[b]In parentheses, in kcal mol^{-1}.
[c]See text.

Table 3. Ozonolysis of *o*-xylene: calculated percentages of **3**, **4**, and **5** from eqs. [12] and [13], the percentages predicted by the resonance description of *o*-xylene, and the experimental result of ref. 6.

	HF				DFT					
	Scaled		Unscaled		Scaled		Unscaled			
	243 K	298 K	243 K	298 K	243 K	298 K	243 K	298 K	**1** ↔ **2**	Experimental
3	19.1	24.6	21.3	27.0	31.1	33.1	31.1	35.5	33.3	32–37
4	57.1	54.4	56.0	53.2	51.1	50.1	51.1	48.9	50.0	42–47
5	23.8	21.0	22.7	19.8	17.8	16.8	17.8	15.6	16.7	19–24

The calculated product ratios are then as follows:

$$[12]\quad \mathbf{3}/\mathbf{5} = V_3/V_5 = \frac{2V_b + 2V_c}{V_a + V_d} = \frac{2k_b + 4k_c}{k_a + 2k_d} = \frac{2e^{-\Delta G_b^{\ddagger}/RT} + 4e^{-\Delta G_c^{\ddagger}/RT}}{e^{-\Delta G_a^{\ddagger}/RT} + 2e^{-\Delta G_d^{\ddagger}/RT}}$$

$$[13]\quad \mathbf{4}/\mathbf{5} = V_4/V_5 = \frac{2V_a + V_b + V_c + 2V_d}{V_a + V_d} = \frac{2k_a + k_b + k_c + 2k_d}{k_a + k_d} = \frac{2e^{-\Delta G_a^{\ddagger}/RT} + e^{-\Delta G_b^{\ddagger}/RT} + 2e^{-\Delta G_c^{\ddagger}/RT} + 4e^{-\Delta G_d^{\ddagger}/RT}}{e^{-\Delta G_a^{\ddagger}/RT} + 2e^{-\Delta G_d^{\ddagger}/RT}}$$

The percentages of **3**, **4**, and **5** calculated using eq. [12] and [13] are collected in Table 3 for two temperatures (–30°C and 25°C), two computational procedures (HF and DFT), and with and without scaling of vibrational frequencies. Table 3 also includes the percentages of **3**–**5** predicted by the resonance description 1 ↔ 2, and the experimental results of Haaijman and Wibaut (6). The scaled DFT results are in almost exact agreement with the resonance prediction.

Concluding remarks

The present work leads to the conclusions that ozone reacts at equal rates at the unsubstituted 3,4- and 4,5- bonds of *o*-xylene (channels *a* and *c* of **8**) and that the 3:2:1 product ratio is determined by these kinetics. Although a 3,4-double bond is present in canonical structure **1** and a 4,5-double bond is present in canonical structure **2**, the resonance interpretation makes no distinction between the 1,2- and 3,4- reactivities of **1**, or between the 2,3- and 4,5- reactivities of **2**. Consequently, the ozonolysis experiment cannot be regarded as confirmation of the existence of localized double bonds in *o*-xylene. Likewise, although FMO theory also leads to a 3:2:1 product ratio, it does this by the incorrect prediction that these products are formed solely via channels *a* and *b*. In short, since the products of ozonolysis of *o*-xylene are determined by the relative energies of the transition states leading to the four possible primary ozonides, these transition states should be the focus of any theory.

A comprehensive computational examination of transannular Diels–Alder reactions of unsubstituted C14 trienes — Barriers, template effects, and the Curtin–Hammett principle

Saul Wolfe, Anthony V. Buckley, and Noham Weinberg

Abstract: A combination of MM3-level molecular mechanics calculations and PM3-level semiempirical molecular orbital calculations has been employed, in conjunction with an algorithm for the comprehensive conformational analysis of cyclic compounds, to obtain 1202 unique 1,3,9-cyclotetradecatriene conformations, distributed over the six possible geometrical isomers, and 70 unique transannular Diels–Alder transition structures leading to the six possible stereoisomeric tricyclic olefins. A kinetic analysis that takes into account all minima of a given geometrical isomer and all transition structures leading to the same tricyclic product leads to a free energy of activation that is almost the same as the free energy difference between the lowest minimum and the lowest transition structure (the Curtin–Hammett principle). A substantial template effect, mainly entropic in origin, is found when the transannular reactions are compared to the Diels–Alder reactions of the cognate 2,4-hexatrienes with the 2-butenes. Although the cyclization of the *trans-cis-trans* triene favours the *cis-anti-cis* over the *trans-anti-trans* product by more than 20 kcal mol^{-1}, the situation is reversed in the acyclic reaction. A cyclic triene that can cyclize directly to a *trans-anti-trans* tricycle can therefore be proposed.

Key words: molecular models, Deslongchamps, Takahashi, *trans-anti-trans* tricycle, MM3, PM3, transition states.

Résumé : On a fait appel à des calculs de mécanique moléculaire au niveau MM3 et des calculs d'orbitales moléculaires semi-empiriques au niveau PM3, en association avec un algorithme pour l'analyse conformationnelle détaillée des composés cycliques pour obtenir 1202 conformations uniques du cyclotétradéca-1,3,9-triène distribuées sur six isomères géométriques possibles ainsi que 70 structures de transition de réactions de Diels–Alder transannullaires conduisant aux six oléfines tricycliques stéréoisomères possibles. Une analyse cinétique qui tient compte de tous les minima d'un isomère géométrique donné et de toutes les structures de transition conduisant au même produit tricyclique conduit à une énergie libre d'activation qui est pratiquement la même que la différence d'énergie libre entre le minimum le plus bas et la structure de transition de plus basse énergie (principe de Curtin–Hammett). On a observé un effet de gabarit important, principalement d'origine entropique, quand on compare les réactions transannulaires aux réactions de Diels–Alder d'hexa-2,4-dienes connus avec des but-2-ènes. Même si la cyclisation du triène *trans-cis-trans* favorise la formation du produit *cis-anti-cis* par rapport à celle du produit *trans-anti-trans* par plus de 20 kcal mol^{-1}, la situation est inversée dans la réaction acyclique. Il est donc possible de proposer un triène cyclique qui se cycliserait directement en un tricycle *trans-anti-trans*.

Mots clés : modèles moléculaires, Deslongchamps, Takahashi, tricycle *trans-anti-trans*, MM3, PM3, états de transition.

Introduction

Although the use of molecular models to rationalize or predict relative stabilities of isomers and results of chemical reactions has a long and rich history (1), there are pitfalls. A model "at best merely *abstracts* a few particular and selected molecular properties" (2), "does not provide an adequate picture of molecular motion" (3), and, in general, assumes fixed bond angles and low barriers to rotation about single bonds "in contrast to the real situation of relatively easily deformable bond angles and substantial barriers to rotation about single bonds" (4).

The recent research of Deslongchamps (5) and Takahashi (6) and their co-workers into a transannular Diels–Alder approach to steroid synthesis illustrates both the predictive capabilities and also some of the limitations of molecular models. For the reaction **1** → **2**, in the general case (R ≠ H), there are eight geometrical isomers of **1** and eight diastereomers of **2**. Examination of Dreiding models of analogs of **1** having R = Me and $m = n = 4$ (5*b*) allowed Deslongchamps and co-workers to predict the relationship between the geometry of **1** and the stereochemistry of **2**. These predictions were accompanied by comprehensive ex-

perimental studies in which cyclization temperatures ranging from 80–365°C and products sometimes different from the predicted were observed. Although closer inspection of models permitted rationalization of unexpected results, it was evident that a more rigorous kinetic analysis, based on appropriate computations, was necessary, and several such studies, involving a limited treatment of the conformational space of reactants and transition structures, have been reported (5*d*, 5*e*, 5*g*, 6*c*).

1 **2**

There is no doubt that the experimental and theoretical treatment of transannular Diels–Alder reactions is in good hands. Nonetheless, some questions remain. For example: (*i*) How many minima and how many transannular Diels–Alder transition structures (TS) exist for each geometrical isomer of **1**? (*ii*) For a given geometrical isomer, do different TS lead to different products? (*iii*) For a given geometrical isomer which minimum produces the lowest energy TS? (*iv*) If there are many minima and many TS, what are the reaction barriers? (*v*) Is the Curtin–Hammett principle (7) relevant? (*vi*) Is there a template effect and, if so, what is its origin? (*vii*) Is a *trans-anti-trans* product directly accessible by a transannular Diels–Alder reaction?

In the present work we attempt to answer these questions for the case of the C14 triene **1**, R = H, m = *n* = 4, by a combination of MM3-level molecular mechanics calculations (8) and PM3-level semiempirical molecular orbital calculations (9), in conjunction with an efficient algorithm for the comprehensive conformational analysis of cyclic compounds (10).

Strategy

Application of the procedure of ref. 10 to 100 000 probe C14 triene structures produced 38 552 closed rings; MM3 minimization of 10 000 of these rings afforded 1370 minima. These were reoptimized, using PM3, to give 1172 *unique* minima (no imaginary frequencies), distributed as follows (double bond geometries are designated C or T, and in the order 1–2–3 shown in **1**): CCC 191, CCT 142, TTC 95, TTT 95, CTC (≡TCC) 350, CTT (≡TCT) 299. The 1172 PM3 structures were then subdivided further into those having s-*cis* or s-*trans* conformations, defined according to the diene dihedral angles: s-*cis* = 0–90°, s-*trans* = 90–180°. The distribution of PM3 minima at this stage is summarized in Table 1.

As a prelude to the calculation of transannular Diels–Alder transition structures, the Gibbs free energies of the 1172 minima were computed at 298 K, using PM3 within the Gaussian 94 (11) and Gaussian 98 (12) programme systems. Then, taking into account the bond lengths found in PM3 transition structures of cognate acyclic Diels–Alder reactions

(see later), the 568 s-*cis* conformations (**A**) were submitted for transition structure search according to the following protocol: (*i*) **a** and **b** bond lengths (see **1**) of 2.2 Å were imposed on each structure, and all other geometrical parameters were optimized; (*ii*) the **a** and **b** bond lengths of **B**, the structures from (*i*), were reduced to 1.6 Å, and the structures were minimized without constraint to yield **C**, stereo and conformational isomers of the tricyclic products **2**; (*iii*) the quadratic synchronous transit method of Schlegel and coworkers (13, 14) was applied to **A**, **B**, and **C** to yield a total of 70 unique stationary points having a single imaginary frequency; (*iv*) the free energies of these transition structures were calculated at 298 K; (*v*) using the reaction path following method of Gonzalez and Schlegel (15), the intrinsic reaction coordinates (IRC) connecting transition structures to their monocyclic precursors and tricyclic products were calculated. This process yielded an additional 30 monocyclic minima, identified in parentheses in Table 1, to make a total of 1202.

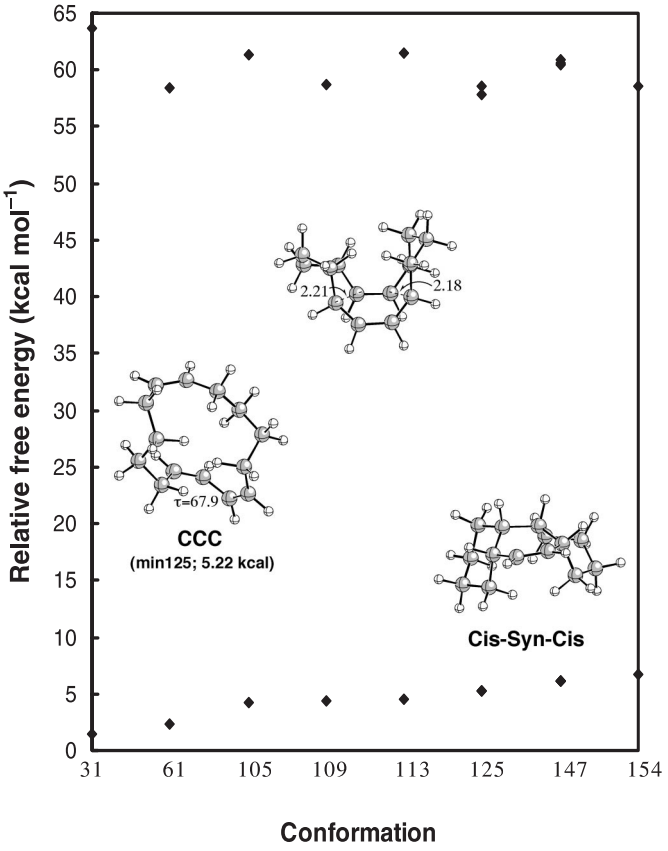
Results

Transannular Diels–Alder reactions

Table 2 summarizes the results. In two cases, CCC and TTT, a single tricyclic product is predicted. In three cases, CCT, TTC, and CTC, two tricyclic products are predicted. The CTT isomer can cyclize in three ways. However, although each of the 11 possible cyclization pathways can be found with the aid of Dreiding models, it is clear from Figs. 1–6 that only in the case of the TTC isomer would more than one transannular Diels–Alder product be

© 2001 NRC Canada

Fig. 1. Transannular cyclization of the CCC triene.



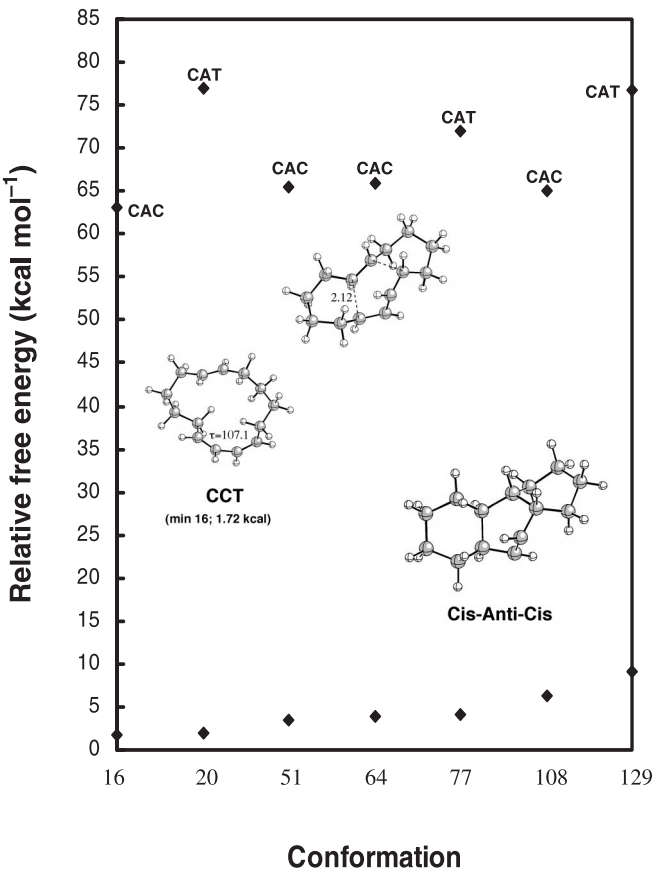


Fig. 2. Transannular cyclization of the CCT triene.

kinetically feasible. This follows from the Curtin–Hammett principle (7), which states, in part (16): "the product composition … is controlled … by the difference in standard free energies … of the respective transition states."

The figures show the free energy of each TS and the free energies of the minima that are IRC-linked to these TS, all relative to the most stable minimum. The figures also provide the ordering of these minima relative to the lowest energy monocyclic minimum, and the stereochemistry of the tricyclic isomer that is produced from each TS. The structures shown in the figures are the TS having the lowest free energy at 298 K, and the minimum and product that are linked to this TS. For example, according to Fig. 1, which refers to the CCC isomer, each of the 11 transannular Diels–Alder TS, whose free energies are ca 58–64 kcal mol^{-1} higher than the free energy of the lowest minimum, cyclizes to the *cis-syn-cis* (CSC) isomer. The 11 TS are linked to minima 31, 61, 105, 109, 113, 125, 147, and 154, of the total of 192 (Table 1), which are, in turn, ca 2–8 kcal mol^{-1} less stable than the most stable minimum. The TS of lowest free energy is derived from minimum 125, whose free energy is 5.22 kcal mol^{-1} higher than that of the most stable minimum. This minimum can be seen in Fig. 7, which shows the free energy and diene dihedral angles of the most stable conformation of each monocyclic isomer.

Cognate acyclic Diels–Alder reactions

The transannular reactions just discussed have acyclic counterparts in the reactions of the *cis*,*cis*-, *cis*,*trans*- and *trans*,*trans*-2,4-hexadienes with *cis*- and *trans*-2-butene, to form the stereoisomeric 3,4,5,6-tetramethylcyclohexenes. Figures 8–10 show the PM3 transition structures of, respectively, the *cis*,*cis*-diene with *cis*- (CCC) and *trans*-2-butene (CCT), the *trans*,*trans*-diene with *cis*- (TTC) and *trans*-2-butene (TTT) and the *cis*,*trans*-diene with *cis*- (CTC) and *trans*-2-butene (CTT). The numbers included in the figures are the **a** and **b** bond lengths (Å) and the relative free energies at 298 K.

As seen in Fig. 8, there are two CCC TS, one, corresponding to *endo* approach of the dienophile, which leads to the *trans-syn-trans* olefin and the other, corresponding to *exo* approach of the dienophile, which leads to the *cis-syn-cis* olefin. The *endo* TS, which minimizes Me–Me repulsive interactions, is 3.91 kcal mol^{-1} more stable, but is not accessible in the corresponding transannular reaction (Fig. 1). This reaction is calculated to lead exclusively to the *cis-syn-cis* isomer, with a prohibitively high barrier (vide infra).

Figure 8 also shows two CCT TS, one leading to the *trans-anti-cis* olefin, and the other, less stable by 8.95 kcal mol^{-1} because of the presence of two Me–Me eclipsing interactions, leading to the *cis-anti-cis* olefin, which has an improbable *trans*-double bond. In the transannular reaction (Fig. 2), the *cis-anti-cis* TS is more stable, despite the formation of a *trans*-olefin, because of the ring strain (not shown) required to achieve the *cis-anti-trans* TS. In each case (TS 20, 77, and 129), one of the C···C bond lengths is at least 2.30 Å.

As seen in Fig. 9, in the case of the TTC reaction, *exo* approach of the dienophile, leading to the *trans-syn-trans* ole-

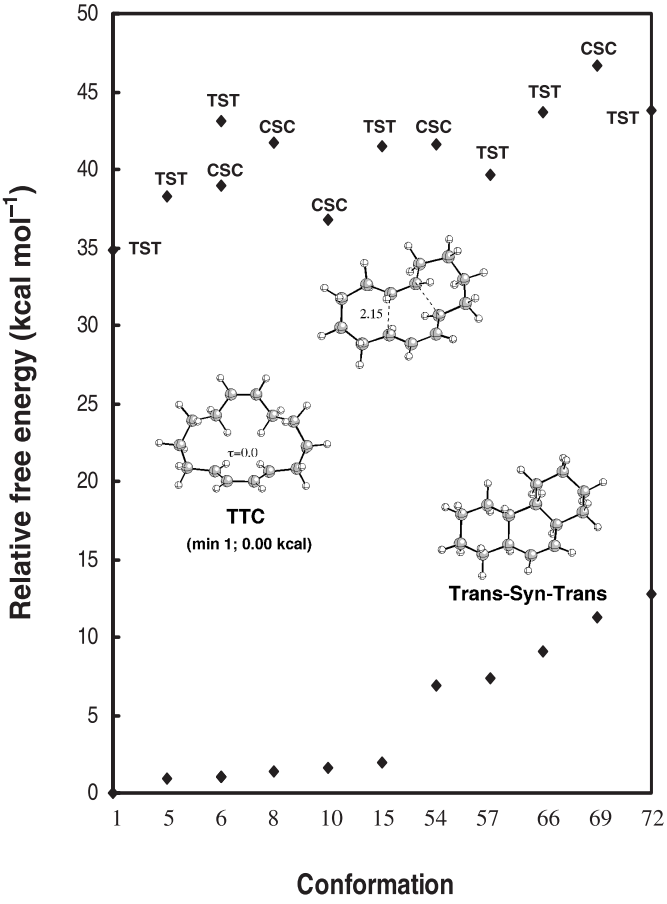
Fig. 3. Transannular cyclization of the TTC triene.



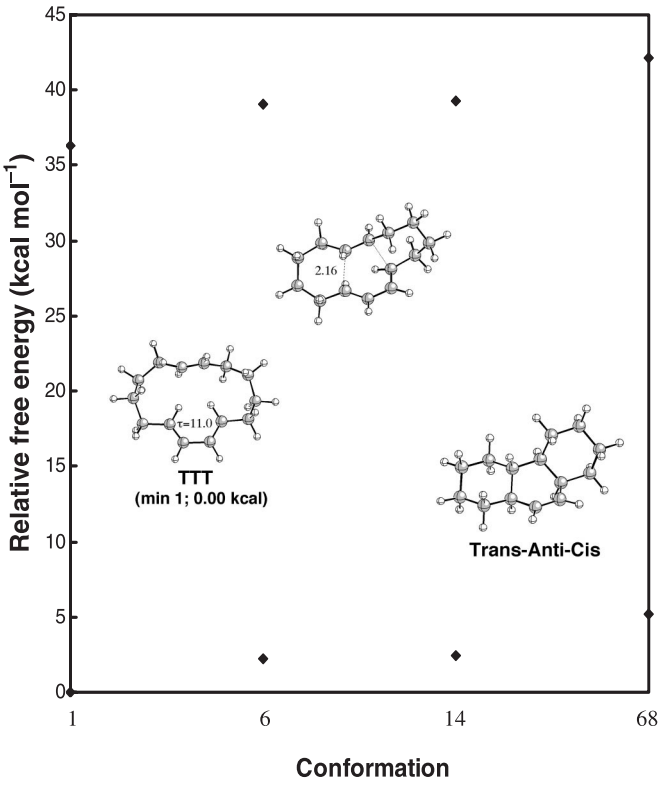


Fig. 4. Transannular cyclization of the TTT triene.

fin, is 1.55 kcal mol^{-1} more stable than *endo* approach, leading to the *cis-syn-cis* olefin. A similar difference is seen in the transannular reaction (Fig. 3).

In the case of the TTT reaction, leading exclusively to the *trans-anti-cis* olefin, Figs. 4 and 9 show very similar C···C bond lengths and diene dihedral angles, presumably because of the absence of strain in the four-carbon bridges of the transannular reaction.

In the case of the TCC reaction (Fig. 10), both *endo* and *exo* approach of the dienophile lead to the same olefin, with the *endo* approach slightly preferred. In the transannular reaction (Fig. 5), the most stable TS (from min 239) is the result of *exo* approach, and *endo* approach is seen only in the very high energy TS (not shown) from minima 32, 110, 115, 138, and 184.

The TCT reaction (Figs. 6 and 10) leads to *trans-anti-trans* and *cis-anti-cis* olefins (all *trans-anti-cis* TS of the transannular reaction lead to *trans*-double bonds in ring B). It is very significant that *the TCT reaction can produce a trans-anti-trans isomer* and that the TS of the acyclic reaction is *more stable* than the *cis-anti-cis* TS. In the transannular reaction, the situation is reversed by more than 20 kcal mol^{-1}! The explanation is that separation of the diene and the dienophile by four-carbon bridges does not allow the *favoured trans-anti-trans* TS to be achieved. Since the *trans-anti-trans* stereochemistry is the preferred result of a transannular Diels–Alder reaction (5), a synthetic strategy that might yield this isomer directly would appear to require a TCT geometry in the macrocycle and separation of the diene and dienophile components by bridges containing more than four atoms. We shall return to this point.

Table 3. Mean free energies of activation ($\Delta G_b^{\ddagger}$) and Curtin–Hammett free energies of activation ($\Delta G_{CH}^{\ddagger}$) (kcal mol^{-1}) of transannular Diels–Alder reactions of geometrical isomers of the C14 triene **1**, R = H, $m = n = 4$.

Discussion

General

The following additional observations are made upon inspection of Figs. 1–6: (*i*) in two cases (TTC and TTT) the most stable TS is produced from the most stable minimum; (*ii*) in one case (CCC) minimum 125 is linked to two, and minimum 147 is linked to three different TS; (*iii*) in two cases (CTC and CTT) the same TS is linked to more than

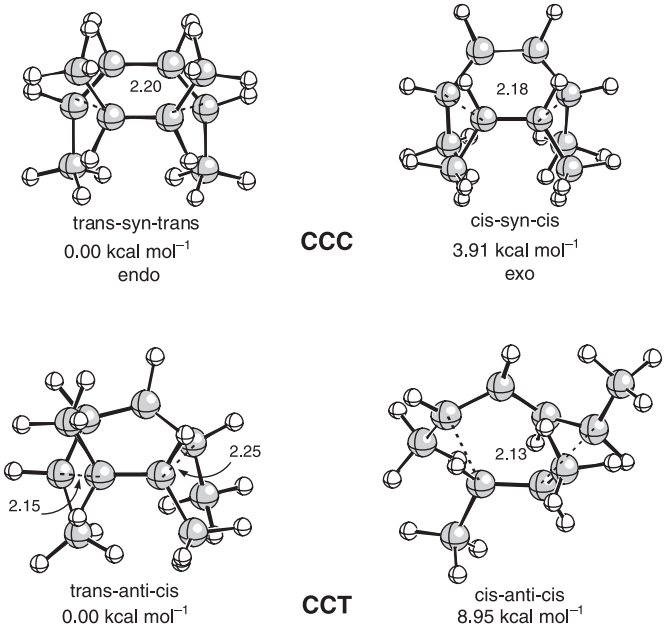

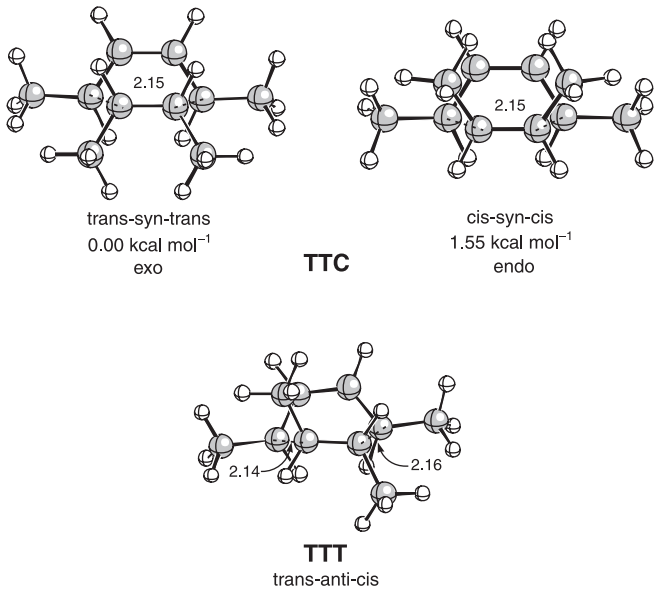

Fig. 9. Transition structures for the intermolecular TTC and TTT reactions.

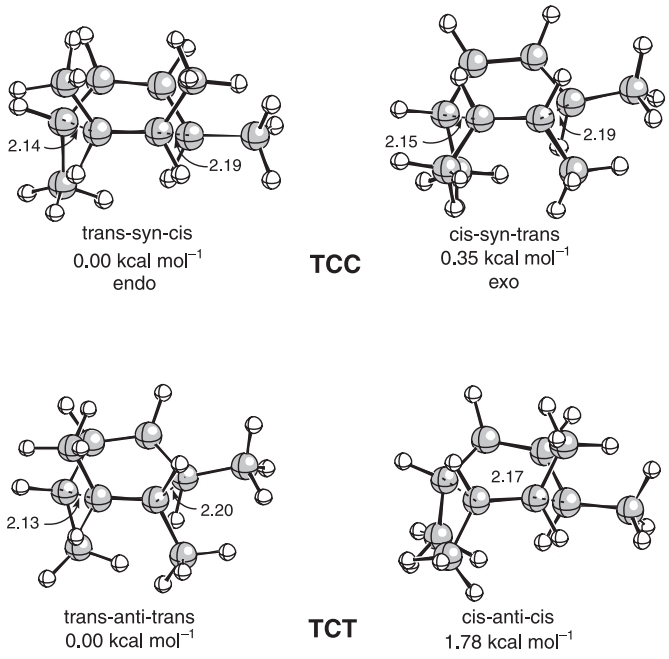
$$[3] \qquad [A_t^r] = \frac{e^{-G_t/RT}}{\sum_{i=1}^{n} e^{-G_t/RT}}[A]$$

are the concentrations of reactive conformations related to the overall concentration [*A*] through appropriate Boltzmann factors.

The overall rate ν is the sum of the partial rates



$$[4] \qquad \nu = \sum_{t=1}^{m} \nu_t$$

and, from eq. [1]–[4],

$$[5] \qquad \nu = \frac{\kappa T}{h} \frac{\sum_{t=1}^{m} e^{-G_t^{\ddagger}/RT}}{\sum_{i=1}^{n} e^{-G_i/RT}}[A]$$

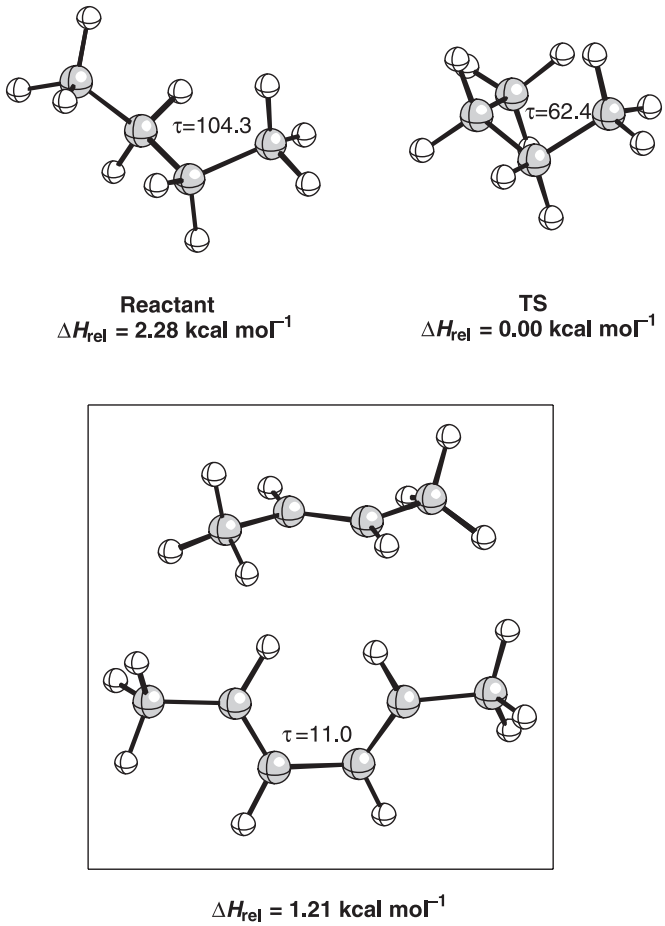
© 2001 NRC Canada

Fig. 10. Transition structures for the intermolecular TCC and TCT reactions.

Since the overall rate ν is

[6] $$\nu = k[A]$$

the overall rate constant k is given by eq. [7],



[7] $$k = \frac{\kappa T}{h} \frac{\sum_{t=1}^{m} e^{-G_t^{\ddagger}/RT}}{\sum_{i=1}^{n} e^{-G_i/RT}}$$

and the corresponding mean standard Gibbs free energy of reaction is

[8] $$\Delta G_b^{\ddagger} = -RT \ln \left[\frac{\sum_{t=1}^{m} e^{-G_t^{\ddagger}/RT}}{\sum_{i=1}^{n} e^{-G_i/RT}} \right]$$

Table 3 summarizes the $\Delta G_b^{\ddagger}$, calculated at 298 K from eq. [8], for each of the transannular Diels–Alder reactions of the present work. This table also includes the Curtin–Hammett barriers ($\Delta G_{CH}^{\ddagger}$), defined (7) *as the free energy difference between the lowest minimum and the lowest TS*. It can be seen that the $\Delta G_b^{\ddagger}$ values, which take into account *all* of the minima and *all* of the TS leading to the same product, are not very different from the Curtin–Hammett barriers. Consequently, although equations analogous to eq. [8] can be derived for $\Delta H_b^{\ddagger}$ and $\Delta S_b^{\ddagger}$, the analysis of template effects that follows in the next section was based on $\Delta H_{CH}^{\ddagger}$, and $\Delta S_{CH}^{\ddagger}$, defined as differences in enthalpy and entropy between the lowest minima and lowest TS.

Fig. 11. Analysis of ground-state destabilization in the cyclization of the TTT isomer.

Template effects

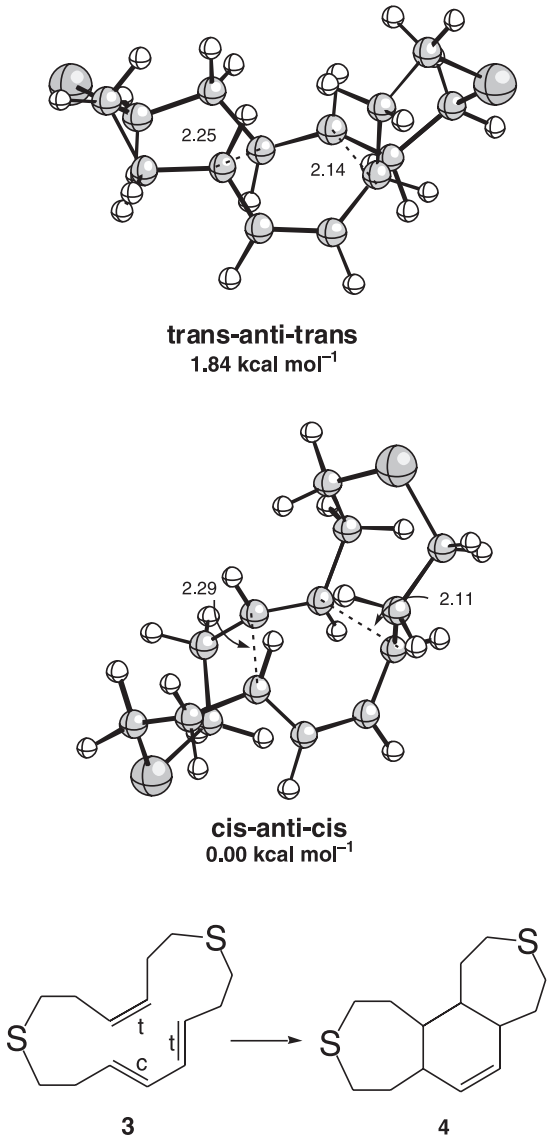


Table 4 compares, for T = 298 K, the Curtin–Hammett free energies of activation of the transannular Diels–Alder reactions (from Table 3), and the enthalpic and entropic contributions to these free energies, with the corresponding quantities for the acyclic Diels–Alder reactions of Figs. 8–10. The latter data were obtained with the assumption that the initial thermodynamic parameters are the sum of the diene and dienophile parameters, i.e., that the reaction coordinate is repulsive between reactants and TS.

There is a significant template effect. With the exception of the very unfavourable CCT reaction, which produces a *trans* double bond, and the TCT reaction that leads to the *trans-anti-trans* product, all transannular reactions have substantially lower free energies of activation than their acyclic counterparts. Since the transannular reactions are unimolecular and the acyclic reactions are bimolecular, there is a uniformly large entropic contribution to the template effect. Interestingly, in the most favourable TTC and TTT transannular reactions there is also a significant enthalpic contribution to the template effect.

This effect appears to be caused by ground-state destabilization in the transannular reactions, as is summarized in Fig. 11. The structure shown at the bottom of the figure is obtained by truncation of the lowest TTT minimum (Figs. 4 and 7) to the corresponding acyclic reactant com-

© 2001 NRC Canada

Fig. 12. Two transition structures for the transannular Diels–Alder cyclization of the triene **3** to the olefin **4**.

plex. The truncated structure is destabilized enthalpically relative to the separated reactants by 1.2 kcal mol^{-1}. The structures at the upper left and upper right of the figure are obtained by truncation of the four-carbon chains of the TTT minimum and TS to the corresponding conformations of *n*-butane. The reduction of the two C-C-C-C dihedral angles, from 104.3° in the minimum to 62.4° in the TS, reduces the ring strain by a total of 4.56 kcal mol^{-1}. The total ground-state destabilization (5.77 kcal mol^{-1}) is close to the $\Delta\Delta H^{\ddagger}$ value of 6.11 kcal mol^{-1} seen in Table 4.

Is cyclization to a *trans-anti-trans* product feasible?

It was suggested earlier that the inherently more favourable reaction channel leading to the *trans-anti-trans* stereochemistry cannot be achieved by a cyclic TCT triene in which the diene and dienophilic components are separated by four atoms. Inspection of Dreiding models suggested that the addition of a fifth atom to these bridges, as in the dithia compound **3** (Fig. 12) would overcome the problem. A very cursory examination of the cyclization of **3** to **4** produced one TS leading to the *cis-anti-cis* product and one TS leading to the *trans-anti-trans* product. In contrast to Fig. 6, in which every *trans*-anti-*trans* TS is destabilized by at least 20 kcal mol^{-1}, the free energy difference between the two structures of Fig. 12 is only 1.84 kcal mol^{-1}. A comprehensive examination of the cyclization of the TCT isomer of **3** is currently in progress.

Ref.: Can. J. Chem. **79**, 110 (2001).

After this paper was published we became aware of an earlier report (M.S. Newman and E. Kilbourn. J. Org. Chem. **35**, 3186 (1970)) concerning a 2,2-dialkoxyoxirane. Our claim, that we were the first to isolate such a compound, is therefore not correct.

Adventures in organometallic NMR: steric restraints, slowed rotations, and skeletal rearrangements

Michael J. McGlinchey

Abstract: The structures and NMR fluxionality of a wide variety of organometallic complexes (including tetrahedral cluster cations and systems of the type $(C_nR_n)ML_3$, where R = Et, Ph) are discussed. Barriers to tripodal and peripheral substituent rotations are reported, and the relevance of correlated rotations to molecular machines is outlined. Haptotropic shifts in (cyclopenta[*def*]phenanthrenyl)ML_n and (cyclopenta[*l*]phenanthrenyl)ML_n complexes are rationalized in terms of the aromatic character of the transition states. Likewise, the barriers to silatropic shifts in polyindenylsilanes can be correlated with the aromaticity of the intermediate isoindenes. Finally, the use of cobalt clusters to control cyclohexane ring conformations is described.

Key words: NMR ring currents, fluxionality, correlated rotations, molecular rearrangements, haptotropic shifts.

Résumé : Les structures et la non-rigidité à l'échelle de temps de la RMN d'une grande variété de complexes organométalliques (dont des clusters tétraédriques cationiques et des systèmes du type $(C_nR_n)ML_3$ dans lesquels R = Et, Ph) sont discutées. Les barrières de rotation des substituants tripodes et périphériques sont données et le rapport entre les rotations concertées et les machines moléculaires est souligné. Les déplacements haptotropiques dans les complexes (cyclopenta[*def*]phénanthrényl)ML_n et (cyclopenta[*l*]phénanthrényl)ML_n sont rationalisés en termes du caractère aromatique des états de transition. De la même manière, les barrières des déplacements silatropiques dans les polyindénylsilanes sont corrélées avec l'aromaticité des intermédiaires isoindènes. Enfin, l'utilisation de clusters de cobalt pour contrôler la conformation de cyclohexanes est décrite.

Mots clés : courants de cycle en RMN, non-rigidité, rotations concertées, réarrangements moléculaires, déplacements haptotropiques.

Prologue

At the outset, I wish to acknowledge Alcan for their continued support of the inorganic chemistry community in Canada, and also to thank CSC for administering the awards program that provides recognition and encouragement to researchers and teachers whose activities cover a wide spectrum of the enormous enterprise we call Chemistry.

Since arriving at McMaster 28 years ago, my graduate and undergraduate thesis students, postdoctoral collaborators, and I have worked in a number of apparently diverse areas. These have encompassed the use of metal vapours as synthetic reagents (1–6), the chemistry of metal π-complexes (7–12), NMR spectroscopic studies of transition metal nuclei, such as ^{45}Sc (13), ^{47,49}Ti (14), ^{61}Ni (15), ^{91}Zr (16), hitherto unexplored in organometallic systems (17), syntheses and fluxional behaviour of metal hydrides (18), metal clusters (19–32), organometallic derivatives of natural products (33), and the stabilization of short-lived intermediates such as benzyl anions (34) or cations (35, 36), silyl cations (37), trimethylenemethane (38), and tetramethylenebenzene (39). More recently, we have focused our attention on the migrations of organometallic moieties across polycyclic surfaces and on the molecular dynamics of sterically hindered molecules.

In this brief overview, I shall attempt to show how several of these seemingly very disparate topics in fact followed a common thread as our research progressed in a semiorderly fashion.

Metal vapours, ring currents, and diamagnetic anisotropy

In 1972, the chemistry of metal vapours was still very much in its infancy (40); in those days researchers built their own relatively unsophisticated equipment from glass-sewer piping and resistance-heated ceramic crucibles — a far cry from today's commercially available metal evaporators with their electron gun technology (41). Nevertheless, one could vaporize metals such as chromium (1–6), nickel (42), or

 DOI: 10.1139/cjc-79-9-1295 © 2001 NRC Canada

Scheme 1. Synthetic routes to $(C_6F_5X)Cr(C_6H_6)$ sandwich complexes.

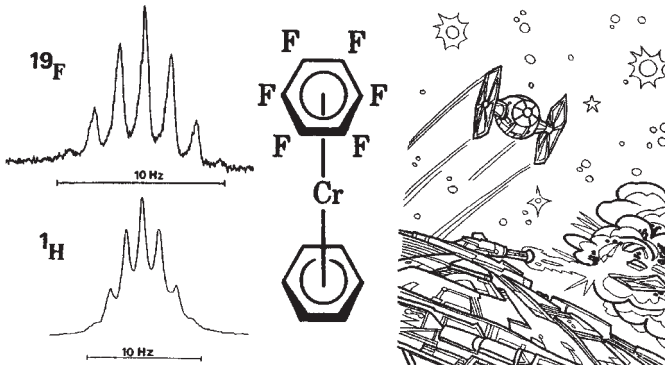
germanium (43), cocondense them onto a liquid nitrogen cooled surface with a potential ligand, and generate novel organometallics. Typically, we were able to prepare synthetically useful quantities of previously unavailable sandwich complexes, as illustrated in Scheme 1.

Parenthetically, one should note the topicality of the sandwich complex $(C_6F_6)Cr(C_6H_6)$ (**1**) whose sixfold symmetry was remarkably reminiscent of the Star Wars "tie fighters" that were in vogue at that time.

The NMR spectra of these new systems revealed a number of surprising facets, such as the clear inter-ring $J_{H,F}$ couplings in $(C_6F_6)Cr(C_6H_6)$ (**1**) shown in Fig. 1 (4), or the magnitude of the $J_{F,F}$ values in $(C_6F_5X)Cr(C_6H_6)$ sandwiches, as exemplified by the phosphine complex **2** (44). Typically, in fluoroarenes, the coupling between *ortho* fluorines is ≈20 Hz, while *meta* couplings are normally approximately 4 Hz; in the sandwich complexes, the corresponding $^3J_{F,F}$ and $^4J_{F,F}$ values are in the ranges of 90–110 and 40–50 Hz, respectively. These very marked changes wrought upon the ^{19}F chemical shifts and fluorine–fluorine coupling constants within the pentafluorophenyl rings upon complexation to a $(C_6H_6)Cr$ moiety made us reflect upon the possible influence of the metal on the aromatic ring current.

We, therefore, sought a sensitive probe with which to monitor changes in the aromatic ring current, but which was also sufficiently distant from the metal as to be unaffected by it directly. The classic work of Cram and co-workers (45) had demonstrated that protons positioned directly above an aromatic system, as in the alkyl chain of a cyclophane, were markedly shielded. Our idea was then to synthesize a metal complex of a cyclophane, and to compare the chemical shifts of the protons above the ring in both the free and the

Fig. 1. ^{19}F and ^1H NMR spectra of $(C_6F_6)Cr(C_6H_6)$ (**1**); each resonance is a septet because of inter-ring coupling.



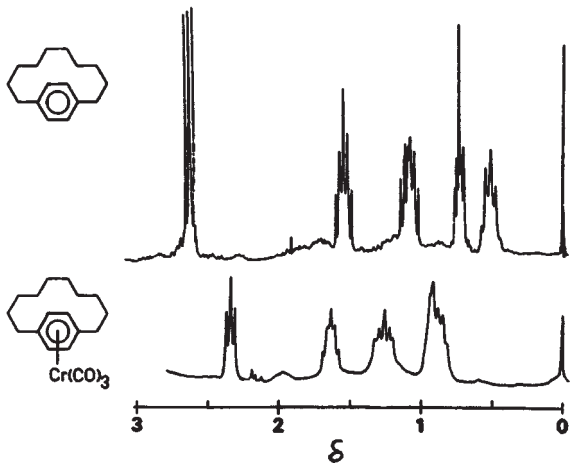


Fig. 2. 220 MHz ^1H NMR spectra of [10]paracyclophane (**3**) and its $Cr(CO)_3$ complex **4**.

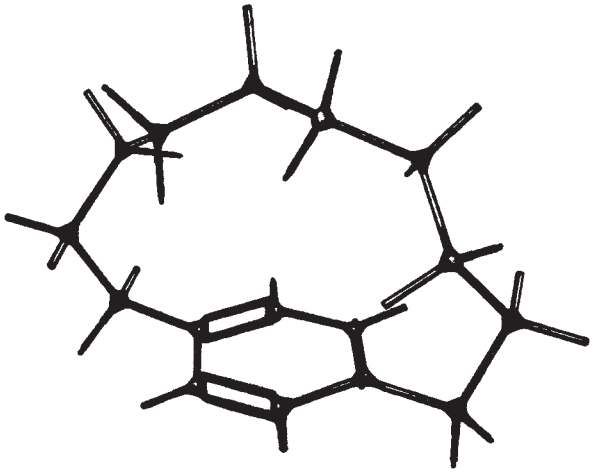


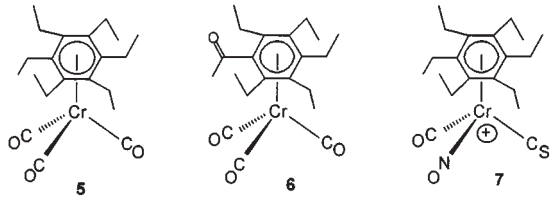
complexed systems. At that time (1975), a 220 MHz spectrometer was considered a high-field instrument, and fortunately, we were able to acquire ^1H NMR spectra of [10]paracyclophane (**3**) and of its $Cr(CO)_3$ complex (**4**) and they are shown in Fig. 2 (46).

It is evident that, in the complex, those protons positioned in the shielding cone of the ring current (β, γ, δ, and ε methylene groups) are now less shielded; in contrast, the α-methylene protons, which lie in the deshielding region, have now moved to lower frequency. Our conclusion was that the aromatic ring current had been attenuated upon complexation. Since that time, several researchers have investigated this phenomenon, with occasionally confusing results (47). Interestingly, while some authors have raised the possibility that complexation of an arene to a chromium tricarbonyl unit actually renders the system *antiaromatic* (48), very recent NICS calculations do not support this view (49).

Returning to the mid-1970s, a crucial criterion to be satisfied when evaluating ring current contributions to proton chemical shifts was, of course, a reliable molecular geometry. Since [10]paracyclophane is a liquid, we chose to take advantage of the molecular modeling programs that were just being developed, notably by Allinger at the University of Georgia. The experimentally measured chemical shifts for

© 2001 NRC Canada

Fig. 3. Fieser molecular model of [10]paracyclophane used to calculate proton positions relative to the arene ring centre, and hence to evaluate ring current shifts.



the methylene groups of [10]paracyclophane, in conjunction with the calculated geometry (shown in Fig. 3 as a Fieser model) revealed that the standard Waugh–Fessenden–Johnson–Bovey ring-current model (50, 51) had serious inadequacies.

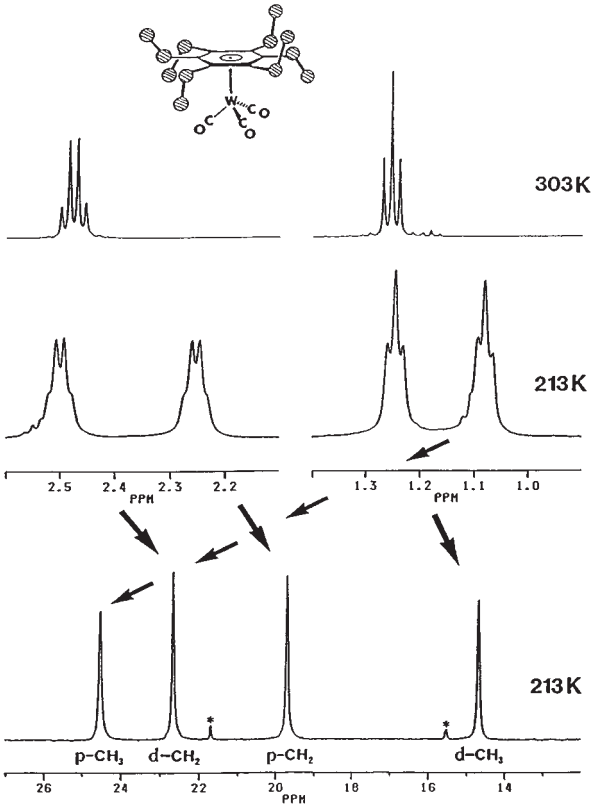
This semiclassical model and the ring-current tables derived from it have been used many thousands of times since their inception, and presumably, the majority of users have never considered its rather flimsy theoretical underpinnings. In brief, Waugh and Fessenden (50) attributed the entire 1.5 ppm chemical shift difference between the protons in benzene and the vinylic protons in 1,3-cyclohexadiene to the ring current effect. They then calculated the effect of an *in-plane* six-electron current on a benzene proton. Since this calculation predicted too large a deshielding (2.78 ppm), the in-plane current was split into two loops, one above and the other below the ring plane, until the desired 1.5 ppm deshielding was achieved; this occurred at a loop separation of 1.28 Å, and since that time, constant use has bestowed an imprimatur on this decidedly empirical model. The present status of NMR studies on cyclophanes, and of the relevance of ring current calculations, has recently been comprehensively reviewed (52).

In 1975, Barfield et al. (53) showed that one could not ignore the anisotropic contributions of the ring carbons to the chemical shifts of protons proximate to arene rings. This approach required a knowledge of the ^{13}C NMR tensor elements of the ring carbons and such data are, in principle, obtainable from measurements in the solid state. Fortuitously for us, the leading pioneer in this area, John Waugh at MIT, graciously agreed to measure the ^{13}C NMR tensor elements of a series of (arene)$Cr(CO)_3$ complexes, where the arene was C_6H_6, C_6Me_6, and C_6Et_6.

These experiments yielded a number of fascinating results: (*i*) the major change in tensor elements upon complexation occurs for σ_{22}, the radial element, which is shielded by approximately 50 ppm; this would induce a field along each carbon–hydrogen axis and may account for the large upfield (low frequency) shift always observed for the aromatic protons when an arene is coordinated to a $Cr(CO)_3$ moiety; (*ii*) in the solid-state spectrum of $(C_6Et_6)Cr(CO)_3$ (**5**), the isotropic chemical shifts of the ring carbons, methylene carbons, and methyl carbons are all doubled. This observation suggested to us that the sixfold symmetry of the hexaethylbenzene (HEB) ligand had been broken such that the ethyls projected alternately above and below the plane of the arene ring, and raised the possibility that such a slowing of the ethyl rotations might be detectable in a solution spectrum of **5** at a sufficiently low temperature.

5 **6** **7**

When I wrote the first draft of the manuscript to be published jointly with John Waugh (54), I somewhat whimsically referred to HEB as "*a hexapodous ligand with tentacular ethyl groups*"; fortunately my distinguished coauthor pointed out that I was mixing not only Latin and Greek, but also arms and legs! However, the paper also makes some serious points that still have relevance today. As is well-known, there have been many attempts to relate NMR chemical shifts to a variety of molecular properties, and we offered the following comment: "one would hope that, as more data become available, theories relating substituent parameters to isotropic shifts of carbon or fluorine nuclei in free or π-complexed aromatic systems will be superseded by correlations with appropriate tensor elements". It is gratifying to note that such data are now commonly available, and that Canadian scientists such as R.E. Wasylishen (55) have become prominent in this field.



Molecular propellers and bevel gears

With the goal of determining the barrier to ethyl rotations in $(HEB)M(CO)_3$, where M = Cr, Mo, W, their variable-temperature ^1H and ^{13}C NMR spectra were recorded in CD_2Cl_2 and it was shown that this fluxional process could indeed be slowed on the NMR time scale (46*b*, 56), as illustrated in Fig. 4. Moreover, the proposed structure with alternating proximal and distal ethyl groups was confirmed X-ray crystallographically by Mislow and co-workers (57).

The question that now arose concerned the barrier to tripodal rotation and whether it was correlated with the ethyl rotations; that is, does this system function as a molecular analogue of a bevel gear? Clearly, one must construct a molecule in which the ethyl and tripodal rotations can be monitored independently, and we were able to accomplish this in two ways. Firstly, replacement of one ethyl group by an acetyl substituent, as in **6**, breaks the threefold symmetry such that, at low temperature, the slowed tripodal rotation yields a ^{13}C NMR spectrum in which the carbonyl environments are split in a 2:1 ratio (58); the barrier to tripodal rotation was evaluated as 9.5 ± 0.5 kcal mol^{-1}. More elegantly, perhaps, the ^{13}C NMR spectrum of the chiral cation $[(C_6Et_6)Cr(CO)(CS)(NO)]^+$ (**7**) exhibits at low temperature six ring-carbon environments, six methylene signals, and six methyl resonances, as shown in Fig. 5 (59). Simulation of

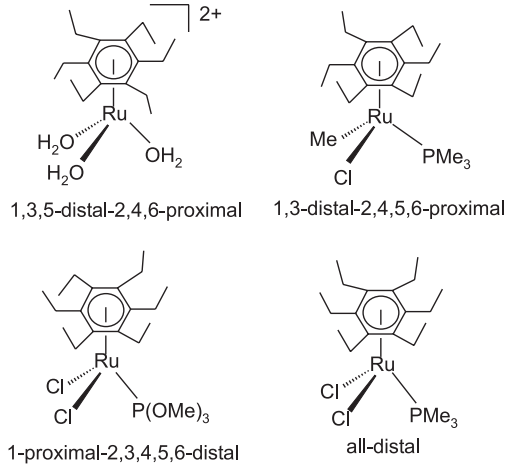
these spectra yield values of 9.5 ± 0.5 and 11.5 ± 0.5 kcal mol^{-1} for the tripodal and ethyl rotation barriers, respectively, showing that these two processes are not correlated. Subsequently, in a beautiful series of papers, Siegel and Kilway (60) used subtle stereochemical arguments to verify these conclusions.

At first sight, one might suspect that increasing the bulk of the tripodal substituents might enhance the steric interactions between themselves and the ethyl substituents, thus favoring the development of a molecular bevel gear. However, the $(HEB)Cr(CO)_2L$ system has other conformations available to it, and replacement of a carbonyl group by ligands with increasingly larger cone angles merely results in loss of the alternating proximal–distal arrangement of ethyl groups (61). Likewise, this phenomenon is also found in the $(HEB)RuCl_2L$ series, where the ethyl substituents have been shown to adopt the 3:3, 4:2, 5:1, or 6:0 conformations,[1] several of which are depicted in Fig. 6, thus demonstrating that placing too much steric pressure on a system can cause it to respond so as to frustrate one's plans.

In light of the conformational variability of hexaethylbenzene, it was deemed necessary to incorporate aryl substituents that, in principle, could not simply rotate away from the potential steric hindrance. Since we had already been working with metal complexes containing pentaphenylcyclopentadienyl or hexaphenylbenzene ligands (62), we chose to extend this study to include larger C_nPh_n systems.

Fig. 5. Variable-temperature 125 MHz ^{13}C NMR spectra of $[(C_6Et_6)Cr(CO)(CS)(NO)]^+$ (**7**) showing slowed ethyl and tripodal rotation on the NMR time scale.



The peripheral phenyls in $(C_5Ph_5)ML_n$ complexes adopt a propeller-like geometry with dihedral angles (θ) of approximately 50° relative to the central ring; this represents a compromise between the sterically inaccessible fully coplanar geometry (θ = 0°) and the minimally hindered orientation (θ = 90°) whereby all conjugation is lost. In the series $[C_5Ph_5]^-$, C_6Ph_6, $[C_7Ph_7]^+$, the increasing radius of the central ring is counterbalanced by the changing angle between the peripheral phenyls, which decreases from 72 to 60 to 51.4°. Interestingly, however, the most crowded of these systems, i.e., $[C_7Ph_7]^+$, responds not merely by orienting the phenyls such that the average θ value is approximately 80° but also by allowing the central seven-membered ring to fold into a gentle boat conformation (63), as in Fig. 7.

As noted above, pentaphenyl-cyclopentadienyl complexes give rise to propeller structures and, when the ML_n unit is asymmetric as in $(C_5Ph_5)Fe(CO)(HC{=}O)(PMe_3)$ (**8**), the stereogenic metal centre combined with the helicity of the

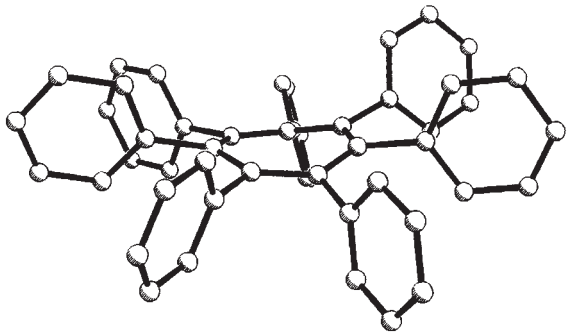
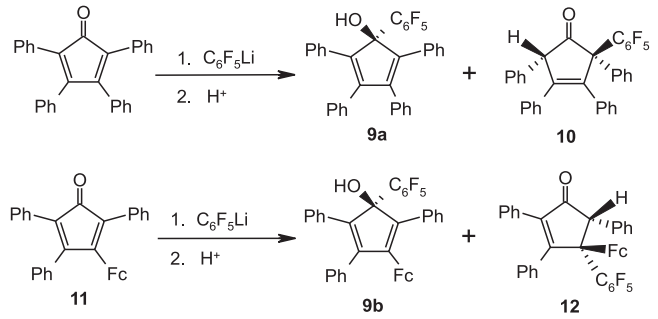
Fig. 6. X-ray crystallographically determined structures of $[(C_6Et_6)Ru(H_2O)_3]^{2+}$, $(C_6Et_6)RuCl(Me)[PMe_3]$, $(C_6Et_6)RuCl_2[P(OMe)_3)]$, and $(C_6Et_6)RuCl_2(PMe_3)$.



propeller (clockwise or anticlockwise) gives rise to diastereomers. However, oscillation of the peripheral phenyl rings interconverts diastereomers **8a** and **8b**. To follow the dynamics of such systems, and to determine whether the rotations of the peripheral aryl substituents and of the ML_n moiety are correlated, one must incorporate independent probes for both processes.

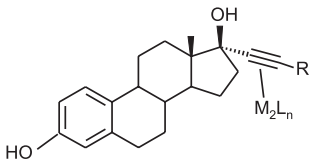


We have shown in a straightforward fashion that, in **8**, the barrier to tripodal rotation is ≈8.7 kcal mol^{-1}; this is readily accomplished since the five central-ring carbon environments become different when the process is slowed on the NMR time scale (62*a*). Slowed peripheral aryl rotation would render the proximal and distal ring edges inequivalent, but severe peak overlap, even on a 500 MHz spectrometer, makes such a determination an extremely difficult task. Our goal, therefore, was to synthesize complexes of the type $[C_5Ph_4(C_6F_5)]ML_n$, which would not only avoid the problem of extensive ^{1}H NMR peak overlap in the aromatic region, but also take advantage of the much larger ^{19}F chemical shift range.[2] However, this also requires the availability of $C_5Ph_4(C_6F_5)OH$ (**9a**) as a starting material. This

Fig. 7. X-ray crystal structure of the $[C_7Ph_7]^+$ cation showing the nonplanarity of the central ring.

Scheme 2. Reactions of substituted cyclopentadienones with pentafluorophenyllithium (Fc = ferrocenyl).

apparently trivial synthesis remains a challenge: treatment of tetracyclone with C_6F_5Li yields **9a** in poor yields, although sufficient for an X-ray crystallographic characterization (64). The major product is **10**, the result of a 1,6-addition process (see Scheme 2). Interestingly, with 3-ferrocenyl-2,4,5-triphenylcyclopentadienone (**11**), the principal site of nucleophilic attack is at the ferrocenyl-bearing ring carbon to give **12**, and the alcohol **9b** is only a minor product.



Current extensions of these concepts involve the use of arenes possessing peripheral substituents that are even more sterically demanding, and particular goals at present include hexanaphthylbenzene as well as systems of the type C_6Ph_5R, where R is an (η^5- or η^6-indenyl)ML_n moiety.

Steroids, terpenes, and metal-stabilized cluster cations

Concomitant with our studies concerning correlated motions of molecular fragments, we have investigated a wide range of fluxional processes. We have already discussed some examples of rotational fluxionality; let us now turn our attention to systems exhibiting translational stereochemical nonrigidity. As part of a 20-year collaboration with Professor Gérard Jaouen in Paris, a series of studies on the biochemical activity of organometallic derivatives of hormonal steroids (65–75) had led us inevitably into the world of chirality and other aspects of stereochemistry. In particular,

17 $ML_n = ML_n' = Co(CO)_3$
18 $ML_n = ML_n' = Mo(CO)_2Cp$
19 $ML_n = Mo(CO)_2Cp$, $ML_n' = Co(CO)_3$

17α-alkynylestradiol derivatives (**13**) that are complexed to a dimetallic fragment such as $Co_2(CO)_6$ or $(C_5H_5)_2Mo_2(CO)_4$ (66) show a remarkable ability to bind to specific receptor sites that are of crucial importance to the detection and possible treatment of breast cancer. Lack of space does not permit us to discuss this and other fascinating applications (76, 77) of bio-organometallic chemistry, but the interested reader may wish to consult the reviews describing the pioneering work of Jaouen and Vessières (78).

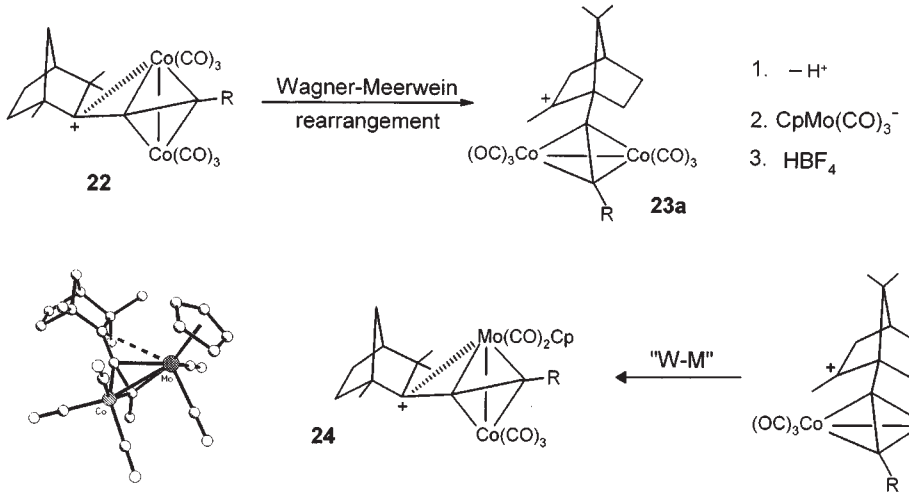
Metal complexes of steroids are, of course, chiral but we decided to invert the emphasis of the project in that one could also use such ligands to impose chirality onto a cluster so as to reveal hitherto hidden fluxional processes. For example, the tricobalt cluster $MeO_2C\text{-}CCo_3(CO)_7$(*arphos*) (**14a**) exists as a racemic mixture and resists all attempts to separate the enantiomers, implying the existence of a low-energy process that interconverts them (Scheme 3). Replacement of the methyl by an isopropyl group, as in **14b**, generates diastereotopic methyl environments whose NMR resonances undergo exchange with a barrier of ≈13 kcal mol^{-1} (79). A more elegant approach is to use a chiral substituent (either steroidal or terpenoid) at which point the two diastereomers of **15** yield different ^{31}P NMR resonances; it was subsequently demonstrated that the rapid interconversion of the enantiomers of **14** (or the diastereomers of **15**) occurs by migration of the Ph_2As terminus of the *arphos* ligand between two cobalt vertices with concomitant scrambling of the carbonyls (79, 80).

Scheme 5. Ring-opening of a dicobalt-bornyl cluster cation.

20 **21**

As noted previously, the dicobalt alkynyl-estradiol complex **13a** attaches itself strongly to hormonal receptor sites, and it was suspected that this binding was related to the ability of the metal cluster fragment to stabilize a cationic charge on the a carbon atom — a phenomenon that had been brilliantly exploited in synthetic studies by Nicholas (81, 82). We chose to take advantage of this effect to investigate the bornyl cation because of its pivotal role in the long-running controversy over the structures of classical vs. nonclassical cations (see ref. 83, with comments by P.V.R. Schleyer).

Treatment of camphor with an alkynyl anion yields, upon hydrolysis, the *endo* alkynol, which readily forms bimetallic complexes **16** containing cobalt or molybdenum vertices; upon protonation with HBF_4 these precursors yield the corresponding cations **17**–**19** (Scheme 4) (84, 85). The molybdenum-containing cluster cations **18** and **19** have been crystallographically characterized (86) and possess normal carbon—carbon bond lengths and angles — not surprisingly, since the charge is primarily located on the metal. This contrasts with Laube's now classic studies on the purely organic cations which strongly support a nonclassical formulation (87).



In contrast, the dicobalt cation **20** is readily identified by its NMR spectrum at –40°C but, when allowed to warm to room temperature, it undergoes a ring-opening that leads ultimately to the cluster-complexed alkynylcyclohexadiene, **21** (Scheme 5).[3]

Very different behaviour is exhibited by the corresponding fenchyl cation **22**, which readily undergoes a Wagner–Meerwein shift to place the dicobalt-alkynyl substituent at the bridgehead position in **23a**. Moreover, upon replacement

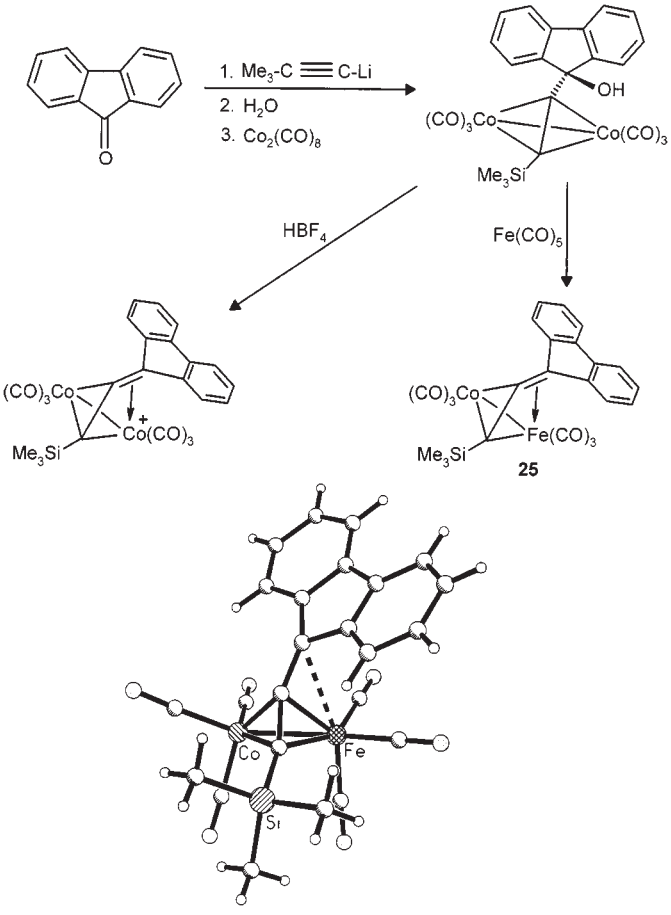
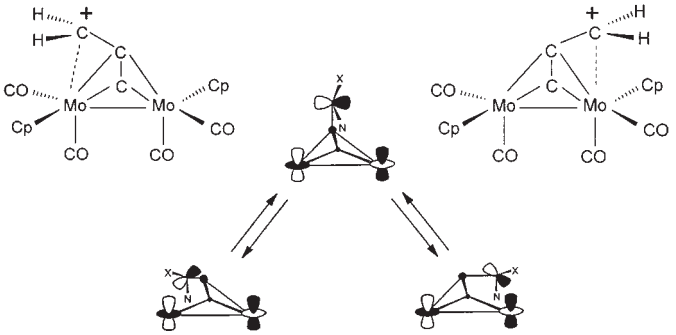


Scheme 6. Wagner–Meerwein skeletal rearrangements of metal-stabilized fenchyl cations.

of a tricarbonylcobalt vertex by an isolobal dicarbonyl(cyclopentadienyl)molybdenum group, as in **23b**, subsequent reprotonation reverses the sense of the original Wagner–Meerwein rearrangement so as to regenerate the fenchyl skeleton in which the cationic site is stabilized by complexation to an *exo* molybdenum vertex in **24** (Scheme 6) (88). Evidently, the direction of terpenoid rearrangements can be subtly controlled by an appropriate choice of stabilizing metal centre.

The outstanding ability of metal clusters to stabilize carbocations (89, 90) suggested that it might be possible to prepare hitherto unavailable species such as the antiaromatic fluorenyl, indenyl, and cyclopentadienyl cations which possess 12π-, 8π-, and 4π-electrons, respectively. In the event, these predictions were justified, and treatment of the appropriate ketones with an alkynyl anion, complexation to a dicobalt hexacarbonyl unit, and protonation yielded the hoped-for cluster-stabilized cations that were readily identified by NMR spectroscopy (91). Moreover, replacement of a $[Co(CO)_3]^+$ vertex by the isolobal neutral $Fe(CO)_3$ moiety gave the corresponding mixed-metal species that could be characterized by X-ray crystallography, and the structure of the fluorenyl cluster **25** is shown in Scheme 7.

Scheme 7. Cobalt- or iron-stabilized antiaromatic fluorenyl cations.



Rearrangement pathways: a combined NMR, X-ray crystallographic, and calculational approach

Fluxional behaviour of cluster-stabilized propargyl cations

The availability of a reasonably large number of structurally characterized metal-cluster stabilized propargyl cations of the type $[Cp_2Mo_2(CO)_4(RC{\equiv}C\text{-}CR'R'')]^+$, together with the corresponding variable-temperature NMR data, allowed us to establish a viable trajectory for the fluxional process that exchanges the cationic site between metal vertices, as illustrated in Scheme 8. Molecular orbital calculations at the extended Hückel level yielded an energy hypersurface from which the lowest energy trajectory for cation migration could be extracted (92); as shown in Fig. 8, the favoured structure places the cationic carbon close to one metal vertex and rotated so as to optimize the overlap between the vacant *p*-orbital on carbon with the filled *d*-orbital on the metal. In the transition state, the CH_2 group is oriented orthogonally with respect to the metal–metal vector so as to maintain

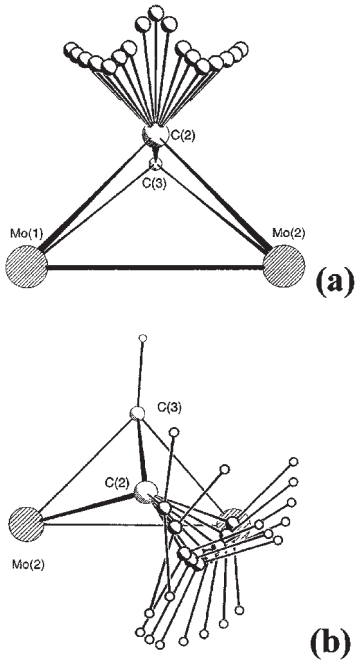
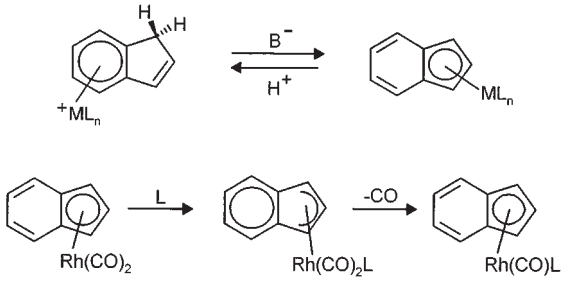
Scheme 8. Antarafacial migration of an α-methylene group between metal centres in a tetrahedral dimolybdenum-cluster cation; note how the *exo*- (X) and *endo*- (N) substituents maintain their relative positions.

overlap with an out-of-phase combination of metal *d*-orbitals.



Now, an examination of the known X-ray structures of the $[Cp_2Mo_2(CO)_4(RC{\equiv}C\text{-}CR'R'')]^+$ cluster cations reveals that for those possessing a primary cationic site (R′ = R″ = H), the Mo···C$^+$ distance is ≈2.45 Å; for secondary cations (R′ = alkyl, aryl, ferrocenyl; R″ = H), this value increases to 2.55–2.65 Å, while for tertiary cations the Mo···C$^+$ distance can exceed 2.75 Å. As originally proposed by Bürgi and Dunitz (93), an appropriately selected set of X-ray crystal structures can provide a series of snapshots of a reaction pathway, and in the present case we can readily see how the experimental data can be mapped onto the calculated trajectory.

NMR measurements had already established that for clusters possessing a primary, secondary, or tertiary cationic site, respectively, the migration barrier falls from ≈20 to approximately 11 kcal mol^{-1}. Taken together, the molecular orbital calculations and the NMR and X-ray experimental data provide a coherent and relatively complete picture of the molecular dynamics of these metal-stabilized cationic systems.

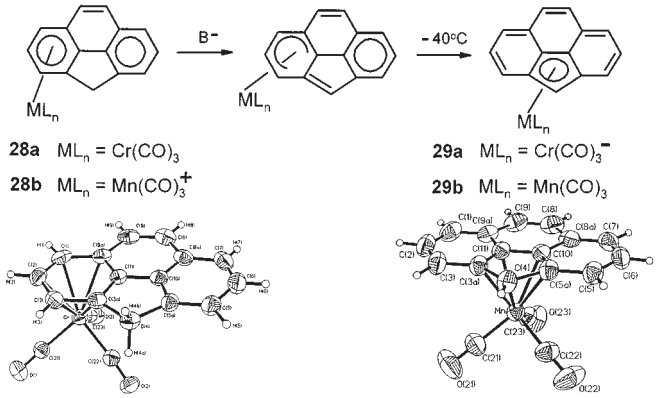


Haptotropic shifts across polycyclic surfaces

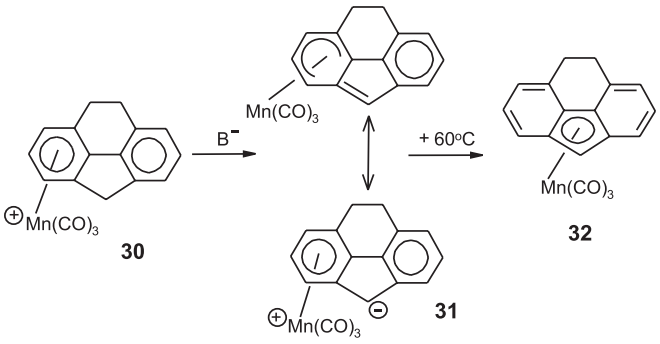
The capacity to carry out catalytic processes on surfaces may be related to the ability of the reacting species to migrate across the surface towards each other. It is therefore of considerable interest to understand the factors that come into play when organometallic moieties are placed onto a hydrocarbon surface and allowed to find their most favored sites of attachment. It has long been known that deprotonation of (η^6-indene)ML_n species, where ML_n = $Cr(CO)_3$, $Mo(CO)_3$, $(C_9H_7)Fe^+$, $(C_5Me_5)Rh^{2+}$, $(C_5Me_5)Ir^{2+}$, or $(C_2H_4)_2Rh^+$, results in migration of the metal fragment onto the five-membered ring, as in Scheme 9 (94); similar behaviour has been reported in the corresponding fluorenyl systems (95). These η^6 to η^5 processes are reversed on protonation, and such rearrangements are known as haptotropic shifts. A second phenomenon that is relevant to this observation is the so-called indenyl effect whereby ligand substitution in, for example (η^5-indenyl)$Rh(CO)_2$, proceeds approximately 1×10^8 times more rapidly than for the corresponding η^5-cyclopentadienyl system. This has been interpreted in terms of a slippage of the organometallic moiety into an η^3-structure, thus leading to a low-energy transition state possessing 6π-aromatic character (96).

Fig. 8. (*a*) EHMO-calculated trajectory of the α-carbon during the migration process; (*b*) calculated trajectory of the CH_2 fragment as it migrates between metal vertices (note the twisting motion as it approaches a molybdenum atom).

Scheme 9. Haptotropic shifts and ligand substitution reactions in (indenyl)ML_n systems.



The possibility of combining these two concepts, whereby one might facilitate haptotropic shifts by providing a low-energy pathway with enhanced aromatic character, seemed to us to be attractive option. To this end, we chose to investigate the organometallic chemistry of cyclopenta[*def*]-phenanthrene (**26**) and of cyclopenta[*l*]phenanthrene (**27**). The $Cr(CO)_3$ and $Mn(CO)_3^+$ derivatives of **26** were readily preparable and, upon deprotonation, underwent facile η^6 to η^5 rearrangement (97). Figure 9 shows the X-ray crystal structures of (η^6-cyclopenta[*def*]phenanthrene)$Cr(CO)_3$ (**28a**) and of (η^5-cyclopenta[*def*]phenanthrenyl)$Mn(CO)_3$ (**29b**), which represent the before and after situations, respectively.



In contrast, as depicted in Scheme 10, hydrogenation of the C(4)—C(5) linkage to form [(η^6-4,5-dihydrocyclopenta[*def*]-phenanthrene)$Mn(CO)_3]^+$ (**30**) allowed the isolation of the zwitterionic intermediate, **31**, which only underwent the η^6 to η^5 haptotropic shift to give **32** when heated at 60°C for 1 h. These observations are readily explained in terms of the favored migration trajectory in which, as shown by EHMO

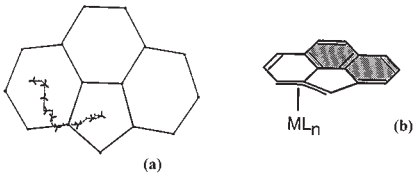
calculations, the metal does *not* follow the least-motion pathway (98). (While there is no doubt that Density Functional Theory gives much more reliable quantitative results, we can carry out an EHMO calculation on such a hypersurface in just a few hours, and this guides our synthetic strategies.) Traversal of the common bond between the six-membered and five-membered rings is a symmetry-forbidden process (99). Instead the organometallic fragment takes a more circuitous route, shown in Fig. 10*a*, which allows the development of a 10π naphthalene-type transition state, as illustrated in Fig. 10*b*. It is evident that loss of the C(4)—C(5) double bond, as in **30**, disrupts the potential aromaticity of the transition state and raises the barrier for haptotropic shifts.

Let us compare these results with those for a series of (η^5-cyclopenta[*l*]phenanthrenyl)ML_n complexes (**33**) where ML_n = $Mn(CO)_3$, $TiCl_3$, $Fe(C_5H_5)$, or $Rh(C_2H_4)_2$, for which protonation does *not* effect a haptotropic shift.[4] Indeed, their behaviour is much more reminiscent of the known reactivity of the corresponding (η^5-cyclopentadienyl)ML_n complexes; typically, protonation of **33** where ML_n = $Rh(C_2H_4)_2$, yields 1-butene, and follows the classic pattern established by Cramer (100) for $(C_5H_5)Rh(C_2H_4)_2$. Molecular orbital calculations reveal that migration onto the central six-membered ring is greatly disfavored since it would disrupt the aromatic

Fig. 10. (*a*) Calculated migration pathway of a $Mn(CO)_3$ fragment during an η^6 to η^5 haptotropic shift, via (*b*) an aromatic naphthalene-type transition state.



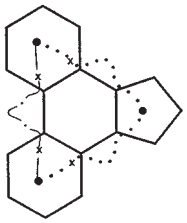


Fig. 11. Calculated migration pathways for haptotropic shifts in the (cyclopenta[*l*]phenanthrenyl)ML_n system (**33**) where ML_n = $Fe(C_5H_5)$; transition states are marked with an X.

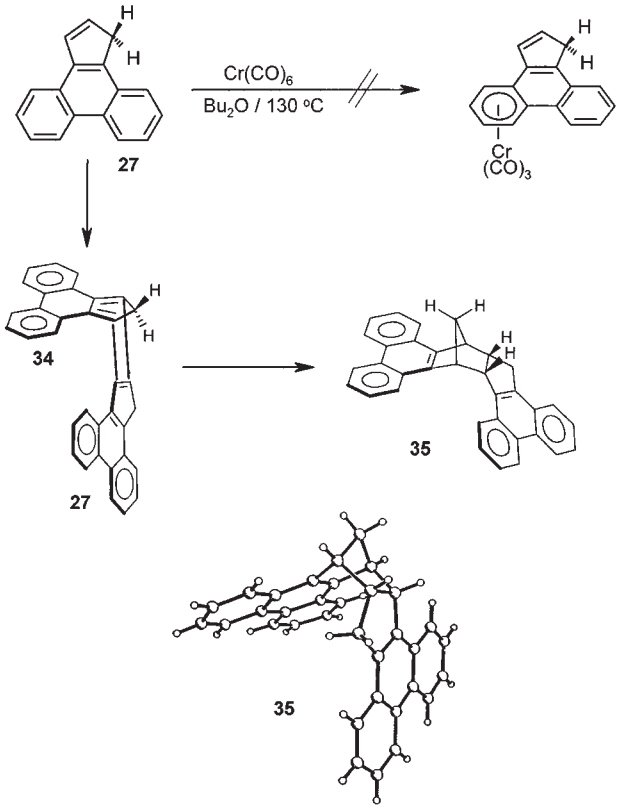
character of all the peripheral rings. The energetically most viable pathways for haptotropic shifts between peripheral η^5 and η^6 sites are shown in Fig. 11 and again follow a circuitous route around the periphery of the ligand.

Attempts to prepare η^6-derivatives of **27** have thus far been thwarted by the propensity of the free ligand to undergo a [1,5]-hydrogen shift to generate the dibenzoisoindene, **34** that in turn reacts in a Diels–Alder fashion with its progenitor to yield the dimer **35**, as in Scheme 11 (101).

Sigmatropic shifts across polycyclic surfaces



The haptotropic migrations described already are controlled by the interactions between the frontier orbitals of the organometallic fragment (which are primarily of metal *d*-character) and the π-manifold of the polycyclic hydrocarbon (99). However, it has long been known that σ-bonded groups, attached through either a main group or transition element, can undertake circumambulations with activation energies appropriate for study by variable-temperature NMR techniques. The classic mechanistic work in this area was the pioneering study by Cotton and co-workers (102), in which the 1,2-shift of a σ-$Fe(CO)_2(\eta^5$-$C_5H_5)$ fragment over a cyclopentadienyl ring, as in **36a**, was first elucidated and the barrier evaluated as 10.7 kcal mol^{-1}. (This can be reformulated in Woodward–Hoffmann terms as a [1,5]-suprafacial sigmatropic shift.) A crucial component in the original argument (103) was the nonfluxional character of the indenyl analogue, (η^1-C_9H_7)$Fe(CO)_2(\eta^5$-$C_5H_5)$ (**37a**) since a migration of the iron atom to the adjacent carbon would require the intermediacy of an isoindene **38a** with consequent loss of aromaticity (Scheme 12). We shall return to this point presently.

The ease of migration of silyl groups, for example in trimethylsilylcyclopentadiene, **36b** was elegantly demon-

[4] S.S. Rigby. Unpublished results from this laboratory.

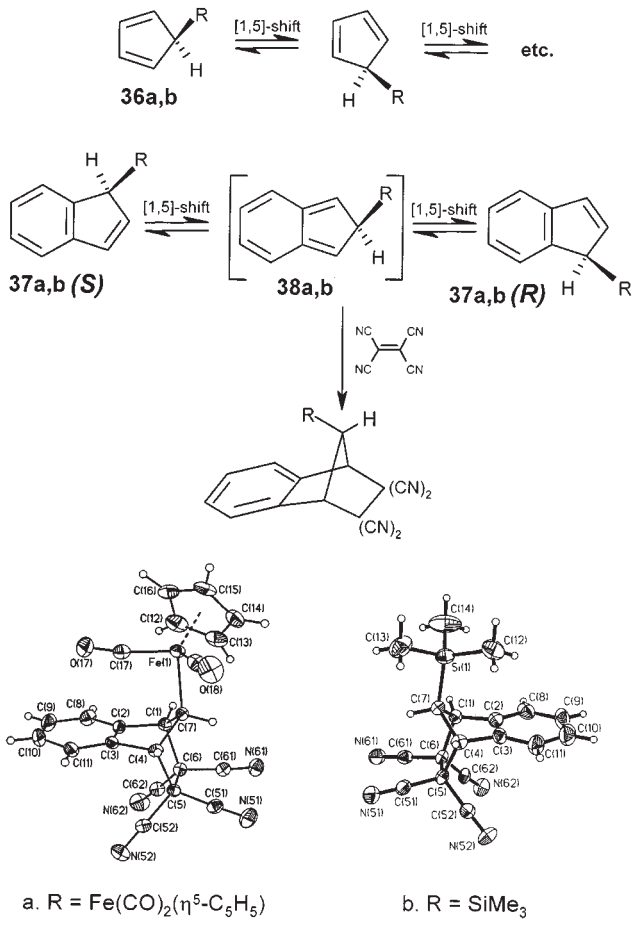
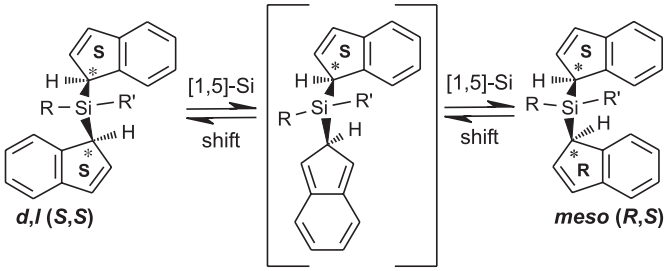
Scheme 11. Diels–Alder trapping of the dibenzoisoindene **34**.



strated by Davison and co-workers (104) who also showed that the corresponding trimethylsilylindene, **37b** was likewise fluxional. However, in the latter case, there was a substantially increased activation energy (≈25 rather than 15 kcal mol^{-1}) reflecting the decrease in aromatic character in the transition state. Subsequent work by McMaster and Stobart (105) using a chiral (Me)(Ph)(*i*-Pr)Sn substituent confirmed the symmetry-allowed nature of the sigmatropic shift process. Moreover, the isoindenes **38a** and **38b** have each been intercepted by reaction with tetracyanoethylene, and the resulting Diels–Alder adducts characterized by X-ray crystallography (106, 107).



Our own involvement in this project arose as the result of our interest in the stereochemical requirements of ansa-metallocenes, which have been intensively studied as Ziegler–Natta catalysts (108). Bis(1-indenyl)dimethylsilane exists in both *meso* and *d*,*l* forms, which are separable (109), but can interconvert via the series of [1,5]-silatropic shifts depicted in Scheme 13 (110).

The corresponding tris(1-indenyl)silanes raise considerably the sterochemical complexity of the system, which now exists in four forms: two pairs of enantiomers that are, of course, diastereomeric with respect to each other (Scheme 14). The complete story would take too long to relate; suffice it to say that the eight magnetically inequivalent vinylic C(2) sites can be mapped onto the eight vertices of a cube. More interestingly, the network of exchanging allylic hydrogen environments at C(1) and vinylic hydrogens at C(3) can be mapped onto the sixteen vertices of a tesseract (hypercube), while the edges of this four-dimensional object represent symmetry-allowed [1,5]-suprafacial sigmatropic

Scheme 12. [1,5]-Sigmatropic shifts in (*a*) Fe- or (*b*) Si-substituted indenes.

Scheme 13. Interconversion of *meso*- and *d*,*l*-bis-(1-indenyl)dimethylsilanes via a series of [1,5]-silatropic shifts.

shifts (107). Such apparently complex interconversions of stereoisomers are now routinely resolvable by means of modern two-dimensional NMR techniques at the high magnetic fields currently available (106).

Returning briefly to the question of the nonfluxional behaviour of $(\eta^1\text{-}C_9H_7)Fe(CO)_2(\eta^5\text{-}C_5H_5)$ (**37a**), the original difficulty arose as the result of its thermal instability whereby loss of the two carbonyls above ≈80°C yields benzoferrocene (103). Nowadays, however, a simple two-dimensional exchange experiment (EXSY) clearly shows (Fig. 12) that the proton environments at C(1) and at C(3) are indeed interconverting and, as anticipated for a system

passing through an isoindene structure, the measured barrier of ≈25 kcal mol^{-1} is substantially higher than for the cyclopentadienyl complex **36a** (106).

Cobalt clusters as stereochemical switches

As a final comment, we note that metal clusters can affect the course of a chemical reaction not merely through their electronic properties but rather by the enhanced stereochemical requirements of a bulky substituent. Some years ago, we reported that complexation of a dicobalt hexacarbonyl moiety onto the alkyne linkage of 2-methyl-1-phenylethynylcyclopentanol (**39**) brought about a conformational ring flip such that the acetylenic unit moved from its original pseudo-axial site into the less-hindered pseudo-equatorial position in the cluster **40**, as shown in Scheme 15 (112).

Scheme 15. Complexation-induced ring flip in an alkynylcyclopentanol.

We have very recently extended these ideas to the alkynylcyclohexanol system, and have shown that it is possible to control the ring conformation.[5] The most spectacular examples involve the *trans*- and *cis*-isomers of 1,4-bis(triphenylsilylethynyl)cyclohexane-1,4-diol (**41** and **42**), respectively. In the *trans*-isomer, addition of a $Co_2(CO)_6$ fragment to each of the axial alkyne substituents causes a ring flip such that both cluster units now occupy equatorial sites in **43** (Fig. 13). However, in the *cis*-isomer, the molecule chooses to alleviate the steric strain imposed by the incorporation of two bulky groups by adopting a well-defined twist-boat conformation, **44**, illustrated in Fig. 14. These molecules, as well as a series of related alkyne clusters, have all been characterized by X-ray crystallography, and the resulting modifications in their chemical reactivity are now being investigated.

Closing remarks

In this report, I have tried to show how our research goals have progressed from the purely synthetic to a fuller understanding of the molecular dynamics of a wide range of organometallic systems. With the techniques and instrumentation currently available, one can establish not merely the energetics of fluxional processes but also the precise pathways by which they occur. Moreover, by gaining an understanding of the electronic and steric factors involved, a certain degree of control may be attained. As we learn the rules of the game, we see that the possibility of designing and building molecular machines is becoming a more viable objective.

Acknowledgments

During the course of my time in Canada, I have had the privilege of working with a superb group of undergraduates, graduate students, and postdoctoral collaborators, many of whom are cited in the references. It has also been my good fortune to have interacted with a number of outstanding scientists, some of whom are or were my own colleagues at McMaster, especially Alex Bain, Brian Sayer, and Don Hughes for their NMR expertise, Jim Britten and Colin Lock for X-ray crystal structure determinations, and also Michael Baird (Queen's) as well as my long-time collaborator Gérard Jaouen in Paris. I have learned much from numerous conver-

An analysis of the hydration thermodynamics of the CONH group

Giuseppe Graziano

Abstract: The hydration thermodynamics of the CONH group play a fundamental role for the stability of the native conformation of globular proteins, but cannot be measured in a direct manner. The values of the thermodynamic functions have to be extracted from experimental measurements on model compounds using group additivity approaches. The estimates determined by Makhatadze and Privalov in the temperature range 5–100°C are used in the present study in view of their qualitative reliability. They are analyzed by means of a suitable approach that couples scaled particle theory calculations with the application of the modified Muller's model. It results that the negative entropy change is caused by the excluded volume effect for cavity creation, exaggerated in liquid water by the small size of water molecules themselves; the negative enthalpy change is determined by the H-bond energetics, formation of CONH–water H-bonds, and reorganization of water–water H-bonds. The negative heat capacity change, a striking feature of CONH hydration thermodynamics, is because the H-bonds in the hydration shell of the CONH group are less broken than those in bulk water in the temperature range examined.

Key words: peptide group, hydration, excluded volume effect, H-bonds, two-state model, negative heat capacity change.

Résumé : La thermodynamique de l'hydratation du groupe CONH joue un rôle fondamental dans la stabilité de la conformation de base des protéines globulaires, mais elle ne peut être mesurée directement. Les valeurs des fonctions thermodynamiques ont été extraites de mesures expérimentales sur des composés modèles en faisant appel à l'approche de l'additivité des groupes. Pour notre étude, compte tenu de leur fiabilité qualitative, on a utilisé les évaluations de Makhatadze et Privalov dans la plage de température allant de 5 à 100°C ans. On les a analysées à l'aide d'une approche appropriée qui met à profit des calculs de la théorie des particules graduées avec l'application du modèle modifié de Müller. On en déduit que: le changement négatif d'entropie est provoqué par l'effet de volume exclu pour la création de la cavité, exagéré dans l'eau liquide par la faible taille des molécules d'eau elles-mêmes; le changement négatif d'enthalpie est déterminé par les énergies impliquées dans les liaisons hydrogènes, la formation de liaisons hydrogènes CONH–eau et la réorganisation des liaisons hydrogènes eau–eau. Le changement négatif de capacité calorifique, une caractéristique importante dans la thermodynamique de l'hydratation du CONH, résulte du fait que, dans la plage de températures étudiée, les liaisons hydrogènes dans la couche d'hydratation du groupe CONH sont moins brisées que celles dans l'eau dans son ensemble.

Mots clés : groupe peptidique, hydratation, effet de volume exclu, liaisons hydrogènes, modèle à deux états, changement négatif de capacité calorifique.

[Traduit par la Rédaction]

Introduction

The structural organization of globular proteins is strongly influenced by the interactions of their constituent groups with water (1, 2). Consequently, it is important to gain a molecular level understanding of the hydration of proteins and their basic groups (3, 4). Among the latter, the CONH group is a fundamental unit and the hydration of this group is the focus of the present investigation. Very recently, the solvation thermodynamics of the peptide group has been investigated theoretically for its role in determining helix propensities (5). However, such approaches did not consider the temperature dependence of the thermodynamic functions, which is a central topic of the present study.

Following the Ben-Naim's analysis (6), hydration is defined as the transfer of a molecule from a fixed position in the ideal gas phase to a fixed position in water. The thermodynamics of this process do not include the effects due to the difference in the molar volume available to the solute molecule in the two phases (they are related to the translational degrees of freedom of the solute particle). Such effects are automatically excluded by using the molar concentration scale in the analysis of transfer experiments (6). Clearly, the Ben-Naim's definition of hydration accounts solely for the changes in thermodynamic functions due to the interactions of the solute molecule with water because there are no interactions in the ideal gas phase (i.e., what hydration is really about).

The optimum situation for a theoretical study would be to contrast the results of calculations against real experimental data. However, it is not possible to obtain real data for the

CONH group in a direct manner. The contribution of the CONH group to the changes in thermodynamic functions upon hydration has to be singled out by applying approaches based on the assumption of group additivity (7). Since this assumption is not strictly correct, especially when molecules contain polar groups (8), the estimates of the hydration thermodynamics for the CONH group existing in the literature have to be considered qualitatively correct, but not quantitatively exact. Notwithstanding, we would like to show that a suitable theoretical approach can rationalize well established and striking features of the CONH hydration thermodynamics.

In particular, the negative heat capacity change associated with the hydration of the CONH group completely contrasts with the positive values associated with the hydration of nonpolar moieties (9). The latter, as emphasized in previous works (10, 11), originate in the strong temperature dependence of H-bond reorganization among water molecules in the hydration shell. We would like to show that the difference in the sign of the heat capacity change is due to the physical characteristics of H-bond reorganization around the two chemically diverse classes of solutes. Specifically, the H-bonds in the hydration shell of nonpolar groups prove to be *more* broken than those in bulk water, whereas the H-bonds in the hydration shell of the CONH group are *less* broken than those in the bulk. Finally, the approach developed by Sharp and Madan (12–14) to calculate the hydration heat capacity change of both nonpolar and polar solutes is analyzed and contrasted against that devised in the present article.

Theory section

Adopting the standard state proposed by Ben-Naim (6), all the entropy change associated with solvation (i.e., gas to liquid transfer) is due to solvent reorganization since the solute molecule is in a fixed position, and its internal degrees of freedom are assumed to be unchanged on transfer (15). A liquid solvent, however, is a condensed phase in which each molecule occupies a finite volume. These simple and geometrical facts imply that insertion of a solute molecule gives rise to an excluded volume effect for the solvent molecules (10, 15). Since the molecular hard cores are impenetrable, solute insertion reduces the number of spatial configurations accessible to solvent molecules. This is a general effect common to all solvents. In response to volume exclusion, solvent molecules reorganize further providing another contribution to the entropy change (15). For water the latter contribution is clearly associated with a reorganization of H-bonds. Therefore, the hydration entropy change is given by:

$$[1] \qquad \Delta S^{\bullet} = \Delta S_x + \Delta S^h$$

where ΔS_x is the contribution due to the excluded volume effect and ΔS^h is the contribution attributable to the reorganization of H-bonds. Computer simulations have shown that the excluded volume effect is independent of the H-bonding potential when the density is fixed (16) and is essentially a geometric effect related to the size of solvent molecules. These findings support the validity of eq. [1]. Estimates for ΔS_x can be simply calculated from the Gibbs energy cost of cavity creation:

$$[2] \qquad \Delta S_x = -\Delta G_c/T$$

because ΔG_c is exactly related to the excluded volume effect and is a measure of the probability that the region of space, which a solute molecule would exclude to solvent molecules, is observed to have no solvent occupants when the solute is absent (17). On the other hand, ΔS^h can be evaluated in a hybrid manner by the difference $\Delta S^{\bullet} - \Delta S_x$.

The hydration enthalpy change of nonpolar compounds is given by the sum of two terms: the solute–water van der Waals interaction energy and the enthalpy contribution due to H-bond reorganization among water molecules in the hydration shell (9, 15). However, for the hydration of the CONH group, in view of its H-bonding capability, a correct separation of the solute–water interactions from the water–water ones is practically impossible. As a consequence, we do not try to separate anything and assume that the hydration enthalpy change is entirely due to H-bond contributions:

$$[3] \qquad \Delta H^{\bullet} = \Delta H^h$$

where ΔH^h takes into account both the formation of H-bonds between the CONH group and water molecules and the reorganization of H-bonds among the water molecules in the hydration shell (i.e., the van der Waals contribution is absorbed into the H-bonding energetics). Adopting this definition for ΔH^h, it is not possible to link ΔH^h and ΔS^h by means of the enthalpy–entropy compensation relationship (18), because they refer to different processes.

By combining eqs. [1] and [3], the hydration Gibbs energy change is:

$$[4] \qquad \Delta G^{\bullet} = \Delta H^h - T(\Delta S_x + \Delta S^h)$$

It is the sum of three contributions (*i*) the negative entropy change due to the excluded volume effect for cavity creation; (*ii*) the negative enthalpy change due to H-bond contributions, formation of CONH–water H-bonds, and reorganization of water–water H-bonds; and (*iii*) the entropy change due to water–water H-bond reorganization.

Finally, on the basis of eq. [3], the hydration heat capacity change is:

$$[5] \qquad \Delta C_p^{\bullet} = (\partial \Delta H^h/\partial T) = \Delta C_p^h$$

It arises from the temperature dependence of H-bond energetic contributions in the hydration shell of the CONH group.

The purpose of the present work is to analyze with such an approach the hydration of the CONH group over the temperature range 5–100°C. It will be shown that the H-bond energetics can be reproduced quite well by means of the modified Muller's model (15), which is briefly outlined below.

Modified Muller's model

Muller devised a model to calculate the contributions to hydration thermodynamics of nonpolar solutes arising from H-bond reorganization (19). By extending an earlier model developed by Angell (20), he considered that water molecules, in the bulk as well as in the hydration shell, exist in equilibrium between two H-bonding states. The lower state can be viewed as an intact H-bond, and the upper state as a

© 2001 NRC Canada

broken H-bond. The model has been modified by Lee and Graziano (15) to take into account the possibility that both the lower and upper states change passing from the bulk to the hydration shell. Accordingly, the H-bond contributions to the hydration heat capacity, enthalpy and entropy changes are given by:

$$[6] \quad \Delta C_p^h = (n^h/RT^2)[(\Delta H_{hs}^\circ)^2 f_{hs}(1 - f_{hs}) - (\Delta H_b^\circ)^2 f_b(1 - f_b)]$$

$$[7] \quad \Delta H^h = n^h[\Delta H_U - (1 - f_{hs})\Delta H_{hs}^\circ + (1 - f_b)\Delta H_b^\circ]$$

$$[8] \quad \Delta S^h = n^h[\Delta S_U - (1 - f_{hs})\Delta S_{hs}^\circ + (1 - f_b)\Delta S_b^\circ - R\Delta F]$$

where f_{hs} and f_b represent the fraction of broken H-bonds in the hydration shell and in the bulk, respectively; and in eq. [8], $\Delta F = F_{hs} - F_b$, with $F_b = f_b \ln f_b + (1 - f_b) \ln (1 - f_b)$, and F_{hs} similarly defined for the hydration shell: these are the "mixing" entropies characteristic of all the mixture models (21).

These equations contain seven parameters: ΔH_b° and ΔS_b° are the differences in enthalpy and entropy, respectively, between the two states in the bulk; ΔH_{hs}° and ΔS_{hs}° have the same meaning for the hydration shell; n^h is the number of H-bonds in the hydration shell; ΔH_U and ΔS_U are the differences in enthalpy and entropy, respectively, between the upper states in the hydration shell and those in the bulk. All these parameters are assumed to be temperature independent.

It must noted that, even though liquid water is known to have a continuum of energy levels, experimental evidence for the existence of two H-bonding states came from spectroscopic measurements, showing isobestic points in both IR and Raman spectra as a function of temperature (22). Recently, Hayward and Haymet (23), by performing molecular dynamics simulations on a realistic central force water model, have shown that the distribution of pairwise H-bond energies is a bimodal function (i.e., the total interaction energy between neighboring water pairs minus the van der Waals contribution). The strict geometric requirements for H-bond formation imply the existence of two distinguishable molecular distributions, not single configurations, that may be labeled intact and broken H-bonds. In addition, the physical reliability of the modified Muller's model has been validated by Dill and co-workers (24) using Monte Carlo simulations and the Mercedes-Benz model for water.

Clearly, the parameter values have to be determined in a robust manner to use the model (also see the *Appendix* section). By using the difference in heat capacity between liquid water and steam, and Pauling's estimate that $f_b = 0.15$ at 0°C (25), Muller calculated $\Delta H_b^\circ = 9.8$ kJ mol^{-1} and $\Delta S_b^\circ = 21.6$ J K^{-1} mol^{-1} (19). These estimates are close to those determined by Walrafen et al. (26), analyzing Raman spectra of liquid water in a large temperature range. This implies that the f_b values are reliable, since $f_b = K_b/(1 + K_b)$, where $K_b = \exp[-(\Delta H_b^\circ/RT) + (\Delta S_b^\circ/R)]$ is the thermodynamic constant governing the rupture equilibrium of H-bonds in the bulk. Therefore, two such parameter estimates are retained in the present work.

To evaluate n^h, we assume that each of the water molecules in the hydration shell of the CONH group is involved, on the average, in two H-bonds belonging to the hydration shell. Thus, $n^h = 2N_{H_2O}$, where N_{H_2O} is the number of water molecules in the hydration shell. This assumption differs from that used for nonpolar compounds by Muller ($n^h = (3/2)N_{H_2O}$) (19), but it is dictated by the need to also take into account the H-bonds formed by the CONH group with water molecules, because we have considered $\Delta H^\bullet = \Delta H^h$. This is the fundamental point to apply the modified Muller's model to a polar group that forms H-bonds with water molecules. The value of N_{H_2O} for the CONH group is estimated from the results of a Monte Carlo study of *N*-methylacetamide (NMA) in TIP4P water (27). Jorgensen and Swenson (27) found that there are 21 water molecules in the first hydration shell of NMA: 18 surround the two methyl groups and 3 are H-bonded to the CONH group (i.e., 2 at the carbonyl oxygen and 1 at the hydrogen on nitrogen). The latter number is reliable in view of the electronic structure of the peptide group, and therefore, $N_{H_2O} = 3$ for the CONH group.

The four remaining parameters cannot be fixed a priori, but are related to each other by eqs. [6]–[8]. Therefore, the model is under determined and a set of models are generated, each corresponding to a specific value of one selected parameter. The independent parameter selected is ΔH_U, and the other three parameters, namely ΔH_{hs}°, ΔS_{hs}°, and ΔS_U, are calculated using the values of ΔC_p^h, ΔH^h, and ΔS^h at 25°C in eqs. [6]–[8], as outlined in detail in ref. 15. The only difference with respect to the treatment in ref. 15 is that the compensation relation $\Delta H^h = T\Delta S^h$ is not considered at all in the present calculations. It should also be noted that, according to the devised procedure, the value of ΔS^h serves only to estimate ΔS_U, because, for each selected ΔH_U, ΔH_{hs}° and ΔS_{hs}° are determined from the values of ΔC_p^h and ΔH^h at 25°C.

When all the seven parameters are known, eqs. [6]–[8] allow the calculation of ΔC_p^h, ΔH^h, and ΔS^h at any temperature. The physical reliability of the different models is tested by comparing the ΔC_p^h values calculated with those of $\Delta C_p^\bullet$ over the whole temperature range. We use this procedure because the heat capacity change proves to be the more sensitive probe of the H-bonding situation in the hydration shell.

Scaled particle theory calculations

The Gibbs energy cost of cavity creation in water is calculated as a function of temperature by means of the following equation from scaled particle theory (SPT) (28, 29):

$$[9] \quad \Delta G_c = RT[K_0 + K_1(\sigma_2/\sigma_1) + K_2(\sigma_2/\sigma_1)^2 + K_3(\sigma_2/\sigma_1)^3]$$

where $K_0 = -\ln (1 - \xi)$, $K_1 = u = 3\xi/(1 - \xi)$, $K_2 = u(u + 2)/2$, $K_3 = \xi P v_1/RT$. In these relations R is the gas constant, ξ is the volume packing density of pure solvent, which is defined as the ratio of the physical volume of a mol of solvent molecules over the molar volume of the solvent, v_1 (i.e., $\xi = \pi\sigma_1^3 N_{av}/6v_1$), σ_1 and σ_2 are the hard-sphere diameters of the solvent and solute molecules, respectively, and P is the pressure.

50	–54.6	–61.1	–40.7	–48.0
75	–53.6	–62.5	–44.7	–46.9
100	–52.2	–63.8	–48.4	–45.8

Concerns about the treatment of pressure in SPT calculations have been raised by various authors (30, 31). Pierotti (29) pointed out that, contrary to most comments in the literature, SPT, as applied to real solutions, does not refer specifically to hard-sphere fluids, but to fluids whose density and pressure are determined by the actual intermolecular potential and whose molecules have "effective" spherical hard cores. This implies that the experimental value of P rather than the theoretical value of the hard-sphere fluid should be preferred in SPT calculations. We adopt this view and consider P = 1 atm (1 atm = 101.325 kPa), the hydrostatic pressure over liquid water, in all calculations.

It is well known that the results of SPT calculations depend strongly upon the values selected for σ_1 and σ_2 (31, 32). For this reason great care is needed to select the hard-sphere diameters by resorting to all relevant and reliable experimental data. For water, we use σ = 2.75 and 2.80 Å, both of which are close to the distance between two H-bonded water molecules, as revealed by the location of the first peak in the oxygen–oxygen radial distribution function of liquid water (33–35). Clearly, there is uncertainty in the size to be assigned to the CONH group, which is not a sphere. The physical or van der Waals volume of the CONH group, obtained by considering a system of interlocking spheres with radii equal to the van der Waals radii of the involved atoms, amounts to 18–20 cm^3 mol^{-1} (36), which would correspond to a sphere with a diameter of 3.8–4.0 Å. On the other hand, the analysis of experimental measurements in terms of group additivity has led to the following estimates for the partial molar volume of the CONH group at 25°C in water: 20 (37), 19.3 (38), 22.3 (8), 20.6 (39), and 19.8 (40) cm^3 mol^{-1}. As a consequence, we select two different values for the hard-sphere diameter of the CONH group, σ = 3.5 and 4.0 Å, which should span the right size range of the peptide group. In this regard, it should be noted that the hard-sphere diameter of ethylene, which is structurally similar to the peptide group, amounts to 4.07 Å (41).

In performing calculations, the hard-sphere diameters of water and CONH group are considered temperature independent. The temperature dependence of ΔG_c, apart from the RT factor, originates from that of the experimental water density, which is accurately known in a wide temperature range (42).

