown that at the B3LYP/6-311G(f), 6-31G level of theory the observed gas phase geometry of ferrocene is reproduced with high accuracy. The rather small basis set (6-31G) used for the ligands were demanded by the large computational cost to use a larger basis set in the geometry determination. Only minor changes in the geometrical parameters were found when the 6-311G(f,d) basis set were use for compound **1**. All molecules were fully optimized in the given point group. Recently, McKee (1*o*) has studied the energetics of the protonation reaction and the geometry of protonated ferrocene at the Hartree–Fock (HF) and second-order perturbation theory (MP2) level. Neither of these methods yields a reasonable geometry for **1**, as has been shown by several authors (8), as opposed to DFT calculations that reproduce the observed ferrocene geometry very well.[2] Consequently, the geometries reported by McKee differ much from the B3LYP/6-311G(f),6-31G geometries shown in Fig. 3.

Thus, it has been possible to locate the potential energy minima for both carbon protonated and iron protonated **1**, i.e., **3** and **4**, respectively (Fig. 3).

Structure **3** is 12 kJ mol^{-1} more stable than **4**. In **3** the protonated carbon is close to be sp^3 hybridized. The *endo*-C—H bond distance is 1.19 Å, and the corresponding *exo*-bond distance is 1.09 Å, i.e., 0.1 Å shorter. The *endo*-H—Fe distance is 1.785 Å.

In the iron protonated structure **4**, which has C_{2v} symmetry, the *endo*-H—Fe bond distance is 1.486 Å, and the *endo*-H—C proton distance to the nearest ring carbons is 1.891 Å. The ring-C-H bonds are 7° out of the plane made up of the ring carbons, i.e., the hydrogen-bonded carbons are slightly rehybridized towards sp^3.

These data clearly show that in both structure **3** and **4** the *endo*-proton participates in nonlinear bonds, i.e., C-H···Fe (agostic interaction (9) and C···H-Fe bonds, respectively. Formally, these bonds are hydride bridges. In the rearrangement of **3** to **4** the *endo*-H—C bond length increases by 0.701 Å and the H—Fe distance decreases 0.299 Å. The rearrangement is also accompanied by other structural changes than rehybridization, e.g., bond distances in the rings changes. The potential energy maximum on the reaction coordinate for the isomerization of **3** to **4** is only 13.6 and 1.7 kJ mol^{-1} above the minima for **3** and **4**, respectively. The structure (**5**) corresponding to the maximum is shown in Fig. 3*c*. In **5** the Fe—H bond is bent towards the hydride accepting ring carbon and slightly elongated to 1.498 Å. The *endo*-C—H bond distance is shorter than in **4** by 0.2 Å. The low barrier (1.7 kJ mol^{-1}) for the transfer of the hydride beween iron and carbon suggests that the first vibrational level may be in the vicinity of the potential energy maximum for the proton transfer, i.e., that the hydride might be delocalized between carbon and iron.

Other possible low-barrier processes in the ferrocenonium ion (**2**) have also been identified. The rotation of the non-hydride bridged ring relative to the hydrogen-bonded one reveals a shallow potential energy surface. The highest barrier is only 0.45 kJ mol^{-1}. Rotation of the Fe—H bond relative to the rings in **4** yields a barrier of 17.2 kJ mol^{-1}, and this barrier gives an indication that the Fe-H···C bond in **4** is quite strong. A lower barrier (3.1 kJ mol^{-1}) is obtained for the process in which one of the rings in **4** rotates relative to the Fe—H and the other hydrogen-bonded ring which are kept fixed.

Thus, our combined computational results indicate that the *endo*-proton, which is imbedded in the electron cloud from iron and the rings, might be delocalized between iron and all 10 carbons.

The ^1H chemical shifts for the ferrocenonium ions **3** and **4** and the reference CH_2Cl_2 have been calculated using the GIAO method (10). The 6-311G(f,d,p) basis set was used in the B3LYP-GIAO calculations. As a further test of the basis set dependency, the relatively large cc-pVTZ basis set were used on the carbon and hydrogen atoms. Only minor change of the relative shift was found with the larger basis set. To

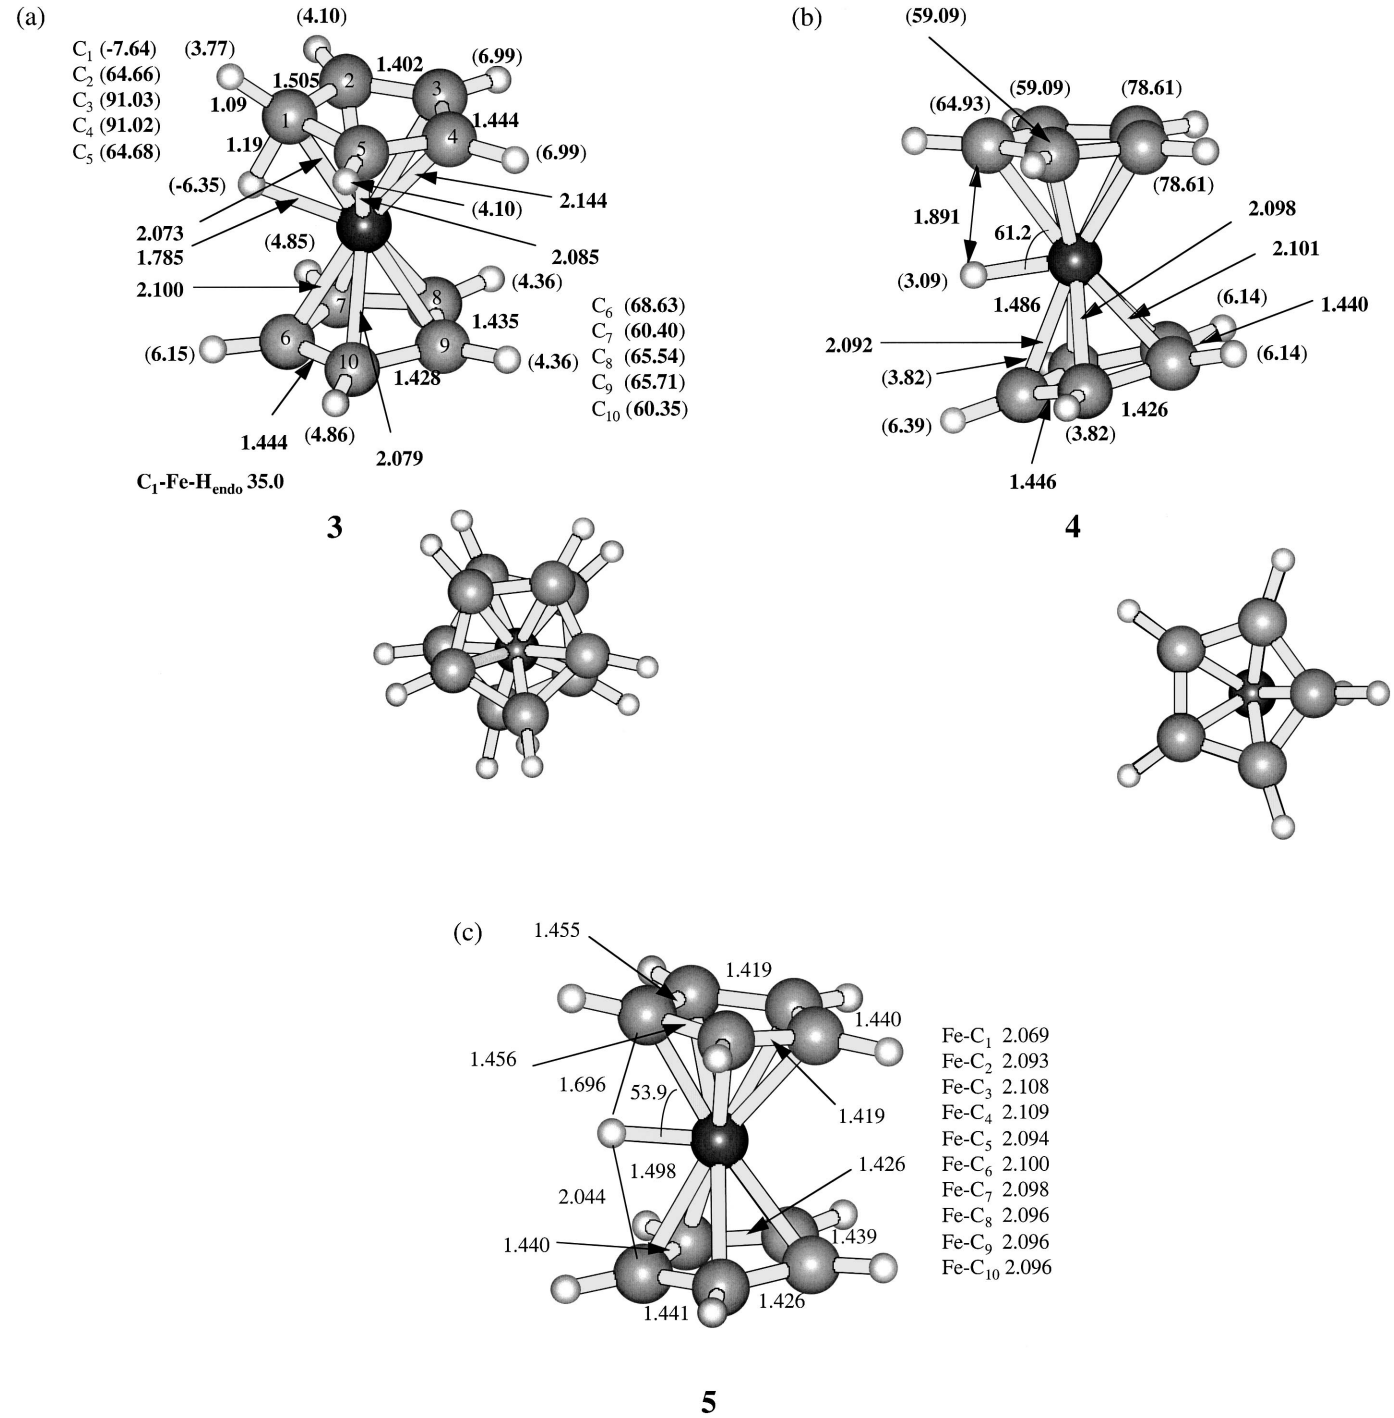
Fig. 3. Calculated structures for carbon protonated **2**, i.e., **3** (*a*), iron protonated **2**, i.e., **4** (*b*), and for the transition state for the interconversion of the intramolecularly nonlinear hydrogen-bonded species **3** and **4**, i.e., **5** (*c*). Bond distances, selected bond angles, ^{1}H NMR, and ^{13}C NMR chemical shifts (in parentheses) are shown.



our surprise, it was the *endo*-proton in the carbon protonated species **3** rather than the proton in the iron protonated species **4** that showed a "hydrid" shift. The estimated *endo*-proton chemical shifts were δ –6.35 for **3** and δ 3.09 for **4**. The average value of the two shifts is –1.63, which is close to the observed value –1.67. The calculated average shift for the 10 ring protons (which show large shift variations) in **3** and **4** are similar, and the average of the averages is 5.16, which is close to the observed value 5.12.

At the B3LYP/6-311G(f),6-31G level of theory the calculated Mulliken group charges for the carbon protonated species **3** are for Fe 0.99, for the protonated cyclopentadienyl ligand 0.10, and for the cyclopentadienyl ligand –0.09. The *endo*-hydrogen in **3** has a charge of 0.10 and the *exo*-one

© 1999 NRC Canada

0.16, leaving the rest of the protonated cyclopentadienyl unit with a charge of –0.16, i.e., with a charge somewhat more negative than the other iron–ligand.

The iron-protonated species **4** has the following calculated group charges: Fe 0.69, each of the cyclopentadienyl rings 0.125, and the iron-bonded hydrogen 0.06.

Thus, the rearrangement from **3** to **4** results in charge redistribution. The iron charge becomes less positive by 0.3 units of charge, and the ligands (excluding the *endo*-hydrogen) become more positive by 0.34 charge units. The *endo*-hydrogen changes its charge from 0.10 to 0.06.

Experimental and computational section

Preparation of $[^2H_{10}]$-ferrocene ($[^2H_{10}]$-1)

A modified procedure described by Mueller-Westerhoff et al. (1*p*) was used to prepare $[^2H_{10}]$-**1**.

D_2OBF_3 was prepared from boron trifluoride and deuteriumoxide using an earlier described procedure (1*p*). Deuteriumoxide (5 mL, Glaser, >99.80 atom% D) was boiled in a flask while a stream of nitrogen was passed through the liquid for 1.5 h. The flask was then placed in an ice–methanol bath, and BF_3 gas (AGA gas, >99.994 vol.%) was bubbled through the liquid until saturation. The temperature was kept at ca. 0°C. The solution was used immediately after preparation.

Ferrocene (Aldrich, 98%, 206 mg, 1.1 mmol) was sublimated at 10^{-1} mbar (1 bar = 100 kPa) at 70°C. Under nitrogen, ferrocene was added into freshly prepared D_2OBF_3 (5 mL). The reaction mixture turned yellow–brown and was stirred for 40 min. Then, deuteriumoxide 50 mL was added and the mixture was stirred for another 15 min. The solution was then extracted with 10 × 25 mL methylene chloride. The methylene chloride phases were washed with water, dried over $MgSO_4$, and evaporated. To increase the deuterium content in $[^2H_{10}]$-ferrocene, the above procedure was repeated with the modification of a longer reaction time (2 h 20 min) The ^1H NMR spectrum in $CDCl_3$ with the internal reference CH_2Cl_2 at 19°C showed only traces of hydrogen (0.1% H) at 4.18 ppm.

Protonation of ferrocene (1) and $[^2H_{10}]$-1

To avoid oxidation side reactions, the reactions with the superacid have been conducted in an inert atmosphere and at low temperatures. The ions were generally prepared directly in 5 mm NMR tubes (Wilmad 503-PS) using a special ion generation technique (4). Typically, degassed solutions of (ca. 5 mg in ca. 150 μL CD_2Cl_2) were mixed into ca. 0.5 mL degassed superacid (HSO_3F:SO_2ClF, 1:10 v/v or HSO_3F:SO_2ClF:SO_2F_2, 1:6:1, v/v/v) at ca. –120°C, yielding ionic solutions ca. 0.025 M in ion. The CD_2Cl_2 used was from Cambridge isotope laboratories (>99.9% D), HSO_3F from Aldrich and SO_2F_2 from Matheson Gas Products, respectively. The SO_2ClF was freshly prepared from SO_2Cl_2 and NH_4F using an earlier described procedure.[3]

NMR spectroscopy

The spectra were recorded using a Varian Unity 500 instrument operating at 499.92 MHz and equipped with a 5 mm variable temperature ID500-5 indirect detection probe from Nalorac. ^1H chemical shifts were referenced to $CHDCl_2$ (δ 5.32). The spectra were obtained at ca. –120°C. One-dimensional ^1H spectra and ^{13}C spectra were recorded with standard parameters.

Computational methods and procedures

All calculations were done using density functional theory (DFT) with the Becke three-parameter hybrid functional with the Lee et al. (5) correlation functional, known as the B3LYP method (6). All the DFT calculations were done with the Gaussian 94 program (7). The build-in basis sets 6-311G(f), 6-311G(f,d,p), and 6-31G were used in this investigation. The 6-311G basis set generated the following contracted basis functions: Fe: [9s, 5p, 3d], C: [4s, 3p], and H: [3s]. The f, d, and p letters denotes additional polarization functions of the f-type for Fe, of d-type for C, and of p-type for hydrogen. In a recent work, Broo[2] showed that at the B3LYP/6-311G(f),6-31G level of theory the observed gas phase geometry of ferrocene and the crystallographic geometry of ferrocenophane were reproduced with high accuracy. The rather small basis set (6-31G) used for the ligands were demanded by the large computational cost to use a larger basis set in the geometry determination. Only minor changes in the geometrical parameters were found when the 6-311G(f,d) basis set were used for ferrocene.[2] All the molecules in this work were fully optimized in the given point group. All stationary points were verified by diagonalizing the Hess matrix. For the reported equilibrium geometries no negative eigenvalues were found. The reported transition states have one negative eigenvalue.

The chemical shift calculations were done with the GIAO method (10). The 6-311G(f,d,p) basis set was used in the B3LYP-GIAO calculations. All the shifts in Fig. 3 are relative to the experimental reference CH_2Cl_2 (^1H shift 5.32 ppm; ^{13}C shift 54.00 ppm). The geometry of reference compound CH_2Cl_2 was calculated at the B3LYP/6-31G and at the B3LYP/6-311G(d,p) levels of theory. The calculated shielding constants were C: 128.9536 and 111.1165 ppm and H: 27.7922 and 26.7781 ppm, respectively.

Electronic effects on enol acidity and keto–enol equilibrium constants for ring-substituted 2-tetralones

Xudong Yao and Ralph M. Pollack

Abstract: Equilibrium constants for the ionization of a variety of phenyl-substituted 2-tetralones (pK_a^K), for the ionization of their enols (pK_a^E), and for keto–enol tautomerization (pK_E) were determined. Hammett plots of pK_a^K and pK_a^E vs. σ^- are linear with slopes ($-\rho$) of –1.66 ± 0.06 and –0.90 ± 0.03, respectively, except for deviations of the points corresponding to 6-nitro-2-tetralone (**1b**) and its enol. We have previously attributed the negative deviation of **1b** from the correlation for the acidities of the ketones obtained with the more limited set of data to the lack of a free electron pair on C-1 of the free tetralone (Nevy et al.). The negative deviation of the point for **1b** from the correlation for the acidities of the enols suggests that charge transfer from the hydroxyl group of the enol to the nitro group is less important than it is for phenols. This study represents the first systematic study of electronic effects on equilibria among ketone, enol, and enolate in aqueous solution.

Key words: enol, acidity, equilibrium, substituent, conjugation.

Résumé : On a déterminé les constantes d'équilibre pour l'ionisation d'un certain nombre de 2-tétralones substituées sur le noyau phényle (pK_a^K), pour l'ionisation de leurs énols (pK_a^E) et pour la tautomérisation cétoénolique (pK_E). Les courbes de Hammett pour les valeurs de pK_a^K et de pK_a^E en fonction de σ^- sont linéaires, avec des pentes ($-\rho$) respectives de –1,68 ± 0,06 et –0,90 ± 0,03 si l'on exclut les déviations du point correspondant à la 6-nitro-2-tétralone (**1b**) et son énol. En se basant sur une corrélation d'acidités de cétones obtenue avec un ensemble plus petit de données, on a antérieurement attribué la déviation négative de **1b** à l'absence d'une paire d'électrons libres en C-1 de la tétralone libre (Nevy et al.). La déviation négative du point pour **1b** pour les acidités des énols suggère que le transfert de charge à partir du groupe hydroxyle de l'énol vers le groupe nitro est beaucoup moins important que pour les phénols. Cette étude représente la première étude systématique d'effets électroniques sur l'équilibre entre une cétone, son énol et l'énolate en solution aqueuse.

Mots clés : énol, acidité, équilibre, substituant, conjugaison.

[Traduit par la Rédaction]

Introduction

The determination of equilibrium constants for the interconversion of aldehydes and ketones with their enols has been of interest since the early 1900s (1). Several methods have traditionally been used to detect enols in equilibrium with the corresponding carbonyl compounds, but these methods often gave conflicting results. In the early 1980s, Kresge and co-workers (2) and Capon et al. (3) sparked a resurgence in the area of enol chemistry by developing methods to generate enols in greater than equilibrium concentration. These kinetic approaches enabled the accurate measurement of keto–enol equilibrium constants for simple aldehydes and ketones, as well as rates of enolization and ketonization, and acidity constants for both the ketones and the enols. In parallel, Rappoport and co-workers investigated keto–enol equilibrium constants for sterically hindered aryl-substituted ketones, which produce enols that are kinetically and (or) thermodynamically stable relative to simple systems (4). Keto–enol equilibrium constants are now available for a variety of simple ketones, as well as for more complicated systems (1).

Studies of substituent effects on the keto–enol equilibrium have revealed several factors that govern these equilibria. For aryl aldehydes and ketones, the primary effect of the substituent on keto–enol tautomerization is on the stability of the ketone, rather than the enol (1). However, for α-aryl ketones, the effect of the aryl group on ketone stability is

Received September 30, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

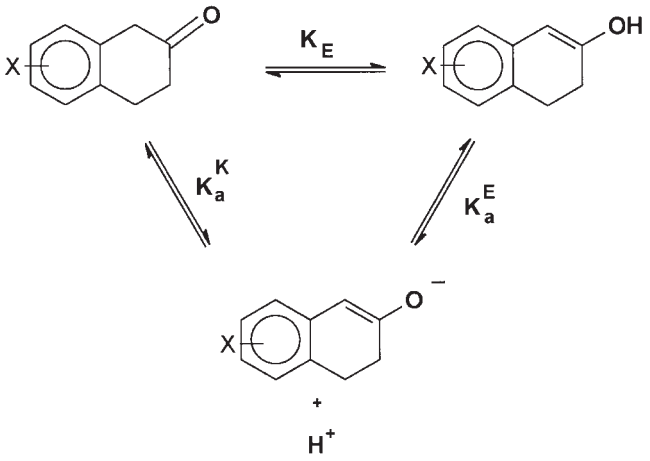
Scheme 1.



minimal (1), whereas enolization results in stabilization due to conjugation between the carbon–carbon double bond of the enol and the phenyl group. On the basis of the dependence of the enol content of ring-substituted 2-phenylpropionaldehydes in DMSO on σ^- (ρ = 0.72) (5), Toullec (1) suggested that the conjugation of the aryl ring with the double bond involves little π electron transfer (6). This conclusion is somewhat surprising considering the possibility of direct resonance interaction between the aryl ring and the hydroxyl group through the double bond. Rappoport, on the other hand, has interpreted the same data to suggest that there is "an important dipolar contribution to the enol ground state having a negative charge on the β-aryl group" (4*d*, 7). This system, however, is complicated by the potentially less than optimal coplanarity of the *p* orbitals of the phenyl ring with those of the double bond, which might cause a diminished interaction between the ring substituents and the OH group of the enol.

To isolate electronic effects on keto–enol equilibria and ionization of enols, we have examined the dependence of the equilibrium constants on substituent for substituted 2-tetralones (**1a**–**1j**) (Scheme 1). As a fused α-aryl ketone, 2-tetralone has no direct resonance between the phenyl ring and the carbonyl group, and therefore the electronic effect on the ketone stability is minimal. In addition, the carbon–carbon double bond and the phenyl ring of the enol should be almost coplanar (8), which allows maximal resonance and charge transfer. We report here the pK_a's of both the ketones (pK_a^K) and the enols (pK_a^E) of a variety of substituted 2-tetralones, from which the substituent effect on the keto–enol tautomerization can be derived. This study represents the first systematic study of electronic effects on equilibria among ketone, enol, and enolate in aqueous solution.

Experimental

Materials

Unless otherwise mentioned, all chemicals were reagent grade or better, purchased commercially and used without further purification. ^{1}H NMR spectra were recorded in $CDCl_3$ with TMS as an internal standard on a General Electric QE-300 spectrometer. Melting points were determined on a Mel-Temp apparatus and are uncorrected. 2-Tetralone (**1a**), 6-nitro-2-tetralone(**1b**), 6-methoxy-2-tetralone (**1d**), 7-nitro-2-tetralone (**1e**), 7-chloro-2-tetralone (**1f**), and 5,7-dinitro-2-tetralone (**1g**) were available from previous work (9). 6-Chloro-2-tetralone (**1c**) was synthesized as before, mp 67–68°C (lit. (9*a*) 67.0–67.5°C). Recrystallizations from mixed solvents were performed by adding cosolvent until the solution became cloudy, followed by heating until clarification.

*7-Methyl-2-tetralone (**1h**)*

A mixture of *m*-methylphenylacetic acid (3.40 g, 22.6 mmol) and 100 mL 2 M thionyl chloride in dichloromethane solution (200 mmol) was stirred overnight. The solvent and excess thionyl chloride were distilled off. The resulting *m*-methylphenylacetic chloride was vacuum distilled and dissolved in ca. 20 mL anhydrous dichloromethane. This solution was added dropwise under argon to a stirring suspension of anhydrous aluminum chloride (4 g, 30 mmol) in 120 mL anhydrous dichloromethane cooled at –15°C, while ethylene was bubbled through the reaction mixture. The reaction was stopped after 1.5 h. After work-up as for **1f** (9*a*), column chromatography (silica, Merck 60, 1:4 ethyl acetate:hexane) gave a 1:2 mixture of 5-methyl-2-tetralone and 7-methyl-2-tetralone (estimated from integration of protons on C-1 carbon from ^{1}H NMR), 1.76 g (combined yield 52.1%). 7-Methyl-2-tetralone was obtained from two recrystallizations of this mixture from methanol–water (1.03 g, 28%), mp 57.5–59.5°C (lit. (10) 57–59°C). ^{1}H NMR ($CDCl_3$) δ: 2.33 (s, 3H, CH_3), 2.57 (t, J = 6.0 Hz, 2H, H4), 3.03 (t, J = 6.0 Hz, 2H, H3), 3.55 (s, 2H, H1), 6.95 (s, 1H, H8), 7.03 (d, J = 7.5, 1H, H5), 7.13 (d, J = 7.5 Hz, 1H, H6). Anal. calcd. for $C_{11}H_{12}O$: C 82.46, H 7.55%; found: C 82.28, H 7.61%.

*6-Iodo-2-tetralone (**1i**)*

p-Iodophenylacetic chloride was obtained using a similar procedure as above, from *p*-iodophenylacetic acid (150 mg, 0.57 mmol) and 1.2 mL 2 M thionyl chloride in dichloromethane solution (2.3 mmol). With excess anhydrous aluminum chloride (3.0 g, 20 mmol), the acid chloride was reacted with ethylene to give 6-iodo-2-tetralone. Chromatography (hexane:ethyl acetate, 10:1.5) and recrystallization from hexane and ethyl acetate gave pure **1i** (58 mg, yield 37%), mp 60.5–62.0°C. UV (1 N NaOH): 312 nm. ^{1}H NMR ($CDCl_3$) δ: 2.53 (t, J = 6.6 Hz, 2H, H4), 3.02 (t, J = 6.6 Hz, 2H, H3), 3.53 (s, 2H, H1), 6.88 (d, J = 7.8, 1H, H8), 7.55 (d, J = 7.8 Hz, 1H, H7), 7.51 (s, 1H, H5). Anal. calcd. for $C_{10}H_9IO$: C 44.14, H 3.33%; found: C 44.22, H 3.38%.

*6-Chloro-7-nitro-2-tetralone **(1j)***

6-Chloro-2-tetralone (1.1 g, 6.1 mmol) was slowly added to 8 mL of 90% nitric acid at –25°C, with nitrogen bubbling through the solution. After addition was completed, the reaction mixture was stirred for 8 min, poured onto a mixture of sodium hydroxide (6.5 g) in water and ice (50 mL) and 200 mL ethyl acetate, and then shaken vigorously. Work-up followed the procedure for the preparation of **1e** (9*a*). The major product from chromatography was 6-chloro-7-nitro-2-tetralone, which was recrystallized from hexane – ethyl acetate (0.19 g, yield 14%), mp 130–132°C. UV (1 N NaOH): 317 nm. ^{1}H NMR ($CDCl_3$) δ: 2.60 (t, J = 6.6 Hz, 2H, H4), 3.14 (t, J = 6.6 Hz, 2H, H3), 3.63 (s, 2H, H1), 7.46 (s, 1H,

Table 1. Equilibrium constants for ionization of substituted 2-tetralones and their enols and for keto–enol equilibria.

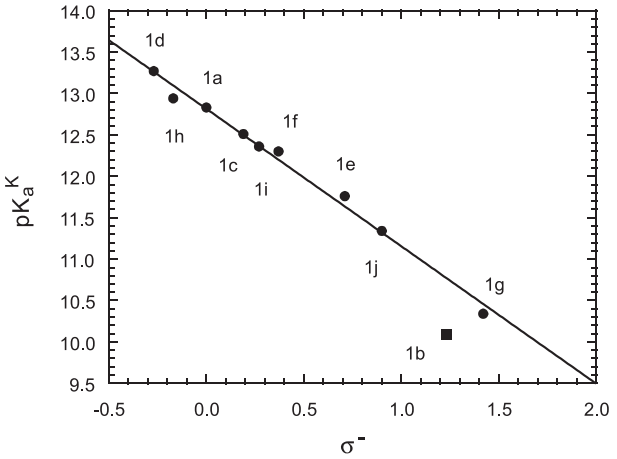
Substituent	σ^{-a}	$pK_a^{K\,b}$	pK_a^{E}	pK_E
6-MeO (**1d**)	–0.27	13.27 (± 0.05) [c]	9.64 (± 0.05)	3.63 (± 0.10)
7-Me (**1h**)	–0.17	12.94 (± 0.01)	9.52 (± 0.01)	3.42 (± 0.02)
H (**1a**)	0	12.83 (± 0.01) [c]	9.44 (± 0.04)	3.39 (± 0.05)
6-Cl (**1c**)	0.19	12.51 (± 0.03) [c]	9.31 (± 0.02)	3.20 (± 0.05)
6-I (**1i**)	0.27	12.36 (± 0.02)	9.23 (± 0.02)	3.13 (± 0.04)
7-Cl (**1f**)	0.37	12.30 (± 0.07) [c]	9.09 (± 0.06)	3.21 (± 0.13)
7-NO_2 (**1e**)	0.71	11.76 (± 0.02) [c]	8.81 (± 0.01)	2.95 (± 0.03)
6-Cl-7-NO_2 (**1j**)	0.90	11.34 (± 0.03)	8.56 (± 0.01)	2.78 (± 0.04)
5,7-$(NO_2)_2$ (**1g**)	1.42	10.34 (± 0.06) [c]	8.14 (± 0.03)	2.20 (± 0.09)
6-NO_2 (**1b**)	1.23	10.09 (± 0.02) [c]	7.69 (± 0.02)	2.40 (± 0.04)

[a] σ^- for 5,7-$(NO_2)_2$ is calculated as twice the value of σ_m for a nitro group, σ^- for 6-Cl-7-NO_2 is taken as the sum of σ_m of a nitro group and σ_p of a chloro group. σ values are from reference 13.

[b] pK_a^K's are *concentration* pK_a's based upon the concentration of all species except for the pK_a^K of **1b**, which is a *mixed* pK_a based upon concentrations of solute and activity of hydronium ion. These constants are used in the same correlation since determinations of the pK_a^K under both conditions gave essentially the same value (9*a*).

[c] Reference 9*a*.

Fig. 1. Plot of the pK_a^K of substituted 2-tetralones vs. σ^-. The slope (–1.66 ± 0.06) was calculated *without* the inclusion of the point for **1b**.



H5), 7.72 (s, 1H, H8). Anal. calcd. for $C_{10}H_8ClNO_3$: C 53.23, H 3.57, N 6.21%; found: C 53.26, H 3.63, N 6.19%.

Determination of the acidities of the ketones and the enols

Titration of the ketone was performed spectrophotometrically according to our previously described procedure (9*a*). For determination of the acidities of the enols, rapid quenching experiments were performed using a Hi-Tech QP/SF 53 stopped-flow spectrophotometer. Basic solutions of the respective tetralones were formed by mixing an aqueous solution of the tetralone (ca. 10 mM containing 6.6% v/v MeOH) with 0.1 N or 0.01 N NaOH solution in a 1:1 ratio. After a delay of 0.5–5 s, these solutions were then rapidly quenched in a 5:1 ratio with a range of buffers (containing 3.3% v/v MeOH), HOAc–NaOAc buffer (pH 4.0–6.0), KH_2PO_4–$Na_2B_2O_7$ buffer (pH 5.8–9.2), $NaHCO_3$–Na_2CO_3 (pH 9.2–11.0), or Na_2HPO_3–Na_3PO_4 (pH 11.0–12.0). The decay in the absorbance was recorded for more than 10 half-lives of a pseudo-first-order decay equation at 265 nm, except at 306 nm for **1j** and 340 nm for **1b**. The experimental temperature was 25.0 ± 0.1°C, and the ionic strength was 0.16, controlled by NaCl. The final pH of the quenching solution was determined by mixing equivalent solutions outside the stopped-flow. pH measurements were made with a Radiometer PHM85 pH meter, and were corrected for the concentration of sodium ion.

Results

Titration of substituted 2-tetralones

Substituted 2-tetralones are relatively acidic compared to most simple ketones, so that their pK_a's can be determined from direct titration in aqueous solution of hydroxide ion or buffer. We previously determined the pK_a's of compounds **1a–1g** (9*a*); in this work, pK_a's for **1h–1j** were determined similarly, and the combined results for **1a–1j** are given in Table 1. A plot of these pK_a's vs. σ^- (Fig. 1) is linear, except for the point corresponding to **1b**, with a slope ($-\rho$) of –1.66 ± 0.06, in agreement with the ρ value (1.72 ± 0.07) obtained previously with a more limited set of data from **1a**–**1g** (9*a*).

Titration of 2-tetralone enols

The relatively acidic nature of these ketones makes it possible to generate solutions of the enolate ions by mixing the ketones with solutions of sodium hydroxide. Since protonation of the enolate ion occurs more rapidly on oxygen than on carbon, the enols can be generated by quenching the enolate in an appropriate buffer. The absorbance of enol solutions of **1a**–**1j** generated in this manner was monitored at a wavelength (265 nm, except at 306 nm for **1j** and 340 nm for **1b**) where the enol has a stronger absorbance than the enolate ions. Conversion of the enol to the ketone results in a pseudo-first-order decay of the absorbance. However, the initial absorbance of the solution, obtained by extrapolation of the absorbance to the time of mixing,[2] can

[2] Since the half-life for these reactions are typically about 100 ms, and the mixing time is less than 5 ms, these extrapolations should have little error.

Fig. 2. Plot of the pK_a^E of substituted 2-tetralone enols vs. σ^-. The slope (–0.90 ± 0.03) was calculated *without* the inclusion of the point for **1b**.

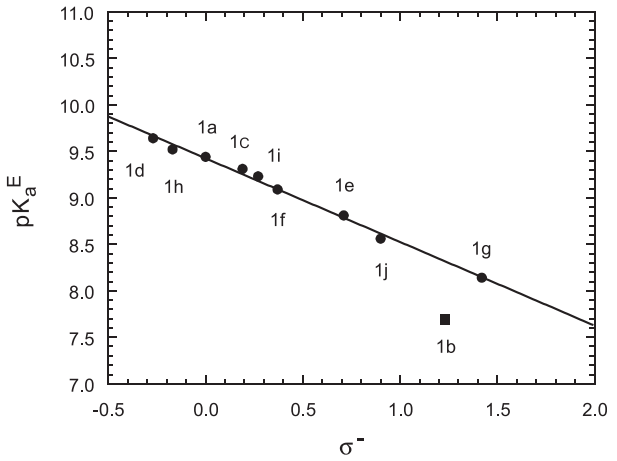

Fig. 3. Plot of the pK_E of substituted 2-tetralones vs. σ^-. The slope (–0.77 ± 0.05) was calculated *with* the inclusion of the point for **1b**.

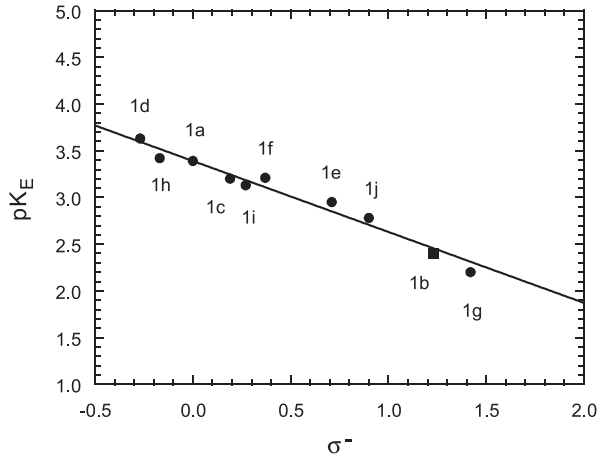

be used to determine the pK_a of the enol (pK_a^E). At this time, only the fast equilibrium between enol and enolate is observed. When this absorbance is plotted versus the pH of the final solution, a titration curve is obtained, which reflects the pK_a of the enol. These data were fit to eq. [1], where $[E]_t$ is the total concentration of enol and enolate, ε_E and ε_E^- are extinction coefficients for the enol and enolate, respectively, b is the light path length, and K_a^E is the acidity constant of the enol. The pK_a^E's for the 2-tetralone enols are summarized in Table 1. A plot of these pK_a^E's vs. σ^- is linear (ρ = 0.90 ± 0.03) with all points falling on the correlation, except the point for **1b** (Fig. 2).

$$[1] \qquad A_0 = b\,[E]_t\,(\varepsilon_E^- K_a^E + \varepsilon_E\,10^{-pH}) / (K_a^E + 10^{-pH})$$

Keto–enol equilibrium constants of 2-tetralones

The thermodynamic relationship among the ketone, enol, and enolate ion allows the equilibrium constants for the tautomerization of 2-tetralones (pK_E) in Table 1 to be calculated from the acidities of the ketones and the enols using eq. [2] (Table 1). The calculated pK_E for 2-tetralone obtained in this manner is 3.47 ± 0.04, in agreement with our previous result (3.64 ± 0.05) based on kinetics (8). A plot of pK_E vs. σ^- gives a slope (–ρ) of –0.77 ± 0.05, with all points including **1b** falling on the correlation line (Fig. 3).

$$[2] \qquad K_E = K_a^K / K_a^E$$

Discussion

Electronic effects on equilibria among 2-tetralones, their enolates and their enols

Electron-withdrawing substituents on the phenyl ring increase the acidities of both the ketones and the enols. The effect on the ketones is about twice that on the enols, with a ρ for pK_a^K of 1.66 compared to a ρ of 0.90 for pK_a^E. An instructive way to understand the decreased sensitivity to substitution of the enols compared to that of the ketones is to dissect the dissociation of the ketones into tautomerization from the ketones to the enols, followed by dissociation of the enols. Thus, a substantial portion of the electronic effect for ionization of the ketones (ca. 50%) is manifest in the enolization. The calculated ρ value of 0.76, $\rho(pK_E) = \rho(pK_a^K) - \rho(pK_a^E)$, for the tautomerization from ketone to enol shows that electron-withdrawing substituents enhance the tautomerization. Because the electron pair on the enol oxygen can be delocalized to the phenyl ring through resonance, electron-withdrawing substituents are expected to stabilize the enol more than the ketone. A similar result was obtained by Albrecht, who found a ρ value of 0.72 (with σ^-) for the enolization of 2-arylpropionaldehydes in DMSO (5). However, it is difficult to directly compare this value with the ρ for the tetralone series due to the difference in solvent composition in the two systems.

Keeffe and Kresge (11) have noted that there is a linear relationship between pK_a^K and pK_E, with a slope of 1.4, for a wide variety of simple aldehydes and ketones. This relationship demonstrates that structural effects on ketone acidity are due in large part to their effects on the keto–enol equilibria. Compounds with α-aryl substituents show deviations from this correlation in the direction of greater acidity of the carbonyl compound than predicted. Thus, 2-tetralone itself is approximately $10^{6.4}$-fold more acidic than acetone, but the relative acidities of the enols differ by only $10^{1.7}$-fold (8, 12). Therefore, the effect of the α-phenyl group on the dissociation of the ketone is predominantly due to an effect on the stability of the double bond, with little contribution from an effect on enol acidity. In contrast, electronic effects of ring substituents on enol acidity for the 2-tetralones are substantial, with the effect on ketone acidity due in almost equal parts to effects on enolization and enol acidity.

***p*-Nitro group as a probe for charge transfer**

For a Hammett plot of pK_a vs. σ^-, a negative deviation of *p*-nitro substituted compound means that the charge transfer for this specific equilibrium is larger than that upon ionization of phenol (the defining reaction), and zero deviation means a similar degree of charge transfer. From the plot of the pK_a's of both the ketone and the enol (Figs. 1 and 2), a negative deviation, or "enhanced" acidifying effect (9*a*), of 6-nitro-2-tetralone (**1b**) is observed. We previously attributed the enhanced effect of a 6-nitro group on the acidity of the 2-tetralone (10-fold) to the lack of a free electron pair on

© 1999 NRC Canada

the C-1 carbon (9*a*). Thus, no resonance stabilization for the 6-nitro group in the free tetralone is lost upon ionization. In contrast, in the ionization of phenol there is compensating resonance in the un-ionized acid.

Surprisingly, however, although direct resonance is possible for both the enol and the enolate, the acidity of the *enol* of 6-nitro-2-tetralone is also greater than predicted from the correlation with σ^- based on the other substituted enols (ca. 7-fold) (Fig. 2). Thus, relative to the ionization of *p*-nitrophenol, there is a greater increase in *direct* resonance interaction between the oxygen of the enol(ate) and the nitro group upon ionization. This result suggests that there is diminished stabilization of the enol by charge transfer from the hydroxyl group of the enol to the nitro group, consistent with the proposal of Toullec that the conjugation of the aryl ring with the double bond involves little π electron transfer for β-aryl enols (1).

The extent of charge transfer into the phenyl ring in the enol of 2-tetralone may also be probed by a consideration of the substituent effect on the enolization. A plot of pK_E vs. σ^- is linear, but in this case the point for 6-nitro-2-tetralone lies on the correlation line. If there were no direct resonance interaction between the hydroxyl group of the enol and the 6-nitro group, it would then be expected that this equilibrium would show a correlation with σ rather than with σ^-. Thus, this result suggests that there still is some direct resonance interaction between the hydroxyl group of the enol and the phenyl ring, although significantly less than there is in the enolate anion.

Electrophilic aromatic substitution in substituted anilines; kinetics of the reaction with 4,6-dinitrobenzofuroxan

Michael R. Crampton, Lynsey C. Rabbitt, and François Terrier

Abstract: Kinetic results are reported for reaction of aniline and six of its *N*- and ring-substituted derivatives with 4,6-dinitrobenzofuroxan (DNBF) in water – dimethyl sulfoxide mixtures. In acidic solution σ-adducts, the result of electrophilic substitution in the anilines, are formed with bonding between a ring-carbon atom of the anilines and the 7-position of DNBF. Reaction normally occurs at the 4-position of the aniline unless this carries a substituent, when reaction occurs at the 2-position. A value of 2.0 for k_H/k_D, the kinetic isotope effect, indicates that in the reaction with aniline bond formation is largely rate determining in the substitution pathway. The results allow estimates to be made for the pK_a values relating to carbon protonation of the anilines.

Key words: electrophilic substitution, σ-adducts, 4,6-dinitrobenzofuroxan, ambident reactivity of anilines.

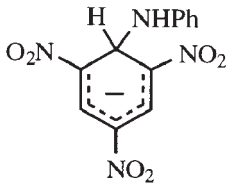
Résumé : On rapporte les données cinétiques relatives à la réaction de l'aniline (et six de ses dérivés substitués sur l'azote et sur le noyau) avec le 4,6-dinitrobenzofuroxane (DNBF) dans des mélanges formés d'eau et de diméthylsulfoxyde. En solutions acides, il se forme des adduits-σ, résultant d'une substitution électrophile sur les anilines, qui lient un atome de carbone du noyau des anilines et la position 7 du DNBF. La réaction se fait généralement en position 4 de l'aniline, à moins que cette position porte un substituant; la réaction se fait alors en position 2. Une valeur de 2,0 pour l'effet isotopique cinétique, k_H/k_D, indique que, dans cette réaction la formation de la liaison avec l'aniline constitue l'étape cinétiquement déterminante de la réaction de substitution. Les résultats permettent d'évaluer les valeurs de pK_a associées à la protonation du carbone des anilines.

Mots clés : substitution électrophile, adduits-σ, 4,6-dinitrobenzofuroxane, réactivité ambidente des anilines.

[Traduit par la Rédaction]

Aniline and its substituted derivatives usually act as nitrogen nucleophiles. Thus, reaction with 1,3,5-trinitrobenzene (1, 2) in dimethyl sulfoxide (DMSO) in the presence of a strong base gives N-bonded σ-adducts, **1**; reaction with substrates carrying good leaving groups may result in substitution leading to diphenylamine derivatives (3–5).

Nevertheless, the ambident reactivity of aniline and its derivatives has been shown in reactions with 4,6-dinitrobenzofuroxan, DNBF. Here σ-adducts have been observed



1

involving nucleophilic attack either through nitrogen or through a ring carbon atom *para*- or *ortho*- to the amino function (6–10).

The high electrophilic reactivity of DNBF is well known (5, 11, 12). In fact, it has been shown to be a more powerful electrophile than the 4-nitrobenzenediazonium ion (13) or the proton (14). Previously kinetic studies have been reported of electrophilic substitutions involving reactions of DNBF with pyrroles (14), 5-substituted indoles (13), 3,4-diaminothiophene (15), 3-methoxythiophene (16), and hydroxy- and methoxy-substituted benzenes (17). In the present work, we report kinetic studies of the reactions of aniline and some *N*-substituted or ring-substituted derivatives with DNBF in water–DMSO mixtures. Measurements were made in acidic solutions where the anilines are very largely protonated. Here the results are in accord with the reactions, shown in Scheme 1, leading to the formation of carbon bonded σ-adducts. In the case of anilines **2a**–**e**, reaction was found to occur *para* to the amino position. However,

when the 4-position is blocked, reaction occurs *ortho* to the amino function to yield products **5f** and **5g**.

These reactions may be regarded as neutral nucleophile–electrophile combination reactions (18), and are examples of electrophilic substitution in the aniline ring. The powerful activating effect of the amino group towards electrophilic substitution in aromatic systems has been noted previously (19, 20). There are many examples of halogenation (21, 22) and of hydrogen exchange (23) in aniline derivatives. One of the aims of the present work was to use the reaction with DNBF to compare the reactivity of aniline with other aromatic systems.

Results and discussion

^{1}H NMR spectra have been reported previously for the products of reaction of DNBF and several amines (6–10). Our results relating to 1:1 mole ratio mixtures of DNBF and amines **2a**–**g** in [$^2H_6$] DMSO are given in Table 1. The spectra, showing bands at δ 5.3–5.6 and δ 8.7 for the hydrogens at the 7′ and 5′ positions of DNBF, are typical of C-adduct formation (5, 13, 14, 17), consistent with the production of **4a**–**e**. In 4-substituted anilines, the band due to the 7′ proton is at δ 5.8, consistent with the formation of **5f** and **g**. In solutions containing higher mole ratios of aniline to DNBF, there was NMR evidence for the kinetically controlled formation of N-bonded adducts followed by conversion to the thermodynamically more stable C-bonded adducts. In the case of aniline, **2a**, bands due to the N-bonded adduct were at δ 6.04 and 8.64, at positions similar to those reported previously (10).

Kinetic measurements were conveniently made in water–DMSO mixtures. Most data relate to a solvent composition of 30/70 (v/v) water/DMSO, although for comparison some measurements using aniline were made in 70/30 and 50/50 (v/v) water/DMSO mixtures. All measurements were made in the presence of excess hydrochloric acid. This had the effect of reducing the concentrations of free amines to very low levels, and under these conditions there was no evidence for nucleophilic attack via the nitrogen centre of the anilines.

[1] DNBF + H_2O $\rightleftharpoons$ (**6**) + H^+

(**6**)

A further beneficial effect of the acidic media was to reduce the equilibrium concentrations of the hydroxy adduct, **6**, of DNBF which is known to form in neutral media, as shown in eq. [1].

Spectrophotometric measurements, using the absorbance of **6** at 470 nm, gave values for K_{H_2O}, defined in eq. [1], of 0.0196 ± 0.0008 mol dm^{-3} in 70% DMSO and 0.0045 ± 0.0002 mol dm^{-3} in 50% DMSO. These values are in excellent agreement with literature values of 0.019, 0.0040, and 0.00080 mol dm^{-3} in media containing 70, 50, and 30% DMSO, respectively (24).

Reaction with aniline

The equilibrium between DNBF and **6** is established rapidly. Similarly, any adduct formation resulting from attack of aniline as a nitrogen nucleophile on DNBF will be a rapid process (3, 5). The UV/visible spectra in Fig. 1 show that in acidic solutions there is a slow reaction between DNBF and aniline, giving a band at 489 nm. In view of the NMR data, this is attributed to the C-bonded adduct **4a**. It has been reported (9, 10) that di-adducts may be formed by reaction of both N- and C-centres of an aniline molecule with two molecules of DNBF. There was no evidence for such 1:2 interaction in our systems, which contain very low, 4 × 10^{-5} mol dm^{-3}, concentrations of DNBF. Kinetic data, with concentrations of aniline hydrochloride and free hydrochloric acid in large excess of the DNBF concentration, indicated that adduct formation was an accurately first-order process. Values of k_{obs}, the measured rate constant, are in Table 2. The results show that at constant concentration of free acid, values increase linearly with the concentration of aniline hydrochloride. However, values decrease with increasing acid concentration. This observation indicates that reaction is likely to involve free aniline rather than its protonated form. Hence, we define by eq. [2] a rate constant *k*, which is related by eq. [3] to the constants for individual steps shown in the scheme. There is no evidence from NMR or UV/visible spectra of the accumulation of **3**, the intermediate in the substitution pathway. It may be shown that *k* is related to k_{obs} by eq. [4], where K_a is the acid dissociation constant of the anilinium ion. This equation allows for the small concentration of the hydroxy-adduct **6** in equilibrium with DNBF. In 70/30 (v/v) DMSO/water, the pK_a value for the anilinium ion is known to be 3.41 (25). Hence, at the acid concentrations used [H^+] >> K_a, allowing eq. [4] to be simplified to give eq. [5].

Fig. 1. UV-vis spectra for the reaction in 30/70 (v/v) water/DMSO of DNBF, 4 × 10^{-5} mol dm^{-3}, with aniline hydrochloride 0.05 mol dm^{-3} and hydrochloric acid 0.03 mol dm^{-3}. The absorbance at 489 nm increases with time.

[b]Measured at 494 nm.

[c]Calculated from eq. [5] with K_a 8.7×10^{-4} mol dm^{-3} and K_{H_2O} 0.0196 mol dm^{-3}.

$$[4] \qquad k_{obs} = k[\text{aniline } H^+]\left(\frac{K_a}{K_a + [H^+]}\right)\left(\frac{[H^+]}{[H^+] + K_{H_2O}}\right)$$

$$[5] \qquad k = \frac{k_{obs}}{K_a}\frac{(K_{H_2O} + [H^+])}{[\text{aniline } H^+]}$$

The invariance of values, in Table 2, of k with acid concentration or aniline hydrochloride concentration confirms that reaction involves free aniline rather than the anilinium ion.

The availability of pentadeuterioaniline, $C_6D_5NH_2$, allowed the evaluation of the kinetic isotope effect, k_H/k_D, on the substitution reaction. Measurements were made in media containing 70, 50, and 30% DMSO by volume and are reported in Table 3. For accuracy of comparison, measurements were made simultaneously on deuteriated and nondeuteriated systems using the multicell facility in the

spectrophotometer. These values, rather than the value of 3.7 dm^3 mol^{-1} s^{-1} for k_H in 70% DMSO, were used in the calculation of the isotope effect. It is known that ring-deuteriation has only a small effect on the acidity of anilinium ions (26), thus in water values are 4.71 for $C_6H_5NH_3^+$ and 4.74 for $C_6D_5NH_3^+$. We have assumed that values for K_a are unaffected by deuteriation in the DMSO–water mixtures. The overall value of k contains contributions from k_1, k_2, and k_{-1} as indicated in eq. [3]. It is likely that the values of k_1 and k_{-1} will show only small changes with isotopic substitution, since these involve secondary isotope effects. However, the value of k_2 that involves carbon–hydrogen bond cleavage is likely to show a primary isotope effect of ca. 7. These assumptions, together with the observed value of k_H/k_D = 2.1, lead to a value for k_{-1}/k_2 of 0.2 for aniline with k_1 = 1.2k. This indicates that, as with most electrophilic substitution reactions (19), the k_1 step, the initial attack, is largely rate determining. A similar situation was reported in reactions of

DNBF with substituted indoles (13, 14). However, in reactions with 1,3,5-trimethoxybenzene, a larger isotope effect was observed showing that here proton loss from the intermediate is more kinetically significant (17).

Our results show that for substitution in aniline, the value of the isotope effect is independent of the solvent composition in the range 30–70% DMSO. The small increase in k from 1.1 dm^3 mol^{-1} s^{-1} in 30% DMSO to 4.2 dm^3 mol^{-1} s^{-1} in 70% DMSO is thus likely to reflect a similar increase in value for k_1. This may indicate slightly better solvation by DMSO than by water of the charged polarizable intermediate **3**. The value of the rate constant for attack of water on DNBF shown in eq. [1] also increases with DMSO content of the solvent (24).

[b]pK_a values in water for protonation on carbon

[c]Values of k in 30/70 water/DMSO were multiplied by 2.3/4.0.

Reaction with substituted anilines

Data analogous to that reported in Table 2 were obtained for reaction of DNBF with the substituted anilines **2b**–**g**. Results are given in Tables 4–9. Values of k calculated from eq. [5] using the value of K_a appropriate to the particular substituted anilinium ion are summarized in Table 10.

The results show that the value of k, the rate constant for adduct formation, increases on *N*-methylation. However, further methylation to give the *N*,*N*-dimethyl derivative results in a reduction in reactivity. Successive *N*-methylations might be expected to increase reactivity by increasing the electron releasing ability of the amino group. Thus σ^+ values (27, 28) are –1.30 for *para*-NH_2 and –1.70 for *para*-NMe_2, with the NHMe group showing intermediate behaviour (29). However these σ^+ values relate to largely aqueous media, while our results were obtained in media rich in DMSO. It is known that DMSO is an extremely good hydrogen-bond acceptor (30, 31), and in this solvent the stabilization of the cationic moiety of the intermediate, **3**, will be expected to increase as the number of NH bonds available for hydrogen-bonding increases. This effect may temper the increase in electron donation expected on *N*-methylation. A similar argument may be used (25) to explain the reduced acidity of the anilinium ion, pK_a = 3.41, in DMSO–water relative to the *N*,*N*-dimethyl derivative, pK_a = 2.99.

The values of k for reaction at the 4-positions of **2d** and **2e** are considerably higher than that for aniline. Here the electron releasing effect of the 3-substituent is dominant with σ^+ values reported as –0.31 for methyl and –0.78 for methoxy (32). There may be some steric retardation here, since the substituents are *ortho* to the reaction centre.

When the 4-position is blocked, reaction occurs at the 2-position, *ortho* to the amino function. Here the values for k are reduced relative to that for aniline. These reductions probably represent a steric effect to nucleophilic attack, although steric inhibition of solvation in the intermediates leading to the adducts **5** is a possibility.

Rate constants are available (17) for reaction, in 50/50 (v/v) water/DMSO, of DNBF at the 4-position of 1,3-dimethoxybenzene (0.52 dm^3 mol^{-1} s^{-1}) and with 1,3,5-trimethoxybenzene (205 dm^3 mol^{-1} s^{-1}). Comparison of these values with data in Table 10 shows that the 4-amino group is considerably more activating, in terms of carbon nucleophilicity, than the 4-methoxy group.

Comparison with other π-excessive aromatics

It is of interest to compare our results for the nucleophilicity of aniline derivatives towards DNBF with those for other arenes. Most of the literature data refer to a solvent system of 50/50 (v/v) water/DMSO, whilst our data generally refer to 30/70 (v/v) water/DMSO. However, for aniline we have data in both media and have assumed that the solvent effect will be similar for substituted derivatives. Data are in Table 11. It has been shown previously (16) that there is an approximately linear relationship between carbon nucleophilicities towards DNBF, and pK_a values in water for carbon protonation. On the assumption that the anilines obey the same relationship, the pK_a values for C-protonation may be estimated. For aniline and its N-methylated derivative values of ca. –6 to –5 are obtained, while values for 3-methylaniline and 3-methoxyaniline are ca. –4.7 and –3, respectively. The results clearly show that in water N-protonation of the anilines, with pK_a ca. 4, is strongly favoured over ring protonation.

Experimental

4,6-Dinitrobenzofuroxan was prepared by the Drost method (33); mp 172°C (lit. (16, 33) 172–174°C). All other reagents and solvents were the purest available commercial products.

^{1}H NMR spectra were recorded using a Varian Mercury 200 MHz spectrometer. UV-vis spectra and kinetic measurements were made at 25°C with a Perkin–Elmer Lambda 2 spectrophotometer, a Shimadzu UV-2101 PC spectrometer, or an Applied Photophysics SX-17 MV stopped-flow spectrophotometer. Reported rate constants are the means of several determinations and are precise to ±5%. Potassium chloride was used to maintain ionic strength I ($\equiv (1/2)\Sigma c_i z_i^2$) 0.1 mol dm^{-3} in those solutions with lower ionic concentrations.

^{15}N nuclear polarization in the reactions of diallyl ether with nitrogen dioxide

Robert P. Claridge, Ross W. Millar, and John H. Ridd

Abstract: The reaction of diallyl ether with nitrogen dioxide in organic solvents yields a mixture of *cis* and *trans* 2,3-bis(nitromethyl)-tetrahydrofurans, *cis* and *trans* 2-nitratomethyl-3-nitromethyl-tetrahydrofurans and a number of straight-chain compounds with one to four nitro groups. Under the conditions used, the cyclic compounds form the main products when the solution of nitrogen dioxide is slowly added to the solution of diallyl ether but not when the reverse mode of addition is used. When ^{15}N-nitrogen dioxide is used, the products show strong ^{15}N nuclear polarization: the 2,3-di(nitromethyl)-tetrahydofurans give an emission signal, and one straight-chain product with two nonequivalent nitro groups shows both an emission signal and an enhanced absorption signal. For both the cyclic and straight-chain products, the nuclear polarization is consistent with the successive reactions of diallyl ether with two nitrogen dioxide radicals with uncorrelated spins.

Key words: diallyl ether, nitrogen dioxide, ^{15}N nuclear polarization, CIDNP.

Résumé : La réaction de l'oxyde de diallyle avec le bioxyde d'azote dans des solvants organiques conduit à un mélange de *cis*- et *trans*-2,3-bis(nitrométhyl)tétrahydrofuranes, de *cis*- et *trans*-2-nitratométhyl-3-nitrométhyltétrahydrofuranes et d'un certain nombre de composés linéaires portant d'un à quatre groupes nitro. Dans les conditions utilisées, les composés cycliques sont les principaux produits lorsqu'on additionne le bioxyde d'azote lentement à la solution d'oxyde de diallyle; ce n'est toutefois pas le cas lorsqu'on fait l'addition inverse. Lorsqu'on utilise du bioxyde d'azote marqué au ^{15}N, les produits montrent une forte polarisation nucléaire du ^{15}N: les 2,3-di(nitrométhyl)tétrahydrofuranes donnent un signal d'émission et un produit linéaire portant deux groupes nitro non équivalents donne un signal d'émission ainsi qu'un signal d'absorption augmenté. Pour les produits tant cycliques que linéaires, la polarisation nucléaire est en accord avec les réactions successives de l'oxyde de diallyle avec deux radicaux de bioxyde d'azote ayant des spins n'ayant pas de corrélation.

Mots clés : oxyde de diallyle, bioxyde d'azote, polarisation nucléaire du ^{15}N, « CIDNP ».

Introduction

The reaction of electrophilic radicals with diallyl ether has been known for many years to lead both to addition to the double bonds and to cyclization to form derivatives of tetrahydrofuran (1). The cyclization reaction was first established in the free radical induced reaction of perfluoroalkyl iodides with diallyl ether (1) but similar results are obtained in the photochemical reaction of tosyl iodide and tosyl bromide with diallyl ether (2). The radical addition of tetrafluorohydrazine to diallyl ether is accompanied by about 50% cyclization to derivatives of tetrahydrofuran (3). The ready cyclization of diallyl ether following radical addition to one of the double bonds has been discussed by Beckwith and Schiesser (4). However, other products can be formed: thus, the reaction of diallyl ether with *tert*-butoxy radicals leads instead to H-abstraction (5).

The present work involves the reaction of diallyl ether with nitrogen dioxide in organic solvents.[2] This is an extension of our previous studies on the reactions of nitrogen dioxide with alkenes (6) and dienes (7) and offers the possibility of comparing the extent of ^{15}N nuclear polarization in the addition and cyclization reactions.

Results

To determine the product composition, the reactions were carried out by the mixing of solutions of nitrogen dioxide and diallyl ether in the same organic solvent. When reaction was complete, the solvent was removed under reduced pres-

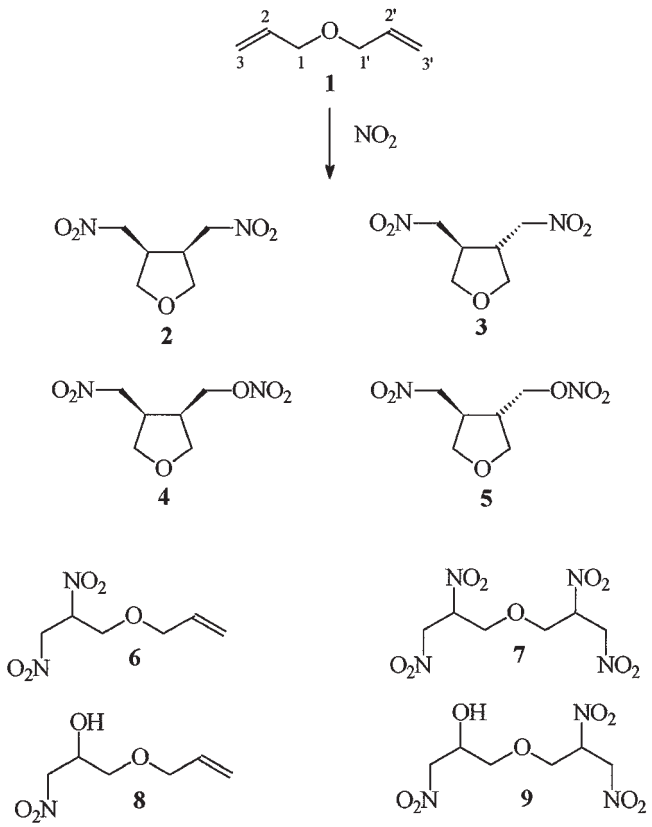
Scheme 1.



sure, and after separation by HPLC, the products were identified by a combination of ^1H and ^{13}C NMR spectroscopy and CI mass spectrometry; with some labelled compounds, ^{15}N NMR spectroscopy was also used. Plots of the NMR spectra are available elsewhere (7). The products identified are shown in Scheme 1. In this identification, the ^{13}C NMR spectra were of particular value for the high field signal at ca. 40 δ_C was characteristic of the cyclic compounds (1), and the patterns of signals from combinations of the $CH_2NO_2CHNO_2$-, CH_2NO_2CHOH-, and CH_2 = CH– groups were easy to recognize. The ^{13}C signals are compared with those calculated from an empirical program (8) in Table 1. In the identification of the *cis* and *trans* cyclic compounds, we have relied on earlier arguments (1*b*) that the ^{13}C signals in related *trans* compounds are slightly downfield to those in the *cis* compounds.

The product composition is very sensitive to the order of mixing of the reagents. The results for the runs in Table 2 show that, when the solution of nitrogen dioxide is added to the solution of diallyl ether, the major products are the cyclic tetrahydrofuran derivatives **2**–**5**, but when the solution of diallyl ether is added to the solution of nitrogen dioxide, the major products are the open-chain derivatives **7** and **9**. The combined yields in Table 2 show that a considerable amount of material remained unidentified in each run, and the small yields of the cyclic compounds in the third run were not separated into the *cis* and *trans* compounds.

The studies of ^{15}N nuclear polarization were carried out using ^{15}N labelled nitrogen dioxide (99% ^{15}N). Because of

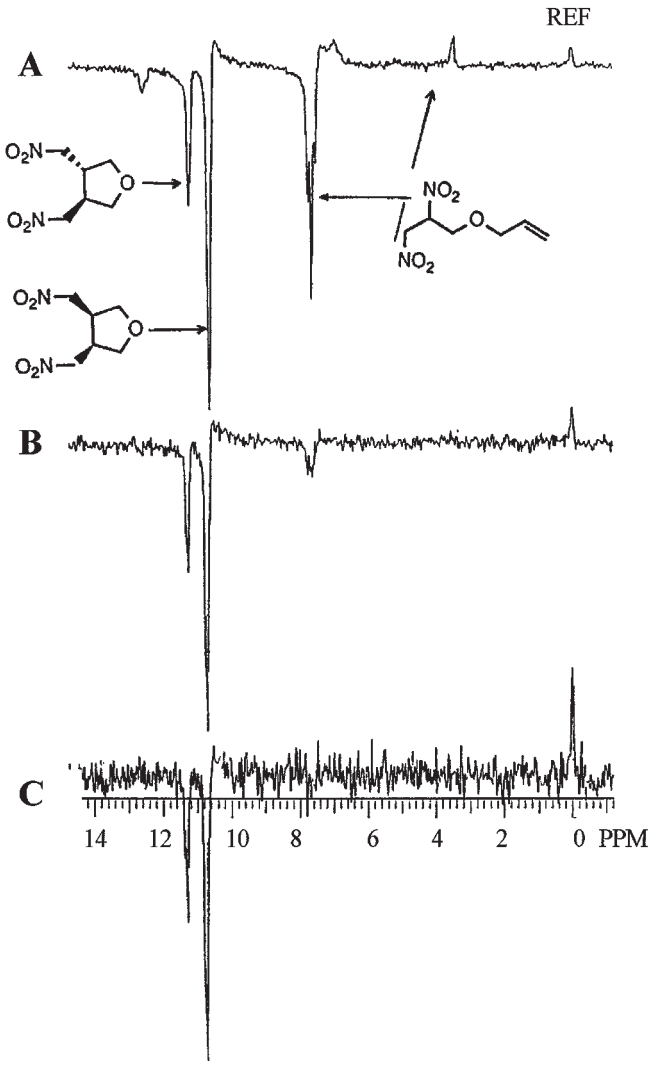
the speed of the reaction, the solution of diallyl ether in an NMR tube was very rapidly mixed with rather more than 2 equiv. of labelled nitrogen dioxide in the same solvent ($CDCl_3$); the tube was then frozen with liquid nitrogen and allowed to thaw out in the cavity of the NMR machine. Analysis of the products formed under these conditions, including some experiments on a somewhat larger scale, showed that the main products are the tetrahydrofuran derivatives **2**, **3** and the open-chain derivatives **6** and **8**. These were isolated from the reaction mixtures, and the ^{15}N NMR chemical shifts are listed in Table 3. The distinction between the ^{15}N signals in the dinitro compound **6** was based on the complexity of the coupling, for the nitrogen atom on C^3 is coupled to three protons but that on C^2 is coupled to five protons.

The ^{15}N NMR spectrum of the products taken after complete reaction in deuterochloroform is shown in Fig. 1 together with the identification of a number of the peaks. The *cis* dinitro compound **2** is the predominant cyclic product; this accords with the results obtained in dichloromethane (Table 2). The very different ^{15}N NMR spectra obtained during reaction are shown in Fig. 2: both cyclic dinitro compounds give emission signals and, for the open-chain dinitro compound **6**, the signal of one nitro group appears in emission and that for the other appears in enhanced absorption (compare with the signal for nitromethane present as a reference).

Discussion

The formation of the straight-chain products listed in Scheme 1 is consistent with what is known concerning the

Fig. 2. ^{15}N NMR spectra taken during the reaction of diallyl ether with nitrogen dioxide in deuterochloroform. Times: *A*, 1 min; *B*, 3 min; *C*, 5 min.



addition of nitrogen dioxide to unsaturated systems (6). The first nitrogen dioxide molecule appears always to add via a C—N bond and at the position that gives rise to the most stable radical; the subsequent reaction of this radical with a second nitrogen dioxide molecule gives a mixture of products resulting from addition via the nitrogen or via the oxygen. The nitroalcohols are presumably formed from the ready hydrolysis of the initial nitronitrites. It is also entirely reasonable that the addition of the solution of nitrogen dioxide to that of diallyl ether should give mainly the cyclic products, while the reverse mode of addition should give mainly the open-chain products, for the presence of excess nitrogen dioxide in the solution should favour addition (Scheme 2, Path B) rather than cyclization (Scheme 2, Path A).

The formation of the cyclic nitronitrates **4** and **5** rather than the corresponding nitroalcohols was unexpected but when the major part of the reaction follows the cyclization pathway, there must be excess nitrogen dioxide left in the solution, and this may lead to the oxidation of any cyclic nitronitrites to nitronitrates. This formation of nitronitrates in the reaction of phenanthrene with nitrogen dioxide has

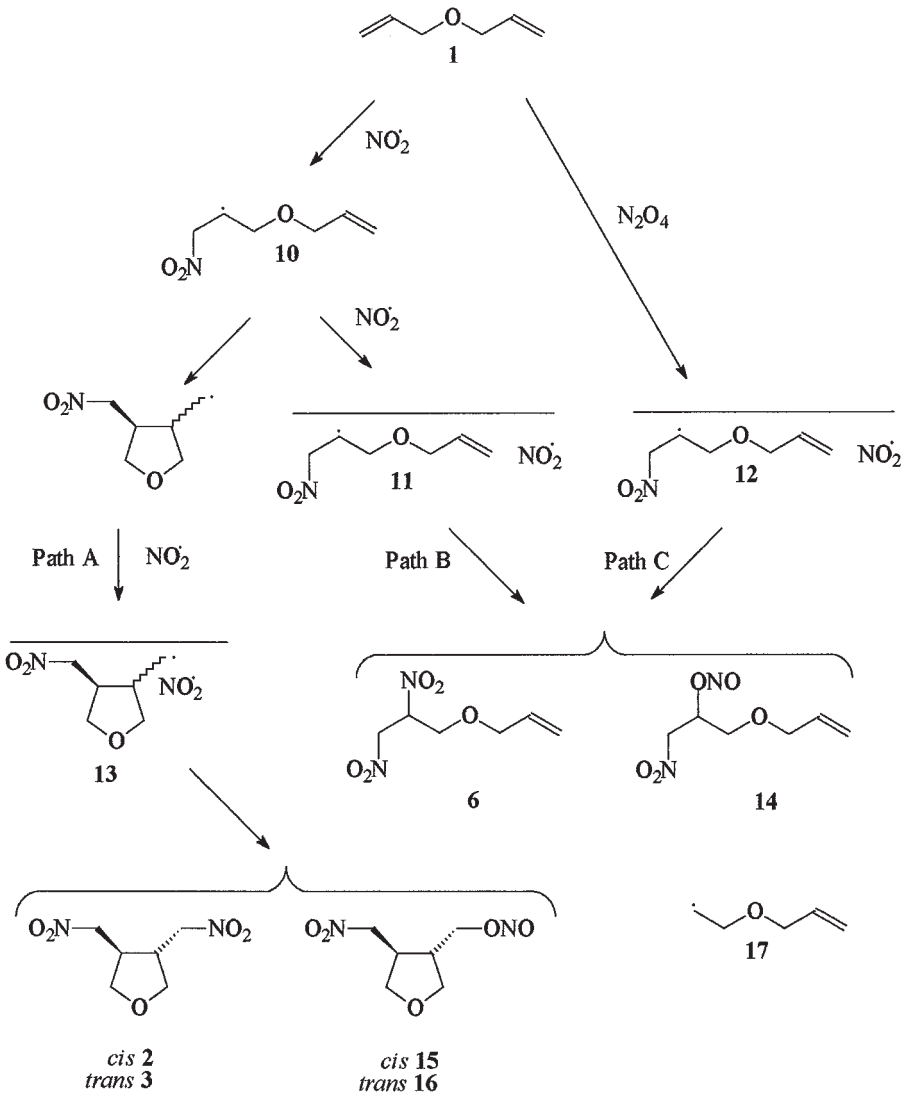
Scheme 2.



been ascribed to the reaction of the first-formed nitronitrites with nitrogen dioxide (9). The absence of a corresponding nitronitrate from the open-chain products identified (Scheme 1) is curious but there may not be a problem here for the ratio of products formed in these reactions of diallyl ether depends very much on the conditions and ca. 10–30% of the products were unidentified (Table 2).

In considering the ^{15}N polarization observed during reaction (Fig. 2), it is simplest to look first at the open-chain product **6**. Here the nitrogen atom at C^3 gives an absorption signal and that at C^2 gives an emission signal. This is as expected from Kaptein's rules (10) as applied to the ^{15}N nucleus (11) for the reaction of the radical **11** with molecular nitrogen dioxide on the reaction path shown in Scheme 2, Path B. Following earlier discussions (12, 13), the *g*-value of the NO_2 radical has been taken (14) to be 2.0000 and the *g*-values of the organic radicals to be >2.0000; this is in agreement with the listed *g*-values for a wide range of related carbon radicals (15). In this argument, the radical pair **11** is considered to be formed by the diffusion together of the radicals; the radical pair has therefore uncorrelated spins and (in the terminology of Kaptein (10)) is an F-precursor. With the cyclic dinitro compounds, the ^{15}N NMR signals of the two nitro groups are superimposed, but since the signal from the second nitro group should be the stronger,[3] the overall signal should be in emission, as observed.

The above observations accord with those found in the addition of nitrogen dioxide to alkenes (13), but in one respect, the present observations provide further evidence on the reaction mechanism. Although the previous studies of ^{15}N nuclear polarization were consistent with the reaction of the alkene with two separate nitrogen dioxide molecules, the earlier work left open the possibility that the major part of the product was formed through the reaction of the alkene with molecular dinitrogen tetraoxide (Scheme 2, Path C); a possibility given some support from kinetic studies of re-

[3] In the radical pair **13**, the ^{15}N hyperfine coupling constant of the nitrogen dioxide radical should be greater than that of the nitro group attached to the organic radical.

© 1999 NRC Canada

lated reactions (16, 17). Since the radical pair **12** shown in Scheme 2, Path C, is necessarily formed in a singlet state (an S-precursor (10)), the resulting ^{15}N nuclear polarization for each nitrogen atom in the product should be of opposite phase to that formed in Scheme 2, Path B, and probably also considerably weaker, since none of the radical pairs on Path C requires a triplet–singlet transition for combination to occur. Hence, the signals observed previously, and for the dinitro compound **6** in the present work, could also be the resultant polarization from the combination of the reaction Paths B and C in Scheme 2.

However, in the present work, the cyclic dinitro compounds can hardly be formed by a direct reaction with dinitrogen tetraoxide because of the time required for cyclization to occur. The presence of the nuclear polarization implies that the reaction of such singlet radical pairs as **12** occurs within approximately the time of a molecular encounter, and although the time required for the radical **10** to undergo cyclization is probably very short,[4] it must still be long in comparison with the lifetime of the singlet radical pair **12**. Hence, the nuclear polarization observed in the formation of the cyclic structures **2** and **3** must reflect simply the path involving successive reactions with two separate nitrogen dioxide molecules. It is then significant that the comparison of the signals during and after reaction shows that the enhancement of the signals is approximately the same for the cyclic and straight-chain structures. The relative intensities of the signals for the two cyclic structures and that for the "second" nitro group of **6** (also initially in emission) are very similar in the first polarized spectrum (spectrum **A**, Fig. 2) and the final spectrum (Fig. 1). For the straight-chain structure **6**, there is therefore no indication here of any major contribution from the separate reaction path (Scheme 2, Path C) involving attack by dinitrogen tetraoxide and leading to the opposite phase of ^{15}N nuclear polarization. The greater persistence with time of the emission signals for the cyclic structures (Fig. 2, spectra B and C) can be understood if, in the final stages of the reaction, cyclization predominates over the addition of nitrogen dioxide to the double bonds. This is, of course, the expected consequence of the fall in the concentration of nitrogen dioxide in the solution.

We conclude therefore that, under the conditions used, the reaction of diallyl ether with nitrogen dioxide occurs predominantly by the successive reactions of the substrate with two nitrogen dioxide radicals with uncorrelated spins.

Experimental

Materials

The nitrogen dioxide was obtained from ARGO International. It was purified by distillation over phosphorus pentoxide in a stream of dry oxygen using an all glass apparatus. The resulting white solid was kept over phosphorus pentoxide in a deep freeze at –16°C. ^{15}N-labelled nitric acid (99.5% ^{15}N) was obtained from MSD isotopes. Diallyl ether (99% purity) was obtained from Aldrich and was used without further purification. Dichloromethane and hexane were high-purity solvents obtained from Romil; they were refluxed over calcium hydride and under nitrogen for an hour before use and then distilled and collected over preactivated 3 Å molecular sieves and degassed using ultrasound.

^{15}N-nitrogen dioxide was prepared by heating lead ^{15}N-nitrate in an all glass apparatus flushed with argon before and after reaction. The product (yield 83%) was collected as white crystals in a trap at –80°C. The labelled lead nitrate was obtained from the reaction of a suspension of lead oxide (Aldrich) with aqueous ^{15}N-nitric acid. After stirring for 3 h, the solution was filtered and the solvent removed under reduced pressure to yield ^{15}N-labelled lead nitrate (yield 100%).

Experimental procedure

The preparation of the solutions and the reactions were carried out under nitrogen. In the experiments carried out to identify the products formed, a solution of nitrogen dioxide was added to a stirred solution of diallyl ether in the same solvent using a syringe pump. The reactions were carried out either at room temperature or at 0–5°C. In some experiments, the order of addition was reversed. The usual time of addition was 30 min.

After addition was complete, stirring was continued for ca. 3 h, and the solvent was then removed under reduced pressure. The reaction mixture was passed down a "flash" silica column eluting with ethyl acetate, and the products were then separated by HPLC using 2 × 25 cm × 1 cm silica columns (particle size 0.005 mm) and refractive index detection. When the molar ratios of diallyl ether:nitrogen dioxide were 1:2, the mobile phase employed was ethyl acetate:hexane (1:4 vol/vol), but when the corresponding molar ratios were 1:4, a mobile phase of ethyl acetate:hexane (1:1 vol/vol) was used first to remove the more polar components; the remaining components were then separated as before. The apparatus used included a Waters M6000 pump, a Waters R401 refractive index detector, a Rheodyne injection valve, and a Hewlett Packard integrator HP 3396a. The yields were estimated from the weights of material isolated or the relative areas of the HPLC peaks after calibration.

The ^{1}H, ^{13}C, and ^{15}N NMR spectra of the separated products were carried out in deuterochloroform or acetone-d_6 using a 400 MHz Varian VXR400 spectrometer. The CIMS measurements were carried out at the London University School of Pharmacy using ammonia as the ionizing gas.

Reactions and products

Compounds **2**–**9** appear to be new but, unfortunately, it has not been possible to characterize them completely. The experiments were carried out on a small scale partly because of the possible danger of explosions with the polynitro compounds and partly because of the cost of the ^{15}N labelled nitrogen dioxide. The ^{13}C NMR chemical shifts are given in Table 1, the ^{15}N NMR chemical shifts are given in Table 3, and the details of the ^{1}H NMR spectra and CIMS spectra are given below.

The first run described below is an example of the "normal" mode of addition (adding the solution of nitrogen dioxide to the solution of diallyl ether); the second run is an example of the reverse mode of addition. The product yields are those listed for the second and third runs in Table 2.

[4] The rate coefficient for the cyclization of the related radical **17** has been given as 8.5×10^6 s^{-1} (4).

A solution of diallyl ether in dichloromethane at 0°C was added dropwise over a period of 30 min to a stirred solution of nitrogen dioxide in dichloromethane at the same temperature. The reaction mixture was stirred for a further 2 h at 0°C, and the solvent was then removed under reduced pressure yielding a yellow oil. After a product analysis as described above, the reaction yielded a mixture of the two 2,3-bis(nitromethyl)-tetrahydrofurans **2** and **3**, a mixture of the two 2-nitratomethyl-3-nitromethyl-tetrahydrofurans **3** and **4**, and the following.

Bis*(2,3-dinitropropyl) ether* ***7***: ^{1}H NMR (CD_3COCD_3) δ: 4.12 (dd, 4.21, 11.09 Hz, 2H), 4.34 (dd, 3.62, 11.09 Hz, 2H), 5.18 (dd, 2.39, 16.57 Hz, 2H), 5.38 (dd, 9.69, 16.56 Hz, 2H), 5.67 (m, 2.29, 3.62, 4.21, 9.69 Hz, 2H); this compound decomposed before a CIMS spectrum could be obtained.

2,3-Dinitropropyl 2′-hydroxy-3′-nitropropyl ether ***9***: ^{1}H NMR ($CDCl_3$) δ: 3.64 (dd, 7.66, 17.16 Hz, 1H), 3.67 (dd, 8.99, 17.16 Hz, 1H), 4.15 (dd, 4.11, 11.05 Hz, 1H), 4.33 (dd, 3.62, 11.05 Hz, 1H), 4.48 (m, 2H), 4.68 (dd, 5.15, 10.05 Hz, 1H), 4.88 (bs, 1H), 5.20 (dd, 9.90, 16.45 Hz, 1H), 5.45 (dd, 2.31, 16.45 Hz, 1H), 5.63 (m, 1H); CIMS *m/z*: 271 ($M.NH_4^+$), 253 (M^+), 224 ($M.NH_4^+ - 47$), 204 ($M^+ - 47$), and 179 ($M.NH_4^+ - 96$).

Experiments with ^{15}N-nitrogen dioxide

For the study of CIDNP effects, ^{15}N-lead nitrate (0.061 g) was heated in a small flask with a tapped gas inlet and sidearm. The system was then purged with dry argon, and the evolved ^{15}N-nitrogen dioxide was collected in deuterochloroform (0.25 mL) in an acetone–cardice bath. The process was repeated three times, and the solution of nitrogen dioxide was then added by syringe to a solution of diallyl ether (0.0153 g) in deuteriochloroform (0.25 mL) within an NMR tube containing ^{15}N-nitrobenzene in an inner reference tube. The tube was briefly shaken (2 s) and immediately immersed in liquid nitrogen. Then the tube, while still frozen, was placed in the preshimmed and locked Varian 400 MHz NMR spectrometer, and acquisitions started immediately. The spectra taken during reaction were recorded using 10 pulses with an acquisition time of 5 s and a pulse delay of 12 s; the times quoted refer to the midpoint of the acquisitions. The final spectrum was taken after 24 h using 6000 pulses.

The reaction mixtures from this and related experiments on a larger scale were analyzed as described above and yielded the ^{15}N-labelled derivatives of **2**, **3**, and **8** each of which gave one signal in the ^{15}N NMR spectrum (Table 3). An additional product gave two ^{15}N NMR signals (δ_N 373.7, 377.9) in the range for nitro groups and close to the signals given by the dinitro compound formed by the addition of nitrogen dioxide to 2-ethylbut–1-ene (δ_N 373.3, 385.3) (13). From this and from the analysis of the ^{1}H NMR spectrum, the product was identified as the dinitro compound **6**: ^{1}H NMR ($CDCl_3$) δ: 3.87 (m, 10.70, 4.58 Hz, J_{HN} 3.55 Hz, 1H), 3.99 (m, 5.78, 2.56, 1.25 Hz, 2H), 4.11 (m, 10.7, 4.1 Hz, J_{HN} 1.7 Hz, 1H), 4.70 (m, 13.25, 4.96 Hz, J_{HN} 2.47 Hz, 1H), 5.21–5.35 (m, 4H), 5.78 (m, 16.56, 11.01, 5.78 Hz, 1H).

Aggregation and ion pair acidity in THF: lithium and cesium enolates of α-phenylcyclohexanone[1]

Daniel Ze-Rong Wang and Andrew Streitwieser

Abstract: The lithium (**1**) and cesium (**2**) enolates of α-phenylcyclohexanone, PCH, have been studied in THF at 25°C. Both form monomer–dimer equilibria with $K_{1,2}$ = 2.8 × 10^3 M^{-1} for **1** and 1.8 × 10^3 M^{-1} for **2**. The ultraviolet-visible (UV-vis) spectra of the monomers and dimers were derived from the spectra of the enolates at a series of concentrations by singular value decomposition. Measurements of the ion pair p*K* values gave p*K* = 12.7 for **1** and 19.8 for **2**. The monomers of **1** and **2** are alkylated by benzyl halides faster than are the dimers.

Key words: carbon-acid ionization, enolate ions, ion pairs, ion pair acidity, aggregation, dimerization constants, alkylation.

Résumé : On a étudié les énolates de lithium (**1**) et de césium (**2**) de l'α-phénylcyclohexanone (PCH) en opérant à 25°C, dans le THF. Les deux sels donnent des équilibres monomère–dimère avec des $K_{1,2}$ = 2,8 × 10^3 M^{-1} pour le composé **1** et 1,8 × 10^3 M^{-1} pour le composé **2**. En procédant à une décomposition à une valeur particulière, on a déduit les spectres ultraviolet-visible (UV-vis) des monomères et des dimères à partir des spectres des énolates à une série de concentrations. Des mesures des p*K* de la paire d'ion permettent de déduire les valeurs de p*K* des composés **1** (12,7) et **2** (19,8). Sous l'influence des halogénures de benzyle, les monomères des produits **1** et **2** sont alkylés plus rapidement que des dimères.

Mots clés : ionisation d'un acide carboné, ions énolates, paires d'ions, acidité d'une paire d'ions, agrégation, constantes de dimérisation, alkylation.

[Traduit par la Rédaction]

Introduction

Keto–enol equilibrium constants and their pK_a values are now known for a number of simple carbonyl compounds in aqueous solution and in DMSO, in large part through the work of Kresge (1) and Bordwell (2), respectively. A selected set of values is summarized in Table 1. For several years, we have determined the ion pair acidities of a number of ketones in THF solution. In this solvent, the enolates are ion-paired and frequently aggregated (3). It is as ion pairs that these metal enolates in THF are used in synthesis; thus, we have referred to the corresponding equilibria between such enolates and ketones as "ion pair acidities" generally in reference to a scale of ion-paired indicators (4). Some of these results are summarized in Table 2. The p*K* values in this table are defined by eq. [1] in terms of the equilibria in eq. [2] in which InH is a suitable indicator and M is either lithium or cesium.

[1] $$pK(RH) - pK(Ind\text{-}H) = -\log K$$

Received November 11, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

The p*K* values are given absolute numbers by assigning to fluorene its pK_a in DMSO, 22.9 (per hydrogen) (2, 4). Extensive tables of p*K* values for the indicators are now available for both the lithium (5, 6) and cesium (7) scales. To the previously determined results in Table 2, we add the results from the present work on the lithium **1** and cesium **2** enolates of 2-phenylcyclohexanone.

Spectral analyses

Treatment of 2-phenylcyclohexanone (PCH) with diphenylmethylcesium gave the conjugated cesium enolate **2** directly. Treatment of PCH with a lithium base gave a small absorption for the enolate **1** followed by a slower increase in this absorption. This behavior is interpreted as shown in Scheme 1 by initial formation predominantly of the unconjugated enolate, **3**, which does not absorb in the UV region studied, followed by gradual rearrangement to the conjugated lithium enolate. The mixture of **1** and **3** is stable in the absence of ketone.

Accordingly, the reaction mixture of ketone with lithium base was allowed to stand for at least 2 days to ensure complete conversion to **1** before the spectral measurements. In each of several runs, the enolate solution was diluted with known amounts of THF to obtain spectra as a function of concentration. For both **1** and **2**, λ_{max} varies with concentration. Over a concentration range of about 10^{-3}–10^{-5} M, λ_{max} for **1** ranges from 316.5 to 332 nm, for **2** from 345.5 to

354 nm. This result indicates that different aggregates have significantly different spectra (8). In both cases, normalized spectra showed an isosbestic point, at 320.5 nm for **1** and 349.0 nm for **2**, indicating that only two components make significant contributions in both cases. These were shown as detailed below to be the monomer and dimer. The absorbance at the isosbestic points varied linearly with concentration; ε = 18 392 ± 91 for **1** and 16 602 ± 38 for **2**.

The spectra were analyzed by singular value decomposition (SVD) (9); the composite results of several runs are given in Fig. 1. In agreement with previous results, the dimer absorbs at shorter wavelength than the monomer, and the lithium enolate absorbs at shorter wavelength than the cesium enolate (10, 11). The latter result shows that both the lithium and cesium enolates are contact ion pairs.

The monomer and dimer spectra were used to deconvolute the spectral mixtures for determining the compositions of each spectrum. The concentration of dimer was plotted against the square of the monomer concentration in order to obtain the dimerization constant, $K_{1,2}$, as given by eq. [3]. For **1** the results of three runs are in good mutual agreement over a range of total enolate concentration up to 10^{-3} M with $K_{1,2}$ = 2988 ± 17 M^{-1}; this result has high *precision* but the *accuracy* is expected to be much less. The results for four runs with **2** show more variation with $K_{1,2}$ = 1627 ± 13, 1945 ± 9, 1974 ± 12, 2328 ± 11 M^{-1}; each run by itself has good precision as indicated by the errors given as standard deviations, but the variation from the average value of 1969 M^{-1} among them is almost 10%. Nevertheless, the linearity of the plots for **1** and **2** confirms that these are monomer–dimer species; if significant amounts of higher aggregates were involved a higher order function would be required and these plots would curve upward.

Scheme 1.

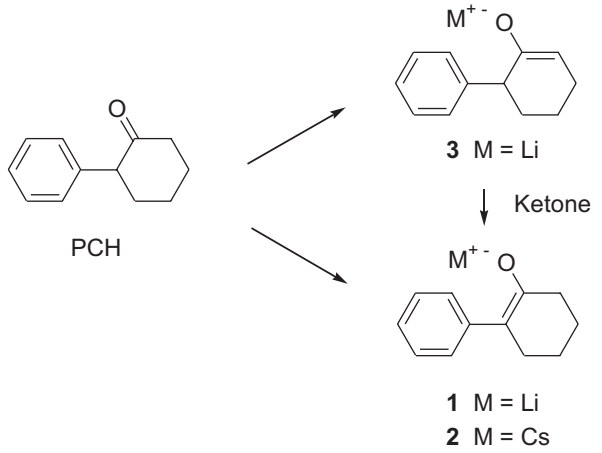

Fig. 1. Spectra of dimer (D) and monomer (M) of **1** and **2** as determined by SVD; λ_{max} are 327.5, **1**(M); 314.5, **1**(D); 356.5, **2**(M); 344.5 nm, **2**(D).

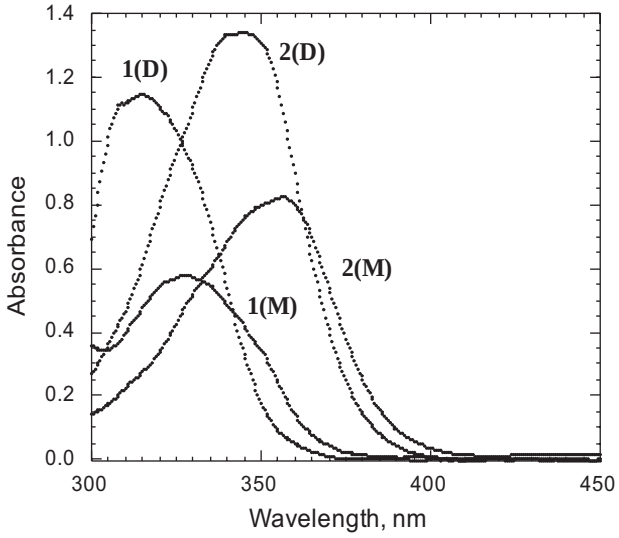

$$[3] \qquad 2M \overset{K_{1,2}}{\Leftrightarrow} D, \qquad K_{1,2} = [D]/[M]^2$$

Once the extinction coefficient of **1** was known, it was possible to do kinetic measurements of the conversion of **3** to **1**. Treatment of known amounts of the ketone with known amounts of the deprotonating reagent 9-lithio-9,9,10-trimethyl-9,10-dihydroanthracene gave initially and rapidly a 0.16 ratio of **1** to **3**. This was followed by a slow conversion of **3** to **1**, as shown by a gradual increase in the spectrum of **1**. The rate of this increase was determined for the first 10% reaction as an initial rate; since **3** has no useful spectrum, its concentration was determined as the difference between that of the deprotonating agent used and **1**. A series of eight runs with initial concentrations of [**1**] = 1.66 × 10^{-4} M and [**3**] = 8.60 × 10^{-4} M, and with [PCH] varying from 6.6 × 10^{-5} M to 3.8 × 10^{-4} M, gave the result in eq. [4].

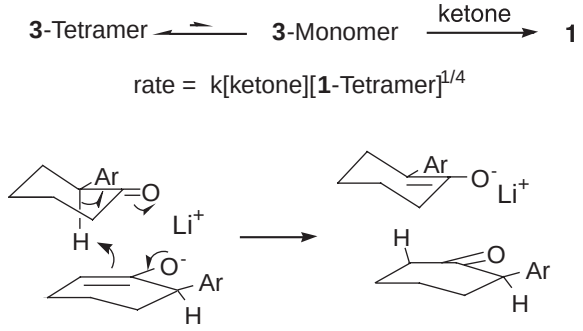
Scheme 2.



[4] log rate ($M\ s^{-1}$) = –3.02 ± 0.28
+ (0.941 ± 0.076) log [PCH], R^2 = 0.962

This result shows that the reaction is first order in the added ketone. A second series of 10 runs was carried out with [PCH] held constant at 2.74×10^{-4} M and [**3**] varying from 8.9×10^{-4} M to 2.9×10^{-3} M to give the result in eq. [5], which shows that the reaction is 1/4 order in [**3**].

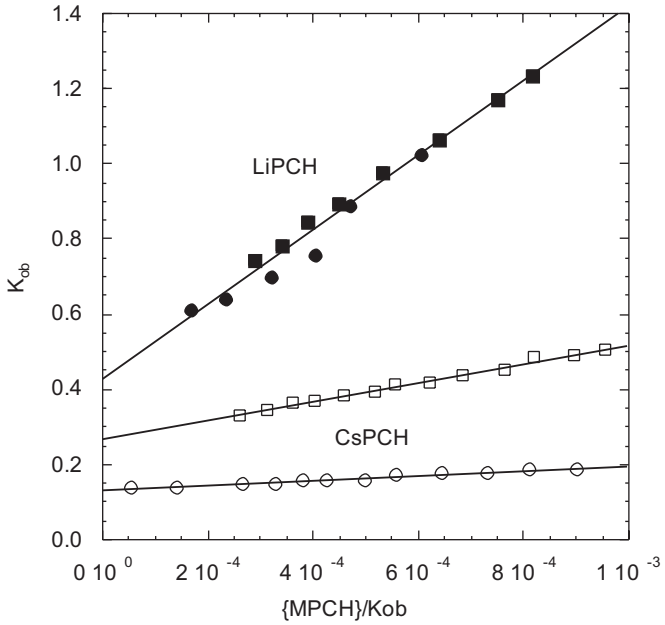
[5] log rate ($M\ s^{-1}$) = –5.72 ± 0.02
+ (0.250 ± 0.008) log [**3**], R^2 = 0.991

These kinetic results indicate that **3** is present predominantly as a tetramer but that the small amount of monomer in equilibrium reacts with ketone to produce **1** and the ketone (Scheme 2). Kinetically favored deprotonation of the less hindered nonconjugated hydrogen is not new. Beutelman et al. (12) and Xie and Saunders (13), for example, have found that deprotonation of several ketones with LDA in THF at 0°C gives predominantly the less substituted lithium enolate. What is new is the present demonstration that proton transfer from the ketone is much faster with the enolate monomer than with an aggregate at 25°C. This result is relevant to recent interest in enantioselective protonations of lithium enolates with chiral protonating agents (14), because it is a rare example of a demonstrated kinetic protonation of a coordinated lithium enolate monomer in equilibrium with an aggregate. The other point of interest is that the less stable **3** forms a monomer–tetramer mixture compared to the monomer–dimer of **1**, in agreement with the generalization that aggregation is lower for more stable alkali enolates (8).

Acidity measurements

Equilibria were measured (eq. [2]) for the enolates with suitable indicators. A suitable indicator is one for which λ_{max} is sufficiently different from that of the enolate to permit facile determination of both and an equilibrium constant sufficiently close to unity so that accurately measurable amounts of both are present at equilibrium. 1,3-Diphenylindene (DPI, pK = 12.32 (6)) was used for **1**; two indicators, 9-*p*-(dimethylaminophenyl)fluorene (DMAPhFl, pK = 19.28)[3] and phenyl-2,3-benzofluorene (Ph-2,3-BF, pK = 18.92 (7)) were used for **2**. From the known amounts of ketone and indicator used and the amounts of the ion pairs from the spectral analyses, the equilibrium constants for eq. [2] were calculated. For lithium enolates, however, a correction is required because at the high dilutions used ([Li-Ind] = 10^{-4} to 10^{-5} M) significant amounts of the lithium salts of the indicators are dissociated to free ions. The free-ion spectra are close to those of the solvent-separated indicator ion pairs, and the concentrations were corrected using $K_{dissoc} = 10^{-5}\ M^{-1}$ (4). The lithium enolate contact ion pairs are not significantly dissociated. The cesium salts of the indicators have dissociation constants 10^{-2}–10^{-3} that of the lithium salts (4), and no correction is necessary.

Fig. 2. Plot of observed equilibrium constant (eq. [2]) from pK measurements of LiPCH (**1**) and CsPCH (**2**) vs. {MPCH}/K_{ob}. Closed circles and squares are two runs of **1** with the same indicator, 1,3-diphenylindene (DPI). The equation of the LiPCH line shown is K_{ob} = (0.43 ± 0.02) + (993 ± 42){**1**}/K_{ob}. Two indicators were used with CsPCH: open squares with 9-*p*-(dimethylaminophenyl)fluorene (DMAPhFl), K_{ob} = (0.268 ± 0.006) + (252 ± 9){**2**}/K_{ob}; open circles with phenyl-2,3-benzofluorene (Ph-2,3-BF), K_{ob} = (0.133 ± 0.002) + (66.5 ± 3.6){**2**}/K_{ob}.



The effect of aggregation is to increase the observed equilibrium constant, K_{ob}, in eq. [2] as the enolate concentration is increased; the equilibrium is displaced to the right as monomer is converted to the aggregate. The corresponding equilibrium constant defined for the monomer enolate defines pK_o and can be obtained from a plot of K_{ob} vs. {MPCH}/K_{ob} (9) in which {MPCH} is the formal concentration of the metal enolate as determined, for example, from its absorbance at $\lambda_{isosbestic}$. Such plots are shown for the equilibrium constants of LiPCH, **1**, and CsPCH, **2**, in Fig. 2. For LiPCH, the intercept gives K_o = 0.43 and the slope = $2K_{1,2}K_o^2$ (9) from which pK of **1** (monomer) = 12.69 ± 0.02 and $K_{1,2}$ = 2710 M^{-1}. The latter number is close to that obtained from the SVD analysis and is probably somewhat

[3] This value differs slightly from that (19.23) given in ref. 7 because of additional measurements.

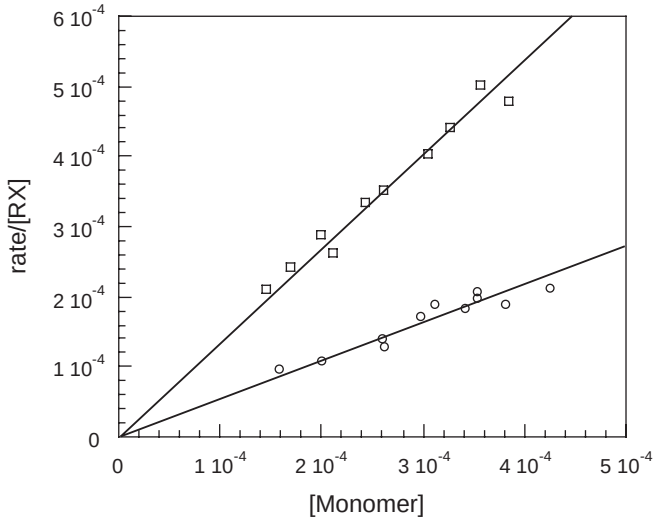
Fig. 3. Rates/[RX] (s^{-1}) vs. monomer concentrations (M) for reaction of **1** (squares, [RX] = 0.006 97 M, k_2 = 1.34 ± 0.02 M^{-1} s^{-1}) and **2** (circles, [RX] = 0.00708 M, k_2 = 0.546 ± 0.013 M^{-1} s^{-1}) with *m*-chlorobenzyl bromide and *p*-*t*-butylbenzyl chloride, respectively, in THF at 25°C.



more accurate. We take $K_{1,2}$ = 2.8 × 10^3 as the best value. The results for CsPCH with two different indicators gave mutually consistent results. With DMAPhFl (open squares in Fig. 2), the intercept is 0.27 (from which p*K* = 19.85) and the slope gives $K_{1,2}$ = 1725 ± 63. With Ph-2,3-BF (open circles in Fig. 2), the intercept of 0.13 gives p*K* = 19.80 and the slope gives $K_{1,2}$ = 1868 ± 123. The $K_{1,2}$ values are in the range given by the SVD treatment above. We take as average values, p*K* = 19.82, $K_{1,2}$ = 1.8 × 10^3 M^{-1}. The fact that the plots in Fig. 2 are linear also shows that only monomers and dimers contribute significantly in this concentration range; if higher aggregates were important, a higher power of {MPCH}/K_{ob} would be required (9) and the plots would curve upward.

With these acidities added to Table 2, some relationships can be made even though no one compound has been studied in all three solvent systems, water, DMSO, and THF. Several comparisons between water and DMSO in Table 1 follow the well-known phenomenon that aqueous p*K* values of species involving oxide ion conjugate bases are lower than the corresponding p*K* values in DMSO undoubtedly because of hydrogen-bond stabilization of the anions in water. For the ketones in Table 1 this difference ranges from about 5 to 8 p*K* units. Two comparisons can be made between DMSO and THF, since the p*K* of *p*-phenylisobutyrophenone is expected to be quite close to that for isobutyrophenone (10, 11). The cesium ion pair p*K* values thus differ from the DMSO values by no more than 1 p*K* unit. The slightly greater acidity in THF indicates that cesium cation is bound electrostatically to the vinyloxide ion slightly more than to the delocalized carbanions used as indicators. The lithium p*K* values, however, are about 7–9 p*K* units lower than those of the cesium enolates and, indeed, are in the same range as the aqueous values if not even lower. Lithium cation as the smallest alkali cation is bound tightly to the enolate oxide anion. Since the free-ion acidities must be the same, these differences mean that the corresponding dissociation constants of lithium enolates are several orders of magnitude less than the cesium enolates (4).

The role of conjugation is shown not only by the comparison of 2-indanone with 1-indanone in Table 1 but also by comparison of conjugation with phenyl and with *p*-biphenylyl. The *p*-phenyl substituent decreases the p*K* of dibenzyl ketone by 1 unit on the cesium scale. The conjugated enolate systems **1** and **2** are, as expected, less basic than the nonconjugated enolates of *p*-phenylisobutyrophenone but the difference for lithium, 3.1 p*K* units, is substantially less than that for cesium, 5.3 p*K* units. A simple interpretation is that the tighter lithium ion pair electrostatically impedes delocalization of charge.

Alkylation kinetics

Previous kinetic studies with other lithium and cesium enolates reacting with alkyl halides and sulfonates have shown that the rate constants for the enolate monomers are much greater than for the aggregates (10, 11, 15) These results are extended to reactions of **1** and **2**. Convenient rates were found for the reaction of **1** with *m*-chlorobenzyl bromide and for **2** with *p*-*t*-butylbenzyl chloride. The alkyl halide concentrations were used in large excess so that the reactions are pseudo first order in enolate, but only initial rates (about 10% reaction) were used to avoid possible complications with mixed aggregates from the products. Rates at fixed concentrations of the enolate and varying [RX] show the reactions to be, as expected, first order in alkyl halide. For 7.79 × 10^{-4} M **1** and *m*-chlorobenzyl bromide varying from 7.4 × 10^{-3} to 2.4 × 10^{-2} M, log rate = –3.55 + (1.07 ± 0.07) log [RX] and for **2** = 8.02 × 10^{-4} M and *p*-*tert*-butylbenzyl chloride varying from 5.6 × 10^{-3} to 1.5 × 10^{-2} M, log rate = –3.82 + (0.95 ± 0.03) log [RX]. Similar log–log plots at constant [RX] and varying enolate concentrations give fractional slopes; for example, 0.58 for **1** and 0.57 for **2**. More meaningful are direct comparisons of the initial rates divided by [RX] with the concentrations of monomer as shown in Fig. 3. The plots are those of straight lines with no apparent curvature and show that the reactions are first order in monomer. In the points at the righthand side of the plots, the amount of enolate present as dimer is substantially greater than that present as monomer; thus, if there were any significant contribution by reaction with dimer, the plots would show an upward curvature. We conclude that $k_{monomer} >> k_{dimer}$ in agreement with the other cases we have studied.

This relative reactivity is rationalized on the basis of **4** as a reasonable structure for the dimer (16). In the monomer, the enolate oxygen is coordinated to a single metal cation; in the dimer, it is coordinated to two cations and is accordingly effectively less nucleophilic.

Experimental section

2-Phenylcyclohexanone was purified by sublimation, mp 61°C (lit. 59–60°C (17), 56–58°C (18), 59.5–60°C (19)) and was >99% pure by GC. The indicators and bases used were available from previous studies. Solutions of the cesium enolate **2** were prepared by adding solutions of diphenylmethylcesium to the ketone and using *p*-biphenylyldiphenylmethane as an endpoint indicator; the cesium salt is bright red compared to the greenish yellow of **2**. The initial solutions were diluted with THF to produce a series of solutions of varying concentration for spectral analysis. Spectra were taken with a thermostated cell block in the floor of a glovebox and connected to an external spectrometer by fiber optics cables (9). Because of the formation of **3**, spectra of **1** were more difficult to obtain. A sample procedure follows: to a 1 mm UV cell was weighed 0.485 g of THF and 0.113 mg of PCH. Then, 4.0 μL (an excess) of the lithium base (9-lithio-9,10,10-trimethyl-9,10-dihydroanthrance), ca. 0.2 M in THF, was added to deprotonate the PCH. To a small vial was added 0.418 g of THF and 0.514 mg of PCH ([PCH] = 6.2×10^{-3} M). Varying amounts (2–5 μL) of this PCH solution were added to the UV cell to titrate the base, until the endpoint was reached. Small additional amounts of the PCH solution were added, mixed well, and allowed to stand in order to ensure that all of the unconjugated enolate had converted into the conjugated enolate. This procedure took several days. At this point, the solution was diluted with varying amounts of THF for spectral analysis.

Alkylation kinetics at fixed enolate concentrations utilized previously prepared enolate solutions which were added to several 1 mm cells. Each cell was equilibrated in the cell block for several minutes, and varying known amounts of benzylic halide were weighed into the cell, mixed quickly, and the initial rate of loss of absorbance of enolate was measured. For fixed concentrations of alkylating agent, a stock solution was added to a cell, equilibrated, and an aliquot of a batch solution of enolate was added by micro syringe such that the volume change was less than 5%.

Structure–reactivity correlations in the reaction of 2,4-dinitrophenyl X-substituted benzoates with alicyclic secondary amines

Ik-Hwan Um, Ji-Sook Min, and Hye-Won Lee

Abstract: Apparent second-order rate constants (k_{app}) have been measured spectrophotometrically for the reaction of 2,4-dinitrophenyl X-substituted benzoates with a series of alicyclic secondary amines in H_2O containing 20 mol% DMSO at 25°C. The microconstants involved in the reaction (k_{-1}/k_2, k_1, and k_1k_2/k_{-1}) have also been calculated. The magnitude of k_{app}, k_1, and k_1k_2/k_{-1} values increases with increasing amine basicity and with increasing acid strengthening ability of the acyl substituent X. The k_{-1}/k_2 value decreases from ca. 6.5 to 0.3 with increasing the amine basicity, but remains almost constant upon changing the acyl substituent X for a given amine, indicating that the rate-determining step is governed by the basicity of amine but not by the electronic nature of the acyl substituent X. The Brønsted-type plots for k_{app} show a break at pK_a = 9.1, supporting the assumption that a change in the rate-determining step occurs from rate-limiting breakdown to formation of the addition intermediate as amine basicity increases. The corresponding Brønsted-type plots for k_{-1}/k_2, k_1, and k_1k_2/k_{-1} are linear but their β values are different. σ^+ constants show better correlation with log k_{app}, log k_1 and log k_1k_2/k_{-1} for the reaction with low basic amines (pK_a < 9.1), while σ constants exhibit better correlation for the reaction with highly basic amines (pK_a > 9.1). The magnitude of ρ_1 is identical to that of ρ_{app} and ρ_{eq} for a given amine.

Key words: aminolysis, Brønsted-type plot, structure–reactivity correlations, rate-determining step.

Résumé : Faisant appel à la spectrophotométrie et opérant à 25°C dans H_2O contenant 20 mol% de DMSO, on a mesuré les constantes de vitesse apparentes du deuxième ordre de benzoates (portant un substituant X) de 2,4-dinitrophényle avec une série d'amines alicycliques secondaires. On a calculé les microconstantes impliquées dans la réaction (k_{-1}/k_2, k_1 et k_1k_2/k_{-1}). L'amplitude des valeurs de k_{app}, k_1, k_1k_2/k_{-1} augmente avec une augmentation de la basicité de l'amine et avec une augmentation de l'habilité du substituant acyle X à augmenter l'acidité. Les valeurs de k_{-1}/k_2 diminuent d'environ 6,5 à 0,3 avec une augmentation de la basicité de l'amine, mais elles demeurent pratiquement constantes pour un changement de substituant acyle X pour une amine donnée; ceci indique que l'étape cinétiquement déterminante est fixée par la basicité de l'amine, mais pas par la nature électronique du substituant acyle X. Les courbes de type Brønsted pour k_{app} présentent un bris à un pK_a = 9,1; ce résultat supporte l'hypothèse selon laquelle il se produit un changement dans l'étape cinétiquement limitante à cause d'un bris cinétiquement limitant dans la formation de l'intermédiaire lorsque la basicité de l'amine augmente. Les courbes de type Brønsted correspondantes pour $k_{-1}k/_2$, k_1 et k_1k_2/k_{-1} sont linéaires, mais leurs valeurs β sont différentes. Pour les amines de faible basicité (pK_a < 9,1), les constantes σ^+ donnent une meilleure corrélation avec log k_{app}, log k_1 et log k_1k_2/k_{-1} alors que les constantes σ conduisent à une meilleure corrélation pour la réaction avec les amines plus fortement basiques (pK_a > 9,1). Pour une amine donnée, l'amplitude de ρ_1 est identique à celle de ρ_{app} et de ρ_{eq}.

Mots clés : aminolyse, courbe de type Brønsted, corrélations structure-activité, étape cinétiquement déterminante.

Introduction

The aminolysis reaction of carbonyl compounds is one of the most intensively investigated reactions due to the interest in biology as well as in chemistry (1–6). The reactions of carboxylic acid derivatives with amines have been suggested to proceed through a stepwise mechanism with an addition intermediate or through a concerted mechanism without an intermediate (1–6). Linear free energy relationships such as Hammett and Brønsted-type correlations have been most frequently used to investigate the reaction mechanism (7). Aminolyses of carboxylic esters with a good leaving group have often shown a break or a curvature in Brønsted-type plots from a large slope (β_{nuc} = 0.8 ± 0.1) to a small one (β_{nuc} = 0.2 ± 0.1) as the basicity of the attacking amine increases (3, 4). Such a break or a curvature in Brønsted-type plots has been attributed to a change in rate determining step (RDS) of a stepwise reaction. Generally, the RDS of aminolysis of carboxylic esters has been suggested to be depend-

ent on the basicity of the leaving group and the attacking amine, i.e., the RDS changes from the rate-determining breakdown of the addition intermediate to the rate-determining formation of the intermediate as the basicity of amines increases (3, 4).

However, until recently, most studies were directed to investigate the reaction mechanism by changing the basicity of the leaving or attacking groups. The effect of the acyl group on reaction rates as well as on reaction mechanisms has been rarely investigated (8–10). We have carried out a systematic study as shown in Scheme 1, and evaluated all the microconstants involved in the aminolysis reactions to obtain further information about the reaction mechanism.

Results and discussion

All the reactions in the present study obeyed pseudo-first-order kinetics up to over 90% of the total reaction. Pseudo-first-order rate constants (k_{obs}) were obtained from the equation, $\ln (A_\infty - A_t) = -k_{obs}t + c$. The correlation coefficients of the linear regressions were always higher than 0.9995. The plots of k_{obs} vs. [>NH] were linear, indicating that general base catalysis by a second amine molecule is absent. Therefore, one can derive a rate equation, as eq. [1], where [S] and [>NH] represent the concentration of the substrate and the amines used, respectively. Apparent second-order rate constants (k_{app}) were determined from the slope of the plots of k_{obs} vs. [>NH]. The k_{app} values obtained in this way are summarized in Table 1. It is estimated from replicate runs that the error in any particular measured rate constants is less than ± 3%. Under pseudo-first-order conditions, eq. [1] can be simplified into eqs. [2] and [3].

$$[1] \qquad \text{Rate} = \frac{k_1 k_2}{k_{-1} + k_2}[\text{S}][>\text{NH}]$$

$$[2] \qquad \text{Rate} = k_{obs}[\text{S}], \qquad \text{where } k_{obs} = \frac{k_1 k_2}{k_{-1} + k_2}[>\text{NH}]$$

$$[3] \qquad k_{app} = \frac{k_1 k_2}{k_{-1} + k_2}$$

Reaction mechanism

As shown in Table 1, the k_{app} value increases with increasing the basicity of amines and with increasing acid strengthening ability of the acyl substituent X. In Fig. 1 is demonstrated the effect of amine basicity on reactivity, which was statistically corrected by using *p* and *q*, i.e., $p = 2$ (except $p = 4$ for piperazinium ion) and $q = 1$ (except $q = 2$ for piperazine) (11). The Brønsted-type plots in Fig. 1 are nonlinear for all the acyl substituents. Such a nonlinear Brønsted-type plot has often been observed in aminolyses of esters with a good leaving group, and used as evidence of a change in the rate determining step, i.e., the RDS changes

Fig. 1. Plots of logarithm of k_{app} versus pK_a of the conjugate acid of amines for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

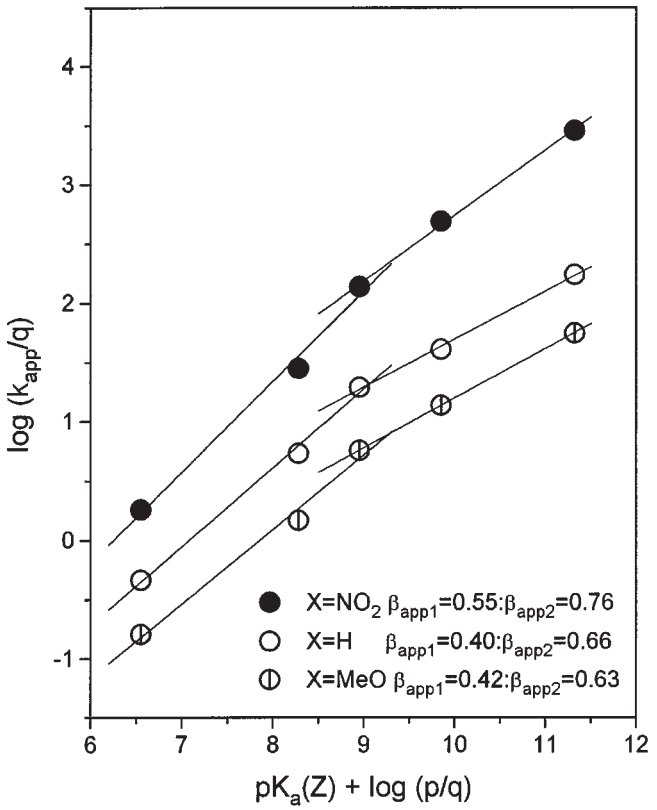

Fig. 2. Plots of logarithm of k_{app} versus σ_X (or σ_X^+) constants for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

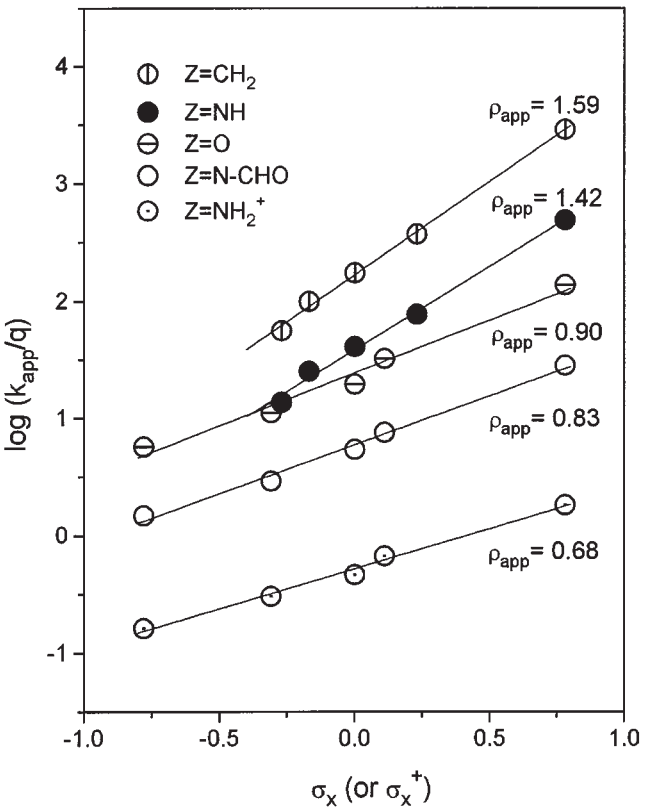

from breakdown of the addition intermediate to formation of the intermediate as the attacking amine becomes more basic than the leaving group by 4~5 pK_a units (12). Figure 1 shows that the position of the break is about 9.1, which is 5 pK_a units higher than the pK_a of the conjugate acid of the leaving group (pK_a of 2,4-dinitrophenol = 4.1). Therefore, one can suggest that the RDS in the present aminolysis changes from the k_2 step to the k_1 step in Scheme 1 as the amine becomes more basic than morpholine (pK_a > 9.1).

It is noted that the position of the break in Fig. 1 is nearly unchanged although the electronic nature of the acyl substituent X varies significantly, suggesting that the RDS change is governed by the basicity of amines but not by the acyl moiety. The β_{app2} (the slope in Fig. 1 for the low basic amines, pK_a < 9.1) has been calculated to be 0.63, 0.66, and 0.76 for the acyl substituent X = MeO, H, and NO_2, respectively. The β_{app1} value (the slope in Fig. 1 for the highly basic amines, pK_a > 9.1) is 0.42, 0.40, and 0.55 for X = MeO, H, NO_2, respectively. Therefore, the electronic nature of the acyl substituents X affects the magnitude of the slopes in the Brønsted-type plots (both β_{app1} and β_{app2}).

Figure 2 demonstrates the effect of acyl substituent on reactivity. Good linear Hammett plots are observed for all the amines studied. However, interestingly, log k_{app} shows good linear correlation with σ constants for the reactions with highly basic amines (pK_a > 9.1) but with σ^+ constants for the ones with low basic amines (pK_a < 9.1). σ^+ constants were derived from the solvolysis of $ArCMe_2Cl$ in 90% acetone–water mixture at 25°C, and used for reactions in which a positive charge is developed at the reaction centre which can resonate with an electron-donating group (EDG) (13). Accordingly, negative ρ values have generally been obtained when σ^+ constants were used. However, as shown in Fig. 2, the slope of the Hammett plots (ρ_{app}) is positive. Therefore, the present result is quite unusual and suggests that the ground-state stabilization by resonance or hyperconjugation is significant for the reactions with the low basic amines as shown in Scheme 2.

The ρ_{app} values of the Hammett plots in Fig. 2 are much larger for the reactions with the highly basic amines (ρ_{app} = 1.42~1.59) than for the ones with the low basic amines (ρ_{app} = 0.68~0.90). Since the attack of amines to the carbonyl carbon to form an addition intermediate would be accelerated by an electron withdrawing group (EWG) but retarded by an EDG in the acyl moiety, one would expect a large ρ value for the reactions where the RDS is the first step (k_1) in Scheme 1. On the contrary, the departure of the leaving group from the addition intermediate would be disfavoured by an EWG but favoured by an EDG in the acyl moiety. Accordingly, the ρ value has been suggested to be small when the RDS is the k_2 step due to the opposite substituent effect, and the magnitude of ρ values has often been used to determine the RDS for two step reactions (8–10). Based on the magnitude of the ρ_{app} values in the present system, one can suggest that the RDS is the k_2 step for the reactions with the low basic amines (small ρ_{app}) and the k_1 step for the ones with the highly basic amines (large ρ_{app}).

Table 2. Summary of k_{-1}/k_2 values for the aminolysis reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines in H_2O containing 20 mol% DMSO at 25°C.

	k_{-1}/k_2				
Amine (Z)	X = 4-NO_2	4-Cl	H	4-Me	4-MeO
Piperidine (CH_2)	0.397	0.364	0.316	0.364	0.397
Piperazine (NH)	0.694	0.671	0.637	0.671	0.694
Morpholine (O)	1.24	1.27	1.31	1.27	1.24
1-Formyl piperazine (NCHO)	1.72	1.81	1.96	1.81	1.72
Piperazinium ion (NH_2^+)	4.61	5.29	6.58	5.29	4.61

Recently, we reported a ρ value of 2.4 for the reaction of 4-nitrophenyl X-substituted benzoates with phenoxide ion under the same reaction conditions in which the nucleophilic attack by phenoxide ion was proposed to be the RDS (14). The ρ_{app} value for the present aminolysis with the highly basic amines is 1.5 ± 0.1, which is much smaller than the one for the reaction with the anionic nucleophile. However, the difference in the ρ value between the two systems is considered not to be due to any difference in the reaction mechanism, but due to the difference in the type of nucleophiles (phenoxide anion vs. neutral amine). Since phenoxide anion would donate electrons more significantly to the acyl moiety in the transition state (TS) than the neutral amines, it would be natural to observe a larger ρ value for the former system than the latter one.

Evaluation of microconstants

To get insight into the reaction mechanism, it is necessary to determine all the microconstants involved in the present aminolysis reactions. The method used to calculate the microconstants is based on Castro's procedure (12*c*) as follows.

As suggested in the preceding section, the RDS is considered to change from the k_2 to k_1 step as the amine becomes more basic than morpholine (or pK_a > 9.1). Therefore, eq. [3] can be simplified into eqs. [4] and [5].

$$[4] \qquad k_{app} = k_1k_2/k_{-1} = Kk_2, \qquad \text{when } k_2 << k_{-1}$$

$$[5] \qquad k_{app} = k_1, \qquad \text{when } k_2 >> k_{-1}$$

Let β_{app2} and β_{app1} represent the slope for the Brønsted plots in Fig. 1 for the reactions with the low and the highly basic amines, respectively. Then, one can express β_{app1} and β_{app2} as eqs. [6] and [7], respectively.

$$[6] \qquad \beta_{app1} = d(\log k_1)/d(pK_a)$$

$$[7] \qquad \beta_{app2} = d(\log k_1k_2/k_{-1})/d(pK_a) = \beta_{app1} + d(\log k_2/k_{-1})/d(pK_a)$$

Equation [7] can be rearranged as eq. [8]. Integral of eq. [8] from pK^0 to pK_a results in eq. [9], where pK^0 represents the position of the break in Fig. 1.

$$[8] \qquad \beta_{app2} - \beta_{app1} = d(\log k_2/k_{-1})/d(pK_a)$$

$$[9] \qquad (\log k_2/k_{-1})_{pKa} - (\log k_2/k_{-1})_{pK^0} = (\beta_{app2} - \beta_{app1})(pK_a - pK^0)$$

The values of β_{app1} and β_{app2} for the reaction of 2,4-dinitrophenyl benzoate (X = H) were calculated to be 0.66 and 0.40, respectively, and pK^0 is 9.1. Since $k_2 = k_{-1}$ at pK^0, the term $\log (k_2/k_{-1})_{pK^0}$ is zero. Therefore, one can simplify eq. [9] as eq. [10], which allows one to calculate the k_2/k_{-1} values for all the amines studied in the present system.

$$[10] \qquad \log (k_2/k_{-1})_{pKa} = 0.26(pK_a - 9.1)$$

In a similar manner, the k_2/k_{-1} values for the other systems (X = NO_2, Cl, Me, MeO) have been calculated and summarized in Table 2.

The k_2 value has been suggested to be constant upon changing the basicity of amines for aminolysis reactions of a given substrate (15, 16). However, the k_{-1} value would be inversely proportional to the basicity of amines. Therefore, one can expect that the k_{-1}/k_2 values become larger with decreasing amine basicity. In fact, as shown in Table 2, k_{-1}/k_2 values increase from ca. 0.3–6.5 as amine basicity decreases. The magnitude of k_{-1}/k_2 values is larger than 1 for the low basic amines (pK_a < 9.1) and smaller than 1 for the highly basic amines (pK_a > 9.1), indicating that the RDS changes from the k_2 to k_1 step as the amine becomes more basic than morpholine (or pK_a > 9.1). This is consistent with the preceding suggestion based on the nonlinear Brønsted-type

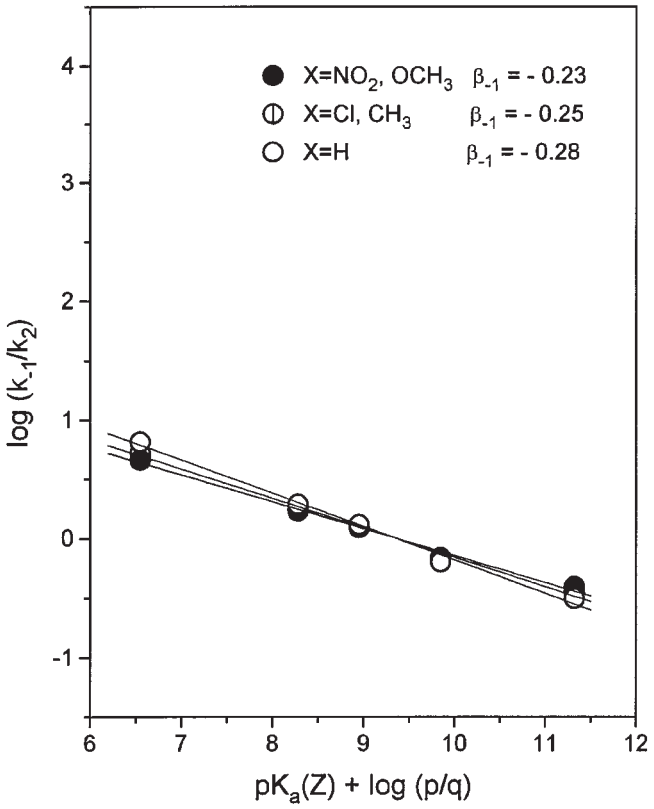
Fig. 3. Plots of logarithm of k_{-1}/k_2 versus pK_a of the conjugate acid of amines for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.



plots shown in Fig. 1 and the difference in the magnitude of the ρ values shown in Fig. 2.

Figure 3 demonstrates the effect of amine basicity on the k_{-1}/k_2 values. Linear Brønsted-type plots are observed for all the acyl substituents X. Since the k_2 value has been suggested to be constant upon changing the basicity of amines (15, 16), the magnitude of the slope in Fig. 3 (β_{-1}) would be governed mainly by k_{-1}. The β_{-1} value was calculated to be about 0.25, indicating that log k_{-1} is little sensitive toward the basicity of the amines used. Such a small β_{-1} value obtained in the present system is consistent with the recent suggestion by Colthurst and Williams (9*b*), that k_{-1} would not be sensitive to the basicity of nucleophiles.

Both the k_{-1} and k_2 steps would be accelerated by an EDG but retarded by an EWG in the acyl moiety for a given amine. Accordingly, k_{-1}/k_2 values would be expected to be constant upon changing the acyl substituent X. In fact, as shown in Table 2, the magnitude of k_{-1}/k_2 values appears to be nearly constant although the acyl substituent changes from a strong EDG to a strong EWG for a given amine, clearly supporting the preceding argument that the position of the RDS change (pK^0) would not be influenced by the electronic nature of the acyl substituents but governed by the basicity of the leaving group and the attacking amines. However, it has been recently suggested that pK^0 and the k_{-1}/k_2 ratio increase with increasing electron-withdrawing ability of the acyl moiety in aminolyses of aryl carbonates and thionocarbonates, which is inconsistent with our present result (15, 16).

$$[11] \quad k_1 = k_{app} (k_{-1}/k_2 + 1)$$

Equation [3] can be rewritten as eq. [11], which allows the calculation of the k_1 values using the known values of k_{app} and k_{-1}/k_2 from Tables 1 and 2. The k_1 values calculated in this way are summarized in Table 3. One can see that the magnitude of k_1 decreases with decreasing the basicity of amines and with decreasing acid strengthening ability of the acyl substituent X. The data in Tables 1 and 3 reveal that k_1 is always larger than the corresponding k_{app}. However, the difference in the magnitude of k_1 and k_{app} becomes small as amine basicity increases for a given acyl substituent X, because the k_{-1}/k_2 values decrease with increasing amine basicity.

Figure 4 shows the effect of amine basicity on the magnitude of k_1 value. One can notice that log k_1 is linearly correlated with the basicity of amines for all the acyl substituent X. The magnitude of the slopes in Fig. 4 (β_1) was calculated to be 0.55, 0.38, and 0.41 for X = NO_2, H, and MeO, respectively. The β_1 value is about twice the value of β_{-1}, indicating that the k_1 step is about twice more sensitive than the k_{-1} step toward the basicity of amines for a given acyl substituent X.

Figure 5 demonstrates linear Hammett plots for all the amines studied. One can see that log k_1 is better correlated with σ constants for the reactions with the highly basic amines (pK_a > 9.1) and with σ^+ constants for the low basic amines (pK_a < 9.1). Besides, the magnitude of the slopes in Fig. 5 (ρ_1) is much larger for the reactions with the highly basic amines than for the ones with the low basic amines. One can notice that the magnitude of ρ_1 and ρ_{app} values is same. However, this is not so surprising if one analyses eq. [11]. Since the k_{-1}/k_2 value has been shown to be almost constant upon changing the acyl substituent X for a given amine, log k_{app} = log k_1 + constant. Consequently, the slopes in the plots of log k_1 vs. σ (or σ^+) and log k_{app} vs. σ (or σ^+) should be identical each other for a given amine.

Fig. 4. Plots of logarithm of k_1 versus pK_a of the conjugate acid of amines for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

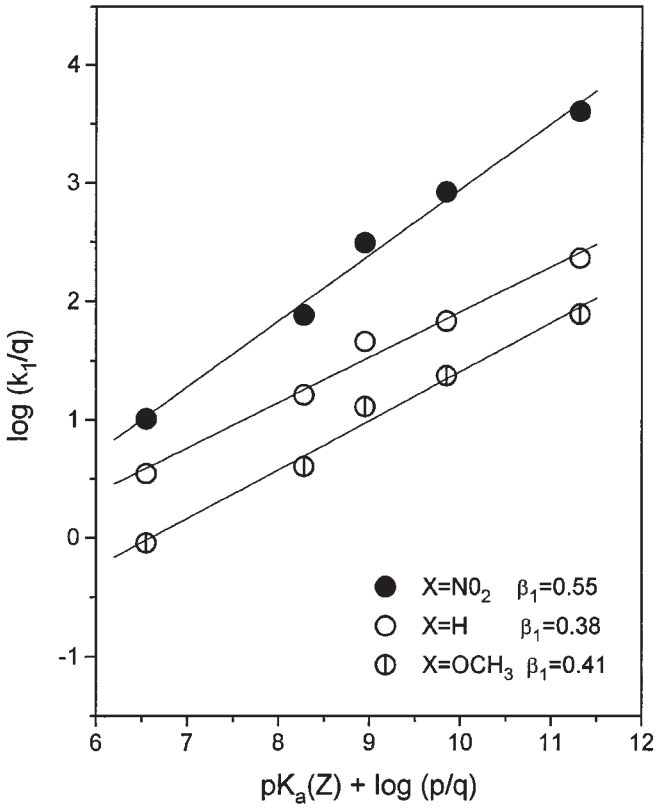

Fig. 5. Plots of logarithm of k_1 versus σ_X (or σ_X^+) constants for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

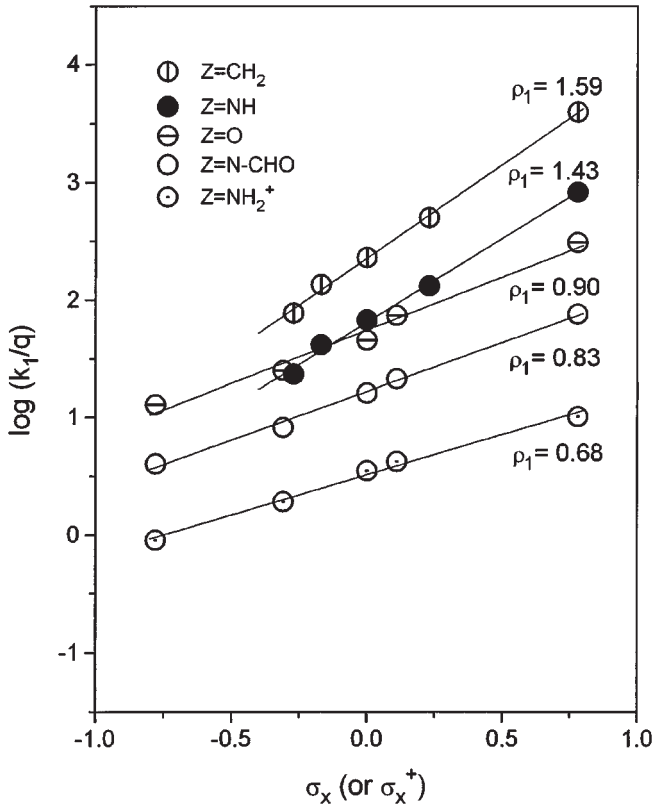

The Kk_2 (= k_1k_2/k_{-1}) values have been calculated from the known values of k_1 and k_{-1}/k_2, and summarized in Table 4. The Kk_2 value decreases with decreasing amine basicity and with increasing acid weakening ability of the acyl substituent X, as expected. Comparison of the data in Tables 3 and 4 reveals that the magnitude of Kk_2 is larger than the corresponding k_1 for the highly basic amines but smaller than k_1 for the low basic amines. However, this is not so surprising either, since $k_2/k_{-1} > 1$ for the reactions with the highly basic amines (pK_a > 9.1) and $k_2/k_{-1} < 1$ for the low basic amines (pK_a < 9.1), as shown in Table 2.