Experimental data

Makhatadze and Privalov (3, 4), by analyzing the hydration thermodynamics of small model compounds using the molar concentration scale and the group additivity principle, determined $\Delta H^\bullet$ = –(59.6 ± 1.3) kJ mol^{-1}, $\Delta G^\bullet$ = –(48.9 ± 2.5) kJ mol^{-1}, and $\Delta S^\bullet$ = –(35.9 ± 9.4) J K^{-1} mol^{-1} at 25°C for the CONH group. Such estimates for the hydration thermodynamics of the peptide group appear reliable. Indeed, Cabani et al. (8), in their outstanding analysis of hydration thermodynamic functions in terms of group additivity, determined $\Delta H^\bullet$ = –59.9 kJ mol^{-1} at 25°C, and using their hydration Gibbs energy data for the components of the CONH group, one obtains $\Delta G^\bullet$ = –48.7 kJ mol^{-1} at 25°C. Furthermore, for the peptide group, Wadso and co-workers (43) obtained $\Delta H^\bullet$ = –(58 ± 4) kJ mol^{-1}, and the vapor pressure data on NMA of Wolfenden (44), corrected for the contribution of the two methyl groups, gave $\Delta G^\bullet$ = –49.8 kJ mol^{-1}, always at 25°C.

However, to obtain a complete characterization of the hydration process, the temperature dependence of the thermodynamic functions $\Delta H^\bullet$, $\Delta S^\bullet$, and $\Delta G^\bullet$ has to be known. This is readily obtained by determining $\Delta C_p^\bullet$ in a large temperature range. Makhatadze and Privalov (45) measured, by means of differential scanning calorimetry (DSC), the partial molar heat capacity of triglycine, tetraglycine, and pentaglycine, then, by subtracting the heat capacity of the molecule in the gas phase, they obtained the hydration heat capacity changes in a large temperature range. Moreover, Makhatadze and Privalov (3, 45) dissected such values by means of a group additivity approach to single out the $\Delta C_p^\bullet$ contribution of the CONH group; such values are listed in the second column of Table 1. They obtained that $\Delta C_p^\bullet$ is negative and decreases in magnitude in the range 5–100°C; in particular, it amounts to –63.4 J K^{-1} mol^{-1} at 25°C. In this respect, Cabani et al. (8) determined $\Delta C_p^\bullet$ = –89.7 J K^{-1} mol^{-1} for the CONH group at 25°C, while the recent measurements of the partial molar heat capacities of several tripeptides by Hedwig and co-workers (46) should lead to a value of about –70 J K^{-1} mol^{-1} at room temperature. In addition, the CONH contribution to the heat capacity change associated with the dissolution into water of solid cyclic dipeptides and with the transfer of liquid *N*-alkylamides to water was found to be –(60 ± 6) (47) and –(65 ± 5) J K^{-1} mol^{-1} (48), respectively, at 25°C.

Makhatadze and Privalov (3, 4) used their $\Delta C_p^\bullet$ estimates to calculate $\Delta H^\bullet$, $\Delta S^\bullet$, and $\Delta G^\bullet$ in the range 5–100°C, starting from the values at 25°C. These data are collected in Table 1 and are analyzed using the approach devised above to try to reach a molecular level understanding of the hydration thermodynamics of the CONH group.

Note: ΔG_c is estimated by means of SPT; ΔS_x is calculated as $\Delta S_x = -\Delta G_c/T$ and ΔS^h is calculated as $\Delta S^h = \Delta S^\bullet - \Delta S_x$.

sponding values of ΔS_x, obtained according to eq. [2], are listed in the third and fourth columns of Table 2. The work of cavity creation proves to be large and positive and increases with temperature, as already pointed out and discussed (10, 11). The values of ΔS_x are negative, little dependent on temperature, and larger than those of $\Delta S^\bullet$ in the whole range 5–100°C, regardless of the σ values used for water and the peptide group. The excluded volume effect is responsible for the negative hydration entropy of the CONH group. This finding is in line with the analysis of the hydration thermodynamics of noble gases, aliphatic and aromatic hydrocarbons, and aliphatic alcohols (11, 15, 49). The excluded volume effect is so large in water because it is exaggerated by the small size of water molecules themselves (10, 16). This is the physical origin of the fact that the hydration entropy change, at room temperature, is always negative regardless of the chemical nature of the group considered, polar or nonpolar. Indeed, Cabani et al. (8) suggested that the entropy does not appear to be the proper function to distinguish the hydration of polar from nonpolar groups.

Having determined ΔS_x in the 5–100°C temperature range, we can obtain estimates for ΔS^h by means of eq. [1]; the values are listed in the fifth column of Table 2. They are positive and decrease on raising temperature, regardless of the σ values used for water and the peptide group. The reorganization of H-bonds causes an increase in entropy, probably related to an increase in the configurational disorder of water molecules.

The situation for the hydration enthalpy change can be highlighted as follows. Jorgensen and Swenson (27) determined that the energetic interactions of NMA in TIP4P water, at room temperature, amount to –116 kJ mol^{-1}. By correcting for the contribution of the two methyl groups (50), one would obtain that the energetic interactions of the CONH group with water amount to –96 kJ mol^{-1}. This estimate is significantly larger than the $\Delta H^\bullet$ value at 25°C (–59.6 kJ mol^{-1}), because it does not take into account the enthalpy contribution due to the reorganization of water molecules upon CONH insertion. To make H-bonds with the CONH group, water molecules have to reorient, decreasing the net number of or the strength of some of the water–water H-bonds. The point is that there is no clear-cut way to separate the CONH–water contribution from the water–water contribution to $\Delta H^\bullet$. For this reason we assume in eq. [3] that all of $\Delta H^\bullet$ is due to H-bond reorganization.

We can now proceed in the application of the modified Muller's model. By fixing $n^h = 6$ and ΔH_U in the range –10–0 kJ mol^{-1}, and using $\Delta C_p^h = \Delta C_p^\bullet = -63.4$ J K^{-1} mol^{-1}, $\Delta H^h = \Delta H^\bullet = -59.6$ kJ mol^{-1}, and $\Delta S^h = \Delta S^\bullet - \Delta S_x = 44.3$ J K^{-1} mol^{-1} at 25°C, we have calculated the parameters ΔH_{hs}°, ΔS_{hs}°, and ΔS_U. They are collected in Table 3 (we recall that the choice of the ΔS^h value at 25°C is not really important because it only affects ΔS_U). Then, the values of f_{hs} and ΔC_p^h in the range 5–100°C have been computed for each choice of ΔH_U. The f_{hs} estimates are listed in Table 4 together with those of f_b, whereas the ΔC_p^h estimates are listed in Table 5 together with the $\Delta C_p^\bullet$ values.

To select the modified Muller's model closer to reality, we have compared the calculated ΔC_p^h functions with the $\Delta C_p^\bullet$ data. The comparison indicates that none of the models exactly reproduces the temperature dependence of $\Delta C_p^\bullet$; this is

100	–52.2	–49.3	–36.7	–22.3	–5.6	13.8	36.3

Note: The values of $\Delta C_p^\bullet$ are reported for comparison purposes. All the heat capacity values are in J K^{-1} mol^{-1}.

obviously related to the simplicity of the modified Muller's model. A satisfactory agreement, however, occurs for $\Delta H_U = -8.0$ kJ mol^{-1}; ΔC_p^h shows a monotonous decrease in magnitude as a function of temperature similar to that of $\Delta C_p^\bullet$, even though the steepness becomes too large beyond 75°C. Adopting the choice $\Delta H_U = -8.0$ kJ mol^{-1}, the two-state equilibrium of H-bonds in the hydration shell of the CONH group is characterized by $\Delta H^\circ_{hs} = 10.5$ kJ mol^{-1}, $\Delta S^\circ_{hs} = 14.6$ J K^{-1} mol^{-1}, and $\Delta S_U = 5.7$ J K^{-1} mol^{-1}, so that $f_{hs} = 0.077$ at 25°C. In contrast, the two-state equilibrium of H-bonds in the bulk is characterized by $\Delta H^\circ_b = 9.8$ kJ mol^{-1} and $\Delta S^\circ_b = 21.6$ J K^{-1} mol^{-1} so that $f_b = 0.205$ at 25°C. Therefore, as emphasized by the values reported in Table 4, the H-bonds in the hydration shell of the CONH group appear to be less broken than those in the bulk (remember that the hydration shell H-bonds are both the CONH–water and water–water H-bonds).

This happens because they are enthalpically stronger, $\Delta H^\circ_{hs} > \Delta H^\circ_b$, and their rupture causes a smaller entropy gain, $\Delta S^\circ_{hs} < \Delta S^\circ_b$ (i.e., it is expected for the large negative charge density on the carbonyl group and the positive charge density on the nitrogen atom). Furthermore, the hydration shell of the CONH group corresponds to a potential energy well of –8.0 kJ per mol of H-bond, accounting for the strong energetic interactions of the peptide group with water molecules. The entropy change plays a pivotal role in the two-state equilibrium, but it is difficult to attach a clear physical meaning to quantities like ΔS°_{hs} and ΔS°_b. In general, they should be a measure of the broken state degeneracy. As a consequence, the finding $\Delta S^\circ_{hs} < \Delta S^\circ_b$ can be explained by saying that the broken state of H-bonds has a lower degeneracy in the deep energy well around the CONH group than in bulk water (i.e., the strong energetic interactions not involved in the two-state equilibrium restrict the orientations available to interacting partners). Finally, the functions ΔH^h and $\Delta S_x + \Delta S^h$ calculated with the modified Muller's model characterized by $\Delta H_U = -8.0$ kJ mol^{-1} agree well with the values of $\Delta H^\bullet$ and $\Delta S^\bullet$ in the range 5–100°C (results not shown).

Discussion

Edsall (51) was the first, in 1935, to point out that $\Delta C_p^\bullet$ is large and positive for the hydration of nonpolar compounds, but negative for the hydration of polar ones. The microscopic determinants of this difference, however, have not been definitely assessed. A simple two-state model, such as that proposed by Gill et al. (52) to calculate $\Delta C_p^\bullet$ for nonpolar compounds, cannot produce negative values (i.e., consider that only one of the two terms in the square brack-

© 2001 NRC Canada

ets of eq. [6] would be present). Muller's model, however, can produce both positive and negative values of the heat capacity change by distinguishing the two-state equilibrium in the hydration shell from that in the bulk (19). In fact, eq. [6] shows that negative values of ΔC_p^h could arise in two limiting ways (*i*) if $f_{hs} = f_b$, which would require $\Delta H_{hs}^\circ < \Delta H_b^\circ$; or (*ii*) if $\Delta H_{hs}^\circ = \Delta H_b^\circ$, which would require $f_{hs} < f_b$. Actually, our calculations indicate that negative values of ΔC_p^h, with a temperature dependence similar to that of $\Delta C_p^\bullet$, are obtained with $\Delta H_{hs}^\circ > \Delta H_b^\circ$ and $f_{hs} << f_b$ (i.e., $\Delta S_{hs}^\circ < \Delta S_b^\circ$). In other words, the physical origin of the negative heat capacity change is in the fact that the H-bonds in the hydration shell of the CONH group are more intact than those in the bulk, over the whole temperature range of 5–100°C. This scenario is entirely different from that existing in the hydration shell of nonpolar compounds (10, 11, 15), where the H-bonds are always more broken than those in the bulk, leading to large positive ΔC_p^h values that decrease in a continuous manner with temperature. Therefore, the application of the modified Muller's model leads to the conclusion that (*i*) in the hydration shell of nonpolar solutes, $\Delta H_{hs}^\circ > \Delta H_b^\circ$ and $\Delta S_{hs}^\circ > \Delta S_b^\circ$ so that $f_{hs} > f_b$; (*ii*) in the hydration shell of the peptide group, $\Delta H_{hs}^\circ > \Delta H_b^\circ$ and $\Delta S_{hs}^\circ < \Delta S_b^\circ$ so that $f_{hs} << f_b$.

These results are a reflection of the different structural organization of water around the CONH group and nonpolar moieties. Monte Carlo simulations of NMA in water (27) showed that the carbonyl oxygen – water oxygen radial distribution function has a sharp peak at 3 Å with a small area, characteristic of the geometric restrictions proper of H-bonds; whereas the methyl – water oxygen radial distribution function has a broad peak centered near 4 Å with a large area, reflecting the existence of a disordered clathrate cage of water molecules around nonpolar groups.

Recently, Makhatadze et al. (53) pointed out that the temperature dependence of $\Delta C_p^\bullet$ for the CONH group depends on the model compounds from which it is singled out. Specifically, $\Delta C_p^\bullet$ would be always negative in the range 5–100°C, but it would increase with temperature more rapidly than the data reported in the second column of Table 1. In this regard, it should be noted that the modified Muller's models characterized by $\Delta H_U = -6.0$ or -4.0 kJ mol^{-1} give rise to a more pronounced temperature dependence of ΔC_p^h. Because these two models are characterized by $\Delta H_{hs}^\circ > \Delta H_b^\circ$ and $f_{hs} << f_b$ (see Tables 3–5), the emerging picture of the hydration shell does not qualitatively change, confirming that the H-bonds are substantially more intact than in the bulk.

An intriguing feature of the hydration thermodynamics of the CONH group is the following: $\Delta H^\bullet$ becomes more negative on increasing temperature because $\Delta C_p^\bullet$ is always negative. In other words, the CONH hydration is more exothermic at 100°C than at 25°C, even though the difference is small, amounting to only 4.2 kJ mol^{-1}. This finding is counterintuitive and difficult to grasp, but a better understanding can be reached. Since $\Delta H^\bullet = \Delta H^h$, we analyzed eq. [7] when $\Delta H_U = -8.0$ kJ mol^{-1}. A large contribution to ΔH^h comes from ΔH_U because, when multiplied times $n^h = 6$, it provides –48.0 kJ mol^{-1} at all temperatures. Passing to the other two terms, it emerges that $(1 - f_{hs})\Delta H_{hs}^\circ$ is larger in magnitude than $(1 - f_b)\Delta H_b^\circ$ over the whole temperature range: 9.7 kJ mol^{-1} vs. 7.8 kJ mol^{-1} at 25°C, and 8.8 kJ mol^{-1} vs. 6.2 kJ mol^{-1} at 100°C. Therefore according to eq. [7], the balance between the rupture of H-bonds in the bulk and the formation of H-bonds in the hydration shell is always exothermic; but it is slightly more exothermic at 100°C than at 25°C because f_{hs} increases with temperature less rapidly than f_b (i.e., $f_{hs} = 0.077$ at 25°C and 0.163 at 100°C, whereas $f_b = 0.205$ at 25°C and 0.363 at 100°C, see Table 4). This seems to be a clear and reliable explanation of the strange temperature dependence of $\Delta H^\bullet$.

A final point deserves attention. The value $N_{H_2O} = 3$ selected to perform the calculations with the modified Muller's model for the CONH group is different from the estimate that is obtained from the ratio of cavity surface areas (i.e., $N_{H_2O} \approx 6$). This is an important topic. For polar groups it is not correct to consider linear relationships of the hydration thermodynamic functions vs. the accessible surface area (ASA) (54), because the number of H-bonded water molecules does not depend on ASA, but on the chemical nature and charge density of the polar group itself (55). The breakdown of linear relationships between thermodynamic functions and ASA for the hydration of polar compounds has carefully been pointed out by Karplus and co-workers (56). Also this feature can be accounted for by our treatment, as demonstrated by the reliability of the functions calculated.

Relationship with the approach by Sharp and Madan

Sharp and Madan developed an interesting approach to calculate the hydration heat capacity change for charged, nonpolar, and polar solutes, by a combination of the random network model (RNM) of water and Monte Carlo simulations (12–14).

The random network model developed by Sceats and Rice (57), is based on the idea that liquid water retains much of the tetrahedral H-bonding network of ice, even with a randomly distorted connectivity. The fundamental assumption of RNM is that all H-bonds in liquid water are intact but they may be stretched and bent to an extent that depends on temperature and pressure. The existence of broken H-bonds in liquid water is not explicitly recognized. The basic elements of RNM are the following three structural parameters: (*i*) the mean H-bond length (*d*) corresponding practically to the position of the first peak in the oxygen–oxygen radial distribution function of water; (*ii*) the standard deviation in H-bond length (*s*); (*iii*) the root-mean-square value of the H-bond angle θ, which is defined as the smallest O···O-H angle formed by two neighboring water molecules.

Henn and Kauzmann (58) extended the RNM and provided an accurate function for the Helmholtz free energy of pure liquid water from which the thermodynamic properties were derived over a wide temperature range. Sharp and Madan used such a function to obtain explicit expressions for the heat capacity in terms of the H-bond structural parameters, with contributions mainly from H-bond stretching and bending (12–14). By setting d_0, s_0, and θ_0 as the average H-bond structural parameters for bulk water, the presence of a solute will modify such values for the water molecules in the hydration shell, leading to a change in heat capacity

$$[10] \quad \Delta C_p^h = C_p(d,s,\theta) - C_p(d_0,s_0,\theta_0)$$

where ΔC_p^h is the heat capacity change per H-bond perturbed by the solute. Sharp and Madan calculated the net

© 2001 NRC Canada

hydration heat capacity change by summing overall the H-bonds perturbed by the solute. In this manner they assumed that the reorganization of H-bonds among the water molecules in the hydration shell of the solute is the fundamental determinant of $\Delta C_p^\bullet$.

Performing Monte Carlo simulations in TIP4P water at constant temperature and pressure, Sharp and Madan determined the probability distribution function of the H-bond angle θ for bulk water and for the water molecules in the first hydration shell of various solutes (12–14). The distribution function of bulk water proves to be bimodal with a large peak centered at θ ≈ 12° and a small peak centered at θ ≈ 52°, producing an overall root-mean-square value of 29° (i.e., the area of the first peak is about four times larger than that of the second one). In addition, the linear H-bonds are slightly shorter than the bent ones. Therefore, bulk water consists of two H-bond populations: a predominantly linear population and a small but significant population of slightly longer and more bent H-bonds. The distribution function of θ for water molecules in the hydration shell of solutes is always bimodal, but (*i*) nonpolar groups cause a small increase of the peak at 12° and a corresponding decrease of the peak at 52°; and (*ii*) cations and polar groups cause a decrease of the peak at 12° and an increase of the peak at 52°. As a consequence, the overall root-mean-square value of θ is 22–24° for nonpolar solutes, and about 50° for cations and polar groups. Such changes are the main determinants of the heat capacity increase due to nonpolar solutes, and of the heat capacity decrease due to cations and polar groups (see eq. [3] in ref. 13).

In qualitative agreement with experimental data, Sharp and Madan obtained negative ΔC_p^h values for cations and positive ΔC_p^h values for nonpolar solutes, and interpreted their results with a demonstrative two-state model: H-bonds in the hydration shell of nonpolar groups are less distorted than those in the bulk because the perturbation is weak, whereas the opposite is true for those around cations because the perturbation is strong (see Fig. 4 of ref. 13). Clearly, it is very difficult to contrast such interpretation against that resulting from the application of the modified Muller's model because it is not at all clear the relationship existing between the distortion of H-bonds and the two states, broken and intact, postulated by Muller for H-bonds. In geometric terms one might argue that the H-bond between two water molecules is broken when θ is around 50°. Nevertheless, we note that Sharp and Madan computed the H-bond length and angle only for the pairs of water molecules that were H-bonded (i.e., those for which the oxygen—oxygen distance was less than or equal to 3.4 Å; this cutoff value corresponds to the first minimum in the oxygen–oxygen radial distribution function of liquid water). Clearly, such a procedure mainly probed intact H-bonds and neglected broken ones, introducing a significant bias in the analysis of Monte Carlo simulations.

Furthermore, the results reported in Table 3 of ref. 12, Fig. 2 of ref. 13, and Table 2 of ref. 14 indicate unequivocally that the calculated estimates of ΔC_p^h amount roughly to 50% of the experimental $\Delta C_p^\bullet$ values (i.e., for methane ΔC_p^h = 124 J K^{-1} mol^{-1} vs. $\Delta C_p^\bullet$ = 209 J K^{-1} mol^{-1}; for *n*-butane ΔC_p^h = 208 J K^{-1} mol^{-1} vs. $\Delta C_p^\bullet$ = 383 J K^{-1} mol^{-1}; for ethanol ΔC_p^h = 100 J K^{-1} mol^{-1} vs. $\Delta C_p^\bullet$ = 197 J K^{-1} mol^{-1}; for NMA ΔC_p^h = 75 J K^{-1} mol^{-1} vs. $\Delta C_p^\bullet$ = 167 J K^{-1} mol^{-1}; for K^+ ΔC_p^h = –34 J K^{-1} mol^{-1} vs. $\Delta C_p^\bullet$ = –72 J K^{-1} mol^{-1}; all such values are at 25°C). Therefore, the Sharp and Madan approach significantly underestimates the hydration heat capacity change for all the solutes studied and cannot be considered entirely satisfactory. In addition we raise the following general concerns.

(*i*) The hydration enthalpy change for a nonpolar solute is given by (10, 11):

$$[11] \quad \Delta H^\bullet = E_a + \Delta H^h$$

where E_a is the average solute–water interaction energy (mainly from van der Waals interactions in the case of nonpolar solutes), and ΔH^h is the enthalpy change due to the H-bond reorganization among the water molecules in the hydration shell. According to the theoretical calculations by different research groups (50, 59–62), E_a is a large negative quantity and $|E_a| > \Delta H^\bullet$ for all the nonpolar solutes considered (i.e., according to Jorgensen's calculations (50), for propane E_a = –27.6 kJ mol^{-1} vs. $\Delta H^\bullet$ = –21.0 kJ mol^{-1}; for neopentane E_a = –36.0 kJ mol^{-1} vs. $\Delta H^\bullet$ = –22.8 kJ mol^{-1}; for *n*-pentane E_a = –41.8 kJ mol^{-1} vs. $\Delta H^\bullet$ = –26.0 kJ mol^{-1}; all the values are at 25°C). This means that the reorganization of H-bonds in the hydration shell of nonpolar solutes is an endothermic process at room temperature ($\Delta H^h > 0$) and cannot lead to a net gain of H-bonds or to an increase in the population of linear and short H-bonds. To have $\Delta H^h > 0$, the H-bonds in the hydration shell should be more broken or more bent than those in bulk water. This is a general result (see the work by Levy and co-workers (62) for a recent and detailed analysis), but entirely neglected by Sharp and Madan in their approach, which is solely devoted toward the calculation of the hydration heat capacity change (i.e., it does not consider the other thermodynamic functions).

In addition, careful computer simulations by Laidig and Daggett (63), Mancera (64*a*), and Chau and Mancera (64*b*), using very reliable models of liquid water, have unequivocally found $f_{hs} > f_b$ for the hydration shell of nonpolar solutes over a large temperature range, lending support to the physical picture emerging from the application of the modified Muller's model. In particular, it is astonishing that the results of Mancera and of Sharp and Madan on the same system, namely methane in TIP4P water, are at odds. In all probability the inconsistency is because Mancera searched for both broken and intact H-bonds, whereas Sharp and Madan searched for intact H-bonds exclusively.

(*ii*) In the case of polar solutes it is necessary to distinguish the charged species from the neutral ones because they interact differently with the surrounding water molecules and cause different perturbations of the H-bonding network. In fact, according to the Sharp and Madan approach, urea causes a very weak perturbation of the H-bonding network of water (65), in marked contrast with the behavior of cations such as K^+ and Cs^+. Charged species have strong electrostatic interactions with the dipole moment of water molecules, but do not form direct H-bonds, whereas polar but neutral species form direct H-bonds with water molecules. Specifically the CONH group forms three H-bonds with water and the contribution of such H-bonds to $\Delta H^\bullet$ and $\Delta C_p^\bullet$ should be taken into account in view of their expected importance. Instead Sharp and Madan have considered

© 2001 NRC Canada

solely the H-bonds among water molecules in the hydration shell of the various solutes: the role played by the direct solute–water H-bonds in the case of polar molecules such as NMA and ethanol was completely neglected. This is a serious failure in our opinion. On the contrary, the approach devised in the present article, by recognizing that the hydration enthalpy change originates from both the formation of direct CONH–water H-bonds and the reorganization of water–water H-bonds, tries to account for the contribution of both of them to $\Delta C_p^{\bullet}$.

(*iii*) Sharp and Madan calculated solely the values of ΔC_p^h at 25°C, but entirely neglected the temperature dependence of the hydration heat capacity change. This point is very important and cannot be eluded. As the modified Muller's model calculations emphasize for both nonpolar and polar solutes (11, 15), the temperature dependence of ΔC_p^h is the fundamental feature to select the model closer to reality. Many different models can reproduce the $\Delta C_p^{\bullet}$ values at 25°C, but very few of them show the qualitatively correct temperature dependence of the heat capacity change. This implies that the temperature dependence of the calculated ΔC_p^h function is a necessary test to verify the general validity of the Sharp and Madan approach. However, such a test has not been performed yet.

Even though the Sharp and Madan approach may appear more appealing from a theoretical point of view, we believe that our treatment merits attention for the physical reliability of obtained results and for its usefulness in trying to establish a clear molecular picture of the heat capacity change upon hydration of both polar and nonpolar solutes.

Conclusion

We have shown that a simple theoretical approach, combining SPT and the modified Muller's model, is able to explain in a reliable manner most features of the CONH hydration thermodynamics in the 5–100°C temperature range. The negative entropy change is caused by the excluded volume effect related to the creation in liquid water of a cavity suitable to host the solute. More important, the negative heat capacity change is because the H-bonds in the hydration shell of the peptide group, both CONH–water and water–water H-bonds, are significantly more intact than those in bulk water. Such a conclusion may have a wide-ranging impact both in solution thermodynamics and in the field of protein folding.

Appendix

An important point is the robustness of the results obtained with the modified Muller's model to changes in the parameters selected for bulk water. Very recently, Dill and co-workers (66) claimed that the *correct* values of ΔH_b° and ΔS_b° are those that best fit the configurational heat capacity of water as a function of temperature. The configurational heat capacity of water is not an experimental quantity, but it was calculated theoretically by Eisenberg and Kauzmann (67), subtracting the contributions due to molecular translations, rotations, and vibrations from the experimental heat capacity of bulk water in the whole liquid range (i.e., the configurational heat capacity should contain only the contributions due to the H-bonding network). Adopting this procedure, one obtains ΔH_b° = 8.0 kJ mol^{-1} and ΔS_b° = 20.1 J K^{-1} mol^{-1}, so that f_b = 0.312 at 25°C. Such estimates correspond exactly to those determined originally by Angell (20), are significantly different from those of Muller (i.e., ΔH_b° = 9.8 kJ mol^{-1} and ΔS_b° = 21.6 J K^{-1}mol^{-1}), and lead to a larger fraction of broken H-bonds in bulk water at all temperatures.

The *correct* values of ΔH_b° and ΔS_b° have been used to perform another complete set of calculations with the modified Muller's model for the peptide group, adopting the same procedure described in the text. Namely, we fixed n^h = 6 and ΔH_U in the range –10–0 kJ mol^{-1}, and used $\Delta C_p^h = \Delta C_p^\bullet$ = –63.4 J K^{-1} mol^{-1}, $\Delta H^h = \Delta H^\bullet$ = –59.6 kJ mol^{-1}, and $\Delta S^h = \Delta S^\bullet - \Delta S_x$ = 44.3 J K^{-1} mol^{-1} at 25°C. The calculated parameters ΔH_{hs}°, ΔS_{hs}°, and ΔS_U are collected in Table A1, whereas the calculated values of f_{hs} and ΔC_p^h, in the temperature range 5–100°C, for each choice of ΔH_U, are listed in Tables A2 and A3, respectively. A look at such tables soon emphasizes that the main conclusion of the work is robust: to have negative values of ΔC_p^h that decrease in magnitude in a continuous manner with temperature, f_{hs} has to be significantly smaller than f_b at all temperatures. The models closer to reality seem to be those characterized by ΔH_U in the range of –10 to –6 kJ mol^{-1}, which are qualitatively very similar to those obtained with the bulk parameters of Muller.

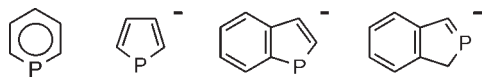
Synthesis and characterization of manganese complexes of the dibenzophospholyl ligand

Andreas Decken, Melanie A. Neil, and Frank Bottomley

Abstract: Manganese carbonyl complexes bearing dibenzophospholyl (DBP) and 1-phenyldibenzophosphole (Ph-DBP) ligands have been prepared. Reaction of Li-DBP with $Mn(CO)_5Br$ gave $(\mu_2\text{-DBP})(\mu_2\text{-Br})Mn_2(CO)_8$, while reaction of bis(1,1′-dibenzophospholyl) and $Mn_2(CO)_{10}$ yielded $(\mu_2\text{-DBP})_2Mn_2(CO)_8$. The phosphine adducts $(Ph\text{-DBP})Mn_2(CO)_9$ and $(Ph\text{-DBP})_2Mn_2(CO)_8$ were obtained by reaction of Ph-DBP and $Mn_2(CO)_{10}$. The ligands are σ-bonded through the phosphorus atom in all complexes. The compounds were characterized by ^1H, ^{13}C, and ^{31}P NMR and IR spectroscopy, mass spectrometry, and X-ray diffraction.

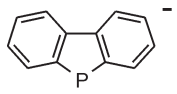
Key words: dibenzophospholyl, dibenzophosphole, manganese, heterocycle.



Résumé : On a préparé des complexes de manganèse-carbonyle portant des ligands dibenzophopholyle (DBP) et 1-phényldibenzophosphole (Ph-DBP). La réaction du Li-DBP avec du $Mn(CO)_5Br$ conduit à la formation de $(\mu_2\text{-DBP})(\mu_2Br)Mn_2(CO)_8$ alors que la réaction du bis(1,1′-dibenzophospholyl) avec le $Mn_2(CO)_{10}$ conduit à la formation du $(\mu_2\text{-DBP})_2Mn(CO)$. Par réaction avec du Ph-DBP et du $Mn_2(CO)_{10}$, on a obtenu les adduits phosphinés (Ph-DBP)Mn(CO) et (Ph-DBP)Mn(CO). Dans tous ces complexes, les ligands sont liés à l'atome de phosphore par une liaison σ. Les composés ont été caractérisés par spectroscopie IR, par RMN du ^1H, ^{13}C et ^{31}P, par spectrométrie de masse et par diffraction des rayons X.

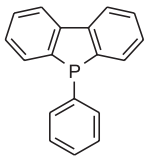
Mots clés : dibenzophospholyle, dibenzophosphole, manganèse, hétérocycle.

[Traduit par la Rédaction]



Introduction

Aromatic heterocycles containing phosphorus have been of much interest as ligands in transition metal complexes (1–4), especially in view of their potential applications in catalysis (5–7). Early studies focused on complexes of phosphinine and phospholyl, in part because ligands **1** and **2** were readily accessible. However, benzannelated phospholyl ligands such as **3** and **4** have recently emerged as interesting alternatives (8–14).



1 **2** **3** **4**

Their hydrocarbon analogues primarily bind through the π-electron system, but **1**–**4** can also ligate metals through the phosphorus lone pair, resulting in complexes containing ligands with σ-, π-, and mixed-bonding modes. Phospholyls display a high degree of aromaticity (15–20), but the hapticity as a ligand is controlled by substituents and the metal to which they are coordinated. The degree of aromaticity of benzannelated phospholyls has not been established, but both σ- and π-bonding have been found in complexes containing **3** and **4**. Such diversity can also be expected in complexes of dibenzophospholyl (DBP, **5**), although very little is known about the ligating abilities of this ligand.

5

We are exploring the chemistry of DBP with emphasis on the differences between its modes of coordination and those of the fluorenyl analogue, and of ligands **2**–**4**. In light of the facile synthesis and high stability of the fluorenyl complexes $(\eta^1\text{-}C_{13}H_9)Mn(CO)_5$ and $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$ (21–25),[2] we began with the preparation of manganese carbonyl complexes of the dibenzophospholyl anion **5**, and of 1-phenyldibenzophosphole (Ph-DBP, **6**).

6

The characterization, structures, and properties of the products are reported here.

Experimental

General considerations

All reactions were carried out under an atmosphere of argon utilizing standard Schlenk techniques. Solvents were dried and distilled according to standard procedures (26). Melting points were measured in open glass capillaries using a Gallenkamp melting point apparatus and are uncorrected. ^{1}H, ^{13}C, and ^{31}P NMR spectra were recorded on a Varian Unity 400 spectrometer operating at 399.99, 100.6, and 161.31 MHz, respectively. The ^{1}H and ^{13}C NMR spectra were referenced relative to tetramethylsilane and the ^{31}P NMR spectra were referenced relative to external triphenylphosphine (δ = –6.0). Electron impact (EI) and fast atom bombardment (FAB) mass spectrometry experiments were performed on a Kratos MS-50 mass spectrometer, with 3-nitrobenzyl alcohol as the FAB matrix and helium as the bombarding gas. Infrared spectra were obtained on a Bruker IFS 25 instrument. Unless otherwise stated, all reagents were obtained from commercial suppliers and used without further purification. Manganese pentacarbonylbromide (27), 1-phenyldibenzophosphole (28), and bis(1,1′-dibenzophospholyl) (29) were prepared according to literature procedures. Lithium shavings were obtained from lithium rods (99% under mineral oil). Flash chromatography was carried out using Merck silica gel (330–400 mesh). Elemental analyses were preformed by Galbraith Laboratories, Knoxville, Tennesee.

Preparation of (μ_2-dibenzophospholyl)-(μ_2-bromo)-dimanganese-octacarbonyl (7)

To a solution of 1-phenyldibenzophosphole (0.45 g, 1.73 mmol) in THF (5 cm^3) was added lithium shavings (10-fold excess) and the mixture stirred overnight at room temperature. The solution was decanted and aluminum trichloride (0.077 g, 0.58 mmol) added, resulting in a dark brown-red solution (29, 30). The mixture was added dropwise to a solution of $Mn(CO)_5Br$ (1.898 g, 6.9 mmol) in THF (20 cm^3) producing a dark orange solution. After stirring overnight at room temperature, the solvent was removed under vacuum and the crude product purified by flash chromatography using a 1:1 mixture of ether:hexane to give **7** as an orange solid. Yield: 0.72 g, 1.20 mmol, 69%, mp 250°C (dec.). FAB-MS *m/z* (%): 596 (0.2) $[C_{20}H_8{}^{79}BrPMn_2O_8]^+$ ($[M]^+$); 484 (4) $[C_{16}H_8{}^{79}BrMn_2O_4P]^+$, $[(C_{12}H_8P)Mn_2(CO)_4{}^{79}Br]^+$; 349 (4) $[C_{14}H_8Mn_2O_2P]^+$, $[(C_{12}H_8P)Mn_2(CO)_2]^+$; 238 (5) $[C_{12}H_8PMn]^+$; 183 (18) $[C_{12}H_8P]^+$. IR (KBr disk) (cm^{-1}) ν_{CO}: 1968 (s, br), 2001 (s, br), 2057 (m-s). ^{1}H NMR (acetone-d_6) δ: 8.95 (dd, *J* = 8.0, 8.0 Hz, 2H), 8.21 (d, *J* = 8.0 Hz, 2H), 7.77 (m, 2H), 7.66 (dd, *J* = 8.0, 8.0 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 215.28 (d, $J_{P,C}$ = 13 Hz, CO), 212.80 (d, $J_{P,C}$ = 18 Hz, CO), 208.08 (d, $J_{P,C}$ = 9 Hz, CO), 144.94 (d, $J_{P,C}$ = 25 Hz), 141.45 (d, $J_{P,C}$ = 6 Hz), 129.53 (s), 129.30 (s), 127.76 (s), 121.86 (s). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: –42. Anal. calcd. for $C_{20}H_8BrO_8PMn_2$: C 40.20, H 1.35; found: C 39.66, H 1.46.

Compound **7** (0.15 g, 0.25 mmol) in xylenes (5 cm^3) was heated to reflux. Within 10 min the colour of the solution changed from orange to yellow and a yellow precipitate formed. After 1 h the mixture was cooled to room temperature, the precipitate separated by filtration and washed with hexane to give a bright yellow solid. The solid was identified as **11** by IR, ^{1}H NMR, and mass spectrometry and by unit cell determination of single crystals grown by vapour diffusion of CH_2Cl_2–hexanes at –23°C (see below). Yield: 0.082 g, 0.12 mmol, 96%. The remaining solution was concentrated to dryness under vacuum and the resulting orange-brown solid identified as $(\mu_2\text{-}Br)_2Mn_2(CO)_8$ based on IR spectroscopy (31) and mass spectrometry. Yield: 0.054 g, 0.11 mmol, 88%. EI-MS$^+$ *m/z* (%): 436 (0.4) $[C_6{}^{79}Br_2Mn_2O_6]^+$, $[Mn_2(CO)_6{}^{79}Br_2]^+$; 408 (23) $[C_5{}^{79}Br_2Mn_2O_5]^+$, $[Mn_2(CO)_5{}^{79}Br_2]^+$; 380 (8) $[C_4{}^{79}Br_2Mn_2O_4]^+$, $[Mn_2(CO)_4{}^{79}Br_2]^+$; 352 (2) $[C_3{}^{79}Br_2Mn_2O_3]^+$, $[Mn_2(CO)_3{}^{79}Br_2]^+$; 324 (4) $[C_2{}^{79}Br_2Mn_2O_2]^+$, $[Mn_2(CO)_2{}^{79}Br_2]^+$; 296 (84) $[C^{79}Br_2Mn_2O]^+$, $[Mn_2(CO)^{79}Br_2]^+$; 268 (6) $[{}^{79}Br_2Mn_2]^+$; 166 (36) $[C_2Mn_2O_2]^+$, $[Mn_2(CO)_2]^+$; 158 (100) $[{}^{79}Br_2]^+$.

Preparation of (1-phenyldibenzophosphole)-dimanganese-nonacarbonyl (9) and di(1-phenyldibenzophosphole)-dimanganese-octacarbonyl (10)

To a solution of dimanganese decacarbonyl (1.56 g, 4 mmol) in xylenes (25 cm^3) was added a solution of 1-phenyldibenzophosphole (1.04 g, 4 mmol) in xylenes (25 cm^3). The mixture was heated at reflux for 3 h, cooled to room temperature, and the insoluble materials removed by filtration. The filtrate was concentrated to dryness via trap-to-trap distillation under vacuum. Products **9** and **10** were separated by column chromatography using hexanes. Yield of yellow **9**: 0.43 g, 0.69 mmol, 17%, mp 179–181°C. EI-MS$^+$ *m/z* (%): 510 (13) $[C_{23}H_{13}PMn_2O_5]^+$, $[(C_{18}H_{13}P)Mn_2(CO)_5]^+$; 482 (19) $[C_{22}H_{13}PMn_2O_4]^+$, $[(C_{18}H_{13}P)Mn_2(CO)_4]^+$; 427 (52) $[C_{22}H_{13}PMnO_4]^+$, $[(C_{18}H_{13}P)Mn(CO)_4]^+$; 405 (64) $[C_{16}H_8PMn_2O_4]^+$, $[(C_{12}H_8P)Mn_2(CO)_4]^+$; 399 (25) $[C_{21}H_{13}PMnO_3]^+$, $[(C_{18}H_{13}P)Mn(CO)_3]^+$; 371 (49) $[C_{20}H_{13}PMnO_2]^+$, $[(C_{18}H_{13}P)Mn(CO)_2]^+$; 343 (9) $[C_{19}H_{13}PMnO]^+$, $[(C_{18}H_{13}P)Mn(CO)]^+$; 334 (23) $[C_8Mn_2O_8]^+$, $[Mn_2(CO)_8]^+$; 315 (81) $[C_{18}H_{13}PMn]^+$; 260 (96) $[C_{18}H_{13}P]^+$; 183 (95) $[C_{12}H_8P]^+$. Solutions of **9** and **10** in refluxing xylenes decomposed over a period of 12 h to yield 1-phenyldibenzophosphole (**6**) as shown by ^{31}P and ^{1}H NMR.

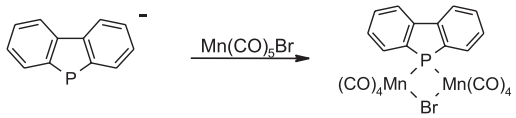
© 2001 NRC Canada

Preparation of bis(μ_2-dibenzophospholyl)-dimanganese-octacarbonyl (11)

A solution of dimanganese decacarbonyl (0.28 g, 0.710 mmol) in xylenes (10 cm^3) was added dropwise to a solution of bis(1,1′-dibenzophospholyl) (0.26 g, 0.710 mmol) in xylenes (10 cm^3) to give a yellow mixture. This was heated to reflux, becoming very dark brown in colour. Within 30 min a yellow solid precipitate formed. After 1.5 h the orange-brown mixture was slowly cooled to room temperature. The solvent was decanted and the solid washed with hexane (40 cm^3) to give **11** as a bright yellow solid. Yield: 0.39 g, 0.27 mmol, 78%, mp 240°C (dec.). EI-MS^+ *m/z* (%): 588 (86) $[C_{28}H_{16}P_2Mn_2O_4]^+$, $[(C_{12}H_8P)_2Mn_2(CO)_4]^+$; 560 (73) $[C_{27}H_{16}P_2Mn_2O_3]^+$, $[(C_{12}H_8P)_2Mn_2(CO)_3]^+$; 476 (100) $[C_{24}H_{16}P_2Mn_2]^+$, $[(C_{12}H_8P)_2Mn_2]^+$; 421 (74) $[C_{24}H_{16}P_2Mn]^+$, $[(C_{12}H_8P)_2Mn]^+$; 366 (86) $[C_{24}H_{16}P_2]^+$, $[(C_{12}H_8P)_2]^+$; 238 (18) $[C_{12}H_8PMn]^+$; 183 (90) $[C_{12}H_8P]^+$. IR (KBr disk) (cm^{-1}) ν_{CO}: 1970 (s), 1998 (s), 2058 (s). ^{1}H NMR (acetone-d_6) δ: 8.89 (m, 2H), 8.33 (d, *J* = 7.6 Hz, 2H), 7.84 (dd, *J* = 7.6, 7.6 Hz, 2H), 7.74 (dd, *J* = 7.6, 7.6 Hz, 2H). ^{13}C NMR (acetone-d_6, HMQC and HMBC) δ: 146, 142, 129, 129, 127, 122. ^{31}P NMR (acetone-d_6, HMBC) δ: –83. Anal. calcd. for $C_{32}H_{16}O_8P_2Mn_2$: C 54.86, H 2.30; found: C 54.36, H 2.34.



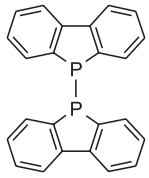
Heating **11** in refluxing xylenes or decane for 3 h yielded only intractable decomposition products.

X-ray diffraction experiments

Crystals suitable for diffraction studies were grown at –23°C by vapour diffusion of CH_2Cl_2–hexanes (**7**, **8**, **11**), CH_2Cl_2–methanol (**9**), or ether–pentane (**10**). Single crystals of **7** and **9** were mounted in thin-walled glass capillaries. Data were collected on a Rigaku AFC5R diffractometer using ω – 2θ scans at 16° per min to a max of 6 scans, ±*h*, –*k*, and ±*l* being collected in each case. Absorption corrections were made using ψ-scans. Crystal decay was not observed for **9** and a decay of 4% was corrected for **7**. Crystals of **8** and **11** were mounted on thin-glass fibers using epoxy cement, and crystals of **10** were coated with Paratone-N oil, mounted on a glass fiber, and frozen in the cold nitrogen stream of the goniometer. Data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and ϕ scans with a scan width of 0.3° and 30 s exposure times. A hemisphere of data was collected at a detector distance of 4 cm. Crystal decay was not observed. The data were reduced (SAINT) (32) and corrected for absorption (SADABS) (33).

All structures were solved by direct-methods and refined by full-matrix least-squares on F^2 (SHELXTL) (34). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined isotropically where possible. Calculated positions and refinement based on a riding model were employed for **8** and **9** as well as the solvent molecule in **10**. Crystallographic data are summarized in Table 1 and selected interatomic distances and angles are presented in Tables 2–6 in the *Discussion* section.[3]

Scheme 1.



5 **7**

Results

Synthesis and properties

Compound **7** was formed by the reaction between Li-DBP and $Mn(CO)_5Br$ in THF at room temperature (Scheme 1).

The yields of **7** increased when $Mn(CO)_5Br$ was in excess, reaching a max at a $Mn(CO)_5Br$:Li-DBP ratio of 4:1; ratios below 2:1 yielded predominantly bis(1,1′-dibenzophospholyl) (**8**) as well as **7**.

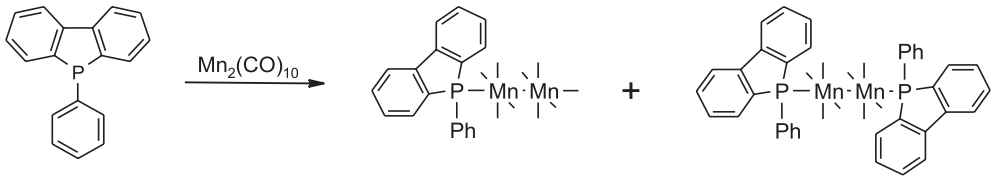
8

Complexes **9** and **10** were obtained by heating at reflux a solution of **6** and $Mn_2(CO)_{10}$ in xylenes (Scheme 2).

Compound **11** was obtained by heating at reflux a solution of **8** and $Mn_2(CO)_{10}$ in xylenes (Scheme 3).

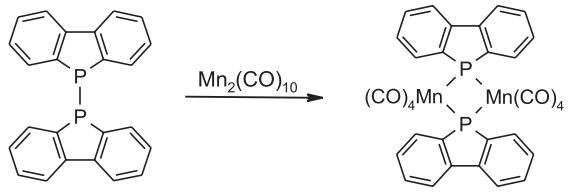
The products were characterized by elemental analysis, IR and NMR spectroscopies, and mass spectrometry, and X-ray diffraction. The complexes were either orange (**7**) or yellow (**9**–**11**) diamagnetic, crystalline solids. They were mildly air sensitive, but indefinitely stable under an inert atmosphere, both in solution and in the solid state. Compound **11** was insoluble in nonpolar hydrocarbons and only sparingly soluble in polar organic solvents. The remaining complexes were soluble in polar organic solvents, but sparingly soluble in nonpolar hydrocarbons. Compound **7** gave **11** and $(\mu_2\text{-Br})_2Mn_2(CO)_8$ when heated in refluxing xylenes (Scheme 4).

Compounds **9** and **10** decomposed slowly in refluxing xylenes to give **6** as the only product containing phosphorus, while **11** yielded only intractable decomposition products on prolonged heating in refluxing xylenes or decane.



Discussion

Summarizing the results, reaction of the DBP anion **5** with $Mn(CO)_5Br$ yielded the complex $(\mu_2\text{-DBP})(\mu_2\text{-Br})Mn_2(CO)_8$ (**7**), and reaction of bis(1,1′-dibenzophospholyl) (**8**) with



[3] Tables of crystallographic data, atomic coordinates, interatomic distances and angles, anisotropic displacement parameters, and hydrogen atom coordinates have been deposited. Copies may be purchased from the Depository of Unpublished Data (DUD No. 4304), Document Delivery, CISTI, National Research Council Canada, Ottawa, ON, Canada K1A 0S2 (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). Crystallographic data for the structures has been deposited with the Cambridge Crystallographic Data Centre (CCDC 161701 (**7**), 161702 (**8**), 161703 (**9**), 161704 (**10**), and 161705 (**11**)). Fig. 2. View of **9**, thermal ellipsoids at the 30% probability level.

$Mn_2(CO)_{10}$ gave $(\mu_2\text{-DBP})_2Mn_2(CO)_8$ (**11**). The phosphine adducts $(Ph\text{-DBP})Mn_2(CO)_9$ (**9**) and $(Ph\text{-DBP})_2Mn_2(CO)_8$ (**10**) were obtained when Ph-DBP (**6**) was reacted with $Mn_2(CO)_{10}$. In all of the complexes the manganese was σ-coordinated by the phosphorus atom of the ligand. There was no involvement of the ligand's π-electrons. In contrast, the fluorenyl complex $(\eta^5\text{-}C_{13}H_9)Mn(CO)_3$ was prepared by reaction of the fluorenide anion with $Mn(CO)_5Br$ (21)[2], while η^5-phospholyl complexes were obtained by reaction of either 1-phenylphospholes or bis(1,1′-phospholyls) with $Mn_2(CO)_{10}$ (35–39).

The related phosphindolyl ligands **3** and **4** can act as π-donors (8, 29, 40) and it seemed reasonable that DBP could behave as a π-donor ligand as well. However, it appears that increasing benzannelation of the phospholyl skeleton decreases the ability of the ligand to bind in an η^5-fashion. Coordination of a metal to the central five-membered ring in DBP would result in a very unfavourable loss of local aromaticity in the six-membered rings. This effect is reduced for the phosphindolyl ligands **3** and **4** because of the lower degree of benzannelation and is absent for the phospholyl ligand **2** because it is not benzannelated. This argument is supported by the observation

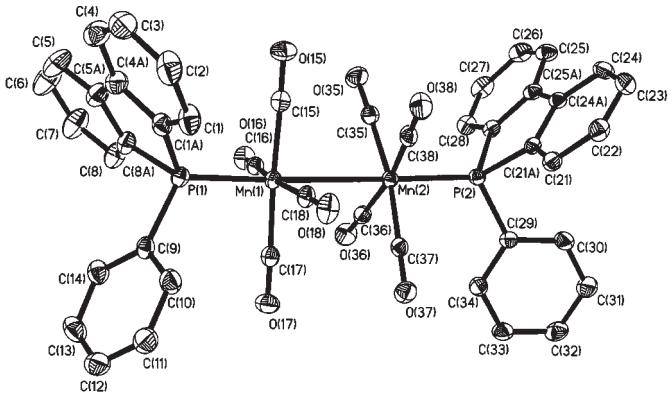
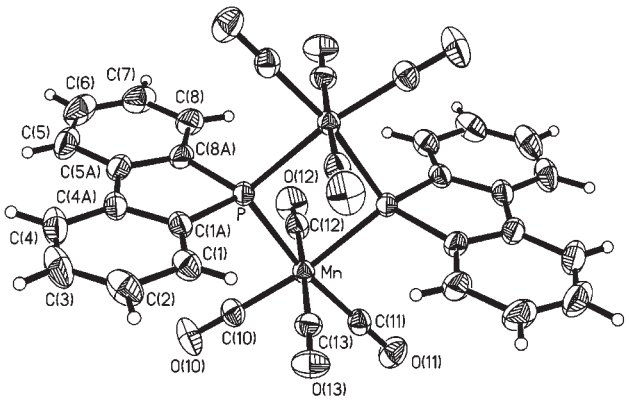
Fig. 3. View of **10**, thermal ellipsoids at the 30% probability level. Hydrogen atoms have been omitted for clarity.





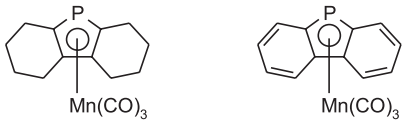


Fig. 4. View of **11**, thermal ellipsoids at the 30% probability level.

that the phosphindolyl ligand **3** (BP) can form (η^5-BP)$_2$Sm(THF)$_2$, whereas DBP gave (η^1-DBP)$_2$Sm(THF)$_4$ (29).

Local aromaticity in the six-membered rings is absent in the hydrogenated ligand DBP-H$_8$, for which the π-complex (η^5-DBP-H$_8$)Mn(CO)$_3$ (**12**) is known (39). There was no evidence for (η^5-DBP)Mn(CO)$_3$ (**13**) even as an intermediate in the reaction of **5** and Mn(CO)$_5$Br to give **7**.

12 **13**

Ligands **2**–**4** normally coordinate through their π-electrons and complexes containing bridging phospholyl ligands, as found in (μ_2-DBP)(μ_2-Br)Mn$_2$(CO)$_8$ (**7**) and (μ_2-DBP)$_2$Mn$_2$(CO)$_8$ (**11**) are rare. It was proposed on the basis of IR spectroscopy that (μ_2-BP)(μ_2-Br)Mn$_2$(CO)$_8$, a product of the reaction of Mn(CO)$_5$Br with **3**, contains a bridging phospholyl ligand (35). The only analogues of **7** that have been crystallographically analyzed are Cu and Ag complexes of **4** (10–13). The closest analogue to **11** is (μ_2-BP)$_2$Mn$_2$(CO)$_8$, isolated as a by-product from the reaction of Mn(CO)$_5$Br with **3** (35). Complexes in which the μ_2-DBP ligand has been authenticated are limited to (μ_2-DBP)$_2$Mo$_2$(CO)$_8$ and (μ_2-DBP)$_2$Mo$_2$(H-DBP)(CO)$_7$ (41).

The addition of a P—P bond across an Mn—Mn bond, as is the case in the reaction of **8** with Mn$_2$(CO)$_{10}$ to yield the bridged complex (μ_2-DBP)$_2$Mn$_2$(CO)$_8$ (**11**) is unusual for phospholyl compounds, but was observed for diphosphines, as in the reaction between Ph$_2$P—PPh$_2$ and Mn$_2$(CO)$_{10}$, which gave (μ_2-PPh$_2$)$_2$Mn$_2$(CO)$_8$ (42). The thermal rearrangement of **7** to yield **11** and (μ_2-Br)$_2$Mn$_2$(CO)$_8$ is surprising. An associative bimolecular mechanism is unlikely because the steric bulk of the DBP ligand would prohibit formation of the requisite dimer. The reaction most probably proceeds by breaking the Mn—P and Mn—Br bonds, followed by recombination of the resulting radicals. The reaction is quantitative and driven by the insolubility of **11**.

Molecular structures

A thermal ellipsoid plot of **7** is shown in Fig. 1 and selected interatomic distances and angles are presented in Table 2. The phosphorus atom is tetrahedrally coordinated and the manganese atoms adopt a distorted octahedral geometry. The four-membered Mn$_2$PBr ring forms a planar parallelogram with almost equal P—Mn distances (2.374(2) and 2.370(2) Å) and Mn—Br distances (2.536(1) and 2.548(2) Å). Obtuse angles are found at the bromine (93.12(5)°) and phosphorus atoms (102.20(7)°) and acute angles at the manganese centers (average, 82.34(6)°). The DBP skeleton is planar and almost orthogonal to the Mn$_2$PBr ring (torsion angle, 87.6°). The Mn···Mn distance is 3.692 Å and therefore no direct Mn–Mn interaction is present. Few compounds containing the (μ_2-PR$_2$)(μ_2-X)Mn$_2$(CO)$_8$ unit have been structurally characterized; their metric parameters compare well with those for **7** (43–45).

Thermal ellipsoid plots of **9** and **10** are depicted in Figs. 2 and 3, and interatomic distances and angles are presented in Tables 3 and 4, respectively. Both **9** and **10** contain six-coordinate manganese and four-coordinate phosphorus. The Ph-DBP ligand is axial in both complexes, as is common in Mn$_2$(CO)$_{10-n}$(PR$_3$)$_n$ (n = 1, 2) derivatives for steric reasons (46). The carbonyl groups of the Mn(CO)$_4$ units are staggered in both molecules. The Ph-DBP ligands adopt orientations in which the P–Ph tensors are staggered with respect to the carbonyl ligands on the nearest metal atom. In the disubstituted complex **10**, the Ph-DBP ligands are oriented such that the two phenyl groups are in a *cis*-conformation. The geometry of the Ph-DBP ligands in **9** and **10** are similar to other Ph-DBP metal complexes (47).

A thermal ellipsoid plot of **11** is shown in Fig. 4 and selected interatomic distances and angles are presented in Table 5. Compound **11** crystallizes in the monoclinic space group *C*2/*c* with four molecules per unit cell. The molecule is symmetric and as a result the Mn$_2$P$_2$ ring is planar, the two DBP ligands reside in the same plane and are orthogonal to the Mn$_2$P$_2$ ring. In the four-membered ring, the angles at phosphorus are 102.12(2)° and thus identical to that found in **7**, while the angles at the manganese centers in **11** are 77.88(2)°, compared to 82.34(6)° in **7**. The Mn$_2$P$_2$ ring exhibits two sets of Mn—P distances: 2.3670(4) and 2.3718(5) Å. These are comparable to those

in related bis(μ_2-phosphido)-dimanganese-octacarbonyls (48). The Mn···Mn distance is 3.686 Å, precluding a direct Mn–Mn interaction.

Compounds containing P—P bonds, such as bis(1,1′-dibenzophospholyl) (**8**) are of current interest (49–51). A thermal ellipsoid plot of **8** is shown in Fig. 5 and selected interatomic distances and angles are presented in Table 6.

Compound **8** crystallizes in the monoclinic space group $P2_1/n$ with two molecules per unit cell, each molecule lying on an inversion center. As a result the two DBP ring systems are coplanar. This is in contrast to the homologue 9,9′-bicarbazyl (**14**) where the two ring systems make a torsion angle of 72° (52). The difference in the torsion angles of **8** and **14** is explained by the decrease in repulsive H···H interactions as a consequence of the longer P—P (2.2501(6) Å) vs. N—N (average, 1.370 Å) distance.

14

The P—P distance in **8** is similar to other hindered diphosphines which range from 2.244(2) to 2.260(2) Å (53–55). Diphosphines with sterically less demanding substituents display shorter P—P bond lengths (2.190(1)–2.217(1) Å) (49, 56–59).

Acknowledgments

Professor T. Stanley Cameron (Dalhousie University) is thanked for the diffraction data for **7** and **9**, Dr. Larry Calhoun (UNB) for assistance with the NMR experiments, and Mr. Gilles Vautour (UNB) for mass spectrometry. We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support of this work.

Cadmium complexes of thiones. Part II.[1] A synthetic, solution, and solid-state MAS $^{111/113}$Cd NMR study of cadmium complexes of 1,3-thiazolidine-2-thione, and the structures of [tetrakis(1,3-thiazolidine-2-thione)cadmium] trifluoromethanesulfonate ($[Cd(C_3H_5NS_2)_4](CF_3SO_3)_2$) and [tetrakis(1,3-thiazolidine-2-thione)cadmium][tetrakis(nitrato-*O,O′*)cadmate] ($[Cd(C_3H_5NS_2)_4][Cd(O_2NO)_4]$)

Umarani Rajalingam, Philip A.W. Dean, Hilary A. Jenkins, Michael Jennings, and James M. Hook

Abstract: Treatment of $Cd(O_3SCF_3)_2$ with the stoichiometric quantity of 1,3-thiazolidine-2-thione (tztH) allows isolation of $[Cd(tztH)_4](O_3SCF_3)_2$ (**1**). When tztH:Cd ≥ 2 the reaction of $Cd(NO_3)_2{\cdot}4H_2O$ with tztH leads to $[Cd(tztH)_4][Cd(O_2NO)_4]$ (**2**). The structures of both **1** and **2** have been determined by single crystal X-ray analysis. Colourless crystals of **1** are orthorhombic, space group *Fdd*2, with eight molecules per unit cell (Z = 8) of dimensions a = 20.139(3), b = 23.332(5), c = 14.214(3) Å. Those of **2** are tetragonal, space group $I\bar{4}$, with four molecules per unit cell (Z = 4) of dimensions a = 13.8853(11), c = 8.077(2) Å. The discrete homoleptic cation $[Cd(tztH)_4]^{2+}$ is characterized for the first time in **1** and **2**. The cations are of point group symmetry C_2 and S_4 in **1** and **2**, respectively. In both cases the ligands are S-bound, and the CdS_4 kernel is a squashed tetrahedron. In **2**, the eight-coordinate anion $[Cd(O_2NO)_4]^{2-}$ is characterized for the second time. ^{113}Cd CP MAS NMR data are reported for solid **1** and **2**, and also for solids produced by fusing $Cd(NO_3)_2{\cdot}4H_2O$ with different molar ratios amounts of tztH, and by fusing $Cd(O_3SCF_3)_2$ with six mol equivalents of tztH. In the $Cd(NO_3)_2{\cdot}4H_2O$:tztH mixtures, species identified include unreacted cadmium salt **2** ($[Cd(tztH)_4](NO_3)_2$) and possibly $Cd(tztH)_3(NO_3)_2$. $[Cd(tztH)_4](NO_3)_2$ becomes the major species only when a significant excess of tztH is used. In the mixtures with tztH:Cd > 4, neither $Cd(NO_3)_2{\cdot}4H_2O$ nor $Cd(O_3SCF_3)_2$ form complexes containing more than four tztH ligands. Reduced-temperature ^{111}Cd NMR data are reported for $Cd(ClO_4)_2{\cdot}6H_2O$:tztH mixtures in MeOH. Species identified are $Cd(tztH)_w^{2+}(solv)$ (w = 0–3).

Key words: 1,3-thiazolidine-2-thione, cadmium complexes, X-ray analysis, ^{113}Cd CP MAS NMR, solution ^{111}Cd NMR, tetrakis(1,3-thiazolidine-2-thione)cadmium(2+) cation, tetrakis(nitrato-*O,O′*)cadmate(2–) anion.

Résumé : Le traitement du $Cd(O_3SCF_3)_2$ avec une quantité stoechiométrique de 1,3-thiazolidine-2-thione (tztH) permet d'isoler le $[Cd(tztH)_4](O_3SCF_3)_2$ (**1**). Quand le tztH:Cd ≥ 2, la réaction du $CD(NO_3)_2{\cdot}4H_2O$ avec la tztH conduit à la formation de $[Cd(tztH)_4][Cd(O_2NO)_4]$ (**2**). Les structures des composés **1** et **2** ont été déterminées par diffraction des rayons X par un cristal unique. Les cristaux incolores du composé **1** sont orthorhombiques, groupe d'espace *Fdd*2, avec a = 20,139(3), b = 23,332(5) et c = 14,214(2) Å et Z = 8. Ceux du composé **2** sont orthogonaux, groupe d'espace $I\bar{4}$, avec a = 13,8853(11) et c = 8,077(2) Å et Z = 4. Dans les composés **1** et **2**, on a pu caractériser pour la première fois le cation homoleptique individuel $[Cd(tztH)_4]^{2+}$. Les cations sont respectivement de symétries ponctuelles C_2 et S_4.

Dans chacun des cas, les ligands sont liés au soufre et le noyau CdS_4 est de forme tétraédrique aplatie. Dans le composé **2**, l'anion octacoordiné $[Cd(O_2NO)_4]^{2-}$ a été caractérisé pour la deuxième fois. On rapporte les données RMN du ^{113}Cd par la méthode CP MAS pour les composés solides **1** et **2** ainsi que pour les solides obtenus par fusion du $Cd(NO_3)_2 \cdot 4H_2O$ avec des rapports molaires divers de tztH ainsi que par la fusion du $Cd(O_3SCF_3)_2$ avec six équivalents molaires de tztH. Dans les mélanges $Cd(NO_3)_2 \cdot 4H_2O$:tztH, les espèces identifiées comprennent le sel de cadmium qui n'a pas réagi, **2**, $[Cd(tztH)_4](NO_3)_2$ et possiblement du $Cd(tztH)_3(NO_3)_2$. Le $[Cd(tztH)_4](NO_3)_2$ ne devient l'espèce majeure que lorsqu'on utilise un excès significatif de tztH. Dans les mélanges où la tztH:Cd > 4, ni le $Cd(NO_3)_2 \cdot 4H_2O$ ni le $Cd(O_3SCF_3)_2$ ne forment de complexes comportant plus de quatre ligands tztH. On rapporte les données relatives à la RMN du ^{111}Cd à température réduite pour des mélanges de $Cd(ClO_4)_2 \cdot 6H_2O$:tztH dans le MeOH. Les espèces identifiées sont les $Cd(tztH)_w^{2+}$ (solv) (w = 0–3).

[Traduit par la Rédaction]

Introduction

NMR spectroscopic and structural studies of complexes containing Cd—S bonds have been of long-standing interest in one of our laboratories (1*a–g* and refs. therein). Very recently we have extended this chemistry to include a structural and NMR spectroscopic study of complexes of cadmium with pyridine- and quinoline-thiones (2). In the present paper, we have extended our study of complexes of thiones to those of the heterocyclic ligand 1,3-thiazolidine-2-thione (tztH). Although tztH is known to have an interesting chemistry as a ligand (3), relatively few complexes of this ligand with cadmium have been reported (4–8), and there are no structural or metal NMR data available for homoleptic complexes of tztH with cadmium.

tztH

We provide here structural and solid-state ^{113}Cd NMR data for two salts containing the $[Cd(tztH)_4]^{2+}$ cation. One is an unexpected double salt, and in light of its occurrence, we have also explored the solid-state metal NMR data of mixtures obtained by fusing together tztH and $Cd(NO_3)_2 \cdot 4H_2O$ or $Cd(O_3SCF_3)_2$ (abbreviated $Cd(trif)_2$). Fusion of tztH and $Cd(NO_3)_2 \cdot 4H_2O$ was used earlier (7) to prepare a compound of formula $Cd(tztH)_4(NO_3)_2$.

Experimental

Methods and materials

All manipulations were carried out under an atmosphere of dry N_2(g) in a glove box or with a vacuum–N_2(g) manifold or under Ar(g) in a glove bag. Analar grade solvents (MeCN, $CHCl_3$, CH_2Cl_2, Me_2CO, Et_2O, toluene) were dried over 3 Å molecular sieves and deoxygenated using Ar(g) prior to use.

Before use, thiazolidine-2-thione (tztH) (Aldrich) was recrystallized from ethanol, and $Cd(NO_3)_2 \cdot 4H_2O$ (BDH) and $Cd(ClO_4)_2 \cdot 6H_2O$ (Alfa; both deliquescent) were both dried to a constant hydration state under vacuum in the heated port of the glove box. The literature method was used for the synthesis of anhyd $Cd(trif)_2$ (9). The metal triflate, nitrate, and perchlorate were weighed out in the glove box.

*Synthesis of $[Cd(tztH)_4](CF_3SO_3)_2$ (**1**)*

1,3-Thiazolidine-2-thione (1.19 g, 10.0 mmol) was dissolved in a solution of $Cd(trif)_2$ (1.02 g, 2.48 mmol) in 30 mL of MeCN:CH_2Cl_2 (3:1). At this stage, a 5 mL-portion of the mixture was diluted with another 10 mL of MeCN:CH_2Cl_2, then kept in a freezer (–15°C) for the production of single crystals for X-ray diffraction. The remaining solution was also kept in the freezer and from it, after a few days, was isolated 0.64 g of colourless crystals. These were washed with cold diethyl ether and dried in vacuum. Allowing the filtrate to again stand in the freezer for several days resulted in a further 0.31 g of product. The total prorated yield was 52%, mp 145 to 146°C. Anal. calcd. for $C_{14}H_{20}F_6N_4O_6S_{10}Cd_2$: C 18.95, H 2.27, N 6.31; found: C 19.75, 20.00, H 2.13, 2.25, N 6.08, 6.19. An X-ray analysis of **1** reveals no occluded solvent, and also there was no trace of any Cd-containing impurity in its solid-state ^{113}Cd NMR spectrum (see below).

*Synthesis of $[Cd(tztH)_4][Cd(NO_3)_4]$ (**2**)*

Solutions of $Cd(NO_3)_2 \cdot 4H_2O$ (0.525 g, 1.70 mmol) in MeCN (8 mL) and tztH (0.801 g, 6.72 mmol) in MeCN (10 mL) were mixed at room temperature. After 30 min, colourless crystals were separated by filtration and potential data crystals for X-ray analysis were taken, after which, the bulk was washed with ice cold diethyl ether and vacuum dried. Yield: 1.079 g (67.7%). Anal. calcd. for $C_{12}H_{20}N_8O_{12}S_8Cd_2$: C 15.19, H 2.12, N 11.80; found: C 15.32, 15.14, H 1.55, 1.59, N 11.74, 11.65. The crystals melt in the range 145.8 to 146.4°C, turning yellow with bubbling.

Compound **2** (identified by elemental microanalysis) was also formed from mixtures containing $Cd(NO_3)_2 \cdot 4H_2O$:tztH = 1:2.

Fused tztH:$Cd(NO_3)_2$ and tztH:$Cd(trif)_2$ mixtures

A weighed amount of the thione was added to a tube that contained a teflon-coated magnetic stirrer bar and was topped with a ground-glass socket. In the glove box, the appropriate metal salt was weighed into a tipping tube (10) having the matching ground-glass cone. In the glove bag, the two halves were joined. Then the thione was melted and the metal salt was tipped in with stirring to produce a homoge-

neous mixture. The mixture was cooled to solidify it, finely ground in the glove bag, and used for the solid state NMR measurements, either directly or after repeated washings with toluene (3 × 5 mL of toluene per 0.6 g of $Cd(NO_3)_2 \cdot 4H_2O$) followed by drying and regrinding.

NMR spectra

Proton-decoupled solution 63.59 MHz ^{111}Cd NMR spectra were measured at UWO, using a Varian XL-300 spectrometer system, a typical acquisition time of 0.6 s, and inverse-gated decoupling to avoid the negative Overhauser effect (in the more usual ^{113}Cd region, artifacts were present in the frequency range of interest; no primary isotope effect is expected between ^{111}Cd and ^{113}Cd NMR spectra). The spectra were measured with samples in protiated solvents in 10 mm o.d. NMR tubes and a preshimmed field. A ^{2}H field-frequency lock was not used since the field drift was negligible. The samples were referenced to external $Cd(ClO_4)_2$(aq) (0.1 M) at ambient probe temperature (294 ± 2 K). Concentrations of samples in 10 mm o.d. NMR tubes were prepared on the basis of mass of sample per volume of solvent. For variable temperature NMR spectra, 30 min was allowed for thermal equilibration at each temperature.

Solid-state ^{113}Cd NMR spectra were acquired at UNSW using a Bruker MSL-300 spectrometer operating at 66.549 MHz with a Bruker WB-4BL double air-bearing cross-polarization probe. Samples of ca. 100 mg of the cadmium complexes were packed into 4 mm o.d. rotors made from partially stabilized zirconia and subjected to magic-angle spinning (MAS) at 2–8 kHz. Spectra were acquired at ambient probe temperature (292 K) using single-contact cross-polarization (CP) experiments with high-power ^{1}H decoupling during acquisition. Isotropic signal positions were found by comparing spectra acquired at two different MAS rates. After some experimentation, the following parameters were found to be optimal: pulse width, 3.3 μs (90°); contact time, 20 ms; recycle time, 60 s; acquisition time, 10–30 ms. Free induction decays were acquired and zero-filled to 8K prior to Fourier transformation. Usually 64–256 scans were sufficient for good signal to noise. The Hartman–Hahn match was set using $CdSO_4 \cdot 8H_2O$, which was also used as a secondary external reference that gives two signals (δ_{Cd} = –64.6 and –77.4) relative to 0.1 M $Cd(ClO_4)_2$(aq) (11).

All simulations of the MAS spectra were carried out using the Bruker Winfit program and gave the following parameters: the principle components δ_{11}, δ_{22}, δ_{33} with $\delta_{11} > \delta_{22} > \delta_{33}$; $\delta_{iso} = 1/3(\delta_{11} + \delta_{22} + \delta_{33})$. From these parameters, the span, $\Omega = |\delta_{33} - \delta_{11}|$, and the skew, $\kappa = 3(\delta_{iso} - \delta_{22})/\Omega$ (12), could be derived. The values of δ have an estimated error of ±1 ppm.

X-ray structure determinations

Crystals of **1** and **2** were obtained during their syntheses (see *Experimental* section). The data crystals were mounted

in glass capillaries, and data were collected on a Siemens P4 diffractometer using XSCANS software. Crystal data and refinement parameters for **1** and **2** are listed in Table 1, while final positional parameters and equivalent isotropic thermal parameters for the two compounds are given in Tables 2 and 3. Selected interatomic distances and angles appear in Tables 4 and 5, for **1** and **2**, respectively.[5] In both cases, unit cell parameters were calculated from 25 centred high-angle reflections in the range $15 < 2\theta < 25$.

For **1**, systematic absences were consistent with the uniquely determined space group *Fdd*2, borne out by successful solution of the structure. The data were processed, semiempirical absorption corrections based on φ-scan data were applied, and full-matrix least-squares refinement on F^2 was performed using direct methods and the SHELXTL 5.03

program package (13). The cation is located on a twofold axis, while the anion is at a general position. All non-hydrogen atoms of the cation were refined with anisotropic thermal parameters. There was disorder of the anion over two positions; the occupancies were 0.6 and 0.4 for the *a* and *b* anions, respectively. In the anions, all atoms were refined isotropically. The largest residual electron density peak (0.53 e $Å^{-3}$) was associated with S(24). In the final stages of refinement, $R = 5.01$ and $R_w = 11.95$.

For **2**, systematic absences were consistent with the space groups *I*4, *I*4/*m*, and $I\bar{4}$. The acentric option ($I\bar{4}$) resulted in chemically reasonable and computationally stable results. Processing of the data, application of absorption corrections, and refinement were carried out as for **1**. All non-hydrogen atoms were refined with anisotropic thermal parameters. The largest residual electron density peak (0.258 e $Å^{-3}$) was associated with the Cd cation. In the final stages of refinement, $R = 1.80$ and $R_w = 4.53$.

Fig. 1. A view of the cation in $[Cd(tztH)_4](trif)_2$ (**1**). Non-hydrogen atoms are shown as 50% probability thermal ellipsoids.

Results and discussion

Crystal structure of $[Cd(tztH)_4](trif)_2$ (1)

The crystal structure of **1** consists of discrete cations and anions, the anions being disordered. The structure of the cation is shown in Fig. 1. Selected bond distances and angles are given in Table 4.

In the cations, the ligands behave as S-donors. In an earlier study (6) it was suggested on the basis of IR spectroscopy that N-bonding of tztH occurred exclusively in this cation. However, tztH acts as a monodentate S-donor in catena-$CdCl_2$(tztH) (8). In **1**, the cation has C_2 point group symmetry. The Cd—S bond distances are 2.540(3) and 2.519(3) Å and are similar to the 2.5163(7) Å found for $[Cd(Py2SH)_4]^{2+}$ (Py2SH = 2-(1*H*)-pyridinethione) as the nitrate salt (2), but are shorter than the 2.605(2) Å found for catena-$CdCl_2$(tztH), in which the Cd atoms are six-coordinate (8).

The S-Cd-S angles range from 117.62(15) to 106.78(10)°. The CdS_4 kernel exhibits flattening along the C_2 axis, with S(1)-Cd-S(1A) and S(3)-Cd-S(3A) angles being larger than the other four S–Cd–S angles. A more regular flattening of the same type is observed for $[Cd(Py2SH)_4](NO_3)_2$ (1).

The Cd-S-C angles fall within the range observed for corresponding M-S-C angles in the literature (8, 14). Coordination produces relatively little change in the geometry of the ligand compared with that for the free ligand (15), as is commonly observed (8, 14). The atoms S(1)-C(1)-N(1)-S(2)-C(3) and S(3)-C(4)-N(2)-S(4)-C(6) lie in planes (mean deviations 0.008 and 0.022 Å, respectively). The atoms C(2) and C(5) (at the "flap" of the envelope conformation of their five-membered rings) lie out of their respective planes by 0.145 and 0.301 Å, respectively. The torsion angles Cd(1)-S(1)-C(1)-N(1) and Cd(1)-S(3)-C(4)-N(2) are 148.8 and –163.3°, respectively.

Spectrum of: (*a*) **1**; (*b*) **2**; (*c*) unwashed 1:4 $Cd(NO_3)_2{\cdot}4H_2O$:tztH mixture; (*d*) toluene-washed 1:4 $Cd(NO_3)_2{\cdot}4H_2O$:tztH mixture; (*e*) unwashed 1:6 $Cd(NO_3)_2{\cdot}4H_2O$:tztH mixture; (*f*) unwashed 1:2 $Cd(NO_3)_2{\cdot}4H_2O$:tztH mixture.

Crystal structure of $[Cd(tztH)_4][Cd(O_2NO)_4]$ (2)

This salt is comprised of discrete $[Cd(tztH)_4]^{2+}$ cations and $[Cd(O_2NO)_4]^{2-}$ anions. Figure 2 shows the ions, and selected bond distances and angles are presented in Table 5. Both ions have point group symmetry S_4. In the cation, the ligand is again S-bound. The Cd—S distance (2.5329(9) Å) is the same as the long Cd—S distance found in **1**. The CdS_4 kernel exhibits a tetragonal compression, the two independent S-Cd-S angles being 105.91(2) and 116.85(5)°. There is a strong resemblance to the distortion found for the CdS_4 kernel of $[Cd(Py2SH)_4](NO_3)_2$, which has been discussed in detail (2). The Cd-S-C angle of 105.04(12)° falls between the values observed for **1**, while the overall ligand geometry is similar to those in **1**: S(1)-C(1)-N(1)-S(2)-C(3) are planar (mean deviation, 0.033 Å), with C(2) out of plane by 0.367 Å. The Cd(1)-S(1)-C(1)-N(1) torsion angle is 163.1°.

Within the $[Cd(O_2NO)_4]^{2-}$ anions, the nitrate anions are bonded in an anisobidentate manner, with Cd(2)—O(2) and Cd(2)—O(3) being 2.575(4) and 2.294(3) Å, respectively. The O(2)-Cd(2)-O(3) bite angle is 52.22(9)°. The $[Cd(O_2NO)_4]^{2-}$ anion has been described once previously; it occurs in $[CdL^4(NO_3)_2][Cd(O_2NO)_4]$ (**3**, L^4 = 1,5,9,13-tetramethyl-1,5,9,13-tetra-azacyclohexadecane) (16). In **2**, the arrangement of the O-atoms in the anion is S_4-dodecahedral (17). The Cd—O bond distances and the O-Cd-O bite angle for $[Cd(O_2NO)_4]^{2-}$ in **2** are similar to those found for $[Cd(5)(O_2NO)_4]^{2-}$ in **3** (in ligand **1**, Cd—O = 2.55(2) and 2.27(2) Å, bite angle = 52.4(5)°; in ligand **2**, Cd—O = 2.60(2) and 2.27(2) Å, bite angle = 51.5(6)°), despite the lower symmetry of the latter. (The anion $[Cd(4)(O_2NO)_4]^{2-}$ in **3** appears to be still less symmetrical, though some disorder was evident. It is noteworthy that in this latter anion the individual ligands appear to be more symmetrically bound than in **2** or the corresponding $[Cd(5)(O_2NO)_4]^{2-}$ anion.) The anisobidenticity of the nitrate ligands in $[Cd(O_2NO)_4]^{2-}$ in **2**, where Δr (Cd—O) is 0.280(5) Å, is smaller than for homologous $[Zn(O_2NO)_4]^{2-}$ (as its Ph_4As^+ salt), where Δr (Zn—O) is 0.47(1) and 0.57(1) Å (18), but larger than in isoelectronic $Sn(O_2NO)_4$, in which Δr (Sn—O) varies from 0.00(1) to 0.06(1) Å (19).

Cadmium NMR spectra of 1 and 2

At 293 K exchange-averaged ^{111}Cd NMR spectra are observed for mixtures of $Cd(NO_3)_2{\cdot}4H_2O$ and tztH, e.g., δ_{Cd} increases monotonically from –95 to +125 as tztH:Cd is increased from 0 to 7.5 in a solution having 0.1 mol of Cd per L in MeOH. Presumably mixtures of species of the general type $[Cd(tztH)_w(NO_3)_x(MeOH)_y(H_2O)_z]^{2-x}$ (abbreviated $Cd(tztH)_w^{2+}(solv)$) are being formed in these mixtures. Unfortunately, poor solubility precludes reduced temperature solution NMR studies. Complexes of tztH with $Cd(ClO_4)_2$ are more soluble (and also more soluble than the corresponding triflates), and incremental addition of tztH to

Note: See text for description of Ω and κ and Fig. 3.
[a] δ_{11}, δ_{22}, δ_{33} found at very low spinning speeds (925 Hz).
[b] This signal was isotropic down to a spinning speed of 1600 Hz.
[c] In $[Cd(tztH)_4](NO_3)_2$.
[d] In solid mixtures after fusion.
[e] In $[Cd(tztH)_4][Cd(O_2NO)_4]$.

$Cd(ClO_4)_2$ (0.07 mol L^{-1} of solvent) allowed observation of slow-exchange ^{111}Cd NMR spectra for several new species $Cd(tztH)_w^{2+}$(solv) in MeOH at 189 K: δ_{Cd} = –14, 73, 153, and 453 for w = 0, 1, 2, and 3, respectively (the complex with w = 4 is poorly soluble).

Neither **1** nor **2** were soluble enough in noncoordinating solvents for the measurement of their metal NMR spectra in solution, so the ^{113}Cd NMR spectra of the solids were measured. The ^{113}Cd CP MAS NMR spectrum of solid **1** showed a single line with δ_{Cd} (isotropic) = 586, having very low span (Fig. 3*a* and Table 6). This spectrum is clearly that of the $[Cd(tztH)_4]^{2+}$ cation, with its CdS_4 kernel, as found in the structural determination. For comparison, the solution ^{113}Cd NMR chemical shifts of $[Cd(Py2SH)_4]^{2+}$ (in which the 2-(1*H*-pyridinethione) is S-bound) and $[Cd(SPh)_4]^{2-}$ have been reported as 603 and ~590 ppm, respectively, (1*e*, 1*g*, 2). The ^{113}Cd CP MAS NMR spectrum of solid **2** consists of two resonances (Fig. 3*b*): the first has δ_{Cd} (isotropic) = 557, with no evidence of anisotropy, and can again be assigned to $[Cd(tztH)_4]^{2+}$. The change in δ_{Cd} of the $[Cd(tztH)_4]^{2+}$ cation on changing from **1** to **2** (29 ppm) is the same order of magnitude as found for other cadmium complexes when the counterion is changed, e.g., 23 ppm for $CdCl_4^{2-}$ when the cation is changed from thiaminium (as the monohydrate) to Et_4N^+ (20). Such changes are due to a combination of small changes in geometry of the cadmium complex and the change in its crystallographic environment. The second signal observed for solid **2**, δ_{Cd}(isotropic) = –131, has a spectrum consistent with axial symmetry: it must be due to the $[Cd(O_2NO)_4]^{2-}$ anion. For comparison, δ_{Cd} = –100 (20) for the distorted dodecahedral CdO_8 kernel (comprised of O-atoms from both NO_3^- and H_2O) found in $Cd(NO_3)_2 \cdot 4H_2O$ (21).

A compound described as $[Cd(tztH)_4](NO_3)_2$ has been synthesized by reaction of the metal salt with a small excess of the molten ligand, followed by repeated washing with toluene (6). In our studies, during which either MeCN or Me_2CO was used as solvent, **2** was isolated even from mixtures that contained significantly more than two equivalents of tztH. Therefore, we thought it worthwhile to scrutinize the solid products of the reaction of $Cd(NO_3)_2 \cdot 4H_2O$ and molten tztH using ^{113}Cd CP MAS NMR. The results of this study are summarized in Table 6. Typical spectra are included in Fig. 3. While there is some variability, probably reflecting the efficiency of stirring, the spectra of 1:4 Cd:tztH mixtures (e.g., Fig. 3*c*) typically show a signal at 586 ppm, which by comparison with the solid-state spectrum of **1** can be assigned to $[Cd(tztH)_4](NO_3)_2$, and also a pair of signals at 558 and –131 ppm that can be assigned to **2**. In addition, the signal of an axially symmetric species is observed at 83 ppm ($\delta_{11} = \delta_{22}$ = 271, δ_{33} = –294). We tentatively assign this spectrum to $Cd(tztH)_3(NO_3)_2$, since its intensity increases relative to that of **2** as the tztH:Cd ratio of the fused mixtures is increased (Fig. 3). Washing 1:4 fusion mixtures with toluene changes the ratio of species present but in our hands does not produce pure $[Cd(tztH)_4](NO_3)_2$ as indicated by the solid-state NMR spectrum (e.g., Fig. 3*d*). Increasing the relative amount of tztH in the fusion mixture to 1:6 (Fig. 3*e*) or higher increases the amount of $[Cd(tztH)_4](NO_3)_2$, as expected, and we conclude that a significant excess of tzt over the required 1:4 ratio must have been used in the literature synthesis of this compound. A mixture produced by fusion of a mixture in which Cd:tztH = 1:2 leads to a further species, although **2** and the possible $Cd(tztH)_3(NO_3)_2$ persist also (Fig. 3*f*). The new species has δ_{Cd} = –119, δ_{11} = 8, $\delta_{22} = \delta_{33}$ = –183. The isotropic chemical shift and the span (Ω) of the new species are very close to those of $Cd(NO_3)_2 \cdot 4H_2O$ (20, 22), and therefore, this spectrum is assigned to the nitrate itself.

After $Cd(trif)_2$ has been fused with six mol equivalents of tztH, the only ^{113}Cd NMR signal observed for the solidified mixture is a signal at 586 ppm that by comparison with the spectrum of pure **1** can be assigned to $[Cd(tztH)_4]^{2+}$. Thus Cd(II), as the nitrate or triflate, does not bind more than four tztH ligands even when the metal salt is fused with excess tztH. In contrast, CdS_6 kernels have been reported in complexes of Cd(II) with the thiocarbonyl S-donors *N*,*N*-dimethylthioformamide (23)[6] and thiourea (24). The CdS_6 kernel also occurs in various tris- (chelate) complexes of

[6] $Cd(trif)_2$ forms a 1:4 complex in the solid state (23*b*).

Cd(II) with the anions of dithioacids (25); these have ^{113}Cd chemical shifts of ca. 200 ppm, more shielded than, and therefore distinct from, those observed in the present paper.

$Ti_5Si_{1.3}Sb_{1.7}$ — The first titanium silicide antimonide, forming a crystal structure not found in either binary system

Holger Kleinke

Abstract: $Ti_5Si_xSb_{3-x}$ can be prepared by melting mixtures of Ti, Si, and $TiSb_2$. The ternary phase with $x = 1.32(5)$ crystallizes in the W_5Si_3 type (space group *I*4/*mcm*, $Z = 8$, for $x = 1.32(5)$: $a = 1034.6(2)$, $c = 515.2(1)$ pm), while Ti_5Sb_3 and Ti_5Si_3 adopt the Yb_5Sb_3 type and the Mn_5Si_3 type, respectively. The Si and Sb atoms share two sites in $Ti_5Si_{1.32(5)}Sb_{1.68}$: one site is located within a linear chain with short interatomic bonds, which is almost exclusively occupied by Si (i.e., 92(1)% Si and 8% Sb), whereas the second site, being occupied by 80(2)% Sb and 20% Si, shows no significant interactions between the main group elements. Band structure calculations reveal the new silicide antimonide being metallic as a consequence of partly filled Ti *d* states. The structure is mainly stabilized by bonding Ti—Sb, Ti—Si, and Si—Si interactions.

Key words: titanium, silicide, antimonide, crystal structure, electronic structure, structure and bonding.

Résumé : On peut préparer le $Ti_5Si_xSb_{3-x}$ par fusion de mélanges de Ti, Si et $TiSb_2$. La phase ternaire dans laquelle $x =$ 1,32(5) cristallise comme le W_5Si_3 (groupe d'espace *I*4/*mcm* et $Z = 8$ pour $x = 1,32(5)$ avec $a = 1034,6(2)$ et $c =$ 515,2(1) pm) alors que les Ti_5Sb_3 et Ti_5Si_3 cristallisent plutôt comme le Yb_5Sb_3 et Mn_5Si_3, respectivement. Les atomes de Si et de Sb occupent deux sites dans le $Ti_5Si_{1,32(5)}Sb_{1,68}$: un site se trouve dans une chaîne linéaire avec de courtes liaisons interatomiques occupées presque exclusivement par du Si (soit 92(1)% de Si et 8% de Sb) alors que le deuxième site, occupé par 80(2)% de Sb et 20% de Si ne présente pas d'interactions significatives entre les éléments du groupe principal. Des calculs de structure de bande révèlent que le nouveau siliciure antimoniure est métallique en raison d'un remplissage partiel des états *d* du Ti. La structure est stabilisée principalement par des interactions de liaison Ti—Sb, Ti—Si et Si—Si.

Mots clés : titane, siliciure, antimoniure, structure cristalline, structure électronique, structure et liaison.

[Traduit par la Rédaction]

Introduction

The concept of mixing closely related metal atoms, such as niobium and tantalum, was used for the synthesis of a variety of hitherto unknown sulfides crystallizing in unprecedented structure types. The earliest examples include $Nb_{4.92}Ta_{6.08}S_4$ (1), $Nb_{6.74}Ta_{5.26}S_4$ (2), $Nb_{1.72}Ta_{3.28}S_2$ (3), and $Nb_{0.95}Ta_{1.05}S$ (4), whose structures exhibit mixed Nb and Ta occupancies in different ratios on the crystallographically independent metal atom sites. The three criteria for the so-called DFSO materials (DFSO = differential fractional site occupancies) developed on these findings were: (*i*) the metal atom sites are occupied by mixtures of two different metal atoms; (*ii*) these occupancies vary from site to site; and (*iii*) the crystal structure does not occur in any of the two corresponding binary systems (5, 6). DFSO-stabilized materials are not limited to sulfides or to metals of the same group only, as the discovery of some phosphides and antimonides of this kind revealed (e.g., $(Zr,Nb)_{11}P_4$ (7), $(Hf,Mo)_2P$ (8), $(Hf,Nb)_{10}Ni_3P_5$ (9), $(Zr,V)_{13}Sb_{10}$ (10), $(Zr,V)_{11}Sb_8$ (11), $(Hf,Ti)_7Sb_4$ (12), and (Zr,Ti)Sb (13)). In most cases, the different site preferences of the different metal atoms were investigated and well-understood. Related to the DFSO topic are the articles covering the phosphides $Zr_{2.7}Hf_{11.3}P_9$ (14) and ZrHfP (15), where Zr atoms of the parent phosphides $Zr_{14}P_9$ (16) and Zr_2P (17), respectively, were in part replaced by Hf atoms in an ordered way.

Although the DFSO concept was used for the syntheses of several new metal-rich compounds, which mostly enriched our knowledge of possible crystal structures, the transfer to using different anionic components just started. In the structures of the mixed chalcogenides $(Nb,Ta)_9(S,Te)_5$ (18), $Ta_5(S,Te)_2$ (19), $Ta_5(Se,Te)_3$ (20), $Ta_5(S,Se)_2$ (21), $Ta_9(S,Se)_4$ (21), and $Ta_6(S,Te)_4$ (22), the lighter (and smaller) chalcogen atoms generally prefer the smaller voids. The discovery of the first two antimonide-selenides $Zr_2(Sb,Se)$ (23) and $Zr_7(Sb,Se)_4$ (24), both published most recently, suggests a wider range of possible mixed occupancies. The latter two compounds, exhibiting different mixed occupancies, have no counterpart in the binary Zr-Sb and Zr-Se systems, and can thus be considered as *anionic* DFSO compounds. The same holds true for $Zr(Si,Sb)_2$, (ZrSiS structure), wherein the two main group positions are occupied by: (*i*) a Si–Sb mixture;

and (*ii*) an Sb atom (25). The mixed-halide zirconium cluster compounds, though representing a different kind of chemistry, belong to the same category in that sense that new structures were achieved by using different anionic constituents (26, 27). Excluding so-called solid solutions like $CoGe_xP_{1-x}$ (28), only a few compounds with anionic sites occupied by mixtures of elements of the fourth and fifth main group were reported (e.g., $Hf_{27}(Si,P)_{16}$ (29)). In a further expansion of the DFSO concept, we report here on the second silicide antimonide exhibiting mixed Si–Sb occupancies, which complies to the criteria of anionic DFSO compounds.

Experimental section

Synthesis

The binary antimonide $TiSb_2$ was prepared first to minimize weight loss arising from vaporization of elemental antimony during the process of arc-melting. $TiSb_2$ was synthesized in a solid–liquid reaction of the elements in the stoichiometric 1:2 ratio at 650°C in an evacuated fused silica tube. Thereafter, titanium, $TiSb_2$, and silicon in the ratio of 4:1:1 were ground, thoroughly mixed, and then pressed to a pellet. In the final reaction step, the pellet was arc-melted twice under a flow of argon on a water-cooled copper hearth. The powder X-ray diffraction pattern obtained from the ground sample gave no evidence of the formation of any binary titanium silicide or antimonide, but pointed towards the existence of $Ti_3Si_xSb_{1-x}$ (Cr_3Si type like Ti_3Sb (30)). Therefore, energy dispersive analyses of X-rays, performed by using a scanning electron microscope with an additional EDX device, were carried out on selected crystals. No impurity atoms were detected; the standardless EDX analyses yielded an averaged Ti:Si:Sb ratio of 5:1.0(2):1.7(2).

Crystal structure

A small crystal of prismatic shape was selected under an optical microscope for the data collection using a diffractometer with an area detector system. After correcting for Lorentz and polarization effects, a numerical absorption correction was applied. The systematic extinction of $l = 2n + 1$ for all *0kl* reflections (in addition to the integral extinctions, namely $h + k + l = 2n + 1$) restricted the possible space groups to *I*4*/mcm*, *I*4*cm*, and $I\bar{4}c2$. The structure solution and refinement in the centrosymmetric space group *I*4*/mcm* were successful and converged smoothly (programs SHELXS and SHELXL (31)). Refinements in the acentric space groups *I*4*cm* and $I\bar{4}c2$ did not lead to any improvements of the *R* values or different ordering, but resulted in strong correlations instead.

The structure solution straightforward gave the four atomic positions as known from the W_5Si_3 structure type. Identifying the one Si site of the W_5Si_3 type with two short distances to two symmetry equivalent Si sites of 258 pm (E1) as Si and the other one (E2) as Sb, yielded the formula Ti_5SiSb_2 with very different displacement parameters of the E positions (namely U_{eq}(E1) = 50(20) pm^2; U_{eq}(E2) = 188(7) pm^2). Refining both E sites as being mixed occupied by Si and Sb improved the residual factors significantly (e.g., $R(F_o)$ decreased from 0.0565 to 0.0428) and yielded uniform displacement parameters. In the sum, full occupancy of each site was assumed for this refinement. The refined Si:Sb ratios were 92(1):8 for E1 and 20(2):80 for E2, giving a refined formula of $Ti_5Si_{1.32(5)}Sb_{1.68}$. Crystallographic details can be found in Table 1. Positional and equivalent displacement parameters and occupancy factors are given in Table 2.

Table 1. Crystallographic data for $Ti_5Si_{1.32(5)}Sb_{1.68}$.

Chemical formula: $Ti_5Si_{1.32(5)}Sb_{1.68}$
Formula weight: 481.87 g mol^{-1}
a = 1034.6(2) pm
c = 515.2(1) pm
V = 551.5(2) 1 × 10^6 pm^3
Z = 8
Space group: *I*4*/mcm* (No. 140)
T = 22°C
λ = 71.069 pm
ρ_{calcd} = 5.795 g cm^{-3}
μ = 151.1 cm^{-1}
$R(F_o)^a$ = 0.043; $R_w(F_o^2)^b$ = 0.088

$^a R(F_o) = \Sigma||F_o| - |F_c|| / \Sigma|F_o|$.
$^b R_w(F_o^2) = [\ \Sigma[w(F_o^2 - F_c^2)^2] / \Sigma[w(F_o^2)^2]]^{1/2}$.

Electronic structure

The band structure calculations were performed on hypothetical Ti_5SiSb_2. The structural parameters were taken from the refinements on $Ti_5Si_{1.32(5)}Sb_{1.68}$, using Si parameters for E1 and Sb parameters for E2. Within the self-consistent TB–LMTO–ASA program (TB–LMTO–ASA = tight binding – linear muffin tin orbitals – atomic spheres approximation) (32, 33), the density functional theory (34) is used with the local density approximation (LDA). The integration in *k* space was performed by an improved tetrahedron method (35) on a grid of 1331 *k* points in the irreducible section of the first Brillouin zone.

The Mulliken overlap populations (MOPs) (36), serving as an indicator for relative bond orders, were calculated for all interatomic distances using the Extended Hückel approximation (37–39) on hypothetical Ti_5SiSb_2 by solving the eigenvalue problem on 80 *k* points of the first Brillouin zone. The silicon and antimony parameters were used as published before (40), while the ionization potentials of titanium were optimized by charge iteration on Ti_5SiSb_2, with the Slater exponents and coefficients taken from standard sources (40). All parameters are summarized in Table 3, and a list of the distances and MOPs is presented in Table 4.

Results and discussion

Crystal structure

$Ti_5Si_{1.32(5)}Sb_{1.68}$ crystallizes in the W_5Si_3 structure type (Fig. 1), whereas Ti_5Sb_3 (41) and Ti_5Si_3 (42) occur in different structure types, namely in the Yb_5Sb_3 and the Mn_5Si_3 type, respectively. With both E sites being mixed occupied by different ratios of Si and Sb, this silicide antimonide can be classified as a typical DFSO-stabilized material.

Several binary compounds M_5E_3 (M = transition metal atom; E = main group element) are reported to adopt the W_5Si_3 structure type (43). Here, E is almost exclusively an

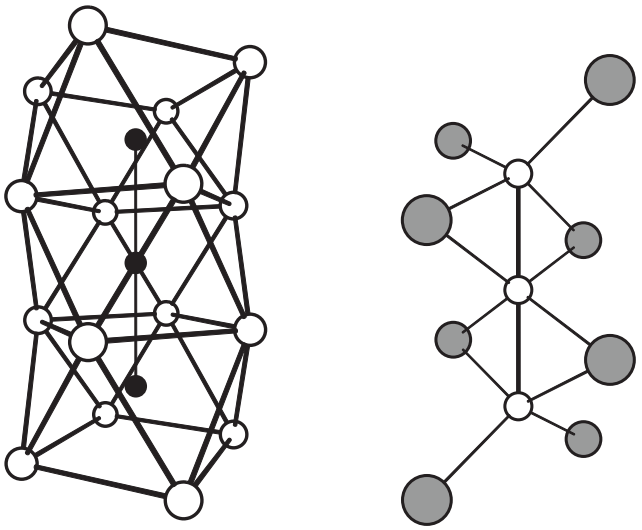
element of the third or fourth main group. In general, pnictides and chalcogenides are unlikely to form the W_5Si_3 type because of the short E—E distances therein. Exceptions are a vanadium arsenide, where defects in the As chain are explainable by either an As deficiency or mixed V and As occupancies (44), and the tellurides $A_xK_4Te_3$ (A = Ca, Sr) (45) which can be considered as electron-precise compounds $(A^{2+})_{0.5}(K^{1+})_4(Te^{1-})(Te^{2-})_2$, each Te^{1-} forming two one-electron-two-center bonds. Also, ternary antimonides $Zr_5M_xSb_{3-x}$ (M = Fe, Co, Ni; $x \approx 0.5$) (46) and $Hf_{10}M_xSb_{6-x}$ (M = V, Cr, Mn, Fe, Co, Ni, Cu; $0.8 \leq x \leq 1.5$ for M = Fe) (47) are known to crystallize in ternary variants of the W_5Si_3 type. Therein, the linear E1 chain consists of different mixtures of M and Sb atoms; the M:Sb ratio may vary between 3:1 and 2:3, whereas the second E site (E2) is exclusively occupied by Sb atoms — in contrast to the situation in $Ti_5Si_{1.32(5)}Sb_{1.68}$.

Probably the compound most similar to $Ti_5Si_{1.3}Sb_{1.7}$ is the isostructural niobium silicide stannide "Nb_5SiSn_2". In this case, the site occupancies have not been investigated, i.e., both the E1 and E2 site exhibited negative displacement parameters when identified as silicon and tin, respectively, as

Fig. 1. Projection of the structure of $Ti_5Si_{1.32(5)}Sb_{1.68}$ along [0 0 1]. Symbols: Ti (white circles), E1 (black circles), E2 (gray circles). Only Ti—Ti bonds are shown.



obtained from a Guinier powder pattern (48). Another related compound is V_4SiSb_2, which forms a defect variant of the W_5Si_3 structure: the metal position on site 4*k* is unoccupied, and Si and Sb occupy, without mixing, the 4*a* and 8*h* sites, respectively, (49). Thus, the Si atom in V_4SiSb_2 corresponds to the E1 site in $Ti_5Si_{1.3}Sb_{1.7}$, and the Sb atom to the E2 site.

The structure of $Ti_5Si_{1.3}Sb_{1.7}$ can be described based on two (interconnected) different columns running parallel to the tetragonal *c* axis. These two columns are interconnected by numerous Ti—Sb and Ti—Ti bonds. One column consists of face-condensed E1-centered Ti_8 square antiprisms. The other column comprises edge-sharing Ti-centered $E2_4$ tetrahedra, a condensation which results in a linear Ti chain with short interatomic distances = *c*/2 = 258 pm, by symmetry equidistant to the E1—E1 contacts in the linear E1 chain (Fig. 2).

As often found in metal-rich compounds, numerous valence electrons remain available for the formation of homoatomic bonds between the transition metal atoms Ti. Here, one short and several intermediate Ti—Ti bonds (namely, 258 and 301–333 pm) occur, resembling the Ti—Ti bond lengths in Ti_5Si_3 (258 and 314–320 pm). Elemental titanium crystallizes in the hexagonal closed packing (Mg type) with interatomic distances of 289 and 295 pm, and

Fig. 2. Column of face-condensed E1-centered Ti_8 square antiprisms (left) and of edge-condensed Ti-centered $E2_4$ tetrahedra (right). Symbols: Ti (white circles), E1 (black circles), E2 (gray circles).

Ti_5Sb_3 comprises several Ti—Ti distances starting at 284 pm.

The Ti—E distances are in the expected range, indicating strong bonding heteroatomic interactions. Note that E1 comprises primarily Si atoms and E2 mainly Sb atoms. The Ti—E1 distance of 267 pm is slightly larger than the sum of the Pauling single bond radii of $r_{Ti} + r_{Si}$ = 132 pm + 117 pm = 249 pm (50), which makes it comparable to the Ti—Si bonds observed in Ti_5Si_3 (Mn_5Si_3 structure, 257–280 pm). Similarly, the Ti—E2 distances range from 272 to 302 pm, while the Ti—Sb contacts in Ti_5Sb_3 are between 271 and 295 pm ($r_{Ti} + r_{Sb}$ = 132 pm + 139 pm = 271 pm).

The site preferences of Si and Sb are mostly ruled by size differences, and maybe also — to a smaller extent — by the different preferences to form homoatomic bonds. As a consequence of the parallel running equidistant E1 and Ti chains, the E1—E1 and Ti—Ti distances of 258 pm are considered to be a compromise; the 258 pm are somewhat short for a Ti—Ti bond, but too long for a strong Si—Si bond. Using Pauling's equation $d(n) = d(1) - 60$ pm $\times \log n$ (with n = Pauling bond order; $d(1) = 2r_{Si}$ = 234 pm), the bond order is estimated to be 0.40, smaller than the bond order of 1/2 expected based on the geometry of the chain (10, 11, 13, 51–53). The latter contributes — in addition to entropy effects — to the (minor) incorporation of Sb into the E1 chain, since the Sb atom is significantly larger than a Si atom (r_{Si} = 117; r_{Sb} = 139 pm). On the other hand, the E2 site mainly comprises Sb atoms, because an edge-condensation of Ti-centered Si_4 tetrahedra would unambiguously lead to unreasonably short Ti—Ti contacts.

Electronic structure

The band structure of the structure model Ti_5SiSb_2 is shown in the left part of Fig. 3, emphasizing via the *fat band representation* (54) the Si-based bands. The symmetry lines are chosen according to Bradley and Cracknell (55). The bands lowest in energy have Sb 5*s* character, followed by the two Si 3*s* bands with high dispersion. The latter results from the Si—Si bonds running parallel to [0 0 1]. Three-dimensional metallic properties are predicted based on the band structure, for several Ti-based bands cross the Fermi level along Z–Γ and X–P, i.e., parallel to the c^* axis, as well as along Γ–X (parallel to a^*), which leads to three-dimensional metallic conductivity because of the tetragonal symmetry. Small shifts of the Fermi level, e.g., arising from different Si:Sb ratios, cannot change the metallic character.

As depicted in the atomic projections of the densities of states (right part of Fig. 3), the region around the Fermi level E_F is dominated by Ti states. Basically all Sb *s* and *p* states occur more than 2 eV below E_F, as does the main part of the Si states. In the latter case, however, the antibonding Si states appear well above E_F (+3 eV).

Assuming a bond order of 1/2 for the Si—Si bond, a tentative assignment of oxidation states yields $(Ti^{1.8+})_5Si^{3-}(Sb^{3-})_2$. This assumption is supported by the differences in the electronegativities (EN) (EN(Ti) < EN(Si) < EN(Sb), e.g., Allred–Rochow: 1.32 < 1.74 < 1.82) and the absence of any bonds between the main group elements, except of the one in the linear E1 chain, and the presence of the Ti—Ti bonds. The Mulliken charges obtained for Ti_5SiSb_2 of +0.26 for Ti, –0.25 for Si, and –0.53 for Sb confirm the trend.

In the crystal orbital Hamiltonian populations (COHPs), the densities of states are weighted according to the bonding and antibonding contributions, comparable to the crystal orbital overlap populations known from the Extended Hückel theory (56). The COHPs, shown in Fig. 4, reveal that only a few antibonding states, namely in the Si—Si bond, are filled in the structure model of Ti_5SiSb_2. The heteroatomic Ti—Si and Ti—Sb interactions are optimized, for the Fermi level falls right between the bonding and antibonding states. On the other hand, the Ti—Ti interactions could use more valence electrons to fill more bonding states, i.e., to become stronger.

A more detailed look at the Mulliken overlap populations (Table 4) reveals that all Ti—Ti bonds < 333 pm are significantly bonding with MOPS > 0.07, though the shortest one stands out in this group with MOP = 0.35. These values may be compared to the Ti—Ti bonds in metallic titanium, in the structure of which the bonds of 289 and 295 pm exhibit MOPs of 0.23 and 0.22, respectively. Correspondingly, the bonding character of the Ti—Si, Ti—Sb, and Si—Si interactions is reflected in reasonably large positive overlap populations, as well.

Conclusion

The hitherto unknown titanium silicide antimonide $Ti_5Si_{1.32(5)}Sb_{1.68}$ has been successfully synthesized and characterized by single-crystal investigation, energy dispersive analyses of X-rays, and electronic structure calculations. In contrast to the binary compounds Ti_5Si_3 (Mn_5Si_3 type) and Ti_5Sb_3 (Yb_5Si_3 type), $Ti_5Si_{1.32(5)}Sb_{1.68}$ occurs in the W_5Si_3 structure type. While the Ti atoms occupy the W sites, the Si and Sb atoms fill in mixed occupancies, but in different ratios, the two Si sites of the W_5Si_3 structure. The Si atoms prefer the smaller site with two short homoatomic interactions. Thus, the possibility of Si and Sb atoms sharing one crystallographic position, has been used here for the first

time to create a new compound with a structure not found in either binary system.

$Ti_5Si_{1.32(5)}Sb_{1.68}$ is a metallic conductor, independent of the exact Si:Sb ratio. The structure is stabilized by heteroatomic Ti—Si and Ti—Sb interactions, and additionally by (pseudo)homoatomic Ti—Ti and Si—Si bonds, while Sb—Sb interactions are negligible.

New low-spin Co(II) complexes with novel tripodal 1,1,1-tris(dimethylphosphinomethyl)ethane ligand: electron transfer kinetics and spectroscopic characterization of $Co(II)P_6$ and $Co(II)P_3S_3$ ions in aqueous solution

Satoshi Iwatsuki, Kenji Obeyama, Nobuyoshi Koshino, Shigenobu Funahashi, Kazuo Kashiwabara, Takayoshi Suzuki, and Hideo D. Takagi

Abstract: Substitution-inert Co(II) complexes with tripodal 1,1,1-tris(dimethylphosphinomethyl)ethane were produced in aqueous solution by the controlled-potential electrolysis. EPR studies indicated that the $Co(II)P_6$ and $Co(II)P_3S_3$ species are in the low-spin $t_{2g}^6e_g^1$ state. The analyses of the absorption spectra of the Co(II) species in solution indicated significant Jahn–Teller distortion in $Co(II)P_6$ and $Co(II)P_3S_3$ ions as expected for the low-spin d^7 electronic configuration, while less distortion was observed for the $Co(II)S_6$ ion. Kinetic studies of the redox reactions involving these Co(III/II) species confirmed that the electron self-exchange reactions for the $Co(III/II)P_6$ and $Co(III/II)P_3S_3$ couples are relatively fast ($k_{ex} \sim 1 \times 10^4$ dm^3 mol^{-1} s^{-1}), which is consistent with the results for other low-spin – low-spin Co(III/II) couples. It was concluded that the nephelauxetic effect of the P-donor atom stabilizes the low-spin state in Co(II), and that the rather rapid electron exchange rates for these Co(III/II) couples were explained by the lack of the spin reorganization process required for the ordinary low-spin – high-spin Co(III/II) couples.

Key words: cobalt(III/II), spin state, EPR study, kinetics, electron transfer.

Résumé : Faisant appel à l'électrolyse à potentiel contrôlé, en solution aqueuse, on a préparé des complexes de Co(II) comportant du 1,1,1-tris(diméthylphosphinométhyl)éthane tripodal et qui sont inertes vis-à-vis des substitutions. Des études de RPE indiquent que les espèces $Co(II)P_6$ et $Co(II)P_3S_3$ se trouvent dans un état $t_{2g}^6e_g^1$ de faible spin. Comme on pouvait s'y attendre pour la configuration électronique d^7 de faible spin, les analyses des spectres d'absorption des espèces Co(II) en solution mettent en évidence l'existence d'une distorsion importante de Jahn–Teller dans les ions $Co(II)P_6$ et $Co(II)P_3S_3$; on a toutefois observé moins de distorsion pour l'ion $Co(II)S_6$. Les études cinétiques des réactions redox impliquant ces espèces Co(III/II) ont confirmé que les réactions d'auto-échanges électroniques des couples $Co(III/II)P_6$ et $Co(IIII/II)P_3S_3$ sont relativement rapides ($k_{éc} \sim 1 \times 10^4$ dm^3 mol^{-1} s^{-1}) et ces observations sont en accord avec les résultats obtenus avec d'autres couples Co(III/II) de faible spin – faible spin. On en conclut que l'effet néphélauxétique de l'atome de P-donneur stabilise l'état de faible spin dans Co(II) et que les vitesses d'échanges électroniques relativement rapides observées pour ces couples Co(III/II) peuvent être expliquées par l'absence de processus de réorganisation de spin requis pour les couples Co(III/II) ordinaires de faible spin – spin élevé.

Mots clés : cobalt(III/II), état de spin, étude RPE, cinétique, transfert d'électron.

[Traduit par la Rédaction]

Introduction

The Co(III/II) electron transfer reactions have been intensively studied to identify the cause of sluggishness in low-spin – high-spin Co(III/II) couples, and various reaction mechanisms have been postulated to explain such specific behaviors (1–6). For the deeper understanding of the electron transfer reactions of Co(III/II), it seems essential to synthesize new stable Co(III) and Co(II) complexes and examine their reactivities. Kashiwabara and co-workers (7–13) intensively explored various Co(III) complexes with multidentate ligands possessing phosphorus atoms as donors. This research was carried out to examine the electronic states and structures of the new type of Co(III/II) couples stable in aqueous solution.

Among the low-spin Co(II) complexes, only bis(1,4,7-trithiacyclononane)cobalt(II) and some other encapsulated

complexes such as the 8-methyl-1,3,13,16-tetraaza-6,10,19-trithiabicyclo[6.6.6]eicosane (azacapten) complex have been kinetically analyzed (14–16). This is partly because some of the low-spin cobalt(II) are thermodynamically unstable (17), while others are substitution labile in solution. The redox potentials for selected Co(III/II) couples are listed in Table 1, in which it is seen that the standard redox potentials for some low-spin – low-spin couples are relatively higher than those for the ordinary low-spin – high-spin couples. However, several species such as tris(1,10-phenanthroline)cobalt(III/II) and tris(2,2′-bipyridine)cobalt(III/II) couples exhibit rather high redox potentials although Co(II) in these complexes are in the high-spin state at room temperature, indicating that the redox potentials of these complex ions are determined not only by the energy levels of HOMO for Co(II) and LUMO of Co(III) but also by the solvation free-energy difference between Co(II) and Co(III) species in relation to the size of the ions in each oxidation state and specific solute–solvent interactions such as the hydrogen bonding. Therefore, the redox potentials of Co(III/II) couples cannot be a good measure for the ligand-field strength and the relevant spin states of the redox couple. In other words, structural analyses of both Co(III) and Co(II) species in solution, by means of rather classical but very reliable EPR and UV–vis spectroscopy, is essential for the understanding of the structure–reactivity relation in the Co(III/II) systems.

From the kinetic point of view, it has been indicated that the electron self-exchange rate constants between the low-spin Co(III) and the high-spin Co(II) species are rather slow compared with those between low-spin Co(III) and low-spin Co(II) species (14). The necessity of extra reorganization energy for the multi-spin process has been generally accepted for the explanation of such a difference in the self-exchange rate constants. For example, it has been reported that the spin reorganization of the octahedral d^7 Co(II) in the high-spin state ($t_{2g}^5 e_g^2$) during the activation process of the electron exchange reaction requires as much as 103 kJ mol^{-1} for the $[Co(NH_3)_6]^{3+/2+}$ couple (1).[2] In this case, a kind of pre-equilibrium between the high-spin Co(II) and the low-spin Co(II) states exists before the electron transfer (ET) process.

[1] $\quad Co(II)^*[hs] \rightleftarrows Co(II)^*[ls]$

(<103 kJ mol^{-1} in the case of hexaammine complex)

[2] $\quad Co(III)[ls] \rightleftarrows Co(III)[hs]$

(<259 kJ mol^{-1} in the case of hexaammine complex)

[3] $\quad Co(II)^*[ls] + Co(III)[ls] \rightleftarrows Co(III)^*[ls] + Co(II)[ls]$

[4] $\quad Co(II)^*[hs] + Co(III)[hs] \rightleftarrows Co(III)^*[hs] + Co(II)[hs]$

The lower energy process (eq. [1]) is taken to be the preferred pathway. However, recent analyses of magnetic moment and microwave absorption of various Co(II) species in solution indicate that such a low spin – high spin equilibrium is extremely rapid (it requires only several nanoseconds) and the spin-equilibrium constant is not as large as it was originally suggested: the slow ET rates in such a reaction system has been attributed to the large inner-sphere reorganization in the low-spin Co(II) ($t_{2g}^6 e_g^1$) species, which is suppose to exhibit significant Jahn–Teller distortion (5). More recent studies by Swaddle and co-workers (3) support the explanations by Beattie et al. (4, 5).

It is a very difficult task to find inert low-spin Co(III) – high-spin Co(II) redox couples suitable for the measurements of both reduction and oxidation cross reactions in solution: many of these couples possess rather low redox potentials and the high-spin Co(II) species are very labile. The latter reason prevents us from precise investigations of the nature of the reactions involving Co(II) complexes in more detail. We have started to investigate the reactivity of a series of Co(III/II)–P_nS_{6-n} and –P_nN_{6-n} (P_nS_{6-n} and P_nN_{6-n} represent multidentate ligands with n = 0–6). In this article, we report new types of low-spin Co(II) species stable in aqueous solution. The structures of $Co(II)P_6$ and $Co(II)P_3S_3$ in solution were analyzed by the spectrophotometric and EPR methods. The oxidation and reduction reactions of these complexes were studied at ambient pressure.

[2]The estimated free energy difference between two different spin states in this article is erroneous as they used the reorganization parameter (for the vertical transition) instead of multiplying by 1/4. Therefore, the energy difference between the two spin states are smaller than the values shown in eqs. [1] and [2].

Experimental

Materials

$[Co(mmtp)_2](BF_4)_3$ (mmtp = tris(1,1,1-dimethylphosphinomethyl)ethane) was synthesized and purified by the previously reported method (13, 18). $[Co(mmtp)(ttcn)](BF_4)_3$ was synthesized from the trichloride salt of the mono-mmtp complex with ttcn (ttcn = 1,4,7-trithiacyclononane) (12, 13). $[Co(ttcn)_2](ClO_4)_3$ and $[Co(ttcn)_2](ClO_4)_2$ were synthesized by the literature method (19). $[Ru(NH_3)_6]Cl_3$ and $[Co(sep)]Cl_3$ (sep = 1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane) were obtained from Aldrich.

Measurements

A BAS100BW electrochemical analyzer (Bioanalytical Systems) was used for the measurements of cyclic voltammograms and for the controlled-potential electrolyses. JASCO V-560 and Shimadzu UV-1600 spectrophotometers were used to record the absorption spectra in solution. A Hitachi U-3400 UV–vis–near-IR spectrophotometer with the integration sphere was used for recording the absorption spectra of solid samples. A JES-RE IX X-band spectrometer was used for the measurements of EPR spectra of Co(II) species in solution. A Unisoku stopped-flow apparatus equipped with a controlled-potential electrolysis chamber (20) was used for the kinetic measurements. Sample solutions for kinetic measurements were prepared with twice-distilled water and degassed by Ar. All measurements were carried out under Ar atmosphere. The ionic strength of the sample solutions was adjusted by potassium chloride. The electrochemical measurements were carried out by using a thermostated cell (25°C) with a glassy carbon working electrode, a platinum wire counter electrode, and a Ag/AgCl reference electrode. Potassium chloride was used as the supporting electrolyte.

Results and discussion

Electrochemical measurements

The redox potentials of $[Co(ttcn)_2]^{3+/2+}$, $[Co(mmtp)(ttcn)]^{3+/2+}$, and $[Co(mmtp)_2]^{3+/2+}$ couples are summarized in Table 1. The peak separations for these couples are typically 69 mV and the ratios of the anodic and cathodic peak currents were 1:0.996, indicating that the signals are reversible. The E^0 value for $[Co(mmtp)(ttcn)]^{3+/2+}$ was closer to that for the $[Co(mmtp)_2]^{3+/2+}$ couple, rather than that for $[Co(ttcn)_2]^{3+/2+}$. Therefore, it seems that Co(II) oxidation state is destabilized by the substitution of one ttcn ligand for mmtp. The crystallographic data for the $[Co(mmtp)_2]^{3+}$ species (13) indicates that the Co—P bond is elongated because of the strong *trans* influence and probably by the steric hindrance of the rather bulky phosphine ligand.[2] The same argument may even be possible for the bond lengths between slightly larger Co(II) centers and the P-donor atoms, because of the strong σ-donicity of the P-atom and (or) the Jahn–Teller distortion expected for the low-spin d^7 configuration (see following discussion for the spin states of $Co(II)P_6$ and $Co(II)P_3S_3$). It seems that the thermodynamic stability of the Co(II) species in solution is somewhat lowered by the consecutive substitution of ttcn by the mmtp ligand. However, a spectroelectrochemical study of these complexes revealed that the Co(II) species produced by the controlled-potential electrolyses were substitution inert: reoxidation of the reduced solution either by peroxodisulfate salt or by electrolysis reproduced the original Co(III) species (yield > 95% after ca. 1 h).

EPR measurements

Aqueous solutions of $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$ were prepared by the controlled-potential electrolyses at –550 and –500 mV vs. Ag/AgCl, respectively. The EPR spectra of these solutions at room temperature are shown in Fig. 1. A multiplet caused by the coupling with ^{59}Co (I = 7/2) and ^{31}P (I = 1/2) were observed at g_{iso} = 2.08 and 2.05 for $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$, respectively, which may be compared with the value (g_{iso} = 2.10) estimated for low-spin $[Co(ttcn)_2]^{2+}$ in aqueous solution. It has been reported (21) that the g_{iso} value observed for the metal ions depends on the ligand-field strength: the g_{iso} value decreases to a value close to that for the free electron upon increasing the ligand-field strength. Therefore, the g_{iso} values obtained for the $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$ complexes indicate that these complexes are in the low-spin electronic state and the ligand field of phosphine is larger than or comparable to that of thioether, which is consistent with the spectrophotometric observations described in the following section. The values of the g_{iso} parameter indicate that the ligand field increases in the order of $P_3S_3 > P_6 > S_6$.

Absorption spectra

The absorption spectra of the $[Co(ttcn)_2]^{3+}$, $[Co(mmtp)(ttcn)]^{3+}$, and $[Co(mmtp)_2]^{3+}$ species are shown in Fig. 2, and the energies corresponding to the two *d–d* transitions are summarized in Table 2, in which the 10*Dq* values as well as the Racah *B* parameter were calculated by the following equations (22, 23):

$$[5] \quad E\,(^1A_{1g} \rightarrow {}^1T_{1g}) = 10Dq - C \text{ or } E\,(^1A_{1g} \rightarrow {}^1T_{2g}) = 10Dq + 16B - C, \text{ where } C = 4B$$

It seems that the ligand-field strength of the P-atom is, as expected, rather large and is comparable to that of the S-atom in the thioether ligands. On the other hand, the nephelauxetic effect of the P-atom is larger than or compara-

[2] The previously reported analysis for the crystal structure of $[Co(mmtp)_2][Co(CN)_6]\cdot nH_2O$ (n = 2.25) was found to be erroneous. The space group $Pca2_1$ (No. 29) was incorrectly assigned, and the corrected one is *Pcam* (No. 57, $b\bar{a}c$ setting). Using the absorption-corrected intensity data (supplied by Professor Ohba), the structure was reanalyzed. It was found that four Co atoms (Co(A), Co(B), Co(C), and Co(D)) are located at the positions having their site symmetry of .2., ..*m*, $\bar{1}$, and ..*m*, respectively. Five O-atoms corresponding to the hydrated water were observed, and two of them were located on a crystallographically plane of symmetry. Thus, the analysis indicated that the number of hydrated water (n in the above formula) is 4, which is consistent with the elemental analysis. The details of the structural analysis and the parameter obtained are deposited in supplementary. We have also found that the bis(mmtp)rhodium(III) analog ($[Rh(mmtp)_2][Co(CN)_6]\cdot 4H_2O$) is isomorphorous to this cobalt(III) complex (T. Suzuki, unpublished work).

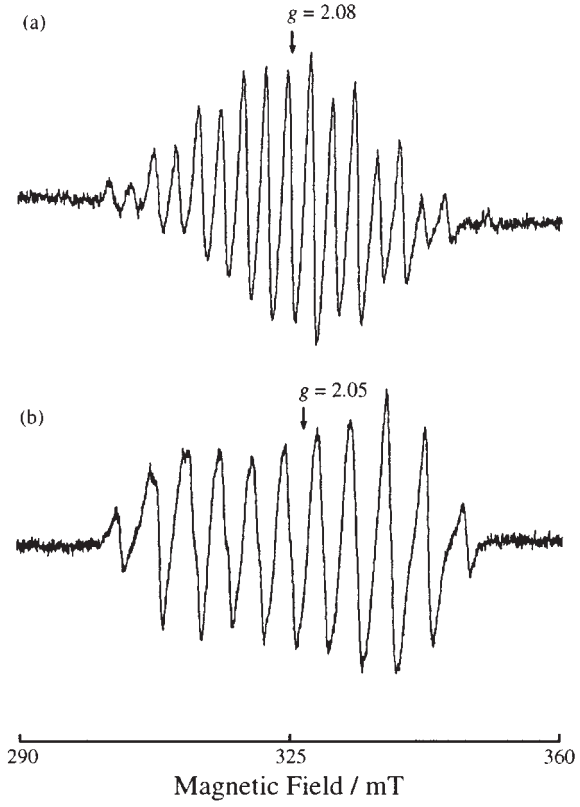
Fig. 1. EPR spectra of Co(II) produced by the controlled-potential electrolyses in aqueous solution at room temperature: (*a*) $[Co(mmtp)_2]^{2+}$, hyperfine coupling constants were estimated as 2.87 mT with Co(II) and as 5.74 mT with P by the simulation; (*b*) $[Co(mmtp)(ttcn)]^{2+}$, hyperfine coupling constants were estimated as 4.2 mT with Co(II) and as 5.45 mT with P by the simulation.



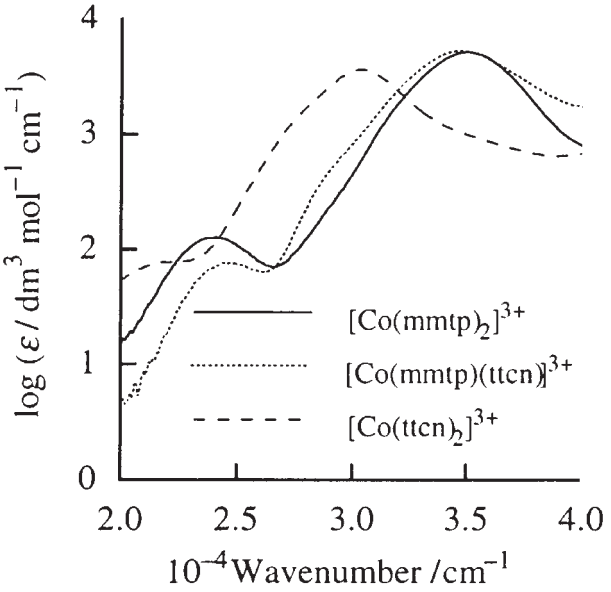


Fig. 2. Absorption spectra of Co(III) species in aqueous solution.

ble to that for the S-atom. These results indicate that the σ-donicity of the mmtp ligand is as large as that for ttcn, and the covalency of the Co—P bonds is as large as or larger than that for the Co—S bonds, probably through the strong π-interaction between the central Co(III) and the P-atom, coupled with the rather large σ-interaction.

In Fig. 3, the absorption spectra of $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$ in aqueous solution are shown. The spectroelectrochemical analyses of $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$ produced by the controlled-potential electrolyses revealed that $[Co(mmtp)_2]^{2+}$ and $[Co(mmtp)(ttcn)]^{2+}$ ions in aqueous solution exhibited only one or two absorption maxima in the visible region (λ = 678 nm (ε = 38 $dm^3\ mol^{-1}\ cm^{-1}$) and 924 nm (ε = 43), and λ = 638 nm (ε = 41), respectively). The absorption spectrum of $[Co(ttcn)_2]^{2+}$ in acetonitrile was reported by Wieghardt et al. (λ = 730 nm (ε = 11) and 560 nm (sh)) (19). However, their assignment of these two peaks ($^4T_{1g} \rightarrow {}^4T_{2g}$ and $^4T_{1g} \rightarrow {}^4A_{2g}$, respectively) was wrong as this complex is in the low-spin state (19, 24). It should be noted that one of the coordination axes of the Co(II) center with the low-spin d^7 electronic configuration may be elongated by the Jahn–Teller distortion, which causes splitting of the e_g level (Fig. 4); the ^2E_g ground term for the octahedral field splits into $^2A_{1g}$ (ground state) and $^2B_{1g}$ (excited state). The crystal structure of $[Co(ttcn)_2](ClO_4)_2$ indicates that the Jahn–Teller distortion is not very large (25). Therefore, the $^2A_{1g} \rightarrow {}^2B_{1g}$ transition should be observed at a much lower energy region. The absorption spectrum for $[Co(ttcn)_2](ClO_4)_2$ reported in this study is identical to that reported by Wieghardt et al. (19). It is plausible that the absorption spectrum in solution and that in the solid state may be different, as the fluxionality of the ttcn complexes has been observed even in the Pt(II) complex (26). Moreover, it is possible that the Jahn–Teller distortion may be enhanced in solution to produce a square-planar or square-pyramidal conformation. To examine the structure of $[Co(ttcn)_2]^{2+}$ in solution, we measured the diffuse reflectance spectrum of solid $[Co(ttcn)_2](ClO_4)_2$, which is shown in Fig. 5. In the solid state, $[Co(ttcn)_2](ClO_4)_2$ exhibits one broad absorption band in which two separate peaks at 474 (21 000 cm^{-1}) and 561 nm (18 000 cm^{-1}) was observed. The very broad band starting at ca. 1000 nm indicates that the absorption in the 730 nm region observed in solution also exists in the solid state but it is not well-resolved in the reflectance spectrum. This observation indicates that the structure of $[Co(ttcn)_2]^{2+}$ in the crystal is retained in solution. Therefore, the absorption at λ = 730 nm (ε = 11) and 560 nm (sh) are assigned to either $^2A_{1g}(^2E_g) \rightarrow {}^2_aT_{1g}$ or $^2A_g(^2E_g) \rightarrow {}^2_aT_{2g}$. In such a case, the 10*Dq* value is estimated as ca. 13 700 cm^{-1} (12, 19), and the structure of $[Co(ttcn)_2]^{2+}$ is identical both in the solid state and in solution: the Jahn–Teller splitting is not very large.

On the other hand, the absorption spectra of $[Co(mmtp)(ttcn)]^{2+}$ and $[Co(mmtp)_2]^{2+}$ ions in solution are very different from that for the $[Co(ttcn)_2]^{2+}$ ion. The absorption bands at 631 nm for $[Co(mmtp)(ttcn)]^{2+}$ and at 678 nm for $[Co(mmtp)_2]^{2+}$ may be assigned to the $^2A_{1g}(^2E_g) \rightarrow {}^2_aT_{1g}$ transition. However, we could not observe the absorption corresponding to the $^2A_{1g}(^2E_g) \rightarrow {}^2_aT_{2g}$, and $^2A_{1g}(^2E_g) \rightarrow {}^2_bT_{1g}$ transitions in such a case. On the other hand, a new band at 924 nm appeared for the latter complex. It has been reported (27) that severely distorted $[Co(NO_2)_6]^{4-}$ exhibits a

[a]Not observed.

Fig. 3. Absorption spectra of $[Co(mmtp)_2]^{2+}$, $[Co(mmtp)(ttcn)]^{2+}$, and $[Co(ttcn)_2]^{2+}$ in aqueous solution.

low-energy absorption band at ca. 1000 nm, which was assigned to the $^2A_{1g} \rightarrow {}^2B_{1g}$ transition from which the Jahn–Teller stabilization energy ($4E_{JT}$) was estimated as 8400 cm^{-1}. It is plausible that the Jahn–Teller distortion in $[Co(mmtp)_2]^{2+}$ is very large: the distortion may be comparable to that for the NO_2^- complexes. By assuming that the absorption bands at 678 and 924 nm correspond to the $^2A_{1g} \rightarrow {}^2_aT_{1g}$ and $^2A_{1g} \rightarrow {}^2B_{1g}$ transitions, respectively, the $10Dq$ and E_{JT} values are estimated as 14 700 and 2700 cm^{-1} for the $[Co(mmtp)_2]^{2+}$ complex. It is reasonable to consider, then, the absorption bands for the $^2A_{1g} \rightarrow {}^2_aT_{2g}$, and $^2A_{1g} \rightarrow {}^2_bT_{2g}$ transitions are located at energies higher than 500 nm. The absorption spectrum for the $[Co(mmtp)(ttcn)]^{2+}$ complex seems to possess the nature of both $[Co(ttcn)_2]^{2+}$ and $[Co(mmtp)_2]^{2+}$: an absorption at 631 nm and a broad band at 1100 nm region. The former band may be assigned to the $^2A_{1g} \rightarrow {}^2_aT_{1g}$ transition, while the latter band corresponds to the $^2A_{1g} \rightarrow {}^2B_{1g}$ transition: the Jahn–Teller distortion decreases in the order of $[Co(mmtp)_2]^{2+} > [Co(mmtp)(ttcn)]^{2+} >> [Co(ttcn)_2]^{2+}$. The higher-energy absorption bands corresponding to the $^2A_{1g} \rightarrow {}^2_aT_{2g}$, and $^2A_{1g} \rightarrow {}^2_bT_{1g}$ transitions are located at wavelength region shorter than 500 nm. Therefore, we conclude that the coordination by P-atom causes large tetragonal distortion from the octahedral symmetry because of the Jahn–Teller effect and (or) the strong *trans* influence of the P-donor, together with the steric effect originating from the bulky dimethylphosphine group.

Kinetic studies

The oxidation reactions of Co(II) by $[Ru(NH_3)_6]^{3+}$ and the reduction reactions of Co(III) by $[Co(sep)]^{2+}$ ion were studied with the ionic strength of 0.1 mol dm^{-3} at various temperatures. The change in the absorption at 300 nm was used for the measurements of oxidation reactions, while the absorption change at 415 nm region was used to monitor reduction reactions. Pseudo-first- order conditions, [Co(II)] << [Ru(III)] and [Co(III)] >> $[Co(sep)^{2+}]$, were used. Kinetic

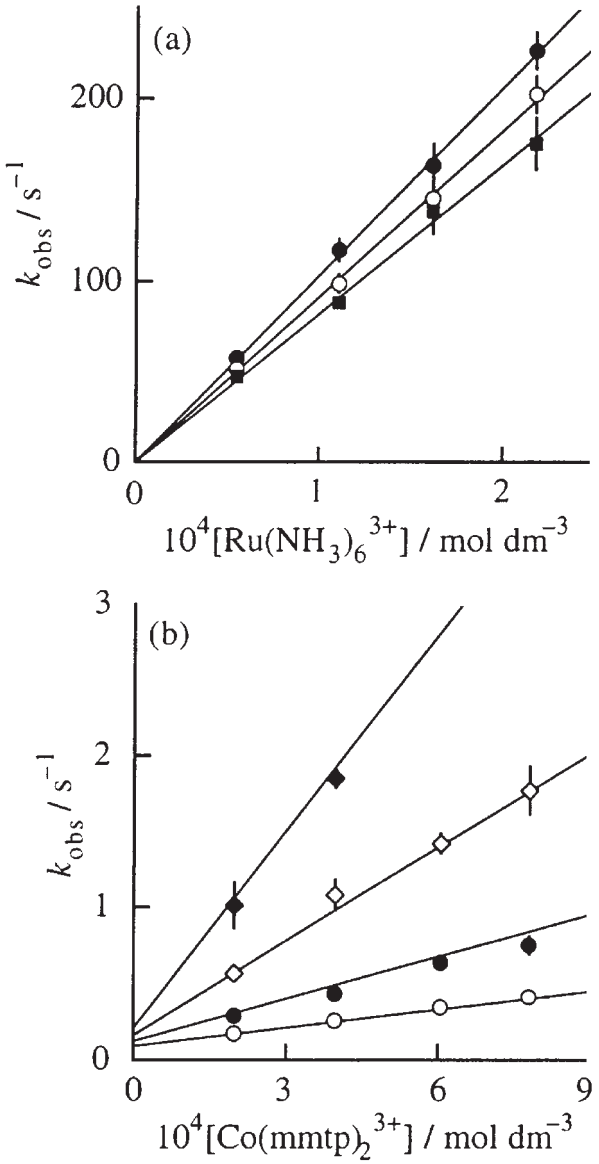

Fig. 5. Diffuse reflectance spectrum of solid $[Co(ttcn)_2](ClO_4)_2$.

traces fit first-order curves for more than three half-lives. The plots of the apparent first-order rate constant against the concentration of the excess reagent were linear (Fig. 6),[3] and the second-order rate constants were calculated from the slopes of the plots. For the reduction reaction of $[Co(mmtp)_2]^{3+}$ by $[Co(sep)]^{2+}$ (Fig. 6*b*), completion of the reactions was not expected under the experimental conditions (the potential difference between these two couples is merely 50 mV). The intercepts that appear in Fig. 6*b* are, therefore, taken as the evidence of the back reaction. However, no significant deviation from the pseudo-first-order kinetics was observed for these reactions up to three half-lives as mentioned above. The addition of excess $[Co(sep)]^{3+}$ to the reaction mixture did not alter the observed pseudo-first-order rate constant, either. Therefore, we decided that the second-order rate constants estimated from the slopes of the plots in Fig. 6*b* are fairly reliable. However, it was not fruitful to estimate the equilibrium constant for this reaction because of the significant errors in estimating the values of the intercepts. Instead, we directly estimated the rate constant for the back reaction, the results of which are also listed in Table 3. The second-order rate constants and related activation parameters are summarized in Table 3.

The electron self-exchange rate constants for the $[Co(mmtp)_2]^{3+/2+}$ and $[Co(mmtp)(ttcn)]^{3+/2+}$ couples were estimated by the Marcus cross relation (28, 29) as 2×10^4 and 6×10^4 dm^3 mol^{-1} s^{-1} from the oxidation and reduction cross reactions of the $[Co(mmtp)_2]^{3+/2+}$ and $[Co(mmtp)(ttcn)]^{3+/2+}$ couples, respectively. The difference in the self-exchange rate constants estimated from the oxidation and reduction cross reactions is taken to be within the acceptable errors inherent in the Marcus cross relation. The value of k_{ex} ($\sim 1 \times 10^4$ dm^3 mol^{-1} s^{-1}) is comparable to those for the other low-spin – low-spin Co(III/II) couples with encapsulated N_3S_3 and S_6 ligands (30, 31), while the self-exchange rate constant for the $[Co(ttcn)_2]^{3+/2+}$ couple (ca. 1×10^5 dm^3 mol^{-1} s^{-1}) is slightly larger than this value (16, 23, 32).

Fig. 6. Dependence of the first-order rate constant (k_{obs}) for the redox reactions of $[Co(mmtp)_2]^{3+/2+}$ couple on the concentration of excess reagent: (*a*) oxidation reaction of $[Co(mmtp)_2]^{2+}$ with $[Ru(NH_3)_6]^{3+}$ at: (■) 5, (○) 15, and (●) 25°C; and (*b*) reduction reaction of $[Co(mmtp)_2]^{3+}$ with $[Co(sep)]^{2+}$ at: (○) 15, (●) 25, (◇) 35, and (◆) 45°C.

The kinetic studies concerning the low-spin – high-spin Co(III/II) couples have, in many cases, been limited to the observations of the reduction reactions of Co(III), because of the lability of high-spin Co(II) species. Moreover, the very low redox potentials of such low-spin – high-spin Co(III/II)

Table 3. Second-order rate constants and activation parameters for the redox reactions of Co(III/II).

	k_{12} (dm^3 mol^{-1} s^{-1})	$\Delta H^{\ddagger}$ (kJ mol^{-1})	$\Delta S^{\ddagger}$ (J K^{-1} mol^{-1})	k_{ex} (dm^3 mol^{-1} s^{-1})[a]
$[Co(mmtp)_2]^{2+}$ + $[Ru(NH_3)_6]^{3+}$	1.03×10^6	5.5 ± 0.4	–111 ± 1	1.0×10^4
$[Co(mmtp)_2]^{3+}$ + $[Co(sep)]^{2+}$	9.26×10^2	58.3 ± 0.1	7.5 ± 0.1	2.3×10^4
	(1.23×10^2)[b]	(18.2 ± 0.2)[b]	(–144 ± 1)[b]	(2.2×10^4)[b]
$[Co(mmtp)(ttcn)]^{2+}$ + $[Ru(NH_3)_6]^{3+}$	3.85×10^5	13.6 ± 0.9	–93 ± 3	9.6×10^4
$[Co(mmtp)(ttcn)]^{3+}$ + $[Co(sep)]^{2+}$	8.20×10^3	56.9 ± 0.2	–33.7 ± 0.1	2.2×10^4

Note: I = 0.10 mol dm^{-3} (KCl), T = 25°C.
[a]Self-exchange rate constant of Co(III/II) couples.
[b]Values obtained from the reverse reaction.

couples made it impossible to find suitable reducing reagents, that is the necessity of prereduction of the species made it difficult to precisely determine the concentration of the reducing reagents. Therefore, the kinetic studies with excess reductants and the kinetic studies of the oxidation reactions of such Co(III/II) couples are scarce, although such a study is essential to examine the mechanisms postulated to date, including the gating phenomenon. Recently several nonconcerted ET reactions have been reported in which the innersphere reorganization process takes place before the very fast outersphere ET with minimal outersphere reorganizations (33–36).

In this study, self-exchange rate constants for the low-spin – low-spin Co(III/II)–S_6, –P_3S_3, and –P_6 complexes were estimated. The self-exchange rate constants for these couples decreased in the following order: $[Co(ttcn)_2]^{3+/2+}$ > $[Co(mmtp)(ttcn)]^{3+/2+}$ > $[Co(mmtp)_2]^{3+/2+}$. Spectroelectrochemical analyses indicated that the Jahn–Teller distortion of the Co(II) species increases in this order. Therefore, it seems that the electron transfer reactions involving low-spin – low-spin Co(III/II) couples follow the norm of the ordinary outersphere ET regime: the degree of the innersphere reorganization that is related to the Jahn–Teller distortion in the $t_{2g}^6 e_g^1$ Co(II) state may govern the rate of electron transfer. Although the Co(II) species investigated in this study are in the low-spin electronic state, it is suggested that the investigation of a series of inert Co(II) with multidentate P_nS_{6-n} and P_nN_{6-n} ligands provides some inert low-spin Co(II) and spin-crossover Co(II) species.

Conclusion

In this study, we reported the characteristics and kinetic behavior of new low-spin cobalt(II) species electrochemically generated in solution. The ligand field of the P-donor is comparable to or larger than that of the S-donor because of the significant covalent character of the Co(II)—P bonds: the nephelauxetic parameter is smaller for Co—P than that for Co—S. However, large Jahn–Teller distortion in the $Co(II)P_6$ complex causes the relatively slow electron self-exchange rate constant for the Co(III/II)–P_6 couple compared with the Co(III/II)–S_6 couple.

Quinoxaline-1,2,3-dithiazolyls — Synthesis, EPR characterization, and redox chemistry

A. Wallace Cordes, James R. Mingie, Richard T. Oakley, Robert W. Reed, and Hongzhou Zhang

Abstract: Oxidation of quinoxalineaminothiol with SCl_2 or S_2Cl_2/Cl_2 affords a series of compounds based on the quinoxaline-1,2,3-dithiazole framework QDTA. Under highly oxidizing conditions, the 1,2,3-dithiazolyl ring is opened to afford the acyclic dichlorosulfimino-sulfenyl chlorides Cl_x-QDTA-Cl_3 (x = 0, 1, 2). Reduction of these "trichloro" compounds leads to ring closure. For x = 2, reduction using S_2Cl_2 affords the dithiazolylium chloride [Cl_2-QDTA][Cl]. For all values of x, reduction with iodide ion (3 mol equiv) affords the corresponding dithiazolyl radical [Cl_x-QDTA]. The radicals can be isolated in good yield in crude form, but attempts to purify them by vacuum sublimation lead to thermal degradation. The radicals have nonetheless been fully characterized by EPR spectroscopy, and the assignments of the observed hyperfine coupling constants cross-matched with those obtained by computation at the B3LYP/6-31G** level. The structures of the trichloro compounds Cl_x-QDTA-Cl_3 (x = 1, 2) have been confirmed by X-ray crystallography. Crystal data: Cl-QDTA-Cl_3, monoclinic, space group $C2/c$, a = 30.561(5) Å, b = 4.9764(9) Å, c = 22.247(4) Å, β = 131.822(14)°, V = 2521.4(8) Å^3, Z = 8, $R(F)$ = 0.043, and $R_w(F)$ [$I \geq \sigma(I)$] = 0.049; Cl_2-QDTA-Cl_3, orthorhombic, space group $Pnma$, a = 18.627(12) Å, b = 6.848(4) Å, c = 10.926(7) Å, V = 1393.7(15) Å^3, Z = 4, $R(F)$ = 0.047, and $R_w(F)$ [$I \geq 3\sigma(I)$] = 0.060.

Key words: thiazyl radicals, molecular conductors, EPR spectroscopy, quinoxaline, DFT calculations.

Résumé : L'oxydation du quinoxalineaminothiol avec du SCl_2 ou du S_2Cl_2/Cl_2 conduit à la formation d'une série de produits dérivés du squelette quinoxaline-1,2,3-dithiazole (QDTA). Dans des conditions d'oxydation extrêmes, le cycle 1,2,3-dithiazolyle s'ouvre pour conduire à la formation de chlorures de dichlorosulfimine-sulfényles, Cl_x-QDTA-Cl_3 (x = 0, 1, 2). La réduction de ces composés "trichloro" conduit à une fermeture de cycle. Lorsque x = 2, la réduction à l'aide de S_2Cl_2 conduit à la formation du chlorure de dithiazolylium [Cl_2-QDTA][Cl]. Pour toutes les valeurs de x, la réduction à l'aide de l'ion iodure (trois équivalents) conduit à la formation du radical dithiazolyle correspondant [Cl_x-QDTA]. Les radicaux ont été isolés avec de bons rendements à l'état brut, mais les essais en vue de leur purification par sublimation sous vide à conduit à leur dégradation thermique. On a toutefois pu faire une caractérisation complète des radicaux par spectroscopie RPE et les attributions des constantes de couplage hyperfins observées correspondent bien à celles qui peuvent être faites sur la base de calculs au niveau B3LYP/6-31G**. Les structures des composés Cl_x-QDTA-Cl_3 (x = 1, 2) ont été confirmées par diffraction des rayons X. Les données cristallographiques: Cl-QDTA-Cl_3, monoclinique, groupe d'espace $C2/c$, a = 30,561(5) Å, b = 4,9764(9) Å et c = 22,247(4) Å, β = 131,822(14)°, V = 2521,4(8) Å^3, Z = 8, $R(F)$ = 0,043 et $R_w(F)$ [$I \geq \sigma(I)$]] = 0,049; Cl_2-QDTA-Cl_3, orthorhombique, groupe d'espace $Pnma$, a = 18,627(12) Å, b = 6,848(4) Å et c = 10,926(7) Å, V = 1393,7(15) Å^3, Z = 4, $R(F)$ = 0,047 et $R_w(F)$ [$I \geq 3\sigma(I)$] = 0,060.

Mots clés : radicaux thiazyles, conducteurs, spectroscopie RPE, quinoxaline, calculs DFT.

[Traduit par la Rédaction]

Introduction

During the last decade, research into the design of neutral radical conductors has developed along two slightly different paths, one searching for materials comprised of purely carbon-based π-frameworks, the other exploring radicals with heterocyclic (non-carbon based) systems. The two approaches share common challenges, including the requirement for materials in which: (*i*) solid state dimerization is suppressed; and (*ii*) intermolecular charge transfer is energetically facile. Several variations of the phenalenyl radical, the archetypal model behind the organic radical conductor concept (1), have recently been developed to address these issues, with encouraging results (2–4). In the heterocyclic arena several structural databases have been established, first on 1,2,3,5-dithiadiazolyls (DTDAs) **1** (5), and more recently on 1,3,2- and 1,2,3-dithiazolyls (DTAs) **2** (6–9) and **3** (10–12). Cyclic thioaminyls have also been pursued (13). While the initial focus of this work was on how to inhibit dimerization, the importance of the energetics of charge

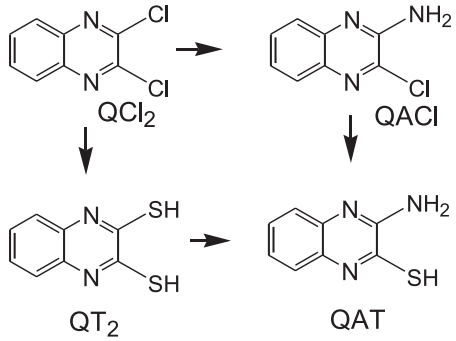
Table 1. Computed (B3LYP/6-31G**) ion energetics (in eV) for radicals **1**–**7**.



Compound	IP	EA	ΔH_{disp}	χ
1	7.82	1.02	6.81	4.42
2	6.77	–0.41	7.18	3.15
3	7.01	0.34	6.67	3.68
4	7.60	2.14	5.46	4.87
5	7.81	2.57	5.23	5.19
6	6.95	1.33	5.63	4.14
7	7.24	1.93	5.32	4.60

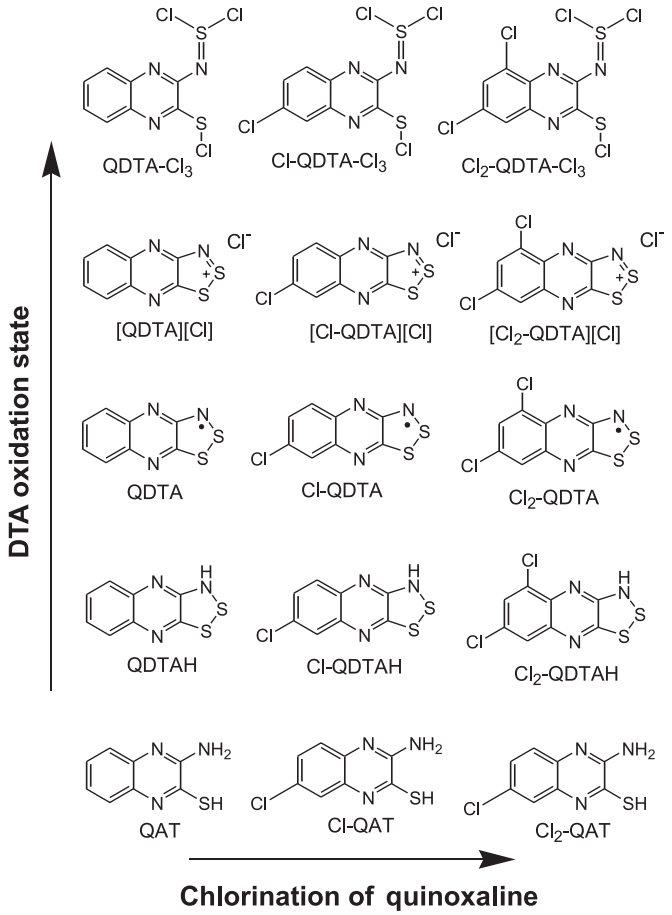
transfer is now well-recognized (14), and efforts to understand and control molecular ionization potentials (IP), electron affinities (EA), and the corresponding solution redox potentials (15) are being vigorously pursued.

With this latter end in mind we prepared and characterized the 1,3,2- and 1,2,3-dithiazolyls **4** (8) and **5** (11). The thiadiazolopyrazine (TDP) substituent on these radicals is extremely electron withdrawing, and causes an increase in both the molecular IP and EA relative to those of simple (monocyclic) DTAs. More importantly the substitution causes a dramatic decrease in the disproportionation enthalpy ΔH_{disp} (ΔH_{disp} = IP – EA) of the radical and, insofar as the gas-phase ΔH_{disp} can be related to the coulombic barrier to charge transfer in the solid state, the observed trend is encouraging. Structural analysis on **4** revealed that the radical does not dimerize (at room temperature), but the molecular spins remain isolated, and the material can be considered as a Mott–Hubbard (16) insulator. By contrast, molecules of **5** dimerize in the solid state, but magnetic and conductivity measurements indicate that the free spins present as defects serve as carriers of charge (11). As a continuation of this work, i.e., the development of structure and (or) property relationships in heterocyclic radicals, we wished to compare the two quinoxaline based systems **6** and **7**. The 1,3,2-compound **6** has been known for some time (17), although its solid-state structure and magnetic properties were reported only recently (7). By contrast the 1,2,3-compound **7** was hitherto unknown. Herein, we report the synthesis and characterization of a series of derivatives based on this "1,2,3-QDTA" skeleton.

Scheme 1.

Results and discussion

Ion energetics



As noted above, one of the crucial factors in the design of neutral radical conductors is the requirement for materials with low disproportionation energies (ΔH_{disp}) (8, 11, 14, 15). Within the parlance of Pearson (18), we seek soft radicals, i.e., molecules which exhibit a low absolute hardness parameter η (where η = (IP – EA)/2). At the outset of this work, we set about exploring by computation, within an ab initio context, the ion energetics of series of 1,3,2- and 1,2,3-dithiazolyls. In Table 1 we provide the computed (B3LYP/6-31G**) IP and EA values for a range of such compounds. The results refine earlier (largely MNDO) estimates, and confirm that a simple 1,2,3,5-DTDA radical **1** has a lower ΔH_{disp} value, it is softer than a simple 1,3,2- or 1,2,3-DTA **2** or **3**. While on this basis both **2** and **3** systems appear to be less effective than **1**, the properties of the latter cannot be modified appreciably by substitution (the radical SOMO is nodal at the substituted carbon). By contrast the fusion of electron-withdrawing groups onto either of the DTA frames **2** or **3** leads to marked changes in ion energetics; both the IPs and EAs are increased. Accordingly the radicals become far more electronegative, i.e., χ = (IP + EA)/2 increases, but because the change in EA outpaces the change in IP, the radical disproportionation energy ΔH_{disp} (ΔH_{disp}= IP – EA) is decreased; in essence the radicals become softer. The most powerful electron sink that we have found is the TDP group, but the radicals so produced (**4** and **5**) are extremely electronegative. The quinoxaline residue affords slightly harder, but less electronegative systems, i.e., **6** and **7**. Having fully characterized the electrochemical properties, EPR, and solid-state properties of **4**, **5**, and **6** (1,3,2-QDTA), radical **7** (1,2,3-QDTA), therefore, became a desirable target for synthesis.

Synthesis

Quinoxalineaminothiol (QAT), the preferred starting material for the synthesis of QDTA **7**, is potentially accessible by a number of routes (Scheme 1) (19). The first involves the conversion of dichloroquinoxaline QCl_2 to the corresponding aminochloro derivative QACl, followed by thiation of the latter with sodium sulfide. However, while the first step is straightforward, the second provides only a low yield (10%) of QAT. The alternative pathway, involving the amination

© 2001 NRC Canada

Scheme 2.

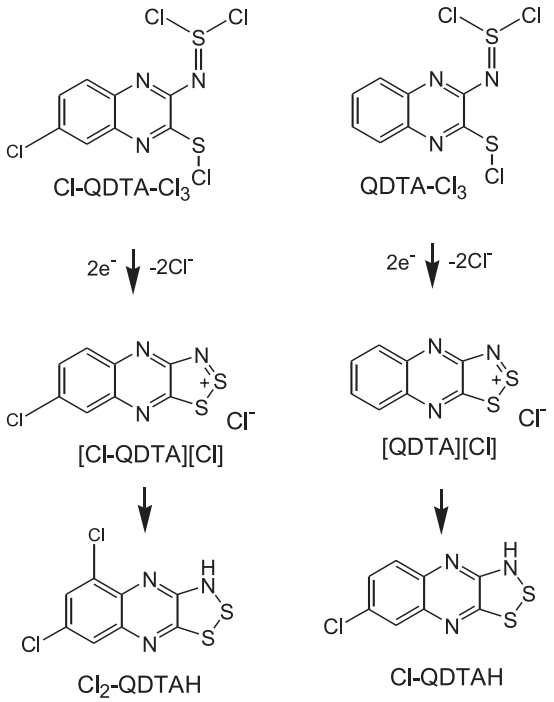
of the intermediate dithiol QT_2, which is easily accessible from QCl_2, affords QAT in much higher overall yields.

Cyclization of QAT to a 1,2,3-dithiazole by treatment with sulfur chlorides proved to be a far more complex process than we had anticipated. Elaboration of the overall sequence of events is facilitated by reference to the manifold of oxidation states and compounds illustrated in Scheme 2.[2] Broadly speaking the nature of the product is a function of the oxidizing power of the sulfur chloride employed. Based on our experience with **5**, we were aware that sulfur monochloride would only produce an imide, e.g., QDTAH. It was therefore not surprising to find that reaction of QAT with S_2Cl_2, in stoichiometric amounts or in excess, afforded an insoluble orange powder exhibiting υ(NH) stretching bands in its IR spectrum. Sulfur dichloride proved to be a stronger but less selective oxidant. Thus, when heated at reflux in acetonitrile with excess SCl_2, QAT was oxidized directly to the open chain dichlorosulfimino-chlorosulfenyl or "trichloro" derivative Cl-QDTA-Cl_3. Attempts to prevent oxidation of the benzene ring were, for a long time, unsuccessful. Eventually, and somewhat to our surprise, we discovered that treatment of QAT with chlorine gas, followed by the addition of excess sulfur monochloride (at room temperature), gave rise to the precipitation of yellow crystals of QDTA-Cl_3. Attempts to recrystallize this material for analytical purposes were always thwarted by its partial conversion, upon dissolution in CH_3CN, into Cl-QDTA-Cl_3. That the quinoxaline ring was unsubstituted was confirmed by hydrolysis of the compound and recovery of QAT.

Cl-QDTA-Cl_3 is relatively resistant to further oxidation; indeed, it is conveniently recrystallized from acetonitrile saturated with chlorine gas. However, when Cl-QDTA-Cl_3 is heated at reflux in acetonitrile with excess sulfur monochloride, a dark orange crystalline precipitate of the salt [Cl_2-QDTA][Cl] (as a CH_3CN solvate) is produced. In essence the open chain trichloro unit is closed to a dithiazolylium cation, while the quinoxaline ring is further chlorinated. [Cl_2-QDTA][Cl] was then easily oxidized with chlorine to the corresponding trichloro derivative Cl_2-QDTA-Cl_3.

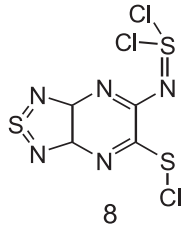
With the set of three trichloro compounds in hand, we explored their reactions with reducing agents. While Cl_2-QDTA-Cl_3 was easily reduced with a stoichiometric amount of iodide ion or excess S_2Cl_2 to Cl_2-QDTA-Cl, reduction of Cl-QDTA-Cl_3 required a more careful choice of reducing agent. Eventually, we found that hexamethyldisilane reacts with Cl-QDTA-Cl_3 to afford what we believe to be to [Cl-QDTA][Cl]. However, attempts to recrystallize this material led to its conversion to an insoluble solid exhibiting υ(NH) stretching bands and which, upon hydrolysis, afforded the dichlorinated aminothiol Cl_2-QAT. An analogous sequence of events was encountered upon reduction of QDTA-Cl_3. We interpret these observations in terms of the susceptibility of the dithiazolylium salts [QDTA][Cl] and [Cl-QDTA][Cl] to rearrange, with chlorination of the quinoxaline ring, to an imide (Scheme 3).

In our attempts to generate the radical oxidation states QDTA, Cl-QDTA, and Cl_2-QDTA we explored a variety of reducing agents (KI, Bu_4NI, Ph_3Sb, Zn), solvents (CH_3CN, SO_2), and starting oxidation states (Cl_x-QDTA-Cl_3 or [Cl_x-QDTA][Cl]). The most reliable method involved the use of potassium iodide in CH_3CN or SO_2 (see *Experimental* section). All three radicals could be isolated in crude form, as black crystalline solids, but purification for analytical purposes was extremely inefficient. Vacuum sublimation of the products from the crude matrix, the preferred purification method for heterocyclic radicals, inevitably led to decomposition and low recovery of sublimed product (<10%). Curiously, once isolated, the sublimed material could be resublimed with little or no loss.



Crystal structures

The initial intent of this work was to characterize the structure and transport properties of the 1,2,3-QDTA radical in the solid state. However, the lability of this material, and its chlorinated derivatives Cl_x-QDTA (x = 1, 2), militated against the isolation of the material in sufficient quantity and quality to allow single crystal X-ray analysis. Nonetheless we were able to establish the crystal structures of the two trichloro derviatives (Cl_x-QDTA-Cl_3). These determinations



[2] The trichloro compounds depicted in Scheme 2 are identified by means of general formulas, e.g., Cl_x-Q-Cl_3; the degree of chlorination of the quinoxaline residue is indicated by the value of x. The dithiazole derivatives are labelled [Cl_x-QDTA][Cl] (cationic state), [Cl_x-QDTA] (radical state), [Cl_x-QDTAH] (imide state). The corresponding aminothiols are labelled Cl_x-QAT.

Scheme 3.

confirmed the presence of the dichlorosulfimino-sulfenyl chloride functional group in both compounds, and also established unequivocally the position(s) of chlorination on the benzene ring in the QDTA framework. Crystal data for these two compounds is provided in Table 2[3], and a summary of pertinent intramolecular structural features is given in Table 3. ORTEP drawings of the two molecules, showing atom numbering, are given in Fig. 1. In Cl-Q-Cl_3, the quinoxaline framework is planar to within 0.018 Å, with the N-1 and S-2 atoms lying, respectively, –0.058 and +0.016 Å from this plane. In Cl_2-Q-Cl_3, all the atoms save Cl-1 lie on a crystallographic mirror plane. The structural features of the dichlorosulfimino-sulfenyl chloride unit are very similar, with a short (localized) N=S double bond, and mirror the trends observed in compound **8** (11).

8

EPR spectra

The X-band EPR spectra of the three quinoxaline-based 1,2,3-DTA radicals, recorded at ambient temperature on samples dissolved in oxygen-free CH_2Cl_2, are shown in Figs. 2–4. The spectra are extremely complex; in the case of 1,2,3-QDTA **7** itself, coupling is observed to all three nitrogens as well as all four protons. In the chlorinated derivatives, some simplification is achieved by virtue of a reduction in the proton count, and $^{35/37}$Cl coupling is negligible. Nonetheless, extraction of hyperfine coupling required full spectral simulation; these are also shown in Figs. 2–4. The observed hyperfine coupling constants drawn from these simulations are summarized in Table 4 along with computed values at the B3LYP/6-31G** level; the latter served as an aid in making assignments. The correspondence between the observed and computed a_N values is relatively good (the latter being consistently about 15% higher), so that absolute assignments are relatively unequivocal. Such is not the case for the various a_H values. While we have been able, in all cases, to observe the expected number of ^{1}H couplings, the computed a_H values are several times larger than those derived experimentally. Thus, while we are relatively confident with the matches shown in Table 4 for H_1 and H_3, those for H_2 and H_4 are less certain.

Experimental

Quinoxalineaminothiol (QAT) was prepared by the conversion of commercially available (Aldrich) dichloroquinoxaline into quinoxalinedithiol (QT_2) (19), followed by the treatment of the latter with aqueous ammonia; the crude product was purified by recrystallization from benzonitrile. Sulfur monochloride, potassium iodide, and dichloroquinoxaline were obtained commercially (Aldrich), and used as received. Chlorine gas and sulfur dioxide gas (Matheson) were also used directly. The solvents dichloroethane (Fisher) and acetonitrile (Fisher HPLC grade) were dried by distillation from P_2O_5. All reactions were carried out under an atmosphere of nitrogen. Melting points are uncorrected. Elemental analyses were performed by MHW Laboratories, Phoenix, Arizona. Infrared spectra were recorded (at 2 cm^{-1} resolution on Nujol mulls) on a Nicolet Avatar FT-IR spectrometer. Low resolution mass spectra (70 eV, EI, DEI and CI, DCI, FAB) were run on a Finnigan 4500 quadrupole mass spectrometer (at McMaster University) and a VG 7070 mass spectrometer (at the University of Waterloo).

Preparation of QDTA-Cl_3

A gentle stream of chlorine gas was passed over a slurry of QAT (1.0 g, 5.64 mmol) in 10 mL of acetonitrile held at 0°C (ice bath) for 10 min. Within 60 s of initiating the chlorine flow, a solution of excess S_2Cl_2 (ca. 1.0 g) in 5 mL of CH_3CN was added dropwise to the mixture. After 5 min, the chlorine flow was halted, and the flocculent yellow solid filtered off under nitrogen, washed with 2 × 5 mL acetonitrile saturated with chlorine, and dried in vacuo. The crude (moisture-sensitive) product, QDTA-Cl_3 (0.845 g, 2.70 mmol, 48%) was used directly in all subsequent reactions. Attempts to purify this compound by recrystallization

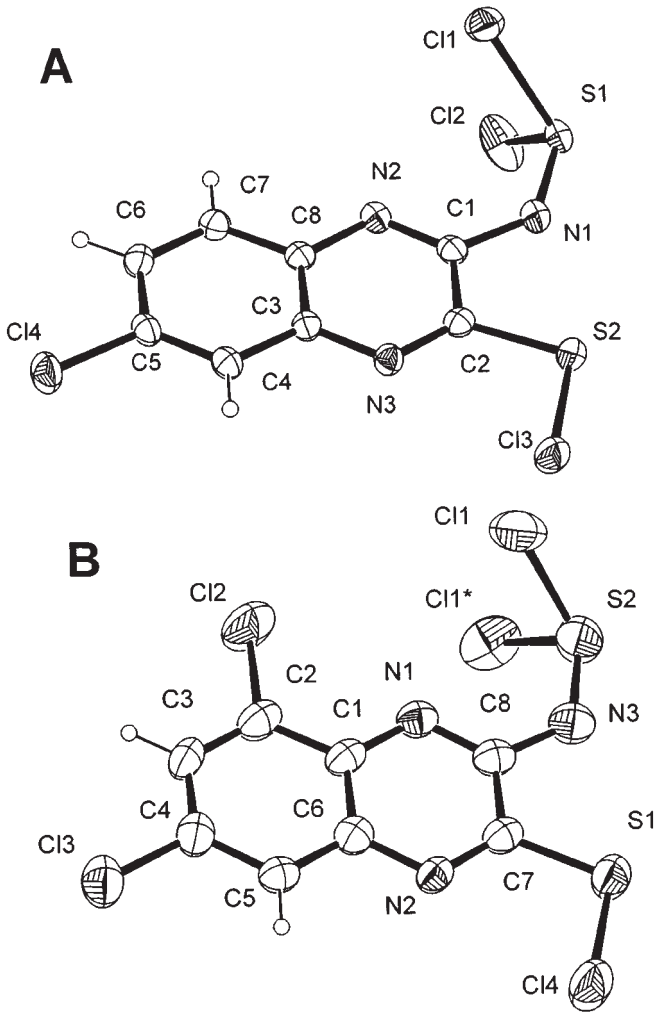
led to its partial conversion to Cl-QDTA-Cl_3, but the integrity of the quinoxaline skeleton was confirmed by hydrolysis of QDTA-Cl_3 to QAT. IR (1600–400 cm^{-1}): 1329 (s), 1292 (w), 1228 (m), 1161 (m), 1113 (m), 1017 (w), 903 (w), 805 (w), 754 (vs), 714 (w), 698 (w), 625 (vw), 593 (vw), 553 (vw), 539 (s), 458 (s).



Preparation of Cl-QDTA-Cl_3

Excess (4 mL) of SCl_2 was added to a slurry of QAT (1.00 g, 5.64 mmol) in 30 mL of CH_3CN at room temperature. The mixture was stirred for 1 h during which time it changed color from red to yellow. The canary yellow precipitate was filtered off, washed with 2 × 10 mL portions of CH_3CN, and dried in vacuo; (1.3 g, 3.75 mmol, 66%). The product Cl-QDTA-Cl_3 (0.500 g, 1.44 mmol) was recrystallized from acetonitrile containing 2 mL of SCl_2 (to enhance the solubility of the compound). On cooling, lustrous yellow needles were formed: dec > 85°C. Preparation of Cl_2-QDTA-Cl_3

Excess S_2Cl_2 (4 mL) was added to a slurry of QAT (2.00 g, 11.3 mmol) in 60 mL of acetonitrile. The mixture was warmed gently to produce a red precipitate. Chlorine gas was then passed over the solid until a bright yellow precipitate was produced. Following the addition of more S_2Cl_2 (4 mL) the mixture was heated at reflux for 0.5 h. As the mixture reached the boiling point the solid dissolved to give

Preparation of [Cl_2-QDTA][Cl]·CH_3CN

Excess S_2Cl_2 (4 mL) was added to a slurry of Cl-Q-Cl_3 (1.50 g, 4.32 mmol) in 50 mL of CH_3CN. As the mixture was heated to reflux the solid dissolved to give a dark red-brown solution. After half an hour at reflux the solution was allowed to cool to room temperature. The orange brown crystalline solid which precipitated on cooling was filtered off, washed with 2 × 10 mL portions of CH_3CN, and dried in vacuo. The product [Cl_2-QDTA][Cl]·CH_3CN (1.25 g, 3.55 mmol, 82%) was recrystallized from acetonitrile containing a few drops of SCl_2. Infrared and elemental analysis confirmed that the compound (dec > 85°C) was solvated with 1 mol of acetonitrile. MS *m/z*: 274 (M^+, 100%). IR (cm^{-1}): 3425 (m), 3286 (w), 3214 (w), 3117 (w), 1639 (w), 1599 (w), 1358 (m), 1241 (w), 1208 (w), 1110 (s), 975 (w), 846 (s), 681 (s), 657 (w), 587 (m), 541 (w), 439 (m). Anal. calcd. for $C_8H_5Cl_2N_3S$: C 39.04, H 2.05, N 17.07; found: C 38.88, H 1.94, N 16.96.

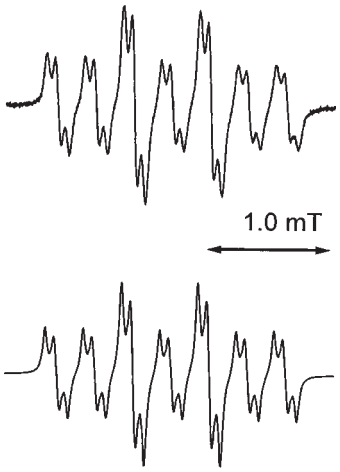
Fig. 3. X-band EPR spectrum (above) of Cl-QDTA, g = 2.0082, in CH_2Cl_2, and simulation (below) with L:G = 0.03, LW = 0.041 mT. Derived coupling constants are provided in Table 4.



Generation of radicals Cl_x-QDTA (x = 0, 1, 2)

The same basic procedure was used for all three radicals. Three mol equiv of finely powdered and oven dried (100°C) potassium iodide were added to a slurry of Cl_x-Q-Cl_3 (ca. 1.0 g) in 10 mL of acetonitrile at room temperature. The mixture was then stirred for 20 min at room temperature, and the black solid (a mixture of Cl_x-QDTA and KCl) was filtered off, washed with cold acetonitrile, and dried in vacuo. The radicals were separated from the KCl matrix by gradient sublimation at 110–60°C per 1 × 10^{-2} torr (1 torr = 133.322 Pa). Overall recovery of the radicals was, however, extremely low; yields were generally <10% based on the amount of Cl_x-Q-Cl_3 used.

QDTA: dec > 150°C. IR (1600–400 cm^{-1}): 1582 (w), 1537 (vw), 1340 (w), 1323 (w), 1223 (m), 1140 (s), 1066 (m), 949 (m), 873 (w), 845 (w), 786 (w), 753 (s, br), 639 (w), 590 (w), 577 (w), 491 (w), 427 (w). Insufficient quantity of this material was obtained in a pure (sublimed) form for elemental analysis; but the integrity of the quinoxaline skeleton was confirmed by hydrolysis to QAT (vide supra). The radical itself was characterized by its EPR spectrum.

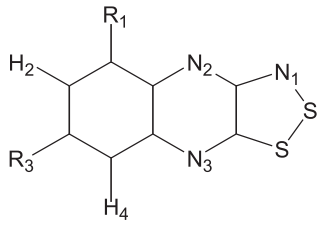
X-ray measurements

X-ray data were collected at 293 K on ENRAF-Nonius CAD-4 and Rigaku Mercury CCD diffractometers with monochromated Mo K_α radiation. Crystals were mounted on glass fibers with silicone and data were collected using θ/2θ (Cl-QDTA-Cl_3) and ω (Cl_2-QDTA-Cl_3) scans. The structures were solved using direct methods and refined by full-matrix least-squares which minimized $\Sigma w(\Delta F)^2$.

EPR spectra

X-band EPR spectra were recorded (on radicals dissolved in degassed CH_2Cl_2) on a Bruker EMX-200 spectrometer; hyperfine coupling constants were obtained by spectral simulation using Simfonia (20) and WinSim (21). Lorentzian:Gaussian (L:G) ratios and line widths (LW) used in the simulations are provided in the figure captions.



Density functional calculations

Adiabatic ionization potentials and electron affinities were calculated by means of ΔSCF calculations run on Pentium II workstations using the B3LYP-DFT method, as contained in the Gaussian 98W suite of programs (22). Geometries were optimized using the 6-31G** basis set, within the constraints of C_s (planar) symmetry; frequency calculations were not performed. Elsewhere (23), we have noted that the release of

planarity in 1,2,3-dithiazole anions can lead to S—N bond cleavage (a prediction echoed by electrochemical experiments). The present electron affinity results should therefore be viewed as estimates only.

Summary and conclusions

The development of cyclic and heterocyclic π-radicals suitable for applications as conductive molecular materials requires the pursuit of highly delocalized systems with favorable ion energetics, i.e., a low ΔH_{disp}. In this regard, the 1,2,3-QDTA systems investigated here represent appealing targets. However, from a synthetic standpoint, the construction of a 1,2,3-dithiazole ring on a quinoxaline framework is by no means trivial. The oxidizing conditions that successfully allow the synthesis of the ternary radical **5** by cyclization of an aminothiol are, in the present case, sufficiently harsh to cause chlorination of the benzene residue of the quinoxaline framework. This leads to a rich array of partially chlorinated derivatives, both cyclic and acyclic. We have nonetheless been able to isolate and characterize, by EPR spectroscopy, three 1,2,3-QDTA radicals. The EPR spectra of these radicals reveal a high degree of spin delocalization, similar to that observed in **5**, and much more so than observed in corresponding 1,3,2-system **6**.

While all the QDTA radicals reported here are stable indefinitely at room temperature, attempts to purify them by vacuum sublimation, and hence investigate their transport properties, have been thwarted by their tendency to thermally decompose. We attribute this instability to the delocalization of spin density onto the benzene residue, with a consequent tendency for the radicals to associate via C—C linkages, and thence rearrange. In the light of the present results, the thermal stability of **5** is remarkable, and empha-

Synthesis, characterization, and thermodynamics of tertiary phosphine cobalt(III) Schiff-base complexes

Mozaffar Asadi and Ali Hossein Sarvestani

Abstract: [Co(5-nitroSalen)(PBu_3)]$ClO_4 \cdot H_2O$ and [Co(Salpd)(PBu_3)]$ClO_4 \cdot H_2O$ were synthesized and characterized. The stability constants and the thermodynamic parameters were measured spectrophotometrically for 1:1 adduct formation of [CoL(PBu_3)]$ClO_4 \cdot H_2O$, (L = Salen, 5-nitroSalen, Salpd), and [Co(Salen)(PMe_2Ph)]$ClO_4 \cdot H_2O$ as acceptors with $P(OR)_3$ (R = Me, Et, *i*-Pr) as donors, in acetonitrile solvent and in constant ionic strength (I = 0.01 M) and at various temperatures. The trend of the reactivity of cobalt(III) Schiff-base complexes with PBu_3 axial ligand toward a given donor is as follows: 5-nitroSalen > Salen > Salpd.

Also, the following reactivity trend of the donors toward a given cobalt(III) Schiff-base complex is in the operation: $P(O\text{-}i\text{-}Pr)_3 > P(OEt)_3 > P(OMe)_3$.

Key words: cobalt(III) Schiff-base complexes, thermodynamic parameters, trialkylphosphite, adduct complexes, stability constants.

Résumé : On a effectué la synthèse et on a caractérisé les complexes suivants: [Co(5-nitroSalen)(PBu_3)]$ClO_4 \cdot H_2O$ et [Co(Salpd)(PBu_3)]$ClO_4 \cdot H_2O$. Faisant appel à des méthodes spectrophotométriques, on a mesuré les constantes de stabilité et les paramètres thermodynamiques pour la formation d'adduits 1:1 entre les complexes accepteurs [CoL(PBu_3)]$ClO_4 \cdot H_2O$ dans lesquels L = Salen, 5-nitroSalen et Salpd et [Co(Salen)(PMe_3Ph)]$ClO_4 \cdot H_2O$ et les $P(OR)_3$ (dans lesquels R = Me, Et, *i*-Pr) comme accepteurs, dans l'acétonitrile comme solvant, à force ionique constante (I = 0,01 M) et à diverses températures. La tendance de la réactivité des complexes des bases de Schiff du cobalt(III) avec le ligand PBu_3 axial est donnée par la séquence suivante: 5-nitroSalen > Salen > Salpd.

Du côté des donneurs vis-à-vis d'un complexe donné d'une base de Schiff du cobalt(III), la tendance est exprimée par la séquence suivante: $P(O\text{-}i\text{-}Pr)_3 > P(OEt)_3 > P(OMe)_3$.

Mots clés : complexes de bases de Schiff avec le cobalt(III), paramètres thermodynamiques, trialkylphosphite, adduits de complexes, constantes de stabilité.

[Traduit par la Rédaction]

Introduction

Many Co(III)–Salen tertiary phosphine complexes have been suggested as models for the vitamine B_{12} coenzyme (1–3). The properties of these Salen complexes were examined with the aim to gain an insight into the chemistry of the related biological molecules. Some extensive works have been done on these models (4–8). Recently the kinetics of ligand replacement reactions of the axial H_2O in the *trans*-$[Co(en)_2(H_2O)(Me)]^{2+}$ complex have been studied by Hamza et al. (9). The equilibrium of the adduct formation of $[Co(Salen)X]^+$ (X = tertiary phosphines) with NO_2^- has been studied. It was shown that the equilibrium constants decrease according to the following trend: $PPh_3 < PEtPh_2 < PBu_3$ (10). The formation constants for some $[Co(Salen)(PR_3)_2]^+$ were examined in acetonitrile and in ethanol 95% (11).

In this work, the new complexes [Co(5-nitroSalen)(PBu_3)]$ClO_4 \cdot H_2O$ and [Co(Salpd)(PBu_3)]$ClO_4 \cdot H_2O$ were synthesized and characterized. Thermodynamics of cobalt(III) Schiff-base complexes of the types [CoL(PBu_3)]$ClO_4 \cdot H_2O$, where L = Salen, 5-nitroSalen, Salpd, and [Co(Salen)(PMe_2Ph)]$ClO_4 \cdot H_2O$ as acceptors with ($P(OR)_3$, R = Me, Et, *i*-Pr) as donors, in acetonitrile solvent have been examined. By comparing the spectral and the thermodynamical properties of the synthesized complexes, we aimed to investigate the effects of different electronic and steric situations.

Instrumentation

The UV–vis spectra were recorded by a Jusco V-530 spectrophotometer. The NMR spectra were recorded by a Bruker Avance DPX 250 MHz spectrometer, and IR spectra were recorded by a PerkinElmer 781 IR spectrophotometer.

Synthesis of the complexes

The ligands Salen, 5-nitroSalen, and Salpd were prepared according to the literature (12). The [Co(Salen)-(PBu_3)]$ClO_4 \cdot H_2O$ and [Co(Salen)(PMe_2Ph)]$ClO_4 \cdot H_2O$ complexes were prepared by the methods described previously (10, 11).

The general procedure for the synthesis of the [Co(5-nitroSalen)(PBu_3)]$ClO_4.H_2O$ and [Co(Salpd)(PBu_3)]$ClO_4.H_2O$ is as follows: to a refluxing solution of Salpd (0.57 g, 2.01 mmol) or 5-nitroSalen (0.71 g, 2.01 mmol) in methanol (70 mL), were added $Co(OAC)_2 \cdot 4H_2O$ (0.50 g, 2.01 mmol) and tributylphosphine (0.5 mL, 2.01 mmol). The reaction mixture was refluxed for 1 h. The formed Co(II) complex was oxidized by blowing air into the solution for 2 h, and the solution was filtered. To the filtrate, an appropriate amount of sodium perchlorate (0.30 g, in 10 mL water) was added. The green crystals were formed after 24 h. The crystals were washed with some methanol, recrystallized in acetone–ethanol (95%), and dried in vacuum at 65°C.

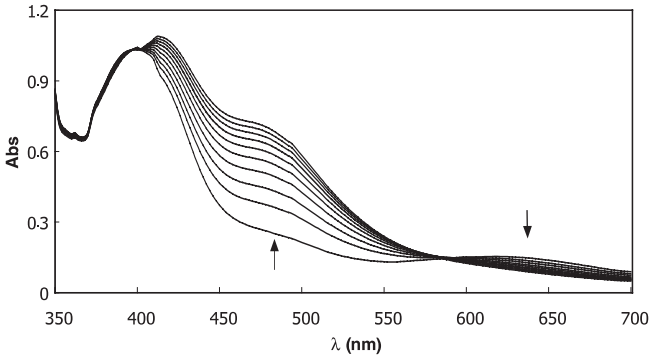
Thermodynamic studies

The adduct complexes were obtained from the reaction of the acceptors with the donors, according to the eq. [1]:

$$[1] \qquad [CoLX]^+ + P(OR)_3 \longleftrightarrow [CoLX(P(OR)_3)]^+$$



where L = Salen, Salpd, and 5-nitroSalen, X = PBu_3 and PMe_2Ph (only for Salen), R = Me, Et, and *i*-Pr.

A solution from each complex with a concentration at about 1×10^{-4} M and a constant ionic strength (I = 0.01 M) by tetraethylammonium perchlorate was prepared. From this solution, 2.5 mL was transferred into the thermostated cell compartment of the UV–vis instrument which was kept at constant temperature (±0.1°C) by circulating water and was titrated by the phosphite. The titration was done by adding aliquots of the phosphite with a Hamilton syringe (μL). The donors' concentrations were varied one- to three-fold in excess.

The absorption measurements were carried out at a fixed wavelength where the difference in absorption between the substrate and the product was the largest after the equilibrium was assessed. These fixed wavelengths for the systems are listed in Tables 1–4. The adduct formed shows an absorption different from the acceptor, while the donors show no absorption at those wavelengths.

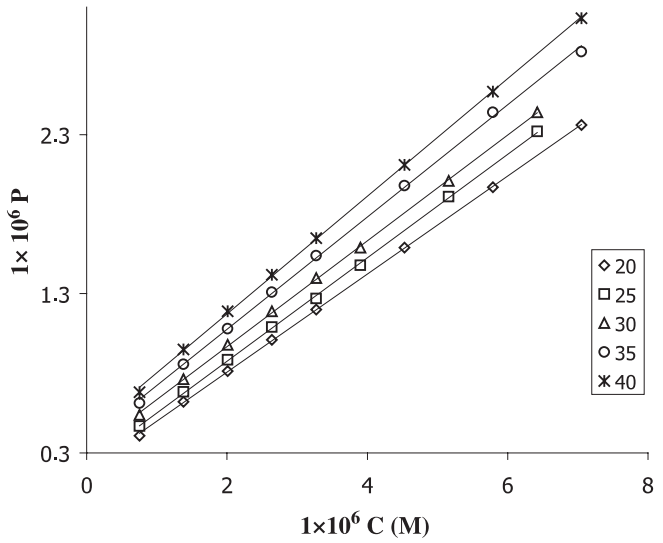
Fig. 1. Spectrophotometric titration of $[Co(Salen)(PMe_2Ph)]^+$ with $P(O\text{-}i\text{-}Pr)_3$ in acetonitrile (I = 0.01 M Et_4NClO_4, T = 30°C).

Results and discussion

The characterization of the complexes

The new complexes $[Co(5\text{-nitroSalen})(PBu_3)]ClO_4 \cdot H_2O$ and $[Co(Salpd)(PBu_3)]ClO_4 \cdot H_2O$ were identified by elemental analysis, IR, NMR, and electronic spectra. The other complexes were identified only by IR, NMR, and electronic spectra.

Spectral characterization



IR spectra: The absence of the coordinated water in all the studied complexes was confirmed by the absence of the absorption band around 3100 cm^{-1} (10). The absorption band around 1625–1640 cm^{-1} is related to the azomethane group, and the aromatic double bonds appeared at 1600–1605 cm^{-1} (13).

Electronic spectra: The electronic spectra, of all the studied complexes, show an absorption at 600–700 nm in non-coordinated solvent, that indicate the five-coordinated structure for them. All complexes show an intensive absorption band at 370–400 nm. This band did not reallychange in all the reactions studied. The absorption band at 600–700 nm vanished and the six-coordinated product species showed an absorption band at 400–500 nm (10). All measurements for the thermodynamic studies were carried out in this range. As an example, the variation of the electronic spectra for $[Co(Salen)(PMe_2Ph)]^+$, titrated with the $P(O\text{-}i\text{-}Pr)_3$, is shown in Fig. 1. The isosbestic points for this system show that there is only one reaction in equilibrium. The same is valid for other systems.

The ^1H NMR spectra: The ^1H NMR spectral data have been presented in the *Experimental* section. The NMR spectra of these complexes are consistent with the suggest formulation and show that the cobalt in these complexes is low-spin. The interesting point in the NMR of these complexes is the aromatic proton signals that are resolved in four groups in the ^1H NMR. For example, in $[Co(Salpd)(PBu_3)]^+$ these signals arranged from δ = 6.55 to 7.17 in the form of triplet, doublet, doublet, and triplet, that are related to the protons in the positions of 5, 3, 6, and 4 to the azomethane group, respectively. In the complex of $[Co(5\text{-nitroSalen})(PBu_3)]^+$, because of the NO_2 group, the aromatic proton signals shifted to the low field in such a way that the proton in the position 6 to the azomethane overlaps with the azomethane proton at δ = 8.51.

Fig. 2. The linear plot for $[Co(Salen)(PBu_3)]^+$ with $P(OEt)_3$ system at various temperatures (T = 20–40°C).

$P = \dfrac{C_A^\circ C_D^\circ}{A - A_A^\circ - A_D^\circ}$, $C = (C_A^\circ C_D^\circ)$.

Thermodynamic interpretations

The equilibrium constants of the various cobalt(III) Schiff base complexes studied were calculated by using Ketelaar et al.'s (14) equation

$$[2] \qquad \frac{C_A^\circ C_D^\circ}{A - A_A^\circ - A_D^\circ} = \frac{1}{(\varepsilon_C - \varepsilon_A - \varepsilon_D)}\left[\frac{1}{K} + (C_A^\circ + C_D^\circ)\right]$$

where C_A° and C_D° are the initial concentrations of the acceptor and the donor, respectively. A is the optical density of the solution including the acceptor and the donor; A_A° and A_D° are the optical densities of the pure acceptor and the pure donor in the solution of concentration C_A° and C_D°; ε_C, ε_A, and ε_D are the molar extinction coefficients of the complex, the acceptor, and the donor, respectively. K is the stability constant of the formed complex and the cell optical path length is 1 cm. A plot of $(C_A^\circ C_D^\circ/(A - A_A^\circ - A_D^\circ))$ vs. $(C_A^\circ + C_D^\circ)$ should produce a straight line if only the 1:1 complex is formed, while a mixture of 1:1 and 1:2 or only 1:2 complex in a system would lead to a curve. The stability constants of the studied cobalt(III) Schiff base complexes were calculated from the ratio of the slope to the intercept by the least-squares method using Excel 5 computer software. The K measurements were repeated at least twice and were reproducible. The linear plots for $[Co(Salen)(PBu_3)]^+$ with $P(OEt)_3$ at various temperatures are shown in Fig. 2, which signifies that only 1:1 complex is formed. Similar plots are obtained for other systems.

The thermodynamic parameters of the studied cobalt(III) Schiff base complexes were calculated by use of the well-known van't Hoff eq. [3]:

$$[3] \qquad \ln K = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R}$$

where K is the stability constant, R is the gas constant, and T is the temperature in kelvin scale. Thermodynamic parameters of the studied cobalt(III) Schiff base complexes were obtained from the linear plots of ln K vs. $1/T$. The values of $\Delta H°$ and $\Delta S°$ were obtained from the slope and the intercept, respectively, by using the Excel computer program.

The stability constants and the thermodynamic parameters data are collected in Tables 1–8. The stability constants are given for the formation of 1:1 adducts only.

The acceptor property of cobalt(III) Schiff base complexes

It was suggested (15) that when Co(III) ion is chelated in a macrocycle having delocalized electronic structure, the complex loses its transition character and might become kinetically labile. The extent to which this happens is likely to be strongly dependent on the structure of the planar chelating system acting as acceptor of the donated charge. It can be concluded that in the ground state, the thermodynamic effects and even the kinetic *trans*-effects are mainly due to the charge donation to the cobalt atom via the σ-bond (2). Therefore the equatorial Schiff base ligands and the strong σ-donors like phosphines in the axial position can affect the stability of six- or five-coordinated cobalt(III) Schiff base complexes. The phosphine axial ligand *trans*-effect on the thermodynamics of the five-coordinated Co(III) Schiff base complexes has been well-studied (10, 11), but the *cis*-effect appears to be far less evident in this literature. We tried to find the steric and the electronic effects of some Schiff bases on the thermodynamic parameters of five-coordinated Co(III) Schiff base complexes. The steric effect of the axial phosphine ligands and the entering ligands were also studied. The thermodynamic aspect of the influence of the equatorial Schiff bases' ligands can be clearly seen from Tables 1, 3, and 4, and show the trend of Salpd < Salen < 5-nitroSalen, irrespective of the nature of the axial ligand. These results are in agreement with the trend of nucleophilicity of the cobalt atom in the Schiff base complexes toward the electrophiles.

The electronic effect of the equatorial Schiff base ligands

The electron-withdrawing property of the substituent groups on the Schiff base can influence the ability of the acceptor property of the complexes. The presence of an NO_2 withdrawing group causes 5-nitroSalen to become a weaker Schiff base than the unsubstituted Salen. Therefore, the cobalt atom in the $[Co(5\text{-nitroSalen})(PBu_3)]^+$ complex has more acceptor property than $[Co(Salen)(PBu_3)]^+$ and forms more stable complexes with donors (Tables 1 and 3).

The steric effect of the equatorial Schiff base ligands

By increasing the steric interactions of the Schiff base, the five-coordinate complex becomes more stable and the formation constant of this type decreases with an increase in steric interactions. Therefore, the five-coordinated $[Co(Salpd)(PBu_3)]^+$ complex has less acceptor ability than $[Co(salen)(PBu_3)]^+$ (Tables 1 and 4).

The effect of the axial ligand

The steric effect of the axial ligand is more important than the equatorial (10, 11). The stability constants for the PMe_2Ph axial ligand with lower steric interactions are more larger than PBu_3 (Tables 1 and 2). The difference between the nucleophilicity of the phosphites in the $[Co(Salen)(PMe_2Ph)]^+$ is better seen because of the decrease in steric interactions (Table 2).

Effect of the donors

In this work, we have examined three donors, $P(OMe)_3$, $P(OEt)_3$, and $P(O\text{-}i\text{-}Pr)_3$. The phosphite complexes are often similar to the phosphines but the phosphites tend to be more basic and less sterically hindered (16).

In addition to the electronic property, the phosphites have an important steric factor that is demonstrated by the Tolmane cone angle. The cone angles (degrees) for these phosphites are 107, 109, and 130°, for $P(OMe)_3$, $P(OEt)_3$, and $P(O\text{-}i\text{-}Pr)_3$, respectively (17). The steric interaction is increased with an increase in cone angle.

In the Salen and 5-nitroSalen complexes, the stability constants were increased by increasing Tolmane cone angles of the phosphites, which is in contrast to what is expected;, therefore, it seems that the electronic effect of the phosphites is more important than the steric effect toward the given acceptor (Tables 1–3), and there is an increasing tendency for the

© 2001 NRC Canada

adduct formation in the order $P(OMe)_3 < P(Oet)_3 < P(O\text{-}i\text{-}Pr)_3$. By increasing the steric interactions in the Salpd complex, the stability constant is decreased when the Tolmane cone angle increased (Table 4) and this order changes to $P(OMe)_3 < P(O\text{-}i\text{-}Pr)_3 < P(OEt)_3$.

The lower stability constant of the trimethylphosphite may be attributed to a "keto–enol" type of rearrangement to produce a phosphoryl linkage (18), but the triethylphosphite do not show this property (19).

Thermodynamic parameters

The heat of formation

The $\Delta H°$ value and its sign, is dependent on two factors: one of these factors, is the solvation effect and the other one is the heat of formation of the complex (20). The solvation effect for five- and six-coordinated complexes is not that different due to the same charge, although it seems that the five-coordinated complex is better solvated. The solvation effect for the donors is related to the interaction of solvent with the phosphites and this contribution for $\Delta H°$ can be positive after the equilibrium. In all cases, $\Delta H°$ values are negative, and it shows that the complex-formation contribution of $\Delta H°$ values is more important (Tables 5–8). For example, the heat of formations of $P(OMe)_3$ toward the acceptors are related to the stability constants for these systems (Tables 5–8).

Concerning the electronic effect contribution, the $\Delta H°$ values for $[Co(5\text{-nitroSalen})(PBu_3)]^+$ are more negative than the $[Co(Salen)(PBu_3)]^+$, and it shows that the complex formation in 5-nitroSalen is more important (Tables 5 and 8).

Concerning the steric effect of the equatorial Schiff base ligand on heat of formation, the $\Delta H°$ values for $[Co(Salpd)(PBu_3)]^+$ are nearly the same as $[Co(Salen)(PBu_3)]^+$. It can be due to the second factor, and there is some positive value from the solvation effect for $[Co(Salen)(PBu_3)]^+$, especially with $P(OEt)_3$ and $P(O\text{-}i\text{-}Pr)_3$ (Tables 5 and 7). The steric effect of the axial ligand is important and the enthalpy change values show this effect (Tables 5 and 6).

For a given acceptor, the solvation effect is different for the donors. $\Delta H°$ values for the triisopropylphosphite are less negative than triethylphosphite and these are in contrast to the stability constants. For example, the heat of formation for $[Co(Salen)(PMe_2Ph)]^+$ is smaller than the others, although the complex formation is the greatest. This is repeated for $[Co(Salen)(PBu_3)]^+$ and $[Co(5\text{-nitroSalen})(PBu_3)]^+$, and it seems that this donor is better solvated, and it reduces the overall enthalpy (Tables 1–8). The importance of this factor is better seen in the entropy.

The entropy

The $\Delta S°$ value and its sign, is also dependent on two factors: one of these factors is the difference in the number of the particles of the initial substances and the product complexes. The second factor is the liberation of the solvent molecules from the solvation shells (20). Concerning the first factor, the entropy change is decreased while the second factor is increased, but the net entropy change in most cases is negative, and it shows that the first factor is more important. The entropy change for trimethyl- and triethylphosphite properly decreases with increasing stability constant and indicates that the first factor is more important (Tables 5–8). For example, the entropy changes of $P(OMe)_3$ toward the acceptors are related to the stability constants for these systems and with increasing complex formation, the entropy change is decreased. The more negative entropy change for $P(OMe)_3$ in Table 6 is related to the higher stability constant for this system. The entropy change for triisopropylphosphite is governed by the second factor i.e., the libration of the solvent molecules, and it is less negative and is sometimes positive, although the stability constants are larger than the others. For example, the entropy change for $[Co(Salen)(PMe_2Ph)]^+$ complex with $P(O\text{-}i\text{-}Pr)_3$ is positive (Table 6), although the complex formation is the highest.

Conclusion

In this work, efforts were made to provide a quantitative measure of Schiff base effect on the acceptor property of Co(III) in some cobalt(III) Schiff base complexes, such as $[Co(Salen)(PBu_3)]^+$, $[Co(Salen)(PMe_2ph)]^+$, $[Co(5\text{-nitroSalen})(PBu_3)]^+$, and $[Co(Salpd)(PBu_3)]^+$, through adduct formation with $P(OMe)_3$, $P(OEt)_3$, and $P(O\text{-}i\text{-}Pr)_3$ in acetonitrile. The stability constants and the thermodynamic parameters obtained have showed the following trend of acceptor property of theSchiff-base complexes: 5-nitroSalen > Salen > Salpd.

Calculations on the electronic structure and nonlinear second-order susceptibilities of fulleropyrrolidine–tetrathiafulvalene(C_{60}PY–TTF) based on donor–bridge–acceptor dyads

Wei Fu, Hong-Xing Zhang, Ji-Kang Feng, and Wei Li

Abstract: The semiempirical INDO calculations were carried out to investigate the charge-transfer interaction and to evaluate the second-order nonlinear susceptibilities for a series of fulleropyrrolidine–tetrathiafulvalene(C_{60}PY–TTF) dyads, C_{60}PY, and C_{60}PY-$(CH{=}CH)_n$-TTF (n = 0–6). The equilibrium geometries, electronic structures, and UV–vis spectra of these C_{60}PY–TTFs D–B–A dyads were determined by using ZINDO methods. On the basis of electronic spectra, we calculated the β for the dyads using the ZINDO-SOS expression, and found that these dyads have relatively large β. The calculated values of β are 48.78, 62.34, 97.90, 123.24, 183.78, 189.43, 193.45, 195.82 × 10^{-30} esu for C_{60}PY and C_{60}PY-$(CH{=}CH)_n$-TTF (n = 0–6), respectively, which shows the enhancing effect when TTF is introduced. The β significantly increases as n increases from 0–3; and it tends to be saturated in the end.

Key words: ZINDO-SOS, CI, structure, spectra, C_{60}PY–TTF.

Résumé : On a effectué des calculs semi-empiriques INDO dans le but d'étudier l'interaction de transfert de charge et pour évaluer les susceptibilités non linéaires du deuxième ordre, β, d'une série de dyades fulléropyrrolidine–tétrathiafulvalène (C_{60}PY–TTH), le C_{60}PY et des C_{60}PY-$(CH{=}CH)_n$-TTF (n = 0 à 6). Utilisant des méthodes ZINDO, on a déterminé les géométries d'équilibre, les structures électroniques et les spectres UV–vis des dyades C_{60}PY–TTF D–B–A. Sur la base des spectres électroniques et faisant appel à une expression ZINDO-SOS, on a calculé la valeur β pour les dyades et on a trouvé que ces dyades ont des valeurs de β relativement élevées. Les valeurs calculées pour β sont respectivement de 48,78, 62,34, 97,90, 123,24, 183,78, 189,43, 193,45, 195,82 × 10^{-30} esu pour le C_{60}PY et les C_{60}PY-$(CH{=}CH)_n$-TTF (n = 0 à 6); ces valeurs mettent en relief une augmentation de la valeur de β à l'introduction du TTF et une augmentation progressive de β lorsque n passe de 0 à 3 alors que la valeur devient alors saturée.

Mots clés : ZINDO-SOS, CI, structure, spectre, C_{60}PY–TTF.

Introduction

Over the past two decades, interest has increased tremendously in nonlinear optical phenomena because of potential applications both in scientific and technological areas (1–4). Growing attention has been paid to the design and synthesis of novel organic molecules with large second-order optical nonlinearities for the sake of their possible applications in optical signal processing, optical computing, and telecommunications (5). Recent results suggested that molecule-based organic nonlinear optical (NLO) materials possess many superior NLO characteristics, such as ultrafast response times, low dielectric constants, good processability characteristics, and enhanced nonresonant NLO response (6). The existence of a donor–π-acceptor (D–π-A) structure in a molecule has been identified as the most prominent molecular feature in the search for high molecular second-order NLO susceptibilities (β) (7–9). A variety of hyperpolarizable D–π-A organic molecules containing various acceptor units (7–9) such as nitro, cyano (10), sulfonyl, polycyanovinyl (11–13), babituric acid (14), or dianonium salts (15) and donor units (6–8) mainly diarylamines, alkoxyaryl groups, ferrocene (16, 17), 1,3-dithionle ring (10–13), or the TTF (18–20) have frequently been reported. In spite of these varieties of chromophores used, seeking more efficient donors, acceptors, and conjugating moieties still tempts researchers for the NLO compounds (21, 22).

Fullerenes, in particular the readily available C_{60} and C_{70}, are famous highly spherical delocalized π electron systems, that are expected to be excellent and potential electron acceptors in artificial photosynthesis influencing substantially the electron transfer process because of their symmetrical shape, large size, properties of the π-conjugated electron system, and high electron affinity (2.7 ± 0.1 eV) (23–25). Associating with appropriate electron donors through π-conjugated bridges, efficient NLO fullerene compounds are hopefully to be developed.

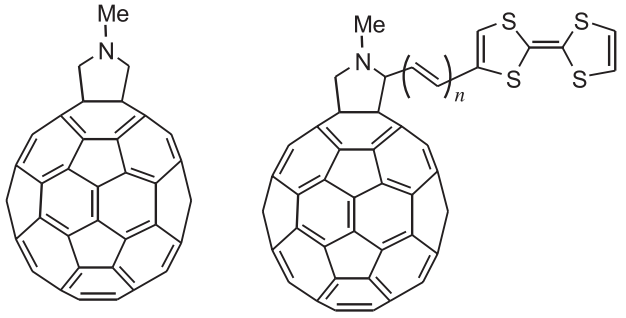
Among the electron donors in NLO compounds, TTF dyads are intriguing candidates due to their high conjugation and strong ability to donate electrons. Some conventional organic TTF compounds exhibit satisfactory second-order NLO properties (19, 20). Thus, at an initial qualitative level, the relatively large nonlinear optical responses of the TTF-derived chromophores are anticipated; they are reminiscent of traditional organic π-chromophoric units, in that TTF donor is linked through a π-conjugated moiety with a C_{60}-type acceptor. In fact, C_{60}PY-(CH=CH)$_n$-TTF (n = 0, 1) have been synthesized (26) and weak electron transfer from TTF to C_{60} has been observed. We expect that C_{60}PY–TTF dyads may have good NLO properties, which stimulates the present theoretical investigation.

The semiempirical INDO (intermediate neglect of differential overlap) calculations were carried out to investigate the charge-transfer interaction and to evaluate the β for a series of C_{60}PY–TTF dyads as shown in Fig. 1. The equilibrium geometry, electronic structure, and UV–vis spectra of these C_{60}PY–TTFs based on D–B–A dyads are determined by using ZINDO methods. The UV–vis spectra results were calculated by the INDO-CI method. On the basis of electronic spectra, the β values for the dyads were evaluated by using the ZINDO-SOS expression. The results show that the calculated values of β are 48.78, 62.34, 97.90, 123.24, 183.78, 189.43, 193.45, 195.82 × 10^{-30} esu for C_{60}PY and C_{60}PY-(CH=CH)$_n$-TTF (n = 0–6), indicating the significant increase when TTF was introduced.

Theoretical method



A quantitative description of molecular NLO response is derived from a power series expansion of the molecular polarization upon interaction with an oscillating external electromagnetic field (eq. [1]).

$$[1] \qquad P_i = \sum_j \alpha_{ij} E_j + \sum_{j\geq k} \beta_{ijk} E_j E_k + \sum_{j\geq k\geq l} \gamma_{ijkl} E_j E_k E_l + \ldots$$

Here, P_i is the molecular polarization induced along the ith axis, E_j is the jth component of the applied electric field, α is the linear polarizability, β is the first hyperpolarizability or the second-order susceptibility, and γ is the second hyperpolarizability or the third-order susceptibility. α, β, and γ describe the responsivity of the molecule to an electromagnetic perturbation and are constants for a given molecular geometry and external electromagnetic field. The β and γ are responsible for second- and third-harmonic generation respectively.

Several theoretical approaches for accurate calculation of β have been developed. Ab initio CPHF computations are numerically more accurate and precise, however, the results are not easily amenable to chemical interpretation and require substantial allocations of computational resources. Computationally intensive methods such as coupled Hartree–Fock (27), derivative Hartree–Fock (28), and correlated wave (29) ab initio procedures are applicable to molecules of only limited size (30). In contrast, the semiempirical-SOS method permit a basic understanding of origin of the NLO response in a chemical sense, by identifying the molecular excited states primarily responsible for NLO response within the SOS formalism. The

ZINDO-SOS method is of proven reliability in the description of molecular nonlinear optical properties (31*a–f*), many successful studies (17, 23, 25, 30, 32*a–c*) demonstrated that the ZINDO-SOS-derived nonlinear optical responses to be in agreement with the experiment. The second-order susceptibilities (25, 33*a–c*) and third-order susceptibilities (23, 32*c*, 34*a–c*) of dozens of molecules have been reported in our previous work. The sum-over-states (SOS) expression for the individual components of the second-order susceptibility tensor has been given from perturbation theory (35, 36):

$$[2] \qquad \beta_{ijk} + \beta_{ikj} = \frac{1}{4h^2} \left\{ \sum_{\substack{n\neq n' \\ n\neq g \\ n'\neq g}} (r^j_{gn'} r^k_{n'n} + r^k_{gn} r^i_{n'n} r^j_{gn}) \times \right.$$

$$\left(\frac{1}{(\omega_{n'g} - \omega)(\omega_{ng} + \omega)} + \frac{1}{(\omega_{n'g} + \omega)(\omega_{ng} - \omega)} \right) +$$

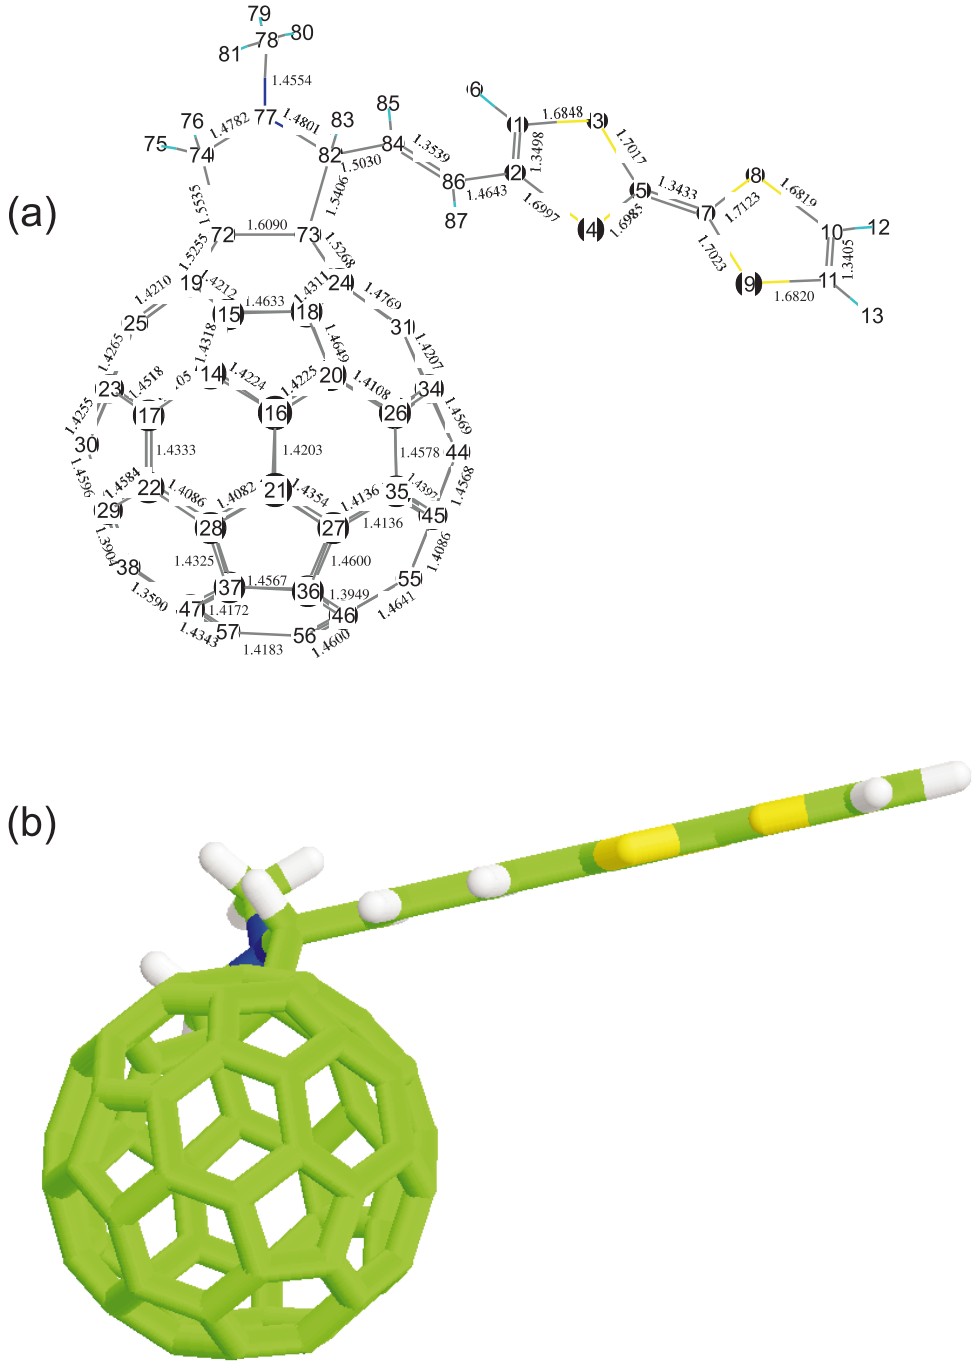
$$(r^i_{gn} r^j_{nn} r^k_{gn} + r^i_{gn'} r^k_{nn} r^j_{gn}) \times$$

$$\left(\frac{1}{(\omega_{n'g} - 2\omega)(\omega_{ng} - \omega)} + \frac{1}{(\omega_{n'g} + 2\omega)(\omega_{ng} + \omega)} \right) +$$

$$(r^j_{gn'} r^k_{n'n} r^i_{gn} + r^k_{gn'} r^j_{n'n} r^i_{gn}) \times$$

$$\left(\frac{1}{(\omega_{n'g} - \omega)(\omega_{ng} - 2\omega)} + \frac{1}{(\omega_{n'g} + \omega)(\omega_{ng} + 2\omega)} \right) +$$

$$4 \sum_n \left\{ \left[r^j_{gn} r^k_{gn} \Delta r^i_n (\omega^2_{ng} - 4\omega^2) + \right. \right.$$



$$\left. r^i_{gn} (r^k_{gn} \Delta r^j_n + r^j_{gn} \Delta r^k_n)(\omega^2_{ng} + 2\omega^2) \right] \times$$

$$\left. \left. \left(\frac{1}{(\omega^2_{ng} - \omega^2)(\omega^2_{ng} - 4\omega^2)} \right) \right\} \right\}$$

Where the summations are over the complete sets of eigenstates $|n>$ and $|n'>$ of the unperturbed molecular system. The quantities $r^i_{gn'}$ and $r^i_{nn'}$ are matrix elements of the ith components of the dipole operator between the unperturbed ground and excited states and between the two excited

states, respectively; $\Delta r_n^i = r_{nn}^i - r_{gg}^i$ is the difference between the excited-state and ground-state energies. Although all 27 components of the β tensor can be computed, only the vector component in the dipolar direction (β_μ) is sampled by electric field-induced second-harmonic generation (EFISH) experiments. β_μ is given by

$$[3] \qquad \beta_\mu = (\mu_x\beta_x + \mu_y\beta_y + \mu_z\beta_z)/(\mu_x^2 + \mu_y^2 + \mu_z^2)^{1/2}$$

where

$$[4] \qquad \beta_i = \beta_{iii} + 1/3\sum_{i\neq j}(\beta_{jii} + \beta_{iji} + \beta_{iij}) \qquad i, j \in (x, y, z)$$

The all-valence ZINDO technique (37) was employed to provide the transition dipole moments and the transition energies needed in the SOS expressions (eq. [2]). Standard parameters and basis functions were used. In the computation of a series of C_{60}PY–TTF dyads, the 290 low-energy transitions between SCF and MECI electronic configurations were chosen to undergo CI mixing. The 290 states were found to be sufficient for effective convergence of the SOS procedure.

Results and discussion

Geometric structure

By using the INDO/2 (included in ZINDO package) method, the geometries of dyads **1**–**8** (shown in Fig.1) were optimized. The same method has previously been employed to obtain the equilibrium geometry of C_{60} where R_{6-6} = 1.3979 Å and R_{5-6} = 1.4507 Å (32*c*) compared with R_{6-6} = 1.40 Å, R_{5-6} = 1.45 Å in the NMR experiment (38). The optimized structure for C_{60}PY–TTF is shown in Fig. 2 with molecule **3** as an example and its bond lengths are comparable with that of C_{60}. A pyrrolidine ring is fused with a 6,6-ring junction of C_{60} (see Fig. 2*a*). By the addition reaction, the C_{72}—C_{73} bond becomes a single bond with 1.6090 Å of bond length compared with 1.614 Å in ((3,4-dimethoxyphenyl)methano) fullerene (39). The single bond (C_{72}—C_{73}) has a bond order of 0.9539 from the INDO/2 calculation. C_{72}—C_{73} is protruded from C_{60} sphere (see Fig. 2*a*), which causes all the surrounding C—C bonds to be stretched. For example, the C_{72}—C_{19} bond distance is 1.5255 Å, the C_{73}—C_{24} distance is 1.5268 Å, and in the pyrrolidine portion C_{74}—C_{72} is 1.5535 Å and C_{82}—C_{73} is 1.5406 Å. For the other bond in the C_{60} part, as it is farther and farther from the C_{72}—C_{73} bond, its bond length changes less and less compared with that of C_{60}. For molecule **3**, the calculated eight C—S bonds distances are between 1.68–1.72 Å, compared with C—S 1.714 Å (40) for tetrahydrothiophene. For the pyrrolidine part, the calculated C_{74}—N_{77}, C_{82}—N_{77}, and C_{78}—N_{77} distances are 1.4782, 1.4801, and 1.4554 Å, respectively, (see Fig. 2*a*), which are comparable with 1.467 Å of the N—C standard single bond (41). The INDO calculation showed that the distance from C_{35} to the center of the C_{60} sphere is 3.698 Å, longer than 3.5477 Å in the original C_{60}, calculated at the same level.

The lateral figures of molecule **3** are shown in Fig. 2*b*, which indicates that the TTF fragment and methine bridge are coplanar.

UV–vis spectra

The calculated wavelength and oscillator strength of the UV absorptions for dyads **1**–**8** are listed in Table 1 with the experimental values and the results of C_{60} listed for comparison. Figure 3 shows a brief diagram for the calculated absorption of molecule **3** as an example. The UV–vis spectra of dyads **1**–**8** retains the main electronic feature of C_{60}. For both series of C_{60}PY–TTF dyads and C_{60} spectra, the UV region absorption is dominant. For these C_{60}PY–TTF dyads, there are three strong absorption peaks near 213–219, 236–240, and 247–250 nm corresponding to those of 213, 236, and 250 nm for C_{60} (32*c*), and in consistence with 211, 227, and 256 nm for the experiment (43), respectively. From molecule **2**–**8**, the 213–219 nm absorption tends to red-shift and the oscillator strength increases. In the latter molecular orbital analyses of molecule **4**, we can find that the absorption band, which has strong oscillator strength that will certainly enhance the second-order nonlinearity, originates from the mixing of TTF with C_{60}PY.

Because of the interaction between the C_{60}PY and TTF parts, the weak absorptions above 410 nm become significant for the C_{60}PY–TTF dyads, while there are no absorptions in the original C_{60} over the 410 nm region. The

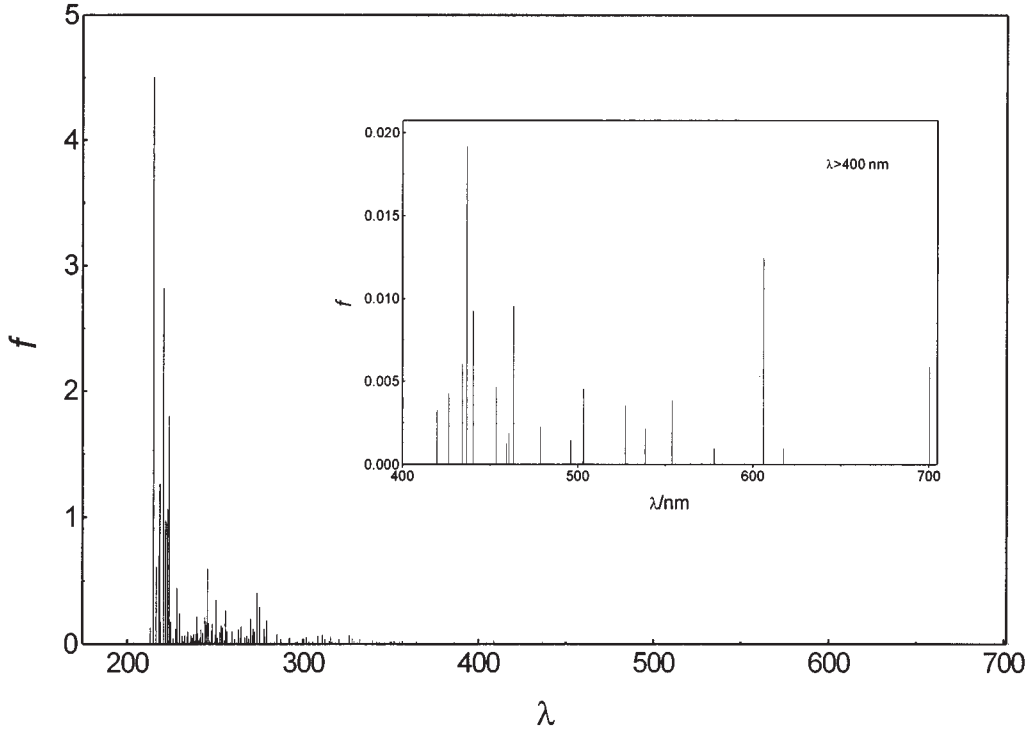
Fig. 3. The UV–vis spectrum of molecule **3**.



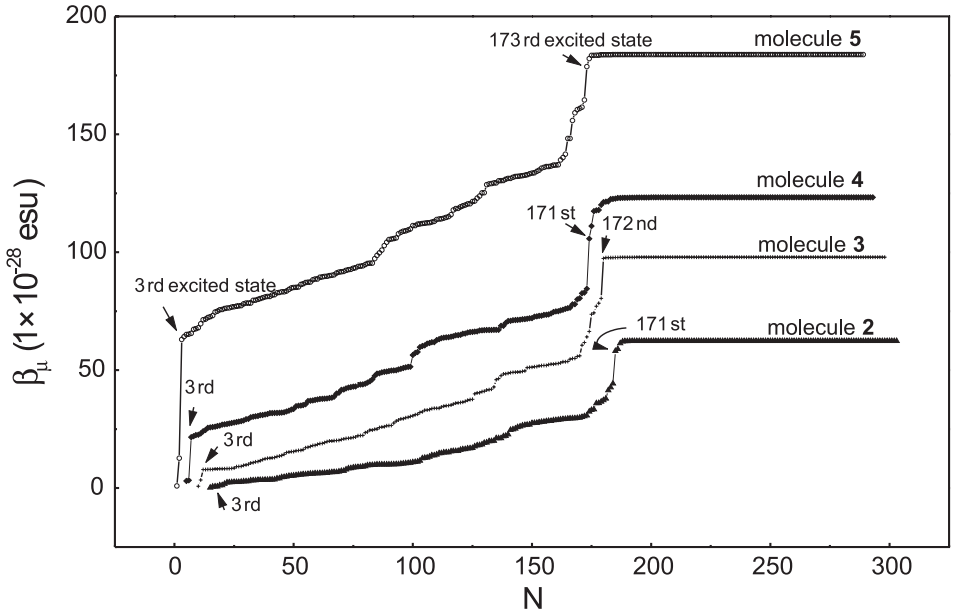


Fig. 4. β values plotted against numbers of excited states for molecules **2**–**5**.

characteristic absorption peaks of C_{60}PY–TTF dyads are in the region over 410 nm, and shown in Table 1. For molecule **3**, the absorption band over 410 nm was amplified and inserted in Fig. 3. There are three new absorption bands at 700–730 nm (except molecule **1** at 599.5 nm and molecule **2** at 639.0 nm), 592–640 nm, and 429–431 nm. Among them, the 429–431 nm absorption band owns relatively large oscillator strength and is consistent with the observed band in the 430 nm region for molecules **1**–**3**.