Figure 6 exhibits the effect of amine basicity on Kk_2. One can see linear Brønsted-type plots. The magnitude of the slopes in Fig. 6 (β_{eq}) has been calculated to be 0.78, 0.66, and 0.64 for X = NO_2, H, and MeO, respectively. Since the magnitude of k_2 values has been suggested to be constant upon changing the basicity of amines (16, 17), the slope in the plots of log Kk_2 vs. pK_a (e.g., β_{eq}) and log k_1/k_{-1} vs. pK_a (e.g., $\beta_1 - \beta_{-1}$) should be same. In fact, it has been calculated that $\beta_{eq} = \beta_1 - \beta_{-1}$ for all the acyl substituents.

Figure 7 demonstrates the effect of acyl substituent X on Kk_2. Good linear Hammett plots are obtained for all the amines used. Interestingly, as observed in Figs. 2 and 5, log Kk_2 shows good linear correlation with σ constants for the reactions with the highly basic amines but with σ^+ constants for the low basic amines. Besides, the slopes in Fig. 7 (ρ_{eq}) are much larger for the highly basic amines than for the low basic ones, as observed in Figs. 2 and 5.

Since the magnitude of k_{-1}/k_2 values are almost constant upon changing the acyl substituent X for a given amine, the slopes of the plots of log Kk_2 vs. σ (or σ^+) and log k_1 vs. σ (or σ^+) should be same for a given amine. In fact, one can notice that the magnitude of ρ_{eq} and ρ_1 is identical for a

Fig. 6. Plots of logarithm of Kk_2 versus pK_a of the conjugate acid of amines for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

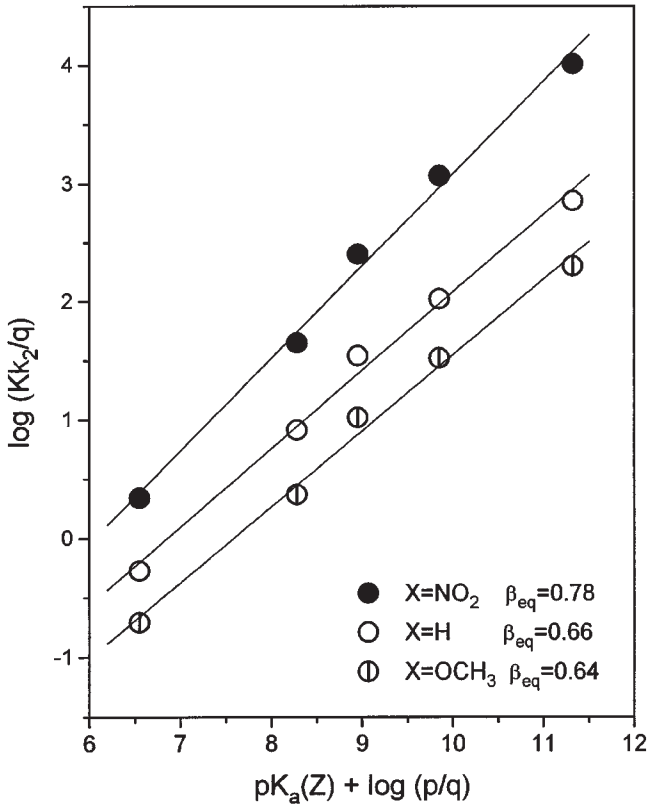

Fig. 7. Plots of logarithm of Kk_2 versus σ_X (or σ_X^+) constants for the reaction of 2,4-dinitrophenyl X-substituted benzoates with secondary alicyclic amines (Z) in H_2O containing 20 mol% DMSO at 25°C.

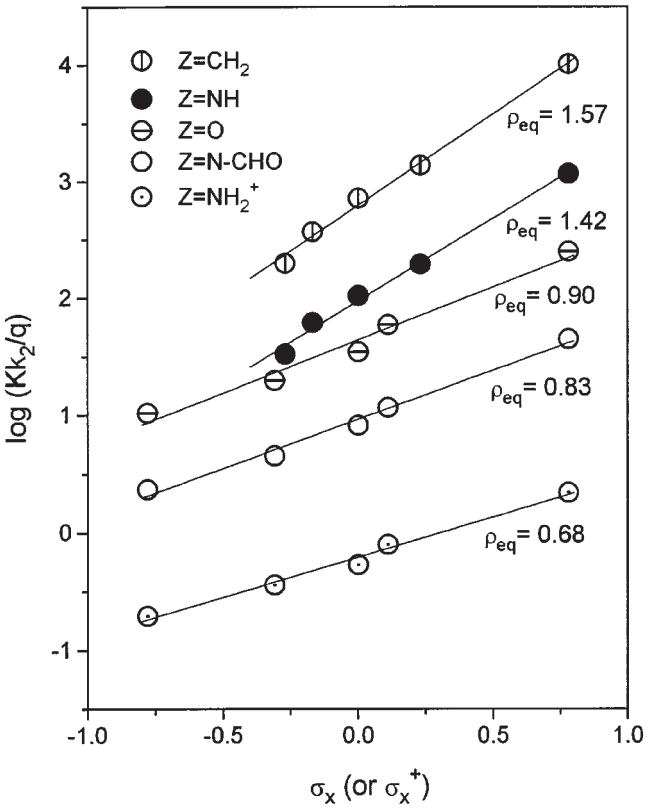

given amine. The present study clearly shows that the ρ_{app} and ρ_{eq} values are identical to the ρ_1 value for a given amine, and the magnitude of ρ_1 dominates that of ρ_{app} and ρ_{eq} (see Figs. 2, 5, and 7).

As mentioned in the preceding section, the magnitude of ρ_{app} and ρ_{eq} has been generally suggested to be small for the reactions in which the leaving group departure occurs in the RDS (9, 10), since the effect of acyl substituents on the k_1 and k_2 steps would be opposite. In fact, the magnitude of ρ_{app}, ρ_{eq}, and ρ_1 has been shown to be much smaller for the reactions with the low basic amines (pK_a < 9.1) in which the leaving group departure is the RDS than for the ones with the highly basic amines (pK_a > 9.1) in which the leaving group departure occurs after the RDS. However, the present result clearly suggests that the small ρ_{app} and ρ_{eq} values for the low basic amines are not due to the opposite substituent effect on the k_1 and k_2 steps, but due to small ρ_1 value for the low basic amines.

Experimental

Materials

2,4–Dinitrophenyl X-substituted benzoates (X-$C_6H_5CO_2C_6H_3$-$(NO_2)_2$-2,4) were easily prepared from the reactions of X-substituted benzoyl chlorides with 2,4-dinitrophenol in the presence of triethylamine in methylene chloride (18). Their purity was checked by means of melting points and spectral data such as IR and ^{1}H NMR characteristics. The amines and other chemicals used were of the highest quality available. To eliminate a solubility problem, 20 mol% dimethyl sulfoxide (DMSO) – H_2O mixture was used as the reaction medium. DMSO was distilled over calcium chloride at a reduced pressure (bp 64~66°C at 6~7 mmHg) (1 mmHg = 133.3 Pa) and stored under nitrogen. Doubly glass distilled water was further boiled and cooled under a nitrogen atmosphere just before use.

Kinetics

The kinetic studies were performed with a Hitachi U-2000 model UV-vis spectrophotometer for slow reactions ($t_{1/2}$ = 10 s) or with an Applied Photophysics SX-17MV stopped-flow spectrophotometer for fast reactions ($t_{1/2}$ < 10 s) equipped with a Neslab RTE-110 constant temperature circulating bath to keep the reaction mixture at 25.0 ± 0.1°C. The reactions were followed by monitoring the appearance of the leaving 2,4-dinitrophenoxide at 410 nm. All the reactions were carried out under pseudo-first-order conditions in which the amine concentrations were at least 20 times greater than the substrate concentration. The amine stock solution of ca. 0.2 M was prepared in a 25.0 mL volumetric flask under nitrogen atmosphere by adding 2 equiv. of amine to 1 equiv. of standardized HCl solution in order to obtain a self-buffered solution. All the solutions were transferred by Hamilton gas-tight syringes. Other details of kinetic methods were reported previously (19).

Conclusions

The present study has allowed us to conclude the following. (*i*) The RDS of the present aminolysis reactions changes from the k_2 step to the k_1 step as the amine becomes more basic than the leaving group by ca. 5 pK_a units. (*ii*) σ^+ constants give better correlation with log k_{app}, log k_1, and log Kk_2 when the k_2 step is the RDS (e.g., the reactions with the low basic amine, pK_a < 9.1). However, σ constants show better correlation when the k_1 step is the RDS (e.g., the reactions with highly basic amines, pK_a > 9.1). (*iii*) The magnitude of k_{-1}/k_2 is nearly constant upon changing the acyl substituent for a given amine, indicating that the RDS is not governed by the electronic nature of the acyl substituent X. (*iv*) The magnitude of ρ_1 is identical to that of ρ_{app} and ρ_{eq} for a given amine. (*v*) The magnitude of ρ_{app}, ρ_1, and ρ_{eq} is much smaller for the reactions with the low basic amines (pK_a < 9.1) than for the ones with the highly basic amines (pK_a > 9.1). (*vi*) The small values of ρ_{app} and ρ_{eq} for the reactions in which the RDS is the k_2 step is not because the effect of the acyl substituents on the k_1 and k_2 step is opposite, but because the corresponding ρ_1 value is small.

The effect of metal ions on the reaction of hydrogen peroxide with Kraft lignin model compounds

Yujun Sun, Michael Fenster, Annie Yu, Richard M. Berry, and Dimitris S. Argyropoulos

Abstract: Peroxide bleaching is significantly affected by transition and alkaline earth metals. Isolating the effects of different transition and alkaline earth metals on the reactions of peroxide with different representative lignin structures allows the separation of the positive from the negative contributions of these metal ions. In this work, five monomeric or dimeric phenolic lignin model compounds were treated with alkaline hydrogen peroxide in the absence or presence of Mn^{2+}, Cu^{2+}, Fe^{3+}, and Mg^{2+}. We followed the disappearance of the starting material and the progress of demethylation, radical coupling and oxalic acid formation were followed. Transition metals increased the reactivities of all the lignin model compounds with hydrogen peroxide in the order $Mn^{2+} > Cu^{2+} > Fe^{3+}$, which is the same as the order of activity toward peroxide decomposition while Mg^{2+} stabilized the system. Demethylation, radical coupling, and oxalic acid formation were all increased by the presence of transition metals in the system and decreased by the addition of Mg^{2+}. The acceleration of the total degree of reaction and of the demethoxylation reactions improves peroxide bleaching, but the increase in the radical coupling reactions can affect the further bleachability of pulp while the increase in the formation of oxalic acid could lead to a greater probability of scaling.

Key words: lignins, hydrogen peroxide, peroxide bleaching, reactivity, chemical pulps, metal compounds, alkali treatment, transition metals, delignification.

Résumé : Le blanchiment au peroxyde est affecté d'une façon significative par les métaux de transition et alcalinoterreux. En isolant les effets des divers métaux de transition et alcalinoterreux sur les réactions du peroxyde avec diverses structures représentatives de lignine, on peut séparer les contributions positives et négatives de ces ions métalliques. Dans ce travail, cinq composés modèles de lignine phénolique monomère ou dimère ont été traités par du peroxyde d'hydrogène en milieu alcalin, en présence ou en l'absence de Mn^{2+}, Cu^{2+}, Fe^{3+} et Mg^{2+}. On a suivi la disparition du produit de départ et le progrès de la déméthylation, du couplage radicalaire ainsi que de la formation d'acide oxalique. Les métaux de transition augmentent les réactivités de tous les composés modèles de la lignine avec le peroxyde d'hydrogène et l'ordre de cet effet est $Mn^{2+} > Cu^{2+} > Fe^{3+}$, le même que celui de l'ordre d'activité vis-à-vis de la décomposition du peroxyde; le Mg^{2+} stabilise le système. En présence de métaux de transition dans le système, les vitesses de déméthylation, de couplage radicalaire et de formation d'acide oxalique sont toutes augmentées; l'addition de Mg^{2+} les diminue. L'accélération du degré total de réaction et des réactions de déméthoxylation améliore le blanchiment au peroxyde, mais l'augmentation des réactions de couplage radicalaire peut éventuellement affecter la possibilité de pousser le blanchiment de la pulpe alors que l'augmentation de la formation d'acide oxalique peut éventuellement conduire à une plus grande probabilité de d'encrassement.

Mots clés : lignines, peroxyde d'hydrogène, blanchiment par le peroxyde, réactivité, pulpes chimiques, composés métalliques, traitement alcalin, métaux de transition, délignification.

Introduction

Hydrogen peroxide interacts with lignin via two different sets of reactions; perhydroxyl anions nucleophilically attack and eliminate lignin chromophores, while free radical species, formed through the decomposition of hydrogen peroxide, cause the oxidative degradation of phenolic lignin structures converting them to carboxylic acids (1). Free-radical species have also been claimed to participate in chromophore elimination reactions (2–5). During hydrogen peroxide bleaching of chemical pulps, the presence of transition metal ions and in particular manganese, copper, and iron is known to catalyze peroxide decomposition. In contrast, magnesium is known to stabilize peroxide. In the absence of transition metal ions, the decomposition of hydrogen peroxide proceeds via a homogeneous, pH dependent, bimolecular reaction involving hydroperoxy anions (6, 7). Earlier efforts aimed at revealing the reaction details between lignin model compounds and alkaline hydrogen peroxide in the absence of transition metal ions have shown that hydrogen peroxide degrades phenolic units to low molecular weight aliphatic carboxylic acids (8–14). However, Gierer and Imsgard (15) have shown that phenolic units are stable to alkaline peroxide but are reactive to hydroxy radicals arising from the decomposition of hydrogen peroxide. Abbot et al. (6, 7, 16) have also demonstrated that differences exist in the catalytic action of manganese, copper, iron, and magnesium ions toward peroxide decomposition in the presence and absence of pulp. Despite the fact that chelation and even an acid wash is frequently used to remove the transition metal ions from the pulp prior to bleaching, it is undeniable that traces of such species still remain in the system contributing to the complexity of the reaction sequences. The large variety of highly reactive species present in such reactions coupled with the complex structural features of residual Kraft lignin has made it difficult to define the interaction of alkaline peroxide with residual Kraft lignin and transition metal ions.

The continued international effort toward implementing environmentally benign bleaching sequences, which now often include pressurized (17, 18) and high-temperature (19, 20) peroxide warrants closer attention to be paid at the fundamentals of the reactions of alkaline hydrogen peroxide with residual Kraft lignins and its model compounds. Residual Kraft lignin contains significant amounts of condensed structures such as 5-5′, α-5, diphenylmethane, and stilbene units (21–23). Despite such structures being abundant in residual Kraft lignin, to date there have been no studies dealing with their reactions with alkaline hydrogen peroxide and the effect of transition metals in such a system. The aim of this work is to evaluate the reactivity of residual Kraft lignin moieties with alkaline hydrogen peroxide in the presence and absence of transition metals. In particular, a series of model compounds representing typical structures found in residual Kraft lignin were allowed to react with alkaline hydrogen peroxide in the presence and absence of manganese, iron, copper, and magnesium ions.

Experimental

Materials

The model compounds used during this investigation were 4-methylcatechol (**1**), 3-methoxy-4-hydroxytoluene or creosol (**2**), the condensed dimer containing a 5-5′ linkage (**3**), the condensed dimer containing an α-5 linkage (**4**), and the condensed dimer containing a methylene linkage (**5**). Catechol (**1**) and creosol (**2**) were purchased from Aldrich Chemicals and used without further purification. Model compounds **3**, **4**, and **5** were synthesized following literature procedures (24, 25). Hydrogen peroxide (30%) and magnesium sulfate (98.0%) were purchased from ACP Chemicals, and iron(III) sulfate (97.0%), sodium hydroxide of semiconductor purity (99.99%) were purchased from Aldrich Chemical Co. Copper(II) sulfate (98.4%) was purchased from Baker Chemicals, while manganese sulfate (99.8%) was purchased from Fisher Scientific Co. The remaining reagents and solvents were of analytical grade or better. The water used in this study was first distilled and then passed through a nanopure analytical deionization system (Barnstead).

Reactions of model compounds with peroxide

The precise reagent stoichiometry was established by considering a benzene ring as one unit. As such the ratio of model compound/peroxide/NaOH was 1/3/2 (on molar basis) for mononuclear models **1** and **2** and 1/6/4 for dinuclear models **3**, **4**, and **5**. The concentration of metal ions used during this study was 0.5% for compounds **1** and **2** and 1% for compounds **3**, **4**, and **5**. This concentration was in excess of the solubility limit of the hydroxides under the alkaline conditions used in this work. Therefore, the metal ions present should be considered as being present as their hydrous oxide precipitates in equilibrium with the oxidation mixture.

The model compound (100 mg) was mixed with a known volume of deionized water, never exceeding 20 mL. The pH was adjusted to 12 by adding a predetermined amount of 1 N NaOH, and then the solution of the metal ion (0.01 N) was added. Hydrogen peroxide was then added using a 100 mL syringe. Finally, the total volume was made up to 25 mL with water. All reactions were carried out in stainless steel bombs equipped with a glass liner immersed in a hot water bath maintained at 80°C for 2 h.

Reaction work-up procedure

At the end of the reaction a 2.0 mL aliquot of reaction mixture was withdrawn, and the concentration of residual peroxide was determined using an iodometric titration. The pH of the reaction mixtures was then adjusted to 2 using 10% HCl, and the acidified mixture was extracted with ethyl acetate (3 × 50 mL) and chloroform (3 × 50 mL). The organic extracts were stirred over anhydrous magnesium sulfate, filtered, and concentrated using a rotary evaporator with the water bath set at 25°C. The aqueous phase was freeze-dried, and the resulting solid was extracted with acetone. The extracts from the organic and aqueous phases were combined, dried at room temperature, and subjected to GC/MS analyses. The H_2O_2 consumption data and reaction yields are tabulated in Table 1.

Analytical methods

GC/MS analyses were carried out on a Hewlett Packard 5972 mass spectrometer interfaced to a Hewlett Packard 5890-A gas chromatograph equipped with a DB-5 30 m × 0.25 mm packed silica capillary column. The injection port temperature was 280°C, and the oven temperature was raised from 70 to 250°C with a gradient of 15°C/min. The products were analyzed after being silylated using N,O-bis(trimethylsilyl)acetamide. The compounds were identified by comparing their fragmentation patterns with those of commercially available or independently synthesized authentic samples.

Product quantification was carried out by using a gas chromatograph coupled to a flame ionization detector under conditions identical to those described previously. The product ratios were evaluated by using 4-methoxyphenol as the internal chromatographic standard. The GC response factors relative to the standard were determined using one of two methods. For commercially available compounds, their response factors were obtained by mixing known volumes of the compound with standard solutions, followed by GC area measurements. For compounds that were not available, their relative response factors were calculated by using the Effective Carbon Number (ECN) concept (26, 27). The contributions to ECN for specific functional groups are shown in Appendix.

The major MS fragmentation patterns for trimethylsilylated compounds discussed in this work are as follows: –*m/z* (relative intensity %): product **1**: 268 (M, 35%), 253(6), 180(10), 165(6), 149(6), 73(100); 1.01: 219 (M – 15, 3%), 190(5), 147(81), 133(4), 73(100); 1.02: 233 (M – 15, 30%), 147(100), 117(23), 73(45); 1.03: 260 (M, 9%), 245(4), 147(29), 143(79), 73(100); 1.04: 356 (M, 26%), 341(2), 267(50), 179(40), 147(15), 73(100); 1.05: 534 (M, 16%),

Results and discussion

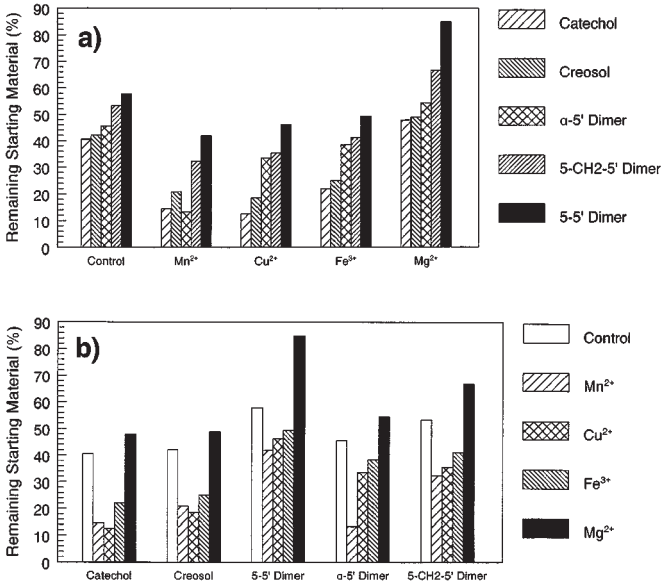
Table 1 shows the H_2O_2 consumption, the total amounts of identified products (excluding any remaining starting materials), the amounts of unidentified compounds, and those that could not be detected by GC. The yields of products recovered after the reaction varied between 67 and 92%. Severe degradation of model compounds with the formation of volatile and highly water soluble products likely accounts for the unrecovered material.

Effect of metal ions on the reactivity of hydrogen peroxide with residual Kraft lignin model compounds

The mechanism of alkaline hydrogen peroxide delignification of chemical pulps is complicated due to the complexity of the lignin structure and the large variety of reactive species formed during the process. Figures 1*a* and 1*b* display the reactivities of the examined lignin model compounds toward alkaline H_2O_2 in the presence or absence of metal ions. By presenting the same data in different ways, two sets of evaluations and comparisons can be made: one addressing the reactivity of the various lignin models in the presence (or absence) of the same metal ion (Fig. 1*a*) and the other the influence of the various metal ions on the same model compound (Fig. 1*b*).

The plots of Fig. 1*a* show that, in general, the reactivities of the five model compounds examined was of the following order: catechol (**1**) > creosol (**2**) > α-5′ dimer (**4**) > 5-CH_2-5′ dimer (**5**) > 5–5′ dimer (**3**). This reactivity order is what one would expect by considering the degree of activation caused

Fig. 1. The reactivity (reflected by the amount of remaining starting material) of the various residual Kraft lignin model compounds examined during this work, in the presence and absence of various metal ions: (*a*) displays the data as a function of the individual metal ions added; (*b*) displays the data as a function of the individual model compounds examined.



by the groups present on the aromatic rings, i.e., OH > OCH_3 > CH_3 > C_6C_5. The high reactivity of catechol moieties is in accord with the finding of Francis and Reeve (28). Our data also show that the more activated the aromatic structure, the greater its reactivity toward alkaline hydrogen peroxide, irrespective of the metal ion being added. The presence of metal ions did not significantly alter the above reactivity order but did change the extent of reactions.

Johansson and Ljunggren (29) have demonstrated, using model compounds, that during oxygen delignification the presence of two phenolic hydroxyl groups on an aromatic ring considerably increases its reactivity toward oxygen; methylcatechol was found to be more reactive than creosol. In addition, Johansson and Ljunggren (29) have shown that the reactivity of a mononuclear aromatic structure is greater than its dinuclear analogue. Similarly, using critical oxidation potential data, Kratzl et al. (30) have arrived at the same conclusions. In these respects, our findings are in complete agreement with the literature claims despite different systems having been examined. Since hydroxyl and superoxide anion radicals are the two major radical species produced from the stepwise reduction of oxygen and from the decomposition of hydrogen peroxide (31) and since these radicals are more reactive toward phenolic compounds than peroxide or oxygen, it is not surprising that the data that emerges from the present study parallels the mechanistic information already described for oxygen delignification.

Compared to our control runs, the addition of metal ions dramatically affected the reactivities of the examined model compounds toward alkaline hydrogen peroxide (Fig. 1*b*). The transition metals increased the extent of reaction between hydrogen peroxide and the model compounds, as evidenced by the decreased amounts of remaining starting material present after the reaction (compared to the control).

© 1999 NRC Canada

The presence of magnesium ions, however, protected all model compounds from being decomposed as evidenced by the increase of the remaining starting material (Fig. 1*b*).

Of the transition metals evaluated in most cases, the manganese ions caused the greatest increase in reactivity, while iron caused the least. The range of reactivity was particularly large for the dinuclear model compounds. Similar conclusions describing the effect of these ions toward decomposing peroxide have appeared in the literature (16, 32). Smith and McDonough (33) have demonstrated that the oxidation of compound **5** and the decomposition of peroxide was aided by transition metals in the following order: $Mn^{2+} > Cu^{2+} > Fe^{3+}$, their results being somewhat different at longer reaction times.

Our data are also in agreement with the speculation of Brown and Abbot (16) that transition metals decompose peroxide with the subsequent formation of a number of reactive species and that these species in turn react with lignin considerably faster than alkaline peroxide itself. The transition metals can also affect the reactivity of alkaline peroxide with phenolic moieties in lignin. Transition metal ions such as Mn^{2+}, Cu^{2+}, and Fe^{3+} may act as electron acceptors catalyzing phenoxy radical formation. The formation of such radicals is thought to be the rate-determining step in the oxidation of phenols, with copper ions being particularly effective (33, 34). This increase in reactivity caused by copper ions is seen in this present work. Catechol **1** and creosol **2** were oxidized more efficiently in the presence of copper ions than in the presence of any other metals (Fig. 1*b*).

The mechanism of action of magnesium salts in peroxide and oxygen delignification has been the subject of considerable literature discussions (7, 32, 35–37). In general, magnesium ions are thought to stabilize alkaline hydrogen peroxide either by deactivating the transition metals, by forming protective Mg-metal complexes around them (37), or by stabilizing superoxide anion radicals via the formation of stable magnesium superoxide complexes, thereby disrupting free-radical chain decomposition reactions (32). The stabilizing action of magnesium ions is clearly reflected in the data of Fig. 1*b*, since in its presence, the reactivity of all model compounds with alkaline hydrogen peroxide was significantly reduced.

Radical coupling reactions

Literature accounts have documented that aqueous hydrogen peroxide decomposes to yield molecular oxygen and water via various free-radical intermediates, particularly when the process is catalyzed by transition metal ions (38, 39), i.e.,

$$H_2O_2 + OH^- \leftrightarrow HO_2^- + H_2O$$

$$H_2O_2 + HO_2^- \rightarrow HO^\cdot + O_2^{\cdot -} + H_2O$$

$$HO^\cdot + O_2^{\cdot -} \rightarrow OH^- + O_2$$

The various radical species formed interact with phenolic compounds, giving rise to phenoxyl radicals, which then become involved in coupling and (or) rearrangement reactions. Gierer et al. (40) who have examined the detailed chemistry that operates between lignin model compounds and hydroxyl radicals have arrived at the conclusion that under alkaline conditions coupling is the dominant reaction.

In an effort to examine the role of the different transition metal ions in inducing the formation of radical coupling products in phenolic residual Kraft lignin moieties, particular attention was paid to accurately quantifying the fraction of products which were of high molecular weight. Such compounds could not be volatilized and consequently could not be detected by gas chromatography. To these values the amount of identified and (or) rearranged products was then added, yielding the total amount of radical coupling products formed. More specifically, the following identified products (Table 2) were considered the result of radical coupling reactions: for compound **1**: 1.05; for compound **2**: 2.06–2.09; for compound **3**: 3.05, 3.06; for compound **4**: 4.09; for compound **5**: 5.05 and 5.06.

The data of Fig. 2 show that of transition metal ions induced the formation of considerable amounts of coupling products. Manganese ions caused the highest formation of radical coupling products for all examined model structures.

Of the three transition metal ions examined in this effort, Fe^{3+} ions were found to generate the least amount of radical coupling products. This is consistent with the data of Landucci (34) who reported that, in alkaline media, Fe^{3+} ions cannot abstract an electron from a phenol or a phenolate anion. The beneficial effects of Mg^{2+} ions are once again apparent in the data of Fig. 2. The presence of Mg^{2+} significantly reduced the amount of radical coupling products being formed, except for creosol, which was also particularly sensitive to all of the transition metals.

In summary, the data presented in this section suggest that the negative effects of transition metals in peroxide bleaching are not only due to peroxide decomposition reactions which reduce its efficiency, but also to the formation of stable structures through radical coupling reactions which also make residual Kraft lignin harder to oxidize. The radical coupling data of Fig. 2 can explain the relatively poor response of Kraft pulp toward chlorine dioxide after oxygen or peroxide delignification (41). Radical coupling products formed in residual Kraft lignin during an oxygen and a peroxide stage are more susceptible to reaction with chlorine or ozone rather than chlorine dioxide (42). Since the role of magnesium ions in the presence of different transition metal ions has not been addressed in detail, the focus of a subsequent investigation in our laboratory will be precisely this, with emphasis on radical coupling product formation.

Reaction product profiles

Scheme 1 shows the structures of the main reaction products detected for all examined model compounds, while Table 2 depicts the determined amounts for each product. However, some minor identified products and certain intermediates are not shown. The following discussion will be focused on the effect of the various metal ions on product profiles without delving into the detailed reaction mechanisms responsible for the formation of these products, since such efforts have been adequately covered by other authors (9, 40, 43).

If the main reactive species during alkaline hydrogen peroxide bleaching was the hydroperoxide anion, enone and carbonyl containing moieties would react while phenolic or

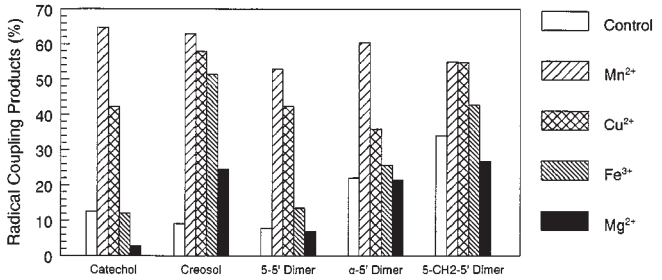
Fig. 2. The amounts of radical coupling products formed during the reaction of alkaline hydrogen peroxide with various residual Kraft lignin model compounds in the presence or absence of various metal ions.



catecholic centres would not (15). The structures of the detected products, however (Scheme 1), show that significant degradation and radical coupling reactions have occurred. Such products are formed from the interaction of the decomposition products of hydrogen peroxide with model compounds **1**–**5**.

The reaction products detected from the interaction of catechol **1** and creosol **2** with alkaline hydrogen peroxide in the presence and absence of the various transition metal ions indicate that the primary route for the breakdown of such phenolic moieties consists of ring opening followed by more severe fragmentation (9). In addition, 5-5′ and 5-O-4′ coupling products were present (products 1.05 and 2.06–2.09) as a consequence of carbon- and oxygen-centred radical coupling reactions. As well, the detected radical coupling products were found to increase in the presence of Mn^{2+}, Cu^{2+}, and Fe^{3+} ions (Table 2). Carbon-centred radicals are thought to efficiently recombine, since the resulting dimers have lower critical oxidation potentials (COP) than the original monomers (30).

Oxalic acid (entries 1.01, 2.01, and 4.01; Table 2) is of particular significance to peroxide bleaching operations, since oxalate salts are known to form detrimental deposits on bleach plant process equipment. Table 2 and Fig. 3 show that compounds **1**, **2**, and **4** generated a large amount of oxalic acid, and catechol **1** produced the most. The amount of formed oxalic acid increased in the presence of transition metal ions, while the presence of magnesium ions significantly suppressed the formation of oxalic acid, bringing it to levels lower to those of the control experiments.

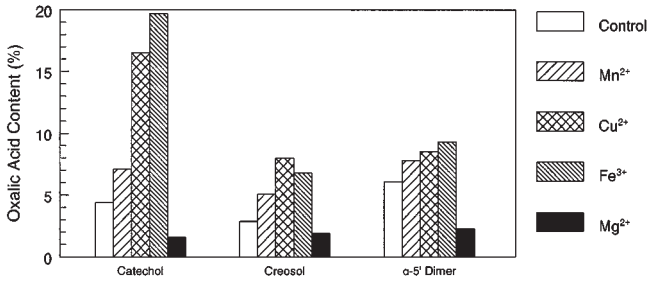
Fig. 3. The amounts of oxalic acid formed during the reaction of alkaline hydrogen peroxide with three Kraft lignin model compounds in the presence and absence of various metal ions.



Products 2.05, 2.07, and 2.09 show the occurrence of demethoxylation reactions. These are significant reactions, since free phenolic hydroxyl groups predispose the structure of lignin to further oxidation. The sum of product 2.05, 2.07, and 2.09 shows the scale of demethoxylation reaction; product 2.05 is likely the precursor of products 2.07 and 2.09. The sum of 2.05, 2.07, and 2.09 shows that demethoxylation reactions prevail in the presence of transition metal complexes. Hydroxyl radicals forming from the decomposition of hydrogen peroxide are known to induce demethoxylation (14, 40). Copper ions caused the greatest degree of demethoxylation, while the presence of magnesium ions significantly suppressed demethoxylation reactions, bringing them to levels lower than those of the control experiments.

During the 60's, Kartzl's team (30, 44) investigated the fundamentals of the interaction of oxygen with phenols under delignification conditions. Their research efforts, amongst others, led to a comprehensive qualitative understanding of radical coupling reactions that cause the formation of biphenolic structures and their eventual degradation to 1-methyl-3-methoxy-4-hydroxy benzoic acid, acetone, and carbon dioxide. Since the underlying chemistry of oxygen and peroxide delignification stages are similar, it was not surprising to discover that the dominant degradation product arising from the interaction of alkaline hydrogen peroxide with the biphenolic 5-5′ dimer was 1-methyl-3-methoxy-4-hydroxy benzoic acid (compound 3.04, Table 2). Residual traces of the corresponding aldehyde (compound 3.03) were also apparent in some cases, signifying that the aldehyde is the precursor to the acid during the oxidation. The small amounts of the aldehyde also signified that the oxidation of aldehyde 3.03 to acid 3.04 is a very rapid reaction under alkaline peroxide delignification conditions.

Since it is conceivable that the radical coupling product 2.06 (which is model compound **3**) would convert to acid 3.04 and traces of aldehyde 3.03, it is interesting to note that no 1-methyl-3-methoxy-4-hydroxy benzoic acid (3.04) was detected amongst the degradation products of compound **2**. This may indicate that under alkaline peroxide delignification conditions the formation of radical coupling products is faster than their further degradation. The precise determination of the energies of activation for these reactions may further substantiate such a conclusion.

Amongst the three dimers examined, the α-5′ dimer **4** was found to be the most reactive followed by dimer **5**, as evidenced by the amount of remaining starting materials after the reaction (Fig. 1*a*). This is not surprising when one considers that these compounds contain a benzylic carbon which is known to be relatively labile. That the α-5′ dimer **4** was slightly more reactive than dimer **5** may be explained on the basis of spin density considerations, taking into account the stability of the resulting radicals after cleavage at the benzylic centre. It is also worth noting that compound **4** yielded the rearrangement product 4.09 (Scheme 1), which is formed by the coupling of a phenoxy and a benzyl radical followed by rearomatization. Similar reaction products were found by Gierer et al. (40) when they treated creosol with hydroxyl radicals. The presence of lactonic acids 5.05, 5.06, amongst the degradation products of model **5**, provides evidence that the muconic acid pathway was also operational. This pathway involves the initial formation of catechols possibly via an initial, radically induced, demethylation reaction followed by their oxidation to *ortho*-quinones. Such moieties may then be attacked by hydroperoxide anions, forming dioxetanes, followed by carbon–carbon bond scission of the dioxetane ring, giving rise to the corresponding carbonyl-containing fragments (15). Structures of similar nature were also present amongst the degradation products of dimers **3** and **4**, i.e., products 3.05 and 4.08.

Concluding remarks

(*i*) Transition metals have the positive effects of accelerating the total degree of reaction and the demethoxylation reactions. They also have the negative effects of increasing the rate of radical coupling reactions, which can affect the further bleachability of pulp, and significantly increasing the amount of oxalic acid generated by peroxide bleaching reactions. (*ii*) Magnesium ions have exactly the opposite effects probably because of the deactivation of the small quantities of transition metals present in even control samples. (*iii*) Oxygen and peroxide delignification reactions are very similar. (*iv*) The order of reactivity of the phenolic lignin models towards hydrogen peroxide was determined by the degree of activation of the aromatic ring by the various ring substituents. The presence of metal ion did not alter this reactivity order. (*v*) The addition of metal ions induced the formation of radical species by initiating the decomposition of hydrogen peroxide to radicals and (or) catalyzing the formation of phenoxy radical directly. In this work, the overall catalytic ability of the transition metals toward increasing the reactivity of phenolic models was found mostly to be $Mn^{2+} > Cu^{2+} > Fe^{3+}$, which is the same as the order of activity toward peroxide decomposition.

Reactivity of aminyl radicals in radical nucleophilic substitution reactions with diphenylphosphide anion

Gabriela S. Foray, Alicia B. Peñéñory, and Roberto A. Rossi

Abstract: The photostimulated reactions of *N*-cyclopropyl-*N*-ethyl *p*-toluensulfonamide (**4**) with diphenylphosphide ions (**2**) in liquid ammonia gave 1,3-bis(diphenylphosphinyl)-1-(*N*-ethyl)propylamine, isolated as the oxide **5**, and 1,3-bis(diphenylphosphinyl)-1-propanol, isolated as the oxide **6**, all of them corresponding to the aperture of the cyclopropylaminyl radical intermediate. The reaction of **4** with **2** in excess and longer reaction times gave only **5** (73% yield). The photostimulated reactions of *N*-(*n*-butyl)-*N*-cyclobutyl *p*-toluensulfonamide (**13**) with **2** in liquid ammonia gave, after oxidation, *N*-(*n*-butyl)-*N*-cyclobutyl diphenylphosphonamide (**14**) in 94% yield. All these reactions occur by the radical nucleophilic substitution in which aminyl radicals are intermediates. The order of the magnitude of the rate constant for the coupling reaction of a dialkylaminyl radical with **2** could be intermediate between those of the rearrangements of the cyclopropyl and cyclobutylaminyl radicals.

Key words: aminyl radicals, $S_{RN}1$ reactions, radical clocks, photochemistry.

Résumé : Les réactions photostimulées du *N*-cyclopropyl-*N*-éthyl *p*-toluènesulfonamide (**4**) avec les ions diphénylphosphure (**2**), dans l'ammoniac liquide, conduisent à la 1,3-bis(diphénylphosphinyl)-1-(*N*-éthyl)propylamine, isolé sous la forme d'oxyde (**5**), et de 1,3-bis(diphénylphosphinyl)-propan-1-ol, isolé sous la forme d'oxyde (**6**); tous ces produits correspondent à l'ouverture du radical cyclopropylaminyle intermédiaire. La réaction du produit **4** avec **2** en excès et l'utilisation de temps de réaction plus longs conduisent à la formation exclusive du produit **5** (rendement de 73%). Les réactions photostimulées du *N*-(butyl)-*N*-cyclobutyl *p*-toluènesulfonamide (**13**) avec **2** dans l'ammoniac liquide conduit, après oxydation, au *N*-(butyl)-*N*-cyclobutyl diphénylphosphonamide (**14**) avec un rendement de 94%. Toutes ces réactions se produisent par le biais d'une réaction de substitution radicalaire nucléophile dans laquelle les intermédiaires sont des radicaux aminyles. L'ordre de grandeur de l'amplitude de la constante de vitesse de la réaction de couplage d'un radical dialkylaminyle avec le composé **2** se situerait à une valeur intermédiaire entre celles des réarrangements des radicaux cyclopropyl- et cyclobutyl-aminyles.

Mots clés : radicaux aminyles, réactions $S_{RN}1$, horloges radicalaires, photochimie.

[Traduit par la Rédaction]

Nucleophilic substitution by electron transfer is an area of great interest which has increased considerably in the last 20 years (for reviews on $S_{RN}1$ see ref. 1). Several substrates have been described to react by a chain radical mechanism of nucleophilic substitution or $S_{RN}1$. The mechanism of the reaction is a chain process, and the propagation steps are shown in Scheme 1.

According to this mechanism the radical anion of the substrate $(RX)^{-\cdot}$ is formed, in the initiation step, by an electron transfer (ET) from a suitable electron source. The $(RX)^{-\cdot}$ formed fragments to give a radical and the anion of the leaving group (eq. [1]). The radical can react with the nucleophile to afford the radical anion of the substitution product (eq. [2]), which by ET to the substrate (eq. [3]), affords the substitution product and $(RX)^{-\cdot}$ to continue the chain process.

All of the examples known imply the reaction of a carbon-centered radical with an appropriate nucleophile. We are interested in the study of the reactivity of heterocentered radicals with nucleophiles, and more specifically, the study of aminyl radicals.

Recently, we have reported the first example of an $S_{RN}1$ reaction involving a nitrogen-centered radical (2). Thus, *N*,*N*-di-(*n*-butyl)-*p*-toluensulfonamide (**1**) reacts under irradiation with diphenylphosphine ion (**2**) in liquid ammonia, giving, after oxidation, the corresponding phosphonamide (**3**) in good yields (79%). This reaction proceeds by an $S_{RN}1$ mechanism in which the aminyl radicals are intermediates ([eq. 4]).

Received November 4, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

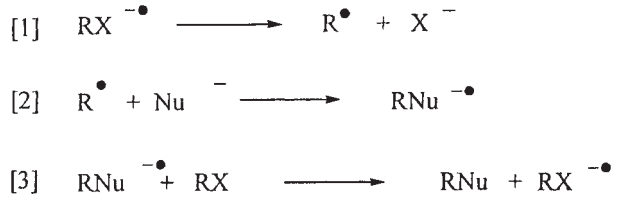
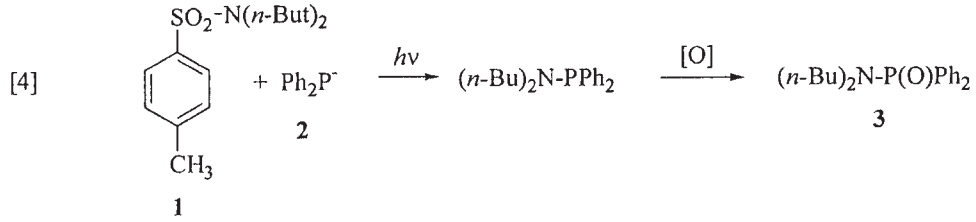
Scheme 1.



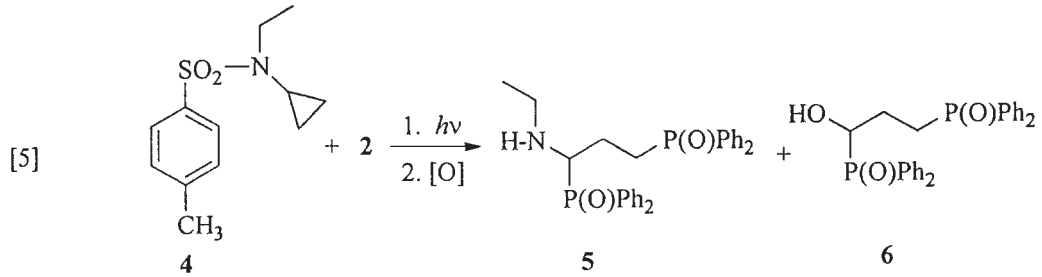
In this reaction, the reduction of the dibutylaminyl radical to di-*n*-butylamine is a competitive process. This result led us to suppose that the coupling reaction was not as fast as in the case of aromatic radicals.[2] It has been suggested that the coupling of **2** with 2-quinolyl radicals is diffusional (4).



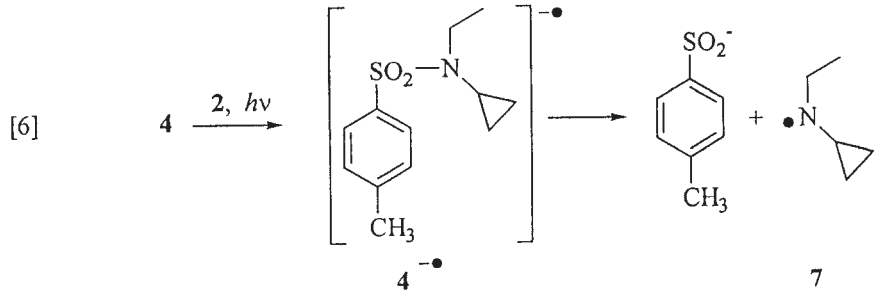
Rate constants for the rearrangement of different aminyl radicals, like the ring opening of cyclopropyl and cyclobutyl aminyl radicals are known (5). Substrates that give cyclopropyl and cyclobutyl aminyl radicals could, in principle, be used as clock reactions (6), and it could be possible to estimate the order of the rate constant for the coupling reaction between the dialkylaminyl radical and **2**.

Results and discussion

The photostimulated reaction of *N*-cyclopropyl-*N*-ethyl *p*-toluensulfonamide (**4**) with **2** in liquid ammonia gave, after oxidation, compounds containing the diphenylphosphinyl group, identified as **5** and **6** in 8 and 20% yield, respectively (eq. [5]) (Table 1, expt. 1).[3]



The yields of these products increase as does the concentration of **2**. Thus, when the molar relation was 1:2.6, 69% of **5** and 24% of **6** were quantified. No products containing the cyclopropyl aminyl moiety were detected. There was no reaction in the dark, and the substrate was recovered in high yield (Table 1, expt. 4). When the time of irradiation was reduced to 5 min, 18% of **5** and 12% of **6** were produced. This photoinduced reaction was inhibited by the presence of *p*-dinitrobenzene and di-*tert*-butylnitroxide, a strong electron acceptor and a radical trap, respectively (Table 1, expts. 5–7). When the photostimulated reaction was treated with DMSO, the liquid ammonia was allowed to evaporate, and the reaction was kept during 4 days, **5** was the only product isolated (73% yield).



[2] Coupling rate constants for aromatic radicals with nucleophiles have been determined, and most of them are in the order of 10^7–10^{10} (see ref. 3).

[3] Small amounts of 3-(diphenylphosphinyl) propanal, isolated as the oxide, was detected (<2% yield).

10	**13** (1.0)	2.6	94	—	—

[a]Performed in ca. 350 mL of liquid ammonia under nitrogen atmosphere, irradiation time 30 min with two 400 W lamps.

[b]**4** and **11** were dissolved in ca. 2 mL of anhydrous diethyl ether prior addition to the reaction flask.

[c]Determined by GC or HPLC using the internal standard method, based on the concentration of the substrates.

[d]Products coming from the coupling reaction of **2** with a nitrogen centered radical.

[e]Products coming from coupling reaction of **2** with a carbon-centered radical.

[f]Dark reaction.

[g]5 min of irradiation.

[h]*p*-Dinitrobenzene (20 mol%) was added.

[i]Di-*tert*-butylnitroxide (20 mol%) was added.

[j]After 30 min of irradiation DMSO was added to the reaction mixture and was stirred for 4 days under nitrogen atmosphere.

[k]Quantified after isolation from silica-gel chromatography.

From all these results, it is concluded that **4** reacts under irradiation with **2** by the $S_{RN}1$ mechanism, with aminyl radicals as intermediates. Under irradiation, anion **2** transfers one electron to **4**, giving the radical anion $\mathbf{4}^{-\cdot}$, which after fragmentation yields *p*-toluensulfonate ion and the cyclopropylethylaminyl radical **7** (eq. [6]).

Radical **7** can undergo two possible reactions, i.e., it can couple with **2**, giving radical anion $\mathbf{8}^{-\cdot}$ (vide infra), which after electron transfer affords the substitution product **8** (eq. [7]), or it can rearrange to a carbon-centered radical, **7′**, which is able to react with the anion **2** to yield, finally, the substitution product **9** ([eqs. [8] and [9]).

[7] 
[8] 
[9] 
The amount of products **8** and **9** depends on the rate for the coupling of **7** with nucleophile **2** as well as on the concentration of **2** (eq. [7]), and on the rate of ring opening of the cyclopropylaminyl radical **7** to yield the radical **7′**. The rate constant for rearrangement of **7** was determined in benzene at 50°C and is ca. 10^9 s^{-1} (5). From the relation of products **8** to **9**, and taking into account the rate constant for ring opening of **7**, it would be possible to estimate the rate constant for coupling of cyclopropylalkylaminyl radical **7** with **2**. Unfortunately, **8** was not observed experimentally, and the reaction gave only products coming from the ring opening of the aminyl radical **7**.

[10] 
10

[11] 
11 12

Product **9** was not isolated as such, since the imine group can react further with **2** to yield the addition product **10**, which upon oxidation affords **5** (eq. [10]). Product **9** can also yield, as a result of aqueous work-up, the aldehyde **11** (hydrolysis of the imine group), which also adds **2** or diphenylphosphine to the carbonyl group, giving the addition product **12**, which after oxidation renders **6** (eq. [11]).

The relation **5**/**6**, depends on the concentration of **2** and on the rate of the addition reaction to the imine group. Thus, the amount of **5** increases as the concentration of **2** increases. Upon treatment of a liquid ammonia photostimulated solution of **4** and excess of **2** with DMSO, the liquid ammonia allowed to evaporate, and the reaction mixture kept for 4 days under a nitrogen atmosphere (to avoid hydrolysis of the imine), only product **5** was obtained in 73% (Table 1, expt. 8).

The fact that only open chain products were obtained means that the rearrangement of **7** is faster than the coupling with anion **2** (the product from coupling of the aminyl radical with **2** is not observed).

To establish the extent to which the rate of the coupling reaction competes favourably with the rate of rearrangement of the *N*-cycloalkylaminyl radicals, we synthesized *N*-(*n*-butyl)-*N*-cyclobutyl *p*-toluensulfonamide (**13**), which upon photostimulated reaction with the nucleophile (electron transfer), and ulterior fragmentation could afford *N*-(*n*-butyl)-*N*-cyclobutyl aminyl radicals, which, in term, are known to ring open in a slower fashion than the cyclopropyl analogue **7** (5).

Thus, the photostimulated (30 min) reaction of **13** with anion **2** in liquid ammonia gives, after oxidation, *N*-(*n*-butyl)-*N*-cyclobutyl-*P,P*-diphenylphosphonamide (**14**) (66% of isolated product) (eq. [12]),[4] (Table 1, expt. 9).[5] When the molar relation was 1:2.6, 94% of **14** was quantified (Table 1, expt. 10).

[12] 
13 14

From these results, we can conclude that the rate constant for the coupling reaction of a dialkylaminyl radical with **2** is not diffusional as in the case of aryl radicals, and its order of magnitude could be estimated to be intermediate between that for the rearrangement of the cyclopropyl and that of the cyclobutylaminyl radicals (2×10^9 and 1.6×10^6 s^{-1} at 50°C in benzene, respectively) (5). On the other hand, aminyl radicals are unequivocally intermediates in these reactions.

Experimental section

General methods

^1H and ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer, and all spectra are reported in δ (ppm) relative to Me_4Si, with $CDCl_3$ as solvent. ^{31}P NMR were performed on a Bruker AC-300 spectrometer, using H_3PO_4 as external reference and $CDCl_3$ as solvent. The IR spectra were recorded on a Nicolet FT 5-SXC spectrometer, and the mass spectra were obtained with a Finnigan Model 3300 mass spectrometer. Gas-chromatographic analyses were performed on a Hewlett Packard 5890 Series II with a flame-ionization detector and the data system Spectra Physics 4290, on a HP-1 capillary column (methyl silicone gum, 5 m × 0.53 mm, 2.65 μm film thickness). High-performance liquid chromatography (HPLC) was performed on an LKB Model 2249 instrument with a LKB Model 2122 UV-visible detector, Spherisorb ODS-2 column (5 μm, 250 × 4 mm i.d.) and a Spectra Physics SP-2400 data system. Column chromatography was performed on silica gel (70–230 mesh ASTM). Irradiation was conducted in a reactor equipped with two 400-W UV lamps emitting maximally at 350 nm (Philips Model HPT, water-refrigerated).

Materials

N-Cyclopropyl-*N*-ethyl *p*-toluensulfonamide (**4**) (^1H NMR δ: 0.70 (m, 2H), 0.84 (m, 2H), 1.14 (m, H), 2.43 (s, 3H), 3.28 (q, 2H, *J* = 7.3 Hz), system A2B2 7.24 (d, 2H, *J* = 8.25 Hz), 7.74 (d, 2H, *J* = 8.25 Hz)) and *N*-(*n*-butyl)-*N*-cyclobutyl *p*-toluensulfonamide (**13**) (^1H NMR δ: 0.93 (t, 3H, *J* = 7.3 Hz), 1.31 (m, 2H), 1.6 (m, 4H), 2.03 (m, 4H), 2.41 (s, 3H), 3.09 (m, 2H), 4.12 (q, H, *J* = 8.4 Hz), system A2B2 7.28 (d, 2H, *J* = 8.28 Hz), 7.74 (d, 2H, *J* = 8.28 Hz)) were synthesized from the alkylation of the cyclopropyl or cyclobutyl *p*-toluensulfonamide (7) with iodoethane or *n*-bromobutane under phase-transfer conditions in good

[4] Only mere traces of a possible product from the rearranged carbon-centered radical was observed.

yields (75–83%) (8). Diphenylphosphide ions (**2**) were prepared from the reaction of triphenylphosphine (Fluka) with 2 equiv. of sodium metal in liquid ammonia. The sodium amide formed was neutralized with *tert*-butyl alcohol. DMSO (Carlo Erba) was distilled under vacuum and stored over molecular sieves (4 A).

Photostimulated reaction of *N*-cyclopropyl-*N*-ethyl *p*-toluensulfonamide (4) with 2

The following procedure is representative of all the reactions. Into a three-necked, 500 mL round-bottom flask equipped with a cold finger condenser charged with dry ice – ethanol, a nitrogen inlet, and a magnetic stirrer were distilled 350 mL of ammonia. Triphenylphosphine (0.8 mmol) and sodium metal (1.6 mmol) were added to form **2**, and then *tert*-butyl alcohol (0.8 mmol) was added. Substrate **4** (0.5 mmol) was dissolved in ca. 2 mL of anhydrous diethyl ether prior addition to the reaction flask. After 30 min of irradiation the reaction was quenched by the addition of ammonium nitrate. Ammonia was allowed to evaporate. Water (50 mL) was added to the residue and the mixture extracted with diethyl ether. The ether extract was analyzed by HPLC (petroleum ether:methylene chloride:acetone:ethyl acetate:methanol: 1:1:1:1:0.3), and the substitution products **5** and **6** were quantified using *N*,*N*-dibutyl *p*-toluensulfonamide as internal standard.

1,3-Bis(diphenylphosphinyl)-1-(*N*-ethyl)propylamine (5)

It was isolated by silica-gel chromatography with petroleum ether/diethyl ether (25:75). IR (KBr) (cm^{-1}): 3414.9, 3286.7, 3058.2, 2963.5, 2935.6, 2868.7, 1665, 1436.5, 1274.9, 1118.9. ^{1}H NMR δ: 0.92 (t, 3H), 1.8 (m, 2H), 2.4 (m, 4H), 3.52 (m, 1H), 7.6 (m, 20H).^{13}C NMR δ: 15.44 (s, CH_3), 24.65 (dd, CH_2, $J_{C–P}$ = 8.14 Hz, $J_{C–P}$ = 12.21 Hz), 25.78 (dd, CH_2, $J_{C–P}$ = 5.42 Hz, $J_{C–P}$ = 17.6 Hz), 42.77 (d, CH_2, $J_{C–P}$ = 8.14 Hz), 57.6 (dd, CH, $J_{C–P}$ = 12.2 Hz, $J_{C–P}$ = 78.7 Hz). The aromatic signals without assignment due to the high complexity of the system. ^{31}P NMR δ (H_3PO_4 85%): 31.73, 33.58.[5]

1,3-Bis(diphenylphosphinyl)propanol (6)

It was isolated by silica-gel chromatography with petroleum ether/diethyl ether (25:75). IR (KBr) (cm^{-1}): 3300, 1433, 1176, 1124, 729, 696. ^{1}H NMR δ: 1.8 (m, 1H), 2.5 (m, 4H), 4.6 (m, 1H), 7.6 (m, 20H).^{13}C NMR δ: 24.2 (d, CH_2, $J_{C–P}$ = 4.1 Hz), 27.9 (dd, CH_2, $J_{C–P}$ = 13.6 Hz, $J_{C–P}$ = 70.5 Hz), 70.7 (dd, CH, $J_{C–P}$ = 4.1 Hz, $J_{C–P}$ = 89.5 Hz), aromatic signals without assignment due to the high complexity of the system. ^{31}P NMR δ (H_3PO_4 85%): 31.78, 36.09.[5]

***N*-*n*-Butyl-*N*-cyclobutyl-*P*,*P*-diphenylphosphonamide (14)**

It was isolated by silica-gel chromatography with diethyl ether. ^{1}H NMR δ: 0.70 (t, 3H), 1.05 (m, 2H), 1.44 (m, 4H), 1.89 (m, 2H), 2.16 (m, 2H), 2.94 (m, 2H), 3.82 (m, 1H), 7.42 (m, 6H), 7.76 (m, 4H).^{13}C NMR δ: 13.56 (s, CH_3), 14.72 (s, CH_2), 20.05 (s, CH_2), 29.96 (d, CH_2, $J_{C–P}$ = 4.07 Hz), 34.07 (d, CH_2, $J_{C–P}$ = 2.71 Hz), 43.19 (d, CH_2, $J_{C–P}$ = 4.07 Hz), 52.09 (d, CH, $J_{C–P}$ = 4.07 Hz), 128.2 (d, $^3J_{C–P}$ = 13.57 Hz), 131.4 (d, $^4J_{C–P}$ = 2.71 Hz), 132.2 (d, $^2J_{C–P}$ = 9.49 Hz), 132.9 (d, $^1J_{C–P}$ = 127.5 Hz). MS, *m*/*z* (rel. intensity): 327 (0.26), 299 (3.59), 284 (11.69), 244 (9.53), 243 (11.41), 215 (3.28), 202 (43.37), 201 (98.84), 126 (16.22), 125 (15.4), 98 (100), 97 (83.5), 84 (13.85), 83 (8.32), 77 (4.33), 70 (6.9), 69 (5.3), 57 (12.19), 56 (13.45), 55 (11.4), 43 (3.31), 42 (2.97), 41 (3.34).

Reaction of 4 with 2 in the dark

The described procedure was followed. In this case, however, the reaction flask was wrapped with aluminum foil.

Redox switching of carbohydrate binding to ferrocene boronic acid[1]

Andrew N.J. Moore and Danial D.M. Wayner

Abstract: The redox properties of ferrocene boronic acid in aqueous buffers from pH 4 to pH 12 have been investigated using cyclic voltammetry. It is shown that the proton transfer equilibrium is under thermodynamic control over the range of scan rates employed (20–5000 mV/s), leading to pK_a values of 10.8 and 5.8 for the ferrocene and ferrocenium forms, respectively. In the presence of sorbitol, fructose, or glucose, the voltammetric behaviour of ferrocene boronic acid at pH 7 is consistent with reversible formation of a carbohydrate – boronic acid complex. However, in all cases, the complexation–dissociation is under kinetic control. Analysis of the voltammetric response as a function of scan rate and carbohydrate concentration, together with an independent spectroscopic determination of the binding constant to the ferrocene form, allows all of the kinetic and thermodynamic constants for each system to be determined. In general, it is found that the binding constants ferrocenium form are about two orders of magnitude greater than those for the ferrocene form. It is possible that this redox dependent switching of the carbohydrate binding can be exploited in amperometric or potentiometric sensing devices.

Key words: electrochemistry, boronic acid, binding constants, pK_a.

Résumé : Faisant appel à la voltampérométrie cyclique, on a étudié les propriétés redox de l'acide ferrocène boronique dans des solutions aqueuses tampon à partir d'un pH de 4 jusqu'à un pH de 12. On montre que l'équilibre du transfert de proton est sous contrôle thermodynamique dans tout l'intervalle de vitesse de balayage utilisé (20–5000 mV/s), conduisant à des valeurs de pK_a de 10,8 et de 5,8 respectivement pour les formes ferrocène et ferricinium. En présence du sorbitol, du fructose ou du glucose le comportement voltampérométrique de l'acide ferrocène boronique à pH 7 est en accord avec la formation réversible d'un complexe hydrate de carbone – acide boronique. Cependant, dans tous les cas, la complexation–dissociation est sous contrôle cinétique. L'analyse des réponses voltampérométriques en fonction de la vitesse de balayage et de la concentration en hydrate de carbone, ainsi qu'une détermination indépendante par spectroscopie de la constante de jonction de la forme ferrocène, permet de déterminer toutes les constantes cinétiques et thermodynamiques de chaque système. On a trouvé, en général, que la constante de jonction de la forme ferricinium est de deux ordres de grandeur supérieure à celle de la forme ferrocène. Il est possible que cette réaction redox qui dépend de la commutation du point de jonction de l'hydrate de carbone, peut-être exploité dans des senseurs ampérométrique ou potentiométrique.

Mots clés : électrochimie, acide boronique, constantes de jonction, pK_a.

[Traduit par la Rédaction]

Introduction

Although complexation of diols by boronic acids has been well known for a number of years (1) it has been shown, recently, that these complexes may be used for the molecular recognition of carbohydrates for sensors (2–9) for transportation across biological membranes (10–13) or for racemic resolution of free sugars (14). While the structures of these complexes are not well understood (15), the kinetics and thermodynamics of complex formation and dissociation have been shown to involve a number of proton – hydroxide ion equilibria in aqueous solution (Scheme 1) (16–20). From the observed pH dependence of the rates of complex formation and dissociation it has been shown that (*i*) for a given boronic acid, as the pK_a of the diol decreases the stability constant of the complex increases (18), (*ii*) for a given diol, as the pK_a of the boronic acid decreases, the stability constant of the complex increases (18), and (*iii*) the kinetics of complex dissociation is dominated by hydroxide ion addition to the trigonal form (19). Thus, the formation of the complexes are believed to follow the mechanism indicated by the large arrows in Scheme 1.

With these guidelines in mind, it then follows that, in principle, one electron oxidation of either the boronic acid or the diol can be used to modulate the binding properties of the system, since it is well known that this results in a decrease (often dramatic) in the pK_a of the acidic protons. This would then form the basis of a redox switchable complexing agent that can form the basis of a simple chemical sensor. The thermodynamic and kinetic criteria for the design (or selection) of a boronic acid is straight forward: both the oxi-

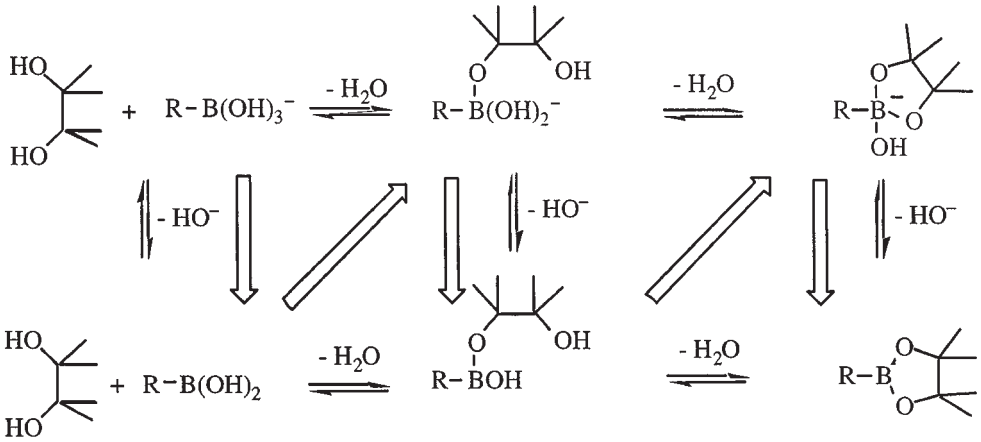
Scheme 1.



dized and reduced forms must be chemically stable, the redox process must occur in close proximity to the boronic acid group in order to maximize the change in pK_a, and the complexation must be reversible on the time scale of the measurement. We have chosen to study ferrocene boronic acid as a model for a redox switchable complexing agent for sugars. Cyclic voltammetric analysis allows the determination of the pK_a values of both oxidized and reduced forms as well as the determination of the kinetics and thermodynamics of binding of sorbitol, fructose, and glucose.

Experimental

Materials

All materials were purchased from Aldrich. Ferrocene boronic acid was synthesized by lithiation of ferrocene in THF (21), addition of the lithioferrocene in solution to a solution of trimethylborate in THF (8), followed by acidic work-up.

Cyclic voltammetry

Cyclic voltammetry was performed with a PAR model 273A Potentiostat interfaced to a 386 base PC using the EG&G model 270 software package. The cell was a standard three-electrode setup using a 3 mm diam. glassy carbon working electrode, a platinum coil counter electrode, and a Ag/AgCl reference electrode. Potentials reported are with respect to this reference which gave a standard potential for potassium ferricyanide of 0.231 V at pH 7.6.

Volammetric experiments were carried out in aqueous buffers. All buffers were prepared using distilled deionized water, with 1 M KCl as supporting electrolyte. For the titration of ferrocene boronic acid the following buffers (0.1 M) were used: potassium hydrogen phthalate (pH 4.0–6.0), potassium phosphate, dibasic (pH 6.0–8.0), sodium tetraborate decahydrate (pH 7.0–10.0), and sodium carbonate (pH 10.0–12.5). Sodium hydroxide or hydrochloric acid were added to adjust to the desired pH. The pH of the solutions was measured using a Cole–Parmer Chemcadet 5986-25 pH/mV meter.

Cyclic voltammetry in the presence of sugars

Varying amounts of sugar were added to a 90 μM solution of ferrocene boronic acid in phosphate buffer (0.1 M, pH 7.6, 1 M KCl). Voltammograms were recorded between –0.25 and 0.5 V at scan rates of 100, 200, 500, 1000, and 2000 mV/s. Alternatively, the potential was held for 20 s at 0.5 V before being cycled between 0.5 and –0.25 V. Digital simulation of the voltammograms was performed using DigiSim 2.0 software (Bioanalytical Systems Inc., W. Lafayette, Indiana). The two adjustable parameters (see text) were optimized manually by overlaying the experimental and calculated voltammograms. The estimated errors represent the limits outside of which the fit the experimental data is unacceptable based on relative peak currents for the anodic and cathodic waves.

UV-vis titrations with sugars

A 60 μM solution of ferrocene boronic acid in phosphate buffer (0.1 M pH 7.6) was prepared. An amount of sugar sufficient to prepare a solution of the desired concentration was placed in a volumetric flask, and a small amount of the Ferrocene boronic acid solution was added. After complete dissolution of the sugar, the solution was diluted to volume. Complexation of the sugar and ferrocene boronic acid was measured by determining the absorbance increase at 622 nm, using a Cary 3 UV-visible spectrophotometer. Errors in the binding constants are based on the average of three independent determinations.

Results and discussion

Determination of pK_a values

As far as we are aware, only one report of the electrochemistry of ferrocene boronic acid has appeared (22). In this study, a standard potential, $E°$, of 0.250 V vs. Ag/AgCl in water/methanol (1:1, v/v) containing 0.1 M $NaClO_4$ was obtained. The pH of the solution was not reported. We have studied the ferrocene–ferrocenium boronic acid couple over a pH range between 4 and 12. Under these conditions and at all pH values, the redox process remained quasireversible (i.e., $E_p^a - E_{pc} \approx 75$ mV), indicating that the redox system is under thermodynamic control with respect to proton transfer. Thus, the apparent standard potential ($E°_{expt}$) is determined by the pK_a values of the oxidized and reduced forms of the boronic acid (eq. [1]). The $E°_{expt}$ values (estimated as the midpoint between the anodic and cathodic waves) as a function of the pH are shown graphically in Fig. 1 along with the

Scheme 2.

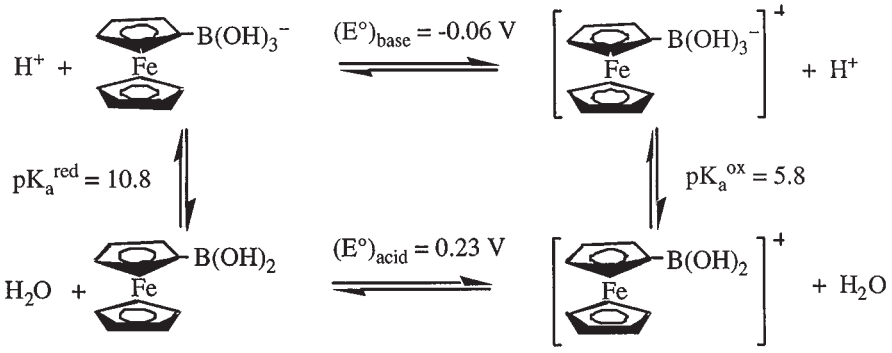

Fig. 1. The pH dependence of the apparent standard potential, $E°_{expt}$, of ferrocene boronic acid (90 μM) in various buffers (see Experimental).

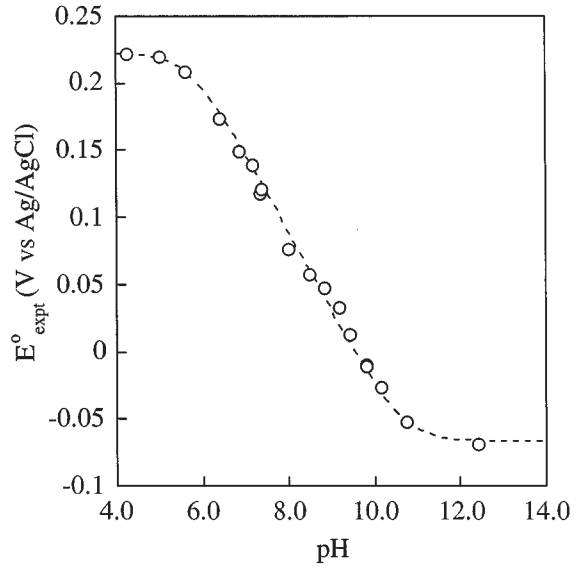


nonlinear least-squares fit to eq. [1]. To cover the pH range, four different buffer systems were employed (see Experimental). The fact that the standard potentials were the same within experimental errors for the points where the buffer systems overlap confirmed that any interaction of the boronic acid with the buffer was too weak to influence the standard potential. The analysis allowed the evaluation of the standard potentials of the trigonal (acid) and tetrahedral (conjugate base) forms of ferrocene boronic acid as well as the pK_a values of the ferrocene and ferrocenium forms. These results are shown in Scheme 2.

$$[1] \qquad (E°)_{app} = (E°)_{acid} - 0.059 \log\left(\frac{[H^+] + K_a^{ox}}{[H^+] + K_a^{red}}\right)$$

As expected, oxidation of the ferrocene resulted in a decrease in the pK_a of the boronic acid. In this case the change is about 5 pK units. The pK_a of the ferrocene form is typical of those values reported for simple alkyl or aryl boronic acids (18). Oxidation of the ferrocene results in a modest decrease in pK_a, since the electron transfer is predominantly associated with changing the oxidation state of the iron center. Nevertheless, the pK_a of the ferrocenium boronic acid is one of the lowest reported for a substituted boronic acid (e.g., 4-nitrophenyl boronic acid has a pK_a of 6.96 (18) and 3-pyridinium boronic acid has a pK_a of only 4.0 (23)).

Table 1. Thermodynamic and kinetic data for the binding of some sugars to ferrocene and ferrocenium boronic acid.

	Sugar		
Constant	Sorbitol	Fructose	Glucose
K_1 (M^{-1})[a,b]	11	4	0.05[c]
k_1 ($M^{-1}s^{-1}$)[d]	165	8	0.05
k_{-1} (s^{-1})[e]	15	2	1
K_2 (M^{-1})[f]	1900	1600	20
k_2 ($M^{-1}s^{-1}$)[d]	3100	2700	20
k_{-2} (s^{-1})[e]	1.6	1.7	1

[a]Determined spectrophotometrically at pH 7.6 (see text).
[b]Errors are ±10%.
[c]Error is ±20%.
[d]Determined by digital simulation of the voltammetric waves. The error in these values is approximately ±10%.
[e]This is not an independent variable: $k_{-1} = k_1K$.
[f]Determined by cyclic voltammetry, see Scheme 4. The error in this value is determined by the error in $\Delta E° \approx \pm 10$ mV leading to an error in the equilibrium constant of ±30%.

Spectrophotometric determination of sugar binding to ferrocene boronic acid

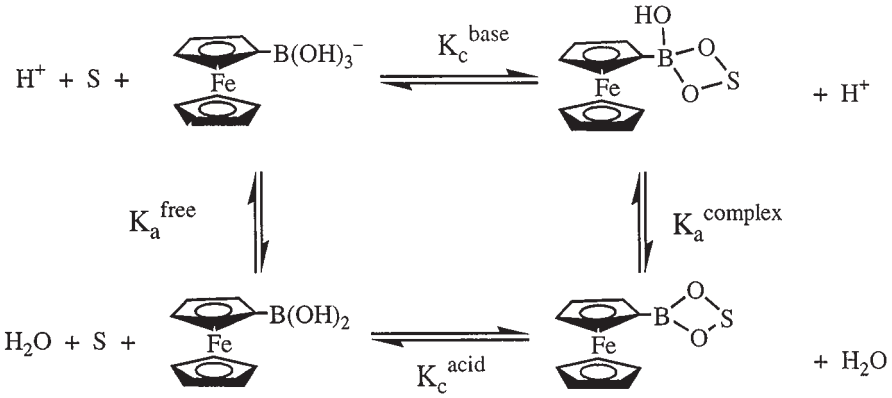
The addition of a sugar to a solution (pH 7.6) of ferrocene boronic acid resulted in the appearance of a broad visible absorption with a maximum at 622 nm which depended on the concentration of the sugar. The apparent equilibriium contant for the complexation was determined by fitting the concentration dependence of this absorption to eq. [2], where A_{622} is the optical density at 622 nm, ε_{free} and $\varepsilon_{complex}$ are the respective extinction coefficients of the free and complexed ferrocene boronic acid and K_c^{obs} is the observed equilibrium constant. Values determined for sorbitol, fructose, and glucose are given in Table 1.

$$[2] \qquad A_{622} = \varepsilon_{free}[FcB(OH)_2]_{tot} + (\varepsilon_{complex} - \varepsilon_{free})\left(\frac{K_c^{obs}[FcB(OH)_2]_{tot}[S]}{1 + K_c^{obs}[S]}\right)$$

The observed equilibrium constants are actually composite values that represent the complexation of the sugar with both the trigonal (K_c^{acid}) and tetrahedral (K_c^{base}) forms of the boronic acid. The relationship between the observed equilib-

© 1999 NRC Canada

Scheme 3.



rium constant (K_c^{obs}) and the independent proton transfer equilibria is shown graphically in Scheme 3 (where S represents a sugar) and by eq. [3].

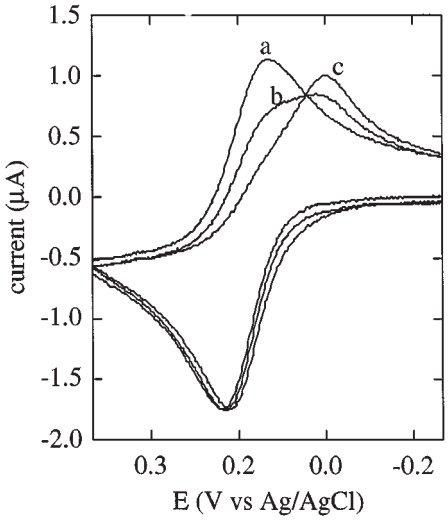
$$[3] \qquad K_c^{obs} = K_c^{base}\left(\frac{[H^+] + K_a^{complex}}{[H^+] + K_a^{free}}\right)\frac{K_a^{free}}{K_a^{complex}}$$

Thus, at low pH, $K_{csup}^{obs} = K_c^{acid}$ and at high pH, $K_c^{obs} = K_c^{base}$. In general, it has been found from potentiometric titrations, i.e., measuring the pH of a solution of boronic acid as a function of concentration of sugar, that the complexed boronic acid is more acidic than the uncomplexed form. In these cases, complexation results in a decrease in pH. However, in the present case, we have use buffered solutions so the addition of a sugar is expected to lead to an increase in the overall equilibrium concentration of the total boronic acid that exists in the tetrahedral form. In this analysis, we have assumed a 1:1 boronic acid to sugar stoichiometry. In nonaqueous solution, it has been shown that glucose forms a weak 1:1 complex and a more well-defined 2:1 complex (15). However, in that study the concentration of the boronic acid was high (about 100 mM and a concentration ratio acid:sugar of 2:1) compared to the concentration in this study (about 0.1 mM and an acid:sugar ratio of 1:50). Thus, it is reasonable to expect only a 1:1 complex to form under our conditions.

Voltammetry in the presence of sugars

Cyclic voltammograms were measured between 100 and 2000 mV/s both in the absence and presence of added sugars. The pH chosen for these experiments of 7.6 was conveniently between the pK_a values of the ferrocene and ferrocenium forms (see above). Unlike the voltammetry as a function of pH, in the presence of the sugars it was clear that the complexation was not under thermodynamic control. Rather than observing a monotonic change in the apparent $E°$ with increasing concentration of sugar, a very different picture emerged. Voltammetry, initially in the direction of oxidation, had a small effect on the anodic wave (Fig. 2). However, the cathodic wave was clearly split into two closely spaced waves, separated by ca. 130–150 mV, which integrated to a total of one electron. Increasing the concentration of sugar increased the contribution of this new cathodic wave (Fig. 2). At a fixed concentration of sugar, variations in the scan rate were consistent with rates of complexation–dissociation be-

Fig. 2. Cyclic voltammogram (background substracted) of ferrocene boronic acid at 100 mV s^{-1} with (*a*) 0.0 mM sorbitol, (*b*) 1.0 mM sorbitol, and (*c*) 5 mM sorbitol.



ing competitive with the time scale of the experiment (Fig. 3). This behaviour is typical of a square scheme (24) under chemical kinetic control and is consistent in this case with the fast complexation and slow dissociation of the ferrocenium form on the time scale of the voltammetric experiment. These results are in contrast to fluoride binding studies reported by Shinkai and co-workers (22) who studied the complexation of fluoride to ferrocene boronic acid. In this case, similar to protonation redox couple appears reversible at all fluoride concentrations and scan rates (i.e., under thermodynamic control). There was a clear preference for binding to the ferrocenium form (i.e., the $E°$ shifted to more negative potentials in the presence of fluoride ion).

It is possible to make a rough guess at the relevant equilibrium constants from Fig. 2. A shift in standard potential by 140 mV for the complexed versus uncomplexed boronic acid requires that the binding constant in the oxidized (ferrocenium) form be larger than in the reduced (ferrocene) form by a factor of about 250 (Scheme 3). Under slow scan conditions the ratio of bound to unbound ferrocenium is about 1:1 when the concentration of sorbitol is about 1 mM. Thus, an estimate for the equilibrium constant in the oxidized form is [oxidized complex]/([sugar][free ferrocenium]). Since at this

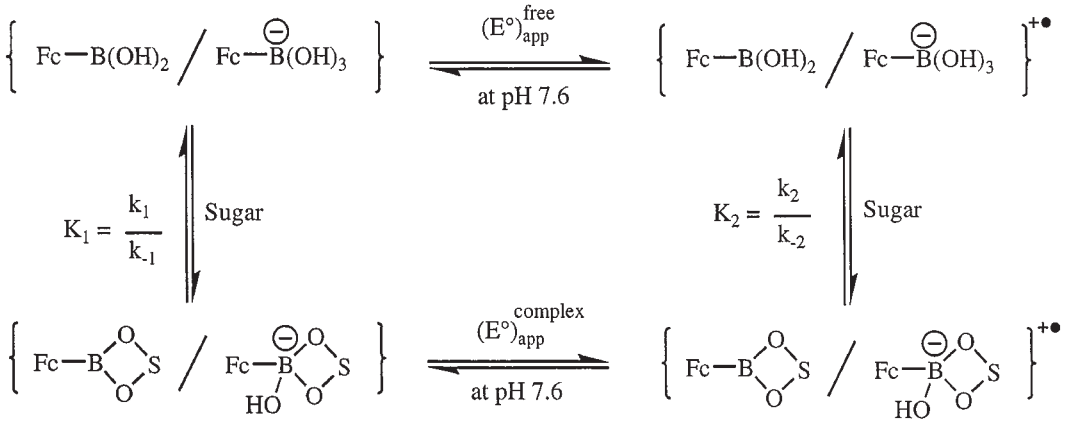

Fig. 3. Cyclic voltammograms (background substracted) of ferrocene boronic acid (90 μM) in a phosphate buffer (0.1 M) with KCl (1 M) with 1 mM sorbitol at a scan rate of (*a*) 100 mV s^{-1}, (*b*) 500 mV s^{-1}, (*c*) 1000 mV s^{-1}, and (*d*) 2000 mV s^{-1}. The corresponding simulations in the same order using the parameters in Table 1 are shown in (*e*)–(*h*). The voltammograms were initially scanned from –0.25 V to 0.5 V.

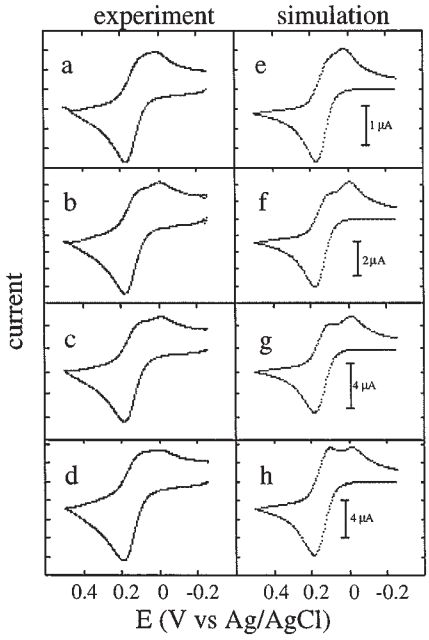

Fig. 4. Cyclic voltammograms (background substracted) of ferrocene boronic acid (90 μM) in a phosphate buffer (0.1 M) with KCl (1 M) with 1 mM sorbitol at a scan rate of (*a*) 100 mV s^{-1}, (*b*) 500 mV s^{-1}, (*c*) 1000 mV s^{-1}, and (*d*) 2000 mV s^{-1}. The corresponding simulations in the same order using the parameters in Table 1 are shown in (*e*)–(*h*). In these experiments, the potential was held at 0.5 V for 20 s, and the voltammograms were initially scanned from 0.5 V to –0.25 V.

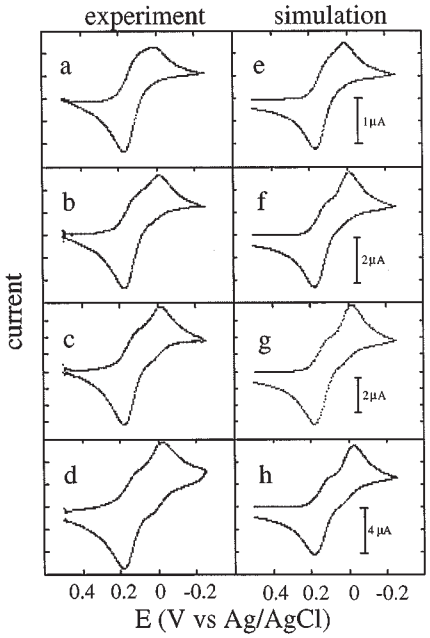

concentration the [oxidized complex] ≈ [free ferrocenium], an equilibrium constant on the order of 1000 M^{-1} is obtained. A more precise value can be extracted by examining the scan rate dependence of the voltammogram as function of sugar concentration (see below).

The second cathodic wave begins to be chemically reversible at scan rate greater than 2 V/s (Fig. 4). This can be clearly observed by holding potential for 20 s at 0.5 V (to build up the concentration of the oxidized form) then recording the voltammogram by scanning initially in the direction of reduction. Under these conditions, it is possible to use digital simulation methods to extract the kinetic and thermodynamic parameters for the complexation of the sugars with both the ferrocene and ferrocenium forms. In fact, only there are only two independent parameters that must be fit to the experimental data. At the high scan rates, the standard potential of the complex can be measured directly. The $E°$ of the uncomplexed ferrocene boronic acid and the apparent equilibrium constant for the complexation of ferrocene boronic acid were determined independently (see above) so the equilibrium constant for complexation to the ferrocenium boronic acid is fixed by a thermochemical cycle (Scheme 4). The data are given in Table 1. Since the equilibrium constants are known, only two rate constants are required to complete the scheme (Scheme 4). These rate constants were determined by iterative fitting of the experimental voltammograms. The rate and equilibrium constants

© 1999 NRC Canada

are given in Table 1, and a comparison of the experimental and simulated voltammograms are shown in Figs. 3 and 4.

There are a number of interesting features of the data in Table 1. Oxidation of the ferrocene moiety results in a decrease in the pK_a of the boronic acid which, not unexpectedly, leads to an increase in the apparent binding constant. It should be reiterated that the extracted equilibrium constants are composite values (eq. [3]) that apply only to the pH of the experiment (7.6). We have not attempted to separate the kinetic and thermodynamic parameters for the individual acid and conjugate base. However, the decrease in the apparent $E°$ value, which is close to the $E°$ of ferrocene boronate (Scheme 2), is consistent with the complexed ferrocene boronic acid being almost entirely in the tetrahedral form. It is this significant decrease in the pK_a of the complexed ferrocene boronic acid (1) that is likely responsible for the change in the apparent standard potential at this pH.

It is interesting to compare the equilibrium constants obtained with those reported recently by Ori and Shikai (25) for a chiral ferrocene boronic acid derivative. In this derivative, which contains an adjacent *N*,*N*-dimethyl-1-aminoethyl group, modest chiral selectivity for sugars was observed. Interestingly, while the equilibrium constants for complexation with the ferrocene form were similar to those reported in our work (Table 1), the equilibrium constants for complexation with the ferrocenium form were only one order of magnitude larger. This was evident from the only 50 mV decrease in the apparent $E°$ for the complexed versus uncomplexed form. Although Ori and Shikai (25) suggested that the ferrocenium boronic acid derivative was more acidic (and thus had a higher affinity for the saccharides), the pK_a of neither oxidation state was determined, nor was the pH dependence of the reported constants considered. Rate constants for complexation and dissociation were not determined. The only modest change in the standard potential and the equilibrium constants may be related to a subtle change in steric demand upon oxidation.

The fact that oxidation of the ferrocene moiety leads to an increase in the equilibrium constant for binding with a sugar by about two orders of magnitude may be useful in the design of chemical sensors based on potentiometric or amperometic detection. On one hand, the binding event can be used to induce current flow at constant potential by maintaining the electrode potential between the standard potential for the free and complexed forms. On the other hand, the electrode potential can be used to switch binding on or off for detection by other nonelectrochemical means. In both cases, the advantage of such a system is that a reversible redox process of a group that in itself is a "spectator" vis-a-vis the binding process can be used to modulate or switch the reversible chemical reactivity at a remote site.

An important criterion for use in chemical sensors is the long-term stability of the ferrocene–ferrocenium species. Simple ferrocenium derivatives (especially those with electron deficient substituents) are unstable in the presence of nucleophilic species (including water). In some cases, the stability can be improved by encapsulation as guest–host complexes such as cyclodextrins (26). While it may seem surprising that the ferrocenium boronic acid complexes are stable for several minutes at pH 7.6 (i.e., the time scale of the measurements), the long term stability of these complexes have not yet been determined. The fact that the complex exists in the tetrahedral form at neutral pH (i.e., the boron has a formal negative charge) undoubtedly contributes to the apparent enhanced stability, much in the same way that ferrocenium carboxylate is less reactive in water than the methyl ester. Futher studies are underway to determine the long term stability and explore applications of this system.

The electrochemical reduction of α-nitrocumene in a protic and basic medium on large surface area (porous) electrodes: electronation–protonation or electrocatalytic hydrogenation?

Elisa Soazara Chan-Shing, Denys Boucher, and Jean Lessard

Abstract: The electrochemical reduction of α-nitrocumene (**1**) has been investigated under controlled potential, at a mercury pool cathode and at Raney metal (Raney nickel, Raney cobalt and Devarda copper) and fractal nickel electrodes in basic aqueous ethanol. A comparison of the product distribution from the reduction at Hg (electronation–protonation (EP) mechanism) and that from the reduction at Raney metals and fractal nickel has shown that both the electrocatalytic hydrogenation (ECH) and EP mechanisms can be involved at large surface area (porous) transition metal electrodes in a basic protic medium. Cyclic voltammetry was used to determine the reduction potential of **1** at Hg and at bright polycrystalline nickel, cobalt, and copper cathodes in the same medium.

Key words: electrocatalytic hydrogenation, electroreduction, 2-nitro-2-phenylpropane, Raney metal cathodes, mechanism.

Résumé : La réduction électrochimique, à potentiel controlé, de l'α-nitrocumène (**1**) a été étudiée, en milieu hydroéthanolique basique, sur Hg, sur des électrodes de métaux de Raney (nickel de Raney, cobalt de Raney et cuivre de Devarda) et sur des électrodes de nickel fractal. Une comparaison de la distribution de produits obtenue par réduction sur Hg (mécanisme d'électronation–protonation (EP)) avec celles obtenues par réduction sur les électrodes de métaux de Raney et sur l'électrode de nickel fractal démontre que les deux mécanismes, celui d'électronation–protonation (EP) et celui d'hydrogénation électrocatalytique (HEC), interviennent sur les électrodes de métaux de transition à grande surface spécifique (poreuses) en milieu basique protique. La voltamétrie cyclique a été utilisée pour déterminer le potentiel de réduction de **1,** dans le même milieu, sur des électrodes de Hg et des électrodes de nickel, cobalt et cuivre polycristallins.

Mots clés : hydrogénation électrocatalytique, électroréduction, 2-nitro-2-phénylpropane, cathodes de métaux de Raney, mécanisme.

Introduction

Unprotonated hydroxylamines are not reducible by electron transfer (1). As a consequence, the electrochemical reduction of aromatic nitro compouds (2–4) and tertiary nitroalkanes (5, 6) at a mercury electrode in neutral and basic (pH > 5) protic media, which proceeds by successive electron and proton transfer steps (electronation–protonation (EP) mechanism), stops at the hydroxylamine. At a mercury electrode, primary and secondary nitroalkanes are not reducible at pH > 13 because they exist as nitronate anions which are not reducible by electron transfer (EP mechanism) (1) but are reducible in neutral protic media and the reduction stops at the hydroxylamine (5, 6). In contrast, the electrochemical reduction of nitro compounds at Raney metal electrodes (Raney nickel (R-Ni), Raney cobalt (R-Co), and Devarda copper (D-Cu)), in basic and neutral aqueous methanolic solutions, gives the corresponding amine in high yields and current efficiencies, both for nitroaryl (7–9) and nitroalkyl (10) compounds. Therefore, in basic and neutral protic media, the electrochemical reduction, at Raney metal electrodes, of arylhydroxylamines and alkylhydroxylamines to the corresponding amines must involve an electrocatalytic hydrogenation (ECH) mechanism, that is, reaction with chemisorbed hydrogen, M(H) (reactions [2]–[4]), generated by reduction of water (reaction [1]) (7–10).

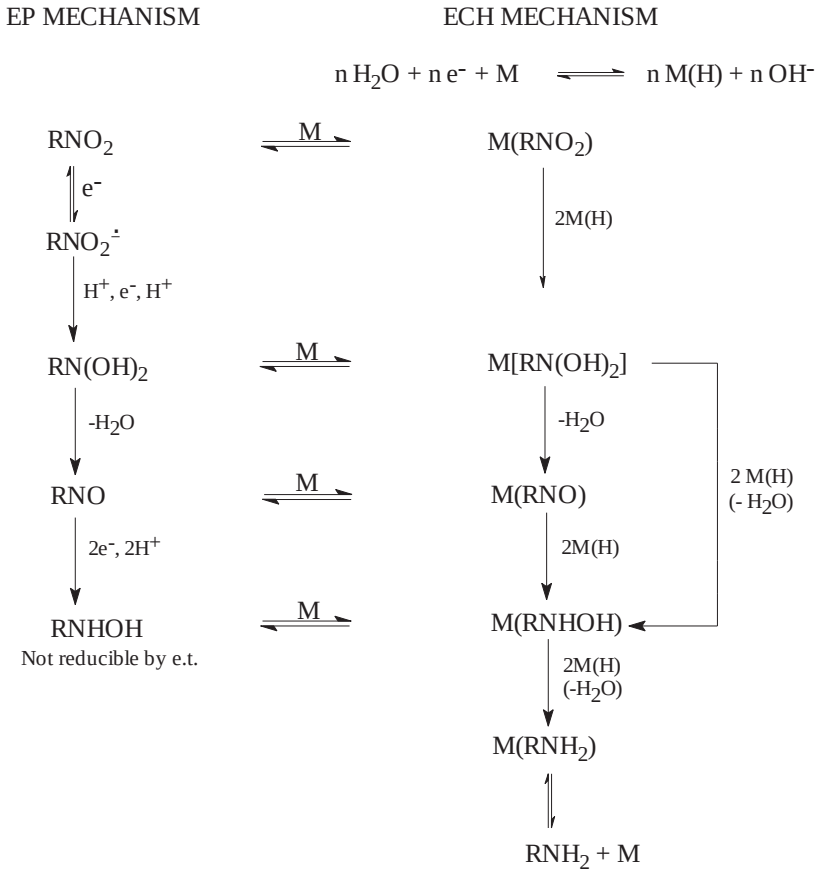
Scheme 1.



Since the reduction potential of water to chemisorbed hydrogen M(H) is very close to that of nitro groups, their reduction to the corresponding hydroxylamines ($RNO_2 \rightarrow$ RNHOH), at Raney metal electrodes and in neutral and basic media, could involve an ECH or an EP mechanism or both (see Scheme 1) (7–10). The electrochemical reduction of primary and secondary nitroalkanes at Raney metal electrodes and pH > 13 must involve the reaction of the nitronate anion with chemisorbed hydrogen (ECH mechanism) (Scheme 2) (10). Interestingly, at Raney metal electrodes, if dehydration of the intermediate dihydroxylamine is slower than its reaction with chemisorbed hydrogen, the hydroxylamine could be formed directly by electrocatalytic hydrogenolysis of the dihydroxylamine which could be formed by an EP or an ECH mechanism (see Schemes 1 and 2).

One way to distinguish between an EP and an ECH mechanism for the electrochemical reduction of nitro compounds to hydroxylamines at Raney metal electrodes would be to use a molecule, the reduction of which would give a different product distribution depending on the reduction mechanism. Coté et al. (11) reported that 2-iodonitrobenzene was not effective to distinguish between the EP and ECH mechanisms, since the product distribution was similar for its electrochemical reduction at mercury (EP mechanism), for its catalytic hydrogenation at Raney metals (involving reaction with chemisorbed hydrogen as in ECH) and for its electrochemical reduction at Raney metal electrodes.

In this paper, we report that, in the electrochemical reduction of α-nitrocumene (**1**), at electrodes with a large surface area (porous electrodes) and in basic hydroorganic solutions, both the EP and ECH mechanisms can participate and compete.

Experimental

^{1}H and ^{13}C Nuclear Magnetic Resonance (NMR) spectra were obtained on a Brucker AC-300 MHz instrument. IR spectra were taken with a Perkin Elmer 1600 series FTIR. Mass spectra and exact masses were obtained with a ZAB-2F model VG instrument.

α-Nitrocumene (**1**) (Scheme 3) was prepared as described by Kornblum et al. (12) and its ^{1}H NMR spectrum was identical with that reported. IR ($CHCl_3$) cm^{-1}: 1543 and 1349 (NO_2); ^{13}C NMR ($CDCl_3$) δ: 140.5 (C3), 129.0 (C4, C5), 125.2 (C6), 90.0 (C2), 27.5 (C1); HRMS, *m*/*z*: 119.0863; calcd. for C_9H_{11} ($M^+ - NO_2$): 119.0861.

α-Aminocumene (**3**) was prepared by preparative electrolysis of **1** at a Raney nickel (R-Ni) electrode in EtOH/H_2O 40:60 w/w + KOH 0.15 M or preparative electrolysis of α-azidocumene at a R-Ni electrode in MeOH/H_2O 93:7 w/w + NaCl 0.2 M. IR ($CHCl_3$) cm^{-1}: 3446 and 3621 (NH_2); ^{1}H NMR ($CDCl_3$) δ: 7.4 (m, 4H, arom), 1.5 (s, 6H, CH_3), 1.25 (s, 2H, NH_2) (lit. (12): 7.1–7.2 (m, 5H), 1.41 (s, 8H)); HRMS, *m*/*z*: 136.1129; calcd. for $C_9H_{14}N$ $(MH)^+$: 136.1126.

Bicumyl (**6**) was prepared by preparative electrolysis at a mercury pool in EtOH/H_2O 40:60 w/w + KOH 0.15 M: mp 117–118°C, white powder (lit. (13): 115–117°C); ^{1}H NMR ($CDCl_3$) δ: 7.1 (m, 10H, arom), 1.3 (s, 12H, CH_3); ^{13}C NMR

($CDCl_3$) δ: 146.4 (C3), 129.0 (C5), 127.0 (C6), 125.6 (C4), 43.4 (C2), 30.0 (C1); HRMS, *m*/*z*: 238.1709; calcd. for $C_{18}H_{22}$: 238.1721.

Distilled ethanol and distilled water were used to prepare solutions of KOH 0.15 M in ethanol–water 40:60 w/w. Solutions for all voltammetric analyses and preparative electrolyses were deoxygenated by bubbling through dry and oxygen-free argon saturated with ethanol. An argon atmosphere was maintained throughout the experiments which were carried out at room temperature.

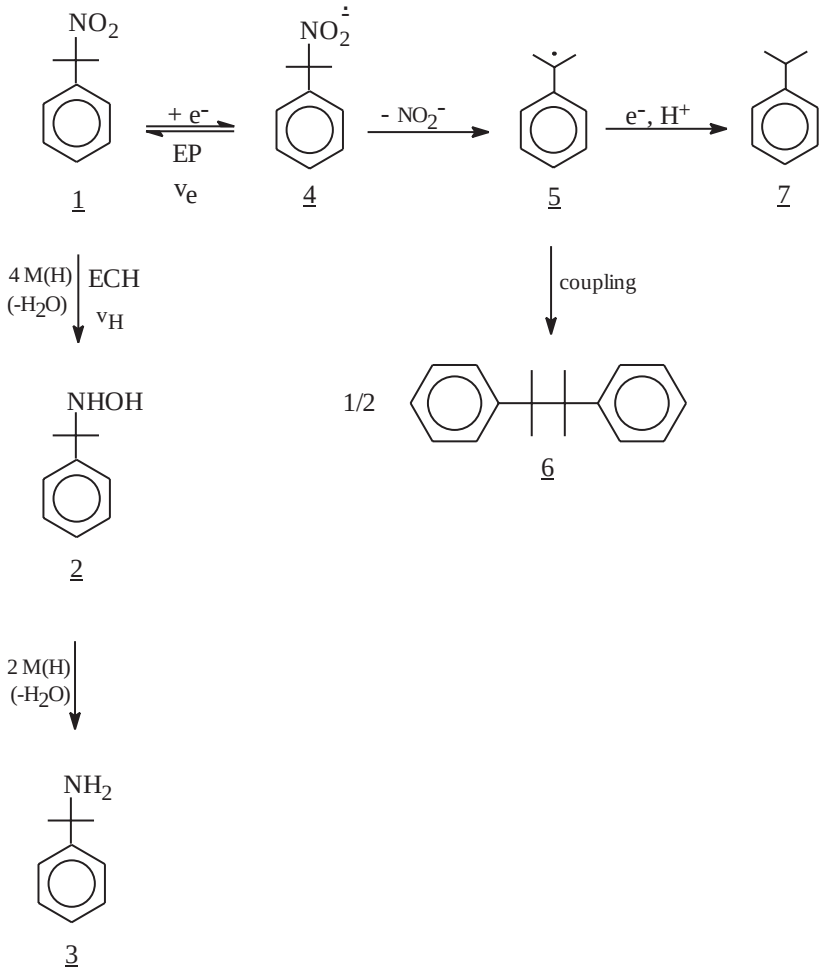
The cyclic voltammetry experiments were performed using a Princeton Applied Research (PAR) 173 potentiostat and a single-compartment cell with three electrodes containing 5 mL of a 5×10^{-4} M solution of α-nitrocumene (**1**). A carbon rod was used as counter-electrode. An Ag/AgCl/Cl^- electrode whose potential was adjusted to that of an SCE served as reference. The working electrode was a hanging mercury drop or a metal disc (polycrystalline Ni, Co, or Cu) having a geometric area of 3.14 mm^2. The solid electrodes were polished with 0.05 mm micropolish alumina (Buehler) before each use. The controlled-potential preparative electrolyses were carried out using an Electrosynthesis Company (ESC) 410 potentiostat with an ESC 640 coulometer and an amperometer connected in series within the auxiliary circuit. For the electrolyses at a mercury pool, a vertical glass cell with two concentric compartments (cathodic compartment: 40 mL; anodic compartment: 10 mL) and a platinum grid as counter electrode were used. For the electrolyses at a Raney metal (R-M) electrode, a two-compartment glass H-cell (40 mL for each compartment) with a Nafion-324 (E-I du Pont de Nemours and Co.) membrane as separator and a counter electrode consisting of two carbon rods placed side by side were used. The same reference electrode as above was used and positioned near the surface of the mercury pool or, for the Raney metal electrodes, near the surface of the electrode facing the counter electrode.

The R-Ni alloy (Ni-Al 50:50 w/w) powder was purchased from Aldrich, the R-Co alloy (Co-Al 31:69 w/w) powder from Alfa AESAR, the Devarda copper (D-Cu) alloy (Cu-Al-Zn 50:45:5 w/w) powder from BDH, and Co and Cu powders were purchased from Fisher. The Raney alloy precursory electrodes were prepared by pressing, at room temperature, 5 g of R-Ni alloy powder (R-Ni electrodes) or 5 g of a mixture of Raney metal alloy powder (4 g) and particles (1 g) of the corresponding transition metal (Co or Cu for R-Co and D-Cu electrodes, respectively) at a pressure of 14.5×10^7 kg m^{-2}. The pressed electrodes were activated by leaching in 10% aqueous NaOH for 2 h at 50°C. If not used immediately, the electrode was kept in a 0.1 M aqueous solution of NaOH. The fractal nickel powder was purchased from INCO (filamentary nickel powder type 255), and the electrodes were prepared by pressing 5 g of powder as above.

The controlled-potential electrolyses at R-M electrodes were run at the so-called zero-current potential. The procedure was as follows. After leaching, the electrode was washed with distilled water and rinsed with EtOH/H_2O 40:60 w/w and placed in the cathodic compartment containing the deoxygenated electrolyte. A steady current of 100 mA was maintained until a charge of 100 C was passed (hydrogen evolution). Then the potential was increased slowly until the current reached zero (zero-current potential: –1.1 V for R-Ni and for R-Co electrodes and –1.2 V for D-Cu electrodes). The substrate (33 mg, 0.2 mmol, 5 mM solution) was added,

© 1999 NRC Canada

Scheme 3.



the current increased suddenly and then decreased steadily and slowly until reaching a near-zero value when the substrate was almost completely consumed. Aliquots of 0.3 mL were taken and analyzed by VPC using a DB-5 column (30 m, 0.25 μ) with a Hewlett Packard (HP) 5790 chromatograph equipped with an FID detector and an HP 3390A integrator. The products were identified by comparing their retention times with those of authentic samples. When the electrolysis was completed, the electrode was rinsed (EtOH then ether) and the products were extracted from the catholyte and the mass balance and yield of products were determined by VPC using the internal standard method.

Catalytic hydrogenations on nonpolarized electrodes were performed in the same cell as that used above. The electrode (catalyst) was placed in the cathodic compartment containing the deoxygenated solution. Its potential was lowered in order to reach a steady current of 100 mA and was kept at this value until 100 C had passed. Then, the circuit was opened and the electrode put to ground in order to depolarize it. The counter and reference electrodes were removed. The organic substrate was added, and aliquots of 0.3 mL were taken for analysis as above. Catalytic hydrogenations were also performed with the Raney metal powder obtained by leaching the commercial alloy powder. After leaching, the Raney metal particles were washed with water and transferred into a round-bottomed flask containing the deoxygenated solution. The substrate was added under a hydrogen atmosphere which was maintained throughout the reaction.

Results and discussion

Cyclic voltammetry was used to determine the reduction potential of α-nitrocumene (**1**) in basic (KOH 0.15 M) aqueous ethanol (ethanol–water 40:60 w/w). At a hanging mercury drop electrode (HMDE), two reduction peaks were observed on the cathodic sweep, the first peak at –1.13 V vs. SCE, corresponding to the one-electron reduction to the radical anion **4**, and the second cathodic peak at –1.45 V, to the reduction of **4** to the hydroxylamine **2** (see Scheme 3 for the structures of **4** and **2**). On the reverse scan: (*i*) no anodic peak corresponding to the oxidation of the radical anion **4** appeared even when the potential was inverted immediately after the first cathodic peak and the sweep rate was increased from 100 to 500 mV s^{-1}, thus showing that the cleavage and (or) the protonation of the radical anion were faster than its oxidation to **1** on the voltammetric time scale as observed before in aprotic medium (13); and (*ii*) there was one oxidation peak at –0.46 V corresponding to the oxidation of hydroxylamine **2** to nitrosocumene (not shown in Scheme 3), the reduction of which gave a cathodic peak at –0.60 V on the second cathodic scan. At a polycrystalline bright Ni electrode, no cathodic peak was observed because

[d]Computed current efficiencies do not take into account the initial charge 100 C used for charging the electrode.

[e]Zero-current potential (see Experimental).

the reduction of nitrocumene (**1**) was hidden by the reduction of water (hydrogen evolution) at ca. –1.1 V. At polycrystalline bright Co and Cu electrodes, only one cathodic peak appeared in the cathodic sweep at –1.3 and –1.15 V, respectively. No anodic peak was seen on the reverse scan at any of the polycrystalline metal electrodes. Thus, the reduction of nitrocumene (**1**) occurs at similar potentials at mercury and at polycrystalline metal electrodes, and these reduction potentials are also similar to the so-called zero-current potential (potential at which no current flows at an electrode charged with chemisorbed hydrogen, see Experimental) used for the electrolyses at Raney metal and fractal nickel electrodes (–1.07 to –1.2 V vs. SCE). Thus, electron transfer to (electronation of) α-nitrocumene (**1**) generating the radical anion **4** could occur at Raney metal and fractal Ni electrodes at the zero-current potential in basic medium, and it does occur, as will be seen below.

The results of bulk electroreduction of α-nitrocumene (**1**) at a mercury pool and at ca. –1.15 V vs. SCE in basic (pH > 13 and pH 10) ethanol–water (40:60 w/w) solutions are recorded in Table 1. The main product was bicumyl (dimer **6**), resulting from the cleavage of radical anion **4** to cumyl radical (**5**) and nitrite anion followed by coupling of two cumyl radicals (**5**) (Scheme 3). Cumene (**7**), the product of reduction of radical **5**, was formed in small amounts (~2%). The other products not shown in Scheme 3 were α-methylstyrene (7% at pH > 13, 1% at pH 10) and cumyl alcohol (<1% at pH > 13, 19% at pH 10). The yield of dimer **6** was higher at pH > 13 than at pH 10. This is due to a faster protonation of radical anion **4** at pH 10 competing with its cleavage. The resulting neutral radical (not shown in Scheme 3) was then reduced rapidly to the hydroxylamine **2** which is unstable and decomposed to α-methylstyrene and cumyl alcohol (14).[2] The results of Table 3 clearly show that reduction of α-nitrocumene (**1**) by electron transfer in basic medium gives bicumyl (**6**) as the main product. The current efficiencies were lower than 100% and were lower at pH 10 than at pH > 13. This is most probably due to the reduction of water competing with the reduction of **1**.

The results of the controlled-potential reduction of α-nitrocumene (**1**) at Raney metal electrodes in basic (pH > 13) aqueous ethanol are summarized in Table 2. As shown in entry 1, at a R-Ni electrode and at the zero-current potential (–1.1 V), which corresponds to the potential of formation of radical anion **4** at a Hg cathode as already pointed out, α-aminocumene (**3**) was formed in a 97% yield (Table 2, entry 1). Only 2% of bicumyl (**6**) was formed. This shows that, under the conditions used, both the reduction of water to chemisorbed hydrogen (M(H)) and the reaction of α-nitrocumene (**1**) with M(H) were about 50 times faster than the electronation of **1** (see Scheme 1). Therefore, at the zero-current potential and at pH > 13, 98% of the electrochemical reduction of α-nitrocumene (**1**) at a R-Ni electrode proceeds via an ECH mechanism.

At a potential more negative than the zero-current potential (–1.2 V, see Table 2, entry 2), the amount of dimer (**6**) increased to 20%, the amount of amine having decreased accordingly to 75%. This can be readily explained by an in-

[2]Details of a study, as a function of pH, of the electroreduction of α-nitrocumene, *p*-cyano-α-nitrocumene, and *p*-methoxy-α-nitrocumene at mercury and in aqueous ethanol will be reported in a subsequent paper.

[d]Zero-current potential (see Experimental).

crease of the rate of electronation of α-nitrocumene (**1**), v_e (Scheme 3), due to an increase of k_e, as the potential becomes more negative, the rate of reaction of **1** with M(H), v_H (Scheme 3), increasing less rapidly.

At a R-Co electrode (Table 2, entry 3), the electrochemical reduction of α-nitrocumene (**1**) at the zero-current potential, under the same conditions as those used for reduction at R-Ni, gave a much larger proportion of dimer **6** (24–31%) than the reduction at R-Ni (2%, entry 1) and less amine **3** accordingly (73–66%). Thus, on a R-Co electrode, the reaction of α-nitrocumene (**1**) with M(H) (ECH mechanism) competes less effectively with its electronation than on a R-Ni electrode: $(v_H/v_e)_{R\text{-}Ni} \approx 48.5 >> (v_H/v_e)_{R\text{-}Co} \approx 2.5$ (Scheme 3). This is in agreement with the fact that R-Co is less efficient than R-Ni as catalyst for catalytic hydrogenation (CH) (15–17). Copper catalysts are still less efficient than cobalt catalysts for CH (17), and as result, the electrochemical reduction of α-nitrocumene (**1**) at a D-Cu electrode, again at the zero-current potential and under the same solvent and pH conditions, gave the dimer **6** as the major product (75–77%) and the amine **3** as the minor product (15–20%). Thus, at a D-Cu electrode, the reaction of α-nitrocumene (**1**) with M(H) was now slower than its electronation: $(v_H/v_e)_{D\text{-}Cu} \approx 0.25$. It is noteworthy that, as the ECH process becomes less efficient with respect to the EP process (v_H/v_e becomes smaller), the desorption of M(H) to give molecular hydrogen (reaction [5] and (or) reaction [6]), which competes with its reaction with the adsorbed organic substrate, becomes more important as shown by the decrease in current efficiency from 72% with a R-Ni electrode to about 10% with a D-Cu electrode. The electrochemical desorption of M(H) (reaction [5]) competes also with the electronation of α-nitrocumene (**1**). So, the situation is quite complex.

$$[5] \quad M(H) + H_2O + e^- \xrightarrow{\text{Heyrovsky}} H_2 + M + OH^-$$

$$[6] \quad M(H) + M(H) \underset{\leftarrow - - - -}{\xrightarrow{\text{Tafel}}} H_2 + M$$

The hydrogenation steps in the ECH mechanism shown in Scheme 1 are exactly the same as in the classical catalytic hydrogenation (CH) (reaction of the adsorbed organic substrate with M(H) followed by desorption of the product(s) (7–9)). The main differences between ECH and CH are two-

© 1999 NRC Canada

fold: (*i*) M(H) is generated in situ by reduction of water in the former (reaction [1]) and by thermal dissociation of molecular hydrogen in the latter (reverse of reaction [6]); (*ii*) the catalyst is negatively polarized in the former and is not polarized in the latter. Since the catalyst is not polarized in CH, the sole product formed by CH of α-nitrocumene (**1**) should be the amine **3** assuming that the nonpolarized catalyst cannot transfer an electron to nitrocumene (**1**). Then, CH constitutes the best model of an ECH mechanism. We therefore studied the CH of α-nitrocumene (**1**) under the same solvent and pH conditions and on the same catalysts as those used for the ECH experiments, that is on Raney metal "electrodes" which had been initially charged with chemisorbed hydrogen by reduction of water in the absence of α-nitrocumene (**1**) but then, after opening the circuit, had been connected to the ground. These CH experiments were carried out under an argon atmosphere as for the electrolyses. The product distribution was compared with that obtained by carrying CHs on a freshly leached Raney catalyst powder under a H_2 atmosphere at atmospheric pressure and room temperature. The results are summarized in Table 3.

The most striking feature of Table 3 is the formation of some bicumyl (**6**) in all the CH experiments with the nonpolarized electrodes as catalysts (entries 1–3, 6, and 8). Thus, some electronation of α-nitrocumene (**1**) did occur on the nonpolarized Raney metal electrodes and, in the case of D-Cu electrode (entry 8), to a nonnegligible extent (20–31%). Such electronation is not due to reduction of nitrocumene (**1**) by the transition metal (Ni, Co, or Cu) but to its reduction by the residual aluminum left after leaching (18). This was confirmed by the following experiments. (*i*) α-Nitrocumene (**1**) was quantitatively recovered when treated with fractal Ni particles or with a Cu metallic powder in the same basic medium. (*ii*) No bicumyl (**6**) was formed when CH of α-nitrocumene (**1**) was carried out on a Raney metal powder which was prepared by extensive leaching of the Raney alloy (leaching for 8 h at 70°C in 30% aqueous NaOH; see Table 3, entries 5, 7, and 10). (*iii*) Bicumyl (**6**) was formed only when residual aluminum was still present in the catalyst (according to eq. [7], 0.6 mg of Al would reduce up to 33 mg of **1**), that is, in all experiments performed with the

$$[7] \qquad Al + 3RNO_2 + 4OH^- \longrightarrow Al(OH)_4^- + 3RNO_2$$

nonpolarized electrodes (entries 1–3, 6, 8, and 9) leached under milder conditions (2 h at 50°C in 10% aqueous NaOH), in order to effect leaching of the surface layers of the disc only (more vigorous leaching conditions led to complete disintegration of the disc). (*iv*) Finally, bicumyl (**6**) and cumene (**7**) were formed in 28–39 and 1% yields, respectively, together with 7–3% of amine **3** and 25–28% of products (α- methylstyrene and α-hydroxycumene) resulting from decomposition of hydroxylamine **2** (15, 16) when α-nitrocumene (**1**) was reduced with metallic aluminum (powder) always in the same basic medium. So, on a nonpolarized catalyst containing residual aluminum, there is a competition between reaction of adsorbed α-nitrocumene (**1**) with chemisorbed hydrogen present on the catalyst (as in Scheme 1) and its reduction by electron transfer from aluminum according to eq. [7] (19). The fact that, with the less active hydrogenation catalysts R-Co and D-Cu, much more bicumyl (**6**) was formed on the polarized catalysts (24–31 and 76%, respectively; see Table 2, entries 3 and 4) than on the nonpolarized catalyst (7 and 20–31%, respectively; see Table 3, entries 6 and 8), shows that direct electron transfer from a negatively polarized electrode was faster as would be expected. It is noteworthy that, when there was no residual aluminum present in the R-Co and D-Cu catalysts, not only electronation of nitrocumene (**1**) did not occur but there was no CH either (see Table 3, entries 7 and 10). This was not the case with R-Ni free of residual aluminum (Table 3, entry 5). This suggests that in the the case of R-Co and D-Cu, the presence of residual aluminum would favor the CH process possibly by influencing the adsorption energies of hydrogen and of the organic substrate. The catalytic activity of the catalyst in CH, that is, the rate of reaction of the adsorbed organic substrate with M(H), must depend on the energy of adsorption of hydrogen as well as on the energy of adsorption of the organic substrate (M-H and M-substrate bond energies), and the same should hold for the electrocatalytic activity of large surface area electrodes in ECH of organic substrates. These energies of adsorption depend on the metal itself (Ni, Co, or Cu in this work), and for a given metal, for instance, R-Ni and fractal Ni, on the nature of the adsorption sites as noted by Bockris and Minevski (20) and Lasia (21). The nature of the adsorption site depends on (*i*) the type of crystallographic structure (the crystal plane, a step, or an edge) exposed for adsorption; (*ii*) irregularities in the crystallographic surface structure; (*iii*) impurities strongly bound to the surface; (*iv*) a small amount of a second metal, such as aluminum, forming alloy (17). For instance, the nature of the M—H bond may vary from a nearly covalent bond (22, 23), an adsorbed state producing a large increase in the free electron density in the metal surface (23), to a hydridic bond (22). So, the knowledge of the various factors and forces involved is as yet insufficient to be able to pinpoint the exact reasons of the differences in electrocatalytic activity observed in this work.

The results presented and discussed so far show that α-nitrocumene (**1**) can be used to evaluate the competition between the ECH and EP processes (the ratio v_H/v_e) in Scheme 3) for the electrochemical hydrogenation at porous electrodes. This competition can be used to compare the activity of various electrode materials for the ECH process at zero-current potential. The results of Table 2 show clearly that the activity of Raney metals decreases in the order R-Ni (entry 1) > R-Co (entry 3) > D-Cu (entry 4) as already discussed. The activity of fractal Ni was evaluated also. The results of entry 1, Table 2, show that fractal Ni ($v_H/v_e \approx 1.4$) is more active than D-Cu ($v_H/v_e \approx 0.25$) but somewhat less active than R-Co ($v_H/v_e \approx 2.53$). Upon decreasing the potential to –1.2 V (entry 2, Table 2), the rate of electronation (v_e) increases, and the ratio of v_H/v_e decreases accordingly ($v_H/v_e \approx 0.27$) as was observed with R-Ni electrodes (compare entry 1 ($v_H/v_e \approx 48.5$) and entry 2 ($v_H/v_e \approx 3.8$) and of Table 4).

Fractal Ni was found to be completely inactive for CH of α-nitrocumene (**1**) in basic aqueous ethanol either using fractal Ni particles under a hydrogen atmosphere or pressed fractal Ni electrodes initially charged with M(H) and put to ground. α-Nitrocumene (**1**) was quantitatively recovered as in the attempted CH on R-Co and D-Cu catalysts free of residual aluminum.

Conclusions

In the electrochemical reduction of α-nitrocumene (**1**) in basic aqueous ethanol, at solid electrodes with large specific surface areas (porous electrodes), two mechanisms of electrohydrogenation can be operative: namely, an ECH mechanism giving α-aminocumene (**3**) and an EP mechanism giving products derived from the cumyl radical (**5**), itself resulting from a rapid elimination of the nitrite anion from the α-nitrocumyl radical anion (**4**) (Scheme 3). The relative rates of the ECH and EP processes depend on the potential imposed, the rate of electronation (EP process) increasing upon decreasing the potential. These relative rates depend also on the nature of the transition metal (Ni, Co, Cu) and, for a porous metal, on the surface structure of the electrode (R-Ni, fractal Ni). Thus, α-nitrocumene (**1**) can be used to evaluate the electrocatalytic activity of an electrode for the ECH process. The following order of electrocatalytic activity was determinated at the so-called zero-current potential (potential at which no current flows at an electrode charged with chemisorbed hydrogen): R-Ni > R-Co > fractal Ni > D-Cu.

It is noteworthy that R-Co, fractal Ni, and D-Cu were completely inactive for catalytic hydrogenation of α-nitrocumene (**1**) at an atmospheric pressure of molecular hydrogen. On the other hand, when residual aluminum was present on the catalyst charged with chemisorbed hydrogen, both catalytic hydrogenation at atmospheric pressure and reduction by metallic aluminum (electron transfer) occurred on D-Cu in a ratio close to 70/30. This suggests that the presence of residual aluminum favors the catalytic hydrogenation process.

Classical variational rate theory portraits of the dynamical stereochemistry of the F + H_2 → FH + H reaction

Irina Rutenburg and Gerald W. Koeppl

Abstract: A general classical variational theory of reaction rates is applied to the F + H_2 → FH + H reaction. The variational theory gives the rate as the equilibrium flux of phase points through a trial surface which divides reactants from products and is varied to obtain a least upper bound for the rate. This dividing surface (DS) is defined by a power-series expansion of the H-H internuclear separation (r) in internal coordinates R and θ, i.e., r = F(R, θ) where R is the approach coordinate and θ is the orientation angle. The downhill simplex algorithm is used to search the space of 6 and 10 variational parameters of second- and third-order expansions of the DS and obtain minimum values for the canonical rate constant or, in the microcanonical formulation of the theory, the energy-dependent mean reaction cross section. The presence of angle-dependent terms in the DS makes it possible to describe the dynamical stereochemistry of atom–diatom reactions in a new and useful manner. Portraits of the dynamical stereochemistry are obtained by plotting contours of the density of reaction systems on the DS; such plots are reactivity relief maps of the DS. Reactivity relief maps show how the field of reactivity which surrounds the diatomic reactant molecule expands with increasing temperature and energy. Results are presented here for a new power series formulation of the DS which obeys a condition: $\partial F(R, \theta)/\partial\theta = 0$ at $\theta = \pi/2$ which is appropriate for reaction of a homonuclear diatomic molecule. The relationship between reactivity relief maps obtained using quadratic and cubic formulations of the new DS and the locations of angle-dependent energy barriers for reaction is described. Variational and classical mechanical trajectory results are used to show how energy-dependent factors, which correct the variational mean reaction cross section for trajectories which cross and recross the DS, depend on the orientation angle.

Key words: variational, transition, rate, dividing, surface.

Résumé : On applique la théorie variationnelle générale classique des vitesses de réaction à la réaction F + H_2 → FH + H. Selon la théorie variationnelle, la vitesse est donnée par le flux à l'équilibre des points de phase à travers une surface de référence qui divise les réactifs des produits et que l'on fait varier pour obtenir une valeur limite de la vitesse. Cette surface de division (SD) est définie par une expansion en série de puissance de la distance internucléaire H-H (r) dansles coordonnées internes R et θ, c'est-à-dire r = F(R, θ) dans laquelle R est la coordonnée d'approche et θ est l'angle d'orientation. On utilise l'algorithme simplex de descente de la pente pour rechercher l'espace de 6 et de 10 paramètres variationnels des expansions des deuxième et troisième ordre de la SD et pour obtenir les valeurs minimales de la constante de vitesse canonique ou, dans un formulation microcanonique de la théorie, la section droite moyenne qui dépend de l'énergie. La présence de termes qui dépendent de l'angle dans la SD fait qu'il est possible de décrire la stéréochimie dynamique des réactions atome–diatome d'une manière nouvelle et utile. On obtient des portraits de la stéréochimie dynamique en traçant des contours de la densité des systèmes réactionnels sur la SD; de tels tracés sont des cartes en relief de la réactivité sur la SD. Les cartes en relief de la réactivité montrent comment s'effectue l'expansion du champ de la réactivité qui entoure la molécule de réactif diatomique avec une augmentation de la température et de l'énergie. Les résultats sont présentés ici pour une nouvelle formulation de la série de puissance de la SD qui obéit à la condition: $\partial F(R, \theta)/\partial\theta = 0$, à $\theta = \pi/2$ qui est approprié pour la réaction d'une molécule diatomique homonucléaire. On décrit la relation entre les cartes de relief de réactivité obtenues à l'aide de formulations quadratique ou cubine de la nouvelle SD et les positions des barrières d'énergie de la réaction qui dépendent de l'angle. On utilise les résultats de trajectoires mécanique variationnelle et classique pour montrer

Introduction

The classical variational theory of chemical reaction rates gives the rate as the equilibrium flux of reaction systems through a trial surface. This theory was introduced by Pelzer and Wigner (1), and developed and generalized further by Horiuti (2), Keck (3, 4), Marcus (5), Koeppl (6, 7), Pechukas (8–10), and Pollak (11), Truhlar et al. (12–14), and others (15–17). The study and development of this theory in its various forms continues to be an active area of research (18–35). In the most general development of the theory by Keck, the trial surface divides the phase space of the reaction system into reactant and product regions. The trial surface is usually referred to as a dividing surface (DS). In practice, the theory is nearly always applied using a DS which is a function of internal coordinates of the reaction system. The transition state theory (TST) of chemical reaction rates is a special case of the variational theory. The conventional version of TST, developed by Eyring and co-workers (36, 37) and Evans and Polanyi (38), gives the reaction rate for a particular DS (4, 39). This DS passes through a saddle point of the potential-energy surface and is perpendicular to the unbound normal coordinate of the transition state.

The variational rate, i.e., the equilibrium flux of reaction systems through a particular DS, is an upper bound because phase points which start in the reactant region of configuration space can cross and recross the DS regardless of whether they proceed ultimately to the product region. Furthermore, phase points which do not originate in the reactant region, but are present in the equilibrium flux, can cross and recross the DS. The DS can be varied to obtain a minimum upper bound for the reaction rate. The variational rate will equal the actual rate of reaction if the DS is crossed only once by all reactive trajectories. For a classical microcanonical formulation of the variational theory, the reaction rate corresponds to an ensemble of reaction systems of fixed total energy E. It is possible to find DSs at energies up to some value E' which give the actual rate (40). For the classical canonical formulation of the variational theory, the rate corresponds to an ensemble of reaction systems for temperature T which contains trajectories with energies above E'; hence, it is impossible to find a DS which gives the actual rate.

The accuracy of the classical variational theory for a given DS can be determined by comparing variational values of the canonical rate constant at a given temperature or energy-dependent mean reaction cross section at a given energy with corresponding values calculated by executing a Monte Carlo sample of classical mechanical trajectories. The same Born–Oppenheimer potential-energy function (PEF) must be used for the variational and trajectory calculations. Morokuma and Karplus (41) and Koeppl and Karplus (42) were the first to determine the accuracy of TST in this unequivocal manner for collinear reactions and reactions in three-dimensional space, respectively. In a theory versus experiment test of the accuracy of TST, one cannot be sure whether error is caused by failure of the variational theory or inaccuracy of the PEF.

The Born–Oppenheimer PEF for a given electronic state of the chemical reaction system is often referred to as a potential-energy surface (PES). For a collinear atom–diatom reaction, a trajectory can be plotted as a mass point moving on the potential-energy surface (43). In most applications of classical variational and trajectory theories, it is assumed that reaction takes place on the PES for the electronic ground state of the reaction system, i.e., the electronic state does not change during chemical reaction.

Koeppl (7) developed a general classical variational treatment for atom–diatom reactions. The Koeppl formulation of the variational theory is based on a method developed by Martin and Raff (44). Expressions were derived for the microcanonical and canonical formulations of this theory which give the energy-dependent mean reaction cross section and canonical rate constant, respectively, for the most general DS defined by configuration space coordinates. A numerical method which uses the downhill simplex algorithm was developed to evaluate these quantities by determining constants (variational parameters) of terms in first, second, and third-order expansions of the DS in the internal coordinates of the reaction system. Sverdlik and Koeppl (45) applied this treatment to the $H' + HH \rightarrow H'H + H$ and $H + I_2 \rightarrow HI + I$ reactions.

Rutenburg and Koeppl (46) applied this treatment to the $F + H_2 \rightarrow FH + H$ reaction for a series of three PEFs in which an important feature of the interaction potential was varied in a systematic manner. The steepness of the profile of the angle-dependent barrier for chemical reaction increased in the PEF series. The $F + H_2$ reaction was chosen for this study because it has been the subject of many theoretical and experimental studies. Many attempts have been made to calculate an accurate potential-energy function for this reaction (47–59). Rutenburg and Koeppl showed how the angle-dependent terms, i.e., terms containing the angle θ which the H_2 internuclear axis makes with a line from atom F to the center-of-mass of H_2, in the power series formulation of the DS made it possible to characterize the dynamical stereochemistry of atom–diatom reactions in a new and useful way. This was done by plotting contours of the variational flux density of reaction systems through the DS. Flux density contours were plotted in the space of internal coordinates θ and R where R is the distance between atom F and the center-of-mass of H_2; at each point on the DS, the value of the H_2 internuclear separation is defined by the function which defines the DS. They also characterized the dynamical stereochemistry in a less detailed manner by dividing the full range of orientation angle θ (0–π) into equal intervals and calculating the contribution to the canonical rate constant or energy-dependent mean reaction cross section for each interval to show how this quantity varies with θ.

© 1999 NRC Canada

Levine and co-workers (60, 61) and others (62, 63) have used the concept of an orientation-dependent critical configuration for reaction and other concepts to characterize the dynamical stereochemistry of atom–diatom reactions. Although their work does not make explicit use of a DS, for certain reactions including the F + H_2 reaction, the DS implied by their approach must pass through angle-dependent potential-energy barriers for chemical reaction. The barriers are located at saddle points in the *r*–*R* space defined by fixing the orientation angle θ. For the F + H_2 reaction, Rutenburg and Koeppl obtained contour plots of the variational flux density on the DS for quadratic DSs which showed that regions of large flux density on the DS did not follow the path of the angle-dependent barriers for chemical reaction over the entire range in θ from 0 to π. Regions of large flux density were expected to follow the positions of the barriers because the barriers correspond to the minimum energy for chemical reaction at each value of the orientation angle. This unexpected behavior, found for all three of the PEFs studied, could be caused by a DS function which was not flexible enough to pass through the angle-dependent barriers for chemical reaction and follow the path of steepest ascent from them and (or) because entropic as well as enthalpic factors determine the path of regions of large flux density.

The present work is concerned in part with studying this unexpected behavior. Reactivity relief maps are calculated using a cubic expansion of the DS to learn whether a more flexible function would yield the expected behavior. Variational searches were also performed using a new expansion which contains $\sin^2\theta$ factors; these factors ensure that the function which defines the DS has a continuous derivative with respect to θ at $\theta = \pi/2$, a condition which should be satisfied for a homonuclear diatomic reactant. We performed classical variational calculations for two potential-energy functions developed by Truhlar et al. (49) (designated T1 and T2).

We are not concerned with comparing theoretical and experimental rate constants in the present work. The T1 and T2 PEFs cited above yield variational rate and semiclassical trajectory rate constants which are in reasonable agreement with experiment. We are concerned instead at this stage of our work with the relationship between classical variational results and features of reasonable PEFs for the F + H_2 reaction, and using the variational theory to characterize the dynamical stereochemistry for these PEFs. We are also interested in the relationship between the accuracy of the classical variational theory, i.e., the accuracy of the no-recrossing assumption of transition state theory, for a given reasonable PEF and the temperature for a canonical ensemble and energy for a microcanonical ensemble of reaction systems. We determine this accuracy in the present work by comparing variational and classical mechanical trajectory results for the same PEF. Our ultimate goal is a semiclassical formulation of the general variational theory which makes theory and experiment comparisons meaningful.

We are also concerned here with the characterization of the difference between the variational flux through the DS and the accurate flux determined by calculating classical mechanical trajectories. Variational and trajectory results are used to show how energy-dependent factors which correct the variational mean reaction cross section for trajectories which cross and recross the DS depend on the orientation angle.

Finally, we show how variational values of the energy-dependent mean reaction cross section can be used to calculate the canonical rate constant and how the effect of such a complete optimization of the canonical rate constant depends on temperature.

The equations for the canonical rate constant and microcanonical mean reaction cross section for a general configuration space DS are presented in Sect. 1. The derivation of these equations is given in ref. 7. Expressions for DSs used in the present work and corresponding expressions for the canonical rate constant are given in Sect. 2.

Canonical variational results are presented in Sect. 3. The determination and significance of DSs which pass through angle-dependent saddle points and follow the path of steepest ascent from them are described.

In Sect. 4, variational and trajectory energy-dependent differential (angle-dependent) mean reaction cross sections are used to show how energy-dependent transmission and product factors which correct the variational mean reaction cross section for the error of the no-recrossing approximation of transition state theory depend on the orientation angle. The effect of microcanonical optimization on the canonical rate constant at three temperatures is described.

Concluding remarks are given at the end.