The lowest energy absorptions at 599.5, 639.9, 700.3, 722.7, 724.3, 725.6, 726.0, and 728.4 nm for dyads **1**–**8** comes from the electron transitions from HOMO to LUMO and relate with the forbidden absorption of C_{60} at 558.3 nm (35). The addition of pyrrolidine destroys the spherical conjugated π-electron structure of C_{60} and makes the *Ih* symmetry of C_{60} broken, so the forbidden absorption in C_{60} appears and shifts to 599.5 nm in C_{60}PY. When the TTF fragment is introduced, the 639.0 nm absorption significantly red-shifts

8	6.26	195.82	152.77
C_{60}–AN_{cal} (25)		32.17	
C_{60}–AN_{exp} (44)		67 ± 20	

(700.3 nm) further. As the length of the methine bridge *n* increases (from 1 to 6), this absorption red-shifts from 700.3 to 728.4 nm and the oscillator strength increases also. We analyzed the component of this absorption band and found that the methine bridge and TTF fragment play important roles for molecules **3**–**8** but not for molecule **2**. Therefore, the lowest energy absorption of molecules **3**–**8** gets more significant red-shift than molecule **2** due to the charge transfer from the C_{60} part to the methine bridge. The 592–640 nm absorption originates from the charge transfer from TTF to C_{60}, which is illustrated in the latter discussion section of NLO properties, and this absorption band significantly contributes to the second-order susceptibility. The 429–431 nm absorption corresponds to the observed band in the 430 nm region for molecules **1**–**3**. Taking molecule **3** as a representative, the absorption at 429–431 comes from the transition from HOMO-4 to LUMO+8. The component on the C_{60} part is dominant for HOMO-4 and LUMO+8. Therefore, this absorption comes from the electron transfer on the three-dimensional conjugative sphere of C_{60}.

NLO properties

On the basis of the optimized geometric structures and electronic spectra, the nonlinear second-order optical susceptibilities β_{ijk} and β_μ were calculated by using the ZINDO-SOS method.

In the SOS expression (eq. [2]) for β, the summation is over the complete sets of eigenstates $|n>$, $|m>$, and $|q>$ of the unperturbed system. They have to be truncated in practical calculations (17) for feasibility. In eq. [2], the dominator of each term includes ω_{ng} and $\omega_{n'g}$. When *n* and *n*′ increase, the energy differences between the ground state and the excited states will increase, i.e., the denominator will increase more and more. It means the contribution for β will become less important when *n* and *n*′ reach a certain value. Li et al. (25) demonstrated that 197 excited states were found to be sufficient for effective convergence for C_{60} (35). We considered that the series of C_{60}PY–TTF dyads are more complicated than C_{60}, so it is necessary to include 290 configurations in the calculations of β. Figure 4 illustrates the relationship between the number of the excited states involved and the values of β_μ (ω = 1.064 μm), which indicates that β_μ converges when the number of excited states exceed 190. The converged β_μ is simplified as β. The values of β relate to ω, the laser field frequency. ω is taken at 1.064 μm located at the nonresonant region (see the discussion about dispersion in the latter section). The converged values of β are listed in Table 2 where the β_0 corresponds to ω = 0. The calculated (25) and experimental (44) values of C_{60}–aniline (C_{60}–AN) are listed in Table 2 for comparison. Table 2 also shows that $\beta_8 \sim \beta_7 \sim \beta_6 \sim \beta_5 > > \beta_4 > \beta_3 > \beta_2 > \beta_1$. As we expected, the inclusion of TTF makes β increase significantly compared with C_{60}–pyrrolidine, then enhances the second-order NLO response. In accordance with the traditional organic chromophore designing guidelines, the greater electron delocalization in the C_{60}PY–TTF structures leads to the larger second-order NLO responses. For example, as the length of the bridge in the C_{60}PY–TTF molecules increases (see dyads **2**–**8**), the calculated response increases from 62.34 to 97.90, 123.24, 183.78, 189.43, 193.45, and 195.82×10^{-30} esu for β, respectively. It shows that β trends to be saturated as $n > 3$, which is in accordance with the effect of conjugation length on β for many traditional organic push–pull π-conjugated molecules (30, 34, 45).

Figure 4 illustrates the β accumulations up to 290 excited states for molecules **2**–**5**. While molecules **6**–**8** have the same characteristics as molecule **5**. As shown in Fig. 4, the first several excited states and the excited states around the 171st make main contributions to β.

In 1975, Oudar (2, 3) developed the famous two-level approximation as shown below

$$[5] \qquad \beta_\mu = \frac{3e^2\hbar}{2m} \frac{Wf\Delta\mu}{[W^2 - (2\hbar\omega)^2][W^2 - (\hbar\omega)^2]}$$

Where ω is the frequency of the laser field, $W = \hbar\omega_n$ is the transition energy from ground state to a specific excited state *n*, *f* is the oscillator strength of the transition, and Δμ is the difference of dipole moments between the excited state and ground state. Equation [5] clearly indicates the contribution of an excited state to β.

In the low-lying excited states, the third excited state plays important roles as shown in Fig. 4. The third excited state for molecules **2**–**5** lies at 592.2, 605.9, 611.6, and 638 nm with oscillator strength of 0.0037, 0.0125, 0.0231, and 0.0436, respectively, that comes from the electron transfer from HOMO-2 to LUMO. From eq. [5], the contribution of the third excited states to β should follow the order **5** > **4** > **3** > **2**, even though the contribution for molecule **2** is too small to notice due to the small oscillator strength, which shows clearly in Fig. 4. The component on the C_{60} part is dominant for the LUMO orbitals of the above four molecules. The HOMO-2 orbital is shown in Fig. 5 which demonstrates that the component on the C_{60} part is dominant for the HOMO-2 orbital of molecule **2** but the HOMO-2 orbitals of molecules **3**–**5** contain a significant contribution of methine bridge, while molecule **5** also contains the contribution from the TTF fragment. Maybe this is why the absorption peak generated from the third excited state red-shifts (Table 1) from molecule **2** to **5**. According to the two-level approximation formula (eq. [5]), the contribution of the third excited state to β is 0.129, 5.896, 20.248, and 58.818×10^{-30} esu for molecules **2**–**5**, respectively. The difference in Mulliken charge (ΔQ) between the ground state and the third excited

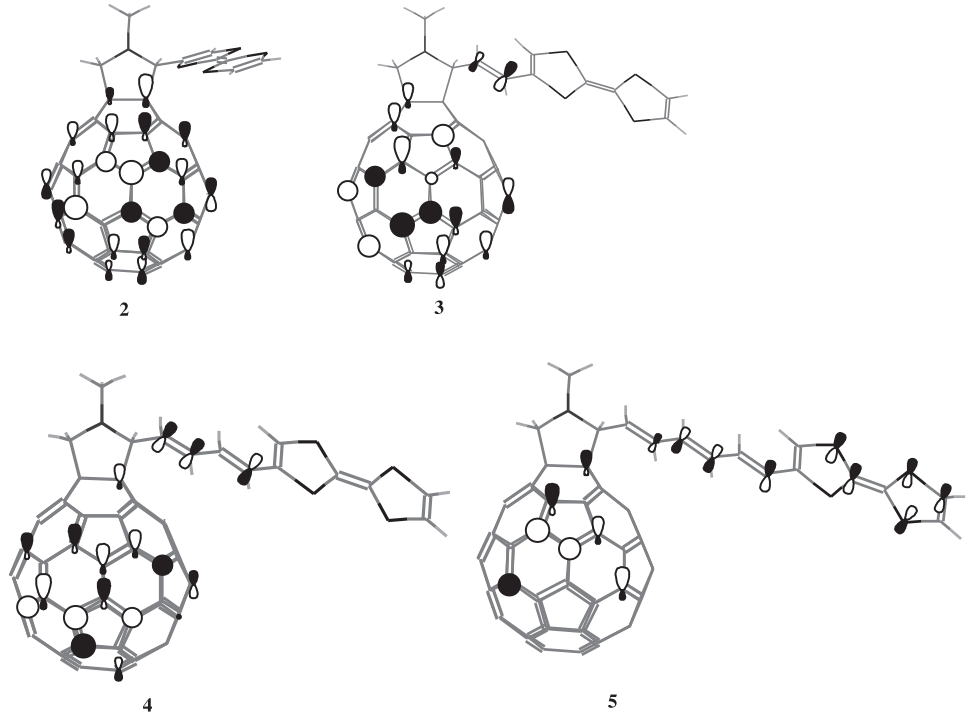

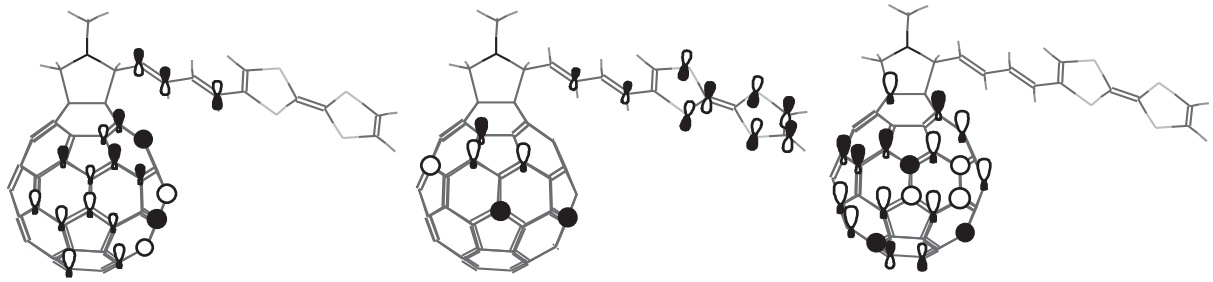

Fig. 6. Frontier orbital of molecule **4**.

state is listed in Table 3 for molecules **2**–**5** which indicates the charge transfer increase from molecule **2** to **5**, consistent with the traditional point of view that the larger charge transfer enhances. We noticed that the contribution to β from the low-lying excited band for molecule **5** is much more considerable, because of the relatively strong charge transfer from TTF to C_{60} through the methine bridge for molecule **5** (as shown in Table 3). Molecules **6**–**8** are similar to molecule **5**, since they have the similar excited state structure and transition properties in both low-lying and high-lying excited states, with molecule **5**.

Now let us examine the 171st, 172nd, 171st, and 173rd excited states which induce absorption at 213.0, 214.7, 216.6 and 219.4 nm in the high-energy excited band of molecules **2**–**5**, respectively, that evidently contribute to β. We have analyzed the component of these absorptions and found that they are similar. Taking molecule **4** as an example, the 216.6 nm absorption of molecule **4** comes from the mixing of electron transition from HOMO-11 to LUMO+11; HOMO-10 to LUMO+3, LUMO+4, LUMO+5, LUMO+11; and HOMO-5 to LUMO+12. The weight of these six transitions is 5.8, 25.6, 8.9, 10.2, 12.9, and 6.9%, respectively. Among them, the component on the C_{60} part is dominant for HOMO-10, LUMO+3, LUMO+4, LUMO+5, LUMO+11, and LUMO+12 orbitals, while the HOMO-5 orbital contains the contribution of the ethylene bridge and the HOMO-11 orbital contains the contribution of the TTF fragment. The LUMO+11, HOMO-5, and HOMO-11 orbitals are shown in Fig. 6, which shows that the transition from HOMO-11 to LUMO+11 is equivalent to the electron transfer from TTF to C_{60}, and the other transitions are equivalent to the electron transfer on the three-dimensional conjugation sphere of C_{60}; they were regarded as the source of the second-order NLO susceptibility. In the molecules involved, these absorptions are very strong and do have much larger oscillator strength than other absorptions. With reference to the two-level approximation (eq. [5]), these excited states should overwhelmingly contribute to β and the same conclusion is indicated in Fig. 4.

As mentioned above, the important excited state that evidently contributes to β for molecule **2**–**5**, contains not only the low-lying excited states but also the high-lying excited

ones. The contribution of the low-lying excited states increase as the number of methine bridges increase from 0 to 3, therefore, $\beta_5 > \beta_4 > \beta_3 > \beta_2$. The calculated results indicate that the contribution of low-lying excited states on β of molecule **6**–**8** is similar to that of molecule **5**. Therefore, $\beta_8 \sim \beta_7 \sim \beta_6 \sim \beta_5$, showing a saturation phenomenon of the π-conjugation length. In the conventional π-conjugated push–pull polyenes, one anticipates an enhancement in the β value with an increase in π-conjugation length between the electron-donation and electron-withdrawing groups. The relationship between the π-conjugation bridge length and NLO response has been discussed in several publications (46–49).

It is known from above analyses that the series of C_{60}PY–TTF dyads have different sources of NLO response compared with conventional push–pull organic conjugation molecules. As usual, the low-energy excited state controls the NLO response of the molecule for conventional push–pull organic conjugation molecules. In most cases, the first excited state inducing the transition from HOMO to LUMO controls the NLO response of molecule and there is no strong absorption in high-energy excited states, so β will soon converge with the number of excited state increasing. But there are strong absorptions for C_{60}PY–TTF dyads in the high-lying excited states that significantly contribute to β. The contribution to β in low-energy excited states increases as the number of ethylene bridges increase. The significant charge transfer will take place when $n > 3$ (n is the number of ethylene bridges). Unfortunately, only molecule **2** and **3** ($n = 0$, $n = 1$) were synthesized in the experiment and weak electronic transfer was observed in the IR region, which is in accordance with our calculated results.

To compare the differences between C_{60}PY–TTF dyads and conventional organic compounds, with -CHO and two-cyanovinyl groups substituting C_{60} in C_{60}PY–TTF dyads, we designed molecules **9** and **10** (see Fig. 7) and calculated their UV–vis spectra and β using the ZINDO-SOS method.

[a]Calculated by ourselves by ZINDO-SOS method.
[b]As described in ref. 20 by FF–PM3 method.
[c]As described in ref. 20 by EFISH experiment.

Fig. 9. The relationship between β and different electric field frequencies for molecule **3**.

The calculated and observed values of these molecules are listed in Table 4.

Table 4 shows that the spectra and β of molecules **9** and **10** are in accordance with observed values and calculated values by Lucas et al. (20). This indicates that the ZINDO method is applicable to the TTF system. Figure 8 shows the β accumulation with excited states up to 50 for molecule **10**. It can be seen that the first excited state that induces the 615 nm absorption controls the NLO response and the β converges after 20 excited states. It confirms our analyses. Lucas et al. (20) showed that molecules **9** and **10** are considered excellent NLO materials with big β. Table 4 also lists the β of molecule **3**, which has a similar structure to molecules **9** and **10** and has a higher β than that of molecules **9** and **10**.

Taking molecule **3** for example, we have examined the dispersions of the β (see Fig. 9). Figure 9 displays the calculated dispersion curve for β (–2ω; ω, ω) of molecule **3** as a function of frequency (ω). The calculated data can be extrapolated to zero static quantity β (0; 0,0). We take ω = 1.064 μm (1.17 eV) in all calculations, and it is in the nonresonant area.

Conclusion

The semiempirical INDO calculations were carried out to investigate the charge-transfer interaction and to evaluate the second-order susceptibilities (β) for a series of C_{60}PY–TTF dyads. The calculated values of β are 48.78, 62.34, 97.90, 123.24, 183.78, 189.43, 193.45, 195.82 × 10^{-30} esu for C_{60}PY and C_{60}PY-(CH=CH)$_n$-TTF (n = 0–6), respectively, which shows a dramatic increase when TTF was introduced. The second-order NLO response not only comes from the contribution of the low-lying excited states but also comes from that of the high-lying ones. The NLO properties of C_{60}PY–TTF dyads can mainly be attributed to the result of electron transfer on the three-dimensional conjugation sphere of C_{60} and the electron transfer from TTF and the methine bridge to the C_{60} part. Finally, we compared the result of C_{60}PY–TTF dyads with conventional organic compounds, which were similar to the structure of C_{60}PY–TTF dyads, and found that the second-order nonlinear optical susceptibilities of C_{60}PY–TTF dyads were much higher.

^{1}H NMR studies of proton transfer equilibria in hydrogen bonds — the role of the entropy

Roland Langner and Georg Zundel

Abstract: The influence of the entropy on the proton transfer equilibria AH···B ⇄ A$^-$···H$^+$B in the dimethylphosphinic acid (DMP)-*N*-base and in the methanesulfonic acid (MSA)-*N*-oxide hydrogen bonds is studied by ^{1}H NMR spectroscopy as a function of the ΔpK_a, i.e., the pK_a of the base minus the pK_a of the acid. It is shown that with increasing ΔpK_a the proton transfers to the N-oxide acceptor. In the DMP + N-base family of systems, first the double-minimum proton potentials ($\Delta H = 0$) occurs and only with further increasing ΔpK_a do the POH···N ⇄ PO$^-$···H$^+$N equilibria become symmetrical ($\Delta G = 0$). ΔG and ΔH are connected by the Gibbs–Helmholtz equation, $\Delta G = \Delta H - T\Delta S$. Hence, the reason of this effect is the large negative interaction entropy term (ΔS_I) arising from the large order around the polar structure, which shifts the equilibria strongly to the left-hand side. With the MSA-*N*-oxide hydrogen bonds a single-minimum proton potential was found. The minimum shifts with increasing ΔpK_a from the donor to the acceptor of the O···H$^+$···N hydrogen bonds. It is shown that with increasing ΔpK_a the proton potential becomes on average symmetrical, whereas the proton is still largely on the left-hand side. This result is also explained by the large negative interaction entropy due to the order of the environment if the proton is at the acceptor B.

Key words: entropy, hydrogen bonds, infrared, spectroscopy, proton transfer.

Résumé : Utilisant la spectroscopie RMN du ^{1}H en fonction du ΔpK_a, c'est-à-dire du pK_a de la base moins le pK_a de l'acide, on a étudié l'influence de l'entropie sur l'équilibre de transfert de proton AH···B ⇄ A$^-$···H$^+$B dans les liaisons hydrogènes entre l'acide diméthylphosphinique (DMP) et le N d'une base et entre l'acide méthanesulfonique (MSA) et un azote, sous la forme d'oxyde d'azote. On a montré qu'une augmentation du ΔpK_a conduit à un transfert de proton vers l'oxyde d'azote qui agit comme accepteur. Dans la famille de systèmes DMP + N-base, on observe au début un double-minimum des potentiels de protons ($\Delta H = 0$); l'équilibre POH···N ⇄ PO$^-$···H$^+$N ne devient symétrique ($\Delta G = 0$) qu'en augmentant le ΔpK_a encore plus. Les ΔG et ΔH sont liés par l'équation de Gibbs–Helmholtz, $\Delta G = \Delta H - T\Delta S$. On peut en conclure que cet effet est causé par un terme d'entropie d'interaction négative, ΔS_I, qui est très élevé et qui découle d'un ordre très important autour de la structure polaire qui déplace fortement l'équilibre vers la gauche. Avec les liaisons hydrogènes MSA – oxyde d'azote on n'a observé qu'un seul minimum. Les minima se déplacent avec une augmentation des ΔpK_a du donneur vers l'accepteur des liaisons hydrogènes O···H$^+$···N. On a montré qu'avec une augmentation du ΔpK_a, le potentiel des protons prend déjà une forme moyenne qui est symétrique même si le proton est encore principalement vers la gauche. On peut aussi expliquer ce résultat par la présence d'une entropie d'interaction fortement négative qui résulte de l'environnement si le proton se trouve au niveau de l'accepteur B.

Mots clés : entropie, liaisons hydrogènes, infrarouge, spectroscopie, transfert de proton.

[Traduit par la Rédaction]

Introduction

Acid-base equilibria (AH···B ⇄ A$^-$···H$^+$B) play an important role with all proton transfer processes. According to Huyskens et al. (1, 2), families of systems in which proton transfer occurs are characterized according to the following definitions: (*i*) all systems of a family have the same hydrogen bond donor (AH) and all acceptors (B) are also similar molecules; they only differ with regard to the pK_a of B; or (*ii*) the acceptor (B) is always the same and the donors (AH) are similar molecules, which differ only in their pK_a values. The ΔpK_a is defined as pK_a of the acceptor (B) minus the pK_a of the donor (AH) (1, 2).

The pK_a values of the donor and acceptor groups can be in the region of –2 to 10, i.e., such equilibria occur with very acidic as well as with strongly basic systems (3, 4). In systems with higher pK_a of the donors and acceptors, double-minimum proton potentials are present in the AH···B ⇄ A$^-$···H$^+$B hydrogen bonds. In systems with lower pK_a, broad flat single-minima occur in the A···H$^+$··B bonds (4). The enthalpy of the proton transfer process is represented by ΔH. When $\Delta H = 0$, both wells of the double-minimum proton potential are energetically equivalent. The free enthalpy of the proton transfer process is represented by ΔG. When $\Delta G = 0$, the nonpolar and the polar proton limiting structures have the same weight.

In this study we investigate the importance of the interaction entropy (ΔS_I) for equilibria with either a typical double-minimum or a typical broad flat single-minimum proton potential family. The double-minimum family (6) are the dimethylphosphinic acid (DMP, pK_a = 3.8) + N-base systems with POH···N ⇄ PO$^-$···H$^+$N hydrogen bonds, and the broad flat single-minimum proton potential systems are the methanesulfonic acid (MSA, pK_a = –1.92) + N-oxide systems with SO···H$^+$···ON hydrogen bonds (7, 8). In the following, we compare the shape of the proton potential (double-minimum or broad flat single-minimum) with the position of the proton transfer equilibrium (50% proton transfer, i.e., symmetrical distribution of the proton in the hydrogen bonds).

Experimental

The chemicals of the highest available purity were purchased from Fluka or Aldrich. Dimethylphosphinic acid was synthesized as described by Reinhardt et al. (9). Diethylphosphinic anhydride was synthesized by heating dimethylphosinyl chloride with dimethylphosphinic acid ethyl ester under release of ethyl chloride (10). While the first component was obtained by chlorination of the acid with phosphorous pentachloride, the second component was obtained by a conversion of the acid chloride with sodium ethoxide. Diethylbenzylamine was synthesized by nucleophilic aliphatic substitution of benzyl chloride with diethylamine in boiling acetonitrile (11).

The methanesulfinic acid (0.9% water) was dried with a well-defined amount of its anhydride; a 3% excess of anhydride was added to avoid water traces arising from the complex preparation.

The N-oxides were dissolved several times in dry ethanol, followed by removal of the solvent. The bases were recrystallized from dry ethanol.

2,6-Dichloropyridine-*N*-oxide, 2,5-dichlorophyridine-*N*-oxide, 3,5-dichloropyridine-*N*-oxide, 2-chloropyridine-*N*-oxide, 3-chloropyridine-*N*-oxide, and 3-bromopyridine-*N*-oxide were synthesized by direct *N*-oxidation of the substituted pyridine with peroxotrifluoracetic acid with heating (12, 13). 2-Cyanopyridine-*N*-oxide was synthesized by the same procedure, using peroxoacetic acid (12, 13). 4-Chloropyridine-*N*-oxide was synthesized by the reaction of 4-nitropyridine-*N*-oxide with a tenfold excess of acetylchloride with ice cooling, followed by hydrolysis with ice water (14). 4-Dimethylaminopyridine-*N*-oxide was synthesized by nucleophilic aromatic substitution of 4-chloropyridine-*N*-oxide with an aqueous solution of dimethylamine in an autoclave at 150°C (14). Triethylamine-*N*-oxide was synthesized by direct *N*-oxidation of triethylamine with hydrogen peroxide (15). All preparations and transfers of the solutions were performed in a water-free glove box.

Results and discussion

The shape of the proton potential can be determined considering the wavenumber dependence of the intensity of the IR continua (4). The IR continua that extends from 3000 cm^{-1} toward smaller wavenumbers demonstrate that double-minimum proton potentials are present, whereas IR continua in the region 1600–600 cm^{-1} prove the existence of broad flat single-minimum proton potentials in the hydrogen bonds.

The dimethylphoshinic acid + N-base family of systems

Considering the shape and wavenumber distribution, as well as the intensity of the IR continua, it was shown in ref. 4 that on average the dimethylphosphinic acid + 1-methylmorpholine system displays a largely symmetrical double-minimum proton potential for the OH···N ⇄ O$^-$···H$^+$N hydrogen bonds. The ΔpK_a value of the system when ΔH = 0 amounts to 4.3 (4).

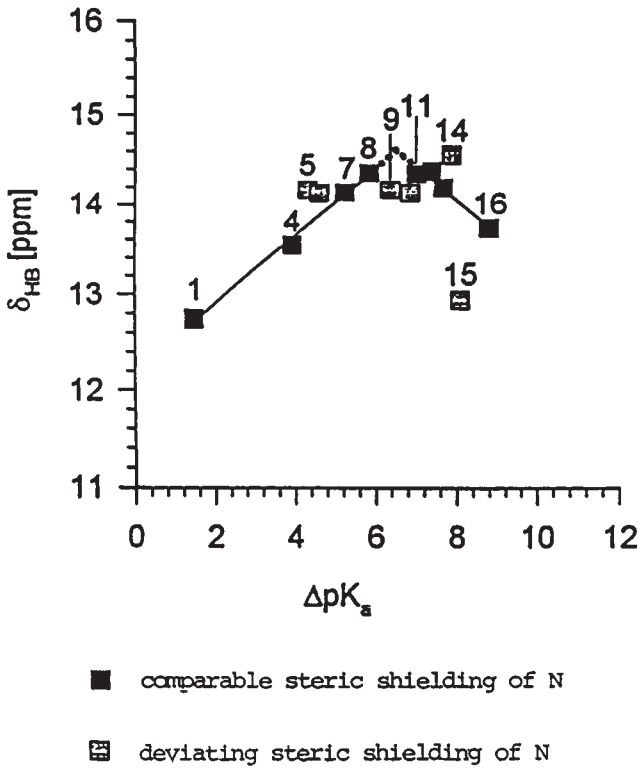
The position of the proton transfer equilibria can be determined from the IR bands (5, 6) or by NMR spectroscopy (5). With this family of systems the IR bands are often strongly masked by the IR continua, therefore, we determined the equilibria using NMR spectroscopy (Table 1). Figure 1 shows the NMR results as a function of the ΔpK_a value. The δ_{HB} values scatter strongly,and therefore, it seems that no precise information can be obtained. An analysis of the data shows, however, that a systematic course is found if one considers only the systems with N-bases having a relatively low and comparable shielding screening of the nitrogen atoms (systems 1, 4, 7, 8, 11–13, 16), indicating that the chemical shift of the proton is also influenced by sterical effects. The points of these systems (black squares) are on straight lines with a cross section at ΔpK_a = 6.5 ± 0.5. Thus, in these DMP + N-base systems 50% proton transfer occurs at ΔpK_a = 6.5 ± 0.5.

In ref. 6 we have seen that with this family of systems the double-minimum proton potential is on average symmetrical (ΔH = 0) with the DMP + 1-methylmorpholine system. The ΔpK_a of this system is 4.3 ± 0.5. Thus, with this family of systems both wells are energetically equivalent with the ΔpK_a = 4.3 ± 0.5 system. As shown above, with this family of systems only 50% proton transfer ($\Delta G°$ = 0) is found with ΔpK_a = 6.5 ± 0.5. Thus, with increasing ΔpK_a of the N-bases (ΔpK_a = 4.3 ± 0.5) the double-minimum proton potential becomes on average symmetrical (ΔH = 0), whereas the 50% proton transfer, i.e., symmetry with regard to the proton transfer equilibrium (ΔG = 0), is reached with ΔpK_a = 6.5 ± 0.5, i.e., with a system with a N-base with higher pK_a.

This result can easily be explained considering the Gibbs–Helmholtz equation. The quantities in this equation can be split (16):

$$-\Delta G = \ln K_{PT} = -\frac{\Delta H_0 + \Delta H_I}{RT} + \frac{\Delta S_0 + \Delta S_I}{R}$$

Herewith the intrinsic quantities ΔH_0 and ΔS_0 describe the behavior of the systems in gas phase. The extrinsic terms ΔH_I and ΔS_I take into account the influence of the environment. In the case of the AH···B ⇄ A$^-$···H$^+$B equilibria in liquids, Onsager's reaction field (17, 18) strongly influences the position of these equilibria. The solvate structure becomes more or less ordered and this order increases the weight of the polar structure A$^-$···H$^+$B. This order results in the large negative entropy values, shifting the equilibria strongly to the left-hand side.



If ΔH = 0, the proton potential is on average symmetrical, i.e., both wells of the double-minimum proton potential are energetically equivalent. The negative ΔS value, however, causes the equilibria be to strongly shifted to the left-hand

side. Thus, with increasing ΔpK_a, initially the proton potential becomes on average symmetrical ($\Delta H = 0$) and with further increasing ΔpK_a the proton transfer equilibrium becomes symmetrical ($\Delta G = 0$). The large interaction entropy term (ΔS_I) arising from the strong order of the solvent around the polar structure is responsible for this effect.

The methanesulfonic acid + N-oxide family of systems

We have considered a family of systems with double-minimum proton potentials. In the following we discuss a family with single-minimum proton potentials: the methanesulfonic acid (MSA) + N-oxide family of systems. All systems studied are summarized in Table 2. The pK_a value of methanesulfonic acid is –1.92 (19). In ref. 8 we have shown that single-minimum proton potentials are present in the $SO\cdots H^+\cdots ON$ hydrogen bonds of these systems. In the case of small ΔpK_a values a relatively narrow single-minimum is present at the donor. With increasing pK_a of the N-oxide, i.e., upon increasing ΔpK_a, this minimum not only shifts in the direction of the acceptor but also becomes very broad and flat. The systems now show large proton polarizability. In system 5 (MSA + 3,5-dichloropyridine-*N*-oxide) the IR continuum is most intense and extends the most toward smaller wavenumbers. From ref. 8 it is known that this system is the system with the most symmetrical proton potential and the largest proton polarizability. The ΔpK_a of this systems amounts to 0.98. The NMR results in Fig. 2 show, however, that the hydrogen-bonded proton is most deshielded in system 11 (MSA + 4-chloropyridine-*N*-oxide). Hence, in the system with the $\Delta pK_a = 2.25$ the hydrogen-bonded proton is equally distributed between the donor and the acceptor. Thus, also with this family of systems, upon increasing the ΔpK_a, first the proton potential becomes on average symmetrical and at systems with higher ΔpK_a values the proton is equally distributed between the donor and the acceptor.

This result is also explained by entropy (*S*). With increasing the ΔpK_a the structures become more polar, and hence, their environments become more ordered. Thus, the amount of the negative entropy increases, shifting the proton in the direction of the donor.

10	MSA + 3-chloropyridine-*N*-oxide	1.79	16.74
11	MSA + 4-chloropyridine-*N*-oxide	2.25	16.81
12	MSA + pyridine-*N*-oxide	2.71	—
13	MSA + 4-phenylpyridine-*N*-oxide	2.75	16.75
14	MSA + 4-methylpyridine-*N*-oxide	3.21	16.51
15	MSA + 4-methoxypyridine-*N*-oxide	5.80	14.40
16	MSA + 4-dimethylaminopyridine-*N*-oxide	5.80	14.40
17	MSA + 1-ethylmorpholine-*N*-oxide	—	12.39
18	MSA + triethylamine-*N*-oxide	7.05	12.32

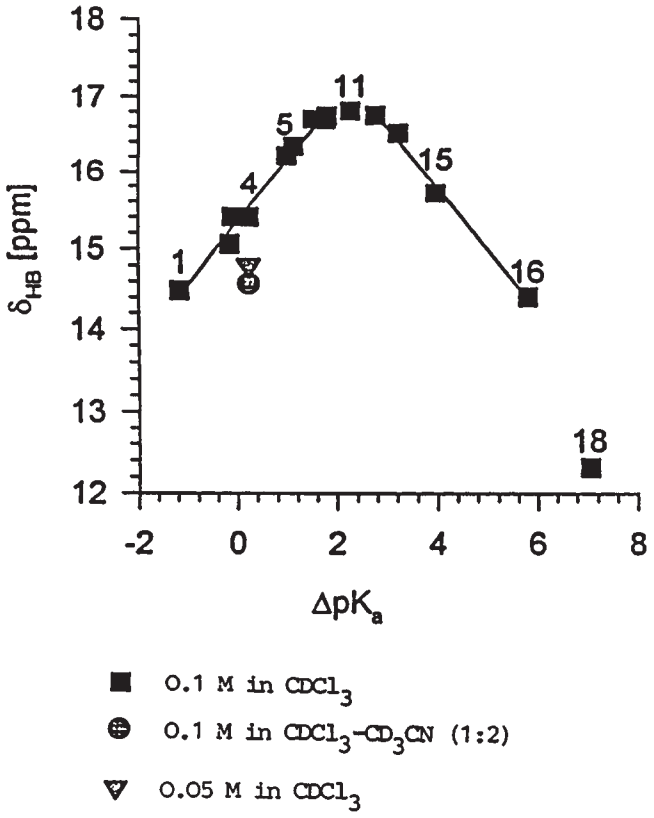

Fig. 2. Chemical shift of the hydrogen-bonded proton as a function of the ΔpK_a value of the MSA + *N*-oxide 1:1 complexes. For numbering of systems see Table 2. At 20°C (0.1 M in $CDCl_3$): (■) 0.1 M in $CDCl_3$; (⊜) 0.1 M in $CDCl_3$–CD_3CN (1:2); (▽) 0.5 M in $CDCl_3$.

Conclusions

With increasing the ΔpK_a of the dimethylphosphinic acid-*N*-oxide systems the double-minimum proton potential first becomes symmetrical ($\Delta H = 0$) and then with further increasing the ΔpK_a the $OH\cdots ON \rightleftarrows O^-\cdots H^+ON$ equilibrium becomes symmetrical ($\Delta G = 0$). The large negative interaction entropy term (ΔS_I) is responsible for this result, which is caused by the large order of the solvent around the polar structure.

A similar result is obtained for the family of the methanesulfonic acid-*N*-oxide systems. In these systems very strong $O^-\cdots H^+\cdots ON$ hydrogen bonds with single-minimum proton potential are present. With increasing the ΔpK_a the proton potential first becomes symmetrical, very broad, and flat. With further increasing the ΔpK_a the distribution of the proton in the hydrogen bonds becomes symmetrical. Again, the entropy interaction is responsible for this effect.

Reanalysis of the biotransformation of 4(20),11(12)-taxadiene derivatives

Di-An Sun, Françoise Sauriol, Orval Mamer, and Lolita O. Zamir

Abstract: Reanalysis of the biotransformation of 4(20),11(12)-taxadiene derivatives by *Absidia coerulea* ATCC 10738a unravelled additional unprecedented rearrangement reactions. 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11(12)-taxadiene (**1**) was converted to 10 new minor taxane derivatives in addition to the previously reported C-1, C-14-hydroxylations and C-15-hydroxylated *abeo*-taxane. In addition, 2-deacetoxytaxinine J (**2**) was successfully metabolized with the same fungi.

Key words: natural products, terpenes and terpenoids, microorganism, oxygenation, rearrangement.

Résumé : Une étude approfondie de la biotransformation des dérivatifs du 4(20),11(12)-taxadiene par *Absidia coerulea* ATCC 10738a a décelé des produits additionnels provenant de réarrangement chimiques. Le 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11(12)-taxadiene (**1**) a été converti en 10 nouveaux dérivés de taxane minoritaires en plus des hydroxylations en C-1, C-14 et de la formation d'un 15-hydroxy-*abeo*-taxane déjà publiés. De plus, le métabolisme du 2-deacetoxytaxinine J (**2**) par le même microorganisme est décrit.

Mots clés : produits naturels, terpènes et terpénoides, microorganisme, hydroxylations, réarrangements chimique.

Introduction

Continuing investigation of the biotransformation of taxane derivatives has shown that a minor variation in the structure can lead to substantially different products (1–16). Substitution patterns of 4(20),11(12)-taxadiene derivatives as well as incubation conditions led to different metabolites. It was reported (4) that a C-5 cinnamoyl group in taxanes, such as 2-deacetoxytaxinine J, taxinine J, taxinine, prevented their metabolism with various microorganisms. We have recently found (17) that when 2-deacetoxytaxinine J is deacetylated at C-7, C-9, and C-10, it is readily biotransformed despite the presence of the C-5-cinnamoyl group. Differently substituted taxanes were metabolized to a taxane with a C10-C11 double bond or unprecedented 1(15→11)*abeo*-taxanes (18). The microbial transformation of 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11(12)-taxadiene with *Absidia coerulea* was reported (4) to give high yields of C-1 (39%) and C-14 (26%) hydroxylation products. In addition, these authors (4) found that 2-deacetoxytaxinine J, which differs from the previous substrate by a cinnamoyl on C-5 instead of an acetyl, could not be metabolized by 25 collected fungi including *A. coerulea* (12).

In this publication, we have reevaluated the metabolism of 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11(12)-taxadiene and found additional products, some of them with unprecedented or rare functionalities, albeit in very low yields. In addition, we succeeded in hydroxylating 2-deacetoxytaxinine J at C-1 (7% yield) and at C-14 (12% yields) with *A. coerulea* ATCC 10738a along with two minor products.

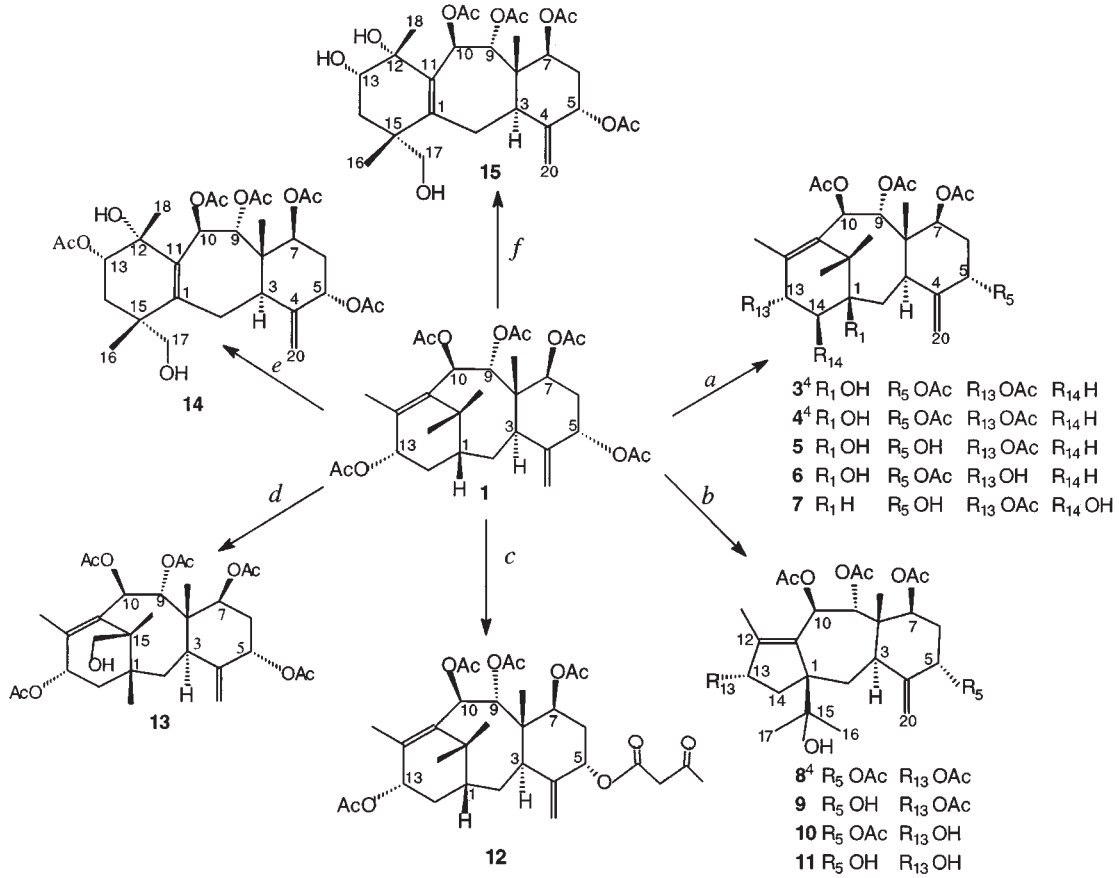
Results and discussion

Substrates, fungi, incubation conditions



The substrate **1** (4, 19, 20) was obtained by semisynthesis from 2-deacetoxytaxinine J (21) by decinnamoylation (22) followed by acetylation. The fungi used in this work was obtained from ATCC and might slightly differ from the Chinese strain used by previous workers (4, 6, 7). The media used for the growth of the culture is also different (6, 7). The isolation and purification of the taxanes obtained from incubation of the substrates **1** and 2-deacetoxytaxinine J (**2**) with *A. coerulea* ATCC 10738a involved chromatographic techniques (flash and thin layer) as well as preparative HPLC.

Characterization of taxanes 3–7 (Scheme 1)

As expected from previous results (4), incubation of the substrate **1** with *A. coerulea* ATCC 10738a led to C-1-hydroxylation, taxane **3**, C-14-hydroxylation, taxane **4** as well as the *abeo*-taxane **8**. Their NMR and mass spectra data

 DOI: 10.1139/cjc-79-9-1381 © 2001 NRC Canada

Scheme 1. Microbial transformation products and yields of taxane **1** by fungi *A. coerulea* ATCC 10738a. (*a*) Yield (%): taxane **3** (9.9), taxane **4** (7), taxane **5** (1.4), taxane **6** (0.3), taxane **7** (0.2). *(b)* Yield (%): taxane **8** (3.1), taxane **9** (0.1), taxane **10** (0.2), taxane **11** (0.3). *(c)* Yield (%): taxane **12** (0.8). *(d)* Yield: taxane **13** (0.2). *(e)* Yield: taxane **14** (0.4). *(f)* Yield (%): taxane **15** (0.1).

were identical to the literature values (4). In addition, taxanes **5**–**7** were isolated. The ^{1}H NMR data of taxanes **5** and **3** (4) are very similar except for the chemical shift of H-5. The chemical shift of H-5 in taxane **5** is shielded compared to taxane **3** (4.27 vs. 5.36 ppm), suggesting the presence of an acetoxy group in **3**. The respective FAB-HRMS data for both compounds confirm that indeed taxane **5** is 7β,9α,10β,13α-tetraacetoxy-1β,5α-dihydroxy-14(20),11(12)-taxadiene. Similarly, taxane **6** differs from **3** (4) only in H-13, which is attached to an OH instead of an acetoxy group. The structure of **6** is therefore 5α,7β,9α,10β-tetraacetoxy-1β,13α-dihydroxy-4(20),11(12)-taxadiene. The NMR data of taxane **7** differ from the known taxane **4** (4) only in H-5. Here too, we see a deacetylation at C-5 (H-5 of **7** 4.27 ppm whereas 5.36 ppm for **4**). The structure of taxane **7** is 7β,9α,10β,13α-tetraacetoxy-5α,14β-dihydroxy-4(20),11(12)-taxadiene.

Characterization of 11(15→1)*abeo*-taxanes 8–11 (Scheme 1)

The 11(15→1)*abeo*-taxanes isolated were easily characterized because they differed from the known compound **8** (4) by a deacetylation at C-5 (taxane **9**), C-13 (taxane **10**), and at C-5 and C-13 (taxane **11**). The NMR data as well as the FAB-HRMS confirm these results. The structure of taxane **9** is therefore 7β,9α,10β,13α-tetraacetoxy-5α-hydroxy-11(15→1)*abeo*-4(20),11(12)-taxadiene. The structure of taxane **10** is 5α,7β,9α,10β-tetraacetoxy-13α-hydroxy-11(15→1)*abeo*-4(20),11(12)-taxadiene and of taxane **11** is 7β,9α,10β-triacetoxy-5α,13α-dihydroxy-11(15→1)*abeo*-4(20),11(12)-taxadiene.

Characterization of taxane 12 with an unprecedented β-keto-butyrate substitution at C-5 (Scheme 1, Table 1)

The only difference between taxane **12** and taxane **1** is the replacement of an acetoxy group by the unusual O-CO-CH_2-CO-CH_3. This group is indicated by the presence of two deshielded proton resonances (3.65 and 3.47 ppm, J = 15.6 Hz) correlated to a single carbon (49.8 ppm) and an extra methyl singlet appearing at a shift characteristic of a methyl next to a ketone (2.30 ppm). The methylene protons shows HMBC correlations to two carbonyls: an ester and a ketone (165.7, 200.1), while the methyl group shows correlation to the ketone carbon. The positioning of that group at 5 is supported by the observation of long range NOE between the methyl-18 and the methylene protons. Such NOE is always observed between cinnamoyl group and methyl-18 due to the U-shape of the molecule. The other evidence is that all the protons of taxane **12** appear at very similar shifts from those of taxane **1** with the exception of H-5, which has a 0.08 ppm downshift of 5.46 ppm from 5.38 ppm of the taxane **1**.

[a]Multiplicity: br (broad), s (singlet), d (doublet), t (triplet), m (multiplet), o (overlapping). The precision of the coupling constants is ±0.25 Hz.
[b]The ^{13}C NMR chemical shifts were extracted from the HSQC and HMBC (for quaternary carbons) experiments (±0.2 ppm).
[c]NOESY intensities are marked as strong (s), medium (m), or weak (w).

Characterization of 16-hydroxylated taxane 13 (Scheme 1, Table 2)

The original four methyls in taxane **1** have been replaced by three methyl singlets and two doublet resonances at 3.70 ppm (11.6 Hz, 1H) and 3.19 ppm (11.6 Hz, 1H), suggesting the insertion of an oxygen in one of the methyls. The appearance of a resonance at 70.0 ppm in the ^{13}C NMR data of taxane **13** confirmed this structure. This new carbon is correlated to those two protons in the HSQC experiment confirming the presence of a CH_2OH group. To assign unambiguously which methyl was hydroxylated, the HMBC experiment was used. This experiment shows that the most deshielded methyl (2.25 ppm) can be assigned to methyl-18 as we observe correlations to the usual C-11, C-12, and C-13. In HMBC, we further note that the methyl appearing at 1.72 ppm can be assigned to methyl-17 as we observe correlations to C-1, C-11, and C-15. This methyl is further correlated to the new hydroxylated carbon (at 70 ppm) confirming that the hydroxylation took place on methyl-16. A correlation between the proton-16 at 3.19 ppm with carbon-11 further confirm the assignment. The NOESY experiment unambiguously determined that the hydroxylation is at 16. Indeed H-13 has a correlation with H-16a and H-16b as well as with H-18. It is interesting to note that this unprecedented hydroxylation on C-16 follows a report in our laboratory of a C-17-hydroxylation (18).

Characterization of taxanes 14 and 15 with an unusual core skeleton (Scheme 1)

The structure of the taxanes **14** and **15** has a very unusual rearranged core. Their structures were determined unambiguously using the usual 2D NMR approach as described below.

*Taxane **14** (Table 3)*

At first, the spectrum of taxane **14** is not that different from the one obtained for regular taxanes. We note the presence of three methyl singlets (more shielded than usual), an *exo*-methylene from H-20, the usual H-7 and H-5 coupled to the methylene protons H-6*a* and H-6*b* and the pair of doublets for H-9 and H-10 coupled together. On the A-ring, H-13 is coupled to the methylene assigned to H-14, as expected. The presence of an extra CH_2OH group is deduced from the

[a]Multiplicity: br (broad), s (singlet), d (doublet), t (triplet), m (multiplet), o (overlapping). The precision of the coupling constants is ±0.25 Hz.
[b]The ^{13}C NMR chemical shifts were extracted from the HSQC and HMBC (for quarternary carbons) experiments (±0.2 ppm).
[c]NOESY intensities are marked as strong (s), medium (m), or weak (w).

appearance of two protons (3.45 (d), 11.0 Hz and 3.20 (d) 11.0 Hz) correlated to a single carbon in the HSQC experiment (68.4 ppm). The most striking evidence that we are dealing with a very different structure derives from the HMBC experiment. The methyl appearing at 1.00 ppm can be assigned to methyl-19 as it is correlated to the usual C-3, C-7, C-8, and C-9. The greatest surprise came from the other two methyls, as neither of them is correlated to two olefinic carbons as would be expected from methyl-18.

Both of these methyls are correlated to different olefinic carbons. The methyl appearing at 1.15 ppm has been assigned to methyl-18 on the basis of its correlation to the hydroxylated C-13. This methyl is also correlated to an oxygenated quaternary carbon (C-12, 70.8 ppm) and to an olefinic quaternary carbon at 134.7 ppm. The other methyl, appearing at 1.09 ppm shows correlation to C-15 quaternary carbon (at 43.4 ppm), C-14 methylene carbon, the new CH_2OH group (68.4 ppm), and to another quaternary olefinic carbon (at 145.6 ppm). The 134.7 ppm olefinic carbon is also correlated to H-9, H-10, and H-2a, while the other olefinic carbon (145.6 ppm) is correlated to H-2a, H-10, and to the protons from the extra CH_2OH group. Such observations are only compatible with an olefinic double bond at the junction of ring A and B as shown on the structure in Scheme 1. The extra CH_2OH group is then assigned to C-17. The presence of an OH group on C-17 was confirmed by the observation of a coupling between the two H-17 protons and a hydroxyl group in an earlier spectrum.

The stereochemistry of that unusual compound can be deduced from the coupling constants and the NOESY experiment. A possible model is shown in Fig. 1. We will first consider the stereochemistry of rings B and C. The very large coupling constant observed between H-2a and H-3 (11.1 Hz) can be explained by a trans diaxial orientation of these two protons. The axial orientation of methyl-19 at the junction of ring B and C is confirmed by the strong NOE observed between H-2a and Me-19. The axial methyl 19 also has NOE with the axial proton H-6b and the equatorial proton H-9 (*cis* respect to Me-19). The lack of NOE between H-10 and Me-19 indicates a *trans* relationship between these two groups, which suggests that H-10 has a *trans* equatorial orientation. The *trans* diequatorial orientation of H-9 and

[d]The shifts and *J* value of 17a and 17b in another spectra are 3.45 dd (10.7, 3.2) and 3.2 dd (10.7, 7.3), respectively. In that spectra, the OH-17 is located at 1.46 dd (7.3, 3.2).

Fig. 1. Stereochemistry of the unusual taxane skeleton of **14** and **15**.

H-10 is supported by a smaller coupling between these two protons (6.6 Hz). The H-7 on the C-ring is in the axial orientation as can be deduced from the large coupling (11.2 Hz) with one of its H-6 neighbours. Due to the small couplings observed for H-5 with the neighboring methylenic protons H-6a/H-6b, this proton must be in the equatorial orientation. The NOE observed between H-3 and H-7 confirms their *cis*-α-orientation. For the A-ring, the NOE observed between the H-3α and the H-17a proton (3.45 ppm) suggests that the C-17 methylene group is in the α-orientation. The large NOE between the proton at position 13 (4.84 ppm) and the β-Me-16 supports a β-orientation. Finally methyl-18 is probably also β because of its large NOE with β-H-13. The NOE between methyl-18 and H-10 can be interpreted as an interaction between these pseudoequatorial Me-18 and H-10, which are spatially close.

*Taxane **15** (Table 4)*

This taxane is very similar to the previous one, the main difference being in the chemical shift observed for H-13, which is much more shielded (3.72 ppm) than in taxane **14** (4.84 ppm). This difference has been attributed to the fact that H-13 is now substituted by an OH group instead of an acetoxy.

Biotransformation of 2-deacetoxytaxinine J (Scheme 2)

We were surprised that the incubation of 2-deacetoxytaxinine J (**2**) with *A. coerulea* ATCC 10738a led to three products. Indeed, it had been reported that 2-deacetoxytaxinine J could not be metabolized by a Chinese species of *A. coerulea* (4).

In metabolite **16** (Table 5), H-1 (at 1.85 ppm) has disappeared and H-14a has a different pattern. It is now coupled to two protons instead of three (H-14a at 2.55 ppm dd,

	1.976 s	20.8

[a]Multiplicity: br (broad), s (singlet), d (doublet), t (triplet), m (multiplet), o (overlapping). The precision of the coupling constants is ±0.25 Hz.
[b]The ^{13}C NMR chemical shifts were extracted from the HSQC.

9.8 Hz, 14.9 Hz). Moreover, the chemical shift of H-14b is 1.52 ppm instead of 0.98 ppm for 2-deacetoxytaxinine J **2**. The most convincing evidence for the oxygenation at C-1 is the additional quaternary carbon at 75.6 ppm obtained from HMBC, where H-14ab, H-16, and H-17 correlate to this carbon. This value is in accordance with other C-1 β-hydroxylations (4, 18). The structure for taxane **16** is therefore 1-β-hydroxy-2-deacetoxytaxinine J. High resolution mass spectra confirmed the elemental composition of the sodiated quasimolecular ion of taxane **16**.

*Taxane **17** (Table 6)*

In the ^{1}H NMR data of taxane **17**, the resonances corresponding to 14a and 14b have disappeared, while an oxygen-bearing methine signal appeared at 3.52 ppm. Confirmation was obtained by the resonance at 79.2 ppm in the ^{13}C NMR (Table 6). The stereochemistry of the 14-hydroxyl group was determined to be β by the NOESY experiment. Indeed, H-14 correlated with H-3 and H-7 correlates with H-3. High resolution mass spectra confirmed the elemental composition of the sodiated quasimolecular ion of taxane **17**.

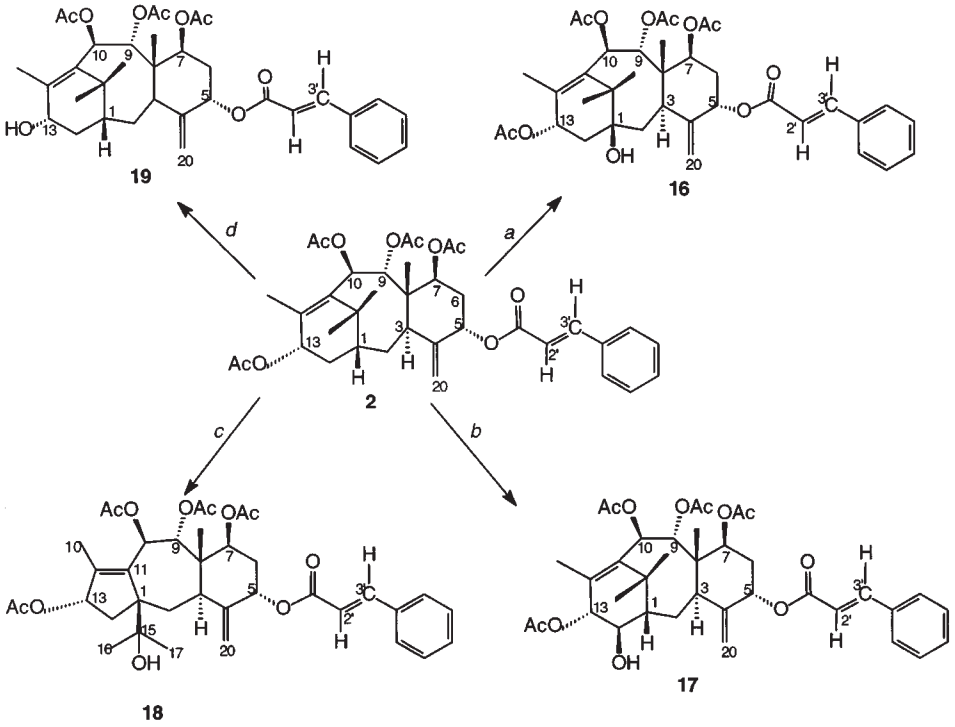
*Taxane **18** (Table 7)*

The ^{1}H NMR data of taxane **18** showed the presence of an *abeo*-taxane with four C-methyls (0.91, 1.11, 1.30, 1.95 ppm) and four acetyls (1.51, 1.97, 1.99, 2.07 ppm). The 11(15→1)-*abeo*-taxane structure was confirmed by the newly introduced carbon at 62.6 ppm and the carbon at 75.4 ppm which are attributed to C-1 and C-15, respectively. Additional HMBC correlations of the protons of Me-16/Me-17 (1.11 and 1.30 ppm) with C-1 (62.6 ppm) and C-15 (75.4 ppm), and Me-16/Me-17 (27.0 and 24.9 ppm) support this structure. The positioning of the other groups are very similar to the starting material; ie, a *trans*-cinnamoyl on C-5 and four acetyls on C-7, C-9, C-10, and C-13. The relative stereochemistry of taxane **18** was determined from the NOESY experiment. High resolution mass spectra confirmed the elemental composition of the sodiated quasimolecular ion of taxane **18**.

Taxane **19** is easily characterized as 13-deacetyl-2-deacetoxytaxinine J by comparison with the NMR data of the substrate 2-deacetoxytaxinine J. The detailed NMR data are described in the *Experimental* section. High resolution mass spectra confirmed the elemental composition of the sodiated quasimolecular ion of taxane **19**.

Experimental

Instrumentation



Flash chromatography was performed on Silica gel 60 (230–400 mesh EM Science). Thin layer chromatography was conducted on Silica Gel 60 F254 precoated TLC plates (0.25 mm, EM Science). The compounds were visualized on TLC plates with 10% sulfuric acid in ethanol and heating on a hot plate. Na_2SO_4 was the drying agent used in all work up procedures. Analytical HPLC was performed on a Waters 600 FHU delivery system coupled to a PDA 996 detector. Preparative and semipreparative HPLC were carried out on a Waters Delta Prep 3000 instrument coupled to a UV 486 Tunable Absorbance detector set at 227 nm (Waters, Montreal, Quebec, Canada). Analytical HPLC was performed with two Whatman partisil 10 ODS-2 analytical columns (4.6 × 250 mm) in series. Semipreparative HPLC was performed with two Whatman partisil 10 ODS-2 Mag-9 semipreparative columns (9.4 × 250 mm) in series. Preparative HPLC was performed with one partisil 10 ODS-2 MAG-20 preparative column (22 × 500 mm). The products were eluted with a 50 min linear gradient of acetonitrile (25–100%) in water at a flow rate of 18 mL min^{-1} (preparative HPLC) and 3 mL min^{-1} (semipreparative HPLC). All the reagents and solvents were of the best available commercial quality and were used without further purification.

NMR and mass spectrometry measurement

All the NMR data were obtained at room temperature on a Bruker Avance-500 spectrometer operating at 500.13 MHz for proton and at 125.77 MHz for carbon-13. The solvent $CDCl_3$ was used as an internal reference (7.25 ppm for proton and 77.0 ppm for carbon-13). The various 2D spectra were acquired and processed using standard procedures. For phase-sensitive 2D experiments (NOESY and HSQC), the data were acquired using the TPPI phase mode. The NOESY experiment was obtained using a mixing time of 0.3 s and a

Scheme 2. Microbial transformation products and yields of 2-deacetoxxytaxinine J by fungi *A. coerulea* ATCC 10738a. (*a*) Yield (%): taxane **16** (6.9). (*b*) Yield (%): taxane **17** (11.5). (*c*) Yield (%): taxane **18** (3.3). (*d*) Yield (%): taxane **19** (0.5).

relaxation delay of 1 s. The intensity of the cross-peaks in the NOESY experiment is designated as strong (s), medium (m), and weak (w). Positive ion fast atom bombardment mass spectra (FAB-MS) were obtained with a Vacuum Generators ZAB-HS double-focussing instrument using a xenon beam having 8 kV energy at 1 mA equivalent neutral current. Low-resolution mass spectra were obtained in glycerol. Samples were dissolved in 0.2 μL DMSO before addition of 0.5 μL glycerol. FAB-HRMS was similarly obtained in glycerol–DMSO at a resolving power of 12 000.

Substrates

The substrate 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11-taxadiene (**1**) (19, 20) was prepared from the acetylation of 2-deacetoxydecinnamoyltaxinine J (23–25). 2-Deacetoxydecinnamoyltaxinine J (**2**) was obtained from the cleavage of the cinnamoyl side chain of 2-deacetoxytaxinine J (**1**), following the procedure of Bathini et al. (22).

Since a detailed NMR data of the substrates are not available in the literature, we are reporting them here for comparison with the biotransformation products.

Incubation, biotransformation procedure

General

Cultures were grown in potato dextrose (24 g L^{-1}, DIFCO laboratories) broth, and was incubated at 25°C and 125 rpm, unless otherwise indicated. The *A. coerulea* ATCC 10738a was first preserved on silica gel and kept in a 4°C cold room to prevent mutation (26). The seed culture was prepared by the addition of several grains of silica gel that absorbed the fungus to 30 mL of medium in a 125 mL Erlermeyer flask. The culture was incubated for 3 days. At preparative scale, to a 2000 mL flask, containing 1000 mL potato dextrose broth, was added a small fraction of the above fungus seed (homogenized before use). The flasks were at first cultured for 3 days. Then to the flasks was added the substrate dissolved in DMSO and continued culturing for another 14 days. At the end of the incubation, the culture was homogenized and extracted with CH_2Cl_2. The CH_2Cl_2 extract was further purified. Culture controls with the same medium and substrate but without fungi were performed at the same conditions.

*For 5α,7β,9α,10β,13α-pentaacetoxy-4(20),11-taxadiene (**1**)*

To each of the three 2 L flasks containing 1 L of medium, was added 160 mg substrate (dissolved in 3 mL DMSO). After 14 days incubation, the culture was extracted with CH_2Cl_2 (500 mL × 3 for 1 L culture). The CH_2Cl_2 crude residue was 509 mg. The extract was first applied to a silica gel flash chromatography column (31 g), eluted with CH_2Cl_2 (300 mL), CH_2Cl_2–MeOH (400:1, 200:1, 150:1; 100:1, 100:1.5, 100:2, 100:3, 100:20 each 300 mL), and ninety 30 mL fractions were obtained. The fractions were combined into 14 fractions based on the TLC. Each of the above fractions were separated by preparative HPLC and finally the following compounds were obtained: **3** (48.8 mg, 9.9%), **4** (33.6 mg, 7%), **5** (6.3 mg, 1.4%), **6** (1.2 mg, 0.3%), **7** (0.7 mg, 0.2%), **8** (15.3 mg, 3.1%), **9** (0.3 mg, 0.1%), **10** (0.9 mg, 0.2%), **11** (1.4 mg, 0.3%), **12** (4.5 mg, 0.8%), **13**

Conclusion

Biotransformation reactions are still difficult to predict. In this work, we have seen that different results can be obtained by slight variations of the source of microorganisms or incubation conditions. Further experiments are in progress in our laboratory to correlate functional groups of a specific taxane with fungal chemical reactions.

Alkaline oxidative degradation of diphenylmethane structures — Activation energy and computational analysis of the reaction mechanism

Lubo Jurasek, Lívia Krištofová, Yujun Sun, and Dimitris S. Argyropoulos

Abstract: A diphenylmethane model compound (2,2′-methylenebis[6-methoxy-4-methylphenol]) and residual kraft lignin were treated with alkaline hydrogen peroxide. Kinetic data for the disappearance of the model and the diphenylmethane structures in the residual lignin was collected. The activation energies for the degradation were found to be similar (54 ± 11 kJ mol^{-1} for the model and 58 ± 5 kJ mol^{-1} for the residual lignin). A comparison of the activation energies with the data of a previous study on a biphenyl model compound (3,3′-dimethoxy-5,5′-dimethyl-[1,1′-biphenyl]-2,2′-diol) showed a substantially higher activation energy for the degradation of the latter. Pathways for the degradation of 2,2′-methylenebis[6-methoxy-4-methylphenol] were proposed and the intermediates subjected to computational analysis using a semiempirical method (PM3). The results suggest that initially a common pathway exists, resulting in 2-[2-hydroxy-3-methoxy-5-methyl-phenylmethyl]-4-methyl-2,4-hexadienedioic acid. Then the pathway branches into three, resulting in three major degradation products. The main driving force of the reactions is the formation of radical sites after reaction with hydroxyl radicals and subsequent radical coupling with perhydroxyl radicals to form peroxides. All the reactions on the pathways are exothermic except for the transformations of peroxides into dioxetanes. The dioxetanes cleave exothermically resulting in ring cleavage and fragmentation. The computed data permitted for the rationalization as to why the diphenylmethane structures appear to be more labile than biphenyl structures under alkaline oxidative conditions.

Key words: activation energy, alkaline oxidative degradation, computational chemistry, lignin, reaction mechanism.

Résumé : On a traité le 2,2′-méthylènebis[6-méthoxy-4-méthylphénol], un diphénylméthane modèle ainsi que de la lignine kraft résiduelle avec du peroxyde d'hydrogène en milieu alcalin. On a recueilli des données cinétiques relatives à la disparition du modèle et des structures diphénylméthane dans la lignine résiduelle. On a trouvé que les énergies d'activation pour la dégradation sont semblables (54 ± 11 kJ mol^{-1} pour le modèle et 58 ± 5 kJ mol^{-1} pour la lignine résiduelle). Une comparaison de ces énergies d'activation avec les données obtenues au cours d'une étude antérieure sur le 3,3′-diméthoxy-5,5′-diméthyl-[1,1′-biphényl]-2,2′-diol, un biphényle modèle, montre que l'énergie d'activation pour la dégradation de ce dernier est beaucoup plus élevée. Des voies réactionnelles sont proposées pour la dégradation du 2,2′-méthylènebis[6-méthoxy-4-méthylphénol] et on a soumis les intermédiaires à une analyse par calculs à l'aide d'une méthode semi-empirique (PM3). Les résultats suggèrent qu'initialement il existe une voie commune conduisant à la formation de l'acide 2-[2-hydroxy-3-méthoxy-5-méthyl-phénylméthyl]-4-méthylhexa-2,4-dièneedioïque. La réaction continuerait suivant trois voies qui conduiraient à trois produits différents. La force motrice principale des réactions est la formation de sites radicalaires après réaction avec des radicaux hydroxyles et le couplage radicalaire subséquent avec des radicaux perhydroxyles qui conduit à la formation de peroxydes. Toutes les réactions de chacune des voies réactionnelles sont exothermiques à l'exception des transformations des peroxydes en dioxétanes. Les dioxétanes se clivent d'une façon exothermique en provoquant des ouvertures de cycles et des fragmentations. Les données calculées permettent de rationaliser pourquoi, dans des conditions oxydantes en milieu alcalin, que les structures de type diphénylméthane semblent plus labiles que celles du type biphényle.

Mots clés : énergie d'activation, dégradation oxydante en milieu alcalin, chimie théorique, lignine, mécanisme réactionnel.

Introduction

Lignin is known to resist total degradation even under the severe conditions of kraft pulping, and only bleaching causes a substantial removal of residual kraft lignin from the fibre. Residual kraft lignin contains a significant amount of chromophoric structures such as biphenyl, diphenylmethane, α-5, and stilbene units (1–4). The process of formation of condensed structures in lignin during various alkaline pulping processes has been recently investigated (4), using quan-

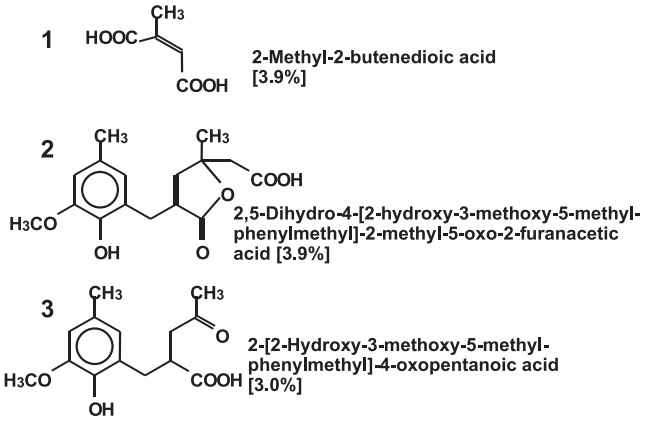

Fig. 1. Comparison of activation energies for the alkaline oxidative degradation of diphenylmethane structures in residual kraft lignin and in the model compound MMMP.

titative ^{31}P NMR spectroscopy. The cleavage of alkyl–aryl ether linkages during the kraft cook leads to the formation of new free phenolic hydroxyls and, consequently, their content in residual lignin as well as in soluble lignin increases during the cook (5). These cleavages lead to an enhancement of the content of condensed structures. Thus, it has been shown recently (4) that kraft pulping of milled wood lignin led to an increased content of stable biphenyl moieties, which eventually became an integral part of the residual kraft lignin structure. After Brunow and co-workers' (6) discovery of dibenzodioxocins in lignin, studies of their degradation under alkaline and kraft pulping conditions have shown conversion of dibenzodioxocins into phenolic alkylated biphenyl-type units within residual kraft lignin (7). Unlike biphenyl structures, which are present in native lignins and accumulate in residual lignin as other structures degrade, the diphenylmethane moieties are formed de novo by condensation of aromatic rings during soda or kraft pulping (4, 8), and analyses have shown that residual lignin in unbleached kraft pulp contains about 20% of diphenylmethane units (9).

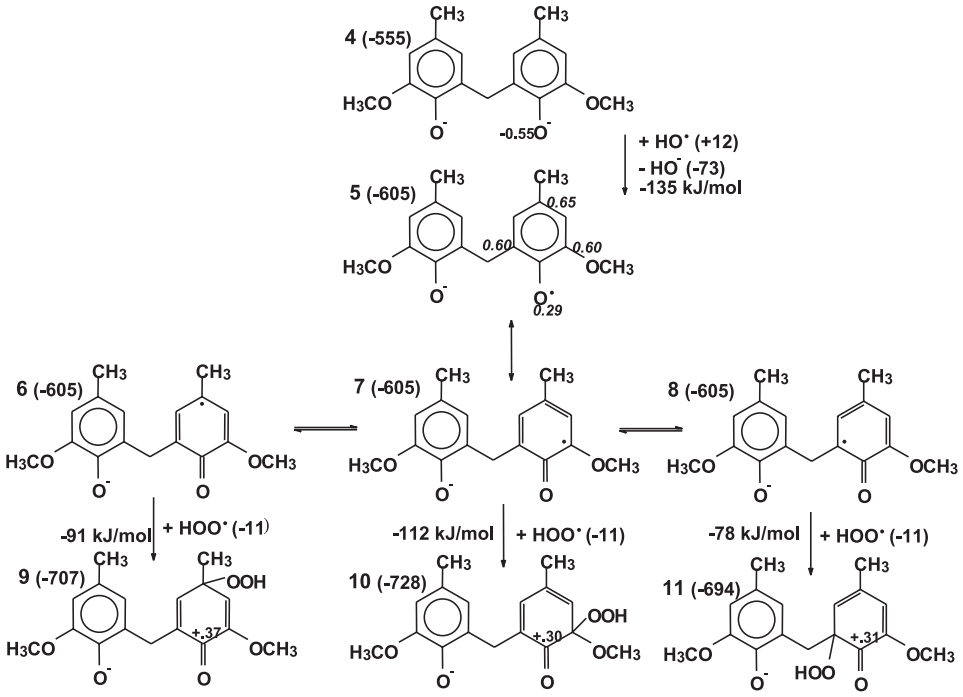
Residual lignin can be degraded by a variety of bleaching reactions using either chlorine compounds or chlorine-free chemistry. Interest in minimizing the content of chlorinated compounds in mill effluents prompted, among other measures, the development of totally chlorine-free (TCF) bleaching based on oxygen chemistry. One of the variants of TCF bleaching is an alkaline hydrogen peroxide treatment. The chemistry of this process has been studied earlier and reactions with both anions and radicals have been considered (10–12). The aromatic rings appear stable to hydroperoxide anions (13) but react with hydroxyl radicals (10), which are believed to be the principal species responsible for the oxidative degradation of lignin (14). An alternative mechanism has been proposed (15) for 2,2′-methylenebis[6-methoxy-4-methylphenol] (MMMP, protonated compound **4**) degradation, which involves a nucleophilic attack by hydroperoxide anion. Hydrogen peroxide reacts with lignin in two ways: (*i*) peroxyl anions (HOO^-) nucleophilically attack and eliminate lignin chromophores — these reactions are rapid and occur at low temperatures; (*ii*) hydroxyl radicals ($HO^{\cdot}$), superoxide radical anions ($OO^{\cdot -}$), or perhydroxyl radicals ($HOO^{\cdot}$), formed through the decomposition of hydrogen peroxide, oxidatively degrade phenolic structures into carboxylic acids. The radical reactions require higher temperature but lead to the scission of C—C bonds, fragmentation, and dissolution of lignin, and thus, to its removal from fibre.

Scheme 1. Degradation products of MMMP according to Sun et al. (18). The yields are in square brackets. These products may be formed by three different routes named butenedioate, furanacetate, and oxopentanoate pathways.

In our previous report (16) on the mechanism of alkaline oxidative degradation of a biphenyl-type model compound (3,3′-dimethoxy-5,5′-dimethyl-[1,1′-biphenyl]-2,2′-diol), we determined the activation energies for the degradation process and proposed various pathways. In the present effort, we focus on an analogous diphenylmethane model compound (MMMP) and on diphenylmethane structures in residual kraft lignin.

Results and discussion

Activation energy



The activation energy for the degradation of MMMP was determined to be 54 ± 11 kJ mol^{-1}, while that for the degradation of diphenylmethane structures in residual kraft lignin was 58 ± 5 kJ mol^{-1} (Fig. 1). The finding that the activation energies are not significantly different suggests that the reaction mechanisms of the degradation may be similar and that MMMP might mimic the behaviour of diphenylmethane structures in lignin. A comparison with our previous study (16) on the activation energy (117 kJ mol^{-1}) for the oxidative degradation of a biphenyl model compound (2,2′-dihydroxy-3,3′-dimethoxy-5,5′-dimethyl-[1,1′-biphenyl]-2,2-diol) shows a substantial difference. Thus, we are finding, in agreement with a previous report (17), that biphenyl structures are more stable in an alkaline oxidative environment and a higher temperature is needed to degrade them effectively. While the activation energies of MMMP and diphenylmethane moieties in lignin are very similar, the apparent rate constants (k_{app} in Fig. 1) are approximately three times lower for lignin than for MMMP.

Proposed mechanism of the oxidative degradation of diphenylmethane structures

The products of degradation of 2,2′-methylenebis[6-methoxy-4-methylphenol] (MMMP) under conditions similar to those used in this work were analyzed previously (18) and the main compounds were identified as shown in

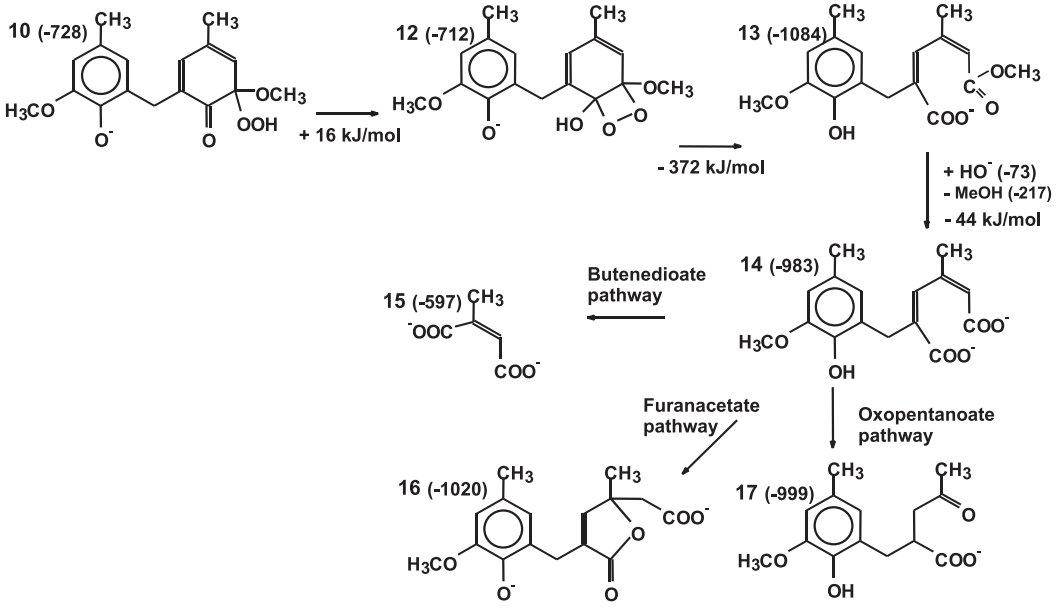
© 2001 NRC Canada

Scheme 2. First part of the common pathway starting with the anion **4** of the model compound (MMMP) leading (via radical mechanisms) to peroxide **10**. Heats of formation of the compounds are given in brackets in kJ mol^{-1}. All reactants were taken into account and computed heats of reactions are shown next to the arrows. Partial charges (underlined) and electron spin densities (in italics) are indicated on some atoms.

Scheme 1. The abundance of the three products was approximately equal (3 to 4%), and none are predominant. It should be noted that the yields reported by Sun et al. (18) and quoted here are based on the starting compound. However, the reaction mixture in which the products were identified still contained 53.3% of unreacted material. Thus, the respective yield figures for compounds **1**–**3** should be quoted as 8.4, 8.4, and 6.4%, respectively. The reaction mixture also contained a number of minor products accounting altogether for 36.6% of the converted material. To these products we should also add oxalic acid, which is accounted for by one of our pathways and was subsequently found upon reinspection of the lab records in a 4% yield. Therefore, approximately 40% of the converted material was accounted for as products.

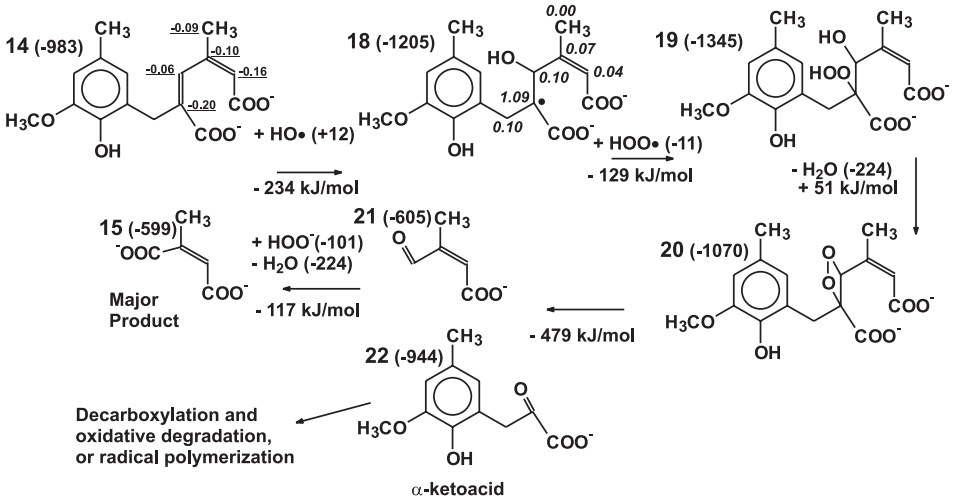
In this work we have made an attempt to devise the simplest reaction pathways explaining the formation of the products determined previously (18). Our efforts were guided by the results of the computations as well as by previously published pathways for oxidative degradation of similar compounds (11–14). The results of this effort suggest the existence of a common initial pathway leading to the formation of an intermediate dicarboxylic compound (2-[2-hydroxy-3-methoxy-5-methyl-phenylmethyl]-4-methyl-2,4-hexadienedioate) (compound **14**). From this intermediate, the pathway branches into three, each of which leads to formation of one of the three main degradation products. We will now describe the proposed pathways in some detail.

The common initial pathway



The oxidative degradation of MMMP is initiated by an electrophilic attack by hydroxyl radicals (Scheme 2). The phenolate groups of the MMMP dianion (**4**) have been computed as the most electronegative sites and therefore, likely points of an attack by electrophilic hydroxyl radicals. The charges on the phenolate groups (–0.55) are more negative than the corresponding groups on an analogous biphenyl model compound investigated previously (17) (charge –0.53), which could contribute to the higher reactivity of MMMP as compared to an analogous biphenyl compound.

The resulting phenoxy radical **5** (Scheme 2), shows high electron spin densities (0.65, 0.60, and 0.60) in three positions on the ring suggesting the three resonant structures **6**, **7**, and **8**, respectively. Any one of these three radical sites could couple with the perhydroxyl radical present in the reaction mixture but one of the resulting peroxides (**10**) is most favorable thermodynamically (heat of formation –728 kJ mol^{-1}, compared with –707 and –694 kJ mol^{-1} of the other two peroxides, **9** and **11**). Therefore, it is reasonable to assume that peroxide **10** is the predominant intermediate. The computed heats of formation of all reactants leading to **10** indicate exothermic reactions, which supports the proposed pathway. We have also attempted to compute the products derived from the other two peroxides (**9** and **11**) but found no feasible pathways leading to the experimentally identified products.



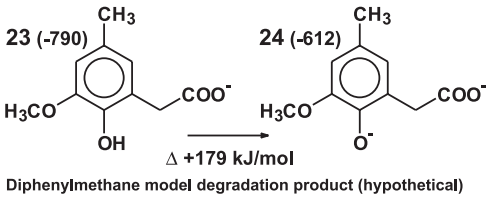
In analogy with our previous study (16), we assume that perhydroxyl radical rather than superoxide radical anion is the reactive species involved in the radical coupling reactions. Couplings with superoxide radical anions gave us products with unreasonably high values of heats of formation. However, our computations were done in vacuo and we plan to address this question again in future using solvated intermediates.

© 2001 NRC Canada

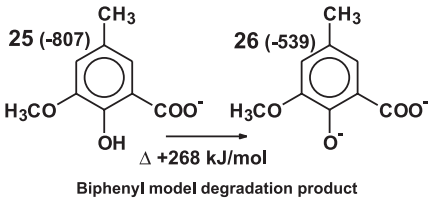
Scheme 3. Second part of the common pathway starting with peroxide **10** and leading to a dicarboxylic intermediate (**14**). The intermediate is a point from which three pathways branch off and lead to the anions **15**–**17** of the main products (**1**–**3**) described by Sun et al. (18). See Scheme 2 for the explanation of symbols.

Scheme 4. The butenedioate branch pathway starts with the dicarboxylic intermediate **14** and proceeds via radical reactions toward a dianion **15** of the degradation product **1**, determined by Sun et al. (18). See Scheme 2 for the explanation of symbols.

The favorable peroxide intermediate **10** is predicted to undergo further degradation as shown in Scheme 3. The peroxide transforms into a dioxetane (**12**) by an endothermic reaction calculated to consume 16 kJ mol^{-1}. The required heat of reaction is similar to that reported for an analogous reaction of the biphenyl model compound studied previously (15 kJ mol^{-1}) (16). The possible meaning of the endothermic reactions for considering the thermodynamic barriers will be discussed later in this section.



Following the formation of the dioxetane **12**, we predict that a highly exothermic C—C scission (formation of **13**) followed by demethylation yields a dicarboxylic intermediate (2-[2-hydroxy-3-methoxy-5-methylphenylmethyl]-4-methyl-2,4-hexadienedioate) **14**. The intermediate provides a branching point for the forthcoming three pathways named butenedioate, furanacetate, and oxopentanoate pathways, respectively, according to the anions **15**–**17**, of the experimentally proven (18) final products **1**–**3**, respectively. We will now discuss the subsequent concurrent pathways.

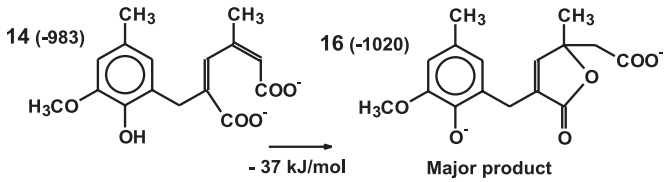


The butenedioate pathway

The pathway is outlined in Scheme 4. The degradation of the intermediate **14** is believed to be initiated by another attack by a hydroxyl radical. Such attack usually occurs at a strongly electronegative site but to substantiate the degradation of the aliphatic chain leading to the formation of one of the final products (**15**), we must assume that the attack by hydroxy radical (and the ensuing radical addition) occurs at a carbon atom with a small negative charge (computed as

© 2001 NRC Canada

Scheme 5. Computations of ionization states of two analogous degradation products (**23** and **25**) suggest preferential ionization of the phenolic hydroxyl of the hypothetical product **23**. See Scheme 2 for the explanation of symbols.



–0.06). The radical addition results in a radical (**18**) with high spin density (1.09) at the site of coupling reaction with a perhydroxyl radical. The coupling results in the formation of a peroxide (**19**). Both the radical addition and coupling reactions are exothermic according to the computations. However, for the peroxide to form the dioxetane (**20**), the computations suggest that 51 kJ mol^{-1} heat has to be supplied.

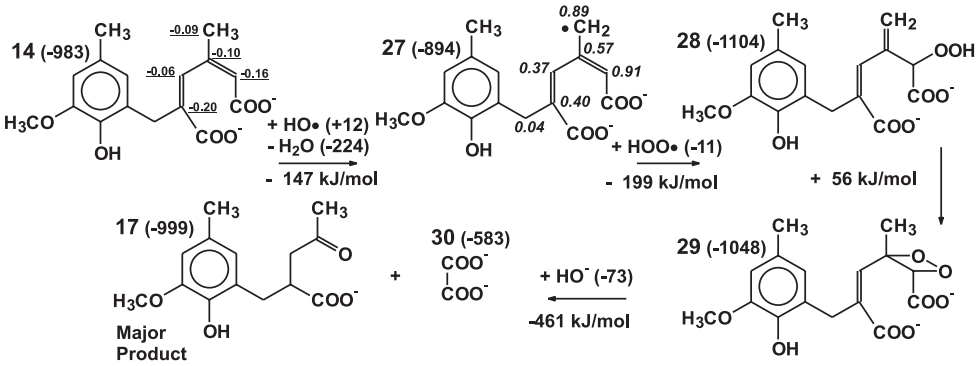
The dioxetane **20** then cleaves exothermically to yield a product (**21**), which upon exothermic oxidation with hydroperoxyl anion, leads to the formation of **15** — an anion of one of the major products (**1**), determined experimentally (18). The degradation of **20** also leads to the formation of an α-keto acid (**22**). An analogous reaction with a biphenyl model compound computed previously (16), led (after decarboxylation and oxidation of an analogous α-keto acid) to the formation of 2-hydroxy-3-methoxy-5-methylbenzoic acid, the main product of the biphenyl model compound degradation. However, no analogous aromatic acid was found among the degradation products of MMMP. Scheme 5 illustrates an attempt to explain this apparent discrepancy. Compound **22** (Scheme 4) may yield the hypothetical intermediate (**23**) (Scheme 6), after decarboxylation and oxidation analogous to that proposed previously (16) for the formation of of 2-hydroxy-3-methoxy-5-methylbenzoic acid (its phenolate anion (**25**) is shown in Scheme 5). However, computations of heats of formation shown in Scheme 5 suggest that the hypothetical product (**23**), compared to **25**, is more likely to yield a phenolate anion (**24**), which would then become subject of an attack by hydroxyl radicals and could undergo further degradation or polymerization reactions. This could explain why the hypothetical intermediate (**23**) is not found among the MMMP degradation products (18). Alternatively, Scheme 5 suggests that the analogous biphenyl model degradation product (**25**) produces a phenolate much less readily. It is therefore unlikely to undergo further degradation reactions and is present among the biphenyl model degradation products (18). It should be noted that in the reactions shown in Scheme 5, the hydrogen ions have been omitted and therefore, the differences in the heats of formation do not indicate the heats of ionization.

Scheme 6. Furanacetate branch pathway starting with the common dicarboxylic intermediate **14** and results in an anion (**16**) of a major degradation product (**2**), determined by Sun et al. (18). See Scheme 2 for the explanation of symbols.

The furanacetate pathway

This branch pathway (Scheme 6) consists of exothermic lactonization of the dicarboxylic intermediate (**14**), yielding an anion (**16**) of the furanacetic acid product **2** (Scheme 1).

The oxopentanoate pathway



This pathway is the third of the branching pathways. Its course is outlined in Scheme 7. As the previous two it also starts from the dicarboxylic intermediate **14**. Computational investigation of several variants of this pathway led to this scheme judged to be thermodynamically most favourable. We presume that an exothermic reaction with a hydroxyl radical leads to hydrogen abstraction from the intermediate **14**, resulting in a benzylic radical species (**27**), with high spin density (0.91) at the site of coupling reaction with a perhydroxyl radical. This exothermic reaction yields a peroxide (**28**). Transformation of **28** into a dioxetane structure (**29**) is predicted to be an endothermic reaction (+56 kJ mol^{-1}). The dioxetane **29** then undergoes an exothermic C—C scission and yields an anion (**17**) of a major degradation product (**3**), identified previously (18). A byproduct of the scission is predicted to be oxalate **30**, originally not noticed (18) due to a very low gas chromatography response factor. A review of the analytical data (unpublished) revealed the presence of about 2% of oxalic acid among the reaction products, in agreement with this prediction.

Alternative radical reactions

In addition to the pathways described above, we explored other reactions as alternatives. Thus, hydrogen abstraction from the diphenylmethyl carbon of MMMP rather than formation of a phenoxy radical was considered as a likely reaction leading to the formation of a stable diphenylmethane radical. However, we could not derive the experimental products (Scheme 1) from this intermediate. Possible alternatives to hydrogen abstraction reactions in Scheme 7 could be hydroxyl radical additions to unsaturated structures. We have computed two such scenarios and were able to arrive at the determined products but the computed reactions appeared thermodynamically less favourable (the barriers were +84 and +115 kJ mol^{-1}). It is interesting to note that Sun et al. (18) reported a low yield (0.5%) of a 1-hydroxylated derivative of compound **2**. This derivative is probably a product of a hydroxyl radical addition reaction. We also computed an alternative to Scheme 4, based on hydrogen abstraction from an unsaturated carbon. Although the alterna-

Scheme 7. The oxopentanoate branch pathway starting with the common intermediate **14** and leading, via radical reactions, to an anion (**17**) of the major product **3**, determined by Sun et al. (18). See Scheme 2 for the explanation of symbols.

tive yielded a barrier marginally lower (+50 instead of +51 kJ mol^{-1}) we did not consider it likely.

There is little doubt that, in addition to reactions proposed in Schemes 2–7, various alternative reactions take place during the oxidative degradation of the diphenylmethane structures. However, the outcome of these reactions may have been either a condensation or conversion of the substrate to carbonate, explaining why the overall yields of the reaction products were not quantitative (see Scheme 1 and a discussion of the yields).

Barriers on the reaction pathways

In our previous investigation (16) of a biphenyl-type model compound, we concluded from our computations that the only endothermic steps on the degradation pathway are transformation reactions of peroxides into corresponding dioxetanes. It should also be noted that *all* such transformations were computed as endothermic. It is significant that the same rule can be extended to all pathways presented in this work on MMMP. Consideration of reaction barriers in this case is somewhat complicated by the branching of the pathway. However, the common initial pathway (Schemes 2 and 3) has one endothermic step (+16 kJ mol^{-1}, Scheme 3) after which there is no barrier to the end of the furanacetate branch (Scheme 6). Therefore, this barrier could be the one controlling the disappearance of MMMP. In comparison, the disappearance of the biphenyl compound encounters a much greater barrier further down the pathway (+94 kJ mol^{-1}) (16). The activation energy for the disappearance of MMMP is also lower (54 ± 11 kJ mol^{-1}) than the previously determined activation energy (117 kJ mol^{-1}) for the biphenyl model (16).

Significant endothermic steps have been computed on the other two branch pathways, butenedioate and oxopentanoate (+51 and +56 kJ mol^{-1}, respectively; see Schemes 4 and 7). These values are similar to the experimentally determined activation energy for the disappearance of the model compound MMMP. It is tempting to speculate that the activation energy reflects these barriers. Thus it seems that not only the disappearance of MMMP but also the formation of the degradation products encounters lower energy barriers than those observed for the degradation pathway of the analogous biphenyl model (16).

Experimental

Materials

MMMP used in this work was synthesized according to Kratzl and Virhopper (19). 3,4-Dimethoxyphenol (97%) was used for GC–FID quantification; 2-chloro-4,4,5,5-tetramethyl-1,3,2-dioxaphospholane (95%) was used as a phosphitylation reagent; magnesium sulphate (99.99%), sodium hydroxide (99.99%), and potassium iodide (99.9%) were purchased from Aldrich. Distilled water used in this study was treated with a NANO pure Analytical Deionization System (Barnstead).

Activation energy

The degradation of 2,2′-methylenebis[6-methoxy-4-methylphenol] (MMMP; an anion of this compound (**4**) is shown in Scheme 2) was carried out in dilute alkali with hydrogen peroxide at four different temperatures (60, 70, 90, and 100°C) for various intervals (5–60 min). The pH of the starting reaction mixture was 12.4. Under the most extreme conditions (100°C for 45 min), the pH dropped to about 10.2 after the reaction. The molar excess of hydrogen peroxide over MMMP was high enough to maintain residual hydrogen peroxide at >15% of the original amount under all conditions of the kinetic study. The amount of unreacted MMMP was identified using GC–FID analyses; the lowest recorded yield was 28% of the original amount.

A similar set of reactions with residual kraft lignin was carried out at 70, 110, and 130°C for 15–90 min. Phenolic hydroxyl groups in the diphenylmetane structures were assayed using quantitative ^{31}P NMR spectroscopy. These structures show a ^{31}P chemical shift signal in the interval 142.7–144.0 ppm. The original amount of these groups was 0.243 mmol g^{-1} and dropped to about 10% of this at the most extreme treatment conditions (90 min at 110°C).

From the reaction rates measured at various conditions, we calculated apparent reaction constants (k_{app}) and determined their errors from the errors of the corresponding plots. The activation energies for the oxidative degradation of: (*i*) MMMP; and (*ii*) diphenylmethane structures in residual kraft lignin, were calculated from the kinetic data using the Arrhenius equation (20). The errors of the E_a estimates were calculated using averages of the errors of the ln (k_{app}) data.

Treatment of 2,2′-methylenebis[6-methoxy-4-methylphenol]

MMMP was oxidized with hydrogen peroxide as a function of time and temperature using a 40-mL glass-lined steel bomb reactor. The molar ratio of MMMP to hydrogen peroxide and sodium hydroxide was 1:6:4, respectively. To approximately 100 mg of MMMP in the glass liner we added 20 mL of deionized water, 1.23 mg of magnesium sulphate in solution, and 58.4 mg of sodium hydroxide in solution. The mixture was heated and stirred for 5 min to solubilize the ingredients. After cooling, 190 μl of 30% aqueous hydrogen peroxide was added and the whole transferred into a glass liner and covered with a glass lid. The reactor was sealed and placed in a preheated oil bath, and kept there for the specified time. At the end of the reaction, the reactor was rapidly cooled and 2 mL of the reaction mixture was withdrawn for measurement of the residual hydrogen peroxide. The pH of the solution after reaction (9.5–11.8) was adjusted to about 2 with 1 N hydrochloric acid. The mixture was then lyophilized and the solids extracted three times with approximately 5 mL of ethyl acetate. Before weighing the solute, the extract was placed into a preweighed vial, allowed to dry at room temperature, and then desiccated in vacuo for 2 days.

Treatment of residual kraft lignin

The procedure was similar to that used for the model compound. Residual kraft lignin from black spruce kraft pulp (50 mg, i.e., 0.273 mmol of C9 units), free of metal, was suspended in 1 mL of deionized water and 1 mL of 1 N sodium hydroxide was added. The pH of the suspension was 13.4. Hydrogen peroxide (65 μl, 30% in water) was then added at the molar ratio of lignin C9 units to hydrogen peroxide, equal to 1:2.3. At the end of the reaction period, the mixture was acidified to pH 2. The precipitated degraded lignin was then lyophilized and brought to constant weight.

Gas chromatography with flame ionization detection (GC–FID)

The analyses were carried out on a Hewlett–Packard 5890A gas chromatograph equipped with a DB-5 capillary column. The injection port temperature was 250°C and the oven temperature was raised from 70°C to 250°C with a gradient of 15°C min^{-1}. One mL of pyridine was added to the dry product and the vial was immediately closed and shaken until all dissolved. Fifty μl were transferred to a new vial and 0.3 mL of pyridine and 100 μL of internal standard solution was added. The internal standard was 3,4-dimethoxyphenol (1.004 mg in 100 μL). *N*,*O*-Bis(trimethylsilyl)acetamide was added as a silylation reagent. The GC response factor relative to the internal standard was determined as follows: accurately measured amounts of the internal standard and diphenylmethane were mixed well in pyridine. Then the sample was silylated and the resulting solution injected. The integrated areas from GC were compared to determine the response factor.

Quantitative ^{31}P NMR analysis

Lignin samples were analyzed for the content of diphenylmethane structures using a previously published method (21).

Computational methods

All compounds listed in the various schemes have been subjected to computational analysis of the geometry-optimized structures. The optimization was done using the third parametrization semiempirical method (PM3) (22, 23) after subjecting the structures to simulated annealing and preliminary optimization with a molecular mechanics method (MM+) derived from the method of Allinger (24). All computational methods were used as implemented by HyperChem Professional, Version 5.11 (HyperCube, Inc.). The details of the computational protocol were the same as described previously (16). The values of heats of formation, charges on individual atoms, and electron spin densities (α–β atomic orbital electron populations) were computed on the optimized structures.

Conclusions

The activation energy for the alkaline oxidative degradation of the diphenylmethane model compound (2,2′-methylenebis[6-methoxy-4-methylphenol]) (MMMP) and diphenylmethane structures in residual lignin is similar (54 ± 11 and 58 ± 5 kJ mol^{-1}, respectively), supporting the relevance of MMMP to represent diphenylmethane moieties of kraft lignins.

The critical steps in the degradation sequence may be the aromatic ring cleavage and the scission of the newly formed aliphatic side chain.

Both aromatic and aliphatic scission mechanisms may be similar and might consist of the following steps: (*i*) formation of radical sites by reactions with hydroxyl radicals; (*ii*) radical coupling reactions of the radical sites with perhydroxyl radicals, resulting in formation of peroxides; (*iii*) transformation of peroxides into dioxetanes; (*iv*) scission of the dioxetane structures.

MMMP is more easily degraded (as reported by Johansson and Ljunggren (17)) than the corresponding biphenyl model for these main reasons: (*i*) the activation energy for the disappearance of MMMP is lower; (*ii*) the critical endothermic reactions on the MMMP degradation pathway require less energy; (*iii*) the initial electrophilic attack by a hydroxyl radical is facilitated by the more electronegative phenolic hydroxyl oxygen; (*iv*) the course of the degradation of the diphenylmethane structures branches into at least three pathways thus providing multiple ways for the structure to degrade; (*v*) carboxylic acid group formation during the degradation of the diphenylmethane moieties provides less protection for the residual aromatic structures due to the greater distance from the phenolic hydroxyl.

The above conclusions from the model compounds can probably be extended to the biphenyl and diphenylmethane structures in lignin.

Acknowledgements

We wish to thank Dr. Peter McGarry (Paprican) for valuable comments and suggestions. Professor Leif Eriksson (Department of Quantum Chemistry, Uppsala University, Sweden) kindly provided us with advice on computation methods.

Unified theory of extraction

Janusz Pawliszyn

Abstract: The sample preparation step in an analytical process typically consists of extraction of components of interest from a sample matrix. This procedure can vary in degree of selectivity, speed, and convenience depending on the approach and conditions used as well as on geometric configurations of the extraction phase and conditions. Optimization of this process aids enhancement in performance of the overall analysis. Proper design of the extraction devices and procedures facilitates rapid and convenient on-site implementation, coupling to separation–quantification, and (or) automation. The key to rational choice, optimization, and design is an understanding of fundamental principles governing mass transfer of analytes in multiphase systems. There is a tendency to divide extraction techniques according to random criteria. In this article, common principles among different extraction techniques are emphasized and a unified approach based on convolution of mathematical functions describing individual steps is presented. This approach considers gas, solvent, liquid polymer, and solid surfaces as extraction phases and air, water, and solids as sample matrices. The parameters that affect the kinetics of extraction techniques are emphasized resulting in new calibration strategies and novel geometric designs.

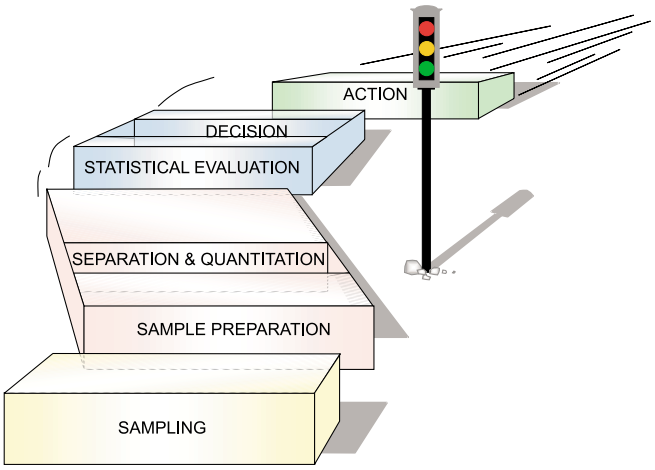
Key words: separations, extractions, microextractions, mass transfer, multiphase equilibria.

Résumé : Dans un processus analytique, l'étape de préparation de l'échantillon consiste généralement en une extraction des composants recherchés d'une matrice d'échantillon. Dépendant de l'approche et des conditions utilisées ainsi que des configurations géométriques de la phase d'extraction et des conditions, le degré de sélectivité de cette procédure peut varier considérablement. L'optimisation de ce processus permet d'augmenter la performance de l'analyse globale. Une mise au point appropriée des procédures et des appareils d'extraction permet d'accélérer et de rendre plus commode leur réalisation sur place ainsi que le couplage séparation/quantification et/ou automation. La clé pour un choix rationnel, une optimisation et une mise au point est une compréhension des principes fondamentaux qui gouvernent le transfert de masse des analytes dans des systèmes multiphases. Il y a une tendance à diviser les techniques d'extraction à l'aide de critères aléatoires. Dans cet article, on fait ressortir des principes communs aux diverses techniques d'extraction et on présente une approche unifiée basée sur des fonctions mathématiques de convolution qui décrivent les étapes individuelles. Cette approche considère les gaz, les solvants, les polymères liquides et les surfaces solides comme des phases d'extraction et l'air, l'eau et les solides comme des matrices d'échantillon. On identifie les paramètres qui affectent la cinétique des techniques d'extraction en raison de nouvelles stratégies de calibration et de nouvelles configurations géométriques.

Mots clés : séparations, extractions, microextractions, transfert de masse, équilibre multiphase.

[Traduit par la Rédaction]

Introduction



The analytical procedure for complex samples consists of several steps typically including sampling, sample preparation, separation, quantitation, statistical evaluation, and decision making (see Fig. 1**)**. Each step is critical for obtaining correct and informative results. The sampling step includes deciding where to get samples that properly define the object or problem being characterized and choosing a method to obtain samples in the right amounts. The objective of the sample preparation step is to isolate the components of interest from a sample matrix, because most analytical instruments cannot handle the matrix directly. Sample preparation involves extraction procedures and can also include "clean up" procedures for very complex "dirty" samples. This step must also bring the analytes to a suitable concentration level for detection and therefore sample preparation methods typically include enrichment. During the separation step of the analytical process, the isolated complex mixture containing target analytes is divided into its constituents, typically by means of a chromatographic or electrophoretic techniques. Quantitation is the determination of amounts of the identified compounds. The identification can be based on a retention time combined with selective detection; more frequently, however, more specific instruments, namely mass spectrometers, are used to eliminate possible errors in quantification due to interferences by confirming identity of analytes. Statistical evaluation of the results provides an es-

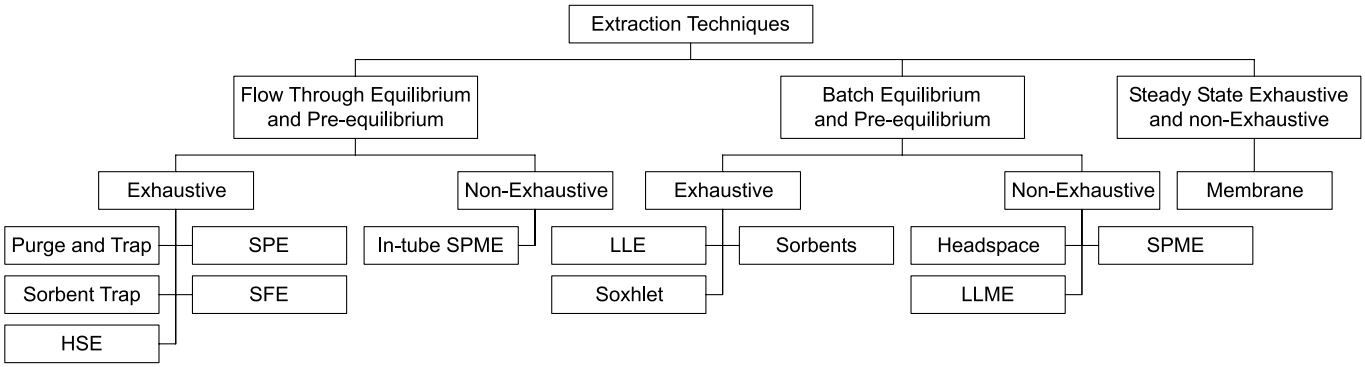
Fig. 1. Steps in analytical process.

timate of the target compound concentration in the sample being analyzed. The data will then support appropriate decisions, which might include a move to take another sample for further investigation of the object or problem.

It is important to note, as emphasized by Fig. 1, that steps in an analytical method follow one after another, and a subsequent step cannot begin until the preceding one has been completed. Therefore, the slowest step determines the overall speed of the analytical process, and improving the speed of a single step may not result in a throughput increase. To increase the throughput of analysis, all steps need to be considered. Also, errors performed in any preceding step, including sampling, will result in the overall poor performance of the procedure.

There have been major breakthroughs in the development of improved instrumentation, which involve miniaturization of analytical devices and hyphenation of different steps into one system. It is recognized that an ideal instrument would perform all the analytical steps without human intervention, preferably directly on the site where an investigated system is located rather than moving the sample to laboratory, as is a common practice in many cases at the present time. This approach would eliminate errors and time associated with sample transport and storage and,therefore, result in more accurate, precise, and faster analytical data. Although such a device has not yet been built, today's sophisticated instruments, such as the gas chromatograph–mass spectrometer (GC–MS) or the liquid chromatograph–mass spectrometer (LC–MS), can separate and quantify complex mixtures and automatically apply chemometric methods to statistically evaluate results. It is much more difficult to hyphenate sampling and sample preparation steps, primarily because the current state of the art in sample preparation techniques employs multi-step procedures involving organic solvents. These characteristics make it difficult to develop a method that integrates sampling and sample preparation with separation methods, for the purposes of automation. The result is that over 80% of analysis time is currently spent on sampling and sample preparation steps for complex samples.

One of the reasons for slow progress in the area of sample preparation is that the fundamentals of extraction involving natural, frequently complex, samples are much less developed and understood compared to more physicochemically simpler systems used in separation and quantification steps such as chromatography and mass spectrometry. This situation creates a feeling that rational design and optimization of extraction systems is not possible. Therefore development of sample preparation procedures is frequently considered to be "art" not "science".



This situation creates a tendency by practitioners and regulatory agencies to prefer exhaustive vs. nonexhaustive techniques (see Fig. 2) even though this choice results frequently in labour intensive and costly procedures. The main objective of the exhaustive techniques is to completely remove all analytes from a sample matrix and transfer them to the extraction phase. The fundamental advantage of exhaustive methods is that in principle they do not require calibration since the vast majority of analytes are transferred to the extraction phase. This objective is accomplished by application of overwhelming volumes of extraction phase. To reduce the amounts of solvents and time required to accomplish exhaustive removal, batch equilibrium techniques (for example, liquid–liquid extractions) are frequently replaced by flow-through techniques. For example, a sorbent bed can be packed with extraction phase dispersed on a supporting material and when sample is passed through analytes are retained on the bed. Large volumes of sample can be passed through a small cartridge and the flow through a well-packed bed facilitates rapid mass transfer. The extraction procedure is followed by reextraction of analytes into small volume of solvent resulting in high enrichment. This strategy is used in sorbent trap techniques and solid phase extraction (SPE) (1). Alternatively, the sample (typically a solid sample) can be packed in the bed and the extraction phase can be used to remove and transport the analytes to the collection point. In supercritical fluid extraction (SFE), compressed gas is used to wash analytes from the sample matrix, while in-purge and trap-atmospheric pressure inert gas performs the same function. In dynamic solvent extraction, such as a Soxhlet, the solvent continuously removes the analytes from the matrix at the boiling point of the solvent. In more recent hot solvent extraction techniques, smaller volumes of organic solvent are used to accomplish higher enrichment at the same time, because of increased solvent capacity and eluting capability at high temperatures and pressures (2).

Alternatively nonexhaustive approaches can be designed based on equilibrium, pre-equilibrium and permeation principles (3). Equilibrium nonexhaustive techniques are fundamentally analogues to the equilibrium exhaustive techniques, however, the capacity of the extraction phase is smaller, and in most cases is not sufficient to remove the majority of analytes from the sample matrix. This is caused by use of a small volume of the extracting phase relative to sample volume (microextraction, such as solvent microextraction or solid phase microextraction (SPME)) (4) or a low K value, for example as is typically encountered in gaseous headspace techniques (5).

Pre-equilibrium conditions are accomplished by breaking the contact between the extraction phase and the sample matrix before the point of equilibrium with the extracting phase has been reached. The devices that are used are frequently identical to the microextraction systems, however, extraction

Fig. 2. Classification of sample preparation techniques.

times are shorter. In permeation techniques, such as membrane extraction, continuous steady state transport of analytes through the extraction phase is accomplished by simultaneous reextraction of analytes.

As the above discussion and as Fig. 2 indicates, there is a fundamental similarity among extraction techniques used in the sample preparation process. In all techniques, the extraction phase is in contact with the sample matrix, and analytes are transported between the phases. For exhausitve techniques, the phase ratio is higher and geometries are more restrictive compared to nonexhaustive approaches to ensure the quantitative transfer of analytes. The thermodynamics of the process is defined by the extraction phase – sample matrix distribution constant. It would be instructive to consider in more detail the kinetics of processes occurring at the extraction phase – sample matrix interface, since this defines the time of the analytical procedure. In many cases, the analytes are reextracted from the extraction phase, but this step is not discussed here since this process is analogues and much simpler in principle compared to removing analytes from a more complex sample matrix. The main objective of this article is to outline the common fundamental principles among various extraction techniques to facilitate a better understanding of selection criteria for appropriate techniques, device geometries, and operational conditions.

Theory

The fundamental thermodynamic principle common to all chemical extraction techniques involves distribution of analyte between the sample matrix and the extraction phase. When liquid is used as the extraction medium then the distribution constant (K_{es})

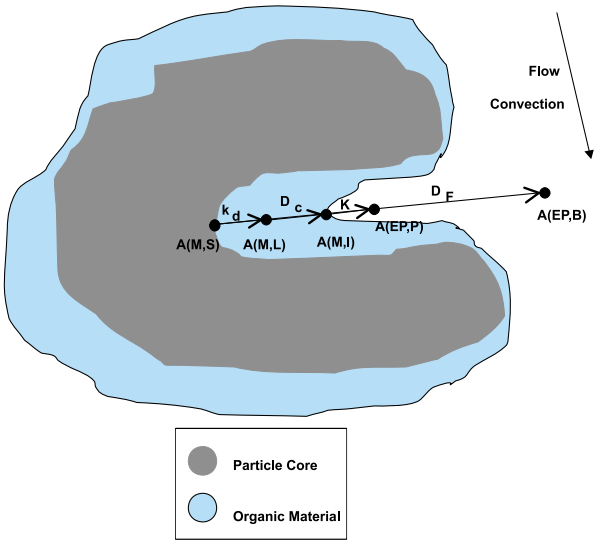
$$[1] \qquad K_{es} = a_e/a_s = C_e/C_s$$

defines the equilibrium conditions and ultimate enrichment factors achievable in the technique, where a_e and a_s are the activities of analytes in the extraction phase and matrix, correspondingly, which can be approximated by the appropriate concentrations. For solid extraction phase adsorption, equilibria can be explained by the following equation:

$$[2] \qquad K^s_{es} = S_e/C_s$$

where S_e is solid extraction phase surface concentration of adsorbed analytes. The above relationship is similar to eq. [1], with the exception that extraction phase concentration is replaced with surface concentration. The S_e term in the numerator indicates that the sorbent surface area available for adsorption must also be considered. This complicates the calibration at equilibrium conditions because of displacement effects and the nonlinear adsorption isotherm (6). The above equations can be used to calculate the amount of analyte in the extraction phase at equilibrium conditions (4). For example, for equilibrium liquid-microextraction techniques and large sample, including direct extraction from the investigated system, the appropriate expression is very simple

$$[3] \qquad n = K_{es}V_eC_s$$



where K_{es} is the extraction phase – sample matrix distribution constant, V_e is the volume of the extraction phase, and C_s is the concentration of the sample. However, in practice kinetic factors, defined by the dissociation constants, diffusion coefficient, and agitation condition, frequently determine the amount of extracted analytes since the overall rates are slow and therefore extraction amounts for limited time experiments do not reach equilibrium values.

The most challenging extractions occur when a solid is present as a part of the sample matrix. This case will be considered as the most general example of extraction since it involves a number of fundamental processes occurring during the extraction. If we assume that a matrix particle consists of an organic layer on an impermeable but porous core and the analyte is adsorbed onto the pore surface, the extraction process can be modelled by considering several basic steps as shown in Fig. 3. To remove the analyte from the extraction vessel, the compound must first be desorbed from the surface (Fig. 3, A(M,S)), then it must diffuse through the organic part of the matrix (A(M,I)) to reach the matrix–fluid interface (A(M,L)). At this point the analyte must be solvated by the extraction phase (A(EP,P)) and then it must diffuse through the static extraction phase present inside the pore to reach the portion of the extraction phase influenced by convection, to be transported through the interstitial pores of the matrix and eventually to reach the bulk of the extraction phase (A(EP,B)). The simplest way to design a kinetic model for this problem is to adopt equations developed by engineers to investigate mass transport through porous media (7, 8).

For the purpose of this discussion we consider the efficient and frequently applied experimental arrangement for removing solid-bound semivolatile analytes, involving the use of a piece of stainless-steel tubing as the extraction ves-

© 2001 NRC Canada

Fig. 3. Processes involved in extraction of heterogeneous samples containing porous solid particles. The terms in the figure are discussed in the text.

sel. The sample is typically placed inside the tubing and a linear-flow restrictor is attached at the end of the vessel to maintain the pressure. During the process, the extraction phase continuously removes analytes from the matrix, which are then transferred to the collection vessel after the expansion of the fluid. This leaching process is very similar to chromatographic elution with packed columns, particularly to the frontal method. The main difference is that in sample preparation analytes are dispersed in the matrix at the beginning of the experiment, whereas in chromatographic frontal analysis a long plug is introduced into the column at the initial stage of the separation process. The principal objective of the extraction is to remove analytes from the vessel in the least amount of time, requiring elution conditions under which the analytes are unretained. In chromatography, on the other hand, the ultimate goal is to separate components of the sample, which requires retention of analytes in the column. Another major difference is that the packing matrix is usually well-characterized in chromatography, but in sample preparation it is often unknown.

One way to develop a mathematical model for this extraction approach is to establish the mass balance equation for the system after carefully considering of the individual mass transfer steps, occurring during the extraction process (see Fig. 3), and specific boundary conditions (9). Extensive investigations on similar topics have already been conducted by engineers, who have studied the mass transfer in porous media (7), and chromatographers (8). In these studies the relationship between various matrix parameters and flow conditions on the elution profile were described mathematically, and verified experimentally. In chromatography this relationship is usually described as contributions from each of the mass transfer steps to the height equivalent to a theoretical plate (HETP). The overall performance of the system can be defined as the sum of the relevant individual components judiciously selected to reflect the most significant individual steps present in the elution process. For the purpose of this discussion, this approach is adopted to develop a model for extraction kinetics in flow-through techniques.

The effect of slow desorption kinetics of analytes from the matrix on the elution profile, can be described as the contribution to the HETP (8), h_{RK}:

$$[4] \qquad h_{RK} = \frac{2ku_e}{(1+k)^2(1+k_o)k_d}$$

where k is the partition ratio, k_d is the dissociation rate constant of the analyte–matrix complex of reversible process, k_o is the ratio of the intraparticulate void volume to the interstitial void space and is expressed as:

$$[5] \qquad k_o = \frac{\varepsilon_i(1-\varepsilon_e)}{\varepsilon_e}$$

where ε_i is intraparticulate porosity and ε_e is interstitial porosity; u_e is the interstitial linear extraction phase velocity expressed as:

$$[6] \qquad u_e = u(1 + k_o)$$

where $u = L/t_0$ is chromatographic linear velocity, L is the length of the extraction vessel, and t_0 is time required to remove one void volume of the extraction phase from the vessel. Chromatographic and interstitial linear velocities are identical if matrix particles have low porosity. This analysis can be extended to elution through a matrix having multiple adsorption sites characterized by different dissociation rate constants by using the approach described by Giddings (10).

The diffusion of the analyte in the liquid or swollen solid part of the matrix is important when polymeric materials are extracted or the matrix has substantial organic content. Its contribution can be expressed as h_{DC}:

$$[7] \qquad h_{DC} = \frac{2}{3}\frac{k}{(k+1)^2}\frac{d_c^2}{D_s}u_e$$

where d_c is the thickness of the matrix component permeable to analyte and D_s is the diffusion coefficient of the analyte in the sample matrix.

The analytes migrate in and out of a pore structure of the matrix during the elution. This can be described as resistance to mass transfer in the fluid associated with the porous nature of the environmental matrices, which gives rise to the following HETP component, h_{DP}:

$$[8] \qquad h_{DP} = \frac{\theta(k_o + k + kk_o)^2 d_p^2 u_e}{30\,k_o(1+k_o)^2(1+k)^2 D_p}$$

where θ is tortuosity factor for the porous particle and D_p is the diffusion coefficient of the analyte in the material filling the pores, which in most practical cases will be an extraction phase, and therefore D_p=D_e, where D_e is the diffusion coefficient of the analyte in the extraction phase. This contribution can be quite important considering the relatively large particle size (about 1 mm) of environmental matrices and becomes particularly important when the pores are filled with dense organic material, such as humic matter rather than the extraction phase.

In the flowing bulk of the fluid an analyte experiences resistance to mass transfer associated with eddy diffusion (ran-

© 2001 NRC Canada

dom paths of the analytes through the vessel filled with the particles), which is given by h_{ED}:

$$[9] \qquad h_{ED} = 2\lambda d_p$$

where λ is a structural parameter and is close to 1 for spherical matrix particles. This contribution to band broadening is the most important factor in HPLC separations and it is expected to remain significant in extractions because of matrices typically having large particle sizes.

In addition, we should also consider analyte diffusion along the axis of the vessel (longitudinal diffusion) which can be defined as h_{LD}:

$$[10] \qquad h_{LD} = \frac{\gamma_M D_e}{u_e}$$

where γ_M is the obstruction factor, which characterize the structure of the matrix. This component is expected to be small. The analyte concentration profile generated during the experiment as a function of time $C(x,t)$ can be represented using the equation that describes the dispersion of a plug of finite width (9):

$$[11] \qquad \frac{C(x,t)}{C_o} = \frac{1}{2}\left\{ ERF\left(\frac{\frac{L}{2} - x - \frac{ut}{1+k}}{\sigma\sqrt{2}} \right) + ERF\left(\frac{\frac{l}{2} + x + \frac{ut}{1+k}}{\sigma\sqrt{2}} \right) \right\}$$

where L is the length of the vessel, C_0 is the initial concentration of analyte in the extraction vessel, and σ is the mean square root dispersion of the band expressed as:

$$[12] \qquad \sigma = \sqrt{Ht\frac{u}{1+k}}$$

where H is equivalent to the HETP in chromatographic systems and is a sum of the contributions discussed above ($H = h_{RK} + h_{DC} + h_{DP} + h_{ED} + h_{LD}$). The mass of analyte eluted from the vessel during a given extraction time t can be calculated from the following equation:

$$[13] \qquad \frac{m(t)}{m_o} = \frac{\int_{-\infty}^{-\frac{1}{2}L} C(x,t)\mathrm{d}x}{C_s L}$$

where, $m(t)$ is the extracted mass of analyte and m_o is the total amount of analyte in the vessel at the beginning of the experiment. We will refer to this function as the time elution profile emphasizing the similarity of the extraction process in this simple case to chromatographic elution.

The above discussion applies only to the situation when the analytes are initially present in a fluid phase, which in flow through techniques corresponds to elution of uniform spikes from the extraction vessel or when weakly adsorbed native analytes are removed from an organic-poor matrix such as sand. In the other words, the above relationships are suitable for systems in which the partitioning equilibrium between the matrix and extraction fluid is reached quickly compared to the fluid flow. They are also suitable to model static – dynamic extractions, under good solubility conditions ($k = 0$), in which the sample is initially exposed to the static extraction phase (vessel is capped) for a time required to achieve equilibrium condition prior to elution by fluid flow. If dynamic extraction is performed from the beginning of extraction, then in the majority of practical cases the system is not expected to achieve the initial equilibrium conditions. This is because of slow mass transport between the matrix and the fluid (for example, slow desorption kinetics or slow diffusion in the matrix). The expected relationship between amount of analyte removed from the vessel versus time can be obtained in this case by convoluting the function describing the rate of mass transfer between the phases $F(\tau)$ with the elution time profile $m/m_o(t)$ derived above (eq. [13]) (11):

$$[14] \qquad \int_{\tau=0}^{\tau=1} \frac{m(t-\tau)}{m_o} F(\tau)\mathrm{d}\tau$$

The resulting function describes a process where elution and the mass transfer between the phases occur simultaneously. In this discussion we will refer to this function as the extraction time profile to emphasize the point that in a majority of extraction cases these two processes are expected to be combined. $F(\tau)$ describes the kinetics of the process, which defines the release rate of analyte from the sample matrix and can include, for example, the matrix–analyte complex dissociation rate constant, the diffusion coefficient, the time constant that describes swelling of the matrix that will facilitate removal of analyte, or a combination of the above. Detailed discussion and applications of this model to describe and (or) investigate processes in supercritical fluid extraction have been described in detail elsewhere (12, 13).

Discussion

The above conclusion can be stated in more general way. Convolution among functions describing individual processes occurring during the extraction, describes the overall extraction process and represents a unified way to describe the kinetics of these processes. The exact mathematical solution to the convolution integral is frequently difficult to obtain, but graphical representation of the solution can be calculated using Fourier transform or numerical approaches. Frequently it is possible to incorporate mathematical functions that describe a combination of the unit processes. In the example of the flow-through system discussed above, the elution function describes the effect of porosity and analyte affinity towards the extraction matrix on the extraction rate. It should be emphasized that the convolution approach considers all processes equivalently. In practice, however, a small number and frequently just one unit process controls the overall rate of extraction.

Determination of the limiting step is not possible by qualitative agreement with the mathematical model since the effect on recovery of most of the unit processes has an

© 2001 NRC Canada

exponential decay nature. To properly recognize them, quantitative agreement and (or) effect of extraction parameters needs to be examined. Identification of the limiting process provides valuable insight on the most effective approach to optimization of the extraction.

In heterogeneous samples for example, the release of solid-bound analytes from sample matrix, through a reversal of chemisorption or inclusion, frequently controls the extraction rate. By recognizing this fact, extraction parameters can be changed to increase the extraction rates. For example, dissociation of the chemisorbed analytes can be accomplished either by using high temperature or by application of catalysts. Recognition of this fact lead to the development of high-temperature supercritical fluid extraction (14), followed by the evolution of both the hot-solvent extraction (15) and microwave extraction approach, with more selective energy focusing at the sample matrix – extraction phase interface (16). There is also an indication that milder conditions can be applied by taking advantage of the catalytic properties of the extraction phase or additives (17). However, to realize this opportunity more research needs to be performed to gain more insight about the nature of interactions between analytes and matrices. The benefits are not only improved speed, but also selectivity resulting from application of appropriate conditions. This strategy of simultaneous extraction and clean-up has been applied successfully to a very difficult case of extraction of polychlorinated dibenzo-*p*-dioxins from fly ash (18).

If the extraction rate is controlled by mass transport of analytes in the pores of the matrix, than the process can be successfully enhanced by application of sonic and microwave energy, which induce convection even in the small dimensions of the pore. Frequently, diffusion through the whole or portion of sample matrix containing natural or synthetic polymeric material controls the extraction rate (19). In this case, swelling the matrix and increasing temperature results in increased diffusion coefficients and therefore increased extraction rates.

For homogeneous samples and flowing fluid extraction phase the description of the extraction process is much simpler and can be based directly on the chromatographic theory for liquid stationary phases. Let us consider another case of the flow-through system where the extraction phase is dispersed as a thin layer inside the extraction bed and the sample flows through the cartridge. The bed can be constructed of a piece of fused silica capillary, internally coated with a thin film of extracting phase (a piece of open tubular capillary GC column; in-tube SPME) (20), or the bed may be packed with extracting phase dispersed on an inert supporting material (SPE cartridge). In these geometric arrangements, the concentration profile along the *x*-axis, of the tubing containing the extracting phase as a function of time (*t*), can be described by adopting the expression for dispersion of a concentration front:

$$[15] \quad C(x,t) = 0.5C_s\left(1 - erf\frac{x - \frac{ut}{1+k}}{\sigma\sqrt{2}}\right)$$

where u_s is linear velocity of the sample through the tube, and k is the partition ratio defined as:

$$[16] \quad k = K_{es}\frac{V_e}{V_v}$$

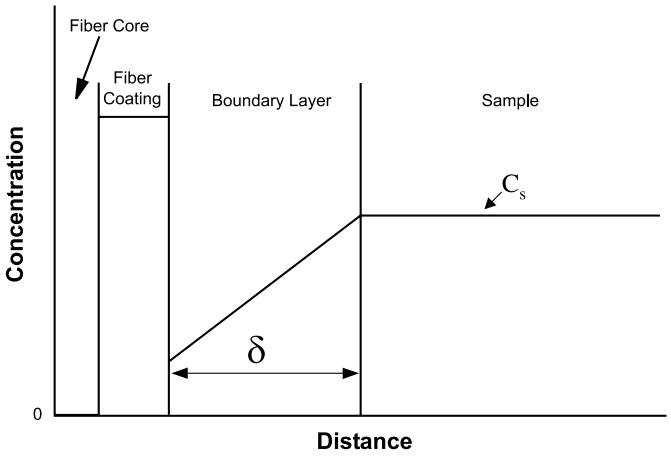
where K_{es} is a extraction phase – sample matrix distribution constant, V_e is the volume of the extracting phase, and V_v is a void volume of the tubing containing the extracting phase. σ is the mean square root dispersion of the front defined as:

$$[17] \quad \sigma = \sqrt{Ht\frac{u}{1+k}}$$

where H is equivalent to the HETP (height equivalent to theoretical plate) in chromatographic systems. This can be calculated as a sum of individual contributions to the front dispersion. These contributions are dependent on the particular geometry of the extracting system as discussed previously in the theory section of this article.

Equation [15] indicates that the front of analyte migrates through the capillary–bed with speed proportional to the linear velocity of the sample and inversely related to the partition ratio. For the in-tube SPME and short capillaries with a small dispersion, the minimum extraction time for in-tube SPME at equilibrium conditions can be assumed to be similar to the time required for the centre of the band to reach the end of the capillary

$$[18] \quad t_e = \frac{L\left(1 + K_{es}\frac{V_e}{V_v}\right)}{u}$$



where L is the length of the capillary holding the extraction phase. For packed bed extractors typical for SPE techniques, analogous equations can be developed. In that case, the calculated time corresponds to the maximum extraction time before breakthrough occurs. As expected, the extraction time is proportional to the length of the capillary and inversely proportional to the linear flow rate of the sample. Extraction time also increases with an increase in the extraction phase – sample distribution constant and with the volume of the extracting phase but decreases with an increase of the void volume of the capillary.

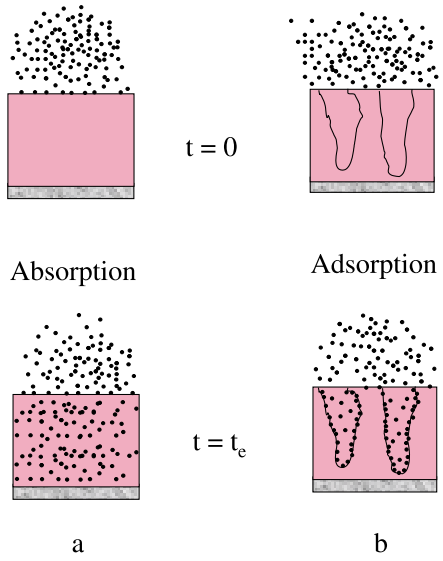
Coupling equations for systems involving convection caused by flow through a tube as discussed above, are frequently not available for other means of agitation and other geometric configurations. In these cases the most successful approach is to consider the boundary layer formed at the interface between the sample matrix and the extraction phase. Independent of the agitation level, fluid contacting a fibre's surface is always stationary, and as the distance from the fibre surface increases, the fluid movement gradually increases until it corresponds to bulk flow in the sample. To model mass transport, the gradation in fluid motion and convection of molecules in the space surrounding the fibre surface can be simplified as a zone of a defined thickness in which no convection occurs, and perfect agitation occurs in the bulk of the fluid everywhere else. This static layer zone is called *Prandtl* boundary layer (see Fig. 4) (21).

A precise understanding of the definition and thickness of the boundary layer in this sense is useful. The thickness of

© 2001 NRC Canada

Fig. 4. Boundary layer model of the mass transfer kinetics between extraction phase and sample matrix.

the boundary layer (δ) is determined by both the rate of convection (agitation) in the sample and an analyte's diffusion coefficient. Thus, in the same extraction process, the boundary layer thickness will be different for different analytes. Strictly speaking, the boundary layer is a region where analyte flux is progressively more dependent on analyte diffusion and less on convection, as the extraction phase is approached. For convenience however, analyte flux in the bulk of the sample (outside of the boundary layer) is assumed to be controlled by convection, whereas analyte flux within the boundary layer is assumed to be controlled by diffusion. δ is defined as the position where this transition occurs or the point at which convection towards the extraction phase is equal to diffusion away. At this point, analyte flux from δ towards the extraction phase (diffusion controlled) is equal to the analyte flux from the bulk of the sample towards δ, controlled by convection.



In many cases when the extraction phase is well-dispersed, forming a thin coating, the diffusion of analytes through the boundary layer controls the extraction rate. The equilibration time (t_e) can be estimated as time required to extract 95% of the equilibrium amount and calculated for these cases from the equation below (4):

$$[19] \quad t_e = B\frac{\delta a K_{es}}{D_s}$$

where a is the extraction phase thickness, D_s is the analyte's diffusion coefficient in the sample matrix, and K_{es} is the analyte's distribution constant between the extraction phase and the sample matrix. B is a geometric factor referring to the geometry of the supporting material upon which the extraction phase is dispersed on. The boundary layer thickness can be calculated for given convection conditions using engineering principles and it is discussed in more detail later. Equation [19] can be used to predict equilibration times when the extraction rate is controlled by diffusion in the boundary layer, which is valid for thin extraction phase coatings (a < 200 microns) and high distribution constants (K_{es} > 100).

The properties of the extraction phase should be carefully optimized. These include both bulk physicochemical properties, such as polarity, and physical properties. The discussion

Fig. 5. Extraction using (*a*) absorptive and (*b*) adsorptive extraction phases immediately after exposure of the phase to the sample (t = 0) and after completion of the extraction ($t = t_e$).

to this point has been limited to extraction by liquid phases. These exhibit wide linear dynamic ranges associated with linear absorption isotherms. They also facilitate gentle sample preparation since chemisorbtion and catalytic properties, frequently associated with solid surfaces, are absent. No loss or modification of the analyte occurs during extraction and (or) desorbtion. Despite these attractive properties of liquid extraction media, solid phases are frequently used because of their superior selectivity and sensitivity for some groups of compounds. There is a substantial difference in performance between liquid and solid coatings (Fig. 5). In the case of liquid coatings, the analytes partition into the extraction phase, where the molecules are solvated by the coating molecules. The diffusion coefficient in the liquid coating allows the molecules to penetrate the whole volume of the coating within a reasonable extraction time if the coating is thin (see Fig. 5*a*). In the case of solid sorbents the coating has a well-defined crystalline structure, which if dense, substantially reduces the diffusion coefficients within the structure. Therefore within the experimental time, sorption occurs only on the porous surface of the coating (see Fig. 5*b*). During extraction by solid phase, compounds with poor affinity towards the phase are frequently displaced at longer extraction times by analytes characterized by stronger binding or those present in the sample at high concentrations. This effect is associated with the fact that there is only a limited surface area available for adsorption. If this area is substantially occupied then a competition effect occurs (6) and the equilibrium amount extracted can vary with concentrations of both the target and the other analytes. On the other hand, in the case of extraction with liquid phases, partitioning between the sample matrix and extraction phase occurs. In this case, equilibrium extraction amounts vary only if the bulk coating properties are modified by the extracted components, which only occurs when the amount extracted is a substantial portion (a few percent) of the extraction phase. This is rarely observed, since extraction–enrichment techniques are typi-

© 2001 NRC Canada

cally used to determine trace contamination, samples however cannot be neglected as a possible course of nonlinearity, when quantifying very complex matrices.

The only way to overcome this fundamental limitation of porous coatings is, as the above figure suggests, to use an extraction time much less than the equilibrium time, so that the total amount of analytes accumulated onto the porous coating is substantially below the saturation value. When performing such experiments, not only it is critical to precisely control extraction times, but also convection conditions since they determine the thickness of the diffusion layer. One way of eliminating the need for compensation of differences in convection is to normalize (use consistent) agitation conditions. For example, the use of mechanical stirring in the laboratory at a well-defined rotation rate or fans for field air monitoring, will ensure consistent convection (22, 23). The short-time exposure measurement described above has an advantage associated with the fact that the rate of extraction is defined by diffusivity of analytes through the boundary layer of the sample matrix and the corresponding diffusion coefficients, rather than by distribution constants. This situation was illustrated in Fig. 6 for cylindrical geometry of the extraction phase dispersed on the supporting rod.

The analyte concentration in the bulk of the matrix can be considered constant when a short sampling time is used and there is a constant supply of an analyte via convection. These assumptions are true for most cases of sampling, where the volume of sample is much greater then than the volume of the interface and the extraction process does not affect the bulk sample concentration. In addition, the solid coating can be treated as a perfect sink. The adsorption binding is instantaneous and essentially irreversible. The analyte concentration on the coating surface is far from saturation and can be assumed to be negligible for short sampling times and relatively low analyte concentrations in a typical sample. The analyte concentration profile can be assumed to be linear from C_s to C_0. In addition, the initial analyte concentration on the coating surface (C_0) can be assumed to be equal to zero when extraction begins. Diffusion of analytes inside the pores of a solid coating controls mass transfer from *b* to *d*.

The function describing the mass of extracted analyte with sampling time can be derived using the analogy of the heat transfer problem, (24) which results in the following equation:

$$[20] \qquad n(t) = \frac{AD_s}{\delta}\int_0^t C_s(t)\mathrm{d}t$$

where *n* is the mass of extracted analyte over sampling time (*t*) in ng, D_s is the gas-phase molecular diffusion coefficient, *A* is the surface area of the sorbent, δ is the thickness of the boundary layer surrounding the extraction phase, B_1 is a geometric factor, and C_s is analyte concentration in the bulk of the sample. It can be assumed that the analyte concentration is constant for very short sampling times and therefore eq. [20] can be further reduced to:

$$[21] \qquad n(t) = \frac{D_s A}{\delta} C_s t$$

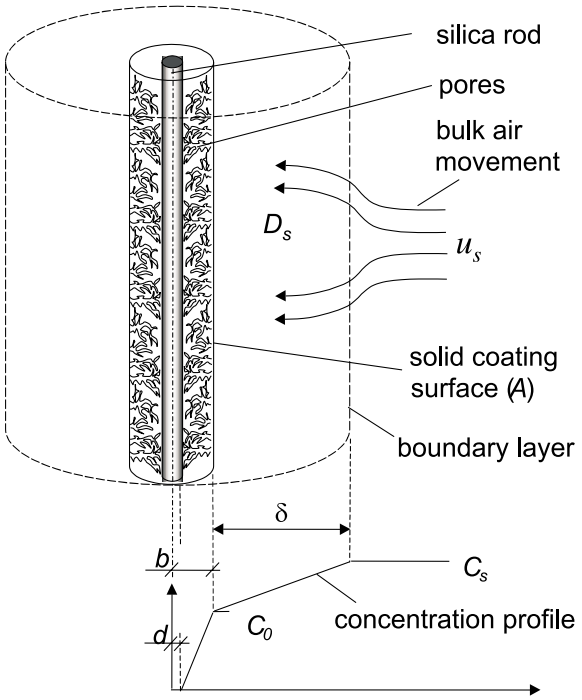
where *t* is the sampling time (25).

It can be seen from eq. [21] that the amount of extracted mass is proportional to the sampling time, the D_s for each analyte, and bulk sample concentration and is inversely proportional to δ. This is consistent with the fact that an analyte with a greater D_s will cross the interface and reach the surface of the fibre coating faster. Values of D_s for each analyte can be found in the literature or estimated from physicochemical properties (25). This relationship allows for quantitative analysis. Equation [21] can be modified to estimate the analyte concentration in the sample for rapid sampling with solid sorbents.

$$[22] \qquad C_s = \frac{n\delta}{B_1 D_s A t}$$

The amount of extracted analyte (*n*) can be estimated from the detector response.

The thickness of the boundary layer (δ) is a function of sampling conditions. The most important factors affecting δ are geometric configuration of the extraction phase, sample velocity, temperature, and D_s for each analyte. The effective thickness of the boundary layer can be estimated for the coated fibre geometry (see Fig. 6) using eq. [23], adapted from heat transfer theory (21)



$$[23] \qquad \delta = 9.52\frac{d}{\mathrm{Re}^{0.62}\, Sc^{0.38}}$$

where *Re* is the Reynolds number ($Re = 2u_s d/\nu$): u_s is the linear sample velocity, ν is the kinematic viscosity of matrix, *Sc* is the Schmidt number ($Sc = \nu/D_s$), and *d* is the fibre diameter. The effective thickness of the boundary layer in eq. [23] is a surrogate (or average) estimate and does not take into account changes of the thickness that may occur when the flow separates and (or) a wake is formed. Equation [23] indicates that the thickness of the boundary layer will decrease with an increase of the linear sample velocity (Fig. 6). Similarly, when sample temperature (T_g) increases, the kinematic viscosity also increases. Since the kinematic viscosity term is present in the numerator of *Re* and in the denominator of *Sc*, the overall effect on δ is small. A reduction of the boundary layer and an increase of the mass transfer rate for an analyte can be achieved in at least two ways, i.e., by increasing the sample velocity and by increasing the sample temperature. However, the temperature increase will reduce the solid sorbent efficiency. As a result, the sorbent coating may not be able to adsorb all molecules reaching the surface and therefore stop to behave as a zero sink for all analytes.

Equations [19] and [21] indicate that use of the headspace above the sample as an intermediate phase might be an interesting approach to accelerate extraction for analytes characterized by high Henry constants. When a thin extraction phase is used, the initial extraction rate and, hence, the extraction time is controlled by the diffusion of analytes through the boundary layer present in the sample matrix. The presence of a gaseous headspace facilitates rapid transport into the extraction phase because of the high diffusion coefficients. To increase the transport from the sample matrix into the headspace the system can be designed to produce a large sample–headspace interface. This can be accomplished by using large diameter vials with good agita-

© 2001 NRC Canada

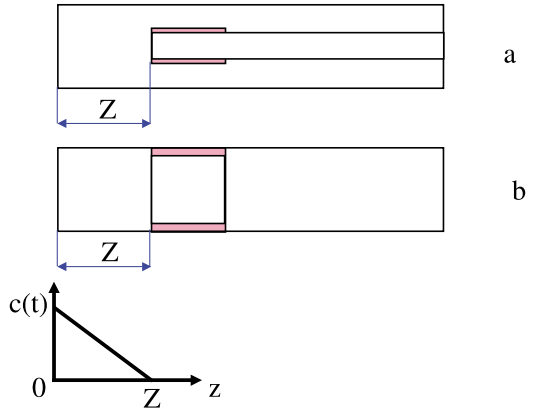


Fig. 6. Schematic of the diffusion based calibration model. The terms are defined in the text.

tion, purge, or even spray systems. At room temperature only volatile analytes are transported through the headspace. For low volatility compounds, heating of the sample is a good approach, if loss in magnitude of the distribution constant can be accepted. The ultimate approach is to heat the sample and cool the extraction phase at the same time. Heating of the sample does not only increases the Henry constant, but also induces convection of the headspace due to density gradients associated with temperature gradients present in the system, resulting in a higher mass transport rates. The cooling of the sorbent increases its capacity. Collection of analytes can be performed in the same vial (26) or can be separated in space similarly as in the purge and trap technique. In the heating-cooling experiments, both kinetic and thermodynamic factors are addressed simultaneously. Headspace approaches are also interesting since adverse affects associated with presence of solids, oily or high molecular weight interferences, which can cause fouling of the extraction phase, are eliminated.

Consideration of different arrangements of the extraction phase is always beneficial. For example, extension of the boundary layer by a protective shield that restricts convection would result in time weighted average (TWA) measurement of analyte concentration (see eq. [21]). Various diffusive samplers have been developed based on this principle. For example, when the extracting phase in SPME device is not exposed directly to the sample, but is contained in a protective tubing (needle) without any flow of the sample through it (see Fig. 7), the diffusive transfer of analytes occurs through the static sample (gas phase or other matrix), trapped in the needle. The system can consist either of an externally coated fibre with extraction phase withdrawn into the needle (Fig. 7*a*) or internally coated needle (Fig. 7*b*).

Fig. 7. SPME–TWA approaches based on the (*a*) in-needle fibre and (*b*) in-needle coating.

These geometric arrangements represent a very powerful method, capable of generating a response proportional to the integral of the analyte concentration over time and space (when the needle is moved through space) (27). In these cases, the only mechanism of analyte transport to the extracting phase is diffusion through the matrix contained in the needle. During this process, a linear concentration profile (shown in Fig. 7) is established in the tubing between the small needle opening, characterized by surface area A and the distance Z between the needle opening and the position of the extracting phase. The amount of analyte extracted (dn) during time interval (dt), can be calculated by considering Fick's first law of diffusion (4)

$$[24] \qquad \mathrm{d}n = AD\frac{\mathrm{d}c}{\mathrm{d}z}\mathrm{d}t = AD\frac{\Delta C(t)}{Z}\mathrm{d}t$$

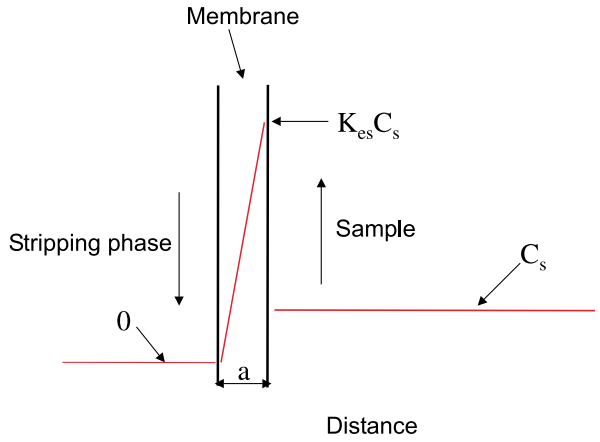
where $\Delta C(t)/Z$ is an expression of the gradient established in the needle between the needle opening and the position of the extracting phase (Z), $\Delta C(t) = C(t) - C_Z$, where $C(t)$ is a time dependent concentration of analyte in the sample in the vicinity of the needle opening, and C_Z is the concentration of the analyte in the gas phase in the vicinity of the coating. C_Z is close to zero for a high extraction phase – matrix distribution constant capacity, therefore, $\Delta C(t) = C(t)$. The concentration of analyte at the coating position in the needle (C_Z) will increase with integration time, but it will be kept low compared to the sample concentration because of the presence of the extraction phase. Therefore, the accumulated amount over time can be calculated as:

$$[25] \qquad n = D\frac{A}{Z}\int C_s(t)d$$

As expected, the extracted amount of analyte is proportional to the integral of the sample concentration over time, the diffusion coefficient of analyte in the matrix filling the needle (D), in the area of the needle opening (A), and inversely proportional to the distance of the coating position in respect of the needle opening (Z). It should be emphasized that eqs. [24] and [25] are valid only in a situation where the amount of analyte extracted onto the sorbent is a small fraction (below RSD of the measurement, typically 5%) of the equilibrium amount in respect to the lowest concentration in the sample. To extend integration times, the coating can be

© 2001 NRC Canada

placed further into the needle (larger Z), the opening of the needle can be reduced by placing an additional orifice (smaller A), or a higher capacity sorbent can be used. The first two solutions will result in low measurement sensitivity. An increase of sorbent capacity presents a more attractive opportunity. It can be achieved by either increasing the volume of the coating or its affinity towards the analyte. An increase of the coating volume will require an increase of the device size. The optimum approach to increased integration time is to use sorbents characterized by large coating – gas distribution constants. If the matrix filling the needle is other then sample matrix then an appropriate matrix–sample distribution constant should be added to numerator in eq. [25] as discussed below in the case of membrane extraction.



The capacity of the extraction phase for the difficult to extract analytes such as polar or ionic species is frequently enhanced by introducing a derivatization step. The objective of this approach is frequently not only to convert the native analytes into less polar analytes that are extracted more efficiently, but also to frequently label them for better detection and (or) chromatography. The most interesting implementation of this approach is simultaneous extraction–derivatization. In this technique, the derivatization reagent is present in the extraction phase during the extraction. The major advantage of this approach is that two steps are integrated into one. There are two limiting cases describing the combination between extraction and derivatization. The first occurs when mass transfer to the fibre is slow compared to the reaction rate. In this case eq. [18], as discussed above, describes the accumulation rate of analytes in the extraction phase.

In the second limiting case, the situation is reversed in that the reaction rate is slow compared to the transport of analytes to the extraction phase. In the other words, at any time during the extraction, the extraction phase is at equilibrium with the analyte remaining in a well-agitated sample, resulting in uniform reaction rate throughout the coating. This is a typical case for thinly dispersed extraction phase, since the equilibration time for well-agitated conditions is very short compared to a typical reaction rate constant. The accumulation rate of the product in the extraction phase (n/t) can then be defined by:

$$[26] \qquad n = V_e k_r K_{es} \int C_s(t)\mathrm{d}t$$

where C_s is the initial concentration of analyte in the sample and k_r is chemical reaction rate constant. In the other words, when the sample is of large volume, such as direct sampling in the field, the reaction and accumulation of analyte in the extraction phase proceeds with the same rate as long as reagent is present in an excess amount. It is worth noting that the rate is also proportional to the extraction phase – sample matrix distribution constant. If the concentration varies during the accumulation, the collected amount corresponds to the integral over concentration and time, similarly as discussed above in the case of time weighted average sampling. For limited sample volume, however, the concentration of analyte in the sample phase decreases with time as it is partitioned into the coating and converted to product, resulting in a gradual decrease of the rate. The time required to exhaustively extract analytes from a limited volume can be estimated using experimental parameters (4).

Fig. 8. Membrane extraction at good sample agitation and stripping conditions. The terms are defined in the text.

For continuous monitoring applications, extraction using membrane is an attractive approach. Permeation through membrane is a specific extraction process where the sorbtion into and desorbtion out of the extraction phase occurs simultaneously (see Fig. 8). The sample (donor phase) is in contact with one side of the membrane where extraction into membrane material occurs, while permeated analytes are removed by the stripping phase (acceptor). For membrane extraction with good flow (agitation) conditions at both acceptor and donor sites and efficient stripping, the rate of mass transport through the membrane is controlled by the diffusion of analytes through the membrane material. The concentration gradient which facilitates transport across the membrane is formed by the difference in analyte concentration between the sample side ($K_{es}C_s$) and the stripping phase (0). The mass transfer rate through the membrane (n/t) can be estimated at steady state conditions using the following equation (28):

$$[27] \qquad n/t = B_2 A D_e K_{es} C_s/a$$

Where A is the surface area of the membrane, D_e is the diffusion coefficient in the membrane material, K_{es} is the membrane material – sample matrix distribution constant, a is a thickness of the membrane, and B_2 is a geometric factor defined by the shape of the membrane. The permeation rate through the membrane is proportional to both the diffusion coeficient (D_e) and the distribution constant (K_{es}). D_e determines the rate of analyte migration through the membrane and K_{es} the magnitude of the concentration gradient generated in the membrane. This information can be used to calibrate the extraction process a priori if these parameters are obtained from tables or experimental data (29).

The concentration of unknown can be calculated by converting the eq. [27]:

$$[28] \qquad C_s = \frac{an}{B_2 A D_e K_{es} t}$$

The membrane material – sample matrix distribution constant K_{es} determines the sensitivity of membrane extraction (see eq. [27]) indicating that the membrane, although a

© 2001 NRC Canada

physical barrier, is also a concentrating medium, analogous to the extraction phase in other configurations. However the concentration in the stripping gas phase are lower compared to the sample since the gradient needs to exist in the membrane to generate diffusive mass transfer through the membrane material (see Fig. 8). Therefore, incorporating sorbent after the membrane would allow concentration of the extract and therefore sensitive analysis (29). When the membrane is in direct contact with the aqueous phase then the mass transfer through the boundary layer surrounding the membrane could contribute to the overall mass transfer in the system. Therefore, for analytes characterized by a high Henry constant, it is important to consider headspace membrane extraction arrangement.

Conclusions

Reliance on physicochemical constants in calibration might appear unconventional or even make some researchers uncomfortable. However as the theory indicates, these constants define the extraction process and there is an opportunity to take advantage of this fact. Physicochemical constants can be frequently estimated from simple experiments or calculated by considering the molecular structures of analytes, extraction phase, and matrix, which adds to attractiveness of this approach. For equilibrium microextraction techniques the extraction phase – sample matrix distribution constant is used to quantify the concentration of analytes in the sample matrix (see eq. [2]). For extraction approaches controlled by the mass transfer in the boundary layer, calibration can be based on the diffusion coefficient in the sample matrix at constant extraction time under well-defined agitation conditions. When the derivatization reaction kinetics controls the extraction rate, the rate constant can provide a means for calibration. In some cases, as in membrane extraction, a combination of constants defines the extraction rate and can be used for calibration. The major argument against using this approach is that physicochemical constants are affected by many experimental parameters, such as temperature and matrix conditions. However, the impact of temperature change can be compensated for and therefore direct calibration for simple matrices is possible (30). For more complex matrices, internal standard or standard addition calibration, applied routinely in exhaustive techniques to monitor recoveries, can be used to compensate for matrix variations (31). In future research, correlations between distribution constants and simple measurements such as turbidity and pH may be found to account for matrix variations and therefore eliminate the need for internal calibration. The advantages of nonexhaustive extraction are its fundamental simplicity and fewer geometric restrictions, which facilitate a number of interesting on-site implementations by integrating the sampling and sample preparation steps. Additionally, more information can be obtained about the investigated system. For example, it is possible to speciate and determine distribution of analyte in multiphase systems since the extraction process does not disturb the equilibria naturally present in the system. Therefore, different forms of an analyte are extracted and quantified according to their corresponding distribution constants and (or) diffusion coefficients.

A better understanding of the fundamentals of the extraction processes facilitates exploration of new opportunities, which makes sample preparation a more vital and scientifically exciting part of the analytical process. The focus in this discussion has been on chemical extraction, purposely neglecting extraction approaches involving mechanical principles, which would introduce an additional level of complexity, although these would be interesting to explore in future development of the technology.

Interaction of human serum albumin with oxovanadium ions studied by FT-IR spectroscopy and gel and capillary electrophoresis

M. Purcell, J.F. Neault, H. Malonga, H. Arakawa, and H.A. Tajmir-Riahi

Abstract: Some oxovanadium compounds have shown potential to inhibit RNase activity, while at the same time not inhibiting DNase activity. Some vanadyl complexes also inhibit protein synthesis in rabbit reticulocytes, but induce activation of protein–tyrosine kinase. To gain an insight into the interaction of oxovanadium ions with proteins, the present study was designed to examine the bindings of $VOSO_4$ and $NaVO_3$ salts with human serum albumin (HSA) in aqueous solution at physiological pH with metal ion concentrations of 0.0001 to 1 mM and HSA (fatty acid free) concentration of 2% w/v. Gel and capillary electrophoresis (CE) and Fourier transform infrared (FT-IR) spectroscopic methods were used to determine the metal ion binding mode, association constant, and the secondary structure of the protein in the presence of the oxovanadium compounds. Gel electrophoresis results showed that a maximum of 20 vanadyl cations (VO^{2+}) are bound per HSA molecule with strong ($K_1 = 7.0 \times 10^7$ M^{-1}) and weak ($K_2 = 6.5 \times 10^5$ M^{-1}) bindings. Similarly, capillary electrophoresis showed two major bindings for vanadyl cation with $K_1 = 1.2 \times 10^8$ M^{-1} and $K_2 = 8.5 \times 10^5$ M^{-1}, whereas vanadate (VO_3^-) has only a weak binding affinity ($K = 6.0 \times 10^3$ M^{-1}) with HSA molecule. The VO_3^- binds mainly to the lysine ε-amino NH_3^+ groups, while VO^{2+} binds possibly to the histidine nitrogen atom and the N-terminal of the α-amine residue. Infrared spectroscopic analysis showed metal ion binding results in major protein secondary structural changes from that of the α-helix (55.0 to 43–44%) to the β-sheet (22.0 to 23–26%), β-antiparallel (12.0 to 13–16%), and turn (11.0 to 17–18%), at high metal ion concentration. The observed spectral changes indicate a partial unfolding of the protein structure, in the presence of oxovanadium ions.

Key words: oxovanadium, protein, binding mode, binding constant, secondary structure, electrophoresis, FT-IR spectroscopy.

Résumé : Certains composés de l'oxovanadium présentent du potentiel pour inhiber l'activité de la RNase tout en n'inhibant pas la DNase. Certains complexes de vanadyle inhibent aussi la synthèse des protéines dans les réticulocytes de lapins tout en induisant une activation de la kinase de la protéine-tyrosine. Ce travail a été entrepris dans le but de mieux comprendre les interactions entre les ions oxovanadium et les protéines et, à cette fin, on a mesuré la fixation de sels de $VOSO_4$ et de $NaVO_3$ avec l'albumine de sérum humain (ASH; ne contenant pas d'acide gras libre) à une concentration de 2% w/v, en solution aqueuse, au pH physiologique et en présence d'ions métalliques à des concentrations allant de 0,0001 à 1 mM. On a fait appel à l'électrophorèse capillaire et sur gel ainsi qu'à des méthodes de spectroscopie infrarouge à transformation de Fourier (FT-IR) pour déterminer le type de fixation des ions métalliques, les constantes d'association et les structures secondaires de la protéine en présence de composés oxovanadium. Les résultats d'électrophorèse sur gel montrent qu'un maximum de 20 cations vanadyles (VO^{2+}) sont liés à la molécule d'ASH avec des fixations fortes ($K_1 = 7{,}0 \times 10^7$ M^{-1}) et faibles ($K_2 = 6{,}5 \times 10^5$ M^{-1}). De la même manière, l'électrophorèse capillaire met en évidence deux fixations principales pour l'ion vanadyle avec $K_1 = 1{,}2 \times 10^8$ M^{-1} et $K_2 = 8{,}5 \times 10^5$ M^{-1} alors qu'on n'observe qu'une seule fixation faible ($K_1 = 6{,}0 \times 10^3$ M^{-1}) d'ASH avec le vanadate (VO_3^-). L'anion VO_3^- si lie principalement aux groupes NH_3^+, ε-amino, de la lysine alors que le cation VO^{2+} se lierait vraisemblablement avec l'atome d'azote de l'histidine et le N-terminal du résidu d'acides aminés. L'analyse par spectroscopie infrarouge montre que la fixation des ions métalliques provoque des changements importants dans la structure secondaire de la protéine qui, à concentration d'ion métallique élevée, passe de 55 à 43–44% de α-hélice, de 22,0 à 23–26% de feuillet-β, de 12,0 à 13–16% de β-antiparallel et de 11,0 à 17–18%. Les changements spectraux observés indiquent que, en présence d'ions oxovanadium, la structure de la protéine se déplie légèrement.

Mots clés : oxovanadium, protéine, mode de fixation, constante de fixation, électrophorèse, spectroscopie FT-IR.

Introduction

Vanadium enters cells as vanadate (VO_3^-), where it is reduced to the vanadyl cation (VO^{2+}) at physiological pH (1–3). These metal ions bind to a variety of biological molecules including proteins, amino acids, nucleic acids, phosphates, and phospholipids and alter their structural properties (2–6). Some of oxovanadium complexes have shown potential to inhibit RNase activity by acting as a transition analogue, while at the same time not inhibiting DNase activity. The activation of cytosolic protein–tyrosine kinase by vanadate ions has been studied and the effects of these cations on the biological actions of insulin were reviewed (7, 8). Similarly, the inhibition effect of vanadyl cations on the activity of Na-, K-ATPase has been investigated (9). The association constants of vanadium complexes formed with different ligands show strong affinity for coordination to both nitrogen and oxygen donor groups (10). Recently, on the basis of the electron spin echo envelope modulation, coordination of the vanadyl cation to nitrogen atoms of Lys ε-amine or the terminal α-amine of a protein or peptide has been demonstrated (11). To better understand the biochemical role of vanadium with respect to its ability to promote and (or) inhibit enzymatic effects in biological systems (3, 11–13), the structural analyses of vanadium–protein complexes, including the metal ion binding sites, the binding constants, and the effects of metal ion coordination on the secondary structure of the protein, are of major biological importance. Thus, the present study is designed to examine, in vitro, the complexation of oxovanadium ions with human serum albumin (HSA).

Human serum albumin (HSA) represents an important and the most abundant protein constituent of blood plasma and serves as a protein storage component. Recently, the three-dimensional structure of HSA was determined through X-ray crystallographic measurements (14). This globular protein, which has many important physiological functions, consists of a single polypeptide chain of 585 amino acids (15, 16). HSA contributes considerably to colloid osmotic blood pressure and realizes the transport and distribution of many molecules and metabolites such as fatty acids, amino acids, hormones, cations and anions, and many diverse drugs. It also makes possible to bind and carry through the bloodstream many drugs that are poorly soluble in water (16). It has been shown that the distribution, the free concentration, and the metabolism of various drugs can be significantly altered as a result of their bindings to HAS (17). Therefore, the interaction of oxovanadium ions with HSA has major biochemical importance.

We now report the gel and capillary electrophoresis as well as Fourier transform infrared (FT-IR) spectroscopic results on the interaction of $VO^{2+}$and VO_3^- with HSA, in aqueous solutions at physiological pH, using various concentrations of oxovanadium ions with a constant concentration of HSA. Spectroscopic evidence regarding the cation binding mode, the association constant, and the secondary structure of the protein are provided here. To our knowledge, our structural information provides the first spectroscopic evidence of a vanadium–HSA interaction that helps elucidation of the nature of this biologically important complexation both in vitro and in vivo.

Materials and methods

Materials

Human serum albumin (HSA) fraction V (fatty acid free) was purchased from Sigma. Hydrated crystalline $VOSO_4$ and $NaVO_3$ salts were from Aldrich and recrystallized from water. D_2O (99.8%D) was from Aldrich. Other chemicals were of reagent grade and used without further purification.

Preparation of stock solution

Human serum albumin (HSA, fatty acid free) was dissolved in Na–phosphate buffer (0.1 M, pH 7.2) containing NaCl (50 mM) to attain the concentration of 4% w/v. The $VOSO_4$ and $NaVO_3$ (0.0002–2 mM) solutions were prepared in double-distilled water. For the samples to be analyzed by FT-IR spectroscopy, a solution of the vanadium salt was added dropwise to the protein solution with constant stirring to ensure the formation of homogeneous solution and to attain the desired metal ion concentrations of 0.0001, 0.001, 0.01, 0.1, and 1 mM with a final protein concentration of 2% w/v. The pH or pD of the solution was adjusted to 6.8–7.5 by the addition of NaOH–NaOD (0.1 M) or HCl–DCl (0.1 M).

Gel electrophoresis

Polyacrylamide gel electrophoresis was performed at room temperature in the buffer system of Laemmli (18), using miniature slab gels (Hoefer Scientific Instruments) containing 8% acrylamide. The gels were stained with Coomassie brilliant blue and scanned with a LKB 2400 Ultro Scan XL laser densitometer. The polypeptide content of the band was evaluated by integration of the peak and molecular weight was estimated from the low molecular weight standards from Bio-Rad. The absorbance of the laser beam at 633 nm was recorded, and the relationship between staining intensity and protein concentration was confirmed to be linear. HSA was diluted in H_2O to attain a final concentration of 1.5 μM and mixed with oxovanadium ions to attain final concentrations of 0.0001–1 mM. The denaturating conditions were optimised to ensure the integrity of the oxovanadium–HSA complexes formed during the migration.

Capillary electrophoresis

P/ACE System MDQ (Beckman) with PDA (photodiode array) detector was used in this study. Uncoated fused silica capillary of 75 μm i.d. and 57 cm length was used. The capillary was initially conditioned by washing with 1 N sodium hydroxide for 30 min, followed by a 15 min wash with 0.1 M sodium hydroxide. Then, it was extensively rinsed with deionized water and the running buffer before use. Samples were injected using a voltage of 10 kV for 5 s. Electrophoresis was carried out at 25 kV for 12 min using normal polarity. All runs were carried out 25°C in a run buffer of Tris–HCl (20 mM, pH 7.2). The electropherograms were monitored at 220 nm. Stock solutions of HSA (1.0% w/v) were prepared in Tris–HCl (8 mM, pH 7.2), and $VOSO_4$ (0.2 mM) and $NaVO_3$ (4 mM) were prepared in deionized water. The capillary inlet and outlet vials were replenished after every run. The VO^{2+} and VO_3^- binding experiments were performed in Tris–HCl (4 mM, pH 7.2) containing a constant concentration of HSA (0.1% w/v) and

© 2001 NRC Canada

various concentrations of VO^{2+} (10^{-6} to 10^{-1} mM) and VO_3^- (10^{-1} to 2 mM). Each sample was allowed to equilibrated for 30 min before injection.

Data analysis

The binding constants for the VO^{2+}–HSA and VO_3^-–HSA complexes were determined by capillary electrophoresis using Scatchard analysis (19–21). The average number (R_f) of oxovanadium ions bound per one binding site of the HSA was determined from the change of the peak height using the following equation:

$$[1] \qquad R_f = (H - H_o)/(H_s - H_o)$$

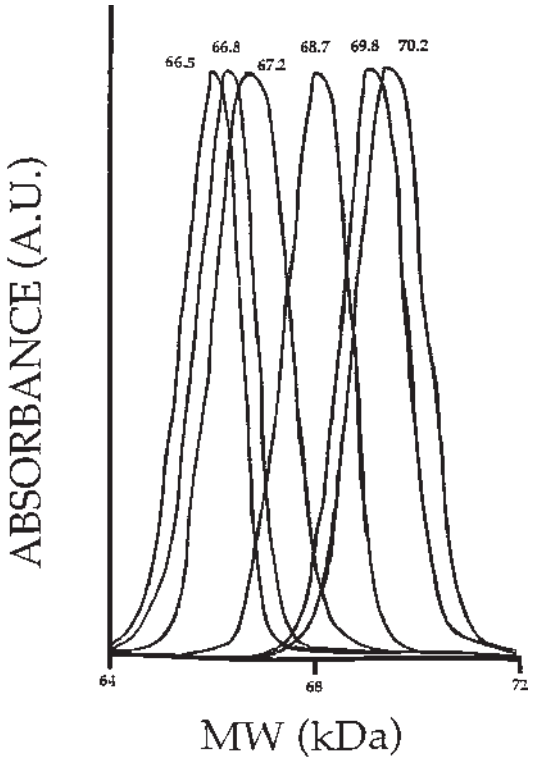
where H is the change of the peak height measured for added oxovanadium ion concentration, and H_o and H_s correspond to the peak heights of the free HSA and the oxovanadium ion saturated, respectively. Using the equation for binding constant

$$[2] \qquad K_b = [\text{oxovanadium ion} - \text{HSA}]/[\text{HSA}][\text{oxovanadium ion}]$$

the experimental oxovanadium ion binding constants (K_b) were then computed by fitting the experimental values of R_f and the oxovanadium ion concentrations to eq. [3].

$$[3] \qquad R_f = K_b[\text{oxovanadium ion}]/(1 + K_b[\text{oxovanadium ion}])$$

The last equation gives a convenient form for Scatchard analysis:



$$[4] \qquad R_f/[\text{oxovanadium ion}] = K_b - K_b R_f$$

The binding constants of VO^{2+}–HSA were also determined by polyacrylamide gel electrophoresis by the same procedure of the capillary electrophoresis except that R_f was calculated from the mobility of each sample, and the logarithmic form of eq. [4] was used instead of eq. [4].

FT-IR spectroscopic measurements

Infrared spectra were recorded on a BOMEMDA3–0.02 Fourier transform infrared spectrometer equipped with a nitrogen cooled HgCdTe detector and a KBr beam splitter. Solution spectra were recorded using AgBr windows with a resolution of 2 cm^{-1} and 100–500 scans. The subtraction of H_2O from protein solution was carried out as reported in our previous reports (22, 23). The difference spectra [(protein solution + vanadium ion solution) – (protein solution)] were generated using the polypeptide antisymmetric and symmetric C—H stretching bands (24), located at 2900–2800 cm^{-1} as internal standard. The protein C—H stretching vibrations exhibit no spectral changes upon metal ion interaction and are, therefore, canceled on spectral subtraction. The accuracy of this method of subtraction was tested by using several control samples with the same protein or metal ion concentrations, which resulted in the formation of a flat baseline. However, a similar absorption scale was used for the spectra of the free protein and its oxovanadium complexes as well as for the difference spectra produced. This method allowed us to obtain meaningful spectral differences between the free protein and its vanadium complexes at different metal ion concentrations. These spectral differences were then used, to characterize the nature of the metal–protein interaction.

Fig. 1. Densitometric profile showing the positions of the vanadyl–HSA complexes from the polyacrylamide gel electrophoresis. Vanadyl–HSA at: 70.2 (1 mM), 69.8 (0.1 mM), 68.7 (0.01 mM), 67.2 (0.001 mM), and 66.8 kDa (0.0001 mM) and HSA free at 66.5 kDa (the maximum error, based on two experiments is 0.3 kDa).

Determination of the secondary structure of the protein

Determination of the secondary structure of HSA and its vanadium complexes was carried out on the basis of the procedure described by Byler and Susi (25). The secondary structure of the protein was determined from the shape of the amide I band, located at 1650–1660 cm^{-1}. Fourier self-deconvolution and second-derivative resolution enhancement were applied to increase the spectral resolution in the region of 1700–1600 cm^{-1}. The second-derivative curves were produced using a point convolution of 11 or 13. The resolution enhancement resulting from self-deconvolution and the second derivative is such that the number and the position of the bands to be fitted are determined. To quantify the area of the different components of the amide I contour, revealed by self-deconvolution and second derivative, a least-square iterative curve-fitting was used to fit the Lorentzian line shapes to the spectra between 1700–1600 cm^{-1}. Before curve-fitting was done, a straight baseline passing through the ordinates at 1700 and 1600 cm^{-1} was subtracted. The baseline is then modified again by the least-square curve-fitting, which allowed for a horizontal baseline to be adjusted, as an additional parameter, to obtain the best fit. It is known that no meaningful curve-fitting can be performed by simple examination of the original infrared spectra, which is why the self-

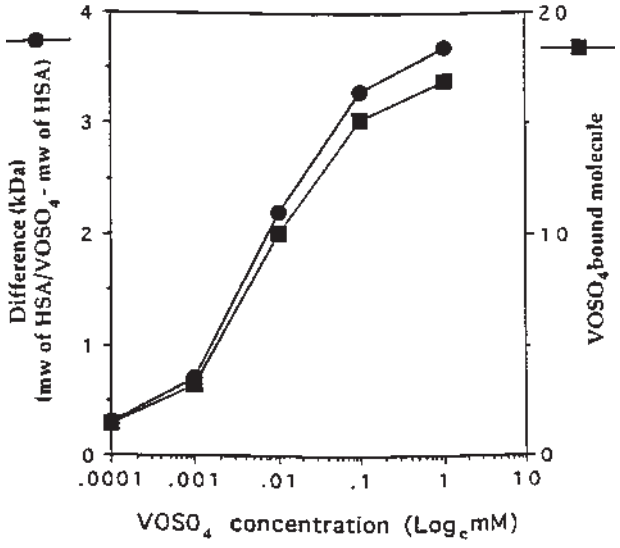

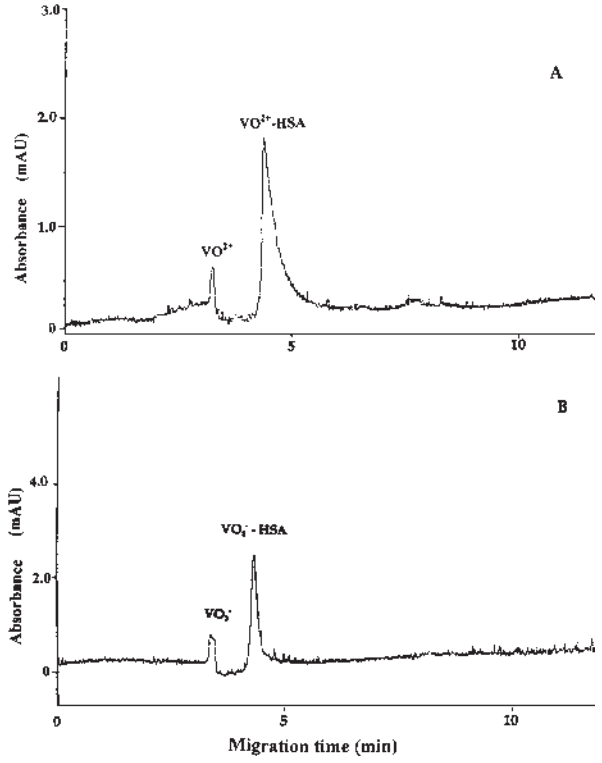

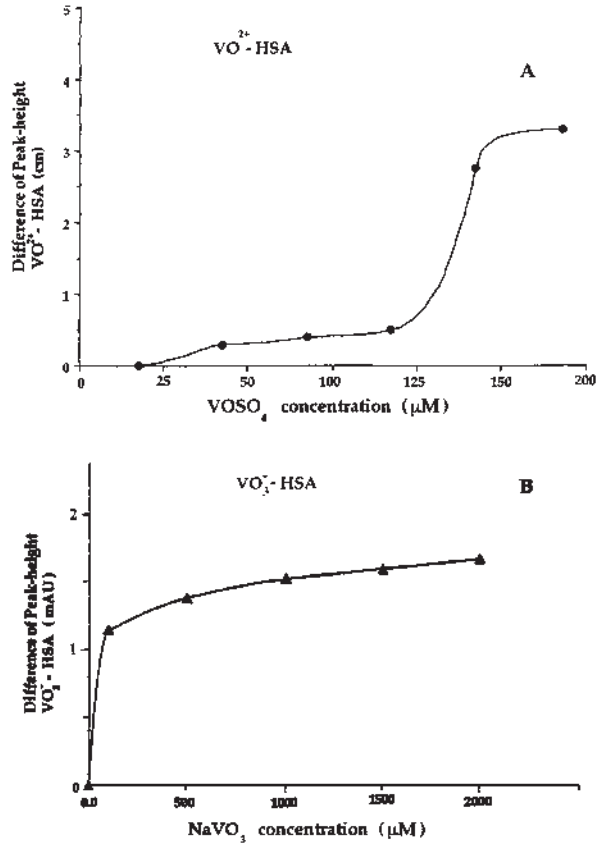

Fig. 3. Electropherograms showing mixtures containing constant concentration (0.1% w/v) of HSA and (*a*) 0.001 mM of $VOSO_4$ and (*b*) 0.1 mM of $NaVO_3$ at 220 nm. The capillary electrophoresis was performed at 25 kV in a run buffer of Tris–HCl (20 mM, pH 7.2).

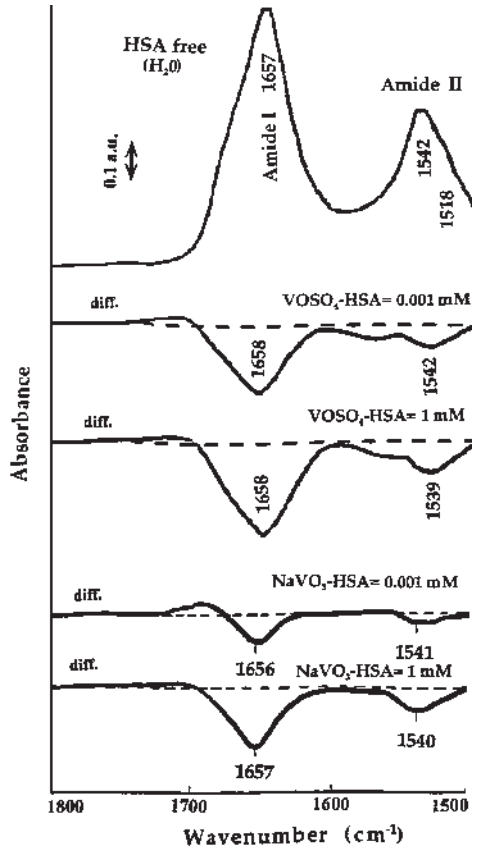
deconvolution procedure has to be carried out first. The curve-fitting was done using 25 simulations. The results of curve-fitting were analysed as follows: each Lorentzian band is assigned to a secondary structure according to the frequency of its maximum; α-helix (1658–1650 cm^{-1}), β-sheet (1615–1640 cm^{-1}), turn (1666–1673 cm^{-1}), random coil (1641–1645 cm^{-1}), and β-antiparallel (1680–1692 cm^{-1}). The area of all the band components assigned to a given conformation are then summed and divided by the total area. The number obtained is taken as the proportion of the polypeptide chain in that conformation. These assignments are consistent with the previous values determined theoretically (24) and experimentally (25). The accuracy of this method was tested on several proteins of the known conformational contents (through X-ray diffraction analysis), such as cytochrome c (α-helix 49%) and RNase A (α-helix 27%) (26, 27), which resulted in 2 to 3% differences. The data treatments of protein conformational analysis are also reported in our recent publication (28).

Fig. 4. Plots for oxovanadium ions concentrations vs. difference of peak heights in (*a*) VO^{2+}–HSA and (*b*) VO_3^-–HSA complexes from free HSA. Incubation of constant concentration (0.1% w/v) of HSA and various concentrations of oxovanadium ions were carried out in Tris–HCl (4 mM, pH 7.2) and the mixtures were subjected to the capillary electrophoresis.



Results and discussion

Gel electrophoresis

To study the nature of vanadium–HSA complexation, polyacrylamide gel electrophoresis was performed. The results obtained from the gel electrophoresis and densitometric measurements are presented in Fig. 1, which clearly show complexation between the VO^{2+} and HSA in aqueous solution. A peak was observed at 66.5 kDa corresponding to the free HSA and the other peaks at 66.8, 67.2, 68.7, 69.8, and

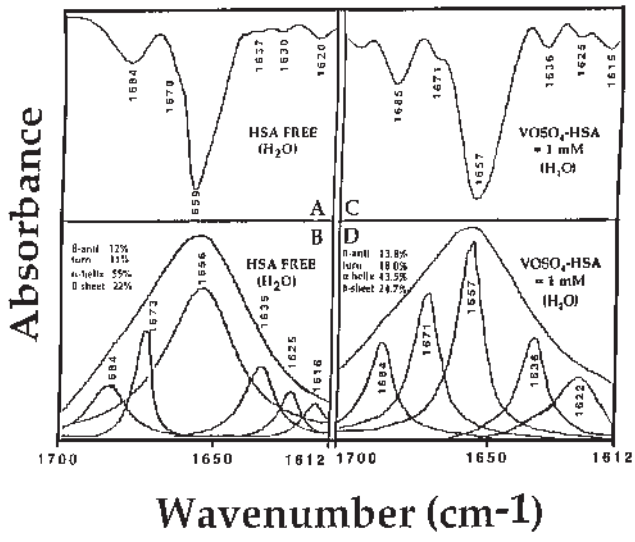
Fig. 5. FT-IR spectra (top first curve) and difference spectra [(protein solution + metal ion solution) – (protein solution)] (bottom four curves) of the free human serum albumin (HSA) and its vanadium complexes in aqueous solution at physiological pH with different metal ion concentrations in the region of 1800–1500 cm^{-1}. The baseline is shown as broken lines.



70.2 kDa are vanadyl protein complexes formed with cation concentrations of 0.0001, 0.001, 0.01, 0.1, and 1 mM, respectively. Figure 2 shows the relationship between vanadyl cation concentrations and the increase of molecular weight relative to free HSA. These results indicate that five distinct complexes are formed with cation–protein molar ratios of 1.5:1, 3.5:1, 10:1, 15:1, and 20:1. We thus suggest that about 1.5–20 vanadyl cations are bound per HSA molecule.

Capillary electrophoresis

In recent years, capillary electrophoresis was used to determine the binding constants of metal–protein complexes (29). The bindings of vanadyl cations and vanadate anions to HSA were also studied by capillary electrophoresis. The mixtures containing various concentrations of oxovanadium ions and constant concentration of HSA were subjected to the capillary electrophoresis. The electropherograms were monitored at 220 nm in a run buffer of Tris–HCl (20 mM, pH 7.2). As shown in Fig. 3, vanadyl cation and VO^{2+}–HSA (Fig. 3*a*) and vanadate anion and VO_3^-–HSA (Fig. 3*b*) were separated by the present condition. Figure 4*a* shows that binding of vanadyl cation to HSA occurred at two steps, since the increase of peak height of VO^{2+}–HSA reached plateaus at vanadyl concentrations of 0.1 and 10 μM. On the contrary, the binding of vanadate anion to HSA occurred at

Fig. 6. Second derivative resolution enhancement and curve-fitted amide I region (1700–1612 cm^{-1}) and secondary structure determination of the free HSA (curves *a* and *b*) and its vanadyl complexes (curves *c* and *d*) in aqueous solution with 1 mM cation concentration.

one step and the peak height of the VO_3^-–HSA reached plateau at vanadate concentration of 100 μM. To estimate the binding constants of the VO^{2+}–HSA and VO_3^-–HSA, Scatchard analysis (19) was performed by using data of R_f (the number of oxovanadium ions bound per one binding site of HSA) and R_f/concentrations of oxovanadium ions. The Scatchard plot for the VO^{2+}–HSA showed a biphasic slope indicating two distinct cation binding site and the binding constants were estimated to be 1.2×10^8 and 8.5×10^5 M^{-1}, respectively. In contrast, the plot for the VO_3^-–HSA showed a monophasic slope and the binding constant was estimated to be 6.0×10^3 M^{-1}.

Furthermore, based on the mobility of each VO^{2+}–HSA complex on the polyacrylamide gel, Scatchard plot for R_f vs. (R_f/concentrations of vanadyl cations) was performed. This analysis showed that vanadyl cation has a strong and a weak binding site. The binding constants for the two sites were calculated to be 7.0×10^7 and 6.5×10^5 M^{-1}, respectively. It should be noted that the binding nature of the VO^{2+}–HSA complexes observed from capillary electrophoresis are almost the same pattern as that of the gel electrophoresis. No binding constant was calculated for the VO_3^-–HSA from gel electrophoresis, due to a weak anion–protein interaction.

Metal cations such as Ni^{2+} and Cu^{2+} show strong affinity towards HSA with the binding constants ranging from 10^5 to 10^6 M^{-1} (17). HSA has two major strong binding sites (30). The first is the cysteine residue in position 34 (site V), which is able to bind Au^+, Ag^+, Hg^{2+}, and Cd^{2+} cations. The second is the so-called amino terminal (site VI), a binding site with high affinity for Ni^{2+} and Cu^{2+} cations, where the key feature is a histidine residue in the third position of the peptide chain (31). The vanadyl cation was shown to have strong affinity towards the imidazole nitrogen atom of histidine residues (11). Furthermore, recent structural analysis of the active site of vanadium chloroperoxidase showed that vanadyl cation binds directly to the nitrogen atom of

Amide I components (cm^{-1})	HSA free (%)	0.001 mM (%)	0.01 mM (%)	0.1 mM (%)	1 mM (%)
1692–1680 β-Antiparallel	12.0 ± 1	12.0 (12.6)	12.5 (12.9)	14.0 (13.6)	13.8 (13.8)
1673–1666 Turn	11.0 ± 1.0	15.0 (11.5)	17.0 (11.9)	17.0 (15.8)	17.0 (17.8)
1658–1650 α-Helix	55.0 ± 3.0	50.0 (53.3)	45.5 (52.4)	43.5 (47.6)	43.5 (43.4)
1641–1645 Random*	11.0 ± 1.0	11.0	12.0	12.0	13.0
1640–1615 β-Sheet	22.0 ± 1.0	23.0 (22.6)	25.0 (22.8)	25.5 (23.0)	25.7 (25.0)

Note: The values in parenthesis are from $NaVO_3$ solution.

*The values of random obtained from D_2O solution are not included in the values from water solution. The mean deviation was 1–3.0% for the free protein and its metal ion complexes.

histidine 496 and indirectly (H-bonding) to histidine 404, positioned in the vicinity of arginine 490, arginine 360, and lysine 353 amino groups (32). Thus, the strong binding constant for VO^{2+}–HSA calculated from gel and capillary electrophoresis probably corresponds to direct cation binding to the histidine imidazole, whereas the weak binding constant probably comes from indirect binding (H-bonding) to a nonspecific site of HSA. On the other hand, it has been reported that the vanadate anion binds weakly to the lysine ε-amino group of HSA with the association constant approximately 1×10^3 M^{-1} (10). Thus, the low binding constant for the VO_3^-–HSA (6.0×10^3 M^{-1}) calculated from the capillary electrophoresis corresponds to an indirect vanadate ion interaction with ε-amino group of lysine residues in HSA.

FT-IR spectroscopy

Additional evidence regarding the complexation of oxovanadium–HSA was obtained by FT-IR spectroscopy. Figure 5 shows FT-IR spectra of the free HSA and difference spectra for the VO^{2+}–HSA and VO_3^-–HSA complexes obtained by subtraction of the free-HSA spectrum from those of the metal–protein complexes. In the free HSA, two major bands for amide I at 1657 cm^{-1} (mainly C=O stretching) and amide II band at 1542 cm^{-1} (C—N stretching coupled with N—H bending mode) (24–27) were observed (Fig. 5). In the difference spectra taken at 0.0001 mM of the oxovanadium ions, a flat line was obtained because no significant intensity changes or spectral shiftings occurred during the incubation (spectra not shown). This is indicative of no major metal–protein interaction at very low vanadium ion concentrations. As the vanadium concentration increased (0.001 mM), two negative features at 1658–1656 and 1542–1541 cm^{-1} were observed, which are attributed to the intensity decrease in the amide I and II bands in the spectra of the oxovanadium–HSA complexes. The decrease of the intensity of the amide I band is due to the reduction of the α-helix structure, whereas the decrease of the intensity of the amide II band is due to the binding of the oxovanadium ions to the nitrogen atom of the CN group. The interaction of oxovanadium ion with the nitrogen atom of the NH group is also evident from the shift of the amide A band at 3303 cm^{-1} (peptide–N-H stretching mode) (24–27), towards a lower frequency at 3290 cm^{-1} (spectrum not shown). The band at 1518 cm^{-1} of the free HSA related to the vibration of tyrosine side chain (33–37) showed no spectral changes, which is indicative of no perturbation of the tyrosine residue in the oxovanadium–HSA complexes. As the metal ion concentration increased (1 mM), the negative features in the difference spectra at 1658 –1656 and 1542–1539 cm^{-1} grew in intensity and shape due to further metal ion complexation and the reduction of the proteins' α-helix structure upon oxovanadium–HAS interaction.

A quantitative analysis of the secondary structure of the protein for HSA and its vanadium complexes in H_2O is given in Fig. 6 and Table 1. The free protein contained largely α-helix (55.0%), along with β-sheet (22.0%), turn structure (11.0%), and β-antiparallel (12.0%). The β-sheet structure is composed of three components at 1616 (inter β-strand), 1625 (intra β-strand), and 1635 cm^{-1} (hydrated) (Fig. 6), which are consistent with the recent spectroscopic studies of HSA (38, 39). In D_2O solution, due to the isotopic substitution (D/H), the presence of a new component band at 1644 cm^{-1} in the spectrum of the free HSA was assigned to the random structure (11%) (Table 1). Upon vanadium interaction, the α-helix structure was reduced from 55.0 to 50–43.5%, whereas the β-pleated increased from 22 to 23–25.7%, the turn structure from 11 to 11.5–17.8%, and the β-antiparallel from 12 to 12.5 –14% at high metal ion concentration (Fig. 6 and Table 1, 1 mM). The narrowing of the band at 1656 cm^{-1} and the broadening of the bands at 1636 and 1622 cm^{-1} in the presence of oxovanadium ions are clear evidence of the reduction of the proteins' α-helix conformation in favor of a β-sheet structure (Fig. 6). The random structure, determined from deuterated samples, showed minor changes upon cation complexation (Table 1). The observed spectral changes are consistent with the major perturbations of the HSA secondary structure upon vanadium-ion coordination. It should be noted that no major secondary structural differences were observed for complexes formed with 0.1 and 1 mM cation concentrations (Table 1). This is indicative of no further cation–protein interaction at 1 mM vanadium concentration. The reduction of the α-helix in favor of the β-sheet structure is indicative of a partial unfolding of protein, in the presence of vanadyl at high cation concentrations. Similar conformational transition from an α-helix to β-sheet structure was observed for the protein unfolding upon protonation and heat denaturation (40–42).

In conclusion, on the basis of electrophoresis and IR spectroscopic results obtained for the oxovanadium–HSA complexes in aqueous solution, the following remarks can be made: (*i*) the metal–protein interaction leads to the formation of several vanadium–protein complexes with stoichiometric ratios of 1.5–20 vanadyl cations per HSA molecule; (*ii*) vanadyl cations show strong and weak bindings with $K_1 = 7.0 \times 10^7$ M^{-1} and $K_2 = 6.5 \times 10^5$ M^{-1} (gel electrophoresis) and $K_1 = 1.2 \times 10^8$ M^{-1} and $K_2 = 8.5 \times 10^5$ M^{-1} (capil-

© 2001 NRC Canada

lary electrophoresis), respectively, whereas vanadate has only a weak binding affinity (K= 6.0 × 10^3 M^{-1}) with HSA molecule; (*iii*) the strong affinity binding for vanadyl cation is related to a direct metal ion interaction with the nitrogen atom of histidine residue, whereas the low affinity binding (6.5 × 10^5 M^{-1}) can be attributed to an indirect cation–protein complexation (H-bonding); (*iv*) the low affinity binding of vanadate anion is also due an indirect coordination of the metal ion through lysine ε-NH_3^+ group; and (*v*) metal ion complexation results in major protein secondary structural changes from that of the α-helix to β-sheet and turn structure.

The metal template effect on *O*-alkylation of tetrahydroxy[3.1.3.1]metacyclophane with 4-(chloromethyl)pyridine to afford tetrakis-[(4-pyridylmethyl)oxy][3.1.3.1]metacyclophanes and their conformational studies

Takehiko Yamato, Kenji Kumamaru, and Hirohisa Tsuzuki

Abstract: An attempted *O*-alkylation of the flexible macrocycle tetrahydroxy[3.1.3.1]metacyclophane (**1**) with 4-(chloromethyl)pyridine (**2a**) in the presence of NaH under THF reflux gave 1,3-di-*O*-substitution product *distal*-**3a** as a major product. In contrast, tetraol **1** was *O*-alkylated with **2a** in the presence of Cs_2CO_3 to afford a mixture of two conformers of tetra-*O*-alkylated product **4a** in a ratio of 77:23 (1,4-*alternate*-**4a**:*partial-cone*-**4a**) in 95% yield. No formation of the cone conformer in the reaction of the tetraol **1** with **2a**, in comparison with those with 2-(chloromethyl)pyridine (**2b**) or benzyl bromide (**2c**) in the presence of NaH or K_2CO_3, which predominantly afforded cone-conformer, might be attributable to the absence of contributions derived from cation–N interactions as well as cation–π interactions. The latter effect might be much smaller because of the decreased π-density of the pyridine ring compared to that of the benzene ring. The structural characterization of these products in solution as well as solid state is also discussed.

Key words: macrocycles, calixarenes, cyclophanes, [3.1.3.1]metacyclophanes, *O*-alkylation, conformation, crystal structure, cation–N interaction.

Résumé : Le produit principal obtenu lors d'un essai d'*O*-alkylation du macrocycle flexible, tétrahydroxy[3.1.3.1]métacyclophane (**1**), par la 4-(chlorométhyl)pyridine (**2a**), en présence de NaH, dans du THF au reflux, est le produit de 1,3-di-*O*-substitution *distal*-**3a**. Par opposition, la *O*-alkylation du tétraol **1** par la **2a**, en présence de Cs_2CO_3, conduit avec un rendement de 95% à un mélange 77:23 de deux conformères, 1,4-alterné:cône partiel, du produit tétra-*O*-alkylé (**4a**). Il n'y a pas de formation du conformère à cône lors de la réaction du tétraol **1** avec la **2a** et ce résultat est en opposition à ceux obtenus lors de la réaction de **1** avec la 2-(chlorométhyl)pyridine (**2b**) ou avec le bromure de benzyle (**2c**), en présence de NaH ou de K_2CO_3 qui conduisent à la formation du conformère à cône; cette différence pourrait être attribuée à l'absence d'une contribution résultant d'interactions N–cation et π–cation. L'amplitude de ce dernier effet est peut-être plus faible en raison d'une diminution de la densité π du noyau pyridine par rapport à celle d'un noyau benzénique. On discute aussi de la caractérisation structurale de ces produits en solution ainsi qu'à l'état solide.

Mots clés : macrocycles, calixarènes, cyclophanes, [3.1.3.1]métacyclophanes, *O*-alkylation, conformation, structure cristalline, interaction N–cation.

[Traduit par la Rédaction]

Introduction

Calixarene and related macrocycles have received considerable attention for their host–guest chemistry as ionophoric receptors (1–4) and as potential enzyme mimics in biology (5). Chemical modification of calixarenes represents an effective and versatile way of producing receptors with highly selective cation-binding properties (6–10). Even minor changes in the regioselective functionalization (11) or conformation (12) of the chemically modified calixarene can be associated with drastic changes in the complexation properties.

Introduction of larger alkyl groups on the phenolic oxygens of calix[4]arenes led to a situation where the OR groups within a cyclophane ring could not pass each other via the oxygen-through-the-annulus rotation (for a comprehensive review of all aspects of calixarene chemistry, see ref. 1). Although there exist four possible conformational isomers in calix[4]arenes (cone, partial cone, 1,2-alternate, and 1,3-alternate), five different conformational isomers, of which 1,4-alternate is newly counted due to the propane bridges, should be expected in tetrahydroxy[3.1.3.1]MCPs (MCP = metacyclophane) (13).

Pappalardo et al. (14) reported on the synthesis of calix[4]arenes bearing pendant pyridine groups on the lower rim as potential ligands for transition metals. Recently, we have also reported the synthesis, conformational studies, and inclusion properties of tetrakis[(2-pyridylmethyl)oxy][3.1.3.1]MCPs derived from tetrahydroxy[3.1.3.1]MCPs (15), which show strong Ag^+ and *n*-butylammonium ion affinity. ^1H NMR titration with $AgSO_3CF_3$ clearly demonstrated that a 1:1 complex is formed with retention of the original symmetry. Interestingly, the conformational changes of the pyridine moiety from the original outward orientation of the ring nitrogen to an inside orientation (toward the cyclophane cavity) was observed in the process of Ag^+ complexation. On the other hand, Reinhoudt and co-workers (16) also reported a well-defined hydrogen-bonded calix[4]arene duplex between tetrakis[(4-pyridylmethyl)oxy]calix[4]arene and calix[4]arene tetracarboxylic acid. Independently, Shinkai and co-workers (17) have extended this type of upper-rim functionalization to larger calixarenes. Thus, there is substantial interest in investigating the synthesis and structures of tetrakis[(4-pyridylmethyl)oxy][3.1.3.1]MCPs with cone and 1,4-alternate conformations, in which the former compounds are anticipated to have the property to form a hydrogen-bonded homocalix[4]arene duplex with the corresponding [3.1.3.1]MCP tetracarboxylic acid.

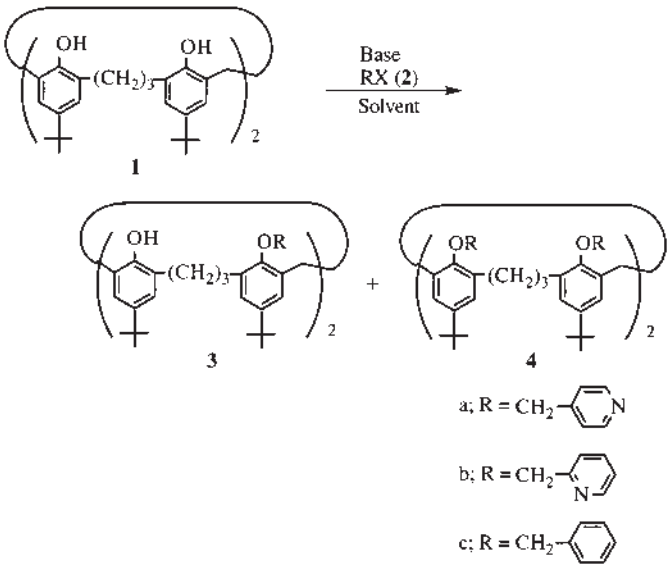
In this paper, we describe the metal template effect on *O*-alkylation of tetrahydroxy[3.1.3.1]MCP with 4-(chloromethyl)pyridine (**2a**) to afford tetrakis[(4-pyridylmethyl)oxy]-[3.1.3.1]MCPs with cone and 1,4-alternate conformations and their conformational studies in solution as well as in the solid state.

Results and discussion

Alkylation of the flexible macrocycles (**1**) with 10 mol equiv of 4-(chloromethyl)pyridine (**2a**) in the presence of 10 mol equiv of NaH under THF reflux gave one pure regioselective isomer, 1,3-di-*O*-substitution product *distal*-**3a**, as a major product, while other possible regioisomers were not observed. In contrast, decreasing the amount of NaH to 5 mol equiv increased the proportion of tetra-*O*-substitution product 1,4-*alternate*-**4a** dramatically (from 2 to 45%). Finally, increasing the amount of reagent to 30 mol equiv in the presence of 5 mol equiv of NaH gave complete *O*-substitution, affording the tetrakis[(4-pyridylmethyl)oxy] derivative (1,4-*alternate*-**4a**) in 95% yield. No formation of other possible conformers, as shown in Fig. 1, has been observed. Unfortunately, a significant recovery of starting compound **1** in the presence of Na_2CO_3, in spite of the condition of large excess of **2a**, was observed. When K_2CO_3 is employed for *O*-alkylation with **2a** only an intractable mixture was obtained. In contrast, tetrahydroxy[3.1.3.1]MCP (**1**) was *O*-alkylated with **2a** in the presence of Cs_2CO_3 to give a mixture of two conformers of tetra-*O*-alkylated product **4a** in a ratio of 77:23 (1,4-*alternate*-**4a**:*partial-cone*-**4a**) in 95% yield. The ratio of the number of the *O*-alkylations is governed by the nature of the base used (NaH or alkali metal carbonates). Thus, when NaH is used in this reaction, the disubstitution product *distal*-**3a** was obtained as a major product in 85% yield. On the other hand, when Cs_2CO_3 was employed, an increase in the formation of tetra-*O*-substitution product **4a** was observed. These results indicate that the

Fig. 1. Possible conformers for *O*-tetrasubstitution of tetrahydroxy[3.1.3.1]MCP (**1**).

alkali-metal cation can play an important role not only on the regioselectivity based on the template effect but also on the number of the *O*-alkylations, as previously observed in the *O*-alkylation of calixarenes (6, 7).



The present results are quite different from the result of *O*-benzylation of tetraol **1** with benzyl bromide **2c** in the presence of NaH, which predominantly afforded *cone*-**4c** (Scheme 1). When Cs_2CO_3 was used in this reaction, a mixture of *cone*- and 1,4-*alternate*-tetra-*O*-alkylated product **4c** in a ratio of 80:20 in quantitative yield was observed (Table 1) (13*d*).

When Cs_2CO_3 was used in this reaction, the ratio of *partial-cone*-**4a** to 1,4-*alternate*-**4a** increased. Because a much larger contribution by Cs^+ (compared to Na^+) to the template effect can be expected, as reported by Harrowfield et al. (18), the larger Cs^+ ion might enlarge the cyclophane ring, (e.g., intermediate **B**) to form sufficient space for ring inversion to afford the thermodynamically stable partial-cone conformer during the *O*-alkylation with **2a**. In contrast, the smaller Na^+ ion might increase the contribution of the metal template effect, which can hold the 4-pyridylmethyl group(s) and the oxide group(s) on the same side of the tetrahydroxy-[3.1.3.1]MCP through cation–O^- and cation–π interactions (19), similar to the *O*-benzylation. However, this effect might be smaller due to the decreased π-density of the pyridine ring as compared to that of the benzene ring (Fig. 2*a*). Therefore, no formation of cone conformer in the reaction of the tetraol **1** with **2a**, (while it was the predominant conformer when 2-(chloromethyl)pyridine (**2b**) was used) in the presence of NaH or K_2CO_3, might be attributable to the absence of contribution derived from cation–N interactions (15).

Although the reason for this finding is not clear from the available results, one might assume that the template effect of the larger alkali metal cation Cs^+ is responsible. Thus, the larger alkali metal cation Cs^+, in spite of being a weaker base when compared to NaH, obviously gives rise to the preferential formation of the cesium phenoxide intermediate

Scheme 1.

B to afford tetra-*O*-substitution product 1,4-*alternate*-**4a**. When a larger base such as Cs_2CO_3 (compared to Na^+ or K^+) is used, a much larger contribution to the template effect can be expected. Thus, the larger Cs^+ ion might enlarge the cyclophane ring of diol **3a** enough to destroy the intramolecular hydrogen bonding between the hydroxy groups on the diarylmethane units. Thus, further *O*-alkylation was observed due to the existence of the dissociated O^- groups. In contrast, the action of the much smaller Na^+ ion might lead to a decrease in the nucleophilicity of phenolic O^- anion by increasing the steric interactions in intermediate **A** during the nucleophlic attack on **2a**. Therefore, the stronger base (NaH) might suppress further *O*-alkylation, in spite of the existence of the dissociated O^- groups, and thus, only afford di-*O*-substitution product *distal*-**3a**.

Furthermore, *O*-alkylation of tetraol **1** with **2a** afforded mainly the 1,3-disubstituted product *distal*-**3a**, instead other possible isomers (1,2-disubstituted product, 1,2-*proximal*-**3a** and 1,4-disubstituted product, 1,4-*proximal*-**3a**). This finding might also be explained by the increase in steric interactions in the sodium phenoxide intermediate **C** at the 1,2-position, in comparison with that in intermediate **D** at the 1,3-position, even with a smaller alkali metal cation (Na^+) (Scheme 2). The different types of intramolecular hydrogen bonding among the hydroxyl groups between the 1,3-diarylpropane units and diarylmethane units should have an effect on the regioselectivity during the *O*-alkylation of tetrahydroxy[3.1.3.1]MCP (**1**).

To study the reaction route from tetraol **1** to tetra-*O*-alkylated product **4a** in more detail, we have attempted to carry out the *O*-alkylation of the possible intermediate **3a** with **2a** in the presence of Cs_2CO_3 (Scheme 3). Similar *O*-alkylation reaction of 1,3-di-*O*-substitution product *distal*-**3a** with **2a** was carried out in the presence of Cs_2CO_3 to yield a mixture of two conformers of tetra-*O*-alkylated product **4a** in a ratio of 86:14 (*cone*-**4a**:*partial-cone*-**4a**) in 95% yield along with the recovery of starting compound (Scheme 3). No formation of the other possible conformers was observed. However, in the presence of NaH or K_2CO_3, *O*-alkylation to afford **4a** under the same reaction conditions was not observed and only recovery of the starting compound **3a** resulted.

These results strongly indicate that, in the case of the *O*-alkylation of tetraol **1** with **2a** in the presence of Cs_2CO_3, the diol (*distal*-**3a**) with a cone conformation could not be an intermediate for the formation of 1,4-*alternate*-**4a**. Thus, the conformation to yield 1,4-*alternate*-**4a** has not been determined by the complete introduction of the second picolyl group. In other word, formation of 1,4-*alternate*-**4a** can be determined when the second picolyl group enters by the ring inversion of the O^- anion on the unmodified phenol unit in triol to form *distal*-**3a** with a 1,4-alternate conformation.

The ^{1}H NMR spectrum of *cone*-**4a** shows a singlet for the *tert*-butyl protons at δ 1.10 and two doublets (J = 2.2 Hz) of equal intensity for the aromatic protons at δ 6.78 and 6.94. Furthermore, the resonance for the Ar*CH*$_2$Ar methylene protons appear as a pair of doublets (δ 3.21 and 4.27, $J_{A,B}$ = 13.7 Hz) (relative intensity 1:1). Although these ^{1}H NMR signals correspond to either the cone or 1,4-alternate conformer, the middle methylene protons for propane bridge (ArCH$_2$*CH*$_2$CH$_2$Ar) are observed as a two multiplets for *cone*-**4a** at δ 1.58–1.68 and 1.92–2.02 (relative intensity 1:1), but only as a single multiplet for 1,4-*alternate*-**4a** at δ 1.58–1.72. The former pattern corresponds to cone conformer because the middle methylene protons for propane bridge ArCH$_2$*CH*$_2$CH$_2$Ar are in different environments, whereas the latter pattern corresponds to the 1,4-alternate conformer because the protons lie in the same environment. Therefore, *cone*-**4a** should adopt a *syn*-oriented cone conformation and not a *anti*-oriented 1,4-alternate conformation.

Although we have not yet succeeded in measuring the X-ray diffraction of cone-tetrakis[(4-pyridylmethyl)oxy][3.1.3.1]MCP (*cone*-**4a**) (15*a*) because it is a viscous oil, we have succeeded in obtaining single-crystal X-ray diffraction results for cone-tetrakis[(2-pyridylmethyl)oxy][3.1.3.1]MCP (*cone*-**4b**). The crystals were obtained by recrystallization from MeOH–$CHCl_3$, and the crystal structure and the atom numbering system of *cone*-**4b** are shown in Fig. 3.

The structure was solved by direct methods (SIR 88)[2] and refined using a full-matrix least-squares method and Fourier synthesis. Compound *cone*-**4b** crystallized in the centrosymmetric triclinic space group $P\bar{1}$ (No. 2) and is located at the general position (Z = 2). The X-ray crystallographic analysis of *cone*-**4b** clearly shows that this compound adopts a cone conformation in the solid state. The dihedral angles of the plane defined by the bridge crabons, C(1)-C(2)-C(3)-C(10)-C(17)-C(18)-C(19)-C(26) with aromatic ring C(4)-C(5)-C(6)-C(7)-C(8)-C(9), C(11)-C(12)-C(13)-C(14)-C(15)-C(16), C(20)-C(21)-C(22)-C(23)-C(24)-C(25), and C(27)-C(28)-C(29)-C(30)-C(31)-C(32) are 61.6, 62.9, 63.4, and 56.7°, respectively. The four pyridylmethyl groups located in the inner cavity point toward the outside and are not parallel with the attached phenolic aromatic planes. The dihedral angles of the pyridine rings with the phenolic rings, C(4)-C(5)-C(6)-C(7)-C(8)-C(9), C(11)-C(12)-C(13)-C(14)-C(15)-C(16), C(20)-C(21)-C(22)-C(23)-C(24)-C(25), and C(27)-C(28)-C(29)-C(30)-C(31)-C(32) are 76.3, 73.7, 69.5, and 81.7°, respec-

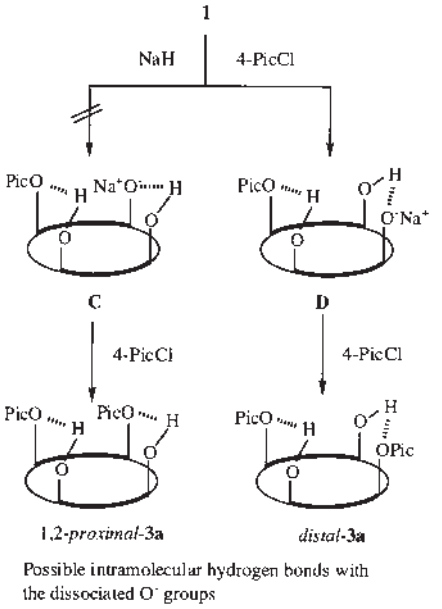
Fig. 2. Ring inversion of *O*-alkylation intermediate of tetraol **1**, and immobilization by metal template.

tively. In addition, the four nitrogen atoms on the pyridine rings are turned toward the *exo*-annulus direction, suggesting that this orientation might be favored to avoid electrostatic repulsion between the lone pair electrons on the nitrogen atoms.

The ^{1}H NMR spectrum of *cone*-**4b** shows a singlet for the *tert*-butyl protons at δ 1.16 and two doublets (J = 2.2 Hz) of equal intensity for the aromatic protons at δ 6.85 and 7.06. Furthermore, the resonance for the ArCH_2Ar methylene protons appears as a pair of doublets (δ 3.29 and 4.44, $J_{A,B}$ = 13.2 Hz) (relative intensity 1:1), corresponding to a symmetrical structure (C_{2v} symmetry). However, the middle methylene protons for propane bridge (Ar$CH_2CH_2CH_2$Ar) are observed as a multiplet for *cone*-**4b** at δ 1.3–1.5 and 1.8–2.0 (relative intensity 1:1), but only as a single multiplet for 1,4-*alternate*-**4b** at δ 1.59–1.64. The former pattern corresponds to cone conformer because the middle methylene protons for propane bridge Ar$CH_2CH_2CH_2$Ar are in different environments, whereas the latter pattern corresponds to the 1,4-alternate conformer because the protons are in the same environment. The similar findings were observed in the ^{1}H NMR spectrum of *cone*-**4a**. Thus, on the basis of the spectral data, a cone conformation is assigned to *cone*-**4a**.

The ^{1}H NMR spectrum of 1,4-*alternate*-**4a** shows a singlet for the *tert*-butyl protons at δ 1.10, a set of doublets ($J_{A,B}$ = 13.4 Hz) for the ArOCH_2Py methylene protons at δ 4.38 and 4.48, and two doublets of equal intensity for the aromatic protons at δ 7.00 and 8.18. Furthermore, the resonance for the ArCH_2Ar methylene protons appear as a pair of doublets (δ 3.42 and 4.43, $J_{A,B}$ = 13.2 Hz) (relative intensity 1:1). Since these ^{1}H NMR signals are observed at slightly different chemical shifts compared to those for *cone*-**4a**, a cone conformation might be also expected. However, as mentioned previously, the middle methylene protons for propane bridge (Ar$CH_2CH_2CH_2$Ar) are observed as a single multiplet at δ 1.58–1.72, which corresponds to the 1,4-alternate conformer, because the middle methylene protons for the propane bridge Ar$CH_2CH_2CH_2$Ar are same environment. Therefore, 1,4-*alternate*-**4a** should adopt an *anti*-oriented 1,4-alternate conformation and not *a syn*-oriented cone conformation. Fortunately, we have succeeded in analyzing single-crystal X-ray diffraction results of 1,4-alternate-tetrakis[(4-pyridylmethyl)oxy][3.1.3.1]MCP (1,4-*alternate*-**4a**). X-ray quality crystals were obtained via recrystallized from MeOH–$CHCl_3$, and the crystal structure and the atom numbering system of 1,4-*alternate*-**4a** are shown Fig. 4.



The X-ray crystal structure was solved by direct methods (MULTAN 80)[3] and refined using a full-matrix least-squares method and Fourier synthesis. Compound 1,4-*alternate*-**4a** crystallized in the centrosymmetric triclinic space group $P\bar{1}$ (No. 2) and is located at the general position (Z = 2). It is clear that this compound adopts the 1,4-alternate conformation, where the facing aromatic rings adopt an *anti*-conformation with respect to each other, and the "stepped conformation" of diphenylmethane moieties, similar to *anti*-[3.3]MCP (20), is favored. The molecular structure of the 1,4-*alternate*-**4a** possesses the following major features: (*i*) the facing phenolic aromatic rings show *anti*-conformation and are almost parallel with each other, and the *O*-appended two pyridine rings similarly adopt a parallel conformation and (*ii*) the *O*-appended two pyridine rings are located almost vertically against the phenolic aromatic rings, although the facing phenolic aromatic rings show an *anti*-conformation and are almost parallel. Thus, the four pyridine rings in 1,4-*alternate*-**4a** are almost parallel.

Ring inversion via oxygen-through-the-annulus rotation is inhibited both for *cone*-**4a** and 1,4-*alternate*-**4a** as no change in the spectrum pattern for the ArCH_2Ar methylene protons below 130°C in $CDBr_3$ is observed.

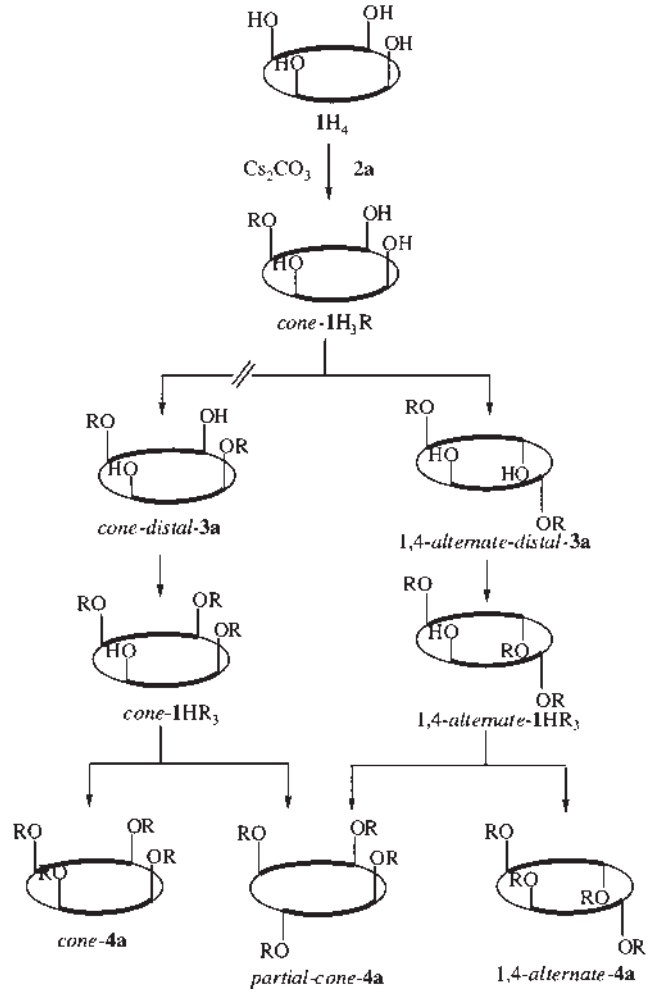
Scheme 2.

Scheme 3.



Interestingly, the heteroaromatic protons of the pyridine rings in *cone*-**4a** are exposed to ring current shielding effects (21, 22) imposed by the opposing pyridine ring among the diphenylmethane linkage and resonate at higher fields with respect to those of the reference compound **6**, which was prepared by *O*-alkylation of 4-*tert*-butyl-2,6-dimethylphenol (**5**) with **2a** in the presence of NaH in 63% yield (Scheme 5).

The magnitude of this shielding, computed as the difference between pertinent pyridine protons of *cone*-**4a** and reference compound **6**, increases significantly with protons H_2 and H_3 (see Table 2). The remarkable shielding effect experienced by the H_3 ($\delta = -0.33$ ppm) protons of the pyridine ring suggests that these protons are located much closer to the opposing pyridine ring than the H_2 ($\delta = -0.15$ ppm) protons, presumably due to the electrostatic repulsions among the nitrogens of two pyridine rings. Thus, all of the nitrogens in the pyridine rings are oriented toward the outside of the cyclophane cavity.

In contrast to *cone*-**4a**, the 1,4-alternate displays much higher upfield shifts for the H_2 (–0.62 ppm) and H_3 (–0.89 ppm) protons of the pyridine ring Since the1,4-*alternate*-**4a** adopts the "stepped conformation" for the diphenylmethane moieties, similar to *anti*-[3.3]MCP (20), face-to-face overlapping between two picolyl group is possible. Therefore, the remarkable shielding effect experienced by the H_3 (–0.89 ppm) protons suggests that these protons are located in closer to the opposing pyridine ring than the H_2 (–0.63 ppm) protons, presumably due to the repulsion among the nitrogen atoms in the pyridine rings, which are located between the diphenylmethane linkages.

Scheme 4.

In contrast, the ^{1}H NMR spectrum of *partial-cone*-**4a** shows four singlets for the *tert*-butyl protons at $\delta = 0.69$, 1.02, 1.34, and 1.45 (relative intensity 1:1:1:1) and four sets of doublets with equal intensity for the aromatic protons. Furthermore, the resonance for the aromatic protons ($H_{2,6}$ and $H_{3,5}$) appeared as four sets of doublets. These signals correspond to an unsymmetrical structure (C_S symmetric conformer). The aromatic protons in the one of the 4-pyridylmethyl groups ($H_{2'}$ and $H_{3'}$) appear at higher fields around δ 7.50 and 6.11, respectively, which strongly supports the view that **4a** adopts a partial-cone conformation. On the basis of the ^{1}H NMR studies and the consideration of CPK model of *partial-cone*-**4a**, three of the four 4-pyridylmethyl groups in the compound point upwards, while the last pyridyl group is folded into the π-cavity formed by three benzene rings and, are thus, strongly

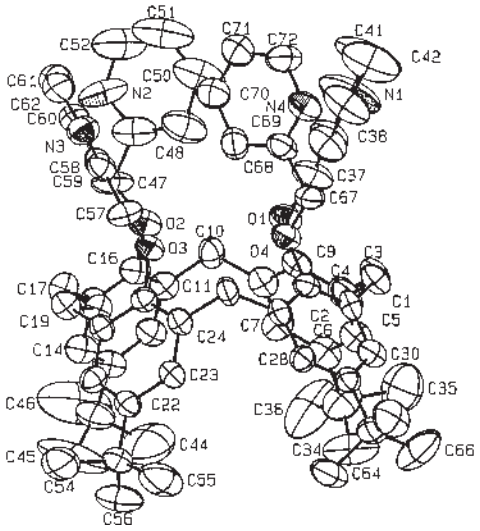
Fig. 3. X-ray crystal structure of *cone*-**4b**. Thermal ellipsoids are drawn at 50% probability. Hydrogen atoms have been omitted for clarity.



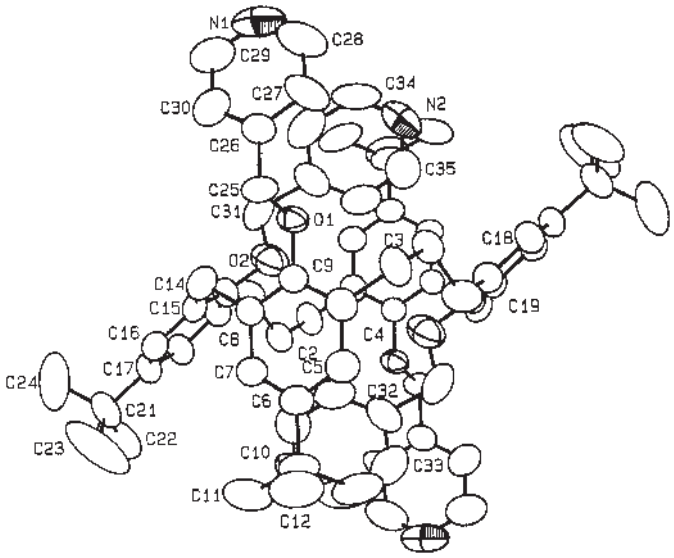


Fig. 4. X-ray crystal structure of 1,4-*alternate*-**4a**. Thermal ellipsoids are drawn at 50% probability. Hydrogen atoms have been omitted for clarity.

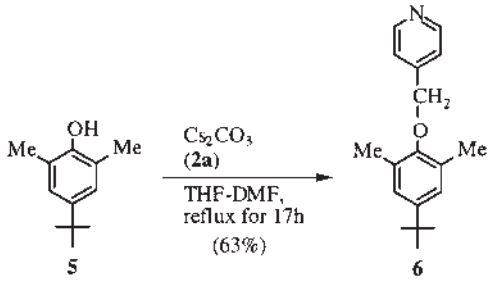

shifted upfield. Furthermore, an upfield shift at δ 0.69 for one *tert*-butyl group is observed, which is attributable to it being located on the pyridine ring of the inverted picolyl group, in spite of the sterically crowded environment. This finding might be attributed to the CH–π interaction (19) between methyl groups of the *tert*-butyl group and the pyridine ring.

In contrast, the ^{1}H NMR spectrum of **3a** shows resonances for the *tert*-butyl protons at δ 1.23 and 1.27 as singlets, for the methylene protons at δ 3.63 and 4.25 ($J_{A,B}$ = 13.2 Hz) as doublets, for the aromatic protons at δ 6.92, 7.03, 7.15, and 7.22 (J = 2.2 Hz) as doublets, and the hydroxy proton at δ 7.84 as a singlet indicating a 1,3-di-*O*-substituted structure.

Although these ^{1}H NMR signals correspond to a cone or a 1,4-alternate conformer, the IR spectrum of diol **3a** shows the absorption of the hydroxy stretching vibration at around

Scheme 5.

3379 cm^{-1}. The ^{1}H NMR spectrum in $CDCl_3$ exhibits the signal for hydroxyl groups around δ = 7.84. The υ_{OH} and δ_{OH} values in diol **3a** in which two hydroxy groups are located in distal positions, show not only a slightly lower frequency but also an upfield shift compared to those of parent compound **1** (υ_{OH} = 3254 and δ_{OH} = 9.35), which implies that a weaker hydrogen bond does exist for **3a** as compared to that in the corresponding calix[4]arene. As shown in Fig. 5, similar chemical shifts were observed as those for distal-bis-(benzyloxy)[3.1.3.1]MCP (**3c**), which adopts a cone conformation. Therefore, bis[(4-pyridylmethyl)oxy][3.1.3.1]MCP (**3a**) also might adopt a cone conformation due to the intramolecular hydrogen bonding between two hydroxy and alkoxy groups. Thus, the hydroxy and alkoxy groups can be strongly held on the same side of the [3.1.3.1]MCP *distal*-**3a**, as shown in Fig. 5.