1. General expressions for the canonical rate constant and microcanonical mean reaction cross section

A. Canonical rate constant for general dividing surface

We consider chemical reactions of the type

[1] $$A + BC \rightarrow AB + C$$

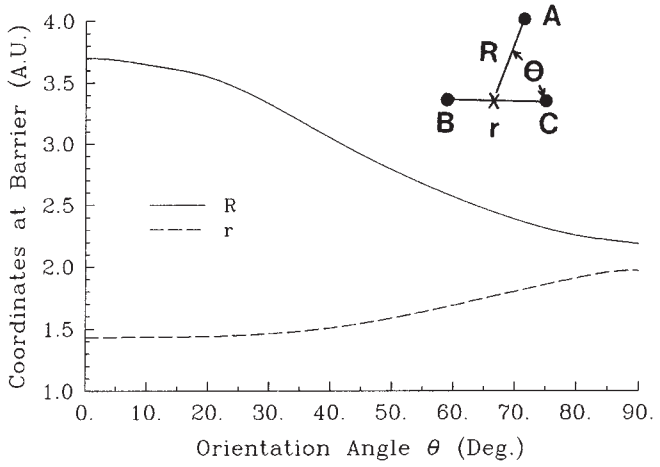
between an atom and a diatomic molecule (7). We assume that electronic transitions do not occur during the reaction and treat the motion of the nuclei classically. The exact classical rate constant is given by (4, 8, 40, 64–67)

[2] $$k^{\text{exact}}(T) = Q_{\rho_s}(T)^{-1} \times \int d\tau\, \mathbf{v}\cdot\mathbf{n}_S \chi_S(\mathbf{q}, \mathbf{p})\, \delta[S(\mathbf{q}, \mathbf{p})] \times \exp[-\beta H(\mathbf{q}, \mathbf{p})]$$

where $\int d\tau$ is an integral operator which sums the flux over the 12 internal (center-of-mass) degrees of freedom of the phase space of the reaction system, $\mathbf{q}$ and $\mathbf{p}$ are the coordinates and momenta of phase space, the delta function $\delta(S)$ restricts the integration to the 11-dimensional phase space surface defined by $S(\mathbf{q}, \mathbf{p}) = 0$, $\mathbf{v}$ is the generalized velocity of a phase point, $\mathbf{n}_S$ is the unit vector normal to the surface, $\chi_S(\mathbf{q}, \mathbf{p})$ (8, 64–66) is the characteristic function, $H(\mathbf{q}, \mathbf{p})$ is the classical Hamiltonian of the reaction system, $\beta = (k_B T)^{-1}$ where k_B is Boltzmann's constant and T the Kelvin temperature, and $Q_{\rho_s}(T)$ is the classical partition function per unit volume for the internal degrees of freedom of the reactants times Planck's constant (h) to the sixth power. The characteristic function $\chi_S(\mathbf{q}, \mathbf{p})$ for the surface is +1 for phase points which cross the surface in the direction of products

© 1999 NRC Canada

Fig. 1. Values of R and r at angle-dependent saddle point of the T2 potential-energy function versus orientation angle.



and were on the reactant side of the surface in the asymptotic past, –1 for phase points which cross the surface in the direction of reactants and were on the reactant side in the asymptotic past, and zero otherwise. The critical assumption of variational TST may be expressed as

$$[3] \qquad \chi_S(\mathbf{q}, \mathbf{p}) = \chi_S^{TST}(\mathbf{q}, \mathbf{p}) = \hbar(\mathbf{v}\cdot\mathbf{n_S})$$

where χ_S^{TST} is the characteristic function of TST, and $\hbar(x)$ is the Heaviside step function. All phase points moving in the direction of products at the dividing surface contribute to the rate. Since the integral operator $\int d\tau\ \delta(S)$ equals $\int d\sigma$ where $d\sigma$ is the 11-dimensional element of reduced phase space of the surface, substitution of eq. [3] in eq. [2] gives the Keck (4) expression for the variational rate constant of transition state theory (TST):

$$[4] \qquad k^{TST}(T) = Q_{\rho_s}(T)^{-1} \times \int d\sigma\ \mathbf{v}\cdot\mathbf{n_S}\ \hbar(\mathbf{v}\cdot\mathbf{n_S})\ \exp\ [-\beta H(\mathbf{q}, \mathbf{p})]$$

The most general dividing surface may be defined by

$$[5] \qquad S(\mathbf{q}, \mathbf{p}, \Omega) = 0$$

where S depends on both configuration (**q**) and momentum (**p**) coordinates of phase space and a set of constants and arbitrary variational parameters (Ω). We consider the case where the surface depends only on configuration coordinates, i.e., the internal coordinates of the reaction system, and is therefore independent of constants of motion in the canonical formulation of the variational theory (4). A surface defined by internal coordinates depends on the total energy of the reaction system in the microcanonical formulation of the variational theory. The most general surface of this type for the reaction considered here may be expressed as

$$[6] \qquad S = r - F(R, \theta) - C = 0$$

where r is the internuclear separation between atoms B and C, R is the distance between atom A and the center of mass of atoms B and C, C is a variational parameter, and the defining function $F(R, \theta)$ depends on additional variational parameters. See the inset of Fig. 1. Function $F(R, \theta)$ defines a surface which provides an unambiguous division of configuration space into reactant and product regions; i.e., a surface which is crossed by all reactive trajectories. It is convenient to choose a set of generalized coordinates (**q**) which makes S a coordinate surface for one of them. Hence, we take

$$[7] \qquad q_1 = r - F(R, \theta) = q_*$$

Coordinate q_* is the generalized reaction coordinate of transition state theory; i.e., $q_* = C$ defines transition state configurations of the reaction system. The integrals of eq. [4] were evaluated using spherical polar coordinates which correspond to the relative Cartesian coordinates of atom C with respect to atom B, and atom A with respect to the center-of-mass of atoms B and C. The rate constant may be expressed as

$$[8] \qquad k^{TST}(T) = (2\pi/\beta)^{1/2}(\sigma_{BC}/\sigma_*)[N_*^C(T)/D_{BC}^C(T)]$$

where σ_{BC} and σ_* are the symmetry numbers of reactant BC and reaction system configuratons on the DS (4, 68, 69), respectively.

The DS function $N_*^C(T)$ is given by

$$[9] \qquad N_*^C(T) = \int_0^\pi \exp\ \{-\beta V[r(\Omega, R, \theta), R, \theta]\} \sin\theta\ d\theta \times \int_0^{R_{max}^{S=0}} r(\Omega, R, \theta)^2 R^2 dR \times [\mu_{BC}^{-1}\{1 + [F_\theta(R, \theta)/r(\Omega, R, \theta)]^2\} + \mu_{A,BC}^{-1} F_R(R, \theta)^2]^{1/2}$$

where $V[r(\Omega, R, \theta), R, \theta]$ is the potential energy for configurations on the DS, $F_R(R, \theta)$ and $F_\theta(R, \theta)$ are partial derivatives of function $F(R, \theta)$ with respect to R and θ, respectively, μ_{BC} and $\mu_{A,BC}$ are reduced masses of atom groups (B, C) and (A, BC), respectively, and $R_{max}^{S=0}$ is a practical limit for the integration over R which is required due to the finite limit for the potential energy as $R \to \infty$ on the dividing surface (44, 70, 71).

The reactant function $D_{BC}^c(T)$ is given by

$$[10] \qquad D_{BC}^c(T) = \int_0^{r_{max}^{BC}} r^2\ \exp\ [-\beta V_{\rho_s}(r)]dr$$

where $V_{\rho_s}(r)$ is the potential energy of BC with atom A on the reaction shell radius, i.e., $R = \rho_S$, and r_{max}^{BC} is a practical limit for r which is required due to the finite limit for the potential energy of reactant BC at dissociation.

B. Energy-dependent mean reaction cross section for general DS

Koeppl (7) used the collisional theory of chemical reactions (72–74) and the appropriate inverse Laplace transform (75) to derive an expression for the energy-dependent mean reaction cross section defined by Morokuma et al. (76) for the reaction A + BC → AB + C:

© 1999 NRC Canada

[11] $$\bar{S}_r(E)^{TST} = (\pi\mu_{A,BC}{}^{1/2}/2)\,(\sigma_{BC}/\sigma_*)[N^{\mu}_*(E)/D^{\mu}_{BC}(E)]$$

The DS function $N^{\mu}_*(E)$ is given by

[12] $$N^{\mu}_*(E) = \int_0^{\pi} \sin\theta\, d\theta \int_0^{\infty} r(\Omega, R, \theta)^2 R^2 \{E - V[r(\Omega, R, \theta), R, \theta]\}^{5/2} \times \hbar\{E - V[r(\Omega, R, \theta), R, \theta]\}\, dR \times [\mu_{BC}{}^{-1}\{1 + [F_\theta(\Omega, R, \theta)/r(\Omega, R, \theta)]^2\} + \mu_{A,BC}{}^{-1} F_R(\Omega, R, \theta)^2\ ]^{1/2}$$

The reactant function $D^{\mu}_{BC}(E)$ is given by

[13] $$D^{\mu}_{BC}(E) = \int_0^{\infty} r^2[E - V_{\rho_s}(r)]^{5/2} \quad \hbar[E - V_{\rho_s}(r)]\, dr$$

The relationship between $\bar{S}_r(E)^{TST}$ and the canonical rate constant is given by

[14] $$k^{TST}(T) = (8\pi\mu_{A,BC})Q_{\rho_s}(T)^{-1}\int_0^{\infty} \epsilon_{BC}(E)\bar{S}_r(E)^{TST} \exp(-\beta E)\, dE$$

where $\epsilon_{Bc}(E) = (64/15)(2)^{1/2}\pi^2\mu_{Bc}^{3/2}\sigma_{Bc}^{-1}D^{\mu}_{BC}(E)$.

2. Dividing surfaces, expressions for canonical rate constant and microcanonical mean reaction cross section, and numerical methods

A. Dividing surface functions used in this work

1. Functions expressed in powers of R *and* θ
Quadratic (Q) DS

[15] $$r = AR + B\theta + C + 1/2(DR^2 + 2ER\theta + F\theta^2)$$

where *A*, *B*, *C*, *D*, *E*, and *F* are variational parameters. This DS was introduced by Sverdlik and Koeppl (45). It is designated linear θ function in figures and tables to distinguish it from the quadratic $\sin^2\theta$ function given below.

Cubic (C) DS

[16] $$r = AR + B\theta + C + 1/2(DR^2 + 2ER\theta + F\theta^2) + 1/6(GR^3 + 3HR^2\theta + 3IR\theta^2 + J\theta^3)$$

where *A*, *B*, *C*, *D*, *E*, *F*, *G*, *H*, *I*, and *J* are variational parameters. This DS was introduced by Sverdlik and Koeppl (45). It is designated linear θ function in figures and tables to distinguish it from the cubic $\sin^2\theta$ function given below.

2. Functions expressed using powers of R *and* $\sin^2\theta$
Quadratic DS

[17] $$r = AR + B\sin^2\theta + C + 1/2(DR^2 + 2ER\sin^2\theta + F\sin^4\theta)$$

where *A*, *B*, *C*, *D*, *E*, and *F* are variational parameters. This DS is introduced here. It is designated $\sin^2\theta$ function in figures and tables to distinguish it from the quadratic function of powers of θ.

Cubic DS

[18] $$r = AR + B\sin^2\theta + C + 1/2(DR^2 + 2ER\sin^2\theta + F\sin^4\theta) + 1/6(GR^3 + 3HR^2\sin^2\theta + 3IR\sin^4\theta + J\sin^6\theta)$$

where *A*, *B*, *C*, *D*, *E*, *F*, *G*, *H*, *I*, and *J* are variational parameters. This DS is introduced here. It is designated $\sin^2\theta$ function in figures and tables to distiniguish it from the cubic function of powers of θ.

B. Expressions for the canonical rate constant

Expressions for the rate constant $[k^{TST}(T)]$ for the $F + H_2 \rightarrow FH + H$ reaction for the DS formulations of Sect. 2A are given below. To simplify our notation, the variational rate constant is henceforth designated $k(T)$. $V[r(\Omega, R, \theta), R, \theta]$ is the PEF for

configurations on the DS. The symmetry numbers σ_{H_2} and σ_* are both two (4). The integration over θ is from 0 to π/2; a factor of 2 is introduced to obtain the rate for reaction at both ends of the symmetrical H_2 reactant.

1. Dividing surface functions expressed using powers of R *and* θ
*Quadratic dividing surface (*θ *function)*

$$[19]\quad k(T) = 2(2\pi/\beta)^{1/2}[D^{c}_{HH}(T)]^{-1}\int_0^{\pi/2}\int_0^{R_{max}^{S=0}}[r(\Omega, R, \theta)R]^2 \sin\theta\, dR\, d\theta \times [\mu_{HH}{}^{-1}\{1+[(B+ER+F\theta)/r(\Omega, R, \theta)]^2\} + \mu_{F,HH}{}^{-1}(A+DR+E\theta)^2]^{1/2} \times \exp\{-\beta V[r(\Omega, R, \theta), R, \theta]\}$$

where *A*, *B*, *C*, *D*, *E*, and *F* are variational parameters.

*Cubic dividing surface (*θ *function)*

$$[20]\quad k(T) = 2(2\pi/\beta)^{1/2}[D^{c}_{HH}(T)]^{-1}\int_0^{\pi/2}\int_0^{R_{max}^{S=0}}[r(\Omega, R, \theta)R]^2 \sin\theta\, dR\, d\theta \times [\mu_{HH}{}^{-1}\{1+[(B+ER+F\theta+(1/2)(HR^2+2IR\theta+J\theta^2))/r(\Omega, R, \theta)]^2\} + \mu_{F,HH}{}^{-1}\{A+DR+E\theta + (1/2)(GR^2+2HR\theta+I\theta^2)\}^2]^{1/2} \times \exp\{-\beta V[r(\Omega, R, \theta), R, \theta]\}$$

where *A*, *B*, *C*, *D*, *E*, *F*, *G*, *H*, *I*, and *J* are variational parameters.

2. Dividing surface functions expressed using powers of R *and sin*^{2} θ
Quadratic dividing surface (sin^2 θ *function)*

$$[21]\quad k(T) = 2(2\pi/\beta)^{1/2}[D^{c}_{HH}(T)]^{-1}\int_0^{\pi/2}\int_0^{R_{max}^{S=0}}[r(\Omega, R, \theta)R]^2 \sin\theta\, dR\, d\theta \times [\mu_{HH}{}^{-1}\{1+[(B+ER+F\sin^2\theta)(2\sin\theta\cos\theta)/r(\Omega, R, \theta)]^2\} + \mu_{F,HH}{}^{-1}(A+DR+E\sin^2\theta)^2]^{1/2} \times \exp\{-\beta V[r(\Omega, R, \theta), R, \theta]\}$$

where *A*, *B*, *C*, *D*, *E*, and *F* are variational parameters.

Cubic dividing surface (sin^2 θ *function)*

$$[22]\quad k(T) = 2(2\pi/\beta)^{1/2}[D^{c}_{HH}(T)]^{-1}\int_0^{\pi/2}\int_0^{R_{max}^{S=0}}[r(\Omega, R, \theta)R]^2 \sin\theta\, dR\, d\theta \times [\mu_{HH}{}^{-1}\{1+[((B+ER+F\sin^2\theta)(2\sin\theta\cos\theta) + (\sin\theta\cos\theta)(HR^2+2IR\sin^2\theta+J\sin^4\theta))/r(\Omega, R, \theta)]^2\} + \mu_{F,HH}{}^{-1}\{A+DR+E\sin^2\theta + (1/2)(GR^2+2HR\sin^2\theta+I\sin^4\theta)\}^2]^{1/2} \times \exp\{-\beta V[r(\Omega, R, \theta), R, \theta]\}$$

where *A*, *B*, *C*, *D*, *E*, *F*, *G*, *H*, *I*, and *J* are variational parameters.

C. Expressions for the microcanonical mean reaction cross section

These expressions may be readily obtained using eqs. [11]–[13] and the DS functions of Sect. 2A. See also refs. 7 and 46.

D. Numerical methods and computational details

The searches performed to determine the 6 and 10 variational parameters of the second and third-order expansions of the DS were made using the downhill simplex algorithm (77–79). See refs. 45 and 46 for a description of the methods used to generate the initial vertices for the searches.

Variational calculations were performed on a VAX 6420 minicomputer. The integrals of functions $N_*^c(T)$ and $D^c_{BC}(T)$ were evaluated using Simpson's rule. The two-dimensional integral which gives $N_*^c(T)$ requires integration over *R* and θ. θ was integrated over the range 0–π/2; the resulting value of the integral was doubled to obtain the flux for reaction at both ends of the H_2 molecule. Appropriate limits for *R* were found by trial and error; the integration range for *R* was usually from 1 to 7 au. A grid of 280 (*R*) by 180 (θ) points was usually used to calculate $N_*^c(T)$. The quantity $D^c_{BC}(T)$ in the denominator of the expression for $k(T)$ was usually calculated using 500 points. The value used for r_{max}^{BC} was usually 7 au.

The simplex method can be readily applied with constraints on the parameter space which is searched. Because

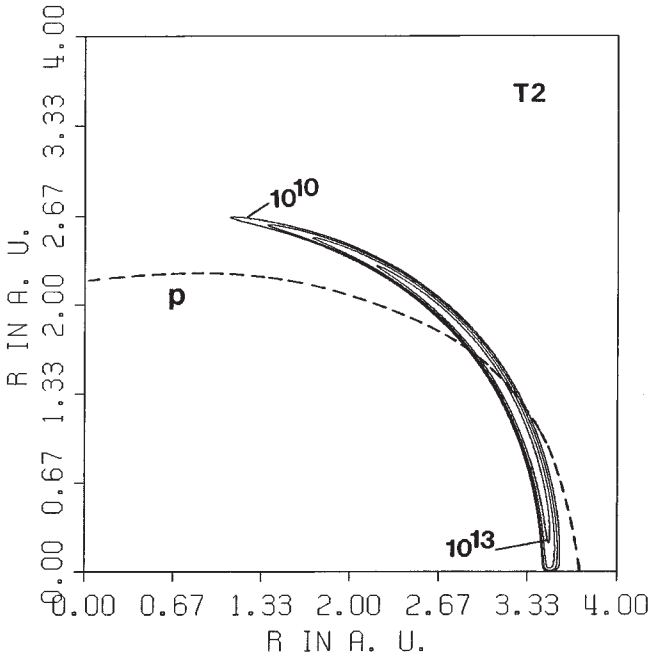
Contours are shown for 10^{10}, 10^{11}, 10^{12}, and 10^{13} arbitrary units. The broken line *p* shows the path of angle-dependent saddle points.



variational searches for quadratic and cubic functions can produce unusual results, restrictions are sometimes imposed on the parameters (see refs. 45 and 46). In the present work, some results are reported for the restrictions: $\partial r/\partial R > 0$ for $0 < \theta < \pi/2$ (denoted *S* for slope restriction) and $V(r^*, R, \theta) > 4.0$ eV at R_{max} where *V* is the potential energy on the DS (denoted *E* for energy limit restriction). Note that r^* is the value of *r* on the DS.

Note that the simplex search algorithm finds a local minimum, not the absolute minimum. Hence, many searches which started with different sets of trial parameters were often made in attempts to find the global minimum for a given DS and PEF.

E. Potential-energy functions

Variational calculations were performed for two PEFs developed by Truhlar et al. (49) designated by them as T1 and T2.

Plots of potential-energy contours for fixed θ in *r* and *R* coordinate space show a single saddle point and no basins for $0 \le \theta \le \pi/2$ for these PEFs. The energy at the saddle point varies with θ. The saddle point energy at θ is the minimum potential energy required for chemical reaction at θ.

The variation of *R* and *r* with θ for the T2 PEF is shown in Fig. 1. This figure shows why the PEFs used in this work present a challenge to the variational theory; the values of *R* and *r* at the angle-dependent saddle point vary markedly with θ. The DS must be flexible enough to span regions of configuration space near angle-dependent saddle points over the θ range where the reaction flux is large in order to minimize the variational rate.

4. Canonical results and discussion

Quadratic and cubic searches for linear θ and $\sin^2$ θ functions

Reactivity relief maps for the F + H_2 reaction for restricted and unrestricted searches showed that high reactive flux contours do not "follow" the path of angle-dependent saddle points over the entire range in θ. For example, the path of angle-dependent saddle points is shown as a broken line on the reactivity relief map for the T2 PEF at 300 K for the Q(*S*) DS in Fig. 6 of ref. 46. The maximum value of the variational flux lies on the small *R* side of the path of angle-dependent saddle points for $\theta \le 28°$ and on the large *R* side for $\theta > 28°$. The integrand of $N^{S}_{*}(T)$ contains the factor exp $\{-\beta V(r^*, R, \theta)\}$; hence, if potential energy alone determines the variational DS, the DS will pass through angle-dependent saddle points where the lowest potential energy on the DS for a specified θ has the highest value and follow the path of steepest ascent from the saddle points over the full range of θ. The maximum value of the flux may not follow the path of angle-dependent saddle points because the location of the variational DS is determined by entropic as well as energetic factors and (or) the formulation of the DS may not be flexible enough to follow the angle-dependent saddle points. We elected to learn whether the quadratic and cubic formulations of the DS used in our studies are capable

of following the paths of steepest ascent from angle-dependent saddle points.

We developed a least-squares method to find such a steepest ascent (SA) DS to compare with the variational DS. Potential-energy contour plots for the T2 PEF were made for a set of θ values. On each plot, a line was drawn through the saddle point which followed the path of steepest ascent from it. Points were read from the line and in this way sets of points were found at each θ which lie on the path of the steepest ascent. The downhill simplex algorithm together with a least-squares criterion was used to find the parameters of a quadratic DS (designated SA DS) which fits the points so generated, i.e., variational parameters were found which minimize the sum of the squares of the difference between the value of *r* for points determined as explained above and the value of *r* given by the SA DS function.

This work met with limited success. By assigning large weights for the fit at saddle points, we were able to find a least-squares SA DS which did a good job of passing close to saddle points over the full range in θ; however, this DS did not do a good job of following the path of steepest ascent from angle-dependent saddle points. We elected to examine an alternative quadratic DS in which θ is replaced with $\sin^2$ θ in the Q DS function. See Sect. 2.A.2. The partial derivative $(\partial r/\partial\theta)_\theta$ is zero at π/2 for this function; this requirement recognizes the symmetry of the F + H_2 interaction potential. Note that the partial derivative of the overlap parameter for HF with respect to θ is also zero at π/2 for the T2 PEF. See ref. 46. The alternative ($\sin^2$ θ) function gave a least-squares DS which did a marginally better job of pass-

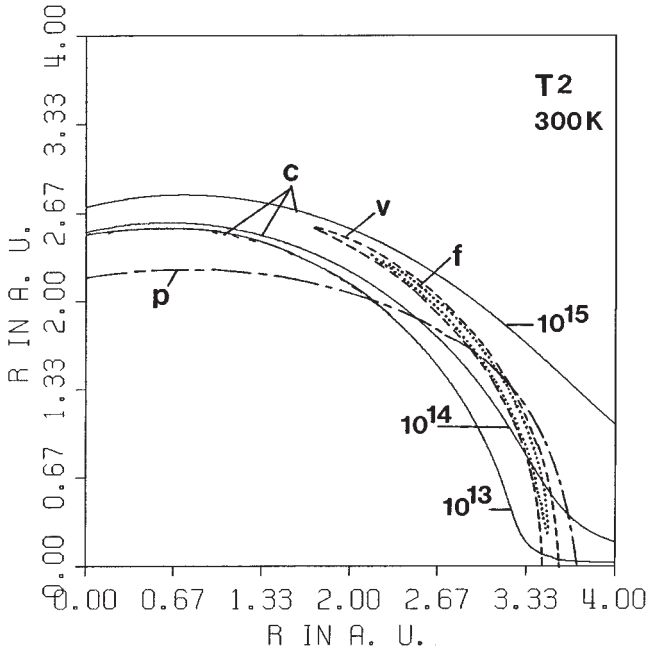
Fig. 6. Contours of several variational theory functions for the T2 PEF: variational flux density for the linear θ C(*S*) DS at 300 K (10^{13} arbitrary units), *f* (·····); potential-energy contour for this DS at 0.15 eV, *V* (-----); and three contours of the configuration factor in arbitrary units, *c* (—). The path of angle-dependent saddle points is also shown, *P* (— - — -).



ing through the saddle points; nevertheless, the alternative quadratic DS did not do a good job of following the path of steepest ascent from the angle-dependent saddle points.

In our earlier study of the H + H_2 and H + I_2 reactions, we found that canonical rate constants calculated using the cubic expansion of the DS (C DS) were close in value to those obtained using the quadratic expansion, i.e., the improvement was negligible. We decided to learn whether this was also true for the F + H_2 reaction and also whether a least-squares SA DS obtained using the more flexible cubic function would do a better job of following the path of steepest ascent from angle-dependent saddle points.

Variational calculations were performed for both the usual (linear θ function) and alternative ($\sin^2$ θ function) formulations of the slope restriction cubic (C(*S*)) DS at 300 K. Rates were also calculated for the least squares SA DSs obtained using both the θ and $\sin^2$ θ cubic functions. Figure 2 shows the collinear potential-energy surface for the T2 PEF. Contours of the potential energy and intersections of four cubic DSs with the (*r*, *R*) plane are shown. Linear θ and $\sin^2$ θ slope restriction variational DSs for 300 K and linear θ and $\sin^2$ θ least-squares SA DSs are shown. The cubic variational and least squares SA parameters are given in Table 1.

The rate constants for the linear θ and $\sin^2$ θ C(*S*) DS at 300 K are 8.908 and 8.960 × 10^{12} cm^3 mol^{-1} s^{-1}, respectively. Figure 3 shows the reactivity relief map for the $\sin^2$ θ C(*S*) DS at 300 K. Figure 4 shows contours of *r* on the DS for the $\sin^2$ θ DS. The rate constants for the cubic DSs are nearly the same, and the reactivity relief maps are very similar; the contours for the highest flux can be superimposed to a good approximation. Contours for lower values of the flux

are tipped more toward the path of angle-dependent saddle points as θ increases for the cubic than for the quadratic DSs. The variation of the *r* contours with θ for the two cubic functions is very similar for values of θ where the contribution to the flux is large. The reactivity relief maps for the cubic DS functions closely resemble that for the Q(*S*) DS. The rate constant for the quadratic DS, 9.178 × 10^{12} cm^3 mol^{-1} s^{-1}, is only slightly larger than the values for the cubic DSs. For the F + H_2 reaction as well as others we have studied, rate constants for the quadratic DS are close to the converged value for a power series DS.

Figure 5 shows the reactivity relief map for the $\sin^2$ θ cubic SA DS at 300 K. The rate constants for the linear θ and $\sin^2$ θ SA DSs are 13.67 and 11.80 × 10^{12} cm^3 mol^{-1} s^{-1}, respectively. Although both SA DSs pass closer to the angle-dependent saddle points than the variational DSs, the rate constants are significantly larger than the variational values. Contours of the same value in reactivity relief maps span larger areas and are thicker in the direction of increasing *R* for SA than for variational DSs. Variational DSs follow the path of steepest ascent from points which are near angle-dependent saddle points better than least-squares SA DSs over the θ range where the reactive flux is large; consequently, the rates are significantly lower. Sets of simplex vertices based on SA DSs were used to initiate variational searches with and without restrictions on variational parameters. These searches converged to smaller variational rate constants and values of DS parameters which were found using other methods to generate initial vertices for simplex searches.

Figure 6 shows that the region of high flux on reactivity relief maps does not cross from the small to the large *R* side of the path of angle-dependent saddle points at intermediate θ because of an entropic effect. This figure shows results for the linear θ C(*S*) DS for the T2 PEF at 300 K. The contour for a large variational flux (marked *f*) is shown with a potential-energy contour for 0.15 eV (marked *v*). Three contours of the configuration factor (marked *c*) of the integrand for $N_*^c(T)$ are also shown.

$$[23] \quad c = \sin\theta\, r(\Omega, R, \theta)^2 R^2 \times [\mu_{BC}^{-1}\{1 + [F_\theta(R,\theta)/r(\Omega,R,\theta)]^2\} + \mu_{A,BC}^{-1} F_R(R,\theta)^2]^{1/2}$$

See eqs. [8] and [9]. This factor excludes only the potential-energy factor exp {$-\beta V(r^*, R, \theta)$}. The path of the angle-dependent saddle points is also shown. The minimum poten-

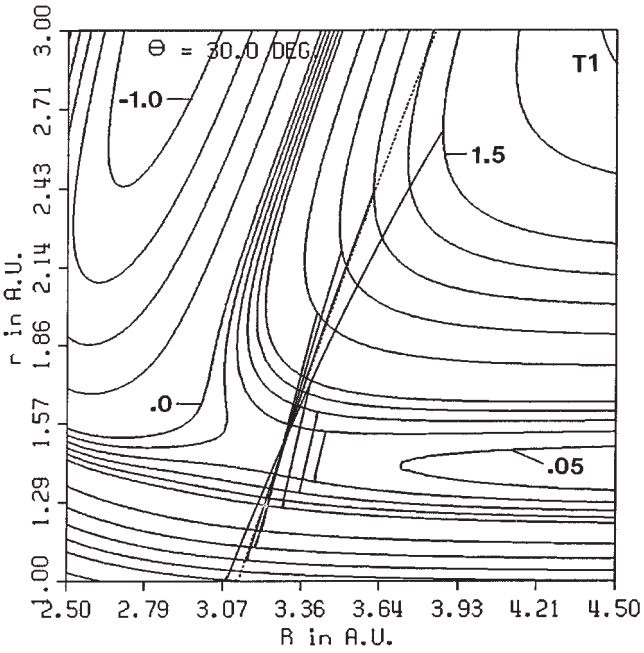
The broken curve shows the cubic slope-restriction dividing surface.



tial energy lies within the 0.15 eV contour; and this minimum corresponds to a good approximation to the maximum of the variational flux. It is the potential-energy factor, not the entropic (configuration) factor, which is responsible for the location of the large flux region on the DS.

We conclude that the large flux region crosses the path of angle-dependent saddle points because the DS can not pass through the angle-dependent saddle points over the entire range in θ where the flux is large and take the path of steepest ascent from them. The variational DS passes from the small *R* side of the saddle point path to the large *R* side as θ increases to stay as close to the saddle points and the path of steepest ascent as possible over the θ range where the flux is large.

It is possible that another DS function exists which does a better job of following the path of steepest ascent from angle-dependent saddle points over the full range of θ, yields rate constants which are significantly lower than values for the quadratic and cubic linear θ and $\sin^2\theta$ DS functions, and gives reactivity relief maps with high flux contours which follow angle-dependent saddle points more closely than the functions studied here. This possibility could be investigated by formulating more DS functions and studying them as we did with the $\sin^2\theta$ DS function. We chose instead to address this point by comparing variational and classical mechanical trajectory results for the Q DS functions used in our earlier studies (45, 46). If variational rate constants, energy-dependent mean reaction cross sections, and angular distributions of reactivity are in good agreement with Monte Carlo trajectory results for the Q linear θ DS, then these DSs are flexible enough to give accurate rate constants and mean reaction cross sections and provide an accurate description of the dynamical stereochemistry of the F + H_2 reaction.

5. Accuracy of variational results

A. Comparison of variational and classical mechanical trajectory mean reaction cross sections

The accuracy of the classical variational theory was studied by comparing values of the energy-dependent mean reaction cross section with classical mechanical trajectory values. Quadratic rather than cubic formulations of the DS were used because of the small cubic versus quadratic gain in accuracy and the relative ease of a quadratic variational search. Calculations were performed for the T1 PEF. The accuracy of the variational theory was determined by comparing variational and trajectory mean reaction cross sections rather than rate constants because the former could be calculated with a much smaller error than the latter in Monte Carlo calculations of the same number of trajectories. The accuracy of the variational theory was also studied by comparing angular distributions of contributions to the energy-dependent mean reaction cross section with corresponding trajectory distributions.

Variational values of the mean reaction cross section were calculated for the slope (*S*) restriction, energy limit (*E*) restriction, and unrestricted (*N*) quadratic DSs for energies of 0.1, 0.25, 0.5, 0.75, 1.0, and 1.5 eV using eq. [11]. The results are compared with classical trajectory values in Table 2. Note that the energy limit and unrestricted values of the mean reaction cross section are the same. The energy limit used was not 4.0 eV, the value used for the canonical calculations, but rather the energy of the microcanonical ensemble. This restriction is easy to satisfy; three variational searches performed with this restriction converged to results obtained for unrestricted searches. We therefore refer to the energy limit results of Table 2 as unrestricted in the text which follows. The value of R_{max} used in the microcanonical calculations was the same as that used for canonical calculations, i.e., 7 au. Values of the mean reaction cross section calculated using the slope restriction are slightly larger than the unrestricted values as expected. The errors cited for the trajectory results correspond to a confidence level of 68%. The difference between the unrestricted variational and trajectory mean reaction cross sections increases with energy as expected; however, the difference at 1.0 and 1.5 eV amounts to only 18 and 25%, respectively. These energies are very high in the sense that the probability that reaction systems have these energies at temperatures commonly used in the study of gas phase reactions is extremely small. Figure 7 shows potential-energy contours for the T1 PEF at orientation angle 30°. The intersections of microcanonical unrestricted quadratic DSs for the energies cited above with the (*r, R*) plane are also shown.

and

$$[27] \qquad \rho(E) = \frac{\langle S_r(E)\rangle^{R\ddagger}}{\langle S_r(E)\rangle^{VT}}$$

The quantity $\langle S_r(E)\rangle^{R\ddagger}$ is defined below.

Many chemists believe that a correction, the transmission coefficient, must be applied to transition state theory because some trajectories which originate in the reactant region cross the DS and subsequently recross it and return to the reactant region. The quantity $\langle S_r(E)\rangle^{R\ddagger}$ is the energy-dependent mean reaction cross section for all reaction systems on the DS that correspond to trajectories which originate in the reactant region and are moving toward products at the DS, regardless of whether the reaction system ultimately reaches the product region. All crossings of the DS from the reactant to the product side which correspond to trajectories which originate in the reactant region contribute to $\langle S_r(E)\rangle^{R\ddagger}$. The factor $\kappa(E)$ provides a correction for multiple crossings of the DS by trajectories which originate in the reactant region. This factor corrects for trajectories which are reflected after crossing the DS and return to the reactant region and for trajectories which are ultimately reactive but cross and recross the DS an odd number of times on their way to the product region.

Another factor, the product factor ($\rho(E)$), must be applied to correct the variational value of the mean reaction cross section. Transition state theory must also be corrected because trajectories which originate in the product region, which are present in the equilibrium flux of reaction systems through DS, can cross and recross the DS and contribute (incorrectly) to the reaction rate, i.e., $k(T)$ and $\langle S_r(E)\rangle^{VT}$ should correspond to the rate of reaction in the absence of products. Hence, the variational theory must also be corrected by applying the factor $\rho(E)$. Note that the product factor is unity if trajectories which originate in the product region do not contribute to the variational flux.

Trajectory and variational results for the unrestricted quadratic DS are summarized in Table 3. The quantity $\langle S_r(E)\rangle^{R\ddagger}$ is determined by calculating the function that defines configurations on the DS ($r - F(R, \theta) - C = 0$) for each time step of each trajectory to detect crossings of the DS by trajectories which contribute to this quantity. The values of the coefficients are given in Table 3. Note that the deviation between variational and trajectory values of the mean reaction cross section at the lowest energy (0.1 eV) caused by trajectories that start in the reactant region and cross the DS more than once appears to be smaller than the deviation caused by trajectories that originate in the product region, i.e., $\kappa(E) > \rho(E)$ for this energy, although there is some overlap of the error ranges. For the energies from 0.5 to 1.5 eV, $\kappa(E)$ is equal to $\rho(E)$ within numerical error for 68% confidence.

C. Accuracy of the no-recrossing approximation of transition state theory

The accuracy of the no-recrossing assumption of transition state theory for collinear atom–diatom reactions has been the subject of many studies (42, 71, 80–85). The application of a DS formulation which includes terms in θ makes it possible to determine how the accuracy of the no-recrossing assumption depends on the orientation angle. One way to do this is illustrated in Fig. 8. This figure shows a plot of both variational and trajectory differential mean reaction cross sections versus θ for energy 1.0 eV. The variational distributions correspond to the Q(N) DS. The results labeled "reactant ‡" correspond to all reaction systems on the DS for trajectories which originate in the reactant region and are moving toward the products at the DS. Alternately, the 5° increments for the mean reaction cross sections $\langle S_r(E)\rangle^{CMT}$, $\langle S_r(E)\rangle^{R\ddagger}$, and $\langle S_r(E)\rangle^{VT}$ and eqs. [25]–[27] may be used to calculate average values of $\kappa(E)$, $\rho(E)$, and $\chi(E)$ for each 5° range of θ. Figures 9–11 show average values of these coefficients versus θ for energies of 0.1, 0.5, and 1.0 eV. For collinear atom–diatom reactions, the correction factors decline more rapidly with increasing energy than for reaction in three-dimensional space. On this basis, one expects deviations from the variational flux to be skewed toward low values of θ. This does not appear to be the case at the lowest energy studied but the overall coefficent χ does appear to show an increasing trend for the energies 0.5 and 1.0 eV. Figure 9 shows that at 0.1 eV the deviation from the variational flux is due more to trajectories which originate in the product region and cross and recross the DS than from those which originate in the reactant region ($\rho < \kappa$) and that

© 1999 NRC Canada

this holds over the entire range of the orientation angle. At the energies 0.5 and 1.0 eV, deviations from the variational flux are due as much to trajectories which originate in the product region and contribute incorrectly to the rate as the reactant region, i.e., $\kappa \simeq \rho$ over the entire range of θ. Finally, although the overall coefficient χ does not show marked variation with θ at any of the energies studied, the failure of the no-recrossing assumption is most significant at intermediate values of θ because the variational flux peaks here.

D. Calculation of the canonical rate constant using energy-dependent mean reaction cross sections

Variational parameters for 13 energy-dependent Q(*N*) DSs at energies of 0.1, 0.125, 0.15, 0.20, 0.25, 0.375, 0.5, 0.625, 0.75, 0.875, 1.0, 1.25, and 1.5 eV were used to calculate the canonical rate constant at temperatures 300, 900, and 1500 K. The DSs at energies of 0.1, 0.15, 0.25, 0.5, 0.75, 1.0, and 1.5 eV are plotted on the potential-energy contour map for 30° in Fig. 7. Energy-dependent mean reaction cross sections were calculated for a range of energies centered on each of the values cited above using an increment of 0.001 eV. The rate constant was calculated using simple quadrature with an energy increment of 0.001 eV to evaluate the integral of eq. [14]. Figure 12 shows the variational mean reaction cross section calculated using the 13 sets of variational parameters and the integrand of the integral of eq. [14] at 1500 K versus energy. The maximum value of the integrand occurs at 0.5 eV. In Table 4, canonical variational rate constants for the Q(*S*) DS at 300, 900, and 1500 K are compared with values calculated using the 13 sets of Q(*N*) energy-dependent variational parameters described above. The improvement obtained by microcanonical optimization is small; the ratios of the microcanonical variational and canonical variational values of the canonical rate constant at 300, 900, and 1500 K are 0.958, 0.965, and 0.978, respectively. The effect of microcanonical optimization decreases with increasing temperature.

Concluding remarks

The general variational theory of chemical reaction rates will help chemists understand transition state theory in a new and richer way. If a chemist is asked to identify the transition state for a collinear reaction on a plot of potential-energy surface, he or she will probably point to the saddle point. A more informed chemist will draw a line or curve through the saddle point that follows the path of steepest ascent from it. A still more informed chemist will draw a curve that misses the saddle point and corresponds to a periodic orbit dividing surface. A variational DS defines a generalized transition state. A generalized variational DS for an atom–diatom reaction in three-dimensional space that depends on the orientation angle provides a description of the dynamical stereochemistry of the reaction. The reactivity relief map shows how the reactive flux through the DS depends upon the location on it. Reactivity relief maps can also be used to show how the field of reactivity that surrounds the reactant expands with increasing temperature and energy. Finally, reactivity relief maps can be used to show how the field of reactivity that surrounds a reactant depends on the identity of the attacking atom and how the field depends on the identity of the diatomic reactant for the same attacking atom. There is more work to be done.

Styrene hydration and stilbene isomerization in strong acid media. An excess acidity analysis[1]

Robin A. Cox

Abstract: Rate constants obtained for the hydration of some ring-substituted styrenes, $YC_6H_4CR{=}CH_2$ (R = H, CH_3, CF_3) (**1**–**3**), and for the isomerization of some *cis*-stilbenes substituted in both rings, $YC_6H_4CH{=}CHC_6H_4Z$ (**4**), in aqueous H_2SO_4, D_2SO_4, and $HClO_4$ media at 25°C and, in some cases, at other temperatures, have been subjected to an excess acidity analysis. Data obtained by different groups and in different media for the same substrates agree very well. The $m^{\ddagger}$ values obtained show that all the substrates react via the A-S_E2 mechanism, rate-determining proton transfer to carbon; the transition state is late, with the proton transfer being about three-quarters complete. The reactivities of **1**–**3** in the aqueous standard state are obtained by extrapolation; they are $1{:}10^3{:}10^{-7}$, respectively. The stilbenes are relatively unreactive; log k_0 values for compounds with substituents in the ring adjacent to the developing positive charge show a good correlation with σ^+ with a large negative ρ^+ value, but those for compounds with substituents in the other ring correlate with σ with a small negative ρ. Extrapolated log k_0 values for **1** and **3** show a good correlation with σ^+, but those for **2** correlate with neither σ^+ nor σ, because the α-CH_3 group twists the molecule and reduces the resonance interaction of ring substituents with the developing positive charge. On the other hand, this effect is not seen in **3**, when the strongly deactivating α-CF_3 group is present, meaning that the transition state is forced to be planar in this case. The activation parameters, solvent isotope effects, and excess acidity slope parameters $m^{\ddagger}m^*$ obtained in the analysis are tabulated and discussed. The parameters obtained for the parent styrenes **1** are very similar to those previously obtained for the phenylacetylenes $YC_6H_4C{\equiv}CH$, meaning that reactions with vinyl cation intermediates and reactions with benzyl cation intermediates can be quite similar.

Key words: styrenes, stilbenes, hydration, excess acidity, LFER, mechanism.

Résumé : Opérant à 25°C (et, dans quelques cas, à d'autres températures), dans des solutions aqueuses de H_2SO_4, D_2SO_4 et $HClO_4$, on a mesuré les constantes de vitesse de réaction pour l'hydratation de styrènes substitués sur le noyau, $YC_6H_4CR{=}CH_2$ (R = H, CH_3, CF_3) (**1**–**3**) et pour l'isomérisation de quelques *cis*-stilbènes substitués sur chacun des noyaux, $YC_6H_4CH{=}CHC_6H_4Z$ (**4**) et on a soumis ces valeurs à une analyse par d'acidité en excès. Les données obtenues par divers groupes et dans divers milieux pour la même substance sont généralement en bon accord. Les valeurs obtenues pour $m^{\ddagger}$ montrent que tous les substrats réagissent par le biais d'un mécanisme A-S_E2 impliquant un transfert de proton vers le carbone dans l'étape cinétiquement déterminante. Les réactivités des composés **1**–**3** dans l'état aqueux standard ont été obtenues par extrapolation; elles sont respectivement égales à $1{:}10^3{:}10^{-7}$. Les stilbènes sont relativement peu réactifs; les valeurs de log k_0 pour les composés portant des substituants sur le noyau adjacent à la charge positive qui se développe donnent une bonne corrélation avec σ^+, avec une valeur négative élevée pour ρ^+; toutefois, pour les composés portant des substituants sur l'autre cycle, la corrélation se fait avec σ et la valeur de ρ est négative et faible. Les valeurs extrapolées du log k_0 des composés **1** et **3** présentent une bonne corrélation avec σ^+, mais celles extrapolées pour le composé **2** ne donnent pas de corrélation soit avec σ soit avec σ^+ en raison du fait que le groupe CH_3 déforme la molécule et réduit l'interaction de résonance des substituants du noyau avec la charge positive qui se développe. Toutefois, on n'observe pas cet effet avec le composé **3** qui comporte le groupement CF_3 fortement désactivant; ce résultat implique que, dans ce cas, une structure planaire est imposée à l'état de transition. On présente les paramètres d'activation, les effets isotopiques du solvant ainsi que les paramètres ($m^{\ddagger}m^*$) relatifs à la pente de l'excès d'activité sous forme de tableau et on les discute. Les paramètres obtenus pour les styrènes parents (**1**) sont très semblables à ceux obtenus antérieurement pour les phénylacétylènes, $YC_6H_4C{\equiv}CH$; ceci signifie que les réactions impliquant des intermédiaires vinylcationiques et celles impliquant des intermédiaires benzylcationiques peuvent être très semblables.

Mots clés : styrènes, stilbènes, hydratation, acidité en excès, « LFER », mécanisme.

Introduction

Rate-determining proton transfer in strong acid media, the A-S_E2 [or Ad-E2, or A(E)+A(N)] mechanism, has until recently been difficult to distinguish from the case in which the proton transfer involved in an acid-catalyzed reaction is a pre-equilibrium process, the A1 mechanism. Rate-determining proton transfer involves general acid catalysis, and Jerry Kresge was one of the first to exploit rate differences in aqueous sulfuric and perchloric acid mixtures (1), later expanded to also include aqueous nitric and phosphoric acids (2), to make this mechanistic distinction. Slightly later, I pointed out that these mechanisms could also be distinguished in sulfuric acid by working at acidities high enough that catalysis by H_3O^+, undissociated H_2SO_4, and $H_3SO_4^+$ as individual species is visible (3).

Jerry Kresge was also among the first to point out, in 1971, that alkene hydration followed an A-S_E2 mechanism rather than the A1 π-complex formation process that had been in vogue until then (4). Many different alkene hydrations in strong acid have been studied since that time, for instance, of vinyl ethers in a series of papers by the Kresge group (5), and of norbornene derivatives by the Lajunen group (6). Kresge has also studied the hydration of various alkenes (7), and thus it seemed appropriate in this paper to analyze the rates of hydration of a number of simple phenyl-substituted alkenes, to compare them among themselves and also with a previous study of the hydrations of a number of different phenylacetylenes (8).

The alkenes chosen for study were a series of phenyl-substituted styrenes **1** for which hydration rate constants as a function of acid concentration at 25°C are available in aqueous H_2SO_4 (9–11), D_2SO_4 (12), and $HClO_4$ (13) media, some compounds having also been studied at other temperatures (9, 13); some phenyl-substituted α-methylstyrenes **2** at 25°C, with data in H_2SO_4 (12, 14) and D_2SO_4 (12); some phenyl-substituted α-trifluoromethylstyrenes **3** in H_2SO_4 at 25°C (15); and a series of *cis*-stilbenes **4** with varying substituents in both rings, for which rate constants for isomerization to the *trans* form as a function of acid concentration are available in aqueous H_2SO_4 at 25°C and some other temperatures (16).

Results

[1] 
The mechanism that applies to the hydrations of the styrenes **1**–**3** is given in eq. [1] (4, 8–13, 15). The hydration of **1** in strong acids is a process that comes to equilibrium, with some unhydrated styrene almost always being present at the end of the reaction, and so the measured rate constants are the sum of those for the forward reaction and for the reverse dehydration. All the rate constants used in this work are for the forward reaction only, having been corrected for the reverse process (9–13); here they are called k_ψ, since they are all pseudo-first-order.

$$[2] \qquad \log k_\psi - \log C_{H^+} = \log k_0 + m^\ddagger m^* X$$

The rate equation that applies to all of the reactions in this paper is eq. [2] (17), where C_{H^+} is the proton concentration, simply the acid molarity for $HClO_4$ solutions. Available operationally defined values are used for H_2SO_4 media, ones which account for the variable extent of dissociation of bisulfate ion at different acidities (30). The excess acidity X for both media is also available (30), and can be easily modified to temperatures other than 25°C if necessary (31). The intercept log k_0 values refer to the rate constant for the reaction in the standard state, which is the same hypothetical ideal 1 M acid solution as that used for pH measurements (30), allowing easy comparison with k_{H^+} values obtained from buffer media, etc. (17). Of the slope parameters, $m^\ddagger$ and m^*, the former depends on the reaction mechanism, being >1 for A1 reactions and <1 for A-S_E2 processes (17), allowing the easy distinction of these two mechanisms; in fact, in the latter case (which applies to the reactions in this paper) it is identical to the term α_A previously defined for these reactions by Kresge et al. (32). However, here $m^\ddagger$ is multiplied by m^*, which refers to the type of substrate present, being ~1 for primary nitroanilines, ~0.6 for carbonyl compounds, ~1.3 for thio-compounds, and so on (30). the carbocations formed here this number is quite large, ~1.8 (8, 33, 34), and the combined $m^{\ddagger}m^{*}$ slopes may well be larger than one because of this.

Application of eq. [2] to the available rate constants for **1***a–l* and **1***n* in sulfuric acid (9–12) leads to the intercept log k_0 values given in Table 1 and the $m^{\ddagger}m^{*}$ slopes given in Table 2; some of the very good straight lines obtained according to eq. [2] are illustrated in Fig. 1. This figure also shows that data obtained by different groups for the same compound (9, 10) are in fact equivalent. For clarity the D_2SO_4 results are not shown; preliminary work showed that the $m^{\ddagger}m^{*}$ slopes in H_2SO_4 and D_2SO_4 are identical, and so from then on both were constrained to be the same. Throughout this work data were analyzed using statistics programs modified from those given by Bevington (35). For simplicity, in cases where only a few data points were available (**1***b*, **1***d*, **1***h*, **1***j*, **1***k*, **1***n*) the $m^{\ddagger}m^{*}$ slopes for them were taken as being the average value for those compounds with plenty of data points, as preliminary work showed this to be statistically valid. Table 2 also contains the derived solvent isotope effect values, enthalpies and entropies of activation based on the standard-state intercepts for those substrates with rate constants at different temperatures available ($m^{\ddagger}m^{*}$ slopes are independent of temperature (31)), and relevant statistical information. In Tables 1 and 2 and throughout this paper the errors quoted are standard deviations.

Some styrenes have also been studied in aqueous perchloric acid (13), and the results of applying eq. [2] to the available rate constants are given in Table 3 and Fig. 2. Comparison with Tables 1 and 2 shows that the log k_0 values for the same compounds in the different media (**1***a*, **1***c*, **1***f*, **1***g*), and the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for **1***f*, agree very well. The

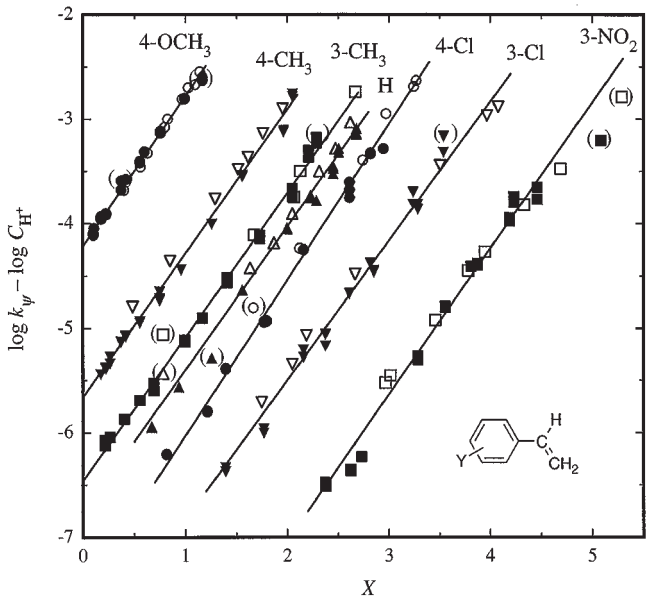
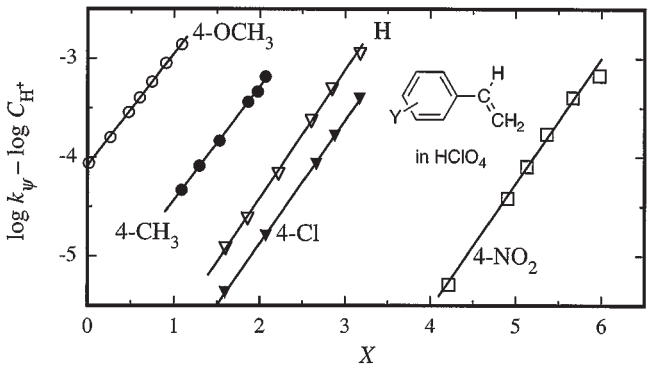
Fig. 1. Excess acidity plots of log k_{ψ} – log C_{H^+} against X for the hydration of some styrenes **1** in aqueous sulfuric acid at 25°C. Closed symbols, data of Coussemant's group (9); open symbols, data of Ellis and Johnson (10). For clarity, only the data for the seven compounds shown are plotted, and results obtained in D_2SO_4 (12) are not included.



$m^{\ddagger}m^{*}$ slopes, however, do not, averaging 1.41 in H_2SO_4 and 1.19 in $HClO_4$. Many groups prefer to use the X_0 scale (based on primary nitroaniline indicators only) (33) rather than X (based on a wide variety of indicators of different types (30)) in aqueous $HClO_4$ media (5–7, 23), since Kresge et al. (36) showed that this offered the best connection between the concentrated aqueous $HClO_4$ and dilute aqueous acid media. In this work, I tried both X and X_0 for **1** in $HClO_4$; X offered the better correlation coefficient in five cases and X_0 in two, although the differences were marginal. X was chosen for this reason and because the comparison with the results obtained using the X scale in H_2SO_4 is more valid. The slopes found using X_0 were smaller in dilute acid and larger in concentrated acid than those obtained using X, and the overall average was much the same (1.22 vs. 1.19), still quite different from the H_2SO_4 value of 1.41.

When eq. [2] is applied to the available rate constants for **2***a–h* in sulfuric acid (12, 14), the intercept log k_0 values given in Table 4 and the $m^{\ddagger}m^{*}$ slopes in Table 5 result. The

Fig. 2. Excess acidity plots of log k_{ψ} – log C_{H^+} against X for the hydration of five styrenes **1** in aqueous perchloric acid at 25°C (13).



data are illustrated in Fig. 3; again for clarity the D_2SO_4 results are not shown. In two cases where only one or two data points were available (**2***b*, **2***g*), there was no choice but to take the $m^{\ddagger}m^{*}$ slopes as being the average value for the remaining compounds. Table 5 also contains the derived solvent isotope effect values and relevant statistical information.

Table 6 contains the results of applying eq. [2] to the available data for **3***a–e* (15), and the data fit is illustrated in Fig. 4. Here, preliminary work showed that the $m^{\ddagger}m^{*}$ slopes for all five compounds were, within experimental error, the same, and so, since few data points were available overall, the slope was constrained to be the same for all the compounds. This worked very well, as can be seen from Fig. 4; the low error on the calculated overall slope, 1.16 ± 0.05, amply justifies this simplification.

[3] 
The A-S_E2 mechanism that applies to **4** is given in eq. [3] (16). This is very similar to eq. [1] for the styrenes, and the same rate equation, eq. [2], applies. This is illustrated for **4***a–l* in aqueous H_2SO_4 at 25°C in Fig. 5 (16), again omitting rate constants obtained in D_2SO_4 and those obtained at other temperatures for clarity. The log k_0 intercepts are given in Table 7 and the $m^{\ddagger}m^{*}$ slopes in Table 8, together with the activation parameters calculated from the different log k_0 intercepts obtained at different temperatures, the solvent isotope effects and statistical information. comparison, the log k_0 values obtained for the compounds that have two equivalent reaction sites (**4***a*, **4***i*, **4***l*) are statistically corrected by subtracting log 2 from them.

The intercept log k_0 values for **1**–**3** are plotted as linear free energy relationships (LFERs) in Fig. 6. Preliminary work showed that the slopes were within experimental error the same for the values obtained in H_2SO_4 and those obtained in D_2SO_4, and so for simplicity these were constrained to be the same, with different intercepts. The values obtained for **1** in $HClO_4$ were not included in the LFER, but they are shown in Fig. 6 for comparison with the H_2SO_4 ones; as can be seen they agree very well. For **1** and for **3** the log k_0 values were accurately linear in σ^+, but for **2** they were linear in neither σ nor σ^+. A double linear regression in σ and σ^+ according to Yukawa and Tsuno (37) gave an r value of ~0.4, and thus the plot of log k_0 for **2** against $\sigma + 0.4(\sigma^+ - \sigma)$ shown in Fig. 6 is linear. Individual results were weighted according to their standard deviations, so the more precise values contribute more than the less precise ones to the linear fit. Values of σ and σ^+ were obtained from a standard source (38), and those not listed there from a newer compilation (39). The ρ^+ values and other summary information is given in Table 9. The solvent isotope effects listed in Table 9 are obtained from the log k_0 values in H_2SO_4 and D_2SO_4 given there, and are the same as the averages of the individual numbers in Tables 2, 5, and 8. Included in Table 9 are the equivalent results previously

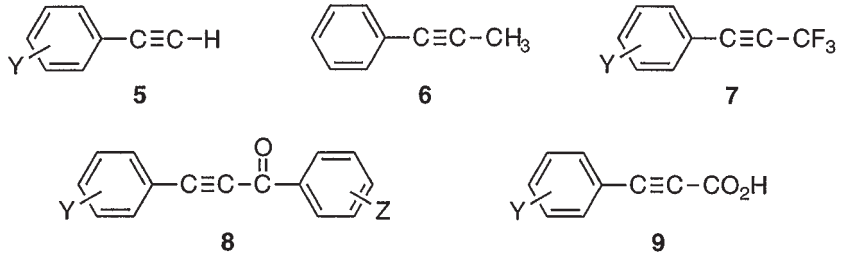
obtained from the phenylacetylenes **5**–**9** (8), for purposes of comparison.

The LFER for **4** is given in Fig. 7 (for clarity only the values measured in H_2SO_4 are plotted); the slopes and intercepts are in Table 9. The individual compounds form a number of different series, resulting in the six different lines shown, and Fig. 7 is the result of a double linear regression of the log k_0 values with σ^+ and σ. Here, the Y substituents are assumed to be on the phenyl group attached to the carbon with the developing positive charge (σ^+ values, large negative slope) and the Z substituents on the phenyl group attached to the other one (σ values, small negative slope).

Discussion

As can be seen from Figs. 1–5, eq. [2] fits the rate constant data for all of the substrates exceptionally well. Deriving it is straightforward; if we call the substrate in eq. [1] or eq. [3] S and the initial protonation is rate-determining, absolute rate theory requires eq. [4] to be true:



© 1999 NRC Canada

Fig. 4. Excess acidity plots of log k_ψ – log C_{H^+} against X for the hydration of five α-trifluoromethylstyrenes **3** in aqueous sulfuric acid at 25°C (13).

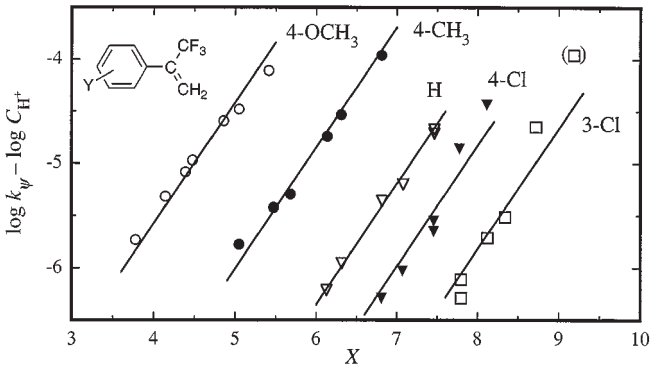


Fig. 5. Excess acidity plots of log k_ψ – log C_{H^+} against X for the isomerization of the *cis*-stilbenes **4** in aqueous sulfuric acid at 25°C (16). For clarity, the results obtained in D_2SO_4 are not included.

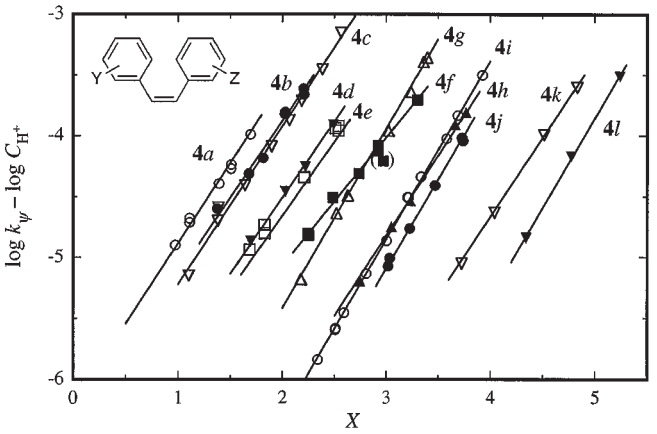

$$[4] \qquad k_\psi C_S = k_0 \frac{a_S a_{H^+}}{f_\ddagger} = k_0 C_S C_{H^+} \frac{f_S f_{H^+}}{f_\ddagger}$$

$$[5] \qquad \log k_\psi - \log C_{H^+} = \log k_0 + \log \frac{f_S f_{H^+}}{f_\ddagger}$$

$$[6] \qquad \log \frac{f_S f_{H^+}}{f_\ddagger} = m^\ddagger \log \frac{f_S f_{H^+}}{f_{SH^+}} \left(= \alpha_A \frac{f_S f_{H^+}}{f_{SH^+}} \right) = m^\ddagger m^* X$$

Canceling and taking logs then gives eq. [5], and eq. [2] results when the activity coefficient ratio term is subjected to the by now very well tested excess acidity assumption of eq. [6] (17). For A-S_E2 mechanisms like eqs. [1] and [3] the terms $m^\ddagger$ and α_A (32) are equivalent, see above. If the k_2 step in eq. [1] were rate-determining, rather than the k_0 step, the water activity or the bisulfate ion concentration would have to be taken into account, and plots like Figs. 1–5 would be curved, as has been amply demonstrated before (22, 24, 28).

It is readily apparent from a comparison of **1**–**3** in Fig. 6 or Table 9 that the activating methyl group in **2** causes it to react three orders of magnitude faster than the unsubstituted **1**, and the deactivating CF_3 group in **3** slows the reaction down by nearly seven powers of 10. (The errors are worse

for **3** because the extrapolation to $X = 0$ is longer for these compounds; being deactivated they require much stronger acid to achieve reaction in a reasonable period of time.) This is what would be expected; it contrasts with the situation in the phenylacetylenes in Table 9, where any sort of substituent slows the reaction down. This probably has a steric component, since the carbon with the substituent is the one being protonated, rather than the one without it in **1**–**3**.

Interestingly, the stilbenes are also deactivated, **4** reacting nearly three orders of magnitude more slowly than **1**. This effect has been seen before; for instance, it has been found that the presence of a mesityl group attached at the functional group slows ketene hydration by a factor of 2200, acid catalysis of the reaction only being observable in strong acid media (41). Presumably, this deactivation is due to ground-state stabilization by the second phenyl ring, and to the inductive electron-withdrawing effect of the phenyl group (40), but there may be a steric component too.

Steric effects certainly show up in the fact that **2** requires a Yukawa–Tsuno plot involving σ and σ^+ to give an LFER, rather than giving a straightforward correlation with σ^+ as all the other substrates do. This must be due to the α-CH_3 twisting the molecule and causing a decrease of conjugation of the double bond with the ring; resonance-effect substituents cannot exert their full influence if this is so (an r value of 0.4 means that they exert only ≈40% of it). The ring does not need to provide so much stabilization with the methyl group also stabilizing the positive charge inductively. This effect does not show up with a strongly electron-withdrawing α-CF_3 substituent present; like it or not, the

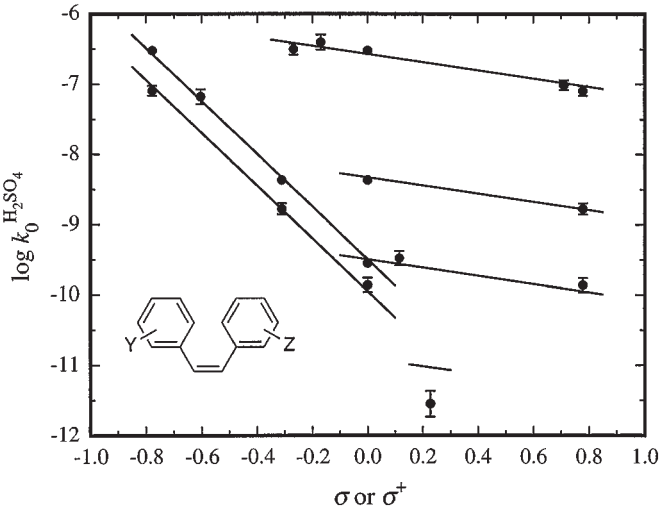
Fig. 7. Linear free energy relationship plots of standard-state rate constants, log k_0, for the isomerizations of the *cis*-stilbenes **4** (intercepts of Fig. 5, Table 7). Plots against σ^+ for the Y substituents and against σ for the Z substituents.



ring must provide all of the stabilization, and this forces the ring and the substituent to be in the same plane, for maximum resonance interaction between the developing positive charge and the ring.

In Fig. 6 the log k_0 values obtained for **1** in $HClO_4$ (closed circles) are plotted for comparison with the values obtained in H_2SO_4. The comparison is in general very good, with the exception of the 4-NO_2 derivative **1***m*, which falls somewhat below the correlation line. However, the error for this compound is much higher than it is for the others. It is gratifying that results obtained in different acid media agree so well; this is what would be expected, since proton transfer is from H_3O^+ in both of the relatively dilute aqueous acid media used in this work (3). Thus, extra justification is provided for the excess acidity approach, and the faith that can be placed in the extrapolated log k_0 values is increased. The $m^{\ddagger}m^{*}$ slopes, however, are not the same in the two media, and for all the substrates there is some variability in the values for individual compounds from the averages in Table 9 (Tables 2, 3, 5, and 8; Figs. 1–5); the author feels that the difference between the H_2SO_4 and $HClO_4$ values for **1**, and other individual differences from the Table 9 averages, are due to differences in m^{*} rather than in $m^{\ddagger}$, but there is no evidence for or against this view at present.

The distinction between A1 and A-S_E2 [or Ad-E2, or A(E)+D(E)] mechanisms depends on the magnitude of $m^{\ddagger}$ (17). All of the values of $m^{\ddagger}m^{*}$ in the Tables are >1, but these have to be divided by m^{*}. Values of this quantity for **1**–**4** are not available, but it is known that typical carbocations such as are produced in the reactions under consideration here have $m^{*} \approx 1.8$ (8, 33, 34), and in all cases division by this leads to $m^{\ddagger} < 1$, demonstrating that all of the substrates in fact react by the A-S_E2 pathway shown in eqs. [1] and [3]. The $m^{\ddagger}$ (or α_A) value can be interpreted like a Brønsted α as being roughly the extent of proton transfer at the transition state (32). If the 1.8 value applies, the extent of proton transfer is 78% for **1** (66% in $HClO_4$), 77% for **2**, 64% for **3**, and 74% for **4** (all values ±~10%). Thus, we have a late transition state in all cases, with the proton being three-quarters transferred for all except **3**, where it is only two-thirds transferred. (However, it must be pointed out that this interpretation differs from the results of very recent theoretical calculations, which compare 1-phenylethanol dehydration with styrene hydration via the same carbocation intermediate, and indicate that whereas the S_N1 transition state for the former reaction is halfway between reactant and

© 1999 NRC Canada

product, in the latter case it is earlier than this (42).) Thus, the slowest reaction has the least advanced transition state, as was observed previously for the phenylacetylenes (8); this counter-intuitive result indicates that a reaction surface such as that used by Chokotho and Johnson (43), rather than a linear profile, is probably necessary for a complete analysis of these reactions.

For some of the phenylacetylenes $m^{\ddagger}m^{*}$ was observed to be a variable function of σ^{+}, which means that the observed ρ^{+} values would be different at different acidities (8). The same effect (but in the opposite direction) had previously been observed for some acylal and thioacylal hydrolyses (44). For the styrenes and stilbenes in this paper, however, the $m^{\ddagger}m^{*}$ values are approximately the same for all the substituents, which means that the ρ^{+} values would be the same at any given acidity as they are in the standard state (values quoted in Table 9). This can be interpreted as indicating that the reactivity–selectivity principle does not apply to **1**–**4** (10, 42, 45).

The ρ^{+} values for **1**–**9** are all approximately the same, quite reasonable numbers between –3.3 and –4.0, except for the compounds with CF_3 substituents, **3** and **7**, where ρ^{+} is significantly more negative (Table 9). This would be expected, because the presence of the strongly electron-withdrawing CF_3 puts much more demand on the ring to supply electrons. Figure 7 for the stilbenes is interesting; for substituents on the ring adjacent to the developing positive charge the log k_0 values follow σ^{+} with a large negative ρ^{+}, but for substituents on the other ring they follow σ, with a small negative ρ value. Thus, the ring on the second carbon plays little part in stabilizing the transition state.

For **1** and **2**, reaction in D_2SO_4 is about 2.5 times slower than it is in H_2SO_4, which seems reasonable, but for the stilbenes, **4**, this factor is 3.6 (Table 9). This would imply a later transition state for **4**, which in terms of the arguments given above means that the m^{*} values for the stilbenes would be smaller than they are for the styrenes. Evidence, however, is lacking.

Activation parameters for some of the substrates are given in Tables 2 and 8. For **4**, $\Delta H^{\ddagger}$ averages 22.5 ± 2.9 kcal mol^{-1} and $\Delta S^{\ddagger}$ –16.8 ± 5.0 cal mol^{-1} K^{-1}. Thus, at 25°C the entropy term contributes only –5 kcal mol^{-1}, so the protonation of **4** is largely an enthalpy-controlled process. The same probably applies to **1** and **5**. The values for **1** in H_2SO_4 are not as reliable as those for **4**, being based on very few data points obtained at temperatures other than 25°C (9): $\Delta H^{\ddagger}$ = 25.6 ± 3.6 kcal mol^{-1}; $\Delta S^{\ddagger}$ = –7.0 ± 7.5 cal mol^{-1} K^{-1}; entropy contribution = –2.1 kcal mol^{-1}. Probably the values obtained in $HClO_4$ are better (Table 3), but there are only two of them (13). Phenylacetylene **5** is very similar to **4**, the averages being $\Delta H^{\ddagger}$ = 19.2 ± 2.2 kcal mol^{-1} and $\Delta S^{\ddagger}$ = –16.3 ± 3.8 cal mol^{-1} K^{-1}, so at 25°C the entropy term contributes –4.9 kcal mol^{-1} (8). The variations in the individual $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values in Tables 2 and 8 are not quite random; there is a tendency for $\Delta H^{\ddagger}$ to increase and for $\Delta S^{\ddagger}$ to become less negative, or even positive, as the ring substituents become more deactivating, particularly for **1**. Thus, the effect of substituents in the benzene ring would seem to be mainly an effect on the enthalpy of reaction, with the well-known tendency of $\Delta S^{\ddagger}$ to be correlated with $\Delta H^{\ddagger}$ (46) counteracting it.

Comparison of the styrenes and stilbenes **1**–**4** with the phenylacetylenes **5**–**9** in Table 9 is instructive more in terms of the similarities than the differences. For instance, $k_{H^{+}}$ in the standard state for styrene itself is 1.7×10^{-7} M^{-1} s^{-1}, and for phenylacetylene, 2.3×10^{-7} M^{-1} s^{-1}. In other words, the latter is marginally more reactive than the former. Insofar as styrenes and stilbenes react via a benzyl carbocation and phenylacetylenes via a vinyl cation, this result might perhaps not have been anticipated, although it has been shown that substituents can have a greater effect on alkyne protonation than they have on alkene protonation, due to the shorter bond from the substituent to carbon, and thus some alkynes are significantly more reactive than the corresponding alkenes are (47). In Table 9, it can also be seen that in this work the phenylacetylenes are found to be more substituent-sensitive than the styrenes (larger negative ρ^{+} value).

The overall conclusion of the work in this paper is that both sets of substrates are reacting in the same way by initial rate-determining carbon protonation, subsequent product-forming reactions being fast. The numerical information given here all refers to the aqueous standard state, and should provide trustworthy data for comparison with the more reactive compounds which can have their reaction rates determined in aqueous solution or aqueous buffer media.

Acknowledgments

I would like to thank Dr. C.D. Johnson for providing rate constant data from a thesis, members of Professor A.J. Kresge's group for information and advice, and Professor T.T. Tidwell for helpful suggestions and discussion, and for reading the manuscript.

Keto ⇄ enol equilibria for and oxidative cyclization to benzofurans of 2,2-ditipyl-1-R-ethenols. Comparison with dimesityl analogs

Joseph Frey and Zvi Rappoport

Abstract: 2,2-Ditipyl-1-R-ethenols (R = H, Me, *t*-Bu; tipyl (Tip) = 2,4,6-triisopropylphenyl) were equilibrated in hexane with their carbonyl isomers. The equilibration was accompanied by an oxidative cyclization of the enols to substituted 2-R-3-tipyl-4,6-diisopropylbenzofurans, which became more facile with the increase in the bulk of R. At 77.5°C in hexane the K_{Enol} values were 90, 0.11, and 0.0011 for R = H, Me, *t*-Bu, respectively. Comparison with K_{Enol} values for the 2,2-dimesityl analogs indicate a higher value for the 2,2-ditipyl derivative with R = H, but lower values for R = Me and *t*-Bu. The factors affecting this difference are discussed.

Key words: 2,2-ditipyl-1-R-ethenols, keto ⇄ enol equilibria, enols oxidative cyclization.

Résumé : Opérant dans l'hexane, on a équilibré les 2,2-ditypyl-1-R-éthénols (R = H, Me, *t*-Bu; tipyle (Tip) = 2,4,6-triisopropylphényle) avec leurs isomères carbonylés. L'équilibre est accompagné par une cyclisation oxydante des énols en 2-R-3-tipyl-4,6-diisopropylbenzofuranes qui devient plus facile avec une augmentation de l'encombrement du groupe R. À 77,5°C, dans l'hexane, les valeurs de $K_{énol}$ sont respectivement 90, 0,11 et 0,0011 pour R = H, Me et *t*-Bu. Une comparaison des valeurs de $K_{énol}$ avec celles des analogues 2,2-dimésityle permet d'observer que, pour R = H, la valeur est plus élevée pour le dérivé 2,2-ditipyle; toutefois, elles sont plus faibles pour R = Me et *t*-Bu. On discute des facteurs qui affectent cette différence.

Mots clés : 2,2-ditipyl-1-R-éthénols, équilibre céto ⇄ énolique, cyclisation oxydante des énols.

[Traduit par la Rédaction]

Introduction

In our previous work on the keto (**1**) ⇄ enol (**2**) equilibria of aryl-substituted stable simple enols (eq. [1]) (1), two trends

[1] $$\underset{\mathbf{1}}{R'ArCHCR}(=O) \underset{}{\overset{K_{Enol}}{\rightleftharpoons}} \underset{\mathbf{2}}{R'ArC{=}C(OH)R}$$

were observed. For the 2,2-dimesityl-substituted series **3** (**1**/**2**, Ar = R′ = Mes = mesityl), the increase in the bulk of an *aliphatic* 1-R substituent reduced K_{Enol} (= [**4**]/[**3**] at equilibrium) in hexane at 80°C in a monotonic way, e.g., from 20 ± 1 for R = H (**3a**/**4a**) to 0.006 for R = *t*-Bu (**3c**/**4c**) (eq. [2]) (2). With R being an aromatic substituent the opposite was observed, i.e., K_{Enol} increased with the increase of the bulk

a: R = H	**a**: R = H
b: R = Me	**b**: R = Me
c: R = *t*-Bu	**c**: R = *t*-Bu
d: R = Ph	**d**: R = Ph
e: R = Mes	**e**: R = Mes

of R, e.g., from 1 for R = Ph (**3d**/**4d**) to 79 for R = Mes (**3e**/**4e**) (3, 4). Increase in the electron-withdrawal ability of R by *m*- and *p*-substituents also increased K_{enol} (4).

The corresponding change in K_{Enol} on changing the 2-substituents was much less studied. For 2-alkyl-1,2-dimesityl-substituted systems **1**/**2**, R = Ar = Mes, R′ = H, alkyl, the carbonyl compound predominates in the equilibria, and although K_{Enol} values could not be measured, since the reaction is too slow (5), $K_{Enol} < 10^{-2}$. Several equilibrium constants were measured for **1**/**2**, R′ = Ar. For the *Z*-1,2-dimesityl-2-phenyl system, **1**/**2**, R = R′ = Mes, Ar = Ph, K_{Enol} = 0.67 (6), a value slightly higher than for its isomers **3d**/**4d**.

It is therefore of interest to use constant 2-substituents bulkier than phenyl or mesityl and to learn how K_{Enol} changes with the change of the 1-substituent. Aryl groups bulkier than mesityl with identical *o*,*o*′-substituents, which

facilitate the study of the equilibria by NMR, are 2,4,6-triisopropylphenyl (tipyl, Tip) and 2,4,6-tri-*tert*-butylphenyl (supermesityl, Sup), or pentamethylphenyl. However, since no Sup_2C-substituted system was so far prepared, the pentamethylphenyl and the tipyl groups are a convenient choice.

2,2-Bis(pentamethylphenyl)ethenols **1**/**2** (Ar = R′ = Me_5C_6) were equilibrated with their carbonyl analogs. The K_{Enol} values given in Table 1, which were higher than with the mesityl analogs (7), were ascribed to electronic and buttressing effects.

The effect of a tipyl group was compared previously with that of a mesityl group. Fuson et al. (8) prepared 2,2-ditipylethenol in order to "bring the amount of hindrance to a maximum" and compared the kinetic stability of 1,2-ditipylethenediol with that of the corresponding mesityl derivative (for a summary see ref. 9). A quantitative comparison is also available: K_{Enol} in DMSO of 2-tipyl-1-acenaphthyl enol is 2.6 compared with 0.3 for the 2-mesityl analog (10). The major source for the relative stability of the enol was attributed to the relief of steric strain on isomerization to the isomeric ketone. The strain arises from the interaction of the *o*-alkyl group and the *p*-electron cloud of the acetonaphthenone system, and that in the enol is regarded to be much smaller (10).

The compounds *E*- and *Z*-1-phenyl-2-tipylethenols and an indanol were formed in a 15:1 ratio from the photoenolization of α-tipylacetophenone, whereas the α-mesityl analog afforded only the indanone (11). This was ascribed to greater stability of the tipyl-substituted enols due to higher steric hindrance of tipyl compared with mesityl.

We had used the greater steric bulk of tipyl compared with mesityl to kinetically stabilize enols of ditipylacetic acid derivatives more than the mesityl derivatives (12). Also, the rotational barriers of the 1- and 2-rings flips for 2,2-ditipylethenol are higher than for the dimesityl analog (13).

Consequently, in order to further evaluate the 2-aryl group effect on K_{Enol} values, several 2,2-ditipyl-1-R-ethenols (**6**) and their carbonyl isomers (**5**) were prepared and equilibrated (eq. [3]). The equilibrations and the accompanying oxidative cyclization reactions are described below.

Synthesis of 2,2-ditipylethanones (5) and 2,2-ditipylethenols (6)

The precursor for compounds **6** and **5** was ditipylketene, which was prepared by us previously (12). Its reduction by $LiAlH_4$ (13) gave 2,2-ditipylethenol (**6a**), which was prepared earlier by Fuson et al. (8). Grignard reactions with MeLi and *t*-BuLi gave 1,1-ditipyl-1-propen-2-ol (**6b**) and 1,1-ditipyl-3,3-dimethyl-1-buten-2-ol (**6c**) as described earlier (13).

In the synthesis of **5c**, three other compounds were formed and identified by NMR, (*i*) ditipylacetic acid, (*ii*) the oxidative-cyclization product, 2-*tert*-butyl-3-tipyl-4,6-di (isopropyl) benzofuran, **7c**, which was described earlier (13), and (*iii*) the ketone, 1,1-ditipyl-3,3-dimethyl-2-butanone (**5c**). Indeed, when the ketene was reacted with *t*-BuLi in refluxing THF, **6c** comprises <5% of the product, and the main products were the acid, **5c** and **7c** (eq. [4]). However, at 0°C, >95% of **6c** was formed, but on work-up, which involved evaporation of the solvent by heating in vacuo on a steam bath, **6c** and **5c** were formed in different ratios, depending

[4] $Tip_2C{=}C{=}O \xrightarrow{t\text{-BuLi}} Tip_2C{=}C(OH)Bu\text{-}t \longrightarrow$ *i*-Pr, Tip, Bu-*t* + $Tip_2CH\text{-}C(=O)\text{-}Bu\text{-}t$

on the length of the heating time. Formation of the side products was avoided by conducting the reaction in ether and evaporation of the solvent at room temperature.

Ketones **5b** and **5c** were prepared by TFA-catalyzed ketonization of their isomeric enols **6b** and **6c** in hexane (eq. [5]). To avoid a competing facile oxidative cyclization to benzofurans **7b** and **7c** in air, especially at higher temperatures, the isomerization of **6b** was performed at room temperature and that of **6c** in vacuum-sealed ampoules. The yields of the ketones were affected by the competitive oxidative cyclization.

[5] $\underset{\textbf{6b}\ \textbf{6c}}{Tip_2C{=}C(OH)R} \underset{}{\overset{TFA,\ hexane}{\rightleftharpoons}} \underset{\textbf{5b}\ \textbf{5c}}{Tip_2CHC(=O)\text{-}R}$

Ditipylethanal **5a** could not be isolated from an equilibrium mixture with 2,2-ditipylethenol **6a**, since **6a** comprises >98% of the mixture. This also provides a mechanistic rationalization for Fuson's method (8) for the formation of **6a**, which involves dehydration of 1,2-ditipylethanediol. A pinacol rearrangement probably generates **5a**, which rapidly isomerizes under the acidic conditions to the more stable **6a**. A similar behavior was observed with 2,2-dimesitylethanal, which was defined as "elusive" (14). The latter was then prepared by pyridinium dichromate (PDC) oxidation of 2,2-dimesitylethanol, which proceeds at neutral pH and which presumably does not involve an enolic intermediate.

An attempt was made to form **5a** by a similar oxidation of 2,2-ditipylethanol **8**. A LAH reduction of ditipylacetyl chloride ($Tip_2CHCOCl$) failed, and ditipylketene rather than the required **8** was obtained by spontaneous elimination of HCl. LAH reduction of methyl ditipylacetate at room temperature in THF gave directly ethenol **6a**. This is probably due to reduction of the ester to the desired **5a**, which, however, isomerized to **6a** under the strongly basic conditions (eq. [6]). In refluxing diglyme, the LAH reduction gave 1,1-ditipylethylene, presumably by elimination of water from the intermediate **8** (eq. [6]). This is interesting, since the method used to prepare 1,1-dimesitylethylene (15) failed in attempted preparation of 1,1-ditipylethylene.

We succeeded in synthesis of **8** in 72% yield by bubbling formaldehyde vapor into a solution in which the ditipylmethyl anion Tip_2CH^- was generated by ultrasonic irradiation of a solution of Tip_2CHOMe in the presence of a Na/K alloy (eq. [7]).

However, when **8** was oxidized with PDC, both **5a** and **6a** were formed (eq. [8]). This is attributed to isomerization of **5a** to **6a** under the mild reaction conditions. Consequently, long reaction times have to be avoided, and the oxidation has to be stopped before completion of the reaction when some **8** still unreacted and **5a** was formed in a low amount, i.e., the **8**:**5a**:**6a** ratio is 5:5:1. Attempted purification of **5a** by chromatography or crystallization was unsuccessful, since both processes led to isomerization to **6a**. Nevertheless, **5a** could be detected by NMR using the characteristic formyl doublet at δ 10.20 (J = 2 Hz) and the CH doublet at δ 6.15. These signals were used in evaluating K_{Enol} for **5a**/**6a**.

Equilibrations and K_{Enol} values

The K_{Enol} values for the **5a**–**5c**/**6a**–**6c** pairs were measured semiquantitatively and compared with values previously measured for the dimesityl (2) and pentamethylphenyl (7) analogs. An accurate determination of K_{Enol} at 80°C, where K_{Enol} values for **3a**–**c** were determined, was not performed due to the easy oxidation–cyclization to benzofurans **7a**–**c**.

Samples of the enol were dissolved in hexane and TFA was added. From the light-protected ampoules kept at 77.5°C, samples were withdrawn, the solvent was evaporated at room temperature, and the **5** to **6** ratios were determined by integration of well-separated signals (usually Tip-H) of the two species in the ^{1}H NMR spectrum of the equilibrium mixture. When the **5**/**6** ratios were identical for two samples taken at sufficiently different reaction times, the ratio was regarded as the equilibrium ratio. However, even in vacuum-sealed pressure ampoules, presumably oxygen-free conditions, the benzofurans were still observed and in up to 5% in the reaction of **6a**. This reduces the accuracy of the measurements. The percentage of enol at equilibrium, the derived K_{Enol} values and K_{Enol} values for the corresponding 1-R-2,2-dimesityl and 2,2-bis(pentamethylphenyl) derivatives are given in Table 1.

Oxidation–cyclization of 2,2-ditipylethenols to 3-tipylbenzofurans

As noted above, during the preparation of **5c**, we observed the formation of benzofuran **7c**, especially at high temperature. In addition, in the course of variable-temperature NMR experiments (13), pure samples of enols

[6] $Tip_2CH\text{-}C(=O)\text{-}OMe \xrightarrow[THF]{(a)\ LiAlH_4} [\underset{\textbf{5a}}{Tip_2CH\text{-}C(=O)\text{-}H}] \rightleftharpoons \underset{\textbf{6a}}{Tip_2C{=}CHOH}$

6a and **6b** in $C_6D_5CD_3$ or in DMSO-d_6 became contaminated by side products formed at >80°C, after 1–2 h. When samples of **6a** and **6b** in the same solvents were kept for 18 h at 110°C, the ^{1}H NMR spectra of pure benzofurans **7a** and **7b** (identical with the side products mentioned above) were obtained, whereas the transformation of **6c** to **7c** was much faster and required only 2–3 h (eq. [9]). We ascribe the enol to benzofuran transformation to air oxidation of the enols, which becomes easier when R is bulkier so that **6c** cyclizes even at room temperature.

[9] $Tip_2C{=}C(OH)R \xrightarrow{\Delta}$ 
6a R = H

Discussion

The effect of β-substituents on K_{Enol} values

We have now three short sets of K_{Enol} values in hexane for β,β-diaryl-1-R carbonyl–enol systems for R = H, Me, *t*-Bu and Ar = Tip, Mes, and Me_5C_6 under nearly similar conditions (Table 1). The qualitative behavior is the same, for R the K_{Enol} values follow the order H >> Me >> *t*-Bu, where the percentage of enol is ≥95% for R = H, 10–78% for R = Me, and 2–0.1% for R = *t*-Bu.

Comparison of the data of Table 1 with the dimesityl systems was already discussed for the pentamethylphenyl system, where the increase in bulk is due to buttressing effect. In the case of the ditipyl system, the effect is related to the increased bulk of the 2,6-substituents, assuming that the difference in the electronic effect of Mes and Tip will be small.

However, before making comparisons, a comment on the accuracy of the data is in order. The advantage of "observing" directly both the carbonyl and the enol species at equilibrium by NMR (excellent data reliability) is also a disadvantage, since only in a relatively narrow range of the equilibrium constants, K_{Enol} values, is the error rather low, i.e., when both species are formed in appreciable quantities (between ca. 10% to ca. 90%). Due to NMR integration, when the concentration of either the carbonyl compound or the enol is ≤2–3%, the relative errors in the concentration and in the derived K_{Enol} value are rather high. This should be taken into account when comparing K_{Enol} values for relatively high or relatively low enol concentration in our systems.

Two interesting points arise from comparison of the dimesityl and the ditipyl systems. First, the α-H-β,β-ditipyl enol **6a** is relatively more stabilized than the α-H-β,β-dimesityl enol **4a**, whereas the relative stability is inversed with the α-alkyl (Me, *t*-Bu) systems. The K_{Enol} values for **5a**/**6a** is even higher than for trimesitylethenol (14), but it is lower than for the pentamethylphenyl system (7). Considering the errors in the values, the higher value for **5a**/**6a** compared with **3a**/**4a** is real. Second, qualitatively, we found that the equilibration rates are affected by the bulk of the α-ring. Whereas for **3b** and **3c** equilibration was achieved after 14 and 8 h, respectively, longer times, i.e., 8 and 4 days were required for the tipyl analogs for reaching equilibrium under almost identical conditions. When **6b** was equilibrated with **5b** at room temperature, the changes in the keto:enol ratios were <2% during several months.

The factors influencing the stability of 2,2-diaryl-1-R-ethenols were previously discussed (1). They involve mainly the extent of Ar-C=C conjugation and steric effect on it. Ph-C=C conjugation at full planarity was estimated as 4.5 kcal mol^{-1} per completely coplanar single ring, and the effect of a change to a mesityl ring was estimated to be small (fully planar Mes-C=C, 4.8 kcal mol^{-1}) (4). This interaction lacks a counterpart in the ketone where the CH is sp^3-hybridized. Steric effects in the aryl group, e.g., by 2,6-alkyl substituents affect the K_{Enol} values in two ways. First, they increase the Ar-C=C dihedral angle and, consequently, decrease the conjugation. Second, the steric repulsion between two geminal bulky aryl groups is better accommodated in the enols with a "formal" 120° angle between these groups than in the carbonyl system with 109° angle. This interpretation suggests that this factor will increase K_{Enol} with the increased bulk of the β-aryl. Moreover, the decrease of K_{Enol} with the increased bulk of R for the **3**/**4** series (2) is accounted for by the sensitivity of the Ar-C=C interaction to steric hindrance. Since the interaction will be larger with the bulkier α-tipyl ring, it explains why enols **6b** and **6c** are destabilized relatively to their mesityl analogs. Unfortunately, supporting crystallographic data for this assumption is not available due to the difficulty in getting good crystals.

On the other hand, the higher stability of **6a** compared with **4a** is puzzling, since the repulsion should distort the bulkier tipyl rings from planarity with the double bond even more than in **4a**. The solid-state structure show that the Ar-C=C torsion angles for **6a** (56.7 and 50.2°) (13) are close to those of **4a** (54.5 and 58.9°) (16). We note that electronic effect resulting from the change Me → *i*-Pr could not account for the observed difference. We conclude that the increase of steric effect and in K_{Enol} values by *m*-Me buttressing is higher than by the change *o*-Me → *o*-*i*-Pr.

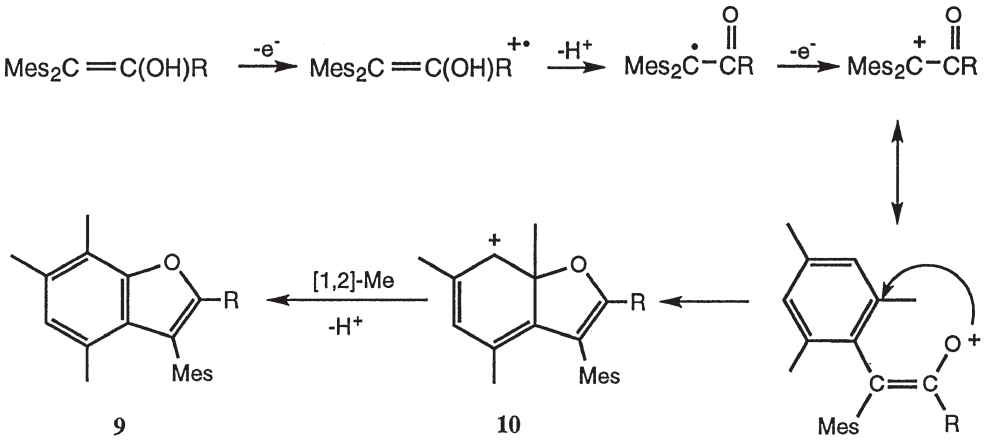
Oxidation of 2,2-ditipylethenols to the benzofurans

The oxidation of enols is a known reaction (1*b*), and it was even stated that the acid-catalyzed oxidation of some carbonyl compounds occurs via their enol tautomers (17). The ozonation of ethenols **4a** and **4e** have been investigated by Bailey et al. (18) who suggested that **4e** and ozone produce at –78°C a radical by hydrogen abstraction from the enolic OH group and isolated a benzofuran as the only product in 2–3% yield.

In studying the reactions of cation radicals derived from enols **4a** and **4c**, Schmittel et al. (19) observed the facile oxidation of the enols, which led to substituted benzofurans. In their proposed mechanism, the cation radical is first deprotonated and then oxidized to the α-carbonyl carbocation (eq. [10]). This in turn cyclizes intramolecularly to form cation **10**, which upon [1,2] methyl shift and subsequent deprotonation affords the benzofuran **9**.

© 1999 NRC Canada

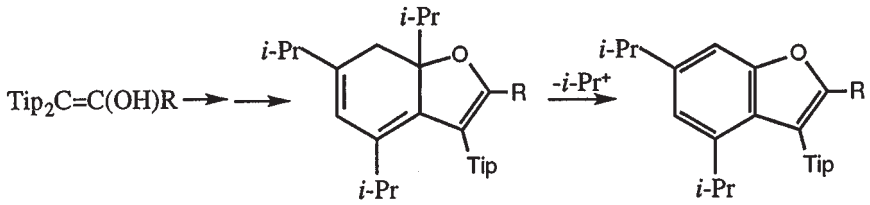
[10]



9 10

The main difference between the benzofurans **9**, derived from enols **4**, and benzofurans **7** lies in the fate of the alkyl substituent on the bridging carbon atom in the intermediate cation. With enols **4**, when Ar = Mes, a [1,2] methyl shift occurs in **10** resulting in a triaalkyl-substituted benzofuran (**9**), after a loss of a proton. When Ar = Tip, expulsion of an isopropyl cation from cation **11** is apparently more favourable energetically than its [1,2] shift, and the product is the substituted benzofuran (**7**) (eq. [11]). This is easily accounted for by the higher stability of the *i*-Pr^+ cation compared with the Me^+ cation.

[11]



6 7 11

Another difference is that the oxidation–cyclization process, reported by Schmittel et al. (19) for enols **4**, occurs only upon addition of one-electron oxidants, and a similar thermal-induced process has not been reported. Thus, the oxidative cyclization of **4a** and **4c** occurs at room temperature but needs a one electron oxidant (e.g., $(4\text{-}BrC_6H_4)_3N^{+\cdot}SbCl_6$) as initiator whereas enols **6a**–**c** undergo a similar process without additional oxidant at a higher temperature for **6a** and **6b** and at room temperature for **6c**. These differences may indicate different stabilities of the radical cations or they may only reflect different relative rates for the [1,2] alkyl shift vs. loss of the alkyl cations.

Experimental section

General methods

Melting points were measured on a Thomas–Hoover apparatus and are uncorrected. FT infrared spectra were measured with a Nicolet Impact 400 spectrometer, and NMR spectra were recorded on Bruker WP 200 SY, Bruker WH 300, and AMX 400 pulsed FT spectrometers operating at 200.13, 300.13, and 400.13 MHz for ^1H and 50.32, 75.48, and 100.62 MHz for ^{13}C, respectively. Low-resolution mass spectra were recorded on a MAT-311 mass spectrometer, and some electron impact (EI) and chemical ionization (CI) mass spectra were recorded on a Finnigan Mat 4600 apparatus. High-resolution mass spectral analyses (HRMS) were conducted at the Mass Spectrometry Center at the Technion, Haifa, on a Finnigan Mat 711 apparatus. Microanalysis was performed at the Hebrew University.

Solvents and materials

Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl, ether from $LiAlH_4$, and benzene from P_2O_5 immediately before use. All purchased reagents were the best commercial samples and were used without purification. Polydeuteriated solvents for NMR spectroscopy (Aldrich), were dried over 4 or 3Å molecular sieves. Solvents used for chromatography were used without purification.

Equilibration studies

Solutions of the enol (10 mg) in spectroscopic hexane (Merck, 5 mL) and TFA (0.025 mL) were sealed in vacuo in pressure ampoules. The ampoules were wrapped in aluminum foil and kept at 77.5 ± 0.1°C for different time spans after which the samples were withdrawn, the solvent was evaporated at room temperature (to avoid oxidation–cyclization), and the ^1H NMR spectra in $CDCl_3$ were recorded. Samples already measured were not reused for further equilibration experiments in order to avoid interference of the formed benzofurans with the equilibration process. Hence, a separate sample was used for each time measurement. Nevertheless, some oxidation products were observed, especially in the case of **6c** but they comprised ≤5% of the equilibrium mixture. The relative ratios of the **5**/**6** species were determined by integration of the Tip-H signals of each

© 1999 NRC Canada

of the keto–enol pairs for **6b** and **6c** and of the vinylic CH and aldehyde CH doublets for **6a**. The integration values, based on these signals, were corroborated by comparing them with integration ratios of additional well-separated signals (e.g., *i*-Pr Me doublets at 0.1–0.3 ppm). To obtain reliable integration, complete relaxation of the various protons was ensured.

2,2-Bis(2,4,6-triisopropylphenyl)ethanol (8)

To a solution of ditipylmethyl methyl ether (860 mg, 1.9 mmol) in dry ether (100 mL) in a three-necked round-bottomed flask fitted with a reflux condenser, an argon inlet, and a closed gas bubbler, about 1.5 g of 4:1 potassium–sodium alloy were added, and the resulting suspension was sonicated in a dry argon atmosphere. After 6 h, formaldehyde vapours were allowed through the deep red solution until a total decolouration was achieved. Isopropanol (50 mL) was added to neutralize the unreacted alloy, and the solution was acidified to pH 2 with 10% HCl. Additional ether (100 mL) was added, the phases were separated, and the organic phase was washed with water (50 mL), dried ($MgSO_4$), and the solvent was evaporated in vacuo. The crude mixture was chromatographed on silica gel using a petroleum ether – ether gradient as eluent. The first fraction was ditipylmethane (180 mg, 22%), mp 73°C (lit. 69.5–70°C) (20). It was followed by 2,2-bis(2,4,6-triisopropylphenyl)ethanol **8** (620 mg, 72%), mp 121–123°C, after recrystallization from hexane.

^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.96 (12H, d, J = 6.7 Hz, *o*-*i*-Pr-Me), 1.03 (12H, d, J = 6.7 Hz, *o*-*i*-Pr-Me), 1.20 (12H, d, J = 6.9 Hz, *p*-*i*-Pr-Me), 2.82 (2H, m, J = 6.9 Hz, *p*-*i*-Pr-CH), 3.33 (4H, m, J = 6.7 Hz, *o*-*i*-Pr-CH), 3.55 (1H, d, J = 5.6 Hz, OH), 4.33 (2H, d, J = 5.6 Hz, CH_2), 5.09 (1H, t, J = 5.7 Hz, Tip_2CH), 6.95 (4H, s, Tip-H). ^{13}C NMR (100.64 MHz, $CDCl_3$) δ: 23.94, 23.97 (2 *p*-*i*-Pr-Me), 24.53, 24.66 (2 *o*-*i*-Pr-Me), 29.08(*o*-*i*-Pr-CH), 33.81 (*p*-*i*-Pr-CH), 46.41 (Tip_2CH), 65.50 (CH_2), 122.60 (*m*-Tip-C), 134.33 (*ipso*-Tip-C), 146.70 (*p*-Tip-C), 147.83 (*o*-Tip-C). FTIR: ν_{max} (Nujol): 3277 (br, OH), 1610 (m, C=C) cm^{-1}. MS (EI) *m*/*z* (relative abundance, assignment): 450 (7%, M), 419 (36%, Tip_2CH), 377 (6%, Tip_2CH – $MeCH{=}CH_2$), 335 (66%, Tip_2CH – $2MeCH{=}CH_2$), 293 (B, Tip_2CH – $3MeCH{=}CH_2$), 251 (67%, Tip_2CH – $4MeCH{=}CH_2$), 246 (11%, $TipCH_2CHO$), 231 (18%, TipCO), 215 (21%, TipC), 209 (21%, Tip_2CH – $5MeCH{=}CH_2$). 2,2-Bis(2,4,6-triisopropylphenyl)ethanal

To a solution of 2,2-bis(2,4,6-triisopropylphenyl)ethanol (**8**) (430 mg, 0.95 mmol) in dry CH_2Cl_2 (20 mL) was added pyridinium dichromate (PDC) (537 mg, 1.43 mmol). The light-protected mixture was stirred in an argon atmosphere at room temperature for 42 h, the salts were filtered through a $MgSO_4$ coated scintered glass filter, and the filtrate was centrifuged at 1200 rpm for 3 min. The supernatant liquid was decanted, and the solvent was evaporated. The ^{1}H NMR of the crude product displayed a spectrum of a 5:5:1 mixture of **8**, aldehyde **5a**, and 2,2-ditipylethenol **6a**. The mixture was chromatographed on a slurry-packed silica column and eluted with a petroleum ether (60–80°C) – ether gradient. Aldehyde **5a** could not be isolated, since it tautomerizes completely to **6a** during the chromatographic separation.

1,1-Bis(2,4,6-triisopropylphenyl)acetone (5b)

1,1-Bis(2,4,6-triisopropylphenyl)-1-propen-2-ol (**6b**) (20 mg, 0.04 mmol) was dissolved in hexane (5 mL), and trifluoroacetic acid (TFA) (1 mL, 20%) was added. The mixture was allowed to stand at room temperature for 24 h, and TFA (1 mL) was again added. After standing at room temperature for 24 additional hours, the solvent was evaporated to dryness, and the mixture was chromatographed on a small slurry-packed silica gel column using a petroleum ether – ether gradient as eluent. Benzofuran **7b** (7 mg, 41%) and ketone **5b** (5 mg, 25%) were isolated and characterized without further purification.

5b: ^{1}H NMR (400 MHz, $CDCl_3$, 240 K) δ: 0.88 (12H, d, J = 6.5 Hz, *o*-*i*-Pr-Me), 1.02 (12H, d, J = 6.5 Hz, *o*-*i*-Pr-Me), 1.20 (12H, d, J = 6.8 Hz, *p*-*i*-Pr-Me), 2.25, 2.42 (2 × 1.5 H, 2 s, 1 Me), 2.75, 2.82 (6H, 2 overlapping m, J = 6.8 Hz, *o*,*p*-*i*-Pr-CH), 5.51, 5.53 (2 × 0.5 H, 2 s, Tip_2CH), 6.87 (4H, s, Tip-H). ^{13}C NMR (100.64 MHz, $CDCl_3$, 273 K) δ: 24.48 (*p*-*i*-Pr-Me), 24.56 (*o*-*i*-Pr-Me), 24.80 (*o*-*i*-Pr-Me), 30.54 (*p*-*i*-Pr-CH), 31.36, 32.87 (2 halves of 1 Me), 34.33 (*o*-*i*-Pr-CH), 57.60, 58.33 (2 halves of 1 Tip_2CH), 65.50 (CH_2), 122.81, 123.02 (*m*-Tip-C), 123.29 (*ipso*-Tip-C), 132.92 (*p*-Tip-C), 147.74, 147.95 (*o*-Tip-C), 210.99, 212.06 (2 halves of 1 C=O). FTIR: ν_{max} (Nujol): 1697 (s, C=O), 1610 (m, C=C) cm^{-1}. 1,1-Bis(2,4,6-triisopropylphenyl)-3,3-dimethyl-2-butanone (5c)

In a pressure ampoule, enol **6c** (10 mg, 0.02 mmol) was dissolved in hexane (5 mL), and TFA (0.025 mL) was added. The ampoule was vacuum-sealed and kept at 77.5°C for 6 days after which the solvent was evaporated. The ^{1}H NMR of the crude product displayed a spectrum of almost pure **5c** with some (<5%) benzofuran **7c**. The mixture was chromatographed on a small slurry-packed silica gel column using a petroleum ether – ether gradient as eluent. **5c** was isolated and characterized by ^{1}H and ^{13}C NMR.

Intermolecular proton transfer in catalysis by carbonic anhydrase V

J. Nicole Earnhardt, Chingkuang Tu, and David N. Silverman

Abstract: The dehydration of bicarbonate catalyzed by carbonic anhydrase is accompanied by the transfer of a proton from solution to the zinc-bound hydroxide. We have investigated the properties of proton transfer from donors in solution, mostly derivatives of imidazole and pyridine, to a truncated mutant of carbonic anhydrase V with replacements that render the active site cavity less sterically constrained, Tyr 64 → Ala and Phe 65 → Ala. Catalysis was measured by determining the rate of exchange of ^{18}O between the CO_2–HCO_3^- system and water, and rate constants for proton transfer were estimated as the rate-limiting step in the release of $H_2{}^{18}O$ from the enzyme to solution. Each proton donor enhanced catalytic activity in a saturable manner. The resulting rate constants for proton transfer when compared with the values of pK_a of the donor and acceptor gave a Brønsted plot of high curvature. These data could also be described by Marcus theory which showed an intrinsic barrier for intermolecular proton transfer near 0.8 kcal/mol and a work term or thermodynamic contribution to the free energy of reaction near 10 kcal/mol. This low intrinsic kinetic barrier for proton transfer is very similar to nonenzymic bimolecular proton transfer between nitrogen and oxygen acids and bases in solution. However, the significant thermodynamic contribution suggests appreciable involvement of solvent and active-site organization prior to proton transfer. These Marcus parameters are very similar to those describing intramolecular proton transfer from His 64 in carbonic anhydrase, suggesting similarities in the intra- and intermolecular proton transfer processes.

Key words: carbonic anhydrase, proton transfer, Marcus theory, carbon dioxide.

Résumé : La déshydratation du bicarbonate catalysée par l'anhydrase carbonique est accompagnée par le transfert d'un proton de la solution à l'hydroxyde lié au zinc. Nous avons étudié les propriétés du transfert de protons de donneurs en solution, principalement de dérivés de l'imidazole et de la pyridine, vers un mutant tronqué de l'anhydrase carbonique V avec des remplacements qui rendent la cavité du site actif stériquement moins encombrée, Tyr 64 → Ala et Phe 65 → Ala. On a mesuré la catalyse en déterminant la vitesse d'échange du ^{18}O entre le système CO_2–HCO_3^- et l'eau et on a évalué les constantes de vitesse pour le transfert de proton en faisant l'hypothèse qu'il s'agit de l'étape cinétiquement limitante dans le transfert du $H_2{}^{18}O$ de l'enzyme à la solution. Chaque donneur de proton augmente l'activité catalytique d'une façon saturable. Quand on compare les constantes de vitesse pour le transfert de proton avec les valeurs de pK_a du donneur et de l'accepteur, on obtient une courbe de Brønsted qui comporte une grande courbure. Ces données peuvent aussi être décrites par la théorie de Marcus qui met en évidence une barrière intrinsèque pour le transfert intermoléculaire de proton près de 0,8 kcal/mol et un terme de travail ou une contribution thermodynamique à l'énergie libre de la réaction près de 10 kcal/mol. Cette faible barrière cinétique intrinsèque pour le transfert de proton est très semblable au transfert de proton bimoléculaire non enzymatique entre l'azote et l'oxygène d'acides et de bases en solution. Toutefois, la contribution thermodynamique significative suggère une implication appréciable du solvant et une organisation du site actif avant le transfert de proton. Ces paramètres de Marcus sont très semblables à ceux qui décrivent le transfert intramoléculaire de proton à partir du His 64 de l'anhydrase carbonique; ceci suggère l'existence de similarités entre les processus de transfert de proton intra- et intermoléculaires.

Mots clés : anhydrase carbonique, transfert de proton, théorie de Marcus, bioxyde de carbone.

[Traduit par la Rédaction]

Small buffers in solution such as imidazole and derivatives can act as proton donors and acceptors to enhance the maximal rate of catalysis by carbonic anhydrase (CA) (1–3). Such enhancement is also observed in mutants of isozyme II in which the predominant intramolecular proton shuttle residue His 64 is replaced with Ala (2). The rate enhancement occurs in the second stage of catalysis shown in eq. [2] for the dehydration direction. A series of proton transfer steps

Received November 18, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

reestablishes the zinc-bound water form of the enzyme following the conversion of HCO_3^- into CO_2, eq. [1]. Here, BH represents buffer in solution or a proton donor that is part of the enzyme itself.

$$[1] \quad HCO_3^- + E\text{-}ZnH_2O \rightleftarrows CO_2 + E\text{-}ZnOH^- + H_2O$$

$$[2] \quad E\text{-}ZnOH^- + BH \rightleftarrows E\text{-}ZnH_2O + B^-$$

These buffer enhancements have been observed in steady-state experiments and in ^{18}O exchange at chemical equilibrium and are saturable and consistent with proton transfer to the zinc-bound hydroxide (3–5). The maximal rate constants of catalysis by variants of CA lacking His 64 but enhanced by proton transfer from these buffers often are similar to their counterparts containing His 64. The introduction of proton shuttles through site-directed mutagenesis or buffers in solution both are capable of achieving proton transfer rates nearly as rapid as in the most efficient carbonic anhydrase II.

In this study, a series of structurally homologous imidazole, pyridine, and morpholine buffers were used as proton donors in catalysis by a truncated mutant of CA V lacking a single predominant proton shuttle. The buffers met several criteria: a small size, a heterocyclic ring with nitrogen atoms, and only methyl substitutions on the ring. In using not only more proton donors but also donors of a more extended range of pK_a values, we extend earlier work on proton transfer to CA II (6). For the enzyme, we chose a truncated mutant of the well-studied murine CA V in which the active site was made less sterically constrained by the double replacements Tyr 64 → Ala and Phe 65 → Ala (Y64A/F65A CA V). This also has the advantage that intermolecular proton transfer from external donors can be compared with intramolecular proton transfer in Y64H/F65A CA V containing the proton shuttle His 64 (7).

Rates of catalysis were measured by ^{18}O exchange at chemical equilibrium, offering the advantage that measurements can be made in the absence of buffer or in the presence of large amounts of buffer. Such measurements are difficult using steady-state methods that depend on changes in absorbance of a pH indicator. The exchange of ^{18}O between CO_2 and water was measured by mass spectrometry to determine rate-limiting proton transfer from these buffers to the zinc-bound hydroxide in the dehydration direction of catalysis.

Rate constants for proton transfer are presented in a free-energy plot, similar to previous studies of intramolecular proton transfer in mutants of human CA III containing a histidine as a proton shuttle (8). A curvature was found in this free-energy plot that is characteristic of a fast and efficient proton transfer. Application of Marcus rate theory shows that this proton transfer has the small intrinsic energy barrier (near 0.8 kcal/mol), which is also characteristic of nonenzymic rapid proton transfer between nitrogen and oxygen acids and bases in solution. The Marcus parameters yield a thermodynamic component of the free energy of reaction (near 10 kcal/mol), indicating that there is a significant involvement of energy requiring processes such as solvent reorganization or enzyme conformational change, similar to intramolecular counterparts in catalysis by carbonic anhydrase.

Methods

Enzymes

Bacterial expression vectors optimized for efficient site-directed mutagenesis and protein synthesis as described by Tanhauser et al. (9) were used to prepare murine carbonic anhydrase V and mutants. Mutant forms of murine CA V were created using a mutating oligonucleotide (10) in the pET31 expression vector system. All mutations were confirmed by DNA sequencing of the expression vector used to produce the mutant protein. All of the expressed enzymes in this work were truncated forms lacking the first 51 amino-terminal residues. In a sequence numbering scheme consistent with CA II, the expressed CA V variants began at residue 22, Ser. This truncated form of murine CA V (denoted mCA Vc by Heck et al. (11)) has been shown to have identical catalytic properties to CA V expressed from both a full-length coding sequence and a 30 residue truncation of murine CA V (11).

Mutants of carbonic anhydrases V were purified by affinity chromatography on a gel containing *p*-aminomethylbenzenesulfonmamide coupled to agarose beads as described by Heck et al. (11). The resulting enzymes were greater than 95% pure, determined by polyacrylamide gel electrophoresis. Concentrations of wild-type murine CA V and mutants were determined from the molar absorptivity of 4.3×10^4 M^{-1} cm^{-1} at 280 nm (11). The concentration of enzyme was also determined by titration with the inhibitor ethoxzolamide using a Henderson plot (12).

Oxygen-18 exchange

Mass spectrometry was used to measure the rate of catalyzed and uncatalyzed exchange of ^{18}O between CO_2 and water.

$$[3] \quad HCOO^{18}O^- + EZnH_2O \rightleftarrows EZn^{18}OH^- + CO_2 + H_2O$$

$$[4] \quad BH + EZn^{18}OH^- \overset{k_B}{\rightleftarrows} B^- + EZn^{18}OH_2 \overset{H_2O}{\rightleftarrows} B^- + EZnH_2O + H_2{}^{18}O$$

This method is based on experiments of Mills and Urey (13) and is described in its application to carbonic anhydrase by Silverman (14). The kinetic equations for the redistribution of ^{18}O from the CO_2–HCO_3^- system to water were solved to obtain two rates in the ^{18}O exchange catalyzed by carbonic anhydrase (15, 16). The first is R_1, the rate of exchange of HCO_3^- and CO_2, as shown in eq. [3]. The substrate dependence of R_1 is given by

$$[5] \quad R_1/[E] = k_{cat}^{ex}[S]/(K_{eff}^{S} + [S])$$

in which k_{cat}^{ex} is a rate constant for maximal interconversion of CO_2 and HCO_3^-, K_{eff}^{S} is an apparent substrate binding constant, and [S] is the concentration of substrate, CO_2 or HCO_3^- or both (17). In theory and in practice, $k_{cat}^{ex}/K_{eff}^{CO_2}$ is equal to k_{cat}/K_m for hydration obtained by steady-state methods (17). The second rate is R_{H_2O}, the rate of release from the active site of water bearing substrate oxygen, as shown in eq. [4] (14). In this mechanism, a proton converts

[a] pK_a(donor) is equal to –log K_B in eq. [7]. pK_a values were determined from pH titration of 10 mM solutions of buffers with the ionic strength maintained near 0.2 M with the addition of Na_2SO_4. Standard errors in pK_a were less than 1%.

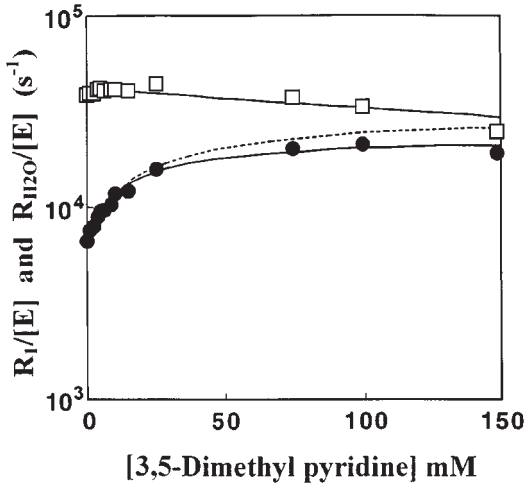
[b] pK_a(zinc-bound water) – pK_a(donor), the pK_a(zinc-bound water) was 7.1 ± 0.2 in Y64A/F65A CA V in the absence of buffer.

[c] k_B^{obs} and K_{eff}^B were determined from the dependence of R_{H_2O}/[E] as a function of the concentration of protonated buffer in catalysis by Y64A/F65A CA V at pH values equal to pK_a of buffer and under the experimental conditions described in the legend of Fig. 1. Where applicable the data for R_{H_2O}/[E] were corrected for the apparent inhibition manifested in R_1/[E]. Values of k_B^{obs} and pK_a for the donor and acceptor were then applied to eq. [7] to determine the k_B values listed for each buffer.

[d] Experimental conditions are described in the legend to Fig. 1. For this buffer, the data are means and standard errors of four measurements of R_{H_2O}/[E] using a saturating concentration of buffer. The value of k_B was determined from eq. [7].

[e] Data was obtained from the difference in R_{H_2O}/[E] determined from a pH profile of CA V Y64H/F65A (C.K. Tu, unpublished data) and Y64A/F65A CA V, the experimental conditions are described in the legend of Fig. 2.

Fig. 1. The dependence of R_{H_2O}/[E] (●) and R_1/[E] (□) on concentration of 3,5-dimethyl pyridine at pH 6.3 and 25°C. The total concentration of all species of CO_2 was 25 mM, and the total ionic strength of solution was maintained at a minimum of 0.2 M by addition of Na_2SO_4. Values of R_{H_2O}/[E] were fit to eq. [6], yielding a value for k_B^{obs} of (1.7 ± 0.1) × 10^4 s^{-1} represented by the solid line. The broken line is a fit to the same equation for R_{H_2O}/[E] when corrected for the apparent inhibition in R_1/[E].



zinc-bound hydroxide into zinc-bound water which then allows rapid exchange with solvent water. The steps measured by R_{H_2O} are separate and distinct from those of the interconversion of CO_2 and HCO_3^- in eq. [3].

Measurements of the isotopic content of CO_2 were made using an Extrel EXM-200 mass spectrometer with a membrane inlet probe (14). Solutions contained 25 mM total substrate ([CO_2] + [HCO_3^-]). Total ionic strength of solution was maintained at a minimum of 0.2 M with Na_2SO_4, and the temperature was 25°C unless otherwise noted. For determination of solvent hydrogen isotope effects, all pH measurements are presented as uncorrected pH meter readings. This procedure causes the approximate cancellation of the effects of D_2O on both the pH meter and the ionization constant of titratable groups. Solvent hydrogen isotope effects for catalysis by Y64A/F65A CA V were determined for several of the buffers of Table 1 by measuring the pH profiles for R_{H_2O}/[E] in 99.8% D_2O.

Results

Saturable enhancement of catalysis by buffers

We have determined the effect of imidazole, pyridine, and morpholine, and some of their methylated derivatives as proton donors to Y64A/F65A CA V in catalysis of ^{18}O exchange. These proton donors enhance R_{H_2O}/[E] in a saturable manner with relatively little effect on R_1/[E], the rate of interconversion of CO_2 and HCO_3^-. These effects are demonstrated in Fig. 1 for the activation of R_{H_2O}/[E] by 3,5-dimethyl pyridine. Note that there is a very slight inhibition of the catalysis of R_1/[E] caused by this addition. Similar results were reported for the saturable activation of R_{H_2O}/[E] by imidazole also catalyzed by this mutant (18). The data for Y64A/F65A CA V enhanced by 3,5-dimethyl pyridine and each buffer listed in Table 1 can be described by eq. [6], which assumes proton transfer from buffers, designated BH, to the zinc-bound hydroxide (3).

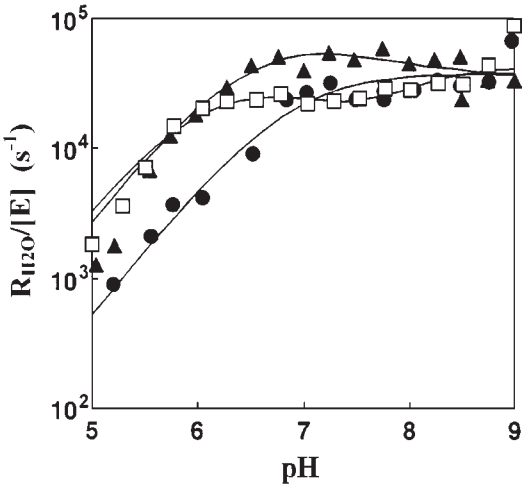
Fig. 2. Variation with pH of $R_{H_2O}/[E]$, the proton-transfer dependent rate constant for the release from the enzyme of ^{18}O-labeled water, catalyzed by Y64A/F65A CA V in the (●) absence of buffer, and in the presence of (□) 100 mM 3,5-dimethyl pyridine, and (▲) 100 mM imidazole at 25°C. For Y64A/F65A in the absence of buffer, the solid line represents a nonlinear least-squares fit of eq. [7] to the data with the pK_a of the donor >9 and acceptor equal to 6.9 ± 0.3 and the rate constant for proton transfer, $k_B = (3.7 \pm 0.4) \times 10^{-4}$ s^{-1}. The total ionic strength of solution was maintained at 0.2 M by addition of Na_2SO_4; the total concentration of all species of CO_2 was 25 mM; at 25°C.



[6] $$R_{H_2O}/[E] = k_B^{obs}[BH]/(K_{eff}^{B} + [BH]) + R_{H_2O}^{0}$$

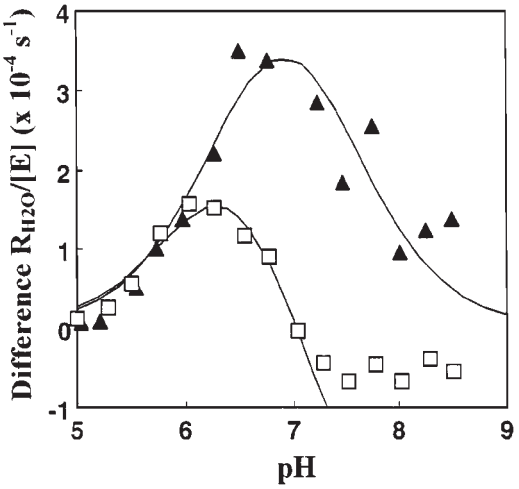
Here, k_B^{obs} is the observed rate constant for the exchange of ^{18}O to water that is enhanced by the buffers as proton donors, and K_{eff}^{B} is an apparent binding constant of the buffer to the enzyme. [E] and [BH] are the concentrations of total enzyme and total buffer. $R_{H_2O}^{0}$ is the rate of release of ^{18}O into solvent water in the absence of buffer and represents the contribution to proton transfer from the enzyme and other sources such as solvent water. Equation [6] was fit to the experimental values of $R_{H_2O}/[E]$ using least-squares methods to determine k_B^{obs} and K_{eff}^{B}. Listed in Table 1 are the values K_{eff}^{B} for each buffer.

pH dependence of buffer enhancement

The pH dependence of $R_{H_2O}/[E]$ catalyzed by Y64A/F65A CA V was determined in the absence and presence of saturating concentrations of two buffers, 3,5-dimethyl pyridine and imidazole (Fig. 2). Although it was not determined that these buffers were saturating at all pH values of Fig. 2, each of the homologous buffers of Table 1 was tested over a range of pH from 5.4 to 8.6. In these experiments, concentrations of each buffer were sufficient to saturate even the buffer of weakest binding. A difference plot of $R_{H_2O}/[E]$ for the data in Fig. 2 is shown in Fig. 3. This analysis is similar to previous pH profiles of $R_{H_2O}/[E]$ catalyzed by human CA III and mutants of human CA III in the presence of large concentrations of small buffers (3, 5, 19).

The maximal, pH-independent rate constant k_B for proton transfer from the donor group to the zinc-bound hydroxide and the corresponding pK_a values of the donor and acceptor

Fig. 3. The difference in $R_{H_2O}/[E]$, the proton-transfer dependent rate constant for the release from the enzyme of ^{18}O-labeled water, between Y64A/F65A CA V in the absence and presence of (□) 100 mM 3,5-dimethyl pyridine and (▲) 100 mM imidazole at 25°C. Experimental conditions are described in the legend to Fig. 2. The solid lines are nonlinear least-squares fits of eq. [7]. For 3,5-dimethyl pyridine, the donor pK_a = 6.2 ± 0.1, acceptor pK_a = 6.9 ± 0.1, and $k_B = (2.5 \pm 0.8) \times 10^5$ s^{-1}. For imidazole, the solid lines describe the donor pK_a = 6.4 ± 0.1, acceptor pK_a = 7.5 ± 0.1, and $k_B = (7.2 \pm 1.6) \times 10^5$ s^{-1}. The fit to the data points for the difference between Y64A/F65A in the absence and presence of 100 mM 3,5-dimethyl pyridine at pH >7.0 was not considered.



were determined from the fit of the data in Figs. 2 and 3 to eq. [7]

[7] $$R_{H_2O}/[E] = k_B/\{(1 + K_B/[H^+])(1 + [H^+]/K_E)\}$$

in which $R_{H_2O}/[E]$ can be interpreted in terms of the rate constant from a predominant donor group to the zinc-bound hydroxide (8). Here, K_B is the ionization constant for the donor group, and K_E is the ionization constant of the zinc-bound water molecule. The values of k_B and pK_a for the donor and acceptors determined for the difference between Y64A/F65A in the absence of buffer and Y64A/F65A in the presence of saturating amounts of buffer are given in the legend of Fig. 3 and are described in more detail in the following sections. In the absence of buffer, $R_{H_2O}/[E]$ determined for Y64A/F65A CA V has a maximum near 4×10^4 s^{-1} at high pH (Fig. 2). This can be interpreted as the contribution to k_B from proton shuttles of high pK_a on the enzyme (18).

The maximum near pH 6.5 in the pH profile for 100 mM 3,5-dimethyl pyridine (Fig. 2) is due to the capacity of 3,5-dimethyl pyridinium to act a proton donor. This is supported by the difference between the pH profile for $R_{H_2O}/[E]$ for Y64A/F65A CA V in the presence and absence of 3,5-dimethyl pyridine shown in Fig. 3. This difference plot shows the bell-shaped pH dependence consistent with a single proton shuttle and corresponding to a proton transfer capacity ($R_{H_2O}/[E]$) of $(2.5 \pm 0.8) \times 10^5$ s^{-1} in the presence of saturating 3,5-dimethyl pyridine. Similar results were obtained upon addition of imidazole to Y64A/F65A (Figs. 2 and 3).

pK_a of zinc-bound water

The pH dependence of k_{cat}/K_m for the hydration of CO_2 is dependent on the ionization state of the zinc-bound water and therefore yields its pK_a (1, 20). The pK_a 7.1 ± 0.2 for the zinc-bound water in the double mutant Y64A/F65A CA V was determined from the pH dependence of k_{cat}/K_m obtained from ^{18}O-exchange methods. This value of pK_a for the zinc-bound water agrees within experimental error with the pK_a 6.9 ± 0.3 determined from the pH profiles of R_{H_2O}/[E] (Fig. 2). As a control, these pK_a values were compared to those determined in the experiment shown in Fig. 3 in which saturating amounts of two buffers, 3,5-dimethyl pyridine and imidazole, were added to Y64A/F65A CA V. In each case, the pK_a of the zinc-bound water determined from R_{H_2O}/[E] was not greatly changed from that of the mutant Y64A/F65A CA V determined in the absence of buffer (Fig. 2). This finding supports the assumptions used in Table 1 that the pK_a of the zinc-bound water remains relatively unchanged upon addition of buffer to the enzyme.

pK_a of buffers

The pK_a values of the buffers listed in Table 1 were determined by pH titration of each buffer in solution (see legend of Table 1). The pH profile of R_{H_2O} catalyzed by Y64A/F65A CA V was also carefully determined in the presence of saturating amounts of two buffers, 3,5-dimethyl pyridine and imidazole (Figs. 2, 3). The value of the pK_a for 3,5-dimethyl pyridine measured from R_{H_2O} was nearly identical to that determined from titration of the buffer in solution, (Table 1, Fig. 3). However, the buffer imidazole had its pK_a decreased by 0.8 pH units in measurements of R_{H_2O}/[E]; but as will be described in the coming sections, imidazole behaves differently compared with the other buffers tested.

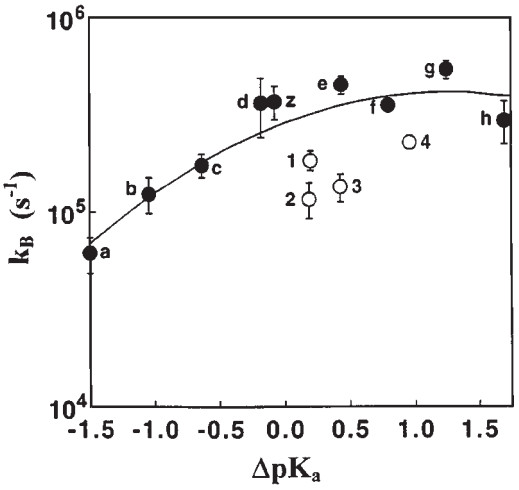
Solvent hydrogen isotope effects

The solvent hydrogen isotope effects (SHIE) were measured for catalysis by Y64A/F65A CA V in the presence of three buffers with values of pK_a near the pK_a of the zinc-bound water. At concentrations of buffer that saturated R_{H_2O}, the SHIE on k_B were 3.4 ± 0.1 for 3,5-dimethyl pyridine; 2.0 ± 0.4 for 3,4-dimethyl pyridine; and 1.8 ± 0.2 for 1-methyl imidazole. Values for solvent hydrogen isotope effects were determined to be near unity on k_{cat}/K_m for the steps of the interconversion of CO_2 and HCO_3^-, a stage separate and distinct from the proton transfer steps in catalysis.

Discussion

The enhancement of catalysis by carbonic anhydrase caused by introduction of proton donors in solution has been well documented (1–3, 6) In this study, we have extended this previous work to a group of homologous buffers to investigate rate–equilibria relationships in intermolecular proton transfer to the active site of carbonic anhydrase. Our goal is to understand this proton transfer process at the level described for nonenzymic bimolecular proton transfers as described by Kresge (21). This ultimately involves application of Marcus theory to proton transfer in an enzyme's active site (22).

Fig. 4. Dependence of the logarithm of k_B (s^{-1}) on ΔpK_a ($pK_{a(ZnH_2O)} - pK_{a\ (donor)}$). Values of k_B are listed in Table 1, and the experimental conditions are described in the legend of Table 1. The value of pK_a for each buffer and the zinc-bound water are determined as described in Table 1. The solid line is a nonlinear least-squares fit of eq. [9] to the Marcus equation for points *a* through *h*. This fit yielded values of $\Delta G^{\ddagger}_0$ of 0.8 ± 0.5 kcal/mol, w^r of 10.0 ± 0.2 kcal/mol, and w^p of 8.2 ± 1.0 kcal/mol.



Enhancement of catalysis

As depicted in eqs.[3] and [4], R_{H_2O}/[E] measures a proton transfer dependent step of catalysis that is separate and distinct from the interconversion of CO_2 and HCO_3^-. The addition of each buffer listed in Table 1 to Y64A/F65A CA V increased R_{H_2O}/[E] in a saturable manner (Fig. 1). This is consistent with the role of buffer as a second substrate and the formation of an enzyme–substrate complex involving buffer. Several arguments suggest that the rate constant for proton transfer to the zinc-bound hydroxide, k_B, is measuring the rate-determining step of catalysis. First, previous work from ^{18}O-exchange and steady-state experiments, pH profiles, and solvent hydrogen isotope effects has demonstrated that the high values of k_B and k_{cat} found for CA V represent the rate-determining step in catalysis (7, 11). Second, these measures of maximal rates of catalysis yield solvent hydrogen isotope effects for k_B from 1.8 to 3.4 for three buffers with values of pK_a near that of the zinc-bound water. This is consistent with rate-limiting proton transfer for k_B. Therefore, the activation of R_{H_2O}/[E], as well as k_{cat}, upon increasing concentrations of buffer, is a significant measure of the effect of buffer on proton transfer. The contribution from proton shuttle residues on the enzyme itself has been reported earlier (18).

Brønsted analysis

The buffers studied in Table 1 were found to fall into three classes. The first class consists of buffers *a* through *h* that are methyl-substituted imidazoles, pyridine, and methyl-substituted pyridines at the 3, 4, and 5 positions, and morpholine. The rate constants determined for proton transfer in Y64A/F65A CA V in the presence of the buffers *a* through *h* correlated with the difference in pK_a of the zinc-bound water as acceptor group and the buffer as donor

Table 2. Marcus theory parameters for proton transfer in isozymes of carbonic anhydrase.

System	Proton donor	$\Delta G^{\ddagger}_0$ (kcal/mol)	w^r (kcal/mol)	w^p (kcal/mol)
CA V	Buffers[a]	0.8 ± 0.5	10.0 ± 0.2	8.2 ± 1.0
CA III	His 64[b]	1.4 ± 0.3	10.0 ± 0.2	5.9 ± 1.1
	His 67[c]	1.3 ± 0.3	10.9 ± 0.1	5.9 ± 1.1
	Glu or Asp 64[d]	2.2 ± 0.5	10.8 ± 0.1	4.0 ± 1.6
Nonenzymic	Buffer to buffer[e]	2.0	3.0	

[a]The data were obtained by a least-squares fit of eq. [9] to rate constants for proton transfer for points *a* to *h* given in Fig. 4 and Table 1. For this calculation, $\Delta G^{\ddagger} = -RT \ln (hk_B/kT)$ and $\Delta G^{\circ} = RT \ln [(K_a)_{ZnH_2O}/(K_a)_{donor}]$.

[b]See ref. 8.

[c]See ref. 29.

[d]See ref. 30.

[e]See ref. 25.

(Fig. 4). Such Brønsted relationships are described by eq. [8] (23–25):

$$[8] \qquad \log (k_B) = \beta[pK_a(\text{acceptor}) - pK_a(\text{donor})] + \text{constant}$$

The slope β of a Brønsted plot provides information on the transition-state structure in terms of the degree of charge transfer between reactants and products in the transition state (21). Proton transfer reactions involving carbon acids or bases usually yield slow rates and result in linear Brønsted relationships whereas fast proton transfer reactions between nitrogen and oxygen acids and bases are characterized by an observed variation in slope β over a relatively small range of pK_a values (3–5 pK_a units). This curvature is also observed in Fig. 4 for the buffers *a* through *h*. This observation establishes that the intermolecular proton transfer involving carbonic anhydrase (Fig. 4) shares an intrinsically low kinetic barrier with these nonenzymic proton transfers; that is, this conclusion is independent of the application of Marcus theory to proton transfer in an enzyme's active site that is described below.

The second class of buffers are also methyl-substituted pyridines, however, these pyridines have a methyl substitution at the 2 or 6 position (designated "1" through "4" in Table 1). The rate constants for proton transfer, k_B, from these buffers to the zinc-bound hydroxide showed greater scatter from the Brønsted plot than the previous class of buffers (Fig. 4). An explanation for this observation is that methyl groups at carbons 2 or 6 may sterically hinder access to the nitrogen and its general acid and base properties in substituted pyridines (26), in contrast to the buffers *a* through *h*.

Finally, the buffer imidazole is in a class by itself in that it has a greater rate constant for proton transfer to Y64A/F65A CA V than any buffer listed in Table 1. Its small size, similar pK_a to the conjugate acid of the proton acceptor zinc-bound hydroxide, and lack of steric hindrance in the active site may all be factors in the enhancements of proton transfer observed for Y64A/F65A CA V in the presence of this buffer.