In conclusion, an interesting result was obtained by introduction of 4-picolyl groups into the hydroxy groups of tetraol **1**. We have demonstrated for the first time that *O*-alkylation of the flexible macrocycle **1** with 4-(chloromethyl)pyridine gave tetra-*O*-alkylated products with cone or 1,4-alternate conformation, which could show promising complexation properties and interesting stereochemistry. The alkali metal cation can play an important role for the conformer distribution because of the template effect. While, to date, only three stereoisomers have been obtained, variation of the alkylation conditions and reagents could lead to different derivatives, which will serve as interesting building blocks for larger potential host molecules. Further studies of the structural and chemical properties of **3a** and **4a** are in progress.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton NMR spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. Gas–liquid chromatography (GLC) analyses were performed on a Shimadzu gas chromatograph (GC-14A; silicone OV-1, 2 m; programmed temperature rise, 12°C min^{-1}; carrier gas nitrogen, 25 mL min^{-1}).

Fig. 5. Intramolecular hydrogen bonds in *distal*-**3a**.

Materials

Synthesis of 6,13,22,29-tetra-*tert*-butyl-9,16,25,32-tetrahydroxy[3.1.3.1]metacyclophane (**1**) was previously described (13*a*, *b*).

*Alkylation of **1** with 4-(chloromethyl)pyridine (**2a**) in the presence of NaH to afford distal-**3a***

A mixture of **1** (400 mg, 0.57 mmol) and NaH (230 mg, 5.70 mmol, 60%) in dry THF (10 mL) was heated at reflux for 1 h under N_2. Then a solution of 4-(chloromethyl)pyridine (**2a**) (5.56 mmol) (prepared by neutralization of 4-(chloromethyl)-pyridine hydrochloride (939 mg, 5.70 mmol) in *N*,*N*-dimethylformamide (DMF) (5.5 mL) with a solution of triethylamine (0.8 mL, 5.70 mmol) in THF (11 mL) at room temperature) was added and the mixture was heated at reflux for an additional 17 h. After cooling the reaction mixture to room temperature, it was acidified with 1 N HCl (10 mL) and extracted with CH_2Cl_2 (2 × 100 mL). The combined extracts were washed with water (2 × 50 mL), dried (Na_2SO_4), and condensed under reduced pressure to give a yellow oil. The residue was washed with either to give crude *distal*-**3a** (430 mg, 85%) as a colorless precipitate. Recrystallization from MeOH–$CHCl_3$ (3:1) afforded 6,13,22,29-tetra-*tert*-butyl-9,25-dihydroxy-16,32-bis[(4-pyridylmethyl)oxy][3.1.3.1]metacyclophane (*distal*-**3a**) as colorless prisms; mp 257–260°C. MS *m*/*z*: 886 (M^+). IR (KBr) (cm^{-1}): 3379 (OH). ^{1}H NMR ($CDCl_3$) δ: 1.23 (s, 18H), 1.26 (s, 18H), 2.17–2.45 (m, 4H,), 2.59–2.68 (m, 4H), 2.87–2.95 (m, 4H), 3.64 (d, *J* = 13.7 Hz, 2H), 4.18 (d, *J* = 13.7 Hz, 2H), 4.95 (d, *J* = 14.2 Hz, 2H), 5.49 (d, *J* = 14.2 Hz, 2H), 6.92 (d, *J* = 2.4 Hz, 2H), 7.02 (d, *J* = 2.4 Hz, 2H), 7.14 (d, *J* = 2.4 Hz, 2H), 7.22 (d, *J* = 2.4 Hz, 2H), 7.63 (d, *J* = 5.4 Hz, 2H), 7.84 (s, 2H, OH), 8.36 (d, *J* = 5.4 Hz, 2H). Anal. calcd. for $C_{60}H_{74}N_2O_4$ (887.27): C 81.22, H 8.42, N 3.16; found: C 81.49, H 8.28, N 3.27.

*Alkylation of **1** with **2a** in the presence of Cs_2CO_3*

A mixture of **1** (400 mg, 0.57 mmol) and Cs_2CO_3 (3.70 g, 11 mmol) in dry THF (10 mL) was heated at reflux for 1 h under N_2. Then a solution of **2a** (17.1 mmol) was added and the mixture heated at reflux for an additional 17 h. After cooling the reaction mixture to room temperature, it was acidified with 1 N HCl (10 mL) and extracted with CH_2Cl_2 (2 × 100 mL). The combined extracts were washed with water (2 × 50 mL), dried (Na_2SO_4), and condensed under reduced pressure to give a yellow oil. The residue was purified by column chromatography over silica gel with MeOH–CHCl, (1:1) to give a mixture of 1,4-*alternate*-**4a** and *partial-cone*-**4a** in a ratio of 77:23 as a colorless solid. Treatment with a small amount of ether gave 1,4-*alternate*-**4a** (396 mg, 55%) as a colorless solid. Attempted isolation of pure *partial-cone*-**4a** failed.

1,4-Alternate-6,13,22,29-tetra-tert-*butyl-9,16,25,32-tetrakis-[(4-pyridylmethyl)oxy][3.1.3.1]metacyclophane (1,4-*alternate-***4a**)*: Colorless prisms (MeOH–$CHCl_3$ (3:1)), mp > 300°C. MS *m*/*z*: 1068 (M^+). ^{1}H NMR ($CDC1_3$) δ: 1.10 (s, 36H), 1.58–1.72 (m, 4H), 2.13–2.24 (m, 4H), 2.51–2.64 (m, 4H), 3.42 (d, *J* = 13.2 Hz, 2H), 4.38 (d, *J* = 13.4 Hz, 4H), 4.43 (d, *J* = 13.2 Hz, 2H), 4.48 (d, *J* = 13.4 Hz, 4H), 6.52 (d, *J* = 5.9 Hz, 8H), 7.00 (d, *J* = 2.0 Hz, 4H), 7.18 (d, *J* = 2.0 Hz, 4H), 7.99 (d, *J* = 5.9 Hz, 8H). Anal. calcd. for $C_{72}H_{84}N_4O_4$ (1069.5): C 80.86, H 7.92, N 5.24; found: C 80.90, H 7.95, N 5.30.

Partial-cone-6,13,22,29-tetra-tert-*butyl-9,16,25,32-tetrakis[(4-pyridylmethyl)oxy][3.1.3.1]metacyclophane (*partial-cone-***4a**)*: Colorless oil. ^{1}H NMR ($CDCl_3$) δ: 0.69 (s, 9H), 1.02 (s, 9H), 1.34 (s, 9H), 1.45 (s, 9H), 1.6–3.0 (m, 12H), 3.40 (d, *J* = 13.2 Hz, 1H), 4.01–5.05 (m, 11H), 6.11 (d, *J* = 5.9 Hz, 2H), 6.52 (d, *J* = 5.9 Hz, 2H), 6.61 (d, *J* = 5.9 Hz, 2H), 6.63 (d, *J* = 2.4 Hz, 1H), 6.65 (d, *J* = 2.4 Hz, 2H), 6.68 (d, *J* = 2.4 Hz, 1H), 6.71 (d, *J* = 5.9 Hz, 2H), 6.82 (d, *J* = 2.4 Hz, 1H), 6.93 (d, *J* = 2.4 Hz, 1H), 7.10 (d, *J* = 2.4 Hz, 1H), 7.40 (d, *J* = 2.4 Hz, 1H), 7.50 (d, *J* = 5.9 Hz, 2H), 7.91 (d, *J* = 5.9 Hz, 2H), 8.26 (d, *J* = 5.9 Hz, 2H), 8.41 (d, *J* = 5.9 Hz, 2H).

*Alkylation of distal-**3a** with **2a** in the presence of Cs_2CO_3*

A mixture of *distal*-**3a** (200 mg, 0.225 mmol) and Cs_2CO_3 (366.5 mg, 1.13 mmol) in dry THF (5 mL) was heated at reflux for 1 h under N_2. Then a solution of **2a** (6.75 mmol) was added and the mixture heated at reflux for an additional 17 h. After cooling the reaction mixture to room temperature, it was acidified with 1 N HCl (10 mL) and extracted with CH_2Cl_2 (2 × 100 mL). The combined extracts were washed with water (2 × 50 mL), dried (Na_2SO_4), and condensed under reduced pressure to give a yellow oil. The residue was purified by column chromatography over silica gel MeOH–CHCl, (1:1) to give a mixture of *cone*-**4a** and *partial-cone*-**4a** in a ratio of 86:14 as a colorless oil. Treatment with a small amount of ether gave *cone*-**4a** (195 mg, 81%) as a colorless oil.

Crystal data and refinement details for *cone*-4b and *1,4-alternate*-4a

The unit cell constants (Table 3) were derived from least-squares analysis of the settings, on an Enraf–Nonius CAD4 FR 586 diffractometer, with 25 reflections for both cone-6,13,22,29-tetra-*tert*-butyl-9,16,25,32-tetrakis-[(2-pyridylmethyl)oxy][3.1.3.1]metacyclophane (*cone*-**4b**) and 1,4-alternate-6,13,22,29-tetra-*tert*-butyl-9,16,25,32-tetrakis[(4-pyridylmethyl)oxy][3.1.3.1]metacyclophane (1,4-*alternate*-**4a**) and in the range of 29.0° < θ < 30.7° for *cone*-**4b** and 35.0° < θ < 35.9° for 1,4-*alternate*-**4a**. The intensities of all independent reflections with 2.7° < 2θ < 144.0° for *cone*-**4b** and 5.8° < 2θ < 149.8° for 1,4-*alternate*-**4a** were measured with ω–2θ scan (ω scan width = 0.8 + 0.14 tan θ); Ni-filtered Cu Kα radiation (λ = 1.54184 Å) was used. The structure was solved uneventfully by direct method (SIR88)[2] for *cone*-**4b** and by direct method (MULTAN 80)[3] for 1,4-*alternate*-**4a**, along with difference Fourier syntheses and refined by the full-matrix least-squares method. All calculation was performed on a Micro VAX 3100 computer using a Mo1EN program package.[4]

In the case of *cone*-**4b**, full-matrix least-squares refinement on *F* with all non-hydrogen atoms anisotropic and hydrogens isotropic fixed at B_{eq} = 4.0 Å^2. The weighting scheme is $\omega = 4F_0^2/[(\sigma I_0)^2 + 0.0016F_0^4]$. Final *R* and R_w values are 0.116 and 0.143, respectively (refined on *F*). All calculation was performed on a MicroVAX3100 using Mo1EN.[4] Unfortunately, it was very difficult to improve the *R* value, even by utilizing several techniques, but the ORTEP drawing[5] depicted in Fig. 3 offers the sufficient information to discuss the conformation of

Binding of anti-inflammatory drug indomethacin with cyclodextrin and DNA: solubility, spectroscopic, and voltammetric studies

I.S. Shehatta and M.S. Ibrahim

Abstract: The interaction of the anti-inflammatory drug indomethacin (IMC) with α-, β-cyclodextrins (CDs) and calf thymus deoxyribonucleic acid (ct-DNA) have been investigated in the Britton–Robinson (BR) buffer (pH = 7.2) using solubility, spectroscopic, and voltammetric methods. The measurements show that the IMC molecule, acting as an intercalator, is inserted, from the *p*-chlorobenzoyl part, into the cavity of the cyclodextrins as well as into the base-stacking domain of the ct-DNA double helix. Upon addition of β-CD in a buffered IMC solution, the solubility of IMC increases and the Gibbs free energies of transfer of the drug from aqueous solution to the cavity of β-CD are negative and increase negatively with increasing β-CD concentration. The interaction of IMC with CDs and ct-DNA causes hypochromism and bathochromic shifts in the absorption spectra, along with pronounced changes in the electrochemical behaviour of the drug. The stoichiometry of complexes formed in solution is inferred to be 1:1. The binding constants were calculated from the increase of the solubility, the strong hypochromism, and the decrease in peak current of IMC upon the addition of the host molecules. IMC has a higher affinity for β-CD than for α-CD, as the IMC–β-CD interaction is the most exergonic. Binding is interpreted in terms of the intercalative (hydrophobic) interactions with the ct-DNA helix (i.e., the stacked base pairs) or within CD cavity.

Key words: cyclodextrin, ct-DNA, anti-inflammatory drug, indomethacin, binding constant, solubility, spectra, voltammetry.

Résumé : Faisant appel à des méthodes basées sur la solubilité, la spectroscopie et la voltampérométrie et opérant dans un tampon de Britton-Robinson (BR) (pH = 7,2), on a étudié l'interaction entre l'indométhacine (IMC), un antiinflammatoire, et les α- et β-cyclodextrines (CD) et l'acide désoxyribonucléique de la thyroïde du veau (ct-DNA). Les mesures montrent que la molécule d'IMC s'intercale, à partir de la portion *p*-chlorobenzoyle, dans la cavité des cyclodextrines ainsi que dans le domaine d'empilement des bases de la double hélice du ct-DNA. Par addition de β-CD dans une solution tamponnée d'IMC, la solubilité de l'IMC augmente; les énergies libres de Gibbs du transfert du médicament à partir de la solution aqueuse vers la cavité de la β-CD sont négatives et elles augmentent de façon négative avec une augmentation de la concentration de β-CD. L'interaction de l'IMC avec les CD et le ct-DNA provoque une hypochromie et une bathochromie dans les spectres d'absorption et des changements importants dans le comportement électrochimique du médicament. On fait l'hypothèse que la stoechiométrie des complexes qui se forment en solution est 1:1. Les constantes de fixation ont été calculées à partir de l'augmentation de la solubilité, la forte hypochromie et la diminution du courant de sommet de l'IMC lors de l'addition de molécules hôtes. L'affinité de l'IMC est plus grande pour la β-CD que pour la α-CD parce que l'interaction IMC–β-CD est la plus exergonique. La fixation est interprétée en termes de la facilité des interactions d'intercalation (hydrophobes) dans l'hélice de la ct-DNA (c'est-à-dire les paires de bases empilées) ou à l'intérieur de la cavité de la CD.

Mots clés : cyclodextrine, ct-DNA, médicament antiinflammatoire, indométhacine, constante de fixation, solubilité, spectres, voltampérométrie.

[Traduit par la Rédaction]

Introduction

Host–guest interactions play central roles in many biochemical processes such as the mechanism of drug action, enzyme–substrate interactions, immunological responses, and the storage and retrieval of genetic information (1, 2). There is growing interest in exploring the binding of small molecules with cyclodextrins (CDs) and DNA. Inclusion complexes of CDs have received extensive attention in the pharmaceutical field, especially in the design of drug formulation (3). Such complexation improves the aqueous solubility, dissolution, chemical stability, and bioavailability of

various drugs that are poorly soluble in water, which in turn leads to an increase in the plasma level peak resulting in a reduction in drug doses. The DNA-binding studies are important for the rational design and construction of new and more efficient drugs targeted to DNA (4, 5). These are extremely useful in understanding the DNA sequence recognition by drugs as well as by proteins. The specific interaction between a drug and DNA results in some changes in physical and chemical properties and has a potential importance for a better understanding of its therapeutic efficiency. A common feature in their structures, which characterizes both CD and DNA, are that they have a hydrophilic coat and a hydrophobic core. The hydrophilic groups (OH in CDs and PO_4^{3-} in DNA) of these macromolecules oriented to the exterior creating sites available for intercalative (hydrophobic) interactions.

Although, spectroscopic studies for CD or DNA systems are extensively reported, the voltammetric method is scarcely found in literature despite that electrochemical methods provide a useful complement to the other spectroscopic methods, e.g., for nonabsorbing species, weak absorption bands, overlap of electronic transition with those of the DNA molecule, and also when the difference of absorbance between free and complexed forms is small. Moreover, the electrochemical behaviours are valuable in elucidating some mechanisms of the drug action in vivo (6).

Indomethacin (1-(4-chlorobenzoyl)-5-methoxy-2-methyl-1-indol-3-acetic acid) is a nonsteroidal anti-inflammatory agent, widely used as an analgesic drug in the treatment of rheumatoid arthritis and other degenerative joint diseases, gout, and acute-musculoskeletal disorders. However, this compound is practically insoluble in water unless it is in alkaline media, where it undergoes hydrolysis to 5-methoxy-2-methylindol-3-yl acetate and 4-chlorobenzoate (7). Formulation of such a lipophilic drug is frequently hampered by its poor aqueous solubility, which can limit its therapeutic applications. The therapeutic activity is also impaired by the instability of the drug. To overcome these problems various methods have been used such as micellar (8) or liposomal (9) suspensions and CD derivatives (10), which affect the stability and solubility of indomethacin in aqueous solutions. Nonsteroidal, anti-inflammatory drugs generally cause ulceration as a result of slow dissolution of the drug, which provides high local drug concentraction, resulting in mucosal damage. Their ulcerogenic potencies could be reduced by CD complexation (11), which increases the dissolution and absorption rates and consequently result in a reduction of drug-induced gastric ulceration.

Therefore, and in continuation of our work (12–14)[2], the present work is devoted to study the interaction of IMC with α- and β-CDs and ct-DNA. This has been investigated by solubility, cyclic voltammetry, and differential pulse stripping voltammetry as well as UV–vis spectroscopy techniques. From the variation in the solubility, peak current, and absorption spectra, the formation constant (*K*) of these interactions were obtained.

Experimental

Instrumentation

Differential pulse stripping voltammetry (DPSV) and cyclic voltammetry (CV) were carried out using a PAR Model 264A polarographic analyzer – stripping voltammetry in conjunction with a PAR Model 303A HMDE and advanced X-Y recorder Model RE0151. An Ag/AgCl saturated KCl reference electrode and a Pt wire auxiliary electrode were used. A PAR Model 305 stirrer was also used for DPSV. The ultraviolet and visible absorption spectra were obtained using a Shimadzu UV-2101PC, UV–vis scanning spectrophotometer.

Reagents and procedure

Calf thymus deoxyribonucleic acid (ct-DNA), α-CD, β-CD, and IMC were obtained from Sigma and were used as received without further purification. Stock standard solution of ct-DNA was prepared by dissolving the ct-DNA in H_2O and stored at 4°C and discarded after no more than four days. Monitoring the absorption spectrum at 260 and 280 nm was done to check the purity of the ct-DNA. The concentration of the stock solution of ct-DNA (5.43×10^{-5} M in nucleotide phosphate, NP) was determined by UV absorbance at 260 nm using the molar extinction coefficient (ε) of 6600 M^{-1} cm^{-1} (15). It is noteworthy that the prepared ct-DNA solution in phosphate buffer gave ratio of UV absorbance at 260 and 280 nm (A_{260}:A_{280}) of approximately 1.9, indicating that the ct-DNA was sufficiently protein-free (16). Stock solutions of α-CD and β-CD were prepared by dissolving the desired weights in water. Stock solutions of IMC were prepared by dissolving an appropriate amount of the drug in methanol. The supporting electrolyte was a Britton–Robinson (BR) buffer prepared in the usual way, by adding appropriate amounts of sodium hydroxide (0.2 M) to an orthophosphoric acid, acetic acid, and boric acid mixture (0.04 M each). All chemicals were reagent grade (Merck, Darmstadt). Double-distilled water was used to prepare the solutions. The pH was measured using a pH-meter Model M64 (ORION) and is accurate to ±0.05 pH unit. In case of ct-DNA, the absorbance was recorded against a blank containing all reagents of the working sample except IMC.

For voltammetric measurements the test solution was placed in a polarographic cell of volume ≈15 mL and deoxygenated by passing nitrogen for 15 min. In the case of DPSV, the accumulation was performed on the HMDE and the solution was stirred at the accumulation potential of E_{acc}= 0.0 V for 30 s. The voltammetric response was obtained using a pulse repetition time of 0.2 s, within an amplitude of 100 mV and a scan rate of 20 mV s^{-1} (or 100 mV s^{-1} for CV, unless otherwise stated). When preconcentration of the stirred solutions was done, a quiescent period of 15 s was allowed before the potential scan was started. Typical CV peak potentials were reproducible to better than ±5 mV and DPSV peak potentials to ±2 mV.

Keeping both the concentration of the IMC and the total volume of solution constant (10 mL) the absorption and the electrochemical procedures were carried out, while varying the CD or ct-DNA concentration.

Solubility measurements were carried out according to the phase solubility method of Higuchi and Connors (17). An excess amount of the anti-inflammatory drug IMC was mixed with Britton–Robinson buffer solution (10 mL, pH = 7.2) containing various concentrations of β-CD ($0–5 \times 10^{-3}$ M).

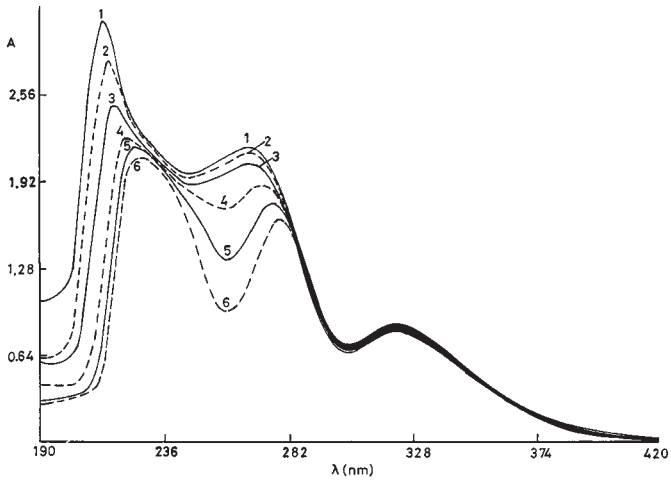
1	0.87
2	1.51
3	2.09
4	2.57
5	3.02

The screw-cap glass vials containing these suspensions were shaken until equilibrium had been reached (24 h), followed by another 10 h without shaking. The contents of each vial were filtered through a Whatman filter membrane (0.2 μm pore size). The filtrate was analyzed spectrophotometrically at 266 and 319 nm for the total amount of IMC dissolved.



All experiments were carried out at the ambient temperature (25.0 ± 0.5°C). The solubility values are the average of the three replicates.

Methanol is the solvent of choice due to its (*i*) ability to dissolve IMC appreciably; (*ii*) structural similarity to water along with other solvents; and (*iii*) low affinity for binding with CD (18), which renders it a poor competitor with IMC for CD.

Results and discussion

Solubility, voltammetric behaviour, and absorption spectra of IMC change dramatically as a result of binding to CDs or ct-DNA. These changes have been quantified to estimate the formation constants and to evaluate the binding modes of CDs and ct-DNA. The pH value as well as the constituent of the buffer has a pronounced effect on the interaction between IMC and either CD or ct-DNA. It was found that the Britton–Robinson buffer (BR) solution (pH = 7.2) has much greater hypochromicity and cathodic peak current reduction than the other buffers investigated. This behaviour suggests that the ionized IMC species (pK_a = 4.2 (7)) are favoured for the binding with CDs or ct-DNA compared to the non-ionized ones. Moreover, such a buffer is suitable to prevent the DNA from acid or basic denaturing, as well as to avoid the DNA reduction, since it reduced in acid medium (19). Therefore, the BR buffer (pH = 7.2) was considered optimum and used throughout the present work.

Fig. 2. UV–vis spectra of IMC (1.0×10^{-4} M) in BR buffer (pH = 7.2, 20% methanol) in the (1) absence and presence of (2) 5.43; (3) 10.8; (4) 21.7; (5) 27.1; and (6) 32.5 μM ct-DNA.

Solubility studies

The IMC is known to have very poor aqueous solubility (0.004 mg mL^{-1} at 298.15 K) (20). Like all the carboxylic acids, the solubility of indomethacin is greatly influenced by pH (20). This is due to the ionization of carboxylic group being enhanced with increasing pH, hence the solubility increases. At lower pH values the solubility decreases as a result of suppression of this ionization. On the other hand, the solubilized indomethacin will decrease the pH and the depression in pH increases with increasing the solubility of IMC. Thus, in order to compare the actual relative solubilizing capacity, the measurements should be done in buffer solution with constant pH. Therefore, the solubility measurements were carried out in BR buffer solution (0.1 M, pH = 7.2). The capacity of the buffer used is sufficient and high enough to maintain a constant pH value even for the higher IMC concentrations. This is in agreement with Hammad and Müller (20). They observed that the solubility (concentration) of IMC has a constant value at ≥0.02 M phosphate buffer. They used 0.067 M phosphate buffer in measuring the solubility of IMC in different micelles. This is emphasized from the measurement of the pH of the indomethacin solutions in presence of various β-CD concentrations ($0–5 \times 10^{-3}$ M). It was found that only a very slight drop in pH occurred, e.g., the pH of the IMC solutions decreases from pH = 7.20 without β-CD to 7.17 at higher concentration of β-CD (5×10^{-3} M).

Figure 1 shows the phase solubility profile representing the effects of increasing concentrations of β-CD on the apparent solubility of IMC in aqueous solution. An increase in the solubility of the complex with respect to the free form was observed. In aqueous solutions of IMC–β-CD complexes, the free drug molecules are in equilibrium with the drug molecules entrapped within the cavity. Thus, on increasing the concentration of β-CD more IMC molecules will transfer from the aqueous solution to the hydrophobic cavity of β-CD. Therefore, one can expect that more IMC dissolved in water in the pressence of β-CD than that dissolved in absence of it and consequently, the solubility of IMC increases with increasing the concentration of β-CD. A linear plot was obtained and represented by the following equation:

$$[1] \qquad C_{IMC} = 9.38 \times 10^{-4} + 0.475 C_{\beta\text{-CD}} \qquad R = 0.998$$

Therefore, the solubility curve for IMC was classified as type A_L, according to Higuchi and Connors classification (17), indicating the formation of a 1:1 IMC–β-CD complex.

The apparent stability constant (K = 966 M^{-1}) of the formed complex was calculated from the solubility diagram according to eq. [2]

$$[2] \qquad K = \text{slope}/S_o(1 - \text{slope})$$

using the slope of the phase solubility diagram and the determined IMC solubility in water (S_o).

The Gibbs free energies of transfer of IMC from aqueous solution to the cavity of β-CD (Table 1) have been calculated from the following equation:

$$[3] \qquad \Delta_{trans}G = -RT \ln (S/S_o)$$

where S and S_o are the solubilities of IMC in presence and absence of β-CD, respectively. As can be seen from Table 1 the $\Delta_{trans}G$ values are negative and increase negatively with increasing β-CD concentration. This indicates that the transfer process is spontaneous and supports the view that β-CD is more favourable environment than water for IMC. Moreover, the interaction between IMC and β-CD increases with increasing β-CD content.

Spectrophotometric studies

Indomethacin was characterized as having ultraviolet absorbance maxima at 212, 266, and 319 nm in 20% (v/v) methanol–water BR buffer (pH = 7.2). Some important changes in the absorption spectrum of IMC were observed upon the addition of ct-DNA (Fig. 2). The absorption bands at 212 and 266 nm shifted to longer wavelength. Also, this spectrum showed strong decreases in the peak intensities (hypochromicity) on increasing the concentration of ct-DNA. A continuous decrease in the intensity of IMC absorption was followed by saturation at high concentrations of ct-DNA. Such pronounced hypochromism and bathochromism were suggested to be due to a strong intercalation of the IMC molecule into ct-DNA base pairs (21). This implies a close proximity of the IMC chromophore of the ct-DNA base pairs, i.e., a strong overlap between the electronic states of the intercalating chromophore and that of the ct-DNA bases occur. The association of the ct-DNA and guest (IMC) molecule is governed by the following thermodynamic equilibrium:

$$[4] \qquad \text{ct-DNA} + \text{IMC} \rightleftarrows \text{ct-DNA–IMC}$$

and thus the formation constant is defined as:

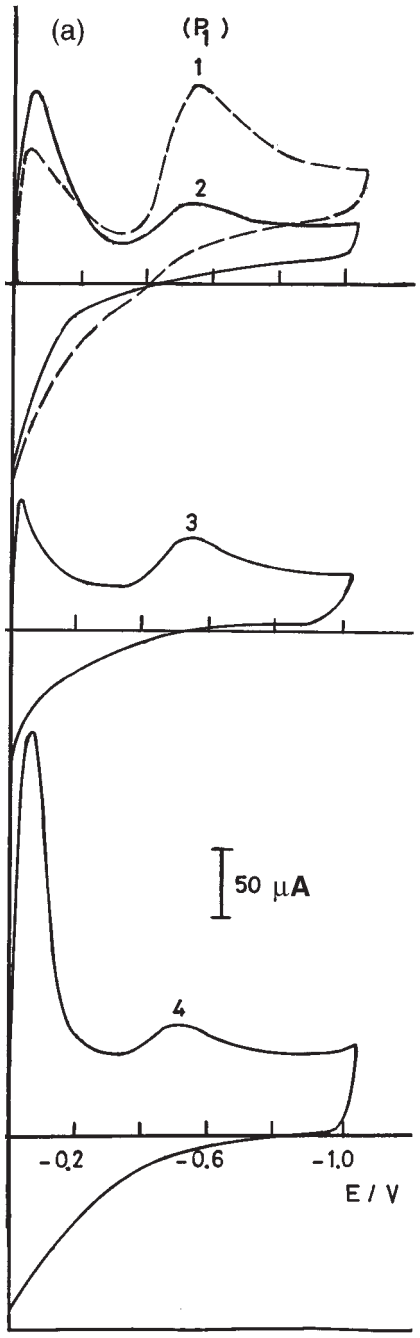
$$[5] \qquad K = [\text{ct-DNA–IMC}]/[\text{ct-DNA}][\text{IMC}]$$

assuming the most common host:guest ratio of 1:1.

The formation constant (K) was determined from the differences in absorbance (A) due to ct-DNA intercalation using the Hildebrand–Bensei double reciprocal plot (22)

$$[6] \qquad 1/\Delta A = (1/K[\text{IMC}]\Delta\varepsilon\, L_T) + (1/[\text{IMC}]\Delta\varepsilon)$$

in which [IMC] is the total concentration of indomethacin, L_T is the total concentration of ct-DNA, $\Delta\varepsilon$ is the difference in the molar absorpitivities for the free and the complexed IMC, and ΔA is the observed change in absorbance of the IMC at 266 nm by the addition of ct-DNA. The plot of $1/\Delta A$ vs. 1/[ct-DNA] gives good linearity with correlation coefficient ≥0.98 and was utilized to evaluate the K and $\Delta\varepsilon$ values from the intercept and slope, respectively. The formation constant is given in Table 2.



The binding constant of IMC with ct-DNA was also determined from absorption titration by using the Scatchard plot. In this method, $[\text{ct-DNA}]/(\varepsilon_A - \varepsilon_F)[\text{ct-DNA}]$ plot is constrcuted according to eq. [7] (21):

$$[7] \qquad [\text{ct-DNA}]/(\varepsilon_A - \varepsilon_F) = [\text{ct-DNA}]/(\varepsilon_B - \varepsilon_F) + 1/K(\varepsilon_B - \varepsilon_F)$$

where ε_A, ε_F, and ε_B are the apparent extinction coefficient ($\varepsilon_A = A_{observed}/[\text{IMC}]$), the extinction coefficient for free IMC ($\varepsilon_F = 2.12 \times 10^4$ M^{-1} cm^{-1} at 266 nm), and the fully bound form, respectively. From eq. [7] the K is given by the ratio of the slope to intercept. According to the experimental data of the absorption titration, the regression equation of

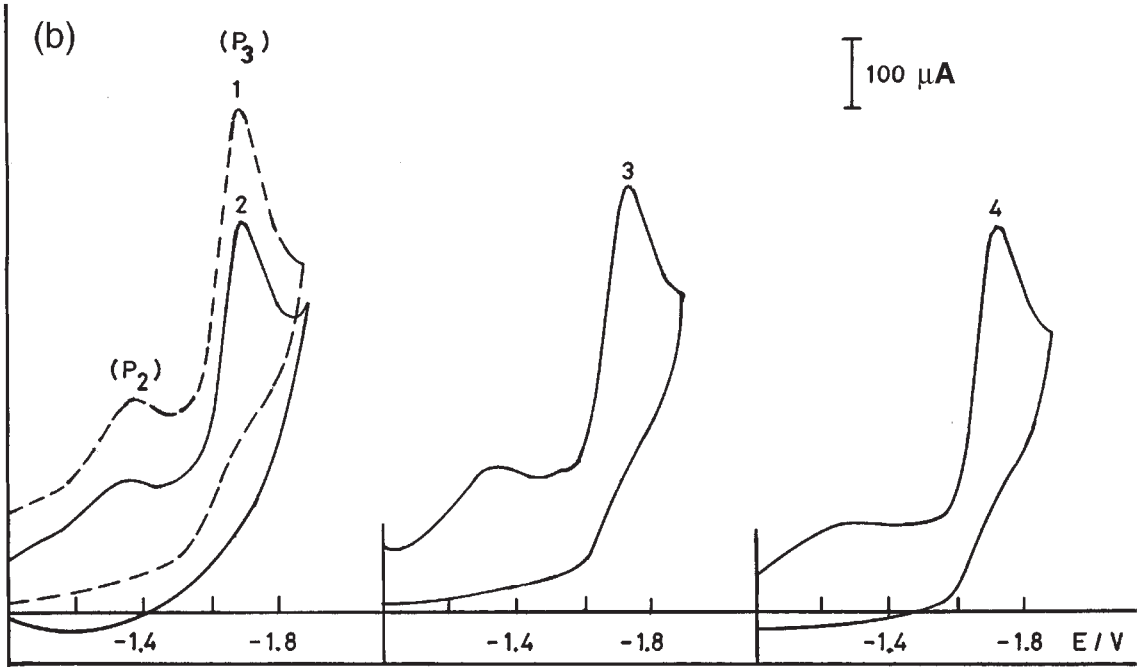
Fig. 3a. Cyclic voltammograms for IMC solution (1.0×10^{-4} M) obtained in BR buffer (pH = 7.2, 20% methanol) at HMDE, scan rate 200 mV s^{-1}, and potential scan from E_s = 0.0 to E_f = –1.0 V. (1) IMC only; (2) 1 + 2.39×10^{-5} M ct-DNA; (3) 1 + 5.94×10^{-3} M α-CD; and (4) 1 + 5.94×10^{-3} M β-CD.

eq. [7] is [ct-DNA]/($\varepsilon_A - \varepsilon_F$) = ($3.794 \times 10^{-4}$[ct-DNA] – 1.459×10^{-8})/K (R = 0.9797). The linear correlation revealed that the binding number was 1, i.e., one IMC molecule only interacts with one nucleotide phosphate in DNA. From the slope and the intercept of the above equation, log K = 4.41, which is exactly the value obtained using the double reciprocal method. Also, the estimated $\Delta\varepsilon = (\varepsilon_B - \varepsilon_F)$ value is 2.64×10^3 M^{-1} cm^{-1}, yielding $\varepsilon_B = 2.38 \times 10^4$ M^{-1} cm^{-1}.

On the other hand, the UV–vis absorption spectra indicate the inclusion complex formation of IMC and β-CD. The UV spectrum of IMC in BR buffer (pH = 7.2) is altered when the β-CD was added. The absorption bands at 212 and 266 nm shifted to longer wavelength as well as the absorbance peak decreased with increasing concentration of β-CD. Such observed spectral changes continue to occur until they reach a limiting value owing to the complete inclusion of the chromophore in the cavity of β-CD. The formation constant of IMC–β-CD complex (Table 2) was determined by a procedure similar to that used in the determination of K for IMC–ct-DNA complex.



Voltammetric studies

The few previous electrochemical studies on the reduction of IMC at mercury electrode (23, 24) prompted us to use the voltammetric method to trace the interaction of IMC with asymmetric environment of the ct-DNA or with CDs. Typical cyclic voltammetric (CV) behaviours of IMC in the absence and in the presence of ct-DNA or CDs are shown in Fig. 3. Working with the HMDE, the absorbed IMC compound and its reduction products exhibit complicated voltammograms, varying with concentration, pH value, temperature, content of organic solvent, sweep rate and complex formation. Only at low concentration (9.9×10^{-5} M), 20% methanol in the BR buffer solution (pH 7.2, 25°C), and with aid of fast sweep (200 mV s^{-1}) the IMC exhibit three cathodic peaks at –0.55 (P_1), –1.40 (P_2), and –1.68 V (P_3) as shown in Fig. 3. Under these conditions the complications caused by adsorption layers and the chemical splitting reaction (25) have little effect. The first cathodic peak (P_1), which appears at less negative potential, can be assigned to the reduction of the Hg–IMC complex (26). The second peak (P_2) was attributed to the reduction of the amide carbonyl corresponding to two electrons process and the third peak (P_3) is believed to be a kinetic wave (27). Furthermore, the absence of any peaks in the reverse scan as well as the shift of the peak potential to more negative values on increasing the scan rate (v) revealed the irreversible nature of the reduction peaks.

The addition of an excess of ct-DNA in IMC solution caused the peak currents to diminish considerably (Fig. 3, curve 2). The peak current decreased to about 40, 62, and 77% for P_1, P_2, and P_3, respectively, of that in the absence of ct-DNA. In terms of this result, it seems that binding of IMC to the large, slowly diffusing ct-DNA causes the decrease in the peak current of the IMC in the presence of an excess of ct-DNA, which results in the considerable decrease in the apparent diffusion coefficient of the IMC–ct-DNA adduct. This is emphasized from the decrease in slope of the linear $i_p - v^{1/2}$ plots ($R \geq 0.9989$), where the slope values are 36.1 and 30.9 nA $mV^{-1/2}$ $s^{-1/2}$ in absence and presence of ct-DNA, respectively. From these values, the diffusion coefficient (D_f) of the free IMC was found to be 2.81×10^{-7} cm^2 s^{-1}, whereas $D_b = 2.06 \times 10^{-7}$ cm^2 s^{-1} for the bound IMC (in presence of 2.39×10^{-5} M ct-DNA, NP). These values are within the range obtained by Carter et al. (28). It is noteworthy that the cyclic voltammogram of ct-DNA solution (5.43×10^{-5} M, NP) did not exhibit any Faradaic processes at potentials between 0.0 and –1.85 V vs. Ag/AgCl electrode under our experimental condition; it showed only a small

Fig. 3b. Cyclic voltammograms for IMC solution (1.0×10^{-4} M) obtained in BR buffer (pH = 7.2, 20% methanol). Potential scan from E_s = 1.0 to E_f = –1.85 V. Other conditions as in Fig. 3*a*.

reduction (<10%) in charged current, compared to that of ct-DNA free supporting electrolyte.

In presence of α-CD or β-CD, the peak potentials as well as the peak currents of IMC are influenced (Fig. 3, curves 3 and 4). The decrease in the peak currents can be attributed to the decrease in *D* value for IMC species in presence of the host molecule (28). This is again supported by the decrease in the slope of the linear $i_p - v^{1/2}$ plots ($R \geq 0.9989$) accompanied by the addition of host molecules. It is noteworthy that the current could also be diminished if the hosts caused an increase in the solution viscosity with a corresponding decrease in the diffusion coefficients. However, no change in solution viscosity could be detected over the range 0.5–10.0 mM CDs or 5–50 μM ct-DNA.

Further evidence for the interaction of IMC with α- and β-CDs and DNA comes from the differential pulse stripping voltammetry (DPSV). In presence of different concentrations of ct-DNA (as a representative example), the cathodic peak potentials as well as the peak currents of IMC are influenced (Fig. 4). The cathodic peak potentials of the first and second peaks shifted to more positive potential, indicating that the reduction of IMC molecule is enhanced when it enters ct-DNA-stacking region, a region with lower polarity. On the other hand, the currents of the first (P_1) and second (P_2) peaks as well as the peak height of the third (P_3) are strongly decreased with increasing concentration of ct-DNA revealing that an interaction has occurred between IMC and ct-DNA.

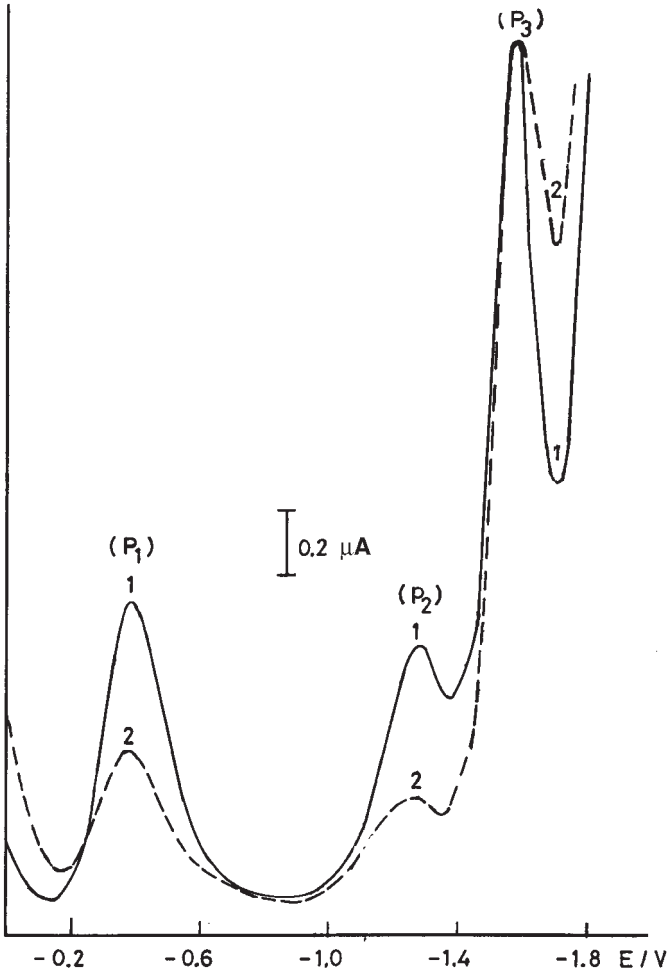
Based on the variation in the peak current, the formation constants of the complexes formed between IMC and CDs or ct-DNA were determined. For l:1 complex the following equation could be deduced based on Feng et al. (19):

$$[8] \qquad \frac{i_o}{i_o - i} = \frac{1}{(1-C)} + \frac{1}{K(1-C)[H]}$$

where i_o and i are the peak currents of the free IMC and that in the presence of CD or ct-DNA, respectively, [*H*] is the concentration of CD or ct-DNA, and *C* is the proportional constant. According to eq. [8], from $(i_o/i_o - i)$ vs. 1/[*H*] plot, the ratio of the intercept to the slope gives the vaue of *K*. Our experimental data at pH 7.2, which are in good agreement with those obtained from spectrophotometry experiments, are listed in Table 2.

The obtained *K* value is higher than those obtained previously for IMC–β-CD (log *K* = 2.88) at 303 K using NMR spectroscopy (29) and for IMC-hydroxypropyl–β-CD (log *K* = 2.98) using the kinetic method (10). Although, the obtained *K* value for β-CD is higher than the published values, the present value is in the range of the published ones, within the experimental error of the different methods, which lends credibility to these measurements. Also, the difference in the host molecules, temperature, and other conditions, including buffer solution, its components, and its ionic strength, could contribute to the difference in *K* value.

Mode and driving forces of inclusion complex



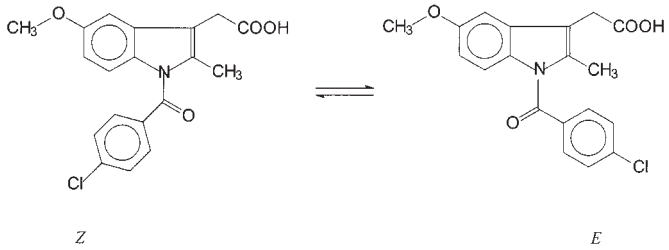
The supposed 1:1 association complex is inferred from the fitting of the experimental data from three independent techniques to the different equations. In all cases the regression coefficients ≥0.98 suggesting that IMC interacts with CD or ct-DNA in molar ratio of 1:1.

For the formation of IMC–CD complex the drug is transferred from aqueous solution to the CD cavity with the displacement of the incorporated water molecules to the bulk water, i.e.,

$$[9] \qquad \mathrm{IMC_{aq}} + [\mathrm{CD(H_2O)}_n]_{\mathrm{aq}} = [\mathrm{CD{-}IMC(H_2O)}_{n-x}] + x(\mathrm{H_2O})_{\mathrm{aq}}$$

© 2001 NRC Canada

Fig. 4. Differential pulse stripping voltammograms for IMC (1.0×10^{-4} M) in BR buffer (pH = 7.2, 20% methanol) at HMDE in the absence (1) and presence (2) of 3.8×10^{-6} M ct-DNA. Scan rate 20 mV s^{-1}, accumulation time 30 s, E_{acc} = 0.0 V, and pulse amplitude 100 mV.



The changes in Gibbs energy values (ΔG) for the binding of IMC with the CDs or ct-DNA were calculated from the well-known relationship:

$$[10] \quad \Delta G = -RT \ln K$$

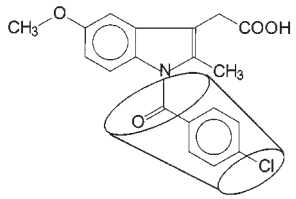
These values (Table 2) are negative indicating that the binding process is favourable and spontaneous.

The driving forces for CD inclusion complexes are still the subjects of controversy. Numerous factors have been found as contributing to the binding forces for the formation of various CD inclusion complexes (30), including hydrogen bonding between the hydroxyl groups of CD and the guest molecules, van der Waals interactions between the host and the guest molecules, hydrophobic interactions (in the present case including dehydration of the hydrophobic part of drug, i.e., the water molecules lose their lattice structure), the transfer of the high enthalpy water molecules from the cavity of CD to the bulk water, and the conformational change of the CD molecule upon the ligand binding.

Scheme 1.

Varying the percentage of methanol carried out a quantitative study of the effect of organic modifier in the binding of IMC to CD. Table 2 reports the values of *K*, determined voltammetrically for IMC–β-CD (as a representative example) at 20 and 40% (v/v) methanol. The *K* value at 40% (v/v) methanol decreased to 66% of that in 20% (v/v) methanol. This confirms that addition of methanol reduced the affinity of the IMC for the CD, and increased the affinity for the bulk buffer (31). The decrease in the *K* value and consequently the $-\Delta G$ values, with increasing methanol content suggests that water plays an important role in the association process. Thus, the hydrophobic interactions have a significant contribution to the binding reaction. The decrease in the polarity of the medium with the addition of methanol is unfavourable for hydrophobic interaction between IMC and CD.

The importance of hydrogen bonding is marginal, because the modified CD (incapable of hydrogen bonding) did not show a drastic change for the substrate binding (32). Moreover, alkanediols form less stable complexes with CD than the corresponding alkanols (12–14), in spite of the former having more hydrogen bond sites than the latter. The difference of the hydrophobicity (as indicated from the partition coefficients) between alkanols and alkanediols was suggested to be responsible for favourable binding of CD with alkanols.



On the other hand, the release of configurational strain in the CD ring has also a minor contribution for complex formation, as indicated from the conformational energy calculation (33).

Based on the ^{1}H NMR spectroscopy (34), single crystal X-ray diffraction results (35), and theoretical calculations (36), the IMC molecule exists in solution as a mixture of *E*- and *Z*- isomers (Scheme 1) and the *Z*-isomer is the most thermodynamically stable form. But, the data obtained by both intermolecular nuclear Overhauser enhancement (NOE) and rotating overhauser enhancement (ROE) as well as the energy calculations on the IMC–β-CD complex showed that the *E*-isomer is a more favourable conformation for the entry into the CD cavity than the *Z*-isomer (34). Hence, the major complex in solution is IMC-*E*–β-CD.

Since, IMC-*E* has two different lipophilic parts (*p*-chlorobenzoyl and the indol ring) under the influences of noncovalent interactions, it can be accommodated in the host cavity by four different modes of inclusion. Two modes of entry by *p*-chlorobenzoyl part may occur either through the larger or the smaller rim of the truncated cone of the CD. The other two modes of entry involve the indol part of IMC-*E*. We believe that the IMC–β-CD complex could be formed (next page), in which the *p*-chlorobenzoyl part of IMC-*E* isomer enters the hydrophobic cavity of β-CD truncated

© 2001 NRC Canada

cone. This is in good agreement with that proposed based upon the molecular dynamics and energy calculations on the four different modes of inclusion (34).

β-CD binds IMC more strongly than α-CD as indicated from the large *K* and $-\Delta G$ values. These results indicate that the size of the cyclodextrin cavity plays an important role in the formation of the complex. On the basis of size, the cavity size of β-CD seems to be optimal for entrapment of the IMC molecule, whereas in α-CD the binding leads to the formation of a more unstable complex. In other words, the *p*-chlorobenzoyl group should fit very snugly into the β-CD cavity, and should not be able to fully penetrate into the α-CD cavity.

On the other hand, three different modes are reported for the binding of small molecules to the DNA double helix, including (*i*) electrostatic interactions with the outer negative-charged DNA phosphates; (*ii*) groove binding; and (*iii*) intercalative binding, in which the small molecule or the drug intercalates into the relatively nonpolar interior of the DNA helix, i.e., the aromatic group is stacked between base pairs. Therefore, the large hydrophobic moiety is expected to facilitate the intercalation into the helix.

The strong hypochromicity observed with IMC in the presence of increasing amounts of ct-DNA is attributable to a mode of binding that involves a strong stacking interaction between an aromatic chromophore and the base pairs of ct-DNA.Such a large hypochromic change strongly suggests that the aromatic chromophore is in close proximity to the ct-DNA bases. In addition to the strong decrease in the peak intensities, a large red shift and the appearance of an isosbestic point at 281 nm was also observed in the spectra. All of these various spectral changes show that the IMC molecule, acting as an intercalator, is inserted into the base-stacking domain of the ct-DNA double helix.

Furthermore, voltammetric data, i.e., shifts in peak potential and changes in limiting current with the addition of ct-DNA, are consistent with the interchelation of IMC into the ct-DNA base stack. Also, the large binding constant observed for IMC is indicative of the high affinity of the IMC chromophore for the DNA base pairs.

Regioselective upper-rim functionalizations of calix[4]arene by diphenylphosphino groups

Jonathan Gagnon, Martin Vézina, Marc Drouin, and Pierre D. Harvey

Abstract: The regioselective upper-rim functionalization of calix[4]arene have been performed to prepare all the multisubstituted diphenylphosphine derivatives. In addition, the X-ray structures of 5,17-dibromo-11,23-bis(diphenylphosphino)-25,26,27,28-tetra-*n*-propoxycalix[4]arene and 5,11,17,23-tetrakis(diphenylphosphino)-25,26,27,28-tetra-*i*-propoxy-calix[4]arene have been determined. Regioselective functionalizations have been achieved using methods that involve appropriate choices of bases, alkyllithium–solvent systems, stoichiometry, and reaction times. A new and convenient method for selectively preparing derivitized calix[4]arenes at proximal positions in relative large scale quantity has been developed and involves a transesterification of the distal diester derivative into the proximal isomer.

Key words: calix[4]arenes, phosphine, upper-rim, X-ray structure, transesterification.

Résumé : On a réalisé la fonctionnalisation régiosélective de la anneau supérieure du calix[4]arène dans le but de préparer tous les dérivés multisubstitués de la diphénylphosphine. De plus, on a fait appel à la diffraction des rayons X pour déterminer les structures du 5,17-dibromo-11,23-bis(diphénylphosphino)-25,26,27,28-tétra-*n*-propoxycarix[4]arène et du 5,11,17,23-tétrakis(diphénylphosphino)-25,26,27,28-tétra-*i*-propoxycalix[4]arène. La fonctionnalisation régiosélective a été réalisée à l'aide de méthodes impliquant des choix appropriés de bases, des systèmes alkyllithium–solvant, de stoechiométrie et de temps de réaction. On a mis au point une nouvelle méthode pratique de préparer sélectivement et sur une échelle relativement grande des calix[4]arènes dérivatisés dans des positions proximales; elle implique une transestérification du diester distal en isomère proximal.

Mots clés : calix[4]arènes, phosphine, anneau supérieure, structure par diffraction des rayons X, transestérification.

[Traduit par la Rédaction]

Introduction

Calix[4]arenes are versatile molecules that are easy to synthesize (1) and are well-known for the host–guest chemical applications that they provide (1, and for an example also see ref. 2). Indeed with their ability to interact with cationic species in the ionophoric section of the cavity located at the lower rim, a great deal of important research in the area of ion transport, novel sensors, and selective receptors have been performed (3). On the other hand, the supramolecular chemistry offered with their cone conformation, also allows neutral organic guests to interact with the hydrophobic upper-rim cavity. Although multiple examples of neutral guests are already reported for molecules such as toluene (4), acetone (5), alkanes, and other substrates (6), applications have not been fully developed. The chemistry in the area of complexation of transition metals onto calix[4]arene has been mainly focused in the lower rim (7), and it is only recently that some examples of upper-rim derivatized calix[4]arene with transition metal-containing fragments, have appeared (8–10). In fact, such complexes are attractive because of potential applications in regioselective reactivity. When a metal catalyst fragment is anchored at the upper-rim, it is placed near the proximity of a cavity where a guest organic molecule may reversibly bind. Hence, the interactions between the metal fragment and the organic substrate will be molecularly localized. In addition, for multiphosphinated ligands, coordination of more than one metal is conceivable. In this way the multidentate calix[4]arene device can also act as a platform molecule for the construction of polymetallic architectures.

Recently we reported the preparation and the characterization of the monophosphinated calix[4]arene using both the diphenyl- and di-(*i*-propyl)-phosphine groups (9), along with their corresponding oxides, and some rhodium(I) and rhodium(III) complexes (9, 10). We now wish to report the preparation of the complete series of upper-rim diphenylphosphine functionalized calix[4]arenes, which are potential multidentate ligands capable of coordinating soft transition metals. During the course of this work, regioselective derivatizations were necessary. Indeed regioselective lithiation at positions 5 and 17 of a tetrabrominated calix[4]arene, and the *n*-propylation, 3,5-dinitrobenzoylation, and benzoylation at positions 25 and 27 of the tetrahydroxycalix[4]arene will be discussed. A novel and convenient method for converting the 25,27-diester- into the 25,26-diester-27,28-dihydroxycalix-[4]arene has been developed using sodium hydride.

Results and discussion

Tetraphosphines

To secure the cone conformation, calix[4]arene (**1**) is derivatized along the lower rim with propyl residues. It is now well-established that a three-carbon chain is the smallest group, when placed in the lower-rim, required to avoid rotations of the phenyl fragments around the bridging methylenes (11). Reinhoudt and co-workers (12) have developed an efficient propylation procedure of calix[4]arene using sodium hydride in DMF. In this work, this propylation method has been successfully applied for both *n*- and *i*-propyl leading to compounds **2a** and **2b**, respectively (Scheme 1). The cone conformation for all propylated derivatives has been confirmed by ^{1}H NMR, where the typical pattern for methylene protons is observed. Since propylation of *p*-bromocalix[4]arene is much slower than that of the parent calix[4]arene **1**, the propylation was carried out prior to bromination, which affords **3a** and **3b**, respectively.

The synthesis of 5,11,17,23-tetrakis(diphenylphosphino)-25,26,27,28-tetramethoxycalix[4]arene has been reported by Atwood and co-workers (13) with aims to design a molecular device for metal-cation extractions. Based on their procedure of using *n*-BuLi in THF at –78°C, the lithiation reaction was attempted on **3a** to synthesize the corresponding tetraphosphine derivative. However, the disubstituted 5,17-dibromo-11,23-bis(diphenylphosphino)-25,26,27,28-tetrapropoxycalix[4]arene (**5**) is selectively and reproducibly obtained, even with an excess of *n*-BuLi. Performing a subsequent lithiation and phosphination on compound **5** does not lead to the desired tetraphosphine compound **4a**. Examination of literature X-ray structures of the *n*-butyl- and *tert*-butyllithium species crystallized, in general, from ether or alkane solvents, reveals a strong tendency for aggregation (14). In ethers, tetrameric (distorted cubic) and quasi-planar dimeric structures are observed for the *n*-butyl- and *tert*-butyllithium derivatives, respectively, and one ether molecule per lithium is attached to the metal. In alkanes, octahedral and tetrahedral geometries are depicted for the *n*-butyl- and *tert*-butyllithium derivatives, respectively, with evidence for short metal–metal contacts, and no crystallization of solvent molecules. The cases where no solvent molecule is bonded to the lithium atoms offer more favorable geometries, with respect to steric interactions, for lithium–bromide exchange. Similarly, the planar dimeric structure found in [(*t*-BuLi)$_2$·(diethylether)$_2$] exhibits relatively unobscured metal atoms. In contrast, the tetrameric [(*n*-BuLi)$_4$·(1,2-dimethoxyethane)$_4$] cluster shows tetracoordinated lithium atoms that are relatively encumbered. It is anticipated that the first and second lithium–bromide exchange at the 5- and 17-positions of the tetrabromocalix[4]arene in **3a** and **3b** proceeds without any major steric restrictions. However, since the lithium atom has a strong tendency to bind ether molecules (15), the intermediate 5,17-dibromo-11,23-dilithium-25,26,27,28-tetrapropoxycalix[4]arene·2THF (speculative) appears to be severely sterically demanding for an efficient interaction with the already encumbered tetrameric [(*n*-BuLi)$_4$·(THF)$_4$]. While this speculative explanation seems reasonable, an X-ray structure of the 5,17-dibromo-11,23-dilithium derivative with THF or another ether molecule must definitely be obtained to confirm this hypothesis. As stated above, the bromide–lithium exchange followed by phosphination with chlorodiphenylphosphine affords the 5,17-diphosphine-11,23-dibromo derivative (**5**) as the sole product (discussed below).

However, we succeeded in achieving the perphosphination of **3a**. The phosphination proceeds via a bromide–lithium exchange followed by a substitution reaction with chlorodiphenylphosphine. The tetralithiated intermediate is predictably generated either with *n*-BuLi in benzene, or with *t*-BuLi in benzene or THF. Subsequently, reactions with chlorodiphenylphosphine leads to **4a** and **4b** (Scheme 1). The purification of these compounds is performed from multiple precipitations via the additions of acetone to a dichloromethane solution. This procedure leads to pure products, but the yields are modest. Among the impurities, some partially substituted calix[4]arenes, due to incomplete phosphination reactions, are found. The expected $^3J_{\mathrm{P,H\ calixarene}}$ of ~ 8 Hz is measured for **4a** and **4b**: this coupling constant is observed for all the phosphinated derivatives in this work. Both tetraphosphines **4a** and **4b** afforded single crystals of suitable quality for X-ray crystallography, but only the better quality data are reported for **4b**. The structure reveals the predicted cone conformation (Fig. 1). Three of the diphenylphosphine residues form a helical geometry, while the fourth one points in the other direction. The angles between the face-to-face phenyl groups are 88.18(0.11) and 1.19(0.20)°. The flattened bowl structure is typical in the solid state.

The success of the procedure reported by Atwood and coworkers (13) is consistent with the presence of various conformers in equilibrium (cone, partial cone, and 1,2- and 1,3-alternate) as revealed by the ^{1}H NMR data. Since the cone conformation is not retained, the bromide atoms may acquire nonsterically demanding environments in some specific geometries. This equilibrium may explain why, in this case, the tetrasubstitution can be achieved with alkyllithium in THF, which forms aggregates in this medium.

5,17-Diphosphine

Compound **5** conveniently exhibits two bromides at the remaining positions (positions 11 and 23) for further derivatizations. Single crystals of suitable quality for X-ray crystallography were obtained from slow THF–pentane vapor diffusion (Fig. 2). The structure confirms the diphenylphosphino disubstitution at positions 5 and 17 and the cone conformation. The molecule adopts a geometry belonging to the C_2 point group where the diphenylphosphine fragments are oriented in a helical fashion. In contrast with the tetraphosphine **4b**, the cone angles are very different, where the bromophenyl units are rotated inward (–16.72(0.26)°) and the diphenylphosphinophenyl groups are still rotated outward (85.2(0.12)°). Steric hindrance is likely responsible for this difference.

The 5,17-diphosphine compound (**9**) can be prepared via two alternative routes (Scheme 2). The first one is a four-step procedure from **1** and involves dipropylations, brominations, and phosphinations. Indeed, selective propylations at the distal positions (positions 25 and 27) are easily obtained using one equivalent of the weak base K_2CO_3 (16). Literature shows that these protons are the most acidic, as the resonance-stabilized dianionic species is stabilized by

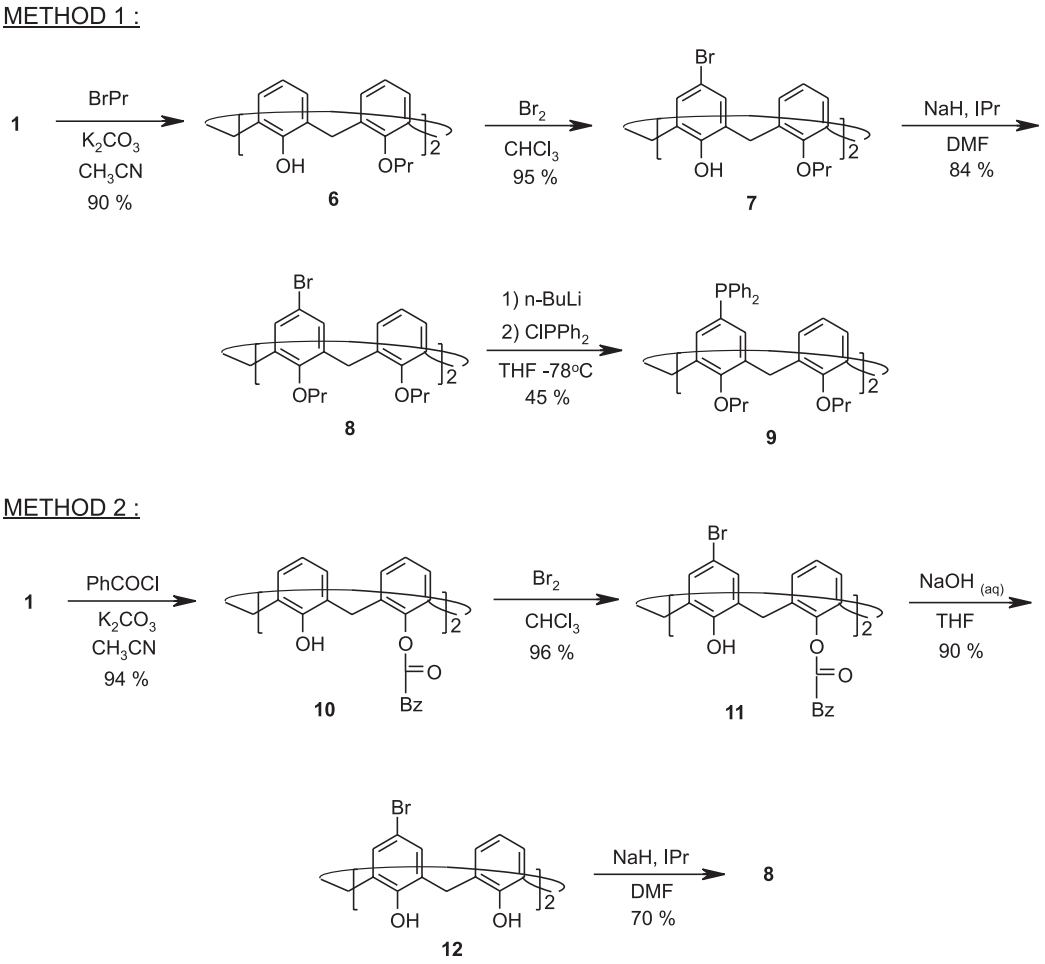
intramolecular hydrogen bonds with the remaining protons. Thus, propylation of the two first hydroxy groups occurs selectively at these positions, to afford compound **6** (16) in good yields. To subsequently obtain compounds **7** and **8**, bromination followed by a second propylation is performed.

Shinkai and co-workers (17) proposed a bromination step involving the use of 2 equiv of Br_2 in $CHCl_3$ at 0°C for 1 h, to afford the desired product in 87% yield. Later Larsen and Jorgensen (18) claimed that this procedure led to a mixture of products involving several impurities, which could not be separated using recrystallization or column chromatography. Our attempts to reproduce this reaction show that in fact these impurities result from incomplete brominations. To overcome this problem, Larsen and Jorgensen (18) reported an alternative method using 8 equiv of *n*-BuLi in THF at –78°C for 30 min in the presence of **3a**, followed by quenching with water, in 88% yield. In this work, an excess of Br_2 and a shorter reaction time (5 min), allows selective and complete monobromination resulting in compound **7**, which is purified by recrystallization. This selectivity is explained by the greater reactivity of the *para*-position of the phenol group in comparison with the propoxylbenzene. This bromination procedure is a key step for the synthesis of compound **26** (triphosphine, discussed below). The propylation reaction is subsequently performed using *n*-iodopropane in DMF for 48 h to afford **8** as a sole product. The last steps consist of lithiation and phosphination reactions with *n*-BuLi and $ClPPh_2$ in THF to obtain the diphosphine **9**, which is purified by column chromatography.

Matt and co-workers (19) reported another convenient way to prepare **9** from **8** in two steps using a procedure of diphosphorylation with Ph_2POEt–$NiBr_2$ (20), which results in a bis(phosphine oxide). The next step involves the reduction of this phosphine oxide with phenylsilane to afford compound **9**. We have indeed been able to reproduce these results.



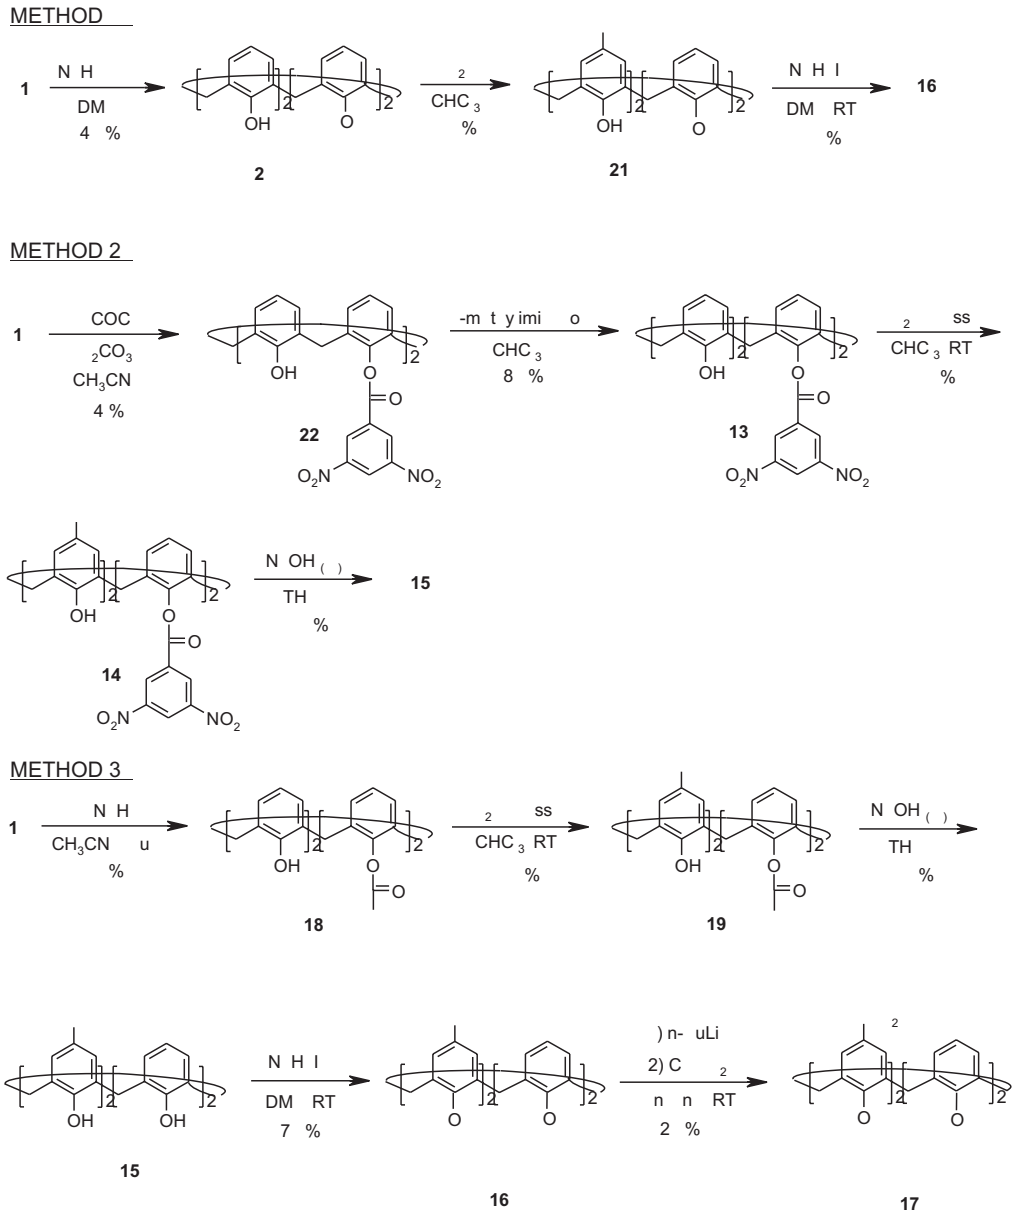
The second investigated route involves the diesterification of **1** to produce **10**, where the ester groups are anchored at the 25- and 27-positions. This reaction proceeds via a double proton abstraction of the two most acidic protons, followed by a substitution reaction with benzoyl chloride. This derivatization induces a greater difference in electron density between the phenol and phenylbenzoyl residues. In this way, the subsequent brominations can be performed selectively at the highly electron-rich phenol sites without considering reaction time. The ester groups are then easily hydrolyzed, and the cone conformation is still maintained via H-bonding as confirmed by ^1H NMR. The standard propylation of this compound provides compounds **8**, which is the precursor of the final product **9**.

5,11-Diphosphine

This desired and challenging diphosphine **17** is prepared from three alternative routes as summarized in Scheme 3.

© 2001 NRC Canada

Scheme 2. Two different synthesis pathways for compound **9**.



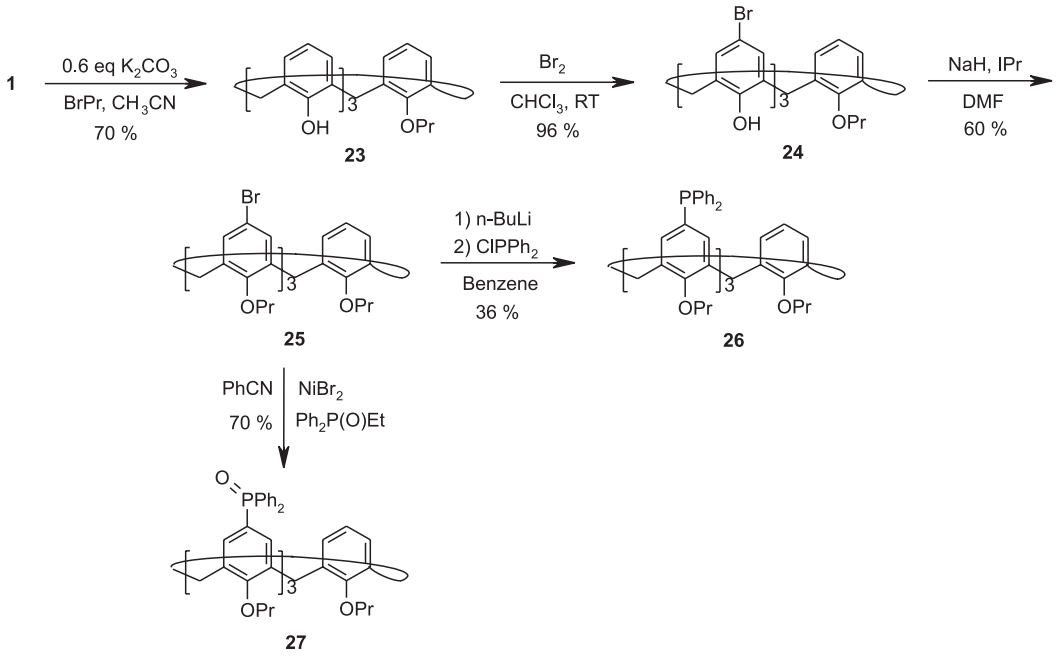
Reinhoudt et al. (21) demonstrated that propylation of **1** using NaH in DMF produce the intermediate compound 25,26-dipropoxycalix[4]arene in the cone conformation. For short reaction times, the 25,26-dipropoxycalix[4]arene compound **20** is observed as one of the intermediates. Unfortunately, the yield for this specific 1,2-disubstitution is low (45% in our work) making this route less attractive. We find that the reaction mixture also contains unreacted **1** and tetrapropylated **2a**. The relative amount of the desired product **20** is best acheived after a 2 h reaction time. Nonetheless, this compound has been prepared and used as precursor. The subsequent bromination and alkylation reactions can be performed with expected results (i.e., formation of compound **16**).

The second strategy is based on the work of Gutsche and co-workers (22), which reports the preparation of 25,26-di(3,5-dinitrobenzoyl)-27,28-dihydroxy-5,11,17,23-tetra(*tert*-butyl)calix[4]arene from 25,26,27,28-tetrahydroxy-5,11,17,23-tetra(*tert*-butyl)calix[4]arene in the presence of 3,5-dinitrobenzoyl chloride using 1-methylimidazole in acetonitrile. Indeed diester **13** can be synthesized from this methodology, but in very low yield (15–40%). Several impurities were found in the mixture, including the monoester derivative, the starting material, and the corresponding 25,27-diester. The presence of this 25,27-diester compound the is the key to understanding this mechanism and will be discussed below. Compound **13** is poorly soluble, which on one hand has the potential to allow the selective preparation of the desired product, but on the other hand, does not permit preparation on a large scale. The major drawback is that the product must be purified by column chromatography. In an attempt to avoid this important solubility problem, 3,5-dinitrobenzoyl chloride was replaced by benzoyl chloride. Surprisingly, the reaction between **1** and benzoyl chloride in presence of 1-methylimidazole in acetonitrile did not lead to the disubstituted calix[4]arene as the major product, but produced the corresponding triester as major product. Stubbornly, some of this triester compound is still formed even when only one equivalent of benzoyl chloride is used in this reaction. Nonetheless, bromination affords **14** in good yields, as anticipated. Then compound **15**, which is necessary to synthesize **17**, is convieniently obtained by ester cleavage of **14** in basic solution.

The third method involves an intramolecular transesterification of **10** to **18**. Recently, Markovsky et al. (23) reported an elegant intramolecular phosphotropic rearrangement at the lower rim of the calix[4]arene from the 25,27- to the 25,26-positions, hence providing a important clue about the mechanism. Compound **10** is prepared from **1** using K_2CO_3. Again, the two most acidic protons are readily abstracted, allowing the 25,27-diesterification of **1**. The subsequent transesterification of **10** to **18** proceeds with one equivalent of sodium hydride in good yield. This strong base in

© 2001 NRC Canada

Scheme 3. Different synthesis pathways for compound **17**.



acetonitrile abstracts one of the two remaining protons, generating a phenolate intermediate over a period of 20 h, during which the transesterification occurs. This intramolecular reaction allows for equilibrium between the two disubstituted compounds. The generated 5,11-diester monoanion is stabilized by an intramolecular H-bond between the hydroxy and phenolate groups, which drives the equilibrium to the right. Acidification of the solution leads to the targeted diester **18**, which is obtained in a pure state after column chromatography to eliminate some traces of the reactant. Diester **18** exists in a partial cone conformation with both OH groups pointing in the same direction according to its ^{1}H NMR spectra. This reaction is almost complete in refluxing acetonitrile (82°C), but is not complete even after one week in refluxing THF (66°C). In addition, no transesterification is observed when two or more equivalents of sodium hydride are used. In this case, the dianionic species are generated and electrostatic repulsions between the negatively charged phenolates (doubly deprotonated calix[4]arene) may be at the origin of this selective structure. Interestingly, the 25,26-species can be converted back to the 25,27-compounds by using an excess of bases (two equivalents or more). The following steps include the well-established selective bromination, ester cleavage, propylation, and phosphination to achieve the synthesis of the desired 5,11-diphosphine compound (**17**).

Based upon these experiments, the preparation of the 25,27-di(3,5-dinitrobenzoyl)-26,28-dihydroxycalix[4]arene (**22**) in its pure state has been performed to shed some light on the mechanism for the conversion of **1** into **13**. The preparation of **22** is achieved using **1** in the presence of 3,5-dinitrobenzoyl chloride and potassium carbonate in acetonitrile. Subsequently, **22** is placed in the presence of 1-methylimidazole to produce **13**. This procedure affords better yields. In conclusion, one equivalent of potassium carbonate allows for the preparation of the corresponding

© 2001 NRC Canada

Scheme 4. Synthesis of compound **27**.

25,27-diesters. The transesterification proceeds using an additional equivalent of base to generate a monophenolated calix[4]arene anion. In this work sodium hydride and 1-methylimidazole were used for the conversion of **10** to **18** and **22** to **13**, respectively. The fact that Gutsche and co-workers (22) did not observe the 25,27-di(3,5-dinitrobenzoyl)-26,28-dihydroxy-5,11,17,23-tetra(*tert*-butyl)calix[4]arene may be related to the electron-donor inductive effect of the *tert*-butyl group rendering the corresponding monophenolate anion more basic. Hence in this case, only the monophenolated calix[4]arene is generated, which readily promotes the transesterification. When a large excess of 1-methylimidazole was used (up to 20 equivalents) to see whether the transesterification would be precluded (as seen in the reaction of **10** to **18** with an excess of sodium hydride), the transesterification was still observed.

Gutsche and co-workers (22) also reported the hydrolysis of 25,26,27-tri(3,5-dinitrobenzoyl)-28-hydroxy-5,11,17,23-tetra(*tert*-butyl)calix[4]arene to 25,26-di(3,5-dinitrobenzoyl)-27,28-dihydroxy-5,11,17,23-tetra(*tert*-butyl)calix[4]arene in the presence of 4-methylimidazole. However, the tribenzoyl ester **28** mentioned above could not be converted to **18** by this method.

From the three described methods, the last one, which utilizes benzoyl chloride and intramolecular transesterification with NaH, was found to be the most convenient. The low solubility of **13**, and also the low yield for the selective propylation of **1** into **20**, make the other described methods much less appealing.

Triphosphine

The strategy for preparing the triphosphine derivative involves the preparation of the monopropoxycalix[4]arene (**23**) (Scheme 4). This can be achieved by abstracting a proton with one equivalent of base. However, when the monophenolated calix[4]arene intermediate is generated an equilibrium sets in, to form the 25,27-diphenolate-26,28-dihydroxycalix[4]arene intermediate and **1**, as evidenced by the appearance of the dipropoxy compound **6** either with the increase or decrease in the amount of base used. By using 0.5 equivalent of K_2CO_3, the monopropoxy derivative **23** is the major product, mixed with **6** and **1**. Compound **6** is easily removed by recrystallization, and subsequently, **23** is purified by column chromatography. The yield is unavoidably low, but the preparation of the desired compound is attained. The subsequent bromination reaction is selective to the phenol residues. The following propylation reaction is preferably performed with 1-iodopropane instead of 1-bromopropane, since the propylation of the *para*-bromophenol fragments is much slower with the latter reactant. The tribromotetrapropoxy derivative **25** is then obtained. The phosphine oxide derivatization of **25** with Ph_2POEt–$NiBr_2$ was performed successfully, but the subsequent reduction of **27** using the procedure of Matt and co-workers (19), with phenylsilane to form **26**, proved very difficult either using phenylsilane-containing solutions or neat. This reaction leads to a mixture of products, which could not be separated. The desired ligand **26** is generated with *n*-BuLi in benzene, followed by a reaction with chlorodiphenylphosphine, in a modest yield. It is anticipated that the use of *n*-BuLi in THF could lead to 5,17-diphosphine-11-bromo-25,26,27,28-tetrapropoxycalix-[4]arene, similar to that describe for compound **5**. This proposed synthesis may lead to further functionalizations as suggested for **5**.

The syntheses presented can also be applied to the upper-rim multifunctionalization of calix[4]arene by dialkylphosphines. Their preparation and characterization, as well as their complexation with low-valent transition metals, will be reported in due course.

tions involving air- or moisture-sensitive reagents were conducted under nitrogen atmosphere. Column chromatography was performed on 230–400 mesh silica gel (60 Å). All NMR spectra were acquired (^{1}H 300 MHz, ^{13}C 75 MHz, ^{31}P 121 MHz) using the solvent as chemical shift standard, except in ^{31}P NMR, where the chemical shift are relative to D_3PO_4 (85% in D_2O). All the chemical shifts and the coupling constants are given in ppm and Hz, respectively. The lower number of signals in ^{13}C NMR spectra is due to isochronism. Mass spectra were determined at an ionizing voltage of 70 eV. Compounds **1** (23), **2a** (12), **3a** (24), **6** (16), and **23** (25) were prepared according to literature procedures. The syntheses of all new calix[4]arene compouds are reported in the Supporting Information.[2]

Crystal data for calix[4]arene 4b and 5

Crystallographic measurements were made on an Enraf-Nonius CAD-4 automatic diffractometer with graphite-monchromated Cu Kα radiation. Data were collected at 173 K for **4b** and 293 K for **5** using the θ–2θ scan technique to a maximum 2θ value of 120.0° for both compounds; no reflections above the giving angle were observed. The data collection ranges were $\pm h$, $+k$, $+l$; whereby for **4b**: $-20 \le h \le 19$, $0 \le l \le 15$, $0 \le k \le 32$; **5**: $-20 \le h \le 20$, $0 \le l \le 18$, $0 \le k \le 21$. Scans were made with a constant speed of 2.7° min^{-1} and a background time:scan time ratio of 0.25. Space group determination was based upon systematic absences, packing considerations, statistical analysis of intensity distribution, and successful solution and refinement of the structure. The NRCCAD program (26) was used for centering, indexing, and data collection. The NRCVAX programs (27) were used for crystal structure solution by application of direct methods, and the SHELX-97 program (28) was used for refinement by full-matrix least-squares on F^2.

Compound **4b** (5,11,17,23-tetrakis(diphenylphosphino)-25,26,27,28-tetra-*i*-propoxycalix[4]-arene) gives crystals belonging to the monoclinic space group $P2_1/n$ and at 173 K: a = 18.360(2), b = 13.998(2), c = 29.663(2) Å, β = 101.67(8)°, V = 7466.1(15) Å^3, Z = 4, $R(F)$ = 0.0777, and $wR(F^2)$ = 0.2218. One disordered $CHCl_3$ molecule was located on a center of symmetry, the former atoms were refined as isotropic with 0.25 occupancy factor. Compound **5** (5,17-dibromo-11,23-bis(diphenylphosphino)-25,26,27,28-tetra-*n*-propoxycalix[4]arene) gives crystals belonging to the monoclinic space group $I2/a$ and at 293(2) K: a = 17.957(2), b = 16.681(2), c = 19.336(3) Å, V = 5753.0(11) Å^3, Z = 4, $R(F)$ = 0.0694, and $wR(F^2)$ = 0.1829. The molecule is located on a glide plane, and one of the *n*-propyl ligands is disordered. The disordered atoms were refined as isotropic atoms with 0.5 occupancy factor.

DISQUAC predictions on thermodynamic properties of ternary and higher multicomponent mixtures. II. Results for H^E of ternary mixtures containing nonpolar components, or one polar compound, two polar compounds, or one alcohol and hydrocarbons, or CCl_4

Juan Antonio Gonzalez, Javier Carmona, Nicolas Riesco, Isaias Garcia de la Fuente, and Jose Carlos Cobos

Abstract: The ability of the DISQUAC model for predicting excess enthalpies (H^E) of ternary systems on the basis of binary parameters only, i.e., neglecting ternary interactions is analyzed. At this end, DISQUAC results for a set of 95 ternary systems are examined. The solutions studied are formed by only hydrocarbons (or CCl_4); or by one polar compound (not alcohols) and two hydrocarbons (or CCl_4); or by two polar compounds (not alcohols) and one hydrocarbon (or CCl_4); or by one alcohol and two hydrocarbons (or CCl_4). Most of the H^Es analyzed are endothermic, and valid at 298.15 K and atmospheric pressure. The mean deviation between experimental values and DISQUAC results is 5.5% for the ternary systems and 6.5% for the constituent binaries (181 mixtures). The interaction parameters used are valid for the description of thermodynamic properties of binary systems: vapor–liquid equilibria (VLE), liquid–liquid (LLE), and solid–liquid equilibria (SLE), H^E and excess heat capacities at constant pressure (C_p^E), as well as H^E and VLE of ternary solutions. Predictions are, in most of the cases, independent of the mixture compounds, or the number of groups present in the system. Larger deviations underline typical shortcomings of the group contributions methods (e.g., Patterson's effect; branching). Note that results for the ternaries and for the constituent binaries are of the same order. This is not the case for the Dortmund version of UNIFAC. The mean deviations obtained using this model are 10.5% and 14% for the ternary and binary mixtures, respectively. Results from other models (original UNIFAC, Flory's theory, Nitta–Chao, UNIQUAC association model) for a number of systems are also compared to those obtained using DISQUAC.

Key words: predictions, H^E, ternary systems, binary parameters, geometrical methods, Flory, group contributions.

Résumé : On a analysé l'habilité du modèle « DISQUAC » à prédire les enthalpies en excès, H^E, de systèmes ternaires uniquement sur la base de paramètres binaires c'est-à-dire en négligeant les interactions ternaires. À cette fin, on a analysé les résultats « DISQUAC » obtenus pour un ensemble de 95 systèmes ternaires. Les solutions étudiées ne sont formées que d'hydrocarbures (ou de CCl_4) ou d'un composé polaire (ne comportant pas d'alcool) et de deux hydrocarbures (ou de CCl_4) ou de deux composés polaires (ne comportant pas d'alcool) et d'un hydrocarbure (ou de CCl_4) ou d'un alcool et de deux hydrocarbures (ou de CCl_4). La plupart des valeurs de H^E analysées sont endothermiques et elles sont valides à 298,15 K et à pression atmosphérique. La déviation moyenne entre les valeurs expérimentales et celles calculées à l'aide du modèle « DISQUAC » est de 5,5% pour les systèmes ternaires et de 6,5% pour les constituants binaires (181 mélanges). Les paramètres d'interaction utilisés sont valides pour la description des propriétés thermodynamiques suivantes de systèmes binaires (équilibres vapeur–liquide, VLE, liquide–liquide, LLE, et équilibre solide–liquide, SLE, H^E, capacités calorifiques en excès à pression constante, C_p^E) ainsi que pour H^E et VLE de solutions ternaires. Dans la plupart des cas, les prédictions sont indépendantes des composés présents dans les mélanges ou du nombre de groupes présents dans le système. Les déviations plus importantes observées mettent en relief les imperfections des méthodes de contributions des groupes (par exemple, l'effet de Patterson, la ramification). Il faut aussi noter que les résultats sont du même ordre pour les constituants ternaires ou binaires. Ceci n'est pas le cas pour la version Dortmund d'UNIFAC. Les déviations moyennes obtenues à l'aide de ce modèle sont de 10,5% et 14% respectivement pour les mélanges ternaires et binaires. On a aussi comparé les résultats obtenus à l'aide du modèle

DISQUAC avec ceux obtenus avec d'autres modèles (UNIFAC originale, théorie de Flory, Nitta–Chao, modèle d'association UNIFAC) pour un certain nombre de systèmes.

Mots clés : prédictions, systèmes ternaires, paramètres binaires, méthodes géométriques, contributions de groupes.

[Traduit par la Rédaction]

Introduction

Although large amounts of data have been reported in the literature for binary systems, data for ternary mixtures and higher multicomponent solutions are scarce. This is due to the time and effort required to obtain a meaningful set of multicomponent data. So, one of the most important tasks of the thermodynamics is to provide predictions on thermodynamic properties of multicomponent mixtures using data obtained from more simple systems and, in the case of VLE, for pure substances.

Of course, the most essential step is to pass from binary to ternary systems and to determine the extent to which the properties in these mixtures can be predicted on the basis of binary data and to assess when data reflecting ternary interactions are absolutely needed.

In the field of correlation and prediction of multicomponent data, many efforts have been developed on the basis of statistical thermodynamics methods, several theoretical solution models, and semiempirical equations (1–20). Nevertheless, each method seems to have its own area of application limited to particular types of systems. These difficulties continue to grow with increasing the number of components. For example, in the case of alcoholic solutions, the classical association model (1), based on the so-called formation of polymeric species of alkanol molecules through hydrogen bonding, must be improved depending on the chemical nature of the remainder components (2–14). These improvements affect the physical contribution to the thermodynamic properties (5, 6, 12–14), as well as to the chemical contribution (2–14). So, in ternary mixtures with two alkanols and one active nonassociating compound, complex formation should be considered in all three combinations because of the charge transfer of the self-associating and active components.

The semiempirical equations more commonly used (Redlich–Kister, Colinet, Scatchard–Hillert, Tsao–Smith) (18–20) to predict H^E of ternary systems are geometrical methods to establish the contribution of each one of the three binaries involved to the ternary H^E. For asymmetric equations with respect to numbering of components, it is of great importance which component is designated as component 1 (19–20). An additional problem comes from that H^E of the constituent binaries must be known to apply these equations and the same occurs for association models.

Group contribution models (21–26) are powerful methods to predict ternary data (VLE and (or) H^E) neglecting ternary interactions. That is, only information from the set of binary systems which contain the groups present in the ternary system analyzed is needed. However, it must be elucidated what type of the information used is relevant to improve predictions. For example, it has been shown that the classical UNIFAC model (21) provides reliable results on H^E of ternary systems when the interaction parameters are obtained using only H^E of binary mixtures (22). However, these interaction parameters are not useful for VLE calculations.

The DORTMUND version of UNIFAC (23, 24) (hereafter, merely UNIFAC) is a modified UNIFAC model which uses a new combinatorial term and temperature-dependent interaction parameters. UNIFAC improves VLE and H^E results for binary and ternary systems in comparison to the original model (23).

We are engaged in a systematic study on the ability of the DISQUAC model (25, 26) to predict VLE and H^E of multicomponent mixtures using binary parameters only. One of the main features of DISQUAC is that the interaction parameters are assumed to be dependent on the molecular structure. Although this means to leave the classical concept of group contribution, is essential for practical purposes. As a matter of fact, it leads to improved predictions, mainly in the case of branched and cyclic molecules, and for the first members of homologous series. Results for ternary systems are also improved. For example, in the first paper of this series (27), we obtained a mean deviation of 2.2% between calculated and experimental pressures for VLE at isothermal conditions of a set of 39 mixtures. DISQUAC results are indeed reliable over a wide range of temperature and for any type of ternary system, even for those with some binary with a miscibility gap (27). Moreover, we have already shown that DISQUAC accurately describes H^E of ternary systems containing one 1-alkanol and two hydrocarbons (28), or two 1-alkanols and one alkane (29), or H^E of 1-alkanol + linear ketone + hydrocarbon mixtures (30). Here, we present DISQUAC predictions on H^E, essentially at 298.15 K, for a set of 95 ternary systems. Some of them have been studied previously, but are included to develop a more complete study. At this end, DISQUAC results are compared to those provided by UNIFAC (23) and Flory (31) models. This is interesting because of the different way of application of such models. DISQUAC uses structure-dependent interaction parameters, UNIFAC averaged parameters, and Flory parameters which are calculated from the H^E measurements of the constituent binaries of the ternary considered.

Other models, such as Nitta–Chao (20) or UNIQUAC association solution model (9, 10), are also considered briefly.

Ternary systems considered

The mixtures treated (Table 1) can be classified as follows: Group I: mixtures containing only hydrocarbons (or CCl_4); Group II: mixtures of one polar compound (not alcohols) and two hydrocarbons (or CCl_4); Group III: mixtures with two polar compounds (not alcohols) and one hydrocarbon (or CCl_4); Group IV: mixtures of one alcohol and two hydrocarbons (or CCl_4). Experimental data are valid at atmospheric pressure and most of them are at 298.15 K. On

[a]Symbols: 3-pentanone (2CO2), ethylpropanoate (2COO2), methyl *tert*-butylether (MTBE), *tert*-amylmethylether (TAME), 2,3-dimethylbutane (23DMB), diisopropylether (DIPE), 2-hexanone (1CO4), 2-propanone (1CO1), 2-butanone (1CO2), 1,2-dimethylbenzene (12DMBZ), 1-hexylamine ($6NH_2$), di-*n*-propylether (3O3), di-*n*-butylether (4O4), 2,5-dioxahexane (1O2O1), tetrahydrofuran (THF), butanenitrile (4CN), 2-propanone (1CO1), methanol (MeOH), ethanol (EtOH), 1-propanol (1-PrOH), 1-butanol (1-BuOH), 1-pentanol (1-PeOH), 1-hexanol (1-HxOH), 1-octanol (1-OcOH), 2-propanol (2-PrOH), methyl-cyclohexane (m-C_6H_{12}).

[b]T = 293.15 K.

[c]T = 303.15 K.

[d]T = 318.15 K.

[e]T = 308.15 K.

[f]T = 313.15 K.

[g]T = 333.15 K.

the other hand, the ternary solutions studied are characterized by endothermic H^E, except the 2-propanone + $CHCl_3$ + cyclohexane system, which is strongly exothermic.

Results for the binary mixtures involved in the ternary solutions are also given. When it was possible, we considered those binaries investigated in the original works on the ternary mixtures treated.

Models

DISQUAC

Assessment of geometrical parameters

The relative molecular volumes (r_i), the surfaces (q_i), and the surface fractions (α_{si}) of all the molecular species have been calculated on the basis of the group volumes and surfaces recommended by Bondi (32), taking the volume and the surface of methane arbitrarily as unity (33). Values of r_i and q_i of the groups referred to in this work are given in the literature (see Table A1 of *Appendix* for references).

Theory

The equations used to calculate thermodynamic properties in the framework of DISQUAC are given elsewhere (34). The temperature dependence of the interaction parameters is expressed in terms of the dispersive (DIS) and quasichemical (QUAC) interchange coefficients $C^{DIS}_{st,\,l}$ and $C^{QUAC}_{st,\,l}$, where s, t are the different groups present in the mixture and l is the order of the interchange coefficient: l = 1 (Gibbs energy), l = 2 (enthalpy), l = 3 (heat capacity). For the QUAC part, the coordination number is z = 4.

Values of the interchange coefficients

Most of the interchange coefficients used in this work are available in literature (see Table A1 of the *Appendix* for references). Only a few of them have been estimated for this paper (Table A2 of *Appendix*). In mixtures containing two oxaalkanes, the interchange coefficients corresponding to the oxygen/oxygen contacts were neglected.

It should be emphasized that the DISQUAC interaction parameters are considered as dependent on the molecular structure, and so, in a given homologous series, each molecule of solute has its own set of interchange coefficients. Nevertheless, some general trends concerning their variation with the molecular structure have been pointed out. In mixtures formed by polar but not self-associated compounds, such variation is usually attributed to inductive effects on DIS coefficients and steric effects on QUAC coefficients (35, 36). On the other hand, we have found in many series containing alcohols what seems to be a general rule: the QUAC coefficients for l = 1 and l = 3 are independent of the alcohol size. This is still valid for l = 2, although some exceptions are found. So, in systems involving *sec*-alkanols one can distinguish two ensembles depending on the situation of the OH groups (e.g., 2-alkanols and 3-alkanols), each one characterized by a different second QUAC interaction parameter (37).

The regular change with the molecular structure of the interaction parameters makes it easy to estimate new parameters when experimental data are not available (38).

Modified UNIFAC (Dortmund version)

Modified UNIFAC (23) differs from the original UNIFAC (21) by the combinatorial term and the temperature dependence of the group interaction parameters. Equations used to calculate G^E and H^E are given elsewhere (23).

Assessment of geometrical and interaction parameters

In modified UNIFAC, main groups are defined to improve correlations. For example, $CHCl_3$ and methanol are considered as homogeneous molecules. The main groups may be subdivided in different subgroups, which have different geometrical parameters. The subgroups within the same main group are assumed to have identical group energy-interaction parameters.

[a]Number of ternary systems.
[b]Number of binary mixtures.

The geometrical parameters, the relative van der Waals volumes, and the relative van der Waals surfaces of the different subgroups are not calculated from molecular parameters like in the original UNIFAC but fit together with the interaction parameters to the experimental values of the thermodynamic properties considered. The geometrical and interaction parameters are taken from the literature (23, 24) and used without modification.

Flory's model

The extension of Flory's theory (31) to ternary systems has been developed by Brostow and Sochanski (39). Equations are summarized elsewhere (40).

Here, a binary system is characterized by some properties of the pure compounds (molar volume, isobaric expansivity, isothermal compressibility) and by a coefficient X_{ij} which denotes the mixed-pair interchange interaction energies be-

tween sites on species i and j. These coefficients were fitted to the corresponding binary H^E data assuming that the molecules are approximately spherical. H^E of the ternary solution is predicted using the three X_{ij} values calculated for the constituent binaries.

As it is known, this model provides information on H^E and excess volumes (V^E), but can only be applied to mixtures containing weakly polar compounds and inert components (e.g., methyl *tert*-butylether + *n*-hexane) (40) or compounds of identical chemical nature, such as systems containing two 1-alkanols (41) or two alkoxyethanols (42).

Results and discussion

DISQUAC and UNIFAC calculations for the ternary systems considered are listed in Table 1. Table 2 presents this comparison between DISQUAC and Flory's theory. Results are summarized in Tables 3 and 4.[2] Table 5 shows comparisons between DISQUAC and other different models. Figures 1–6 show some results in a graphical way.

In Tables 1 and 2, deviations between experimental and calculated results are included. They are defined as:

$$[1] \qquad \text{dev}(H^E) = \{[1/N\ \Sigma(H^E_{exp} - H^E_{calc}) / H^E_{max}]^2\}^{1/2}$$

where N is the number of experimental points for each system. Tables 3–5 list mean deviations for a set of N_S mixtures defined as:

$$[2] \qquad \text{Mdev}\ (H^E) = \Sigma\,\text{dev}\ (H^E)/N_S$$

From the results presented along these tables, some statements can be given: (*i*) In most of the cases, DISQUAC predictions are independent of the mixture compounds (Table 3). Certainly, the mean deviations are somewhat larger for Groups II and III. It is due to the very large discrepancies observed for some ternary mixtures. For example, for DIPE + *n*-C_6 + *n*-C_{16}, dev (H^E) = 0.25 and for MTBE + TAME + isooctane, dev (H^E) = 0.32. These results reveal some of the typical shortcomings of group contribution methods (see below): Patterson's effect (43, 44) and branching, respectively. DIPE + *n*-alkanes mixtures are characterized by interaction parameters which are independent of the *n*-alkane. Deviations for DIPE + *n*-C_6, + *n*-C_{10}, or + *n*-C_{16} are 0.022, 0.13, and 0.30, respectively, indicating that the model does not take into account the extra endothermic con-

[2]A detailed comparison between experimental data and results from DISQUAC, UNIFAC, and Flory models for the binary constituent mixtures is available upon request.

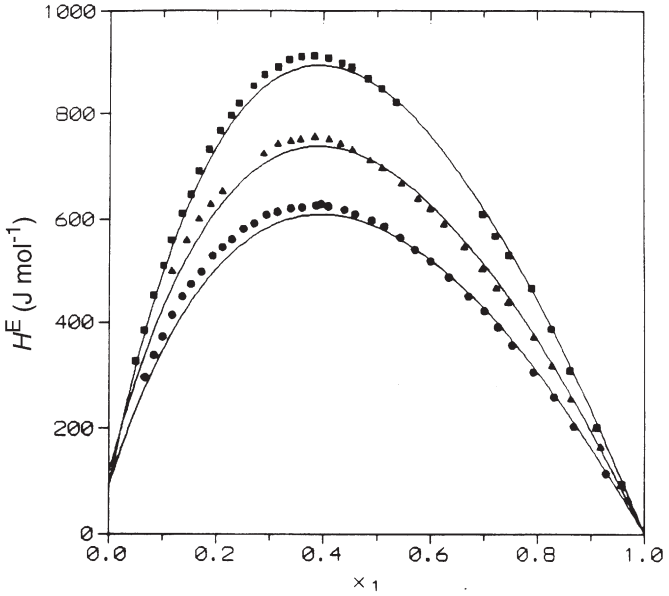

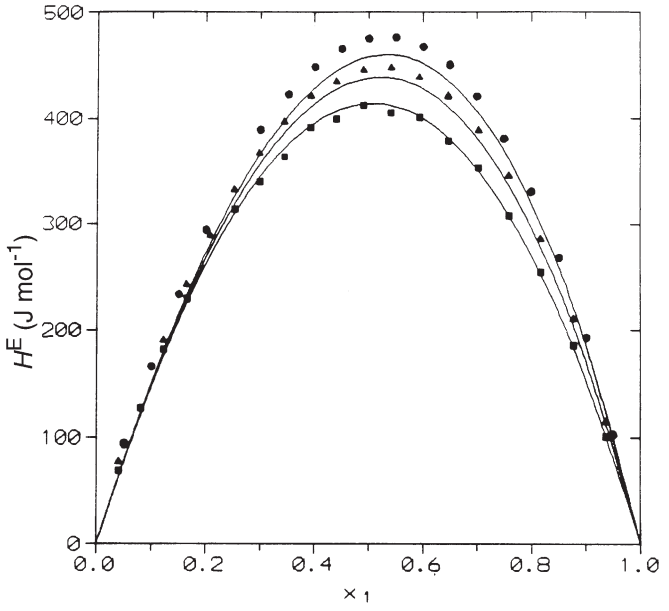

Fig. 2. H^E at 298.15 K for MTBE (1) + *n*-hexane (2) + *n*-decane (3) at different x_2:x_3 ratios. Points, experimental results (40): (●) x_2:x_3 = 0.3477, (▲) x_2:x_3 = 0.9984, (■) x_2:x_3 = 3.1408. Lines, DISQUAC calculations.

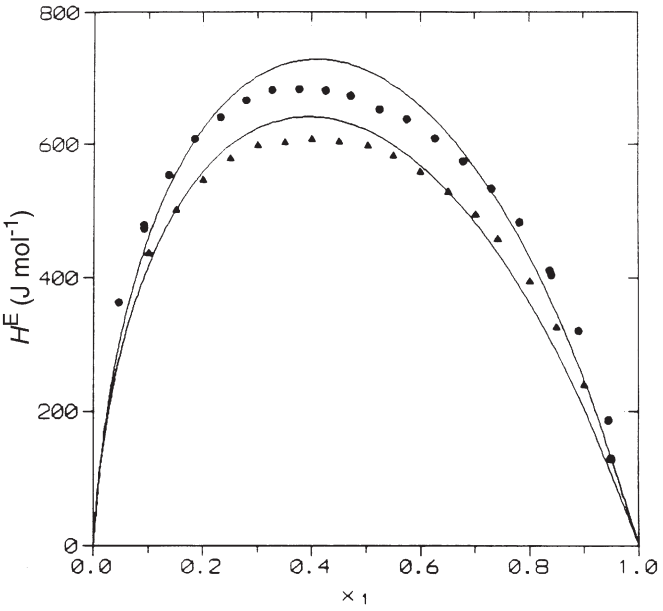
tribution to H^E due to order destruction of the longer *n*-alkanes upon mixing (43, 44). Solutions containing linear or branched alkanes (e.g., *n*-C_8 and isooctane) are characterized by the same interaction parameters. This leads to a large deviation for the MTBE + isooctane system, dev (H^E) = 0.32 (for MTBE + *n*-C_8, dev (H^E) = 0.014). Note that if in Group III, the system MTBE + TAME + isooctane is not considered, then Mdev (H^E) = 0.045.

Fig. 3. H^E at 298.15 K for ethanol (1) + *n*-hexane (2) + *n*-decane (3) at different x_2:x_3 ratios. Points, experimental results (90): (●) x_2:x_3 = 0.3339, (▲) x_2:x_3 = 2.9841. Lines, DISQUAC calculations.



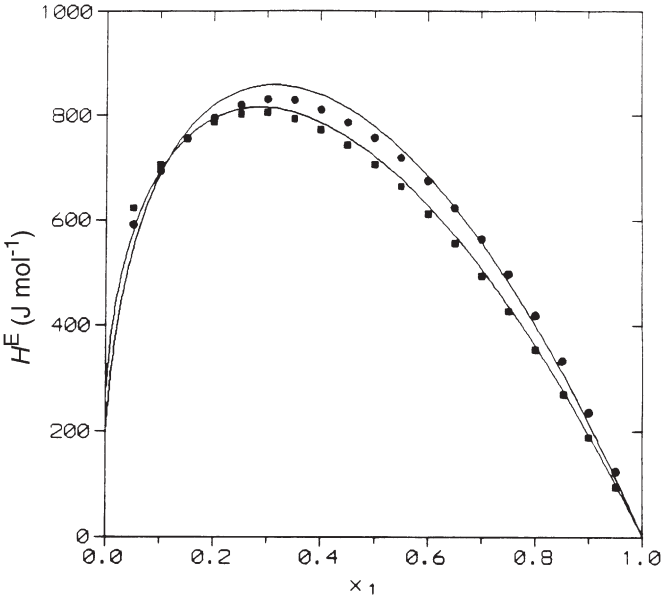


Fig. 4. H^E at 298.15 K for 1-propanol (1) + C_6H_{12} (2) + *n*-decane (3) at different x_2:x_3 ratios. Points, experimental results (93): (●) x_2:x_3 = 0.3325, (■) x_2:x_3 = 2.9995. Lines, DISQUAC calculations.

(*ii*) DISQUAC predictions are also independent of the number of contacts present in the system. For example (see Table 1), system nos. 25 (MTBE + *n*-C_6 + *n*-C_{10}) and 66 (ethanol + *n*-C_6 + *n*-C_{10}) have two different characteristic groups and one contact; system nos. 33 (MTBE + C_6H_{12} + *n*-C_{10}), 50 (2,5-dioxahexane + MTBE + *n*-C_7), or 75 (ethanol + C_6H_{12} + *n*-C_8) have three groups and three contacts, while system no. 90 (2-propanol + C_6H_6 + C_6H_{12}) has four

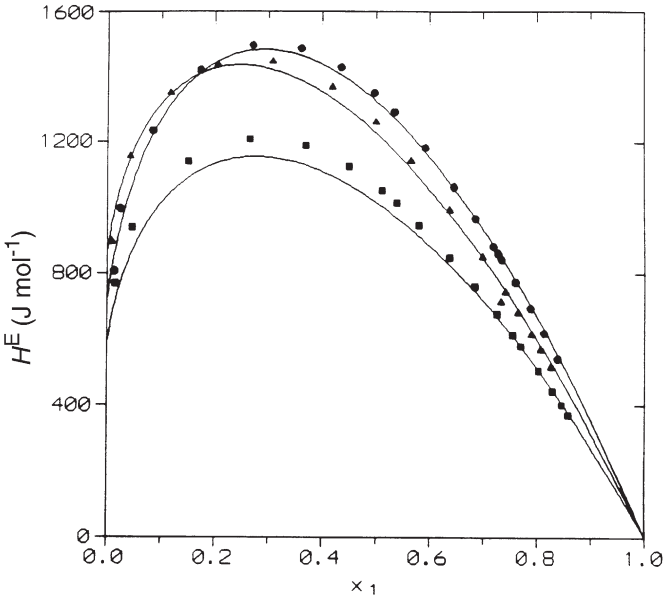

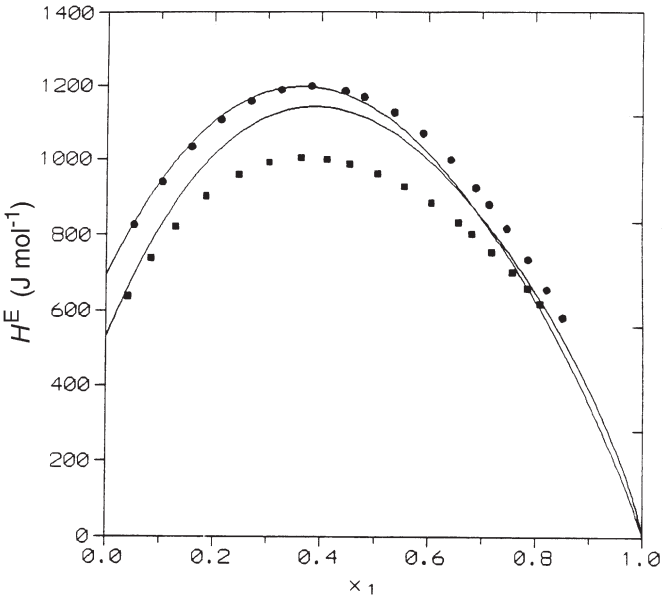

Fig. 6. H^E at 298.15 K for cyclohexane (1) + methanol (2) + C_6H_6 (3) at different x_2:x_3 ratios. Points, experimental results (85): (●) x_2:x_3 = 0.2529, (■) x_2:x_3 = 1.504. Lines, DISQUAC calculations.

groups and six contacts.[3] Deviations are similar for all of them as results depend, in some extent, on the source of the experimental measurements.

(*iii*) Deviations obtained using DISQUAC are of the same order for the ternary solutions and for the related binaries (Table 3). Therefore, the model describes consistently the data set analyzed, neglecting ternary interactions. The larger mean deviation observed for binaries included in Group III is due to the fact that those binary mixtures containing only oxaalkanes were treated, neglecting the interactions between oxygen–oxygen contacts. However, these solutions show low H^E values and this approximation is not important when calculating H^E of the related ternary mixture.

(*iv*) DISQUAC improves UNIFAC results (Tables 1, 3) due to the interaction parameters are assumed to be structure-dependent. Of course, this also means that the number of interaction parameters used in DISQUAC is higher (see below). For a similar reason, the Flory's model improves DISQUAC results for systems included in Groups II and III (Tables 2, 4) as each binary mixture is characterized by one adjustable specific interaction parameter. Note that DISQUAC and Flory's model yield similar results for solutions of Group I because they are applied in a similar way.

(*v*) However, the use of a larger number of parameters does not always imply better results. The classical UNIFAC model has been applied to predict H^E of ternary systems using interaction parameters fitted to only H^E measurements (method A in Table 5), or using interaction parameters fitted to H^E measurements of the constituent binaries (method B in Table 5) (22). The second procedure slightly improves results, which are not far from those obtained using semiempirical equations (22) (see Table 5). However, the interaction parameters were not suitable for VLE calculations. On the other hand, procedure B and semiempirical equations present the limitation of requiring the binary data related to the ternary system studied and cannot be applied when these data are not available. It is noteworthy that DISQUAC predictions are similar to those provided by semiempirical equations (Table 5) and that interaction parameters can be used to predict VLE, LLE, SLE, H^E, and C_p^E of the binary mixtures and VLE and H^E of the ternary systems.

(*vi*) UNIFAC provides quite large deviations for the binary mixtures, except for those belonging to Group I. It is remarkable that these deviations are larger than for the ternaries (Table 3). As already mentioned, the classical application of the group contribution concept leads to remove a number of very important effects in mixtures: Patterson's effect (43, 44) (in C_6H_6, C_6H_{12}, DIPE or MTBE + *n*-alkanes), cyclization (in tetrahydrofuran) (45–49), proximity effects (in 2,5-dioxahexane) (46–48), and branching (in MTBE, TAME, DIPE) (50). Such shortcomings, in some extent balanced for ternary systems, appear clearly when treating binary solutions (48–50). DISQUAC usually provides a better representation of the temperature dependence of H^E (49, 51). For example, for benzene + *n*-alkanes systems, UNIFAC predicts an increasing of H^E with temperature, while just the opposite behaviour is observed.

(*vii*) DISQUAC improves results for systems containing methanol (Tables 1, 3), assumed to be a main group in the framework of UNIFAC. That is, methanol is characterized by its own set of interaction parameters, which are different to those of the remainder alcohols. So, in this case DISQUAC and UNIFAC are applied in the same way. The same occurs for mixtures with $CHCl_3$, but now DISQUAC

[3] For example, in system no. 90, the groups are: OH, CH_2, aromatic, cyclic; and the contacts: OH–CH_2, OH–aromatic, OH–cyclic, CH_2–aromatic, CH_2–cyclic, aromatic–cyclic.

© 2001 NRC Canada

results are poorer (system no. 53). The important point is that both models yield similar mean deviations for the constituent binaries (0.044 and 0.032, for DISQUAC and UNIFAC, respectively), and that DISQUAC accurately represents systems with very strongly specific interactions, e.g., oxaalkanes + $CHCl_3$ (49). Therefore, experimental results should be taken with caution. Note that deviation is also somewhat large for system no. 17, which is taken from the same source. Nevertheless, it should be mentioned that the DISQUAC treatment of binary mixtures including $CHCl_3$ is more difficult because this molecule is considered as built by two groups. UNIFAC also improves results for the ternary systems including hexylamine (nos. 38 and 39). This is probably due to the different database used in the estimation of the interaction parameters.

Comparison with other models

Systems nos. 19–24 have been treated in terms of the Nitta–Chao model (20), which adopts the cell theory of Lee et al. (52) for the liquid state. Recently, DISQUAC provides better results (Table 5). The main advantage of this model is its ability to provide information on V^E.

Some mixtures (see Table 5) have been studied through a model based on an approximation of the radial distribution function and the quasilattice two-liquid theory (15). This model, where each binary mixture is characterized by three adjustable parameters, slightly improves results for ternary mixtures (Table 5). For 11 binary solutions related to the ternaries analyzed, the model provides Mdev (H^E) = 0.016, while DISQUAC yields 0.049.

The Mobile Order theory (13), which takes into account both contributions to the thermodynamic properties, i.e., nonspecific interactions, expressed in terms of the Nearly Ideal Binary Solvent model (53, 54), and that from the formation of the hydrogen-bonded complexes (13) has been applied to systems nos. 66, 67, 82, 83. The absolute mean deviations defined as:

$$[3] \qquad \Delta(H^E)(\text{J mol}^{-1}) = \Sigma|H^E_{calc} - H^E_{exp}|/N$$

are 12, 20, 14, and 22. DISQUAC yields (in the same order): 29, 34, 18, 28.

In the UNIQUAC association theory (9, 10), the partition function is factorized, as in any approximate model applied to complex associated systems, into two terms. The physical interactions are represented by the UNIQUAC equation (55). The chemical contribution is calculated assuming that specific interactions lead to the formation of different associated species according to a well defined set of chemical reactions, each one of them characterized by an equilibrium constant. For higher open multimers, the equilibrium constant is independent of the length of the multimer. This model has been applied widely, but no in a systematic way. For systems nos. 79, 80, 88–91, it provides (9, 10) $\Delta(H^E)$ (J mol^{-1}) = 14, 15, 16, 22, 18, 11. DISQUAC results are: 57, 44, 43, 22, 34, 44.

Therefore, the UNIQUAC association model improves DISQUAC calculations. However, it must be noted that results depend strongly on the polymeric species present in the mixture, what have to be previously elucidated to a reliable application of the model. It is typical for association models, which, on the other hand, only can be applied to mixtures where association is expected. This is their major limitation.

Conclusions

DISQUAC provides reliable predictions on H^E (and also on VLE) of the ternary systems examined using binary parameters only, i.e., neglecting interactions. These predictions are practically independent of the mixtures compounds, or of the number of groups present in the solution. Therefore, DISQUAC should be applied when interaction parameters are available. The interaction parameters used are valid for the description of thermodynamic properties of binary mixtures (VLE, LLE, SLE, H^E, C_p^E), as well as for prediction on H^Es and VLE of ternary systems.

On the other hand, deviations can be rationalized and, if necessary corrected.

The main advantage of UNIFAC is the large available matrix of interaction parameters. In the framework of this model, H^E of ternary systems are better represented than those of the constituent binaries.

Solubility of nonpolar gases in 2,2,2-trifluoroethanol and 1,1,1,3,3,3-hexafluoropropan-2-ol at several temperatures and 101.33 kPa partial pressure of gas

Miguel Angel Sánchez, Ana María Mainar, Juan Ignacio Pardo, María Carmen López, and José Santiago Urieta

Abstract: Solubilities, expressed as mol fractions, of 14 nonpolar gases (He, Ne, Ar, Kr, Xe, H_2, N_2, O_2, CH_4, C_2H_4, C_2H_6, CO_2, CF_4, and SF_6) in 2,2,2-trifluoroethanol (TFE) at 268.15 and 283.15 K and 1,1,1,3,3,3-hexafluoropropan-2-ol (HFIP) at 273.15 and 283.15 K, with the partial pressure of gas being 101.33 kPa for all measurements, are reported. Standard changes in the thermodynamic functions (enthalpy and entropy) have been calculated from the solubilities and their variation with temperature. The Scaled Particle Theory (SPT) model has been used to determine these thermodynamic functions and also the partial molar volumes of the gases in the formed solutions.

Key words: gas solubilities, nonpolar gases, fluoroalcohols, Scaled Particle Theory.

Résumé : On rapporte les solubilités, en forme de fractions molaires, de 14 gazes apolaires (He, Ne, Ar, Kr, Xe, H_2, N_2, O_2, CH_4, C_2H_4, C_2H_6, CO_2, CF_4 et SF_6) dans 2,2,2-trifluoretanol (TFE) à 268,15 et 283,15 K et dans 1,1,1,3,3,3-hexafluorpropan-2-ol à 273,15 et 283,15 K. La pression partielle du gaz a eté 101,33 kPa en toutes les mesures. On a calculé, en utilisant les solubilités et leur variation a l'égard de la temperature, les changes standard des fonctions thermodynamiques enthalpie and entropie. On a employé le modèle SPT pour déterminer ces mêmes fonctions thermodynamiques et aussi les volumes molaires partielles des gazes dans les solutions formées.

Mots clés : solubilité du gaz, gazes apolaires, fluoralcool, Scaled Particle Theory.

Introduction

The gathering of experimental data about the thermodynamical properties of solutions and liquid mixtures is very important to the improvement of industrial equipment and processes and also to achieve a better knowledge of the molecular interactions that rule the liquid state. This is also true of the solutions of gases in liquids.

In this paper, we report the solubilities of gases in fluoroalcohols. Specifically, the solubilities of 14 nonpolar gases (He, Ne, Ar, Kr, Xe, H_2, N_2, O_2, CH_4, C_2H_4, C_2H_6, CO_2, CF_4, and SF_6) have been measured in 2,2,2-trifluoroethanol (TFE) at 268.15 and 283.15 K and 1,1,1,3,3,3-hexafluoropropan-2-ol (HFIP) at 273.15 and 283.15 K, with the partial pressure of gas being 101.33 kPa. The solubilities are expressed as mol fractions of gas dissolved in the liquid and have been determined taking the real behaviour of the gas phase into account. The aim of this work was to establish the influence of temperature on solubility for values below 298.15 K on systems that we had already studied (1, 2). Moreover, these data together with those previously reported permits us to calculate the standard changes of enthalpy ($\Delta\overline{H}^0_{m,2}$) and entropy ($\Delta\overline{S}^0_{m,2}$) for the solution process from the temperature dependence of the solubility.

The reported results are inscribed in a study of the solubilities of gases in mixtures of water and fluoroalcohol; mixtures that have gained interest because they offer the possibility of modulating the solvophobic effect, which has relevant influence on the kinetics and the selectivity of organic reactions such as Diels-Alder type reactions (3). The solubility measurement is a way of determining the solvophobic effect.

The Scaled Particle Theory (SPT), which provides expressions for the values of the changes of thermodynamic functions in the solution process, has also been applied to determine the changes in enthalpy and entropy that are then compared with those obtained from the experimental results. Another property that can be calculated with this theory is the partial molar volume of the gas in the solution. The obtained values of the partial molar volumes are compared with those provided by a model based on the regular solution (4).

Experimental

The equipment and procedure used to carry out the solubility measurements have been described in detail elsewhere

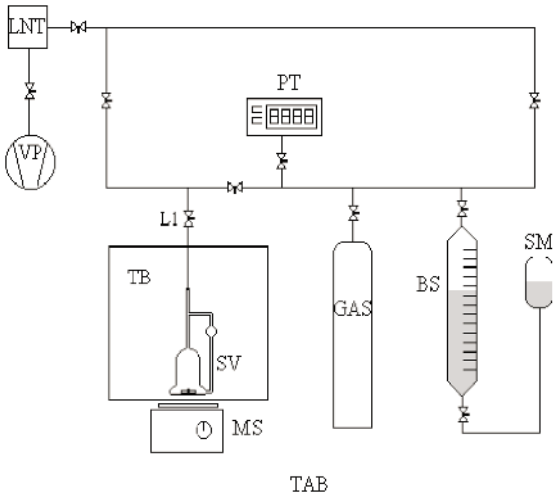
(5). The apparatus is similar to that designed by Ben-Naim and Baer (6) and an scheme of it appears in Fig. 1. The experimental technique is based on the determination of the volume of wet gas (gas saturated with solvent vapour), which dissolves in a known mass of solvent at constant pressure (approximately 101.33 kPa partial pressure of gas) and temperature. The amount of wet gas is measured through the volume of mercury introduced in a system of burettes to keep the pressure balanced. The solvent is placed in a solution vessel immersed in a water bath whose temperature is maintained within 0.05 K. The whole apparatus is located in a thermostated air bath, with its temperature being controlled within 0.2 K. The temperature of the air bath is greater than that of the water bath to prevent the condensation of the solvent out of the solution vessel. The precision in the mol fraction of dissolved gas (x_2) is estimated to be 1% in the worst case, i.e., for the lowest solubility.

The gases used were: He (99.995%), Ar (99.999%), Xe (99.995%), H_2 (99.99%), N_2 (99.998%), O_2 (99.98%), CH_4 (99.95%), C_2H_4 (99.0%), C_2H_6 (99.90%), CF_4 (99.9%), SF_6 (99.5%), and CO_2 (99.998%), all from Air Liquide España, and Ne (99.9%) and Kr (99.95%) from Linde.

The liquid 2,2,2-trifluoroethanol (TFE) was a Jansen product, whereas 1,1,1,3,3,3- hexafluoropropan-2-ol (HFIP) was purchased from Fluka; both of them with a stated purity >99%. The purities of these liquids were checked by GLC.



Solubilities and thermodynamic properties for the solution process

The data treatment for calculating solubility is a modification (2, 7) of the data reduction method proposed by Wilhelm and Battino (8, 9). The modification takes into account the characteristics of our apparatus, in particular that the gas phase includes solvent vapour that must be discounted and that the temperature of the gas phase in the burettes is different from the temperature in the solution vessel. The method determines the actual amount of gas dissolved in the liquid and also the actual partial pressure over the solution. Then the solubility is corrected to the partial pressure of 101.33 kPa. The calculation was carried out considering both ideal and real behaviour of the gas phase.

In the latter case the second virial coefficients (SVC) for the pure compounds and their mixtures are required. The SVC for the gases were obtained from the literature (10), while those of both pure fluoroalkanols and gas–liquid mixtures were calculated using the method of Maris and Stiel (11). The resulting SCV for HFIP and the corresponding mixtures as a function of the temperature have been reported in a previous paper (2), and those for TFE are listed in Table 1 over the temperature range of 268.15 to 309.15 K.

The differences between solubilities corresponding to the ideal and the real behaviour of the gas phase follow the pattern observed at 298.15 K (1, 2), i.e., when TFE is the solvent the deviations are above the experimental error only for the most soluble gases, whereas in the case of HFIP many of the gases show much high deviations. Table 2 shows the solubilities of gases (real behaviour) in TFE at 268.15 and 283.15 K and in HFIP at 273.15 and 283.15 K. Intervals of the same size were looked for, but were not possible in the case of HFIP whose freezing point is about 269 K. To the best of our knowledge, the solubility data for our gases either in TFE or in HFIP are not available in the literature.

Fig. 1. Scheme of the gas solubility apparatus with the following abbreviations: vacuum pump (VP), liquid nitrogen trap (LNT), pressure transducer (PT), thermostated bath (TB), solution vessel (SV), magnetic stirrer (MS), burettes system (BS), storage of mercury (SM), thermostated air bath (TAB).

The mol fractions of gas in liquid (x_2) for the temperatures considered in this paper along with those at 298.15 K (1, 2) have been adjusted as a function of the temperature using the following polynomial, which is convenient (12) for this rather narrow temperature range.

$$[1] \qquad \ln x_2 = A_0 + \frac{A_1}{T}$$

The coefficients A_0 and A_1, obtained by means of a least-squares method, are been listed in the Table 3, together with the corresponding square regression coefficients.

From the solubility values, changes in the Gibbs energy ($\Delta\bar{G}^0_{m,2}$), enthalpy ($\Delta\bar{H}^0_{m,2}$), and entropy ($\Delta\bar{S}^0_{m,2}$) can be determined for the hypothetical solution process

$$[2] \qquad \text{M (gas, hyp., 101.33 kPa)} \rightarrow \text{M (solution, hyp., } x_2 = 1)$$

using the relations reported by Clever and Battino (12) and Wilhelm et al. (13).

$$[3] \qquad \Delta\bar{G}^0_{m,2} = \mathrm{R}T \ln x_2\ (sat) = -\mathrm{R}T\left(A_0 + \frac{A_1}{T}\right)$$

$$[4] \qquad \Delta\bar{H}^0_{m,2} = \mathrm{R}T\left[\frac{\partial \ln x_2\ (sat)}{\partial \ln T}\right] = -\mathrm{R}A_1$$

$$[5] \qquad \Delta\bar{S}^0_{m,2} = \left[\frac{\partial \ln x_2\ (sat)}{\partial \ln T}\right] + \ln x_2 = RA_0$$

The values of these standard partial molar thermodynamic properties are given in Table 4 for TFE and in Table 5 for HFIP.

Scaled Particle Theory (SPT)

General features

A model often used in the treatment of solubilities of gases in liquids is the Scaled Particle Theory (SPT) because it provides a reasonable mechanism for the solution process, leads to acceptable results for the solubility values, and allows the determination of molecular parameters for the liquid solvent, namely, the effective hard-sphere diameter and the depth of the energy well. Although the theory was developed for organic solvents with low dipole moments (14), it has yielded good results when extended to rather polar liquids (15, 16) or associated solvents like alcohols (9, 17) and even water (18–20). Therefore, its application to these systems can lead to reliable information about TFE and HFIP. According to SPT formalism (9, 13, 14, 21) the solution process takes place in two steps: (*i*) creation in the solvent of a cavity of the right size to accommodate the molecule of solute and (*ii*) insertion of the solute molecule into the cavity and then interaction between solvent and solute.

The thermodynamic functions for the first step are derived using the SPT equations for hard spheres (13, 22). The calculation of the thermodynamic properties associated to the interaction step (13) is usually carried out on the basis of an effective Lennard–Jones (6, 12) potential, corrected with terms that take the dipole–dipole and dipole-induced dipole interactions into account. The hard sphere diameter of the liquid solvent (σ_1) determined with SPT equations is identified with the distance parameter of the potential and then the energy parameter (ε_1/k) can be obtained from the values of the Gibbs energy changes.

Given that the results of the theory concerning values of solubility and change of Gibbs energies for both solvents at 298.15 K have been already considered (1, 2), in this paper we focus on the changes in enthalpy and entropy. The values of the partial molar volume of the solute in solution with

each of the fluoroalcohols at 298.15 K will also be considered.

Enthalpy and entropy of solution

The change of enthalpy accompanying the solution process can be expressed (23) by

$$[6]\qquad \Delta\overline{H}^{0(SPT)}_{m,2} = \left[\frac{\partial\left(\dfrac{\Delta\overline{G}^{0(SPT)}_{m,2}}{T}\right)}{\partial\left(\dfrac{1}{T}\right)}\right]_P = \Delta\overline{H}_c + \Delta\overline{H}_i - \mathrm{R}T + \alpha_P \mathrm{R}T^2$$

where $\Delta\overline{G}^{0(SPT)}_{m,2}$ is the change in the Gibbs energy provided by the model, $\Delta\overline{H}_c$ and $\Delta\overline{H}_i$ are the changes of enthalpy in the formation of cavity and interaction steps, respectively, and α_P is the thermal expansion coefficient of the solvent.

The entropy can be directly obtained from the following relation:

$$[7]\qquad \Delta\overline{S}^{0(SPT)}_{m,2} = \frac{\Delta\overline{H}^{0(SPT)}_{m,2} - \Delta\overline{G}^{0(SPT)}_{m,2}}{T}$$

From values for σ_1 and ε_1/k, these thermodynamic functions can be obtained through SPT. Thus, the partial molar enthalpies of solution ($\Delta\overline{H}^{0(SPT)}_{m,2}$) and partial molar entropies of solution ($\Delta\overline{S}^{0(SPT)}_{m,2}$) can be found in the last columns of Tables 4 and 5. The values used for σ_1, ε_1/k, and α_P have been reported in a previous paper (2).

A point to be remarked is that the change of enthalpy for the formation of the cavity ($\Delta\overline{H}_c$) depends on the following parameter:

$$[8] \qquad l_1 = \left(\frac{1}{\sigma_1}\right)\left(\frac{\partial\sigma_1}{\partial T}\right)_P$$

that expresses the relative variation of the hard sphere diameter as the temperature changes. The calculated enthalpies and entropies correspond to a value of $l_1 = 0$. In relation to this parameter, it is interesting to comment that the original version (14) of the model did not take into account the variation of σ_1 with the temperature. Ben-Naim and Friedman (24) pointed out that this variation should be considered and, therefore, two alternative models (18, 25) were proposed to obtain l_1. Although the temperature dependence of σ_1 has been discussed in some papers (9, 26), the values of enthalpy and entropy changes calculated with these nonzero coefficients do not lead for most gases to better values than those derived when the temperature dependence is not considered (16, 17, 27). In some cases they are actually unable to predict even the sign of the enthalpy change. This is probably because the values for σ_1 vary very slightly and the figures on which the coefficient l_1 depends on are affected by large errors.

As can be seen from the results shown in Tables 4 and 5, the predictions of the SPT formalism for the changes of enthalpy are, in general, not as good as they were for the corresponding Gibbs energy changes. On the other hand, it predicts reasonably well the changes in entropy. All this is in agreement with the acceptable performance of the model from a quantitative point of view.

Partial molar volumes of the gas solutes

The partial molar volume of a gas in the solution can be calculated (14), using the following expression:

$$[9] \qquad \bar{V}_2 = \Delta\bar{V}_c + \Delta\bar{V}_i + \kappa_T RT$$

where $\Delta\bar{V}_c$ and $\Delta\bar{V}_i$ are the volume changes upon cavity formation and charging, respectively, and κ_T is the isothermal compressibility of the solvent.

The value of $\Delta\bar{V}_i$ cannot be estimated but will be small for weakly interacting substances. Thus, for the considered gases it can be made equal to zero. The suitability of this approximation was corroborated in the original paper (14) through the comparison of the results provided by the theory for gases in several liquids. On the other hand, the partial molar volume for the cavity formation is given by

$$[10] \qquad \Delta\bar{V}_c = \left(\frac{\partial\Delta\bar{G}_c}{\partial P}\right)_{T,x} = \left(\frac{\kappa_T}{\alpha_P}\right)\Delta\bar{H}_c + \frac{\pi\sigma_2^3 N_A}{6}$$

where σ_2 is the hard sphere diameter of the gas considered.

The hard sphere diameters (σ_2) and the values of α_P can be found in ref. 2 and the isothermal compressibility (κ_T) was evaluated by means of

$$[11] \qquad \kappa_T = \frac{1}{\rho_1 u^2} + \frac{\alpha_P T V_{m,1}}{C_{P,1}}$$

with u being the speed of sound in the solvent and $C_{P,1}$ the heat capacity at constant pressure of the same solvent. The values of u were measured in our laboratory with a densimeter and sound analyzer Anton Paar DSA 48, whereas the $C_{P,1}$ values were obtained from the literature for TFE (28) and measured for HFIP.[2] The values of α_P, u, $V_{m,1}$ (2), and $C_{P,1}$ are listed in Table 6.

The calculated values of $\bar{V}_2$, for both solvents, are gathered in Table 7. It can be seen that the volumes are somewhat greater when the liquid solvent is HFIP. Given that there are no experimental data available to check the adequacy of the results, we have compared these results with those proposed by Prausnitz and Shair (4) (Table 7). These volumes are valid for nonpolar solvents.

Quite a good agreement can be observed between our results and those of Prausnitz and Shair, except in the case of nitrogen and oxygen, which exhibit rather higher deviations. This agreement is especially remarkable for noble gases in

[2] The measurement of the value of $C_{P,1}$ for HFIP was carried out by the team of Dr. L. Romaní (Universidad de Vigo) by means of a differential scanning calorimeter (Setaram Micro DSC II), which has a precision of ±0.03 J K^{-1} mol^{-1}.

HFIP and for the remaining ones (excluding the mentioned nitrogen and oxygen) in TFE.

The values of Prausnitz and Shair were estimated based on a model (4) that resembles that of SPT in the fact that the model divides the solution process into two steps: (*i*) isothermal condensation of the gas to a hypothetical state having a liquid-like volume and (*ii*) solution of the hypothetical liquid-like fluid into the solvent. As occurs in the SPT formalism, the change in volume accompanying the second step is zero because it is treated considering the formation of a regular solution, i.e., formation that takes place without volume variation.

From this point of view, this second step would practically coincide with the second step in SPT. Indeed, if the volume change ($\Delta\bar{V}_i$) is considered negligible, the insertion of the molecules of gas in the already created cavities and their interaction with the solvent would be a solution process almost identical to that proposed by Prausnitz and Shair. Then the volume associated with the formation of the cavities would be the volume of the hypothetical condensed liquid-like fluid to be accommodated in those cavities and it is not surprising that the two quite different models lead to similar results.

Acknowledgments

The authors gratefully acknowledge the financial support of the Dirección General de Enseñanza Superior e Investigación Científica (DGESIC) Project No. PB98–1624. They also thank Dr. Luis Romaní and his team of the Universidad de Vigo for having kindly measured the heat capacity of HFIP.

Solubility predictions for crystalline nonelectrolyte solutes dissolved in organic solvents based upon the Abraham general solvation model

William E. Acree, Jr. and Michael H. Abraham

Abstract: The Abraham general solvation model is used to predict the saturation solubility of crystalline nonelectrolyte solutes in organic solvents. The derived equations take the form of log $(C_S/C_W) = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_x$ and log $(C_S/C_G) = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + l \log L^{(16)}$ where C_S and C_W refer to the solute solubility in the organic solvent and water, respectively, C_G is a gas-phase concentration, R_2 is the solute's excess molar refraction, V_x is McGowan volume of the solute, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity, π_2^H denotes the solute's dipolarity and (or) polarizability descriptor, and log $L^{(16)}$ is the solute's gas-phase dimensionless Ostwald partition coefficient into hexadecane at 298 K. The remaining symbols in the above expressions are known equation coefficients, which have been determined previously for a large number of gas–solvent and water–solvent systems. Computations show that the Abraham general solvation model predicts the observed solubility behavior of anthracene, phenanthrene, and hexachlorobenzene to within an average absolute deviation of about ±35%.

Key words: solubility predictions, organic solvents, nonelectrolyte solutes, partition coefficients.

Résumé : On a utilisé le modèle général de solvatation d'Abraham pour faire des prédictions relatives à la solubilité de saturation de solutés cristallins non-électrolytes, dans des solvants organiques. Les équations dérivées sont de la forme log $(C_S/C_W) = c + rR_2 = s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_X$ et log $(C_S/C_G) = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + l$ log $L^{(16)}$ dans lesquelles C_S et C_W se réfèrent respectivement à la solubilité du soluté dans le solvant organique et dans l'eau, C_G est une concentration en phase gazeuse, R_2 est la réfraction molaire en excès du soluté, V_X est le volume de McGowan du soluté, $\Sigma\alpha_2^H$ et $\Sigma\beta_2^H$ sont respectivement des mesures de l'acidité et de la basicité de la liaison hydrogène du soluté, π_2^H correspond à un descripteur du caractère dipolaire et de la polarisabilité du soluté et log $L^{(16)}$ est le coefficient de partition d'Oswald, sans dimension, du soluté en phase gazeuse, dans l'hexadécane, à 298 K. Les autres symboles de ces expressions sont des coefficients d'équation connus qui ont été déterminés antérieurement pour un grand nombre de systèmes gaz–solvant et eau–solvant. Les calculs montrent que le modèle général de solvatation d'Abraham permet de prédire le comportement de solubilité observé pour l'anthracène, le phénanthrène e l'hexachlorobenzène dans les limites d'une déviation moyenne absolue d'environ ±35%.

Mots clés : prédictions de solubilité, solvants organiques, solutés non-électrolytes, coefficients de partition.

[Traduit par la Rédaction]

Introduction

Free energy of solvation is an important thermodynamic variable that quantifies the free energy difference between a molecule in the gas phase and the molecule dissolved in a solvent. Free energies of solvation provide valuable information regarding molecular interactions between dissolved solute and surrounding solvent molecules, and can be used to calculate numerical values of partition coefficients that describe the equilibrium distribution of a solute between two immiscible liquid phases. For example, the octanol–water partition coefficient is the free energy of solvation of the solute molecule in wet 1-octanol minus its free energy of solvation in water. Solvation free energies and partition coefficients are of critical importance in many pharmaceutical, environmental, and chemical engineering applications. Solute partitioning between two immiscible phases is the basis for all chromatographic separations. Correlations have been derived for predicting brain–blood partitioning of organic solutes from solutes' measured and (or) calculated free energies of solvation (1, 2), and for estimating aqueous solubilities, soil adsorptions, bioaccumulations, and toxicities of organic compounds from experimental octanol–water partition coefficient data (3–11).

Historically, many of the very early studies focussed exclusively on developing correlational equations based upon octanol–water partition coefficients. Recent studies have shown that the octanol–water partition coefficient may not necessarily be the best indicator of how likely it is for a particular solute molecule to penetrate a lipid bilayer, skin, brain, or central nervous system, or to accumulate in different tissues and body organs. Experimental studies have been expanded to include additional organic solvents, as well as

aqueous micellar solvent media, and to use solute descriptors calculable from structural considerations and (or) easily measured thermodynamic quantities.

In this regard, Abraham and co-workers (12–19) developed expressions for describing the partition of solutes between water and a given solvent

$$[1] \quad \log P = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + vV_x$$

and between the gas phase and a given solvent

$$[2] \quad \log L = c + rR_2 + s\pi_2^H + a\Sigma\alpha_2^H + b\Sigma\beta_2^H + l \log L^{(16)}$$

The dependent variables in eqs. [1] and [2] are the log P (the partition coefficient of solute(s) between water and a given solvent) and log L (Ostwald solubility coefficient). The independent variables are the solute descriptors as follows: R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively, $\Sigma\alpha_2^H$ and $\Sigma\beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity, π_2^H denotes the solute's dipolarity–polarizability descriptor, and log $L^{(16)}$ is the solute's gas-phase dimensionless Ostwald partition coefficient into hexadecane at 298 K. The numerical value of the R_2 solute descriptor can be obtained from the refractive index for solutes that are liquid at 293.15 K. For solids, the refractive index of the hyphothetical liquid at 293.15 K can be calculated, or R_2 can be obtained by the summation of fragments or substructures. The McGowan characteristic volume can be easily calculated from bond and atom contributions. It should be noted that the various c, r, s, a, b, v, and l coefficients depend on the solvent phase under consideration. The r coefficient gives the tendency of the phase to interact with solutes through polarizability-type interactions, mostly via electron pairs. The s coefficient is a measure of the solvent phase dipolarity and (or) polarity, while the a and b coefficients represent the solvent-phase hydrogen-bond basicity and hydrogen-bond acidity, respectively. The l and v coefficients are a combination of the work needed to create a solvent cavity wherein the solute will reside, and the general dispersion interaction energy between the solute and solvent phase. In the case of partition coefficients, where two solvent phases are involved, the c, r, s, a, b, v, and l coefficients represent differences in the solvent-phase properties.

Several earlier studies (20–23) developed the computational methodology for determining the various solute descriptors from measured solubility data for crystalline nonelectrolyte solutes dissolved in organic solvents for which the solvent regressional coefficients were known. In the present communication, the process is going to be reversed in that eqs. [1] and [2] will be used to predict anthracene, phenanthrene, and hexachlorobenzene solubilities in several dry organic solvents. Results of these computations will be compared to published solubility data taken from the chemical literature (24–29), and when available, to predicted values based upon Mobile Order theory, and the UNIFAC and Modified UNIFAC (Dortmund) models.

Methodology

Predictive application of eqs. [1] and [2] is relatively straightforward if: (*i*) all solute descriptors and equation coefficients are known; (*ii*) the aqueous solubility of the crystalline solute at 298 K is available; and (*iii*) the saturated vapor pressure of the solid at 298 K has been measured or can be calculated by extrapolating experimental vapor pressure data determined at slightly higher temperatures back to 298 K. These latter two quantities are needed to convert the predicted log P and log L values into saturation molar solubilities.

Let the solubility in mol dm^{-3} at 298 K be denoted C_S and C_W, respectively, in the organic solvent and in water. The partition coefficient (P) between water and the organic solvent is given by eq. [3]:

$$[3] \quad P = C_S/C_W \text{ or } \log P = \log C_S - \log C_W$$

provided that three specific conditions are met. First, the same solid phase must be in equilibrium with the saturation solutions in the organic solvent and in water (i.e., there should be no solvate or hydrate formation). Second, the secondary medium activity coefficient of the solid in the saturated solutions must be unity (or near unity). This condition generally restricts the method to those solutes that are sparingly soluble in water and nonaqueous solvents. Finally, for solutes that are ionized in aqueous solution, C_W must refer to the solubility of the neutral form.

If the three forementioned conditions are met, eqs. [1] and [3] allow one to predict the molar solubility of the solute (C_S) in all organic solvents for which equation coefficients have been determined. Readers are reminded that in selecting equation coefficients, the "dry solvent" values should be used. Equation [1] actually predicts partition coefficients, and for select solvents both "dry" and "wet" equation coefficients have been reported. For solvents that are partially miscible with water, such as 1-butanol and ethyl acetate, partition coefficients calculated using eq. [3] are not the same as those obtained from direct partition between water (saturated with the organic solvent) and organic solvent (saturated with water). Care must be taken not to confuse the two sets of partitions. In the case of solvents that are fully miscible with water, such as methanol, no confusion is possible. Only one set of equation coefficients have been reported, and the calculated log P value must refer to the hypothetical partition between the two pure solvents. And for solvents that are "almost" completely immiscible with water, such as alkanes, cyclohexane, dichloromethane, trichloromethane, tetrachloromethane, and most aromatic solvents, there should be no confusion because indirect partition through eq. [3] will be nearly identical to direct partition. Hence, if C_W is known, predicted log P values based upon eq. [1] will lead to predicted molar solubilities through eq. [3]. Currently, there are about 40 organic solvents for which dry equation coefficients have been determined.

It should be noted that other research groups (30–33) have proposed fairly similar linear solvation energy relationships for estimating partition coefficients of organic solutes between water and an organic solvent. The similar methods employ slightly different solute descriptors, and to our knowledge, all equation coefficients were determined through regressional analysis of direct experimental partition coefficient data. The equations derived from such partition coefficient data are of marginal use in estimating solute solubilities in organic solvents, except in the very special case that the organic solvent is almost completely immiscible

with water. Our general solvation method differs from competing methods in that we have tried in recent years, to the extent possible, to build separate data bases for dry and wet solvents. This creates a problem for many of the common organic solvents. There is often very little experimental data available, and the tendency is to combine available organic solvent – water partition coefficient measurements (wet solvent) with saturation solubilities, binary liquid–vapor equilibria data, and infinite dilution activity coefficients determined from measured gas chromatographic solute retention volumes on the organic solvent stationary phase (34, 35). Lack of experimental data is the reason that we have been able to deduce *c*, *r*, *s*, *a*, *b*, *v*, and *l* coefficients for only 40 or so dry solvents.

Equation coefficients are tabulated in Table 1 for select organic solvents. The actual numerical values may differ slightly from values reported in earlier publications. Coefficients are periodically revised when additional experimental data becomes available. For example, the initial set of equation coefficients for acetonitrile were based on a data set that contained very few large polycyclic aromatic hydrocarbon solutes. Published solubility data (24, 25, 36, 37) for anthracene, pyrene, naphthalene, biphenyl, acenaphthene, acenaphthylene, fluorene, fluoranthene, and phenanthrene were later added to the database, and the equation coefficients were redetermined. Pyrene, fluoranthene, and anthracene have large excess molar refraction solute descriptors of R_2 = 2.808, R_2 = 2.377, and R_2 = 2.290, respectively. In performing the regressional analysis to determine the solvent coefficients, it is important that the data set contain solutes that span as wide of a range of solute descriptors as possible. The deficiency involving the initial parameterization for acetonitrile has now been corrected. Anthracene, phenanthrene, and other PAH solubilities were used to construct the revised acetonitrile equation. Table 1 lists the most updated set of equation coefficients that we have for each solvent.

Saturation solubilities can also be calculated from predicted log *L* values based upon eq. [2], provided that the solid saturated vapor pressure at 298 K (*VP*°) is available. *VP*° can be transformed into the gas-phase concentration (C_G), and the gas–water and gas–solvent partitions (L_W and L_S) can be obtained through eqs. [4] and [5], respectively.

$$[4] \qquad L_W = C_W/C_G \text{ or } \log L_W = \log C_W - \log C_G$$

$$[5] \qquad L_S = C_S/C_G \text{ or } \log L_S = \log C_S - \log C_G$$

As before, the predictive method will be valid if conditions (*i*)–(*iii*) above are met. In the case of the published log *L* correlations, most of the equation coefficients pertain to either dry solvents or solvents that are almost completely immiscible with water.

Katritzky et al. (38, 39) recently developed log *L* correlations for solutes dissolved in water, methanol, and ethanol

based upon the CODESSA treatment. A major difference between our approach and that of Katritzky et al., is that we use the same exact solute descriptors in each derived correlation. Our descriptors have experimental origin. That is not the case in the Katritzky et al. treatment. There, the authors use a large pool of descriptors, whose numerical values are calculated solely from structural considerations. The authors seek the strongest correlation possible, rather than the correlations that use a common set of descriptors. The reported log *L* correlation for methanol used one set of descriptors, whereas the correlation for ethanol used different descriptors. As a consequence, the authors were unable to compare the two sets of solvent coefficients. Drawing meaningful conclusions based on the coefficients of common descriptors, when the entire descriptor set is not shared, can cause problems because of colinearity. Inert gases were omitted from the Katritzky et al. (38, 39) treatment because atomic species are not appropriate for the optimization methods used. Each approach has its advantages and disadvantages. Our approach gave the better correlations for water, methanol, and ethanol, but is limited in application to those compounds for which solute descriptors are known. Katritzky et al. treatment can be used to predict the solubility behavior of more compounds. The predictive accuracy is not as good, and at the moment, the method is limited to water, methanol, and ethanol. Though not specifically addressed, the Katritzky et al. treatment should be able to correlate organic solvent–water partition coefficients, which are related to gas–solvent and gas–water partitions through $\log P = \log L_S - \log L_W$.

Results and discussion

The chemical literature contains an enormous amount of solubility data that could be used to illustrate the computational methodology and to assess the applications and limitations of the Abraham general solvation model. Acree and co-workers experimentally determined the solubilities of several polycyclic aromatic hydrocarbons (24, 25, 37, 40–42) and pesticides (23, 26, 43) in a wide range of organic solvents of varying polarity and hydrogen-bonding characteristics. Bustamante and co-workers made similar measurements for select drug molecules (i.e., ibuprofen (44), piroxicam (45), niflumic acid (45), naproxen (46), citric acid (47), paracetamol (47), sulfamethoxypyridazine (48), diclofenac (49), and 2-hydroxybenzoic acid (49) and for the insecticide 4-methoxybenzyl 1-(4-chlorophenyl) cyclopropanecarboxylate (50). Large solubility databases also exist for thianthrene (51), *trans*-stilbene (20, 52), buckminsterfullerene (21, 53), diphenyl sulfone (54), metronidazole (55), dimetridazole (55), ipronidazole (55), benzil (56), benzoic acid (57), methyl 4-hydroxybenzoate (58), 4-hydroxybenzoic acid (58), haloperidol (59), 4-aminobenzoic acid (49), 4-nitroaniline (60), 4-nitro-*N*,*N*-dimethylaniline (60), thioxanthen-9-one (61), and ferrocene (62).

After careful consideration, we selected anthracene, phenanthrene, and hexachlorobenzene as the solutes to be studied because the solute descriptors are known, and the needed aqueous solubility and vapor pressure were readily available. The selected solutes do not contain polar func-

[e]Average absolute deviation drops to 39.5% if acetonitrile is excluded from the comparison.

tional groups, thus decreasing the likelihood that the solutes will form solid hydrates or solvates in any of the saturated solutions. Solute properties are listed in Table 2. The numerical values for anthracene and phenanthrene were taken from our publications (12, 63, 64), as well as the solute descriptors for hexachlorobenzene. The logarithm molar solubility of hexachlorobenzene in water is log C_W = –7.68 (65). A value of log L_W = 1.66 at 294.65 K is given by Koelmans et al. (66), and we estimate that this would correspond to a value of log C_G = –9.18 at 298.15 K.

Ferrocene, *trans*-stilbene, buckminsterfullerene, diuron, and monuron were eliminated from consideration because their solute descriptors were determined from the published solubility data (20–23). For these four solutes, the calculations would not represent outright solubility predictions, but rather the ability of eqs. [1] and [2] to back-calculate the solubility data that was used as input values in the solute descriptor computations. Moreover, this information was reported at the time the solute descriptors were determined. Benzoic acid, 4-hydroxybenzoic acid, and 2-hydroxybenzoic acid were not selected due to the fact that carboxylic acid solutes are known to dimerize in hydrocarbon solvents. We did not want to complicate the analysis with concerns regarding whether the dissolved carboxylic acid solutes existed in solution in monomeric and (or) dimeric form, nor did we want to correct the measured aqueous solubilities for the extent of ionization. For solutes that ionized in aqueous solution, C_W must refer to the solubility of the neutral form. Similarly, compounds that would likely form zwitterions were excluded from consideration. Such matters will be addressed in subsequent publications. The remaining solutes were eliminated because of: (*i*) lack of aqueous solubility or vapor pressure data; (*ii*) the solute descriptors were not known; (*iii*) concerns about possible hydrate and (or) solvate formation; or (*iv*) too few of the solvents used in a given solubility study are listed in Table 1. Although not used in the present study, solubility data for these latter solutes will be added to our existing databases for possible inclusion in any additional solvent coefficient determinations.

[a]Values of a_A^{solid} = 0.01943 and V_A = 155.6 cm^3 mol^{-1} were used in the Mobile Order theory predictions.
[b]% Dev. = $100(X_S^{pred} - X_S^{exp})/X_S^{exp}$.

Tables 3–5 compare observed anthracene, phenanthrene, and hexachlorobenzene molar solubilities (C_S^{exp}) to values calculated using the Abraham general solvation model. The model predicts log *P* and log *L* partitions, which were then converted to molar solubilities through eqs. [3] and [4]. For comparison purposes, we have reported the predicted values to either three or four significant figures to be as consistent as possible with the number of significant figures in the experimental values. All published mol fraction solubility data (X_S^{exp}) were converted to molarities by dividing X_S^{exp} by the ideal molar volume of the saturated solution (i.e., $C_S^{exp} \approx X_S^{exp} / [X_S^{exp} V_{solute} + (1 - X_S^{exp}) V_{solvent}]$). Solvent and solute molar volumes used in these conversions are given elsewhere (24–26). Any errors resulting from our estimations of the solutes' hypothetical supercooled liquid molar volumes (V_{solute}) or the ideal molar volume approximation should have negligible effect on the calculated C_S^{exp} values. Anthracene and hexachlorobenzene are fairly insoluble in all of the solvents considered, and the $X_S^{exp} V_{solute}$ term contributes very little to the molar volume of the saturated solution.

Examination of the numerical entries in Tables 3–5 reveals that eqs. [1] and [2] provide a very reasonable (though by no means perfect) estimation of the solubility behavior of anthracene, phenanthrene, and hexachlorobenzene in nonelectrolyte organic solvents. Overall average absolute deviations between predicted and observed values were 34.4 and 34.9% for eqs. [1] and [2], respectively. Expressed on a logarithmic molar scale basis, the Abraham general solvation model estimates the solubilities to within ±0.129 and ±0.122 log units, which is comparable in magnitude to the standard deviations associated with the *c*, *r*, *s*, *a*, *b*, *v*, and *l* coefficients for the individual solvent systems. Standard deviations for most of the individual solvent correlations fell between 0.12 and 0.20 log units. At this point in time we are unable to assign an actual uncertainty to each predicted solubility because of our limited experience in using eqs. [1] and [2] for solubility predictions. We suspect that a value of ±0.15 log units would not be too unreasonable, given the standard deviations in the individual solvent correlations and the comparisons presented in Tables 3–5 and elsewhere (20–23).

Readers will note that in the case of hexachlorobenzene, eq. [2] overpredicts the saturation solubility in several of the solvent systems studied. It might be possible to improve the overall predictive ability of eq. [2] by reestimating the numerical value of log C_G using other published vapor pressure data. It is not our intent, however, to arbitrarily select the vapor phase concentration of hexachlorobenzene that gives the best set of predicted values. Such practices would not provide an unbiased test of the applications and limitations of the Abraham general solvation model. Hexachlorobenzene does have a low vapor pressure at 298.15 K, and there is uncertainty associated both with accurately determining its vapor pressure above a saturated solution, and with extrapolating vapor pressures measured at much higher temperatures back to 298.15 K. This is one of the limitations inherent in using the log *L* correlations of the general solvation model. The computation needs accurate vapor pressure data to convert the predicted log *L* values into saturation molar solubilities. Our past experience in using different solution models has been than the better solution models will generally give predicted values that fall within ±40% or so of the observed solute solubilities. The Abraham general solvation model meets this criterion.

It should be noted that in the case of a few solvents, the measured solubility data was used in the regressional analysis to determine the equation coefficients. We do not believe that this use compromises the solubility predictions. The equation coefficients listed in Table 1 are based on data sets containing experimental solubilities and activity coefficients for more than 40 different organic and inorganic solutes. Removal of any single solute from the data set(s) should have virtually no effect on the derived coefficients.

As stated in the *Introduction*, one of the objectives of the present study is to critically examine the applicability of the Abraham solvation model in regards to solubility predictions. A better appreciation of the model's predictive ability can be gained by comparing the predictions of eqs. [1] and [2] to calculated values based upon several of the competing solution models that are currently being used in the pharmaceutical and chemical industries. Of the many solution models proposed in recent years, Mobile Order theory and the UNIFAC group contribution method are probably two of the only models that are capable of describing solute solubility behavior in such a wide range of solvent mixtures. In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility (ϕ_A^{sat}) as (67–77)

[a]UNIFAC and Modified UNIFAC predictions were taken from Hansen et al. (81).
[b]% Dev. = $100(X_S^{pred} - X_S^{exp})/X_S^{exp}$.

$$[6]\quad \ln\phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5\ln[\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta_A' - \delta_{solvent}')^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. Slightly more complex expressions apply in the case of solute–solvent complexation. The more complex expressions are not used in the present study as they require *a prior* knowledge of the numerical value of the solute–solvent stability equilibrium constant. While one could calculate a general numerical value for the interaction of an aromatic hydrocarbon solute with each of the different solvent classes from the observed solubility data, its subsequent use in the Mobile Order theory equations would not represent outright solubility predictions.

The symbols δ_A' and $\delta_{solvent}'$ denote the modified solubility parameters of the solute and solvent, respectively. Modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen bonding contributions have been removed. Numerical values of $\delta_{solvent}'$ are available in several published compilations (70, 71, 73, 74), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (78) or estimated using known values for similar organic solvents. In eq. [6], V_i is the molar volume of component *i* and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[7]\quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T)\ln(T_{mp}/T)$$

the solute's molar enthalpy of fusion (ΔH_A^{fus}) and heat capacity difference ($\Delta C_{p,A}$) at the normal melting point temperature (T_{mp}). Additonal term(s) must be added if the solute undergoes a phase transition prior to melting (79, 80). Ther-

© 2001 NRC Canada

modynamic models that predict solubility through activity coefficient considerations are limited to those crystalline compounds whose enthalpy of fusion is known or can be reasonably estimated. Lack of heat capacity data often necessitates that the last two terms in eq. [7] be dropped from the ln a_A^{solid} computation.

Tables 6–8 summarize the Mobile Order theory predictions for anthracene, phenanthrene, and hexachlorobenzene. Modified solubility parameters of the three solutes were obtained by forcing eq. [5] to "perfectly" describe the measured solute solubility in hexane, heptane, and octane. The resulting three preliminary δ_A' values for each solute were then averaged to give δ_A' = 20.32 $MPa^{1/2}$ (anthracene), δ_A' = 20.45 $MPa^{1/2}$ (phenanthrene), and δ_A' = 20.10 $MPa^{1/2}$ (hexachlorobenzene). The averaged values were used in all subsequent predictions. The last columns in Tables 6–8 show that Mobile Order theory predicts the observed mol fraction solubilities (X_S^{exp}) to within an average absolute deviation of ±109.5%. Mobile Order theory grossly overestimates the solubility of both anthracene and phenanthrene in acetonitrile. We suspect that the overestimation results from either failure of the Scatchard–Hildebrand solubility parameter theory to describe nonspecific interactions between acetonitrile and the two polycyclic aromatic hydrocarbons, or perhaps from an incorrect value for this solvent's modified solubility parameter. If acetonitrile is excluded from the comparison, the average absolute deviations for the anthracene and phenanthrene solubility predictions are reduced to ±39.6 and ±39.5%, respectively. The predictions for hexachlorobenzene are considerably worse. The melting point temperature of hexachlorobenzene (T_{mp} = 505.0 K) is significantly above 298.15 K, and there could be errors and (or) uncertainties associated with the a_A^{solid} calculation. The two heat capacity terms in eq. [7] were dropped from the calculation because the needed heat capacity terms were not available in the chemical literature. These terms become increasingly more important for solutes with high melting point temperature. This is an inherent problem with all thermodynamic models that predict saturation solubilities from activity coefficients based on the hypothetical supercooled liquid solute standard state. Thermodynamic models that base transfer properties upon the solute's gas-phase properties experience similar difficulties in predicting solubilities from organic solvent – gas phase partition coefficients of highly nonvolatile crystalline solutes. The needed vapor pressure data may not be known with sufficient accuracy to enable accurate solubility predictions.

Finally, the predictive ability of the Abraham general solvation model is compared to the UNIFAC and Modified UNIFAC (Dortmund) group contribution models. These latter two models estimate activity coefficients from structural considerations and molecular interactions involving the various functional groups on the dissolved solute and solvent molecules. Numerical entries in Table 9 were taken from a recent paper by Hansen et al. (81). The authors studied only three polycyclic aromatic hydrocarbons (anthracene, pyrene, and fluoranthene). For the most part, the predicted values fell with ±35% of the observed solubility data. It is expected that had the authors studied phenanthrene that the deviations would be similar. Based upon the comparisons presented above, we conclude that the Abraham general solvation model is comparable to, if not superior than, Mobile Order theory and the UNIFAC and Modified UNIFAC (Dortmund) models when it comes to predicting solute solubility in organic solvents.

Synthesis of chloro(2-methylimidazole)ruthenium(III) complexes and their aqueous solution chemistry, and the crystal structure of $[2\text{-MeImH}]_2[RuCl_5\text{2-MeIm}]$

Craig Anderson

Abstract: 2-Methylimidazole (2-MeIm) reacts with $RuCl_3$ in aqueous acidic ethanolic medium to give $(2\text{-MeImH})_2[RuCl_5(2\text{-MeIm})]$ (**1**) and $(2\text{-MeImH})[RuCl_4(2\text{-MeIm})_2]$ (**2**) (2-MeImH = protonated 2-methylimidazole), the ratio depending on reaction conditions used. Molecule **1** crystallizes in the space group *Pnma*: a = 14.046(2), b = 17.294(2), and c = 8.2778(12) Å. The ^{1}H NMR spectra of these ruthenium(III) complexes have been measured and show peaks with large isotropic shifts and large line broadening characteristic of such paramagnetic complexes. The aquation of complexes **1** and **2** were followed by proton NMR spectroscopy. 1,2-Dimethylimidazole (1,2-diMeIm) reacts with $RuCl_3$ in methanolic solution to give $[RuCl_3(1,2\text{-diMeIm})(H_2O)S]$ ($S=H_2O$ (**3a**) or CH_3OH (**3b**)). The aquation reactions of complexes **3a** and **3b** were followed by ^{1}H NMR.

Key words: ruthenium, paramagnetic, antitumour, NMR.

Résumé : Le 2-méthylimidazole (2-MeIm) réagit avec le $RuCl_3$, en solution aqueuse acide, dans un milieu éthanolique, pour conduire à la formation de $(2\text{-MeImH})_2[RuCl_5(2\text{-MeIm})]$ (**1**) et de $(2\text{-MeImH})[RuCl_4(2\text{-MeIm})_2]$ (**2**) (2-MeImH = 2-méthylimidazole protoné) dans des rapports qui varient selon les conditions réactionnelles. Le composé **1** cristallise dans le groupe d'espace *Pnma*, avec a = 14,046(2), b = 17,294(2) et c = 8,2778(12) Å. On a mesuré les spectres RMN du ^{1}H de ces complexes du ruthénium(III) et ils comportent de pics présentant des larges déplacements isotropes et l'important élargissement des raies caractéristique de tels complexes paramagnétiques. On a suivi l'aquation des complexes **1** et **2** à l'aide de la RMN du proton. Le 1,2-diméthylimidazole (1,2-diMeIm) réagit avec le $RuCl_3$, en solution méthanolique, pour conduire à la formation des complexes $[RuCl_3(1,2\text{-diMeIm})(H_2O)S]$, dans lesquels $S = H_2O$ ou CH_3OH, **3a** et **3b**. Les réactions d'aquation des complexes **3a** et **3b** ont été suivies par RMN du ^{1}H.

Mots clés : ruthénium, paramagnétique, antitumoral, RMN.

[Traduit par la Rédaction]

Introduction

Interest in ruthenium imidazole complexes stems from their possible uses as anti-tumour agents (1–3), their radiosensitizability (4), more recently their potential use as immunodeciency drugs (5), and more generally, as models for transition-metal interaction with more complex biological substrates, such as the purine bases of DNA (6). Clarke and co-workers (7) have reported several papers with numerous examples of ruthenium(III) ammine complexes that also contain coordinated imidazole or purine, which are fully characterized including ^{1}H NMR spectra. The crystal structures (1), solution chemistry (8, 9), and reactivity with nitrogenous ligands (10) of $(ImH)[RuCl_4Im_2]$ (**4**) and $(ImH)_2[RuCl_5Im]$ (**5**) have been reported. Little is known, however, of analogous 2-methylimidazoles complexes, although $(2\text{-MeImH})[RuCl_4(2\text{-MeIm})_2]$ (**2**) has been reported as a red solid (1). Also, a report has been made of the reaction of ruthenium trichloride and several 2-methylimidazoles, but the products were not fully characterized (11). It is well-known that paramagnetic ruthenium(III) complexes give NMR spectra with peaks that have both large linewidths and large isotropic shifts (7, 8, 12, 13). The 2-methylimidazole complexes are no exception. However, these complexes have NMR spectra much different than for analogous 1-methylimidazole and 4-methylimidazole chloro-complexes previously reported (8). These differences can be attributed to the 2-methylimidazole ligand, which has the methyl group *ortho* to coordinated nitrogen, and therefore causes steric interactions in the bonding of the ligand to the metal centre. 2-Methylimidazole, for example, is known not to react with ruthenium(II) bipyridine species due to steric interactions, whereas other methylated analogues have (14).

The results of the formation of chloro-(2-methylimidazole)ruthenium(III) paramagnetic complexes and their aqueous solution chemistry will be reported here. An attempt has also been made to use proton NMR not only as a means of characterizing these paramagnetic compounds but also to monitor the progress of their aquatic reactions. Also to be reported here, is the first ruthenium(III) structure containing coordinated 2-methylimidazole.

Experimental

Instruments and methods

^{1}H NMR spectra were recorded on Varian XL-300 or Bruker AMX 300 spectrometers. Sweep widths of 50 000 or 100 000 Hz were used at pulse rates of 0.04 s. The peaks were referenced to residual solvent peaks (D_2O, $\delta = 4.8$) and given with respect to Me_4Si; downfield being positive.

Infrared spectra were recorded down to 200 cm^{-1} on a PerkinElmer 1600 FT-IR apparatus as either KBr or CsI pellets. In the case of KBr pellets, noise existed below 240 cm^{-1}.

Crystal structure of (2-MeIm)$_2$[RuCl$_5$(2-MeIm)]

X-ray diffraction data were obtained with an Enraf-Nonius CAD-4 diffractometer using Mo Kα radiation. The cell parameters were calculated by least-squares refinement on 25 higher angle reflections ($20° < \theta < 23°$). Space groups *Pnma* and $Pn2_1a$ (alternate definition of $Pna2_1$) were both consistent with the systematic absences. The structure was solved in the space group *Pnma*. Crystal data are given in Table 1.

Four standards were used to monitor intensity every hour and orientation every 200 measurements. Variations remained within ±2.0% during data collection. A half sphere of data (7308 reflections) was collected by the ω–2θ scan technique. The usual corrections for the effects of Lorentz and polarization were applied.

From the Patterson map, the Ru atom was found to lie on a crystallographic mirror plane. The remaining atoms were located from structure–factor and ΔF calculations. The structure was refined on F^2 by full-matrix least-squares. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed at idealized positions. All calculations were done with the SHELXTL package (15).[1]

Preparation of (2-MeIm)$_2$[RuCl$_5$(2-MeIm)] (1)

Ruthenium trichloride ($RuCl_3$) (0.413 g) was heated at reflux in a 0.5 M HCl aqueous–ethanolic solution (1:1, 40 mL) for 2 h. The solution became blue-green. The volume of the solution was then reduced to approximately 5 mL. This solution, which had subsequently turned bright red, was cooled to room temperature. To this was added 2-methylimidazole (2.4 g) in aqueous HCl (2 mL, 8 M). The resulting solution, which had remained red, was stirred and heated to 50°C for 10 min. It was cooled down to room temperature and then placed at 8°C for 24 h. Later it was placed at (–15°C) for two weeks, at which time red crystals had appeared. The solid was filtered and washed quickly with cold ethanol. The crystals were bright ruby red, but were covered with a red-brown dust or a dark red oil. The dust and (or) oil were washed away with several washings with water. A single red crystal was characterized crystallographically and shown to be (2-MeImH)$_2$[RuCl$_5$(2-MeIm)] (**1**). The brownish-red powder was assigned as (2-MeImH)[RuCl$_4$(2-MeIm)$_2$] (**2**). The NMR spectra before washing (see *Discussion*) of these materials showed a mixture of the two species (**1** and **2**) at a ratio of 4:1, respectively, but only peaks due to **1** remained after washing (Fig. 1). All the crystals in the batch had the same habit, and several crystals were taken at random from the batch and their cell parameters checked against those of the structure determination. All of these matched confirming that the crystals were the same product, namely, complex **1**. Selected IR data ν(Ru-Cl) (cm^{-1}): 270 (m), 290 (s), 305 (vs), 655 (s), 665 (s), 1080 (s), 1090 (s). Selected ^{1}H NMR data (fresh solution of **1**) (**1a**, see *Discussion*) δ: 32.2 (CH_3), –6.8 (H5); cation: 2.58 (CH_3), 7.24 (H4/H5). The pH of a fresh solution decreased from approximately 7 to 3 and then stabilized at ca. 2 after several hours. The ratio of complex **2** to complex **1** obtained was higher (1:1) when higher concentration of ligand was used. ^{1}H NMR for **2** (D_2O) δ: 38.2 (CH_3), –5.9 (H5) (see Table 2 for complete ^{1}H NMR data).

Reaction of 2-methylimidazole and RuCl$_3$ and NMR studies of reaction products

2-MeIm reacts with commercial ruthenium chloride to give (2-MeImH)$_2$[RuCl$_5$(2-MeIm)] (**1**) (Scheme 1). The ^{1}H NMR spectrum of complex **1** measured in D_2O (Fig. 1) has one set of peaks and is assigned to the mono-aqua species [RuCl$_4$(2-MeIm)(H$_2$O)]$^-$ (**1a**) analagous to the conclusions determined for similar complexes from previous reports, i.e., that tetrachloro complexes and not pentachloro species are present immediately in aqueous solution. The peaks for **1a** appear at +32.2 ppm for the methyl group and at –6.8 ppm for the H5 proton (numbering is given in Table 3). The H5 proton is assigned due to its similar chemical shift and linewidth to those described previously (8). The H4 proton was not found in the +165 to –165 ppm region searched. The

[1] Crystallographic data (excluding structure factors) for complex **1** may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre (CCDC No. 169 216). Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Note: Symmetry transformation used to generate equivalent atoms *a*: *x*, $-y + 3/2$, *z*.

crease in the intensity of the previously existing peaks (Table 2). The methyl peak and the H5 peak are observed at 45.5 and –3.8 ppm, respectively, for $[RuCl_3(H_2O)_2(2\text{-MeIm})]$ (**1b**) and at 35.1 and –4.9 ppm, respectively, for $[RuCl_3(H_2O)(2\text{-MeIm})_2]$ (**2a**). The peaks for methyl groups and H5 protons can be matched by comparing relative intensities (3:1). Two general points can be made: (*i*) the peaks for H5 protons shift downfield on aquation, analogous to those previously studied (8) and (*ii*) the peaks for the methyl group appear anywhere from +10 to +50 ppm and showed no general pattern of shifting upon aquation. Two differences exist in the NMR of the 2-methylimidazoleruthenium(III) complexes compared to the chlororuthenium(III) imidazole complexes already reported: (*i*) only two peaks are seen, one for the H5 proton and one for the 2-Me group, the third peak, expected for the H4 proton is either lost in the baseline or less-likely obscured by other peaks and (*ii*) the peak for the 2-Me group appears at extremely low field. No such low-field peaks for methyl resonances with other chloroimidazole complexes have been observed, however, extreme downfield peaks are observed for related ammine complexes (7).

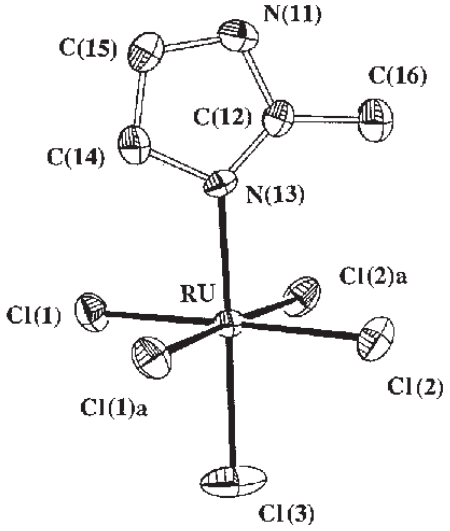
Description of the structure

The unit cell of $(2\text{-MeImH})_2[RuCl_5(2\text{-MeIm})]$ (**1**) contains four approximately octahedral ruthenium(III) anions ($[RuCl_5(2\text{-MeIm})]^{2-}$) and eight protonated 2-methylimidazole units acting as counterions. This is analogous to $(ImH)_2[RuCl_5Im]$ already published (1). A crystallographic mirror plane including the ruthenium, the coordinated 2-MeIm, and Cl3 cuts the ruthenium moiety in half. Therefore, there are three types of chloride ligands: Cl1 and Cl2, together with their mirror images, define by the equatorial plane and Cl3, which occupies an axial site *trans* to the nitrogen. The Ru—Cl3 bond (2.383(2) Å) is significantly longer than Ru—Cl1 and Ru—Cl2 (ave. 2.366(1) Å) bonds, which are the same length within experimental error (Table 3). This same pattern was observed in the analogous $(ImH)_2[RuCl_5Im]$, for which the longer bond length is attributed to the chloride being *trans* to the strong nitrogen donor (1). The Ru—Cl *trans* to N is also much shorter than the analogous bond in $[RuCl_5Im]^{2-}$ (2.446(2) Å). The Ru—N bond length (2.104(5) Å) is normal (1). The Ru—Cl bonds *trans* to Cl are in the range found for the other ruthenium(III) compounds (16).

The 2-methylimidazole ligand lies on a crystallographic mirror plane and is therefore perfectly planar. However, coordination does not take place exactly along the N lone pair: the ligand is tilted away from the chlorides because of steric interactions between the methyl group and the chloride ligands (Fig. 2). The angle Ru-N13-C12 (133.6(4)°) is significantly larger than Ru-N13-C14 (119.3(4)°) (Table 3). No such large differences have been found for other imidazole complexes without a 2-methyl group (1, 10). This distortion is attributed to the steric effect of the methyl group as the distances between the methyl carbon and the Cl2 and Cl2a ligands is 3.44(1) Å, which is less than the sum of the Van der Waals radii (3.6–3.9 Å) (17). Therefore, the effect can be expected to be present in solution where the NMR spectra were recorded.

The $[RuCl_5(2\text{-MeIm})]^{2-}$ ions form layers in the mirror planes perpendicular to *b* at $y = 1/4$ and 3/4. Within the layer, a hydrogen bond exists between the coordinated imidazole HN11 atom and two equatorial Cl1 ligands on an adjacent anion. The N11···Cl1 distances (3.327(6) Å) (Table 3) are large, which is in agreement with this hydrogen bond being bifurcated with the hydrogen at equidistance from each chloride. The 2-methylimidazolium cations form layers between those of the anions. They show hydrogen bonding on both sides, i.e., HN21 and HN23 to the chloride ligands, thus confirming that hydrogens are present on both N21 and N23 and that the species is protonated. Two different HN23's bond to each axial Cl3, whereas one HN21 is bonded to each of the two Cl2 atoms. These interactions are strong, with the N···Cl separation being approximately 3.11 Å.

$RuCl_3$ and 1,2-dimethylimidazole: formation and NMR spectroscopy



The reaction between an activated solution of ruthenium trichloride and 1,2-dimethylimidazole (1,2-diMeIm) does not form a complex with coordinated imidazole as it did in the case of 2-MeIm. Therefore, a different synthetic route was employed (Scheme 2).

The reaction was done in methanol and in the absence of acid or water. The commercial ruthenium trichloride was heated at reflux with 2 equivalents of KCl under inert atmosphere for 16 h, at which time the solution was green. The ligand was added and heated at reflux for 0.5 h and then stirred at room temperature overnight. After the solvent was removed, the residue was a blackish tar and was, therefore, characterized only by ^1H NMR spectroscopy. The products obtained from the reaction mixture decomposed within three days when left in solution.

The spectrum of the tar, measured immediately upon dissolving in D_2O, showed two major Ru(III) products assigned to $[RuCl_3(H_2O)_2(1,2\text{-}Me_2Im)]$ (**3a**) and $[RuCl_3(CH_3OH)(H_2O)(1,2\text{-}$

Fig. 2. Molecular structure of complex **1.**

MeIm)] (**3b**) on the basis of a similar study with the 9-methylhypoxanthine ligand carried out under similar conditions (18). Two sets of peaks (Table 2) were observed for the major Ru(III) products: +39.9, +11.4, and –6.4 ppm (2-Me, NMe, H5, respectively) for **3a** and +33.4, +17.3, +18.6, and –7.2 ppm (2-Me, NMe/CH_3OH, H5, respectively) for **3b**. For complex **3b** the peaks at +17.3 and +18.6 are of equal intensity and are assigned to coordinated methanol and the *N*-methyl group of the coordinated ligand, but cannot be individually assigned. Peaks present in much lesser intensity are most probably due to mixtures of *fac*- and *mer*-$[RuCl_3(MeOH)_2(1,2\text{-}Me_2Im)]$. As in the 2-MeIm system the H4 signals are not seen in the spectrum. Once the NMR solution had been aged for several hours all of **3b** had been converted to **3a** by substitution of methanol by an aqua ligand (i.e., all of the peaks associated with **3b** had disappeared and only the peaks for **3a** were present). All peaks associated with other minor species with coordinated methanol (from +12 to +30 ppm) had also disappeared and had converted to complex **3a** as well. After a period of two days, a new product, **3c** had begun to form, although the peaks associated with **3a** were still present in majority. Molecule **3c** has peaks at +37.2, +11.2, and –6.5 ppm for 2-methyl, *N*-methyl, and H5 protons, respectively, and is assigned the structure $[RuCl_2(H_2O)_3(1,2\text{-}Me_2Im)]^+$. The 3:3:1 ratio of the peaks is consistent with the assignment. However, other peaks were found in the diamagnetic portion of the spectrum indicating decomposition to ruthenium(II) complexes.

Discussion

Chlororuthenium(III) complexes with imidazole, 1-methylimidazole, and 4-methylimidazole ligands show the same general pattern in the NMR spectra, i.e., all peaks are shifted upfield compared to free ligand (8). In contrast, a downfield shift is found for the 2-methyl group of complex **1**. This is, however, in agreement with methyl protons of coordinated imidazole of ammineruthenium complexes, which have the methyl protons shifted in the opposite direction from the corresponding ring protons (i.e., downfield) (5). The H5 proton is most easily assigned to the narrowest peak and is always upfield compared to the free ligand values and virtually unchanged whether the ligand is methylated or not,

Scheme 2.

$$RuCl_3 + MeOH \rightarrow \text{“}RuCl_3\text{”}$$

$$\text{“}RuCl_3\text{”} + KCl + 1,2\text{-}Me_2Im \rightarrow [RuCl_3(1,2\text{-}Me_2Im)(H_2O)S]$$

$$S = H_2O\ (\mathbf{3a}),\ MeOH\ (\mathbf{3b})$$

$$\mathbf{3b} + H_2O \rightarrow [RuCl_3(H_2O)_2(1,2\text{-}Me_2Im)]\ (\mathbf{3a})$$

$$\mathbf{3a} + H_2O \rightarrow [RuCl_2(H_2O)_3(1,2\text{-}Me_2Im)]^+\ (\mathbf{3a})$$

similar to those previously reported (7, 8). The H4 protons of the complexes reported here are not observed and it is presumed that their linewidth are too large and therefore the peaks are lost in the baseline.

Although the metal—ligand bond lengths in complex **1** are similar to those of complexes $(ImH)[RuCl_4Im_2]$ (**4**), $(ImH)_2[RuCl_5Im]$ (**5**), and $(4\text{-}MeImH)[RuCl_4(4\text{-}MeIm)_2]$ (**6**) (1, 2), there is, however, a significant difference in the Ru-N3-C2 angle, which is much more obtuse than in all the other reported structures (1, 2, 6, 8) (133° compared to 128° for **4**, 127° for **5**, and 125° for **6**) (1). It can be concluded that this change in geometry introduces a steric factor that causes different contributions in the geometric factor for the isotropic shift term, thus the huge difference in observed shift. The 2-MeIm-complex has the methyl group closer than the accepted van derWaal radii and is, therefore, in close contact with the field of the chloride ligands. The ligand is also hindered from rotating and therefore the methyl group lies directly between the chloride ligands (7). Clarke et al. (7) have stated that ligands that have methyl groups *ortho* to the coordinated atom are unable to rotate thus changing the isotropic shift to downfield values compared to the upfield values of protons at the same position, but also admonished that it is difficult to separate isotropic shifts into their dipolar and contact components when rotation is hindered. This lack of rotation greatly effects both contact and dipolar terms (7). This effect may also account for the unobserved H4 protons. The steric bending caused by the C2 methyl group pushes the H4 proton closer to Ru and would have a pronounced effect on the contact interaction, whereas the electon donating methyl group on the ring may effect the dipolar (electronic) term (7). Recently, ruthenium pyrazine complexes have been reported where the *ortho* protons are too broad to be seen (19). Furthermore, Keppler et al. (9) have stated that the isotropic shifts for $[RuCl_4Im_2]^-$ are mainly dipolar in nature because the ratios of isotropic shifts matched well the ratio of the geometric term $(3\cos^2 s - 1)/r^3$, where s is the dihedral angle between the principal symmetry axis and the Ru–H vector, and r is the Ru–H distance (based on crystal structure). For complex **1** these ratios are 2.0:1 for isotropic shifts and 1.5:1 for geometric ratio, indicating that the shifts are perhaps not completely dipolar in nature and the contact term plays a significant role in determination.

The 2-MeIm case is clearly different from the others with respect to NMR spectroscopy. The room for quantifying these observations into chemical shifts is available, but somewhat difficult due to the controversies involved in assigning contributions to terms in the equations (5, 7). The proton NMR spectra of these complexes are sensitive to small structural and electronic perturbations, therefore, assignments and quantifying peaks must be done with caution. The NMR spectra reported here should help in determining the reactiv-

© 2001 NRC Canada

ity of these ruthenium complexes and aid in determining the reasons for their activity as anticancer drugs.

Acknowledgments

We would like to thank Michel Simard and Christian Tessier for help with the crystallographic work. We would like to thank Orgometa Laboratories for financial and moral support. Financial support from the Beretta and Keats Funds is also acknowledged.

An experimental and theoretical approach to phosphonodithioato complexes: molecular orbital analysis by hybrid-DFT and EHT calculations on *trans*-bis[*O*-alkyl-phenylphosphonodithioato]Ni^{II}, and vibrational assignments

M. Carla Aragoni, Massimiliano Arca, Francesco A. Devillanova, John R. Ferraro, Francesco Isaia, Francesco Lelj, Vito Lippolis, and Gaetano Verani

Abstract: The synthesis and the full spectroscopic characterization (FT-IR, FT-Raman, ^{31}P CP MAS NMR) of *trans*-bis[*O*-ethyl-phenylphosphonodithioato]Ni^{II} (**3**) are reported. On the basis of hybrid-Density Functional Theory (DFT) calculations and Extended Hückel Theory (EHT) calculations, performed on the simpler *trans*-bis[*O*-methyl-phenylphosphonodithioato]Ni^{II} (**2**) model complex, the electronic structures of phosphonodithioato complexes in their ground states are fully described, and in particular the vibrational features are deeply analyzed, allowing an unprecedented insight into the vibrational features of *trans*-bis-*O*-methyl-phenylphosphono- and *trans*-bis(isopropylamidophosphono)-dithioato complexes of nickel(II), palladium(II), and platinum(II).

Key words: phosphonodithioato complexes, IR, Raman, DFT calculation.

Résumé : On rapporte la synthèse et la caractérisation spectroscopique complète (FT-IR, FT-Raman, ^{31}P CP MAS RMN) du *trans*-bis[*O*-éthyl-phénylphosphonodithioato]Ni^{II} (**3**). Sur la base de calculs de densité fonctionnelle hybride (DFT) et de calculs de Hückel étendus effectués (EHT) sur le complexe modèle plus simple, *trans*-bis-[*O*-méthyl-phénylphosphonodithioato]Ni^{II} (**2**), on présente une description complète des structures électroniques des complexes phosphonodithioato dans leurs états fondamentaux et, en particulier, on a analysé en détail les caractéristiques vibrationnelles ce qui permet d'obtenir une vue sans précédent des caractéristiques vibrationnelles des complexes *trans*-bis-*O*-méthyl-phénylphosphono- et *trans*-bis(isopropylamidophosphono)-dithioato du nickel(II), du palladium(II) et du platine(II).

Mots clés : complexes phosphonodithioato, IR, Raman, calculs DFT.

[Traduit par la Rédaction]

Introduction

Many reports have been published on the syntheses, characterizations, and reactivities of phosphoro- (1) and phosphinodithioates (2), since these compounds and their metal complexes have found wide application in industrial and agricultural fields (3), e.g., additives to lubricant oils (4), extraction reagents for metals (3, 5), flotation agents for mineral ores, and insecticides, rodenticides, and pesticides (3, 6). However, the chemistry of phosphono- and amido-phosphonodithioates has been only scarcely investigated, probably because of synthetic difficulties (7). Recently (8), we have reported a novel synthetic route to the preparation of square-planar metal-phosphonodithioates deriving from Lawesson's Reagent (LR, 2,4-bis(4-methoxy-phenyl)-[1,3,2,4]-dithiadiphosphetane-2,4-disulfide (**1**), see Scheme 1) (9), mainly known as thionation agent. First, these complexes were obtained as by-products in the synthesis of a new class $[M(R,R'timdt)_2]$ (M = Ni, Pd, Pt; R,R′timdt = monoreduced form of disubstituted imidazolidine-2,4,5-trithione) of neutral metal-dithiolenes (10, 11), obtained by sulphuring disubstituted imidazolidine-2-thione-4,5-diones with **1** in the presence of a suitable metal powder or salt and of an alcohol, used because of solubility reasons (8). More generally, **1** was proved to react with nucleophilic alcohols (ROH) and amines ($R'NH_2$) to induce the opening of the P_2S_2 tetra-atomic ring, yielding phosphonodithioato and amidophosphonodithioato anions. Furthermore, their reaction with Ni^{II},

Pd^{II}, and Pt^{II} salts (MCl_2 for M = Ni, Pd; K_2MCl_4 for M = Pd, Pt) gives the corresponding phosphono- and amido-phosphono-dithioato complexes (12). These can also be obtained in a one-pot reaction by reacting **1** and the metal salts in the presence of the nucleophilic reagent. This route proved to be particularly well-suited for the synthesis of phosphonodithioato complexes deriving from light alcohols, since these can be used directly as solvents (8). Pursuant to our interest in this field, to understand the electronic and spectroscopic features of dithiophosphonato complexes, calculations based on Density Functional Theory (DFT) (13) have been performed on *trans*-bis[*O*-methyl-phenylphosphono-dithioato]Ni^{II} (**2**, Scheme 1), chosen as a model compound. In fact, DFT calculations are assuming a primary role, since they give reliable results with inorganic compounds containing transition metals (11, 14) in their ground or excited states (15). With this in view, we have prepared *trans*-bis[*O*-ethyl-phenylphosphonodithioato]Ni^{II} (**3**), starting from 2,4-diphenyl-[1,3,2,4]-dithiadiphosphetane-2,4-disulfide (**4**). Complex **3** was previously reported, but only the cell constants and an average Ni—S distance were published (16, 17).

Results and discussion

Molecular orbital analysis

The geometry optimization of *trans*-bis[*O*-methylphenyl-phosphonodithioato]Ni^{II} (**2**, see Scheme 1) has been performed starting from the structural data determined by X-ray diffraction on *trans*-bis[*O*-ethyl-(4-methoxyphenyl)phosphono-dithioato]Ni^{II} (**5**) and has correctly led to a square-planar coordination of the central metal ion, with the phosphorus atoms slightly out of the coordination plane (Fig. 1). In Table 1, a comparison between the calculated bond distances and angles and those measured by X-ray diffraction on **5** (8) (where the phenyl is replaced by a *p*-methoxyphenyl) and *trans*-bis[isopropylamido-(4-methoxyphenyl)phosphono-dithioato]Ni^{II} (**9**) (where the ethoxy group is replaced by an isopropylamine moiety) (12) is reported. As found in the case of other hybrid-DFT calculations on Ni complexes deriving from sulphured ligands (8, 11), the metal—sulphur distances are slightly overestimated (a distance of 2.278 Å has been calculated, compared to an average value of 2.20 Å found experimentally) (17), while the remaining calculated bond distances and angles are similar to the experimental ones reported for **5** (8) and *trans*-bis[(4-methoxyphenyl)-*O*-methyl-phosphonodithioato]M^{II} (M = Pd (**7**) and Pt (**8**)) complexes (12).[2] Some differences regarding the orientation of the substituents to the phosphorus atom [S(1,2)-P(2)-O(1), S(1,2)-P(1)-C(2), P(1)-O(1)-C(1)] should be attributed to crystal packing effects. The comparison can also be extended to the reported structures of the Pd^{II} and Pt^{II} analogues of **2**, where values similar to those reported for **5** and **9** were found (17). To qualitatively understand the interactions between the atomic orbitals (AO's) of the Ni^{II} ion and the molecular orbitals (MO's) of the two ligand units, the Fragment Molecular Orbitals (FMO) approach within the Extended Hückel Theory (EHT) is employed. In Fig. 2 an interaction diagram showing the orbitals, whose eigenvalues lay in the range between –8 and –15 eV, is reported. In the idealized molecular C_{2h} point group the five 3*d* AO's span in three a_g ($d_{x^2-y^2}$, d_{z^2}, d_{xy}) and two b_g (d_{xz}, d_{yz}) representations. The $21a_g$ highest occupied molecular orbital (HOMO) of **2** is a π-MO largely made up of the $d_{x^2y^2}$ AO (25%), which is raised in energy by the antibonding interaction with the $21a_g$ FMO of the ligands, constituted by a combination of sulphur 3*p* AO's perpendicular to the coordination plane. The interaction between the $14b_g$ FMO of the ligands (in plane sulphur *p* AO's) with the d_{xz} and d_{yz} AO's (25 and 16%, respectively) origins the σ-type $14b_g$ lowest unoccupied molecular orbital (LUMO). This MO happens to lay at roughly the same energy as three other nonbonding MO's ($22a_g$, $19b_u$, $13a_u$), which are π-orbitals arising from the combinations of the 2*p* AO's of the aromatic carbon atoms. The HOMO-1 $13b_g$ also contains a contribution of Ni AO's (namely d_{yz} and d_{xz}, 25 and 15%, respectively) π-interacting with a b_g combination of 3*p* sulphur AO's. Metal *d* AO's also contribute to other MO's at lower energies, such as $20a_g$ (49% d_{z^2}, 16% d_{xy}), 18 a_g (32% $d_{x^2-y^2}$, 2% d_{z^2}, 11% d_{xy}), $15a_g$ (2% d_{z^2}, 8% d_{xy}), and $7b_g$ (28% d_{xz}).

Vibrational assignments

The calculation of harmonic frequencies from DFT energy gradients allows one to verify the optimized geometry and to obtain an unprecedented insight into the vibrational spectra of such complexes (Tables 2–4). Only two negative frequency values have been calculated (–84 and –82 cm^{-1}), which are related to rotations of methyl and phenyl groups, and therefore, are due to the presence of a constrained inversion center. A first examination of the simulated spectra (Fig. 3) shows that the use of transferable scaling factors (18), depending on the nature of the single vibrations, gives better results compared to uniform scaling factors. In this case, the slight differences found between the calculated and the experimental bond lengths and angles force the use of scaling factors that are quite different from unity, because of the unharmonic nature of the experimental vibrations. In general, scaling factors have been obtained by comparing the calculated harmonic frequency values to those measured for **3** and *trans*-bis[(4-methoxyphenyl)-*O*-methyl-phosphonodithioato]Ni^{II} (**6**), depending on the group involved in the vibrations. Because of the presence of an inversion centre, the IR spectra are expected to show only the

[2] To ascertain if the differences between the calculated and the experimental bond lengths and angles were to be attributed to the hybrid nature of the functional B3LYP, geometry optimization followed by frequency calculations have been performed with the same basis set on the simplified *trans*-bis[*O*-methyl-methylphosphonodithioato]Ni^{II} model complex, with three different functional, namely BLYP, BPW91, and B3LYP. Both the calculated geometries and frequencies are similar in the three cases. As regards the $(PS_2)_2Ni$ local moiety, the bond distances and angles calculated for the model complex are very similar to those calculated for **2** (Table 1). Although the BPW91 functional slightly reduces the overestimation of the Ni—S bond distances (2.282, 2.249, 2.278 Å for BLYP, BPW91, and B3LYP), it tends to calculate elongated P—S (2.044, 2.025, 2.020 Å for BLYP, BPW91, and B3LYP), P—O (1.656, 1.652, 1.628 Å for BLYP, BPW91, and B3LYP), and P—C (1.849, 1.836, 1.829 Å for BLYP, BPW91, and B3LYP) distances, compared to the experimental average values determined for **5** (Table 1). As regards frequency calculations, the results are also pretty similar, since the three functionals calculated the same number of bands in the same order, BLYP functional leading to smaller absolute wavenumber values.

antisymmetric modes, and the Raman spectra only the symmetric ones. At any rate, as far as the ligand units are concerned, for each mode, two combinations (symmetric and antisymmetric) are possible, among which the symmetric combinations appear in the Raman spectra and the antisymmetric ones in the IR spectra. Since the two ligand groups are independent, the two combinations are almost degenerate in energy. Therefore, symmetric vibrational modes related to the two ligand units appear in the IR spectra through their antisymmetric combinations, as well as symmetric coupling of antisymmetric vibrations are Raman active.

An examination of the vibrational frequencies calculated for **2** shows that the bands having the highest energies can be found in the region 3100–2900 cm^{-1} (Table 2). In this region the symmetric and antisymmetric C—H stretching normal modes are calculated, and can be found in all the dithiophosphonato complexes, with minor differences due to the nature of the substituents.

Below 1600 cm^{-1}, the first band found in the FT-IR and Raman spectra of **6** is a strong peak at 1597 and 1590 cm^{-1}, respectively, sided by a less intense peak falling at 1567 cm^{-1} in both spectra. These peaks correspond to the two possible

Note: In this region calculated symmetric and antisymmetric modes fall at the same frequencies.

combinations of ν_s and ν_{as} C—C stretching of the phenyl rings, and are very weak in the FT-IR spectrum of **3** (IR: 1585 and 1571 cm^{-1}; Raman: only 1586 cm^{-1}). In the simulated spectrum of **2** (Table 3) these two bands are also calculated to be very weak (2.2 and 0.5 km mol^{-1}, respectively). Therefore, this suggests that the presence of the methoxy substituent in the *para* position of the phenyl ring causes an enhancement in the intensity of the bands in the IR spectra, which is presumably due to the negative charges on the oxygen atoms, which enhance the variation in the dipole mo-

ments. Many differences can be found in the vibrational spectra of **3** and **6** in the region of 1500–1400 cm^{-1}. In particular, four normal modes are calculated to be IR-active and they fall at 1449, 1446, 1426, and 1408 cm^{-1}: the first two are due to rocking and scissoring modes of the methyl groups, the third to an umbrella wagging of the methyl

group, and the fourth to a combination of C—C stretching and C-C-H in plane bending of the phenyl rings. Since the first two modes are almost degenerate in frequency, these four normal modes result in three bands in the simulated spectrum. The first and the third bands are found in the FT-IR spectrum of **3** at 1436 (the shift due to the presence of an ethyl instead on a methyl group) and 1389 cm^{-1}, while the umbrella deformation is not found in **3**, since no OCH_3 group is present. With regards to **6**, the bands are more numerous due to the presence of another OCH_3 group, as a substituent, at the phenyl ring, whose C–H deformations should fall in the same region. Such deformations can be considered responsible for a very strong IR band at 1500 cm^{-1}, which is found almost identical in the corresponding complexes **7** and **8** (12), and in *trans*-bis[isopropylamido-(4-methoxyphenyl)-phosphonodithioato]M^{II} (M = Ni (**9**), Pd (**10**) and Pt (**11**)). This region of the vibrational spectrum shows only very weak bands in the Raman spectra of all compounds.

The bands between 1300 and 1100 cm^{-1} are attributed to vibrations mainly regarding bending modes of the bonds in the aromatic rings. Among them, the bands falling at 1182 and 1177 cm^{-1} in the FT-IR spectra of **3** and **6**, respectively (calculated at 1182 cm^{-1} for **2**), are also found with remarkable intensities in their symmetric combination in the Raman spectra (1184 and 1175 cm^{-1} in **3** and **6**, respectively). It is interesting to note that in this case the presence of the substitution in the phenyl ring also causes an increase in the intensities of the IR bands. Only the IR bands falling at 1113, 1113, and 1118 cm^{-1} (exactly the same values of the Raman peaks) in the simulated spectrum of **2** and in those of **3** and

Fig. 3. Simulated FT-IR spectrum based on calculated scaled harmonic frequencies for model complex **2**, experimental middle-IR (1700–450 cm^{-1}) and far-IR (450–50 cm^{-1}) spectra for complexes **3** and **6**. The bands corresponding to same normal modes are connected by dotted lines. Vertical arrows are related to bands involving the methoxy group bound to the phenyl ring in complex **6**.

6, respectively, are strong, possibly because of the P—C stretching contribution to the vibrational mode. The most intense band in the whole simulated spectrum of **2** is found at 1003 cm^{-1} and is due to a pure (calculated reduced mass 7.1 amu) C—O stretching normal mode. This band in fact is found as a very strong IR peak both in **3** (1014 cm^{-1}) and in **6** (1003 cm^{-1}). The side band found in FT-IR spectrum of **5** at 1030 cm^{-1} is absent in **3** and can, therefore, be tentatively attributed to the C—O stretching vibration of the methoxy substituent at the phenyl ring. In fact, while the peak around 1000 cm^{-1} is absent in amidophosphonodithioato complexes **9–11**, the ν_{O-CH_3} vibration is found at 1020, 1019, and 1019 cm^{-1} for **9**, **10**, and **11**, respectively. In the Raman spectra of complexes **3** and **6**, the peak around 1000 cm^{-1} is strong only for **3**, while for **6** the band is weak.

In the FT-IR spectrum of **3** the strong peak found at 959 cm^{-1} (very weak in the Raman spectrum at 961 cm^{-1}) is absent in the calculated spectrum of **2**. Therefore, this band should be due to a vibrational mode of the ethoxy substituent, since it is also absent in **6** but present in **5** at 941 and 943 cm^{-1} in the FT-IR and Raman spectra, respectively. Conversely, in the FT-IR spectrum of **6**, the band at 836 cm^{-1} (Raman 839 cm^{-1}), absent in **3** and in the simulated spectrum of **2**, appears in all the vibrational spectra of compounds derived from **1** and, consequently, it might be due to another mode of the methoxy substituent at the phenyl.

Moving to lower frequencies, a very intense IR band is found at 783 and 789 cm^{-1} (786 and 801 cm^{-1} in the Raman spectra) for compounds **3** and **6**, respectively; this band can be correlated to the vibration calculated for **2** at 749 cm^{-1}, which is due to a combination of P—O stretching and C—H out of plane deforming of the phenyl ring. These vibrations, in the region between 750 and 500 cm^{-1} (fingerprint region), are mainly due to out of plane ring deforming of the phenyl moieties and to the P—S and P—O stretching modes. In particular, the band calculated at 631 cm^{-1} is attributed to the antisymmetric stretching of the P—S bonds and appears as an intense peak in all the vibrational spectra of all the synthesized complexes (**3**: 627 (IR), 623 (Raman) cm^{-1}; **5**: 623 (IR), 616 (Raman) cm^{-1}; **6**: 622 (IR), 618 (Raman) cm^{-1}; **7**: 611 (IR), 611 (Raman) cm^{-1}; **8**: 612 (IR), 612 (Raman) cm^{-1}; **9**: 608 (IR), 600 (Raman) cm^{-1}; **10**: 599 (IR), 596 (Raman) cm^{-1}; **11**: 598 (IR), 599 (Raman) cm^{-1}).

In the far-IR region (Table 4) the antisymmetric S-Ni-S bending appears at 470 and 435 cm^{-1} for **3** and **6**, respectively. This band, calculated at 435 cm^{-1} for **2**, depends strongly on the groups bound to the phosphorus atoms, and in fact varies by about 60 cm^{-1} on passing from phosphonodithioato (435, 431, 429 cm^{-1} for **6**, **7**, and **8**, respectively) to amidophosphonodithioato complexes (496, 497, 495 cm^{-1} for **9**, **10**, and **11**, respectively), while its position is virtually independent of the metal, indicating similar force constants for this bending mode. Therefore it is not surprising that the change of the alkoxy group determines a clear variation in the position of this band. Following the same trend found for the antisymmetric stretching, the symmetric one falls in the Raman spectra at 470 cm^{-1} for **3**, 440 cm^{-1} for **6**, 432 cm^{-1} for both **7** and **8**, and 463 cm^{-1} for **9**, **10**, and **11**. The antisymmetric metal—sulphur stretching is calculated at 351 cm^{-1} to be the most intense band in this region and is found at roughly the same frequency in the FT-IR spectra of both **3** and **6**. This band falls at 356, 314, and 308 cm^{-1} for compounds **9**, **10**, and **11**, respectively, and is

© 2001 NRC Canada

found at 346, 316, and 303 cm^{-1} for **5**, **7**, and **8**, respectively. The symmetric Ni—S stretching, calculated at 323 cm^{-1}, is found in the FT-Raman spectra of all complexes: 308 (**3**), 311 (**5**), 314 (**6**), 326 (**7**), 316 (**8**), 313 (**9**), 327 (**10**), and 316 cm^{-1} (**11**), with the bands being shifted according to the ratio between the different metal–sulphur bond strength constants and the respective reduced masses. According to the previous assignments the symmetric stretching frequency is found at higher frequencies compared to the unsymmetric ones for nickel-complexes **3**, **5**, **6**, and **9**, as well as in the calculated spectrum of **2**. Surprisingly, in the case of Pd and Pt complexes **7**, **8**, **10**, and **11** this trend is inverted. Another band, calculated at 358 cm^{-1} as a symmetric combination of torsions around the P atoms, can be found in the Raman spectra at 343 (**6**), 342 (**7**), 342 (**8**), 342 (**9**), 344 (**10**), and 345 cm^{-1} (**11**). This band becomes weaker in the case of **3** and **5** (340 and 344 cm^{-1}, respectively). Finally, in the lowest frequency region of the far-IR and Raman spectra the bands are originated by deforming of the metallacycle PS_2Ni ring and by alkoxy group rotations.

Conclusions

The synthesis of *trans*-bis[*O*-ethyl-phenylphosphonodithioato]Ni^{II} (**3**) confirms the reactivity of substituted [1,3,2,4]-dithiadiphosphetane-2,4-disulfides towards nucleophilic reagents, previously explored by us on commercially available Lawesson's Reagent (**1**). The complex has been fully characterized by spectroscopic techniques. At any rate, the most interesting results come from an examination of the DFT-calculated vibrational frequencies, which allows us to deeply investigate not only the FT-IR and FT-Raman spectra of **3**, but also those of other phosphono- (**6**–**8**) and amidophosphono-dithioato (**9**–**11**) complexes previously reported by us.

Experimental

All the reagents and solvents were purchased from Aldrich or Merck and were used without further purification. Elemental analyses were performed with an EA1108 CHNS-O Fisons instrument. Fourier transform infrared spectra (FT-IR) were recorded on a Bruker IFS55 spectrometer at room temperature using a flow of dried air. Far-IR (500–50 cm^{-1}) spectra (resolution 2 cm^{-1}) were recorded as polythene pellets with a Mylar beam-splitter and polythene windows. Middle IR spectra (resolution 2 cm^{-1}) were recorded as KBr pellets, with a KBr beam-splitter and KBr windows. FT-Raman spectra were recorded with a resolution of 2 cm^{-1} on a Bruker RFS100 FT-Raman spectrometer, fitted with an In-Ga-As detector (room temperature) operating with a Nd-YAG laser (excitation wavelength 1064 nm) with a 180° scattering geometry. Solid state ^{31}P CP MAS NMR spectra were recorded on a Varian Unity Inova 400 MHz instrument operating at 161.9 MHz with samples packed into a zirconium oxide rotor. The ^{31}P NMR chemical shifts were calibrated indirectly through the H_3PO_4 85% peak (δ 0.0). Quantum-chemical calculations were performed using the commercially available suite of programs Gaussian 98 package (19). Density Functional Calculations (DFT) (13) were performed on **2** using the hybrid B3LYP functional (which uses a mixture (20) of Hartree-Fock and DFT exchange along with DFT correlation: the Lee–Yang–Parr correlation functional (21) together with the Becke's gradient correction) (22).[3] The 6–31G(*d*) basis sets (23) were employed throughout. Integration was performed numerically using a total of 7500 points for each atom (Ultrafinegrid option). Starting from geometrical parameters determined for **5** (8), and avoiding introduction of any geometrical constraints but the inversion centre, a geometry optimization was performed and the results of the calculations were examined with the Molden 3.6 program (24). The optimized structure was verified by normal-mode harmonic frequency analysis. Harmonic frequencies were obtained using the second derivatives of the DFT energy, computed by numerical differentiation of the DFT energy gradients. Calculated harmonic frequencies were extracted from the output file and converted in a simulated spectrum with the Tabfreq program after application of the scaling factors, using DFT-calculated intensities and a halfbandwidth of 10 cm^{-1}. According to a referee suggestion, the computational results[2], both the geometry optimization and the frequency calculations, have been repeated on the simpler *trans*-bis[*O*-methyl-methylphosphonodithioato]Ni^{II} model complex, using BLYP, BPW91, and B3LYP functionals and the same 6–31G(*d*) (23) basis set for all atoms. The first two functionals are pure-DFT functionals, combining the Becke's (25) 1988 exchange functional with the Lee et al.'s (including both local and nonlocal terms) (26), and Perdew and Wang's (27) 1991 gradient-corrected correlation functionals, respectively. The qualitative MO analyses have been obtained by means of Extended Hückel Theory (EHT) (28) using the CACAO (Computer Aided Composition of Atomic Orbitals) program package (29) on the hybrid-DFT optimized geometry, regularized to obtain an idealized C_{2h} symmetry. The interaction diagram was generated using the fragment molecular orbital (FMO) approach (30). Parameters used in EHT calculations were taken from the standard database of CACAO.

*Synthesis of 2,4-diphenyl-[1,3,2,4]-dithiadiphosphetane-2,4-disulfide (**4**)*

Compound **4** was synthesized according to literature methods (31), by reacting $(PhP)_3S_3$ with an excess of elemental sulphur in carbon disulfide.

*Synthesis of $C_{16}H_{20}O_2P_2S_4Ni$ (**3**)*

An excess of $NiCl_2 \cdot 6H_2O$ was reacted with **4** (2.7 g, 8 mmol) in absolute ethyl alcohol solution (100 mL). The filtered solid was recrystallized from CH_2Cl_2–EtOH (1:1 v/v) solution. Yield: 3.56 g, 7.2 mmol, 90%; mp 179°C. FT-IR (3500–450 cm^{-1} KBr; 450–50 cm^{-1} polythene) (cm^{-1}): 3050 (vvw), 3020 (vvw), 2975 (mw), 2930 (w), 2896 (w), 2857 (vvw), 1585 (w), 1571 (vw), 1481 (vw), 1468 (mw), 1449 (w), 1436 (ms), 1389 (m), 1307 (w), 1309 (w), 1282 (vw), 1182 (mw), 1157 (m), 1113 (vs), 1069 (w), 1014 (vs),

[3] Gaussian 98 *z*-matrix input and output file, optimized cartesian coordinates of atoms in complex **2**, list of unscaled calculated harmonic frequencies, IR activity, reduced mass, force constants, and atom displacements for each calculated vibration are available from author on request.

Tests for aromaticity applied to the pentalenoquinones — A computational study

C. Delamere, C. Jakins, and E. Lewars

Abstract: Criteria for aromaticity and antiaromaticity were applied to the four pentalenoquinones, 1,2-, 1,5-, 1,4-, and 1,6-pentalenoquinone, i.e., bicyclo[3.3.0]octa-4,6,8-triene-2,3-dione (**7a**), bicyclo[3.3.0]octa-3,5,8-triene-2,7-dione (**7b**), bicyclo[3.3.0]octa-1(5),3,7-triene-2,6-dione (**7c**), and bicyclo[3.3.0]octa-1(5),3,6-triene-2,8-dione (**7d**). Geometry optimizations and frequency calculations were done with the pBP/DN* DFT method as implemented in Spartan, and single-point HF/3-21G calculations to obtain Löwdin bond orders (Spartan), as well as HF/6-31G* NICS calculations (Gaussian 98) were also carried out. Geometries and bond orders, chemical hardness, and NICS values gave no definite indication of aromatic or antiaromatic character. However, homodesmotic ring-opening reactions to give acyclic analogues indicated that **7a** and **7b** are nonaromatic (resonance energies –11 and 5 kJ mol^{-1}) while **7c** and **7d** are antiaromatic (resonance energies –83 and –54 kJ mol^{-1}). The resonance energies were obtained with the aid of an estimate of the strain energy of the molecules **7** (86 kJ mol^{-1}) by a novel extrapolation procedure on hydropentalenes. Calculated pBP/DN* activation energies for Diels–Alder reactions with ethyne and ethene placed **7a** and **7b** in an "unreactive" class similar to 1,3-butadiene and fulvene, and **7c** and **7d** in a "reactive" class, similar to cyclopentadienone.

Key words: aromaticity, pentalenoquinones, DFT, hardness, NICS, homodesmotic, resonance energy, bicyclo[3.3.0]octatrienediones.

Résumé : On a appliqué les critères d'aromaticité et d'antiaromaticité aux quatre 1,2-, 1,5-, 1,4- et 1,6-pentalénoquinones, soit les bicyclo[3.3.0]octa-4,6,8-triène-2,3-dione (**7a**), bicyclo[3.3.0]octa-3,5,8-triène-2,7-dione (**7b**), bicyclo[3.3.0]octa-1(5),3,7-triène-2,6-dione (**7c**) et bicyclo[3.3.0]octa-1(5),3,6-triène-2,8-dione (**7d**). On a effectué les optimisations de la géométrie et les calculs de fréquences à l'aide de la méthode « pBP/DN* DFT » telle qu'implémentée dans Spartan; on a aussi effectué des calculs ponctuels HF/3-21G pour obtenir les ordres de liaison de Löwdin (Spartan) ainsi que des calculs « NICS » au niveau HF/6-31G* (Gaussian 98). Les géométries et les ordres de liaison, la dureté chimique et les valeurs « NICS » ne donnent aucune indication concernant le caractère aromatique ou antiaromatique des composés. Toutefois, des réactions d'ouverture de cycle homodesmotiques conduisant à la formation d'analogues acycliques indiquent que les composés **7a** et **7b** ne sont pas aromatiques (énergies de résonance de –11 et 5 kJ mol^{-1}) alors que les composés **7c** et **7d** sont antiaromatiques (énergies de résonance de –83 et –54 kJ mol^{-1}). Les énergies de résonance ont été obtenues à l'aide d'une évaluation de l'énergie de tension des molécules **7** (86 kJ mol^{-1}) par le biais d'une nouvelle méthode extrapolation appliquée aux hydropentalènes. Les énergies d'activation calculées par la méthode pBP/DN* pour les réactions de Diels–Alder avec l'éthyne et l'éthène suggèrent que les composés **7a** et **7b** font partie de la classe de composés non réactifs, comme le buta-1,3-diène et le fulvène alors que les composés **7c** et **7d** font partie de la classe des composés réactifs, semblables à la cyclopentadiénone.

Mots clés : aromaticité, pentalénoquinones, « DFT », dureté, « NICS », homodesmotique, énergie de résonance, bicyclo[3.3.0]octatrièndiones.

[Traduit par la Rédaction]

Introduction

In this paper we consider five probes of aromaticity (1–4), namely structure, chemical hardness, magnetic properties, energy relative to an acyclic reference molecule, and reactivity, and apply them to the pentalenoquinones.

We outline these criteria here and discuss them in detail below with reference to the title molecules. The structural criterion tends to manifest itself in the deviation of bond lengths and bond orders from those expected from the normal Kekulé structures. Chemical hardness indicates the resistance of the electronegativity of a molecule to changes in electron density. A hard molecule is like a rigid container that does not yield as electrons are forced in, so the electron density builds up, resisting the ingress of more electrons. This is associated with the relatively large HOMO–LUMO

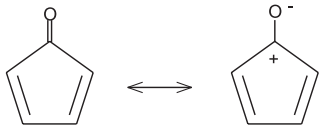
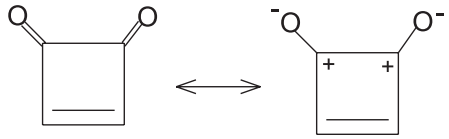
gaps of many aromatic molecules. The magnetic properties of aromatic molecules have been attributed to the presence of a diamagnetic ring current, the shielding effect of which on a nucleus at or above the ring center is readily calculated. Enhanced stability of a cyclic molecule relative to an acyclic reference structure is perhaps the definitive test, and the most satisfying definition, of aromaticity; we use it here as the decisive probe. Finally, chemical reactivity can provide clues to the presence of aromaticity and, more dramatically, antiaromaticity, which latter tends to be associated with extraordinarily high reactivity.



The study of aromaticity (1–4) began with hydrocarbons and moved on to consider monocations and monoanions, then ketones like cyclopropenone and cycloheptatrienone (tropone) which are potentially aromatic by virtue of possessing monocation character. Cyclopropenone (**1**) (5) and cycloheptatrienone (**2**) (6) are at least candidates for aromaticity (the status of cycloheptatrienone in this regard is debatable), because polarization of the C—O bond might confer on them some of the electronic character of, respectively, the cyclopropenyl and cycloheptatrienyl ions (Hückel 4*n* + 2 species) (1). In contrast to the three- and seven-membered ring ketones, cyclopentadienone (**3**) should, if anything, be *destabilized* by *anti*aromaticity (1, 7), since its role model, gratis carbonyl polarization, would be the cyclopentadienyl cation (8), and indeed this ketone is highly reactive (9, 10).

1



2

3

In the conceptual progression from hydrocarbons to ions to ketones, quinones are logically the next candidates for examination for possible aromatic (or antiaromatic) character. In the simplest analysis, quinones corresponding to antiaromatic hydrocarbons are candidates for aromaticity, and quinones corresponding to aromatic hydrocarbons are potentially antiaromatic. Thus, cyclobutadienoquinone (cyclobutenedione) (**4**) and the cyclooctatetraenoquinones (cyclooctatrienediones) (**5a** and **5b**) (Fig. 1), could be aromatic to the extent that the dipolar canonical form contributes to a reasonably planar structure, e.g.,

4

The dications corresponding to **4** (11) and **5a**, **5b** (12) (the cyclobutadiene dication and the cyclooctatetraene dication, respectively) are 4*n* + 2 species, and are possibly aromatic (the unsubstituted cations have apparently not been reported), while the hydrocarbons cyclobutadiene (13) and (the hypothetical) planar cyclooctatetraene are calculated (14, 15) to be antiaromatic. In comparison with the work on cyclopropenone and cycloheptatrienone, little has been reported on the question of aromaticity in quinones. Cyclobutadienoquinones are well-known, but the question of their aromaticity does not appear to have been exhaustively studied (16). The history of the cycloctatetraenoquinones has been briefly reviewed (17). The 1,2-quinone was reported in 1977 (18) and the 1,4-quinone in 1975 (19), but the question of their putative aromaticity was not specifically addressed experimentally, and apparently the only subsequent work on these compounds has been the computational study by Jakins and Lewars (17); this indicated that these quinones are nonplanar and nonaromatic. The quinones of azulene (e.g., the 1,2-quinone **6**, Fig. 1) have been relatively recently the objects of theoretical (20, 21) and experimental (22) work. As derivatives of a 10-π-electron aromatic system, they potentially have 8-π-electron perimeters and might show antiaromatic properties.

This paper addresses primarily the question of the aromaticity of the pentalenoquinones **7** (Fig. 1), using as probes geometries and bond orders (23), chemical hardness (24–26), NICS (nucleus-independent chemical shift) (27–30), a variant of isodesmic reactions (31, 32) similar to that used by Glukhovtsev et al. (15), and Diels–Alder reactivity. We classify these quinones as fulvene-like (**7a**), monocyclopentadiene-like (**7b**), and dicyclopentadiene-like (**7c** and **7d**), and designate them the 1,2-, 1,5-, 1,4-, and 1,6-quinones, respectively, using numbering based on an "aromatic" nucleus (cf. naphthalene) rather than a bicyclo[3.3.0] system. Molecules **7** are formally derivatives of the very antiaromatic pentalene **8** (33), and being almost perforce planar (in contrast to the cyclooctatetraenoquinones), they are reasonable candidates for aromatic properties. However, **7c** and **7d** may electronically resemble cyclopentadienone, rather than being peripherally delocalized, and so could be antiaromatic. In any case, the chemistry of such highly conjugated carbonyl compounds should be interesting. The pentalenoquinones are, structurally, cross-linked cyclooctatetraenoquinones (Fig. 2). Gaviña and co-workers (34–37) have trapped **7c** (34) and **7d** (35) and the 3-phenyl derivative of **7d** (36), all short-lived molecules, and reported for **7d** and its 3-phenyl derivative (and cyclopentadienone and 3-phenylcyclopentadienone) simple Hückel and MINDO/3 calculations (37).

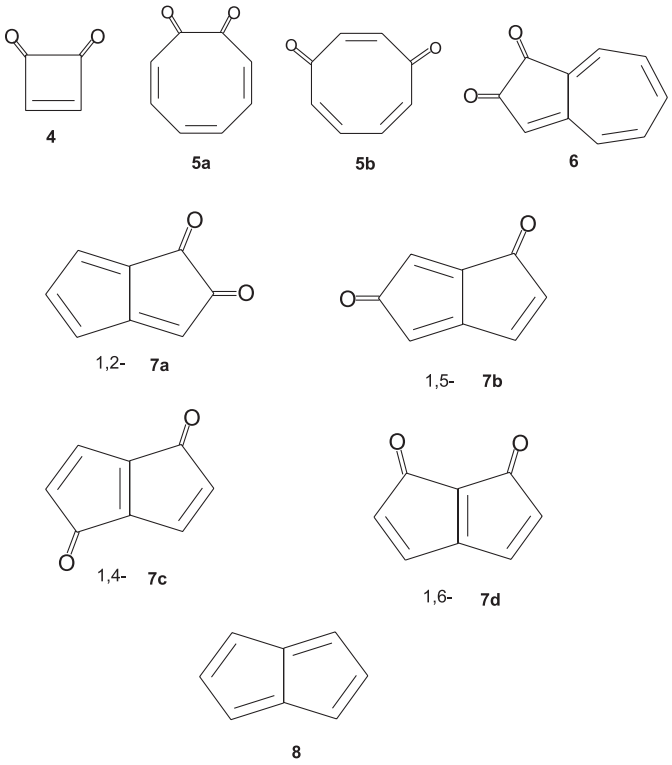
Fig. 1. Quinones corresponding to antiaromatic and aromatic hydrocarbons. Potentially aromatic quinones are **4**, **5**, and **7**. Potentially antiaromatic: **6**. The quinones **7** of pentalene (8) are the subject of this paper.



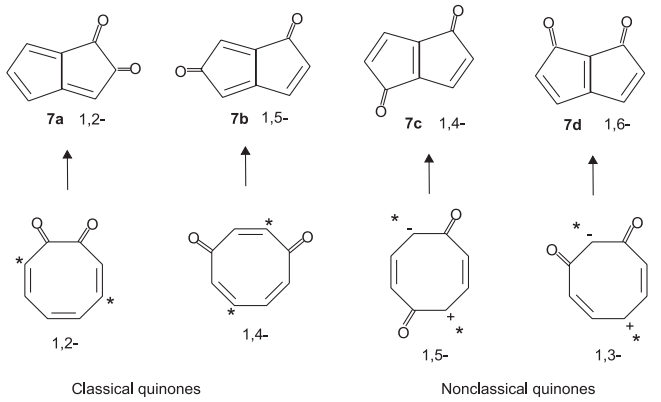


Fig. 2. The pentalenoquinones can be conceptually derived from the quinones of cyclooctatetraene by transannular cross-linking. The fulvene-like (**7a**) and monocyclopentadiene-like (**7b**) quinones are related to normal (classical) cyclooctatetraeneoquinones, while the dicyclopentadiene-like (**7c** and **7d**) quinones are related to dipolar (nonclassical) "quinones" of cyclooctatetraene.