Marcus rate theory

The curvature in Brønsted plots, similar to that found in Fig. 4, can be interpreted quantitatively through Marcus theory which provides an intrinsic energy barrier for proton transfer and work terms that correspond to the energy required to align the reactants into the reaction complex for both forward and reverse directions (25, 27). In analogy with nonenzymic transfers, w^r is the energy required to arrange the acceptor and donor groups and the surrounding water structure in the active site appropriate for the proton transfer in the dehydration direction (8). The work term w^p is the energy required for the same reorganization in the reverse direction of catalysis. $\Delta G^{\ddagger}_0$ is then the intrinsic kinetic barrier with the appropriate active site orientation. The measured overall free energy for the reaction is given by $\Delta G^{\circ} = w^r + \Delta G_R^{\circ} - w^p$, where ΔG_R° is the standard free energy of reaction in the complex with appropriate orientation for proton transfer.

The Marcus rate theory for proton transfer relates the observed overall activation barrier for proton transfer, $\Delta G^{\ddagger}$, to the intrinsic energy barrier $\Delta G^{\ddagger}_0$

$$[9] \qquad \Delta G^{\ddagger} = w^r + \{1 + \Delta G_R^{\circ}/4\Delta G^{\ddagger}_0\}^2 \Delta G^{\ddagger}_0$$

The intrinsic energy barrier $\Delta G^{\ddagger}_0$ is the value of $\Delta G^{\ddagger}$ when ΔG_R°, the standard free energy of reaction with the required active-site orientation, is zero. $\Delta G^{\ddagger}_0$ is then the barrier to reaction when the proton transfer is free of any thermodynamic constraints (25, 27). The slope of the Brønsted plot, β in eq. [8], is identified in terms of the Marcus parameters as $d\Delta G^{\ddagger}/d\Delta G^{\circ}$ and provides the connection between the curvature of the Brønsted plot and the Marcus theory.

A least-squares fit of the Marcus equation to the free-energy plot representing the rate constants for proton transfer from buffers *a* through *h* of Table 1 to the zinc-bound hydroxide of the mutant CA V were found to fit the Marcus equation (Fig. 4). The values for the intrinsic energy barrier and work terms are given in Table 2 and legend to Fig. 4. The intrinsic energy barrier for the proton transfer was found to be low with large work functions in both the forward and reverse directions (Table 2). These values determined for the contribution of external proton donors to catalysis are very similar in magnitude to the Marcus parameters describing intramolecular proton transfer from His 64 and His 67 to the zinc-bound hydroxide in mutants of human CA III (Table 2). This low intrinsic energy barrier for proton transfer is also very similar to nonenzymic proton transfer between nitrogen and oxygen acids and bases in solution (Table 2; 25). However, the large energy barrier present in the work terms of this and previous studies is large compared to work terms of 3 kcal/mol for nonenzymic reactions (24, 25). This has been interpreted as a requirement for water reorganization and possible conformation change in the active site to provide a hydrogen-bonded water pathway for proton transfer between the proton shuttle and the zinc-bound hydroxide (8). Some of

© 1999 NRC Canada

the uncertainties in the Marcus parameters derived from Fig. 4 may be due to the use of the solution values of the pK_a values of the buffers. These were measured more precisely than the pK_a of the buffers bound to the enzyme and determined from the pH profile of R_{H_2O}.

Conclusions

It is significant that proton transfer to carbonic anhydrase from external donors as quantitated by the Marcus theory is similar to proton transfer from His 64 or His 67 in the active site itself. This suggests that the water structure and possibly protein conformation appropriate for proton transfer is about equally well formed to support catalysis by buffers or by His 64, and is probably reflecting the great flexibility of many different water structures of approximately equal energy in the active site. The Marcus theory indicates that the formation of the required water structure and (or) conformational change requires considerable energy (~10 kcal/mol), but when it occurs the proton shuttles in a facile manner, similar to nonenzymic bimolecular proton transfers. The Marcus parameters obtained for His 64 and His 67 required the use of mutants of carbonic anhydrase with replacements at position 198. These replacements of Phe 198 in human CA III altered the pK_a of the zinc-bound water and allowed the construction of a Brønsted plot by varying the pK_a of the proton acceptor in dehydration. All of the data of Fig. 4 were obtained with one enzyme. Therefore, the Marcus parameters that characterize proton transfer in this study are not predominately due to the changes in the structure at the active site of the mutants.

The similarity between intermolecular proton transfer from external donors and proton transfer from His 64 is emphasized by the position of point *z*, representing Y64H/F65A murine CA V, on the same line of Fig. 4 that represents intermolecular transfer. This supports the hypothesis that proton transfer involving His 64 and external donors utilize intervening water structures of similar free energy. Such a water structure is observed in the active site in the crystal structure of CA V (28), but of course this need not be the catalytically relevant water structure. This comment about proton donors does not extend to imidazole which is a more efficient proton donor in catalysis than the other buffers of Table 1. Imidazole also had a rate constant for proton transfer in catalysis greater than that observed for Y64H/F65A CA V which contains the internal proton donor His 64 (Table 1); however, the value of k_B for imidazolium as a proton donor in catalysis by Y64A/F65A CA V is comparable to catalysis in the absence of external buffers by CA II which has His 64 as proton donor (30).

Geometric isotope effects in crystalline sodium hydrogen bis(4-nitrophenoxide) dihydrate

Maurice M. Kreevoy and Victor G. Young, Jr.

Abstract: The crystal structure of sodium hydrogen bis(4-nitrophenoxide) dihydrate, **1**, with deuterium replacing hydrogen in the bridge and the structural water molecules, has been determined crystallographically at 113, 173, and 295 K. The structure of **1** had previously been determined at similar temperatures (Kreevoy et al.). The O,O distances are 1.5–1.7 pm greater in the deuterated compound than in the undeuterated, at all three temperatures, providing another example of an Ubbelohde effect in a Speakman–Hadži compound. The temperature invariance of the Ubbelohde effect at temperatures up to room temperature is evidence against centralization of the hydron within this temperature range. It has previously been suggested (Kreevoy et al.) that simplification of the IR spectrum of **1** with increasing temperature is due to an increase in the rate of the hydron shift between the two basic oxygens. This suggestion is strengthened by the elimination of hydron centralization as an alternative. The O,O distance in **1** also increases with temperature, and the dihedral angle between the mean planes of the two aromatic rings decreases. Similarly, the increase in the O,O distance with isotopic substitution is accompanied by a small decrease in the dihedral angle; another geometric isotope effect. Ubbelohde effects in Speakman–Hadži compounds make the geometric isotope effects found computationally in the critical complexes for hydron, hydrogen atom, or hydride transfer more credible.

Key words: low-barrier hydrogen bond, Speakman–Hadži compound, geometric isotope effect, Ubbelohde effect.

Résumé : Opérant à 113, 173 et 295 K, on a déterminé la structure cristalline du dihydrate du bis(4-nitrophénolate) de sodium et d'hydrogène, **1**, dans lequel du deutérium remplace l'hydrogène dans le pont et dans les molécules structurales. La structure de **1** a été déterminée antérieurement à des températures semblables (Kreevoy et al.). À ces trois températures, les distances O,O sont de 1,5–1,7 pm plus grandes dans le composé deutéré que dans le produit non deutéré; ce résultat fournit un autre exemple d'un effet Ubbelohde dans un composé Speakman–Hadži. L'invariance avec la température de l'effet Ubbelohde à des températures allant jusqu'à la température ambiante prouve qu'il n'y a pas de centralisation de l'hydron dans cette plage de température. Il a été suggéré antérieurement (Kreevoy et al.) que la simplification du spectre IR du composé **1** avec une augmentation de la température est due à une augmentation dans la vitesse de déplacement de l'hydron entre les deux oxygènes basiques. Cette suggestion est corroborée par l'élimination de la centralisation de l'hydron comme alternative. La distance O,O dans **1** augmente aussi avec la température et l'angle dièdre entre les plans moyens des deux noyaux aromatiques diminue. De la même manière, l'augmentation de la distance O,O avec la substitution isotopique est accompagnée par une faible diminution de l'angle dièdre; un autre effet isotopique géométrique. Les effets Ubbelohde dans les composés Speakman–Hadži rendent plus plausibles les effets isotopiques géométriques calculés d'une façon théorique dans les complexes critiques pour les transferts d'hydron, d'atome d'hydrogène ou d'hydrure.

Mots clés : liaison hydrogène avec faible barrière, composé Speakman–Hadži, effet isotopique géométrique, effet Ubbelohde.

[Traduit par la Rédaction]

Introduction

The infrared spectrum of crystalline sodium hydrogen bis(4-nitrophenoxide) dihydrate (**1**) becomes simpler as the temperature is raised from 14 K to room temperature (1). A number of bands, which are separate below about 200 K, merge above 250 K. The changes are reminiscent of the changes with temperature in the NMR spectra of substances in which isomeric structures are interconverting reversibly (2). As the temperature is increased, the isomerization rate increases. When the isomerization frequency exceeds the frequency difference between a pair of related bands, those bands merge, and only their average is observed. The changes in the IR spectrum of **1** were interpreted like similar changes in NMR spectra.

The hydrogen bis(4-nitrophenoxide) ion is a Speakman–Hadži anion (3) with the two 4-nitrophenoxide groups bridged by a very short hydrogen bond. The bridging proton appears to be distributed between two sites (1). The estimated

isomerization rate constant was close to kT/h at temperatures around 225 K (1). The transfer of the bridging proton between the basic oxygen sites provides an intuitively attractive structural interpretation for the isomerization. The transfer exchanges the roles of a 4-nitrophenoxide ion and a 4-nitrophenol. The ^{13}C NMR spectrum shows only one kind of 4-nitrophenoxide carbon, even at 12 K (4). This confirms that the proton transfer frequency is at least 10^4 s^{-1} even at that temperature (1, 4).

However, the interpretation of such observations in IR spectra is much less secure than the interpretation of the corresponding phenomena in NMR spectra. In the absence of chemical changes, the width, position, and splitting of bands in NMR spectra are not expected to change much with temperature. But the increased population of vibrationally excited levels may change these features significantly in an IR spectrum, even in the absence of isomerization (5). In the present case, progressive centralization of the bridging proton with increasing temperature could be responsible for all or part of the effect. Centralization has been suggested as a major reason for similar changes in the IR spectrum of a carboxylic acid – carboxylate complex in a noncrystalline phase (6). Centralization has been discounted in the present case (1) because the results of rotational-echo, double-resonance ^{13}C NMR experiments at room temperature appear incompatible with a centralized proton (4).

In addition, the neutron diffraction pattern of **1** at 105 K is more satisfactorily analyzed if the bridging hydrogen is treated as two half-hydrogens (1). Also, the distance between the basic oxygens increases steadily with temperature, whereas it would be expected to decrease if the hydrogen became centralized (1). Nevertheless, further evidence on this point is desirable.

In the present paper, we add the observation that the distance between the basic oxygens increases when deuterium is substituted for hydrogen in the short hydrogen bond at all temperatures between about 110 K and room temperature. (The deuterium compound is designated **1-d**. It is deuterated in the water molecules as well as in the bridging position.) This sort of secondary geometric isotope effect was first observed by Ubbelohde and Gallager (7). It is expected if the bridging hydron is distributed between two sites in **1** and **1-d** (8). The O,O distance is shortened because this allows better delocalization of the hydron between the two sites, thereby reducing the requirement for zero-point energy to satisfy the uncertainty principle. The bond is shortened more in the hydrogen compound because its lower mass makes its zero-point energy requirement larger. If the hydron were centralized, delocalization would be complete, and very little further shortening would occur.

We also note that the dihedral angle formed by the planes of the two aromatic rings appears to decrease systematically as the O,O distance increases, in response both to temperature changes and isotopic substitution.

It seems likely that the barrier separating the two sites is very low, because delocalization would be negligible for both **1** and **1-d** otherwise. Therefore, **1** and **1-d** resemble critical configurations for hydron transfer (9, 10).[2] The present observations strengthen the argument for geometric isotope effects on the critical configurations for hydrogen (hydron, hydrogen atom, or hydride) transfer (9–11).

Experimental

Material

The compound **1-d** was prepared from **1** by recrystallization from D_2O. This exchanges the bridging hydrogen and also the hydrogens of the waters for deuterium, but does not introduce deuterium into the aromatic groups (3). Past experience (4) indicates that exchange in the bridging position is negligible in the solid state.

Crystallography

The present paper reports results taken from the crystal structure of **1-d** at 113 and 173 K and at room temperature. Comparable data has been previously reported for **1** (1, 3). The cryostat, which permitted us to obtain a crystal structure of **1** at 103 K, would not maintain a constant temperature below 113 K during the present work. Fortunately, none of the quantities of interest appears to be sharply temperature dependent, so we have treated the 103 and 113 K results as comparable, and both as comparable with the neutron diffraction results obtained at 105 K.

Crystals with dimensions between 0.09 and 0.5 mm and volumes between 6×10^{-3} and 2×10^{-2} mm^3 were mounted on glass fibers and used for structure determination. Nitrogen evaporating from liquid nitrogen was used for cooling. Monitoring of standard reflections indicated no need to correct for sample decay or instrumental drift. Direct methods, supplemented by full-matrix least-squares difference Fourier cycles, gave preliminary structures containing all the atoms except the hydrogens (12). In the final refinement, all the hydrogens except the bridging hydrogen and the water hydrogens were placed in ideal locations and treated as riding atoms (12). The water hydrogens were individually refined (12). The bridging hydrogen was treated as two half-hydrogens, one of which was refined, and the other located by symmetry. Hydrogens were assumed to be isotropic, and each was assigned a single, isotropic displacement parameter, because there was insufficient information in the diffraction patterns to assign two displacement parameters to each. The heavier atoms were refined with individual, anisotropic displacement parameters (12).

A Siemens SMART system was used to collect data. An initial set of cell constants was calculated for each from reflections harvested from three sets of 20 frames. Final cell constants were calculated from large sets of strong reflections from the data collections. Random hemispheres of reciprocal space were surveyed to about 7.1 pm, and space groups were determined from systematic absences and intensity statistics (12). Structures were determined using the SHELXTL V5.0 suite of programs (12).

[2] The critical configuration has been defined as the most probable structure for crossing the hardest-to-attain dividing surface that separates reactants from products (9). This definition reserves the term "transition state" for the structure at the highest point (the saddle point) on the minimum energy path from reactants to products.

[a] $R_{X,Y}$ is the distance between atom X and atom Y.

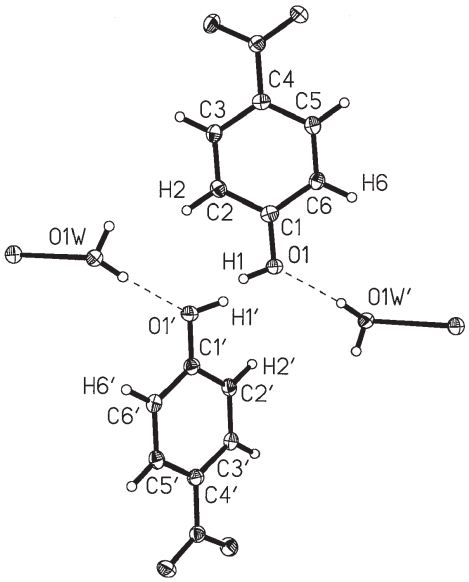
[b] The quantities in parentheses after the numerical values are the standard deviations of the values (1, 3, 12).

[c] All temperatures are uncertain by 2–3 K.

[d] Taken from ref. 1.

[e] The original data for **1** at 295 K was rerefined using the SHELXTL program suite (12) so as to make all the reported parameters and their uncertainties comparable. The rerefinement resulted in only very minor changes.

Fig. 1. An ORTEP structure of **1** based on X-ray diffraction at 103 K (1), showing the identification system for atoms discussed in the text. The primed and unprimed atoms are related by a rotational axis of symmetry. H1 and H1′ are half-hydrogens, which implies that each of the two sites is occupied half of the time. Structures based on X-ray diffraction at other temperatures, or based on diffraction by **1-d** instead of **1**, are indistinguishable by inspection. The structure based on neutron diffraction shows the half-hydrogens closer together, but they remain off of the O,O line (1). Otherwise, the structure based on neutron diffraction is also indistinguishable by inspection from the one shown.



The crystallographic parameters of **1-d** at the three temperatures are similar to those which have previously been reported for **1** (1, 3).

Results

The Ubbelohde effect

Figure 1 shows the structure of **1** and establishes a numbering system to identify the atoms. The distance between two atoms, X and Y, is indicated by $R_{X,Y}$. The dihedral angle formed by the mean least-squares planes (12) of the two aromatic rings is Ø. The structure in Fig. 1 is based on the X-ray diffraction pattern of **1** at 103 K. Its general appearance is not changed either by changing the temperature or by substituting deuterium for the readily exchangeable hydrogens. However, $R_{O1,O1'}$ and Ø show small changes both with temperature and isotopic substitution. These changes are shown in Table 1. For comparison, Table 1 also shows $R_{O1,O1W}$, which seems to show very slight variation with temperature, and only random variation with isotopic substitution, so that the magnitude of the scatter can be judged.

At each temperature, $R_{O1,O1}$(D) is greater than $R_{O1,O1}$(H). The average difference is 1.6 pm. The standard deviation of these distances is 0.2–0.3 pm. The $R_{O1,O1W}$ are sometimes larger for **1**, and sometimes larger for **1-d**. The average difference between them is 0.6 pm. Thus, there is little doubt that the geometric isotope effect (Ubbelohde effect) is real. The effect does not appear to be very temperature sensitive. The uncertainties preclude any further conclusion about systematic variation of the Ubbelohde effect, but the effect does not disappear at temperatures up to room temperature.

Another geometric isotope effect

The average standard deviation of Ø is 0.05°. On going from room temperature to around 110 K, Ø increases by 0.4° in both **1** and **1-d**. At the same time, $R_{O1,O1'}$ decreases by 2.7 pm, for both isotopic variants. The dihedral angle decreases with isotopic substitution at all three temperatures, but the average decrease is only 0.11°. If this were a single, isolated observation, we would not regard it as significant. However, in each case, both for temperature change and for isotopic substitution, Ø decreases when $R_{O1,O1'}$ increases. Because of their consistency, we believe that these changes are real. The changes in response to isotopic substitution are another geometric isotope effect.

Apart from $R_{O1,O1'}$ and Ø, the structures of **1** and **1-d** were not notably different.

Discussion

Origin of the Ubbelohde effect

Ground vibrational states are the minimum energy states that satisfy the uncertainty principle. To meet this requirement, both **1** and **1-d** have expectation values of $R_{O1,O1'}$ smaller than the value at the potential energy minimum, because reducing $R_{O1,O1'}$ permits more delocalization of the hydron. The increased uncertainty in the hydron coordinate value reduces the required uncertainty in momentum, thereby reducing the energy requirement. Because the mass of hydrogen is less than that of deuterium, the effect is larger in **1** than in **1-d**.

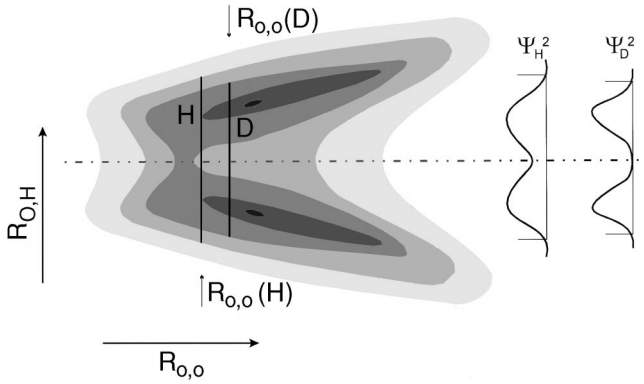
Fig. 2. A two-dimensional cartoon attempting to show the relation of potential energy, plotted perpendicular to the page, as a function of the O,O distance, $R_{O,O}$, and the O,H distance, $R_{O,H}$. The vertical lines show the suggested hydrogenic stretching oscillations at the expectation values of $R_{O,O}$ in **1** and **1-d**. The potential energy minima are the small closed figures to the right of the $R_{O,D}$ line. Even though the same potential surface is used for **1** and **1-d** (following Born–Oppenheimer), the one-dimensional potential functions for hydrogenic stretching are different. The figures off to the right of the potential surface attempt to show the squares of the vibrational wave functions. None of this is based on calculation. It attempts to illustrate the ideas described in the text.



Such changes in structure must not cost more in potential energy than they save in vibrational energy. Ordinarily, they are very small. If the motions of the atoms near the potential energy minimum are governed by steep, approximately harmonic forces, structural changes are expensive, yield little delocalization, and, therefore, little reduction in the required vibrational energy. However, the antisymmetric stretch of the bridging hydron in a Speakman–Hadži compound is governed by a low-barrier double minimum potential function (13). The central barrier can be reduced, so that it ultimately falls below the lowest vibrational eigenvalue, by reducing the bridged O,O distance (8, 13–16).[3] When the lowest vibrational eigenvalue is slightly below the top of the central barrier, a small decrease in the O,O distance can yield a considerable delocalization of the hydron, with a corresponding decrease in the vibrational energy requirement. As noted, these effects are less pronounced in **1-d** than in **1**. These ideas are illustrated by a cartoon in Fig. 2.

Tunneling results in a progressive increase in hydron delocalization as the O,O distance decreases. Without tunneling, the hydron would either be completely delocalized, if the vibrational eigenvalue was above the central barrier, or insignificantly delocalized, if it was below. An Ubbelohde effect would occur if hydrogen could achieve delocalization by shortening the O,O distance, but deuterium could not. But the effect would be rare, since the eigenvalues of substances differing only by isotopic substitution are similar. In fact, the effect always appears to occur in Speakman–Hadži compounds, for a considerable range of O,O distances (14).[4] Thus, the concept of tunneling is supported by these observations on stable substances.

Recent theoretical studies have generally concluded that the lowest allowed eigenvalues of the O,H asymmetric stretch in Speakman–Hadži compounds is above the central barrier (17–19),[5] contrary to our present conclusions, and contrary to the results obtained with the same and related substances in solution (13, 20). We believe that the most important cause for the discrepancy is the use of the harmonic oscillator approximation by theoreticians to evaluate the zero-point energy, with a force constant obtained from the curvature at the potential energy minimum. This procedure considerably overestimates the zero-point energy for a shallow double-minimum potential function (13, 21). The condensed phase results may also be influenced by the permittivity of the condensed media.

The Ubbelohde effect does not imply a breakdown of the Born–Oppenheimer approximation (22).

Implications for IR spectra

The observation of the Ubbelohde effect at all three temperatures is additional, strong evidence that the hydron is not centralized in its vibrational ground state, and does not become centralized at temperatures up to room temperature. This, taken together with the NMR observations (4) and the monotonous increase with temperature of $R_{O1,O1'}$, removes the possibility that the simplification of the IR spectrum of **1** with increasing temperature (1) is mainly due to the centralization of the hydron.

Increasing temperature leads to increases in the population of low-lying excited vibrational states. When a molecule in one of these low-lying excited states is excited in one of its valence vibrations, its excitation frequency may be slightly different from that of a molecule in the vibrational ground state. As a result, valence vibration bands in the mid-IR tend to broaden as temperature increases. Such broadening might lead to the apparent merging of some bands as the temperature increases. This is the only remaining alternative to the kinetic explanation of the observed changes in the IR spectrum of **1** that we are aware of. However, the changes in the spectrum of **1** are more dramatic than those which are usually observed, and they appear to affect only a limited number of bands, while others remain distinct and sharp (1). We therefore conclude that an increase in the rate of prototropic isomerization is the main cause of the merging of the IR bands (1). The rate constants calculated (1) should be valid, though quite inexact.

Thermal and isotopic variation of Ø

The decrease in Ø with increasing temperature is well outside of its standard deviation, and very probably real. It is correlated with the increase in $R_{O1,O1'}$, which probably increases with temperature due to excitation of the O,O stretching vibration (23). It seems intuitively likely that Ø is increased by nonbonded atom repulsions. The impression that the structure incorporates nonbonded atom repulsions is

[3] Additional references on this point can be found in refs. 15 and 16.
[4] Ubbelohde effects appear to have been found wherever they have been sought among Speakman–Hadži compounds. The largest effect we are aware of is 2.7 pm (14).
[5] References 17–19 are merely a selection of recent, relevant papers that came to hand. A systematic search would yield a much longer list.

© 1999 NRC Canada

strengthened by the fact that the two half-hydrogens do not lie on the O,O line in the neutron structure (1). Repulsions between atoms of one ring and those of the other could be relieved either by increasing $R_{O1,O1'}$ or by increasing Ø so the increase in $R_{O1,O1'}$ would allow a decrease in Ø. However, we are not able to identify the specific atoms involved, and we do not dismiss the possibility that these characteristics are intrinsic to the hydrogen bond itself.

Substitution of deuterium in the bridging position also increases $R_{O1,O1}$, but the effect is only about half as big as the effect of increasing the temperature from about 110 K to room temperature. Isotopic substitution also decreases Ø. These effects are similar in size to the standard deviations, but they are consistent, and consistent with the effect of temperature, so we believe they are real. The isotope effect on Ø seems to be a result of the isotope effect on $R_{O1,O1}$, which is, itself, a secondary isotope effect.

The Ubbelohde effect and critical configurations

Within the Born–Oppenheimer approximation (22), the conventional transition states for a hydrogen (hydron, hydrogen atom, or hydride) transfer and the corresponding deuterium transfer are the same (9, 10). However, computational studies indicate that such reactions probably occur most commonly by barrier penetration at donor–acceptor distances slightly larger than those in the corresponding transition states (corner-cutting tunneling) (9, 10, 24).[2] Since this effect is more important when the transfered mass is smaller, there are geometric isotope effects on the structures of the critical configurations.[2]

The criteria by which the critical configuration is found are different from those that are at work to give the structures that are observed in stable Speakman–Hadži anions, but the bases of the effects are the same. The calculated isotope effect on the heavy atom separation in the critical configuration for hydrogen transfer is about 5 pm (10). This is about twice the larger observed Ubbelohde effects (14). The existence of a related effect in stable structures is strong support for a geometric isotope effect in critical configurations.

New chloride anion receptors: trifluoromethyl sulfonylated polyamines

H.S. Lee, X.Q. Yang, J. McBreen, D. Vyprachticky, and Y. Okamoto

Abstract: A new chloride anion receptor, derivatized oligoethylene oxide CF_3SO_2 substituted tetraamine (**3**), was synthesized. This compound exhibited strong Cl^{-1} ion binding properties in nonpolar solvents such as benzene. Neutral red and Nile blue chloride dye molecules do not dissolve in benzene. However, when compound (**3**) was added to a benzene solution containing the solid dye compounds, the color of the solution immediately turned to dark blue, and the intensity of the color proportionally increased with the concentration of (**3**). The phenomena indicated that the Cl^- ions of Neutral red or Nile blue chloride are complexed with (**3**), thereby resulting in an increase in the solubility of the Neutral red or Nile blue cations in benzene. The dissociation of chloride anions from 4,4′,4′′-trimethoxytriphenyl chloromethane in a benzene solution proceeded with addition of compound (**3**) and increased with increasing time at room temperature. In contrast, another tetraamine compound (**4**) which was substituted with a less electron withdrawing group, CH_3SO_2, did not complex with Cl^- anions in a benzene solution.

Key words: Cl^- anion receptor, trifluoromethyl sulfonated tetraamine, ion pair dissociation.

Résumé : On a synthétisé un nouveau récepteur de l'anion chlorure, une trifluorométhylsulfonyltétraamine dérivatisée par de l'oligooxyde d'éthylène (**3**). Dans des solvants non polaires comme le benzène, ce composé donne lieu à une forte fixation de l'ion Cl^{-1}. Les molécules des colorants chlorés, rouge neutre et bleu Nil, ne se dissolvent pas dans le benzène. Toutefois, lorsqu'on ajoute du composé (**3**) à une solution benzénique contenant les colorants solides, la couleur de la solution passe immédiatement au bleu foncé et l'intensité de la couleur augmente d'une façon proportionnelle à la concentration de (**3**). Le phénomène indique que les ions Cl^- du rouge neutre et du bleu Nil sont complexés par (**3**) et qu'il en résulte une augmentation dans la solubilité des cations du rouge neutre et du bleu Nil dans le benzène. Lors de l'addition du composé (**3**) à une solution benzénique de 4,4′,4′-triméthoxytriphénylchlorométhane à la température ambiante, il se produit une dissociation des anions chlorures qui augmente avec le temps. Par ailleurs, une autre tétraamine (**4**) substituée par un groupe moins électroaffinitaire, le CH_3SO_3, ne donne pas de complexes avec les anions Cl^- en solution dans le benzène.

Mots clés : réception de l'anion Cl^-, tétraamine trifluorométhylsulfonée, dissociation en paire d'ions.

[Traduit par la rédaction]

Introduction

Host–guest molecular systems have attracted much attention during the past two decades (1). Although various compounds, which are cation receptors, have been investigated widely, the number of host molecules for anion complexation is very small (2). To accomplish anion binding, most of the reported host molecules have positively charged sites (3), Lewis acid metal centers (4), or hydrogen bond forming moieties (5–8).

Recently, we have synthesized a family of polyamine compounds as anion receptor molecules (9). A strong electron withdrawing CF_3SO_2 group was substituted on the nitrogen atoms of linear and cyclic tetramines (Fig. 1). When the amine hydrogen atoms are substituted by CF_3SO_2 groups, the nitrogen becomes electropositive and expedites the complexation with an anion. Therefore, the CF_3SO_2 substituted polyamine compounds exhibit an anion binding property. The degree of the anion complexation depends on the number of CF_3SO_2 groups substituted, the structure of amine compounds, and the nature of the complexed anions (9).

We have used Near Edge X-ray Absorption Fine Structure (NEXAFS) spectroscopy at the Cl K edge to elucidate the formation of the complexes between the Cl^- ions and the amine compounds; NEXAFS is a useful tool for the study of the coordination symmetry of the Cl^- ions both in solution and in the solid state. Detailed NEXAFS spectroscopy studies showed that the Cl^- ions of LiCl in THF were complexed strongly with the nitrogen atoms of compounds (**1**) and (**2**) of Fig. 1 (9).

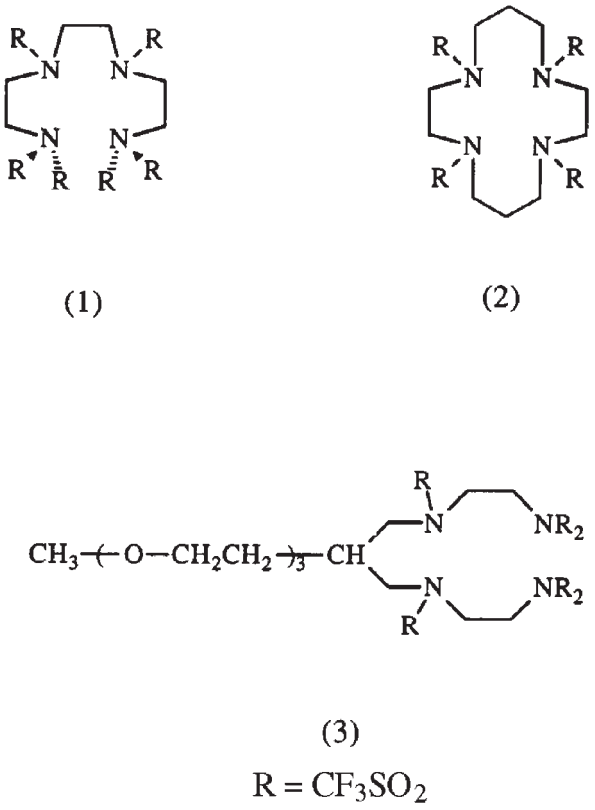

Fig. 3. UV-vis spectra of the reaction products of Nile blue chloride (NB) (1.7×10^{-5} mol), and compounds (**3**) or (**4**) in benzene solutions (10 mL) at room temperature: (*a*) NB (saturated solution); (*b*) NB + 3.4×10^{-5} mol of (**4**); (*c*) NB + 1.7×10^{-5} mol of (**3**); (*d*) NB + 3.4×10^{-5} mol of (**3**). The UV-vis spectra were taken 24 h after mixing.

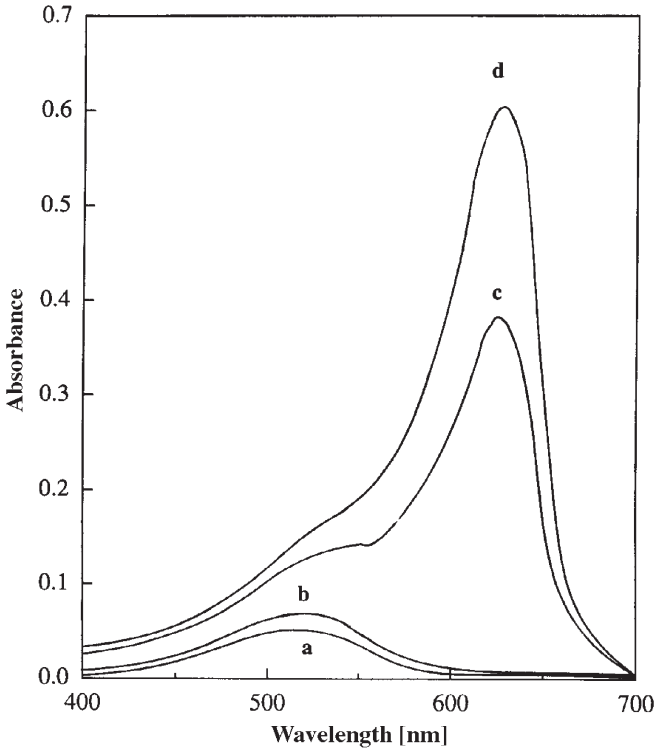

Fig. 2. UV-vis spectra of the reaction products of Neutral red (NR) (1.7×10^{-5} mol), and compounds (**3**) or (**4**) in benzene solutions (10 mL) at room temperature: (*a*) NR (saturated solution); (*b*) NR + 1.7×10^{-5} mol of (**3**); (*c*) NR + 3.4×10^{-5} mol of (**3**); (*d*) NR + 5.1×10^{-5} mol of (**3**); (*e*) NR + 3.4×10^{-5} mol of (**4**). The UV-vis spectra were taken 24 h after mixing.

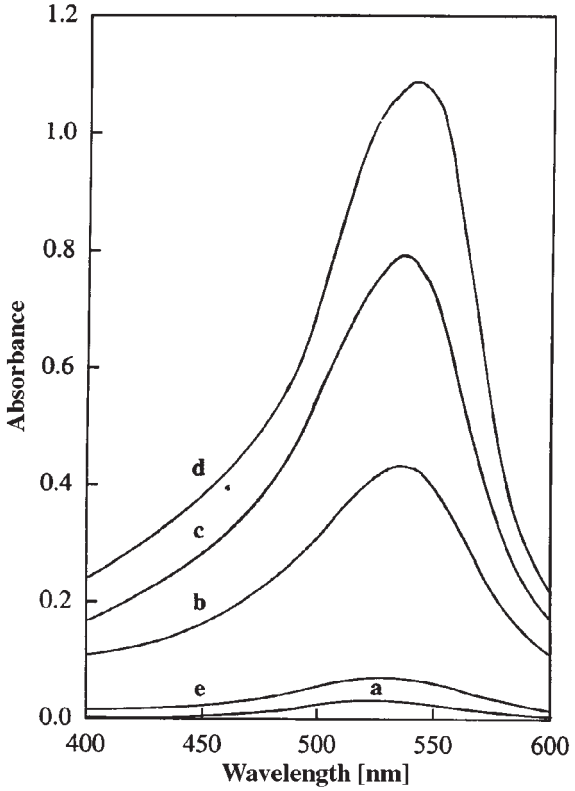

We have also found that the addition of compounds (**1**) or (**2**) to THF solutions of LiCl increased the ionic conductivity by two to three orders of magnitude compared to solutions without an amine compound. This effect can be ascribed to the formation of complexes of Cl^- ions with the nitrogen atoms of the amine compounds, thereby resulting in an increased concentration of free Li^+ ions, which in turn increase the ionic conductivity.

Results and discussion

The tetraamine compounds (**1**) and (**2**) are not soluble in nonpolar solvents such as benzene. Thus, to solubilize the amine compound and its anion complex, we have synthesized an oligoethylene oxide derivative of CF_3SO_2 substituted tetraamine (**3**).

The ^{35}Cl NMR spectrum of LiCl in THF showed a single sharp peak for ^{35}Cl. Upon the addition of the amine compound (**3**) to the THF solution (1:2 molar ratio), the peak corresponding to Cl^- became very broad, presumably the result of average quadruple coupling which would occur as a result of bound chloride (10). In this study, we report examples of the Cl^- receptive behavior by compound (**3**) in benzene solution.

Neutral red dye does not dissolve in benzene at room temperature. However, when the tetraamine compound (**3**) was added to a benzene solution containing solid Neutral red

Fig. 4. Structures of Neutral red and Nile blue chloride. The reaction scheme with compound (**3**) is also shown.

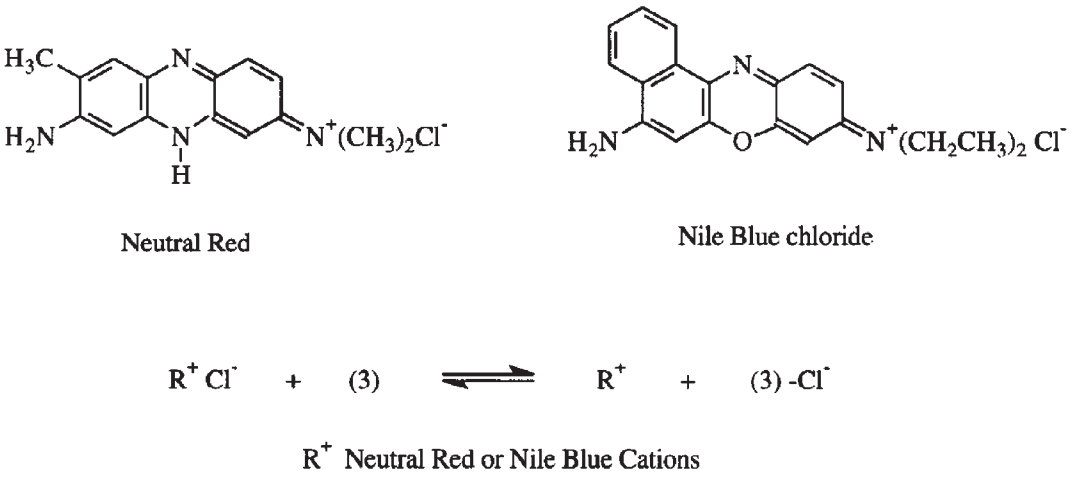

Fig. 5. UV-vis spectra of the reaction products of equimolar reactions (2.7×10^{-5} mol) of 4,4′,4″-trimethoxytriphenyl chloromethane and compounds (**3**) or (**4**) in benzene (40 mL) at room temperature as a function of time: (*a*) $(MeOC_6H_4)_3C$-Cl; (*b*) $(MeOC_6H_4)_3C$-Cl + (**3**) after 5 min; (*c*) $(MeOC_6H_4)_3C$-Cl + (**3**) after 12 h; (*d*) $(MeOC_6H_4)_3C$-Cl + (**3**) after 10 days; (*e*) $(MeOC_6H_4)_3C$-Cl + (**4**) after 10 days.

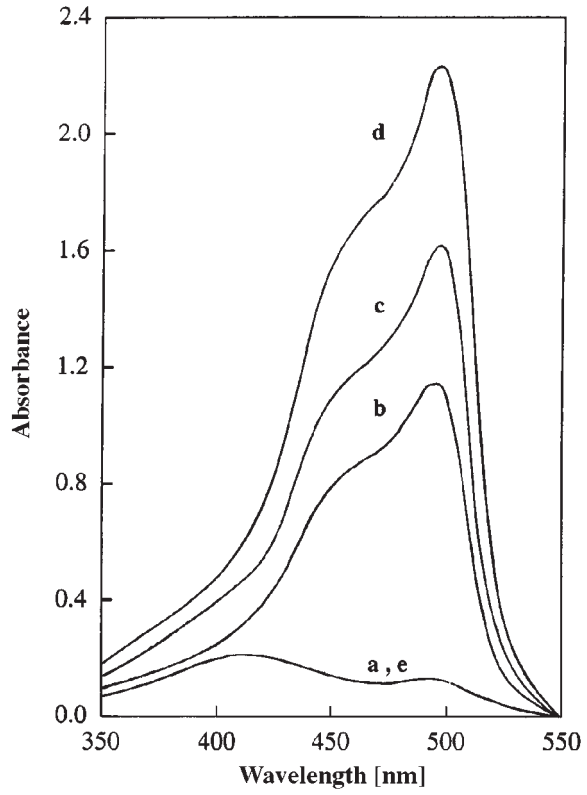

compound at room temperature, the color of the solution immediately turned to dark blue, and the intensity of the color was proportionally increased with increasing concentrations of (**3**) (Fig. 2). The Cl^- ion of Neutral red was complexed with the amine compound (**3**), resulting in an increased solubility of the dissociated Neutral red cation moiety in benzene solution. Similar phenomena were also observed with other dye molecules such as Nile blue chloride (Fig. 3). Figure 4 shows the structures for both Neutral red and Nile blue chloride.

Additionally, a compound where CH_3SO_2 instead of CF_3SO_2 groups were substituted on the nitrogen atoms of the tetraamine was synthesized (**4**). When compound (**4**) was added to benzene solutions containing dye molecules, the dye compounds did not dissolve, and the color of the solutions remained unchanged. These results indicated that the weaker electron withdrawing group, CH_3SO_2, did not create a sufficiently strong electropositivity on the nitrogen atoms to form a complex with the Cl^- ions.

The chloride anion of 4,4′,4″-trimethoxytriphenyl chloromethane has little dissociation in benzene at room temperature. However, with addition of the Cl^- ion receptor (**3**), the dissociation of chloride anion proceed in yielding the trimethoxytriphenylmethyl cation,

$$(CH_3OC_6H_4)_3CCl + (\mathbf{3}) \rightarrow (CH_3OC_6H_4)_3C^+ + (\mathbf{3})\text{-}Cl^-$$

whereas compound (**4**) has no effect on the dissociation of the chloride anion (Fig. 5). The data in Fig. 5 also indicate a long-term effect on the degree of complexation. However, this was not studied in detail.

Under similar conditions, the chloride ion of triphenyl chloromethane did not react with compound (**3**). Without the electron-donating para methoxy groups, the C—Cl bond is stronger and does not dissociate in the presence of compound (**3**).

To summarize, these results show that CF_3SO_2 substituted polyamine compounds form complexes with Cl^- ions and enhances ion pair dissociation in nonpolar solvents such as benzene. Further studies are needed to elucidate the stoichiometry and kinetics of these processes.

Experimental

Materials

Neutral red (~90%), Nile blue chloride (~90%), trimethoxytriphenyl chloromethane, trifluoromethanesulfonic anhydride, triphenyl chloromethane, and organic solvents were

purchased from Aldrich Chemical Co. and used without further purification.

Characterization

A Varian U-plus 300 MHz instrument was used for ^{1}H NMR spectroscopy. UV-vis absorption spectra were obtained by means of Varian Cary 2300 UV-vis spectrometer. IR data were obtained on an Analect FX 6260 Fourier transform infrared spectrometer.

Synthesis

*6-(3,6,9-Trioxadecyl)-1,1,4,8,11,11-hexatrifluoromethylsulfonyl-1,4,8,11-tetraazaundecane (**3**)*

The compound (**3**) was prepared by the route shown in Scheme 1.

*Diethyl 3,6,9-trioxadecyl malonate (**3**)*

Diethyl malonate, 80 g (0.05 mol), was added dropwise to a suspension of 12.0 g (0.5 mol) of sodium hydride in 600 mL of anhydrous tetrahydrofuran at room temperature. After the evolution of gas was completed, 114 g (0.5 mol) of 3,6,9-trioxadecyl bromide was added, and the solution was heated at 80° for 5 h. The precipitate was filtered off, and the solvent was evaporated. The residue was dissolved in ether, washed with water, and dried over magnesium sulfate. The ether was evaporated, and the crude product was distilled, bp 120–125°/0.05 mmHg (1 mmHg = 133.3 Pa). The yield

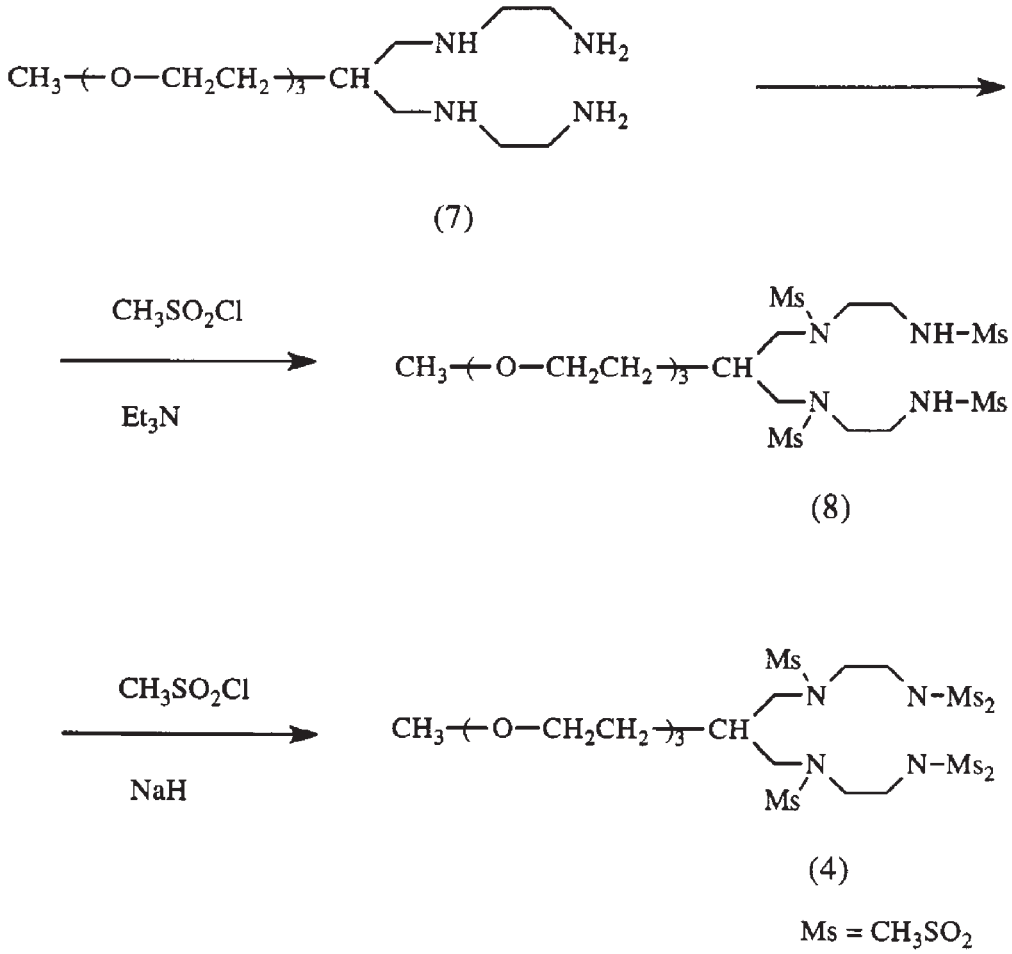
Scheme 2. Reaction scheme for preparation of compound (**4**).



was 122 g (80%). NMR ($CDC1_3$) δ 1.30 (t, 6H), 2.15 (q, 2H), 3.40 (s, 3H), 3.45~3.70 (m, 11 H), 4.20 (q, 4H) ppm.

N,N′-*Bis(2-aminoethyl)-3,6,9-trioxadecyl malonodiamide (**6**)*

A mixture of 58.6 g (0.19 mol) of compound (**5**) and 200 mL (3 mol) of ethylene diamine was heated at 90° for 15 h. The solution was evaporated to dryness, tetrahydrofuran was added to the residue, and the insoluble material was removed by filtration. The solvent was removed under vacuum, and the residue was dried at 60°/0.05 mmHg. The yield was 56.1 g (88%). NMR ($CDC1_3$) δ 1.75 (s, 6N-H), 2.20 (q, 2H), 2.80 (q, 4H), 3.10~3.80 (m, 18H) ppm.

*6-(3,6,9-Trioxadecyl)-1,4,8,11-tetraazaundecane (**7**)*

Compound (**6**), 53 g (0.16 mol), was dissolved in anhydrous tetrahydrofuran, and the solution was added dropwise to 800 mL of 1 M borane in tetrahydrofuran at 0°. The reaction mixture was heated for 24 h. The solvent was evaporated, the residue was dissolved in water, and then the basicity of the solution was adjusted with sodium hydroxide to pH = 13. Water was removed under reduced pressure, and the residue was treated with ethanol. The ethanol upper layer was decanted from the lower sticky layer. The ethanol solution was then evaporated to dryness. The residue was dissolved in tetrahydrofuran, and any insoluble material was removed by filtration. After removing the solvent, the product was distilled, bp 160–165°/0.05 mmHg. The yield was 38.2 g (78%). NMR (CD_3OD) δ 1.40~1.90 (m, 3H), 2.40~2.60 (m, 12H), 3.40 (s, 3H), 3.50–3.80 (m, 10H), 4.00 (s, 6H) ppm.

*6-(3,6,9-Trioxadecyl)-1,1,4,8,11,11-hexatrifluoromethyl-1,4,8,11-tetraazaundecane (**3**)*

Compound (**7**), 6.12 g (0.02 mol), and triethylamine (12.5 g, 0. 12 mol) were dissolved in 160 mL of anhydrous chloroform and cooled to –20°. Trifluoromethanesulfonic anhydride (34.9 g, 0. 12 mol) was added into the solution under a nitrogen atmosphere. The addition was carried out over 3 h, and the solution was stirred 1 h at room temperature. The reaction mixture was washed with water, and the solution was dried over magnesium sulfate. Chloroform was evaporated, and a solid product was recrystallized from methanol. The yield was 17.2 g (78%) of pure needle crystals, mp 93-95°. NMR ($CDCl_3$): δ 1.50~1.90 (m, 3H), 3.40 (s, 5H), 3.50~3.90 (m, 18H), 4.00~4.50 (m, 4H) ppm. Elemental analysis for $C_{20}H_{28}O_{15}N_4S_6F_{18}$ (**3**), calcd.: C 21.85, H 2.55, N 5.10, S 17.49, and F 31.16; found: C 21.97, H 2.74, N 5.01, S 17.42, and F 30.72.

*6-(3,6,9-Trioxadecyl)-1,1,4,8,11,11-hexamethylsulfonyl-1,4,8,11-tetraazaundecane (**4**)*

The compound was synthesized by a similar method as described for the preparation of (**3**) using methanesulfonyl chloride instead of trifluoromethanesulfonic anhydride (Scheme 2).

© 1999 NRC Canada

*6-(3,6,9-Trioxadecyl)-1,4,8,11-tetramethylsulfonyl-1,4,8,11-tetraazaundecane (**8**)*

Compound (**7**), 4.30 g (0.015 mol), and triethylamine (6.7 g, 0.065 mol) were dissolved in 50 mL of anhydrous chloroform, and the solution was cooled with an ice bath. Methanesulfonyl chloride, 7.5 g (0.065 mol), was added dropwise to the solution over a period of a half hour, and the mixture was stirred for another half hour. The solution was washed with water and dried over anhydrous magnesium sulfate. Chloroform was evaporated to give 8.2 g (88%) of viscous liquid product (**8**). NMR ($CDCl_3$–CD_3OD) δ 1.5~2.0 (m, 3H), 2.8~3.0 (m, 12H), 3.3~3.5 (m, 15H), 3.55~3.7 (m, 10 H), 3.8 (s, 2H) ppm. IR (neat): 3289, 3020, 2934, 2878, 1453, 1325, 1148, 1096, 971, 920, 765 cm^{-1}.

*6-(3,6,9-Trioxadecyl)-1,1,4,8,11,11-hexamethylsulfonyl-1,4,8,11-tetraazaundecane (**4**)*

Compound (**8**), 8.2 g (0.013 mol) in 50 mL of anhydrous tetrahydrofuran was added dropwise into a suspension of 0.7 g (0.029 mol) of sodium hydride in 80 mL of tetrahydrofuran. Methanesulfonyl chloride, 3.7 g (0.033 mol), was then added to the solution. The mixture was heated at 60° for 1 h. The inorganic salt was filtered off, and the filtrate was stirred with diluted aqueous sodium hydroxide. After extraction with chloroform, a pure semisolid product (**4**) was obtained. The yield was 7.5 g (75%). NMR ($CDCl_3$) δ 1.5~2.0 (m, 3H), 2.8~3.0 (m, 8H), 3.35 (s, 21H), 3.45~3.7 (m, 10H), 3.8~4.1 (m, 4H) ppm. IR (neat): 3016, 2953, 2879, 1456, 1333, 1154, 1086, 966, 853, 764, 533 cm^{-1}.

Acid-catalyzed decomposition of diazodiphenylmethane in dimethylsulfoxide

Robert Eliason

Abstract: Acid-catalyzed decomposition of diazodiphenylmethane (DDM) has been studied in DMSO containing varying amounts of water. The reaction was found to be first-order in DDM and first-order in acid. The Brønsted plot for a series of carboxylic acids is curved with the H^+ point falling below the curve defined by the carboxylic acids. In near-anhydrous DMSO, kinetic hydrogen isotope effects (KIEs) are 1.7 and 1.6 for acetic acid and chloroacetic acid, respectively. The chloroacetic acid KIE increases with increasing water concentration, rising to 2.9 at 3.6 M water. As a function of $[H_2O]$, k_{HA} for chloroacetic acid shows a sharply defined minimum occurring at 1 M water. This behavior and the water effect on KIE suggest that the carboxylic acid-catalyzed reactions in near-anhydrous DMSO do not use the AS_E-2 mechanism attributed to the reaction of DDM in hydroxylic solvents. A mechanism, leading to an azoalkane, is suggested. Either directly or indirectly, this may lead to diphenylcarbene, which would account for the observed products: benzophenone, benzhydrol, and benzhydryl esters. For the H^+ catalyzed decomposition of DDM in near-anhydrous DMSO, benzophenone is not found among the products, and we suggest that this reaction does not undergo a change in mechanism and continues to use the AS_E-2 mechanism.

Key words: decomposition mechanism, kinetics, solvent effect, reaction with carboxylic acids.

Résumé : On a étudié la décomposition acidocatalysée du diazodiphénylméthane (DDM) dans le DMSO contenant des quantités variables d'eau. On a trouvé que la réaction est du premier ordre en DDM et du premier ordre en acide. La représentation graphique de Brønsted pour une série d'acides carboxyliques est incurvée et le point pour H^+ se trouve en dessous de la droite définie par les acides carboxyliques. Dans le DMSO pratiquement anhydre, les effets cinétiques de l'hydrogène (EICs) sont de 1,7 et 1,6 respectivement pour l'acide acétique et l'acide chloroacétique. L'EIC de l'acide chloroacétique augmente avec une augmentation de la concentration en eau lorsqu'on passe de 2,9 à 3,6 M en eau. Le graphique représentant $[H_2O]$ en fonction de k_{HA} de l'acide chloroacétique présente un minimum bien défini se produisant à 1 M. Ce comportement et l'effet de l'eau sur l'EIC suggèrent que les réactions catalysées par les acides carboxyliques dans le DMSO pratiquement anhydre ne font pas appel au mécanisme AS_E-2 que l'on attribue généralement à la réaction du DDM dans les solvants hydroxyliques. On suggère un mécanisme pour la réaction conduisant à un azoalcane. Ceci peut conduire directement ou indirectement au diphénylcarbène qui pourrait expliquer la formation des produits observés: benzophénone, benzhydrol et esters benzhydryles. Pour la décomposition catalysée par H^+ du DDM dans le DMSO pratiquement anhydre, on n'observe pas de benzophénone parmi les produits et on suggère que cette réaction n'est pas soumise à un changement de mécanisme et qu'elle continue à faire appel au mécanisme AS_E-2.

Mots clés : mécanisme de décomposition, cinétiques, effet de solvant, réaction avec des acides carboxyliques.

[Traduit par la Rédaction]

The reaction of diazodiphenylmethane (DDM) with acid has long been a kineticist's favorite (1–11). Its mechanism in hydroxylic solvents is well established as AS_E-2 (Scheme 1) and is characterized by kinetic isotope effects (KIEs) between 2.5 and 4, depending on solvent and catalyzing acid.

In near-anhydrous acetonitrile, a KIE of 3.3 was obtained when the reaction was catalyzed by perchloric acid, suggesting that the reaction occurs by the AS_E-2 mechanism (3). In contrast, when the reaction is carried out in aprotic solvents with low concentrations of sulfonic or carboxylic acids, the KIE falls to values ~1 (4, 5). It has also been reported that the reaction becomes zeroth-order in DDM in anhydrous acetonitrile with *p*-toluenesulfonic acid as the catalyst (4). This behavior was not noted in a study of the reaction in 19 dipolar, aprotic solvents (including acetonitrile), with either benzoic or acetic acid as catalyst (5). Instead, it was found that the reaction is kinetically first-order in diazodiphenylmethane and that the rate law contains both a first-order and second-order term in acid. Dimethylsulfoxide and *N*,*N*-dimethylformamide solvents were two notable exceptions in which only the first-order term in acid was observed. The study also determined the KIEs for benzoic and acetic acids

Received October 26, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

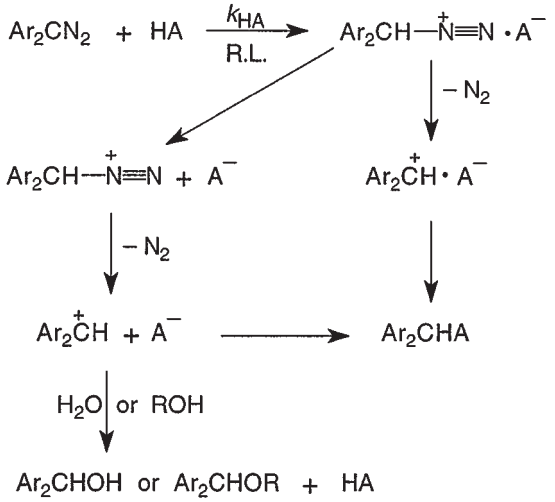
Scheme 1.



in ethyl acetate and acetone. The KIEs for the second-order term (first-order in both diazodiphenylmethane and acid) were in the range of 0.6–1.8, and for the third-order term (first-order in diazodiphenylmethane and second-order in acid) the KIEs ranged from 4.2 to 7.3. To account for these observations, it was suggested that for the second-order reaction the first step of Scheme 1 becomes reversible, and one of the subsequent steps becomes largely rate-limiting (4, 5). The third-order reaction was accounted for by reaction of an acid dimer with DDM (5).

Given the behavior in DMSO compared to the other aprotic solvents, we undertook an investigation of the reaction in DMSO containing varying amounts of water. Isotope effects, products, the effect of acid strength on reactivity, and the effect of water concentration up to 12 M are reported. For carboxylic acid induced reactions, but not for those induced by H^+, a change in mechanism does appear to occur. The mechanistic change appears to involve the opening of a new pathway rather than just a shift to a later rate-limiting step within the general framework of Scheme 1. A candidate mechanism is proposed.

Experimental section

Materials

Dimethylsulfoxide (Aldrich Chemical Co.), dried as described previously (12), was used for all kinetic experiments; DMSO containing 0.01% water was later purchased commercially (Burdick and Jackson Laboratories, Inc.) and was used directly for product analysis experiments. Diazodiphenylmethane was prepared by the method of Nenitzescu and Solomonica (13) and was purified by recrystallization from methanol and then from petroleum ether (bp 30–60°C). Acetic acid-*d* was a gift from Dr. B. Spencer Meeks, Jr., was prepared by him (14), and was assumed to contain the same isotopic purity as the deuterium oxide (99.8 atom% D) from which it was prepared. Trifluoromethanesulfonic acid was distilled prior to use (bp 162–164°C; lit. (12) 162°C). Chloroacetic acid-*d* was prepared by reaction of freshly distilled (bp 103–104°C) chloroacetyl chloride (0.31 mol; Matheson Colman and Bell; practical grade) with deuterium oxide (0.27 mol; Bio-Rad Laboratories; specified 99.87 atom% D). The reaction mixture was fractionally distilled, and the middle fraction (bp 183.5°C) was used. The isotopic purity was assumed to be the same as that of the deuterium oxide.

Bis(triphenylphosphonium)nitrogen(1+) trifluoroacetate (PNP trifluoroacetate) was prepared after the method of Martinsen and Songstad (15). The white solid was recrystallized from methanol–water solution (mp 184.5–185.5°C).

Anal. calcd. for $C_{38}H_{38}O_2NP_2F_3$: C 70.02, H 4.64, N 2.15, P 9.51; found: C 70.20, H 4.63, N 2.02, P 9.76.

All other reagents were commercial products of the highest available purity and were used as received.

Procedures

The kinetic procedures have been previously described (2). All kinetic measurements were performed in a spectrophotometer cell holder, at constant temperature, 25.0 ± 0.2°C. Except for trifluoroacetic acid, the k_{HA} values in DMSO were determined in unbuffered carboxylic acid solutions. The k_{HA} for trifluoroacetic was determined in solutions containing enough PNP trifluoroacetate to produce a 1:1 buffer ratio.

The water content of the DMSO used in all experiments was determined from the intensity of its absorption at 3400 cm^{-1} (12). The adventitious water content never exceeded 0.048 M for product analysis experiments, 0.045 M for kinetic experiments, or 0.18 M for experiments in which the water concentration was varied when trifluoromethanesulfonic acid was used as the catalyst.

Five mmol of DDM were used in each product determination. When either chloroacetic acid or trifluoromethanesulfonic acid was added to the DDM, 11 mmol of the acid were used. Thermal decomposition was accomplished by dissolving the DDM in 20 mL DMSO and heating this solution for 3 h in a boiling water bath. Acid-catalyzed decomposition was done by dissolving the DDM in 10 mL of DMSO and the acid in 10 mL of DMSO. Both solutions were cooled in an ice bath until the DMSO began to freeze. Then the acid solution was added, dropwise, to the stirred DDM solution while cooling it in the ice bath. All the acid-catalyzed reaction mixtures were kept overnight in the dark before workup. In one experiment, the chloroacetic acid solution was heated to 110°C in an oil bath. The DDM solution was placed in the hot oil bath, and the hot acid solution was added dropwise with stirring to the DDM solution. This mixture was kept in the oil bath for 3 h before workup. In every experiment, the reaction mixture turned yellow. The following workup procedure was used for all experiments. The reaction mixture was poured into 80 mL water. The resulting solution was extracted four times with 20 mL diethyl ether. The combined ether extracts were washed four times with 20 mL of 5% aqueous sodium bicarbonate; then three times with 20 mL water. The ether solution was dried over anhydrous magnesium sulfate. The ether was removed from the products under reduced pressure (water aspirator). In each case, an oily residue was left after the ether removal. An IR spectrum was taken of each product mixture, and the products were identified by comparison with known spectra. In those experiments that were heated, crystals formed in the product mixture. The crystals were separated and identified by IR spectroscopy.

Results

Pseudo first-order rate constants, k_{obs}, were determined from plots of log $(A_t - A_\infty)$ versus time. (See Tables 1–8 for k_{obs} values of DDM in various acids.) The reactions were followed for about three half-lives (>75% completion), and these plots were completely rectilinear, showing no systematic deviations. Figures 1 and 2 show that reactions of DDM with both chloroacetic and trifluoromethanesulfonic acids are first-order in DDM. In Fig. 1, the DDM concentration between the curves differs by a factor of 2.2 as determined by the initial absorbance. The observed rate constant, k_{obs}, for curve A was 5.37×10^{-4} s^{-1} and for curve B 5.70×10^{-4} s^{-1}. The reaction in curve B was followed to about 90% completion, which represents 3.2 half-lives. The plot shows no indication of curvature over that extent of reaction. If the first 10% of reaction of curve A is compared with the last 10% of reaction in curve B, there is over a 10-fold difference in DDM concentration, and yet the slopes of the two curves are essentially equivalent. A similar argument can be made using the data in Fig. 2. In this case, there is slightly less than

The circles are not error circles; they merely identify the points.

a 10-fold difference in DDM concentration between the first part of curve C and curve D, but the slopes of these curves are similar. If the reaction were actually zeroth-order in DDM, there would be a corresponding 10-fold increase in the slopes of the plots shown in Figs. 1 and 2. No such increase is apparent. Since reactions like these are also first-order in DDM when the solvent is 12 M water in DMSO (7), we concluded that this was true throughout our range of interest. We also concluded that the reaction was first-order in DDM for both strong and weak acids.

[d]Reference 39.

[e]From ref. 5. The value given, 1.2×10^{-3} M^{-1} s^{-1}, was measured at 37°C. An activation energy of 12.5 kcal mol^{-1} was assumed in order to estimate the 25°C value.

A catalytic coefficient for H^+, k_H, was obtained from dilute (<0.13 M) trifluoromethanesulfonic acid solutions. At such concentrations in DMSO, trifluoromethanesulfonic acid has been considered to be completely dissociated (16), and we have also made this assumption. The slope of a plot of k_{obs} as a function of $[H^+]$ is k_H.

Table 9 lists the carboxylic acid dissociation constants, K_{HA}, and the catalytic coefficients, k_{HA}. Trifluoroacetic acid is significantly dissociated in DMSO. So the reactions were run with 1:1 buffer solutions, and the catalytic coefficient was determined from a plot of the quantity, $k_{obs} - k_H[H^+]$, against $[CF_3COOH]$. Dichloroacetic acid is the next most strongly dissociated. In the most dilute solution used, 0.0125 M, it is 0.6% dissociated, and the resulting $k_H[H^+]$ term contributes 5% to k_{obs}. The remaining carboxylic acids were assumed to be undissociated, and in these other cases the fractional contribution of $k_H[H^+]$ to k_{obs} was smaller still. Thus, the carboxylic acid coefficients, k_{HA}, were the slopes of plots of k_{obs} as a function of the acid concentration, [HA]. The slopes of all these linear plots were evaluated by the method of least squares. The average deviation of points from the lines was ~2%, and the intercepts were indistinguishable from zero. The range of [HA] studied was typically 0.01–0.1 M, and the experimental points defined linear relations. We concluded that contributions to the rate from terms higher than first order in acid were not present. The benzoic catalytic coefficient was estimated from the value at 37°C given by Chapman et al. (5). An activation entropy of –35 cal mol^{-1} deg^{-1} was assumed. This seemed appropriate for a bimolecular reaction producing ions in a nonaqueous solvent (17). This leads to an activation energy of 12.5 kcal mol^{-1}.

The variation of k_H with water concentration is shown in Fig. 3. The water concentration was varied from under 0.1 M to over 8 M. Each point represents the average of triplicate determinations. The point at 12 M water is from a previous study (7).

The effect of water concentration on the catalytic coefficient for chloroacetic acid and for chloroacetic acid-d_1 was also determined. All the measurements were made with

~0.1 M acid. The catalytic constants are shown in Figs. 4 and 5, and the isotope effects in Fig. 6. They have not been corrected for a $k_H[H^+]$ contribution. The pK_{HA} for chloroacetic acid drops from 9.00 in DMSO to 5.69 in a water–DMSO mixture of mole fraction DMSO, X_{DMSO}, of 0.445 (18). Assuming that pK_{HA} is a linear function of X_{DMSO} (18), a pK_{HA} of 7.5 is obtained by interpolation at a water concentration of 3.55 M. This leads to a $k_H[H^+]$ contribution to k_{obs} of 0.3% at 0.1 M. At lower water concentrations, the $k_H[H^+]$ contribution would be lower still. The isotopic purity of the chloroacetic acid-d_1 was assumed to be equal to that of the deuterium oxide from which it was prepared, which was specified as 99.87% atom percent D. Since the near-anhydrous DMSO contained 0.045 M water, k_{LA}[2] was extrapolated to 100% D by assuming a linear function of the atom fraction D. The probable errors of the experimental k_{LA} values were ~5%, and the extrapolation to 100% D adds to the uncertainty of the k_{DA} values, which we estimated to be ~10%. The uncertainty of the isotope effects is, then, ~15%.

For acetic acid, a value of k_{DA}, 1.97×10^{-5} M^{-1} s^{-1}, and an isotope effect, 1.7, were also obtained, in the same manner as described above.

Reaction products were determined by comparing the IR spectra of product mixtures with published standards[3] and with the IR spectrum of an authentic sample of benzhydryl chloroacetate that was prepared for this purpose. At or below 25°C with trifluoromethanesulfonic acid in DMSO containing 0.045 M water, the sole product was benzhydrol. It is likely that any benzhydryl trifluoromethanesulfonate formed in the original reaction would have been converted to benzhydrol during the work-up. Less than 2% of benzophenone can have been present, since its very strong and distinctive carbonyl band would have been easily detected, and it was not. The same experiment was conducted using chloroacetic acid, and in this case the product mixture consisted of benzhydryl chloroacetate, benzhydrol, and benzophenone in comparable quantities. No other products could be detected. When the same reactants were allowed to react at 110°C, ~3% of solid tetraphenylethene separated from the rest of the product mixture that proved to be benzhydrol and benzophenone in about equal proportions. Because of coincidences in the IR spectra, we cannot be certain that a small amount of tetraphenylethene was not present among the

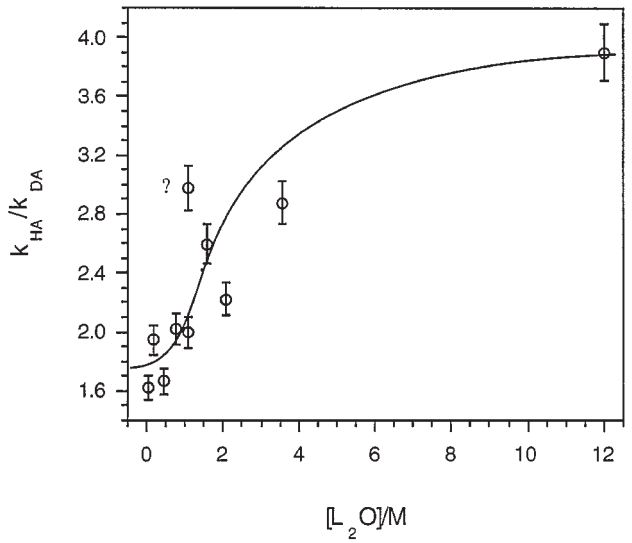
Fig. 6. Isotope effects on chloroacetic acid catalytic coefficients as a function of water concentration. (L may be either H or D.) The point at 12 M L_2O is from a previous study (7). The error bars indicate estimated uncertainties in measurements. The point marked with a question mark is substantially removed from the curve defined by other points, including points at essentially the same L_2O concentration, and although no error was identified the point is discounted. The solid line is a plausible smooth curve through the circles.



products of the lower-temperature reaction. When DDM was heated in the same DMSO without any added acid, about 40% of the product crystallized spontaneously. This proved to be mostly benzophenoneazine with a small amount of tetraphenylethene. The remaining 60% consisted of benzophenone and benzhydrol.

Discussion

There are two general ways in which a reaction can change under a change in reaction conditions. Without changing the sequence of steps, a new step may become rate-limiting. Alternately, a new reaction channel may open up: that is, a new sequence of steps, which was uncompetitive under the old conditions, may become competitive under the changed conditions. Earlier workers (4, 5) have favored the first alternative based, in part, on the behavior of the reaction rate on changing the water concentration. As the water concentration was decreased from 11 to 2 M, the reaction rate increased to a maximum after which the rate decreased sharply (4). We believe our results favor the second alternative.

A plot of k_{HA} for chloroacetic acid versus $[H_2O]$ produces an interesting bimodal curve (Fig. 4). The general trend of increasing k_{HA} with increasing $[H_2O]$ can be rationalized. Addition of water to DMSO would increase the dielectric constant of the solvent mixture and, specifically, would increase its solvation power for anions, since DMSO cannot act as an H-bond donor. A solvent with increased water would be better able to stabilize a charged transition state relative to the uncharged reactants. The activation free energy would be lowered, and the reaction rate increased. Thus, we concluded that the reaction probably involves charge formation in the transition state. The minimum which

Scheme 2.

$$Ar_2CN_2 + HA \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ar_2CHN_2^+ + A^-$$

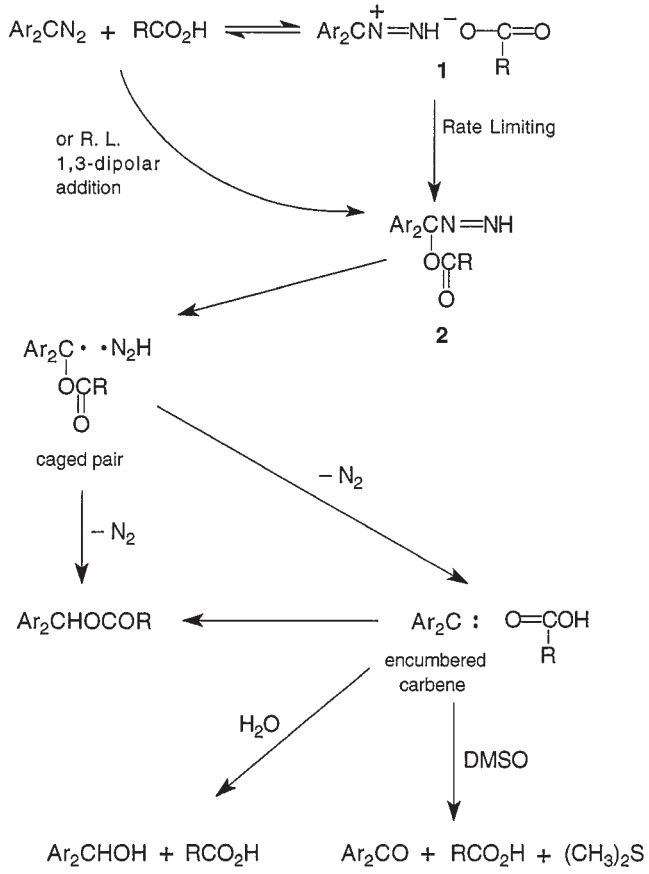
$$Ar_2CHN_2^+ \xrightarrow{k_2} \text{Products}$$

occurs at approximately 1 M water could be explained as due to a change in reaction mechanism. A mechanistic change from rate-limiting proton transfer (AS_E-2) to a pre-equilibrium step followed by a rate-limiting step (A-1) on going from high to low water concentration has been previously proposed (Scheme 2) (4, 5). The k_1 step will be rate-limiting if $k_2 >>> k_{-1}[A^-]$, which is apparently the case at high $[H_2O]$. Decreasing the water content of the solvent would decrease the solvation of the carboxylic anion and increase the free energy of this species. The resulting activation free energy decrease would cause the $k_{-1}[A^-]$ term to become larger than k_2 at some point. When $k_{-1}[A^-] >>> k_2$, then the mechanism would have become A-1 at low $[H_2O]$. If this general picture is true that the decrease in k_{HA} is a result of a decrease in the solvation of the incipient carboxylate anion in the transition state, then k_{HA} should be some function of K_{HA} at various $[H_2O]$. The decrease in K_{HA} with decreasing $[H_2O]$ is a reflection of the inability of the solvent to solvate the anion. A plot of k_{HA}/K_{HA} versus $[H_2O]$ should give a curve that breaks downward at the point where the mechanism changes from AS_E-2 to A-1 because decreased anion solvation would greatly increase $k_{-1}[A^-]$ term. The hypothesis is tested in Fig. 5 in which K_{HA} is that for benzoic acid obtained from data of Kolthoff et. al. (19, 20) and Fiordiponti et. al. (21), since similar data for dichloroacetic acid was unavailable. As can be seen, the curve breaks sharply upward upon going below 1 M water. We take this to indicate that there has not been a simple shift in the rate-limiting step of the mechanism of Scheme 1 but that an entirely new mechanistic pathway is being employed.

This alternative pathway must account for the reduction of the isotope effect on the carboxylic acid catalytic coefficient but must still provide for general acid catalysis by carboxylic acids and must account for the alteration of the product distribution to include a substantial amount of benzophenone. We believe the mechanism shown in Scheme 3 meets these requirements. The first step consists of reversible proton transfer to nitrogen with the carboxylate group still strongly associated (intermediate **1**). It has been shown that for diazomethane in super acid media protonation can occur on nitrogen (22). The second step involves rate-limiting internal attack by the carboxylate anion on carbon to produce intermediate **2**. These two steps lead to kinetics that conform to general-acid-catalysis. The KIE for the reaction would depend on the isotope effect of the reversible equilibrium step. It is expected that the zero-point separation for H and D going from OH to NH bonds would be similar, and this would result in an isotope effect around unity. Calculations of equilibrium isotope effects from OH and NH stretching frequencies predict a K_H/K_D of ~1 for non-hydrogen-bonded NH and 1.4 for hydrogen-bonded NH (23). This suggests that the association of the carboxylate anion with the hydrogen in **1** may give a KIE of about 1.4, which is close to the values observed for acetic and chloroacetic acids.

© 1999 NRC Canada

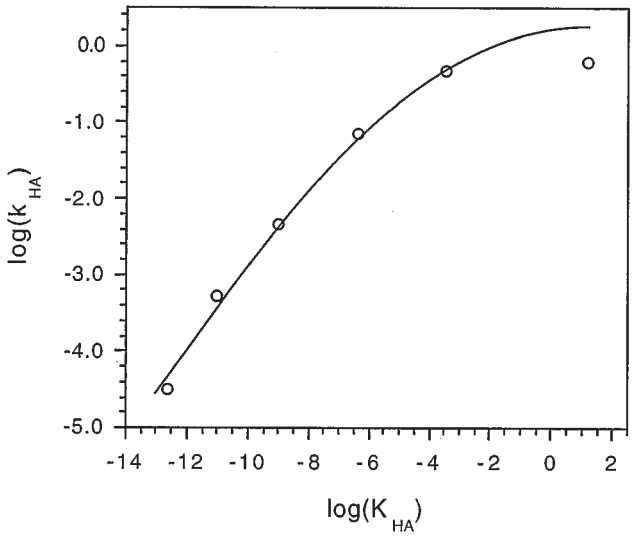
Scheme 3.



An alternative to the two-step mechanism outlined above is a rate-limiting 1,3 dipolar addition of the carboxylic acid to DDM (shown in Scheme 3). Dipolar additions to diazoalkanes are common (24). Although addition of carboxylic acids to diazoalkanes has not been previously recognized, 1,3-dipolar additions of a thiol to a nitrile imine and methanol to an azomethine imine (25) have been. Since the molecular acid is involved, it would give rise to general-acid-catalysis. The transition state of this 1,3-dipolar addition would involve heavy atom motions in the reaction coordinate as well as hydrogenic motion. It is reasonable, therefore, that the isotope effect should be small.

Both these pathways should depend on the nucleophilicity of the A fragment in HA. They would, then, become uncompetitive if the acid is perchloric or trifluoromethanesulfonic acid and would become more competitive for carboxylic acids in non-hydroxylic solvents. Since either pathway is basically a proton transfer reaction, the reaction might, quite reasonably, produce the curved Brønsted plot shown in Fig. 7 (26). The H^+ point would fall below the plot because it is structurally different from the carboxylic acids (27, 28). In fact, we believe that H^+ catalysis provided by trifluoromethanesulfonic acid occurs via the AS_E-2 mechanism (Scheme 1). A plot of k_{H+} versus [H_2O] (Fig. 3) follows the same pattern obtained for the hydrolysis of ethyl vinyl ether in DMSO occurring by the AS_E-2 mechanism (29).

Fig. 7. A log–log plot of the data from Table 9 of catalytic coefficients as a function of dissociation constants. The solid line has no theoretical significance. It is merely a smooth curve through the carboxylic acid points.



The fragmentation of diazoalkanes is well documented (30). It may be symmetrical if the reactant is symmetrical but is unsymmetrical if the reactant is unsymmetrical (31). In the present case, the cleavage of the N—C bond of **2** is energetically much easier than the cleavage of the N—H bond,[4] and we suggest, therefore, the one-bond cleavage shown giving a caged radical pair. Cage recombination gives benzhydryl chloroacetate if the hydrogen is transferred to carbon or gives diphenylmethylene plus chloroacetic acid if the hydrogen is transferred to one of the carboxyl oxygens. In both cases, N_2 is liberated. We envision that the diphenylmethylene produced is an encumbered carbene. Diphenylcarbene is known to insert into the OH bond of methanol (34).[5] This carbene could then react with chloroacetic acid, with which it is associated, to give benzhydryl chloroacetate, and with water, present in small amounts, to give benzhydrol. Oda et al. (36) found that diphenylcarbene is oxidized by DMSO to benzophenone; thus, this reaction could produce the benzophenone found in our product mixtures. The benzhydrol could also arise from hydrolysis of benzhydryl chloroacetate in the product analysis workup and (or) from a residual contribution from the AS_E-2 mechanism. Since benzhydryl chloroacetate and benzhydrol are also the products of the AS_E-2 mechanism (Scheme 1), they could also be produced in simple variants of that scheme. However, we believe that benzophenone is most easily explained with the aid of a carbene precursor. Benzophenone could also be produced by reaction of triplet diphenylmethylene with O_2 (37). Closs and Goh (38) have previously observed ~50% yields of stereospecific cyclopropane formation in the acid-promoted reactions of aryldiazomethanes with olefins, and they suggested a carbenoid mechanism.

In this way, the mechanism shown in Scheme 3 can account for all our observations on the carboxylic acid pro-

[4] The CH_3—NH_2 bond has bond energy of 79 ± 3 kcal mol^{-1}, while the H—NH_2 bond has energy of 103 ± 3 kcal mol^{-1} (32). In addition, the acetoxydiphenylcarbinyl radical would be stabilized by over 10 kcal mol^{-1} of resonance energy (33).

[5] This reaction can apparently occur with either the singlet or triplet state (35).

© 1999 NRC Canada

moted breakdown of DDM in near-anhydrous DMSO. While we cannot prove that scheme is unique in doing so, we have shown that all the steps have precedent, and we believe it is correct. We also believe that this is essentially the mechanism for the reaction of DDM with low concentrations of carboxylic acids in other non-hydroxylic solvents.

An ab initio study on the magnetic susceptibility and magnetically induced current density distribution of the bicyclo[3.2.1]octa-3,6-dien-2-yl anion

Nick Henry Werstiuk and Jiangong Ma

Abstract: The molecular susceptibility and the atomic contributions including the basin and surface components calculated at the RHF/6-31+G(d)//6-31+G(d) level of theory along with vector current densities obtained at the 6-31++G(d,p)//6-31+G(d) and 6-31+G(d)//6-31+G(d) levels are reported for benzene (**1**) and correlated — the agreement is excellent — with the results obtained by Keith and Bader with the 6-311++G(2d,2p) basis. This validates our similar studies on the bicyclo[3.2.1]octa-3,6-dien-2-yl anion (**2**) — initially considered to be a bishomoaromatic species — its parent hydrocarbon bicyclo[3.2.1]octa-2,5-diene (**3**), the bicyclo[3.2.1]oct-3-ene-2-yl anion (**4**), and **5**, the lithium complex of **2**. While a magnetic susceptibility exhalation is found in going from **4** to **2**, the increase in atomic surface contribution to $\Delta\chi$ arises predominately (42.6%) from the ethenyl bridge carbons C6 and C7, with C2 + C4 and C3 exhibiting substantially smaller increases (27.4 and 8.3%, respectively). This result, in conjunction with the nature of the vector current density maps of **2** and **4,** provides further evidence that **2** does not possess a ring current as depicted in **2-bh**, the usual representation of "bishomoaromatic" **2**.

Key words: ab initio calculations, IGAIM, CSGT, magnetic susceptibility, induced current density distributions, bicyclo[3.2.1]octa-3,6-dien-2-yl anion.

Résumé : On a calculé la susceptibilité moléculaire et les contributions atomiques, y compris les composants du bassin et de la surface (en opérant au niveau RHF/6-31+G(d)//6-31+G(d) de la théorie) ainsi que les densités de courant vectoriel (obtenues au niveaux 6-31++G(d,p)//6-31+G(d) et 6-31+G(d)//6-31+G(d)) du benzène (**1**) et on a établi une corrélation — pour laquelle l'accord est excellent — avec les résultats obtenus par Keith et Bader avec la base 6-311++G(2d,2p). Cet accord valide notre étude semblable sur l'anion bicyclo[3.2.1]octa-3,6-dién-2-yle (**2**) (considéré initialement comme une espèce bishomoaromatique) et son hydrocarbure parent, le bicyclo[3.2.1]octa-2,5-diène (**3**), sur l'anion bicyclo[3.2.1]oct-3-én-2-yle (**4**) et sur **5**, le complexe lithié de **2**. Alors qu'on observe une exaltation de la susceptibilité magnétique en allant de **4** à **2**, l'augmentation dans la contribution de la surface atomique jusqu'à $\Delta\chi$ provient principalement (42,6%) des carbones C6 et C7 du pont éthényle alors que les augmentations dues à C2 + C4 et C3 sont substantiellement plus faibles (27,4 et 8,3% respectivement). Ce résultat, pris de concert avec la nature des cartes de densité du courant vecteur de **2** et **4** confirme que **2** ne possède pas de courant de cycle tel que montré par **2-bh**, la représentation habituelle du produit « bishomoaromatique » **2**.

Mots clés : calculs ab initio, « IGAIM », « CSGT », susceptibilité magnétique, distributions de densité du courant induit, anion bicyclo[3.2.1]octa-dién-2-yle.

Introduction

The key quantity related to the response of a molecule (or atom) to a magnetic field is the induced current density which gives rise to additional fields at the nuclei. A clockwise circulating (diamagnetic) current generates a field which weakens the applied external field and is said to shield nuclei leading to a shift of ^{1}H and ^{13}C resonances to higher frequencies. On the other hand, an anticlockwise circulating (paramagnetic) current produces a field which strengthens the applied field at the nuclei; the resonances shift to lower frequencies. The induced diamagnetic and paramagnetic currents are of two types. They can be localized or atom-like as in the case of CO_2, or they can have significant components which involve fluxes through interatomic surfaces. Maps of these magnetically induced first-order current density distributions were first illustrated in the pioneering calculational studies of Lipscomb and co-workers (1–3). In following studies, Lazzeretti and Zanasi (4, 5) calculated and analysed the magnetically induced current densities of two Huckel

aromatic systems, benzene (**1**) and the cyclopropenyl cation $C_3H_3^+$, in an attempt to define a physical basis of the ring-current model. Their analyses were based on relatively inaccurate $\mathbf{J}^{(1)}(\mathbf{r})$ distributions which were calculated using the conventional single gauge origin CPHF method. Several incorrect conclusions were drawn in their studies, conclusions which were corrected by Keith and Bader (6, 7). Using their newly developed IGAIM (individual gauges for atoms in molecules) and CSGT (continuous set of gauge transformations) methods, Keith and Bader established that benzene exhibits inner-core paramagnetic and outer diamagnetic ring currents, the latter contributing significantly to the flux of $\mathbf{J}^{(1)}$ through the interatomic surfaces of the ring atoms. In fact, this interatomic flux — the ring current — is responsible for 77% of the parallel component of the molecular magnetic susceptibility. The results of IGLO calculations on benzene and other hydrocarbons have been published (8), and the π and total current densities of a group of monocyclic π-electron systems have been mapped (9).

Experimentally determined ^{1}H and ^{13}C shifts of π-system-containing neutral molecules, carbocations, and carbanions have been used for many years to probe the aromaticity of these species on the assumption that the shifts derive from induced ring currents (10). This was the case for the bicyclo[3.2.1]octa-3,6-dien-2-yl anion (**2**) which attracted the attention of chemists for over 30 years and was the object of a considerable number of studies beginning with the work of Brown and Occolowitz (11). The goal of the research (11–15) was to establish whether the enhanced kinetic and thermodynamic acidities of the methylene hydrogens at C4 of the parent diene **3** and the unusual shifts of selected ^{1}H and ^{13}C resonances of **2** (the ^{1}H resonances of H6 and H7 are shielded by an average of 2.3 ppm relative to the corresponding hydrogen atoms of **3**, and the C6 and C7 of **2** (14) are shielded by an average of 44.0 ppm relative to the corresponding carbons of **3**) derive from the bishomoaromaticity of **2**. It was concluded that **2** is a bishomocyclopentadienide ion (the usual representation is displayed as **2-bh**) possessing a ring current. Yet, the results of calculational studies (16–18), except for those obtained by Brown et al. (19), provided no support that the bicyclo[3.2.1]octa-3,6-dien-2-yl anion was a bishomoaromatic species. For example, the results of calculations at the MCSCF ab initio level led Lindh et al. (18) to conclude that **2** is not bishomoaromatic. In their view, interaction between unoccupied and occupied orbitals necessary to achieve the bicycloaromaticity does not take place due to the large distance between the interacting bridges. They also suggested that stabilization of **2** at the calculated equilibrium internuclear distances is due to an electrostatic interaction between the allylic anion fragment and the remote polarizable double bond. In their view, it is the considerable redistribu-

tion of charge, not benzene-like induced diamagnetic and paramagnetic ring currents, which are responsible for the unusual NMR chemical shifts of **2**. Our interest in exploring the chemistry of carbanions experimentally and calculationally coupled with the availability of the IGAIM and CGST suite of programs at McMaster led us to a computational study of **2**, the parent hydrocarbon of **2**, 2,5-bicyclo[3.2.1]-octadiene (**3**), the bicyclo[3.2.1]octen-2-yl anion (**4**) — the dihydro analogue of **1** — and **5** — the lithium complex of **2**. We showed in an earlier study that IGAIM calculations at the HF/6-31+G(d) level of theory give ^{1}H and ^{13}C chemical shifts of unsaturated hydrocarbons (including benzene which is the archetypal aromatic system) and unsaturated organolithium compounds including **2** that correlate well with experimental data (20). We also obtained the atom electron populations of **2** and its lithium complex with AIM calculations, but found no obvious correlation between the charges on the carbon atoms and the experimental ^{13}C shifts. In this case, our goals were (*i*) to extend our studies on the magnetic response properties of **2** by calculating and analysing the magnetic susceptibility tensors and the current flux through the interatomic surfaces and (*ii*) to obtain information on the induced current flow by calculating the current density maps of **2** and **4**. This paper documents the results of our study.

Computational methods

All the current distributions and susceptibilities were obtained with either IGAIM or CSGT calculations as described by Keith and Bader (6, 7). In a perturbation expansion of the magnetic field induced current $\mathbf{J}(\mathbf{r})$ with respect to the field strength $\mathbf{B}$ as shown in eq. [1],

$$[1]\qquad \mathbf{J}^{(1)}(\mathbf{r}) = -(eN/m)\int d\tau'\{\psi^{(0)*}\hat{\mathbf{p}}\psi^{(1)} + \psi^{(1)*}\hat{\mathbf{p}}\psi^{(0)}\} - (e^2/mc)\mathbf{A}(\mathbf{r})\rho^{(0)}(\mathbf{r}) = \mathbf{J}_{\rho}^{(1)}(\mathbf{r}) + \mathbf{J}_{d}^{(1)}(\mathbf{r})$$

the first-order term in the expansion (1–3, 21) is where $\rho^{(0)}(\mathbf{r})$ is the unperturbed electron density, $\hat{\mathbf{p}}$ is the linear momentum operator, $\mathbf{A}(\mathbf{r})$ is a vector potential (assumed first-order in $\mathbf{B}$), describing $\mathbf{B}$ through Maxwell's equation, $\psi^{(1)}$ is the first-order correction to the unperturbed molecular wave function due to the presence of the magnetic field, and separate terms $\mathbf{J}_{\rho}^{(1)}(\mathbf{r})$ and $\mathbf{J}_{d}^{(1)}(\mathbf{r})$ are called the paramagnetic and diamagnetic contributions to $\mathbf{J}^{(1)}(\mathbf{r})$, respectively. The induced current density distribution $\mathbf{J}^{(1)}(\mathbf{r})$ is related to the measurable magnetic susceptibility tensor χ and to the nuclear magnetic shielding tensor σ^N (for a nucleus with magnetic dipole moment μ^N) according to eqs. [2] and [3], respectively (1).

$$[2]\qquad \mathbf{B}\chi = (\mathbf{1}/2c)\int d\mathbf{r}\{\mathbf{r} \times \mathbf{J}^{(1)}(\mathbf{r})\}$$

$$[3]\qquad \mu^N\sigma^N\mathbf{B} = (-1/c)\,\mu^N\int d\mathbf{r}_N\{\mathbf{r}_N \times \mathbf{J}^{(1)}(\mathbf{r})/\mathbf{r}_N{}^3\}$$

The molecular magnetic susceptibility tensor χ is expressible as a sum of atomic or group contributions ($\chi(\Omega)$). An atomic contribution consists of a basin $\chi_b(\Omega)$ and a surface flux $\chi_f(\Omega)$ component; the former is given by the integral of a magnetization density over the basin of the atom, and the latter by the integral of the flux in the position weighted current density through the interatomic surfaces that the atom shares with its bonded neighbours. The detailed derivations and descriptions of the magnetically induced current density distribution $\mathbf{J}^{(1)}(\mathbf{r})$ and magnetic susceptibility tensor χ are available (22). The coupled-perturbed Hartree–Fock procedure was used for calculating $\mathbf{J}^{(1)}\mathbf{r}$ as coded in CADPAC (23). Geometry optimizations were carried out with Gaussian 92 at the RHF/6-31+G(d) level of theory (24) because ^{1}H and ^{13}C chemical shifts of unsaturated hydrocarbons including benzene, **2**, and **5** are calculated with good accuracy with these geometries (20), and our calculations were subject to hardware limitations. The wave functions obtained with CADPAC were used in IGAIM and CSGT calculations within PROAIMV (25) to obtain the magnetic susceptibilities χ. CURDENDAMP4 and CURDEN (22) were used to obtain the plots of $\mathbf{J}^{(1)}(\mathbf{r})$.

Results and discussion

Molecular susceptibility of benzene

To determine whether IGAIM and CSGT calculations at the HF/6-31+G(d)//HF/6-31+G(d) level of theory give molecular susceptibilities and anisotropies as well as the atomic susceptibilities and their basin and surface components with good accuracy, benzene was studied, and the results correlated with the data obtained by Keith and Bader (6) at the HF/6-311++G(2d,2p) level. The magnetic susceptibility of benzene χ(M) (χ(M) = 1/3($\chi_{xx} + \chi_{yy} + \chi_{zz}$)) and the tensors $\chi^{\perp}$ ($\chi^{\perp} = 1/2(\chi_{xx} + \chi_{yy})$) and $\chi^{\parallel}(\chi_{zz})$ as well as the anisotropy

[a]The symbol $\perp$ refers to the axes perpendicular to the principle rotation axis, and the corresponding values are averaged over both $\perp$ field directions. The symbol $\parallel$ refers to the principle rotation axis. The values in parentheses were obtained at the HF/6-311++G(2d,2p)//HF/6-311++G(2d,2p) level (6). The superscript B indicates the basin contributions shown in italics. The superscript H refers to the flux through the C|H surface. The superscript R refers to the flux through the C|C surface. The superscript T refers to the total current flux contribution. The superscript S (M indicates the molecule) refers to the sum of the basin and total flux contributions.

$\Delta\chi(\chi^{\parallel} - \chi^{\perp})$ are collected in Table 1. The corresponding values obtained by Keith and Bader with the 6-311++G(2p,2d) basis set are given in parentheses. It is seen that the 6-31+G(d) basis set yields values of χ(M) and $\Delta\chi$ for benzene, which are remarkably close to values obtained at the 6-311++G(2d,2p) level of theory and the experimental values. In fact, χ(M) (–53.6 cgs ppm) obtained at the 6-31+G(d) level is closer to the experimental value (–54.8) (26) than the χ(M) (–59.7) obtained with the 6-311++G(2d,2p) basis set. The $\Delta\chi$ of –68.88 calculated at the 6-31+G(d)//6-31+G(d) level of theory — it differs by 1.1 cgs ppm from the value of –67.65 obtained with the 6-311++G(2d,2p) basis set — also agrees well with the experimental value of –59.7 (27). These results are in accord with the findings of Keith and Bader who showed that there is a lack of a serious basis set dependence of the current and its derived properties obtained with the IGAIM and CSGT methods.

That molecular calculations yield the magnetic susceptibility χ(M) of benzene — and its anisotropy $\Delta\chi$ — with good accuracy at the 6-31+G(d)//6-31+G(d) level is an indication that the atomic susceptibilities — and the basin and surface components — should correlate with the values obtained by Keith and Bader with the 6-311++G(2d,2p) basis set. That this is the case is seen in Table 2 where our results along with the Keith–Bader data shown in parentheses are collected. At the 6-31+G(d)//6-31+G(d) level of theory, 95% of the value of $\Delta\chi$ (–65.22/–68.88 × 100) comes from carbon atom contributions, 75% having its origin in a current flowing from the basin of one carbon into that of its neighbour (((–9.71 – (–1.13) × 6)/–68.88) × 100); the values are 96% (–64.92/–67.65 × 100) and 77% (((–10.48 – (–1.79) × 6)/–67.55) × 100), respectively, at the 6-311++G(2p,2d) level. For a field aligned parallel to the principle axis — the ring atoms occupy the *x–y* plane — the surface terms are calculated to be 3.0 and 3.3 times the magnitude of the basin terms obtained at the 6-31+G(d) and 6-311++G(2d,2p) levels of theory, respectively. These surface terms (–9.71 at 6-31+G(d) and –10.48 at 6-311++G(2d,2p)) arise from the flux in the induced current through the interatomic surface separating the basins of the ring carbon atoms. These C|C surface terms exhibit a large anisotropy (Table 1); 8.58 and 8.69 ppm for a single carbon atom at the 6-31+G(d) and 6-311++G(2d,2p) levels of theory, respectively. That the atomic contributions calculated at the 6-31+G(d) level compare well with the data obtained with the larger basis set in our view establishes that calculations on the bicyclic compounds at the 6-31+G(d)//6-31+G(d) level will yield χ(M)

[a]The symbol $\perp$ refers to axes perpendicular to the field direction perpendicular to the plane defined by C3, C6, and C7. The symbol $\parallel$ refers to the principal rotation axes that is perpendicular to the plane defined by C3, C6, and C7. $\chi(\Omega)_{av} = \chi_b(\Omega)_{av} + \chi_f(\Omega)^{H}_{av} + \chi_f(\Omega)^{R}_{av} = (2 \times \chi^{\perp}(\Omega) + \chi^{\parallel}(\Omega))/3$; $\Delta\chi(\Omega) = \chi^{\parallel}(\Omega) - \chi^{\perp}(\Omega)$. The superscripts B, H, R, T, and S are described in Table 2. χ(M) is the sum of the hydrogen and carbon atom basin and flux contributions.

and $\Delta\chi$ and the atomic contributions to these parameters with the accuracy seen for benzene provided that a suitable separation scheme can be written.

Magnetic susceptibilities of bicyclic compounds

The tensors $\chi^{\perp}$ ($\chi^{\perp} = 1/2(\chi_{xx} + \chi_{yy})$) and $\chi^{\parallel}$ (χ_{zz})) along with the χ(M) values, and $\Delta\chi$ values of the bicyclo[3.2.1]-octa-3,6-dien-2-yl anion (**2**), the parent diene **3,** the bicyclo-[3.2.1]octa-3-en-2-yl anion (**4**), and **5**, the lithium complex of **2**, calculated with the 6-31+G(d) basis set are collected in Table 1. Three sets of calculations were carried out on **2** to determine the variation of χ_{zz} as a function of the orientation of the applied field. The field was set (*i*) perpendicular to the plane defined by C3, C6, and C7 (the highlighted atoms of **2-a1**), (*ii*) perpendicular to the plane defined by C1, C2, C3, C4, and C5 (see **2-a2**), and (*iii*) perpendicular to the plane defined by C1, C5, C6, and C7 (see **2-a3**). While the molecular susceptibilities are identical as expected, the anisotropies of **2-a2** and **2-a3** are in the region of 10 cgs ppm less than in the case of **2-a1**. In the case of benzene, the large anisotropy (67.65 cgs ppm) was taken by Bader (7) and Fleischer (8) as evidence in support of the ring current model. Because **2**, **3**, **4**, and **5** are nonplanar species and their $\Delta\chi$s cannot be compared directly with $\Delta\chi$ of benzene, our analysis is based on the variation in $\Delta\chi$ in going from **4** to **2** and **3**. It is seen that $\Delta\chi$ increases from –6.6 to –18.5 cgs ppm when the parent diene **3** is converted into **2**, and it is largest when the field is applied perpendicular to the plane defined by C3, C6, and C7. When an ethano bridge is replaced with an ethenyl bridge in going from **4** to **2**, $\chi^{\parallel}$ increases by –17.3 cgs ppm and $\Delta\chi$ increases by –21.3 cgs ppm. Given that $\Delta\chi$ is –6.7 cgs ppm ($\chi^{\perp} = -14.4$ and $\chi^{\parallel} = -21.1$) for ethene, the enhancement of the susceptibility could be taken as evidence for the existence of a ring current in **2**. When **2** complexes with Li^{+}, $\chi^{\parallel}$ increases marginally to 80.3 cgs ppm, but $\Delta\chi$ decreases to –12.8 because $\chi^{\perp}$ decreases by 7.1 cgs ppm.

To interpret the variations in the magnitudes of the tensors and $\Delta\chi$, we calculated and analysed the atomic susceptibilities partitioned into basin and surface components. Only the atomic contributions arising from the carbon atoms of **2** and **4** and the molecular parameters obtained as sums of the hydrogen and carbon atom contributions calculated with the 6-31+G(d) basis set are given in Table 3. A separation scheme, which may be obtained from the author as supplementary material, was used to obtain the basin and surface contributions. That the scheme is valid is seen in the fact that the molecular tensors obtained by summing the atomic contributions are virtually identical to the ones obtained by the standard molecular calculations. In both cases, the field is aligned parallel to the principle axis that is perpendicular to

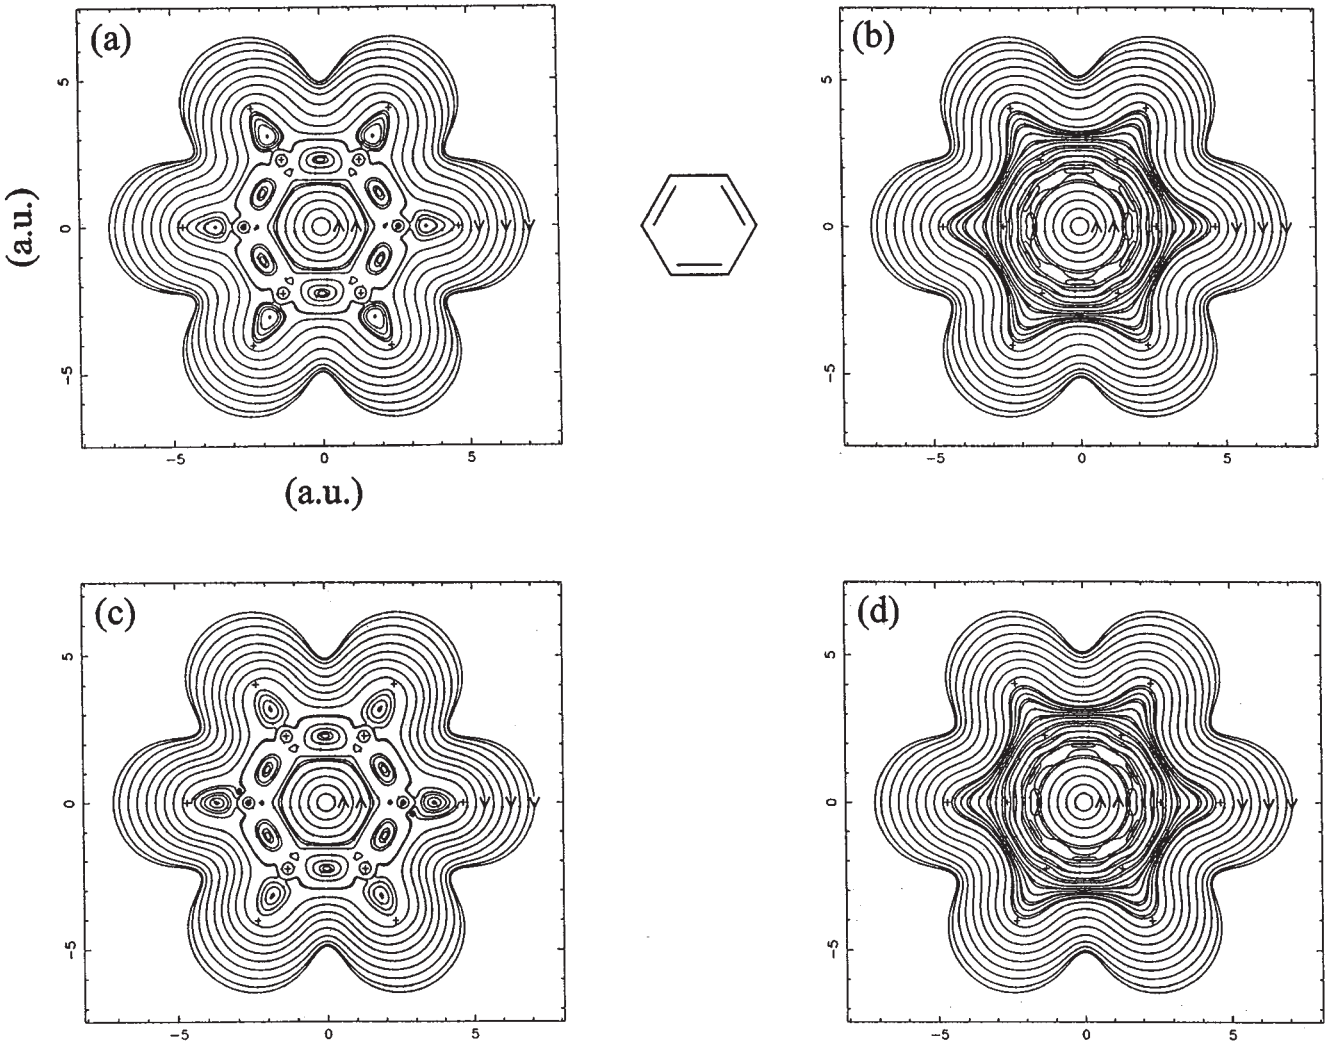
Fig. 1. Display of the vector current density of benzene: (*a*) in the molecular plane obtained at the 6-31+G(d)//6-31+G(d) level; (*b*) 0.8 au above the molecular plane obtained at the 6-31+G(d)//6-31+G(d) level; (*c*) in the molecular plane obtained at the 6-31++G(d,p)//6-31+G(d) level; (*d*) 0.8 au above the molecular plane obtained at the 6-31++G(d,p)//6-31+G(d) level.



the plane defined by C3, C6, and C7. Overall, $\Delta\chi$ and the surface flux contributions to $\Delta\chi$ ($\Sigma\Delta\chi^R$(**2**) – $\Sigma\Delta\chi^R$(**4**) = –20.03 – (–2.83) = –17.20) increase when the ethano bridge of **4** is replaced with the ethenyl bridge of **2**. The percentage contribution of the various carbon atoms to the change in the atomic surface component of χ in going from **4** to **2** are $\Delta\chi^R$(**4** to **2**)(C1 + C5)/$\Delta\Sigma\Delta\chi^R$(**4** to **2**), 7.9% (2 × (–0.75 – (–0.07))/–17.2); $\Delta\chi^R$(C2 + C4)/$\Delta\Sigma\Delta\chi^R$, 27.3% (2 × (–3.91 – (–0.05))/–17.2); $\Delta\chi^R$(C3)/$\Delta\Sigma\Delta\chi^R$, 8.3% (–1.47 – (–1.56))/–17.2); $\Delta\chi^R$(C6 + C7)/$\Delta\Sigma\Delta\chi^R$, 42.6% (2 × (–3.91 – (–1.56))/–17.2); $\Delta\chi^R$(C8)/$\Delta\Sigma\Delta\chi^R$, 13.9% ((–1.12 – (1.28))/–17.20). That the increase in the atomic surface contribution to $\Delta\chi$ in going from **4** to **2** arises predominantly from C6 + C7 (42.6%), with C2 + C4 and C3 exhibiting substantially smaller increases of 27.4 and 8.3%, respectively, establishes that a through-space ring current, usually represented as illustrated in **2-bh**, does not exist in **2** even though there is a significant exaltation of the magnetic susceptibility. The enhanced magnetic susceptibility of **2** does not arise from current flowing from the basin of one ring atom into that of a neighbour.

Current maps

To validate the current maps of **2** obtained at the 6-31+G(d)//6-31+G(d) and 6-31++G(d,p)//6-31+G(d) levels of theory, in-plane and above-the-plane (0.8 au) maps of benzene (Fig. 1) were calculated at these levels of theory and compared with those generated with the 6-311++G(2d,2p) basis by Keith and Bader (7). It is seen that both levels of theory — in this study, we plotted fewer trajectories—reproduce the important features of the in-plane and above-the-plane (0.8 au) maps of benzene obtained at the higher level of theory (7); the in-plane maps (Figs. 1(*a*) and 1(*c*)) exhibit a paramagnetic current flow inside the benzene ring, a diamagnetic flow outside the ring, and diamagnetic current loops located in the C—C and C—H bonded regions. As found at the 6-311++G(2d,2p) level of theory, for a plane displaced 0.8 au (Figs. 1(*b*) and 1(*d*)) there is an inner paramagnetic current flow bounded by an outer diamagnetic flow. Consequently, calculations at the HF/6-311++G(d,p)//HF/6-31+G(d) and HF/6-31+G(d)//HF/6-31+G(d) levels of theory can be used to map the current densities of aromatic

Fig. 2. Display of the vector current density of **2** obtained at the 6-31++G(d,p)//6-31+G(d) level: (*a*) intersecting the plane defined by C3, C6, and C7; (*b*) intersecting the plane 0.8 au below the plane defined by C3, C6, and C7; (*c*) intersecting the plane 0.8 au above the plane defined by C3, C6, and C7; level; (*d*) intersecting the plane defined by C1, C2, C3, C4, and C5; (*e*) intersecting the plane 0.8 au above the plane defined by C1, C2, C3, C4, and C5; (*f*) intersecting the plane defined by C1, C2, C3, C4, and C5 of 4; (*g*) intersecting the plane 0.8 au above the plane defined by C1, C2, C3, C4, and C5 of 4.

species. Because **2** is nonplanar and the induced current density depends on the orientation of the applied field, current maps were obtained with the field applied perpendicular to the plane defined by C3, C6, and C7 (see **2-a1**) and perpendicular to the plane defined by C1,C2, C3, C4, and C5 (see **2-a2)** at the HF/6-31++G(d,p)//HF/6-31+G(d) level. Owing to the complexity of the maps, partial plots are provided. Figure 2(*a*) is a plot of the vector current density of **2** intersecting the plane defined by C3, C6, and C7; Figure 2(*b*) is a display of the vector current density of **2** intersecting the plane 0.8 au below the plane defined by C3, C6, and C7, and 2(*c*) is a display of the vector current density of **2** intersecting the plane 0.8 au above the plane defined by C3, C6, and C7. Figures 2(*a*) and 2(*b*) show clearly that there is no benzene-like ring current in the C3, C6, and C7 plane or 0.8 au below it as would be expected if **2** is a bishomoaromatic species represented by **2-bh**. Figure 2(*d*) is a display of the vector current density of **2** intersecting the plane defined by C1, C2, C3, C4, and C5, and Fig. 2(*e*) is a display of the vector current density of **2** intersecting a plane 0.8 au above the plane defined by C1, C2, C3, C4, and C5. While Figs. 2(*c*–*e*) exhibit a paramagnetic circulation within C1, C2, C3, C4, and C5, this feature appears to be common to the bicyclo[3.2.1]octyl ring system as seen in the displays of the vector current densities of **4** which is not homoaromatic: Figure 2(*f*) is a display of the vector current density in the plane defined by C1, C2, C3, C4, and C5, and Fig. 2(*g*) is the vector current density intersecting the plane 0.8 au above the plane defined by C1, C2, C3, C4, and C5.

Conclusions

That the molecular susceptibility, atomic contributions (RHF/6-31+G(d)//6-31+G(d) level), and vector current densities (6-31++G(d,p)//6-31+G(d) and 6-31+G(d)//6-31+G(d) levels) calculated for benzene correlate well with the results obtained by Keith and Bader (6, 7) with the 6-311++G(2d,2p) basis indicates that these magnetic response properties can be obtained with good accuracy for aromatic compounds at a modest level of theory. Studies on the bicyclo[3.2.1]- octa-3,6-dien-2-yl anion (**2**) and bicyclo[3.2.1]oct-3-ene-2-yl anion (**4**) show that the magnetic susceptibility exaltation found in going from **4** to **2** is due primarily to an increase in atomic surface contributions to $\Delta\chi$ of the ethenyl bridge carbons C6 and C7 (42.6%) with C2 + C4 and C3 exhibiting substantially smaller increases (27.4 and 8.3%, respectively). This result, in conjunction with the nature of the vector current density maps of **2** and **4**, provide evidence that **2** does not possess a ring current as depicted in the usual representation of "bishomoaromatic" **2**.

General acid-catalyzed addition of methanol to (*E*)-*N*-benzylideneanilines

Sadjia Bennour and Jean Toullec

Abstract: The reaction of equilibrium addition of methanol (α-amino ether formation) to benzylideneanilines ($C_6H_5CH{=}NC_6H_4Y$, with Y = H (**1a**), 3-Cl (**1b**), 3-NO_2 (**1c**), 4-CN (**1d**), and 4-NO_2(**1e**)) in methanol is shown to be general acid-catalyzed in carboxylic acid buffers. The mechanism involves fast iminium ion formation followed by base-assisted addition of methanol. The α Brønsted exponents are in the 0.67–0.88 range, and α increases with the electron-withdrawing ability of Y. The same mechanism is valid for $MeOH_2^+$-catalysis, meaning that two solvent molecules are involved in the addition process, one of them playing the role of base. The equilibrium constant, *K*, is increased by electron-withdrawing substituents, log *K* depending linearly on the σ^- substituent parameters. The substituent effects on the forward and reverse catalytic rate constants are analyzed by means of the log $k = \rho^n\sigma^n + \rho^r(\sigma^- - \sigma^n)$ + constant (Young–Jencks) equation. For carboxylic acid catalysis, the ρ^n and ρ^r parameters are in keeping with ca. half C—O bond forming or breaking at the transition state. The catalytic rate constants and α exponent for elimination of $ClCH_2CH_2OH$ in methanol from the $C_6H_5CH(OCH_2CH_2Cl)NH(4\text{-}CNC_6H_4)$ chloroethyl adduct are compared with those for the elimination of methanol from $C_6H_5CH(OCH_3)NH(4\text{-}CNC_6H_4)$. The chloromethyl group makes the reaction slower and α lower. This indicates that proton transfer is a little ahead of C—O bond cleavage at the transition state. Y substituent effects, α values, and the effects of the CH_2Cl group are interpreted on the basis of a More O'Ferrall – Jencks diagram.

Key words: imine, free energy linear relationship, nucleophilic addition, More O'Ferrall – Jencks diagram, Schiff base.

Résumé : On montre qu'en milieu méthanolique la réaction équilibrée d'addition du méthanol sur les benzylidèneanilines ($C_6H_5CH{=}NC_6H_4Y$, avec Y = H (**1a**), 3-Cl (**1b**), 3-NO_2 (**1c**), 4-CN (**1d**) et 4-NO_2(**1e**)) est soumise à une catalyse acide générale lorsqu'elle s'effectue en présence de tampons d'acides carboxyliques. Le mécanisme implique la formation d'ions iminium dans un prééquilibre rapide suivi d'une addition du méthanol assistée par la base conjuguée de l'acide. Les exposants α de Brønsted sont compris entre 0.67 et 0.88 et augmentent avec le caractère électroattracteur de Y. Le même mécanisme est opérant pour la catalyse par les ions $MeOH_2^+$; ceci signifie que deux molécules de solvant sont impliquées dans le processus d'addition, l'une jouant le rôle de base. La constante d'équilibre *K* augmente avec le caractère électroattracteur de Y, ceci se traduisant par une corrélation linéaire entre log *K* et les paramètres de substituant σ^-. Les effets de substituant sur les constantes catalytiques pour les réactions directes et inverses sont analysés au moyen de l'équation de Young et Jencks: log $k = \rho^n\sigma^n + \rho^r(\sigma^- - \sigma^n)$ + constante. Pour la catalyse par les acides carboxyliques, les paramètres ρ^n et ρ^r sont en accord avec un degré de formation ou de coupure de la liaison C—O environ moitié à l'état de transition. Les constantes de vitesse catalytiques ainsi que l'exposant α de Brønsted observés pour l'élimination de $ClCH_2CH_2OH$ dans le méthanol à partir de l'adduit chloroéthylique $C_6H_5CH(OCH_2CH_2Cl)NH(4\text{-}CNC_6H_4)$ sont comparés à ceux de l'élimination du méthanol à partir de l'adduit méthylique $C_6H_5CH(OCH_3)NH(4\text{-}CNC_6H_4)$. Le groupe chlorométhyle provoque un ralentissement de la réaction et une diminution de α, ce qui indique que le transfert du proton à l'état de transition est légèrement en avance par rapport à la coupure de la liaison C—O. Les effets du substituant Y, les valeurs de α et les effets du groupe CH_2Cl sont interprétés sur la base d'une diagramme de More O'Ferrall – Jencks.

Mots clés : imine, relation linéaire d'enthalpie libre, addition nucléophile, diagramme de More O'Ferrall – Jencks, base de Schiff.

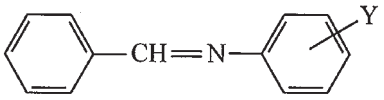
Introduction

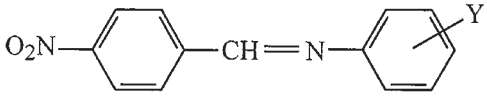
Schiff bases and their derivatives play an important role in many fields of organic chemistry, including biological systems and liquid crystals. However, except studies of Schiff base formation (1, 2) and hydrolysis (1, 3), there is relatively little work dealing with the mechanism of reactions involving these compounds, especially with nucleophilic addition to the imino group. Although the C=N group is isoelectronic with the carbonyl group, the shortage of data for alcohol addition (α-amino ether (α-AE) formation), eq. [1], a reaction similar to the well-documented hemiacetal formation, eq. [2], is striking.

[1] 
[2]

Until 1974, only a few reports had paid attention to α-AE formation (4, 5). At that time, Ogata and Kawasaki (6) examined the addition of methanol and other aliphatic alcohols to benzylideneanilines, **1**, and to *N*-(4-nitrobenzylidene)-anilines, **2**, both essentially substituted at the aniline residue. These authors showed that this reaction is induced by alkoxide attachment to the C=N group and, for *meta* and π-electron-releasing Y substituents, that the logarithm of the equilibrium constant, *K* (eq. [3]) depends linearly on the σ^+ Brown and Okamoto parameters (7), this because of the conjugation between the π orbitals of C=N and the π system of C_6H_4Y.



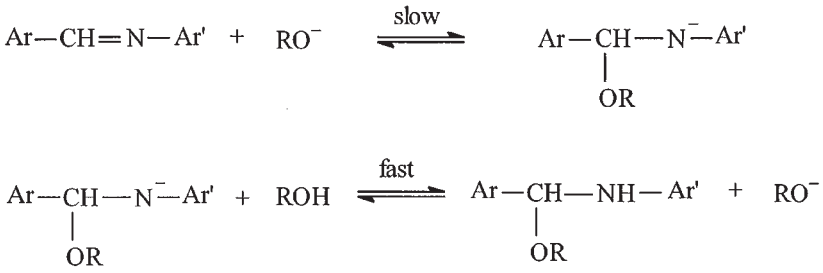
1



2

[3] 
In contrast, the second-order rate constant for the forward reaction depends on Hammett's σ constants with a large and positive ρ value. These data and inverse kinetic solvent isotope effects were interpreted in terms of the mechanism shown in Scheme 1.

Scheme 1.



In a fairly recent paper (8), we examined the substituent effects on the equilibrium and rate and rate constants for methoxide ion-catalyzed methanol addition to **3**. This work was mainly focussed on a dissection of the polar and resonance substituent effects in terms of two-parameter free energy relationships.

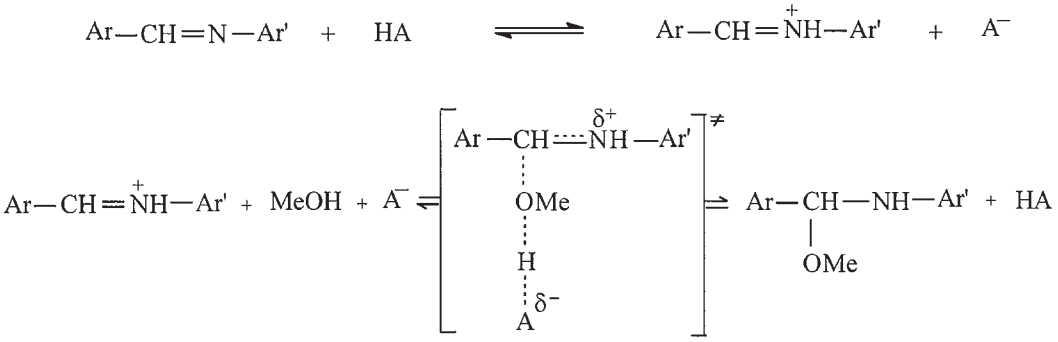
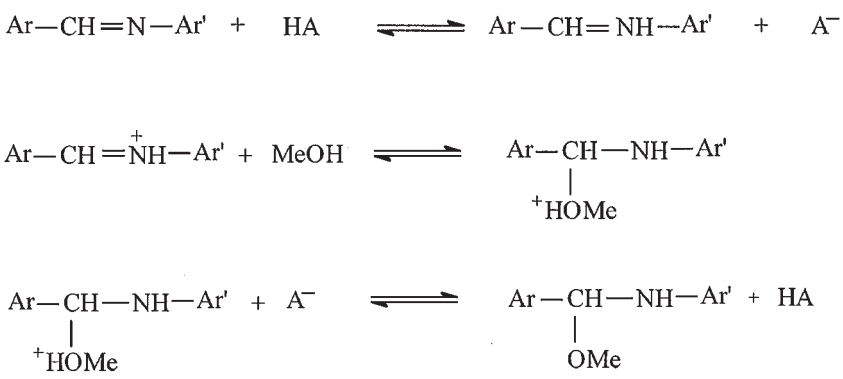
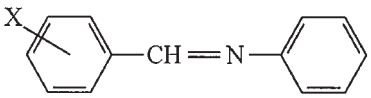
Scheme 2.



Scheme 3.





3

Studies of general acid- and base-catalyzed hemiacetal formation and hydrolysis have played an important role in the development of the theories dealing with concerted mechanisms (9–20). In view of the analogy of Schiff bases (and corresponding iminium ions) with carbonyl compounds, we thought that a general acid-catalyzed mechanism according to Scheme 2 can occur for alcohol addition to the former compounds. This mechanism can be energetically more favorable than the more straightforward specific acid-catalysis mechanism shown in Scheme 3 because of the short lifetimes of the *O*-protonated α-AE intermediates. We therefore examined the rates of methanol addition to **1** in methanolic buffer solutions.

One of the interesting aspects of the reaction of alcohol addition to **1** lies in the possibility of changing substrate electrophilicity by substituents within the aniline residue. Moreover, studies of the effects of Y on the rate constants make it possible to examine the changes in the nitrogen charge on going from the starting materials to the transition states. Since the changes in substrate electrophilicity are expected to be large when Y is a π-electron-withdrawing group, we examined the kinetic behavior with Y = H (**1a**), 3-Cl (**1b**), 3-NO_2 (**1c**), 4-CN (**1d**), and 4-NO_2 (**1e**) in formic, acetic, benzoic, chloroacetic, and cyanoacetic buffers.

Since the equilibrium constants are not known (except for **1a** in methanol (8) and for **1b** and **1c** in methanol–acetonitrile mixture (90:10 v/v) (6)), the values of *K* were measured for **1a**–**e**. As in Ogata and Kawasaki's (6) work, the measurements were carried out in sodium methoxide solutions. The data on *K* are interesting, since the π-electron-withdrawing substituents can be thought to cause large variations of the equilibrium constant by stabilization of the α-AE form. The free energy relationships are expected to include π-electron-withdrawing resonance contributions instead of the π-electron-donating resonance contributions accounted for by Ogata and Kawasaki (log $K - \sigma^+$ plot) in the absence of π-electron-withdrawing substituents, but in the presence of π-electron-donating groups.

Combination of rate and equilibrium data for acid-catalyzed α-AE formation provides a way to calculate the rate constants for acid-catalyzed α-AE cleavage. In this latter process, the charge on the oxygen atom at the transition state depends on the relative degrees of *O*-protonation and C—O bond cleavage: it is positive if *O*-protonation is ahead of C—O bond breaking; it is negative in the reverse situation. It follows that replacing the methyl group by an electron-withdrawing group is highly relevant for mapping the charges of the transition state. By analogy with previous work in the case of hemiacetal breakdown (12, 13), we ex-

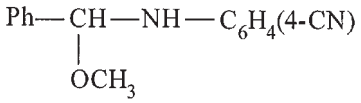
amined the rates of decomposition of **4** in methanol buffer solutions (**4** being preformed in 2-choroethanol), by comparison with those for the breakdown of **5**.



5

Results

Equilibrium constants

The equilibrium constants for the addition of methanol to **1a** has been previously reported (8). For **1b**, K was calculated by eq. [4] (where $[\alpha\text{-AE}]_{eq}$ and $[\text{imine}]_{eq}$ are the equilibrium molarities of α-AE and imine, respectively, at equilibrium) from the absorbances at 325 nm before (A_0) and after (A_∞) equilibration in sodium methoxide solutions [(0.4–3.2) × 10^{-2} M].

$$[4] \qquad K = [\alpha\text{-AE}]_{eq}/a_m[\text{imine}]_{eq} = (A_0 - A_\infty)/a_m A_\infty$$

Under these conditions, the α-AE formed is expected not to absorb, because its absorbance spectrum should roughly correspond to the sum of those for 3-chloroaniline and benzene, and A_∞ and $A_0 - A_\infty$ are proportional to concentrations of free imine and α-AE, respectively. The activity of methanol a_m (a_m = 1 for pure methanol) was taken as the mole fraction of methanol (ca. 0.99) after addition of small amounts of a dioxane solution of **1b**. Since the above method cannot be used for **1c** and **1e** because the spectra of the α-AEs and benzylideneanilines should overlap, we used an indirect method which consists in measuring (at 318 and 325 nm, respectively) the initial, A'_0, and final, A'_∞, absorbances after addition of small amounts of an equilibrated solution of **1c** or **1e** in methanolic acetic acid buffer (ca. 10^{-2} M) to a solution of *N*,*N*-dimethylethylenediamine (DMEDA) (0.04 M) and its monohydrochloride salt (0.04 M). Under these conditions, free imine is quantitatively transformed in **6** (21) by the transimination process shown in Scheme 4. Since the transimination reaction is ca. 10^3 times faster (intramolecular catalysis) than the imine–AE equilibration process in DMEDA buffer, and since **6** does not absorb at the wavelengths at which the measurements were conducted, A'_0 and A'_∞ can be expressed by eqs. [5] and [6], and K is given by eq. [7].

$$[5] \qquad A'_0 = [\varepsilon_{Im}(1 - x_\infty) + \varepsilon_{Add}x_\infty][\text{Im}]_0$$

Table 1. Substituent effects on α-amino ether formation equilibrium constants from **1a**–**e**.[a]

[c]Ogata and Kasawaki data (6).

$$[6] \qquad A'_\infty = [\varepsilon_{An}(1 - x_\infty) + \varepsilon_{Add}x_\infty][\text{Im}]_0$$

$$[7] \qquad K = \frac{[\text{Im}]_0(\varepsilon_{Im} - \varepsilon_{An}) - (A'_0 - A'_\infty)}{(A'_0 - A'_\infty)a_m}$$

In these equations, x_∞ is the mole fraction of imine transformed to adduct, $[\text{Im}]_0$ is the initial concentration of **1c** or **1e**; ε_{Im}, ε_{Add}, and ε_{An} are the molar absorption coefficients of imine, α-AE, and aniline, respectively. The K values were calculated as the slopes of the plots of $[\text{Im}]_0(\varepsilon_{Im} - \varepsilon_{An}) - (A'_0 - A'_\infty)$ vs. $(A'_0 - A'_\infty)a_m$ from the absorbances measured for various initial imine concentrations. The two methods (at 340 and 330 nm, respectively) were used in the case of **1d**; the same results were obtained. Table 1 lists the values of K as well as those calculated from data in methanol–acetonitrile (90:10 v/v) (a_m = 0.92) either from Ogata and Kawasaki's paper (**1a**–**c**) or from new measurements (**1d**). The value of 0.55 calculated for **1c** from Ogata and Kawasaki's data is obviously much too small because of errors due to neglecting the absorbance of the adduct. The equilibrium constants have been confirmed by ^{1}H NMR spectroscopy in CD_3OD solutions containing ca. 10^{-3} M CD_3ONa. For instance, for **1d** the ^{1}H NMR spectrum shows a peak at δ 5.61 ppm, corresponding to the proton of the -C*H*(OMe)- group, which is about three times larger than the -C*H*=N- peak at δ 8.54 ppm.

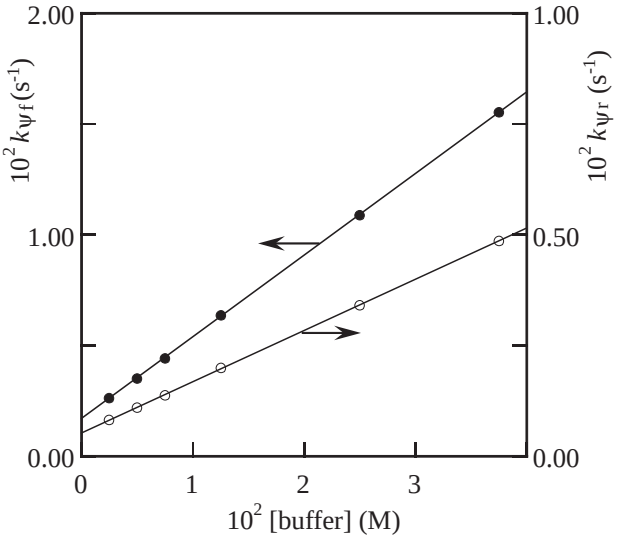
Fig. 1. Dependence of the forward ($k_{\psi f}$) and reverse ($k_{\psi r}$) first-order rate constants on 1:1 sodium acetate – acid buffer concentration (buffer ratio = 1) for α-AE formation by addition of methanol to **1d** at 25°C.



In the case of **1d**, the ΔH^0 and ΔS^0 values were calculated from eq. [8],

$$[8] \quad \ln (K/[\mathrm{MeOH}]^*) = -\Delta H^0/RT + \Delta S^0/R$$

where [MeOH]* is the concentration in pure solvent at 25°C (24.49 M), by plotting ln (K/[MeOH]*) against 1/*T*. The results obtained (ΔH^0 = –6.06 kcal mol^{-1} (stand. dev. = 0.15 kcal mol^{-1}) and ΔS^0 = 24.4 cal mol^{-1} K^{-1} (stand. dev. = 0.5 cal. mol^{-1} K^{-1}) are in disagreement with Ogata and Kawasaki's data (e.g., ΔH^0 = 1.5 kcal mol^{-1} and ΔS^0 = 0 for **2** with Y = 3-NO_2), but are in excellent agreement with those expected by reference to hemiacetal formation (22) (e.g., ΔH^0 = –5.7 kcal mol^{-1} and ΔS^0 = 23 cal mol^{-1} K^{-1} for 4-nitrobenzaldehyde hemiacetal formation for which the equilibrium constant is 3.2 at 25°C). Because of the strong analogy between the two reactions, it can be thought that the ΔS^0 and ΔH^0 values for α-AE and hemiacetal formation should approximately be the same for similar reaction driving forces.

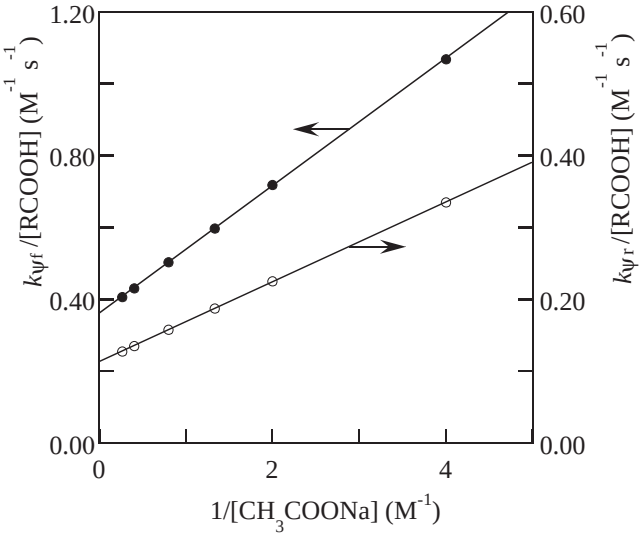
Equilibrium rate constants for methanol addition

Kinetic runs were observed spectrophotometrically for **1a**–**e** at wavelengths of 330, 325, 318, 330, and 325 nm, respectively, in buffer methanolic solutions for various RCOOH and RCOONa concentrations (R = H, CH_3, C_6H_5, CH_2Cl, and CH_2CN). The experimental curves agree with eq. [9],

$$[9] \quad A_t - A_\infty = (A_0 - A_\infty)e^{-k_\psi t}$$

where k_ψ is the sum of the forward, $k_{\psi f}$, and reverse, $k_{\psi r}$, pseudo-first order rate constants for incomplete α-AE formation and breakdown. Whatever Y in **1**, the observed rate constants $k_{\psi f}$ [= $k_\psi Ka_m/(1 + Ka_m)$] and $k_{\psi r}$ [= $k_\psi/(1 + Ka_m)$] were observed to increase linearly with buffer concentration at constant buffer ratio (*r*) and constant ionic strength (I_c = 0.0375 M; NMe_4Br) (see Fig. 1 in the case of **1d** for [sodium acetate]/[acetic acid] = 1)). The $k_{\psi f}$ and $k_{\psi r}$ rate constants were also observed to depend linearly on [RCOOH] at constant carboxylate ion concentration, with slope decreasing when [$RCOO^-$] increased. Such a behavior is typical of general-acid catalysis involving RCOOH and lyonium ion. The rate constants $k_{\psi f}$ and $k_{\psi r}$ can be expressed by eq. [10] (*j* = f or r),

Fig. 2. Plots of the slopes of $k_{\psi f}$ (●) and $k_{\psi f}$ (○) vs. acetic acid concentration against the reciprocal of sodium acetate concentration for formation and breakdown of **1d** methanol adduct.



$$[10] \quad k_{\psi j} = k_j^{\mathrm{MeOH_2^+}}[\mathrm{MeOH_2^+}] + k_j^{\mathrm{RCOOH}}[\mathrm{RCOOH}] + k_0$$

where k_0 is the rate constant in the absence of buffer, $k_j^{\mathrm{MeOH_2^+}}$ and k_j^{RCOOH} are the catalytic rate constants relative to $MeOH_2^+$ and RCOOH, respectively. [$MeOH_2^+$] can be expressed by eq. [11],

$$[11] \quad [\mathrm{MeOH_2^+}] = \frac{K_a[\mathrm{RCOOH}]}{[\mathrm{RCOO^-}]y_\pm^2}$$

where K_a is the acidity constant of RCOOH at I_c = 0; $y_\pm$ is the mean activity coefficient for the $RCOO^-$ and Na^+ ions at I_c = 0.0375 M. Since ion pairs are not expected to be formed in significant amounts under the conditions used (23), $y_\pm$ can be expressed by the Debye–Hückel equation, eq. [12],

$$[12] \quad -\log y_\pm = \frac{A\sqrt{I_c}}{1 + Bq\sqrt{I_c}}$$

where *A* = 1.901 and *B* = 5.1 M^{-1} nm^{-1} (the Debye–Hückel parameters for methanol at 25°C), and *q* is the Bjerrum critical distance ($e^2/2Dk_BT$), which has the value 0.858 nm in this system (24). At I_c = 0.0375 M, $y_\pm$ = 0.632. Since the k_0 constants were observed to be negligible, in agreement with previous data (8), eq. [10] can be written as in eq. [13].

$$[13] \quad k_{\psi j} = \left(\frac{K_a}{[\mathrm{RCOO^-}]y_\pm^2} k_j^{\mathrm{MeOH_2^+}} + k_j^{\mathrm{RCOOH}} \right)[\mathrm{RCOOH}]$$

As illustrated by Fig. 2, the $K_a k_j^{\mathrm{MeOH_2^+}}/y_\pm^2$ and k_j^{RCOOH} coefficients were determined by plotting $k_{\psi j}$/[RCOOH] against 1/[$RCOO^-$]. The k_j^{RCOOH} data are listed in Table 2 as well as

the $k_j^{MeOH_2^+}$ rate constants, calculated when K_a and the estimated value of $y_\pm$ are accounted for. The acidity constants K_a were measured by UV-visible absorption spectroscopy, as described in Experimental Section, by reference to 2,4-dinitrophenol and (or) 2,5-dinitrophenol.

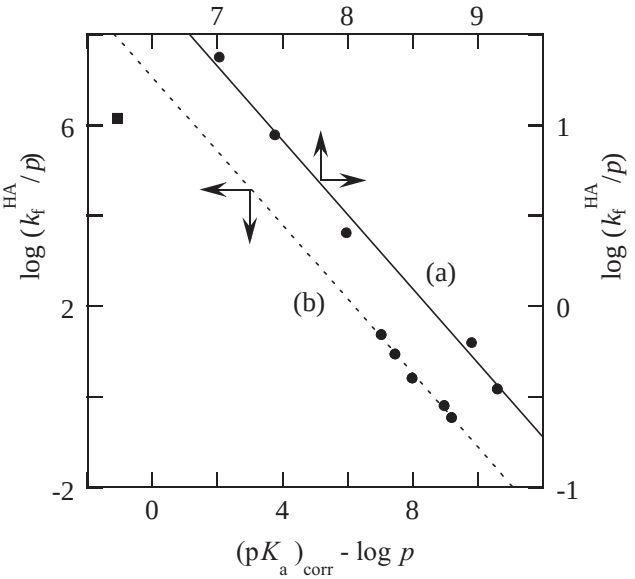
When deriving the catalytic rate constants, it was implicitely assumed that the contribution of the catalytic terms associated with H_3O^+ is negligible, even though the H_3O^+ ions are formed — even in fairly dry methanol — in significant amounts as the result of the proton exchange equilibrium (eq. [14] where K_r = 4.94 M^{-1} at 25°C (25)) between methanol and water.

[14] $$MeOH_2^+ + H_2O \underset{}{\overset{K_r}{\rightleftharpoons}} H_3O^+ + MeOH$$

As already done in similar situations (26), it can be easily shown that the presence of H_3O^+ should not make any significant influence on k_ψ. It was checked that additions of water until concentrations as large as 0.22 M (0.5% w/w) do not cause not any change in the observed rate constants.

Figure 3 shows the Brønsted plot of log k_r^i and log k_f^i (with i = RCOOH or $MeOH_2^+$; statistically corrected by a factor of 2 in the case $MeOH_2^+$) against pK_a^i for **1d**, either (*i*) for carboxylic acids only or (*ii*) including the $MeOH_2^+$ points. Similar Brønsted plots have been plotted for **1b** (4 points), **1c** (5 points), and **1e** (6 points). Table 3 lists the α Brønsted coefficients derived for carboxylic acid general catalysis. Since $k_f^i = Kk_r^i$ similar Brønsted coefficients can be calculated from the k_f^i rate constants.

Fig. 3. Brønsted plots for general acid-catalyzed equilibrium addition of methanol to **1d** in methanol; (●) carboxylic acids; (■) lyonium ion; (*a*) not including the points corresponding to the lyonium ion; (*b*) including the lyonium ion points.



Rate constants for the breakdown of 4 in methanol

Figure 4 shows the variations of absorbance at 330 nm when 25 μL of an equilibrated solution of **4** (formed by allowing a mixture of **1d** (10^{-2} M), sodium acetate (0.05 M), and sodium acetate (0.05 M) to equilibrate at 5°C for 12 h in

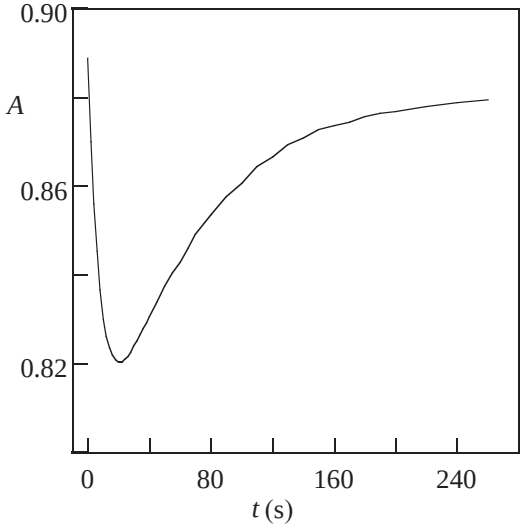
2-chloroethanol) are injected in methanolic acetic acid buffer. The initial absorbance is significantly lower than that expected (ca. 5.9) if **1d** were completely on the imino form. This means that ca. 80% of **1d** had been converted to the 2-chloroethanol adduct in the bulk solution. The initial decreasing curve corresponds to methanol addition to the remaining amounts of free **1d**. The rate constant for this process is close to that observed for the addition of methanol to **1d** under similar conditions. The second process, corresponding to exponential increase of absorbance, is attributed to slow breakdown of the chloroethanol adduct followed by more rapid formation of the methanol adduct according to Scheme 5. The final absorbance corresponds to the free imino form in equilibrium with the α-amino methoxy ether.

The rate constants $k_{\psi b}$ for the breakdown of **4** in methanolic carboxylic buffer solutions (I_c = 0.0375 M; Me_4NBr) were calculated from the two-exponential absorbance curves as described previously in the case of methanol addition to α-methoxystyrenes followed by acetal breakdown (26). The constant $k_{\psi b}$ was observed to agree with eq. [15],

Fig. 4. Kinetic behavior for beakdown of preformed 2-chloroethanol adduct **4**. Methanol; [HCOOH] = 0.025 M; [HCOONa] = 0.025 M. 25°C.



$$[15] \quad k_{b\psi} = \left(\frac{K_a}{[RCOO^-]y_\pm} k_b^{MeOH_2^+} + k_b^{RCOOH} \right) [RCOOH]$$

where $k_b^{MeOH_2^+}$ and k_b^{RCOOH} are the catalytic constants relative to $MeOH_2^+$ and RCOOH, respectively, for the breakdown of the chloroethyl adduct. The $k_b^{MeOH_2^+}$ and k_b^{RCOOH} are listed in Table 4. The slope of the Brønsted plot between log k_b^{RCOOH} and pK_a^{HA} is 0.58.

Discussion

Substituent effects on the equilibrium constant

Figure 5 shows the plot of log *K* against the σ^n parameters (27). The large positive deviations observed for Y = 4-CN (**1d**) and 4-NO_2 (**1e**) from the straight line defined by the other substituents can be attributed to stabilization of the adducts by conjugation of the lone pair of the nitrogen atom with the substituted ring. Such a conjugation is represented by Scheme 6 in the case of **1d** derivative. Figure 5 also shows that a good straight line is observed when the σ^- parameters (28) are used to account for the π-electron-withdrawing effects. The ρ^- value is 1.81 ± 0.10 (correlation coefficient = 0.9994).

As thoroughly discussed in previous papers (8, 29), "direct resonance effects" of substituted aromatic rings and ring

Scheme 6.

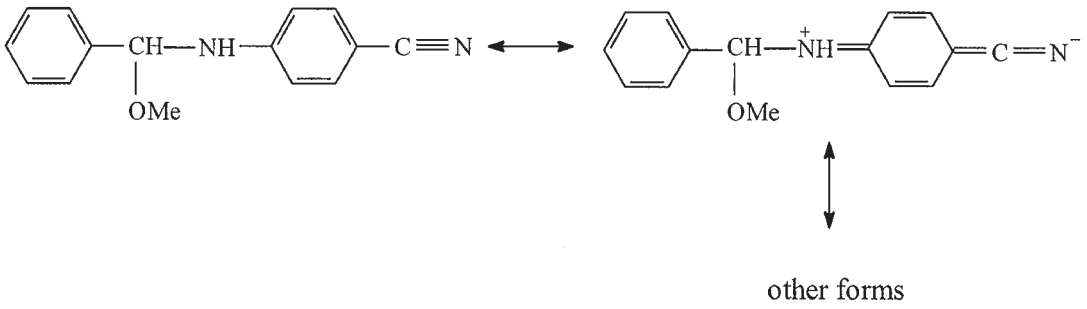

Fig. 5. Plots of the decimal logarithm of the equilibrium constant for the addition of methanol to **1a–e** against σ^n (●) and σ^- (○) substituent parameters.

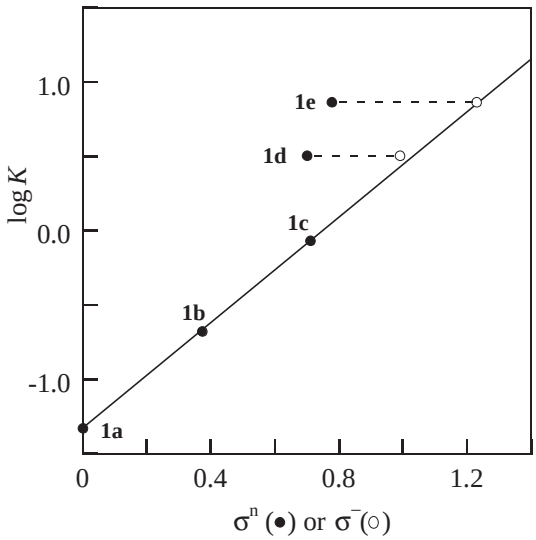


polar effects (including the "resonance-induced polar effect") can be conveniently separated by using eq. [16].

[16] $\log K$ (or $\log k$) = $\rho^n\sigma^n + \rho^r(\sigma^- - \sigma^n)$ + constant

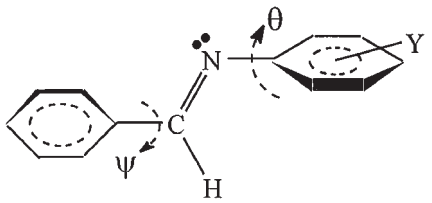
This equation is similar to that suggested by Young and Jencks (30) (and advocated by various authors (17, 29, 31)) in the case of π-electron-donating stabilization of one of the states of the reaction (starting materials, products, or transition state) and is strongly analogous to the Yukawa–Tsuno–Sawada equation (eq. [17]) (32), where the σ parameters are adjusted to account for the duality of the substituent effects.

[17] $\log K$ (or $\log k$) = $\rho^n[\sigma^n + r^-(\sigma^- - \sigma^n)]$ + constant

As also emphasized by Young and Jencks, eq. [16] is preferable because the ratios of the ρ^n or ρ^r values for forward and reverse rate constants correspond to the ρ^n or ρ^r values for full equilibrium. The r^- parameter in eq. [17] equals ρ^r/ρ^n, but its interpretation for the forward and reverse reactions is less straightforward.

For α-AE formation, the $\log K - \sigma^-$ relationship means that ρ^n and ρ^r are approximately equal (a two-parameter treatment gives $\rho^n = 1.79 \pm 0.20$ and $\rho^r = 1.86 \pm 0.36$). These values are lower than for anilinium ion deprotonation ($\rho^n = \rho^r = 2.8$ in water (23); $\rho^n = 3.5$ and $\rho^r = 2.8$ in nitromethane if only the electron-withdrawing substituents are taken into account (33)). The relatively low ρ^r value is probably due to some compensation of the effects on α-AE energy by π-electron-withdrawing substituents effects on the stability of the imino form. It is well-accepted from IR and Raman data (34), UV-visible absorption spectra (35), X-ray diffraction (36), electron-diffractron spectroscopy (37), NMR data (38), and calculations (39) that the aniline ring in (*E*)-benzylideneanilines is twisted (Fig. 6) by a dihedral angle θ (usually significantly larger than 45° when Y is π-electron-demanding) because of a balance between resonance and steric effects, this geometry allowing some interactions of the π orbitals of the aniline ring with the nitrogen lone pair. In contrast, ρ^n looks rather high in view of the charge neutrality of the species involved. These high polar effects stem probably from the large dipole–dipole interactions between the aniline ring and the C=N group.

Fig. 6. Twisted conformation of (*E*)-*N*-benzylideneanilines.

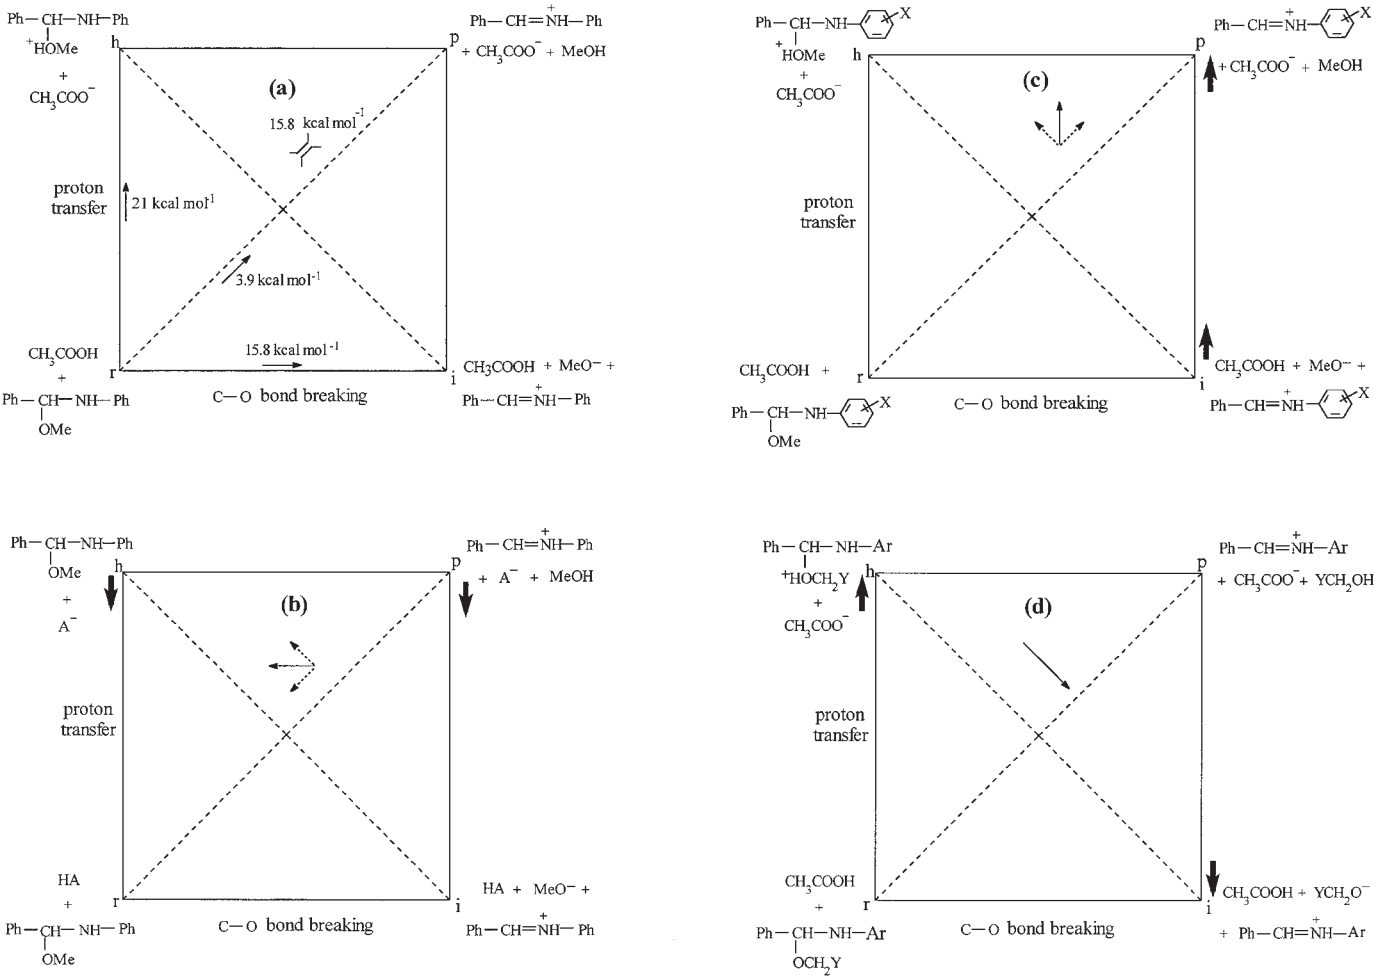


More O'Ferrall – Jencks diagram

The α Brønsted exponents and the substituent effects observed on general acid-catalyzed breakdown (or formation) of α-AEs in methanol can be examined on the basis of the More O'Ferrall – Jencks diagram (40, 41) shown in Fig. 7*a*. This diagram, which is similar to those suggested for general acid- and base-catalyzed breakdown (or formation) of hemiacetals (12–20), shows the different possibilities of mechanism for iminium ion intermediate formation from starting materials, depending on the sequence of C—O bond cleavage and O—H bond formation (proton transfer) in the presence of acids. If the reaction route follows the left edge and top of the diagram, via the upper left corner, protonation of the oxygen atom of the adduct occurs first in a fast preequilibrium, and the reaction is expected to be specific acid-catalyzed. If the reaction follows the bottom and the right edge of the diagram, C—O bond breaking occurs first, and the reaction is not expected to be acid-catalyzed, since proton transfer from acids to the methoxide ion would be fast. General acid-catalysis should occur when the mechanism corresponds to that shown in Scheme 2 with C—O bond breaking and proton transfer occuring concertedly.

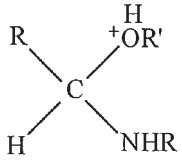
© 1999 NRC Canada

Fig. 7. More O'Ferrall – Jencks diagram for the acid-catalyzed breakdown of α-AEs. (*a*) Free energy labelling for acetic acid-catalyzed methanol addition. (*b*) Changes in reaction coordinates associated with a change (acidity increase) in general acid catalyst. (*c*) Changes reaction coordinates associated with a change in aniline ring substituent (increase in electron-withdrawing ability). (*d*) Changes reaction coordinates induced by substitution of the methyl group of methyl α-AE **5** by the chloroethyl group. Broken arrows parallel to the rp and ih diagonals represent Hammond and perpendicular effects, respectively. Upward and downward bold arrows correspond, respectively, to free energy increase and decrease.



This mechanism is energetically more favorable than the two stepwise mechanisms because the formation of the h or i high energy intermediates is avoided.

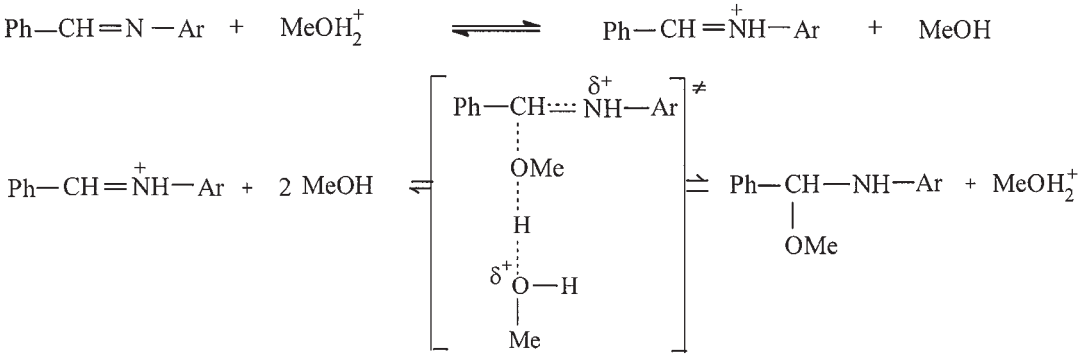
In a way similar to that described previously in the case of hemiacetal breakdown (20), the standard Gibbs free energy differences, $G_h^0 - G_r^0$, $G_i^0 - G_r^0$, and $G_p^0 - G_r^0$ between corners h, i, and p, and starting materials can be calculated by combining the free energy changes for α-EA formation, iminium ion and α-EA protonation, carboxylic acid dissociation, and methanol autoprotolysis. In the case of **1a**, the pK_a value of the corresponding iminium ion (ca. 4) was taken as 4.0 from (8), and that for the protonated methanol adduct was estimated as –6 on the basis of literature data (measured or estimated) on the pK_a of protonated ethers or hemiacetals in water. (For doing so, the pK_a for protonated ethers (42) and hemiacetals (20*b*) were plotted against the Charton σ_I values (43) of the groups attached to the oxygen atom, the σ_I value for the PhCH(NHPh) was estimated as 0.13, and the difference in solvants was neglected, since it is usually observed that the pK_a of unit-charged acids do not differ much on going from water to methanol.) For the acetic acid-catalyzed addition of methanol to **1a**, the $G_h^0 - G_r^0$, $G_i^0 - G_r^0$, and $G_p^0 - G_r^0$ free energy differences were calculated as 21, 15.8, and 3.9 kcal mol^{-1}, respectively. Since, $\Delta G^{\neq}$ = 15.8 kcal mol^{-1}, the transition state for α-AE breakdown lies below corner h and at about the same energy as corner i. The concerted mechanism is obviously more favorable than the two-step mechanism corresponding to specific acid catalysis (sequence r → h → p). It is enforced because of the high energy of the protonated α-AE intermediate **7** in the specific acid-catalysis pathway would make its lifetime too short for this species to be involved as an intermediate. The



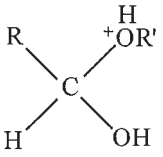
7

© 1999 NRC Canada

Scheme 7.



situation is analogous to that found in the case of acid-catalyzed hemiacetal breakdown (12–20), for which the conjugate acid (**8**) is too short-lived for being intermediately formed. The concerted mechanism is also more favorable than that corresponding to the r → i → p sequence, since the i → p step would require a small but nonnegligible energy of activation.



8

Similar estimates can also be done for $MeOH_2^+$ catalysis. In the case of **1a**, the $G_h^0 - G_r^0$, $G_i^0 - G_r^0$, and $G_p^0 - G_r^0$ free energy differences are 6.3, 15.8, and –11.0 kcal mol^{-1}, respectively. The transition state ($\Delta G^{\neq}$ = 6.3 kcal mol^{-1}) lies at about the same energy level as the protonated α-AE + methanol system (corner h), but the stepwise mechanism is not plausible since, in view of $k_r^{MeOH_2^+} = 1.46 \times 10^8$ M^{-1} s^{-1}, the ΔG^0 = 6.3 kcal mol^{-1} figure for the r → h step — corresponding to an equilibrium constant of $10^{-4.6}$ — would require the intermediate to have a lifetime as low as 10^{-13}–10^{-12} s. Such a lifetime is too short even if the h → p and h → r steps are diffusion-controlled.

α Brønsted exponents

The α values observed for α-AE breakdown (α = 0.67–0.88 for the methoxy adduct and ca. 0.6 for the chloroethyl adduct) suggest that the proton is more than half transferred at the transition state. This is roughly what is expected from theory (12, 20) for an endergonic process with a transition state lying not far from the diagonal because corners h and i of the More O'Ferrall – Jencks diagram have roughly similar high energies. The fact that corner i lies below corner h (this suggesting that the transition state is closer to i than to h) is not probably a matter of concern, since the termolecular diagonal i → h transformation (the "disparity reaction" (20)) would require to go through a relatively high-free energy (low entropy) transition state. Grunwald (20) pointed out that the free energies of the encounter complexes would need to be considered instead of those of systems of separate molecular entities.

It has been suggested in the case of acid- and base-catalyzed hemiacetal breakdown (12, 20) that the observation of linear Brønsted plots requires that changes in the catalyst make the transition state move along a direction roughly parallel to the horizontal edges of the diagram. Figure 7*b* shows the expected displacement of the transition state associated with an increase in catalyst acidity. This displacement is the result of longitudinal (Hammond) and perpendicular effects which are of similar amplitude if, according to Grunwald (20), the intrinsic energy well and the intrinsic energy barrier are equal.

It has been shown above that the points associated with catalysis by $MeOH_2^+$ do not deviate much from the Brønsted plot based on carboxylic acids. This behavior is in line with what is expected if one assumes that the concerted mechanism is still valid. Since such a mechanism is energetically plausible, we conclude that the mechanism of α-AE formation involves two methanol molecules, one playing the role of nucleophile, the other acting as a general base catalyst (Scheme 7).

Table 3 shows that α increases with electron-withdrawing substituent effects. These variations are is in keeping with what is expected. The stronger the withdrawing substituent, the lower the stability of the iminium ion and the upper are corners p and i. In contrast, the effect on corner h is expected to be small because the positive charge in *O*-protonated α-AE lies on the oxygen atom, i.e., far from the substituent. As Fig. 7*c* shows, these relative energy variations should result in large variations in the degree of proton transfer, but in small variations of the degree in C—O bond breaking.

Change in the alkoxy group

As stressed in Introduction, a comparison of the rate constants for the breakdown of **4** and **5** is expected to provide valuable information about the relative extents the concerted proton transfer and C—O bond breaking have progressed at the transition state. Table 4 lists the ratios of the catalytic rate constants on α-AE breakdown (CH_2Cl group effects). Since they are lower than unity, it can be concluded that the oxygen atom is positively charged at the transition state and that proton-tranfer is ahead of C—O bond breaking. As Fig. 7*d* shows, since CH_2Cl makes the *O*-protonated ether much less stable and the alkoxide ion more stable, the change in transition state location should almost exclusively

Fig. 8. Plot of decimal logarithm of the forward catalytic rate constants for acetic acid-catalyzed addition of methanol to **1a–e** against σ^n (●) and σ^- (○) substituent parameters.

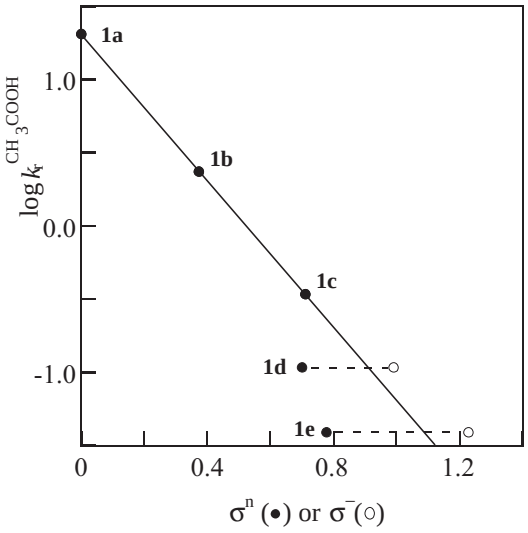

Fig. 9. Plot of decimal logarithm of the forward catalytic rate constants for lyonium ion-catalyzed addition of methanol to **1a–e** against σ^n (●) and σ^- (○) substituent parameters.

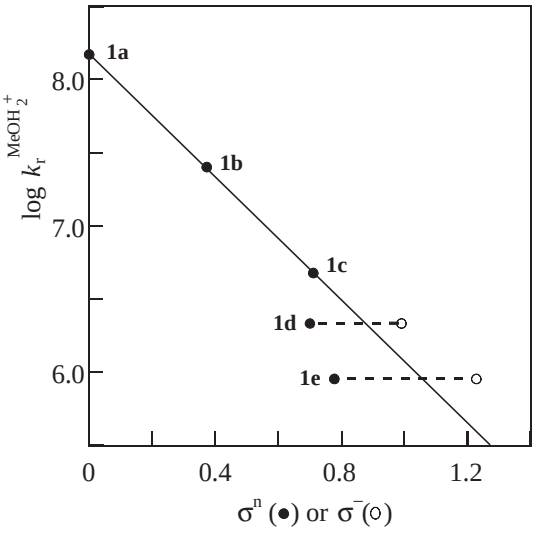

result from perpendicular effects. The large decrease in α, from 0.81 to 0.58 is in line with what is predicted.

Ring substituent effects on the catalytic rate constants

Figure 8 shows the plot of log $K_r^{CH_3COOH}$ against σ^n. The points corresponding to the π-electron-withdrawing substituents deviate negatively from the lines defined by the other points, but data fit eq. [16] very nicely. The same behavior is observed for the other catalysts, including the lyonium ion (Fig. 9). The ρ^n and ρ^r data are given in Table 5. These are fairly independent of R in RCOOH, but both coefficients are a little smaller for catalysis by the lyonium ions. The values ρ^n and ρ^r are thought to be related to the degree of C—O bond breaking at the transition and a comparison with those expected for full bond breaking is worthwhile.

The ρ^n and ρ^r coefficients for the α-AE to iminium ion (r → p) full transformation can be estimated according to the thermodynamical cycle of Scheme 8. These coefficients correspond to the sums of the ρ^n and ρ^r values for iminium ion deprotonation and methanol addition to the Schiff bases. The $(\rho^n)_{eq}$ (4.1) and $(\rho^r)_{eq}$ (2.8) values shown on Scheme 8 for iminium ion deprotonation are those calculated from literature data in nitromethane. It is assumed that the change in solvent is not too much a matter of concern as far as pK_a differences are considered.

The ratios of the ρ^n and ρ^r values between rate and equilibrium constants ((–2.5)/(–4.1) = 0.61 and (–1.50)/(–2.8) = 0.54) for carboxylic acid catalysis are close one another and are in agreement with what is expected on the basis of the energy diagrams. The transition state is closer to p than to r, since the adduct-to-iminium ion transformation is endergonic. For $MeOH_2^+$ catalysis, the ρ^n and ρ^r ratios are smaller ((–2.09)/(–4.1) = 0.51 and (–1.33)/(–2.8) = 0.47, respectively), this being in line with the prediction (Fig. 7*b*) that an increase in the acidity of the catalyst causes an approximately horizontal shift of the transition state, with less C—O bond breaking. It is noteworthy that the ρ^n and ρ^r variations

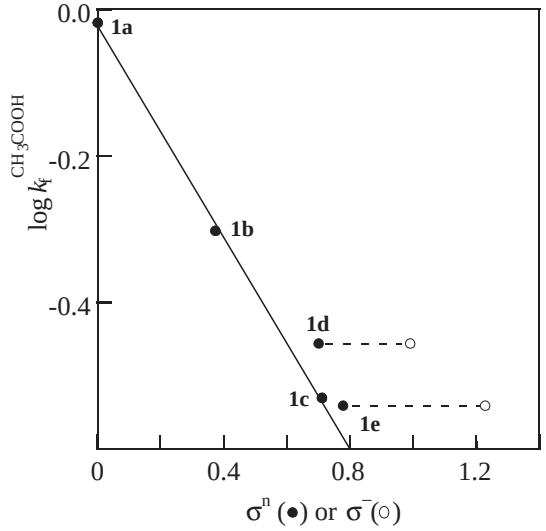

Fig. 11. Plot of the decimal logarithm of the catalytic rate constants for lyonium ion-catalyzed breakdown of **1a**–**e** methanol adducts against σ^n and σ^- substituent parameters.

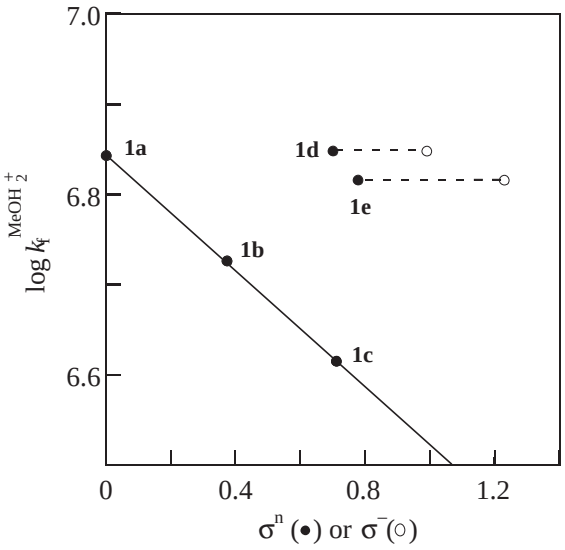

are parallel, this suggesting that there is no imbalance between polar and resonance effects.

Figure 10 shows the plot of log $k_f^{CH_3COOH}$ versus σ^n. The points associated with the π-electron-withdrawing substituents lie above the straight line. This means that –M effects cause the rate increase whereas –I effects make it decrease. This uncommon situation is due to the fact that a σ-electron-withdrawing group *increases* the energy of the transition state because of the positive charge on nitrogen, but that the π-electron withdrawing contribution *decreases* it because the conjugation with the nitrogen lone pair is enhanced by the sp^2-to-sp^3 change in carbon hybridization. As shown in Fig. 11, the phenomenon of inversion between polar and resonance effects is much more pronounced in the case of lyonium ion catalysis. This is because the C—O bond is more formed at the transition state than in the case of carboxylic acid catalysis. The ρ^n coefficient is lower because of less positive charge on nitrogen; ρ^r is larger because of more resonance contribution to the energy of later transition state. Table 5 also lists the values of the ρ^n and ρ^r coefficients on the forward catalytic rate constants. Standard deviations are rather poor probably because the deviations from the straight lines of the **1e** points in Figs. 10 and 11 are smaller than what is expected in view of the data for **1d**. This is probably be due to the fact that the gain in resonance on going from imine to α-AE is less because of more resonance contribution to the energy of the starting material. The θ angle (Fig. 6) has been reported to be close to 90° for Y = 4-NO_2 (36*a*, 38, 39*a*, *b*); this angle is probably lower for Y = 4-CN.

It is interesting to note that the ρ^n values are much smaller when considering the α-AE formation rate constants than those for the reverse reaction. This clearly stems from the large substituent effects on the stability of the imino form. There is compensation between substituent effects on the starting materials and on the transition state. We would like to emphasize the fact that consistent conclusions about bond breaking or formation at the transition state have been reached here through a detailed analysis of the substituent effects on the equilibrium constants and on the rate constants for both directions. A discussion on the substituents only on the basis of α-AEs would have been misleading since the low ρ values could wrongly suggest that C—O bond is almost completely formed at the transition state.

Experimental section

Reagents

1a–**e** were prepared by the previously described condensation of benzaldehyde (ALDRICH) with freshly distilled or recrystallized (from ethanol) anilines (from ALDRICH or ACROS) dissolved in heptane (8). Water was removed by azeotropic distillation by means of a Dean Stark tube. Crystallization was usually observed on cooling and **1a**–**e** were recrystallized twice from ethanol (**1a**), pentane (**1b**), diethyl ether (**1c**), pentane and cyclohexane (**1d**), and cyclohexane and ethanol (**1e**). The melting points were observed to correspond, when available, to literature data (all melting points (uncorrected) in °C): **1a**, 51.5–52 (lit. 52 (44), lit. 52–53 (44), lit. 50.5–51.5 (45), lit. 51–52 (46)); **1b**, 38 ; **1c**, 73 (lit. 71–71.5 (47)); **1d**, 70, and **1e**, 118 (lit. 119.7–121.2 (47), lit. 117–118 (48), lit. 114–117 (49)). Methanol ("Analyzed Baker Reagent") was used as received. Sodium methoxide solutions, prepared by the addition of sodium to methanol, were protected against moisture and carbon dioxide. Acetic acid (reagent ACS, ACROS), methoxyacetic acid (98%, ACROS), benzoic acid (p.a., ACROS), formic acid (reagent ACS, 96%, ACROS), chloroacetic acid (p.a., ACROS), and cynoacetic acid (99%, ACROS) were used as received and the methanolic solutions were pH-metrically titrated (after 1:10 dilution in water). Sodium acetate (anhydrous, reagent ACS, ACROS), benzoate (99+%, ACROS), and formate (99+%, ACS Reagent, ALDRICH) were used as received. Sodium methoxyacetate, chloroacetate, and cyanoacetate solutions in methanol were prepared by mixing equal volumes of freshly prepared equimolecular solutions of the corresponding acid and of sodium methoxide. The solutions obtained were titrated according to an original double-titration method, which consists in titrating two equal amounts of the same solution by HCl 0.1 M and NaOH 0.1 M successively and in recording the pH titration curves. The two pH curves were plotted on the same graph with positive and negative abscissa, respectively, for the volumes of HCl and NaOH solutions added, the inflexion of the whole curve corresponding the perfect neutralization of the small excess in acid or base. Small amounts in acid or in sodium methoxide were added to the bulk solution until getting perfectly neutral solutions. To avoid any acid esterification, the methanolic buffer solutions were prepared directly in the spectrophotometer cells just before the kinetic runs. The required amounts (weighted) of acid were added by a microsyringe to the carboxylate + tetramethylammonium bromide solutions.

Kinetic and equilibrium measurements

Rate and equilibrium measurements at I_c = 0.0376 M (Me_4NBr) and 25 ± 0.1°C were performed as described in (8).

Acidity constant determinations

The acidity constants of the carboxylic acids measured spectrophotometrically by using 2,4-dinitrophenol (pK_a = 7.9 (50)) and 2,5-dinitrophenol as indicators at 400 nm and 436 nm, respectively. The apparent molar extinction coefficients, defined as $\varepsilon_{obs} = A/[phenol]_{st}$, where $[phenol]_{st}$ is the stoichiometric concentration of phenol, were determined for various sodium carboxylate/carboxylic acid concentration ratios. Since ε_{obs} can be expressed by eq. [18],

$$[18] \qquad \varepsilon_{obs} = \varepsilon_{phenate} \frac{K_{ArOH/HA}}{K_{ArOH/HA} + \{[RCOO^-]/[RCOOH]\}}$$

where $K_{ArOH/HA}$ is the ratio of the acidity constants of the indicator and carboxylic acid, K was taken as the value of $[RCOO^-]/[RCOOH]$ at which $\varepsilon_{obs} = \varepsilon_{phenate}/2$. The absorption molar coefficients of the phenoxide ions, $\varepsilon_{phenate}$, was measured as 11 200 M^{-1} cm^{-1} and 4270 M^{-1} cm^{-1} in 1.5 × 10^{-3} M NaOMe, for 2,4-dinitrophenol and 2,5-dinitrophenol, respectively. The pK_a values at I_c = 0.0376 M [$(Me)_4NBr$] for acetic acid, methoxyacetic acid, benzoic acid, and formic acid were measured against 2,4-dinitrophenol and those for chloroacetic acid and cyanoacetic acid against 2,5-dinitrophenol. The pK_a value (9.09) for 2,5-dinitrophenol was determined against formic acid.

Oxidative dealkylation of aromatic amines by "bare" FeO^+ in the gas phase

Mark Brönstrup, Detlef Schröder, and Helmut Schwarz

Abstract: The gas-phase oxidations of aniline, *N*-methylaniline, and *N*,*N*-dimethylaniline by FeO^+ cation are examined by using mass spectrometric techniques. Although bare FeO^+ is capable of hydroxylating aromatic C—H bonds, the fate of the oxidation of arylamines is determined by docking of the FeO^+ unit at nitrogen. The major reactions of the metastable aniline/FeO^+ complex are losses of molecular hydrogen, ammonia, and water, all involving at least one N-H proton. N-alkylation results in a complete shift of the course of the reaction. The unimolecular processes observed can be regarded as initial steps of an oxidative dealkylation of the amines mediated by FeO^+. More detailed mechanistic insight is obtained by examining the C—H(D) bond activation of *N*-methyl-*N*-([D_3]-methyl)aniline by bare and ligated FeO^+ species. The gas-phase reactions of FeO^+ with methylanilines show some similarities to the enzymatic dealkylation of amines by cytochrome P-450. The kinetic isotope effects observed experimentally suggest an electron transfer mechanism for the gas-phase reaction.

Key words: mass spectrometry, gas-phase chemistry, iron, dealkylation, *N*,*N*-dimethylaniline.

Résumé : L'oxidation d'aniline, *N*-méthylaniline et *N*,*N*-diméthylaniline par l'ion FeO^+ dans la phase gazeuse est suivie par spectrométrie de masse. Tant que FeO^+ est capable d'activer des liaisons C—H aromatiques, l'oxidation d'anilines est determinée par la fixation du fer sur l'azote. Les complexes metastabiles d'aniline/FeO^+ expulsent l'hydrogène moléculaire, l'ammoniac et l'eau, qui contiennent toujours au moins d'un proton N-H. La N-alkylation provoque un changement complet dans la réaction. Ainsi, les décompositions unimoléculaires ressemblent aux premiers pas de la dégradation oxidative d'alkylamines. L'activation des liaisons C—H(D) en *N*-méthyl-*N*-([D_3]-méthyl)-aniline par FeO^+ sans ou avec ligands permet d'améliorer la compréhension mécanistique. La réaction de FeO^+ avec les *N*-méthylanilines s'apparente à la désalkylation oxidative des amines par l'enzyme cytochrome P-450. Dans la phase gazeuse, les effets cinétiques des isotopes proposent un mécanisme avec transfert d'un seul electron.

Mots clés : spectrométrie de masse, phase gazeuse, fer, désalkylation, *N*,*N*-diméthylaniline.

Introduction

Whereas alkylation of amines can be achieved easily by simple nucleophilic substitution reactions, N-dealkylation is much more difficult. As evolution led to heme-containing enzymes like cytochrome P-450 or peroxidases fulfilling this purpose under physiological conditions, there has been a continuous interest in revealing the molecular mechanisms of the biochemical N-dealkylation reactions (1–4).

In the literature (2), a long and controversial discussion about the N-dealkylation of aromatic amines **1** by cytochrome P-450 has focused on the sequence of elementary steps (Scheme 1): Dinnocenzo and co-workers (3) have provided support for a radical-type H-atom abstraction ($H^{\bullet}_T$) as a key step (**1** → **2**, path (a)), while Guengerich et al. (4) have argued that initial electron transfer (ET) is rate determining (**1** → $\mathbf{1}^{+\bullet}$, path (b)). Both pathways collapse to the same intermediates en route to C—N bond cleavage, i.e., either the imminium ion $\mathbf{2}^+$ or the α-aminoalcohol **3**, which is formed by a "rebound" of the hydroxyl group from [FeOH] to the substrate. Under physiological conditions, these intermediates undergo hydrolysis to yield the dealkylated amine and the corresponding aldehyde. The most recent studies seem to agree upon initial electron transfer from the amine (5). In essence, the debate concerns two fundamental questions: (*i*) is the transfer of a hydrogen atom (**1** → **2**) a real $H^{\bullet}_T$ or in fact a sequence of ET and deprotonation? (*ii*) does a formal hydride ion transfer (**1** → $\mathbf{2}^+$) occur in a single step (H^-_T), as a combination of $H^{\bullet}_T$ and ET, or even as sequence of two ETs and a deprotonation?

Cytochrome P-450 is commonly believed to involve a high-valent iron oxo species in the active site (2). The most simple model system for this reactive entity is the bare FeO^+ cation in the gas phase (6), which can be generated and studied using mass spectrometry (7). The extreme simplification of the complexity of the biological system permits investigation of the intrinsic chemical behavior of the reactive core under rigorous exclusion of many complicating parameters such as solvent and aggregation effects, counterions, or ligands. For example, the problem that the intrinsic isotope effect might be "masked" due to the chirality of the enzyme

Received December 3, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

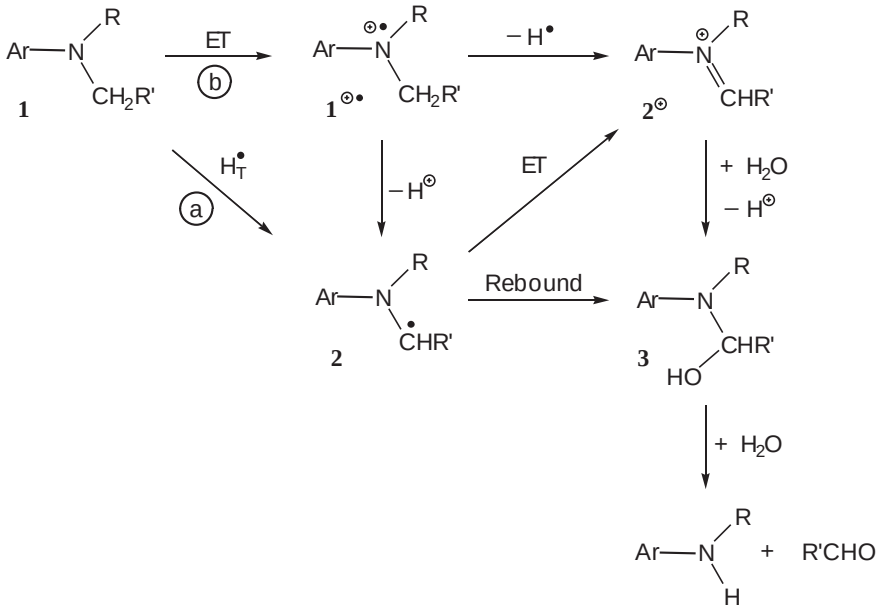

Chart 1.

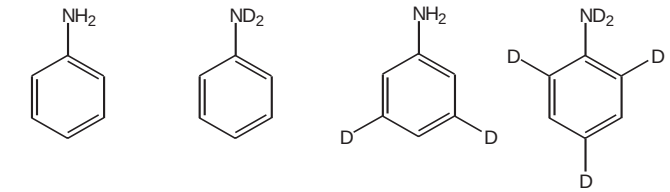

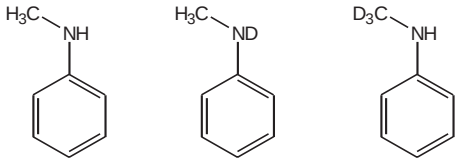

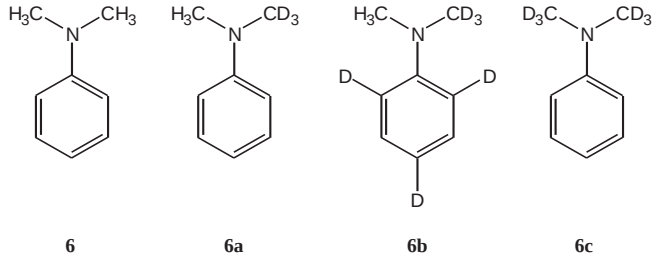

backbone (3*a*, 8) does not exist for the simple model system FeO^+. Further, the role of electronic structure effects can be probed in detail (7, 9). Previous studies have demonstrated that FeO^+ is capable of oxidizing a large number of substrates (7), ranging from simple hydrocarbons such as methane (10), benzene (11), or norbornane (12) to more oxidation-resistant compounds like acetonitrile (13) or hexafluorobenzene (14). Thus, efficient oxidation of aromatic amines by FeO^+ is expected to take place as well. To this end, we used two different mass spectrometric techniques (see experimental section) to investigate the gas-phase reactions of phenylamines C_6H_5-NRR′ **4**–**6** (R, R′ = H, D, CH_3, CD_3; see Chart 1) with the FeO^+ cation. In spite of many differences, the present experiments are entirely complementary to biochemical studies; in addition, they basically address the same fundamental problem. While the present study cannot resolve the above mechanistic controversy, our results may provide valuable new insight into the problem.

Results

First, we describe separately the results obtained with a four-sector mass spectrometer (sector MS) and with an ion cyclotron resonance mass spectrometer (ICR MS). This is followed by a discussion of the mechanistic insight gained from these studies with respect to fundamental aspects of amine dealkylation in the condensed phase.

Sector MS

Metastable aniline/FeO^+ complexes undergo unimolecular losses of molecular hydrogen, ammonia, water, and carbon monoxide (Table 1). Unfortunately, for some of the isotopomers losses of isobaric ammonia and water overlap, thereby preventing a strictly quantitative analysis of the labeling distribution. However, the data of the labeled complexes reveal that the major pathways involve the N—H(D) bonds with a high preference. Thus, for the [*N*,*N*-D_2]-labeled complex **4a**/FeO^+, loss of NH_3 is no longer detected, and the water molecules lost contain preferentially one deuterium atom (-HDO). Losses of H_2O and D_2O are observed to a smaller extent. Complementing this, the label is almost completely retained in the ions for the [3,5-D_2]-labeled species **4b**/FeO^+. The prevailing generations of HDO from **4a**/FeO^+ and D_2O from **4c**/FeO^+ suggest that dehydration preferentially involves cleavages of one N—H(D) and one of the

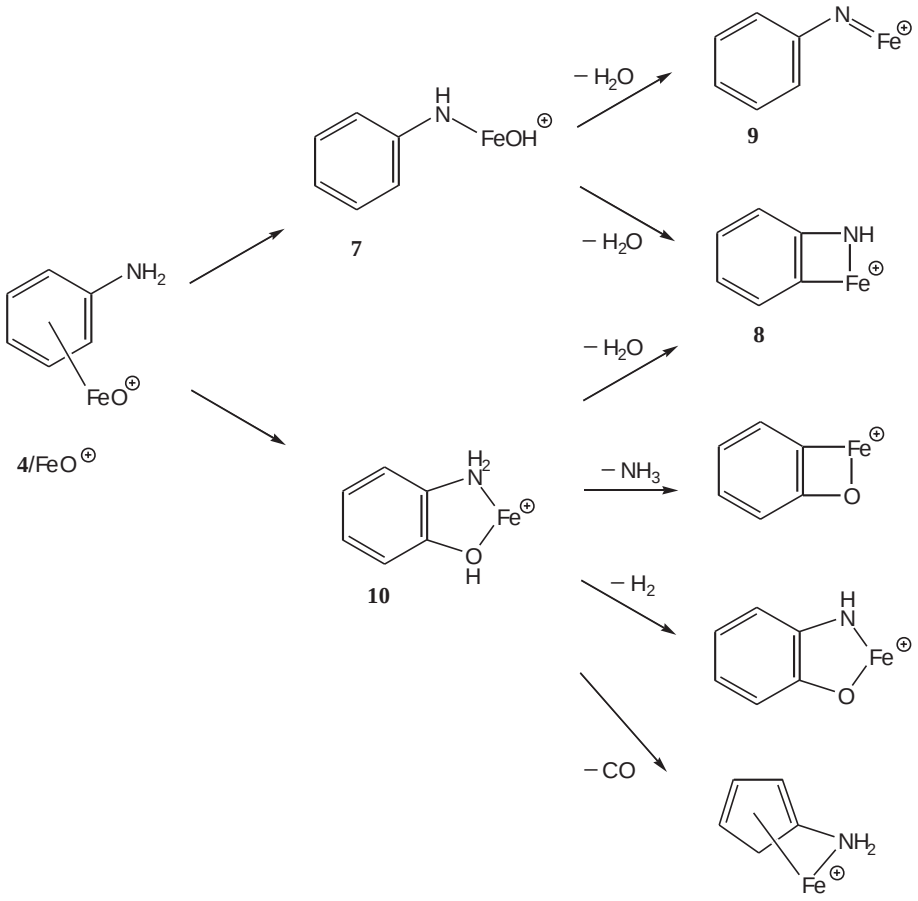
[b]Loss of hydroxy radical was excluded by ICR experiments with high mass resolution in which $[Fe,C_6,H_4,O]^+$ but not $[Fe,C_6,H_6,N]^+$ (both 148 amu) is observed.

[c]These losses are isobaric.

Scheme 2.



arene's *ortho* C—H(D) bonds. A possible mechanistic scenario is depicted in Scheme 2.

Accordingly, initial N—H bond activation (**4**/$FeO^+ \rightarrow$ **7**) is followed by cleavage of the aromatic C—H bond and loss of water, thus affording the metallacyclic species **8**. In analogy to the formation of $FeNH^+$ from FeO^+ and ammonia (15, 16), the significant loss of D_2O from **4a**/FeO^+ can be rationalized by the formation of iron phenylimine **9**. Considering the fact that bare FeO^+ cation is also capable of activating aromatic C—H bonds (11), it is obvious from the product distribution that coordination of FeO^+ at the hetero substitutent governs the reactivity. By reference to previous studies (11, 17, 18), we suggest that oxidation of the aromatic ring competes with attack at the amino group to yield

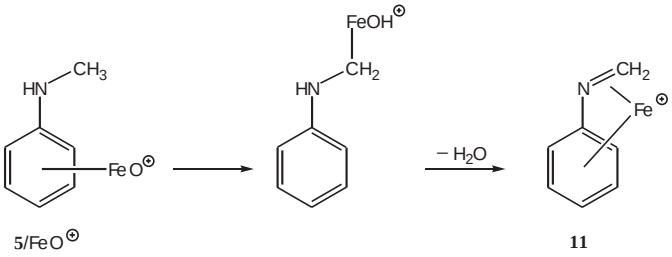
Scheme 3.



10, which is presumably the intermediate for the minor losses of CO, NH_3, and H_2. **10** may also contribute to dehydration (**10** → **8**).

Unimolecular dissociation of metastable **5**/FeO^+ is even more specific and affords loss of water exclusively. Clean shifts from H_2O to HDO losses for the labeled complexes **5a**/FeO^+ and **5b**/FeO^+ further reveal that dehydration can be ascribed to a formal 1,2-elimination of two hydrogen atoms by FeO^+, leading to formation of the imine/Fe^+ complex **11** concomitant with water (Scheme 3).

Thus, N-alkylation dramatically changes the overall course of the reaction compared to aniline/FeO^+ in that activation of aromatic C—H bonds is completely suppressed. Formation of **11** can indeed be regarded as the key step for the oxidative dealkylation of amines considering that aldimines readily hydrolyze in an aqueous environment.

Dehydration is also observed with the *N*,*N*-dimethylaniline complex **6**/FeO^+, but the major reaction corresponds to a loss of neutral FeOH. The expulsions of neutral D_2O and FeOD from **6c**/FeO^+ demonstrate that both reactions involve only the methyl groups. Formation of the imminium ion **12** (Scheme 4) can again be considered as the first step in the oxidative dealkylation of **7**.

Valuable mechanistic insight is obtained from the intramolecular kinetic isotope effect (k_H/k_D) associated with C—H(D) bond activation of **6**. For **6a**/FeO^+ the losses of FeOH and FeOD imply $k_H/k_D = 3.2 \pm 0.3$; similarly, dissociation of **6b**/FeO^+ leads to $k_H/k_D = 2.9 \pm 0.3$. Isotope effects of similar sizes are indicated by the ratio of H_2O and D_2O losses from **6a**/FeO^+ and **6b**/FeO^+; however, the formation of HDO from these complexes indicates some H–D equilibration and (or) competing mechanisms preceding dehydration. It is not our aim to unravel the mechanism of dehydration but, for the sake of consistency, a plausible scenario is included in Scheme 4, which assumes a formally dyotropic (19) rearrangement of an inserted species to a benzylmethylamide/$FeOH^+$ complex **13**, followed by β-hydride elimination. The H_2O:HDO:D_2O ratio obtained from **6a**/FeO^+ and **6b**/FeO^+ reflects the preference of H- over D-bond activation, followed by preferred formation of the internal conjugated double bond **14** rather than **15**.

With respect to the mechanistic debate outlined in the introduction, it is also useful to consider the isotope effect for the metal – free cation radical **6**$^{+\bullet}$. Thus, unimolecular losses of H$^\bullet$ and D$^\bullet$ comprise >95% of the total metastable ion decompositions of **6a**$^{+\bullet}$. Interestingly, the experimentally measured $k_H/k_D = 3.0 \pm 0.3$ associated with loss of H(D) atom is close to that found for **6a**/FeO^+ (vide supra).

ICR MS

To examine the kinetic isotope effect for C—H(D) bond activation of **6** in more detail, the reactions of **6a** with bare and ligated (L)FeO^+ (L = none, C_6H_6, C_6H_5CN) were studied using the ICR technique. Unfortunately, all our attempts to generate (L)FeO^+ complexes with L being a donor-substituted arene have so far been unsuccessful. For example, while the reactions of N_2O with $(C_6H_6)Fe^+$ and $(C_6H_5CN)Fe^+$ can be used to form the corresponding (L)FeO^+ complexes (20), the same procedure results in oxidation of the substrates for L = C_6H_5OH and $C_6H_5OCH_3$.

Three types of reactions are observed in the ICR experiments (Table 2), as follows:

(*i*) Electron transfer from the amine to (L)FeO^+ to afford the cation radical **6a**$^{+\bullet}$. This process can be attributed to the low ionization energy, IE(**6**) = 7.1 eV as compared to IE(FeO) = 8.9 eV (unless noted otherwise, all thermochemical data are taken from ref. 21). Although the arene ligands C_6H_6 and C_6H_5CN in (L)FeO^+ are expected to lower the IE of iron oxide, ligation can obviously not compensate the intrinsic difference of the IEs.

(*ii*) The process of interest is the formal hydride (deuteride) transfer to afford the correspondingly labeled imminium ions via H^-_T and D^-_T, respectively, and neutral FeOH (FeOD).

(*iii*) For the ligated species, a formal ligand exchange of L against **6a** is observed. These processes can be rationalized by the higher binding energy of the electron-rich ligand **6a** compared to C_6H_6 and C_6H_5CN (22). Note, however, that the ions formed may not be intact **6a**/FeO^+, but rearranged species according to Scheme 4.

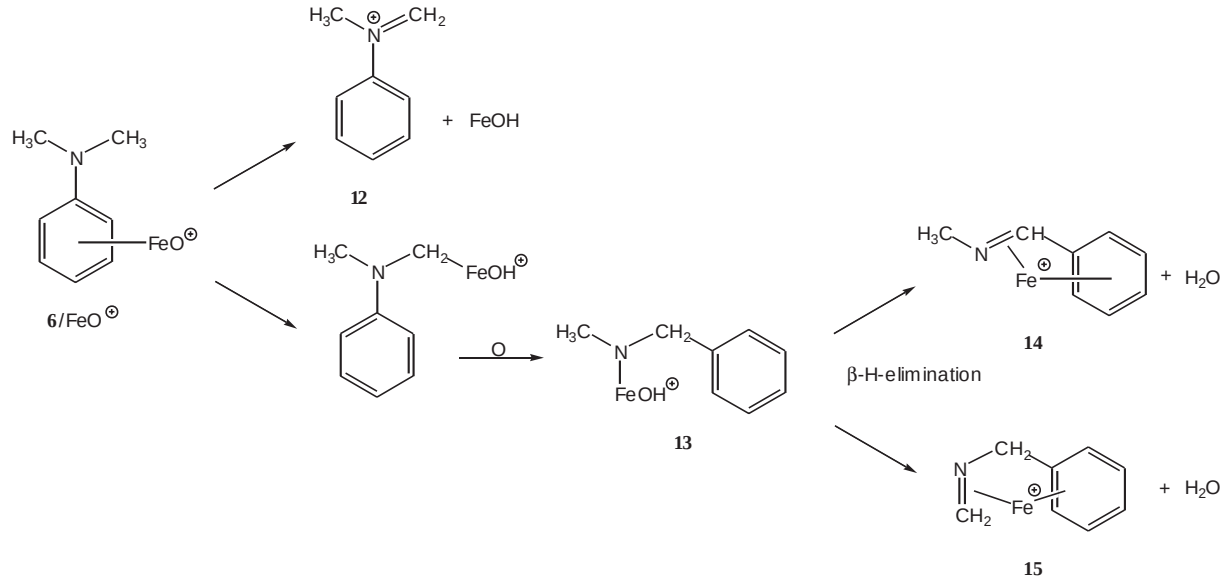
The kinetic isotope effects associated with formal H^-_T and D^-_T from **6a** to FeO^+ show an interesting trend, i.e., an increase from $k_H/k_D = 2.0 \pm 0.2$ for bare FeO^+, to $k_H/k_D = 2.6 \pm 0.2$ for L = C_6H_5CN, and $k_H/k_D = 3.0 \pm 0.2$ for L = C_6H_6. This trend indicates that the size of the isotope effect can be varied by tuning the electronic properties of the ligand (C_6H_6 vs. C_6H_5CN) and also depends on the overall size of the system (FeO^+ vs. (L)FeO^+).

Discussion

In this section, let us try to interpret the gas-phase data with respect to the mechanistic controversy on amine dealkylation by cytochrome P-450 as outlined in the introduction. Compared to the reactions of FeO^+ with other arenes (7, 11, 14–18), the chemistry of aniline and its N-methyl derivatives is governed by coordination of the metal oxide to nitrogen ("docking"). In contrast to the enzymatic reactions, no hint for N—O bond formation is found in the gas-phase model system. Upon N-methylation, only these alkyl groups are attacked specifically by FeO^+. For *N*-methylaniline and

© 1999 NRC Canada

Scheme 4.



N,*N*-dimethylaniline, the reaction intermediates can be ascribed to the key steps towards the oxidative dealkylation of the amines.

Interestingly, the kinetic isotope effects associated with C—H(D) bond activation of metastable **6a**/FeO^+ and **6b**/FeO^+ are lower than or equal to that of unimolecular hydrogen atom loss from the radical cation $\mathbf{6a}^{+\bullet}$ itself. This result indicates that in the gas phase, the reaction most likely follows path (b) in Scheme 1, i.e., initial electron transfer from the amine to the iron oxo unit followed by C—H bond cleavage in the amine cation radical. This interpretation is further corroborated by the fact that electron transfer from the amine to (L)FeO^+ is observed as an efficiently competing process. In this comparison, it has to be kept in mind that the gas-phase reactions sample species generated with quite a different internal energy content than reactions occurring in the condensed phase. Thus, in the diluted gas phase any energy transfer to media is impossible. Moreover, the species under study carry real Coulomb charges that are not shielded by solvation, additional ligands, counterions, etc. Let us illustrate these fundamental aspects by referring to the differences in the reactions of metastable **6a**/FeO^+ in the sector instrument compared to the ion–molecule reaction of bare FeO^+ with **6a** under ICR conditions. For metastable **6a**/FeO^+ and **6b**/FeO^+, losses of FeOH and FeOD with an average isotope effect of $k_H/k_D = 3.0 \pm 0.3$ are observed, as well as loss of water. In contrast, reaction of bare FeO^+ with **6a** gives rise to the amine cation radical via electron transfer along with losses of neutral FeOH and FeOD, having a smaller isotope effect of $k_H/k_D = 2.0 \pm 0.2$. Dehydration is not observed under these conditions. The reason for these seemingly inconsistent results is simply the different starting conditions in both experiments (23). Thus, under ICR conditions bare FeO^+ interacts with the substrate thereby deliberating the full complexation energy $D(\mathbf{6} - FeO^+)$; we use $D(\mathbf{6} - FeO^+) \approx D(\mathbf{4} - Fe^+) = 54$ kcal/mol (22) for lack of other data. In contrast, metastable **6**/FeO^+ examined in sector MS is formed in a chemical ionization plasma, which allows for some collisional cooling. Moreover, in the experiments only those metastable ions are sampled which undergo unimolecular decay in the microsecond (μs) regime. Therefore, it is fair to anticipate that the metastable ions formed upon chemical ionization in the sector MS have a lower average internal energy than the encounter complexes formed under ICR conditions. Consequently, the lifetimes of the encounter complexes and the isotope effects are larger with sector MS. Increase of ion lifetimes also explains why loss of water is observed for the metastable ions, because this obviously requires a more complex mechanism than simple ET or hydrogen atom abstraction occurring under ICR conditions. This line of reasoning is nicely corroborated by the increase of the isotope effects for the ligated (L)FeO^+ ions under ICR conditions. Thus, the high excess energy gained upon complexation of **6a** with (L)FeO^+ can be distributed over various degrees of freedom for L = C_6H_6 and C_6H_5CN, resulting in a higher H/D selectivity than for bare FeO^+. The fact that the KIE is larger for L = C_6H_6 than for L = C_6H_5CN and unligated FeO^+ further suggests a dependence on the electronic properties of the ligands. Thus, the size of the KIE is proportional to the ability to compensate the electron deficiency of bare FeO^+ by a donating ligand. However, the small KIE of bare FeO^+ results from a combination of size and electronic effects. Moreover, as the range of systems studied is very limited, the interpretation outlined above should only be regarded as a qualitative orientation.

Finally, it is worth considering the stability of the putative aminoalkyl radical **2** in somewhat more detail. Unfortunately, not many thermochemical data for α-aminoalkyl radicals are available (24). However, the ionization energy of the *N*,*N*-dimethylaminomethyl radical is rather low (IE = 5.2 eV) (24*e*). The IE of the corresponding *N*-methyl-*N*-phenylaminomethyl radical **2** (Scheme 1) may be even lower due to stabilization by the aromatic substituent. Note, however, that there exists a subtle balance of radical and ion stabilization in this case that has not been examined so far. Notwithstanding, the mere range of the IE of the putative

© 1999 NRC Canada

radical **2**, in the order of 5 eV, questions whether this particular radical is stable in aqueous media at all,[2] with respect to ionization to the imminium ion.

Conclusions

The reactions of FeO^+ with aniline and its N-methyl derivatives are governed by initial docking at the nitrogen atom. A feature of the gas-phase reaction of *N*,*N*-dimethylaniline with bare and ligated FeO^+ is a formal hydride transfer to yield neutral FeOH and the *N*-methyl-*N*-phenylformimine cation, which is a central intermediate in an N-dealkylation process in the condensed phase. The fact that the intramolecular KIE associated with hydride transfer to FeO^+ is smaller than or equals that for unimolecular $H^\bullet$ loss from the *N*,*N*-dimethylaniline cation radical under various experimental conditions suggests that an electron transfer might be the initial elementary step in our gas-phase model system. Besides, the present study demonstrates that the KIE of a given substrate is affected by the electronic environment of the iron oxide core, implying that the interpretation of KIEs for *N*-dealkylation processes derived from certain enzymes or model systems is not necessarily valid for others.

Experimental

In this study, two different mass spectrometric approaches were used. (*i*) Unimolecular reactions of metastable arylamine/FeO^+ complexes were examined by sector mass spectrometry. (*ii*) Ion–molecule reactions of bare and ligated $(L)FeO^+$ ions (L = none, C_6H_6, and C_6H_5CN) were studied with Fourier transform ion cyclotron resonance (ICR) mass spectrometry. This combined approach was chosen for two major reasons. At first, arylamines have a significant memory effect in high-vacuum devices due to adsorption in the device itself as well as in the inlet systems. The ICR instrument is particularly sensitive to this effect and even overnight bakeout does not suffice to completely remove the substrates. Secondly, some of the deuterium-labeled compounds applied in this study are sensitive to H–D exchange with themselves, upon contact with the walls of the inlet systems or the machinery, as well as with background gases (i.e., moisture). For example, pure N-[D_2]-labeled aniline can easily be prepared in large quantities, but once a micromole (μmol) sample is introduced into the machinery, it can undergo H–D exchange with surface protons or intra-/intermolecular exchange with the labile ring protons in *ortho* and *para* positions catalyzed by acidic surfaces. Again, the ICR is more sensitive to this effect. The superior performance of the sector MS in both respects is basically due to a mass-flow effect, because the operating pressure (ca. 10^{-4} mbar; 1 bar = 100 kPa) is about four orders of magnitude higher than the typical ICR conditions (ca. 10^{-8} mbar). Thus, the reactions of aniline, its N-methylated derivatives, and the corresponding deuterium-labeled substrates were screened using sector MS, and only the reactions of the most decisive *N*-methyl-*N*-([D_3]-methyl)aniline with bare and ligated FeO^+ were examined with the ICR technique. The prime advantages of ICR MS compared to chemical ionization in sector MS are that it provides full control of the ions' history and a narrow distribution of their internal energy, i.e., the reactions occur under well-defined conditions at ambient temperature.

Sector MS

Most experiments were performed with a modified VG ZAB/HF/AMD four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sector), which has been described previously (25). Briefly, the metal complexes were generated in a chemical ionization source (CI, repeller voltage ca. 0 V) by 100 eV electron bombardment of an approximately 20:1:1 mixture of N_2O, $Fe(CO)_5$, and the corresponding arylamine. The ions were accelerated to 8 keV kinetic energy and mass selected by means of B(1)/E(1) at a resolution of $m/\Delta m \approx 4000$. Unimolecular fragmentations of metastable ions occurring in the field-free region preceding B(2) were recorded by scanning this sector. All spectra were accumulated and processed on-line with the AMD–Intectra data system; 10–30 scans were averaged to improve the signal-to-noise ratio. Kinetic isotope effects were determined from the peak ratios for isotopologous losses (e.g., loss of FeOH versus loss of FeOD) and are reported as the average of at least three independent measurements with an error of ±10%. Due to the relatively high pressure that prevails in the CI source, efficient collisional cooling of the ions can be assumed, such that excited states of the metal species (26) are not likely to participate in the reactions observed (27).

ICR MS

The experiments were performed with a Spectrospin CMS 47X FT ICR mass spectrometer, which has been described previously (ref. 28; for an introduction to FT ICR mass spectrometry, see ref. 29). Briefly, Fe^+ ions were generated via laser desorption/laser ionization by focusing the beam of a Nd:YAG laser (Spectron Systems, λ = 1064 nm) onto an iron target. The ions were extracted from the source, transferred into the analyzer cell by a system of electrostatic potentials and lenses, decelerated, and trapped in the field of a superconducting magnet (maximum field strength 7.05 T). Prior to ion–molecule reactions, the $^{56}Fe^+$ isotope was mass selected using the FERETS technique (30). FeO^+ was generated by pulsing in N_2O, thermalized with pulsed-in argon, and subsequently mass selected (31). Ligated $(L)FeO^+$ ions were generated by the following sequence (20). At first, mass-selected Fe^+ was reacted with a pulsed-in ca. 10:1 mixture of argon and the desired ligand L (L = C_6H_6, C_6H_5CN). Subsequently, an excess of N_2O was pulsed in to yield the corresponding $(L)FeO^+$ species, which were then mass selected using FERETS and reacted with the substrate. Note that the inverse sequence, i.e., ligating FeO^+ with pulsed-in L does not work, because the reactive FeO^+ cation simply oxidizes the ligands (7). As neutral substrate, only *N*-methyl-*N*-([D_3]-methyl)aniline was used in this study with typical pressures of $(5–15) \times 10^{-9}$ mbar. Ionic reaction products were monitored as a function of reaction time and reactant pressure. The data were accumulated and processed by

[2] The related *N*,*N*-dimethylaminomethyl radical is only observed as a transient intermediate in aqueous solution (24*b* and 24*c*).

means of an ASPECT 3000 minicomputer. Product branching ratios are reported within experimental errors of ±10%.

Substrates

The unlabeled arylamines were commercially available and used without further purification. N-[D_3]-Methylation was achieved by treatment of the corresponding anilines with [D_3]-methyliodide. [*N*,*N*-D_2]-Aniline and [*N*-D]-methylaniline were made by repeated H–D exchange of the undeuterated compounds with CH_3OD at room temperature. [*N*,*N*-2,4,6–D_5]-Aniline was prepared by subsequent H–D exchange of aniline with D_2O catalysed by D_3PO_4 at 100°C, followed by liberation of the base with concentrated NaOH solution (32). [3,5-D_2]-Aniline was made by D–H exchange of [2,3,4,5,6-D_5]-aniline in an excess of water catalyzed by diluted H_2SO_4 (32). [2,3,4,5,6-D_5]-Aniline was obtained in two steps via nitration of [D_6]-benzene and reduction of [2,3,4,5,6-D_5]-nitrobenzene with $NaBH_4$ (33). All labeled compounds were purified by chromatography and characterized by ^{1}H NMR.

The role of the medium in solvent isotope effects on serine protease action

Jiaher Tian, Jue Tan, K. Barbara Schowen, and Richard L. Schowen

Abstract: The hydrolysis of *N*-carbobenzyloxyaminoacyl-*O*-*p*-nitrophenyl esters derived from L-leucine, L-phenylalanine, and L-tryptophan, with catalysis by bovine pancreatic α-chymotrypsin at pH 7.00 at 25.00°C in water containing acetonitrile from 15.0% to 60% (v/v), exhibits values of k_{cat}/K_m that decrease as the 34th to 36th power of the activity of water and values of k_{cat} that are essentially constant. Solvent isotope effects $k_{cat}(H_2O)/ k_{cat}(D_2O)$ range from 2.1 to 3.0 with proton inventories (dependences of $k_{cat}(n)$ on n, the atom fraction of deuterium in the water component of the solvent) that are linear, regardless of the amount of acetonitrile in the medium. The isotope effect on k_{cat} thus appears to arise from a single transition-state site and to be little affected by the medium. Contributions from the medium to solvent isotope effects on enzymic reactions clearly exist but appear not to be detectable in the deacylation reactions of acyl chymotrypsins.

Key words: solvent isotope effects, proton inventories, medium effects, enzyme catalysis, α-chymotrypsin.

Résumé : Pour les réactions d'hydrolyse des esters *N*-carbobenzyloxyaminoacyl-*O*-*p*-nitrophénylés dérivés de la L-leucine, de la L-phénylalanine et du L-tryptophane catalysées par l'α-chymotrypsine pancréatique bovine, à un pH de 7,0, à 25,00°C, dans de l'eau contenant de l'acétonitrile à des concentrations allant de 15,0 à 60% (v/v), les valeurs de k_{cat} sont pratiquement constantes alors que celles de k_{cat}/K_m diminuent en fonction de l'activité de l'eau portée à des puissances allant de 34 à 36. Les effets isotopiques de solvant, $k_{cat}(H_2O)/k_{cat}(D_2O)$ vont de 2,1 à 3,0 avec des inventaires de proton (dépendances de $k_{cat}(n)$ sur n, la fraction atomique de deutérium dans la composante aqueuse du solvant) qui sont linéaires, quelle que soit la quantité d'acétonitrile dans le milieu. Il semble donc que les effets isotopiques sur k_{cat} découlent d'un seul site de l'état de transition et qu'ils ne sont pas très affectés par le milieu. Il est évident qu'il existe des contributions du milieu sur les effets isotopiques du solvant sur des réactions enzymatiques; ils ne semblent toutefois pas décelables dans les réactions de désacylations des acyl chymotrypsines.

Mots clés : effets isotopiques du solvant, inventaires de proton, effets de solvant, catalyse enzymatique, α-chymotrypsine.

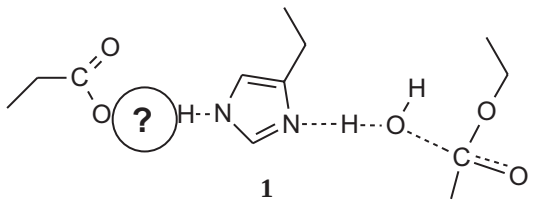
Introduction

Professor A.J. Kresge is one of a small number of scientists who contribute to the shaping of research fields not only through original creations, but also through their role as critics of their own and other work. Kresge has written a number of reviews that often incorporate original work and have had great influence. A review on solvent isotope effects in mixtures of protium and deuterium oxides (1) was the subject of a seminar presented to our research group by Cherie Behn in mid-1967. Its clarity, particularly in illustrating the applications of a form of the Gross–Butler equation developed by Kresge, was so appealing that we immediately set about using the technique in studies of reactions of small molecules (2) and later of enzymes (3). In the vastly simplified version favored by us, the technique has come to be called the *proton-inventory method* (3).

The first application of the method to catalysis by an enzyme, the hydrolysis of *p*-nitrophenyl acetate by α-chymotrypsin, showed that a plot of k_{cat} against the atom fraction, n, of deuterium in mixed isotopic solvents was linear (4). We took this result to indicate that the solvent isotope effect of 2.4 arose from a single site and that the then-fashionable "charge-relay system" was therefore not in operation in the transition state **1** for the rate-limiting deacylation of acetyl-α-chymotrypsin (no change in binding at the question mark as reactant state becomes transition state).



1

The entire isotope effect was therefore taken to arise from the single protonic site bridging between water and histidine. Although structure **1** portrays the transition state for forma-

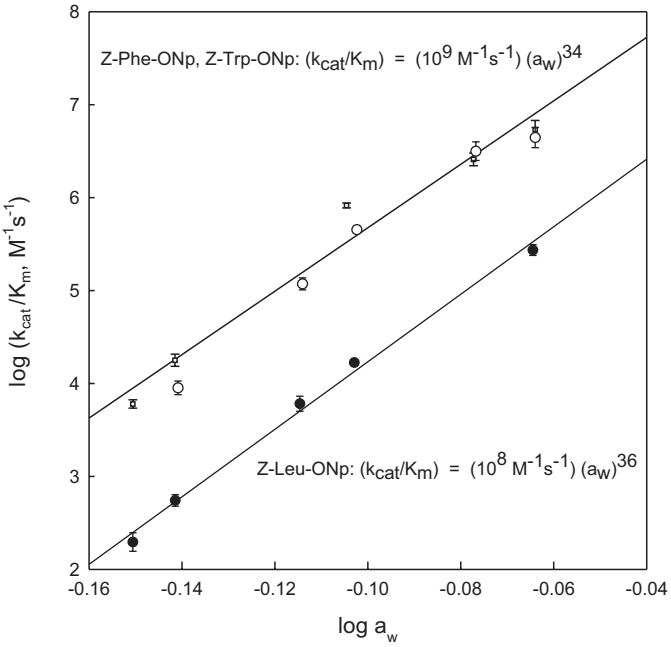
Fig. 1. Dependence of the logarithm of the rate constant k_{cat}/K_m on the logarithm of the activity of water in aqueous acetonitrile solutions for the action of α-chymotrypsin on three substrates. Open squares represent data for *Z*-Phe-ONp at 25.00 ± 0.05°C, pH 7.00 (0.100 M phosphate buffer) in mixtures from 15.1% (v/v) acetonitrile to 60.0% (v/v) acetonitrile. Open circles represent data for *Z*-Trp-ONp at 25.00 ± 0.05°C, pH 7.00 (0.100 M phosphate buffer) in mixtures from 15.0% (v/v) acetonitrile to 49.8% (v/v) acetonitrile. Both data sets can be described by the same linear function, suggesting that the rate in pure water, $a_w = 1$, is diffusional and that the rate decreases in acetonitrile–water mixtures as the 34th power of the activity of water. Filled circles represent data for *Z*-Leu-ONp under the same conditions (mixtures from 15.2% (v/v) acetonitrile to 59.9% (v/v) acetonitrile. They are described by a similar function with a smaller rate constant in pure water and a slightly larger exponent for the activity of water.



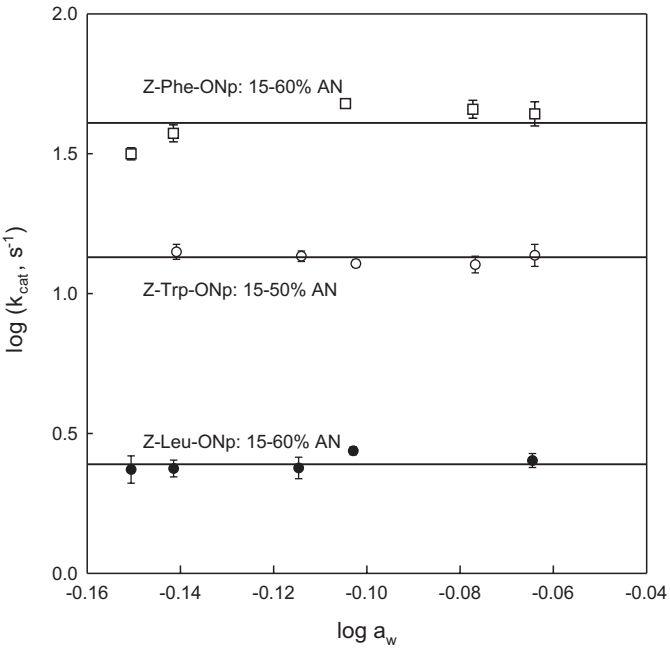
tion of the tetrahedral intermediate, that for decomposition may also contribute to determining the rate. The question of which of these steps is rate limiting does not influence the isotope-effect arguments.

Kresge immediately pointed out (5) the ambiguity of this interpretation, and later expanded on the point with the inclusion of experimental measurements on an enzyme-catalyzed reaction and on host–guest complexation (6, 7). A linear dependence such as we observed (eq. [1]) and attributed to transition-state fractionation of magnitude ϕ_1 at the histidine–water bridge could in fact (eq. [2]) be the result of cancellation between a second-site contribution (of magnitude ϕ_2, for example, at the question mark in **1**) and a medium effect Z^n in the opposite direction.

$$[1] \qquad k_n = k_0 (1 - n + n\phi_1)$$

$$[2] \qquad k_n = k_0 (1 - n + n\phi_1) (1 - n + n\phi_2) Z^n$$

Fig. 2. Dependence of the logarithm of the rate constant k_{cat} on the logarithm of the activity of water in aqueous acetonitrile solutions for the action of α-chymotrypsin on three substrates. Conditions are the same as in Fig. 1. The lines are drawn through the mean values (41 s^{-1} for the Phe substrate, 14 s^{-1} for the Trp substrate, 2.5 s^{-1} for the Leu substrate).



We have now returned to this matter and present herein measurements in which acetonitrile is used to perturb the environment in which deacylation of various acyl-α-chymotrypsins is occurring. The use of organic solvents in the perturbation of enzyme systems is now a well-developed field in terms of both structural and dynamic information (8). The information now presented enables further consideration of the number of sites that are likely to contribute to stabilization of the transition state for enzymic deacylation.

Results

Kinetics of α-chymotrypsin-catalyzed hydrolysis of *N*-carbobenzyloxy-L-aminoacyl-*p*-nitrophenoxides (*Z*-L-aminoacyl-ONp) in mixtures of acetonitrile and protium oxide

The hydrolysis (eq. [3]) of the activated L-amino-acid esters *Z*-Leu-ONp, *Z*-Phe-ONp, and *Z*-Trp-ONp, where Leu means L-leucyl (R = $CH_2CH(CH_3)_2$ in eq. [3]), Phe means L-phenylalanyl (R = $CH_2C_6H_5$ in eq. [3]), and Trp means L-tryptophanyl (R = CH_2-indolyl in eq. [3]), *Z* means $C_6H_5CH_2OCO$, and ONp means O-*p*-nitrophenyl, in aqueous solutions containing from 15.0 to 60% (v/v) acetonitrile at pH 7.00 (phosphate buffer) and 25.0°C obeys the Michaelis–Menten kinetic law (eq. [4], where *v* is the initial velocity, e_0 is the total enzyme concentration, and [S] is the concentration of substrate). The values of the two rate constants k_{cat} and k_{cat}/K_m have been tabulated and are available as Supplementary Material.[2] The values are presented graphically in

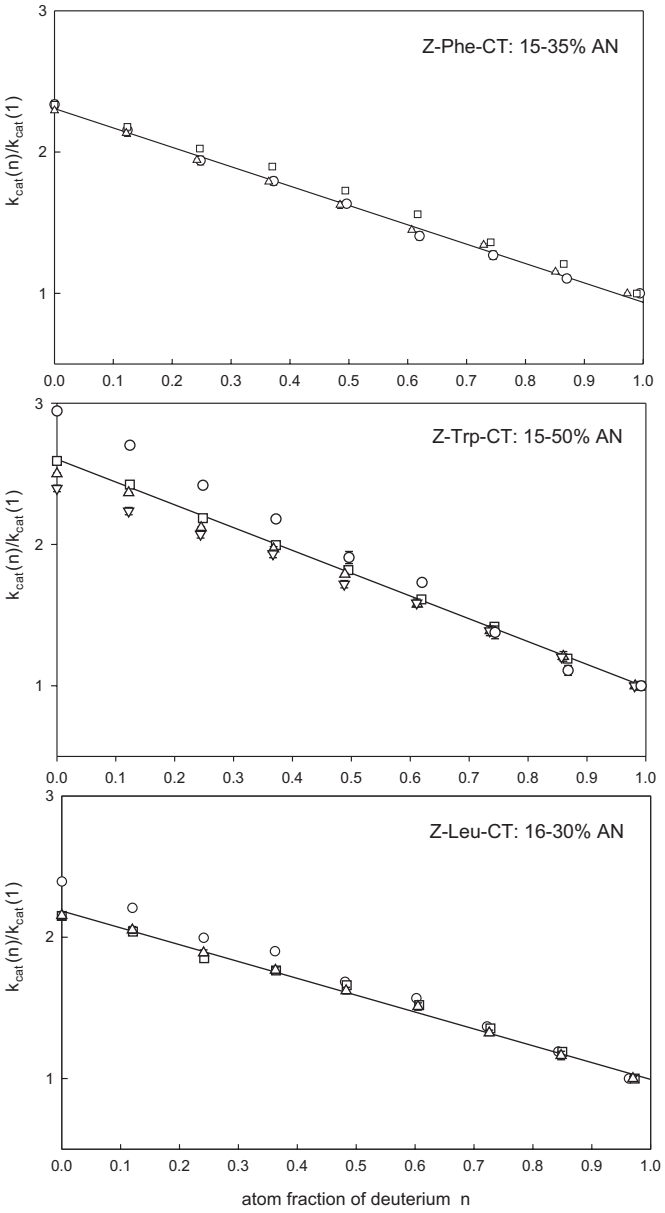
Fig. 3. Proton inventories (rate constant vs. atom fraction of deuterium in mixed isotopic solvents) for k_{cat}, effectively the rate constant for deacylation of each of the three acyl α-chymotrypsins indicated. Conditions are the same as in Fig. 1. The symbols indicate the percentage (v/v) of acetonitrile in the medium: circles (15.1 for the Phe case, 14.8 for Trp, 15.9 for Leu); squares (20.1 for Phe, 19.8 for Trp, 20.0 for Leu); triangles (35.4 for Phe, 35.3 for Trp, 30.3 for Leu); and inverted triangles, 50.1 for Trp. The straight lines are the linear least-squares fits of all data on each plot.



Figs. 1 and 2 as plots versus the activity of water in acetonitrile–water mixtures. Values of the activity of water were obtained as described in the experimental section. Generally consistent results were obtained for *Z*-Phe-ONp in aqueous solutions containing 20%, 50%, and 80% (v/v) acetonitrile at pH 8.00 (triethylamine buffer) at 25.2°C. The values of k_{cat} (s^{-1}) were 59 ± 3 (20%), 48 ± 2 (50%), and 12 ± 1 (80%).

[3] $C_6H_5CH_2OCONHCHRCOONp + H_2O \rightarrow C_6H_5CH_2OCONHCHRCOO^- + {}^-ONp + 2\ H^+$

[4] $v/e_0 = k_{cat}\ [S] / (K_m + [S])$

Isotope effects and proton inventories for k_{cat} in the α-chymotrypsin-catalyzed hydrolysis of *N*-carbobenzyloxy-L-aminoacyl-*p*-nitrophenoxides (*Z*-L-aminoacyl-ONp) in mixtures of acetonitrile and protium oxide and deuterium oxide

The values of the rate constants at saturating concentrations of the substrate in binary mixtures of protium and deuterium oxide are given in the Supplementary Material.[2] The values are presented graphically in Fig. 3 as plots versus *n*, the atom fraction of deuterium in the isotopic solvent mixtures. In mixtures of acetonitrile and water, *n* refers to the atom fraction of deuterium in the aqueous component alone.

Discussion

Dependence of k_{cat} and k_{cat}/K_m on the water content of acetonitrile–water mixtures

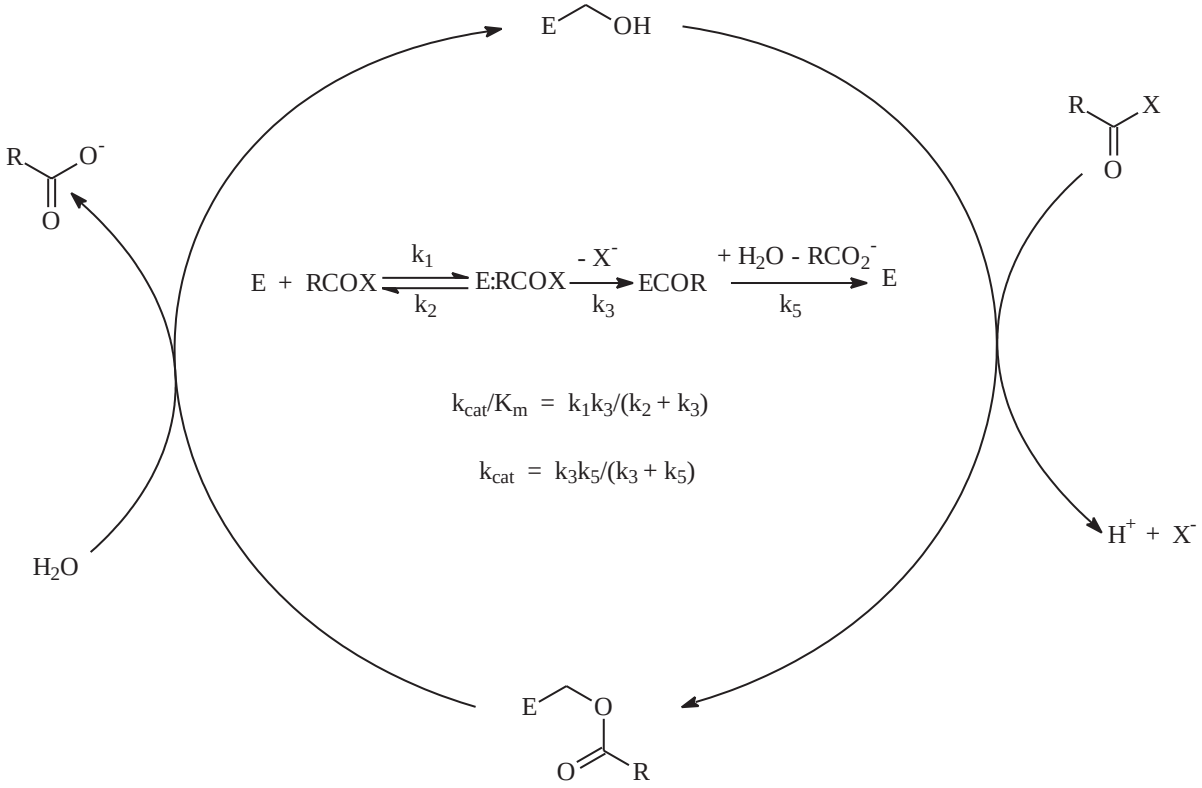
The results of Figs. 1 and 2 show that the rate constant k_{cat}/K_m is greatly dependent on the activity of water in acetonitrile mixtures in the range of 15–60% acetonitrile, while the rate constant k_{cat} is unaffected by the activity (or the molarity) of water in these mixtures. This result seems counterintuitive in terms of the well-established mechanism of action of the serine proteases (9), as shown in Fig. 4. The overall reaction has two stages, acylation of the enzyme by the substrate to form an acyl–enzyme intermediate, and deacylation of the acyl–enzyme intermediate by water to regenerate free enzyme, completing the catalytic cycle. The kinetics, also illustrated in Fig. 4, can be described by the two rate constants k_{cat}/K_m and k_{cat}.

The overall second-order rate constant k_{cat}/K_m leads from free reactants through the transition state for acylation of the enzyme, and can thus be considered the rate constant for the acylation reaction. Although the stoichiometry of this reaction is not explicitly dependent on the amount of water in the medium, the rate constant k_{cat}/K_m nevertheless is a sharp function of the amount of water, decreasing as the 34th to the 36th power of the activity of water. From 15% acetonitrile to 60% acetonitrile, the value of k_{cat}/K_m falls by a factor of 900 (Phe substrate), 500 (Trp substrate, not studied at 60% acetonitrile — the ratio given is for 50% acetonitrile), and 1400 (Leu substrate).

The first-order rate constant k_{cat} leads in principle from either or both of the enzyme complexes E:RCOX (enzyme–substrate complex) and ECOR (acyl–enzyme) to the transition state(s) following them. However, with such reactive esters as the *p*-nitrophenyl species used here, acylation of the enzyme (rate constant k_3) tends to be much faster than acyl transfer to water (rate constant k_5), so that k_{cat} is approximately equal to k_5 and is thus the rate constant for the deacylation reaction. The stoichiometry of this reaction is explicitly dependent on the first power of the water concentration, yet the rate constant varies little and unsystematically over the range 15–60% acetonitrile. The molarity of water varies from 46.9 M in 15% acetonitrile to 22.2 M in 60% acetonitrile, or by a factor of 2.1. The values of k_{cat} in

© 1999 NRC Canada

Fig. 4. Simple mechanistic scheme for the serine proteases, including α-chymotrypsin. The kinetics is shown in the center. The reaction proceeds through an initial acylation stage (right side), the effective rate constant for which is k_{cat}/K_m. The acyl enzyme (bottom) then reacts with water to go through the deacylation stage (left side) for which (in the case of reactive esters where $k_3 >> k_5$) the effective rate constant is k_{cat}.



these limiting solvents are 44 and 32 s^{-1} (Phe substrate); 14 and 14 s^{-1} (Trp substrate, not studied at 60% acetonitrile — the last value is thus for 50% acetonitrile); 2.5 and 2.4 s^{-1} (Leu substrate). For the Phe substrate at pH 8, k_{cat} is 59 s^{-1}at 50% acetonitrile but does decline to 12 s^{-1} at 80% acetonitrile. Clearly the variation in k_{cat} is much smaller than even the stoichiometric first-power prediction (at least below 60% acetonitrile) and greatly smaller than the factors of 500–1400 seen for k_{cat}/K_m.

Simple, speculative explanations of the results can be given. The large factor by which the value of k_{cat}/K_m decreases may be a result of two contributing causes. First, organic solvents such as acetonitrile can compete for the recognition sites of serine proteases and thus may act as competitive inhibitors that increase the work required for binding of the substrate and passage through the transition state for acylation. Second, considerable hydration of the enzyme structure may be required to maintain the flexibility necessary for admission of the substrate to the active site and subsequent reaction.

The fact that k_{cat} is independent of the water content of the medium may result from the strong binding of a nucleophilic water molecule in the active site, thus assuring that all enzyme molecules possess the nucleophilic water regardless of the composition of the external medium.

Proton inventories in mixtures of water and acetonitrile

The data plotted in Fig. 3 show that, with two exceptions, the solvent isotope effects and proton inventories for deacylation of the acyl enzymes formed from the Phe, Trp, and Leu substrates are very similar in various acetontrile–water mixtures. For media from 15 to 35% acetonitrile, the *Z*-Phe enzyme undergoes deacylation with solvent isotope effects of 2.3–2.5 and nearly identical, linear, proton inventories. For media from 20 to 50% acetonitrile, the Z-Trp enzyme undergoes deacylation with solvent isotope effects of 2.4–2.6 and identical, linear, proton inventories. However, for 15% acetonitrile a larger isotope effect (around 3.0) is seen, although the proton inventory remains linear. For 20 and 30% acetonitrile, the *Z*-Leu enzyme undergoes deacylation with solvent isotope effects of 2.1–2.2 and identical, linear, proton inventories. However, for 16% acetonitrile a larger isotope effect (around 2.4) is seen, although the proton inventory remains linear.

The linearity of the proton inventories appears to indicate that, with possible exceptions, the solvent isotope effects arise almost entirely from a single site in the deacylation transition state. This is presumably the protonic bridge between His 57 and the oxygen center of either the water molecule (if generation of the tetrahedral intermediate through attack of water is largely rate limiting) or the serine residue (if decomposition of the tetrahedral intermediate through expulsion of serine is largely rate limiting). The magnitude of the solvent isotope effects (2–3) is consistent with general experience in general acid–base catalyzed reactions (10). The effect does not distinguish between a proton that is "in flight" (i.e., participates in the reaction-coordinate motion) and one engaged in what is currently called a low-barrier hydrogen bond. In agreement with Eliason and Kreevoy (11)

© 1999 NRC Canada

and earlier views we expressed (12), we suspect that a low-barrier hydrogen bond stabilizes the transition state here.

Conclusions

The fact that the proton inventories and solvent isotope effects generally remain linear over a considerable range of solvent compositions suggests that the medium plays no role in controlling the magnitude or character of the *largest contribution* to the solvent isotope effects and proton inventories (see below for smaller contributions). If there were actually multiple contributions to the major part of the isotope effect from generalized medium effects, then it would seem likely that strong variations in the composition of the medium would lead to non-linearity in the proton inventories as the medium-dependent part of the isotope effect was changed. The conclusion that the secondary site (at the question mark in **1** does not generate an isotope effect or participate in catalysis for these deacylation reactions therefore seems justifiable.

There are two exceptions to the observation of constant isotope effect and identical proton inventory in different media. These exceptions are the shifts from an isotope effect of 2.5 to an isotope effect of 3.0 as the acetonitrile content falls from higher values to 15% for the Trp acyl enzyme and from an isotope effect of 2.2 to one of 2.5 as the acetonitrile content falls from higher values to 16% for the Leu acyl enzyme. Both changes in the isotope effect are relatively small (factors of 1.2 and 1.1, respectively) and may in fact signal the incursion of medium effects of the order of 10–20% as the medium approaches pure water. However, the effects are in the same direction as the single-site effect and would therefore not conceal any normal isotope effect from a secondary-site contribution. Thus the absence of a secondary-site contribution appears a reasonable conclusion.

Although there seem to be no generalized medium effects at work in the enzymic deacylation reactions examined here, they certainly exist. Stein et al. (13) and Kresge and coworkers (7) found such effects, for example, in the acylation reactions of the serine proteases. Therefore, Kresge's critique (5) is in general one that requires attention.

Experimental

Materials

Buffer salts and spectranalyzed acetonitrile were obtained from Fisher Scientific Co. Deuterium oxide (99.9%) was obtained from Aldrich Chemical Co. Substrates were obtained from Sigma Chemical Co. and stored in a desiccator below 0°C. Bovine pancreatic α-chymotrypsin (EC 3.4.21.1) was obtained from Sigma Chemical Co. as a salt-free, lyophilized, three-times recrystallized powder with an activity of 42 BTEE units/mg of solid and was stored in a desiccator below 0°C. Distilled water was deionized on an ion-exchange column before use.

Solutions

Buffers were prepared in mixtures of protium oxide, deuterium oxide, and acetonitrile with constant weights of buffer acid and buffer base. Densities of water–acetonitrile mixtures were determined pycnometrically and found to be within 1.2–1.7% of the densities estimated as the weighted average of the densities of the pure solvents. To obtain the activities of water a_w in mixtures of acetonitrile and water, the data of Vierk (14) and of Maslan and Stoddard (15) at 20 and 30°C were fitted to third-order polynomial functions in the mole fraction of acetonitrile. Values at other temperatures were interpolated or extrapolated assuming a linear relation between ln a_w and $1/T$. The effective pH in mixtures of acetonitrile and water, pH*, was estimated by the method of Perrin and Dempsey (16) according to which $pH^* = R - \delta$, where R is the apparent pH as read from a pH-meter equipped with a glass electrode. Values of δ were available from the work of Douheret (17) for some mixtures of acetonitrile and water. These values were fitted to a third-order polynomial in the mole fraction of acetonitrile so that δ could be obtained for other mixtures by interpolation or extrapolation. The magnitude of δ never exceeded 0.1–0.4. The effective pH in mixtures of protium and deuterium oxides was obtained from the customary correction to the glass-electrode reading (3*c*).

Kinetics

Initial rates of enzyme-catalyzed hydrolysis were determined as slopes of absorbance at 400 nm vs. time. Reaction solutions of 3 mL volume in a quartz cuvette, lacking only enzyme, were thermally equilibrated in the cell compartment of an HP 8542A diode-array spectrophotometer and reaction was initiated by injection of 10 μL of enzyme stock solution. After manual mixing, data collection was initiated. Initial rates in absorbance units were converted to molar units on the basis of measured extinction coefficients for acetonitrile–water mixtures. For the range 0–30% (v/v) acetonitrile, the extinction coefficients were constant within 0.1%, so that the average value of 9830 M^{-1} cm^{-1} was used for all cases. Values of k_{cat} and k_{cat}/K_m were obtained by weighted least-squares fitting of specific initial velocities (initial rate/total enzyme concentration) to substrate concentrations in a double-reciprocal (Lineweaver–Burk) formulation.

Photoinduced electron transfer chemistry of 2,3-dicyanonaphthalene[1]

Lorenzo Brancaleon, Darryl Brousmiche, and Linda J. Johnston

Abstract: The electron transfer photochemistry of 2,3-dicyanonaphthalene has been studied by a combination of fluorescence and transient absorption spectroscopy. The singlet excited state has a lifetime of 26 ns in acetonitrile and reacts with aromatic and alkene donors with oxidation potentials less than ~1.8 V with rate constants that are close to the diffusion-controlled limit. Transient absorption measurements demonstrate that the fluorescence quenching leads to efficient formation of free-radical ions. The radical ion yields have been measured for several donors and are compared to those for the more commonly used sensitizer, 1.4-dicyanonaphthalene. In the absence of added donors, direct excitation of 2,3-dicyanonaphthalene provides evidence for photoionization at high laser energy, in addition to triplet formation. The results illustrate the utility of this sensitizer for photoinduced electron transfer reactions.

Key words: photoinduced electron transfer, laser flash photolysis, fluorescence, photosensitizers.

Résumé : Faisant appel à la fluorescence et à la spectroscopie d'absorption des espèces transitoires, on a étudié la photochimie du transfert d'électron dans le 2,3-dicyanonaphtalène. L'état excité singulet possède un temps de vie de 26 ns dans l'acétonitrile et il réagit avec les donneurs aromatiques et alcéniques ayant des potentiels d'oxydation inférieurs à environ 1,8 V, avec des constantes de vitesse qui se rapprochent de la limite sous contrôle de la diffusion. Les mesures d'absorption par les espèces transitoires démontrent que la désactivation de la fluorescence conduit à des ions radicaux libres. Les rendements en ion radical ont été mesurés pour plusieurs donneurs et on les a comparés à ceux du sensibilisateur le plus couramment utilisé, le 1,4-dicyanonaphtalène. En absence de donneurs ajoutés, l'excitation directe du 2,3-dicyanonaphtalène fournit des données qui suggèrent la présence, en plus de la formation d'un triplet, d'une photoionisation à énergie de laser élevée. Les résultats illustrent l'utilité de ce sensibilisateur pour les réactions de transfert d'électron photoinduites.

Mots clés : transfert d'électron photoinduit, photolyse laser éclair, fluorescence, photosensibilisateurs.

[Traduit par la Rédaction]

Introduction

Photoinduced electron transfer (PET) reactions are of increasing utility in synthetic chemistry (1) and of significant importance in areas as diverse as biology and materials science (2). In particular, the use of zeolites as a medium for carrying out PET reactions has potential advantages in minimizing the back electron transfer that limits the efficiency of singlet PET in solution and in controlling product distributions (3, 4). Our recent work in this area (5) has established that 2,3-dicyanonaphthalene (2,3-DCN) is a useful sensitizer, since it is more readily included in X and Y zeolites than other dicyanoaromatics. This work has prompted us to examine the photochemistry of 2,3-DCN in solution and to compare it to other more commonly used cyanoaromatics. We report herein the solution characterization of the photoinduced electron transfer and photoionization behavior of this sensitizer using fluorescence and transient absorption spectroscopies. The results demonstrate that 2,3-DCN has some advantages over certain other cyanoaromatic sensitizers since it has a relatively long fluorescence lifetime and gives reasonably high radical-ion yields. Photoionization of the sensitizer is also observed at high laser energies.

Experimental section

2,3-Dicyanonaphthalene was sublimed and recrystallized from acetonitrile before use. 1,4-Dicyanonaphthalene was prepared according to a literature procedure (6) and purified by chromatography on alumina followed by recrystallization. Donors were purified by recrystallization or passage through a small alumina column. Solvents were spectrograde and were used as received.

Steady state and time-resolved fluorescence measurements were carried out using a PTI spectrometer equipped with single-photon counting capabilities. The laser flash photolysis system has been described in detail (7). For these experiments either a Lumonics EX-530 excimer laser (XeCl, 308 nm, 6 ns/pulse, <40 mJ/pulse), a Molectron UV-24 nitrogen laser (337 nm, 10 ns/pulse, <10 mJ/pulse), or a Lumonics HY750 Nd:YAG laser (355 nm, 10 ns/pulse,

<40 mJ/pulse) was used for sample excitation. Samples were contained in 7 × 7 mm^2 static or flow-through quartz cuvettes and were purged with either oxygen or nitrogen for at least 10 min before use.

Results and discussion

Fluorescence spectroscopy

Fluorescence spectra and lifetimes for 2,3-DCN were measured in a number of organic solvents. The fluorescence spectrum exhibits a structured emission with maxima at 342, 359, and 376 nm in acetonitrile (Fig. 1) that shows a good mirror image relationship with the ground state absorption. The spectrum is independent of the excitation wavelength between 280 and 345 nm and shows no evidence for the broad long-wavelength emission that has been observed in hydrocarbon matrices at low temperature (8). A fluorescence quantum yield of 0.3 for 2,3-DCN in acetonitrile was measured using anthracene in cyclohexane as a standard (Φ = 0.30) (9).

Fluorescence lifetimes for 2,3-DCN in nitrogen-purged solutions were measured by single-photon counting; values obtained ranged from 35.5 ns in cyclohexane to 14.4 ns in dichloromethane, with an intermediate value of 26.0 ns in acetonitrile (Table 1). The latter is somewhat longer than a previous estimate of 13.2 ns (10). The fluorescence of 2,3-DCN is efficiently quenched by oxygen with a measured lifetime of 7 ns for oxygen-saturated acetonitrile. The fluorescence lifetime is unaffected by the ground state concentration over the range 20–80 μM in acetonitrile. For comparison, the fluorescence lifetime for 1,4-dicyanonaphthalene (1,4-DCN) in acetonitrile is 12 ns, in good agreement with literature data (11). Fluorescence lifetimes of 14.9 and 16.6 ns in acetonitrile have been reported for 9,10-dicyanoanthracene and 2,6,9,10-tetracyanoanthracene, respectively (12).

Bimolecular rate constants for quenching of 2,3-DCN fluorescence by a number of aromatic donors were determined by measuring the fluorescence decay as a function of the concentration of added quencher. The data were plotted according to eq. [1] where k_f is the reciprocal of the fluorescence lifetime in the presence of a given concentration of quencher, k_0 is the reciprocal of the fluorescence lifetime in the absence of quencher, and k_q is the quenching rate constant.

Table 1. Fluorescence lifetimes for 2,3-DCN in nitrogen-purged solutions at room temperature.

Solvent	τ_F, ns
Cyclohexane	35.5
Diethyl ether	32.0
Benzene	28.8
Acetonitrile	26.0
Methanol	25.5
Carbon tetrachloride	18.7
Chloroform	15.8
Dichloromethane	14.4

[1] $$k_f = k_0 + k_q(\text{donor})$$

A typical plot for *trans*-anethole (*t*-A) is shown in the inset of Fig. 1, and the quenching rate constants for a series of donors with varying oxidation potentials are listed in Table 2. No change in the 2,3-DCN fluorescence spectrum was observed at the highest concentration of donor used for determining the rate constants. The rate constant for biphenyl quenching is 2.1 × 10^8 M^{-1} s^{-1}, whereas tetramethylbenzene, 1,4-dimethoxybenzene, 4-vinylanisole, and *t*-A all have rate constants at or close to the diffusion-controlled limit. Data for fluorescence quenching of 1,4-DCN by the same series of donors are also included in Table 2. In this case rate constants in excess of 10^{10} M^{-1} s^{-1} were measured for all five donors. These results are consistent with the estimated singlet energies (82.8 and 85.9 kcal from absorption spectra) and reduction potentials (–1.67, –1.28 V vs. SCE in acetonitrile) for 2,3-DCN and 1,4-DCN (13). The Rehm–Weller equation can be used to estimate that electron transfer will be exergonic by ~5 kcal for donors with oxidation potentials of <1.7 V for 2,3-DCN and <2.1 V for 1,4-DCN (15). This is in good agreement with our observations of diffusion-controlled rate constants for quenching of singlet 1,4-DCN with all the donors in Table 1 and with the reduction by two orders of magnitude in the rate constant for quenching of singlet 2,3-DCN by biphenyl, which has E_{ox} of 1.96 V (12). For comparison, the singlet excited state of 9,10-dicyanoanthracene reacts with biphenyl with a rate constant of ~1 × 10^8 M^{-1} s^{-1}, which is very similar to that measured herein for 2,3-DCN (16).

Laser flash photolysis

Excitation of 2,3-DCN (60 μM) in nitrogen-saturated acetonitrile at 308 or 337 nm at low laser energy (<5 mJ/pulse) generates the transient absorption spectrum shown in Fig. 2, with λ_{max} at 410 and 430 nm. The transient decays with mixed kinetics over a period of 50–100 μs, with the observed decay increasing with increasing laser energy, and reacts with oxygen with an observed decay rate constant of 7 × 10^6 s^{-1} in oxygen-saturated acetonitrile. The 430 nm transient is assigned to triplet 2,3-DCN based on its reactivity toward oxygen and the similarity of the observed spectrum

1,4-Dimethoxybenzene	1.35	1.6×10^{10}	1.9×10^{10}	0.24	0.028

[a]Data from refs. 12–14.

Fig. 2. Transient absorption spectra measured 0.3 (●) and 2 (◆) μs after 337 nm (5 mJ/pulse) excitation of 60 μM 2,3-DCN in nitrogen-saturated acetonitrile.

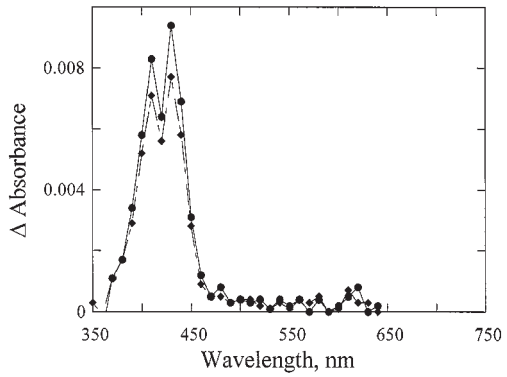

Fig. 3. Transient absorption spectra measured 0.8 (●), 5.2 (◆), and 29 (■) μs after 308 nm (35 mJ/pulse) excitation of 60 μM 2,3-DCN in nitrogen-saturated acetonitrile.

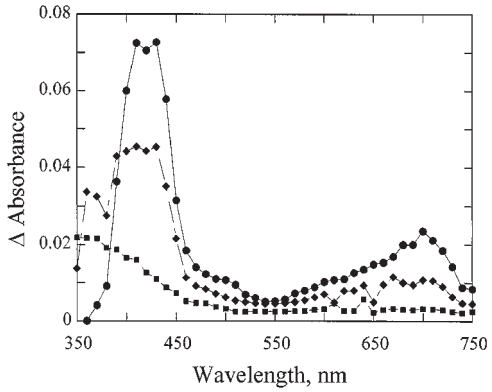


to those for a number of substituted naphthalene triplets (17). Similar spectra are observed in less polar solvents such as diethyl ether and dichloromethane–hexane mixtures.

Excitation of 2,3-DCN in nitrogen-saturated acetonitrile with higher laser energy (>10 mJ/pulse) at either 337 or 308 nm gives more complex transient spectra that show new bands at 700 and 370 nm in addition to the triplet (Fig. 3). There is also a small shoulder at 490 nm. There are clearly two new species, since the lifetime of the 700 nm species (and the shoulder at 490 nm) decreases substantially for oxygen-saturated solutions, whereas the decay kinetics at 380 nm are very similar for oxygen and nitrogen. The yield of both species is lower in oxygen-saturated solution, consistent with reduction of the transient yields via oxygen quenching of singlet 2,3-DCN. These results can be explained by photoionization of 2,3-DCN (eq. [2]) to give a radical cation (380 nm, insensitive to oxygen) and a solvated electron that is trapped by the ground state to give a radical anion (eq. [3], 700 nm absorption). In agreement with this assignment, the 2-cyanonaphthalene radical anion has absorption bands between 650 and 740 nm and 410 and 470 nm in a matrix at low temperature and the corresponding radical cation has a sharper absorption at approximately 700 nm and a broad band at 400 nm (18). Transient spectra obtained at high laser energy in dichloromethane–hexane mixtures also show the formation of the 380 nm transient but the 700 nm absorption is not detected, presumably due to rapid scavenging of the electron or radical anion by the chlorinated solvent.

[2] $$\text{2,3-DCN} \xrightarrow{h\nu} \text{2,3-DCN}^{\bullet+} + e^-_{solv}$$

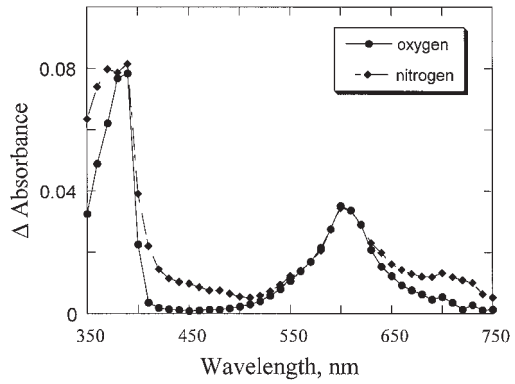
[3] $$\text{2,3-DCN} \xrightarrow{e^-_{solv}} \text{2,3-DCN}^{\bullet-}$$

The yield of the additional long-wavelength signals in acetonitrile was measured as a function of the 308 nm laser energy. Plots of signal intensity at 680 nm vs. laser energy were reasonably linear, except for an induction period at low energies. By contrast, the triplet signal at 430 nm showed pronounced negative curvature over the same range of laser energies, indicative of saturation effects due to either ground state depletion or competitive absorption of the excitation pulse by both ground and triplet states. The difference between the intensity dependence for the triplet and radical ions, in combination with the fact that only the triplet is observed at low energies using 337 nm excitation, suggest that the photoionization – electron trapping process that generates the observed radical cation–anion signals has a two-photon component. It is also possible that electron transfer interactions between singlet 2,3-DCN and the ground state give rise directly to the radical cation–anion pair. However, the laser energy dependence of the transient phenomena and the fact that the singlet lifetime is not dependent on the 2,3-DCN concentration are inconsistent with this hypothesis.

Excitation (337 nm) of 2,3-DCN in the presence of 0.01 M *t*-A in acetonitrile generates the transient spectrum shown in Fig. 4. This concentration of *t*-A does not absorb significantly at the excitation wavelength and, based on the fluorescence data, will result in approximately 75% singlet quenching. Consistent with this, triplet 2,3-DCN is not observed. However, there are strong absorptions at both 600 and 390 nm, in agreement with the reported spectrum for *t*-$A^{\bullet+}$, (19), as well as weaker bands beyond 650 nm, between

© 1999 NRC Canada

Fig. 4. Transient absorption spectra measured 320 ns after 337 nm excitation of 55 μM 2,3-DCN plus 0.01 M *trans*-anethole in nitrogen (◆)and oxygen (●) saturated acetonitrile.



420 and 520 nm and at 365 nm. Spectra recorded for oxygen-saturated solutions are clearly due solely to *t*-A$^{\bullet+}$ (Fig. 4). The additional weaker absorptions that are removed by oxygen can be more readily characterized by excitation of a nitrogen-saturated solution containing tetrabutylammonium chloride as a selective radical-cation scavenger (19). Under these conditions the radical anion (2,3-DCN$^{\bullet-}$) expected as the other product of electron transfer quenching of singlet 2,3-DCN by *t*-A (eq. [4]) should be readily visible. The spectrum obtained, although weak, indicates that 2,3-DCN$^{\bullet-}$ absorbs between 650 and 730 nm, with additional absorption between 420 and 500 nm and at ~365 nm. These results are consistent with the assignment of the weak absorption in the 700 nm region obtained by excitation of 2,3-DCN alone to the radical anion.

[4] $$2,3\text{-DCN}^* + t\text{-A} \rightarrow 2,3\text{-DCN}^{\bullet+} + t\text{-A}^{\bullet+}$$

Triplet 2,3-DCN was also quenched by *t*-A, $k_q = 1.8 \times 10^{10}$ M^{-1} s^{-1}. However, triplet quenching is not accompanied by the formation of *t*-A$^{\bullet+}$, based on the lack of radical-cation signal upon excitation of 2,3-DCN in the presence of 0.4 mM *t*-A. Under these conditions there is approximately 90% triplet quenching and <1% singlet quenching by *t*-A. These results are consistent with the large decrease in available excitation energy for the triplet as compared to the singlet excited state of 2,3-DCN (20).[3]

Transient spectra measured in the presence of sufficient donor to quench >80% of 2,3-DCN singlets were also recorded for biphenyl, 4-vinylanisole, and 1,4-dimethoxybenzene. For both biphenyl and 1,4-dimethoxybenzene, absorptions due to the respective radical cations at 670 and 460 nm were readily detected (18). The 4-vinylanisole radical cation with λ_{max} at 600 nm was also observed; however, the radical cation decayed quite rapidly, with an observed rate constant of ~3×10^6 s^{-1} for 1.7 mM substrate. This short lifetime is due to rapid reaction of the radical cation with the precursor alkene, for which a quenching rate constant of 1.4×10^9 M^{-1} s^{-1} has been reported in acetonitrile (21).

The yields of radical cations obtained by quenching singlet 2,3-DCN and 1,4-DCN were measured for biphenyl, *t*-A, and 1,4-dimethoxybenzene. The required molar absorption coefficients for the radical cations for the latter two donors were estimated by electron transfer quenching of biphenyl radical cation in the following manner. The biphenyl radical cation was generated by electron transfer quenching of singlet 1,4-DCN in the presence of 0.21 M biphenyl in oxygenated acetonitrile. The signal intensity due to biphenyl radical cation was then measured. Either *t*-A or 1,4-dimethoxybenzene was added to an identical aliquot of the same stock solution of 1,4-DCN plus biphenyl. The concentration of donor used was sufficient to quench >99% of the biphenyl radical cations, assuming a diffusion-controlled rate constant, without competing with biphenyl for quenching of the initial 1,4-DCN singlet. The intensity of the donor radical cations at their respective maxima was then measured. By making the reasonable assumption that quenching of the biphenyl radical cation occurs exclusively by electron transfer, the ratio of the secondary donor/biphenyl signal intensities (for an average of three determinations) can be used in combination with the reported molar absorption coefficient of 14 500 M^{-1} cm^{-1} for biphenyl$^{\bullet+}$ (12) to calculate molar absorption coefficients for the donor radical cations. Values of 10 960 and 12 200 M^{-1} cm^{-1} were estimated for the *t*-A and dimethoxybenzene radical cations at 600 and 470 nm, respectively. Note that although these numbers may contain absolute errors due to the biphenyl radical-cation molar absorption coefficient, they provide a consistent set of numbers to use for estimation of the quantum yields, as outlined below.

The yield of the donor radical cations was estimated by measuring the radical-cation signal intensity as a function of laser energy for samples of both the naphthalene plus donor and the benzophenone actinometer. The slopes of these plots, along with the molar absorption coefficients for the radical cation and benzophenone triplet (7800 M^{-1} cm^{-1} at 525 nm in benzene) and a value of 1 for the yield of benzophenone triplet, were then used to calculate the donor radical-cation yields, according to eq. [5]. The values are listed in Table 2. The measured yields were corrected, where necessary, for incomplete quenching of the singlet naphthalene by the donor. To eliminate any contribution from naphthalene radical anions, the radical-cation intensities were measured for oxygenated solutions for cases where a sufficiently high donor concentration could be used to prevent competitive quenching of the singlet naphthalene by oxygen rather than the donor.

[5] $$\Phi(\text{donor}^{\bullet+}) = [\text{slope (donor}^{\bullet+})/\text{slope (^{3}Bp)}]\ [\varepsilon(^3\text{Bp})/\varepsilon(\text{donor}^{\bullet+})]\ [\Phi(^3\text{Bp})]$$

For each of the naphthalene sensitizers the measured radical-ion yield decreases dramatically with decreasing oxidation potential of the donor. For example, for 2,3-DCN the yields are 0.90, 0.57, and 0.24 for biphenyl, *t*-A, and 1,4-dimethoxybenzene. These results are to be expected on the basis of the decrease in the back electron transfer rate with

[3] The singlet energy of 2,3-DCN is estimated at 82.8 kcal/mol as compared to triplet energies for substituted naphthalenes, which range from 58 to 61 kcal/mol (20).

© 1999 NRC Canada

increasing reaction exothermicity in the Marcus inverted region, as studied in detail by Farid and Gould for a variety of singlet sensitizers (12, 22). The measured radical-ion yields for each donor are higher for 2,3-DCN than for 1,4-DCN, consistent with formation of a higher-energy ion pair for the former sensitizer. Note that the difference in reduction potential for the two naphthalenes means that back electron transfer for the initial radical-ion pair is approximately 0.4 V more exothermic for 2,3-DCN than for 1,4-DCN for any given donor. The very high radical-ion yields for biphenyl, particularly for 2,3-DCN, are in good agreement with literature data; for example, a quantum yield for free-radical ion formation for 9,10-dicyanoanthracene/ biphenyl of 0.83 has been reported (15).

Conclusions

A combination of fluorescence and transient absorption spectroscopies demonstrates that singlet 2,3-dicyanonaphthalene undergoes efficient electron transfer quenching by a variety of aromatic and arylalkene donors. Both the radical cations and the 2,3-DCN radical anion have been characterized and their yields compared to those obtained with 1,4-DCN. In both cases the radical-ion yields show the expected increase with increasing oxidation potential of the donor. Our results demonstrate that 2,3-DCN provides a useful alternative to other cyanoaromatic sensitizers, particularly since it has a relatively long singlet lifetime that minimizes the amount of donor required for complete singlet quenching. Although it can be used to oxidize a similar range of donors to the widely used 1,4-dicyanonaphthalene, it has the added advantage of giving substantially higher free radical-ion yields. Surprisingly, laser excitation of 2,3-DCN also leads to photoionization but this appears to be predominantly a biphotonic process that is unlikely to play a role in steady state photoinduced electron transfer reactions.

A mechanism for efficient proton-transfer catalysis. Intramolecular general acid catalysis of the hydrolysis of 1-arylethyl ethers of salicylic acid

Sarah E. Barber, Kathryn E.S. Dean, and Anthony J. Kirby

Abstract: The *tert*-butyl (**1**) and 1-arylethyl ethers (**2**) of salicylic acid are hydrolyzed with efficient general acid catalysis by the ortho-COOH group. The half-life of the neutral COOH form of the *tert*-butyl ether is 15.2 min at 39°, and the estimated acceleration by the COOH group of **2**, X = Me, Y = H is 2.13×10^5. The salicylate leaving group from **2** (X = Me, Y = H) has an effective pK_a of 2.9, compared with a nominal pK_a of 8.52. Analysis of substituent effects in both arylethyl and leaving groups provides the most detailed available mechanistic insight into a reaction involving efficient intramolecular proton-transfer catalysis. The mechanism is very different from classical general acid–base catalysis. Proton transfer takes place very rapidly within a developing strong hydrogen bond, and though an integral part of the C—O cleavage process is practically uncoupled from it. "Strategic delay" of the proton-transfer step, relative to C—O cleavage, makes a significant contribution to efficiency by setting up the conditions for the formation of the strong, intramolecular hydrogen bond.

Key words: catalysis, carboxyl, hydrogen bond, proton transfer, enzyme mechanism.

Résumé : L'hydrolyse des éthers *tert*-butyle (**1**) et 1-aryléthyle (**2**) de l'acide salicylique se fait avec une catalyse acide générale efficace par le groupe -COOH en ortho. La demi-vie de la forme COOH neutre de l'éther *tert*-butyle est de 15,2 min à 39° et l'accélération évaluée de groupe COOH de **2**, X = Me, Y = H, est de $2{,}13 \times 10^5$. Le pK_a effectif du groupe salicylate partant de **2** (X = Me, Y = H) est égal à 2,9 par rapport à un pK_a nominal de 8,52. L'analyse des effets de substituants du groupe arylméthyle et des groupes partants fournit la compréhension mécanistique la plus détaillée possible pour une réaction impliquant une catalyse efficace par transfert intramoléculaire de proton. Le mécanisme est très différent de la catalyse générale acide–base classique. Le transfert de proton se produit très rapidement dans la forte liaison hydrogène qui se développe et, même s'il fait partie intégrale du processus de clivage de la liaison C—O, il n'existe pratiquement pas de couplage avec lui.

Mots clés : catalyse, carboxyle, liaison hydrogène, transfert de proton, mécanisme enzymatique.

[Traduit par la Rédaction]

We are interested in the efficiency and thus the detailed mechanism of intramolecular general acid–base catalysis, as a simple model for the myriad of proton-transfer processes involved in catalysis by enzymes (1). General acid–base catalysis may be presumed to be efficient in enzyme reactions: but effective molarities (EM) for intramolecular proton-transfer catalysis are generally lower by many orders of magnitude than those for intramolecular nucleophilic (cyclization) reactions, rising above 1–10 M only in special cases (2). We have recently reported systems showing intramolecular general acid catalysis with EMs as high as 10^6 M, (3) and have identified as a key factor the development of a strong intramolecular hydrogen bond as the reaction proceeds. For optimum catalytic efficiency this H-bond should be absent in the ground state and strongest in the transition state, a state of affairs that depends critically on geometry and the extent and timing of charge development during the reaction. We report an in-depth investigation of general acid catalysis by the carboxyl group of nucleophilic substitution at carbon (S_N1 and S_N2), a reaction that is particularly well understood. The leaving group is the salicylate monoanion, known to be stabilised by a strong H-bond of well-defined geometry, and the substrates its methyl, *tert*-butyl **1**, and substituted 1-phenylethyl ethers **2**. We can vary the degree of charge development on the leaving group oxygen by varying the carbon centre from which it leaves systematically in the series **2**, by changing the pattern of substitution on both the salicylate leaving group and on the aromatic ring of the 1-phenylethyl group (4).

rapidly in organic solvents, but was stable in aqueous solution as the anion. Compounds of the 1-phenylethyl series **2** were generated from the stable methyl esters (**3**): the esters were made by the Williamson ether synthesis, as described in the experimental section. Stock solutions of the stable carboxylate anions of ethers **2** were prepared by hydrolysing the esters **3** with 1.1 equiv. of KOH in 50% dioxan–water. For all but the most reactive esters, hydrolysis required an overnight reflux. The resulting solutions were diluted, and used directly in kinetic studies (final concentration 10^{-4}–10^{-5} mol dm^{-3}).

Table 1 shows kinetic data for the hydrolysis of the *tert*-butyl ether **1**, and Table 2 summarizes results for the series of 16 1-arylethyl ethers **2** studied in this work. Rates are very sensitive to substitution in the aromatic ring of the 1-arylethyl derivatives, and pH–rate profiles were measured conveniently at 25, 39, and 65°C, respectively, for compounds with X = 4-Me, H, and 3-Br. (In the case of the very reactive compound **2**, X = 4-MeO, Y = 5-NO_2, hydrolysis was too fast to follow below pH 4, even at 1°C, and we could only estimate the plateau rate constant.) Derived rate constants were extrapolated to a common 39°C for the 4-Me and 3-Br systems from variable temperature measurements, which gave the thermodynamic parameters also shown in Table 2.

The reactions of all the salicylic acid derivatives show the same basic features, illustrated in Fig. 1 for the hydrolysis of **1** and **2** (X = H, Y = H, and X = H, Y = NO_2); namely, rapid acid-catalysed hydrolysis at low pH, a plateau between pH 2–4 corresponding to the pH-independent hydrolysis of the COOH form, and no significant reaction above pH 6. The plateau reaction is of primary interest for this work, and derived kinetic data in the tables refer to rate constants k_0 for this process. Rate constants and apparent carboxyl-group pK_a values were calculated from eq. [1]:

$$[1] \qquad k_{obs} = \frac{k_0 + k_H a_H}{1 + (K_a/a_H)}$$

where k_H is the rate constant for the acid-catalysed hydrolysis of the neutral acid form and k_0 the first-order rate constant calculated for its spontaneous hydrolysis. (The alternative interpretation as the kinetically equivalent acid-catalysed hydrolysis of the carboxylate anion has been ruled out in many similar cases.) The pK_{app} values agree with the values expected for the pK_a values of salicylic acid derivatives.

For comparison with the reactions of the salicylic acid derivatives **2,** we measured rates of hydrolysis under the same conditions for a series of simple sterically comparable aryl 1-phenylethyl ethers **4**, with good leaving groups and a 2-NO_2 in place of the *o*-COOH group. These compounds are less reactive than the corresponding salicyl ethers and were mostly studied at 80°C. The data appear in Table 3. The 2,4-dinitrophenyl ethers (**4**, Y = NO_2, X = H, and 4-Me) show pH-independent hydrolysis between pH 4.5 and 9. These reactions are not catalysed by added buffer. (Some amine buffers are an exception, but HPLC examination of the products showed that the products were anilines, and thus that the amines had attacked the aromatic ring, rather than the benzylic centre.) The addition of the strongly nucleophilic thiosulphate (Swain–Scott (5) *n* value –6.4) had no effect on the rate of hydrolysis of **4** (Y = NO_2, X = H), and in the case of **4** (Y = NO_2, X = 4-Me) a six-fold increase in the concentration of thiosulphate gave only a 20% increase in the rate constant. This increase is so small that it is reasonable to suppose that less powerful nucleophiles would have little or no effect on the rates for these compounds. In other cases, a small *negative* effect of increasing buffer concentration could be ascribed to specific salt effects.

In only one case was there convincing evidence for buffer catalysis, and thus for an S_N2 reaction at the benzylic centre. The least reactive 2,4-dinitrophenyl ether **4** (Y = NO_2, X = 3-Br) also showed a pH-independent reaction between pH 4.5 and pH 6.3, at 80°C. Pseudo-first-order behaviour could be observed only at buffer concentrations of 0.08 M or less, but at these concentrations the reaction was catalysed by the free-base form of the buffer (linear dependence on acetate or phosphate concentration, 52% acceleration for 0.08 M phosphate, 50% free base). Extrapolation of the observed rate constants to zero buffer gave the same intercept for both phosphate and acetate buffers (and second-order rate constants of 3.04×10^{-4} and 5.66×10^{-5}, respectively). It seems clear that in this case, against the slowest spontaneous reaction, acetate and phosphate anions do provide some nucleophilic catalysis.

This result suggested that the 1-(3-bromophenyl)ethyl salicyl ethers would be the most likely to show second-order reactions with nucleophiles, but the addition of bromide (Swain–Scott *n* value –3.9) had no effect on the rate of hydrolysis of (**2**, Y = H, X = 3-Br), and the reaction was not catalysed to a measurable extent by the base component of added buffers. The reactions of (**2**, Y = 5-NO_2, X = 3-Br) were studied in the presence of substituted pyridines. These were of particular interest because they catalyse the hydrolysis of salicyl phosphate (6), and we would be able to compare the two β_{nuc} values obtained. However, the rate of reaction was independent of the concentration of cyanopyridine, and a slight rate retardation was seen in the presence of increasing concentrations of nicotinamide.

It is difficult to observe S_N2 reactions with the 1-arylethyl ethers **2** because of the dominant S_N1 reactions of these systems, so we searched carefully for reactions of nucleophiles with the methyl ether **5**. A UV study in water (0.1 M HCl and formate buffer) showed no detectable reaction with 0.9 M iodide or thiocyanate (we should have detected a reaction with a first-order rate constant $\geq 10^{-8}$ s^{-1}), and we could detect no reaction by ^{1}H NMR with iodide in acetonitrile,

DMSO (both run for 2 weeks at 40°C) or water (5 days at 60°). We find no measurable nucleophilic catalysis for any of the salicyl ethers **1** and **2**.

Discussion

Ethers **1** and **2** were designed to show intramolecular general acid-catalysed hydrolysis at a measurable rate.[2] A phenol oxygen is not normally a viable leaving group in the S_N1 or S_N2 reaction in the absence of very strongly electron-withdrawing substituents on the aromatic ring, and the rapid cleavage of the ether C—O bonds confirms that catalysis by the *o*-COOH group is efficient in these systems.

Figure 1 shows pH–rate profiles for the hydrolysis of three representative alkyl salicyl ethers, the unsubstituted *tert*-butyl (**1**) and 1-phenylethyl derivatives and the 5-nitro-

[2] The terms general acid and general base catalysis are commonly used to denote either or both of (*i*) a kinetic dependence on the concentration of the general acid or base, and (*ii*) the *mechanism* of this catalysis, involving rate-determining proton transfer from or to the general acid or base. The intramolecular reaction in the salicylic acid system is so efficient that catalysis by external general acids is not significant.

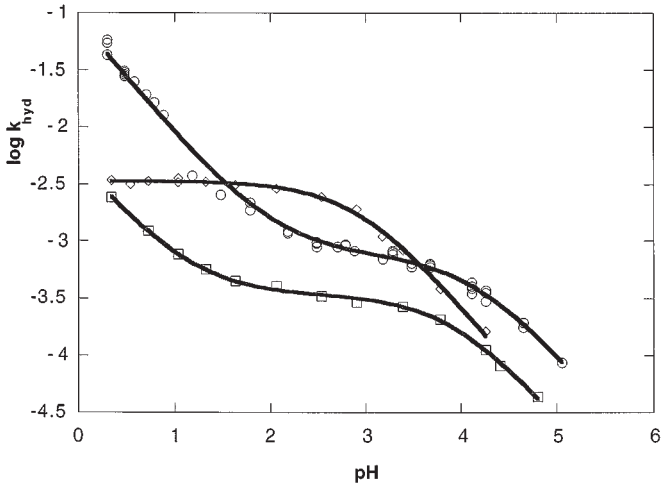
Fig. 1. pH–rate profiles (at 39°C) for the hydrolysis of *tert*-butyl (**1**, circles) and salicyl and 5-nitrosalicyl 1-phenylethyl ethers (**2**, Y = H and NO_2: squares and diamonds, respectively).



salicyl 1-phenylethyl ether (**2**, X = H, Y = NO_2), with the nitro group *para* to the leaving group oxygen. The salicylic acid derivatives **2** studied in this work all showed similar behaviour: more or less well-defined pH-independent regions between pH 2–4, with rates falling off at high pH with the fraction of COOH form present. The presence of this feature for the salicylic acid derivatives, and its absence for their methyl esters is prima facie evidence for catalysis by the carboxylic acid group. The half-life of the neutral COOH form of *tert*-butyl ether **1** is 15.2 min at 39°, less than half that of the unsubstituted 1-phenylethyl ether **2** (X = Y = H, in 10% dioxan:water); which is itself accelerated by a factor of 10 by the introduction of the 5-nitro group.

At low pH specific acid catalysis is observed, for all except the ethers derived from 5-nitrosalicylic acid. (This latter effect is the simple consequence of a high rate of spontaneous hydrolysis combined with a lower k_H for the compounds with the most electronegative leaving groups.)

These rapid hydrolysis reactions are an indication of the efficiency of intramolecular catalysis by the *o*-COOH group in the reactions of salicylic acid derivatives **1** and **2**. The corresponding intermolecular reaction, general acid catalysis of the hydrolysis of similar ethers by carboxylic acids, is too slow to measure, so we cannot estimate effective molarities (EM) (2). As an alternative. we can quantify efficiency by the comparison with the spontaneous reactions of simple ethers **4**. The slope of the linear free energy relationship (β_{LG}) relating the rates of hydrolysis of the series of four compounds **4**, with X = 4-Me to the pK_a of the leaving group is –0.95 ± 0.03 at 80°C. This allows us to estimate an acceleration of 2.13×10^5 by the COOH group of **2**, X = Me, Y = H (at 39°C, based on an estimated pK_a of 8.52 (7) for the phenol OH of salicylic acid). The observed rate of the COOH-catalysed reaction of this compound is equivalent to that expected for the spontaneous departure of the anion derived from a phenol of pK_a = 2.9. The effective pK_a of the leaving group is close to 3 for similar reactions of salicyl acetals (8, 9) and of salicyl phosphate (6).

The effect of nucleophiles on the expulsion of salicylate

The evidence indicates that the enhanced salicylate leaving group departs in a simple S_N1 reaction, and we discuss the details of this process below. We looked also for evidence of catalysis of the attack of nucleophiles (the S_N2 reaction). We could find no detectable reaction at the methyl group of salicylic acid methyl ether **5**; and would expect none for the reaction of the *tert*-butyl ether **1**.

The work of Richard and Jencks (10, 11) has defined the point at which the nucleophilic substitution reactions of 1-phenylethyl derivatives become coupled concerted. No reactions of 1-(4-methylphenyl) ethyl derivatives are concerted: unsubstituted 1-phenylethyl derivatives show a coupled concerted reaction only with azide, but 1-(3-bromophenyl)ethyl chloride shows coupled concerted reactions with azide and with acetate ion, though not with solvent. Consistently, we find evidence for weak catalysis by acetate and phosphate anions of the cleavage of 1-(3-bromophenyl)ethyl 2,4-dinitrophenylether **4** (Y = NO_2, X = 3-Br) at 80°C, but for no other derivative **4**.

Thus, our 1-(3-bromophenyl)ethyl salicyl ethers **2** (Y = 3-Br) are the most likely to show second-order reactions with nucleophiles. We found no evidence of such reactivity. The thermodynamic activation parameters for the cleavage reaction (Table 2) similarly offer no evidence to support nucleophilic participation by water in the transition state for hydrolysis: entropies of activation for the most reactive compounds **2**, X = 4-Me are generally large and positive. Those for the least reactive systems (**2**, Y = 3-Br) are significantly more negative, consistent with more ordering of solvent in the transition states for hydrolysis. Nevertheless, we do not consider that these reactions are solvent assisted, since far better nucleophiles than water show no effect.

These activation parameters can be compared with those obtained for the spontaneous hydrolyses of two 2,4-dinitrophenyl ethers **4** (Table 3). Here also the entropy of activation for the hydrolysis of (**4**, X = 3-Br, Y = NO_2), which shows

evidence of nucleophilic participation with nucleophiles, is more negative than that for the hydrolysis of 4 (X = 4-Me, Y = NO_2), which does not. However, the differences are small and entropies of activation are unreliable mechanistic indicators, particularly in the borderline region which we are considering. It seems clear that the cleavage of the C—O bond of the salicyl ethers 2 generally involves — at the carbon centre — simple, uncoupled S_N1 mechanisms.

The effect of changing cation lifetime

As the substituent X becomes less electron-donating, the lifetime of the 1-phenylethyl cation (**6**) decreases. From the work of Richard et al. (11–13), we know the lifetimes of such cations in 1:1 trifluoroethanol:water. These lifetimes were determined by competition experiments between solvent and azide, or for short-lived cations, by extrapolation of the data obtained for long-lived cations. In water, the lifetimes are reduced by a factor of two.[3] Thus, we can study the effect of the substituent X on the rate of hydrolysis of 1-phenylethyl salicyl ethers and relate this to the cation lifetime.

For a fixed salicylate leaving group (**2**, constant Y) the plateau rate constants, corrected to 39°C, are correlated by the Hammett equation using substituent constants σ^{+} (Table 4). The plots are linear over a range of cation lifetimes, from 10^{-8} s (4-MeO substituent) to 5×10^{-13} s (3-Br substituent). There is no evidence of a change in catalytic mechanism as the cation lifetimes gets close to the point at which its existence may be called into question.

The correlations are generally good and give values of ρ^{+} from –4.5 to –5.3. A number of literature values of ρ^{+} are available for comparison, for the solvolysis of various 1-phenylethyl derivatives. For substituted 1-phenylethyl chlorides in 80% aqueous acetone, $\rho^{+} = -5.5$ (14); for 1-phenylethylacetates in 30% aqueous ethanol, ρ^{+} is –5.7 (15); and for 1-phenylethyl diphenylphosphinates in 80% ethanol–water, ρ^{+} is –5.1 (16). Also Richard et al. (13) correlated rate constants for the acid-catalysed cleavage of 1-phenylethyl alcohols to form the corresponding cations in 1:1 trifluoroethanol:water), obtaining $\rho^{+} = -4.5$. Similar values were observed in this work for the hydrolyses of simple 2,4-dinitrophenyl ethers **4** (Table 3). These are correlated by the Hammett equation with $\rho^{+} = -4.9 \pm 0.5$.

These large, negative values of ρ^{+} indicate similar, substantial charge development on carbon. The fact that the values obtained for the hydrolysis of 1-phenylethyl salicyl ethers are close to those obtained for the solvolyses of other 1-phenylethyl derivatives show that charge development on carbon is also similar.

A more meaningful estimate of the extent of charge development on carbon is obtained by comparing ρ^{+} with the equilibrium value of for complete C—O cleavage, i.e., for the formation of 1-phenylethyl carbocations, ρ^{+}_{eq}. Richard et al. (13) determined ρ^{+} not only for the acid-catalysed cleav-

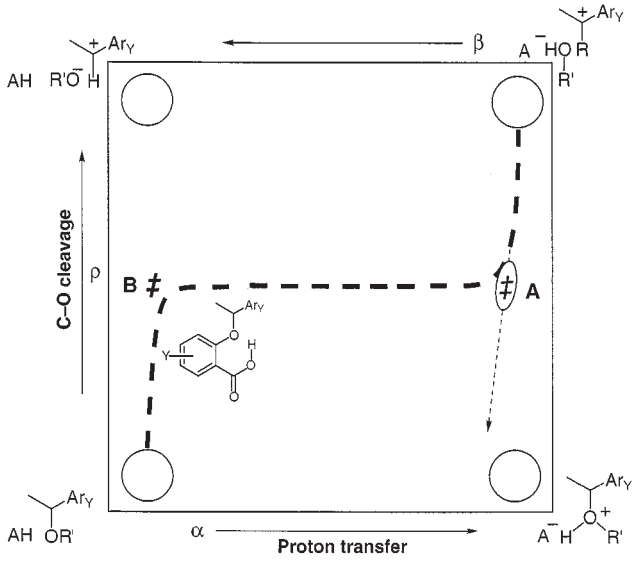
Fig. 2. More O-Ferrall – Jencks potential energy diagram for the intramolecular general acid-catalysed cleavage of 1-arylethyl ethers (**2**) of salicylic acid to salicylate anion and the 1-arylethyl cation **6**. A and B represent, respectively, the approximate locations of the transition state for the reverse reaction, the general base-catalysed hydrolysis of the cations (21), and the forward reaction studied in this work. For details see the text.



age of substituted 1-phenylethyl alcohols, but also for the reverse reaction, the addition of water to the cations, for which ρ^+ is +4.5. The equilibrium value ρ^+_{eq} ($\rho^+_{forward} - \rho^+_{reverse}$) is therefore –9. Using this as an estimate for ρ^+_{eq} for the formation of phenylethyl cations from our ethers suggests that the cleavage of the C—O bond in our salicyl ethers **2** has proceeded about halfway towards the cation in the transition state.[4]

The effect of changing leaving group

When the substituent Y on the aromatic ring of salicylate is varied, both the leaving group capability of the phenol and the strength of the catalytic carboxylic acid group change. Jaffé's simple extension of the Hammett equation (17) (eq. [2]) allows the two effects to be separated.

$$[2] \quad \log (k_H/k_Y)/\sigma_{carboxyl} = \rho_{carboxyl} + (\rho_{phenol} \times \sigma_{phenol})/\sigma_{carboxyl}$$

Values of σ_{phenol} and $\rho_{carboxyl}$ obtained from the Jaffé plots are also given in Table 4. It is evident that in the transition state for the hydrolysis of these 1-phenylethyl salicyl ethers, there is extensive bond cleavage to the leaving group oxygen. The values of ρ_{phenol} may be converted to β_{LG} values by dividing by ρ for the ionization of a phenol, –2.28 (18). The values obtained should be close to normalized β_{LG}, since substituent effects on the carbon basicity of phenolate anions are the same, within experimental error, as those on their proton basicity (19, 20). They are also close to those (0.4–0.5) reported for other salicylic acid acetals (9). So too are the very low values of $\rho_{carboxyl}$, indicating that substantial bond cleavage to oxygen is accompanied by very little proton transfer from the COOH group in the transition state for C—O cleavage. These data complement those for charge development at carbon: rather less than half a full negative charge appears to have developed on the leaving group oxygen in the transition state, as expected if the bond is about half broken, with an apparently very small amount of the developing charge neutralized by proton transfer.

Further evidence that proton transfer in the transition state is not far advanced comes from the solvent deuterium isotope effects. These were measured for four compounds, and are presented in Tables 1 and 2. The values of k^0_H/k^0_D are similar to those obtained for other salicylate derivatives (6, 9), and lead, as before, to the conclusion that proton transfer in the transition state is not as far developed as in a classical general acid-catalysed reaction.

The $\rho_{carboxyl}$ values could be converted into α-values by dividing them by ρ for the ionization of the carboxylic acid, but in this case the operation is of little significance since the ρ values are already close to zero. (The apparent pK_a values for the five substituted compounds are correlated reasonably well by the simple Hammett equation but, surprisingly, give ρ values substantially greater than 1, especially for the set with X = H (Table 4). The value ρ for the ionization of benzoic acids is 1 by definition, and generally close to 1 for substituted benzoic acids.)

There is no evidence for any change in α as the stability of the cation changes (X is varied), indicating that the interaction coefficient P_{xy} is zero. It is not possible to assess whether α changes with changing pK_a of the phenol, because the Jaffé treatment assumes ρ_{phenol} and $\rho_{carboxyl}$ to be constant over the range of compounds studied. If this assumption were not valid the Jaffé equation would not give linear plots. In fact, for one subset of ethers (with X = 3-Br) the plot does not give a good straight line (see the data in Table 3). However, if the extent of proton transfer to the leaving group oxygen were changing over this series, we would not expect the simple Hammett plot (which assumes that the substituent Y affects the phenol oxygen *only*) to give a good straight line; but it does (r = 0.992). We conclude that the nonlinear Jaffé plot is not indicative of varying extents of proton transfer, but rather reflects experimental error.

A final question is whether the extent of bond cleavage to the leaving group in the transition state changes with the stability of the cation. For values of ρ_{phenol} obtained from the simple Hammett correlation (Table 4), ρ_{phenol} is significantly smaller for X = 4-Me than for X = H and X = 3-Br. However, the difference disappears when the Jaffé treatment is applied, and we conclude that this variation also is unlikely to be significant. Our general conclusion is that, as far as C—O cleavage is concerned, the expulsion of salicylate closely resembles the spontaneous expulsion of good leaving groups.

The mechanism for efficient general acid catalysis

The detailed mechanism which emerges for proton-transfer catalysis appears to be very different from the mechanism proposed by Jencks and his co-workers (21, 22) for

[4] There is some variation in the values of ρ^+ as the leaving group changes (Table 4), but the variation is not systematic, and the errors too large to convince us that the effect is significant.

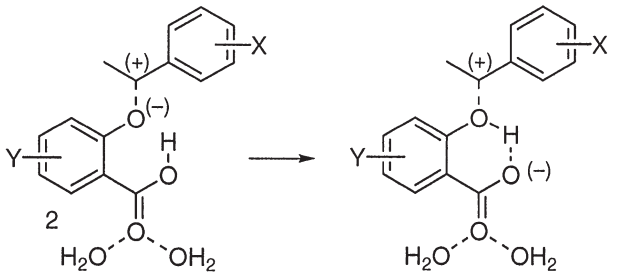
Scheme 1.



the reverse reaction, the general base-catalysed addition of alcohols to 1-phenylethyl cations. The contrast is illustrated in Fig. 2, a More O-Ferrall – Jencks diagram based on the published plot of Richard and Jencks (21). These authors found that addition of alcohols and phenols to moderately stable arylethyl cations **6** is general base catalysed, and shows very small β values: corresponding to large α-values, close to unity, for general acid catalysis of ether cleavage. We by contrast observe very *small* α-values for the cleavage of the salicyl ethers **2**. Richard and Jencks proposed a reaction coordinate close to vertical, and thus very close to the pathway for specific acid catalysis (broken arrow, transition state A in Fig. 2) for the reaction of the 1-(4-methoxyphenyl)ethyl cation with trifluoroethanol, suggesting that general base catalysis will not be observed at all for the addition of alcohols to less stable carbocations. Thus, the evidence indicates that the expulsion of the phenol oxygen catalysed by the *ortho*-carboxylic acid group of salicylate, for which the transition state (B) appears to be located on the opposite side of Fig. 2, is quite different from the same reaction catalysed by external general acids.

This apparent divergence can be resolved if the (vertical) C—O cleavage and (horizontal) proton-transfer processes (Fig. 2) are only very weakly coupled, as indicated by the bold, broken reaction coordinate, with the transition state at B. We have pointed out previously, for the similar departure of salicylate from salicyl phosphate (6), that in the ground state of salicylic acid derivatives in aqueous solution the carboxyl group is likely to be rotated out of the plane of the aromatic ring (as it is in crystal structures of salicylic acid derivatives), while proton transfer takes place most efficiently in the plane, within a developing strong hydrogen bond. At a given stage of the C—O cleavage process of a reactive system **2**, the COOH group must rotate into plane to form the hydrogen bond to the developing oxyanion. If this happens at, or close to, the point where proton transfer becomes thermodynamically favourable, it marks the transition state for the overall process. The apparent contradiction between the observation of efficient proton-transfer catalysis and the evidence that there is little proton transfer from the COOH group in the transition state arises because the proton transfer itself takes place within a strong intramolecular — and thus low barrier (23–25) — hydrogen bond. Because the proton-transfer step is so fast it (*i*) does not contribute significantly to the free energy barrier to reaction, and (*ii*) takes place faster than the solvation shell can respond (Scheme 1). In this situation (related to the "imperfect synchronisation of resonance" identified by Bernasconi (26) in reactions involving proton transfer to carbon), substituent effects (here, the Bronsted α coefficient) lag behind changes in local bond order.

Mechanism and efficiency in intramolecular general acid catalysis

This mechanism in which a rapid proton-transfer step forms an integral part of C—O cleavage, yet is largely uncoupled from it, is the most detailed available for a reaction involving efficient intramolecular proton-transfer catalysis. An important question is whether it is peculiar to the salicylic acid leaving group: the potential delocalization of the developing negative charge of the leaving group oxygen into the COOH group is a relevant special feature of the salicylate system. Comparisons of ρ values for the leaving group suggest that this is not a major factor.

This mechanism also differs significantly from a classical general acid catalysis mechanism. Most well-characterized general species catalysed reactions appear to involve proton transfers strongly coupled to bond making or breaking processes, as indicated by Bronsted coefficients in the region 0.5 ± 0.2. However, intramolecular versions of these reactions are characteristically inefficient. Features of the proposed mechanism which clearly favour efficient catalysis are the development of a strong hydrogen bond in the transition state, and its absence in the ground state (1). This makes possible the horizontal section of the pathway (Fig. 2) for efficient catalysis.

This strategic delay in setting up the hydrogen bond that is central to efficient proton-transfer catalysis is incidental to the salicylate system, but could clearly make an important contribution to catalysis in an enzyme active site, where distance and geometry are under much closer control. The preliminary stages of C—O bond breaking, not a problem in reactive model systems, require separate, perhaps nucleophilic assistance in the case of the poor leaving groups involved in most enzyme-catalysed cleavages of C—OR and P—OR bonds, so details of systems where the two modes of catalysis might work together are of great potential interest. In this context, we find no evidence for catalysis of nucleophilic attack on any ether of salicylic acid. Such negative evidence is not strong, but the leaving group is good enough for nucleophilic attack to be expected for simple 1-(3-bromophenyl)ethyl ethers, on the basis of its observation for the 2,4-ditrophenyl derivative. We can speculate that the timing of the proton-transfer step may be too critical to be coupled with the attack of an outside nucleophile in this very simple model.

Experimental

Materials

Dry THF used in anion reactions was refluxed over sodium before use. Substituted methyl salicylates were obtained commercially (Aldrich) or prepared by esterification of the corresponding salicylic acid (BF_3–methanol). Substituted acetophenones and chlorobenzenes were obtained commercially (Aldrich or Fluka).

Column chromatography was performed on Merck Kieselgel 60 (7734) and flash chromatography on Merck Kieselgel 60 (9385). NMR spectra were recorded on a Varian EM390 instrument and IR spectra on a Perkin–Elmer 297 spectro-

photometer. Mass spectra were determined on a Kratos MS 30 instrument. Melting points (uncorrected) were determined on a Kofler hot stage apparatus.

1-Phenyl ethyl salicyl ethers **2** were prepared in situ by the alkaline hydrolysis of their methyl esters **3**. The esters **3** (Table 5) were in most cases made by the Williamson synthesis, by alkylation of the sodium salt of the methyl salicylate (Method A). Details follow for a representative example.

1-Phenylethyl (2-carbomethoxy)phenyl ether (3, X = H, Y = H)

Methyl salicylate (4 mL) was added to a suspension of sodium hydride (1.36 g) in THF. When effervescence had ceased the mixture was refluxed for 30 min, then cooled. 1-Phenylethyl bromide (5.73 g) and tetrabutyl ammonium bromide (0.97 g) were added and the mixture refluxed for 24 h. THF was removed under reduced pressure and water and ether added. The ether layer was separated and the water layer washed twice more with ether. The combined organic extracts were dried over sodium sulphate and solvent removed under reduced pressure. The residue was purified by column chromatography on silica gel under pressure using 10% ether–hexane as eluant, to give the ether (**3**, X = H, Y = H; 5.68 g, 71%) as an oil. ν_{max}: 1730, 1610, 1580, and 1500 cm^{-1}. δ_H (90 MHz, $CDCl_3$): 7.77 (IH, dd, 8, 2 Hz), 7.5–7.2 (6H, m), 7.0–6.7 (2H, m), 5.37 (lH, q, 6 Hz), 3.91 (3H, s), 1.61 (3H, d, 6 Hz). *m*/*z*: 256 (5%, M^+), 105 (100%, 1-phenylethyl cation) (found: M 256.1095; $C_{16}H_{16}O_3$ requires 256.1099).

Ethers of 5-nitrosalicylic acids were made by aromatic nucleophilic substitution reactions, of the substituted 1-phenylethanolate anion on the 2-chloro-5-nitrobenzoate (method B). For example:

1-(4-Methoxyphenyl)ethyl (2′-carboxymethyl-4′-nitrophenyl) ether 2 (X = OMe, Y = 5-NO_2)

Sodium hydride (0.14 g of a 60% slurry in oil) was suspended in dry THF and 1-(4-methoxyphenyl) ethanol (0.46 g) added. The mixture was refluxed for 30 min, then cooled. Sodium 2-chloro-4-nitrobenzoate was prepared separately by treating 2-chloro-4-nitro benzoic acid (0.61 g) with sodium hydride (0.12 g) in dry THF to give a white slurry of the sodium salt. Tetrabutylammonium bromide (0.1 g) was added and the slurry poured quickly into the solution of alcoholate anion. The mixture was stirred at 50°C for 24 h. Trimethyloxonium tetrafluoroborate (0.89 g) was then added and the mixture stirred for 1 h longer. During this time, the cloudy solution of the acid salt clarified as the carboxylate ion was methylated. The THF was removed under reduced pressure and dichloromethane added. The dichloromethane was extracted three times with 1 M HC1, three times with 1 M potassium bicarbonate, and once with saturated brine. The organic layer was dried over sodium sulphate and the solvent removed under reduced pressure to leave a brown oil. The oil was purified by column chromatography on silica gel under pressure using 25% ether–hexane as eluant to give **2** (X = 4-OMe, Y = 5-NO_2, 0.46 g, 47%) as an oil. ν_{max}: 1740 (C=O), 1620, 1600, 1500, 1520, and 1360 cm^{-1}. δ_H (90 MHz, $CDCl_3$): 8.71 (1H, d, 3Hz), 8.20 (lH, dd, 9, 3Hz), 7.37 (2H, d, 7.5 Hz), 6.95 (1H, d, 9 Hz), 6.91 (2H, d, 7.5 Hz), 5.50 (1H, q, 6Hz), 4.00 (3H, s), 3.81 (3H, s), 1.70 (3H, d, 6Hz). *m*/*z*: 331 (10%, M + 1), 135 (100%, 1-(4-methoxyphenyl)ethyl cation) (found: M^+ 331.1056; $C_{17}H_{17}NO_6$ requires 331.1056).

Aryl 1-phenylethyl ethers **4** were prepared by the same method, by S_NAr substitution on the chloro- or fluoronitrobenzene (e.g., by 1-(4-methylphenyl)ethoxide on 2,4-dinitrofluorobenzene for **4**, X = 4-Me, Y = 4-NO_2). Details are summarized in Table 6.

Kinetic measurements

Stock solutions (5 mM in dioxan) of aryl acetals were injected into buffer solutions in 10% (v/v) dioxan–water (up to 0.4 M total buffer) made up with KCl to ionic strength 1.0 M. Rates of hydrolysis were measured by monitoring the appearance of the aryloxide anion over time, at 39.2°C. Reactions were followed in 10% (v/v) dioxan–water, ionic strength 1.0 M (KCl), for at least three half-lives and end points taken after at least 10. Ether hydrolysis could in most

cases be followed directly by measuring the increase in UV absorbance as the salicylate anion was released, but for most 5-nitrosalicylic acid derivatives the change in absorbance was too small, so a simple pH jump technique was used. Reactions were initiated by injecting a sample of stock solution into 2 mL of buffer to give a final substrate concentration of about 5×10^{-4} mol dm^{-3}: aliquots were taken at intervals and injected into 2 mL portions of pH 10.5 buffer. This quenched the reaction and converted all the 5-nitrosalicylate into the dianion. All pH measurements were made under the conditions of the kinetic experiments using a Radiometer PHM82 pH meter fitted with a Russell CTWL electrode. Activities at pH < 2 were calculated by adding the appropriate activity coefficient correction (e.g., 0.18 at 39°, ionic strength 1.0 M with KCl) to –log [H^+]. The pD of solutions in D_2O was measured by adding 0.4 to the meter reading obtained using the same electrode standardized against H_2O buffers (27).

Ring opening of cyclobutene-1,2-dione and 3-trimethylsilylcyclobutene-1,2-dione. Dimerization/decarbonylation of a bisketene to a ketenylbutenolide

Annette D. Allen and Thomas T. Tidwell

Abstract: Hydrolysis of 3-trimethylsilyl-4,4-dichlorocyclobut-2-ene-1-one (**4**) in H_2SO_4 gave small amounts of cyclobutene-1,2-dione (**2a**) and 3-trimethylsilylcyclobutene-1,2-dione (**2d**). Photolysis of **2a** gave evidence for the formation of the bisketene ($CH{=}C{=}O_2$) (**1a**) in solution for the first time, as identified by the IR band at 2120 cm^{-1} and the ^1H NMR signal at δ 3.20. Thermolysis of **2d** gave evidence for the intermediacy of $O{=}C{=}CHC(SiMe_3){=}C{=}O$ (**1d**), with an ^1H NMR signal at δ 3.43, and the isolation of the unusual ketenyl lactone **6**, which could arise by formation of an unsymmetrical [2+2] ketene dimer from **1d**, followed by rearrangement and decarbonylation.

Key words: bisketenes, cyclobutenediones, ketene dimerization.

Résumé : L'hydrolyse de la 3-triméthylsilyl-4,4-dichlorocyclobut-2-ène-2-one (**4**) dans du H_2SO_4 fournit de faibles quantités de cyclobutène-1,2-dione (**2a**) et de 3-triméthylsilylcyclobutène-1,2-dione (**2d**). La photolyse du produit **2a** fournit des données suggérant pour la première fois qu'il peut y avoir formation du biscétène $(CH{=}C{=}O)_2$ (**1a**) en solution, identifié par la bande IR à 2120 cm^{-1} et du signal en RMN du ^1H à δ 3,20. La thermolyse du produit **2d** fournit des données suggérant la formation, comme intermédiaire, de la $O{=}C\text{-}CHC(SiMe_3){=}C{=}O$ (**1d**) qui présente un signal en RMN du ^1H à δ 3,43; elle permet aussi d'isoler la lactone céténylе inhabituelle **6** qui pourrait provenir de la formation, à partir de **1d**, de la formation d'un cétène dimère non symétrique [2+2] qui serait suivie d'un réarrangement et d'une décarbonylation.

Mots clés : biscétènes, cyclobutènediones, dimérisation de cétène.

[Traduit par la Rédaction]

The parent 1,2-bisketene 1,4-dioxo-1,3-butadiene (**1a**) is calculated at the MP2/6-31G*//MP2/6-31G* level to be most stable in the twisted structure shown, which is only 2.9 kcal/mol less stable than cyclobutenedione **2a** (1). The SiH_3, H, and bis(SiH_3) substituted bisketenes **1b** and **1c** are calculated at the MP2/6-31G*//HF/6-31G* level to be more stable than the corresponding cyclobutenedione **2b**,**c** by 0.5 and 4.9 kcal/mol, respectively (1). The preparation of **1a** by photolysis of the bis(diazoketone) **3** in an Ar matrix at 10 K has been reported (eq. [2]), as characterized by an IR band at 2125 cm^{-1} (2). The formation of **1a** as an unobserved intermediate from the pyrolysis of 4-cyclopentene-1,2,3-trione that gave the observed formation of **2a** has also been proposed (3). Because of our interest in the 1,2-bisketene–cyclobutenedione interconversion (4), it was attractive to attempt to observe **1a** and the Me_3Si analogue **1d** of **1b** in solution.

[1] 
where R = R^1 = H (**a**); R = SiH_3, R^1 = H (**b**); R = R^1 = SiH_3 (**c**); R = $SiMe_3$, R^1 = H (**d**).

[2] 
Results

Two syntheses of **2a** have been reported (5, 6), but because we had noticed that the desilylation of trimethylsilyl substituted cyclobutenones occurred in acid, it was decided to attempt the preparation of **2a** and **2d** in a one-pot procedure. To form a suitable precursor, the reaction of trimethylsilylacetylene with dichloroketene, generated in situ from zinc dechlorination of trichloroacetyl chloride, gave predom-

inant dichlorocylobutenone **4** (eq. [3]) as the major product, as reported by Danheiser and Sard (7).

[3] $CCl_3COCl + Me_3SiC{\equiv}CH \xrightarrow{Zn}$ 
[4] 
4 **5** **2d** **2a**

Hydrolysis of **4** at 60–65°C with concentrated H_2SO_4 for various times followed by quenching in ice water and extraction with ether resulted in the gradual disappearance of **4** with the formation of three new products, identified as described below as the rearranged chloride **5**, **2d**, and **2a**, in the relative yields shown, as measured by ^{1}H NMR (eq. [4], Table 1).

Chromatrographic separation of the product from 260 min reaction time gave **5** (obtained in 95% purity, containing 5% **4**, after three-fold rechromatography) and **2d** (8%). Each of these was fully characterized by spectroscopic means, with distinctive ^{1}H NMR signals in $CDCl_3$ for **5** (δ 0.37, 5.39) and **2d** (δ 0.35, 9.61). After extraction of the reaction mixture from another preparation with ether and evaporation of the solvent, crystallization from pentane gave crystals of **2a**, identified spectroscopically, in good agreement with literature values (5, 6).

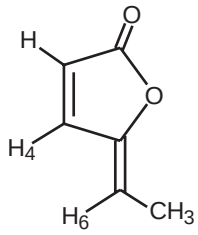
The ^{17}O NMR chemical shift of **2a** was also measured as δ 514.5 ppm. Previous (8) ab initio calculations of ^{17}O chemical shifts of 1,2-cyclobutenediones gave values that deviated by 51 ppm downfield from experimentally available values (for the Cl, Cl and CH_3, CH_3 substituted derivatives), and application of this correction factor to that calculated for **2a** gives a prediction of δ 511 for **2a**, in close agreement to that observed experimentally. This ^{17}O shift is the lowest that has been reported for a cyclobutenedione (8), and is comparable to that of the $SiMe_3$, $SiMe_3$ derivative (499.1 ppm). The low-field shifts of these two compounds are consistent with the observed trend in which electron donor groups cause ^{17}O shifts to higher fields (8).

Upon photolysis of **2a** in isooctane with 300 and 350 nm light at 0°C, partial conversion to the bisketene **1a** was observed, as detected by the IR band at 2120 cm^{-1}, compared to the reported (2) absorption at 2125 cm^{-1} in an Ar matrix. The ^{1}H NMR spectrum showed a signal at δ 3.20 that disappeared with time, which is attributed to the bisketene, and which may be compared to the value for the ketenyl proton of $CH_2{=}CHCH{=}C{=}O$ of δ 4.0 (9). Efforts to observe the ^{13}C NMR spectrum were unsuccessful due to the lack of material.

Other signals appeared and their possible assignments included δ 8.90 (cyclopropenone, reported (10) 9.1 in CH_2Cl_2), 7.04 (maleic anhydride, identical to an authentic sample), 3.01 (succinic anhydride, identical to an authentic sample), and 1.91 (HC≡CH, identical to an authentic sample). These products correspond to the matrix observed products from mono- and bisdecarbonylation (2), the reaction with O_2 (previously (11) observed for $[Me_3SiC{=}C{=}O]_2$), and hydration.

Attempts to observe a UV band which could be reliably ascribed to **1a** and to measure a rate of reformation of **2a** were unsuccessful. From our published correlation (4) of the rates of bisketene ring closure with ketenyl substituent stabilizing parameters SE (log k = –0.292 Σ SE – 2.02), a predicted rate constant is 5.0 × 10^{-5} s^{-1} at 25°C, based on the SE value of 3.9 kcal/mol for H.

Photolysis of degassed solutions **2d** in $CDCl_3$ with 300–350 nm light resulted in the formation of a yellow color and complex ^{1}H NMR spectra, and so these were not pursued further. Thermolysis of **2d** in $CDCl_3$ for 6.7 h at 100°C gave ^{1}H NMR signals attributed to **1d** (^{1}H NMR signal at δ 3.43) and the ketenyl lactone **6** (Scheme 1). Evaporation of the solvent and chromatographic separation (silica gel, 3/2 CH_2Cl_2/hexane) gave **6** as a yellow solid that was identified by its IR spectrum (C=C=O at 2089 cm^{-1}, C=O at 1754, 1738 cm^{-1}, C=C at 1632 cm^{-1}), ^{1}H NMR ($CDCl_3$) δ 0.24 (Me_3Si), 0.28 (Me_3Si), 4.97 (CHC=C=O), and 7.31 (CH=CTMS), the correct M^+ peak (280) using EIMS or FAB, and the expected ^{13}C NMR spectrum. The *Z*-stereochemistry of the exocyclic double bond in **6** is tentatively assigned by analogy with *Z*-5-ethylidene-2(5*H*)-furanone (**7**) for which as in the case of **6** no coupling was detected between H_4 and H_6 in the ^{1}H NMR, whereas for *E*-**7** a coupling of 0.8 Hz was observed (12). Also, the chemical shift of H_4 in **6** (7.31 ppm) is similar to that of H_4 in *Z*-**7** (7.25 ppm).



Z–**7**

A possible mechanism for the formation of **6** from the bisketene **1d** is shown in Scheme 1. In this process, either an intermediate zwitterion **8** may be formed or there may be concerted formation of an unsymmetrical ketene dimer **9**. Either of these species may form the epoxide intermediate **10**, or the cyclopropanone **11**, which could then undergo decarbonylation to **6**. The interconversion of allene oxides analogous to **10** and cyclopropanones has been suggested (13, 14) to occur through oxyallyl species (15), and the reaction of bisketenes with dienes to form ketenylcyclobutan-

Scheme 1.

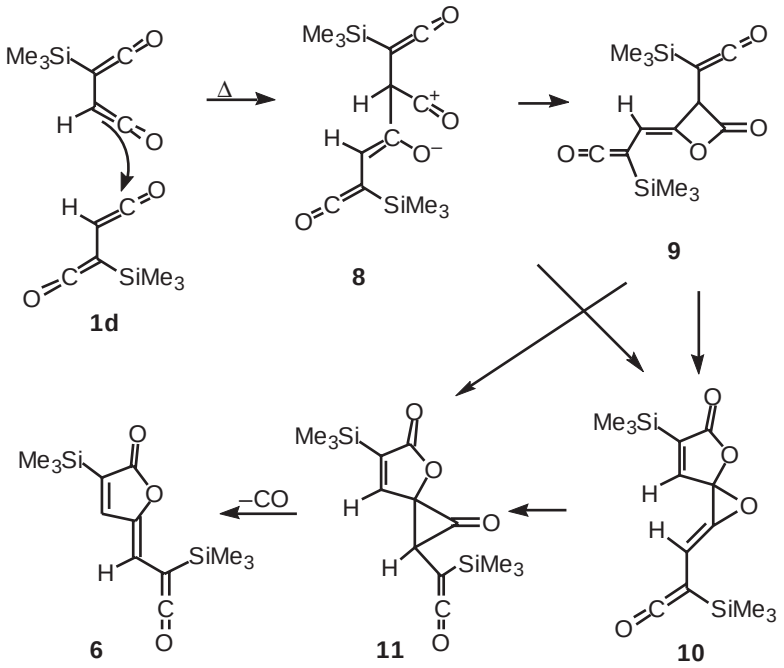

Table 1. Hydrolysis of **4** with H_2SO_4 at various times and relative yields of the products, **5**, **2d**, and **2a**.

	% yield (rel.)			
Time (min)	**4**	**5**	**2d**	**2a**
100	62	17	8	13
160	38	31	15	16
260	14	46	18	19

ones, which are analogous to the β-lactone **9** and which rearrange to spirocyclopropylbutenolides resembling **11**, has been demonstrated (16, 17). The intermediate **8** resembles those proposed as occurring in the mixed dimerizations of ketenes (18).

In summary, the cyclobutenediones **2a** and **2d** serve as precurors for the first solution phase observation of the bisketenes **1a** and **1d**. The latter is the first bisketene observed to undergo intermolecular self-reaction, eventually forming after decarbonylation the unusual ketenyl lactone **6**.

Experimental

General procedures

All reactions were carried out in oven-dried glassware under an atmosphere of N_2 or Ar. NMR spectra were measured with Varian Gemini 200 and XL-400 spectrometers. Infrared spectra were measured using a Nicolet DX FT-IR instrument. Mass spectra were obtained on a VG 70-2505 instrument by Dr. A. Young. Photolyses were carried out with a Rayonet RPR-100 photoreactor.

3-Trimethylsilylcyclobutene-1,2-dione (2d)

Cyclobutenone **4** (0.277 g, 1.3 mmol) was added to 6 mL conc. H_2SO_4 in a round-bottom flask, and the mixture was stirred while heating at 60–65°C for various times. The reaction mixture was added to 20 mL ice water and extracted 10 times with 10 mL portions of ether, and the combined ether layers were dried over $CaSO_4$ with small amounts of K_2CO_3 and evaporated, yielding a yellow oil, and the composition of the product was analyzed by ^{1}H NMR. Chromatography on Me_3SiCl treated silica gel with hexane gave **4** and **5**, and further chromatography (3% EtOAc in hexane) gave **2d** (0.016 g, 8%) as a yellow liquid. IR ($CDCl_3$): 1780 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.35 (s, 9, Me_3Si), 9.61 (s, 1); ^{13}C NMR ($CDCl_3$) δ –2.52, 192.6, 197.7, 201.8, 214.4; UV (isooctane) λ_{max}: 214 nm; EIMS *m/z*: 154 (M^+, 54), 126 (M^+ – CO, 18), 111 (M^+ – CO, CH_3, 12), 98 (M^+ – 2CO, 42), 83 (M^+ – 2CO, CH_3, 97), 73 (Me_3Si^+, 100); HRMS *m/z* calcd. for $C_7H_{10}O_2Si$: 154.0450; found: 154.0456.

2,4-Dichloro-3-trimethylsilylcyclobut-2-ene-1-one (5)

Threefold rechromatography of the hexane eluant from preparation of **2d** (5/95 EtOAc/hexane) gave **5** containing 5% **4**. ^{1}H NMR ($CDCl_3$) δ 0.37 (s, 9, Me_3Si), 5.39 (s, 1, CHCl); ^{13}C NMR ($CDCl_3$) δ –2.21, 69.27, 143.43, 179.64, 180.38; EIMS *m/z*: 208 (M^+, 12), 193 (M^+ – CH_3, 24), 165 (12), 145 (17), 93 (56), 73 (Me_3Si^+, 100); HRMS *m/z* calcd. for $C_7H_{10}Cl_2OSi$: 207.9878; found: 207.9868.

Cyclobutene-1,2-dione (2a)

Cyclobutenone **4** (0.936 g, 4.5 mmol) was stirred with 21 mL conc. H_2SO_4 at 52–67°C for 1.5 h and was worked up as before, and the ether extract was shown by ^{1}H to contain residual **4** (23%), **2a** (35%), and **5** (41%). After evaporation of the ether, the product was crystallized from pentane at –5°C to yield pale yellow crystals of **2a** (ca. 0.01 g, 0.15 mmol, 3%). ^{1}H NMR ($CDCl_3$) δ 9.65 (s, 1, $^1J_{C–H}$ = 185.1 Hz, $^3J_{H,H}$ = 2.9 Hz); lit. (CCl_4) δ 9.73 (5); ($CDCl_3$) δ 9.70, $^1J_{CH}$ = 185.8 Hz (6).

Thermolysis of 2d

A sample of **2d** in Ar degassed $CDCl_3$ in a sealed NMR tube was heated in a boiling water bath for 6.7 h, and the ^1H NMR spectrum was measured at intervals. A signal of δ 3.43 was observed, possibly due to the bisketene **1d**, along with signals assigned to ketenyl lactone **6**. The tube was opened, and the solvent evaporated, and chromatography on silica gel (6/4 CH_2Cl_2/hexane) gave **6**. ^1H NMR ($CDCl_3$) δ 0.24 (s, 9, Me_3Si), 0.28 (s, 9, Me_3Si), 4.97 (s, 1, CHC=C=O), 7.31 (s, 1, CH=CTMS); ^{13}C NMR ($CDCl_3$) δ –2.02, –0.82, 22.31, 104.35, 128.49, 148.04, 148.89, 178.65, 181; IR ($CDCl_3$): 2089 (C=C=O), 1754, 1738 (C=O), 1632 (C=C) cm^{-1}; EIMS *m/z*: 280 (M^+, 44), 265 ($M^+ - CH_3$, 53), 252 (M^+ – CO, 8), 237 (36), 73 (Me_3Si^+, 100).

Photolysis of 2a

A sample of **2a** in isooctane was degassed by a flow of Ar in an NMR tube and then was irradiated for 30 min using a combination of 300 and 350 nm lamps at 5°C. Measurement of the IR showed a band at 2120 cm^{-1} attributed to **1a** which disappeared with a 6 min half-life. Similar photolysis in $CDCl_3$ at –56°C and observation of the ^1H NMR spectra gave a signal at δ 3.20, possibly due to **1a**, and other signals with possible assignments: δ 8.96 (cyclopropenone lit. (10) 9.1 in CH_2Cl_2, δ 7.04 (maleic anhydride, identical to an authentic sample), δ 3.01 (succinic anhyride, identical to an authentic sample), δ 1.91 (acetylene, identical to an authentic sample).

Addition of the nitroxyl radical TEMPO to 1-naphthylketene: formation of an unusual adduct

Jennifer Carter, Michael H. Fenwick, Wen-wei Huang, Vladimir V. Popik, and Thomas T. Tidwell

Abstract: 1-Naphthylketene (**2**), generated by thermal Wolff-rearrangement, is trapped in situ by 2,2,6,6-tetramethylpiperidinyloxy radical (TEMPO, TO·) to form the adduct 1-naphthCH(OT)CO_2T (**4**), whose structure is confirmed by an X-ray determination. The ^{1}H NMR spectrum of **4** displays three CH_3 groups with very high field chemical shifts (δ 0.10–0.47), and this is attributed to the location of these groups in the shielding region above the π system of the naphthyl ring. At –40°C, doubling of most of the ^{1}H NMR signals occurs, and this is attributed to a freezing out of two conformations differing by rotation around the naphthyl—CH bond.

Key words: ketene, TEMPO, restricted rotation, ^{1}H NMR, conformational analysis, free radicals.

Résumé : Le 1-naphtylcétène (**2**) généré par un réarrangement de Wolff thermique peut être piégé in situ par le radical 2,2,6,6-tétraméthylpipéridinyloxy (TEMPO, TO·) pour former l'adduit 1-naphtylCH(OT)CO_2T (**4**) dont la structure a été confirmée par diffraction des rayons X. Le spectre RMN du ^{1}H du composé **4** comporte trois groupes CH_3 avec des déplacements chimiques à très haut champ (δ 0,10–0,47); ce résultat est attribué à la localisation de ces groupes dans la région de blindage au-dessus du système π du noyau naphtyle. À –40°C, la plupart des signaux de la RMN du ^{1}H sont dédoublés; cette observation pourrait être attribuée au fait que deux conformations ne différant que par une rotation autour de la liaison naphtyl—CH sont figées.

Mots clés : cétène, TEMPO, rotation restreinte, RMN du ^{1}H, analyse conformationnelle, radicaux libres.

[Traduit par la rédaction]

Diazoketones are useful sources of ketenes by Wolff-rearrangements, and this reaction has been utilized in a variety of mechanistic and theoretical studies of these intermediates (1). Both thermal and photochemical reactions of diazoketones lead to ketenes which can be trapped by nucleophiles such as H_2O, alcohols, and amines (1). In some cases, the reaction of the diazoketone is proposed to proceed through ketocarbenes, and in the case of photosensitized reactions, evidence for the intermediacy of these species has been provided by trapping of the carbenes with alcohols and amines (1).

Nitroxyl radicals (2) are powerful trapping agents for free radicals, but there has been little utilization of nitroxyls for the reaction with other functional groups and reactive intermediates. Recent reports have appeared of the addition of 2,2,6,6-tetramethylpiperidinyloxy (TEMPO, TO·) to styrene forming PhCH(OT)CH_2OT (3), of hydrogen abstraction from methylbenzenes (3, 4), and of TEMPO reaction with *t*-BuOO· radicals to form the unstable trioxide *t*-BuOOOT (5), but to our knowledge there are no reports of reactions of nitroxyl radicals with diazoketones.

Recently, we have made the first observations of the reactions of a nitroxyl radical with ketenes (6). Thus, TEMPO reacted with $Ph_2C{=}C{=}O$ at room temperature to give, after exposure to air, a peroxide interpreted as arising from TO· attachment to the carbonyl carbon forming a diphenylmethyl radical which combined with O_2 to give a peroxide whose structure was confirmed by X-ray crystallography (eq. [1]). Also, the bisketene $(Me_3SiC{=}C{=}O)_2$ reacted with TEMPO at 90°C to give the maleic anhydride derived from net oxygen atom donation, with expulsion of the piperidinyl radical (eq. [2]).

[1] $Ph_2C{=}C{=}O \xrightarrow{TO\bullet} Ph_2\dot{C}CO_2T \xrightarrow{O_2} TO_2CCPh_2OOCPh_2CO_2T$

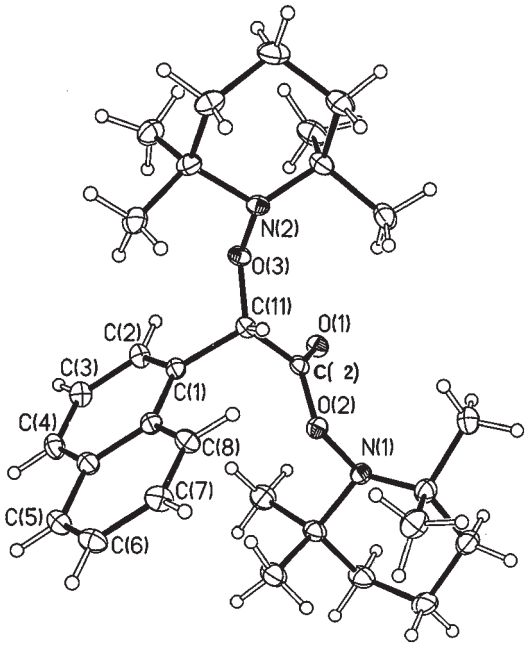
Fig. 1. X-ray structure of **4**.



We now report the utilization of the stable nitroxyl radical 2,2,6,6-tetramethylpiperidinyloxy (TEMPO, TO·) for the examination of the Wolff-rearrangement of 1-naphthyl diazomethyl ketone (**1**), which is known to form ketene **2** upon thermolysis (7). No reaction was observed between **1** and TEMPO in solution at room temperature, but upon heating in refluxing toluene, reaction of **1** occurred and a new product **4** was found in 41% yield (eq. [3]). This was identified as the product of 1,2-addition of two molecules of TEMPO to **2** on the basis of the spectral properties and X-ray structure (Fig. 1). A pathway involving attack of TEMPO at the carbonyl carbon of the ketene forming the radical **3** is proposed by analogy with eq. [1] (6), with subsequent capture of **3** by TEMPO. Recent reports of trapping of α-carbonyl radicals by TEMPO have appeared (8).

Chemical ionization mass spectroscopy shows the expected MH^+ peak for **4** at *m*/*z* 481, and the ester IR peak appeared at 1772 cm^{-1}. The ^1H NMR spectrum, measured at 500 mHz, is, however, extraordinary. At 30°C (Fig. 2*a*) the eight CH_3 groups are nonequivalent because of the slow chair–chair inversion of the piperidinyl ring and also because of the chiral center. The barriers to bond rotation and ring inversion in *N*-alkoxy-2,2,6,6-tetramethylpiperidines have been investigated in detail by Anderson et al. (9, 10), who also report an example of four nonequivalent CH_3 groups in $TOCH_2CH(OH)Ph$ (10). In **4**, each of the CH_3 groups gives rise to a distinct signal, and three of these methyls appear at very high field, δ 0.10, 0.32 (broad), and 0.47, while the others are at δ 1.00, 1.06, 1.07, 1.34, and 1.36. A broad signal at δ 5.9 is assigned to the CHOT proton (at C(11) in Fig. 1). The seven naphthyl protons appear as a two-proton triplet at δ 7.45, a one-proton triplet at δ 7.52, two one-proton doublets at 7.78 and 7.82, and two broad one-proton signals at 7.63 and 8.42. At 60°C (Fig. 2*b*), the naphthyl peaks sharpen while the signals between δ 0.0 and 2.0 become very broad, evidently indicative of enhanced ring inversion of the piperidinyl groups, and the CH(OT) proton at δ 5.89 becomes sharper. At higher temperatures, decomposition of **4** becomes noticeable, and the details of this process are under investigation.

At –40°C (Fig. 2*c*), there is a doubling of many of the ^1H NMR signals of **4** visible at 30°C, with CH_3 signals at –0.03, 0.02, 0.06, 0.37, 0.40, 0.50, 0.88, 1.00, 1.03, 1.05, 1.06 (2 CH_3), 1.29, 1.30 (2 CH_3), and 1.36. The CH_2 signals are spread between δ 1.0 and 2.0, the CH(OT) proton appears as two sharp singlets at δ 5.63 and 6.14 (relative intensity 0.47 and 0.53, respectively), and the naphthyl protons appear as doublets (δ 7.88, 8.29, 8.51), triplets (δ 7.41, 7.59), and multiplets at 7.5 and 7.8.

The doubling of the signals was confirmed by a ^{13}C DEPT spectrum at –40°C (supplementary information)[2], which showed the presence of 16 CH_3 signals between δ 19.97 and 35.14, 7 CH_2 signals, 2 signals for C(11) at δ 83.03 and 90.44, and 11 aryl CH signals. Evidently, three of the CH and one of the CH_2 signals expected for doubling of the resonances were not resolved. In the room-temperature ^{13}C spectrum, no signal for C(11) is visible between δ 80–90 ppm, indicating that this signal is broadened by the coalescence phenomenon observed in the ^1H NMR spectrum. From the observed difference in frequency of 255.8 Hz of the signals for the C(8) proton at –40°C, a rate constant for interconversion of the two conformers of 7.9×10^2 s^{-1} may be esti-

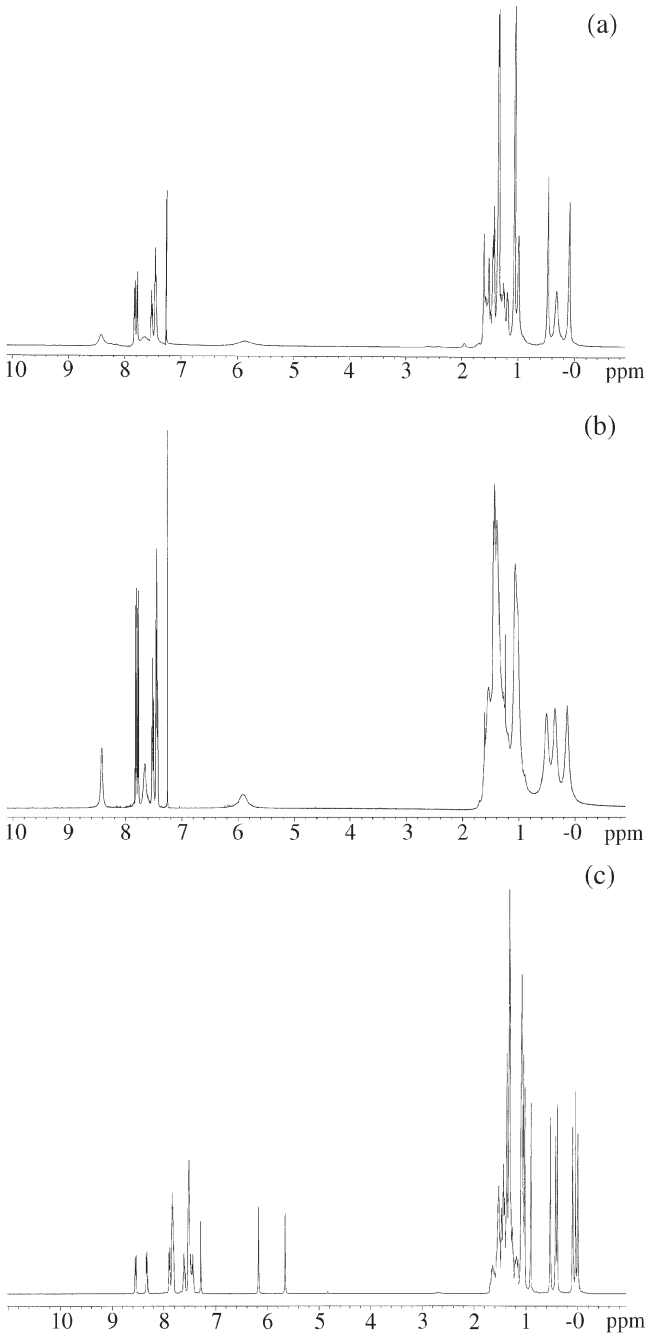
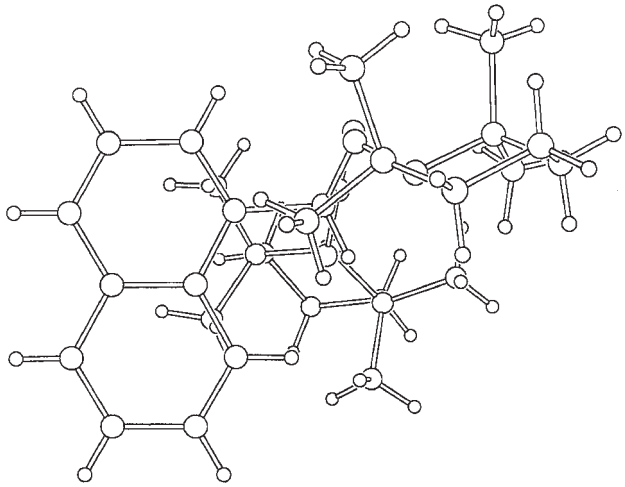
Fig. 2. ^{1}H NMR spectra of **4**. (*a*) 30°C; (*b*) 60°C; (*c*) –40°C.



mated at the coalescence temperature near 25°C, using the formula $T_{1/2} = \sqrt{2}/2\pi\Delta\nu$ (11).

The high field shift of three methyl groups in the ^{1}H NMR spectrum of **4** (Fig. 2) may be explained from the conformation shown in the X-ray structure (Fig. 1), which places two CH_3 groups from one of the piperidinyl moieties and one CH_3 from the other in the shielding regions on either side of the naphthalene ring. As seen in the view from above the naphthalene ring (Fig. 3), these three methyls are in the shielding region along the periphery of the substituted aryl ring.

Fig. 3. View of **4** perpendicular to the naphthyl ring.



The doubling of the NMR signals indicates that two observable conformations are frozen out at low temperatures in near equal amounts, leading to the observation of separate signals for each. To elucidate the structures, semiempirical AM1 molecular orbital calculations (12) were performed using MOPAC 93 (13). The starting geometry for the optimization was taken from the X-ray data, and a series of geometries varying by 20° rotations around the C(2)—C(1)—C(11)—C(12) bond (Fig. 1) were fully optimized. The resulting plot of energy versus the rotation angle is shown in Fig. 4.

The lowest energy conformation calculated is similar to that shown in Fig. 1, with a C(2)-C(1)-C(11)-C(12) torsion angle of –88.8°, as compared to –78.1° in the X-ray structure. In the next most stable conformation, this angle is 111.1°, and the naphthyl ring has undergone a near 180° rotation relative to the side chain. This second conformation differs from the first by $\Delta\Delta H$ of 0.62 kcal/mol, $\Delta\Delta S$ of –1.84 cal K^{-1} mol^{-1}, and $\Delta\Delta G$ of 1.17 kcal/mol. The lowest energy barrier connecting the two is 6.76 kcal/mol.

Although these calculations are not expected to be quantitatively reliable for this large system, there is good qualitative agreement with the experimental observations of two conformations of similar energies and a significant barrier for interconversion in solution. Based on the AM1 calculations, these may be assigned as one resembling the structure found by X-ray, and one with the opposite rotational disposition of the naphthyl ring relative to the side chain.

Density functional calculations (B3LYP/6-31G*//B3LYP/6-31G*) indicate that the attachment of the H_2NO radical to the CH_2 group of $CH_2{=}CH_2$ or $CH_2{=}C{=}O$ is endothermic, by 7.5 and 8.5 kcal/mol, respectively, whereas attachment to the carbonyl carbon of $CH_2{=}C{=}O$ to produce $\cdot CH_2CO_2NH_2$ is exothermic by 18.7 kcal/mol (6). These reactions are much less favorable than the attachment of the much more reactive HO radical for which exothermicities of 35.4 (14), 44.2, and 39.5 kcal/mol, respectively, to the CH_2 termini of $CH_2{=}CH_2$ and $CH_2{=}C{=}O$, and the $C{=}O$ group of latter, have been calculated (15). The naphthylketene **2** is quite reactive toward nucleophiles (16), and the reactivity for radical attachment to the carbonyl carbon should be significantly

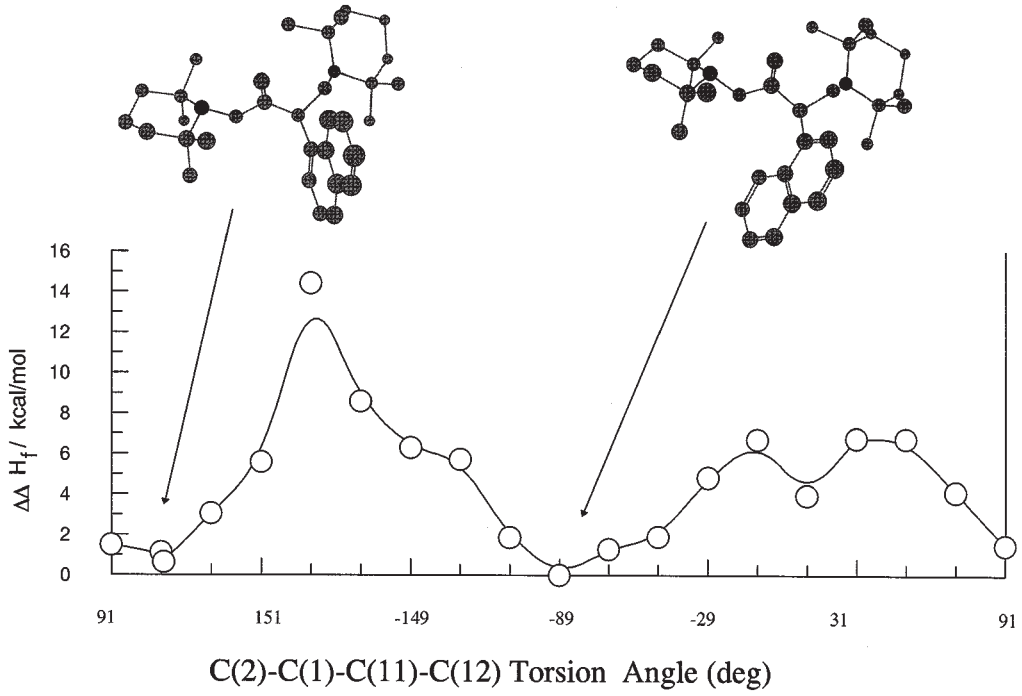
Fig. 4. Enthalpy of formation of **4** versus C(2)-C(1)-C(12)-C(11) torsion angle (calculated at 20° intervals).



enhanced due to delocalization of the unpaired spin by the naphthyl group.

Experimental

2,2,6,6-Tetramethylpiperidinyl 2-(1-naphthyl)-2-(2′-2′,6′,6′-tetramethylpiperidinyloxy)-acetate (4)

A solution of 72.1 mg (0.368 mmol) 1-naphthyl diazomethyl ketone (**1**) and TEMPO (141 mg, 0.903 mmol) was refluxed in 1 mL of toluene for 48 h. The solvent was evaporated, and the resulting solid purified by flash chromatography on silica gel (1/5 EtOAc/hexane) to give **4** (73 mg, 0.15 mmol, 41%), which was further purified by recrystallization from ether–pentane, mp 147–148°C. IR ($CDCl_3$) 1772 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ 0.10, 0.35, 0.47, 1.00, 1.06, 1.07, 1.34, 1.36 (each s, 3, CH_3), 1.0–2.0 (m, 12, CH_2), 5.9 (bs, 1, CHOT), 7.4–7.9 (m, 7, Ar), 8.42 (bs, 1, Ar). ^{13}C NMR ($CDCl_3$) δ 16.6, 16.8, 19.18, 19.91, 20.00, 20.32, 30.22, 31.73, 32.94, 34.47 (b), 38.76, 38.89, 39.88, 40.07, 59.24, 59.49, 59.85, 60.21, 124.77 (b), 125.30, 125.76, 128.01 (b), 133.46, 135.55, 170.61. CIMS (isobutane) *m/z*: 481 (MH^+, 4), 326 (9), 156 (TO^+, 100), 140 (55), 126 (29).

Conclusions

The thermal Wolff-rearrangement forming 1-naphthylketene may be conducted in the presence of the stable free-radical TEMPO with efficient trapping of the ketene as a benzylic acid derivative. The adduct **4** has a remarkable ^1H NMR spectrum arising from the unique structure involved.

Identity-reaction proton transfers from oxygen acids yielding localized vs. delocalized conjugate bases. An ab initio study

James E. Van Verth and William H. Saunders, Jr.

Abstract: Identity-reaction proton transfers from a series of oxygen acids to the corresponding conjugate bases have been studied by ab initio methods at the MP2/6-31+G*//MP2/6-31+G* level. The acids are H_3O^+, $CH_3OH_2^+$, $CH_2=OH^+$, $HC(O)OH_2^+$, $CH_2=CHOH_2^+$, H_2O, CH_3OH, HOOH, $HOCH_2OH$, FOH, FCH_2OH, HC(O)OH, and $CH_2=CHOH$. Gas-phase acidities were calculated at the G2(MP2) level in order to have benchmark values for all acidities regardless of whether experimental values were available. Barriers to proton transfer relative to the separated reactants, ΔH_{TS}, show a straight-line relation to acidity for all but two of the neutral acids and for all but one of the cationic acids. Two neutral acids, HOOH and FOH, show negative deviations that can be attributed to polarizability of the atoms attached to the proton donor oxygens. The cationic acid $HC(O)OH_2^+$ shows a large positive deviation, which probably arises from substantial heavy-atom reorganization from reactant to TS. Charges provide evidence of a lag in delocalization in the reaction of $CH_2=CHOH_2^+$, though it does not show an elevated ΔH_{TS}.

Key words: ab initio, oxygen acids, proton transfer, acidity.

Résumé : Faisant appel à des méthodes théoriques ab initio aux niveaux MP2/6-31+G*//MP2/6-31+G*, on a étudié les réactions d'identité des transferts de proton d'une série d'acides oxygénés vers les bases conjuguées correspondantes. Les acides sont H_3O^+, $CH_3OH_2^+$, $CH_2=OH^+$, $HC(O)OH_2^+$, $CH_2=CHOH_2^+$, H_2O, CH_3OH, HOOH, $HOCH_2OH$, FOH, FCH_2OH, HC(O)OH et $CH_2=CHOH$. Afin d'avoir des valeurs de référence pour toutes les acidités, on a calculé les acidités en phase gazeuse au niveau G2(MP2) pour lequel il n'existe pas de valeurs expérimentales. Pour tous les acides neutres, à l'exception de deux, et pour tous les acides cationiques, à l'exception d'un, les barrières au transfert de proton relatives aux réactifs séparés, ΔH_{ET}, présentent une relation de ligne droite par rapport à l'acidité. Deux acides neutres présentent des déviations négatives, HOOH et FOH; celles-ci peuvent être attribuées à la polarisabilité des atomes attachés aux atomes d'oxygène donneurs de proton. L'acide cationique $HC(O)OH_2^+$ présente une forte déviation positive qui découle probablement d'une réorganisation substantielle des l'atomes lourds du réactif à l'état de transition (ET). Les charges indiquent un décalage dans la délocalisation pour la réaction du $CH_2=CHOH_2^+$; toutefois, elle ne présente pas de valeur élevée pour le ΔH_{ET}.

Mots clés : calculs ab initio, acides oxygénés, transfert de proton, acidité.

Introduction

Proton transfers to or from "normal" or Eigen acids usually occur at a diffusion-controlled (or close to diffusion controlled) rate when the proton transfer is exoergic (1). Slower deprotonation results when the reaction is endoergic, but essentially the only barrier is the endoergicity. Eigen acids are those in which the proton is bound to an electronegative atom such as nitrogen or oxygen. In contrast, carbon acids often deprotonate at much slower rates than Eigen acids of similar acidity. The factors contributing to these barriers have been examined in recent years by means of quantum–chemical calculations as well as experiment.

A clear distinction can be made between carbon acids that yield localized vs. delocalized conjugate bases. Although both, unlike Eigen acids, show significant barriers, the carbon acids yielding delocalized bases deprotonate more slowly than acids of similar acidity yielding localized bases. In general terms, the need for heavy-atom reorganization during proton transfer is considered to raise the barrier to the reaction (2, 3). In a seminal contribution, Kresge (2) argues that the heavy-atom reorganization is only partly complete in the transition structure. The ability of the TS to delocalize the partial negative charge transferred from the base is thus limited, and delocalization lags behind the extent of proton transfer. A more quantitative treatment called the principle of nonperfect synchronization (PNS) has been proposed by Bernasconi (4–6). He presents methods for evaluating the intrinsic barrier, the magnitude of the lag in delocalization, and the contribution of various factors to the lag. More re-

cently, it has been shown by means of VBSCF calculations that the lag results from a balance between the stabilization resulting from resonance and the energy lowering from preservation of as much C---H---C bonding as possible (7).

The validity of the PNS can be most easily tested if contributions from solvent reorganization can be eliminated and the intrinsic barrier determined directly by employing identity reactions. It is not easy to accomplish experimentally, but ab initio calculations are ideally suited to this end. Pioneering work by Scheiner and his co-workers (8–11) on simple systems was followed by studies that treated mainly carbon acids yielding delocalized conjugate bases (12–16). From these studies, it was clear that even in the absence of solvent intrinsic barriers to proton transfers from such carbon acids are higher than expected from their acidity. Furthermore, the charge distributions in the transition structures show that charge delocalization lags well behind proton transfer.

With these results in mind, we became interested in whether the PNS would apply to Eigen acids as well as carbon acids. Until our recent work on nitrogen acids, no computational results in the literature addressed this question. We examined a series of identity reaction proton transfers involving nitrogen acids and their conjugate bases, including both neutral and cationic acids (17). As expected, all of the acids yielding localized conjugate bases showed small or nonexistent barriers to proton transfer. Among the neutral acids, even those yielding delocalized conjugate bases showed negligible barriers. These acids were OCNH, $OCHNH_2$, and $HNCHNH_2$. The reason was shown to be that the transition structures preferred conformations such that the C=O and C=N π bonds attached to nitrogen conjugated with the unshared pairs on the proton-donating nitrogen rather than with the N---H bonding electrons. In the case of the corresponding cationic acids, $OCNH_2^+$, $OCHNH_3^+$, and $HNCHNH_3^+$, there are no unshared pairs on the proton-donating nitrogens, so the only conjugation that can occur is with the N---H bonding electrons. Consequently, as with carbon acids that yield delocalized anions, lags in delocalization and appreciable barriers are observed.

In the case of oxygen acids, even acids of the type ROH_2^+ still have a single unshared pair remaining on oxygen with which a π bond could conjugate. We wished to find out whether the oxygen acids would behave in a manner analogous to the nitrogen acids, or whether they would now all show negligible barriers. Again, the literature provided no guidance. Proton transfers in the simplest systems, OH^- + HOH and HOH + HOH_2^+, have been extensively studied from the early days of molecular orbital computations. It is not the purpose of this paper to provide an exhaustive bibliography, but mention should be made of key early work (18–20) and recent applications of density functional methods (21–23). All of the calculations agree that barriers are small, and in some cases, stable symmetrically hydrogen bonded structures were found rather than a transition structure. The only other proton transfer involving a system similar to those we had studied with carbon and nitrogen acids was the CH_3OH to CH_3O^- reaction (24). Here again, the barriers were quite small when the geometry of the transition structure was optimized.

Computational procedures[2]

Ab initio calculations utilized the Gaussian 92 (25) and Gaussian 94 (26) programs with the standard basis set 6-31+G* (27). Correlation corrections utilized the Møller–Plesset method (28). The enthalpies (ΔH) in the tables (Tables 1, 2) are corrected to constant pressure and for zero-point-energy differences from MP2/6-31+G*//MP2/6-31+G* calculations scaled to 0.95 to account for the overestimation of frequencies by Hartree-Fock methods (29). Enthalpies were further corrected to 298 K for the contributions of the translational, rotational, and vibrational partition functions (30). The vibrational correction is not based on scaled frequencies, for it

is doubtful that low-lying frequencies (the only ones that contribute significantly to the vibrational partition function) bear a predictable relation to experimental values (31). Although many of the calculations were done up to the MP4SDTQ(frozen core)/6-31+G*//MP2/6-31+G* level, the results did not differ much from the complete set done at MP2/6-31+G*//MP2/6-31+G*, so only the latter are reported in Table 2. Where different stable conformations of a species are possible, the most stable one is listed in the tables. All reasonable conformations of reactants and transition structures were, however, optimized. In nearly all cases, the energy difference between the most stable and the next most stable conformation was large enough that the latter should make no significant contribution. No effort was made to locate all possible conformations of the ion-dipole complexes. Our experience with carbon acids has been that the complexes have several conformations very close in energy and easily interconvertible (11, 14). Since the energies of the complexes in the present context are useful only for establishing the magnitude of the central barrier, they were usually not explored exhaustively.

Results and discussion

A comparison of experimental (32)[3] and calculated gas-phase acidities was used to test the adequacy of the levels of our calculations. The results are given in Table 1. Because experimental values are missing for some of the neutral and all of the cationic acids, G2(MP2) (33) calculated values were used as benchmarks. The second column of the table records both experimental and G2(MP2) values, while the remaining three columns record values at three levels of increasing computational flexibility. None of the three had a clear advantage with respect to the other two, so MP2/6-31+G*//MP2/6-31+G* was chosen for subsequent calculations so as to facilitate comparison with the earlier results on nitrogen acids (17).

Where comparisons are possible the G2(MP2) values agree very well with experiment, the difference exceeding 2 kcal in only one case. The same cannot be said for a comparison of the benchmark values and the values in the last three columns, where the MP2/6-31+G*//MP2/6-31+G* acidities are frequently lower by 5 kcal or more, and in one case by more than 10 kcal, than the benchmark values. The situation is a little better for the cationic acids, where the differences are in the range of 2.9–6.9 kcal. Relative values, however, look much better. Linear least-squares correlations of the G2(MP2) values as dependent variable and the MP2/6-31+G*//MP2/6-31+G* values as independent variable show that the latter predict the former with a standard deviation of 1.1 kcal for the neutral and 2.2 kcal for the cationic acids (correlation coefficients 0.998 and 0.974, respectively). Because our analyses do not depend on often unavailable experimental data, these good relative values are deemed adequate.

Table 2 records the stationary points for the identity-reaction proton transfers at MP2/6-31+G*//MP2/6-31+G*. The reactions of $OH^- + H_2O$ and $H_2O + H_3O^+$ have been the subject of experimental studies. Our well depths are in reasonable agreement with experiment (–32 and –26.8 kcal for the former, –31.8 kcal for the latter) (34). The only other experimental results on our systems are alcohol–alkoxide reactions studied by ICR (35). Our methanol–methoxide well

depth is in good agreement with the stabilization energy of –29.3 kcal reported in this paper. Interestingly, the efficiency of the reaction was only 26% rather than the 50% expected for an essentially barrierless process. By the conventional RRKM treatment, this would indicate a significant central barrier, but the authors present computational evidence that the low efficiency is the result of dynamic constraints rather than a potential barrier (36).

Only two of our reactions, those of HOF and H_3O^+, show a symmetrically hydrogen bonded minimum. The others show small potential energy barriers that are, except for $HOCH_2O^-$ + $HOCH_2OH$, below the zero point energy levels of the transition structures. In fact, the very low barriers led us to wonder whether they represented torsional barriers rather than true proton transfer processes. The eigenvectors of the reaction coordinate modes did show significant motion of the proton in all cases, but some also involved motions of other atoms, particularly hydrogens. Animation of the vibrational modes by means of GaussView[4] showed that the highest amplitude motion was proton transfer, but often accompanied by torsional or rocking motion of other atoms. The $CH_2{=}CHOH_2^+$ + $CH_2{=}CHOH$ reaction in particular gave an eigenvector in which most atoms were moving. The animation of the reaction coordinate motion showed that the proton transfer was coupled with disrotatory torsions of the $CH_2{=}CHOH$ fragments moving as units.

At first glance, it would appear that all of these oxygen acids behave as Eigen acids in the sense of showing no significant barriers to proton transfer. Closer examination shows that the situation is a little more complicated. In our previous work (15, 17), we have used plots of ΔH_{TS} vs. acidity as a measure of unusual values of ΔH_{TS}. Acids that showed a lag in charge delocalization were found to have ΔH_{TS} values that fell well above the correlation line. By this measure the neutral acids in Fig. 1 all behave as normal Eigen acids. Two of them, HOF and HOOH, fall well below the line. This is an example of the α-effect. The origins of the α-effect are not entirely clear (37). In the present case, it is probably a consequence of the polarizability of the unshared pairs on the atoms (F and O, respectively) attached to the proton-donor oxygen atoms (15*b*). The slope of the plot is very shallow (slope 0.015) — so much so that all but two of the acids have ΔH_{TS} values within a few kilocalories of each other.

The cationic acids (Fig. 2) show more scatter. Leaving out the point for $HC(O)OH_2^+$, the correlation line actually has a very slightly negative slope (–0.02). That point, however, is above the correlation line by more than 10 kcal. In common with all the other acids, there is no enthalpic central barrier for this reaction, though it does show the highest potential barrier, 2.05 kcal, of all the cationic reactions. We have pointed out previously (15, 17) that ΔH_{TS} is more reliable than $\Delta H^{\neq}$ as a measure of barrier height because it avoids complications arising from special effects on stability of the ion–dipole complex, which have no effect on the rate of product formation relative to return to reactants. A particularly instructive illustration of this point is the reaction $HOCH_2O^-$ + $HOCH_2OH$. This should be a normal Eigen acid, and its ΔH_{TS} is even a little below the correlation line in Fig. 1, but it still shows the highest central barrier of all the oxygen acid reactions. We believe this arises from high stabilization of the ion–dipole complex by hydrogen bonding, which occurs from the oxide oxygen of $HOCH_2O^-$ to both oxygen-bound protons of $HOCH_2OH$. Consequently, we should focus on ΔH_{TS}, not the central barrier, to explore whether a reaction is unusually slow. Apart from details such as the above, the overall picture remains essentially the same whether $\Delta H^{\neq}$ or ΔH_{TS} is plotted in Figs. 1 and 2.

To consider further the reactions that may involve lags in charge delocalization, we chose to compare the way group

charges changed from acid to the TS and from the TS to the base just as we had done for the nitrogen acids (17). The appropriate data, calculated from NPA charges (38), are recorded in Table 3. These must not be taken as quantitatively accurate reflections of the π-electron shifts we are interested in, for they include σ-electron contributions to the total atomic charges. Nonetheless, they should at least show trends because the π electrons tend to be more mobile. Even the two neutral acids, HC(O)OH and CH_2=CHOH, show Δq(TS→base) to be slightly larger than Δq(acid→TS), as expected for systems following the PNS, but the changes are so small that no positive conclusion is warranted.

The one case where ΔH_{TS} is unusually large offers a surprise: Δq(acid→TS) exceeds Δq(TS→base) by a substantial margin, the reverse of the behavior expected from operation of the PNS! There is, however, a very logical reason for this anomaly. $HC(O)OH_2^+$ has a structure that might better be regarded as a complex between $HC(O)^+$ and OH_2, for the C—OH_2 bond is 1.845 Å long, compared to 1.453 Å in TS **3a** and 1.354 Å in HC(O)OH for the same bond (Table 4). Thus, HC(O) has a large positive charge in the acid, which decreases markedly at the TS and undergoes a much smaller decrease from the TS to the product.

Since this behavior overwhelms any electron shifts that might result from operation of the PNS, is there any explanation of the high ΔH_{TS}? We believe an explanation can be found in a suggestion made by Hine (39) more than 20 years ago. He noted that reactions resulting in substantial electronic and concomitant geometric reorganization usually show high barriers. He utilized the Principle of Least Nuclear Motion to argue that a contributor to the transition structure resonance hybrid that possessed a reactant-like electron distribution would be of unusually high energy at the TS because this electron distribution would have to be "squeezed" into the substantially different TS geometry. Since the transition structure results to a first approximation from the intersection of reactant-like and product-like contributors, the result would be a higher energy TS than that for an analogous system that underwent less geometric reorganization.

This leaves the last set of data in Table 3, that for the reaction of CH_2=$CHOH_2^+$ and CH_2=CHOH. Here Δq(TS→base) is almost twice as large as Δq(acid→TS), which would normally be taken as clear evidence for the operation of the PNS. The point for CH_2=$CHOH_2^+$, however, is above the correlation line in Fig. 2 by scarcely more than the scatter of the data. Thus, one normally expected consequence of nonperfect synchronization is not evident in the reaction. Possible further evidence of PNS behavior is afforded by changes in the C—O bond distances (Table 4). For **4a** the change from reactant to TS (–0.057) is smaller than the change from TS to base (–0.071). A reexamination of C—N bond-distance changes in the reactions of the cationic nitrogen acids (17) also reveals lags in Δr(reactant→TS) for the three reactions that show high barriers, those of O=$CHNH_3^+$, HN=$CHNH_3^+$, and O=CH=NH_2^+. For **3b** and **4b**, as in the reactions of the neutral nitrogen acids, none of which display elevated reaction barriers, no such lag is observed.

Table 4. C—O bond distances at MP2/6-31+G*.

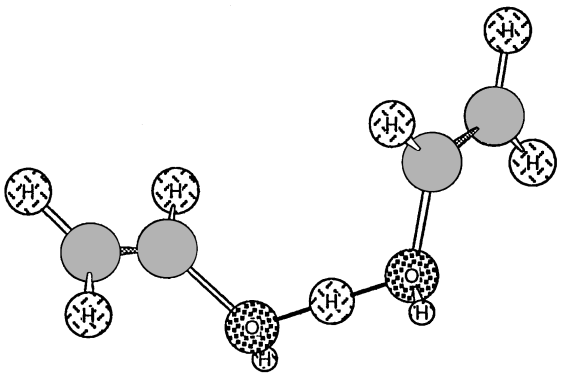
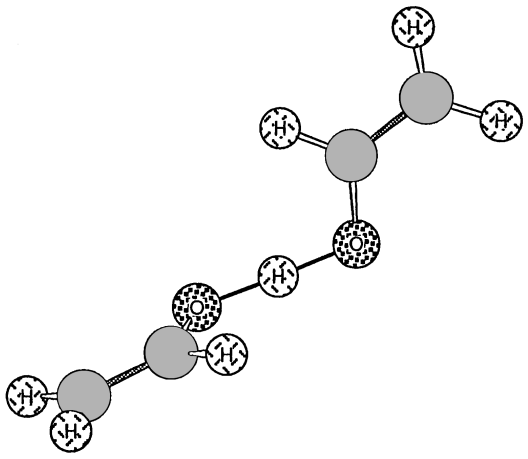
Fig. 4. Transition structures optimized at MP2/6-31+G*//MP2/ 6-31+G* for $CH_2{=}CHOH_2^+$ reacting with $CH_2{=}CHOH$ (**4a**) and $CH_2{=}CHOH$ reacting with $CH_2{=}CHO^-$ (**4b**).



4a



4b

exclude overlap of the π systems with the O---H bonding electrons (H---O-C-O and H---O-C-C dihedral angles of 180°). In these cases, the tendency is to maximize overlap with the unshared pairs on oxygen. Indeed, it has been argued that carboxylate ions are only slightly more resonance stabilized than the corresponding carboxylic acids (40). Cationic transition structure **3a** has its π system oriented so as to overlap mainly with the remaining unshared pair on oxygen (H---O-C-O dihedral angle 22°). In **4a**, there is extensive overlap of the π system with the O---H bonding electrons, but also some overlap with the unshared pair (H---O-C-C dihedral angle 95°). The fact that the cationic oxygen acids have one unshared pair still remaining on oxygen makes it possible that changes in resonance stabilization between the proton donor, the TS, and the product may not be as large as in the reactions of carbon acids and cationic nitrogen acids.

In the present results, the association between delocalization and a high barrier is not as clear as with the carbon and nitrogen acid reactions (15, 17). Nonetheless, the data indicate that when delocalization does occur there is a lag in transfer of charge (**4b**). The results of the VBSCF calculations (7) provide an explanation for this, namely, that in the TS some resonance stabilization must be sacrificed so that as much X---H---X bond energy as possible can be conserved.

An obvious difference between the carbon, nitrogen, and oxygen acid systems is the increasing electronegativity of the donor/acceptor atoms along the series. This should result in increasing importance of contributors such as **1** for the neutral and **2** for the cationic systems to the transition structure resonance hybrid.

$$\underset{\mathbf{1}}{R^-\ H^+\ R^-} \qquad \underset{\mathbf{2}}{RXH\ H^+\ HXR}$$

1 is already an important contributor in the case of the carbon acids as shown by VBSCF calculations on the allyl anion + propene reaction (7). The proton in transit in the carbon acid transition structures has an NPA charge in the range 0.29–0.34 (15*a*). This figure rises to 0.44–0.51 for the neutral nitrogen acids, and to 0.55–0.58 for the neutral oxygen acids. For the cationic acids, the NPA charges are 0.51–0.52 for the nitrogen acids and 0.60–0.63 for the oxygen acids. These numbers cannot be translated directly into contributions from **1** and **2** because they include σ as well as π electron effects, but they certainly should be reliable in showing trends. Thus the contribution of **1** to the neutral acid transition structures must increase in the order carbon < nitrogen < oxygen, and the contribution of **2** to the cationic acid transition structures in the order nitrogen < oxygen. The O---H---O bonding in all of the transition structures we have studied must have a great deal of ionic character.

The hydration mechanism of ketene: 15 years later

Minh Tho Nguyen and Greet Raspoet

Abstract: New insights into the detailed mechanism of the hydration of ketene yielding acetic acid ($H_2C=C=O + H_2O \rightarrow CH_3COOH$) were obtained by theoretical methods in both gas phase and solution. While gas phase calculations were performed using ab initio molecular orbital theory, bulk solvent effects were included using the self-consistent reaction field method (SCRF) and the polarizable continuum model (PCM). The hydration modeled by attack of water clusters containing two, three, and four water molecules confirms that a two-step addition of water to the ketene C=O bond, yielding a 1,1-enediol intermediate as initially demonstrated in 1984, is energetically, slightly but consistently, preferred over a concerted addition across the C=C bond leading directly to the acid product. Attempts to locate a zwitterion intermediate in solution were not successful. At least a cluster of three hydrogen-bonded water molecules is present in the gas phase supersystem to facilitate the proton transfer. Further incorporation of active water molecules in the catalytic water chain induces rather minor energetic improvements on the proton relay, which indicates a certain saturation of the cluster when reaching 3–4 water molecules. Effects of the surrounding solvent bulk do not change qualitatively the facts found in gas phase. The C=O addition mechanism is in better agreement with recent experimental developments in identifying enols of carboxylic acids than other mechanisms involving either a zwitterion or a direct C=C addition, as proposed for years in the literature.

Key words: ketene, ketene hydration, hydration mechanism, solvent effect, ab initio calculations.

Résumé : On a été amené à mieux comprendre le mécanisme détaillé de l'hydratation du cétène conduisant à l'acide acétique ($H_2C=C=O + H_2O \rightarrow CH_3COOH$) grâce à des calculs théoriques tant en phase gazeuse qu'en solution. Alors que les calculs en phase gazeuse ont été effectués en faisant appel à des calculs ab initio basés la théorie des orbitales moléculaires, on a introduit les effets de solvant en utilisant la méthode du champ de réaction autocohérent (MCRA) et le modèle du continuum polarisable (MCP). Comme on l'avait démontré initialement en 1984, l'hydratation modélisée par l'attaque d'agrégats d'eau contenant deux, trois et quatre molécules d'eau confirme qu'une addition d'eau (en deux étapes) à la liaison C=O du cétène conduisant à un intermédiaire ène-1,1-diol est toujours le modèle légèrement préféré d'un point de vue énergétique par rapport à un mécanisme d'addition concertée sur la double liaison C=C qui conduirait directement au produit acide. Les essais faits en vue de localiser un intermédiaire zwitterion en solution se sont avérées infructueux. Dans le supersystème en phase gazeuse, un agrégat d'au moins trois molécules d'eau reliées par des liaisons hydrogènes facilite le transfert d'hydrogène. L'incorporation d'un plus grand nombre de molécules d'eau dans la chaîne catalytique de l'eau induit ne donne lieu qu'à de faibles améliorations énergétiques sur le relais du proton; ceci indique que l'on atteint une certaine saturation de l'agrégat avec 3 ou 4 molécules d'eau. Les effets de l'ensemble du solvant environnant ne changent pas de façon significative les faits observés en phase gazeuse. Le mécanisme d'addition sur le C=O est en meilleur accord avec les développements expérimentaux récents puisqu'il permet d'identifier des énols des acides carboxyliques plutôt que d'autres mécanismes impliquant un zwitterion ou une addition directe sur la double liaison C=C, tel qu'il avait été proposé dans la littérature pendant des années.

Mots clés : cétène, hydratation du cétène, mécanisme d'hydratation, effet de solvant, calculs ab initio.

[Traduit par la Rédaction]

Introduction

Owing to the fact that ketenes are structurally interesting functional groups and basic building blocks in organic synthesis, they have been the subject of intensive study throughout this century and their chemistry has frequently been reviewed (1–7). In the preface of his recent book, Tidwell (7) summarized well the historical development: "The study of ketene chemistry has been marked from the beginning by scientific controversy, disagreement and uncertainty.... Even today, the mechanisms of ketene cycloadditions and ketene hydration are not agreed upon." In fact, the hydration is one of the earliest known reactions of ketenes (eq. [1]). To have a global view on the problems, it seems necessary to briefly

Received November 13, 1998.

This paper is dedicated to Professor Jerry Kresge on the occasion of his 65th birthday.

summarize the literature results on two important topics, namely the hydration mechanism and the existence of enols of carboxylic acids.

[1] 
Summary of earlier results

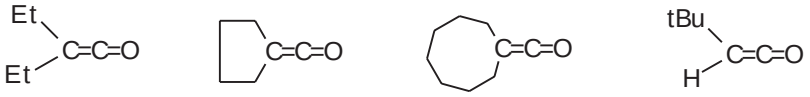
Hydration mechanism

In neutral aqueous solution (pH = 4–9), the hydration was shown to be pH-independent, indicating that it is a nucleophilic reaction of water molecules (8, 9). In solvents other than water, such as dioxane or acetonitrile, no specific effect of the solvents has been observed (9). A solvent kinetic isotope effect $k(H_2O)/k(D_2O)$ lies in the range of 1.7–2.3 for most systems studied, whereas the rate constants are rather dependent on the ketene substituents (10, 11). In the parent ketene ($H_2C{=}C{=}O$), an activation enthalpy and entropy of 43 kJ mol^{-1} and –16 eu, respectively, were measured in pure water (9). Regarding the mechanism, there have been mainly three distinct propositions to account for the course of acid formation.

(1) Tidwell's mechanism: polar transition state

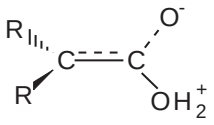
Earlier studies of hydration kinetics of arylketenes (4-$RC_6H_4CH{=}C{=}O$) in pure water performed by Bothe et al. (8) showed that the 4-NO_2 derivative was 13 times more reactive than the 4-CH_3 derivative. These authors (8) did not propose a mechanism at that time but Tidwell and co-workers (10, 12, 13) have subsequently interpreted these data in terms of rate-determining nucleophilic attack at C_α followed by rapid proton transfer (eq. [2]).

[2] 
The possibility of a ketene hydrate intermediate **1**, $H_2C{=}C(OH)_2$, was mentioned by Bothe et al. (9). Subsequently, Tidwell and co-workers studied the hydration of a series of alkylketenes including **2**–**5** (13, 14). The order of the reactivity was found to be **2** < **5** < **4** < **3**.



2 **3** **4** **5**

From these results, the latter authors (13) proposed a mechanism involving an in-plane nucleophilic attack at C yielding a polar transition state **6**, with more negative charge on oxygen than carbon.



6

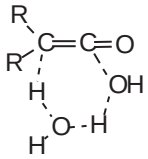
This mechanism accounts for the large rate depression when there are two bulky groups on both sides of the plane, as in **4**. The similar reactivity of ketene, **2**, and **5** led to the suggestion that in alkyl ketenes, electronic effects are small whereas steric effects are large. Overall, this group has not taken any advocacy position on the possible intermediates (cf. ref. 7, p. 577).

(2) Satchell's mechanism: C=C addition

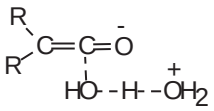
Satchell and co-workers (11, 15–21) extensively investigated the hydration kinetics and were the first group to propose a global mechanism for solvolysis of cumulenes. In particular, they (11–15) measured the rates of hydration of dimethylketene and diphenylketene in ether solution containing up to 0.35 M H_2O. The neutral hydration of diphenylketene was found to be 40 times faster than that of dimethylketene over the range studied. The spontaneous hydration of diphenylketene was found to be first-order in ketene concentration and third-order in stoichiometric water concentration, and that of dimethylketene was second-order in water concentration. Based on these data, Satchell and co-workers (15–21) proposed a concerted nucleophilic

© 1999 NRC Canada

addition of a water dimer perpendicular to the ketene plane across the C=C bond involving a cyclic transition state **7**. However, these authors did not suggest why diphenylketene requires a higher-order in water concentration. The open transition state **8** was mentioned but discarded (15).



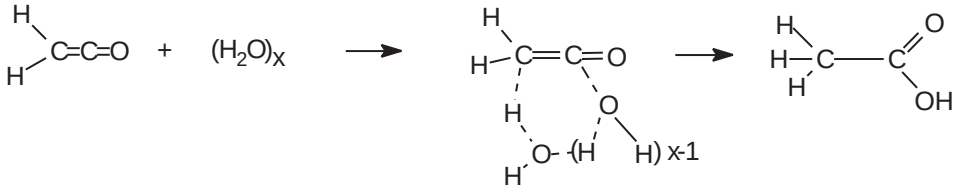
7



8

Later, this group favoured a mechanism involving a cyclic, multimolecular, H-bonded transition state across the C=C bond **9** that is similar to **7** but implies larger water clusters (eq. [3]). It was also suggested that the hydration mechanism may differ in a medium of higher dielectric constants (15–21).

[3]



9

(3) Nguyen–Hegarty's mechanism: C=O addition

In 1984, Nguyen and Hegarty (22) suggested a novel mechanism for ketene hydration that differs fundamentally from the previous ones. Perhaps the most interesting fact was that our proposition was solely based on ab initio molecular orbital calculations. Indeed, we calculated transition state structures for the addition of monomeric and dimeric water across both ketene C=C and C=O bonds. Even though the levels of theory employed at that time were rather low, as compared with today's state-of-the-art methods, two essential results were reported (22): (*i*) the presence of an additional water in the supermolecule is a crucial factor in facilitating the proton transfer within a cyclic transition state and thereby reducing substantially the energy barriers (23–26). In other words, the hydration reaction is better modeled by the attack of a water dimer rather than a water monomer; and (*ii*) addition of a water dimer across the C=O bond giving rise to an 1,1-enediol **1** is energetically favoured over the C=C addition. The compact transition structure **10** is consistent with a negative activation entropy found earlier for the hydration of ketene (9). The preference for C=O addition of water is in contrast with the thermodynamic preference for C_β protonation **11** over O-protonation **12**.

We also suggested that the transformation of an enediol to an acid should be rapid in aqueous solution, and this would probably be the reason for their nonobservation. Indeed, a number of authors have subsequently rejected the possibility of such an initial C=O attack due to the lack of evidence for the existence of enols of carboxylic acids.

Evidence for enediol intermediates in ketenes hydration

There were cases where the presence of an enediol intermediate in ketene hydration has been implied. However, it was not before the nineties that the existence of enediols could be established (27). We refer to a recent review by Kresge (42) for details. Aumann and Worman (28) suggested that an iron–ketene complex reacted reversibly with water giving a primary enediol. Ried and Junker (29) mixed diphenyl and dimethylketenes with various alcohols in the presence of an aryldiazonium electrophile and explained the results by the initial formation of an ester enol.

Hegarty and O'Neill (30) reported in 1987 the first detection of acid and ester enols by using very hindered substituents, such as pentamethylphenyl, that slow down the ketonization. In 1990, the groups of Kresge and Wirz (31, 32) demonstrated that the hydration of a fulvene ketene proceeds via a 6,6-fulvenediol, based on the formation and subsequent decay of a transient intermediate absorbing in the range 280–320 nm. They were also able to generate the unhindered acid enol as a result of the hydration of the hydroxyketene, itself formed by a photochemical route. In the mean time, Hegarty and co-workers (33) studied the hydration of hindered diarylketenes and provided strong kinetic evidence

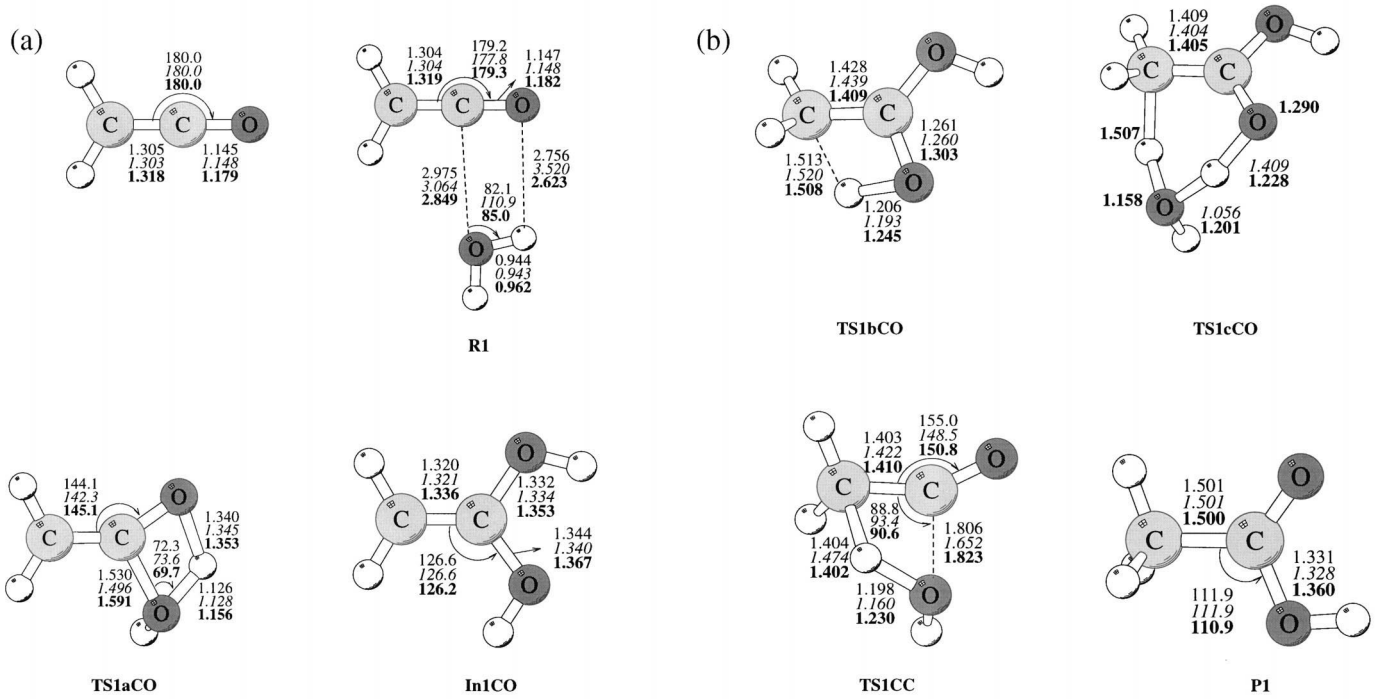
Fig. 1. Selected optimized structures of stationary points along a ketene hydration path with one water molecule across both C=O and C=C bonds. The entries are HF, HF-SCRF (in italics), and MP2 (in bold). The MP2 values are taken from ref. 53 and given for purpose of comparison.



for the intermediacy of 1,1-enediols. Furthermore, they substantiated the fact that the less hindered enediols ketonise rapidly and are insufficiently long lived to be observed by conventional methods. In 1995, the enediol–acid reversibility has been demonstrated by Frey and Rappoport (34) in the hydration of arylketenes by carrying out the reaction in ^{18}O labeled water. The latter authors (35) argued that application of the most recent techniques to detect the enol isomers of simple carboxylic acids, however, remains difficult, because the latter are very much more unstable (34, 35). Recently, Kresge et al. (36–42), Wirtz et al. (43), Guthrie et al. (44, 45), and Hegarty and co-workers (46–48) have produced a massive body of results that constitute a valuable set of detailed information on the chemistry of sterically hindered as well as nonhindered carboxylic acid enols.

From a theoretical point of view, subsequent ab initio calculations by various groups (49–54) have consistently pointed out the kinetic preference for a two-step ketene hydration. Nevertheless, the calculated energy barriers even with a two-water cluster remains larger than the experimental estimate of 43 kJ mol^{-1} reported in ref. 9. This suggests the participation of additional water molecules in the transition state structures (55–57). More recently, the assistance of a cluster of water or reactant molecules is clearly demonstrated in the amination of ketenes (58, 59) or alcoholysis of isocyanates (60). On the one hand, the question of the zwitterion mechanism has not been properly adressed. On the other hand, recent ab initio MO studies (61) on the cycloaddition of ketenes with imines have suggested an initial formation of zwitterionic intermediates in polar solvents. In this context, it seems necessary to reinvestigate the ketene hydration mechanism employing on the one hand larger water clusters as models, and on the other hand, theoretical methods treating appropriately the solvent effect. This is the main purpose of the present study. Concretely, both C=O and C=C additions are considered using progressively larger water clusters from one to four water molecules. The bulk solvent effect is treated by the continuum methods.

Methods of calculation

Ab initio molecular orbital calculations were carried out using the GAUSSIAN 94 (62) set of programs. The stationary points of interest were initially located and characterized by harmonic vibrational analysis employing Hartree Fock (HF) calculations with the dp-polarized 6-31G(d,p) basis set. The relevant structures were then reoptimized at second-order Møller–Plesset perturbation theory (MP2) level with the same basis set. Improved relative energies between stationary points were finally estimated using the quadratic configuration interaction method (QCISD(T)) also with the same basis at MP2 optimized geometries. These relative values were also corrected for zero-point vibrational energies (ZPE) derived from HF/6-31G(d,p) calculations and uniformly scaled by 0.9. The influence of the bulk solvent on the hydration reaction has been tackled employing two different approaches. The solvent is in general represented by a dielectric continuum characterized by its dielectric constant (ε). First, we used a self-consistent reaction field method (SCRF) (63) in which the electrostatic expansion is truncated at the dipole level and a spherical cavity is used. All relevant gas phase stationary structures including water clusters up to four water molecules were reoptimized in aqueous solution (ε = 78.3) using this approach (HF-SCRF/6-31G(d,p)). Furthermore, single-point calculations were done including electron correlation (MP2-SCRF) using both 6-31G(d,p) and

[c]Zero-point energies from HF/6-31G(d,p) and scaled by 0.9.

6-311++G(d,p) basis sets. Another technique, namely the polarizable continuum model (PCM) developed by Tomasi and co-workers (64), has also been applied; this constitutes a more realistic method, using a cavity adapting the molecular shape instead of a sphere. Thus, single-point calculations were performed at the MP2-PCM/6-31G(d,p) level using the gas phase MP2/6-31G(d,p) optimized geometries. In the discussion, the gas phase relative energies quoted refer to the QCISD(T) values, whereas those in solution are obtained from MP2-PCM. Geometrical parameters mentioned are, unless otherwise stated, the gas phase MP2-values.

Results and discussion

Ketene plus one water molecule

While Fig. 1 shows the optimized geometries of the stationary points along the pathway involving one water molecule, Tables 1 and 2 list the corresponding energetic parameters. This system has been examined in previous papers (52, 53), but for the purpose of comparison, parameters optimized at three distinct levels of theory are reported, including the gas phase HF and MP2 as well as the HF-SCRF level using the 6-31G(d,p) basis set. It seems useful to recall the main features. The addition occurs through an initial interaction of weak nature involving an oxygen lone pair and the ketene LUMO which has a dominant contribution from C_α. Due to the weak intermolecular force resulting in **R1**, where the stabilization energy amounts to only –11 kJ mol^{-1}, the energy surface relevant to the orientation of the H_2O molecule in this plane is rather shallow. With this weakly bound complex **R1** as the starting point, the reaction may proceed along two different planes, the one representing an addition to the ketene C=O bond and the other to its C=C bond. Both transition structures characterizing these addi-

tions, **TS1aCO** and **TS1CC**, respectively, are shown in Fig. 1. As expected, both four-membered TSs are not planar, due to the fact that the additions are not pseudo-pericyclic. The optimized geometry of **TS1aCO** reveals a compact structure with a significant bending of ketene at this stage of the reaction (the CCO angle being 145.1°). The hydrogen transfer to the ketene oxygen giving the enediol **In1CO** occurs, but the O—H distance in water remains shorter than that to ketene oxygen; in fact, the O(water)–H and O(ketene)–H distances amount to 1.156 and 1.353 Å, respectively. The newly formed C—O bond is quite short in this TS, its length being 1.591 Å. An imaginary frequency of 1947*i* cm^{-1} is associated with mainly two motions, namely, the oxygen attack and the hydrogen transfer. In **TS1CC**, leading immediately to acetic acid **P1**, the deformation of the attacking water molecule has proceeded to a larger extent (the O—H bond distance being 1.230 Å), whereas the formation of the new C—H bond is also noticeable (1.402 Å). Furthermore, the C—C bond has lost an appreciable amount of its π-contribution, having now a distance of 1.410 Å due no doubt to the distortion of the CH_2 group. This occurs at a quite larger C—O (water) distance of 1.823 Å. The nature of **TS1CC** is confirmed by the imaginary vibrational frequency (ν_i = 2106*i* cm^{-1}) in which the normal mode is a pure migration of hydrogen from the attacking water to the β-carbon.

Relative energies given in Table 3 confirm that the C=O addition is slightly preferred over the C=C. At the highest level of theory, QCISD(T)/6-31G(d,p)+ZPE, the energy barrier for C=O addition amounts to 172 kJ mol^{-1}, which is 9 kJ mol^{-1} lower than that for C=C addition. In spite of intensive attempts, search for a stationary point on the potential surface describing an open zwitterion of the type **6** failed, either in gas phase or in aqueous solution. Inclusion of bulk solvent effects by both SCRF and PCM models does not affect the fact that both C=C and C=O additions have energy

barriers that are too large to be realistic. As reported in Table 4, energy barriers of 160 and 173 kJ mol^{-1} are found in aqueous solution (MP2-PCM/6-31G(d,p), ε = 78.3) for C=O and C=C additions, respectively. It is likely that use of larger basis set will not affect significantly these quantities.

Intramolecular hydrogen shift

The 1,3-hydrogen shift connecting both adducts enediol **In1CO** and acetic acid **P1** has been examined in previous papers (49–54). Here, we wish to add some comments regarding the process in aqueous solution. Note that a significant change in the structure around C_β has taken place as the reaction passes through **TS1bCO**. The carbon atom has changed from a planar to a tetrahedral arrangement of bonds, and the C—C bond has changed from 1.336 Å in **In1CO** via 1.409 Å in **TS1bCO** to 1.500 Å in **P1**. The **TS1bCO** has one imaginary frequency of 2405*i* cm^{-1} whose normal mode is a pure H-atom migration. It is well known that 1,3-sigmatropic shifts in hydrocarbons are orbital symmetry forbidden; the presence of a single orthogonal orbital in the present case seems to be sufficient to make it pseudopericyclic, and thereby more allowed by the same reason, reducing thus the barrier to migration (65). However, due to the strained four-membered ring geometry of the transition structure in which the hydrogen is being transfered from the molecular plane to a *p*-orbital above the plane, and the C-H-

O bond angle is far away from the ideal linearity, the energy barrier remains high. As a matter of fact, the energy of **TS1bCO** relative to **In1CO** amounts to 163 kJ mol^{-1}, at the QCISD(T)/6-31G(d,p)+ZPE level of theory.

This result indicates that a 1,3-H-shift from enediol to acetic acid is not competing energetically with the direct production of acetic acid via **TS1CC**. However, the interconversion is greatly accelerated with the aid of an extra water molecule assisting the 1,3-H-shift. Inclusion of a second water molecule through **TS1cCO** reduces the energy barrier for 1,3-H-shift by an amount as large as 146 kJ mol^{-1}. Such lowering gives rise to an almost barrierless process, having now an activation energy of only 17 kJ mol^{-1} relative to the separated water and ketene species. As a consequence, the conversion of an enediol to an acid in the presence of water is a fast process, in agreement with experimental observations (27). Accordingly, the 1,3-H-shift will be omitted in the further discussion and only the rate-determining attack of water across the ketene C=O bond will be compared to that across the C=C bond.

Ketene plus two water molecules

While Table 3 emphasizes a dramatic decrease of activation energy when an extra water molecule is added in the water chain, Fig. 2 shows the relevant geometrical features. As found in earlier studies (49–53), each of the two additions begins with a preassociative complex, **R2CO** or **R2CC**, overcomes a transition structure, **TS2CO** or **TS2CC**,

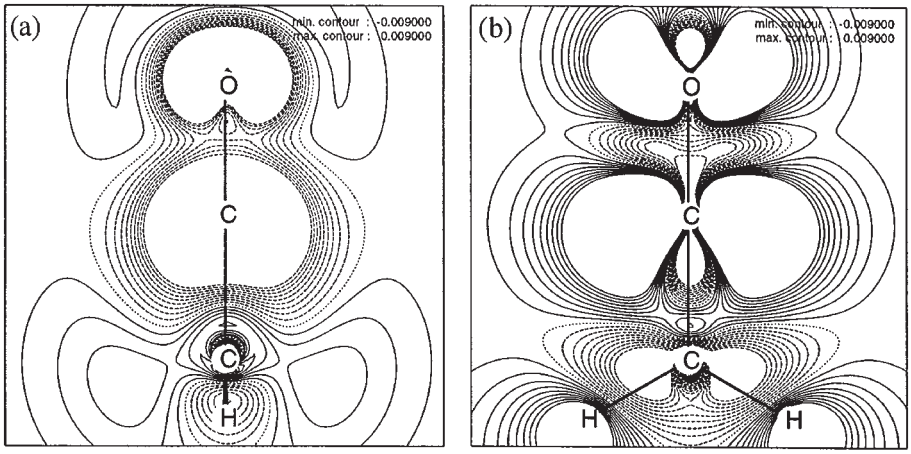
Fig. 4. Contour map of the Fukui function $f^{(-)}$ for ketene in both perpendicular *xy* (*a*) and molecular *yz* (*b*) planes. The solid isocontours correspond to positive values and the broken lines to negative values of the $f^{(-)}$ functions.



and gives a product complex, **In2CO** or **P2CC**. **P2CO** is another complex between acetic acid and water involving the carboxylic functional and therefore more stable than **P2CC**. At the highest QCISD(T) level of calculation, both energy barriers for attack across C=O via **TS2CO** and C=C via **TS2CC** are lowered by 72 kJ mol^{-1}, as compared with those involving one water. The resulting energy barriers turn out to be 100 and 109 kJ mol^{-1}, respectively, with respect to the corresponding initial complexes (Table 2). In a simple view, the addition of one water molecule to ketene via **TS1aCO** and **TS1CC** can be regarded as allowed pseudopericyclic reactions with strained transition state geometries. When the second water is added, the TS geometries are improved, and as a consequence, the barriers drop. As the additions are pseudo-pericyclic, the size of the water chain is not expected to have a large electronic effect on the barrier.

The difference of both additions depends on the plane of attack and can be rationalized in terms of Fukui functions (f) that are the descriptors of reactivity based solely on the properties of the reactants (66). Depending on the type of attack, different sites are indicated as the most reactive site for $H_2C{=}C{=}O$, i.e., the site for which f is largest. Attack of the water system can occur either in the molecular plane (C=O) or in the perpendicular plane (C=C). While Fig. 3 displays contour maps of the Fukui function $f^{(+)}$ for ketene in both *xz* (Fig. 3*a*) and *yz* plane (Fig. 3*b*), Fig. 4 shows contour maps of the Fukui function $f^{(-)}$ (*xz* plane (Fig. 4*a*); *yz* (Fig. 4*b*)). These terms are defined as follows:

$$f_K^+ = [\rho_K(N + 1) - \rho_K(N)]$$

relevant for nucleophilic attack, and

$$f_K^- = [\rho_K(N) - \rho_K\ (N - 1)]$$

relevant for electrophilic attack, where ρ_K is the electron density at the atom K, and N is the number of electrons.

The preferred attack in the *yz* plane proceeds via a nucleophilic attack of O on C_α ($f^{(+)}$ being largest for C_α), while an electrophilic attack occurs by H^+ at oxygen ($f^{(-)}$ being largest for O). This indicates that the ability of the O atom to accept and redistribute a positive charge is of considerable importance, such that attack on O is preferred over attack on C_β. In the *xz* plane, however, the opposite is observed. Electrophilic attack occurs by H^+ at the β-carbon and no longer at oxygen ($f^{(-)}$ being largest for C_β). Thus, the Fukui functions predict that while C=O addition is preferred in the molecular plane of ketene, C=C addition is, as would be expected, preferred in the perpendicular plane.

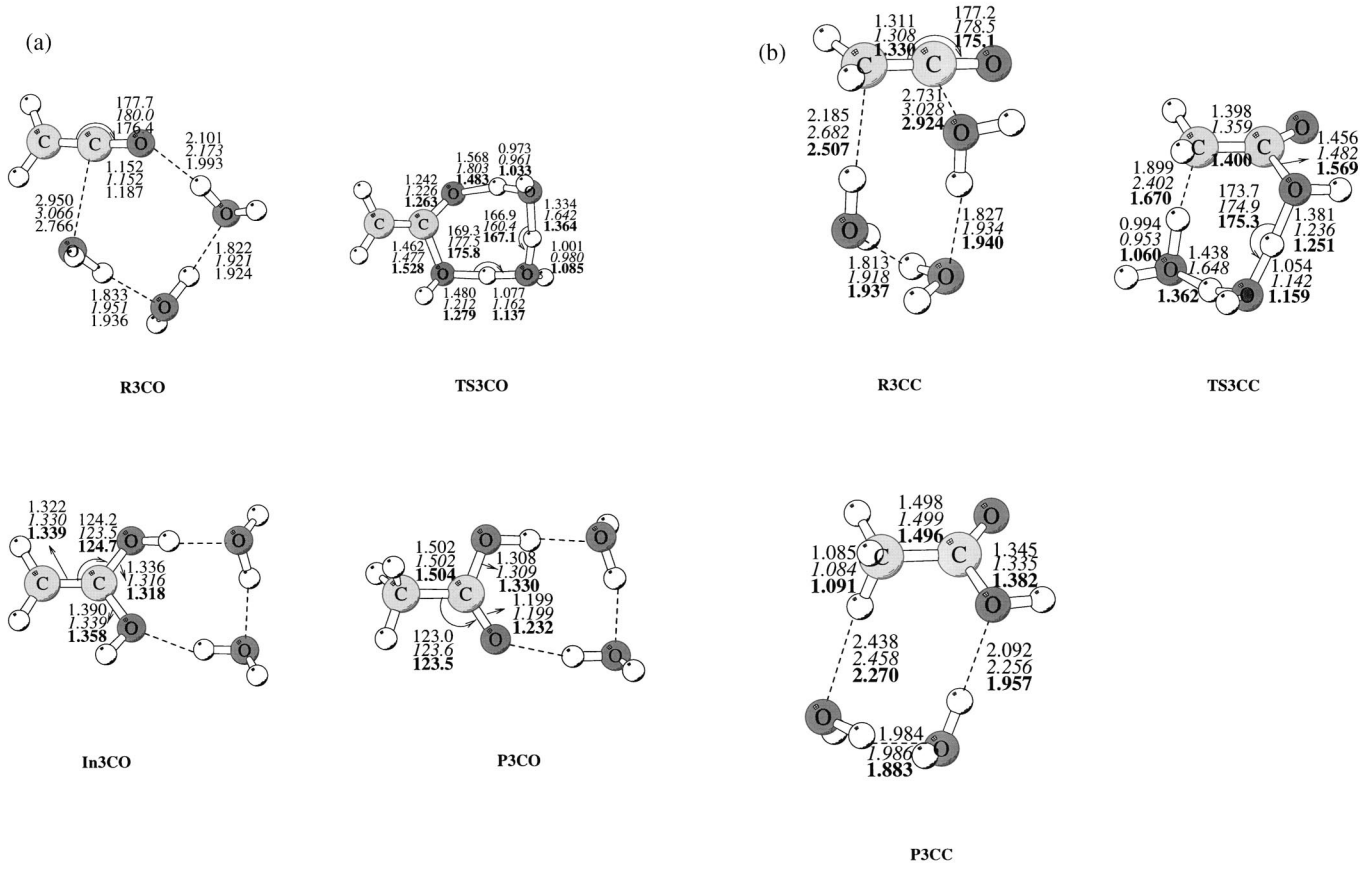
Ketene plus three water molecules

As in the two previous cases, interaction between ketene and a three-water cluster is initiated by strong cyclic intermolecular interactions. Two such eight-membered ring complexes are found, the one **R3CO** involving the ketene C=O bond and the other **R3CC** the C=C bond. While geometrical parameters are displayed in Fig. 5, calculated total and relative energies are given in Tables 1 and 2. Both complexes are characterized by long C_α-oxygen distances, 2.766 and 2.924 Å, respectively. In the latter, the C_β-hydrogen distance is found to be 2.507 Å. The energy lowering by complex formation, obtained at the QCISD(T)+ZPE level, is found to be substantial, –85 and –82 kJ mol^{-1} for **R3CO** and **R3CC**, respectively, with respect to the separated reactants, $H_2C{=}C{=}O + 3H_2O$. Inclusion of an extra water molecule increases further the stabilization upon complex formation by a significant amount. While the complex **R1** is only –15 kJ mol^{-1} below the separated reactants, in the two-water system, a lowering was calculated of –47 kJ mol^{-1} for **R2CO** and –43 kJ mol^{-1} for **R2CC**. The larger the water cluster, the stronger the hydrogen bonds in the corresponding complexes and the more extended the stabilization.

From each of the complexes, the reaction proceeds through the TSs **TS3CO** and **TS3CC** depicted in Fig. 5. The geometry of **TS3CC** indicates that the forming of the new carbon–oxygen bond precedes the establishing of the C—H bond at the C_β carbon. While the former has virtually taken shape, the O—H bond remains unchanged. Nevertheless, the spatial arrangement of the three hydrogen atoms around this carbon is roughly tetrahedral at this stage of the reaction. The electronic reorganisation is also reflected by the elongation of the C=C bond to 1.400 Å in **TS3CC**. The hydrogen atoms linking the water molecules shifted their position and are approximately midway between the neighbouring oxygen atoms. **TS3CC** is characterized by a smaller imaginary

© 1999 NRC Canada

Fig. 5. Selected optimized structures of stationary points along a ketene hydration path with three water molecules across both C=O and C=C bonds. The entries are HF, HF-SCRF (in italics), and MP2 (in bold).



frequency of 292*i* cm^{-1}. The dominant contribution to the associated normal mode is a shift of the attacking hydrogen towards the C_β atom, and concomitant migration of the hydrogen atoms linking the water molecules. Similarly, in **TS3CO**, the imaginary frequency of 201*i* cm^{-1} is associated with a transfer of the hydrogen atom between both water and ketene oxygens.

TS3CO appears to be more compact than **TS3CC**; the hydrogen transfer to O is much more advanced. While HF calculations tend to a ($H_2OH_2OH^+.OH^-$) ionic structure within the water cluster, both MP2 and HF-SCRF levels suggest a less polar form. It is also worth noting that in both TSs, the oxygen attack and the hydrogen transfer take place in two quasi perpendicular planes, a situation similar to hydrogen transfer that in the CO_2 + $(H_2O)_3$ supersystem (56). As revealed by Table 3, the activation energies are 92 and 97 kJ mol^{-1} for attacks across C=O and C=C of ketene, respectively, relative to the reactant complexes. Again, the barriers towards addition to these bonds are virtually of the same magnitude, but with a slight preference for attack on C=O. Regarding the adducts, the complex **P3CC** is far more stable than **In3CO**.

Regarding the entropic contributions to the activation parameters, the difficulty lies rather in the starting point to be taken. If the completely separated system was considered, the activation entropy should be large; if the complex was considered, then the entropy variation was much smaller. In either case, the calculated values do not match well the experimental one mentioned above.

Ketene plus four water molecules

Having established a significant effect in going from two to three water molecules in the water chain, it is interesting to see what happens when the chain is further increased by another water molecule. It is needless to say that in reality, there are several cluster forms of water tetramer, and as a consequence, other addition TSs are expected to exist. Nevertheless, it is not our purpose to explore all the possible approaches. We consider rather the case where the water molecules form a chain in which a successive proton relay occurs; only in this case, the results could best be compared with those of the two and three water chains discussed above.

Optimized geometries of the stationary points including four water molecules are shown in Fig. 6. Again, each addition starts with a preassociative complex (**R4CO** and **R4CC**), passes through a TS (**TS4CO** and **TS4CC**), and finally gives rise to an adduct complex (**In4CO** and **P4CO**). A **P4CC** complex, analogous to **P3CC**, could not be located. The calculations show that as both transition states **TS4CO** and **TS4CC** are approached, the four water molecules move in the form of a compact chain tetramer towards the ketene. At the transition states, the deformation of ketene is an important nuclear motion, involving a significant bending of

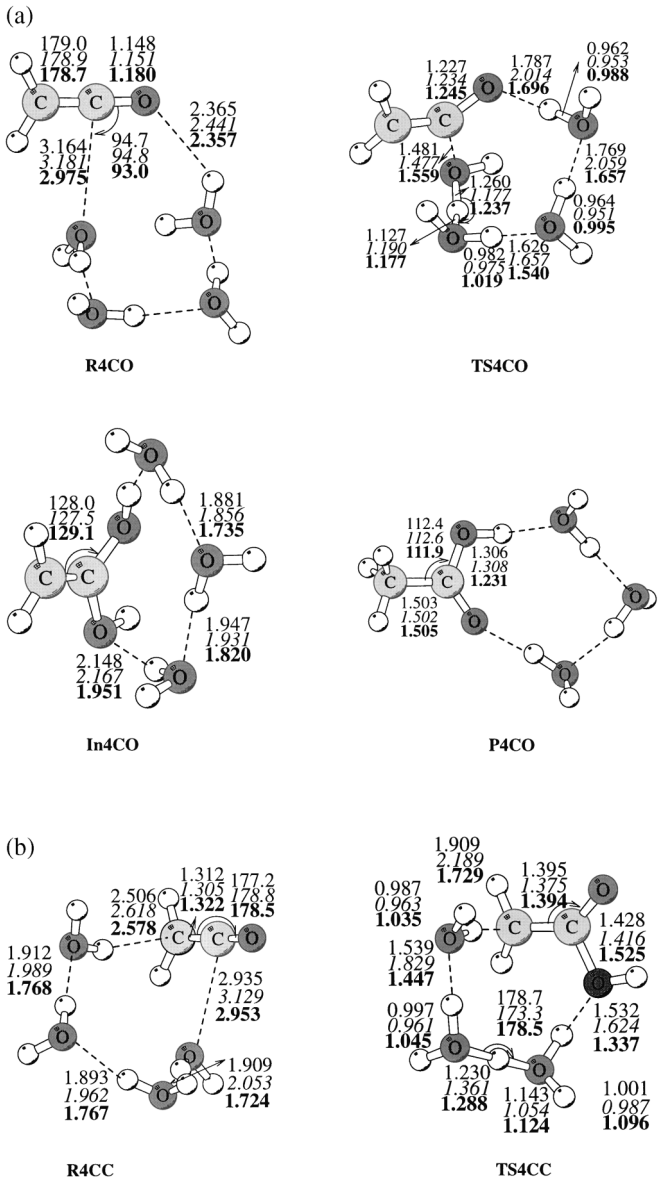

Fig. 7. Schematic energy profiles showing the energy barriers for ketene hydration paths including different chains of water molecules, ($H_2C{=}C{=}O + nH_2O$, n = 1, 2, 3, 4), calculated in gas phase at the MP2/6-31G(d,p)+ZPE level of theory. All barriers are with respect to the corresponding preassociative complexes.

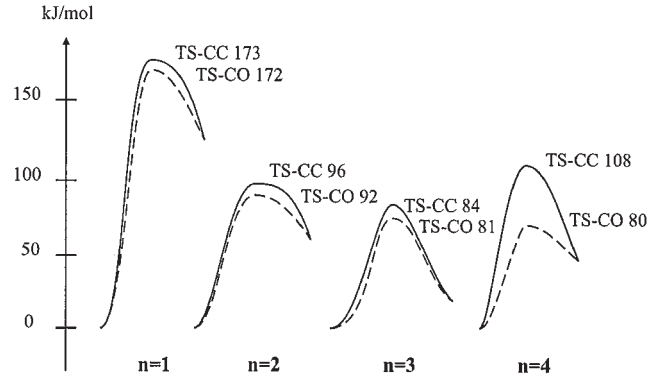

Fig. 8. Schematic energy profiles showing the energy barriers for ketene hydration paths including different chains of water molecules ($H_2C{=}C{=}O + nH_2O$, n = 1, 2, 3, 4), calculated in aqueous solution (ε = 78.3) at the MP2-PCM/6-31G(d,p)+ZPE level of theory. All barriers are relative to the corresponding preassociative complexes.

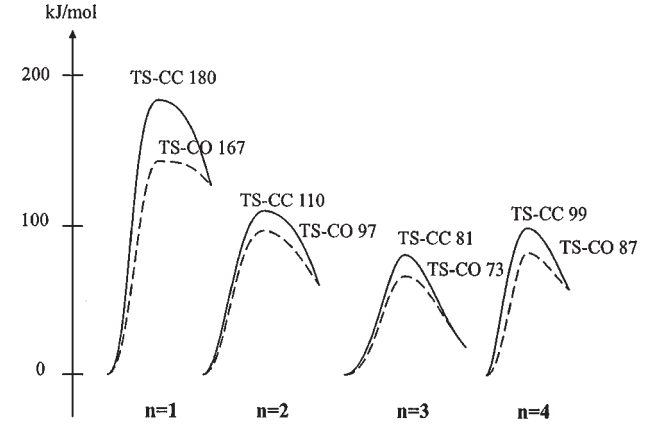

the C=C=O angle. The preference for addition across C=O over C=C can be understood by the extra distortion of the CH_2 group present in **TS4CC**, which makes it energetically less favoured. The results in Table 3 indicate that some saturation of the length of the water chain is reached for C=O attack. The activation energy is only changed by 1 kJ mol^{-1} at the MP2/6-31G(d,p) level of theory. This saturation suggests that the bridging effect is no longer important in chain lengths in the gas phase with more than three water molecules. For C=C addition, the energy barrier is found to be even increased, relative to the three water case, being 28 kJ mol^{-1} higher than the barrier for C=O addition by now. This fact is a further proof for the hydration of ketene occurred by addition of chains of water across the ketene C=O bond rather than the C=C.

Bulk solvent electrostatic influence

Having established the catalytic effect of increasing water clusters during the hydration reaction, we now turn to that of the bulk solvent. Results when the supermolecules are put in a cavity in a dielectric continuum (ε = 78.3) are summarized in Table 4. Gas phase geometries are re-optimized incorporating a continuum by means of a reaction field method (SCRF), and energetic parameters are obtained using single-point calculations with SCRF geometries and both SCRF and PCM models. While the SCRF results show some fluctuations, in particular for the three-water system, the more reliable PCM results give a consistent picture. That is, compared with the reaction pathways of the gas phase system, a trend emerges showing a small change in the energy barrier of, at most, 14 kJ mol^{-1}. A comparison between the energy

© 1999 NRC Canada

barriers in gas phase and aqueous solution is made in Figs. 7 and 8 for both additions across C=O and C=C, including increasing number of water molecules. For the sake of uniformity, only values based on MP2 calculations are employed. We note that the barriers for the four-water cluster with bulk solvation, are higher than the three-water ones. This is presumably due to the use of single-point MP2 energies. Usually, energy barriers obtained from single-point energies are consistent, thanks to the fact that the geometries do not change appreciably in going from one to another level, or that the energy surface is shallow in the saddle region. In this case, the bulk solvation is likely to distort the geometries in different ways in the MP2 level, as compared with that in the HF.

By and large, a passive, nonspecific solvation of the medium does not change the found preference for C=O addition when going from gas phase to liquid phase. Concerning the geometrical parameters of the transition structures, however, a significant difference can be noted between gas phase and continuum. As shown in Figs. 1, 2, 5, and 6, the proton transfer to the ketene oxygen in the various transition structures for water addition is far more completed in gas phase than in aqueous solution. This results in a longer H—O distance in solution, being elongated by at least 0.3 Å relative to the gas phase values. As mentioned above, a zwitterion could not be found, neither in gas phase, nor in solution using different reaction field models.

Concerning the size of the energy barrier, a point of concern, however, remains. Our estimates for this quantity using three-water and four-water clusters amount to about 70–80 and 80–90 kJ mol^{-1}, respectively, which are much larger than the experimental estimate (9) of 43 kJ mol^{-1}. Three possible reasons for this difference can be noted: (*i*) the first is that the atomic basis set employed in this work remains of moderate quality; (*ii*) the second reason, perhaps more importantly, is the fact that the point of references may be not the same. In our evaluation, the preassociation complexes involving ketene and water clusters are taken as the references. Probably, this is not the case in experimental studies. We note that in the four-water cluster case, both TSs actually lie below the separated system $H_2C=C=O + 4H_2O$; an energy barrier only exists when considering the complexes as stationary points; and (*iii*) the third reason is that the treatment of the solvent effect is also far from complete. Treatments using more advanced simulation techniques are certainly necessary for a more quantitative picture of the solvation phenomenon.

Although the reality of a hydration process is far more complex than the model calculations reported here, the proposal of a two-step reaction across the ketene C=O bond involving a chain of three or four water molecules appears overall in better agreement with recent experimental developments in identifying enols of carboxylic acids.

Concluding remarks

In the present paper, the reaction mechanism of the ketene hydration by increasing water clusters has been probed by theoretical methods in both gas phase and aqueous solution. Our calculations provide further evidence that a two-step addition of water across the carbon–oxygen double bond of ketene, yielding first an enediol intermediate is energetically preferred over a concerted addition across the carbon–carbon double bond leading immediately to the carboxylic acid product. Chains of two or three hydrogen-bonded water molecules are expected to be present in the hydration supersystem. A further incorporation of active water molecules induces rather small improvements of the energy barrier. Effects of the surrounding bulk do not change qualitatively the gas phase findings. These results, together with the recent experimental developments in identifying enols of carboxylic acids, do not support either a direct C=C addition or an ionic mechanism involving a zwitterion intermediate.

Fifteen years have passed since we reported the first theoretical results pointing out the preference for a C=O hydration of ketene (22). Thanks to the effort of several groups, there is now compelling experimental and theoretical results supporting this hydration mechanism. The existence of enols of carboxylic acids appears now to be a fact of life. This story also illustrates, once more, the necessary and beneficial symbiosis between theory and experiment in which simple but reliable theoretical predictions may lead to far reaching experimental research. It is interesting to note that in earlier textbooks of organic chemistry (see for example ref. 67), up to the fifties, the ketene hydration was explained as a two-step reaction with the intermediacy of 1,1-enediols. Due to the total lack of evidence, this mechanism was progressively discarded from the sixties. It is now hoped that the enols of carboxylic acids will occupy again their own place in future textbooks.

Theoretical simulation of Brønsted correlations for proton transfer and methyl transfer: the significance of the Brønsted coefficient β

Ian H. Williams and Paul A. Austin

Abstract: Brønsted correlations for proton transfer and methyl transfer between pairs of mimicked 4-substituted pyridines have been simulated by means of AM1 molecular orbital calculations. The enthalpies of activation and of reaction are well correlated by the Marcus relation. The Brønsted correlation is markedly curved for proton transfer for which the Marcus intrinsic barrier is very low (~5 kJ mol^{-1}). Conversely, the Brønsted correlation is almost imperceptibly curved for methyl transfer for which the Marcus intrinsic barrier is very high (~152 kJ mol^{-1}). The slope of the Brønsted correlation provides an approximate measure of the position of the transition structure along the reaction coordinate between the reactant and product encounter complexes. Primary kinetic isotope effects for proton transfer show a broad maximum, centered on $\Delta H_{rxn} = 0$, when plotted against reaction exo/endothermicity only if computed with respect to isolated acids and bases, but intracomplex kinetic isotope effects show a maximum displaced significantly towards the endothermic proton transfers.

Key words: Brønsted correlation, rate–equilibrium relationship, transition state, isotope effect.

Résumé : Faisant appel à des calculs d'orbitales moléculaires AM1, on a simulé des corrélations de Brønsted pour le transfert de proton et pour le transfert de méthyle entre des paires simulées de pyridines substituées en position 4. On a établi une bonne corrélation de Marcus entre les enthalpies d'activation et de réaction. La corrélation de Brønsted est fortement incurvée pour le transfert de proton pour laquelle la barrière intrinsèque de Marcus est très faible (environ 5 kJ mol^{-1}). Inversement, la corrélation de Brønsted est à peine incurvée pour le transfert de méthyle pour laquelle la barrière de Marcus est très élevée (environ 152 kJ mol^{-1}). La pente de la corrélation de Brønsted donne une mesure approximative de la position de la structure de transition sur les coordonnées de la réaction qui se situe entre le réactif et les complexes de rencontre. Lorsqu'on trace une courbe des effets isotopiques cinétiques primaires pour le transfert de proton en fonction de exo/endothermicité de la réaction, ces effets ne présentent un large maximum, centré autour de $\Delta H_{exn} = 0$, que lorsqu'on les calcule par rapport aux acides et aux bases isolés; toutefois, les effets isotopiques cinétiques intracomplexes présentent un maximum qui est fortement déplacé vers les transferts de proton endothermiques.

Mots clés : corrélation de Brønsted, relation vitesse–équilibre, état de transition, effet isotopique.

[Traduit par la Rédaction]

Introduction

The existence of linear free-energy relationships, implying the complete interchangeability of equilibrium and rate constants, was from the very earliest days (1) taken to be one of the simplest and strongest supports of transition state (TS) theory (2). Moreover, it was noted on the basis of simple energy profiles that the more thermodynamically favoured a member of a family of related reactions is, the faster it should proceed, and the earlier its TS should occur along the reaction coordinate; conversely, a thermodynamically unfavourable reaction would be slower and its TS would occur later (cf. Hammond's postulate) (3). Leffler (4) proposed that the slope of a linear correlation between log k and log K (i.e., of $\Delta G^{\ddagger}$ vs. ΔG_{rxn}) could be identifed as a parameter measuring the degree of resemblance of the TS to the products as compared with its resemblance to the reagents. Thus, for a proton transfer from an acid to a series of related bases, the value of the Brønsted coefficient β obtained from the linear correlation $\Delta G^{\ddagger} = \beta \Delta G_{rxn}$ would be interpreted as a measure of the degree of transfer of the proton in the TS. A value of $\beta \approx 0$ would indicate a reactant-like TS in which essentially no proton transfer had occurred from the acid to the base, $\beta \approx 1$ would indicate a product-like TS in which proton transfer was essentially complete, and $\beta \approx 0.5$ would indicate a TS in which the proton was about half transferred (5).

The use of slopes of structure–reactivity correlations (particularly the Brønsted β) as measures of TS structure has come under severe criticism (6) in recent years, but has also been thoughtfully defended with appropriate cautionary notes (7). It has long been recognised that there is a fundamental incompatibility within the corpus of ideas which

Received November 18, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

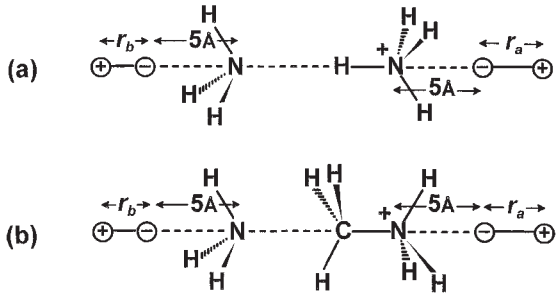
Fig. 1. Positioning of dipoles and ammonia moieties for mimicking of (*a*) proton transfer and (*b*) methyl transfer between substituted pyridines.



arise from TS theory: if the slope of a linear rate–equilibrium relationship is interpreted as some index of TS structure, it must reflect some *constant* property of the TS for the entire family of reactions used to construct the correlation; however, the Leffler principle (4), Hammond postulate (3), and related notions (8) all suggest that changing the reaction energetics should cause *variation* in TS structure within this same family. Modern computational chemistry offers a means by which this paradox may be resolved. For a particular reaction of a series of substituted compounds, the energetics and geometries of reactants, TSs, and products may be obtained from calculated potential energy surfaces. Rate–equilibrium relationships may be constructed from plots of calculated $\Delta G^{\ddagger}$ vs. ΔG_{rxn} (or $\Delta H^{\ddagger}$ vs. ΔH_{rxn}) values. The merit of this approach is that the TS structure, deduced indirectly from the slopes of these plots, may be compared with those determined directly (9). A simulation in this manner for an acyl-transfer process established (10) that (*i*) variation in basicity of the nucleophile led to variation in TS structure but also to a linear extended Brønsted correlation, and that (*ii*) bond-order changes, angular changes, and charge development occurred more-or-less concertedly but bore no obvious relation to the magnitude of the (extended) Brønsted coefficient β_{nuc}. Thus, there was no fundamental incompatibility between the notion of TS variation and the observation of a linear structure–reactivity correlation, but it was concluded that β_{nuc} did not provide a direct measure of TS structure.

We now report results of analogous gas-phase theoretical simulations for families of proton-transfers (eq. [1], R = H) and S_N2 methyl transfers (eq. [1], R = Me) between mimicked pyridine bases (11).

Methods

The MOPAC 6.0 program (12) was used to perform semiempirical RHF molecular orbital calculations with the AM1 Hamiltonian (13). We chose to simulate *only* the polar effect of substituents X and Y modifying the gas-phase basicity of the nucleophiles and nucleofuges in eq. [1], and to consider only 4-substituted pyridines. It was assumed that the contributions from entropy and from the steric component of the enthalpy to the standard Gibbs energies of activation $\Delta G^{\circ\ddagger}$ and the standard Gibbs energies of reaction ΔG°_{rxn} throughout this series would be essentially constant and would not sensibly affect the *relative* values of $\Delta H^{\ddagger}$ and ΔH_{rxn} as determined directly from the AM1 calculated enthalpies of formation. Optimized geometries for the reactant and product ion–dipole complexes and transition structures for proton transfer (R = H) and methyl transfer (R = CH_3) in eq. [1] were obtained within the constraint of a three-fold axis of symmetry. This allowed two important simplifications to be made. First, the rate–equilibrium correlations were constructed as plots of $\Delta H^{\ddagger}$ vs. ΔH_{rxn} only. Second, the pyridine nucleophiles and nucleofuges were *mimicked* by ammonia molecules whose proton affinities were modulated to reproduce the experimental proton affinity (PA) of each base relative to that of ammonia; this enabled the computations to be performed economically (as an undergraduate research project) by avoiding repetitious and uninformative calculation upon the large and constant aryl portions of the nitrogen bases.

Table 1. Dipolar charges, separations, and proton affinities relative to ammonia for mimicked 4-X-substituted pyridines.

X	$\|q\|$	r_b/Å	ΔPA/kJ mol^{-1}
CN	1	0.245	10.5
Cl	2	0.503	41.4
H	2	0.678	54.4
CH_3	2	0.919	71.2
$(CH_3)_2N$	2	1.657	115.5

The mimicking was accomplished (as previously described (10)) by placing a pair of oppositely charged MOPAC "sparkles" (constituting a dipole) on the three-fold axis of ammonia, on the same side as the hydrogens, with the negative charge a constant distance of 5 Å from the nitrogen atom, as shown in Fig. 1. By adjustment of the charge ($|q|$ = 1 or 2) and dipolar separation (in the range 0.2–1.7 Å), the basicity of the ammonia could be suitably tuned. A sparkle is an integral charge at the centre of a spherical repulsive potential (14); if the separation between oppositely charged sparkles is less than 1.0 Å, the energy due to the dipole on its own is subtracted from the total energy. Appropriate variation of the dipole lengths r_a and r_b thus allowed the NH_3 groups a and b to mimic pyridines with 4-CN, 4-Cl, 4-H, 4-CH_3, and 4-$(CH_3)_2N$ substituents; the calculated ΔPA values shown in Table 1 are exactly equal to the proton affinities relative to ammonia as determined experimentally (10). This resulted in 25 pairs of $\Delta H^{\ddagger}$ and ΔH_{rxn} values for each transferring group R = H or CH_3, except that no accurately determined transition structures could be located for proton transfer between the protonated pyridines 4-CN-PyH^+ and 4-Cl-Py H^+ (with the most strongly electron withdrawing substituents) and 4-$(CH_3)_2$N-Py (with the most strongly electron donating substituent). Sparkles have been employed in a similar fashion in AM1 calculations for S_N2 methyl transfer from methyl halides to 2-methylpyridine to represent a solvent effect upon the leaving group (15).

Our earlier theoretical simulation of a rate–equilibrium correlation for transfer of the methoxycarbonyl group between isoquinoline and substituted pyridines, in which the

same range of nucleophiles and the nucleofuge were also mimicked by sparkle-modulated ammonia molecules, has recently been reinvestigated (16) using explicit nucleophiles and nucleofuge in the gas phase and in water (modelled as a continuum). None of the earlier conclusions was altered in the slightest. The mimicking procedure is a convenient and valid approximation, and may be considered as a simple type of hybrid quantum–classical method. Moreover, we may note that there is a good linear correlation between gas-phase proton affinities and aqueous pK_a values for 4-substituted pyridines (10), which suggests that the qualitative trends described in this work may also apply to reactions in solution.

Results and discussion

Brønsted correlations for proton transfer

The relevant AM1 calculated gas-phase enthalpic data for the mimicked reaction series with R = H in eq. [1] are shown in Table 2. The calculated enthalpies of the ion–molecule reactant and product complexes, XPy···HPyY$^+$ and $^+$XPyH···PyY, respectively, and of the transition structures [XPy···H$^+$···PyY]‡ for proton transfer in the double-well potential (Fig. 2) are consistently lower than those of the separated reactant or product species. The enthalpy change ΔH_{PT} for proton transfer between the separated acid and base species, HPyY$^+$ and XPy, becomes more exothermic, or less endothermic, with increasing proton affinity PA of the base (relative to ammonia) from X = CN to X = $(CH_3)_2N$. A similar trend is found for the enthalpy change ΔH_{rxn} for proton transfer between the acid and base within the encounter complex, although the magnitudes are smaller. The most exothermic proton transfer (–22.91 kJ mol^{-1}) is from the

Fig. 2. Double-well enthalpy profile for proton transfer between mimicked pyridine bases.

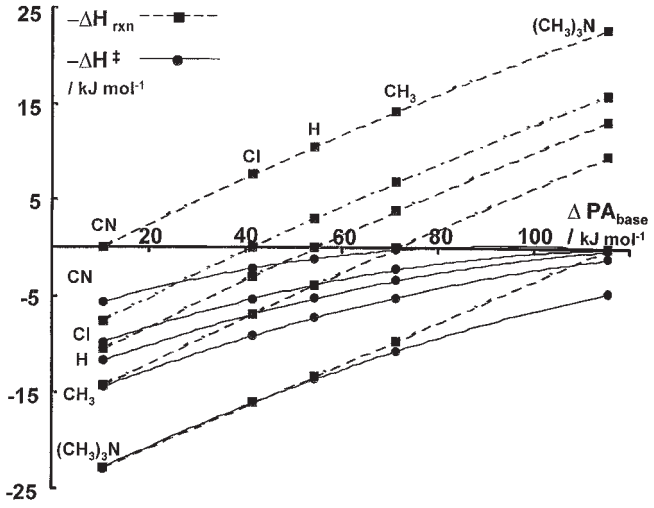
Fig. 3. Simulated Brønsted correlations for intracomplex proton transfers: $-\Delta H^{\ddagger}$ (solid lines) and $-\Delta H_{rxn}$ (broken lines) vs. proton affinities ΔPA of mimicked pyridine bases relative to ammonia.



strongest acid 4-CN-PyH$^+$ and the strongest base 4-$(CH_3)_2$N-Py: for this combination ΔH_{PT} is –105.09 kJ mol^{-1} between the separated species but ΔH_{rxn} is only –22.91 kJ mol^{-1} for the intracomplex reaction. The most endothermic process is the reverse reaction for this system.

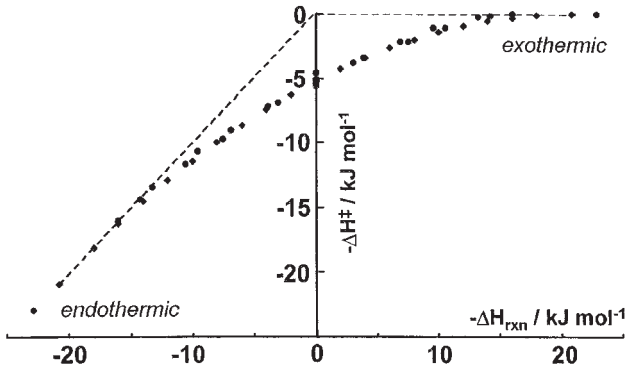
Families of Brønsted correlations may be generated by plotting the (negatives of the) enthalpies of activation and of reaction for intracomplex proton transfer ($-\Delta H_{rxn}$ and $-\Delta H^{\ddagger}$) against the relative proton affinity as the base is varied whilst keeping constant the identity of the acid. The five (very slightly curved) parallel dashed lines in Fig. 3 are the set of correlations of $-\Delta H_{rxn}$ vs. ΔPA; the value of about 0.22 for their slopes reflects the attenuation factor for intracomplex proton transfer as compared with proton transfer between separated acids and bases. The solid lines in Fig. 3 are the correlations $-\Delta H^{\ddagger}$ vs. ΔPA; these curves have slopes tending to zero as the proton affinity of the base is increased in combination with the strongest acid (exothermic proton transfer), but tending to equal the slope of $-\Delta H_{rxn}$ vs. PA as the proton affinity of the base is decreased in combination with the weakest acid (endothermic proton transfer).

However, it is more instructive to plot $-\Delta H^{\ddagger}$ vs. $-\Delta H_{rxn}$ directly for all the reactions on a single graph (Fig. 4); the slope of such a correlation is a normalized Brønsted coefficient β. The circles in Fig. 4 refer to AM1 calculated points. There is only a very small variation in $\Delta H^{\ddagger}$ for the five identity reactions, from 4.60 kJ mol^{-1} for X = Y = $(CH_3)_2$N to 5.58 kJ mol^{-1} for X = Y = CN. The squares in Fig. 4 refer to points calculated according to the Marcus eq. [2] with an intrinsic barrier $\Delta H^{\ddagger}_{int}$ of 5.22 kJ mol^{-1} (= $\Delta H^{\ddagger}$ for X = Y = H); the Marcus equation provides a satisfactory fit to the AM1 calculated data. The slope of the curved Brønsted correlation for proton transfer approaches 0 for the most exothermic and 1 for the most endothermic reactions in accord with expectation (17, 18).

$$[2] \qquad \Delta H^{\ddagger} = \Delta H^{\ddagger}_{int} + \Delta H_{rxn}/2 + (\Delta H_{rxn})^2/16\Delta H^{\ddagger}_{int}$$

The energy differences ΔH_{rc} and ΔH_{pc} (Table 2) represent the strengths of hydrogen bonding between acid and base

Fig. 4. Simulated Brønsted rate–equilibrium correlation $-\Delta H^{\ddagger}$ vs. $-\Delta H_{rxn}$ for proton transfer: circles denote AM1 calculated enthalpies, diamonds denote Marcus-equation calculated values; broken lines show slopes of +1 (endothermic limit) and 0 (exothermic limit).



and between conjugate base and conjugate acid. Increasing the proton affinity of the base increases the hydrogen-bond strength ΔH_{rc} with a given acid and decreases the hydrogen-bond strength ΔH_{pc}. The most exothermic proton transfers are therefore associated with the strongest reactant–complex hydrogen bonds but the weakest product–complex hydrogen bonds. The most endothermic proton transfers are associated with the weakest reactant–complex hydrogen bonds but the strongest product–complex hydrogen bonds.

Bond length and bond-order changes for proton transfer

The bond lengths presented in Table 3 show that strongly hydrogen-bonded complexes have shorter $N_b\cdots H$ distances to the base and longer $H—N_a$ distances in the acid. The $H—N_a$ distance is 1.023 Å in the isolated acid 4-H-PyH$^+$ but is 1.305 Å in the transition structure [HPy$\cdots$H$^{\ddagger}\cdots$PyH‡]; assigning Pauling bond orders (19) *n* of 1.0 and 0.5 to these bonds allows the coefficient *c* in eq. [3] to be determined as 0.407.

$$[3] \qquad n = \exp\,[(R_1 - R_n)/c]$$

A consequence of this definition is that the sums of the bond orders for the intracomplex $N_b\cdots H$ and $H—N_a$ bonds are, respectively, about 1.2 and 0.9 for the strongest and weakest hydrogen bonds; bond orders n_b for $N_b\cdots H$ vary in magnitude from about 0.18 to about 0.34, whereas those for $H—N_a$ range from about 0.73 to about 0.89. In the transition structures, n_b varies from <0.378 for the most exothermic reactions to >0.629. (Note that when the activation energy for either the forward or reverse reaction approaches zero, as in the case of X = $(CH_3)_2$N and Y = Cl or CN, we were unable to determine the transition structures accurately.) This result accords with the Hammond postulate (3): the more exothermic members of this family of related reactions have more reactant-like transition structures, while the more endothermic have more product-like transition structures. Clearly, variation in the exo/endothermicity of proton transfer causes variation in the geometry of the transition structure.

It is important to bear in mind that the absolute accuracy of the bond lengths reported in Table 3 is not the issue of prime concern, but rather the manner in which they change

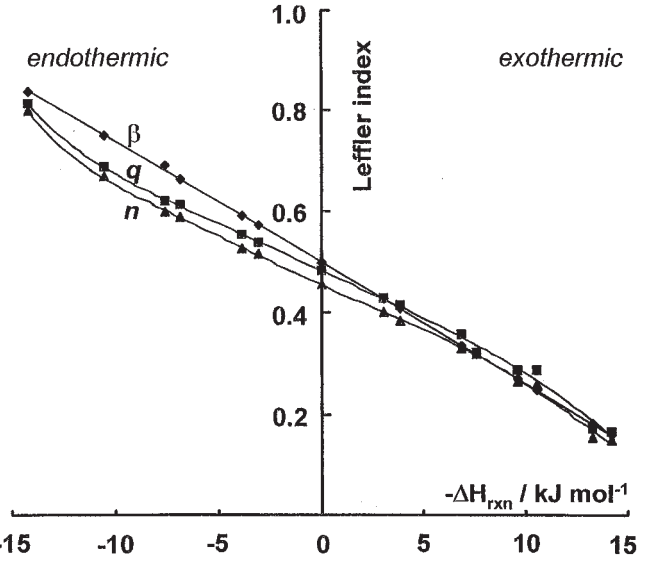
in response to the polar influence of a substituent. Furthermore, since the point of interest is change in the transition state relative to reactants and products, it is useful to consider the *normalized* Pauling bond order $n^{\ddagger}$ for each transition structure, as given by eq. [4].

$$[4] \qquad n^{\ddagger} = [(n_b)^{\ddagger} - (n_b)_{rc}]/[(n_b)_{pc} - (n_b)_{rc}]$$

This quantity is a Leffler index which measures the degree of progress of the transition structure along the reaction coordinate between the reactant and product complexes according to a geometrical criterion for bonding of the transferring proton to the base. Figure 5 shows the value of $n^{\ddagger}$ (triangles) plotted as a function of the exo/endothermicity of the reaction, along with the normalized Brønsted coefficient β (diamonds). The plot of vs. $-\Delta H_{rxn}$ is a straight line, whereas that of $n^{\ddagger}$ vs. $-\Delta H_{rxn}$ is somewhat sigmoidal in nature. Nonetheless, the two quantities do have similar magnitudes across the full range of exo/endothermicities, such that for any particular reaction the value of β does provide a rough estimate for the degree of bonding between the proton and the base in the transition structure.

Fig. 5. Variation in normalized values of Brønsted β (diamonds), charge on basic moiety $q^{\ddagger}$ (squares), and Pauling bond order $n^{\ddagger}$ (triangles) in transition structures for proton transfer with respect to $-\Delta H_{rxn}$.



Charge changes for proton transfer

The value of a normalized Brønsted coefficient is sometimes interpreted as a measure of effective charge in the transition state (20). The formal charge on the nitrogen atom of the basic moiety in this series of proton transfers between (mimicked) substituted pyridines changes from zero to +1 in

going from reactants to products, and in the transition structure it is reasonable to suppose it has some intermediate value. In this study, the net charge q_b on basic moiety was calculated as the sum of the Mulliken charges on all the atoms of the NH_3 group used to mimic the pyridine bases. Values of these group charges in each reactant complex, transition structure, and product complex are given in Table 4. As with the bond lengths considered above, the reliability of the absolute values of these group charges is not the issue of prime concern, but rather the manner in which they change in response to the polar influence of a substituent.

Increasing the proton affinity of the base leads to greater positive charge on the basic moiety in both the reactant and product complexes. The magnitude of the charge mirrors the strength of hydrogen bonding. The values range from 0.095 to >0.194 in the reactant complexes and from <0.489 to 0.609 in the product complexes. In these AM1 calculations the charge on the transferring proton is always about +0.3; thus complete intracomplex proton transfer raises this group charge from between +0.1 and +0.2 (in NH_3) to between +0.8 and +0.9 (in NH_4^+).

A normalized charge $q^{\ddagger}$ may be obtained for each transition structure as the fractional change in the total charge on the basic moiety from its value in the reactant complex to its value in the product complex, as given by eq. [5]; these are indicated by squares in Fig. 5.

$$[5] \qquad q^{\ddagger} = [(q_b)^{\ddagger} - (q_b)_{rc}]/[(q_b)_{pc} - (q_b)_{rc}]$$

This quantity is a Leffler index which measures the degree of progress of the transition structure along the reaction coordinate between the reactant and product complexes according to a criterion of developing charge on the basic moiety. The plot of $q^{\ddagger}$ vs. $-\Delta H_{rxn}$ gives a curve of similar shape to that for $n^{\ddagger}$ vs. $-\Delta H_{rxn}$., which roughly tracks the value of. Strongly exothermic reactions have very low values of $q^{\ddagger}$, strongly endothermic reactions have very high values of $q^{\ddagger}$, and thermoneutral identity reactions have values of $q^{\ddagger}$ rather close to 0.5. Thus, for any particular reaction the value of the normalized Brønsted coefficient also provides a rough estimate for the degree of charge development on the base in the transition structure.

Primary isotope effects for proton transfer

Table 4 also contains semiclassical kinetic isotope effects (KIE = k_H/k_D) for replacement of the transferring proton by a deuteron, within the hydrogen-bonded encounter complex, at a temperature of 298 K. The KIEs are calculated from the vibrational zero-point energies and the partition functions for translation, rotation, and vibration using standard procedures (21); the AM1 method has been shown to reproduce experimental primary KIEs for hydrogen transfer to within 13% (22). These values, plotted as circles in Fig. 6, range from 2.0 for strongly exothermic hydron transfers to a maxi-

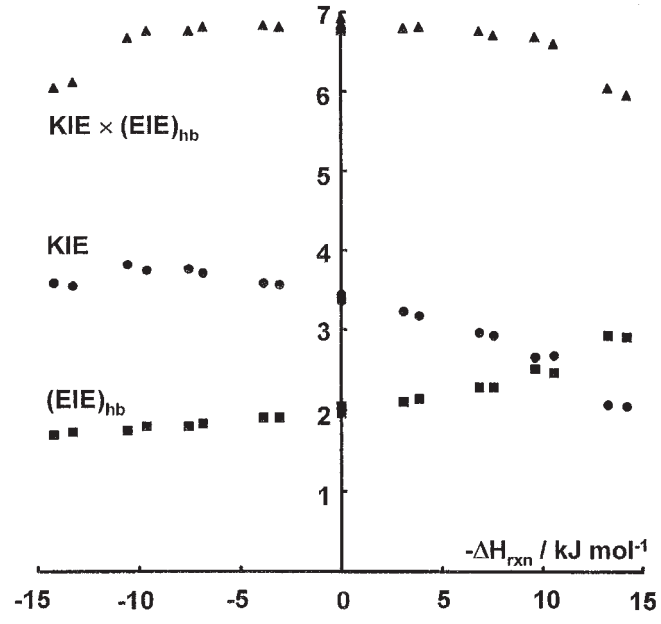
Fig. 6. Semiclassical kinetic isotope effects KIE for intracomplex proton transfer, equilibrium isotope effects (EIE)$_{hb}$ for hydrogen bonding, and overall kinetic isotope effects KIE × (EIE)$_{hb}$ for proton transfer between separated acids and bases, with respect to $-\Delta H_{rxn}$.



mum of about 3.8 for reactions endothermic by about 10 kJ mol^{-1}. Unfortunately, transition structures for hydron transfers between the most strongly basic and acidic groups could not be determined with sufficient reliability to enable us to extrapolate with confidence for processes with $\Delta H_{rxn} > +15$ kJ mol^{-1}, but there is certainly a clear indication that the magnitude of the KIE diminishes for reactions with endothermicities greater than 10.5 kJ mol^{-1}. The identity reactions have KIEs of about 3.4.

It is often thought that the maximum in a plot of the primary kinetic isotope effect against base strength in a series of hydron transfer reactions occurs when the force constants for the making and breaking bonds are equal in the transition state (23, 24). Stretching force constants for the bonds N$_b$···H and H—N$_a$ are presented in Table 5. The transition structures for the identity reactions do indeed each have equal force constants (of about 1.7 mdyn Å^{-1}) (1 dyn = 10 μN) for these bonds. However, the maximum KIE occurs for hydron transfer from 4-H-PyH$^+$ to 4-CN-Py for which F(N$_b$···H) = 2.211 and F(H—N$_a$) = 1.365 in the transition structure. The reason for the apparent anomaly is that the strength of hydrogen bonding in the reactant and product complexes is isotopically sensitive. In other words, there are significant equilibrium isotope effects upon formation of these gas-phase ion–molecule complexes from separated acids and bases. These isotope effects (EIE)$_{hb}$ are largest (>3)

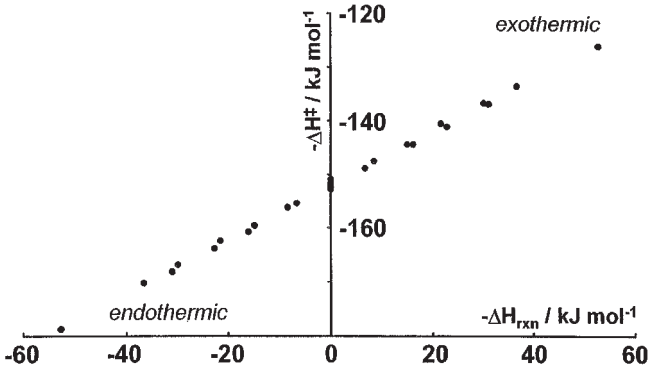
Fig. 7. Simulated Brønsted rate–equilibrium correlation $-\Delta H^{\ddagger}$ vs. $-\Delta H_{rxn}$ for S_N2 methyl transfer.



for the most exothermic reactions and diminish smoothly to <1.7 for the most endothermic processes, as shown by the squares in Fig. 6. The overall primary kinetic isotope effect for hydron transfer between separated acids and bases is given by the product KIE $(EIE)_{hb}$, plotted in Fig.6 as triangles. These isotope effects display a very broad maximum centred on the thermoneutral reactions, with KIE $(EIE)_{hb} \approx 6.8$ for all reactions for which $-10 \leq \Delta H_{rxn} \leq +10$ kJ mol^{-1}, but falling to lower values for the most exothermic and endothermic reactions.

Brønsted correlations for methyl transfer

AM1 calculated gas-phase enthalpic data for the mimicked reaction series with R = CH_3 in eq. [1] are shown in Table 6. The enthalpies of activation ($\Delta H^{\ddagger}$) and of reaction (ΔH_{rxn}) for intracomplex methyl transfer are given relative to enthalpies of formation (H_f) of the reactant complexes XPy···MePyY$^+$. Increasing the proton affinity of the nucleophile causes the methyl transfer to be more exothermic or less endothermic. Plots of $-\Delta H^{\ddagger}$ and $-\Delta H_{rxn}$ vs. ΔPA for methyl transfer (not shown) are less interesting than those for proton transfer (Fig. 3): there are two sets of imperceptably curved parallel lines, those for ΔH_{rxn} having larger slopes than those for $\Delta H^{\ddagger}$. Three clear differences may be noted for methyl transfer as compared with proton transfer: the individual plots are scarcely distinguishable from straight lines; the range of values for both $\Delta H^{\ddagger}$ and ΔH_{rxn} is twice as wide; the absolute values for the barrier heights $\Delta H^{\ddagger}$ are very much larger.

Figure 7 shows a plot of $-\Delta H^{\ddagger}$ vs. $-\Delta H_{rxn}$ for methyl transfer. Linear and second-order polynomials regressions may be achieved with equal confidence; in each case the slope of the linear term is exactly 0.5. The enthalpies of activation for the five identity reactions vary from 151.08 kJ mol^{-1} for X = Y = $(CH_3)_2N$ to 152.88 kJ mol^{-1} for X = Y = CN. A Marcus relation, eq. [2], with an intrinsic barrier $\Delta H^{\ddagger}_{int}$ of 152.09 kJ mol^{-1} (= $\Delta H^{\ddagger}$ for X = Y = H) provides an excel-

© 1999 NRC Canada

lent correlation for the AM1 calculated points. Differentiation of eq. [2] (at constant $\Delta H^{\ddagger}_{int}$) yields an expression for the Leffler index, $\partial\Delta H^{\ddagger}/\partial\Delta H_{rxn}$, which is also the slope of a normalized Brønsted correlation (17, 18).

$$[6] \qquad \partial\Delta H^{\ddagger}/\partial\Delta H_{rxn} = \beta_{Marcus} = 0.5 + \Delta H_{rxn}/8\Delta H^{\ddagger}_{int}$$

With $\Delta H^{\ddagger}_{int}$ = 152.09 kJ mol^{-1}, the value for this Marcus-derived Brønsted coefficient varies from 0.50 by only ±0.04 over the entire range of $-52.72 \le \Delta H_{rxn} \le 52.72$ kJ mol^{-1}. However, the curvature of the Marcus correlation ($1/8\Delta H^{\ddagger}_{int} = 8 \times 10^{-4}$) is five times as great as for the second-order polynomial regression to the AM1 calculated points in Fig. 7.

Bond length and bond-order changes for methyl transfer

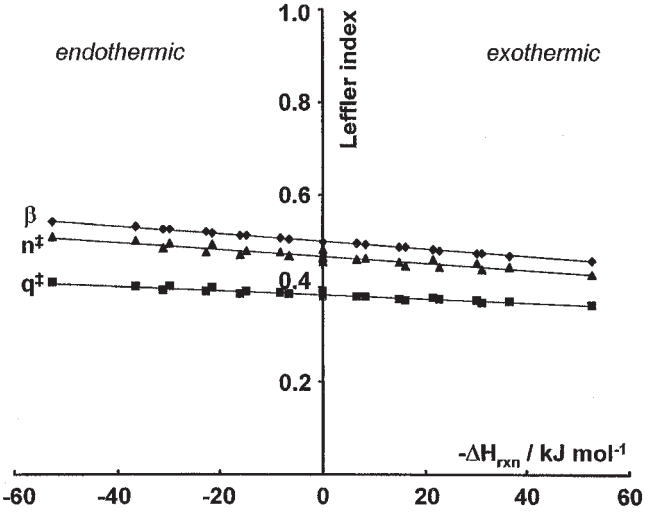
As the data in Table 7 show, better nucleophiles and electrophiles give slightly shorter $N_{nu}\cdots C$ but slightly longer $C—N_{el}$ distances in the reactant complexes $XPy\cdots MePyY^{+}$, although the magnitude of variation is only small. The $C—N_{el}$ distance is 1.476 Å in the isolated electrophile 4H-$PyMe^{+}$ but is 1.843 Å in the transition structure $[4HPy\cdots Me^{\ddagger}\cdots 4HPy]^{\ddagger}$; assigning Pauling bond orders n_{nu} of 1.0 and 0.5 to these bonds allows the coefficient c in eq. [3] to be determined as 0.529. The bond orders n_{nu} in the transition structures vary only a little, but in accord with the Hammond postulate. The sums of the bond orders vary between 1.053 and 1.068 for both the reactant and product complexes, and between 0.968 and 1.034 for the transition structures; there is therefore a high degree of conservation of bond order.

The normalized transition-structure bond orders $n^{\ddagger}$ vary between 0.429 for the most exothermic and 0.509 for the most endothermic intracomplex reactions. Figure 8 shows the values of $n^{\ddagger}$ (triangles) plotted against $-\Delta H_{rxn}$ for methyl transfer; the resulting straight line is parallel with and close to the gently sloping line drawn through the values of β determined by the Marcus relation with $\Delta H^{\ddagger}_{int}$ of 152.09 kJ mol^{-1}. Clearly for any particular methyl transfer reaction the value of does provide a good estimate for the degree of bonding between the nucleophile and the electrophile in the transition structure.

Charge changes for methyl transfer

The small variations in bond orders are mirrored by correspondingly small changes in net charges q_{nu} on the nucleophilic moiety in the methyl transfers (Table 8). The formal charge on the nitrogen atom of the nucleophile changes from 0 to +1 in each reaction, just as for proton transfer. The values of $(q_{nu})_{rc}$ are indeed very close to zero in the reactant complexes for methyl transfer. The overall charge on the XPyMe moiety in the product complexes is the sum of $(q_{nu})_{pc}$ and the net charge on the transferring methyl group; since the latter varies between +0.27 and +0.30, this overall charge is very close to unity. In the transition structures, the value of $(q_{nu})^{\ddagger}$ varies from +0.27 and +0.29, but the net charge on the transferring methyl group has a larger value, of between +0.43 and +0.46. Since the normalized charge is determined solely as the fractional change in q_{nu} and does not consider the effect of the changing charge on the methyl group, the value of $q^{\ddagger}$ underestimates the progress of methyl transfer as compared with $n^{\ddagger}$ and β (Fig. 8).

Fig. 8. Variation in normalized values of Brønsted β (diamonds), charge on basic moiety $q^{\ddagger}$ (squares), and Pauling bond order $n^{\ddagger}$ (triangles) in transition structures for S_N2 methyl transfer with respect to $-\Delta H_{rxn}$.



Brønsted curvature, intrinsic barrier height, and the significance of β

The proton transfers considered in this study are characterized by a very low and essentially constant Marcus intrinsic barrier of just over 5 kJ mol^{-1} and manifest a curved Brønsted correlation, the slope of which varies between 0 and 1 over the range for which the simple Marcus eq. [2] is valid (17, 18, 25), i.e., $-4\Delta H^{\ddagger}_{int} \le \Delta H_{rxn} \le +4\Delta H^{\ddagger}_{int}$; the extent of this range is 21 kJ mol^{-1}. The analogous methyl transfers are characterized by a rather high but still essentially constant Marcus intrinsic barrier of 152 kJ mol^{-1} and manifest what appears to be a linear Brønsted correlation. Very slight curvature may be detected by regression to a second-order polynomial, but a range of enthalpies of reaction extending over 1216 kJ mol^{-1} ($-4\Delta H^{\ddagger}_{int} \le \Delta H_{rxn} \le +4\Delta H^{\ddagger}_{int}$) would be required in order for the slope to change from 0 to 1.

Proton transfer yields a markedly curved Brønsted correlation, and there is a correspondence between the value of β (the instantaneous slope) and the degree of proton transfer in the TS. A similar conclusion was reached in an ab initio MO study of proton transfer between ammonia and a range of alkylamines: calculated energy changes fit the Marcus relation well, and fair agreement was obtained between the Marcus-derived Brønsted coefficient and the position of the transition structure along the reaction coordinate (26).

Methyl transfer yields an apparently linear, but actually very slightly curved, Brønsted correlation whose slope also corresponds to degree of bonding of the nucleophile to the transferring group in the TS, as measured by the Pauling bond order. However, it should be noted here that this correspondence between β and $n^{\ddagger}$ depends upon the value adopted for the coefficient c in eq. [3] for the Pauling bond order. In this study, we have made the assumption that the bond order of the $N_{nu}\cdots C$ and $N_b\cdots H$ partial bonds in the transition structures for methyl transfer and proton transfer is exactly one-half, and have accordingly determined the values of c as

0.529 and 0.407, respectively. A different choice for c would lead to a different conclusion: indeed, Pauling bond orders n_{nu} calculated for these same methyl transfer TSs using $c = 0.3$ led us previously to conclude that β did *not* provide a measure of the degree of bonding to the nucleophile in the TS (27). The normalized charge $q^{\ddagger}$ for methyl transfer, defined as the fractional change in the net charge on the nucleophilic NH_3 moiety, suffers the problem (described above) of not accounting for the variable charge on the transferring methyl itself, and therefore of underestimating the position of the TS along the intracomplex reaction coordinate.

Hori et al. (28) have very recently shown the existence of a linear correlation between calculated barrier heights and relative proton affinities for gas-phase S_N2 methyl transfer reactions of 4-X-substituted pyridines (X = NO_2, H, OCH_3, $N(CH_3)_2$) with chloromethane. Ab initio MP2/6-31+G*//HF/6-31+G* potential energies were employed to evaluate the activation energy with respect to isolated reactants for reaction of each nucleophile relative to reaction of ammonia with chloromethane; the proton affinities were also calculated relative to ammonia (just as in the present work). The slope of the linear correlation was not — and indeed cannot — be interpreted directly as a measure of the position of the TS along the reaction coordinate, in the way that a normalized Brønsted coefficient may be, because the ion–molecule reactant and product complexes were not considered by these workers. However, their calculated trends in bond lengths and charges involving the nucleophile in the TS are completely in accord with the Hammond postulate and with the trends we have reported in the present study. Although we have not only used a semiempirical MO method but also a very simple trick to mimic the substituted pyridines instead of treating the full molecules, the results of Hori et al. do provide welcome evidence (further to our own (16)[2]) to suggest that our approximate procedures are indeed quite reasonable.

Summarizing remarks

We have performed simple MO calculations to simulate intracomplex proton transfer and methyl transfer between series of 4-substituted pyridines. The enthalpies of activation and of reaction are well correlated by the Marcus relation. The Brønsted correlation is markedly curved for proton transfer, for which the Marcus intrinsic barrier is very low (~5 kJ mol^{-1}). The range of validity of the Marcus relation, $-4\Delta H^{\ddagger} \leq \Delta H_{rxn} \leq +4\Delta H^{\ddagger}$, is completely spanned by the range of substituents, strongly electron-withdrawing to strongly electron-donating, available to experiment and simulation.

[2] G.D. Ruggiero and I.H. Williams. Unpublished work.

© 1999 NRC Canada

Thus, the full change in slope from 0 to 1 of the curved Brønsted may be sampled. Conversely, the Brønsted correlation is almost imperceptibly curved for methyl transfer, for which the Marcus intrinsic barrier is very high (~152 kJ mol^{-1}), and the range of ΔH_{rxn} spanned by the substituents considered represents only the central 10% or so of the full range over which the slope changes from 0 to 1. It would be physically impossible to find nucleophiles and (or) leaving groups which could allow the full extent of Brønsted curvature to be expressed. A similar result was obtained by Kreevoy and co-workers (29) in simulations for families of hydride transfer reactions: an essentially linear Brønsted correlation was found for a reaction series with a high Marcus intrinsic barrier of ~87 kJ mol^{-1}.

Nearly a quarter of a century ago, Kresge contributed to a book dedicated to R.P. Bell; his chapter was entitled "The Brønsted relation: significance of the exponent" (5). That article, together with his slightly earlier *Chemical Society Reviews* paper (17), are remarkable for their insight. The present theoretical study, contributed to this issue dedicated to Jerry Kresge, achieves little more than to confirm the correctness of his ideas.

Acid–base chemistry in high-performance lubricating oils

Duncan C. Hone, Brian H. Robinson, David C. Steytler, Roger W. Glyde, and John A. Cleverley

Abstract: We have used stopped-flow kinetic studies to conduct an investigation into the acid neutralization reaction between overbased detergent additives and aqueous acid dispersed as w/o microemulsion droplets. Water-soluble pH indicators have been used to monitor the change in pH during the reaction. The acid neutralization rate was found to be dependent on the concentration of overbased additive, the temperature of the system, and the hydrocarbon chain length of the solvent. The systems are of importance in relation to the mechanism of acid neutralization by engine lubricants.

Key words: overbased detergent additive, acid neutralization, pH indicator, stopped flow.

Résumé : On a fait appel à des études cinétiques à flux stoppé pour étudier la réaction de neutralisation acide d'additifs de détergents surbasiques et de l'acide aqueux dispersé dans des gouttelettes d'une microémulsion e/h. On a utilisé des indicateurs de pH solubles dans l'eau pour évaluer le changement de pH au cours de la réaction. On a trouvé que la vitesse de neutralisation acide dépend de la concentration de l'additif surbasique, de la température du système et de la longueur de la chaîne de l'hydrocarbure agissant comme solvant. Les systèmes sont importants pour le mécanisme de neutralisation acide des lubrifiants de moteur.

Mots clés : additif de détergent surbasique, neutralisation acide, indicateur de pH, flux stoppé.

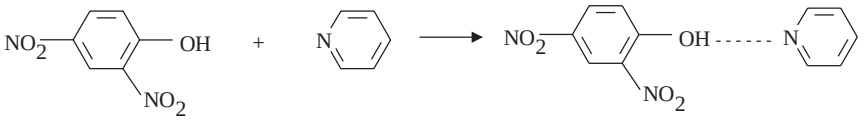
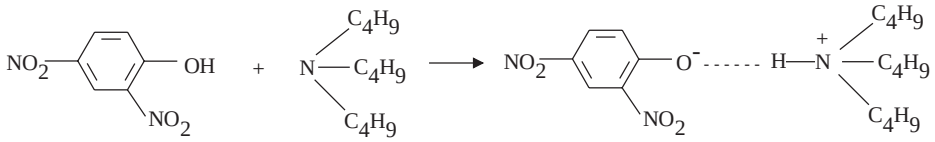
Introduction

Acid–base chemistry in aqueous-based media has, over the 60 years since the pioneering work of Brønsted and Bell, been an important and well-studied area of physical chemistry. By contrast, acid–base chemistry in nonpolar aprotic solvents has received rather less attention. This is particularly true of kinetic studies. In general, it can be stated that the products of a reaction between an organic acid (RH) and a base (B) can be either a hydrogen-bonded complex (RH–B) or a hydrogen-bonded ion pair (R^-–HB^+). Separation of the product components is prevented by the strong attraction between oppositely charged ions in the low-dielectric medium. The product formed will depend primarily on the relative acid–base strength of the reacting partners, as illustrated in the structures (following page).

In both reactions, the association rate constant k_f is close to diffusion controlled (~10^9 dm^3 mol^{-1} s^{-1}).



Weak base — Hydrogen-bonded complex



Strong base — Hydrogen-bonded ion pair

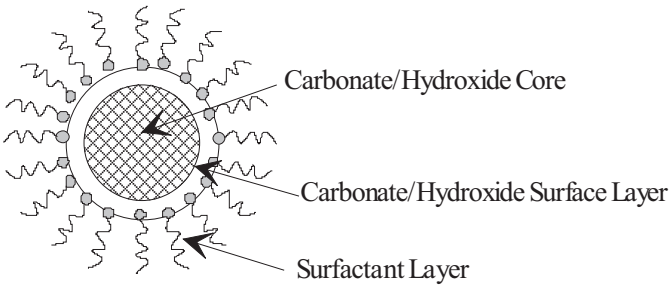
Fig. 1. Schematic diagram of an overbased additive particle.



In lubricating oils, for example, in automobile engines, a range of carbon-based acids (e.g., RCOOH) can be produced as a result of oxidative degradation of the hydrocarbon base oil. In addition, gases that are formed in the combustion process can react with water to produce acidic species such as H_2SO_4, HCl, and HNO_3. For example, fuel supplied for marine diesel engines is normally rich in sulphur, leading to the production of sulphuric acid. Unless neutralized, these acids will attack metal surfaces and this will subsequently lead to corrosion of engine components and to polymerization of organic species, resulting in resin formation and the buildup of deposits. Consequently there is a requirement to continuously neutralize these acids, which form during the operation of an engine. Since large amounts of acid are required to be neutralized it is convenient to supply "basicity" to the oil by means of an overbased additive (or detergent) formulation. This class of additive enables large amounts of sterically stabilized, colloidally dispersed, base to be present in the oil, and is found in nearly all modern oil formulations involving crankcase applications (automobile, truck, marine, etc.).

High-performance oils are now an essential component in modern engines. In addition to the fundamental role of providing a protective film for the metal, and dissipating the heat generated in an engine, such oils have a variety of other tasks. Preventing acid-induced metal corrosion and lubricant degradation is just one of these tasks. Others include, for example, the dispersion of considerable quantities of soot generated in diesel engines and the control of friction to improve the fuel efficiency of the engine. Crankcase lubricants are therefore formulated with a number of different chemical additives (1), in addition to the overbased detergents. Correctly formulated, these additives provide optimum engine performance over a wide range of operating conditions.

Detergent additives are generally surfactant-stabilized colloidal particles of metal carbonates. Their structure is generally believed to fit the model shown in Fig. 1 (2). This consists of a core of basic metal carbonate or a mixture of metal carbonate and metal hydroxide, depending on the cation and the process employed in their production. The core is stabilized by a monolayer skin of surfactant. Both the type of surfactant and the metal used depend on the application required. Surfactants used include sulphonates, phenates, and salicylates. The cation is typically calcium, magnesium, or sodium. The core radius of the overbased particle is usually in the range 15–100 Å. The overall dimension is determined by the additional contribution of the alkyl chain length of the stabilizing surfactant (approx. 10–25 Å, depending on the surfactant employed). Because the particles are small, a large proportion of the core molecules will be located at the surface layer. Size-related measurements are readily made using Small Angle Neutron Scattering (SANS) (3), Dynamic Light Scattering (DLS), Ultracentrifugation, and viscosity studies.

The final product is defined by its Total Base Number (TBN). TBN is the equivalent milligrams KOH per gram of sample and is usually determined by method ASTM D-2896. For example, an overbased additive with a TBN of 300 contains basic material equivalent to 300 mg KOH/g. The synthetic route to an overbased product is summarized by Marsh (4). A typical procedure is as follows: firstly, the acidic form of the surfactant is neutralized by the addition of metal hydroxide to form the neutral metal salt of the surfactant. The system is then carbonated in the presence of excess metal hydroxide and a polar solvent to give the metal carbonate core stabilized by the metal surfactant. The polar solvent is then removed to give the final additive.

The aim of this study is to obtain fundamental kinetic information about the acid-neutralization process occurring in a high-performance engine lubricant. To this end, one mineral acid only has been investigated for the work described in this paper, namely, HCl (although similar results are obtained with other strong acids). The acid has been studied in a microemulsion medium because, in an engine, excess free surfactant and water are often present, which can lead to microemulsification of the acid/water in the oil.

To simplify the base conditions, a model-overbased system, which was prepared by Exxon Chemical, U.K., has been used. This has the essential properties of a commercial detergent additive. In an engine, buildup of acid will not generally occur while sufficient base additive is present, since neutralization is a continuous process. However, to test the ability of the additive to neutralize acid we typically used millimolar (mM) overall concentrations of acid. In an engine, the neutralization reaction will occur over a wide range of operating conditions, e.g., shear rate, temperature, etc. We have studied the neutralization reaction in low alkane chain length (C_7, C_{10}, C_{12}) solvents, which are representative of the solvent viscosity for neutralization in an oil at operational temperatures (100–120°C in the sump).

The neutralization process is found to be rapid and so the stopped-flow method is appropriate to follow its rate. Using this technique, reactions are studied in the ms–s time range. We have devised a spectrophotometric assay, based on pH-responsive dye indicators, to monitor the neutralization process.

Experimental

The overbased additive used in this study as a model system was supplied by Exxon Chemical as a concentrate in a base oil (TBN = 300 mg KOH g^{-1}) and was used without further purification. It contains an amorphous calcium carbonate/hydroxide core stabilized by a high molecular weight alkylbenzene sulphonate surfactant. All additive solutions were diluted in hydrocarbon solvents, supplied by Fisher, before use in kinetic studies. We have estimated the basicity of these solutions by means of a newly defined parameter TBN*, which is effectively the base equivalent (OH^-) molarity of the dispersion. A typical calculation shows how

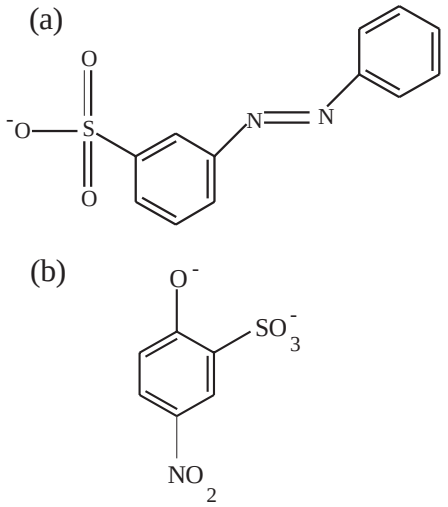
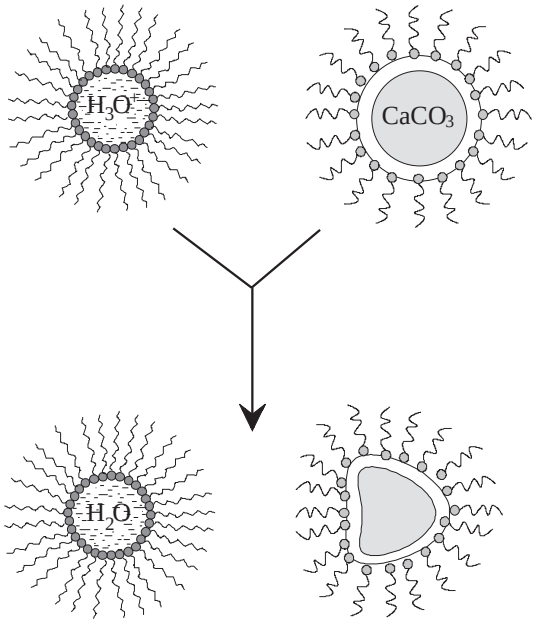
Fig. 2. (*a*) pH indicator methyl orange in unprotonated form (pK_a^{me} = 1.3). (*b*) pH indicator PNPS shown in unprotonated form (pK_a^{me} = 5.1).



the TBN* value is obtained from the TBN for a *y*% w/v solution.

Fig. 3. Schematic diagram of the acid-neutralization reaction taking place between an overbased additive particle and an acidified w/o microemulsion droplet.



$$TBN^* = 10^{-2} \times y\ (g/100\ mL) \times TBN\ (mg/g)/MW\ KOH\ (g\ mol^{-1})\ (MW\ KOH = 56.11\ g\ mol^{-1})$$

For example, for a dilution factor leading to y = 0.5 g/100 mL, TBN* ($[OH^-]$) = 0.0267 mol dm^{-3}.

Water-in-oil (w/o) microemulsion droplets were prepared by dispersing an acidified aqueous solution (typically $[H^+]_{aq}$ = 0.1 mol dm^{-3}) into a surfactant–hydrocarbon mixture. Microemulsions form spontaneously on gentle shaking. The overall hydrogen ion concentration $[H^+]_{ov}$ is given by $[H^+]_{aq}\ \phi$ where ϕ is the volume fraction of the dispersed droplet phase and is typically 0.01–0.03. In our experiments ϕ was kept constant at 0.018. In these systems the basic component is in excess over the microemulsified acid, so that only a small part of the overbased system is neutralized (~10%). The percentage extent of additive neutralization (%N) is given by

$$\%N = ([H^+]^{initial} - [H^+]^{final} / TBN^*) \times 100$$

where $[H^+]^{initial}$ and $[H^+]^{final}$ refer to $[H^+]_{ov}$ and $[H^+]^{final}$ can be readily obtained from analysis of the stopped-flow transient (1/2 amplitude) and the pK_a^{me} of the indicator, where pK_a^{me} is the pK_a of the pH indicator measured in the microemulsion system. (Note that this will be different from the pK_a in water as a result of charge/partitioning effects (5).)

The surfactant used in this work was the sodium salt of sulfosuccinic acid bis(2-ethylhexyl) ester (Sigma), commonly known as Na-AOT (AOT), and was used throughout at an overall concentration $[AOT]_{ov}$ of 0.1mol dm^{-3} and w = 10, where $w = [H_2O]_{ov} / [AOT]_{ov}$. This system forms spherical droplets of well-defined water core, radius r, and it has been shown that the radius, measured in nm, is given for this system, by r/nm = 0.175w (6).

The concentration of droplets is given by [Droplets] = $[AOT]_{ov} \times w^{-2} \times 1.331$. Thus for a microemulsion system in which $[AOT]_{ov}$ = 0.1 mol dm^{-3} and w = 10, [Droplets] = 1.331 × 10^{-3} mol dm^{-3}. HCl (BDH) and AnalaR water (BDH) were used throughout and the pH values were measured with a Radiometer Copenhagen PHM82 standard pH meter. For the measurements reported in this paper the aqueous phase before dispersion was essentially pH 1. Stock solutions of the pH indicators, methyl orange (BDH) (Fig. 2*a*) and 4-nitrophenyl-2-sulphonate (PNPS) (Fluka) (Fig. 2*b*), were prepared in AnalaR water. Spectrophotometric data were obtained at 25°C on an HP8452A diode array spectrophotometer with a resolution of 2 nm. Acid-neutralization data were acquired by mixing microemulsion and overbased solutions in a HiTech stopped-flow apparatus with a dead time of <10 ms. The unit was thermostated to ±0.1°C using a Haake water bath.

Small-angle neutron scattering (SANS) data were recorded on the LOQ instrument at the Rutherford–Appleton Laboratory (RAL), Harwell, U.K. Ultracentrifuge experiments were performed by means of a Beckmann L5-50 ultracentrifuge.

Results and discussion

(*a*) pH indicators

Figure 3 is a schematic diagram of the acid-neutralization reaction taking place between an overbased particle and aqueous acid that is solubilized inside a w/o microemulsion droplet.

The time for neutralization to occur was typically of the order of a few seconds. Due to the difference in sedimentation coefficients between the two product species (i.e., particles and droplets in Fig. 3), the droplets could be separated from the particles after the neutralization reaction had taken place. This was achieved by means of selective sedimentation of the particles using an analytical ultracentrifuge (40 000 rpm for 1.5 h). SANS data on the non-sedimented

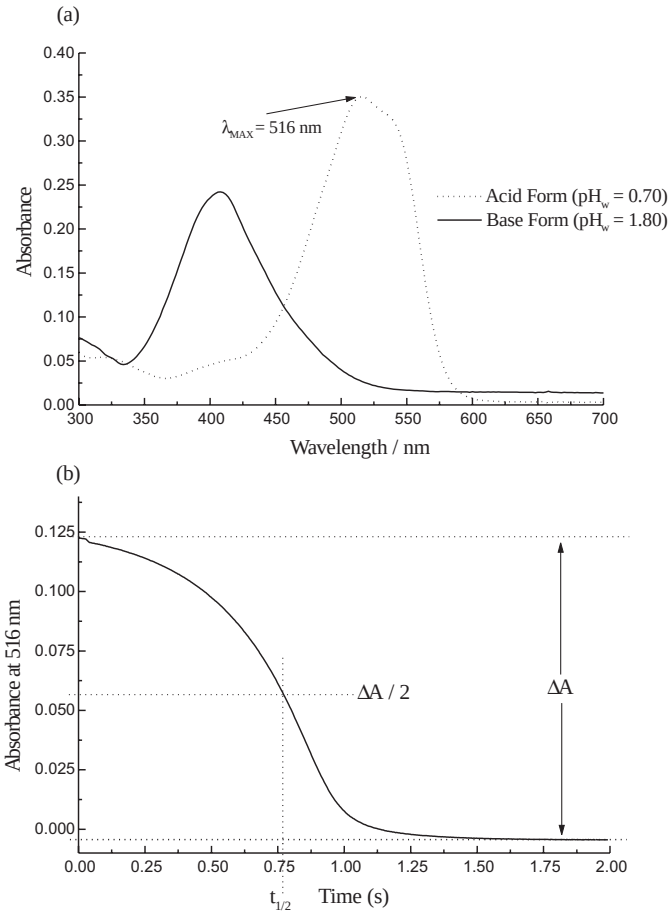
Fig. 4. (*a*) UV–VIS spectrum of methyl orange solubilized in an Na-AOT microemulsion, $[AOT]_{ov}$ = 0.10 mol dm^{-3}, [methyl orange]$_{aq}$ = 5.0 × 10^{-4} mol dm^{-3}. (*b*) Stopped-flow trace for the reaction between 0.2% w/v overbased additive in *n*-heptane and methyl orange – acid droplets. $[AOT]_{ov}$ = 0.10 mol dm^{-3}, [methyl orange]$_{aq}$ = 5.0 × 10^{-4} mol dm^{-3}, $[HCl]_{aq}$ = 1.0 × 10^{-1} mol dm^{-3}.



part of the system (after centrifugation) indicated that the microemulsion water droplets remain the same size after the reaction and that no indicator or water, initially located in the core of the droplets, is transferred to the particles. However, this does not discount the possibility that surfactant molecules are exchanged to some extent between the droplets and particles. Other experiments we carried out using nile blue as the pH indicator show that the water pools of the microemulsion droplets (initially at pH ~7) increase further in pH when mixed with the overbased particles. This leads us to conclude that the preferred mechanism of neutralization involves base transfer from the overbased additive into the water pools of the microemulsion where the acid-neutralization reaction occurs.

Solubilization of water-soluble pH indicators inside the water pools of w/o microemulsions allows any change in pH of the water to be monitored spectrophotometrically (7, 8). The main indicators used were methyl orange (MO) and 4-nitrophenyl-2-sulphonate (PNPS). Figure 4*a* shows the UV–VIS spectrum of MO dispersed in a w/o microemulsion stabilized by the surfactant Na-AOT. In aqueous solution as the ionic strength → 0, MO has a pK_a of 3.44 at 25°C but on solubilization in the microemulsion (pK_a^{me}) this value is lowered by approximately 2 pK_a units.

The state of the water present in the microemulsion droplets studied is quite different from that of the bulk aqueous solution due to the high concentration of sodium ions provided by the AOT. This leads to an increase in ionic strength and the indicator behaviour is affected by the so-called salt error (9). λ_{max} for the acid form of the indicator when solubilized inside the microemulsion is 516 nm. When a diluted solution of overbased additive is mixed with a microemulsion solution, in which the water pool is acidified and hence contains methyl orange in the acid form, there is an observed colour change (red to yellow) as the acid is neutralized and the indicator is converted to the base form. This process is taken to relate to base being released from the overbased particles into the acidified water pools of the microemulsion where neutralization of the acid occurs. The colour change can be monitored by recording the change in absorbance of the acid or base form of the indicator with time.

Using the stopped-flow method, a solution of overbased additive is mixed in equal volumes with the acid – methyl orange microemulsion solution. The absorbance is recorded at λ_{max} for the acid form of the indicator, 516 nm. As acid neutralization occurs there is a decrease in the measured absorbance as shown in Fig. 4*b*.

The reaction is recorded until the absorbance levels off and the indicator has been converted to the base form. The total change in absorbance, ΔA, is recorded and the time taken to reach $\Delta A/2$ is designated as $t_{1/2}$ (s). From knowledge of the pK_a^{me} and $\Delta A/2$, the extent of neutralization (%N) at $t_{1/2}$ can be determined.

Replacing MO with PNPS allows the acid-neutralization reaction to be monitored at a later stage since pK_a^{me} is increased from 1.3 to 5.1. Figure 5*a* shows the UV–VIS spectrum of PNPS dispersed in a w/o microemulsion stabilized by the surfactant Na-AOT. In aqueous solution the pK_a is 6.5 but this is lowered to 5.1 (pK_a^{me}) for the w = 10 microemulsion system.

When the overbased particle is mixed with the acid – PNPS microemulsion the observed colour change is from colourless to yellow. This corresponds to an increase in the base form of the indicator inside the water pools of the microemulsion for which λ_{max} = 398 nm. Figure 5*b* shows the stopped-flow trace recorded at 398 nm using PNPS as the indicator but under the same conditions as Fig. 4*b*.

The observed colour change ($t_{1/2}$) is longer using PNPS. This is as expected due to the higher pK_a^{me} value and, therefore, lower value of $[H^+]^{final}$, since more base must be released from the particle in order that the acid is sufficiently neutralized to convert the indicator to its base form. Therefore the indicator to be used depends on the "pH window" one wishes to observe during neutralization. Table 1 shows the difference in $t_{1/2}$ values obtained using the two different pH indicators under otherwise identical conditions.

It should be noted that in recording the absorbance at the other λ_{max} positions, the base form of methyl orange (λ_{max} = 406 nm) and the acid form of PNPS (λ_{max} = 302 nm) give the same value for $t_{1/2}$ and the expected increase and decrease in absorbance, respectively.

	0.45	20
	0.66	15
	1.04	10

[a]Additive diluted in *n*-heptane, $[Na\text{-}AOT]_{ov}$ = 0.10 mol dm^{-3}, w = 10, $[methyl\ orange]_{aq}$ = 5.0 × 10^{-4} mol dm^{-3}, $[HCl]_{aq}$ = 0.10 mol dm^{-3}.

(*b*) Effect of particle concentration on the neutralization process

Table 2 shows the effect of increasing the concentration of overbased carbonate particles in the hydrocarbon solvent. As the concentration is increased, more base has effectively been added to the system and hence the value of $t_{1/2}$ becomes shorter, i.e., the neutralization becomes faster. Over the particle concentration range investigated, there is a linear relationship between $(t_{1/2})^{-1}$ and [particles] but interestingly there is not a direct proportionality and so a second-order rate constant cannot be derived.

(*c*) Effect of temperature on the neutralization process

The technique outlined has been applied to study the effect of temperature on acid neutralization by overbased additive particles in these systems. As the temperature of the system is increased the value of $t_{1/2}$ decreases, i.e., the reaction becomes faster, as shown in Table 2. The values of $t_{1/2}$ were analysed using a modified Arrhenius plot in which the rate is given by the reciprocal of $t_{1/2}$. This procedure assumes that the pK_a^{me} is essentially independent of temperature. Figure 6 shows that the activation energy, E_A, for these reactions is approximately 55 kJ mol^{-1}.

(*d*) Effect of change of solvents on the neutralization process

Various systems were studied in which the hydrocarbon solvent was systematically changed. Data using the methyl orange system to monitor the change in absorbance are shown in Table 3.

As the chain length of the oil solvent is increased from C_7 to C_{10} to C_{12} using *n*-heptane, *n*-decane, and *n*-dodecane, respectively, the value of $t_{1/2}$ decreases. It is well established, using SANS, that the size (and hence concentration) of droplets is independent of the solvent for these low w systems. However, the upper temperature phase boundary, which leads to clustering of droplets, is lowered as the solvent chain length is increased. This means that interpenetration of the tail groups of the surfactant surrounding the water cores is facilitated. This results in the reaction rate being faster in the higher molecular weight (higher viscosity) solvent.

	0.53	10
n-Dodecane	0.04	30
	0.07	25
	0.09	20
	0.13	15
	0.20	10

[a] Additive concentration = 0.2% w/v, $[Na\text{-}AOT]_{ov}$ = 0.10 mol dm^{-3}, w = 10, $[methyl\ orange]_{aq}$ = 5.0 × 10^{-4} mol dm^{-3}, $[HCl]_{aq}$ = 0.10 mol dm^{-3}.

The results for droplet/particle neutralization can be interpreted if we consider the neutralization reaction occurring as a result of the interaction of two types of colloidal assemblies, the microemulsion droplet and the overbased particle. The surfactant configuration is tightly packed and so interactions between the droplet and particle can be considered as an interaction between two reasonably "hard" spheres. However, the shorter the chain length of the solvent acting as the dispersion medium (e.g., *n*-heptane), the easier it becomes to interpenetrate the surfactant layers stabilizing the overbased particle and the microemulsion droplet, as has indeed been previously shown from kinetic studies of the interactions between two microemulsion droplets in hydrocarbon solvents (10). Likewise, as we move to the longer-chain solvent the interactions become more "sticky" as the longer-chain alkanes penetrate less effectively into the surfactant layer. This type of interaction means that collisions between the particle and droplet will last longer and therefore lead to a higher probability of base transfer and hence acid neutralization. The activation energy is independent of concentration of overbased particles, as would be expected. The relatively high value (E_A = 55 kJ mol^{-1}) clearly indicates that the reactions are not diffusion controlled since the E_A values should then reflect the lower values for the temperature dependence of the viscosity of the solvent.

Summary

The methodology outlined in this paper has been used to study the neutralization behaviour of model overbased detergent additive systems. It is thought that the free excess surfactant present in engine oil formulations disperses the aqueous acid present in a similar way to that of the model w/o microemulsion droplets. The use of water-soluble pH indicator molecules allows the change in pH of the water to be monitored for these reactions in a facile way. More complex additive systems of commercial importance have also been investigated. These systems are those in which a number of other additves (e.g., dispersant) are blended with the overbased detergent additive. Using the technique described in this paper, it has been possible to investigate the effect these additional additves have on the acid-neutralization properties, and the approach provides a new simple diagnostic test of the performance efficiency of lubricant detergent additives.

Multiple changes in rate-determining step in the acid and base catalyzed cyclizations of ethyl *N*-(*p*-nitrophenyl)hydantoates caused by methyl substitution

Iva B. Blagoeva, Anthony J. Kirby, Asen H. Koedjikov, and Ivan G. Pojarlieff

Abstract: The slopes of the pH–rate profiles for the cyclization of 2-methyl- and 2,3-dimethyl hydantoates **1**-NPU and **2**-NPU between pH 1 and 7 change from 1 to 0 and then back to 1. A reaction first order in H^+ was observed with the latter compound. The 2,2,3-trimethyl derivative **3**-NPU showed only one reaction first order in OH^-, but complex acid catalysis is described by slopes 0, –1, 0, and finally –1 again. The cyclizations were general base catalyzed, with Brønsted β values of 0.5–0.6. The OH^- catalysis at higher pH for **1**-NPU and **2**-NPU showed inverse solvent kinetic isotope effects and deviated from the Brønsted relationships, while that for **3**-NPU showed a normal effect and complied with the Brønsted relationship. The accelerations due to the *gem*-dimethyl effect were lost with the OH^- and general base-catalyzed reactions of **3**-NPU. This behaviour is due to a change from the rate-determining formation of the tetrahedral intermediate with **1**-NPU and **2**-NPU to the rate-determining breakdown with **3**-NPU, due to steric hindrance to protonation of the leaving ethoxy group. The OH^- reaction at higher pH involves attack of the ureide anion with **1**-NPU and **2**- NPU, becoming concerted with deprotonation when catalyzed by general bases and changing to acid inhibition of the anion of the tetrahedral intermediate at low pH. With **3**-NPU at higher pH, T^- is in equilibrium and the conjugate acids of the general bases accelerate its breakdown by protonating the ethoxy group. Acid catalysis of the cyclization of **3**-NPU at higher pH is also protonation of the leaving group from T^0 changing to the rate-determining formation of T at lower pH. The latter mechanism is preferred for the cyclization of **2**-NPU.

Key words: *gem*-dimethyl effect, mechanism, general base catalysis, proton transfer, steric hindrance.

Résumé : Les pentes des profils pH–vitesse pour la cyclisation des 2-méthyl- et 2,3-diméthylhydantoates **1**-NPU et **2**-NPU entre les pH 1 et 7 passe de 1 à 0 avant de revenir à 1. Avec le dernier composé, on observe que la réaction est du premier ordre en H^+. Le dérivé 2,2,3-triméthylé **3**-NPU ne donne qu'une réaction du premier ordre en OH^-, mais une catalyse acide complexe décrite par des pentes de 0, –1, 0 et finalement –1 encore une fois. Les cyclisations sont soumises à une catalyse générale par les bases avec des valeurs β de Brønsted qui vont de 0,5 à 0,6. Les **1**-NPU et **2**-NPU soumis à une catalyse par OH^-, à des pH plus élevés, mettent en évidence l'existence d'effets isotopiques cinétiques inverses du solvant et des déviations des relations de Brønsted. Avec OH^-, les accélérations provoquées par l'effet *gem*-diméthyle sont perdues ainsi que les réactions soumises à une catalyse générale par les bases. Ce comportement est dû au fait que dans les cas des **1**-NPU et **2**-NPU l'étape cinétiquement déterminante est la formation d'un intermédiaire tétraédrique alors que dans le cas du **3**-NPU l'étape déterminante est son bris qui est dû à l'empêchement stérique à la protonation du groupe éthoxy partant. La réaction OH^-, à un pH plus élevé, implique une attaque de l'anion uréide par les **1**-NPU et **2**-NPU qui devient concertée avec la déprotonation lorsqu'elle est soumise à une catalyse générale par les bases et qui change à une inhibition acide de l'anion de l'intermédiaire tétraédrique à pH plus bas. Avec le **3**-NPU, à des pH plus élevés, T^- est en équilibre et les acides conjugués des bases générales accélère son bris en protonant le groupe éthoxy. La catalyse acide de la cyclisation du **3**-NPU à des pH plus élevés est aussi la protonation du groupe partant de T^0 qui se change en formation cinétiquement limitante de T à des pH plus faibles. Ce dernier mécanisme est préféré pour la cyclisation du **2**-NPU.

Mots clés : effet *gem*-diméthyle, mécanisme, catalyse générale par les bases, transfert de proton, empêchement stérique.

Introduction

The hydroxide ion catalyzed cyclization of ethyl 2,2,3-trimethyl-5-phenyl hydantoate, **3**-PUE, is slower than that of the dimethyl compound **2**-PUE (1). This result is surprising because the reaction of **3**-PUE should be subject to the *gem*-dimethyl effect (2): indeed, a normal *gem*-dimethyl effect operates on the acid-catalyzed cyclizations of these compounds (**1**-PUE–**3**-PUE) (3, 4). Data on the general acid-base catalysis and solvent kinetic isotope effects (SKIE) on PUE and their 5-methyl analogues (**1**-MUE–**3**-MUE) led us to the conclusion that the loss of the *gem*-dimethyl effect was due to steric hindrance to proton transfer of the leaving ethoxide group, resulting in a change in the rate-determining step (r.d.s.) from formation to breakdown of the tetrahedral intermediate (3). The balance of evidence as to which r.d.s. is preferred, with the less heavily substituted compounds changing into an alternate one in the fully methylated derivatives, was delicate and thus further evidence was sought for these systems. The improved leaving group ability of the *p*-nitrophenylureido group was intended to bias the system towards rate-determining departure of the ethoxy group, thus allowing a simpler evaluation of the various effects. Grounds for such reasoning were the alternative cyclizations of dicarbamoylglycine **4**: the specific base-catalyzed (SBC) ring closure with the *N*-isopropylcarbamoyl moiety was attributed to r.d. attack of the anion while the GBC reaction involved the end aryl group to r.d. departure of the hydroxy group (5).

4

Unexpectedly, the hydroxide-catalyzed reaction of the *p*-nitrophenyl esters mirrored the behaviour of the ureido esters with less negative ω-substituents, showing only a small increase in rate with **3**-NPU compared to a large one under acid catalysis, and a normal SKIE opposed to the inverse one with **1**-NPU and **2**-NPU. In contrast to MUE and PUE, however, the *p*-nitrophenyl derivatives showed highly complex rate profiles, varying extensively upon methyl substitution.

We now report how this interplay of the *gem*-dimethyl effect and reaction mechanism can be understood from an analysis of the reaction profiles, general base catalysis, and SKIE. The results obtained support our previous interpretation of the loss of the *gem*-dimethyl effect in the HO^--catalyzed cyclization in esters **3** and allow further insight into the workings of the *gem*-dimethyl effect in reactions through tetrahedral intermediates.

Experimental

Materials

Inorganic reagents and buffer components were of analytical grade and were used without further purification. Potassium hydroxide and buffer solutions were prepared with CO_2-free distilled water. D_2O and DCl (20 wt.% in D_2O), 99 at.% were from Aldrich.

Ethyl esters of methyl substituted 5-(4-nitrophenyl)hydantoic acids were prepared by reaction of the corresponding amino acid esters with 4-nitrophenyl isocyanate. The amino acid esters were converted into the free base form and distilled prior to use. The typical experimental procedure consisted in addition of 10% excess of 4-nitrophenyl isocyanate (3.3 mmol in 5 mL dry benzene) to an ice-cooled solution of the amino acid ester (3 mmol in 5 mL dry benzene). A heavy precipitate was formed immediately and the reaction mixture was left for 20 min at room temperature. The precipitated product was filtered, washed with dry benzene, and dried in a vacuum desiccator with P_2O_5. The products could not be heated or recrystallized due to their fast cyclization at higher temperatures. **3**-NPU cyclized readily in the presence of traces of moisture and was best stored in sealed ampoules at low temperatures. The purity of the products was checked by NMR and the yields of pure esters were 62–64%.

*Ethyl 3-methyl-5-(4-nitrophenyl)hydantoate (**1**-NPU)*: mp 124–125°C. IR $\nu_{max}(CHCl_3)/cm^{-1}$: 1727 (CO ester), 1676 (CO ureido). ^1H NMR ($CDCl_3$) δ (ppm): 1.31 (t, *J* 7.1 Hz, 3H, CH_3CH_2), 4.15 (s, 2H, N-CH_2), 3.16 (s, 3H, CH_3N), 4.25 (q, *J* 7.1 Hz, 2H, CH_2O), 7.08 (s, 1H, HN), 7.54–8.19 (m, 4H, Ar).

IR $\nu_{max}(CHCl_3)/cm^{-1}$: 1725 (CO ester), 1670 (CO ureido). ^1H NMR (CDCl) δ (ppm): 1.29 (t, *J* 7.1 Hz, 3H, CH_3CH_2), 1.51 (s, 6H, $(CH_3)_2C$), 3.07(s, 3H, CH_3N), 4.21 (q, *J* 7.1 Hz, 2H, CH_2O), 7.28 (s, 1H, HN), 7.49–8.34 (m, 4H, Ar).

Product analysis

The cyclizations of the ethyl hydantoates studied in this paper proceeded quantitatively to the corresponding hydantoins. Good isosbestic points were obtained for all three compounds studied and the end-point absorbances for the kinetic runs were identical within experimental error with the absorbances of model solutions of the respective hydantoins described previously (6).

Kinetic measurements

Rate constants were determined at 25.0 ± 0.01°C under pseudo-first-order conditions in the thermostatted cell com-

partment of a Unicam SP-800 spectrophotometer. The rates of cyclization of the substituted esters were followed by monitoring the decrease of the absorbance at 330 nm due to the 4-nitrophenylureido group. Reactions were initiated by injecting 20 mL of 1×10^{-2} M stock solutions of the substrates in dry THF into 2.7 cm^3 of preheated buffer solution. Ionic strength was maintained constant (1.0 M) with KCl. Measurements of pH values and calculations of the observed pseudo-first-order rate constants (k_{obs}) were as previously described (7). Good linear plots ($r > 0.999$) of $\ln(A_t - A_\infty)$ against time were obtained over three half-lives and k_{obs} values were reproducible to within 3% with the exception of the slow ring closure of **1**-NPU in hydrochloric acid below pH 2 where the hydrolysis of the ester group was significant. Since the product acids cyclized more rapidly than the esters, plots of $\ln(A_t - A_\infty)$ against time sloped downwards with time. In this case the rate constants were obtained from the initial part of the reaction where linearity was preserved: initial rates in 0.1 M Hcl up to ca. 20% conversion in 0.01 M HCl.

Solvent kinetic isotope effects

The solvent kinetic isotope effects (SKIE) for k_H were determined by comparison of k_{obs} values measured in solutions of HCl or DCl of the same concentration. The k_{OH} values for calculation of SKIE were determined by extrapolation to zero buffer concentrations of k_{obs} in phosphate or cacodylate buffers both in H_2O and D_2O. For the hydroxide-catalyzed reaction k_0 values were divided by the activity of HO^- or DO^- to obtain k_{OH} or k_{OD}. pD values were obtained by adding 0.4 to the pH-meter readings and the a_{OD} values were calculated using $pK_w = 14.86$ (8).

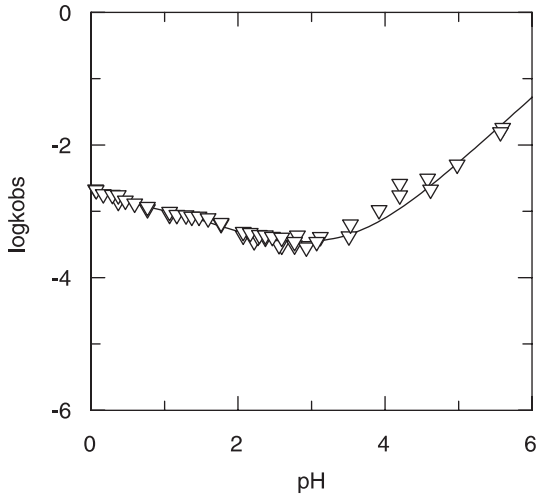
Results and discussion

Rate profiles

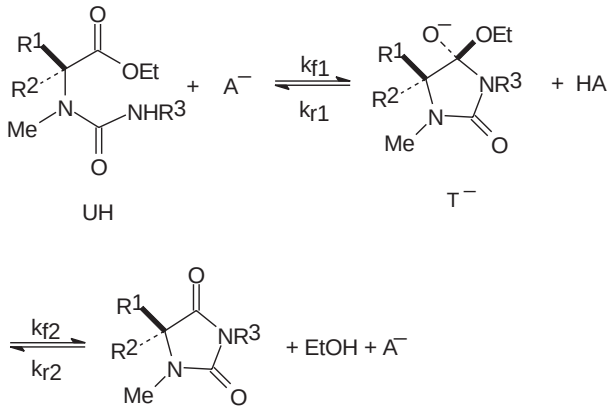
1. Base catalysis

With ureido ester **1**-NPU the slope of the plot of log k_{obs} versus pH changes from 1 to 0 and then back again to 1 (Fig. 1).

Fig 2. Rate profile for the cyclization of **3**-NPU.



Scheme 1.



Below pH = 1, hydrolysis of the ester group was observed and acid catalysis could not be detected. With the faster cyclization of compound **2**-NPU the reaction could be studied up to 1 M HCl and an acid-catalyzed region could be registered in addition to base catalysis. The latter is also best described by equations leading to the same changes of slopes against pH, from 1 to 0 and back again to 1. The minimum between the acid-catalyzed and base-catalyzed regions occurs around pH = 1, illustrating the very poor nucleophilicity of the neutral *p*-nitrophenylureido group. The same minimum occurs around pH 3 with **2**-PUE (3).

The behaviour of ester **3**-NPU, presented separately in Fig. 2 to avoid overlap in the base-catalyzed region, is distinctly different: only one segment, first order in $[OH^-]$, is observed, while the acid catalysis region is complex.

The rate law for base catalysis can be derived from Scheme 1, depicting the main steps in the reorganization of bonds from reactants to products.

The steady state solution is

$$[1] \qquad k_{obs} = \frac{k_{f1}[A^-]k_{f2}[HA]}{(k_{r1} + k_{f2})[HA]}$$

When the bases are water and hydroxide ion this becomes

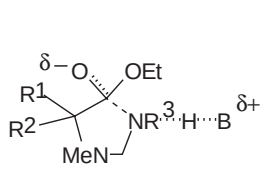
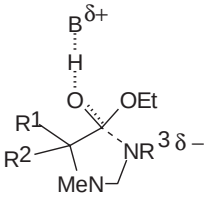
*1(a). Ethyl hydantoates **1**-NPU and **2**-NPU*: Various limiting conditions lead to simplified forms of eq. [2], describing rate profiles with slopes changing from 1 to 0 and then back to 1. In the following discussion[2] we designate the apparent second-order constant at lower pH as $k_{OH}{}^a$ and the one at higher pH as $k_{OH}{}^b$. Two conditions have to be met (9) in order that two different k_{OH} are observed in situations described by eq. [2]. The first is that the two forward fractions for breakdown of T^-, $k_{f2}/(k_{r1} + k_{f2})$, for H_2O and H^+ catalysis, respectively, have to be different. The first one will operate at higher pH and the second one at lower pH. Two different reactions of the same order are usually associated with a change in the rate-determining step; in the case under discussion, when $k_{r1w} < k_{f2w}$ then $k_{r1H} > k_{f2H}$ or vice versa. The second condition for two reactions of the same order to be observed is that the intermediates involved should not equilibrate. In such a case the reactions go simply by the lowest energy path available to, for example, T^-, which in turn corresponds to single first order in the $[OH^-]$ region in the rate profile. In our case two different k_{OH} can be observed when one or both processes are general acid–base catalyzed.

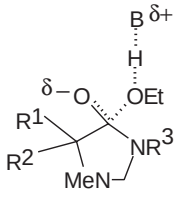
As is generally the case for kinetically equivalent mechanisms, the preference must be based on non-kinetic evidence. Comparison of the rate profiles of Figs. 1 and 2 with the SKIE data listed in Table 1 shows that the $k_{OH}{}^a$ values for **1**-NPU and **2**-NPU, as well as the single k_{OH} constant for **3**-NPU, exhibit normal isotope effects ($k_H > k_D$) These allow a choice between various possible mechanisms. The similarity in the p*K*'s of the *p*-nitrophenylureido group and water, the conjugate acid of OH^-, could give rise to a normal SKIE (10) for proton removal from nitrogen (a p*K* of 14 has been reported for *p*-nitrophenylurea (11)). However, if this step was rate determining, a Brønsted β value of 1 is expected, contrary to the observed values of 0.5–0.6 (vide infra Table 6). Such a deprotonation would be diffusion controlled and would certainly be much faster than the overall rates in at least two of the cases; second-order constants of ca. 10^6–10^7 dm^3 mol^{-1} s^{-1} are observed for the $k_{OH}{}^a$ of **1**-NPU and for the k_{OH} of **3**-NPU (Table 2). Participation of OH^- in a concerted process in which the N—C bond is formed while the NH proton is pulled off (formula **5**, B = OH^-) is also unlikely because, according to the libido rule of Jencks (12), the base has to be of strength intermediate between that of the proton-donating group in the ground and product states. The alternative SB-GAC mechanism for N—C formation, i.e., attack of the ureide anion concerted with proton transfer



5



6



7

to the ester carbonyl leading to T^0 (formula **6**, B = OH^-) was refuted (3) for the ω-methyl and ω-phenyl analogues MUE and PUE as it contradicts Jencks' requirement for T^- to be an unstable intermediate (13); this apparently applies also for NPU to permit the SBC catalyzed reaction of **1**-NPU and **2**-NPU presented by $k_{OH}{}^b$, discussed below. We are thus left with the last possible proton transfer as the cause of the normal SKIE, that is, water donating a proton to the ethoxy group cleaving from T^- (formula **7**, B = OH^-). As discussed before (3), a concerted mechanism is possible with a late C—O bond cleavage. In terms of Scheme 1 and eq. [2], this mechanism requires $k_{r1} > k_{f2}$. The process $k_{OH}{}^a$ is observed at low pH when $k_{r1w} + k_{f2w} < (k_{r1H} + k_{f2H})[H^+]$ so the inequality $k_{r1H} > k_{f2H}$ will apply. When $k_{f1w} > k_{f1OH}[OH^-]$ and if $k_{f2w} > k_{f2H}[H^+]$ in the region for base catalysis, the observed rate constant becomes

$$[3] \qquad k_{obs} = \frac{k_{f1w}k_{f2w}}{k_{r1H}[H^+]}$$

The rate constant first order in $[OH^-]$ at low pH can be then be presented as

$$[4] \qquad k_{OH}^a = \frac{K_{T^-}k_{f2w}}{K_w}$$

where k_{T^-} is the equilibrium constant for formation of T^- when $A^- = H_2O$. Thus at low pH the first order in $[OH^-]$ behaviour is determined by the equilibrium concentration of T^-, and the rate-determining step is the water-catalyzed decomposition of T^-. Such a mechanism is referred to as acid inhibition of T^- (14).

[2]For the sake of brevity exhaustive consideration of the various cases afforded by eq. [2] will be avoided.

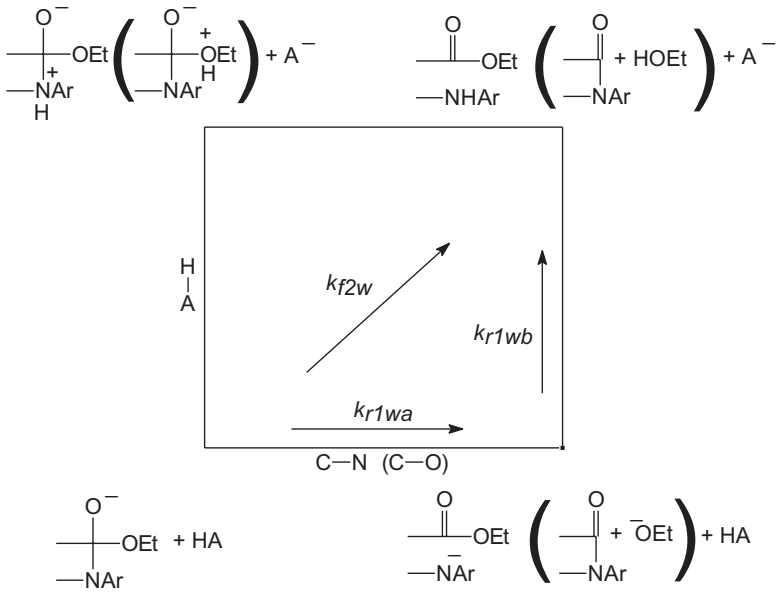
Scheme 2.



Upon increasing the pH, the plateau is reached with **1**-NPU and **2**-NPU when the $[H^+]$ term in the denominator can be neglected. Now $k_{obs} = k_{f1w}$ because, as discussed above, $k_{r1w} < k_{f2w}$ in order for the second slope of 1 in the rate profile to be observed at higher pH. Then $k_{obs} = k_{f1OH}[OH^-]$. With the above limitations eq. [2] can be simplified to

$$[5] \qquad k_{obs} = \frac{k_w + k_{OH}[OH^-]}{1 + k_{2H}[H^+]}$$

where $k_{OH} = k_{OH}^b = k_{f1OH}$, $k_w = k_{f1w}$, $k_{2H} = k_{r1H}/k_{f2w}$, and $k_{OH}^a = k_w/(k_{2H}K_w)$. The rate constants for **1**-NPU in Table 2 were obtained by fitting the rate data to eq. [5]. In the case of **2**-NPU the equation was expanded with a term for acid catalysis.

$$[6] \qquad k_{obs} = \frac{k_w + k_{OH}[OH^-]}{1 + k_{2H}[H^+]} + k_{1H}[H^+]$$

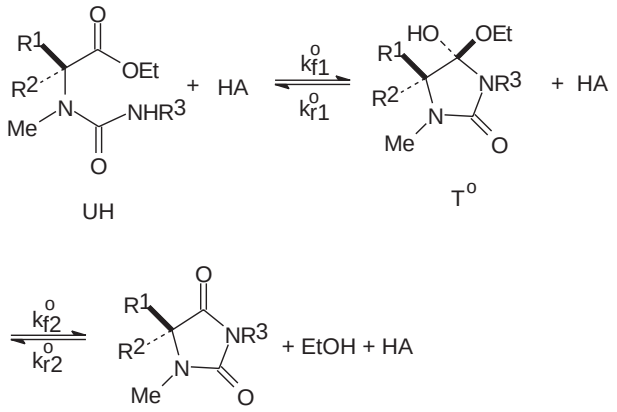
The $k_{OH}{}^b$ constants for **1**-NPU and **2**-NPU refer to an SBC process as evidenced by the inverse isotope effect at pH = 5.6 where, according to Fig. 1, the second first order in $[OH^-]$ process dominates. Because, as already discussed, $k_{r1w} < k_{f2w}$, this is r.d. formation of T^- taking place by preliminary ionization of the ureido esters.

The crossover of reactivities for H_2O and H_3O^+ catalysis of partitioning of the intermediate is an interesting problem. The inequality $k_{r1w} < k_{f2w}$ means that *p*-nitrophenylureido leaves less readily than ethoxide at high alkalinity against expected fugacities while the opposite is true at low pH ($k_{r1H} > k_{f2H}$). The reason for the former inequality can be sought in reactivities of stepwise vs. concerted processes (15). The acid-catalyzed breakdown of T^- can be described by the alternate route diagram (16) shown in Scheme 2. When HA = H_2O, the leaving of the ureido group is a two-step process along the edges of the diagram: splitting off of the ureide anion, $k_{r1w}{}^a$, followed by proton transfer from H_2O to the nitrogen atom, $k_{r1w}{}^b$. This is not a concerted process for reasons discussed above explaining why OH^- cannot act as a general base in the reverse reaction and, in terms of the alternate route diagram, this happens because the energy of the bottom right-hand corner is considerably lower than that of the top-left corner. On the other hand, as discussed above for **3**-NPU, the ethoxy group cleaves along the diagonal in a one-step process with both bonds changing simultaneously, k_{f2w}. This occurs because the energy of the bottom-right corner is raised, ethanol being a weaker acid by more than two p*K* units, and that of the top-left corner is lowered because of the greater basicity of the ethoxy group. Thus a valley along the diagonal is created, with the energy of the transition state apparently lower than that for the attack of the ureide anion.

When HA = H_3O^+ the relationships in the diagram change significantly. Considered in the reverse direction, the

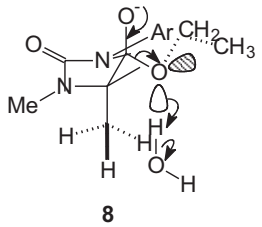
© 1999 NRC Canada

Scheme 3.



deprotonation by water along the right-hand edge is now quite an uphill reaction, offering no easy bypassing of the zwitterions at the top-left corner. These are highly unstable and so will enforce general catalysis. This applies to both reactions, k_{r1H} and k_{f2H} and, when the mechanism is the same, the intrinsically better fugacity of the *p*-nitrophenylureido group determines reactivity.

*1(b). Ethyl hydantoate **3**-NPU*: In contrast to **1**-NPU and **2**-NPU, the rate profile of **3**-NPU (Fig. 2) is characterized by a single rate constant first order in [OH^-]. This implies that the partitioning ratios for water and H^+ catalyzed breakdown of T^- of **3**-NPU are biased in the same way, i.e., no change in the r.d.s. takes place. Why **3**-NPU is different can be understood by comparing with previous results on MUE and PUE (3). The inverse SKIE observed with the $k_{OH}{}^b$ constants for **1**-NPU and **2**-NPU and the normal effect with the k_{OH} constant for **3**-NPU repeat the pattern of **1**–**3**-MUE and PUE. Significant also is the disappearance of the *gem*-dimethyl effect with the k_{OH} of **3**-NPU: in contrast to acid catalysis, where **3**-NPU reacts 15 times faster than **2**-NPU, the rates in the higher pH region are almost the same (Table 2). The change of mechanism brought about by the introduction of the extra methyl group in **3**-MUE or **3**-PUE was explained by steric hindrance to protonation of the oxygen atom of the ethoxy group. The ester ethyl group will adopt the least crowded conformation, blocking easy protonation of the ethoxy oxygen because its lone pairs are effectively shielded in a half-chair conformation by the methyl groups on C-5 and the aryl ring on N-2 (see **8**; for clarity, one of the methyl groups at C-5 in the formula is represented by a single bond).



8

Thus there is good reason to believe that, for **3**-NPU, steric hindrance to protonation determines r.d. breakdown of T^-, concerted with catalysis by water. When the ethyl group is replaced by hydrogen, as is the case with the respective hydantoic acids, the intermediate becomes less crowded and slowing down is no longer observed.[3] The GBC cyclization of thioureido esters (17) and the above-mentioned (5) GBC cyclization of the aryl moiety of the *N*,*N*-dicarbamoylglycine **4** are also believed to be limited by breakdown of T^-.

2. Acid catalysis

The complex course for acid catalysis of the cyclization of **3**-NPU can be accommodated by an equation predicting four regions of slopes 0, –1, 0, and –1 in the rate profile on decreasing pH. Such an equation can be derived from Scheme 3, similar to Scheme 1, involving H^+ and water-catalyzed formation and decomposition of T^0.[4] This would then yield an equation in the format of eq. [2], the superscripts 0 denoting that they are related to T^0.

$$[7] \qquad k_{obs} = \frac{(k^0_{f1w} + k^0_{f1H}[H^+])(k^0_{f2w} + k^0_{f\,2H}[H^+])}{(k^0_{r1w} + k^0_{f\,2w}) + (k^0_{r1H} + k^0_{f\,2H})[H^+]}$$

To describe the rate profile for acid catalysis we chose the combination $k^0_{r1w} > k^0_{f\,2w}$ and $k^0_{r1H} < k^0_{f2H}$ because when [T^-] reaches equilibrium (as assumed in the preferred mechanism for k_{OH} of **3**-NPU) so should [T^0] and the constants for water catalysis are important in the overlapping region. So when all the [H^+] terms are small one gets

$$[8] \qquad k_{obs} = \frac{k^0_{f1w}k^0_{f\,2w}}{k^0_{r1w} + k^0_{f\,2w}} \approx K_{T^0}k^0_{f\,2w}$$

Equation [8], the water-catalyzed decomposition of T^0, is kinetically equivalent to another pathway: the H^+-catalyzed decomposition of T^-, $k_{obs} = K_{T-}\,k_{f2H}$, and the latter is most probably a more efficient one.

After the plateau described by eq. [8], most likely the adjoining slope of –1 is due to acid-catalyzed decomposition of T^0:

$$[9] \qquad k_{obs} = K_{T^0}k^0_{f2H}[H^+]$$

followed by a change in the rate-determining step when $(k^0_{r1w} + k^0_{f2w}) < (k^0_{r1H} + k^0_{f2H})[H^+]$:

$$[10] \qquad k_{obs} = k^0_{f1w}$$

This formally acid-catalyzed reaction according to Scheme 3 is also most likely the kinetically equivalent general base catalysis by water.

Finally, when $k_{f1w} < k_{f1H}[H^+]$

$$[11] \qquad k_{obs} = k^0_{f1H}[H^+]$$

The rate profile can then be described by eq. [12]:

$$[12] \qquad k_{obs} = \frac{(k_{1w} + k_{1H}[H^+])(k_{2w} + k_{2H}[H^+])}{1 + k_{2H}[H^+]} + k_{OH}[OH^-]$$

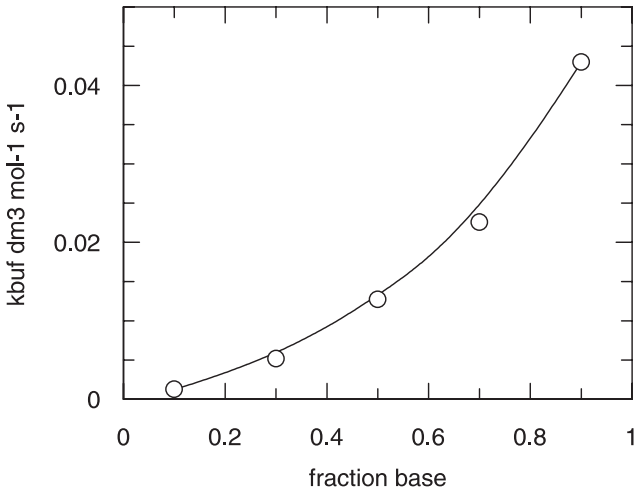
$$k_{OH} = \frac{k_{T^-}k_{f2w}}{K_w};\ k_{2w} = K_{T^-}k_{f2H} \text{ or } = K_{T^0}k^0_{f2w};\ k_{2H} = K_{T^0}k^0_{f2H};$$
$$k_{1w} = k^0_{f1w};\ k_{1H} = k^0_{f1H}.$$

[3] To be published.

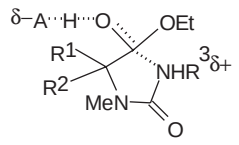
[4] Catalysis by H^+ can be formally assumed to produce T^o as T^+ loses proton to bulk water under diffusion control.

© 1999 NRC Canada

Fig. 3. Plot of k_{buf} against fraction base in acetate buffers for **2**-NPU.



The above assignments of mechanism agree well with the SKIE values listed in Table 1. In 0.90 M LCl it is 0.8 for **2**-NPU. This value applies for a "clean" reaction and is the same as the values of 0.7–0.8 found for ω-phenylhydantoic esters.(4) This and other evidence with the latter (4) supported rate-determining formation of T via the transition state **9**:



9

The somewhat larger SKIE value of 1.1 for **3**-NPU does not contradict the conclusion for k_{f1H} as rate determining at the highest acidity because it is most probably enlarged by contribution from the water-catalyzed reaction. According to Table 1, effects of about 2.5–3 are observed at lower [LCl] with **2**-NPU and **3**-NPU.

3. General base catalysis

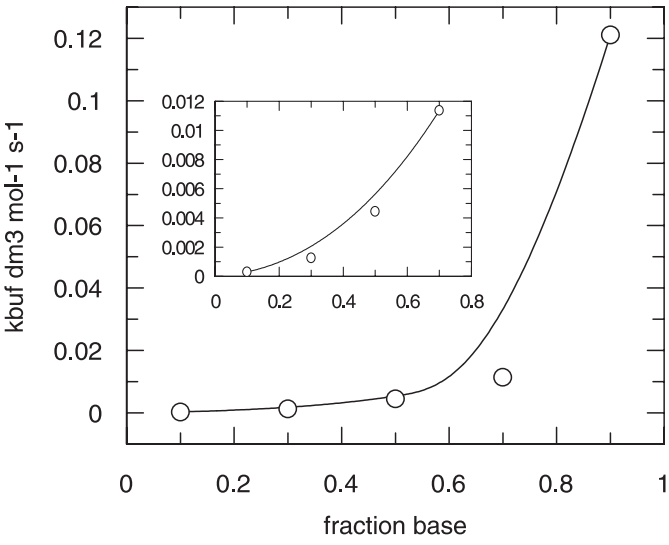
In contrast to the case of ω-phenylureido esters where GC was clearly expressed only in the case of **3**-PUE and difficult to establish with the remaining compounds, the effect of buffer catalysis was significant and could be readily monitored with all three *p*-nitrophenylureido derivatives.

Corrections for buffer failure were carried out as pH varied strongly at low fractions of base in acid phosphate and glycine buffers. Changes in pH were satisfactorily reproduced by solving the equation for the ionization

$$K_{AH} = \frac{(C_A - a_H)a_H}{(C_{AH} + a_H)}$$

where K_{AH} is the dissociation constant at I = 1 M KCl according to ref. 7, C_A and C_{AH} are the concentrations as weighed, and the actual concentration of the buffer components may be approximated as $[A^-] = C_A - a_H$, and $[AH] = C_{AH} + a_H$.

Fig. 4. Plot of k_{buf} against fraction base for **1**-NPU in neutral phosphate. Insert excluding data for 0.9 fraction base.



Plots of k_{buf} vs. fraction (of) base were convex to a varying degree. The "nonlinear" behaviour is illustrated by the examples in Figs. 3 and 4.

This nonlinearity is appreciable when a wide range of buffer ratios are studied. With narrow ranges it is indicated by the negative intercepts in plots of k_{buf} vs. fraction base. A solution was sought by means of equations derived from Scheme 1. When a general base is included in Scheme 1, the full steady state treatment yields a complex solution that can reasonably be analyzed only under simplifying assumptions. The constants for general base catalysis were obtained by nonlinear regression curve fitting of the equations shown below. The parameters describing the rate profile as a function of pH were fed in as known constants. A series of equations were tried: only those that gave good fits will be discussed. Unless stated otherwise, all equations used have a $1 + k_{2H}[H^+]$ term in the denominator; k_{2H} from the rate profiles (Table 2) varies from around 200 in **1** to 30 in **3**, which means that at pH > 3 its influence becomes negligible.

In cases when the general base is HPO_4^{2-} we found previously (3) that upward trends at high buffer ratios are described well by the addition of a $k_{BOH} \times [B] \times [OH^-]$ term interpreted as PO_4^{3-} catalysis. An extensive series of data in neutral phosphate for ester **1** was treated by means of eq. [13]:

$$[13] \qquad k_{obs} = \frac{k_w + k_{OH}[OH^-] + k_B[B] + k_{BOH}[OH^-][B]}{1 + k_{2H}[H^+]}$$

(The k_H term is negligible in neutral phosphate.) This equation gave the very good fit as illustrated in Fig. 5, which compares the experimental with the calculated points (eq. [14] is a multivariable function and cannot be presented as a two-dimensional graph).

The rate constant for catalysis for PO_4^{3-} is obtained as $k_{PO_4^{3-}} = k_{BOH}K_w/K_{HPO_4^{2-}}$.

Alternately the deviations from linearity could be described by equations including a k_{BH} term in the denominator. The following two equations proved most useful with

compounds **1**-NPU and **2**-NPU. They derive from eq. [1] under certain conditions.

$$[14] \quad k_{obs} = \frac{k_w + k_{OH}[OH^-] + k_B[B]}{1 + k_H[H^+] + k_{2BH}[BH^+]}$$

$$[15] \quad k_{obs} = \frac{k_w + k_{OH}[OH^-] + k_B[B] + k_{1BH}[BH^+]}{1 + k_H[H^+] + k_{2BH}[BH^+]}$$

In the case of ester **2**-NPU the term for H^+ catalysis was added as in eq. [6].

Equation [14] is an extension of eq. [5], derived by assuming that k_{BH} behaves as k_{2H} in the case of **1** and **2**, that is, $k_{r1BH} > k_{f2BH}$ and $k_{f2BH}[BH^+] < k_{f2w}$ in the range studied. Then $k_B = k_{f1B}$ and $k_{2BH} = k_{r1BH}/k_{f2w}$ ($k_{f2w} > k_{r1w}$). The increase of $k_{2BH}[BH^+]$ with the decrease of fraction base will cause at the same time $_{kbuf}$ to decrease faster than demanded by a linear function. These assumptions mean that k_B is involved in the formation of T^- and can be measured directly as long as formation of T^- is r.d. for the overall reaction. When k_{2BH} $[BH^+]$ becomes greater than $1 + k_H[H^+]$ there is a change in the r.d.s.; actually eq. [14] predicts reaching the situation determined by eqs. [3] and [4], the first step becoming an equilibrium and T^- giving products by k_{f2w}.

$k_{f2BH}[BH^+]$ not being negligible in eq. [1] and result from $k_{f1w} \times k_{f2BH}$. Independent GAC is another possibility.

However, within the experimental data available for compounds **1** and **2**, a definite choice cannot be made between eqs. [14] and [15]. Equation [15] performed better with **1**-NPU but there is no considerable improvement over eq. [14]. In contrast,with ureido ester **2**-NPU eq. [14] is definitely the better choice as eq. [15] fails. With the stronger buffer bases, acid catalysis becomes unimportant. In acetate and cacodylate buffers, either a straightforward equation for GBC (adding kB × [B] to eqs. [5] or [12]) best described the results or the more complex equations gave insignificant improvement together with unrealistic additional constants.[5]

For compound **3**-NPU the following modification of eq. [12] was preferred in the case of the more acidic buffers such as acid phosphate, glycine, and formate (the latter gave large errors for the BH constants):

$$[16]\quad k_{obs} = \frac{(k_{1w} + k_{1H}[H^+])(k_{2w} + k_{2H}[H^+]) + k_B[B] + k_{1BH}[BH^+]}{1 + k_{2H}[H^+] + k_{2BH}[BH^+]} + k_{OH}[OH^-]$$

The data obtained in acetate were best described by an equation assuming independent GBC. In cacodylate and neutral phosphate only a few measurements at low fraction base could be taken due to the fast reaction and the rate constants were obtained by assuming independent GBC.

The rate constants for GBC listed in Tables 3–5 yield the Brønsted plots shown in Fig. 6. The lines drawn are linear fits obtained from the data for the general bases with pK's between 2 and 6.5. The data for ureido ester **3**-NPU in acid phosphate and glycine buffers deviate strongly from the Brønsted plot and the β-value was determined from the remaining four data points. The slopes of the lines are presented in Table 6. As observed before for the cyclization of ethyl 5-phenylhydantoates, the points for water catalysis fall on the correlation lines. It is noteworthy that the data for OH^- catalysis repeat the pattern observed with the ω-methyl and ω-phenyl analogues of compounds **1**-NPU–**3**-NPU. Esters **1**-NPU and **2**-NPU exhibit strong positive deviations while the point for **3**-NPU fits the line, a behaviour parallel to the SKIE results.

The present series of Brønsted linear relationships for three NPU hydantoates with increasing numbers of methyl groups revealed an unexpected feature: the *gem*-dimethyl effect on

[5] It should be noted also that eq. [13] on the one hand and eqs. [14] and [15] on the other give different k_B constants in principle. With eq. [13] k_B is approached at low [OH^-], while with eqs. [14] and [15] k_B is approached at high [OH^-] (low [BH^+]).

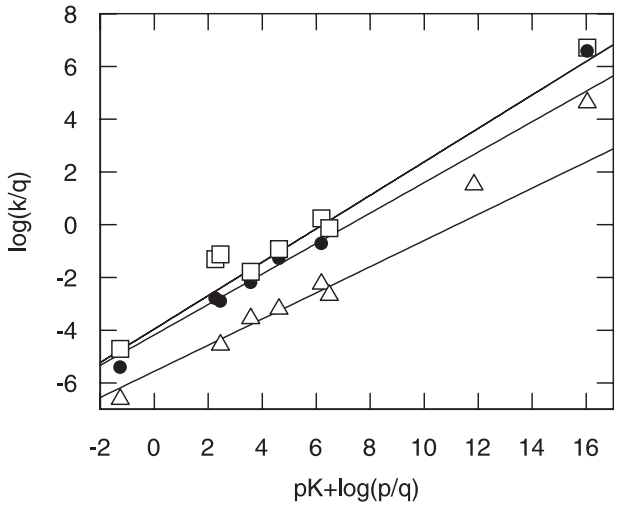
Fig. 6. Brønsted plots of the rates GBC for the cyclization of **1**-NPU (△), **2**-NPU (●), and **3**-NPU (□). See text for linear relationships.



the rates for GBC showed the same saturation behaviour as observed with the OH^- catalysis. Figure 6 demonstrates how, except for the deviating points acid phosphate and glycine, the k_B values for **3**-NPU are insignificantly larger than those for **2**-NPU, though the increases for **2**-NPU over **1**-NPU amount to almost two orders of magnitude. This fact indicates that our previous conclusion (3) on the mechanism of GBC of the cyclization of ω-phenylhydantoic esters is incorrect. No data could be obtained for **1**-PUE. The similarity in the β values of ca. 0.6 for **2**-PUE and for **3**-PUE was interpreted as evidence of the same mechanism and the close catalytic constants as due to an early transition state with respect to ring formation, namely r.d. formation of T^- concerted with deprotonation of the ureido group. If the same mechanism applies to NPU, obviously it does not fit the large *gem*-dimethyl effect observed between **1**-NPU and **2**-NPU. The latter is compatible with two other possibilities. Either GBC of **3**-NPU involves a different mechanism than that of **1**- and **2**-NPU and the similar β values are accidental or all three involve GAC of the breakdown of T^-, the loss of

© 1999 NRC Canada

the *gem*-dimethyl effect with **3**-NPU being caused by steric hindrance to protonation. Actually the question can be answered within the framework of the mechanisms accepted for the rate profiles. GBC must comply with the rate-determining step of the reaction as a whole. Thus under conditions where formation of T^- is rate determining, the GBC reaction cannot proceed with r.d. breakdown unless the r.d.s. for the whole reaction is changed, a situation discussed above in relation to the curvature of the k_{obs} against fraction base plots. In the particular case of NPU, the r.d.s. in the various regions of the rate profiles are established above with a fair degree of certainty. The rate profiles (Fig. 1) indicate that the in whole region above pH 2.5 for esters **1**-NPU and **2**-NPU (the plateau and $k_{OH}{}^b$) where GBC was actually measured the reaction proceeds with rate-determining formation of T. Alternatively, under conditions where an equilibrium between reactant and T^- is established, as assumed for **3**-NPU above pH ca. 4, GBC formation of T^- cannot accelerate the reaction because the $[T^-]/[UH]$ ratio becomes time independent. Thus we have to conclude the **3**-NPU on the one hand and **1**-NPU–**2**-NPU on the other react by different mechanisms and that the similarity in β values is coincidental. Supporting evidence is the fact that the data for GBC by $H_2PO_4^{2-}$ and glycine with **3**-NPU deviate from the log k_B / p*K* correlation; in the low pH region a change in the r.d.s. is indicated by the rate profile.

Thus the best explanation for the loss of the *gem*-dimethyl effect in the GBC cyclizations of **3** appears once again to be a change to r.d. breakdown of the tetrahedral intermediate caused by steric hindrance to proton transfer as assumed by us for the OH^- catalysis of other ureido esters. Thus GBC with **1**-NPU and **2**-NPU has to be attributed to rate-determining formation of T^- concerted with deprotonation of the ureido group, structure **5**, while that with **3**-NPU to the general acid-catalyzed breakdown of T^-, structure **7**.[6]

Effect of cyclodextrin on elimination reactions

Luis Viola and Rita H. de Rossi

Abstract: The reaction of 1-bromo-2-X-2-(Y-phenyl) ethane derivatives (**1**: X = Y = H; **2**: X = Ph, Y = H; **3**: X = H, Y = 4-Ac; **4**: X = H, Y = 3-NO_2; **5**: X = H, Y = 4-NO_2; **6**: X = H, Y = 3-Me; **7**: X = H, Y = 4-Me) in basic solution was studied, and in most cases, only the elimination product is formed. Only (2-bromo-1-phenylethyl)benzene, **2**, yielded significant substitution product, and this yield decreased with the concentration of HO^-. Addition of cyclodextrin (β-CD) diminished (about half for 0.02 M cyclodextrin concentration) the reaction rate of all substrates but **4** and **5**. In the latter two cases, the rate rises. The observed rate-constant value at 0.5 M NaOH is 6.78×10^{-4} s^{-1} (at 40°C) and 1.80×10^{-3} s^{-1} (at 25°C) for **4** and **5**, respectively. Under the same reaction conditions but with 0.01 M β-CD, the corresponding rates were 7.70×10^{-4} s^{-1} and 5.20×10^{-3} s^{-1}. The elimination yield for **2** increased from 64 to 98% when the β-CD changed from zero to 0.02 M at 0.5 M NaHO. Also, there was an increase in the relative elimination products of 20–40% for compounds **6** and **7**. The Hammet ρ values were 1.3 and 2.3 for the reaction in pure solvent and in the presence of β-cyclodextrin, indicating an increase in the negative character of the transition state for the reactions in the latter conditions. The results are interpreted in terms of the formation of an inclusion complex whose structure depends on the substrate.

Key words: cyclodextrin, elimination reactions, inhibition, catalysis.

Résumé : On a étudié la réaction de dérivés du 1-bromo-2-X-2-(Y-phényl)éthane (**1**, X = Y = H; **2**, X = Ph, Y = H; **3**, X = H, Y = 4-Ac; **4**, X = H, Y = 3-NO_2; **5**, X = H, Y = 4-NO_2; **6**, X = H, Y = 3-Me; **7**, X = H, Y = 4-Me) en solution basique et, dans la plupart des cas, il ne se forme que le produit d'élimination. Le (2-bromo-1-phényléthyl)benzène, **2**, est le seul à donner des quantités significatives de produit de substitution et ce rendement diminue avec une augmentation de la concentration de OH^-. L'addition de cyclodextrine (β-CD) diminue (environ de moitié pour une concentration égale à 0,02 M en cyclodextrine) la vitesse de réaction pour chacun des substrats, à l'exception des produits **4** et **5**. Dans ces deux derniers cas, la vitesse augmente. Les valeurs des constantes de vitesse observée, pour une concentration de 0,5 M de NaOH, sont de $6{,}78 \times 10^{-4}$ s^{-1} (à 40°C) et de $1{,}80 \times 10^{-3}$ s^{-1} (à 25°C) pour les composés **4** et **5** respectivement. Dans les mêmes conditions de réaction, mais en présence de 0,01 M de β-CD, les vitesses correspondantes sont de $7{,}70 \times 10^{-4}$ s^{-1} et $5{,}20 \times 10^{-3}$ s^{-1}. Pour une concentration de NaOH égale à 0,5 M, le rendement en élimination pour le produit **2** augmente de 64 à 98% lorsque la concentration en β-CD passe de zéro à 0,02 M. Avec les composés **6** et **7**, on a aussi observé une augmentation des produits d'élimination de 20 à 40%. Les valeurs ρ de Hammett sont égales respectivement à 1,3 et 2,3 pour les réactions dans un solvant pur et celles en présence de β-cyclodextrine; ces valeurs signalent une augmentation du caractère négatif de l'état de transition pour les réactions dans ces dernières conditions. On interprète les résultats en fonction de la formation d'un complexe d'inclusion dont la structure dépend du substrat.

Mots clés : cyclodextrine, réactions d'élimination, inhibition, catalyse.

[Traduit par la Rédaction]

Introduction

Cyclodextrins are cyclic oligomers of α-D-glucose that are produced by enzymatic degradation of starch (1). The more common cyclodextrins have six, seven, and eight glucose units and are called α, β, and γ cyclodextrins, respectively. They have a cavity formed by two rings of CH group of the glucose units and one ring of the glycosidic oxygens. The secondary OH groups are located in the wider rim of the cavity and the primary in the smaller one. Since the cavity is relatively apolar compared with water, it provides a favorable environment for the location of many organic compounds, and the formation of inclusion complexes leads to many interesting changes in the properties of the included compound which result in changes in their reactivity (2). One of the properties of cyclodextrins that has been exploited considerably is the possibility of induction of selectivity in reactions that lead to more than one product. Inclusion of the substrate and (or) the reagent in the cavity leads to different distribution of products when the reactions are compared with the same reaction in the bulk solvent. For example, the iodination of phenol (3) and the photochemical rearrangement of phenyl acetate give an increase in the *para*/*ortho* and *ortho*/*para* ratio of products, respectively, in

the presence of β-CD (4). More recent examples that are important for synthetic applications can be found in the literature (5). The changes in product selectivity may be the result of a different stabilization of the transition state for the formation of the various products.

The elimination mechanism of 2-bromoethylbenzenes is well established, and it proceeds by an E_2 type of mechanism. The transition state for this mechanism has severe stereoelectronic requirements; moreover, competition by substitution often occurs (6). We considered of interest to study this type of reactions in the presence of cyclodextrin to determine the effect of inclusion on the reaction rates and the elimination/substitution ratio. Thus, we studied the reaction of compounds **1**–**7** in basic water solution and the effect of cyclodextrins on their relative yield of elimination and substitution in the cases were the two reactions compete. Compounds with substituents at 3- or 4-position were chosen because it is known that the orientation of the ring in the inclusion complex is quite dependent on the position of the substituent on the ring (7).

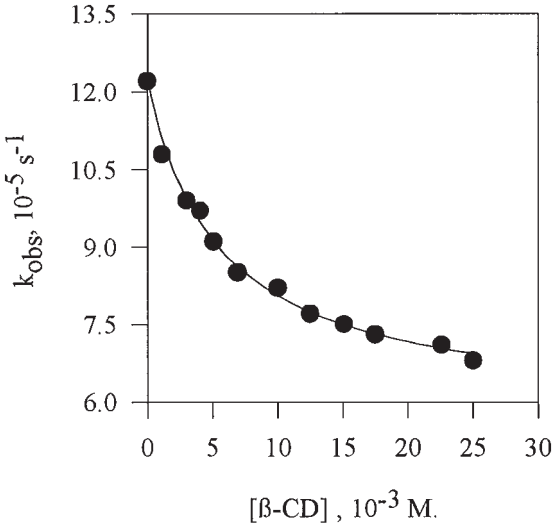
Results

(2-Bromoethyl)benzene (1)

Substrate **1** is very insoluble in water, so dioxane/water 1:9 was used as solvent. Under all our reaction conditions, the only product formed was styrene. The addition of 1.5×10^{-2} M of β-CD produced no changes in the rate. The observed rate constants at 0.5 M OH^- are 1.27×10^{-4} and 1.24×10^{-4} s^{-1}, respectively. The fact that the rate was not affected by β-CD can be attributed to competitive binding by the solvent. Since it is known that dioxane forms inclusion complexes with β-CD (K_{Ass} = 9 M^{-1}) (8), and the association constant of **1** with β-CD should be in the order of 200 M^{-1} (see below), only 10% of the substrate would be bound at the maximum β-CD used.

Ethanol also binds to β-CD but the association equilibrium constant is lower, i.e., 1.2 M^{-1} (9); besides, its smaller size may allow the co-inclusion of ethanol and the substrate as was found in other systems (10).

Fig. 1. k_{obs} vs. β-CD concentration for the reaction of **1**. [HO] = 0.5 M. Temperature, 40°C; solvent, ethanol/water (1:9 v/v); ionic strength, 0.5 M (NaCl as compensating electrolyte). The line was calculated fitting the data to eq. [3].



In ethanol/water 1:9 v/v, the only product formed was styrene, and the observed pseudo-first-order rate constant is linearly dependent of HO^- concentration (Table S1).[2] The slope of a plot of k_{obs} vs. HO^- concentration (not shown) gave the second-order rate constant 2.49×10^{-4} M^{-1} s^{-1} in good agreement with the literature values, i.e., 3.01×10^{-4} M^{-1} s^{-1} (11). At constant HO^- concentration, the reaction was inhibited by the addition of β-CD and showed a saturation effect (Fig. 1). GC analysis of the products showed that the major product formed was styrene, although a small (<5%) amount of the substitution product was also formed but no significant changes in the relative yield of the elimination and substitution products could be detected.

At constant β-CD concentration (0.01 M), there was linear dependence of k_{obs} on HO^-, and the slope was 1.49×10^{-4} M^{-1} s^{-1}, which is about 60% of the value in the absence of

Fig. 2. k_{obs} vs. β-CD concentration for the reaction of **2**. [HO] = 0.5 M. Temperature, 40°C; solvent, ethanol/water (1:9 v/v); ionic strength, 0.5 M (NaCl as compensating electrolyte). The line was calculated fitting the data to eq. [3].

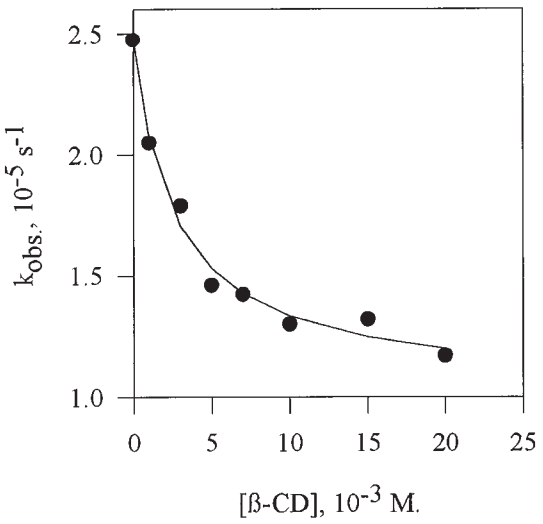

Table 1. Effect of β-CD on the observed rate constant and the elimination yield for the reaction of **2** in basic solution.[a]

β-CD (10^{-3} M)	k_{obs} (10^{-5} M)	Elimination yield (%)
0	24.8	64
1.0	20.3	75
3.0	17.9	79
5.0	14.6	78
7.0	14.2	85
10.0	13.0 (26.2)[b]	79
15.0	13.2	83
20.0	11.7	98

[a]Temperature, 25°C; solvent, ethanol/water (1:9 v/v); ionic strength, 0.5 M (NaCl as compensating electrolyte) unless otherwise indicated; NaOH, 0.5 M. Substrate concentration 2×10^{-5} M.

[b]Soluble starch instead of cyclodextrin.

β-CD. On the other hand, the addition of α-CD did not affect the rate in the range 1×10^{-4}–2.5×10^{-2} M.

(2-Bromoethyl-1-phenylethyl)benzene (2)

This reaction gave substitution as well as elimination products, although the latter is predominant. The concentration of the elimination products increased with that of HO^- in agreement with the known effect of base concentration on the competition between substitution and elimination reactions (6). The observed pseudo-first-order rate is linearly dependent on HO^- concentration with a second-order rate constant of 4.95×10^{-4} M^{-1} s^{-1} (Table S1).[2] The addition of β-CD produces a decrease on the observed rate and shows saturation effect (Fig. 2, Table 1). The yield of the elimination product increases as the amount of CD increases (Table S2).[2] At constant β-CD concentration, there is an increase in the observed rate with HO^- concentration, which is linear but at low concentration the values are somewhat smaller than expected. The elimination yield is higher than in the absence of CD and increases as the OH concentration increases but in a somewhat scattered form (Table S1).[2]

1-(2-Bromoethyl)-4-acetylbenzene (3)

The second-order rate constant obtained from the slope of the linear plot (not shown) of k_{obs} vs. HO^- concentration (Table S1)[2] is 3.3×10^{-3} M^{-1} s^{-1}. There is a modest (~20%) but out of experimental error decrease in the observed rate in the presence of β-CD. The ratio of elimination/substitution products is not affected (Table S2).[2]

1-(2-Bromoethyl)-3-nitrobenzene (4) and 1-(2-bromoethyl)-4- nitrobenzene (5)

The reactions of **4** were measured at 40°C and those of **5** at 25°C. There is linear dependence of the observed rate constant with the HO^- concentration (Table S1)[2] from which a second-order rate constant of 1.33×10^{-3} and $(3.65 \pm 0.17) \times 10^{-3}$ M^{-1} s^{-1} are calculated, respectively, for **4** and **5**. The second-order rate constants for **5** is somewhat higher than the reported values 2.61×10^{-3} (12) and 3.47×10^{-3} M^{-1} s^{-1} (11). The discrepancy may be attributed to the presence of ethanol.

In contrast with the behavior of the substrates described before (**1**–**3**), the addition of cyclodextrin produces an increase in the observed rate constant for both substrates, although for **4** it is at most 10%, with α- or β-cyclodextrin at 0.01 M (Table S2).[2] On the other hand, the increase is more significant for **5**, and saturation effect is observed at three concentrations of HO^- (Fig. 3). The relative increase in rate is higher at lower HO^- concentration, i.e., the ratio of the rate at β-CD = 0.015 M and zero is 3.2, 12.7, and 22.2 for HO^- concentrations 0.49, 0.04, and 0.01 M, respectively. In all cases, only the elimination product is formed.

At constant β-CD concentration, there is nonlinear dependence of the observed rate constant for **5** with HO^- concentration (Fig. 4).

The addition of 3×10^{-2} M concentration of α- or γ-cyclodextrin with HO^- = 0.5 M gives rate constants 3.28×10^{-3} and 3.08×10^{-3} s^{-1}, indicating that both receptors accelerate the reaction in approximately the same amount but less than β-CD, since the value of the observed rate constant in the presence of 0.015 M β-CD is 5.75×10^{-3} s^{-1}.

1-(2-Bromoethyl)-3-methylbenzene (6) and 1-(2-bromoethyl)-4-methylbenzene (7)

The reactions of these substrates were studied at 40°C, there is first-order dependence on the HO^- concentration (Table S1) and the second-order rate constant obtained from the slope of the linear plot (not shown) is 2.23×10^{-4} and 1.84×10^{-4} M^{-1} s^{-1} for **6** and **7**, respectively. The addition of β-CD produces a decrease in the rate and an increase in the relative elimination yield (see Experimental) of about 20% for **6** and 40% for **7** at the higher cyclodextrin concentration used (Table S2). The decrease in the yield of substitution product was confirmed by HPLC.

Discussion

Effect of cyclodextrin on reaction rates

All the reactions studied were affected by the addition of β-CD. To determine whether the effect was due to a medium effect, the observed rate constants were determined in the presence of soluble starch in similar weight concentration as that of β-CD. In Table 2, the data are collected, and it can be

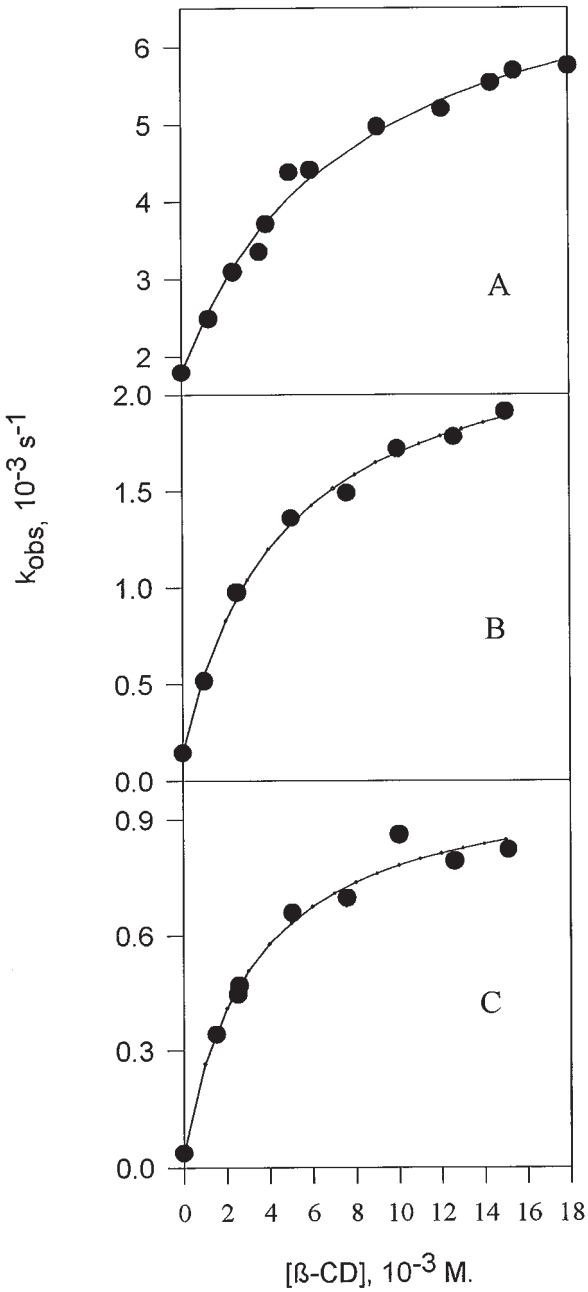
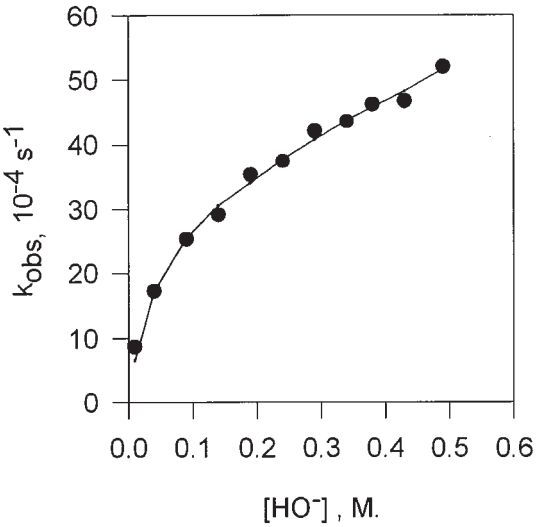
Fig. 3. k_{obs} vs. β-CD concentration for the reaction of **5**. Temperature, 25°C; solvent, ethanol/water (1:9 v/v); ionic strength, 0.5 M (NaCl as compensating electrolyte). [HO] = 0.5 M, A; 0.04 M, B; and 0.01 M, C. The line was calculated adjusting the data to eq. [4].



seen that within experimental error, starch produces no changes in the observed rate constant, which indicates that the effect of β-CD should be attributed to specific interactions. Besides, the addition of β-CD produces a decrease in the absorption at the maximum wavelength for 1-(2-bromoethyl)-4-acetylbenzene and 1-(2-bromoethyl)-4-nitrobenzene. These results indicate that the substrate may form some type of inclusion complex with the β-CD. For the 1:1 inclusion

Fig. 4. Change in k_{obs} with HO^- concentration for the reaction of **5**. [β-CD] = 0.01 M. Temperature, 25°C; solvent, ethanol/water (1:9 v/v); ionic strength, 0.5 M (NaCl as compensating electrolyte). The line was calculated using eq. [9].



complex, there are two possible modes of inclusion, with the aliphatic chain inside the cavity (Fig. 5*A*) and with the aromatic part of the molecule inside (Fig. 5*B*).

The pK_a of β-CD is 12.2 (13), so we suggest that the reaction takes place as indicated in Scheme 1 where k_0, k_1, and k_2 represent the reactions of the free substrate, the substrate complexed with neutral β-CD (CDOH), and the reaction with anionized β-CD (CDO^-), respectively.

The observed rate constant for Scheme 1 is given by eq. [1] where f represents the fraction of ionized β-CD as defined in eq. [2]. Under the conditions of constant HO^- concentration, 0.5 M, $f \approx 1$, then eq. [1] simplifies to eq. [3]:

$$[1] \qquad k_{obs} = \frac{k_0[HO^-] + k_1K_1[HO^-](1-f)[CD] + k_2K_2\,f[CD]}{1 + K_1(1-f)[CD] + K_2\,f[CD]}$$

$$[2] \qquad f = \frac{[HO^-]}{[HO^-] + K_b}$$

$$[3] \qquad k_{obs} = \frac{k_0[HO^-] + k_2K_2[CD]}{1 + K_2[CD]}$$

Fitting the experimental data to eq. [3],[3] k_2 and K_2 were calculated, and the data are collected in Table 3.

The reactions of substrate **5** in the presence of β-CD were studied at three HO^- concentrations, i.e., 0.01, 0.04, and 0.49 M. For each HO^- concentration, the observed rate constant was fitted to an equation of the form of eq. [4] with $a = k_0[HO^-]$ and b and c adjustable parameters given in eqs. [5] and [6]. The calculated parameters are given in Table 4.

$$[4] \qquad k_{obs} = \frac{a + b[\beta\text{-CD}]}{1 + c[\beta\text{-CD}]}$$

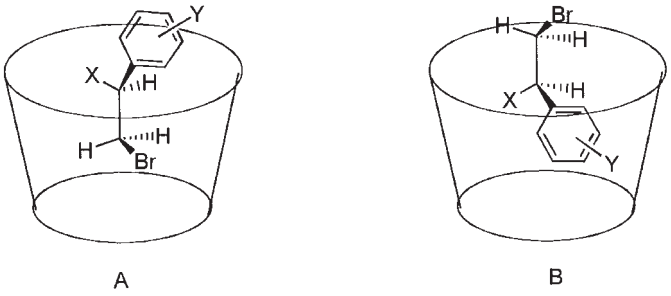
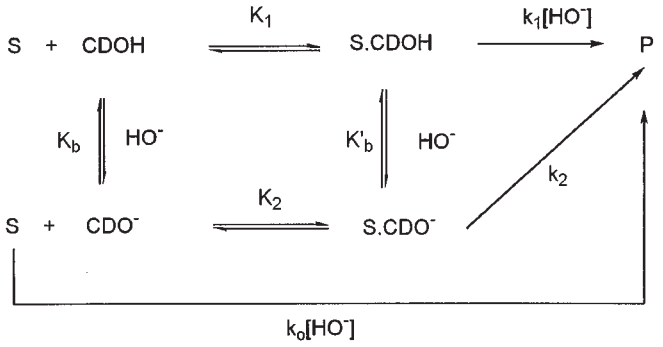
Fig. 5. Schematic representation of the inclusion complexes of compounds **1**–**7**.



Scheme 1.



[5] $$b = (k_1K_1[HO^-](1 - f) + k_2K_2 f)[CD] = (k_1K_1K_b + k_2K_2) f[CD]$$

[6] $$c = K_1(1 - f) + K_2 f$$

The decrease in c as the HO^- concentration increases indicates that the association constant of cyclodextrin anion with the substrate, K_2, is smaller than the corresponding value of the neutral cyclodextrin, K_1. Using the value of c at 0.5 M HO^- as K_2, K_1 can be calculated from the value of c at 0.01 and 0.04 M giving 370 ± 10 M^{-1}. The parameter b divided by f should be constant (see eq. [5]). It can be seen in the last column of Table 4 that similar values are obtained at the two lower concentrations of HO^-, but the value increases considerably at high HO^- concentration. This might indicate that at this high concentration there is some contribution to the overall catalyzed reaction from a pathway involving the substrate complexed with cyclodextrin anion and HO^- (eq. [7]).

[7] $$SCDO^- + HO^- \xrightarrow{k_3} P$$

If reaction [7] takes place, a term $k_3K_2[HO^-]$ should be included in parameter c. Using the average value of b/f for the two lowest concentrations of HO^-, namely, 0.769, k_3K_2 is calculated as 0.777 M^{-1} s^{-1}.

Equation [1] can be rearranged as shown in eq. [8]:

[8] $$\frac{k_{obs}(1 + K_1(1 - f)[CD] + K_2 f[CD]) - k_0[HO^-]}{f} = (k_1K_1K_b + k_2K_2)[CD]$$

Since K_1 and K_2 were calculated as indicated above, the left hand side of eq. [8] can be obtained for each concentration of HO^- using the data at constant β-CD and varying HO^- (Table S1);[2] these values were calculated and are not constant as eq. [8] requires but they show a linear dependence with HO^- concentration with slope 3.86×10^{-3} and intercept 4.87×10^{-3} (plot not shown). From the last two values, k_3K_2 and $k_1K_1K_b + k_2K_2$ can be calculated and are in fair agreement with the values obtained from another set of data, namely, the change in rate with β-CD at constant HO^- (see above). From the results just discussed, it follows that a pathway involving the reaction of the substrate complexed with cyclodextrin anion and HO^- (eq. [7]) is playing some role in the catalyzed pathway. The observed rate constant is then given by eq. [9]:

[9] $$k_{obs} = \frac{k_0[HO^-] + (k_1K_1K_b + k_2K_2 + k_3K_2[HO^-]) f[CD]}{1 + K_1(1 - f)[CD] + K_2[CD] f}$$

The value of k_3K_2 is of the same order of magnitude as that corresponding to the reaction involving the cyclodextrin anion acting as a base, k_2K_2, so it is likely that k_1K_1 is also

1.167 ± 0.099	154 ± 19	0.49	1.150

similar. Therefore, in the sum the term $k_1K_1K_b$ is probably negligible.

Following Kurz treatment (14), which was adapted by Tee (15) to reactions catalyzed by cyclodextrins, we calculated the formal equilibrium constant for the association of the transition state (TS) with β-CD, and the corresponding free energy using eq. [10]:

$$[10] \qquad K^*_{TS} = \frac{[TS.CDO^-]}{[TS][CDO^-]} = \frac{k_2K_2}{k_0[HO^-]}$$

K^*_{TS} is an apparent association constant for the formation of the transition state of the CD-mediated reaction (symbolized as $TS.CDO^-$) from the transition state of the normal reaction (TS) and the β-CD. The logarithm of this quantity is related to the differences in free energy of the transition state of the catalyzed and uncatalyzed reactions under standard conditions. The value of K^*_{TS} is obtained from experimentally measured quantities, so it gives a measure of the binding energy of the transition state to the catalyst for those conditions regardeless of the mechanism. (16) Therefore, K^*_{TS} and its variation can be taken as a criterium of mechanism in similar way as other kinetic parameters such as Bronsted β or Hammett ρ values. According to eq. [10], the change in rate is determined by the strength of binding of the transition state relative to that of the substrate, i.e., $k_2/k_0 = K^*_{TS}/K_2$.

Cyclodextrins may show two basic forms of catalysis: "noncovalent" and "covalent" (1). In the former case, the cyclodextrin binds to the substrate (S) and provides an environment for the reaction that is different from the bulk solvent; in this case, the effect of CD arises from the less polar nature of the cavity (a microsolvent effect) and (or) from the conformational restrains imposed on the substrate by the geometry of inclusion. Another factor that may be important for noncovalent catalysis may be differential solvation effects at the interface of the cyclodextrin cavity with the external aqueous enviroment (17). In the covalent catalysis, there is some type of covalent interactions between the substrate (S) and functional groups on the CD in the rate-limiting step of the reaction. For instance, the anion of CD may function as simply basic catalyst towards acidic substrates included in their cavity (18).

Considering the less polar microenvironment of the cavity of β-CD, and that elimination reactions are faster in less polar solvents, one would expect that all elimination reaction were catalyzed by cyclodextrin. Contrary to the above expectations, all the reactions studied except for compounds **4** and **5** are retarded.

There is no correlation between K^*_{TS} and K_S, which is an evidence that the transition state of the catalyzed or retarded reaction does not correspond to the inclusion complex of the substrate. There are two possible types of 1/1 inclusion complex: one with the aromatic ring inside the cavity and another with the aliphatic chain inside the cavity (Fig. 5). Since all the compounds have the same aliphatic chain, the differences in stability of the two types of complexes should depend on the nature and position of the substituent. The compounds having nitro and acetyl groups are those that have the more hydrophilic moieties, therefore, it is more likely that the major type of interaction is the one represented by *A* in Fig. 5.

When the transition state for the included compound is more stable than that for the free compound, the reaction will be accelerated by cyclodextrin and vice versa (eq. [10]). When the stabilization of the included transition state is higher than that of the substrate, the barrier for the reaction will be lower and consequently the overall rate faster.

The affinity for the substrate is stronger than that for the transition state for all the substrates but **5**, consequently, the reaction is catalyzed as shown in Table 3. This can be associated with a change in the nature of the transition state for this compounds. Several authors (19) have proposed that in these systems the increased withdrawing effect of the substituent changes the transition state from a classic E_2 mechanism towards one with some E_{1cb} character.

The second-order rate constant can be correlated by the Hammet equation, and a value of 1.3 and 2.3 is obtained for k_0 and k_2, respectively, indicating an increase in the carbanionic character of the transition state for the reactions in the presence of CD. The mechanism of the catalyzed step is kinetically indistinguishable from one in which the substrate complexed with neutral cyclodextrin reacts with HO^- (K_1k_1 step in Scheme 1). Then, the increase in the carbanionic character of the transition state may indicate that the base, HO^-, is stronger in the cavity. However, for this pathway to be kinetically significant under our reaction conditions, K_1k_1 should be about 100 times higher than k_2K_2, which seems unlikely considering the values that have been estimated for these two rate constants for compound **5**, so the increase in

© 1999 NRC Canada

carbanionic character of the included transition state may be attributed to esteric constrain in the cavity for a truly E_2 type of mechanism.

Similar effect was observed by Tagaky and co-workers (20) for elimination reactions in micelles. They also found an important increase in the ρ value, which was attributed to a change of the transition state toward a more negative character although the results of isotopic exchange indicated that the mechanism was not E_{1cb}.

Comparing the values of K_2 and K^*_{TS} for substrates **6** and **7** (Table 3), which have the same substituent but in different position, it can be seen that the *meta* substituted compound has a significatively lower equilibrium constant than the *para*. This result indicates that the inclusion of the substrate takes place with the aromatic ring inside the cavity, which is characteristic of benzene derivatives (21). The unfavorable forces that lead to a weaker interaction of the *meta* substituted compound remain in the transition state for the reaction with β-CD because the ratio of K_2 and K^*_{TS} for **6** and **7** are about the same, namely, 0.36 and 0.37, respectively.

Effect of β-CD on the reaction selectivity

In the presence of β-CD, the relative yield of elimination (see Experimental) increases for substrates **6** and **7** by 20 and 39%, respectively. In the case of substrate **2**, the elimination yield increases from 64 to 98% when β-CD increases from 0 to 0.02 M at constant HO^- concentration (Table S2). The free activation energy of the elimination reaction for substrates **1** and **3**–**5** is lower than that of the substitution reaction, and it is possible that β-CD changes the relative energy of these two transition states, however, the change is not big enough, and the substitution product is not formed in detectable amount. On the other hand, the compounds having electron donor substituents produce a decrease in the relative acidity of the hydrogen of the β-carbon increasing the free energy for the elimination reaction, but the substitution is less affected, therefore, the two reactions compete, and the effect of β-CD can be experimentally determined.

The relative yield of elimination products increase with the β-CD concentration, which may be a consequence of microsolvent effect, since elimination reaction are favored over substitution in solvents of low polarity.

Experimental section

The kinetic measurements were carried out on the thermostated cell of a Beckman 24 spectrophotometer connected to a personal computer that was used to acquire and process the kinetic data.

UV-vis spectra were done on a Shimadzu 260 spectrophotometer. RMN were done on a Bruker AD-C 200.

Water was purified in a Millipore aparatus. Dioxane was dried with Na metal and distilled before use over lithium aluminum hydride. Ethanol was distilled and the purity controlled by UV-vis spectrometry. The α- and γ-cyclodextrin (Aldrich), β-cyclodextrin (Roquette),[4] and soluble starch (Mallinkcrodt) were used as received. Inorganic salts were analytical grade and (2-bromo-1-phenyl)ethylbenzene were used as received. 4-Acetyl-1-(2-bromoethyl)benzene was prepared from (2-bromoethyl)benzene and acetyl chloride and $AlCl_3$ in S_2C (22). The purity of the compound was controlled by mass spectrometry, NMR, IR, and thin layer chromatograpy.

1-(2-Bromoethyl)-3-nitrobenzene was obtained from (3-nitrophenyl)ethanol (Sigma) and PBr_3 in benzene (23). The product was identified by NMR.

1-(2-Bromoethyl)-4-nitrobenzene was obtained from (2-bromoethyl)benzene and nitric acid in acetic anhydride as described in the literature (22). 1-(2-Bromoethyl)-3-methylbenzene was obtained according to the literature from (3-methylphenyl)ethanol and PBr_3 in benzene solution (23). The product had 5% of the starting alcohol as determined by NMR. 1-(2-Bromoethyl)-4-methylbenzene was obtained as described in the literature (23) from (4-methylphenyl)ethanol and PBr_3 in benzene. NMR analysis indicated that it contains 20% of the starting alcohol.

Kinetic procedures

Reactions were initiated by adding 10 μL of a concentrated solution of the substrate dissolved in ethanol to 3 mL of a water solution containing all the other constituents. The cell was flashed with nitrogen and stopped. The change in absorption with time was measured at the maximum of the corresponding styrene derivative, namely, styrene 248 nm, diphenylethene 247 nm, *p*-acetylstyrene 282 nm, *m*-nitrostyrene 241 nm, *p*-nitrostyrene 308 nm, *m*-methylstyrene 250 nm, *p*-methyl styrene 249 nm. The yield of products for (2-bromoethyl)- and (2-bromo-1-phenylethyl)benzene was determined from eq. [11]:

$$[11] \quad \%\ \text{elimination} = \frac{(A_\infty - A_0)100}{\varepsilon [S]_0}$$

where A_∞ and A_0 represent the initial and final absorbance at the wavelength of the measurement, S represents the initial substrate concentration, and ε the extinction coefficient of the product.

For all the other compounds, the relative elimination yields (REY) was determined by using eq. [12] were the subscript x and y stand for the reactions in the presence and absence of cyclodextrin, respectively.

$$[12] \quad \text{REY} = \frac{\%E_x}{\%E_y} = \frac{(A_\infty - A_0)_x [S]_{oy}}{(A_\infty - A_0)_y [S]_{ox}}$$

Product analysis

The reactions of (2-bromoethyl)benzene, 1-(2-bromoethyl)-3-methylbenzene, and 1-(2-bromoethyl)-4-methylbenzene were analyzed by HPLC and CGL and the reaction of 1-(2-bromoethyl)-3-nitrobenzene by H^1 NMR using a MCH-5-n cap column of 150 × 4 mm with UV-vis detection. The solvent was water/methanol 4:6 v/v and 0.5 mL/min flow rate. Retention times were 5.69, 21.94, and 24.32 for 2-phenyl ethanol, styrene, and **1**, respectively. GC analyses were carried out in a Konik KNK 3000 HRGC with a column CPSIL 19 CV 6 m long and 0.75 mm diameter.

[4] α- and β-cyclodextrin were generous gift of Ferromet SA, Buenos Aires, Argentina.

Contrasting behaviour in the photosolvolysis of 1- and 2-hydroxy-9-fluorenols in aqueous solution

Maike Fischer, Yijian Shi, Bao-ping Zhao, Victor Snieckus, and Peter Wan

Abstract: The photosolvolysis of 1- and 2-hydroxy-9-fluorenols **4**–**6** has been studied in aqueous solution. All of these 9-fluorenols photosolvolyze efficiently in 1:1 H_2O–CH_3OH, to give the corresponding methyl ether products in high chemical and quantum yields. Whereas the photosolvolysis of the parent 9-fluorenol (**2**, R = H) is known to proceed via the very short-lived and formally ground-state antiaromatic 9-fluorenyl cation (**1**, R = H), the photosolvolysis of 1-hydroxy-9-fluorenol (**4**) proceeds via a much longer-lived (≈5–10 s) fluorenyl quinone methide **9**, which is trappable by ethyl vinyl ether via a [4+2] cycloaddition reaction to give a chroman derivative. Interestingly, 2-hydroxy-9-fluorenol (**5**) photosolvolyzes via a very short-lived intermediate with similar lifetimes as observed for the 9-fluorenyl cation (**1**, R = H), although a corresponding fluorenyl quinone methide intermediate is accessible for this compound. This study demonstrates that the mechanism of photosolvolysis of these types of compounds can be dramatically altered when an aryl hydroxy group is present.

Key words: photosolvolysis, 9-fluorenyl cation, quinone methide, carbocation, antiaromatic.

Résumé : Opérant en solution aqueuse, on a étudié la photosolvolyse des 1- et 2-hydroxy-9-fluorénols (**4**–**6**). Tous ces 9-fluorénols se photosolvolysent d'une façon efficace dans un mélange 1:1 H_2O–CH_3OH; ils conduisent aux éthers méthyliques correspondants avec des rendements chimiques et quantiques élevés. Alors qu'il est bien connu que la photosolvolyse du 9-fluorénol parent (**2**, R = H) se fait par le biais du cation 9-fluorényle (**1**, R = H) qui est formellement un état fondamental antiaromatique de temps de vie très court, la photosolvolyse du 1-hydroxy-9-fluorénol (**4**) se fait par le biais d'un méthide de quinone du fluorényle (**9**) de temps de vie beaucoup plus long (environ 5–10 s) que l'on peut piéger par l'oxyde d'éthyle et de vinyle, par une réaction de cycloaddition [4+2], qui fournit un dérivé chromane. Il est intéressant de noter que le 2-hydroxy-9-fluorénol (**5**) se photosolvolyse par le biais d'un intermédiaire de temps de vie très court, semblable à celui observé pour le cation 9-fluorényle (**1**, R = H) même si l'intermédiaire méthide de quinone de fluorényle correspondant est accessible pour ce composé. Cette étude démontre que le mécanisme de photosolvolyse de ces types de composés peut être dramatiquement modifié lorsqu'un groupe hydroxyaryle est présent.

Mots clés : photosolvolyse, cation 9-fluorényle, méthide de quinone, carbocation, antiaromatique.

[Traduit par la Rédaction]

Introduction

Our first report and subsequent mechanistic studies (1) of the efficient *photo*generation of the *formally* antiaromatic 9-fluorenyl cations (**1**) from 9-fluorenol derivatives (**2**) (eq. [1]) in aqueous solution resulted in renewed interest in the study of the dynamics of highly reactive carbocations of this type (2). Using laser flash photolysis (LFP), it is now established (2*a*) that the lifetime of the parent 9-fluorenyl cation (**1**, R = H) is very short in aqueous solution, in the order of 20 ps, consistent with its destabilized nature, although recent calculations indicate that it is probably not antiaromatic (3). Lifetimes can be extended considerably (to the microsecond range) in the non-nucleophilic but polar 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) (2*b*, *c*).

More recently, we have reported on the photosolvolytic reactivity of hydroxy-substituted benzyl alcohols in aqueous solution and found that for the *o*- and *p*-substituted isomers, long-lived ($\tau >> 10^{-3}$ s) *o*- and *p*-quinone methides (QMs) were efficiently formed (eq. [2]), which are responsible for the observed photosolvolysis of these compounds (4).[3] These results

[2] 
o-QM

indicate that an aromatic hydroxy group can readily alter the photosolvolytic mechanism of benzyl derivatives. We therefore embarked on a study of the photosolvolysis of readily available hydroxy-9-fluorenols **4**–**6**, to investigate the possibility that a similar change in photosolvolytic mechanism can occur for these compounds and whether the corresponding longer-lived fluorenyl-type QMs are formed as intermediates. Such information would be useful in light of the interest in the photosolvolysis of these types of compounds.

6 R = Ph

Results and discussion

Materials

The hydroxy-9-fluorenols **4** and **5** were readily made from a $NaBH_4$ reduction of the corresponding hydroxy-9-fluorenone, which are known compounds. Treatment of 2-hydroxy-9-fluorenone with phenyl magnesium bromide afforded **6**. A new and more versatile method for the synthesis of 1-hydroxy-9-fluorenone was employed, which was based on remote metalation/Suzuki cross coupling methodology developed by Snieckus and co-workers (5).

Product studies

Photolysis of **4**–**6** (argon purged; ~10^{-3} M; 1:1(v/v) H_2O–CH_3OH; RPR-100 photochemical reactor; ~15°C) gave the corresponding methyl ether (e.g., **7**) in high yield in low-conversion experiments (<30%) (e.g., eq. [3]). Control experiments

[3] 
4 **7** **8**

showed no reaction in the absence of irradiation. High-conversion experiments for **4** resulted in formation of low yields of a secondary photoreduction product **8**, which is believed to arise via homolysis of the C-OMe bond (1*b*). Quantum yields for methyl ether formation (Φ_p) for **4**–**6** were determined relative to that of the parent **2** (Φ_p = 0.14 (1*b*)) using ^{1}H NMR. Fluorenols **4** and **5** gave significantly higher Φ_p (Φ_p = 0.48 and 0.24, respectively) compared to the parent **2**, suggesting that both *o*- and *m*-hydroxy substituents aid the photosolvolysis reaction. The presence of a phenyl group at the 9-position in fluorenol **6** further increased the quantum efficiency (Φ_p = 0.44).

We have previously shown that photogenerated *o*-QMs from *o*-hydroxybenzyl alcohols (4)[3] are readily trappable by ethyl vinyl ether (EVE) and other alkoxy alkenes in a [4+2] cycloaddition reaction, to give chroman derivatives. To test for the possibility that the photosolvolysis of **4** might be proceeding via an *o*-QM intermediate (i.e., **9**), photolysis was carried out in the presence of EVE (0.2 M in 3:7 H_2O–CH_3CN), which gave predominantly the *cis*-chroman **10a** (>70% yield), consistent with *endo* attack of EVE on the *o*-QM **9** (eq. [4]). The high diastereoselectivity of this reaction as well as its high efficiency are consistent with a concerted cycloaddition mechanism involving *o*-QM rather than a stepwise mechanism involving a carbocation (4).[3] Attempts to purify *cis*-**10a** on silica gel resulted in substantial isomerization to *trans*-**10b**, presumably via acid-catalyzed epimerization of the acetal carbon. Molecular models of *cis*-**10a** and *trans*-**10b** show that only the former has a

[4]

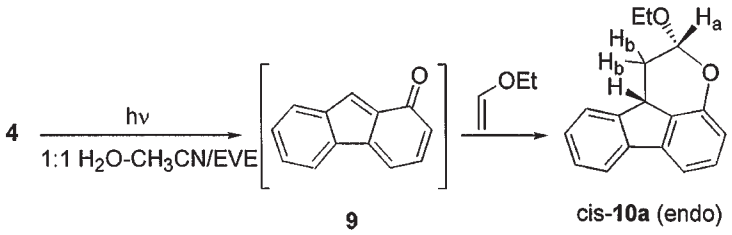

Fig. 1. Absorption spectra of transients generated in neat H_2O via LFP of **4**, monitored ~3 μs after the laser pulse (the insert is a decay measured at pH 1 with τ = (125 ± 2) μs, monitored ~80 ns after the laser pulse).

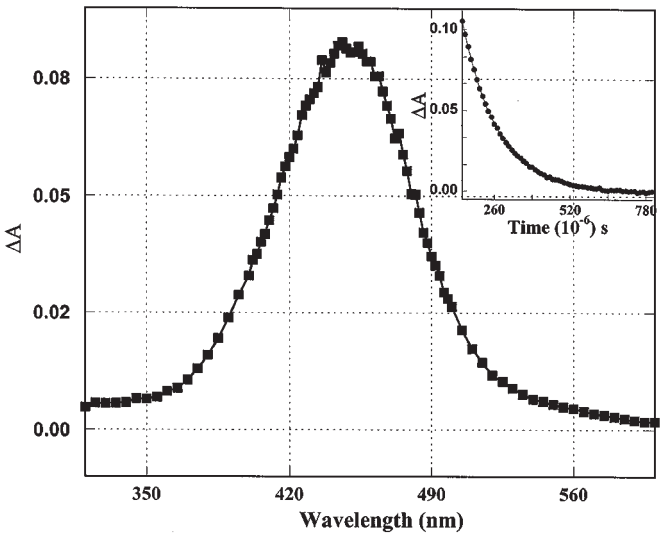
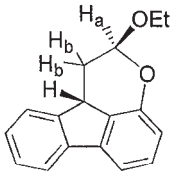


dihedral angle approaching 180° between H_a and one of the H_b protons. Therefore, the *cis*-**10a** adduct was assigned, based on a larger coupling constant observed for H_a coupling with H_b (*cis*-**10a**: δ 5.67 (dd, *J* = 9.6, 3.0 Hz); *trans*-**10b**: δ 5.51 (dd, *J* = 3.0, 1.5 Hz)). Both isomers are susceptible to hydrolysis leading to the aldehyde **10c**.

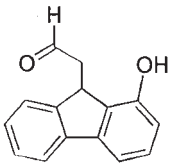
Laser flash photolysis

Laser flash photolysis (LFP) of **4** (266 nm; YAG laser; <35 mJ; 20°C) in neat H_2O resulted in a strongly absorbing and very long-lived transient (τ > > 1 ms, λ_{max} = 450 nm) (Fig. 1), similar to that reported previously for other QMs (4).[3] A lifetime of about 5–10 s was measured using a standard spectrophotometer in aqueous CH_3CN. This long lifetime implies an *o*-QM intermediate (i.e., **9**) rather than a carbocation. This same transient was produced in water throughout the pH 1–12 range. Also, relative quantum yields (as measured by monitoring absorbance change at 450 nm for production of *o*-QM **9**) showed no dependence on pH within this range. However, the lifetime decreased at low pH consistent with acid quenching of the *o*-QM and was eventually measurable by LFP at pH 1 (τ = (125 ± 2) μs).

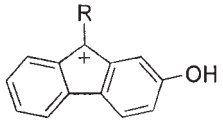
LFP of **5** yielded no observable transient in aqueous solution. This suggested possible formation of the carbocation **11**, which would be too short-lived for detection. To confirm this, we used the solvent HFIP, since McClelland and coworkers (2*b*, *c*) were able to observe a large number of short-lived carbocations including 9-fluorenyl cations in this polar yet weakly nucleophilic solvent. The resulting transient spectrum observed for **5** was similar to that previously reported for **1** generated from the parent **2** in HFIP (λ_{max} = 515 nm) (2*b*). Transient lifetimes measured for **1** (R = H) and the proposed **11** in the same HFIP solvent (lifetimes can vary significantly according to the amount of trace water present in HFIP (2*b*)) were similar (~2 μs), which supports that **5** generates the carbocation **11** rather than the *m*-QM which would be longer lived. It is unlikely that the transient is the radical cation, since the radical cation of **2** has been reported as absorbing at 395, 595, and 645 nm and shown to have a complex decay with lifetimes in the microsecond range in aqueous solution (2*b*). Our transient shows simple first exponential decay with a short lifetime in aqueous solution. This would be consistent with a carbocation, since the parent fluorenyl cation **1** (R = H) has been shown to have a lifetime of less than 20 ps in 9:1 H_2O:CH_3OH (2*a*).



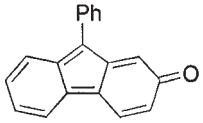
trans-**10b** (exo)



10c



11 R = H
12 R = Ph



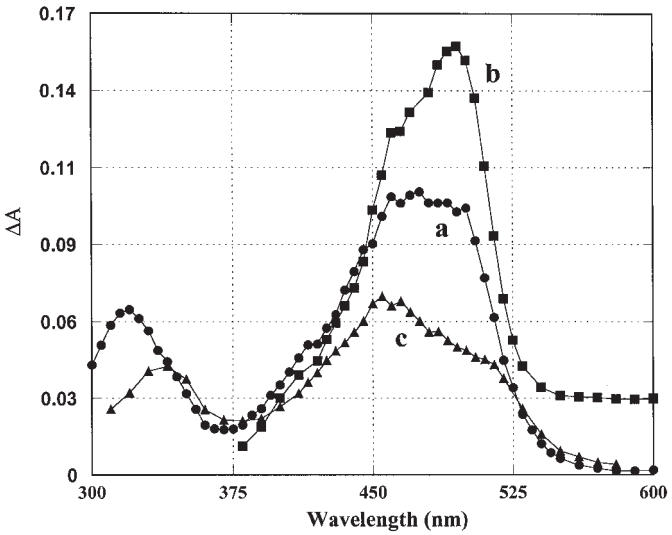
13

To study the kinetics of decay of **11** in aqueous solution, a phenyl group at position 9 was added (i.e., compound **6**). LFP of **6** resulted in a transient absorbing broadly at 480 nm with a lifetime of 47.0 ± 0.4 ns in 100% water (Fig. 2). For comparison, LFP of **3**, whose transient was assigned as the carbocation, gave λ_{max} = 355, 490 nm with τ = 66 ns in 1:4 CH_3CN:H_2O (6). The lifetime observed for **3** in 1:4 CH_3CN:H_2O is comparable to ours in 100% H_2O. Hence, we assign this transient as **12**. An additional absorption band observed at 320 nm (τ = 0.54 μs) is probably due mostly to the radical cation, although a shorter lived component due to a shorter wavelength band of **12** cannot be excluded. As was observed for **3**, the radical cation (weak absorption at 380 nm) can arise from photoionization within the laser pulse (6).

Transient spectra of **12** were taken as a function of pH. At pHs 1 and 7, the single-exponential decay rates were similar,

© 1999 NRC Canada

Fig. 2. Absorption spectra of transients generated via LFP of **6** at pH 6–7 (*a*), 1 (*b*), and 12 (*c*), monitored ~0.1–1 μs after the laser pulse.



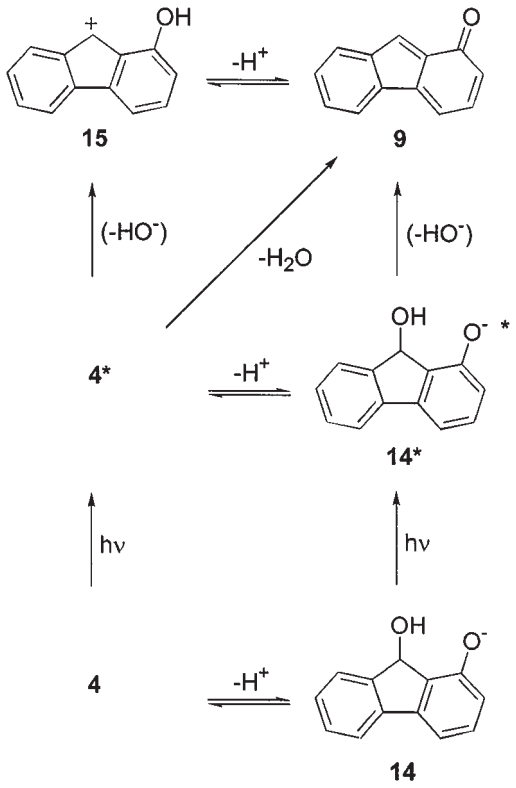
which is consistent with a carbocation whose lifetime would be unaffected by acid. At pH 12, the spectral shape changed considerably (Fig. 2), and its decay was best fitted to the sum of two single exponentials (i.e., two species absorbing in the same region each undergoing single exponential decay). The long lifetime ((0.27 ± 0.03) μs) of the major component (~80%) suggests that *m*-QM **13** rather than carbocation **12** is produced under basic conditions. The minor component (τ = 0.60 μs) is probably due to the aryoxyl radical. At pH 13.7, a similar spectrum and decay were observed as at pH 12. *m*-QM **13** may also be present to a small extent even at pH 7 (pK_a of the ArOH moiety of **12** is probably significant less than 10, due to the electron-withdrawing effect of the positive charge) around since the spectral bandshape observed here is not identical to that observed at pH 1. However, the decay can be fitted to a single exponential. Slight variations in bandshapes may be due to the function of other minor transients that cannot be resolved in the kinetic analysis.

Mechanism of photosolvolysis

Although all of **4**–**6** photosolvolyze efficiently in aqueous solution, as shown by the high quantum yields for methyl ether formation measured in 1:1 H_2O–CH_3OH, it is clear that substantial differences exist with respect to their mechanism of photosolvolysis. The mechanism of photosolvolysis of **2** and **3** is now understood (1) to involve simple heterolytic C—OH bond cleavage from the singlet excited state, to give the corresponding 9-fluorenyl cations **1**. The driving force for forming fluorenyl cations **1** is believed to be due to an inherently stabilized cyclically conjugated 4*n*π system in the excited state (1). Although this driving force is inherent in all of **2**–**6**, the presence of a potentially electron-donating hydroxy substituent, which can also deprotonate in both the ground and excited states, results in the observed complexity in mechanistic behaviour.

It would appear that the observed quantum yields for methyl ether formation measured for **4** and **5** are consistent

Scheme 1.



with the simple heterolytic C—OH cleavage mechanism. Based on Zimmerman's "*ortho-meta*" effect (7), compounds **4** and **5**, which have an *ortho* and a *meta* hydroxy substituent, respectively (relative to the benzylic centre), would both be expected to be more reactive with respect to cleavage of the C—OH bond compared to the parent **2**. Indeed, quantum yields for methyl ether formation for **4** (0.48) and **5** (0.24) are significantly higher than that observed for **2** (0.14), with the "*ortho*" compound **4** having the highest quantum yield. However, LFP results do not support this simple mechanistic view. Rather, LFP results indicate that only **5** and **6** (at pH 7) react via initial C—OH bond heterolysis, to give the corresponding 9-fluorenyl cations **11** and **12** as primary intermediates. The high reactivity of **11** with solvent is such that deprotonation of the phenol proton does not compete whereas the lower reactivity of **12** allows for competition by deprotonation, which gives rise to QM **13**. Indeed, only **13** is generated on direct photolysis of the phenolate of **6**. The formation of the *m*-QM is also expected upon excitation of the phenolate of **5**; however, it was not observable in aqueous basic solution in our experiments. Based on recent work from our group on analogous systems (4*a*), its predicted lifetime in aqueous solution would be below the detection limit of our ns–LFP system.

LFP results for **4** indicate that *o*-QM **9** is observed at all pHs. Three possible pathways may be envisoned for its formation (Scheme 1): (*i*) adiabatic deprotonation of the phenol proton of **4*** to give **14*** followed by loss of hydroxide ion to give **9** (this pathway is identical to that proposed for the photochemistry of hydroxybenzyl alcohols which give rise to QMs (4)[3]); (*ii*) C—OH bond heterolysis to give initially 9-fluorenyl cation **15** followed by deprotonation of the phe-

© 1999 NRC Canada

nol; (*iii*) concerted loss of H_2O from **4*** directly giving **9**. If mechanism (*i*) were operative, it would be difficult to envisage why such a mechanism cannot also operate for **5** and **6**. Mechanism (*ii*) should also be equally applicable to 9-fluorenyl cations **11** and **12**. Thus, the most reasonable mechanism for **4** is a concerted but probably not synchronous loss of water from **4***. This is reasonable considering that both the hydroxy group and the phenolic proton are labile in the excited state, and their close proximity would promote a concerted process. Such a mechanism cannot operate for either **5** or **6**, since the hydroxy group and the phenolic proton are too far apart; therefore, only C—OH cleavage can occur below pH 10. In addition, this pathway would also be consistent with the lack of a pH dependence in the 1–7 range where one would have been expected if deprotonation were required first. No increase in quantum yield for **4** was observed in the 8–12 range, which suggests that excitation of the phenolate results in no further enhancement in QM formation, indicating that the process at lower pH is as efficient.

Experimental section

General

^{1}H NMR spectra were recorded on a Bruker AC-300 (300 MHz) instrument. UV-vis spectra were obtained using a Philips PU 8740 UV-vis scanning spectrophotometer, and the fluorescence spectra were taken on a Photon Technology International A-1010 (PTI) QuantaMaster™ luminescence spectrometer. High-resolution mass spectra were obtained on a Kratos Concept H (EI) instrument and the uncorrected melting points on a Koefler hot stage microscope. IR spectra were recorded on a Bruker IFS25 FTIR spectrometer using a KBr pellet. Photolyses were carried out in 100 mL quartz tubes using a Rayonet RPR 100 photochemical reactor. THF was dried over K and distilled before use.

Materials

2-Hydroxy-9-fluorenone was purchased from Aldrich Chemical Co. 1-Hydroxy-9-fluorenol (**4**) was synthesized according to the multi-step procedure described below.

*2-(*N,N-*diisopropylcarboxamido)phenylboronic acid*

A solution of *N*,*N*-diisopropyl benzamide (6.15 g, 30.0 mmol) in anhydrous THF (30 mL), was added dropwise to a solution of *s*-BuLi (26.8 mL of 1.23 M solution, 33.0 mmol) and *N*,*N*,*N*,*N*-tetramethylethylenediamine (TMEDA) (4.87 mL, 33 mmol) in THF (90 mL) at –78°C. The resulting mixture was stirred at –78°C for 1 h, and $B(OMe)_3$ (7.07 mL, 60.0 mmol) was added dropwise by syringe, then slowly warmed to room temperature over 4 h. Saturated aqueous NH_4Cl was added and THF was removed in vacuo. The residue was subjected to standard work-up (addition of water, extraction with CH_2Cl_2, washing of the organic with saturated brine solution, drying (Na_2SO_4), filtration, and evaporation to dryness in vacuo) to afford the crude product, which was directly used for the cross coupling reaction without purification.

N,N-*Diisopropyl-3′-methoxybiphenyl-2-carboxamide*

A mixture of $Pd(PPh_3)_4$ (0.342 g, 0.296 mmol) and 3-bromoanisole (1.85 g, 9.9 mmol) in dimethoxyethane (45 mL) was stirred at room temperature for 5 min. To this mixture was added dropwise in sequence a solution of 2-(*N*,*N*-diisopropylcarboxamido)phenylboronic acid (3.45 g, 13.8 mmol) in EtOH (7 mL) and a 2 M aqueous Na_2CO_3 solution (7 mL). The resulting mixture was heated to reflux for 12 h, cooled down to room temperature, and the catalyst was removed by filtration. The filtrate was evaporated to dryness. Standard work-up followed by flash chromatography afforded the coupled product (2.61 g, 85%); mp 81–82°C (hexane–EtOAc); IR ($CHCl_3$) (cm^{-1}): 1619; ^{1}H NMR ($CHCl_3$) δ 7.1–7.26 (m, 5H), 7.14–7.08 (m, 2H), 6.88 (ddd, *J* = 8.1, 2.4, 1.0 Hz, 1H), 3.82 (s, 3H), 3.43 (sept, *J* = 6.6 Hz, 1H), 3.23 (sept, *J* = 6.8 Hz, 1H), 1.52 (d, *J* = 6.8 Hz, 3H), 1.29 (d, *J* = 6.8 Hz, 3H), 0.90 (d, *J* = 6.6 Hz, 3H), 0.40 (d, *J* = 6.6 Hz, 3H); MS *m*/*z* (rel. intensity): 311 (M^+, 48), 268 (10), 211 (100), 168 (40).

1-Methoxyfluorenone

To a solution of LDA (4.0 mmol) in THF (10 mL) was added a solution of *N*,*N*-Diisopropyl 3′-methoxybiphenyl-2-carboxamide (0.566 g, 2.0 mmol) in THF (2 mL) at 0°C. The resulting mixture was stirred at room temperature for 10 h to give a purple color. A saturated solution of NH_4Cl was added and THF was removed in vacuo. The residue was extracted with CH_2Cl_2. Standard work-up followed by flash chromatography afforded the product (0.387 g, 92%); mp 140–142°C (EtOH) (lit. (8*a*, *b*) 142–143°C); IR ($CHCl_3$) (cm^{-1}): 1699; ^{1}H NMR ($CHCl_3$) δ: 7.59 (dd, *J* = 7.3, 0.7 Hz, 1H), 7.45–7.37 (m, 3H), 7.25 (td, *J* = 7.3, 2.2 Hz, 1H), 6.98 (d, *J* = 7.3 Hz, 1H), 6.80 (d, *J* = 8.5 Hz, 1H), 3.85 (s, 3H); ^{13}C NMR ($CDCl_3$) δ: 191.8, 158.2, 146.4, 143.1, 136.7, 134.4, 133.8, 129.1, 123.8, 120.1, 113.0, 112.8, 55.8.

1-Hydroxy-9-fluorenone

To a solution of 1-methoxyfluorenone (0.120 g, 0.57 mmol) in CH_2Cl_2 (5 mL), BBr_3 (0.1 mL, 0.85 mmol) was added dropwise at –78°C. The mixture was slowly warmed up to room temperature and stirred for 12 h. Standard work-up followed by flash chromatography afforded the product (0.106 g, 95%); mp 115–117°C (EtOH) (lit. (8*a*–*c*) 117–118°C); IR ($CHCl_3$) (cm^{-1}): 3407, 1688; ^{1}H NMR ($CHCl_3$) δ: 8.41 (s, 1H, OH), 7.59 (d, *J* = 7.3 Hz, 1H), 7.46–7.22 (m, 4H), 6.98 (d, *J* = 7.2 Hz, 1H), 6.73 (d, *J* = 8.4 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ: 196.3, 157.3, 144.1, 137.4, 134.2, 129.0, 124.0, 121.0, 118.1, 117.4, 112.8.

*1-Hydroxy-9-fluorenol (**4**)*

To a stirred solution of 1-hydroxy-9-fluorenone (0.50 g, 2.5 mmol) in 95% EtOH (30 mL) in an ice bath, a solution of $NaBH_4$ (0.29 g, 7.7 mmol) in 95% EtOH was added dropwise. After stirring for 1 h at room temperature, the mixture was heated at 30–35°C for 2 h. Work-up (addition of NH_4Cl, extraction with CH_2Cl_2, drying with $MgSO_4$, filtration, and evaporation to dryness in vacuo) yielded **4** quantitatively. Recrystallization with a two-solvent system of Et_2O and hexanes gave a white solid; mp 152–153 °C; IR (cm^{-1}): 3450 (broad), 3161(very broad); ^{1}H NMR ($(CD_3)_2CO$) δ: 4.50 (s, 1H, OH), 5.76 (s, 1H, Ar_2CH), 6.76

© 1999 NRC Canada

(dd, *J* = 6.5, 2.5 Hz, 1H, arom.), 7.19–7.39 (m, 4H, arom.), 7.59 (d, *J* = 7.4 Hz, 1H, arom.), 7.68 (d, *J* = 7.4 Hz, 1H, arom.), 8.09 (s, 1H, OH); HRMS calcd. for $C_{13}H_{10}O_2$: 198.0681; observed: 198.0679.

*2-Hydroxy-9-fluorenol (**5**)*

To a stirred solution of 2-hydroxy-9-fluorenone (1.50 g, 7.6 mmol) in 95% EtOH (150 mL) in an ice bath, $NaBH_4$ (2.31 g, 61.1 mmol) in 95% EtOH (50 mL) was added dropwise. After stirring for 1 h, the reaction mixture was heated at ~40°C for 1 h. Work-up (addition of $NH_4OC(O)CH_3$, extraction with CH_2Cl_2, drying with $MgSO_4$, filtration, and evaporation to dryness in vacuo) yielded **5** quantitatively. Recrystallization with either toluene or ligroines gave a white solid; mp 193–194°C (lit. (9) 188–189°C); IR (cm^{-1}): 3387 (broad), 3136 (very broad); ^1H NMR ($(CD_3)_2CO$) δ: 4.68 (d, *J* = 7.7 Hz, 1H, OH), 5.47 (d, *J* = 7.7 Hz, 1H, Ar_2CH), 6.84 (dd, *J* = 8.2, 2.3 Hz, 1H, arom.), 7.12 (d, *J* = 2.3 Hz, 1H, arom.), 7.18 (t, *J* = 7.4 Hz, 1H, arom.), 7.29 (t, *J* = 7.4 Hz, 1H, arom.), 7.50–7.55 (m, 2H, arom.), 7.58 (d, *J* = 7.4 Hz, 1H, arom.), 8.54 (s, 1H, OH); HRMS calcd. for $C_{13}H_{10}O_2$: 198.0681; observed: 198.0679.

*2-Hydroxy-9-phenyl-9-fluorenol (**6**)*

The Grignard reagent was prepared by adding dropwise PhBr (43 mL, 0.41 mol) in THF (50 mL) to Mg (10 g, 0.41 mol) in THF (200 mL) under nitrogen. The reaction was initiated by adding an I_2 crystal and applying heat. An aliquot of the resulting PhMgBr (11 mL of the above solution, 15 mmol) was added dropwise via a syringe to a stirred solution of 2-hydroxy-9-fluorenone (1.00 g, 5.10 mmol) dissolved in THF (100 mL) under nitrogen. The reaction was stirred for 1 h and refluxed for 1 h. Work-up (addition of NH_4Cl, extraction with CH_2Cl_2, drying with $MgSO_4$, filtration, and evaporation to dryness in vacuo) yielded ~84% of **6**. Recrystallization with $CHCl_3$ gave a white solid; mp 181–182°C; IR (cm^{-1}): 3369 (broad), 3193 (very broad); ^1H NMR ($(CD_3)_2CO$) δ: 5.10 (s, 1H, OH), 6.77 (d, *J* = 2.4 Hz, 1H, arom.), 6.83 (dd, *J* = 8.2, 2.4 Hz, 1H, arom.), 7.07–7.38 (m, 8H, arom.), 7.59 (d, *J* = 8.2 Hz, 1H, arom.), 7.62 (d, *J* = 7.3 Hz, 1H, arom.), 8.50 (s, 1H, OH); HRMS calcd. for $C_{19}H_{14}O_2$: 274.0994; observed: 274.0992.

Product studies

In a typical photolysis, ~10^{-3} M of substrate in 1:1 (v/v) H_2O–CH_3OH (100 mL) was purged with argon for 15 min before and during irradiation at 254 nm in a Rayonet RPR-100 photochemical reactor equipped with a cooling finger (~15°C). After photolysis, work-up involved extraction with CH_2Cl_2 and drying with $MgSO_4$. The conversion to product was calculated by ^1H NMR. The product quantum yields (Φ_p) were measured relative to that of the parent **2**, using the same number of moles and irradiation times (4 lamps, 1.5 or 3 min). The percent conversion was kept ≤30% to minimize production of the secondary product, the fluorene derivative (≤3%). After isolation by preparative silica gel TLC (solvent: 10% ethyl acetate in CH_2Cl_2), the methyl ether product was characterized by ^1H NMR and HRMS.

*Photolysis of **4***

Photolysis of **4** in 1:1 H_2O–CH_3OH (~10^{-3} M, 1.5 min, 4 lamps, 254 nm) led to 30% methyl ether product and 3% fluorene product. Extended irradiation (2 min, 8 lamps) yielded 51 and 9%, respectively. Methyl ether product: ^1H NMR ($(CD_3)_2CO$) δ: 3.03 (s, 3H, OCH_3), 5.85 (s, 1H, Ar_2CH), 6.12 (s, 1H, OH), 6.81 (d, *J* = 7.6 Hz, 1H, arom.), 7.21–7.43 (m, 4H, arom.), 7.58 (d, *J* = 7.4 Hz, 1H, arom.), 7.65 (d, *J* = 7.4 Hz, 1H, arom.); HRMS calcd. for $C_{14}H_{12}O_2$: 212.0838; observed: 212.0836.

Photolysis of **4** in 3:7 H_2O–CH_3CN (~10^{-3} M, 10 min, 16 lamps, 254 nm) was also carried out in the presence of ethyl vinyl ether (2 mL, 0.2 M). The [4+2] cycloaddition resulted in 73% *endo* adduct (*cis*-**10a**), 8% *exo* adduct (*trans*-**10b**) and 19% hydrolysis product (**10c**). On silica gel (mild acidic conditions), the *cis*-**10a** rearranged to *trans*-**10b** and more of **10c** formed. Silica preparative TLC with CH_2Cl_2:hexanes as solvent was used to isolate all products; *cis*-**10a**: ^1H NMR ($CDCl_3$) δ: 1.31 (t, *J* = 7.0 Hz, 3H, CH_3CH_2), 1.49–1.60 (m, 1H, H_b), 2.76–2.83 (m, 1H, H_b), 3.69–3.80 (m, 1H, CH_3CH_2), 3.93 (dd, *J* = 5.0, 13.0 Hz, 1H, Ar_2CH), 4.07–4.19 (m, 1H, CH_3CH_2), 5.67 (dd, *J* = 9.6 Hz, 3.0 Hz, 1H, H_a), 6.76 (m, 1H, arom.), 7.23–7.32 (m, 3H, arom.), 7.38 (tm, *J* = 7.6 Hz, 1H, arom.), 7.51 (dm, *J* = 7.6 Hz, 1H, arom.), 7.74 (dm, *J* = 7.6 Hz, 1H, arom.); HRMS calcd. for $C_{17}H_{16}O_2$: 252.1151; observed: 252.1144; *trans*-**10b**: ^1H NMR ($CDCl_3$) δ: 1.27 (t, *J* = 7.4 Hz, 1H, CH_3CH_2), 1.38–1.58 (m, 1H, H_b), 2.71 (ddd, *J* = 13.0, 5.2, 1.5 Hz, 1H, H_b), 3.68–3.82 (m, 1H, CH_3CH_2), 4.02–4.18 (m, 2H, CH_3CH_2, Ar_2CH), 5.51 (dd, *J* = 3.0, 1.5 Hz, 1H, H_a), 6.74 (dd, *J* = 7.5, 1.5 Hz, 1H, arom.), 7.16–7.41 (m, 4H, arom.), 7.52 (d, *J* = 7.5 Hz, 1H, arom.), 7.74 (d, *J* = 7.5 Hz, 1H, arom.); HRMS calcd for $C_{17}H_{16}O_2$: 252.1151; observed: 252.1146; **10c**: ^1H NMR ($CDCl_3$) δ: 3.03 (dd, *J* = 19.2, 7.6 Hz, 1H, $C(O)CH_2$), 3.25 (dd, *J* = 19.2, 4.2 Hz, 1H, $C(O)CH_2$), 4.46 (dd, *J* = 7.6, 4.2 Hz, 1H, Ar_2CH), 5.24 (s, 1H, OH), 6.62–6.79 (m, 2H, arom.), 7.18–7.42 (m, 3H, arom.), 7.45 (d, *J* = 7.2 Hz, 1H, arom.), 7.71 (d, *J* = 7.2 Hz, 1H, arom.), 9.84 (s, 1H, C(O)H); HRMS calcd. for $C_{15}H_{12}O_2$: 224.0838; observed: 224.0838. ^1H COSY NMR was used above to show the correlations between signals.

*Photolysis of **5***

Photolysis of **5** in 1:1 H_2O–CH_3OH (~10^{-3} M, 3 min, 4 lamps, 254 nm) led to 27% methyl ether product and 3% fluorene product. Upon extended photolysis (15 min, 16 lamps), the methyl ether product led to a large amount of the secondary fluorene product (17 and 46%, respectively). ^1H NMR ($CDCl_3$) δ: 3.07 (s, 3H, OCH_3), 5.45 (s, 1H, Ar_2CH), 6.89 (dd, *J* = 8.2, 2.3 Hz, 1H, arom.), 7.07 (d, *J* = 2.3 Hz, 1H, arom.), 7.22 (t, *J* = 7.5 Hz, 1H, arom.), 7.35 (t, *J* = 7.5 Hz, 1H, arom.), 7.51 (d, *J* = 7.5 Hz, 1H, arom.), 7.59 (d, *J* = 8.2 Hz, 1H, arom.), 7.62 (d, *J* = 7.5 Hz, 1H, arom.), 8.58 (s, 1H, OH); HRMS calcd. for $C_{14}H_{12}O_2$: 212.0838; observed: 212.0835.

*Photolysis of **6***

Photolysis of **6** in 1:1 H_2O–CH_3OH (~10^{-3} M, 1.5 min, 4 lamps, 254 nm) led to 28% methyl ether product. Also upon extended photolysis (2 min, 8 lamps), the methyl ether product led to some secondary fluorene product (53 and 8%, re-

© 1999 NRC Canada

spectively). An even longer irradiation time (15 min, 16 lamps) resulted in 2 and 84%, respectively. ^{1}H NMR ($(CD_3)_2CO$) δ: 2.91 (s, 3H, OCH_3), 6.70 (d, J = 2.3 Hz, 1H, arom.), 6.89 (dd, J = 8.2, 2.3 Hz, 1H, arom.), 7.13–7.38 (m, 8H, arom.), 7.65 (d, J = 8.2 Hz, 1H, arom.), 7.68 (d, J = 7.3 Hz, 1H, arom.), 8.55 (s, 1H, OH); HRMS (EI) calcd. for $C_{20}H_{16}O_2$: 288.1151; observed: 288.1153.

Laser flash photolysis (LFP)

All transient spectra and lifetimes were obtained using a Nd:YAG laser (Spectra Physics Quanta-Ray GCR-12, <30 mJ) with pulse width of ~10 ns and excitation wavelength of 266 nm. Signals were digitized with a Tektronix TDS 520 recorder. Samples were prepared with OD ≈ 0.3 at 266 nm. Static cells were used for the solvent HFIP, otherwise flow cells for the aqueous solutions. The solutions were purged with oxygen for ~10 min before excitation.

Summary

New insights into the mechanism of photosolvolysis of 9-fluorenols have been obtained by studying simple hydroxy-substituted derivatives whose mechanism of photosolvolysis is more complex than that of the parent compounds. Although the parent 9-fluorenol system is intrinsically highly reactive towards photosolvolysis, we have shown that the quantum efficiency can be further enhanced by hydroxy substitution, *ortho* and *meta* to the benzylic position. It is proposed that the mechanism for **5** and **6** at neutral pH involves simple C–OH heterolysis, to generate the corresponding 9-fluorenyl cations, which in the case of **12**, can form the *m*-QM **13** via deprotonation. The mechanism for **4** probably involves a concerted loss of water to give *o*-QM **9** in one step from the singlet excited state. The structural rigidity and planarity inherent in fluorenyl quinone methides of this type may be useful as photogenerated electrophiles for use in biological systems.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for supporting this research in the form of research grants (to P.W. and V.S.) and a post-graduate scholarship (to M.F.). We also thank L. Diao for some lifetime measurements.

Ab initio test of the usefulness of the Redlich–Teller product rule in computing kinetic isotope effects

L.J. Schaad, Laimutis Bytautas, and K.N. Houk

Abstract: It has been known since the early work of Bigeleisen that incorporating the Redlich–Teller product rule into isotope-effect equations minimizes the importance of low-frequency vibrations. Similar analysis suggests that errors in low frequencies especially are minimized by the use of the Redlich–Teller rule, though its use improves accuracy at all frequencies. However, in the computation of isotope effects, cancellation between isotopomers caused this advantage to vanish exactly in the case of diatomic reactants or products. It does not do so for all polyatomics, and computational experiments again show use of the Redlich–Teller rule to be preferred.

Key words: isotope effect, Bigeleisen equation, Redlich–Teller product rule, formamide, *Z*-1,3-pentadiene.

Résumé : On sait depuis les travaux originaux de Bigeleisen que l'incorporation de la règle du produit de Redlich–Teller dans les équations d'effets isotopiques minimise l'importance des vibrations de basse fréquence. Une analyse similaire suggère que les erreurs dans les basses fréquences sont particulièrement minimisées par l'utilisation de la règle de Redlich–Teller, même si son utilisation améliore la précision à toutes les fréquences. Toutefois, dans le calcul des effets isotopiques, une annulation entre isotopomères a fait disparaître complètement cet avantage dans le cas de réactifs ou des produits diatomiques. Ce n'est toutefois pas le cas pour tous les produits polyatomiques et les expériences de calcul montrent à nouveau que l'utilisation de la règle de Redlich–Teller est préférable.

Mots clés : effet isotopique, équation de Bigeleisen, règle de produit de Redlich–Teller, formamide; *Z*-penta-1,3-diène.

[Traduit par la Rédaction]

Introduction

In a study of secondary kinetic isotope effects (KIEs) in the internal rotation of formamide (1), small differences were found between KIEs computed using eqs. [1]–[3] and using Bigeleisen's (2) modification, eq. [4].

[1] $\mathrm{KIE} = k_H/k_D = \mathrm{MMI} \times \mathrm{VIB}$

The factors in eq. [1] are

[2] $$\mathrm{MMI} = \left(\frac{M_H^{\ddagger} M_D}{M_D^{\ddagger} M_H}\right)^{3/2} \left(\frac{I_{H1}^{\ddagger} I_{H2}^{\ddagger} I_{H3}^{\ddagger} I_{D1} I_{D2} I_{D3}}{I_{D1}^{\ddagger} I_{D2}^{\ddagger} I_{D3}^{\ddagger} I_{H1} I_{H2} I_{H3}}\right)^{1/2}$$

[3] $$\mathrm{VIB} = \left(\prod_{i=1}^{3N^{\ddagger}-7} \frac{e^{u_i^{\ddagger}(D)/2} - e^{-u_i^{\ddagger}(D)/2}}{e^{u_i^{\ddagger}(H)/2} - e^{-u_i^{\ddagger}(H)/2}}\right)\left(\prod_{i=1}^{3N-6} \frac{e^{u_i(H)/2} - e^{-u_i(H)/2}}{e^{u_i(D)/2} - e^{-u_i(D)/2}}\right)$$

and I_1, I_2, I_3 are the principal moments of inertia, M is the total mass of the system, $u_i = h\nu_i/kT$ where ν_i is the vibrational frequency of ith normal mode, h is Planck's, and k is Boltzmann's constant. Bigeleisen incorporated the Redlich–Teller product rule (3) to give

[4] $$\mathrm{KIE} = \left(\frac{\nu_H^*}{\nu_D^*}\right)\left(\prod_{i=1}^{3N^{\ddagger}-7} \frac{\nu_{Hi}^{\ddagger}}{\nu_{Di}^{\ddagger}}\right)\left(\prod_{i=1}^{3N-6} \frac{\nu_{Di}}{\nu_{Hi}}\right) \times \mathrm{VIB}$$

where the first factor in eq. [4] is the ratio of imaginary frequencies in the transition structure.

With perfect computational accuracy, the two expressions must give identical KIEs, but with errors in computed frequencies or force constants, which gives the better result?

A preliminary analysis

The differences in computed KIEs (1) were traced back to small differences of 1–5 cm^{-1} in computed vibrational fre-

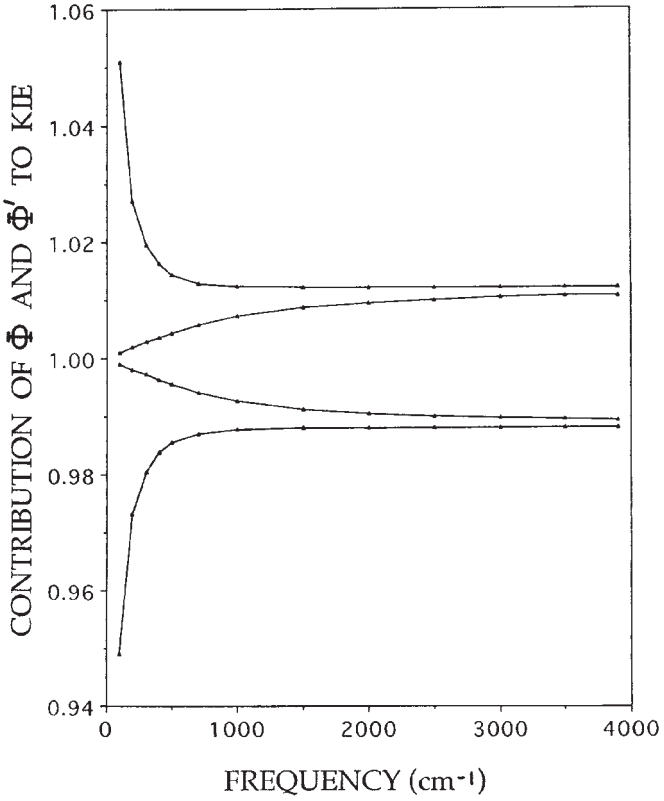
Fig. 1. The ratio of contribution to the isotope effect of frequency ν + Δν to that of frequency ν. The top two curves are for Δν = +5 cm^{-1} and the lower two for –5 cm^{-1}. The top and lowest curves show Φ of eq. [5], which does not use the Redlich–Teller product rule; the two middle curves show Φ′ of eq. [6], which does.



quencies. As Saunders et al. (4) point out, it has long been known that the Bigeleisen eq. [4] is less sensitive to low-frequency vibrations and hence is to be used if these are inaccurately known. To examine this in more detail, we begin by factoring out the contribution of a particular vibrational frequency ν of the H isotopomer of the reactant to the KIE computed from eq. [1]. Next imagine replacing ν by ν + Δν (i.e., a frequency in error by Δν) and factoring out its contribution to the modified KIE. Then dividing the contribution of the incorrect frequency by that of the correct gives the ratio

$$[5] \qquad \Phi(\nu + \Delta\nu) = \frac{e^{h(\nu+\Delta\nu)/2kT} - e^{-h(\nu+\Delta\nu)/2kT}}{e^{h\nu/2kT} - e^{-h\nu/2kT}}$$

In a similar way, one gets the contribution of frequency ν

$$[6] \qquad \Phi'(\nu + \Delta\nu) = \frac{\nu}{\nu + \Delta\nu}\Phi$$

to a KIE computed using using eq. [4] from the Redlich–Teller rule. Equations [5] and [6] are convenient to represent the error in KIE caused by an error Δν in the frequency ν, since multiplying the KIE computed using ν by Φ(ν + Δν) gives the KIE computed using ν + Δν. Equations [5] and [6] are for the H isotopomer of the reactant or for the D isotopomer of the TS. For the D isotopomer of the reactant or the H isotopomer of the TS, the reciprocals of Φ and Φ′ are used.

The factors Φ and Φ′ are shown in Fig. 1 with Δν = ±5 cm^{-1}. The most dramatic effect is, as expected, at low frequencies where eq. [5] goes to +∞ as ν goes to 0 for Δν = 5 cm^{-1} and –∞ for Δν = –5 cm^{-1}. Equation [6] approaches $(e^{h\Delta\nu/2kT} - e^{-h\Delta\nu/2kT})(kT/h\Delta\nu) = 1.000\,024$ at the same limit for both values of Δν. As ν → ∞, eqs. [5] and [6] both approach $e^{h\Delta\nu/2kT} = 1.012$ for Δν = 5 cm^{-1}. and 0.988 for Δν = –5 cm^{-1}. Since Φ′ is closer than Φ to 1 for all ν, it might appear that eq. [4] is obviously the better computational formula.

However, in computing isotope effects there may be error cancellation between the factors Φ or Φ′ for the H and D isotopomers. The errors in the numerator and denominator of these ratios are not independent, since the force constants in which the computational errors occur are the same for both isotopomers, while the masses vary from one to the other but are more accurately known. Consider any chemical reaction involving the diatomic AH as a reactant. Replace AH by the isotopomer AD, and consider the relative rates or equilibria of the two in this reaction. The single frequency of the two isotopomers contributes $\Phi'(\nu + \Delta\nu)_D/\Phi'(\nu + \Delta\nu)_H$ or $\Phi(\nu + \Delta\nu)_D/\Phi(\nu + \Delta\nu)_H$ to errors in relative rates or equilibria, depending upon whether or not one uses the Redlich–Teller formula [4]. From eq. [6], it is seen that these error contributions to the Φ and Φ′ ratios differ by a factor of

$$[7] \qquad \frac{\nu_D}{\nu_H} \times \frac{(\nu + \Delta\nu)_H}{(\nu + \Delta\nu)_D} = \left(\frac{k}{\mu_D} \times \frac{\mu_H}{k}\right)^{1/2} \left(\frac{k + \Delta k}{\mu_H} \times \frac{\mu_D}{k + \Delta k}\right)^{1/2} = 1$$

where the reduced masses $\mu_{H(D)} = m_A m_{H(D)}/(m_A + m_{H(D)})$. Therefore, in this special case, use of the Redlich–Teller product rule gives no better computed value of the isotope effect than do formulas [1]–[3].

In more complicated cases, reduced masses will not cancel in this way; and we do not see how to generalize this result. It is thus not clear whether the Redlich–Teller formula will or will not be of advantage in calculating isotope effects of polyatomics. We have therefore carried out computational studies of the problem in the next two sections.

Secondary KIE in formamide isomerization

Isomerization of formamide occurs by internal rotation of the molecule about the C—N bond (1). RHF/6-31G* optimization of formamide and its transition structure using GAUSSIAN 92 (5) gave energies and geometries in close agreement with Wiberg and Laidig (6). There are two possible transition structures, and the one of lower energy (**A** of ref. 6.) was used. Frequencies were calculated for reactant and transition structure and for their isotopomers with the two Hs of the amide group replaced by Ds. These and principal moments of inertia were then used in a small program to compute KIEs at 321.15 K of 1.132 42 from eq. [1] and 1.129 00 from eq. [4]. The optimizations used the default accuracy of the GAUSSIAN programs.

At first sight, one cannot say which of these values of the isotope effect is more accurate. Fortunately, in addition to the default optimization accuracy, *tight* and *very tight* options are available. Using *tight* optimization gave KIE =

Fig. 2. Error = (computed KIE) – 1.129 17 for 25 sets of computations of the secondary isotope effect in formamide isomerization. Errors are shown by the vertical bars where the dark bar uses the Redlich–Teller product rule and the light bar does not. Each set of a dark bar followed by an adjacent light bar uses the same set of Gaussian random errors between ± 0.000 05 Hartree/(Bohr)^2 added to the Cartesian force constants. The same errors are used for both isotopomers. Here and in the following figures, the errors are sometimes too small to show on the graph.

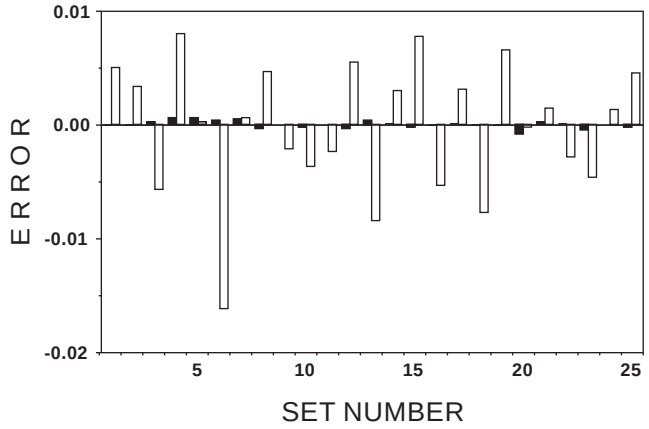

Fig. 3. Calculations are like those of Fig. 2, but with a uniform, rather than Gaussian, error distribution in the range 0 to 0.000 05 Hartree/(Bohr)^2.

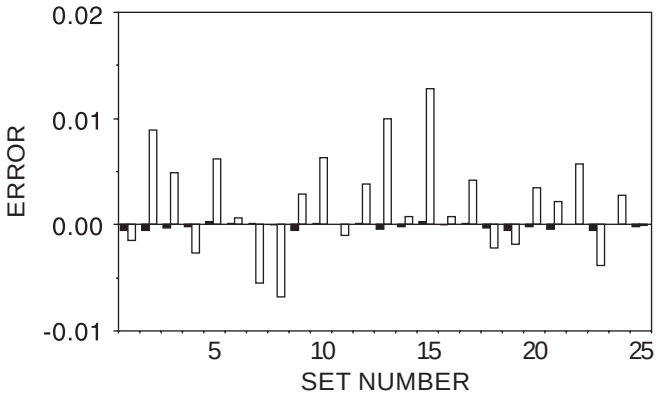
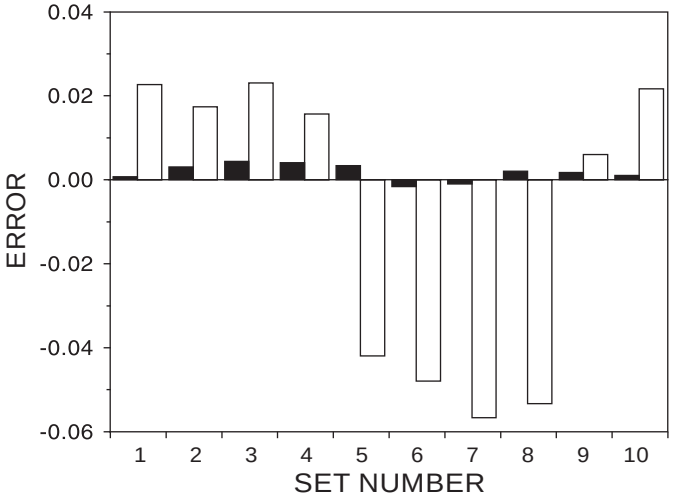


1.129 19 and 1.129 16, respectively, from eq. [1] and eq. [4], while the *very tight* option gave KIE = 1.129 17 from both. Here, the limiting value from the *very tight* optimization lies between the eq. [1] and eq. [4] values in both looser optimizations, and in both of these the Redlich–Teller value of eq. [4] is closer to the limiting value.

Although the geometry and hence the principal moments of inertia vary from *default* to *very tight* optimization, the resulting change in KIE is insignificant and can be ignored. It is sufficient to study the effect of errors in frequencies alone without concern for those in MMI. More exactly, the errors are in force constants, which are the same for both isotopomers, rather than directly in the frequencies themselves. We therefore added random errors to the Cartesian force constants from the *very tight* optimization, then computed the resulting frequencies and KIEs to see whether eq. [1] or eq. [4] is less affected by these errors.

Fig. 4. Calculations are like those of Fig. 2, but different Gaussian random errors are used for isotopomers.



The results of 25 such computer experiments are displayed across the horizontal axis in Fig. 2 for a Gaussian distribution of random errors between ±0.000 05 Hartrees/(Bohr)^2, generated by standard random error programs (7), in the Cartesian force constants, and in Fig. 3 for a uniform random distribution of errors in the range 0 to 0.000 05 Hartrees/(Bohr)^2. The vertical axis shows the difference between each computed KIE and the exact value of 1.129 17. Results are in pairs with a dark bar showing the error in KIE computed using eq. [4] followed by a light bar showing the error using eq. [1]. For each such pair, the same set of force constant errors was used. In a few cases, e.g., the dark bar in the eighth run and the light bar in the last run of Fig. 3, KIE errors are too small to show. In both figures, KIE errors using the Redlich–Teller rule are usually, but not always, considerably smaller. Whether the error in force constants is Gaussian or uniform does not appear to make a large difference in the KIE error.

We also considered the artificial case with Gaussian errors as above, but where different errors were added independently to the same Cartesian force constant of the H and the D isotopomer. Results are in Fig. 4 for 10 computer runs and show considerably larger errors than in Figs. 2 and 3. There thus appears to be some canceling of errors between isotopomers in the real case. Here, too, eq. [4] gives the better result.

Figures 2 and 3 are specific to errors in force constants that are common to both isotopomers so that frequency errors in the two isotopomers are correlated. This is appropriate to the case of an ab initio calculation of KIE. It is also worth considering uncorrelated frequency errors as in the determination of equilibrium isotope effects from experimental frequencies. This can scarcely apply to KIEs, since transition structure frequencies are not experimentally available, but we can use a computed KIE to see whether the effect of uncorrelated frequency errors is very different from what was seen in Figs. 2 and 3. Accordingly, random errors from a uniform distribution over the range between –2.5 and +2.5 cm^{-1} were added to all frequencies from the *very tight* calculation of both isotopomers of reactant and product in the formamide isomerization. Results are in Fig. 5. The larg-

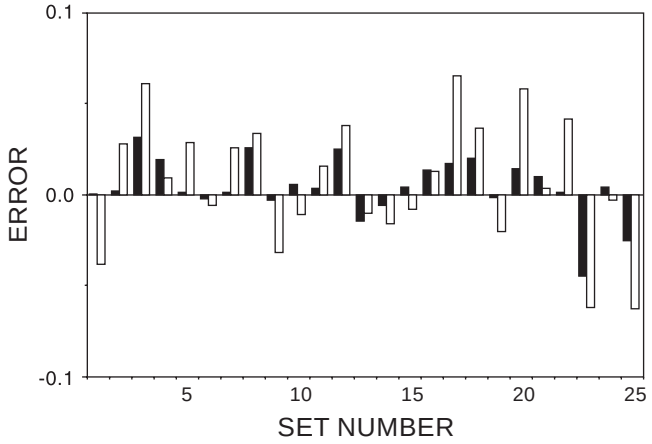
Fig. 5. Calculations are like those of Fig 3, but with a uniform distribution of random errors in the range –2.5 cm^{-1} to +2.5 cm^{-1} added to all frequencies independently.



est errror here is four times the largest in Figs. 2 and 3. Again eq. [4] gives better results than eq. [1], but the advantage appears slightly less than in Figs. 2 and 3.

Primary KIE for H-transfer reaction in *Z*-1,3-pentadiene

To see whether the superiority of the Redlich–Teller expression for the small secondary isotope effect above also holds for larger primary effects, we examined the hydrogen transfer in *Z*-1,3-pentadiene (8–11). The *s-trans* conformer is the lowest energy conformation, but it is in rapid equilibrium with the *s-cis* conformer in which the H transfer occurs.[3] This justifies the use of the *s-trans* conformer as reactant in calculations which give KIE = 2.796. As for formamide, errors from a uniform distribution up to 0.000 05 Hartrees/(Bohr)^2 were added to the Cartesian force constants, and the 25 computer runs in Fig. 6 were carried out. The results show that use of the Redlich–Teller product rule again gives the better accuracy.

Conclusions

Ab initio calculations strongly indicate that eq. [4], which incorporates the Redlich–Teller product rule, is more reliable than eq. [1], which does not, for computing both primary and secondary KIEs in the presence of various kinds of random errors in force constants and frequencies.

Acknowledgment

L.J.S. has known and worked with Professor Kresge for over 40 years and is honored to contribute to this memorial issue. K.N. Houk thanks Professor Jerry Kresge for collaboration and inspiration on many occasions. We thank Professor P.L. Polavarapu for the use of his program VOA to transform Cartesian force constants to frequencies.

Fig. 6. Calculations are like those of Fig. 3, but for the primary KIE of H transfer in pentadiene. Here, error = (computed KIE) – 2.796.

Isotope effects in nucleophilic substitution reactions XI. The effect of ion-pairing, substituents, and the solvent on S_N2 transition states

Kenneth Charles Westaway and W. Jiang

Abstract: The secondary alpha deuterium and primary leaving group nitrogen KIEs and Hammett ρ values found for the free ion and ion-pair S_N2 reactions between benzyldimethylphenylammonium ion and sodium *para*-substituted thiophenoxides in methanol at 20.000°C show how (*i*) ion-pairing of the nucleophile, (*ii*) a change in substituent in the nucleophile, and (*iii*) a change in solvent alters the structure of a Type II S_N2 transition state. Ion-pairing shortens the weaker sulfur – alpha carbon (S—C_α) transition state bond significantly but does not alter the stronger alpha carbon – leaving group (C_α—N) transition state bond as the bond strength hypothesis predicts. However, the effect of ion pairing, i.e., the decrease in the S—C_α bond on ion-pairing, decreases as a more electron-withdrawing substituent is added to the nucleophile, and the S—C_α bond actually increases when the nucleophile is the *p*-chlorothiophenoxide ion. The identical Hammett ρ values of –0.85 and –0.84 for the free ion and ion-pair reactions, respectively, may be observed because, *on average*, the S—C_α bonds are identical in the free ion and ion-pair transition states. When a more electron-donating substituent is added to the nucleophile, an earlier transition state is found in both the ion-pair and free ion reactions. However, the substituent effect is smaller in the ion-pair reactions, presumably because the change in the negative charge on the sulfur atom with substituent is greater in the free ion than in the ion-pair. The substituent effect on transition state structure suggested by the KIEs is not predicted by any of the theories that are used to predict substituent effects on S_N2 reactions. Both the secondary alpha deuterium and primary leaving group nitrogen KIEs and the Hammett ρ values indicate that the transition state is earlier when the solvent is changed from DMF to methanol as the "solvation rule for S_N2 reactions" predicts. This probably occurs because an earlier, more ionic, transition state is more highly solvated (more stable) in methanol.

Key words: nucleophilic substitution, S_N2, isotope effect, transition state, substituent, ion-pair.

Résumé : Les effets isotopiques cinétiques (EIC) secondaires du deutérium en alpha et primaire du groupe partant azoté ainsi que les valeurs de ρ trouvées pour les réactions S_N2 de l'ion libre et de la paire d'ion entre l'ion benzyldiméthylphénylammonium et les thiophénolates de sodium *para*-substitués, dans le méthanol à 20,000°C, montrent comment (*i*) la formation d'une paire d'ions du nucléophile; (*ii*) un changement de substituant dans le nucléophile et (*iii*) un changement dans le solvant peuvent altérer la structure d'un état de transition S_N2 du Type II. Tel que le prédit l'hypothèse de la force de liaison, la formation d'une paire d'ions raccourcit d'une façon significative la liaison d'état de transition soufre – carbone en alpha (S—C_α) qui est plus faible, mais qu'elle ne modifie pas la liaison d'état de transition carbone alpha – groupe partant (C_α—N) qui est plus forte. Toutefois, l'effet de la formation d'une paire d'ions (c'est-à-dire la diminution dans la longueur de la liaison S—C_α lors de la formation de la paire d'ions) diminue lorsqu'on ajoute au nucléophile un substituant plus électroaffinitaire; en fait, la liaison S—C_α s'allonge avec l'ion *p*-chlorothiophénolate. Dû au fait que les longueurs *moyennes* des liaisons S—C_α sont identiques dans les états de transition de l'ion libre et de la paire d'ions, les valeurs ρ de Hammett sont identiques, –0,85 et –0,84 respectivement, pour les réactions de l'ion libre et de la paire d'ions. Quand on ajoute un substituant électrodonneur au nucléophile, on observe un état de transition qui se produit plus tôt pour les réactions tant de l'ion libre que de la paire d'ions. Toutefois, l'effet de substituant est plus faible pour les réactions de la paire d'ions, probablement parce que le changement dans la charge négative sur l'atome de soufre en fonction du substituant est plus grand dans l'ion libre que dans la paire d'ions. L'effet de substituant sur la structure de l'état de transition qui est suggéré par les EIC n'est pas prédit par aucune des théories utilisées pour prédire les effets de substituant sur des réactions S_N2. Tel que le prédit la règle de solvatation des réactions S_N2, les EIC tant secondaire du deutérium en alpha que primaire de l'azote

du groupe partant ainsi que les valeurs de ρ de Hammett indiquent que l'état de transition se produit plus tôt quand on change le solvant de DMF à méthanol. Ceci se produit vraisemblablement parce qu'un état de transition rapide, plus ionique, est plus solvaté (plus stable) dans le méthanol.

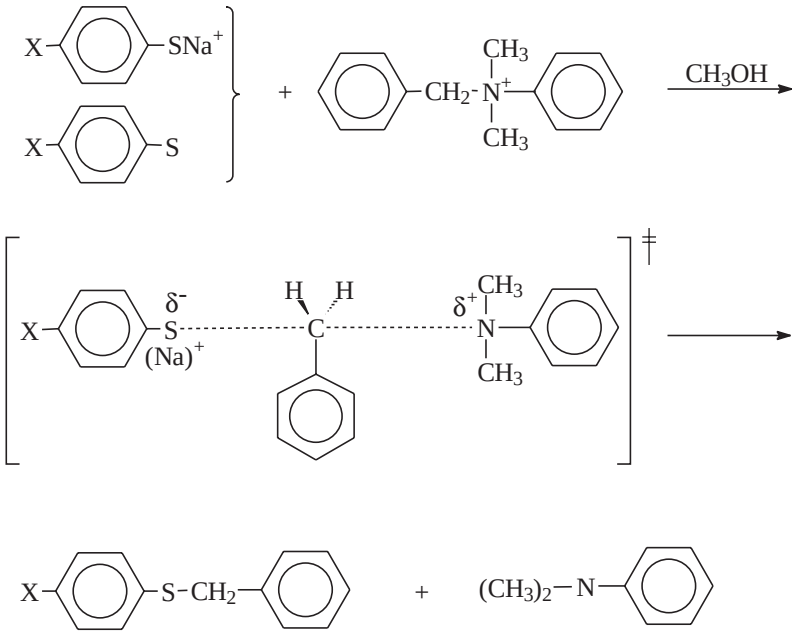
[Traduit par la Rédaction]

Introduction

The secondary alpha deuterium and primary nitrogen leaving group KIEs for the S_N2 reactions (1, 2) between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides, eq. [1],

[1]



were measured in methanol at 20.000 ± 0.002°C when the reacting nucleophile existed as a solvent-separated ion-pair complex and as a free ion (3) to determine how (*i*) ion-pairing of the nucleophile, (*ii*) a change in substituent in the nucleophile, and (*iii*) a change in solvent alters the structure of the S_N2 transition state.

Results and discussion

Form of the reacting nucleophile

Since one of the objectives of this study was to determine the effect of ion-pairing on the structure of the S_N2 transition state, the form of the reacting nucleophile must not change throughout the reaction. The ion-pair/free ion absorbance ratio at a concentration of approximately 3.5×10^{-4} M, Table 1, increases from 0.74 to 1.72 when a more electron-withdrawing group is added to the benzene ring of the sodium *para*-substituted thiophenoxide. This suggests that ion-pairing begins at a lower concentration when a more electron-withdrawing substituent is used. This presumably occurs because the more negative sulfur ion of the *para*-methoxythiophenoxide ion is more strongly solvated by hydrogen bonding to methanol and is, therefore, not able to form an ion-pair as easily as the less strongly solvated *para*-chlorothiophenoxide ion. However, the difference between the salts is small, and all three salts begin ion-pairing near the same concentration. For instance, sodium thiophenoxide begins forming ion-pairs at 1×10^{-4} M (3), and both the sodium *para*-methoxy- and *para*-chlorothiophenoxide salts exist partly as a free ion and partly as an ion-pair at 3×10^{-4} M. The important observation, however, is that all three salts exist completely as the ion-pair at concentrations $\geq 1 \times 10^{-3}$ M. The initial concentration of the sodium *para*-substituted thiophenoxide in every reaction in this study was approximately 5×10^{-3} M and the nucleophile/substrate ratio was 2/1. Therefore, even at 100% reaction, the concentration of the sodium *para*-substituted thiophenoxide solution was still 2.5×10^{-3} M, or approximately three times the concentration (1×10^{-3} M) where the sodium *para*-substituted thiophenoxides exist completely as the ion-pair. This ensured that the nucleophile is the solvent-separated sodium *para*-substituted thiophenoxide ion-pair complex (3) in all the reactions in this study.

The free *para*-substituted thiophenoxide ion required for this study was generated by adding a 2.6 molar excess of 15-crown-5 ether, which complexes the sodium ion in the ion-pair complex converting it into a free *para*-substituted thiophenoxide ion (3, 4). The data in Table 2 show that the amount of ion-pair decreases when 15-crown-5 ether is added to each sodium *para*-substituted thiophenoxide solution. Although only the free ion was observed when the (15-crown-5 ether/thiophenoxide ion) ratio was 0.5 for sodium *para*-

		244	1.36	—	—	2.0

methoxythiophenoxide and sodium thiophenoxide, a (15-crown-5 ether/thiophenoxide ion) ratio of >1.0 was required to convert all the sodium *para*-chlorothiophenoxide into the free ion. The higher (15-crown-5 ether/thiophenoxide ion) ratio required for the sodium *para*-chlorothiophenoxide is presumably needed because this salt is the most prone to ion-pairing. A (15-crown-5 ether/sodium *para*-substituted thiophenoxide) ratio of 2.6 was used in all the free ion reactions in this study to ensure that all of the reacting nucleophile existed as a free ion. It is interesting that increasing the (15-crown-5 ether/sodium *para*-substituted thiophenoxide) mole ratio from 0 to 2.6 does not change the λ_{max} for the free thiophenoxide ion significantly. This suggests that the 15-crown-5 ether does not affect the nucleophile significantly.

Secondary alpha deuterium and primary nitrogen leaving group KIEs

The secondary alpha deuterium and primary nitrogen (leaving group) KIEs for the S_N2 reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides were measured in methanol at 20.000 ± 0.002°C when the reacting nucleophile existed as a solvent-separated ion-pair complex and as a free ion to learn how (*i*) changing the nucleophile from a solvent-separated ion-pair complex to a free ion, (*ii*) changing the *para*-substituent on the nucleophile, and (*iii*) changing the solvent affect the structure of the S_N2 transition state.

The nitrogen KIEs, Table 3, were measured by reacting the nucleophile with both isotopically labelled substrates in the same reaction. Two kinds of the reactions, completes (taken to 100% of completion, 14 half-lives) and partials (stopped at approximately 12.5% of completion) were carried out. The products, a benzyl-*para*-substituted phenyl sulfide and *N*,*N*-dimethylaniline were separated and analyzed by HPLC and a Kjeldahl analysis, respectively. Then, the ammonium sulphate obtained from the Kjeldahl analysis was oxidized quantitatively into nitrogen gas and purified on a high vacuum line. Finally, the $^{14}N/^{15}N$ ratio of the nitrogen gas obtained from the partial and complete reactions was determined on an isotope ratio mass spectrometer, and the primary nitrogen leaving group KIE was calculated from these ratios and the average fraction of reaction from the Kjeldahl and HPLC analyses (1, 2). The secondary alpha deuterium KIEs, Table 4, were obtained by dividing the average rate constants from between three and five kinetic runs using the deuterated and undeuterated substrates, respectively (4).

The effect of ion-pairing on the structure of the S_N2 transition state

A comparison of the secondary alpha deuterium and primary nitrogen KIEs for the free ion and ion-pair reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides in methanol, Table 4, illustrate how ion pairing affects the structure of the S_N2 transition state. The leaving group nitrogen KIEs for the free ion

[d]Standard deviation for the KIE.

and ion-pair reactions are clearly identical within the experimental error of the method. For example, even for the sodium thiophenoxide reactions with the greatest $[(k^{14}/k^{15})_{\text{free ion}} - (k^{14}/k^{15})_{\text{ion-pair}}] = 0.0004$, the difference between the KIEs is much smaller than the experimental error in either isotope effect.[2]

One can deduce how the S—C_α bond changes on ion-pairing by combining the information provided by the secondary alpha deuterium and nitrogen KIEs. The identical nitrogen KIEs for the free ion and ion–pair reactions show that the C_α—N transition state bond is not changed by ion-pairing. Therefore, the change in the secondary alpha deute-

[2]A student "*t*" test (5) indicates that the nitrogen KIEs for the free ion and ion-pair reactions are only different at the 61% confidence level when the nucleophile is the *para*-methoxythiophenoxide ion, at the 23% confidence level when the nucleophile is the thiophenoxide ion, and at the 9% confidence level when the nucleophile was the *para*-chlorothiophenoxide ion.

[a]Standard deviation for the average KIE.

[b]Several of these isotope effects were remeasured when the nitrogen KIEs were measured to ensure that they were correct under the conditions used to measure the nitrogen KIEs. The KIEs that were checked were identical to those in ref. 4. The KIEs from the more complete study (4) are quoted in this table.

[c]The error in the isotope effect is $1/k_D[\Delta(k_H)^2 + (k_H/k_D)^2 \times \Delta(k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the reactions of the undeuterated and deuterated substrates, respectively.

[d]The Hammett ρ values were obtained by changing the *para*-substituent in the nucleophile.

[e]The standard error of coefficient of the ρ value.

rium KIE on ion-pairing must be due to a change in the S- -N distance (6, 7) and the S—C_α transition state bond. Although ion-pairing affects the secondary alpha deuterium KIE (the S—C_α bond), the effect is different for each nucleophile. The $(k_H/k_D)_\alpha$ decreases on ion-pairing by 5% (from 1.27 to 1.22), by 3% (from 1.24 to 1.21), and by 1% (from 1.22 to 1.21) when the *para*-substituent on the nucleophile is methoxy, methyl, and hydrogen, respectively, but increases by 3% (from 1.12 to 1.15) when the *para*-substituent is chlorine. This means the S- -N distance and therefore, the S—C_α bond, is much longer (6, 7) in the free *p*-methoxythiophenoxide ion reaction, longer in the *p*-methylthiophenoxide ion reaction, slightly longer in the free thiophenoxide ion reaction, but shorter in the free *p*-chlorothiophenoxide ion reaction than the S—C_α bonds in the corresponding ion-pair reactions, Fig. 1.

One explanation for the longer S—C_α bond in the free ion transition state is that the sodium ion reduces the electron density on the sulfur atom (4). As a result, the sulfur has to be closer to the alpha carbon to distort the C_α—N bond and cause the reaction. Three out of four cases are consistent with this suggestion. Unfortunately, this is not true for the *para*-chlorothiophenoxide ion reaction, which has a shorter S—C_α bond in the free ion transition state.

The effect of ion pairing becomes smaller as a more electron-withdrawing substituent is added to the nucleophile. Since the electron density on the sulfur atom decreases when a more electron-withdrawing substituent is added to the nucleophile, the strength of the ionic bond between the sodium and sulfur ions would also decrease. This suggests that the difference between the electron density on the sulfur atom of a free ion nucleophile and an ion-pair nucleophile will be smaller when a more electron-withdrawing substituent is on the nucleophile. As a result, the difference between the free ion and the ion-pair secondary alpha deuterium KIEs should be smaller when a more electron-withdrawing group is on the nucleophile. We cannot explain why the effect of ion pairing for the *para*-chlorothiophenoxide ion reaction does not follow this trend.

The identical Hammett ρ values found by changing the *para*-substituent on the nucleophile for the free ion and ion-pair S_N2 reactions, Table 4, suggest that the change in charge on the nucleophilic sulfur atom on going to the transition state is identical for the free ion and ion-pair reactions and, therefore, that the S—C_α transition state bond is not altered significantly when the nucleophile changes from a free ion to an ion-pair. The identical ρ values for the free ion and ion-pair reactions may be observed because, *on average*, the S—C_α bond of the free ion reactions is identical to the S—C_α bond of the ion-pair reactions, Fig. 1.

Another observation is that the major change on ion-pairing occurs in the S—C_α bond, and there is no change in the C_α—N bond. This is predicted by the bond strength hypothesis (8). If ion-pairing can be treated like a substituent effect, changing a free ion to an ion-pair nucleophile lowers the electron density on the nucleophilic sulfur atom, making it a poorer nucleophile. According to the bond strength hypothesis, the weaker S—C_α reacting bond in the S_N2 transition state will change significantly, and little or no change will occur in the stronger C_α—N reacting bond when the nucleophile is changed. Unfortunately, the bond strength hypothesis does not predict how the two transition state bonds will change on ion-pairing.

Substituent effects on the structure of the S_N2 transition state

Although several studies have attempted to determine how a change in substituent in the substrate (9–11) and the leaving group (2, 12, 13) affect the structure of an S_N2 transition state, no study has shown how a change of substituent in the nucleophile changes *both* the nucleophile – alpha carbon *and* the alpha carbon – leaving group bond in an S_N2 transi-

tion state. The secondary alpha deuterium and nitrogen KIEs for the S_N2 reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides show how changing a substituent on the nucleophile affects both reacting bonds in the S_N2 transition state. The $(k_H/k_D)_\alpha$, Table 4, decreases from 1.271 to 1.121 when the *para*-substituent on the free thiophenoxide ion changes from methoxy to chloro. Since the secondary alpha deuterium KIEs are directly related to the S- -N distance in the S_N2 transition state (6, 7), adding a more electron-withdrawing substituent to the nucleophile leads to a transition state with a shorter S- -N distance. The nitrogen leaving group KIEs, Table 4, on the other hand, increase very slightly when a more electron-withdrawing substituent is added to the nucleophile. For instance, the k^{14}/k^{15} increases by 0.0007 when the *para*-substituent on the free thiophenoxide ion changes from methoxy to chloro.[3] This means the C_α—N transition state bond length increases slightly as a more electron-withdrawing substituent is added to the nucleophile.

The relative length of the S—C_α transition state bond can be deduced from the primary nitrogen and the secondary alpha deuterium KIEs. When a more electron-withdrawing substituent is added to the nucleophile, the C_α—N transition state bond becomes slightly longer and the S- -N distance shorter. Therefore, the S—C_α transition state bond must be much shorter when a more electron-withdrawing substituent is added to the nucleophile, Fig. 2.

The substituent effects on the secondary alpha deuterium and nitrogen KIEs for the ion-pair reactions are the same as those for the free ion reactions, Table 4. The $(k_H/k_D)_\alpha$ decreases from 1.216 to 1.150 and there is a small increase[4] (0.0005) in the nitrogen leaving group nitrogen KIE when the *para*-substituent on the ion-pair nucleophile changes from methoxy to chloro. This means that the S- -N transition state distance decreases and the C_α—N bond is slightly longer when a more electron-withdrawing substituent is added to the nucleophile. Again, the nitrogen KIEs indicate that the C_α—N transition state bond length increases very slightly,

[3] A student "*t*" test (5) showed that the nitrogen KIEs for the reactions with the free *p*-methoxythiophenoxide ion and the free *p*-chlorothiophenoxide ion are different at the 97% confidence level.

[4] A student "*t*" test (5) showed the primary nitrogen KIEs for the ion-pair reactions where the nucleophile is the sodium *para*-methoxythiophenoxide ion-pair and the sodium *p*-chlorothiophenoxide ion-pair are different at the 92% confidence level.

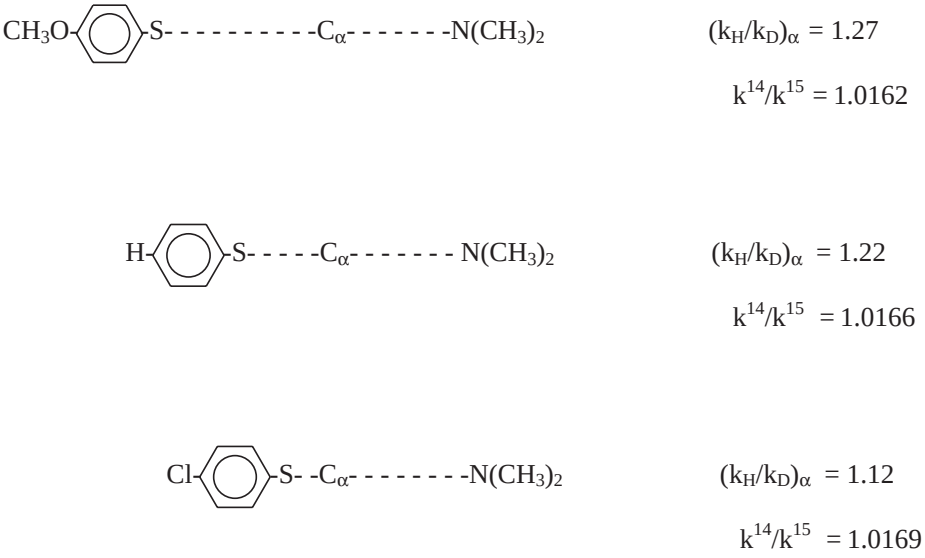
Fig. 2. The relative transition state structures for the S_N2 reactions between benzyldimethylphenylammonium ion and free *para*-substituted thiophenoxide ions in methanol at 20.000°C.



and the secondary alpha deuterium KIEs show that the S- -N distance decreases when a more electron-withdrawing group is added to the nucleophile. Since the S- -N distance decreases when the C_α—N bond becomes longer, the S—C_α bond must be shorter when a more electron-withdrawing substituent is added to the nucleophile in the ion-pair reactions.

The results indicate that both the free ion and ion-pair S_N2 reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides have a later transition state with a shorter S—C_α bond and a slightly longer C_α—N bond when a more electron-withdrawing substituent is added to the nucleophile. This may occur because adding a more electron-withdrawing substituent to the nucleophile pulls electron density away from the nucleophilic sulfur atom, making it a poorer nucleophile. As a result, the nucleophile has to come closer to the alpha carbon to distort the C_α—N bond (cause the reaction), and a later transition state should be observed.

The greater change in the S—C_α bond with substituent can be understood in terms of the bond strength hypothesis (8), which predicts that the weaker S—C_α bond will change significantly but that there will be little or no change in the stronger C_α—N bond when the *para*-substituent on the nucleophile is changed. The decrease in the S—C_α transition state bond length is greater than the increase in the C_α—N transition state bond because the energy obtained by increasing the bond order of the weak S—C_α bond will only lengthen the stronger C_α—N slightly.

The substituent effect is greater in the free ion reactions than in the ion-pair reactions. The $(k_H/k_D)_\alpha$ decreases by 15% in the free ion reactions but only by 7% in the ion-pair reactions when the *para*-substituent on the nucleophile changes from a methoxy to a chloro group. The corresponding change in the k^{14}/k^{15} is 0.0007 in the free ion reactions but only 0.0005 in the ion-pair reactions. A possible explanation for this is that the change in charge on the nucleophilic sulfur atom with substituent is greater in the free ions than in the ion-pairs. A CNDO/2 calculation (4) showed that the decrease in charge on the sulfur is 0.0208 for the free ions but is only 0.0171 for the ion-pairs when the *para*-substituent on the nucleophile changes from methoxy to chloro. Since the substituent effect on the negative charge on the sulfur atom is 22% greater for the free ions, it is not surprising that the greatest substituent effect is found in these reactions.

The substituent effect on transition state structure found in this study can be used to test the theories that predict the substituent effect on transition state structure. The Bell–Evans–Polanyi (BEP) principle (Hammond's thermal postulate) (14) predicts that adding an electron-withdrawing group to the nucleophile makes a poorer nucleophile and increases the free energy of activation for the reaction. This leads to a more product-like transition state with a shorter S—C_α and a longer C_α—N bond. This theory predicts correctly the substituent effect on transition state structure but does not predict the different magnitude of the changes in the two reacting bonds. Thornton's reacting bond rule (15) and the More O'Ferrall – Jencks energy surface method (16, 17) predict that adding a more electron-withdrawing substituent to the nucleophile will lead to a transition state with an unchanged S—C_α bond and longer C_α—N bond. Neither Thornton's rule nor the energy surface method predict the change in the S_N2 transition state that is observed. The Harris–Kurz modification of Thornton's reacting bond rule (18) predicts the transition state will have a longer S—C_α and a shorter C_α—N bond when a more electron-withdrawing substituent is added to the nucleophile. Although the Harris–Kurz theory predicts the change in transition state structure correctly, it does not indicate the relative magnitude of the changes in the two transition state bonds. The Pross–Shaik method (19), which predicts that adding a more electron-withdrawing substituent to the nucleophile will lead to a transition state with a longer S—C_α bond and a shorter C_α—N transition state bond, is clearly not consistent with the experimental results. Critchlow (20) predicted that a change in substituent on the nucleophile will only change the remote C_α—N transition state bond and will not affect

Solvent	Temp. (°C)	$(k_H/k_D)_\alpha$	k^{14}/k^{15}	Hammett ρ value[a]
Methanol	20	1.207 ± 0.008[b]	1.0162 ± 0.0010[c]	–0.84 ± 0.11[d]
DMF	0	1.179 ± 0.010	1.0200 ± 0.0007	–1.70 ± 0.05
DMF	20	1.17[e]	1.018[e]	

[a]The Hammett ρ value was obtained by changing the *para*-substituent on the nucleophile.

[b]The error in the isotope effect is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the reactions of the undeuterated and deuterated substrates, respectively.

[c]Standard deviation of the average KIE.

[d]Standard error of the ρ value.

[e]This KIE is estimated at 20°C.

the S—C_α transition state bond significantly. However, the major change in transition state structure is at the S—C_α bond and Critchlow's theory is not correct. Finally, Westaway's bond strength hypothesis (8) predicts that changing a substituent in the nucleophile, in the leaving group, or at the alpha carbon will change the weaker (S—C_α) reacting bond markedly but that the stronger (C_α—N) reacting bond will not change significantly. This is what is observed for both the ion-pair and free ion reactions. However, the bond strength hypothesis does not predict how the transition state bonds will change when a more electron-withdrawing substituent is added to the nucleophile.

The change in the S—C_α and C_α—N bonds observed in this study is only predicted by Hammond's postulate and the Harris–Kurz theory. However, neither theory predicts that the S—C_α bond order increases significantly while the C_α—N bond order decreases very slightly. While the bond strength hypothesis predicts the relative changes in the two reacting bonds, it does not predict how the reacting bonds will change.

The failure of these rules to predict the substituent effects on the structure of S_N2 transition states is not unique to this study. Westaway and Ali (2) reported that the predictions based on the BEP principle, Thornton's reacting bond rule, the More O'Ferrall – Jencks energy surface method, Critchlow's method, and the Harris–Kurz theory were not consistent with the experimental changes found in transition state structure when the leaving group was altered in the S_N2 reactions between *para*-substituted phenylbenzyldimethylammonium nitrates and sodium thiophenoxide in DMF at 0°C. In another study, Pham and Westaway (21) found that only the bond strength hypothesis was consistent with the change in transition state structure that was observed when the nucleophile was changed in the S_N2 reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxide ions at high ionic strength in DMF at 0°C. Finally, Westaway and Waszczylo (10) observed that the change in the transition state structure found when a substituent on the alpha carbon was changed in the S_N2 reactions between sodium thiophenoxide and *para*-substituted benzyl chlorides in methanol at 20°C, was only predicted by the Harris–Kurz theory, the Pross–Shaik method, and the bond strength hypothesis. In fact, the only theory that is consistent with all the experimental substituent effects that have been found in S_N2 reactions where the *total* transition state structure has been determined is the bond strength hypothesis, and it is only partially successful because it only predicts the relative magnitudes of the changes in the two reacting bonds and does not indicate how these bonds change.

Solvent effect on the structure of the S_N2 transition state

The "solvation rule for S_N2 reactions" (22) suggests that the transition state for a Type II S_N2 reaction (with a neutral and a negatively charged nucleophile in the transition state) will change significantly when the solvent is changed. A comparison of the secondary alpha deuterium and primary leaving group nitrogen KIEs and Hammett ρ values found for the S_N2 reaction between benzyldimethylphenylammonium nitrate and a solvent-separated sodium thiophenoxide ion-pair complex in methanol at 20°C and in DMF at 0°C, Table 5, can be used to test this rule.

Unfortunately, the KIEs in the two solvents were measured at different temperatures. However, the temperature dependence for both these KIEs is small. Shiner et al. (23) found that increasing the temperature by 20°C decreased the $(k_H/k_D)_\alpha$ for several S_N2 reactions by approximately 0.01, and Koshy and Robertson (24) found that increasing the temperature of several S_N2 reactions by 20°C decreased the $(k_H/k_D)_\alpha$ by between 0.002 and 0.014. Applying the average temperature dependence of 0.008 per 20°C to the secondary alpha deuterium KIE of 1.179, found at 0°C in DMF, suggests that this KIE would be approximately 1.17 at 20°C. Therefore, the secondary alpha deuterium KIE in methanol ($(k_H/k_D)_\alpha$ = 1.215 at 20°C) is significantly larger than the $(k_H/k_D)_\alpha$ = 1.179 at 0°C (approximately 1.17 at 20°C) in DMF. No temperature effect has been reported for primary nitrogen leaving group KIEs. However, Turnquist et al. (25) found the chlorine leaving group KIE for the solvolysis of *tert*-butyl chloride decreased from 1.010 87 at 10°C to 1.010 58 at 20°C and that the chlorine KIE for the S_N2 reaction between butyl chloride and sodium thiophenoxide in methanol decreased from 1.009 64 at 0°C to 1.008 95 at 20°C. Thus, the chlorine KIE decreases by 0.000 58 and 0.000 69, respectively, (by an average of 0.0006) when the reaction temperature is increased by 20°C. If one assumes that the temperature effect of a nitrogen KIE can be estimated from the temperature dependence of the chlorine KIE and the maximum chlorine and nitrogen KIEs of 1.0141 and 1.0436, respectively, at 25°C (26), the nitrogen KIE should decrease by approximately 0.0019 when the temperature increases by 20°C. This suggests the leaving group nitrogen

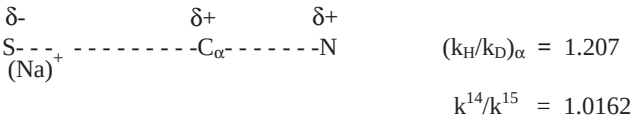
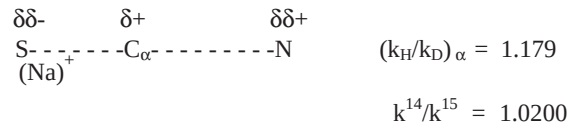
Fig. 3. The relative transition state structures for the ion-pair S_N2 reactions between sodium thiophenoxide and benzyldimethylphenylammonium nitrate in DMF and in methanol.

In methanol:



In DMF:



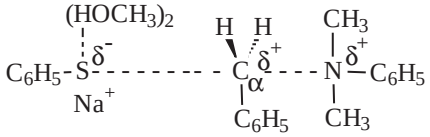
KIE of 1.0200 in DMF at 0°C would be approximately 1.018 in DMF at 20°C and that the nitrogen KIE is significantly larger in DMF than in methanol.

The larger secondary alpha deuterium KIE of 1.215 in methanol ($(k_H/k_D)_\alpha$ = 1.17 in DMF), Table 5, indicates that the S- -N transition state distance is greater in methanol than it is in DMF. The nitrogen KIE, on the other hand, is smaller in methanol than in DMF. This indicates the C_α—N transition state bond is considerably shorter in methanol than in DMF. Because the transition state in methanol has a longer S- -N distance but a shorter C_α—N bond, the S—C_α bond must be much longer in methanol than in DMF. Therefore, an earlier transition state, with a much longer S—C_α and a shorter C_α—N bond, is found in methanol.

The Hammett ρ values measured by changing the *para*-substituent on the nucleophile in DMF and methanol, Table 5, support this conclusion. The greater magnitude of the ρ value in DMF indicates that the change in charge on the nucleophilic sulfur atom is greater on going from the initial state to the transition state in DMF than it is in methanol. Therefore, the S—C_α transition state bond must be shorter in DMF than in methanol. This supports the conclusions based on the KIEs, and it is safe to conclude that an earlier, more highly charged, transition state is found in methanol, Fig. 3.

The earlier transition state in methanol can be rationalized if two assumptions are valid. First, solvation of the S_N2 transition state will occur primarily at the partial negative charge on the sulfur atom, and there will be little or no solvation of the partial positive charges on the alpha carbon and the nitrogen atom because these charges are sterically hindered to solvation, Fig. 4. This means the transition state is solvated by hydrogen bonding to the sulfur atom in methanol whereas it is only solvated by a weaker ion–dipole interaction in DMF. A second assumption is that a more ionic transition state, which would be more highly solvated (more stable) in a hydrogen bonding solvent, would be found in a hydrogen bonding solvent and that a less ionic (polar) transition state would be found in a less ionic (dipolar aprotic) solvent, i.e., the structure of the transition state found in a particular solvent will depend on its stability in that solvent. This means

Fig. 4. The structure of the transition state showing the solvation of the S_N2 transition state by methanol.



that an early, more ionic, transition state would be found in methanol where it is more stable because solvation of the negatively charged sulfur atom is greater. DMF, on the other hand, cannot form hydrogen bonds to the sulfur atom in the transition state and only stabilizes the transition state by a weak ion–dipole interaction. Therefore, a late, less ionic (dipolar) transition state, which would be more strongly solvated in DMF, should be observed in DMF. It is worth noting that this explanation of the solvent effect is supported by the secondary alpha deuterium and nitrogen KIEs found for the S_N2 reactions between sodium thiophenoxide and benzyldimethylphenylammonium nitrate at two different ionic strengths in DMF (21).

Finally, the different transition state structures suggested by the secondary alpha deuterium and nitrogen KIEs measured in methanol and in DMF are consistent with the "solvation rule for S_N2 reactions" (22), which predicts that the transition state for a Type II S_N2 reaction will be very solvent dependent. While the solvation rule does not indicate how the transition state bonds will change when the solvent changes, the results for this system show how a change in solvent will affect a Type II S_N2 transition state.

Conclusions

The secondary alpha deuterium and primary leaving group nitrogen KIEs and Hammett ρ values for the free ion and ion-pair S_N2 reactions between benzyldimethylphenylammonium nitrate and sodium *para*-substituted thiophenoxides in methanol at 20.000°C have shown that ion-pairing of the nucleophile does not affect the alpha carbon – leaving group (C_α—N) transition state bond but changes the nucleophile – alpha carbon (S—C_α) transition state bond significantly. The change in transition state structure on ion pairing is predicted by the bond strength hypothesis because the only change in transition state structure is in the weaker S—C_α bond, and no change occurs in the stronger C_α—N bond. The free ion S—C_α bond is much longer than the ion-pair S—C_α bond in the *para*-methoxythiophenoxide ion reaction, longer than the ion-pair S—C_α bond in the *para*-methylthiophenoxide ion reaction, slightly longer than the ion-pair S—C_α bond in the thiophenoxide ion reaction, but is shorter than the ion-pair S—C_α bond for the *para*-chlorothiophenoxide ion reaction. Thus, the effect of ion pairing (the difference between the S—C_α bond in the free ion and ion-pair reactions) decreases in three out of four comparisons as a more electron-withdrawing substituent is added to the nucleophile. The opposite effect, found with *para*-chlorothiophenoxide ion, cannot be explained. Finally, the identical Hammett ρ values of –0.85 and –0.84 for the free ion and ion-pair reactions, respectively, may be observed because, *on average*, the S—C_α bonds are identical in the free ion and ion-pair transition states.

[a]Standard error of the slope.

When a more electron-withdrawing substituent is added to the nucleophile, a later transition state with a much shorter S—C_α bond and a slightly longer C_α—N bond is found in both the ion-pair and free ion reactions. The later transition state found with the poorer nucleophile is expected because the less negative sulfur has to come closer to the alpha carbon to distort the C_α—N bond and cause reaction. Another discovery is that the substituent effect is smaller in the ion-pair reactions than in the free ion reactions. This may be observed because the change in the negative charge on the sulfur atom with substituent is greater in the free ion than in the ion-pair. The change in transition state structure suggested by the KIEs is not predicted by Thornton's reacting bond rule, the More O'Ferrall – Jencks energy surface method, the Critchlow method, or the Pross–Shaik method but the BEP principle, the Harris–Kurz method, and the bond strength hypothesis partially predict the experimental results. The BEP principle and the Harris–Kurz theory do not predict the very different magnitudes of the changes in the two reacting bonds, and the bond strength hypothesis does not indicate how the transition state bonds will change when a more electron-withdrawing substituent is added to the nucleophile. Thus, none of the theories predict the substituent effects on transition state structure that were found in this study.

A comparison of the secondary alpha deuterium and nitrogen leaving group KIEs in the S_N2 reactions between sodium *para*-substituted thiophenoxide ions and benzyldimethylphenylammonium ion in methanol and in DMF has shown that a change in solvent affects the structure of a Type II S_N2 transition state as the "solvation rule for S_N2 reactions" predicts. Both the KIEs and the Hammett ρ values indicate that an earlier transition state, with a longer S—C_α bond and a shorter C_α—N bond, is found in methanol. This probably occurs because an earlier, more ionic, transition state is more highly solvated (more stable) in methanol.

Experimental

Four liters of methanol (Caledon Laboratories) were dried over 50 g of anhydrous sodium sulfate, then refluxed over 4.0 g of sodium hydroxide (BDH) and 3.4 g of silver nitrate (BDH) for 1 h to remove any aldehyde or acid. Then, the methanol was distilled under a nitrogen atmosphere and stored in a cool, dark place until it was used in a kinetic run. The preparation of the sodium *para*-substituted thiophenoxide salts has been published (6). The synthesis of the deuterated and undeuterated substrates (2) and the procedure used for determining the rate constants (4) have been described previously.

The procedure used to measure the rate constant for the free ion reactions was the same as that used for the ion-pair complex reactions except that approximately 0.20 mL (0.001 mol) of 15-crown-5 ether (Aldrich) was injected into the QAS(H) and QAS(D) stock solutions using a 1 mL Hamilton syringe before the temperature equilibration. This means the free thiophenoxide ion was generated when the nucleophile was injected into the QAS(H) and QAS(D) solutions at the beginning of the reaction. The concentration of the 15-crown-5 ether was approximately 1.26×10^{-2} M (2.6 times the initial concentration of the nucleophile) to ensure that all of the nucleophile was the free ion.

The secondary alpha deuterium KIEs were obtained by dividing the average rate constants from between three to five separate kinetic runs of the undeuterated and of the deuterated substrates. The reactions were followed to between 65 and 70% of completion, and the correlation coefficient for the least-squares line that was used to calculate the second-order rate constant was ≥0.999. The procedure for determining the nitrogen KIEs is identical to that in ref. 2 except that the analysis of the *para*-substituted phenyl benzyl sulfide was done by HPLC rather than by gas chromatography. The $^{14}N/^{15}N$ ratios that were needed to calculate the KIE, were obtained by analyzing nitrogen gas samples from partial and complete reactions on a Micromass Sira 9 dual inlet isotope ratio mass spectrometer at the University of Waterloo.

The HPLC analysis of benzyl *para*-substituted phenyl sulfides

The amount of benzyl *para*-substituted phenyl sulfide formed in each complete and partial reaction was determined by an HPLC analysis using the internal standard technique (27). The analysis involved removing most of the ether from the solution containing the benzyl *para*-substituted phenyl sulfide (2), diluting the sample and the required amount of the 9.879×10^{-4} M nitrobenzene (the internal standard) solution, Table 6, to 50 mL in a volumetric flask with HPLC grade methanol. Then, three 10 μL samples of the solution were injected into the HPLC, and the average (benzyl *para*-substituted phenyl sulfide/internal standard) peak area ratio was determined. The amount of benzyl

© 1999 NRC Canada

para-substituted phenyl sulfide was calculated using the calibration curve.

The HPLC system consisted of a 100 × 5 mm Waters 5PAH 10 μm Radical Pak column, a Waters model 600 multisolvent delivery system, a Waters 490 programmable multiwavelength detector, and a Hewlett Packard model HP3396A integrator. The amount of internal standard, the eluting solvent, the flow rate, and the detector wavelengths for each analysis are given in Table 6. All the calibration curves were straight lines passing through the origin. The slope, correlation coefficient, and the error for each calibration curve are also given in Table 6.

The HPLC analyses of complete reactions showed no trace of methyl phenyl sulfide, and the average percent reaction at the benzyl carbon was 99.3 ± 0.4% when the nucleophile was sodium thiophenoxide and sodium *para*-methoxythiophenoxide. The Kjeldahl analyses of the *N*,*N*-dimethylaniline indicated the complete reactions were 99.8 ± 0.2% complete.

The phosphoryl and the carbonyl group as hydrogen bond acceptors

Agnes M. Modro and Tom A. Modro

Abstract: Formation constants for the hydrogen-bonded complexes between phenol (donor) and selected carbonyl or phosphoryl compounds (acceptors) were determined from IR $\Delta\nu$ shifts. The P=O group is about two orders of magnitude stronger as an acceptor than the C=O group, but no evidence for the enolization of a β-diphosphoryl system was found. The IR absorption band of the phosphoryl group ($\nu_{P=O}$) showed weak response to the involvement in the hydrogen bonding, and the shifts of the donor molecule (ν_{OH}) provide a better measure of the formation constants.

Key words: carbonyl and phosphoryl groups as hydrogen bond acceptors, enolization of a β-difunctional system, determination of K_{assoc} from the IR $\Delta\nu$ shifts.

Résumé : Faisant appel aux déplacements, $\Delta\nu$, de l'IR, on a déterminé les constantes de formation de complexes à liaison hydrogène entre le phénol (donneur) et des composés carbonylés ou phosphorylés choisis (accepteurs). Par opposition au groupe C=O, le groupe P=O donne des complexes qui sont environ deux fois plus forts; on n'a toutefois pas rien observé qui pourrait laisser croire qu'il y a énolisation d'un système β-diphosphoryle. La bande d'absorption IR du groupe phosphoryle ($\nu_{P=O}$) présente une faible réponse à l'implication dans la liaison hydrogène, et les déplacements de la molécule donneur (ν_{OH}) donnent une meilleure mesure des constantes de formation.

Mots clés : groupes carbonyle et phosphoryle comme accepteurs de liaison hydrogène, énolisation d'un système β-bifonctionnel, détermination des K_{assoc} à partir des déplacements ($\Delta\nu$) dans l'infrarouge.

[Traduit par la Rédaction]

Introduction

One of the fundamental concepts in chemistry is that of hydrogen bonding and the carbonyl, as well as the phosphoryl, functionalities are among the most important hydrogen bond acceptor groups in organic molecules. The bibliography of the subject is enormous and spans a long period of time; we mention, for example, a comprehensive study on the relationship between vibrational frequencies and bond distances in the O—H···O H-bonded systems (1), or an excellent introduction to the topic published 30 years later (2). The involvement of the carbonyl group in the intramolecular bonding of the O—H···O=C type is related to the keto–enol tautomerism of dicarbonyl compounds, and this topic is now discussed in various textbooks (see, for example, ref. 3). The ability of the phosphoryl (P=O) and the phosphate (PO_2^-) groups to act as strong hydrogen bond acceptors is also well recognized (4). Much less is known, however, about the relative hydrogen-bonding abilities of the C=O and the P=O groups, both of them playing a key role in many biomolecules. In our earlier work on the 2-hydroxy-3-benzoylpropylphosphonate system, $PhC(O)CH_2CH(OH)CH_2P(O)(OR)_2$, ^1H NMR spectroscopy and X-ray diffraction demonstrated complete regioselectivity in the intramolecular interactions between the β-OH group and the potential acceptor phosphoryl or carbonyl functions in favor of the former (5). In this work we applied IR spectroscopy to investigate the hydrogen-bonding properties of some systems with two acceptor groups linked via the methylene bridge. In two cases (acetylacetone **1** and diethyl malonate **la**) both groups are carbonyl, in one (tetraethyl methylenebisphosphonate **2**) both are phosphoryl, and in the last (triethyl phosphonoacetate **3**) the acceptors are mixed (Scheme 1). Each system is, in principle, capable of tautomerism leading to an enol form stabilized by intramolecular hydrogen bonding to the remaining X=O (X = C, P) group. This effect should, in turn, affect the donor properties of the whole molecule with respect to an external hydrogen bond donor in the formation of an intermolecular H-bonded complex. Phenol **4** was selected as such donor and the interactions of **4** with substrates **1**, **2**, **3**, as well as with some model carbonyl and phosphoryl compounds were studied.

Received October 22, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

Results and discussion

The hydrogen-bonding ability of the phosphoryl compounds was extensively studied by Norwegian and Russian workers about 30 years ago, and a large number of association constants and enthalpies of complexation were obtained. In most cases the IR spectroscopy was applied and the shifts in the vibrational frequency of the *donor* group (usually, the

OH group of a phenol or an alcohol) was used to measure the bonding effects (6). In only one case the association of phosphoryl compounds with proton donors was determined on the basis of the shift in the $\nu_{P=O}$ value (7). Similarly, an extensive study on the hydrogen bond association of phenols with carbonyl compounds was based on the measurements of the IR frequency shifts, $\Delta\nu_{OH}$ (8). Since the $\Delta\nu_{OH}$ could not be applied to the study of the hydrogen bonding of **3**, as the effect would not identify the acceptor group (C=O vs. P=O), we first investigated the problem of the agreement between the data obtained from the frequency shift of the donor ($\Delta\nu_{OH}$), as well as the acceptor ($\Delta\nu_{CO}$, $\Delta\nu_{PO}$) groups. To this purpose, the association between **4** and four simple carbonyl (**1b**–**1e**) and five simple phosphoryl (**2a**–**2e**) compounds (Scheme 2) was studied using the values of the frequency shifts $\Delta\nu_{X=O}$. In case of disagreement with the literature values, another set of K_{assoc} values was determined from the $\Delta\nu_{OH}$ shifts of the donor. The results obtained for those reference compounds are given in Table 1.

Two important conclusions emerge from Table 1. First, for the carbonyl substrates, there is a good agreement between our values of K_{assoc}, obtained from the $\Delta\nu_{C=O}$ shifts, and the literature values, which were obtained by measuring the $\Delta\nu_{OH}$ shifts of the phenol OH group in the carbonyl substrate – **4** hydrogen-bonded complexes. It means that in the C=O···H—O bonding system there is a good (and linear) correlation between the stretching frequencies (hence the bond orders) of the donor, as well as the acceptor group. Second, the correlation fails in the case of the phosphoryl substrates. While the K_{assoc} values obtained from the $\Delta\nu_{OH}$ shifts show good agreement with the reported data (also obtained from the same shifts), using the $\Delta\nu_{P=O}$ frequency shifts led to much lower values of the association constants with the K_{assoc} smaller by a factor between 3 and 40 (!) relative to the values obtained from the $\Delta\nu_{OH}$ shifts. The observed discrepancy is particularly intriguing in view of the fact that both shifts give curves of similar quality when plotted versus concentration changes of the donor or the acceptor, respectively. Figure 1 shows such two plots for the **2a**–**4** hydrogen-bonding system. This result, although complicating the IR spectroscopic studies of the hydrogen bonding by the P=O group, is in general agreement with the properties and bonding characteristics of the phosphoryl function. Solid-state studies demonstrated that although the P=O linkage can accept up to three H-bonds from such donors as P-OH, C-OH, or N-H groups, its length seems to be little affected by acting as the acceptor (ref. 4, p. 963). The IR spectra of compounds with the C=C—P=O moiety show no lowering in $\nu_{P=O}$ of the kind found in the analogous α,β-un-

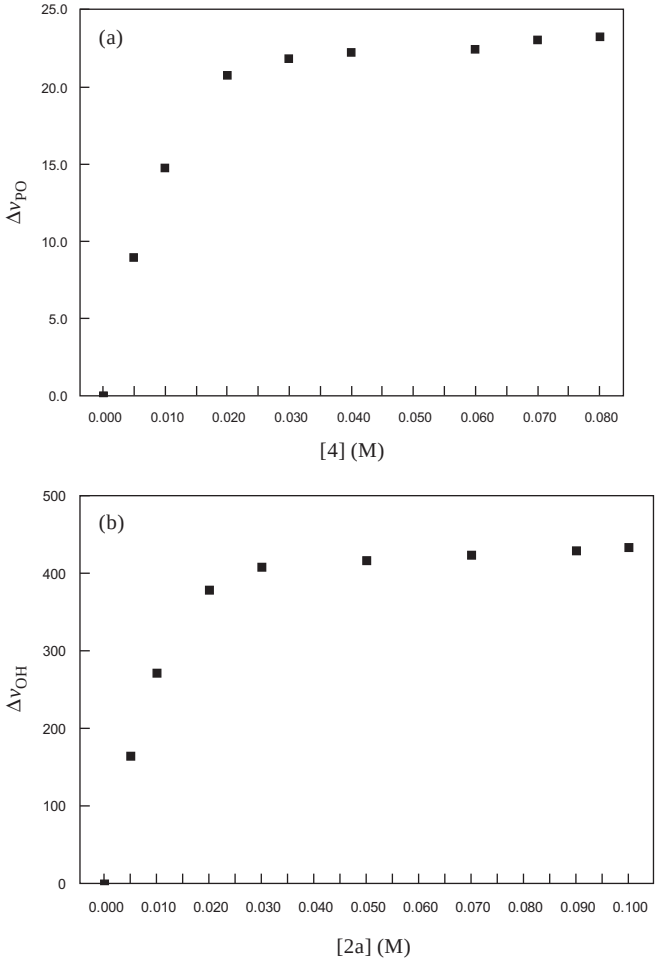
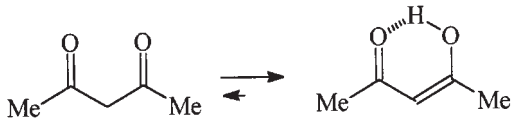
Fig. 1. (*a*) Plot of the $\Delta\nu_{P=O}$ value for **2a** (0.005 M) as a function of the concentration of **4**. (*b*) Plot of $\Delta\nu_{O\text{-}H}$ for **4** (0.005 M) as a function of the concentration of **2a**.



saturated carbonyl compounds (9). The phosphoryl group is a highly polar function and its vibration always produces a strong band in the IR spectrum (10). It seems, however, that the change in the $\nu_{P=O}$ values resulting from the involvement in hydrogen bonding should be used as a qualitative rather than a quantitative measure of the complexation equilibrium. A similar situation exists in the ^{31}P NMR spectroscopy. The ^{31}P NMR chemical shifts (δ_P) reflect direct protonation of the P=O group in phosphine oxides, $R_3P{=}O$ (11), but the change in the δ_P values upon protonation decreases with the number of oxygen ligands and was found to be zero for trialkyl phosphates, $(RO)_3P{=}O$ ("compensating" effect of oxygen atoms) (12).

The IR spectrum of a dilute (0.05 M) solution of acetoacetone **1** in CCl_4 exhibits the absorption band of the carbonyl group at 1616 cm^{-1}. The bathochromic shift of 107 cm^{-1} relative to acetone (**1b**) reflects the effect of the intramolecular hydrogen bonding of the enolic form of **1** (Scheme 3). Recent studies on the keto–enol tautomerism of β-dicarbonyl compounds demonstrated that in CCl_4 approximately 98% of **1** exists in the enolic form (13). In agreement with this result, we have found that the addition of increasing amounts of **4** to solutions of **1** (up to the molar ratio [**4**]/[**1**] = 50) had almost negligible effect on the ν_{CO} value

Scheme 3.



(maximum of $\Delta\nu_{CO}$ = 5 cm^{-1}). The only significant effect observed at higher concentrations of **4** was the shift in the ν_{OH} value, resulting from self-association of phenol (14) and independent of the presence of **1**. It can be concluded that an external donor like **4** does not significantly disturb the intramolecular hydrogen bonding existing in **1**.

Contrary to the situation existing for **1**, it is known that diethyl malonate **la** contains only negligible quantities of its enol form (15). Consequently, **1a** exhibits a strong carbonyl absorption band at 1746.0 cm^{-1}, only 4.7 cm^{-1} greater than that of **1e**; the difference can be explained by an electronic effect of the second ester group in **1a.** The addition of **4** to solutions of **1a** led to a systematic shift of the ν_{CO} value (maximum shift $\Delta\nu_{CO}$ = 31.0 cm^{-1}) from which the association contant, K_{assoc} = 2.5 ± 0.2 M^{-1} was calculated for **1a**. It can be seen that although acetone (**1b**) and ethyl acetate (**1e**) yield very similar values of K_{assoc} with respect to **4**, their "enolizable" analogues, **1** and **1a** behave very differently. While for the highly enolic **1** no K_{assoc} could be obtained, poorly enolic **1a** gave a lower value, but comparable to that obtained for its simple model, **1e**.

If the concept of tautomerism is applied to the substrate **2**, the "enolic" form analogous to that of **1** can be formulated, stabilized by intramolecular hydrogen bonding, as well as by the formation of the "conjugate" C=C—P=O system. Literature reports do not, however, provide support for such an effect. IR studies of a series $Et_2O_3P\text{-}(CH_2)_n\text{-}PO_3Et_2$ show no difference in the $\nu_{P=O}$ and $\nu_{P\text{-}C}$ values for n = 1 and n > 1 members (16). Similarly, a structural study on the bisphosphine oxide, $Ph_2P(O)\text{-}CH_2\text{-}P(O)Ph_2$, showed that the P=O and P—C bond lengths are perfectly within the range observed for other, "non-enolizable," phosphine oxides (17). Our results support the conclusion about the "non-enolizability" of **2**. The IR spectrum of **2** contains a strong band at 1258 cm^{-1}, typical for the "free" P=O group observed for phosphoryl substrates and similar to the values obtained for **2b** and **2c**. The effect of the addition of **4** on the IR spectra of **2** and the effect of the addition of **2** on the ν_{OH} of **4** are identical to those obtained for **2b** and **2c**, indicating independent complexation of both P=O groups in **2** with two molecules of **4** (Scheme 4). As before, the K_{assoc} for the reaction shown in Scheme 4, determined using the $\nu_{P=O}$ shifts (maximum $\Delta\nu_{P=O}$ = 44.6 cm^{-1}) gave a markedly low value of K_{assoc} = 6.8 ± 0.2 M^{-1}. When the ν_{OH} shift of **4** was, however, used for the calculations, a much more acceptable value of K_{assoc} = 398 ± 3 M^{-1} was obtained. This value compares well with the K_{assoc} = 354 M^{-1} obtained for **2c**, supporting the conclusion about viewing the molecule of **2** as a system of two non-interacting P=O functions.

For triethyl phosphonoacetate **3** the behavior of both donor groups was studied. The ester carbonyl group gives rise to a strong band at 1740.2 cm^{-1}, similar to that observed for **1a** and **1e**, thus indicating that there is little, if any, of the enol form present.When increasing proportions of **4** were

[b]Could not be calculated; the shift of 5.0 cm^{-1} occurs upon the addition of small quantities of **4** and does not increase upon further addition.
[c]Not determined in a separate experiment of the effect of the increase of the concentration of a donor on the IR spectrum of **4**.

Scheme 4.

added to the solutions of **3**, the carbonyl group band underwent bathochromic shift to a maximum value of $\Delta\nu_{C=O}$ = 21.4 cm^{-1}. The shift allowed the calculation of the association constant, K_{assoc} = 3.4 M^{-1}, a value that locates **3** in the same group of carbonyl acceptors of the hydrogen bond as **1a**, and not much weaker than the simple ester **1e**. The phosphoryl absorption band in free **3** is $\nu_{P=O}$ = 1269.6 cm^{-1} and upon the addition of **4** it moves to lower wave numbers with the maximum shift of $\Delta\nu_{P=O}$ = 57.2 cm^{-1}. It is clear that the phosphoryl group in the molecule of **3** is not involved in any significant intramolecular hydrogen bonding and with respect to an external donor behaves as its other "nonenolizable" analogues, **2b**, **2c**, and **2**. As with other phosphoryl substrates, the determination of the association constant from the $\Delta\nu_{P=O}$ shift gave an abnormally low value (11.5 ± 1.6 M^{-1}), while the value obtained using the $\Delta\nu_{OH}$ shifts of the donor, K_{assoc} = 381 ± 3 M^{-1}, remains in excellent agreement with the association constants obtained for other phosphoryl substrates. The hydrogen-bonding properties of four bifunctional compounds studied are summarized in Table 2. The results of this study led us to the following conclusions about the hydrogen-bonding properties of the phosphoryl group. (*i*) The P=O group is a strong hydrogen bond acceptor and, with respect to phenol, it is approximately 100-fold more effective than the carbonyl group in a similar molecular structure. (*ii*) Although it acts as a strong acceptor, its involvement in the bonding does not produce great changes in the IR absorption of the phosphoryl group. Spectroscopic changes taking place for the donor molecule offer a more correct measure of the association constants. (*iii*) In the 1,3-diphosphoryl system there is no evidence for tautomerization to the analogue of the enolic form observed for some 1,3-dicarbonyl substrates.

Experimental section

Tetrachloromethane (Aldrich, 99.9%, A.C.S. reagent) was distilled over P_4O_{10} and stored over 4Å molecular sieves. Commercially available substrates **1**, **2**, **3**, and **4** were purified by conventional methods immediately before use. **2c** was prepared according to the literature procedure (18). IR spectra were recorded on a Bomen Michelson 100 spectrometer in CCl_4 solutions using sodium chloride cells of 1 mm thickness and thermostated at 25.0 ± 0.2°C. The formation constants for the hydrogen-bonded complexes, K_{assoc}, were calculated on the assumption that each donor function forms a 1:1 complex with **4**:

© 1999 NRC Canada

[1] $K_{assoc} = [acceptor]_{bonded}/[acceptor]_{free}\ [donor]_{free}$

Solutions (0.005 M) of an acceptor in CCl_4 were prepared and the IR spectra were recorded in order to determine the $\nu_{X=O}$ value for the "free" acceptor. Solutions containing acceptor (0.005 M) and increasing amounts (usually 0.005–0.10 M) of **4** were then prepared and the shifts in the X=O absorption band, $\Delta\nu_{X=O}$ were measured as a function of [**4**]. For all systems in which the hydrogen bonding occurred, smooth curves were obtained, leveling-off at a given concentration of **4**. The $\nu_{X=O}$ value was then taken as that of the absorption for the fully bonded acceptor, $\Delta\nu_{X=O}$ (max), and used for the calculations. The concentrations of the hydrogen-bonded acceptor (and donor) ($[acceptor]_{bonded}$, $[donor]_{bonded}$) were calculated as: $[acceptor]_{bonded} = 0.005\ M \times \Delta\nu_{X=O}/\Delta\nu_{X=O}$ (max), and substituted into eq. [1]. For the K_{assoc} calculated from the IR shift of the donor, the reverse procedure was applied and the IR spectra of **4** (0.005 M) and of its mixtures with increasing concentrations of the acceptor were recorded. The shifts in the ν_{OH} values of the donor were then measured and the K_{assoc} values were calculated as above. Good reproducibility of the formation constants was obtained and the values induded in the tables represent the average of three independent experiments.

Reactions of aryl sulfides and phosphorus(V) esters of thiols with acidic hydrogen peroxide

Clifford A. Bunton, Houshang J. Foroudian, Nicholas D. Gillitt, and Anurag Kumar

Abstract: Oxidations of sulfides and phosphorus(V) esters of thiols by H_2O_2 are catalyzed by H_2SO_4 and $HClO_4$. Sulfides are 4-ZC_6H_4SMe, **1a**–**1e**, respectively, Z = MeO, Me, H, Cl, NO_2; $PhSCH_2CH_2Cl$, **2**, Ph_2S, **3**, and the esters are Ph(R)PO·SEt, **4a**, **4b**, R = Ph, EtO. Electron donation by Z moderately accelerates reaction, but the sulfides are much more reactive than the esters. Reactions are first order in H_2O_2 and substrate, and second-order rate constants, k_2, in H_2SO_4 are related to excess acidity, *X*. Plots of log k_2 against *X* have slopes in the range 0.61–0.85. Rate constants are similar for given concentrations of H_2SO_4 and $HClO_4$, except that with greater than 50 wt.% H_2SO_4 peroxymonosulfuric acid is formed and the observed rate constants then increase. Methanesulfonic acid is a less effective catalyst than the mineral acids. Oxidations of the sulfides are also catalyzed by strongly acidic ion-exchange resins.

Key words: sulfide oxidation, hydrogen peroxide, acid catalysis, excess acidity.

Résumé : Les oxydations sulfures et des esters phosphorés(V) de thiols par le H_2O_2 sont catalysées par le H_2SO_4 et le $HClO_4$. Les sulfures sont 4-ZC_6H_4SMe (**1a–1e** qui portent respectivement Z = MeO, Me, Cl et NO_2), $PhSCH_2CH_2Cl$ (**2**) et Ph_2S (**3**); les esters sont Ph(R)PO·SEt (**4a**, **4b**, R = Ph, EtO). Un groupe Z électrodonneur accélère la réaction d'une façon modérée, mais les sulfures sont beaucoup plus réactifs que les esters. Les réactions sont du premier ordre en H_2O_2 et en substrat et les constantes de vitesse du deuxième ordre, k_2, dans H_2SO_4 sont reliées à l'excès d'acidité, *X*. Les pentes des courbes du log k_2 en fonction de *X* vont de 0,61 à 0,85. Les constantes de vitesse sont semblables pour des concentrations données de H_2SO_4 et de $HClO_4$; toutefois, si la concentration en H_2SO_4 est supérieure à environ 50%, il se forme de l'acide peroxymonosulfurique et les constantes de vitesse observées sont alors plus élevées. L'acide méthanesulfonique est un catalyseur moins efficace que les acides minéraux. Les oxydations des sulfures sont aussi catalysées par les résines échangeuses d'ions fortement acides.

Mots clés : oxydation de sulfure, peroxyde d'hydrogène, catalyse acide, excès d'acidité.

Introduction

Oxidations of two important chemical warfare agents, "Mustard Gas," HD, and *O*-ethyl *S*-[2-diisopropylamino]ethyl methylphosphonothioate, VX, are potentially useful methods for their detoxification (1, 2) (Scheme 1).

Reaction of VX and related compounds probably involves formation of an S-oxide, which rapidly undergoes P—S cleavage and further oxidation at sulfur (2). In reactions with peroxymonosulfate as OXONE ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$), oxygen in the final phosphonate is derived from water rather than the oxidant (3).

Received November 9, 1998.

This paper is dedicated to Jerry Kresge in recognition of his many achievements in chemistry.

Typical oxidants are OCl^- and peroxyacids (1, 2) but alkaline H_2O_2, as HO_2^-, rapidly detoxifies VX and other phosphorus(V) nerve agents (3) by nucleophilic attack, although it is relatively ineffective against chlorosulfides, e.g., HD. The high molecular weight of peroxyacids, including OXONE, and extensive oxidation of the amino group of VX by OCl^-, makes these reagents relatively uneconomical. In contrast, H_2O_2 is an economical oxidant, but its oxidative reactions typically require activation, e.g., by an acylating agent or the hydrogen ion (4–6).

Many nucleophiles, e.g., halide ions, are oxidized by H_2O_2 with acid catalysis (5), and oxidations of sulfides are catalyzed by $HClO_4$ (6). We have examined acid-catalyzed oxidations of sulfides by H_2O_2 (Scheme 2). These sulfides react rapidly with HSO_5^-, giving sulfoxides and, more slowly, sulfones (7, 8). These oxidations have very low activation enthalpies and negative activation entropies and are modestly accelerated by electron-donating substituents, Z (Scheme 2). Rate constants are strongly increased by polar, aqueous, solvents (8), as for other oxidations of sulfides (9, 10). These observations are consistent with "early" polar transition states.

The esters (Scheme 3) are much less reactive than the sulfides (8, 11) and, as with VX, oxidation by HSO_5^- is fol-

lowed by P—S cleavage (1, 2) Sensitivities of rate constants to solvent and temperature are similar to those of the sulfides (8, 11).

Substrates used in the present work are 4-ZC_6H_4SMe, **1**, **a–e**, respectively: Z = MeO, Me, H, Cl, NO_2; $Ph_2SCH_2CH_2Cl$, **2**; Ph_2S, **3**; Ph(R)PO·SEt, **4**, **a**, **b**, R = Ph, EtO. These compounds are nontoxic models for HD and VX.

Reactions of sulfides and esters of thiols by HSO_5^- are modestly accelerated by moderately concentrated H_2SO_4 (12) but it appears that acid catalysis is unimportant. Bentley et al. (13) found that moderately concentrated H_2SO_4 accelerates S_N1 reactions due to its high polarity. They fitted their rate data to the Bentley–Schleyer eq. [1] (14), which is an extension of the Grunwald–Winstein eq. [2] (15).

$$[1] \quad \log (k/k_0) = mY_{OTs} + l N_{OTs}$$

$$[2] \quad \log (k/k_0) = mY$$

The terms Y and Y_{OTs} relate to polarities based, respectively, on solvolyses of *tert*-butyl chloride and sulfonic esters, respectively, and N_{OTs} describes solvent nucleophilicity. The reference solvent is 80% EtOH – H_2O and m and l are reaction parameters (14).

Oxidations of sulfides by IO_4^- and HSO_5^- follow the Grunwald–Winstein equation with $m = 1$, based on Y values in aqueous organic solvents (8, 10, 11) and Y_{OTs} in aqueous H_2SO_4 (12). Values of m are typical of reactions with high sensitivities to solvent ionizing power and polarity (14, 15).

Catalysis by aqueous H_2SO_4 of oxidations by H_2O_2 could involve: (*i*) protonation that generates $H_3O_2^+$ (5, 6); (*ii*) formation of peroxymonosulfuric acid (7, 16); (*iii*) a kinetic solvent effect of aqueous H_2SO_4 (11, 12). The behaviour could be different for catalysis by $HClO_4$ (6), because the aqueous acid probably does not form a peroxy acid with H_2O_2.

[a]At 25.0°C with 1.4×10^{-5} M substrate.

[b]Mean of values (±2%) with 0.8 and 1.4×10^{-5} M substrate.

Rate constants of hydrogen ion catalyzed reactions typically have integral orders with respect to H^+ in dilute acid, with deviations at higher concentrations, because protonating power increases more steeply than concentration. These increases are treated by using acidity functions based on selected indicators (17–19) or in terms of excess acidity scales (20).

Results

Reactions were followed at 25.0°C (unless specified), with H_2O_2 in excess over substrate. First-order rate constants, k_{obs}, with respect to substrate varied linearly with H_2O_2, i.e., $k_{obs} = k_2[H_2O_2]$ (Tables 1 and 2 and Fig. 1). A range of $[H_2O_2]$ was used, depending on the reactivity of the substrate and the acid concentration.

Second-order rate constants, k_2, increased steeply with increasing concentration of H_2SO_4, but without affecting the