Computational methods

Calculations were done on a 600 MHZ Pentium II computer with the Windows NT operating system. Geometries and frequencies for ab initio (38, 39) and DFT (40 (for ref. 40*a*, see refs. 25–43) calculations were obtained with the program PC Spartan Pro.[2] The DFT calculations, designated in Spartan pBP/DN*, employed the perturbational procedure (41) with the Becke–Perdew B88 and P86 functionals (42) (gradient-corrected but nonhybrid) and the numerical DN* basis set (43). The choice and accuracy of these ab initio and DFT levels are commented on below. Geometry optimizations were followed by frequency calculations (44) at the same level to verify that the structure was the desired relative minimum (no imaginary frequencies) or transition state (one imaginary frequency), and to obtain zero-point energies (ZPEs) to correct the frozen-nuclei energy. The imaginary frequency of each transition state was animated to confirm that it corresponded to the expected reaction coordinate. For pBP/DN calculations, the correction factors for ZPEs and frequencies are expected (45) to be ca. 1.01, and no correction was applied to these. Löwdin bond orders (23) were calculated with Spartan. NICS values (27–30) were calculated with the GIAO method as implemented in Gaussian 94W.[3] The NICS values are at the HF/6-31G*//pBP/DN* level, which we find gives essentially the same results as the levels (HF/6-31G* and HF/6-31+G* on B3LYP/6-31G* and MP2/6-31G* geometries) used in the original (27) work. Absolute total energies, ZPEs, and ZPE-corrected energies are available in the supplementary material tables.[4]

Results and discussion

Reliability of the computational methods

The HF/3-21G ab initio method gives good geometries[5] (46, 47) (almost as good as does the slower HF/6-31G* method), but relative energies of only modest accuracy (46, 47) (comparable to those from HF/6-31G* calculations). The pBP/DN* DFT method, implemented in Spartan in a fast and convenient manner, gives good geometries[5] and remark-

[5] For a set of 20 common organic molecules, we found both HF/3-21G and HF/6-31G* calculations to give bond length errors of ca. 0.01 Å and bond angle errors of 1°; pBP/DN* also gave bond length errors of ca. 0.01 Å (slightly worse than the popular B3LYP/6-31G* method) and bond angle errors of 1°. For four isomerizations we found the pBP/DN* activation energy (a more stringent test for energy difference calculations than reaction energies) to be 5–10 kJ mol^{-1} lower than the B3LYP/6-31G* energy, which in turn was ca. 0–10 kJ mol^{-1} lower than experiment and high-accuracy (50) (CBS-Q and G2) methods.

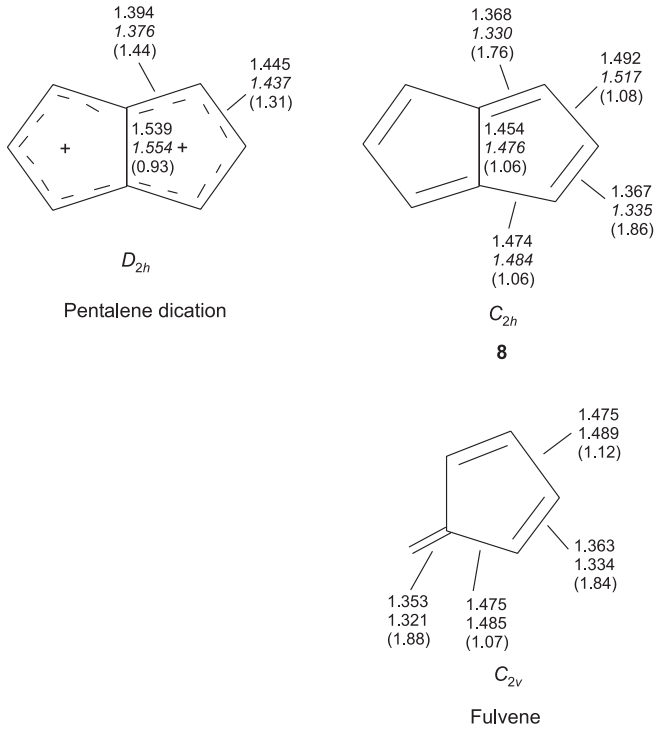
Fig. 3. The pentalenoquinones **7**: bond lengths, bond orders, carbonyl stretching frequencies and symmetries. pBP/DN* and (italics) HF/3-21G bond lengths (Å); Löwdin bond orders (in parentheses) are from HF/3-21G single-point calculations (i.e., geometry unchanged) on the pBP/DN* geometries. The carbonyl stretching vibrations (pBP/DN, cm^{-1}) of **7a**, **7c**, and **7d** are coupled (symmetric and asymmetric), while those of **7b** are essentially independent. Information is also given for the reference molecules **9**–**11**.



ably good energies[5] (48), which are quite similar (49) to those from the B88P86 (i.e., BP86) functional (42) with a 6-311G* basis set. Both HF/3-21G and pBP/DN* geometries should be satisfactory for the conclusions we draw. Realistic absolute energy differences are expected from the pBP calculations, which take correlation energy into account.

Probing electronic structure

Geometry and bond orders

The bond lengths, bond orders, and carbonyl stretching frequencies and symmetry designations of the quinones **7** are shown in Fig. 3, along with the corresponding parameters for the reference molecules *s-trans*-1,3-butadiene (**9**), *s-cis*-1,3-butadiene (**9′**), cyclopentenone (**10**), and cyclopentadienone (**11**). The four quinones are relative potential energy surface minima at the pBP/DN* and HF/3-21G levels (no imaginary frequencies). The bond lengths, and (more obviously) the bond orders, are about as would be expected for normal conjugated ketones. The only clear possible anomalies are the somewhat low frequency of the C-1 carbonyl of **7b**, and the low transannular bond orders (but not lengths) of the formal double bonds of **7c** and, particularly, **7d**. Small changes in bond length can be caused by subtle structural changes and the data in Fig. 3 provide no distinct evidence of unusual effects.

Fig. 4. Pentalene dication, pentalene, and fulvene: bond lengths, bond orders, and symmetries. pBP/DN* and (italics) HF/3-21G bond lengths (Å); Löwdin bond orders (in parentheses) are from HF/3-21G single-point calculations (i.e., geometry unchanged) on the pBP/DN* geometries.

Since any expectation of aromaticity in the quinones **7** is based on the postulate of an aromatic pentalene dication (cf. cycloheptatrienone and the cycloheptatrienyl cation), we give (Fig. 4) results of our calculations on this dication, as well as on pentalene **8** (both were relative potential energy surface minima at the pBP/DN* and HF/3-21G levels) and fulvene, a pentalene subunit. The bond lengths and orders, and the high symmetry of the dication, which lacks any bond length or bond order variation beyond the minimum imposed by the symmetry of a flat bicyclo[2.2.0] system, indicates it to have six-π-electron delocalization around its eight-carbon perimeter, with the transannular bond a single bond. In contrast, pentalene is, like cyclobutadiene (13), a polyene with distinct single and double bonds. The structural criteria, then, are in accord with the view that the dication is aromatic (in agreement with recent conclusions by others (51)).

Hardness

Zhou and Parr (24, 25) have shown that the chemical hardness concept as quantified by Pearson (26) can be a good measure of aromaticity. Hardness (η) is defined in terms of the resistance of chemical potential or electronegativity to a change in electron density, but practical approximate formulas for calculating it are based on HOMO–LUMO energies and on ionization energy and (or) electron affinity (26). The

© 2001 NRC Canada

simple Hückel method (52)[6], used by Zhou and Parr, is not appropriate for molecules like **7**, which are not polyenes or simple heterocyclic derivatives of polyenes, so we calculated hardness from ionization energy and electron affinity:

$$[1] \qquad \eta = \frac{I - A}{2}$$

I and *A* were obtained directly, as pBP/DN* energy differences between the neutrals and the radical ions, all at the geometry of the neutrals (vertical values), not from orbital energies, because while $-E_{HOMO}$ is a fair approximation of *I* (Koopmans' theorem), $-E_{LUMO}$ tends to be a poor approximation of *A* (53). We compare the quinones **7** with one another and with the cyclooctatetraenoquinones **4** and **5** (17). Our *I* and *A* values should be within about 0.2 eV of experimental: cf. other DFT calculations of ionization energies (54) and of electron affinities (55).

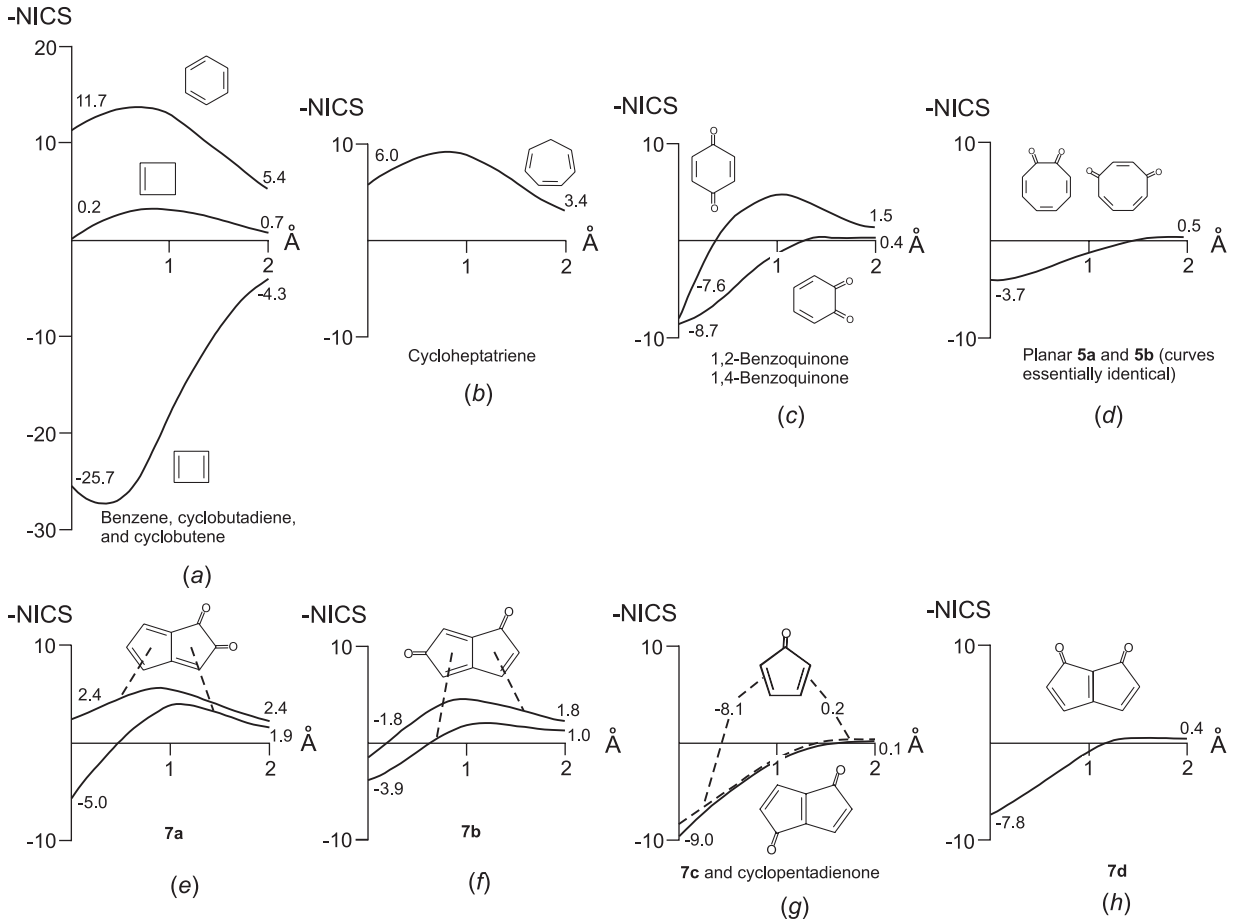
The hardness values provide no reasonable evidence for aromaticity in the pentalenoquinones **7**. This conclusion is based on the similarity of η for the bicyclic (7) and monocyclic (**5a** and **5b**) species: 3.1–3.6 eV cf. 3.6–3.9 eV. The cyclooctatetraenoquinones **5a** and **5b** in their normal, nonplanar conformations are nonaromatic, and even in the hypothetical planar conformations (hilltops with three and two imaginary frequencies, respectively) appear to possess little or no aromaticity. This is indicated (17) by the NICS (27–29) calculations, applied as plots of shielding vs. distance above the ring (30) (NICS curves see below). This conclusion from (17) is reinforced by the fact that there is no significant change in η (less than 0.1 eV) on going from nonplanar to planar **5a** and **5b**. The similarity of η for all eight species suggests that there is no special electronic effect (viz. aromaticity) at work in any of them.

NICS curves

The original (Schleyer et al. (27)) NICS test for aromaticity was based on the shielding of an idealized probe nucleus (56) placed at the center of the ring ("NICS 0"). To avoid local magnetic effects from σ bonds West et al. (28) introduced NICS 2.0, the placing of the probe nucleus 2.0 Å above the center of five-membered rings, and this has also been applied (Veszprémi et al. (29)) to three-membered rings. We use as a probe of aromaticity this very convenient test in the form of a plot of shielding vs. distance above the ring center along a line normal to the ring plane, cf. the method introduced by Morao and Cossio (30) to study aromaticity in transition states. Schleyer et al. (27) defined NICS as the negative of the isotropic shielding, i.e., as –(BQ isotropic), in Gaussian nomenclature. We chose to plot (BQ isotropic) = –NICS vs. distance (plots referred to here as NICS curves), because this gives a positive, roughly Gaussian, curve for the canonical aromatic molecule benzene. Figure 5 shows the NICS curves for **7a**–**7d** and the reference molecules benzene, cyclobutadiene, cyclobutene, cycloheptatriene, 1,2- and 1,4-benzoquinone, planar **4** and **5**, and cyclopentadienone. These curves were constructed from the HF/6-31G*//pBP/DN* NICS values at 0, 0.5, 1.0, 1.5, and 2.0 Å above the ring center. For each molecule the –NICS value at 0.0 and 2.0 Å is given.

Very different looking NICS curves are shown by the aromatic, antiaromatic, and nonaromatic molecules benzene, cyclobutadiene, and cyclobutene, respectively, (Fig. 5*a*). Were these strikingly different patterns general for these three classes of molecules there would be no problem using the shape of the NICS curve as a test for aromaticity. However, this is not the case. The cycloheptatriene curve (Fig. 5*b*) is similar in shape to that for benzene, and while appeal to the controversial notion of neutral homoaromaticity (in the triene (57), or as a general concept (58)) may be a viable option, the curves for the benzoquinones (Fig. 5*c*) also show that the shape of these curves is not really diagnostic for aromaticity; qualitatively, the 1,4-benzoquinone curve somewhat resembles that for benzene, while the 1,2-benzoquinone curve is more like that for a nonaromatic species. Evidently only –NICS 0 values more negative than about –10 can be taken as clear signs of antiaromaticity. The curves for planar (these are hilltops) 1,2- and 1,4-cyclooctatetraenoquinones **4** and **5** (Fig. 5*d*) are as expected for nonaromatic molecules, implying that the actual, nonplanar quinones are nonaromatic (17).

The molecules **7a** and **7b** (Figs. 5*e* and 5*f*) show vaguely Gaussian-shaped curves. These curves, with –NICS 0/ –NICS 2.0 values of –5.0/2.4, 1.9/2.4 (for **7a**) and –1.8/–3.9, 1.8/1.0 (for **7b**), do not provide any particular evidence for either aromatic or antiaromatic character. The molecules **7c** and **7d** (Figs. 5*g* and 5*h*) show curves very similar to that of cyclopentadienone (also shown). Interestingly, the cyclopentadienone NICS curve is itself essentially the same as that for 1,2-benzoquinone (Fig. 5*c*), another species with high Diels–Alder reactivity (59). We tentatively take this as an indication of cyclopentadienone character and a harbinger (below) of high Diels–Alder reactivity in **7c** and **7d**. The NICS curve for the pentalene dication indicates aromaticity: dication, NICS 0 = 5.9, NICS 2.0 = 5.5, cf. benzene 11.7 and 5.4.



Homodesmotic aromatic stabilization energies

The most direct computational test for aromaticity is to see if the cyclic molecule enjoys distinct energetic stabilization compared to an acyclic analogue. This stabilization can be calculated as the strain-corrected (below) energy of a ring-opening reaction which, formally, preserves the numbers of each kind of bond. These *homodesmotic* reactions have been shown by Glukhovtsev et al. (15) to be a good measure of aromatic stabilization and antiaromatic destabilization. For example, to calculate the homodesmotic stabilization energy (HSE) of benzene these workers use the reaction in Scheme 1*a*. On each side of the equation there are, formally, six C—C double bonds, three sp^2-sp^2 C—C bonds, and 18 C(sp^2)—H bonds. Preserving "hybridization pairs" minimizes energy changes due just to bond energy changes (e.g., an sp^2-sp^2 C—C bond is stronger than the corresponding sp^3—sp^3 bond (60)) and should reflect π electron interaction effects. We use a similar but simpler scheme in which the cyclic molecule is opened to an all-*trans* acyclic analogue with the same number of atoms plus two hydro-

Fig. 5. NICS curves (actually –NICS, see text) for benzene, cyclobutadiene, cyclobutene, cycloheptatriene, 1,2- and 1,4-benzoquinone, planar **5a** and **5b**, and the pentalenoquinones **7**, and cyclopentadienone. The –NICS values at 0.0 and 2.0 Å above the ring centers are given.

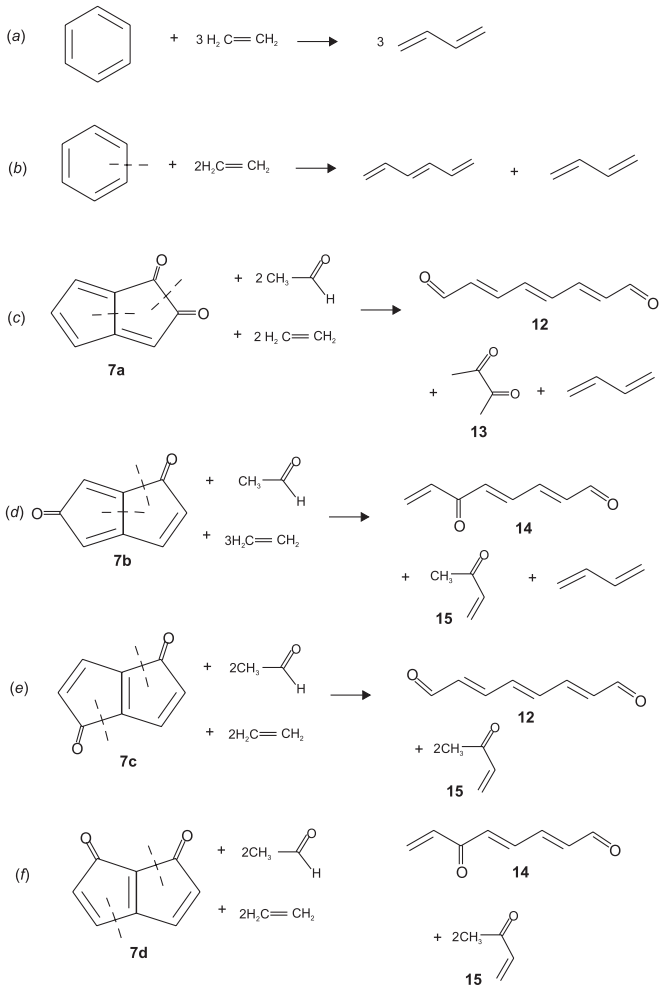
gens (Scheme 1*b*). In effect an sp^2-sp^2 C—C bond is broken using two hydrogens and an sp^2-sp^2 C—C bond is formed. At the pBP/DN* level, the HSE (the reaction energy) for (*a*) and (*b*) is 97.0 and 94.0 kJ mol^{-1}, respectively. Opening cyclobutadiene with two ethenes gives, at the same level, an HSE of –320 kJ mol^{-1}. Adding an estimated strain energy (SE) of 141 kJ mol^{-1} (15) gives –179 kJ mol^{-1} as HSE of cyclobutadiene. Compared to (*E*)-1,3,5-hexatriene, benzene is electronically stabilized by ca. 94 kJ mol^{-1} (the strain energy should be small) and compared to 1,3-butadiene cyclobutadiene is destabilized by ca. 179 kJ mol^{-1}. These numbers are very close to those calculated at the MP4SDTQ/6-31G**//MP2/6-31G** level (15). The resonance energies of benzene and of cyclobutadiene could reasonably be taken as ca. 94 and –179 kJ mol^{-1} kJ mol^{-1} (there is no single, correct definition of resonance energy (1)).

For the quinones **7**, we unzip the molecule with two pairs of hydrogens with concomitant formation of a formally identical pair of C—C bonds (Scheme 2*c*–*f*). This conserves formal conjugation involving C—C and C—O bonds and the HSE corrected for strain should reflect *cyclic* electron interaction effects, which can reasonably be considered as resonance energies; the term will be used in this sense here. Isodesmic reactions in general are not unique. They cannot be implemented unambiguously, by an algorithm, but rather sometimes require one to choose one of several possibilities; they do not represent a *model chemistry* (61). We have chosen to open **7a**–**7d** to give acyclic unbranched fully conjugated molecules, since these should be the appropriate analogs of the bicyclic species. We regard simple opening to the acyclic analogue with the same number of carbons as the most readily apprehended test of aromaticity, and concur that "The HSE (HHSE) scheme … apparently … has become the most dependable tool for obtaining numerical values of RE." (62). We applied homodesmotic reactions to estimate the resonance energies of the pentalenoquinones **7**, using the reactions of Scheme 1. Table 1 gives HSEs calculated from the ZPE-corrected pBP/DN* energies, and resonance energies calculated from the HSEs and the strain energy (below). An example of the calculation of the HSE is given in eq. [2]; using Scheme 1 and the ZPE-corrected absolute energies:

$$\begin{aligned}[2]\quad \text{HSE}\ (\mathbf{7a}) &= (E\ (\mathbf{12}) + E\ (\mathbf{13}) + E\ (\text{butadiene})) \\ &\quad -(E\ (\mathbf{7a}) + 2E\ (\text{ethanal}) + 2E\ (\text{ethene})) \\ &= -922.53187 - (-922.49488)\ \text{h} \\ &= -0.03699\ \text{h} \\ &= -0.03699 \times 2625.5\ \text{kJ mol}^{-1} \\ &= -97.1\ \text{kJ mol}^{-1}\end{aligned}$$

© 2001 NRC Canada

Scheme 1. Reactions are used to calculate homodesmic stabilization energies. The schemes *c–f* used in this paper are based on the type of ring-opening shown in *b*.



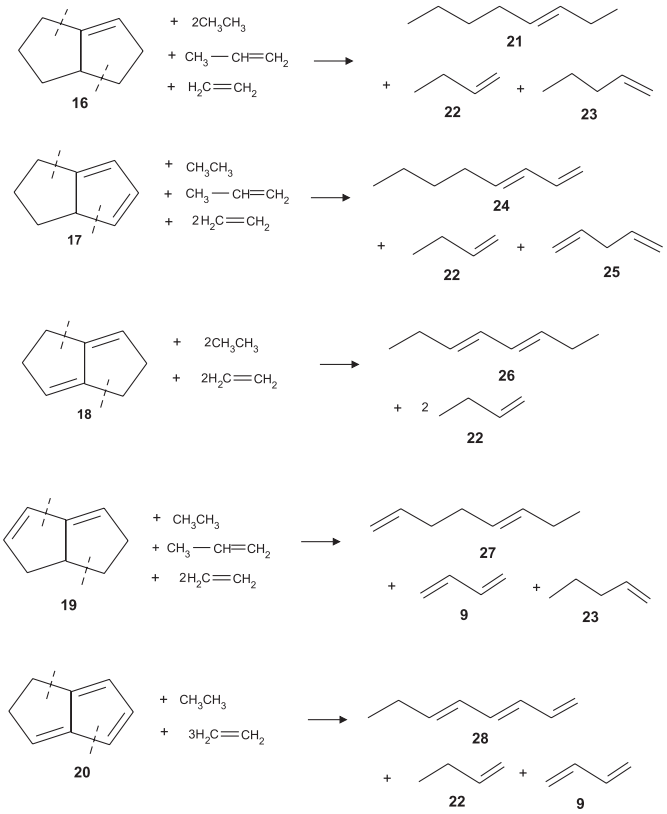


Table 1. Homodesmotic stabilization energies (HSE) and resonance energies (RE) (kJ mol^{-1}) of **7a**–**7d**.

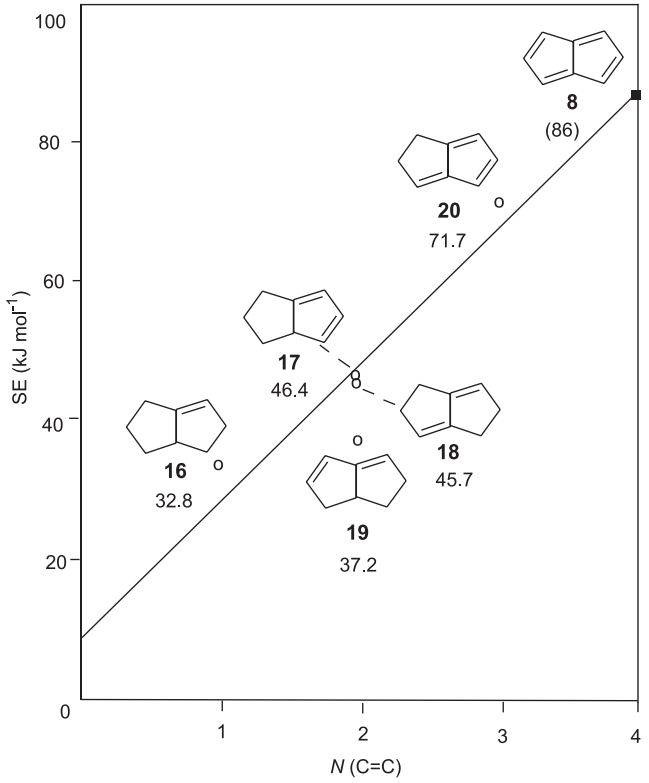
Molecule	HSE	RE
7a	–97.1	–97.1 + 86 = –11
7b	–80.7	–80.7 + 86 = 5
7c	–169.1	–169.1 + 86 = –83
7d	–140.0	–140.0 + 86 = –54

Note: HSE was calculated using the reactions of Scheme 1 and ZPE-corrected pBP/DN* energies. RE is the sum of HSE and strain energy, which latter is estimated to be 86 kJ mol^{-1} (Fig. 6).

The resonance energy, the measure of aromaticity that we seek, is the HSE *plus* any strain energy in the cyclic species (we take the acyclic molecules to be strainless). Thus a negative HSE (a drop in energy) could be due to loss of antiaromatic destabilization, or it could be partially or wholly due to relief of strain; adding the strain energy to the HSE should leave us with the resonance energy. There is no unique definition of strain energy (63). Our purpose here is to disentangle cyclic electron interaction from strain, which appears intuitively to be associated with the σ-bond skeleton. We calculate strain energy (SE) by sneaking up on it: the

Scheme 2. The homodesmotic reactions used to calculate the strain energy (SE) of **16**–**20** (and, by extrapolation (Fig. 6), the strain energy of pentalene (**8**).



ring-opening HSE of a series of increasingly unsaturated hydropentalenes (Scheme 2) was extrapolated to the fully conjugated cyclic molecule to give an estimate (86 kJ mol^{-1}) of the SE of the putative aromatic or antiaromatic molecule: –HSE, *in the absence of any cyclic electron interaction effects*. Since the SE of a strained ring is always positive (opening a strained ring is exergonic), our SE is the extrapolated value of –HSE (*E* (reactants) – *E* (products)). We assume that the SE of the four quinones **7** is about the same as that of pentalene (**8**). The calculated SEs and the extrapolation to the SE of pentalene are shown in Fig. 6.

In estimating the SE of pentalene we avoided molecules with ring-fusion tetrahedral carbons, to sidestep the question of whether to use *cis*- or *trans*-ring fusion. Also, for consistency, double bonds were progressively added to the perimeter, maintaining conjugation. The discrepancy between the SE of the tetrahydropentalenes **17** and **18** (46.4 and 45.7 kJ mol^{-1}) and that of **19** (37.2 kJ mol^{-1}), 9 kJ mol^{-1}, is probably comparable to the error in the HSEs (the differences in 0 K enthalpies), which could well differ from experiment by about 10 kJ mol^{-1} (64). A common way of calculating strain energy is to equate it to the difference between the calculated heat of formation and the heat of formation of a hypothetical strainless structure, obtained by summing the heats of formation of appropriate molecular fragments (65). While this approach could be used for **16**–**20**, for **8** the discrepancy from the hypothetical structure would represent a mixture of strain and antiaromaticity. Our extrapolation approach avoids performing calculations on

© 2001 NRC Canada

Fig. 6. Strain energy of hydropentalenes (kJ mol^{-1}) vs. number of peripheral conjugated C—C double bonds. Extrapolation to N (C=C) = 4 for **8** gives SE = 86 kJ mol^{-1}. The correlation coefficient r^2 of this least-squares extrapolation line is 0.987.

molecules with cyclic delocalization, and consistently uses the same kind of homodesmic ring-opening reactions to calculate SEs in **16**–**20** as was used to obtain the HSEs of the quinones **7**.

Although the purpose of our extrapolation method is not to find "the" strain energy of the pentalene system, but rather what the HSE would be in the absence of antiaromaticity, we briefly supply a check on how HSE ring-opening energies compare with conventional strain energies from heats of combustion.

In Table 2, strain energies are estimated from heats of combustion per CH_2 group for cyclopropane–cyclohexane (66), and compared with HSE strain energies. The (relative to cyclohexane) SEs by the two methods are quite similar. The largest difference is 18 kJ mol^{-1}, and the biggest *change* in relative SE is only 12 kJ mol^{-1}, from cyclopentane to cyclobutane: 82 cf. 70 kJ mol^{-1}. This lends some confidence to the claim that our HSE method really calculates SE.

Adding the HSE to the SE gives the RE. These are shown for the quinones **7** in Table 1. The RE values indicate that **7a** and **7b** are essentially nonaromatic (–11 and 5 kJ mol^{-1}, respectively) and **7c**, particularly, and **7d** (–83 and –54 kJ mol^{-1}, respectively), are antiaromatic. For perspective, in considering the RE values in Table 1, recall that these ring-opening schemes with the pBP/DN* method give benzene and cyclobutadiene REs of 94 and –179 kJ mol^{-1}, respectively, (section **3a** (**4**)). It is instructive to compare the REs of **7a**–**7b** with their relative DFT energies. If all four molecules have about the same strain, the differences in "absolute" energies,

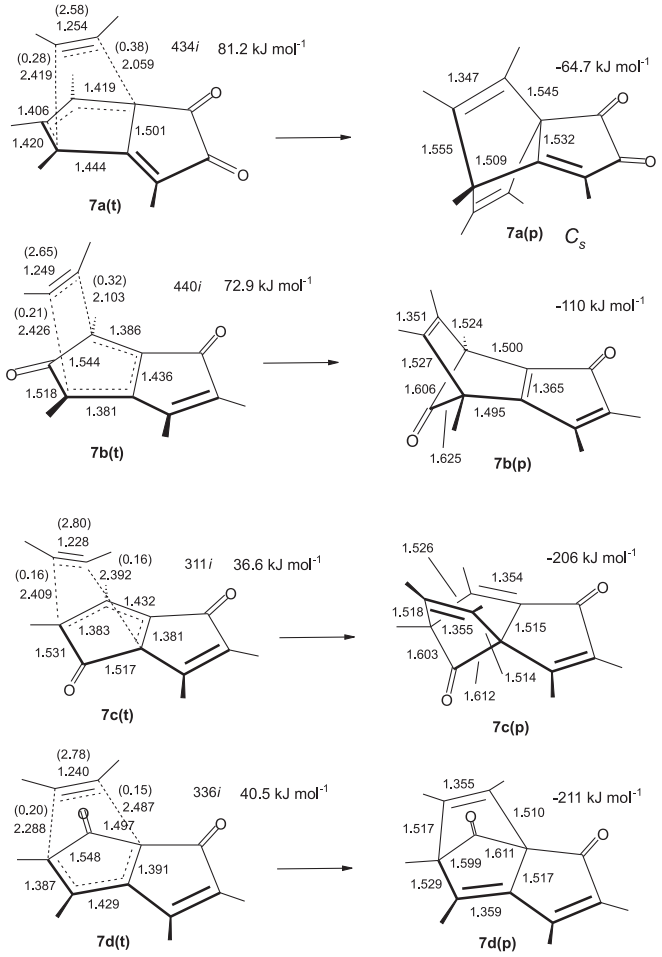
Table 2. Strain energies (SE, kJ mol^{-1}) of cyclopropane–cyclohexane estimated from heats of combustion (ΔH_c) and from pBP/DN* HSEs.

Ring size	$\Delta H_c/CH_2$	Relative $\Delta H_c/CH_2$	Relative SE From ΔH_c	From HSE
3	695.8	37.2	112	99.1
4	685.8	27.2	109	90.6
5	664.0	5.5	27	20.5
6	658.6	0.0	0.0	0.0

Note: For the HSEs, the ring C—C bond was cleaved with 2 CH_3CH_3 to give the acyclic alkane + butane. The relative ΔH_c SE is taken as the number of CH_2 groups × relative $\Delta H_c/CH_2$. The actual (not relative) HSE SE for cyclohexane was 0.95 kJ mol^{-1}.

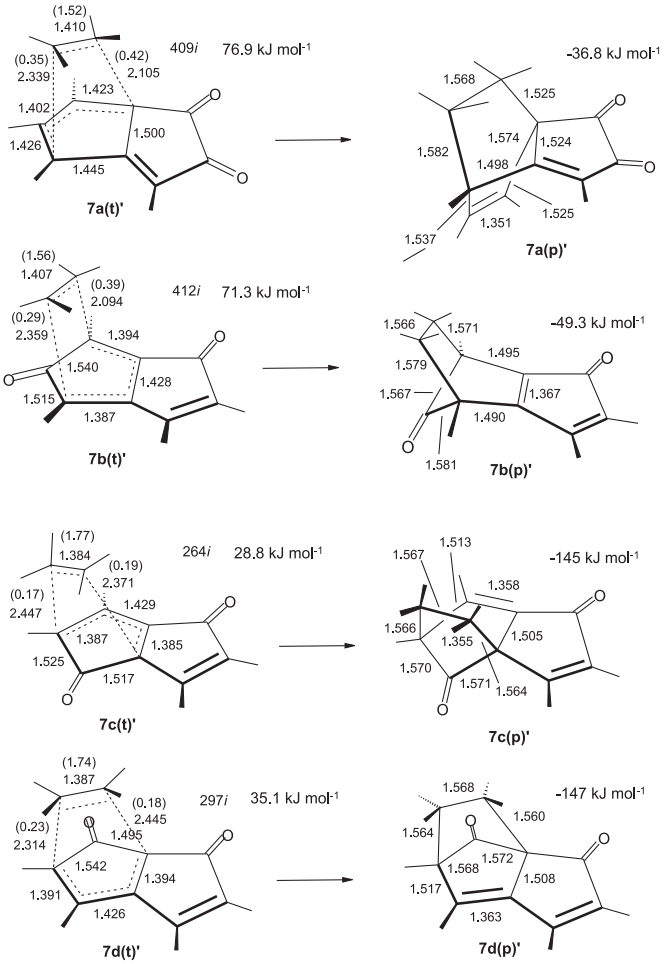
Table 3. Relationship between the DFT (pBP/DN*) energies of the quinones **7** (ZPE-corrected) and their (Table 1) resonance energies.

Molecule	DFT energy	Relative DFT energy	RE
7a	–457.71060	1	–11
7b	–457.71098	0	5
7c	–457.68567	–66	–83
7d	–457.68825	–60	–54



Note: The relative DFT energy of a quinone **7** is E (**7b**) – E (**7**), **7b** being the isomer of lowest energy. The DFT energies are in hartrees and the others in kJ mol^{-1}.

i.e., the relative DFT energies, should reflect the *differences* in aromaticity (or antiaromaticity). In Table 3, we compare the relative DFT energies with the REs calculated by these somewhat elaborate procedures. The maximum discrepancy is 17 kJ mol^{-1} (–66 cf. –83 kJ mol^{-1}), and the comparison is quantitatively in accord with the view that **7a** and **7b** are nonaromatic, while **7c** and **7d** are antiaromatic. The tolerable agreement between the relative energies and the REs should not be obtained if the SEs (which are incorporated in the REs) were actually very different from our estimated value. Note that in contrast to the more hard-won REs, the relative energies by themselves do not reveal the aromatic stabilization or antiaromatic destabilization of the quinones: they tell us only that **7a** and **7b** are of about the same energy, and **7c** and **7d** are about 60 kJ mol^{-1} less stable. For example, as far as the relative energies go, **7a** and **7b** might be aromatically stabilized, and **7c** and **7d** simply nonaromatic.



One possible complication for **7a** is that dipole–dipole repulsion of the proximal carbonyl groups raises the strain energy of this molecule above that due just to angle strain. An estimate of this dipole–dipole strain was made by comparing the energies of planar *s-cis*- and *s-trans*-ethanedial (glyoxal). The pBP/DN* energy of the *s-cis* conformer (C_{2v}, no imaginary frequencies) was found to be 18.6 kJ mol^{-1} higher than that of the *s-trans* conformation (C_{2h}, no imaginary frequencies). Raising the SE of **7a** by 19 kJ mol^{-1} gives a SE of 86 + 19 kJ mol^{-1} = 105 kJ mol^{-1}. This would give a RE of –97.1 + 105 kJ mol^{-1} = 8 kJ mol^{-1}, rather than –11 kJ mol^{-1}, which makes no difference to the above arguments (in fact, it makes **7a** and **7b** even more similar).

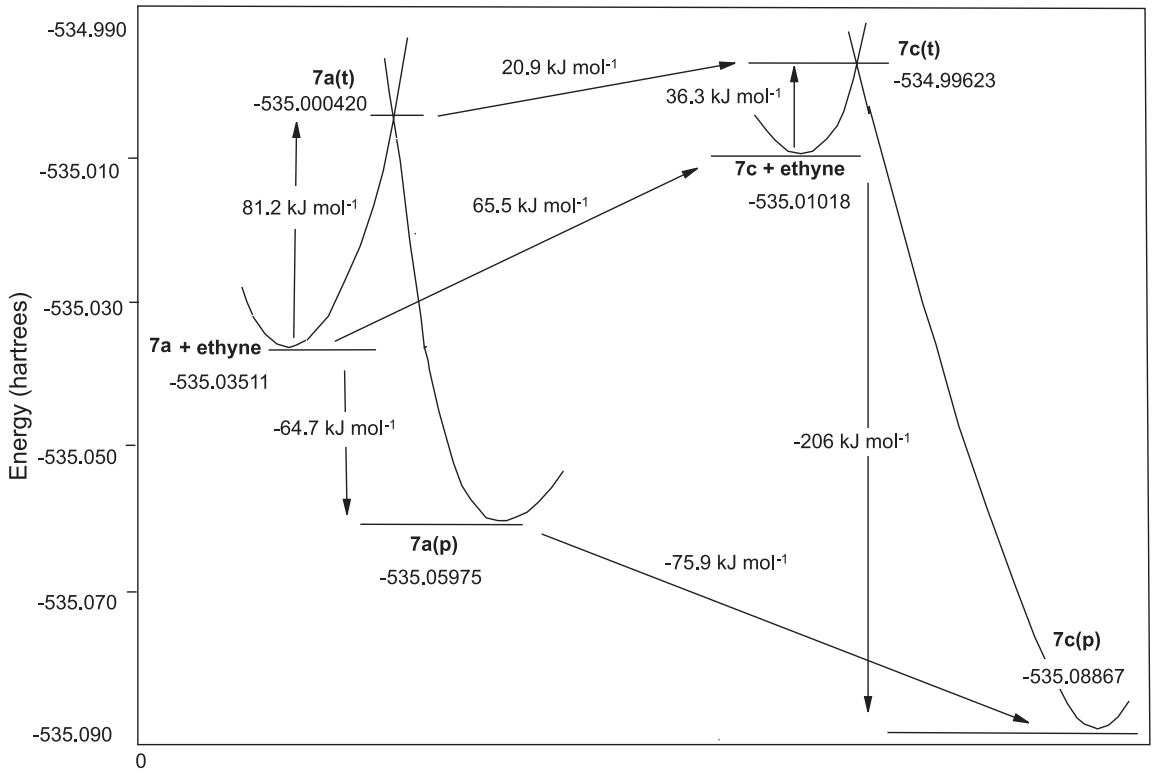
Scheme 3. Selected C—C bond lengths (Å) and (parentheses) Löwdin bond orders of transition states and products from Diels–Alder reactions of **7a**–**7b**, with the quinones acting as dienes toward the dienophile ethyne. The hydrogens at the ends of the C—H bonds have been omitted for clarity. All species are of C_1 symmetry except **7a(p)** (C_s). The imaginary frequency of each transition state is given, as well as, beside each transition state and product respectively, the activation energy and the reaction energy. pBP/DN* calculations.

Scheme 4. Selected C—C bond lengths (Å) and (parentheses) Löwdin bond orders of transition states and products from Diels–Alder reactions of **7a** and **7b**, with the quinones acting as dienes toward the dienophile ethene. The hydrogens at the ends of the C—H bonds have been omitted for clarity. All species are of C_1 symmetry. The imaginary frequency of each transition state is given, as well as, beside each transition state and product, respectively, the activation energy and the reaction energy. pBP/DN* calculations.

Diels–Alder reactivity



The four quinones can in principle undergo the Diels–Alder reaction. Indeed, **7c** and **7d** (34, 35) and the 3-phenyl derivative of **7d** (36) have been trapped as both dienes and dienophiles. Considering **7a**–**7d** as potential dienophiles, if we limit ourselves to those C—C double bonds in immediate conjugation with a carbonyl group then the number of different possible ways the quinones can act as dienophiles is: **7a** 2, **7b** 3, **7c** 2, **7d** 2.

Limiting ourselves to the stereochemically feasible cycloaddition to an *s-cis* moiety, the number of different ways each quinone can act as a *diene* is only one. To facilitate a simple comparison of the Diels–Alder reactivity of the four quinones, we therefore examined computationally the reactivity of **7a**–**7d** and related molecules as dienes, using ethyne and ethene as the dienophiles. The results of these calculations are given in Schemes 3 and 4.

From Scheme 3, the Diels–Alder **7**–ethyne transition states fall into two groups: **7a(t)** and **7b(t)** are (the terms are used here semiquantitatively for descriptive purposes and should not be taken too literally) high-frequency, high-activation energy, and lead to mildly exothermic reactions, while **7c(t)** and **7d(t)** are low-frequency, low-activation energy, and lead to strongly exothermic reactions. In the first group, the imaginary frequency (in all cases animation confirmed that this corresponded to the formation of the two new bonds in a Diels–Alder cycloaddition) is ca. 437*i*, the activation energy is ca. 75 kJ mol^{-1}, and the reaction is 65–110 kJ mol^{-1} exothermic. In the second group, the imaginary frequency is ca. 324*i*, the activation energy is ca. 40 kJ mol^{-1}, and the reaction is ca. 210 kJ mol^{-1} exothermic. Evidently **7a** and **7b** are kinetically and thermodynamically significantly less reactive dienes than **7c** and **7d**. The frequency of a vibrational mode is an indication of the curvature of the potential energy hypersurface along that direction, since fre-

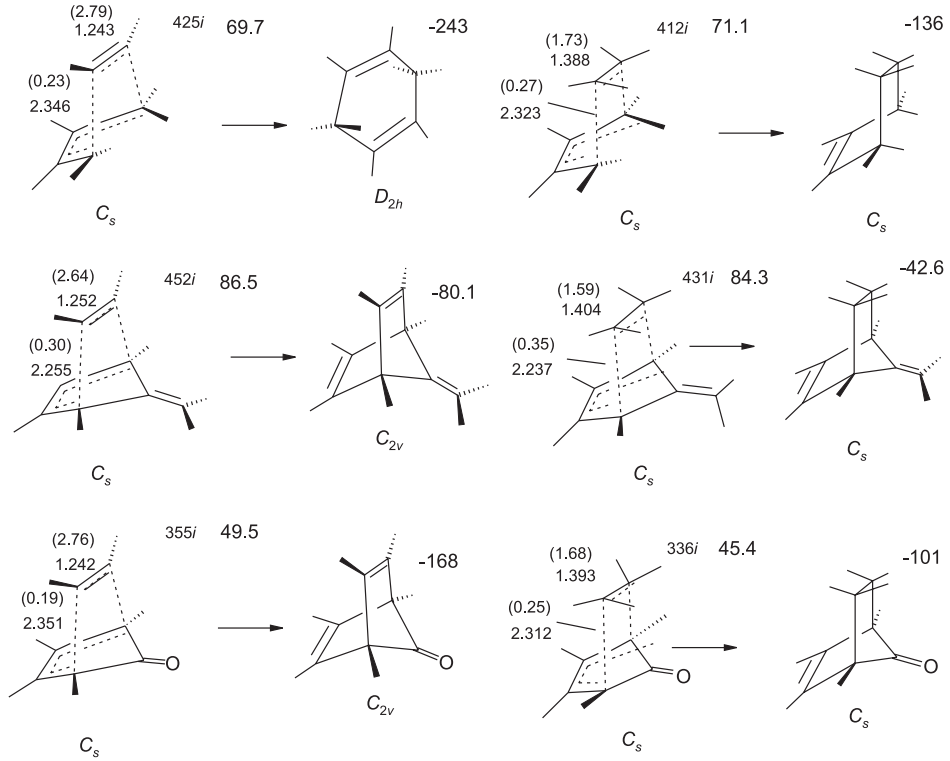
Fig. 7. Change in reaction profile on going from the **7a**–ethyne reaction to the **7c**–ethyne reaction. The transition states are approximated as the crossing points of the reactant and product reaction coordinate curves. Transition state **7c(t)** is "dragged down" by the low-energy product **7c(p)**.

quencies are proportional to (mass-weighted) second derivatives of energy with respect to geometry (67). Relatively "large" imaginary frequencies tend to correspond to relatively high curvature of the potential energy surface along the reaction coordinate in the region of a somewhat late transition state; this also corresponds to a relatively high activation energy and tends to correspond to a relatively weakly exothermic reaction (68). The electronic structures of the transition states agree with this interpretation. Bond orders provide a measure of the lateness of the transition state (69). One can consider the sum of the bond orders of the two forming single bonds, or the bond order of the ethyne central bond. For **7a(t)** and **7b(t)**, the sum of the bond orders for the forming single bonds is 0.28 + 0.38 = 0.66, and 0.21 + 0.32 = 0.53, respectively. For **7c(t)** and **7d(t)**, it is 0.16 + 0.16 = 0.32, and 0.20 + 0.15 = 0.35, respectively. The ethyne C—C bond order is ca. 2.6 for the former two, and ca. 2.8 for the latter two. Bond lengths also are (albeit less obviously) in accord in accord with **7c(t)** and **7d(t)** being earlier than **7a(t)** and **7b(t)**. For example, the ethyne moiety in **7c(t)** and **7d(t)** has a shorter C—C bond than in the other two. For **7c(t)** and **7d(t)** too, the forming C—C bonds are seen to have to "travel" a greater distance toward the bond lengths in the products, if one compares the sum of the bond lengths in the transition state with that in the corresponding product: Σ (lengths in ts) – Σ (lengths in product) (Å): **7a(t)** 1.37, **7b(t)** 1.48, **7c(t)** 1.77, **7d(t)** 1.75.

The long single bond lengths to one of the carbonyl groups in **7b(p)**, **7c(p)**, and **7d(p)**, ca. 1.6 Å, can be ascribed to these bonds being those that tether the carbonyl group in a norbornadienone, a system where these bonds break exceedingly readily with extrusion of carbon monoxide and formation of a benzene ring (70). The corresponding pBP/DN* lengths in norbornadienone itself and in norbornenone are 1.594 and 1.557 Å, respectively.



We also performed calculations on the Diels–Alder reactivity of the quinones **7** with ethene (rather than ethyne). The results are summarized in Scheme 4, which shows the transition states **7(t)′** and products **7(p)′**. The geometric and energetic similarities between the ethyne and ethene reactions are clear. For these Diels–Alder reactions, then, activation and reaction energies, transition state imaginary frequencies, and bond lengths and orders all support the conclusion that **7a(t)** and **7b(t)** are significantly less reactive dienes than **7c(t)** and **7d(t)**.

A referee invoked the Bell–Evans–Polanyi principle (71) and suggested[7] that the lower activation barriers for **7c** and **7d** compared to **7a** and **7b** may be due to the greater product stability for the **7c** and **7d** reactions, and so may not really reflect electronic destabilization in going from **7a** or **7b** to **7c** or **7d**. This may well be the case, as shown by Fig. 7, which depicts changes in absolute DFT energies on going from the **7a** reaction to the **7c** reaction, with the dienophile ethyne (the situation is similar for the other high-barrier and

[7] We thank the referee for this suggestion.

Scheme 5. Selected C—C bond lengths (Å) and (parentheses) Löwdin bond orders of transition states and products from Diels–Alder reactions of 1,3-butadiene, fulvene, and cyclopentadienone with ethyne and with ethene. The hydrogens at the ends of the C—H bonds have been omitted for clarity. The imaginary frequency of each transition state is given, as well as, beside each transition state and product, respectively, the activation energy and the reaction energy. pBP/DN* calculations.

low-barrier pairs, and for the ethene reactions); the transition state is approximated by the crossing of reactant and product reaction coordinate curves. Going from the **7a** to the **7c** reaction, both the reactant energy (taken as the pentalenequinone energy plus the ethyne energy) and the transition state energy increase, but the transition state energy increases less, apparently because it is "dragged down" by the product.

To put these results for the Diels–Alder reactions of ethyne and ethene with the quinones **7** in perspective, we compared them with pBP/DN* calculations on the more familiar Diels–Alder reactions of ethyne and ethene with 1,3-butadiene (the prototypical reactions), with fulvene (cf. the fulvenoid diene system of **7a**), and with cyclopentadienone (cf. the cyclopentadienone systems of **7b**–**7d**). The results of these model calculations are given in Scheme 5. The magnitude of the imaginary frequencies and the bond lengths and orders, and particularly the activation energies, indicate that the cyclopentadienone–ethyne transition state is earlier and of lower activation energy than those for butadiene and fulvene, and of course cyclopentadienone is known to be extraordinarily reactive as a diene (10). The activation and reaction energies place **7c** and **7d** in the same class as cyclopentadienone, with the quinones being a bit more reactive. The butadiene–ethene reaction seems to be anomalous in that its activation energy is between that for fulvene and cyclopentadienone, yet it is more exothermic than the fulvene reaction. That **7a** and **7b** are of the same energy (to within 1 millihartree, 3 kJ mol^{-1}), and that **7b** is calculated to be only slightly more reactive as a Diels–Alder diene than **7a** (activation energy 72.9 cf. 81.2 kJ mol^{-1}), is surprising considering that, formally, **7b** is a cyclopentadienone and **7a** is a fulvene.

The pBP/DN* method may give somewhat low values for Diels–Alder activation energies; for the butadiene–*ethene* reaction, the experimental activation and reaction energies are (72) 105 and –167 kJ mol^{-1}, cf. the pBP/DN* values of 71.1 and –136 kJ mol^{-1}, respectively. However, for a series of molecules, all using this method, comparisons should be reliable. These pBP/DN* parameters are better than those from high-level ab initio (CASSCF) calculations, which gave activation and reaction energies of 156 and –109 kJ mol^{-1}, respectively (72).

There is a relationship between the dienophile LUMO – diene HOMO energy gap and the rates of Diels–Alder reactions (the smaller the gap, the faster the reaction) (73). For the pentalenoquinones reacting with ethyne and with ethene, the activation energy does indeed decrease as the dienophile LUMO – diene HOMO gap decreases. For the reaction with ethyne we have (in the order **7a**, **7b**, **7d**, **7c**) LUMO-(dienophile)–HOMO(diene), eV/activation energy, kJ mol^{-1}: **7a** 15.35/81.2, **7b** 15.28/72.9, **7d** 15.03/40.5, **7c** 14.79/36.6. For the reaction with ethene: 14.32/76.9, 14.25/71.3, 14.00/35.1, 13.76/28.8.

Conclusions

Criteria for aromaticity were applied to the pentalenoquinones **7a**–**7d** using primarily pBP/DN* DFT calculations. Five molecular characteristics were examined: structure

© 2001 NRC Canada

(bond lengths and bond orders), chemical hardness, nucleus-independent chemical shift (NICS) curves, resonance energies (REs), and Diels–Alder reactivity toward dienophiles (ethyne and ethene). The bond lengths and orders and the hardness values gave no obvious indication of unusual electronic characteristics. The NICS curves are intriguing but do not provide any definite evidence for aromaticity or antiaromaticity in the quinones, beyond suggesting that **7c** and **7d** are electronically cyclopentadiene-like, in contrast to **7a** and **7b**.

The clearest evidence for the electronic nature of the pentalenoquinones comes from their calculated REs. These were obtained by adding the strain energy (SE) to the homodesmotic energy change for ring-opening to an acyclic analogue. The SE was taken as that of pentalene, which was estimated by calculating SE as the homodesmotic energy decrease on ring-opening of a series of hydropentalenes and extrapolating to a hypothetical nonantiaromatic pentalene. The REs of **7a** and **7b** are not significantly different from zero, indicating they are simply nonaromatic, but those of **7c** and **7d** are –83 and –54 kJ mol^{-1}, respectively, indicating antiaromaticity. The REs are comparable to the simple relative energies of the quinones, indicating that the values calculated by this somewhat elaborate procedure are meaningful.

The calculated Diels–Alder activation energies (with the quinones acting as dienes), too, divide **7a** and **7b** from **7c** and **7d**. The former pair have activation energies with ethyne (the values with ethene are similar) of ca. 75 kJ mol^{-1}, the latter ca. 40 kJ mol^{-1}. The "unreactive" former pair are similar in activation energies to 1,3-butadiene and fulvene, the "reactive" latter pair to cyclopentadienone. The possibility that the lower activation energies of **7c** and **7d** is due to the greater product stability makes it uncertain to what extent these energies reflect electronic destabilization.

Oxidative coupling of naphtho-9-crown-3 ether: X-ray crystal structure and solution and solid-state NMR analysis of the dimer

G.W. Buchanan, M.F. Rastegar, G.P.A. Yap, A. Moghimi, and M. Ghandi

Abstract: Treatment of naphtho-9-crown-3 ether with $FeCl_3$ and aqueous H_2SO_4 generates bis-naphtho-9-crown-3 ether in ca. 30% yield. This compound crystallizes in the monoclinic $P2_1/n$ space group; a = 9.2004(9), b = 18.0868(17), and c = 13.2078(13) Å, β = 97.799(2)° and Z = 4. ^1H and ^{13}C NMR data have been obtained in solution, and the solid-state ^{13}C NMR spectrum is included for comparison. A chemical shift range of ca. 12 ppm has been found for the oxygenated aliphatic carbons in the solid state, in contrast to the 3 ppm range in the solution ^{13}C NMR spectrum. These results are discussed in terms of the torsional environments of the carbon sites in the crystal structure.

Key words: crown ether, stereochemistry, oxidative dimerization.

Résumé : Le traitement de l'éther naphto-9-couronne-3 par du $FeCl_3$ et du H_2SO_4 aqueux conduit à la formation de l'éther bis-naphto-9-couronne-3 avec un rendement d'environ 30%. Ce composé cristallise dans le groupe d'espace $P2_1/n$ avec a = 9,2004(9), b = 18,0868(17) et c = 13,2078(13) Å, β = 97,799(2)° et Z = 4. On a mesuré les spectres RMN du ^1H et du ^{13}C en solution et on a aussi déterminé le spectre RMN du ^{13}C à l'état solide. Dans les spectres RMN du ^{13}C à l'état solide, les déplacements chimiques des carbones aliphatiques oxygénés sont de l'ordre de 12 ppm alors qu'en solution on les retrouve vers 3 ppm. On discute de ces résultats en termes de l'environnement torsionnel des sites carbonés dans la structure cristalline.

Mots clés : éther couronne, stéréochimie, dimérisation oxydante.

[Traduit par la Rédaction]

Introduction

Recent work from these laboratories (1) described the results of oxidative trimerization of benzo-9-crown-3 ether leading to a novel tris(9-crown-3)triphenylene system. We are interested in comparing the behaviour of the corresponding naphtho-9-crown-3 system, to determine if extended conjugation would lead to a similar type of trimerization, in which case enhanced liquid crystalline properties could result due to the increased propensity for π stacking between layers of the aromatic rings.

Results and discussion

The synthesis, NMR spectra, and X-ray crystal structure of naphtho-9-crown-3 ether (**1**), have been reported previously (2, 3). In the current study, we have found that **1**, in the presence of $FeCl_3$ and aqueous H_2SO_4 at 313 K, dimerizes in 30% yield to afford the bis-naphtho-9-crown-3 system (**2**). This is in contrast to the benzo-9-crown-3 analog, which trimerizes in 25% yield under identical conditions to give a tris(9-crown-3)triphenylene system (1).

Figure 1 shows the ORTEP diagram for **2** and the solid-state ^{13}C NMR spectrum is shown in Fig. 2. Table 1 contains selected atomic bond lengths and angles. Selected torsion angles are collected in Table 2, while crystallographic data are presented in Table 3. Atomic coordinates and anisotropic temperature factors are available as Supplementary Data. Solution ^1H NMR data are in Table 4, and the ^{13}C NMR data collected in Table 5.

X-ray crystal structure

The crystal structure of **2** is found to show some disorder at the O1 and C9 positions, with the refined distribution being 70/30. Details of the structural differences between the disordered forms are described below.

For example, in the major form the C9-O1-C8-C7 torsion angle is 89.8(5)°, while the angle for the C9′-O1′-C8-C7 unit in the minor form is –174.2(8)°. In the case of C9-O1-C8-C13, the torsion angle is –101.2(4)°, whereas that for the C9′-O1′-C8-C13 counterpart is 14.9(13)°. For C11-O(3)-C10-C9, the angle is 123.9(4)°, while that for the same network with the C9′ terminus is 69.0(7)°. Finally, for the O1-C9-C10-O2 unit, a smaller difference is found between the two forms. The torsion angle in this case is –80.8(5)°, while that for the O1′-C9′-C10-O2 counterpart is 68.7(9)°.

Regarding the interplanar angle between the two naphthalene rings, the C13-C14-C15-C16 angle has been found to

be –67.5(4)°, indicating a gauche type relationship between these two essentially planar aromatic units.

It is also of interest to compare the 9-membered ring geometries present in **2** with that which has been determined in naphtho-9-crown-3 itself (3). Table 6 contains a tabulation of the pertinent torsional angle data. It is evident that the major conformation of the C8–C13 ring of **2** bears a remarkable similarity in geometry with that present in the monomer, with the largest difference in torsional angles being only ca. 15°. In contrast, there are very large differences (up to ca. 80°) present in the C16–C21 ring of **2** for three of the nine torsional networks of the 9-membered ring. Since this is a solid-state structure, the conformational differences are most likely due to crystal packing effects.

NMR spectral result

Because of rapid conformational interconversion on the NMR timescale, **2** can be regarded, for solution NMR purposes, as having a twofold axis of symmetry bisecting the C14—C15 bond. Hence, we will discuss assignments for C1–C14 only. Spectra were temperature independent to 173 K.

The starting point for the ^{1}H NMR assignments is the singlet observed for H7 at 7.594 ppm. From results of a NOESY experiment, the correlation to the peri-H5 proton was established. Subsequent ^{1}H–^{1}H COSY results permitted facile assignments of the H4, H3, and H2 resonances.

The coupling constants between the aromatic protons listed in Table 4 were obtained by first-order analysis.

For the aliphatic protons, the ^{1}H–^{1}H COSY experiment permitted establishment of the H9–H10 connectivity. These four protons, which give rise to a complex AA′BB′ spectrum, have chemical shifts that are nearly identical to those found in naphtho-9-crown-3 (2). The internal protons on C11 and

[a]Part of a complex AA′BB′ spin system.

C12 are shielded relative to those on C10 and C9, respectively. This shielding is likely due to the intramolecular aromatic ring current of the nonbonded naphthalene ring. The X-ray geometry indicates a gauche relationship between the two naphthyl moieties; however, oscillatory freedom in solution would bring the C12 and C11 protons into the shielding cone of the nonbonded naphthyl unit at least some of the time.

With respect to the assignment of the solution ^{13}C NMR resonances, results of a heteronuclear multiple quantum correlation (HMQC) experiment gave assignments for all the carbons bearing hydrogen atoms, since all ^{1}H assignments are in hand. Regarding the quaternary carbons, the chemical shift of C8 was established via a heteronuclear multiple bond correlation (HMBC) experiment and is identical to that found in naphtho-9-crown-3 (2), whereas the C13 site is shielded by ca. 3 ppm. Intramolecular ring-current effects may again be the origin of this shielding phenomenon. Dis-

[a, b]Denotes possible assignment interchange.

tinction between C1 and C6 was also accomplished via HMBC, with the C6 shift of 131.0 ppm being identical to that in naphtho-9-crown-3 (2). Here the internal carbon C1 is again shielded, in this case by 0.6 ppm relative to the external C6 site. Finally, the remaining quaternary resonance at 126.2 ppm is attributed to C14.

The 50.3 MHz solid-state ^{13}C NMR spectrum of **2** is shown in Fig. 2. Due to the nonaveraged conformational situation in the solid, the spectrum is a good deal more complex than that observed in solution and some very interesting chemical shifts are observed. For example, in the aliphatic region, only four resonances are observed in solution, with chemical shifts ranging from 71.9 to 74.9 ppm. In contrast, the solid-phase spectrum shows six resolved peaks in the range of 67.2 to 79.0 ppm with relative intensities of approximately 1:1:2:2:1:1. The fact that there is disorder present at the C9/C9′ position in the crystal with a population ratio of ca. 3:1 (vide supra) will introduce some additional complexity into the spectrum. However, it is useful to attempt to assign the resonances based on their torsional environments, since previous work in this field has been remarkably successful with respect to crown ethers, particularly for benzo-9-crown-3 ether (4).

An important part of this discussion is based on the previous results (4) of ab initio calculations of the total shielding of the methyl group of anisole as a function of dihedral angle using a localized orbital local origin (LORG) approach. These results are depicted in Fig. 3.

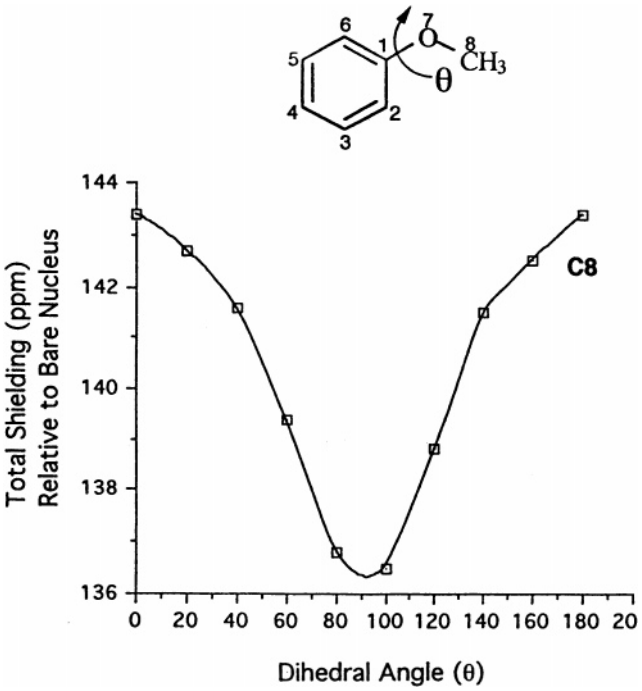
From the X-ray crystal data, one can compare the two C*-O-C-C torsional environments of the C9, C12, C17, and C20 positions, since these are the sites in **2** that are similar to the methyl group of anisole. Then an estimate of the total relative shielding at each of these carbons can be obtained using Fig. 3. For example, the C12-O3-C13-C8 angle is 116.1°, which would give a total shielding of ca. 138 ppm. Similarly, the C12-O3-C13-C14 angle of 70.1° leads to a total shielding of ca. 137.5 ppm. Thus, the total relative shielding for C12 using this approach is expected to be (138.0 + 137.5 ppm) 275.5 ppm. In contrast, the C17-O4-C16-C21 torsion angle is 35.3°, leading to a total shielding of 142 ppm (Fig. 3). For the C17-O4-C16-C15 unit, the torsion angle is 150.9, also leading to a total shielding of ca. 142 ppm. Hence for C17, the contribution would be 142 + 142 = 284 ppm. A similar approach for C9 and C20 leads to values of ca. 272 and 276 ppm, respectively. Thus, a range of chemical shifts of ca. (284–272 ppm) 12 ppm is expected based on this approach, in excellent accord with our experiment. Accordingly, we assign the most shielded aliphatic carbon at 67.2 ppm to C17, and the most deshielded (at 79.0 ppm) to C9. The resonance at 75.9 ppm of relative intensity 2 is assigned to C12 and C20.

With regard to the remaining C10, C11, C18, and C19 sites, some ambiguity in the assignments exists. For C10, the resonance at 78.1 ppm has been assigned. This is because in naphtho-9-crown-3 (**1**), the corresponding carbon has an identical chemical shift in the solid state and the major form of the C8–C13 ring of **2** has essentially the same conformation as that present in **1**. For C11, C18, and C19, we have no clear method to distinguish their chemical shifts, hence the assignments for these carbons at 73.8 (intensity 2) and 69.5 ppm may be interchangeable as noted in Table 5.

Finally, for the quaternary carbons, three distinct resonances are observed in the solid-state spectrum at 156.1 (relative intensity 2), 153.8, and 149.5 ppm. In solution, C8 and C21 appear at 152.5 ppm, while C13 and C16 are at 149.8 ppm. Our assignments in these instances are C8 and C21 at 156.1 ppm, with a distinction between C13 and C16 being made on the basis of the C—O bond lengths in the X-ray crystal structure. The C16—O4 bond length is 1.359(4) Å, while the C13—O3 bond length is 1.369(3) Å. A shorter C—O bond accompanies more double-bond character and thus the carbon would be expected to be deshielded, based on the well-established chemical shift patterns in ^{13}C NMR spectra (5). Accordingly we assign the peak at 153.8 ppm to C16 and the resonance at 149.5 to C13.

Experimental

Materials



The following method was employed for the synthesis of **2**: $FeCl_3$ (9.01 g, 0.0561 mol), concentrated H_2SO_4 (0.5 mL), and dichloromethane (250 mL) were placed in a 500 mL round-bottom flask. To this was added, dropwise with stirring, naphtho-9-crown-3 ether (**1**) (4.30 g, 0.0187 mol) dissolved in dichloromethane (50 mL). The reaction mixture was heated at reflux for 24 h followed by slow addition of

methanol (100 mL) and heated at reflux for another 3 h. After cooling to room temperature, an additional 300 mL of dichloromethane was added and the solution was washed with distilled water (3 × 300 mL). The organic layer was dried over anhydrous sodium sulfate and after filtration the solvent was removed in vacuo to yield 4.2 g of a brown solid. This solid was boiled with hexane (3 × 200 mL), filtered, and dried in vacuo. Column chromatography over silica gel with dichloromethane–diethyl ether (1:9) afforded a light yellow oil, which changed to a solid upon trituration with diethyl ether. Recrystallization from dichloromethane–diethyl ether yielded 1.51 g (35.2%) of pure **2**, mp 209 to 210°C.

NMR spectra

Solution NMR spectra were recorded in $CDCl_3$ solution at 300 K using a Bruker AMX-400 instrument. An Aspect 3000 processing controller was used and all standard microprograms employed are in the Bruker software library.

For the heteronuclear multiple quantum correlation (HMQC) experiment, delays were set for couplings of 135 Hz, whereas for the heteronuclear multiple bond correlation (HMBC) experiment, delays were set for couplings of 7.5 Hz.

The solid-phase ^{13}C NMR spectra were recorded at 50.3 MHz at 300 K using a Bruker ASX-200 solid-state NMR spectrometer equipped with a Bruker 7 mm triple-resonance probe. The magic angle was set accurately using the ^{79}Br resonance of KBr and maximizing the number of rotational echoes in the FID. Magic-angle spinning rates were approximately 5 kHz. ^1H 90° pulses were 3.5–3.8 μs with contact times of 1 ms. Chemical shifts were referenced to the ^{13}C resonance of $Si(Si(CH_3)_3)_4$, which has a chemical shift of 3.7 ppm relative to TMS.

X-ray crystallographic studies and structure refinement[2]

Suitable crystals were selected and mounted on thin glass fibers using viscous oil. Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° scans at 0, 90, and 180°.

Unit-cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied (6). The unit-cell parameters and systematic absences in the diffraction data are consistent with the space group $P2_1/n$. The structure was solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. Atoms O1 and C9 were found disordered with a refined site occupancy of 70/30. The presumed disorder at C10 could not be resolved. Disordered atoms were refined with major and minor contributions at common isotropic parameters. All other nonhydrogen atom positions were refined with anisotropic displacement parameters, and hydrogen atoms

[2] Supplementary material may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada. For information on obtaining material electronically go to http://www.nrc.ca/cisti/irm/unpub_e.shtml. Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Efficient and regioselective synthesis of bridged ring systems by domino Knoevenagel – hetero-Diels–Alder reaction

Lutz F. Tietze, Christian Ott, and Frank Haunert

Abstract: The bridged heterocycles **10**–**12** were efficiently prepared by a domino Knoevenagel – hetero-Diels–Alder reaction of *N*,*N*′-dimethylbarbituric acid **2** and the aldehydes **6**–**8** which contain an allyl moiety as dienophile. In contrast, reaction of **2** and aldehyde **5** with a dimethylallyl moiety leads to the annulated product **9.** For the formation of **10**–**12,** an *exo-Z-syn* and for that of **9** an *endo-E-syn* transition structure is proposed.

Key words: bridged compounds, domino reaction, Diels–Alder reaction, heterocycles, Knoevenagel reaction.

Résumé : On a préparé de façon efficace les hétérocycles pontés **10**–**12** par le biais d'une réaction de Knoevenagel – hétéro-Diels–Alder en domino de l'acide *N*,*N*′-diméthylbarbiturique (**2**) avec les aldéhydes **6**–**8** qui contiennent une partie allylique agissant comme diénophile. Par ailleurs, la réaction du composé **2** avec l'aldéhyde **5** qui contient une partie diméthylallylique conduit à la formation du produit **9** résultant d'une annellation. Pour la formation des composés **10**–**12**, on suggère l'implication d'une structure de transition *exo-Z-syn* alors que celle impliquée dans la formation du produit **9** serait *endo-E-syn*.

Mots clés : composés pontés, réaction en domino, réaction de Diels–Alder, hétérocycles, réaction de Knoevenagel.

[Traduit par la Rédaction]

Introduction

The domino Knoevenagel – hetero-Diels–Alder reaction (reviews, see ref. 1), which was introduced by us as a powerful sequential transformation, has been proven to be a valuable method for the construction of heterocyclic ring systems (2). The reaction can be performed as a two-, three- or four-component transformation using an aldehyde, a 1,3-dicarbonyl, or a hetero-analogous compound and an enol ether or alkene as a dienophile. For the two-component transformation, any type of aromatic aldehyde such as substituted benzaldehydes, heteroaromatic aldehydes, or aliphatic aldehydes containing a double bond in the side chain can be employed to give annulated compounds. The transformations are highly stereoselective leading either to the *cis*-annulated heterocycles with aromatic and α,β-unsaturated aliphatic aldehydes or to the *trans*-annulated compounds with aliphatic aldehydes (2). Thus, reaction of the aromatic aldehyde **1** with *N*,*N*′-dimethylbarbituric acid **2** at room temperature gives exclusively the *cis*-fused tetracycle **4** via **3** in 91% yield (Scheme 1) (3).

So far this domino reaction has been used mostly for the generation of annulated five- to seven-membered ring systems; however; it is also very suitable for the synthesis of bridged heterocycles as described in this paper (4).

Results and discussion

In the domino Knoevenagel – hetero-Diels–Alder reaction of **1** and **2**, a 1-oxa-1,3-butadiene **3** is formed first which undergoes a hetero-Diels–Alder reaction (5) with inverse electron demand. Since the regioselectivity of the cycloaddition is controlled by the coefficients at the dienophile according to the Klopman–Salem eq. [6], a change of the substituents at the dienophile should allow a switch from annulated to bridged products.

For the synthesis of the desired bridged heterocycles we prepared the aromatic and aliphatic aldehydes **6**–**8** with an allyl moiety as dienophile; in addition we have also synthesized aldehyde **5** with a dimethylallyl group as a side chain (Fig. 1). 2-(3-Methyl-3-butenyl)-benzaldehyde **5** and 2-allylbenzaldehyde **6** were easily accessible from 2-bromo-benzaldehyde by formation of an acetal, successive Stille-coupling with the corresponding stannane reagents, and cleavage of the acetal (7). The aliphatic 2-allyl-carbaldehydes **7** and **8** were prepared by allylation and successive oxy-Cope-rearrangement of the corresponding 1-cycloalkene-1-carbaldehydes (8).

First, aldehyde **5** was treated with *N*,*N*′-dimethylbarbituric acid **2** in methanol in the presence of catalytic amounts of ethylenediammonium diacetate (EDDA) for 16 h at room temperature. As expected, the annulated five-membered

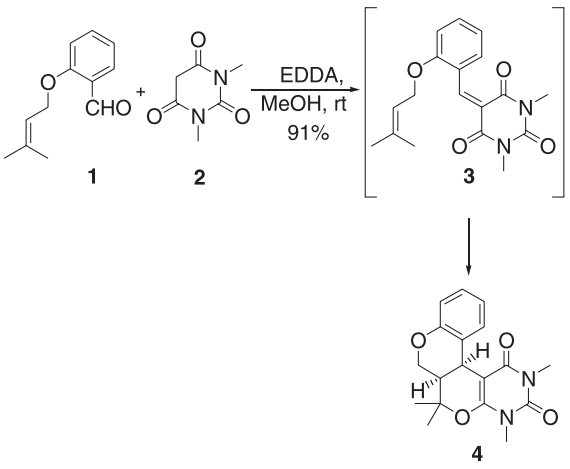
Scheme 1. Synthesis of the *cis*-annulated tetracyclic dihydropyran **4**.



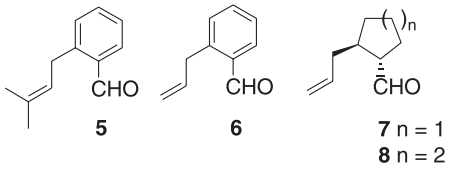


Fig. 1. Substrates for the domino Knoevenagel – hetero-Diels–Alder reaction.

heterocycle **9** was obtained exclusively in 51% yield (Scheme 2). This result is consistent with the large HOMO-coefficient at the terminal carbon of the dienophile moiety in **5**. However, for the regioselectivity of the hetero-Diels–Alder reaction steric effects may also play a role. We assume that the cycloaddition proceeds in a concerted way via an *endo-E-syn* transition structure (Fig. 2) (3).

In contrast, the domino Knoevenagel – hetero-Diels–Alder reaction of **6**, **7**, and **8** with *N*,*N*′-dimethylbarbituric acid **2** in methanol at room temperature with ethylenediammonium acetate as catalyst efficiently provided the novel bridged heterocycles **10**–**12** in 43–69% yield (Scheme 3).

The domino process is highly regioselective, thus, formation of the bridged cycloadducts was observed exclusively. This result is again in agreement with the expectation since the HOMO-coefficient at the terminal carbon of the dienophile should now be much smaller. Here we propose an *exo-Z-syn* transition structure for the hetero-Diels–Alder reaction of the 1-oxa-1,3-butadiene to give a *meta*-addition (Fig. 2) (9). Thus, the intermediate formed benzylidene- and alkylidene-1,3-dicarbonyl compounds have the unique feature that they are not only highly activated 1-oxa-1,3-butadienes due to the second carbonyl group, but they also contain a (*Z*)- and an (*E*)-1-oxa-1,3-butadiene moiety in the same molecule which both can undergo a reaction.

Structure elucidation

The structures of the newly formed compounds were mainly determined by NMR spectroscopy. Exemplary, the ^{1}H and ^{13}C NMR spectra of the bridged heterocycles **10** and **11** are discussed. In the ^{1}H NMR spectrum of **10** the signals

for the diasterotopic protons at C-13 are found at δ = 1.34 and δ = 1.43 with a large geminal coupling of J = 14.3 Hz. 12-H resonates as dd at δ = 4.15 with J = 3.1 and 2.0 Hz. In the ^{13}C NMR spectrum, the resonance for the tertiary carbon C-6 is found at δ = 74.8. In the ^{1}H NMR spectrum of **11**, the signals for 11-H and 5-H are observed as a multiplet at δ = 2.94 and as a ddd at δ = 5.03 with J = 9.2, 3.4, 1.9 Hz, respectively. 4-H_{eq} resonates at δ = 2.48 with J = 13.0, 9.2, and 3.4 Hz and one of the diasterotopic protons of the methano-bridge (C-12) at δ = 1.46 as dt with a large geminal (J = 13.9 Hz) and two smaller vicinal couplings (J = 3.4 Hz). The signal of the second 12-H is shielded in a multiplet at δ = 1.93–2.05 but definitely identified by a ^{1}H–^{1}H-COSY experiment. In the ^{13}C NMR spectrum, the tertiary carbon C-5 resonates at δ = 76.1 and thus confirms the bridged structure of **11**.

Experimental

All reactions were performed under nitrogen or argon atmosphere in flame-dried flasks, and the reactants were introduced by syringe. All solvents were dried by standard methods. All reagents obtained from commercial sources were used without further purification. Thin-layer chroma-

tography (TLC) was performed on precoated silica gel SIL G/UV_{254} plates (Macherey-Nagel GmbH & Co. KG), and silica gel 32–63 (0.032–0.064 mm) (Macherey-Nagel GmbH & Co. KG) was used for column chromatography. UV–vis spectra were taken in CH_3CN with a PerkinElmer Lambda 2 spectrometer. IR spectra were recorded as KBr pellets or as films with a Bruker IFS 25 spectrometer. ^1H and ^{13}C NMR spectra were recorded with a Varian XL 200, VXR 200, and VXR 500 or a Bruker AMX-300 with tetramethylsilane (TMS) as internal standard in chloroform-d_1 or benzene-d_6. Multiplicities of ^{13}C NMR peaks were determined with the APT pulse sequence. Mass spectra were measured at 70 eV with a Varian MAT 311A, high-resolution mass spectra with a Varian MAT 731 instrument. Melting points are uncorrected and were measured with a Mettler FP 61. The following abbreviations are used in the text: DE = diethyl ether, EE = ethyl acetate, PE = petroleum ether, EDDA = ethylenediammonium diacetate.

(6*aS*,11*bR*)-(±)-2,4,6,6-Tetramethyl-6,6*a*,7,11*b*-tetrahydro-4*H*-5-oxa-2,4-diaza-benzo[*c*]fluorene-1,3-dione (9)

A solution of aldehyde **5** (331 mg, 1.90 mmol) in CH_2Cl_2 (1 mL) was slowly added to a suspension of *N*,*N*′-dimethylbarbituric acid (312 mg, 2.00 mmol) and 20 mg EDDA in dry methanol (10 mL) and the reaction mixture was stirred 16 h at room temperature. The solvent was evaporated in vacuo and the crude product purified by column chromatography (EE:PE = 1:1) to give 302 mg of **9** (0.97 mmol, 51% yield). R_f = 0.26 (EE:PE = 1:2). MS (70 eV, EI) *m*/*z* (%): = 312 (100) [M^+], 297 (80) [M^+ – CH_3], 156 (63) [$C_6H_8N_2O_3^+$], 41 (43) [$C_3H_5^+$]. UV (CH_3CN) λ_{max} (log ε) (nm): 265 (3.98). Conclusion

In addition to the synthesis of annulated heterocycles the domino Knoevenagel – hetero-Diels–Alder reaction is also a very efficient method for the preparation of bridged heterocyclic compounds.

A synthesis of 6,11-disubstituted benzo[*b*]carbazoles

Heidi L. Fraser and Gordon W. Gribble

Abstract: Sequential regioselective addition of organolithium reagents to indolo[1,2-*b*]isoquinoline-6,11-quinone (**7**) followed by sodium borohydride reduction of the intermediate diol **10**, which is not isolated, affords 6,11-disubstituted 5*H*-benzo[*b*]carbazoles **11**. The tandem combination of methyllithium and lithium triethylborohydride (Super Hydride) gives 6-methylbenzo[*b*]carbazole (**24**).

Key words: benzo[*b*]carbazole, organolithiums, indolo[1,2-*b*]isoquinoline-6,11-quinone, ellipticine, indole.

Résumé : L'addition régiosélective séquentielle de réactifs organolithiens à l'indolo[1,2-*b*]isoquinoléine-6,11-quinone (**7**), suivie d'une réduction par le borohydrure de sodium du diol intermédiaire **10** qui n'a pas été isolé, conduit à la formation de 5*H*-benzo[*b*]carbazoles 6,11-disubstitués (**11**). La combinaison en tandem du méthyllithium et du triéthylborohydrure de lithium (« Super Hydrure ») conduit au 6-méthylbenzo[*b*]carbazole (**24**).

Mots clés : benzo[*b*]carbazole, organolithiens, indolo[1,2-*b*]isoquinoléine-6,11-quinone, ellipticine, indole.

[Traduit par la Rédaction]

The ellipticine family of alkaloids and related pyridocarbazoles and benzocarbazoles (**1**–**6**, Fig. 1) continue to be intensively studied as novel DNA active compounds and potential anticancer agents (for reviews see ref. 1; for recent work, see ref. 2). For example, S16020–2 (**4**) is one of the most potent such analogues yet discovered, and 9-chloro-4-hydroxy-2,3,5,11-tetramethyl-6*H*-pyrido[3,2-*b*]carbazole (**6**) has high in vivo antitumor activity against L1210 and P388 leukemia, B16 melanoma, and M5076 sarcoma (2).

As an extension of our previous work on the synthesis of ellipticine and other pyridocarbazoles (for reviews of our early work see ref. 3; 4, 5), we describe herein the synthesis of 6,11-disubstituted benzo[*b*]carbazoles **11**. Thus, sequential regioselective addition of organolithiums to indolo[1,2-*b*]isoquinoline-6,11-quinone (**7**) followed by reduction of the intermediate diol **10** gives **11** (Scheme 1). Our earlier experience showed that low temperatures are necessary during the organolithium addition to preclude the ring-opening **8** → **9** prior to consumption of all of the organolithium reagents. If this does occur, then ketone **9** can react with the organolithium to give tertiary alcohol **12**, useless for this approach.

Results and discussion

As we have shown earlier (5), indole (**13**) is readily converted to quinone **7** in 67% overall yield (Scheme 2). Thus, a standard C-2 lithiation of 1-(phenylsulfonyl)indole (**14**) with LDA (6) followed by reaction with phthalic anhydride (**15**) affords keto acid **16** in 86% overall yield from indole. Cleavage of the phenylsulfonyl group and cyclization with hot acetic anhydride furnishes the desired quinone **7**. Treatment of **7** with methyllithium (2 equiv) followed by reduction of the crude diol mixture with sodium borohydride gives 6,11-dimethyl-5*H*-benzo[*b*]carbazole (**18**) in 87% yield (5). With this result it became of interest to examine the sequential addition of different organolithium reagents to quinone **7**.

Based on our previous studies (5–7), we anticipated that the ketone carbonyl in **7** would be more reactive than the lactam carbonyl towards organolithium addition. Indeed, treatment of **7** with 1 equiv of methyllithium at –100°C followed by the addition of 1 equiv of *n*-butyllithium affords, after reductive work-up, 11-*n*-butyl-6-methylbenzo[*b*]carbazole (**19**) as the major product (61% yield). The regioisomeric 6-*n*-butyl-11-methylbenzo[*b*]carbazole (**20**) is obtained in 12% yield (Scheme 3). Reversing the order of addition yields **20** exclusively in 72% yield.

The isomer assignments of **19** and **20** are based on the respective methyl proton chemical shifts, which in turn were established from NOESY data obtained with 6,11-dimethylbenzo[*b*]carbazole (**18**). Thus, the C-6 methyl protons (2.85 ppm) show a NOESY cross peak with the indole NH (7.91 ppm) and one adjacent aromatic proton (H-7, 8.10 ppm). In contrast, the C-11 methyl protons (3.25 ppm) interact with *two* aromatic protons (H-1, 8.37 ppm and H-10, 8.31 ppm). Moreover, as we have observed previously with

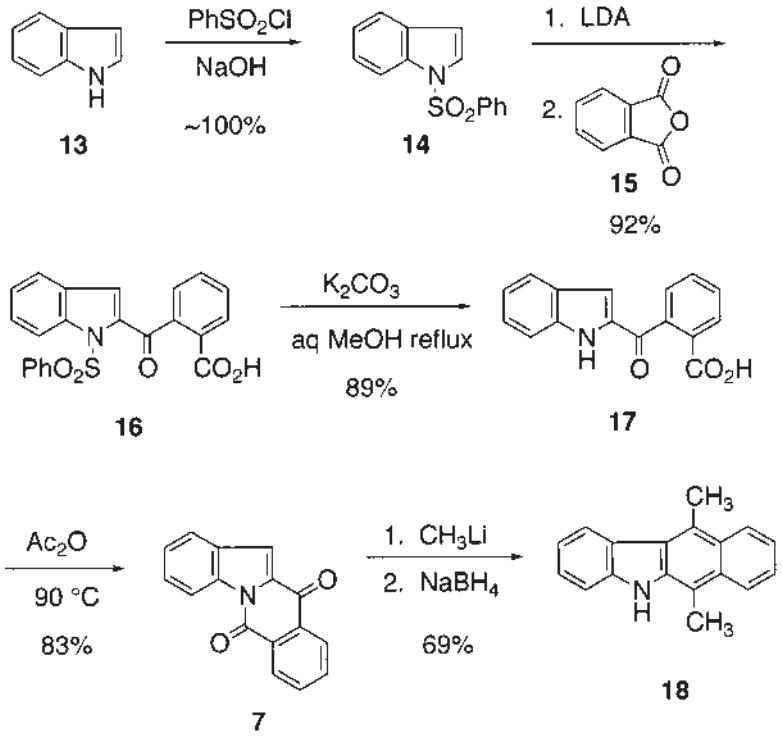
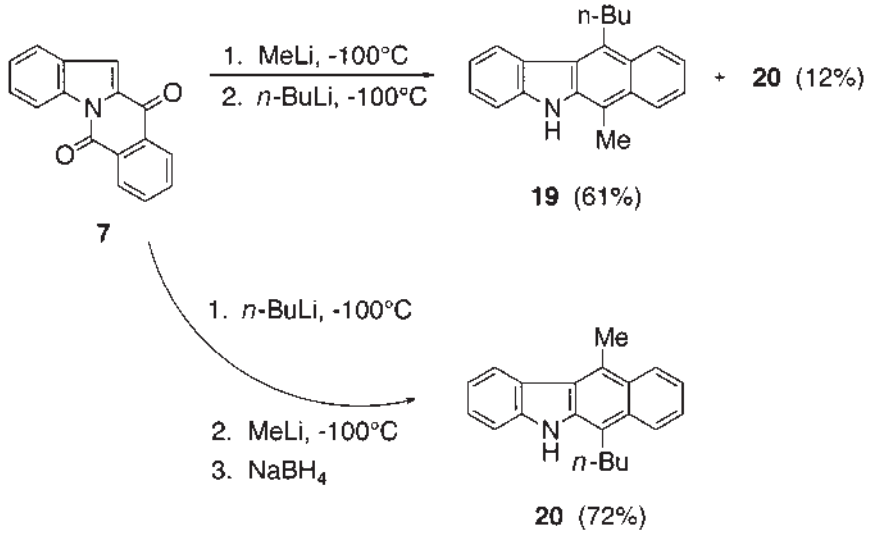
Fig. 1. Ellipticine alkaloids and related antitumor pyridocarbazoles.

Scheme 1.



pyridocarbazoles (5, 7), a methyl group in the C-11 position is significantly deshielded by the indole benzene ring. The methyl group chemical shifts observed for **19** (2.81 ppm) and **20** (3.67 ppm) are consistent with this deshielding effect.

Similar results were obtained with reactions of phenyllithium with quinone **7**. Thus, treatment of **7** with 2 equiv of phenyllithium affords 6,11-diphenylbenzo[*b*]carbazole (**21**), in 70% yield after reductive work-up. Sequential treatment of **7** with 1 equiv each of phenyllithium then methyllithium affords **22** (37%) and **23** (22%). The reverse order of organolithium addition is somewhat more regioselective giving **23** (47%) and **22** (18%). These two isomers were distinguished by their characteristic methyl group chemical shifts (3.28 ppm for **22**; 2.91 ppm for **23**).



The use of hydride nucleophiles has been more problematic and only one combination of reagents has been fruitful.

22, $R^1 = Ph$, $R^2 = Me$
23, $R^1 = Me$, $R^2 = Ph$
24, $R^1 = Me$, $R^2 = H$

Treatment of quinone **7** with methyllithium followed by Super Hydride ($LiBHEt_3$) affords 6-methylbenzo[*b*]carbazole (**24**) in 56% yield, after reduction of the intermediate diol with sodium borohydride. The reverse sequence of reagents as well as several attempts (Super Hydride, DIBAL, $LiAlH_4$) to effect hydride addition to both carbonyl groups, which would give the parent 5*H*-benzo[*b*]carbazole, were unsuccessful and led only either to complex mixtures or partial reduction. For example, reduction of **7** with sodium borohydride alone affords the hydroxy lactam **25** (86% yield) resulting from conjugate reduction of the indole double bond and ketone reduction (Scheme 4). The stereochemistry of **25** was established by 2D NMR experiments (COSY, NOESY) and coupling constants. The methine proton at C-11 is trans to the

proton at C-11a (J = 11.5 Hz), and the coupling constants between C-11a-H and the protons at C-12 (J = 8.7 and 9.4 Hz) are consistent with this stereochemistry.

In summary, we have shown that 6,11-disubstituted benzo[*b*]carbazoles are accessible via the sequential addition several organolithium reagents to indolo[1,2-*b*]isoquinoline-6,11-quinone (**7**). The use of Super Hydride in this strategy allows for the synthesis of 6-methylbenzo[*b*]carbazole (**24**).

Experimental section

General experimental

Melting points were determined in open capillaries and are uncorrected. Elemental analyses were done by Atlantic Microlab Inc., Atlanta, Georgia. High resolution mass spectra (HRMS) were carried out at the University of Illinois at Urbana-Champaign, School of Chemical Sciences, Mass Spectrometry Laboratory, Urbana, Illinois. All ^{1}H NMR, ^{13}C NMR, HMQC, COSY, and NOESY spectra were generated with a Varian Unity Plus NMR spectrometer (300 Hz) unless specified otherwise. Tetramethylsilane (TMS) and deuterated solvents were used as internal reference ($CDCl_3$, acetone-d_6, DMSO-d_6, or CD_3OD). Chemical shifts are reported in parts per million (δ) downfield from TMS. The apparent multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, b = broad), number of protons, and coupling constants (J = xHz) are reported where appropriate. Low resolution mass spectral data were generated on a Hewlett-Packard 5890 (70 eV). Infrared spectra were taken with a PerkinElmer 1600 series FT IR spectrophotometer and are referenced to the 1601 cm^{-1} band of polystyrene. Ultraviolet spectra were taken with a Hewlett-Packard 8451A diode array spectrophotometer in 95% ethanol. Thin layer chromatography was done on Whatman brand 20 × 20 cm polyester backed silica plates with fluorescent indicator. Plates were visualized by 254 nm UV light. Alternative visualization was accomplished by treatment with a solution of ceric ammonium sulfate in 10% H_2SO_4. Preparative TLC was done on silica gel 60 F254 1 mm 20 × 20 plates from VWR. Flash chromatography was carried using Fisher or SELECTO brand silica gel 60 PF254 (230–400 mesh). Alkyllithiums were standardized prior to use by titration against dried diphenylacetic acid under an atmosphere of N_2 at 0°C. Tetrahydrofuran was freshly distilled from sodium–benzophenone under N_2. Anhydrous reactions were done with glassware dried for 24 h at a temperature of 120°C or greater. Apparatus was assembled hot and cooled under an atmosphere of N_2. Alternatively, glassware was assembled and dried by treatment with flame of a propane torch and cooled under an atmosphere of N_2.

*1-(Phenylsulfonyl)indole (**14**) (8)*

To a stirred suspension of powdered sodium hydroxide (67.45 g, 1.69 mol) and tetra-*n*-butylammonium hydrogen sulfate (4.70 g, 0.014 mol) in methylene chloride (660 mL) at 0°C, indole (**13**) (60.58 g, 0.517 mol) was added neat via a powder funnel under N_2. A solution of benzenesulfonyl chloride (63.8 mL, 0.50 mol) in methylene chloride (40 mL) was added to the ice-cold suspension over 20 min, not allowing the temperature to surpass 20°C. The reaction mixture was stirred vigorously for 3 h via mechanical stirring. The resulting solid was filtered and the filtrate was concentrated in vacuo to give a light pink solid (144.7 g), which was triturated with hexanes to yield 133.1 g (100%) of **14** as white crystals: mp 77–79°C (lit. (8) mp 78 to 79°C).

*1-(Phenylsulfonyl)indol-2-yl 2-carboxyphenyl ketone (**16**) (5)*

To a stirred solution of LDA in THF (10 mL) (generated from diisopropylamine (0.60 mL, 4.25 mmol) and *n*-BuLi (1.7 mL, 4.27 mmol, 2.5 M in hexane) at –78°C), was added 1-(phenylsulfonyl)indole (**14**) (1.11 g, 4.27 mmol) in THF (10 mL) at –78°C under N_2 over 5 min. The reaction mixture was stirred at –78°C for 2 h and was then warmed to 14°C over 30 min. The reaction mixture was recooled to –78°C, followed by rapid addition of a solution of phthalic anhydride (**15**) (0.64 g, 4.27 mmol) in THF (5 mL). The reaction mixture was allowed to warm to room temperature overnight. The reaction mixture was concentrated in vacuo, and the residue was dissolved in water (20 mL). The solution was cooled to 0°C and acidified with 20% HCl. The tan solid which formed upon acidification was collected by vacuum filtration and dried in vacuo to afford 1.60 g (92%) **16** as a tan solid. The solid was recrystallized from acetone to yield 9.12 g of **16** as a tan solid (89%): mp 212 to 213°C (lit. (5) mp 212 to 213°C). ^{13}C NMR (acetone-d_6) δ (ppm): 186.0, 167.5, 134.3, 131.7, 131.3, 130.1, 129.6, 129.4, 128.1, 128.0, 124.3, 123.6, 120.7, 115.6.

*2-Carboxyphenyl 2-indolyl ketone (**17**) (5)*

A solution of keto acid **16** (6.94 g, 17.14 mmol) and K_2CO_3 (9.6 g, 0.068 mol) in MeOH (175 mL) and H_2O (60 mL) was refluxed for 5 h under N_2. The reaction mixture was cooled, and the MeOH was removed in vacuo. Water (100 mL) was added, and the acidity was adjusted to pH 2 with 20% HCl. The aqueous layer was extracted with EtOAc (3 × 200 mL), the organic layers were combined and washed with brine (2 × 50 mL), dried (Na_2SO_4), and concentrated in vacuo. The crude solid was recrystallized from acetone to yield 4.03 g (89%) of **17** as a tan solid: mp 234–236°C (lit. (5) mp 234 to 235°C).

*Indolo[1,2-*b*]isoquinoline-6,11-quinone (**7**) (5)*

Keto acid **17** (3.01 g, 11.4 mmol) was suspended in acetic anhydride (560 mL) and heated to 90–109°C for 24 h under N_2. The reaction mixture was cooled to room temperature and kept at 0°C for 12 h. The gold needles that formed were collected by vacuum filtration (1.84 g, 65%). The Ac_2O present in the filtrate was removed by vacuum distillation (10–20 torr (1 torr = 133.322 Pa)) and the residue was recrystallized from acetone to yield 0.49 g of **7** as gold needles (overall yield 83%): mp 217 to 218°C (lit. (5) mp 217 to 218°C). ^{1}H NMR (acetone-d_6) δ (ppm): 8.41 (d, 1H), 8.24 (dd, 1H), 8.15

(dd, 1H), 7.93–7.79 (m, 3H), 7.65 (s, 1H), 7.57 (t, 1H), 7.36 (t, 1H).

*6,11-Dimethyl-5*H*-benzo[*b*]carbazole (**18**) (5)*

To a stirred solution of quinone **7** (130 mg, 0.530 mmol) in THF (25 mL) at –100°C under N_2 was added MeLi (0.8 mL, 1.13 mmol, 1.4 M in ether) dropwise via syringe. The resulting dark green solution was stirred at –90°C for 2 h and was warmed to room temperature overnight. The solvent was removed in vacuo and the residue was dissolved in absolute EtOH (50 mL). The solution was then heated to reflux and $NaBH_4$ (1 pellet, 1.0 g, 27.0 mmol) was added; another pellet of $NaBH_4$ was then added after every 24 h of reflux. The reaction was refluxed for a total of 78 h. The reaction was cooled to room temperature, the EtOH was removed in vacuo, and the residue was partitioned between H_2O (300 mL) and CH_2Cl_2 (200 mL) with stirring for 48 h. The layers were separated, the aqueous layer was acidified with concd HCl to pH 2 and extracted with CH_2Cl_2 (1 × 100 mL); the aqueous layer was basified with KOH pellets to pH 12 and extracted with CH_2Cl_2 (1 × 100 mL); the aqueous layer was then neutralized with concentrated HCl and extracted with CH_2Cl_2 (1 × 100). This process was repeated twice. The organic layers were combined, dried over (Na_2SO_4), and concentrated in vacuo to yield 0.24 g of a yellow residue, which was chromatographed (2:1, hexanes:CH_2Cl_2) to yield 90.3 mg (69%) of **18** as a light yellow solid: mp 211 to 212°C (lit. (5) mp 211–213°C). ^{1}H NMR (DMSO-d_6) δ (ppm): 8.39 (t, 2H), 8.16 (d, 1H), 7.91 (br s, 1H), 7.62–7.45, (m, 4H), 3.25 (s, 3H), 2.85 (s, 3H). ^{13}C NMR (acetone-d_6) δ (ppm): 126.7, 124.7, 124.5, 123.9, 123.4, 121.9, 118.9, 110.5, 15.6, 12.9.

*11-*n*-Butyl-6-methyl-5*H*-benzo[*b*]carbazole (**19**)*

To a stirred yellow solution of quinone **7** (119.6 mg, 0.450 mmol) in THF (20 mL) at –100°C under N_2 was added 1 equiv of MeLi (0.3 mL, 0.450 mmol, 1.4 M in ether). The solution was stirred for 15 min at –100°C, then 1 equiv of *n*-BuLi (0.2 mL, 0.450 mmol, 2.0 M in hexanes) was added, increasing the temperature to –95°C which was recooled to –100°C immediately. The reaction mixture was warmed to room temperature gradually overnight. The solvent was removed by vacuum, the residue was dissolved in 95% EtOH (50 mL) to which a $NaBH_4$ pellet (1 pellet = 1.0 g, 27 mmol, crushed) was added, and the solution was heated to reflux. Another $NaBH_4$ pellet was added after 24 h of refluxing. The reaction mixture was refluxed for a total of 67 h, cooled to room temperature, and concentrated in vacuo. The residue was partitioned between CH_2Cl_2 (200 mL) and H_2O (100 mL) and the two layers were stirred for 12 h. The layers were separated. The originally basic aqueous layer was acidified to pH 2 with concd HCl and extracted with CH_2Cl_2 (1 × 50 mL). The aqueous acid layer was neutralized with NaOH pellets and extracted with CH_2Cl_2 (1 × 50 mL). The aqueous layer was rebasified with NaOH pellets to pH 12 and extracted with CH_2Cl_2 (1 × 50 mL). The entire extraction process was repeated. The organic layers were combined, washed with brine (2 × 25 mL), dried (Na_2SO_4) and concentrated in vacuo to give 156.7 mg of a brown oil. The oil was then chromatographed (1:1, hexanes:CH_2Cl_2) to obtain 61% (78.5 mg) of the major isomer as a film and 12% (15.5 mg) of the minor isomer also as a film. Attempts to purify these compounds for elemental analysis were unsuccessful. Major isomer **19**: MS *m*/*z*: 287 (M^+), 273, 244 (100%), 230, 202, 143, 120. HRMS calcd. *m*/*z*: 287.1674; found *m*/*z*: 287.1666. UV (95% EtOH) λ_{max} (nm): 296 (5.70), 320 (5.17), 334 (4.23), 380 (5.05), 398 (5.09). *6-*n*-Butyl-11-methyl-5*H*-benzo[*b*]carbazole (**20**)*

To a stirred solution of quinone **7** (145.2 mg, 0.550 mmol) at –60°C under N_2 was added 1 equiv of *n*-BuLi (0.3 mL, 0.55 mmol, 2.1 M in hexanes). This was stirred for 15 min while cooling the reaction to –100°C, at which time 1 equiv of MeLi (0.4 mL, 0.55 mmol, 1.4 M in diethyl ether) was added. The solution was then warmed to room temperature overnight. The solvent was removed in vacuo, the residue was dissolved in EtOH (60 mL) and treated with a $NaBH_4$ pellet (1 pellet = 1.0 g, 27 mmol, crushed), and the solution was refluxed. After refluxing for 15 h, another $NaBH_4$ pellet (1 pellet = 1.0 g, 27 mmol, crushed) was added to the refluxing solution. The reaction mixture was refluxed for a total of 80 h. The reaction was cooled and the solvent was removed by vacuum. The residue was partitioned between CH_2Cl_2 (200 mL) and H_2O (100 mL) and the two phases were stirred over 12 h. The layers were separated. The basic aqueous layer was acidified to pH 2 with concd HCl and extracted with CH_2Cl_2 (1 × 50 mL). The aqueous layer was neutralized with NaOH pellets and extracted with CH_2Cl_2 (1 × 50 mL). The aqueous layer was rebasified with NaOH pellets to pH 12 and extracted with CH_2Cl_2 (1 × 50 mL). The extraction process was repeated. The organic layers were combined, washed with brine (2 × 25 mL), dried (Na_2SO_4), and concentrated in vacuo to yield an orange oil. The oil was chromatographed (3:1, hexanes:CH_2Cl_2) to give 113.7 mg (72%) of **20** as a light yellow film. This compound could not be crystallized. MS *m*/*z*: 287 (M^+), 244 (100%), 229, 202, 120. HRMS calcd. *m*/*z*: 287.1674; found: *m*/*z* 287.1666. UV (95% EtOH) λ_{max} (nm): 298 (5.80), 322 (5.31), 336 (5.21), 386 (5.12), 404 (5.17). Isomerization of (*Z*)-alkenylsilanes to (*E*)-isomers with hydrosilane and $RhI(PPh_3)_3$

Atsunori Mori, Eisuke Takahisa, Yasushi Nishihara, and Tamejiro Hiyama

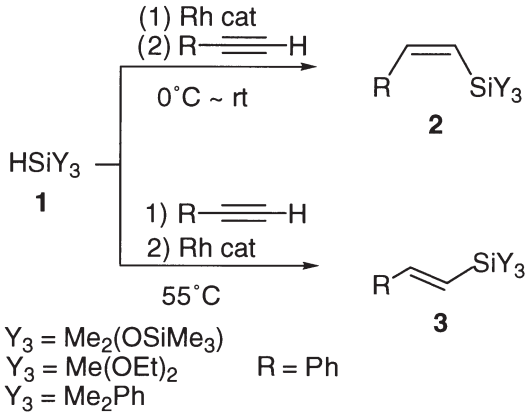
Abstract: Isomerization of (*E*)-2-phenylethenylsilanes to the (*Z*)-isomers is found to easily take place at 60°C within 1 h using 20–100 mol% of a hydrosilane and 0.1 mol% of $RhI(PPh_3)_3$ and is understood in terms of insertion of alkenylsilanes to hydridorhodium followed by β-hydride elimination.

Key words: hydrosilylation, isomerization, $RhI(PPh_3)_3$, alkenylsilane, hydrosilane.

Résumé : On a observé que l'isomérisation des (*E*)-2-phényléthénylsilanes en isomère (*Z*) se produit facilement à 60°C, pendant une heure, en présence de 20 à 100% d'un hydrosilane et de 0,1 mol % de $RhI(PPh_3)_2$. On peut l'expliquer en termes d'une insertion d'alcénylsilanes sur l'hydridorhodium, suivie d'une élimination β d'hydrure.

Mots clés : hydrosilylation, isomérisation, $RhI(PPh_3)_2$, alcénylsilane, hydrosilane.

[Traduit par la Rédaction]



Introduction

Regio- and stereoselective hydrosilylaton of terminal alkynes leading to alkenylsilanes is a significant reaction in organic synthesis as well as organometallic chemistry (1). Among a number of transition-metal catalysts endowed with a variety of features, rhodium complexes show high activity as well as characteristic selectivities. We recently disclosed that rhodium-catalyzed hydrosilylation of terminal alkynes using a hetereoatom-substituted hydrosilane (e.g., **1a** and **1b**) produced (*Z*)-alkenylsilanes (**2**) or (*E*)-alkenylsilanes (**3**) depending on the reaction procedure as shown in Scheme 1 (2).

Meanwhile, we observed that (*E*)-alkenylsilanes **3** were obtained through isomerization of initially produced (*Z*)-isomers **2**. This observation suggests that the hydrosilylation might have occurred through *trans*-addition of a hydrosilane to give **2** followed by isomerization to *cis*-adduct **3**. This isomerization is unusual in view of stereochemistry of hydrosilylation (3, 4)[3,4]. We report here that the isomerization of **2** to **3** is promoted by the presence of a hydrosilane and $RhI(PPh_3)_3$. We also discuss the mechanistic aspect of the isomerization.

When a mixture of phenylacetylene and pentamethyldisiloxane (**1a**) was heated at 60°C in the presence of 0.1 mol% of $RhI(PPh_3)_3$, the reaction leading to (*E*)-2-phenylethenylsilane **3a** proceeded highly selectively (1). At 26% conversion, the ratio of resulting (*Z*)-2-phenylethenylsilane (**2a**) and (*E*)-isomer (**3a**) was 92:8. The isomer ratio gradually changed in favor of **3a** as the reaction proceeded. At 89% conversion, the ratio was 37:62; at >99% conversion, 0:100 (Scheme 2).

Scheme 1.

In the presence of 0.1 mol% of $RhI(PPh_3)_3$ only, **2a** did not isomerize at 60°C in 24 h (see Table 1, entry 1), whereas the isomerization started to take place rapidly when 10 mol% of pentamethyldisiloxane (**1a**) was added to the mixture, and after 1 h a 65:35 mixture of (*Z*)-isomer **2a** and

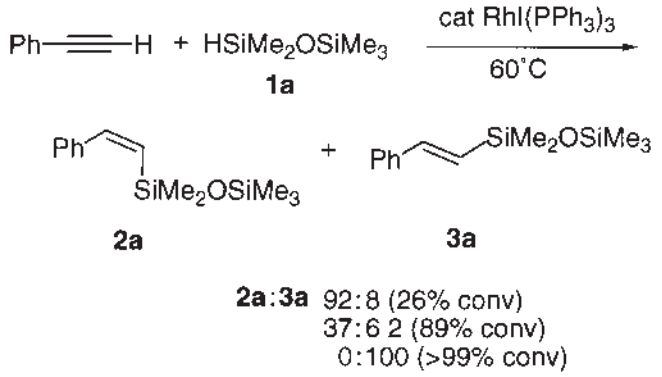
Scheme 2.



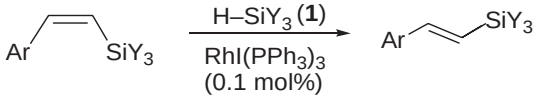


Table 1. Isomerization of (*Z*)-alkenylsilanes.[a]

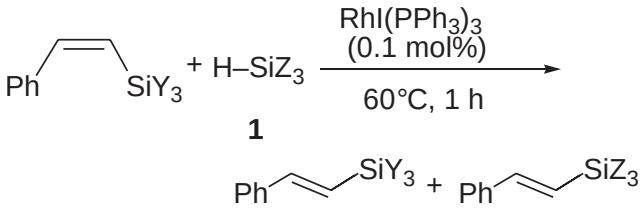
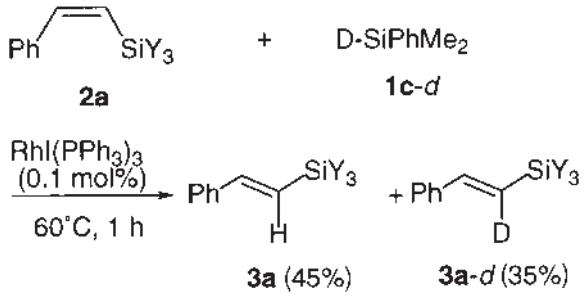


Entry	(Z)-Alkenyl-silane (% Z)	1	Mol	Time (h)	(*Z*):(*E*)[b]
1	**2a** (99)		None	24	97:3
2		**1a**	0.1	1	65:35
3				2	61:39
4			+0.6[c]	1	0:100
5			0.2	1	24:76
6			0.3	1	0:100
7	**2a′**[d] (95)		0.1	1	27:73
8			0.2	1	0:100
9	**2b** (93)	**1b**	0.1	1	2:98

[a]All reactions were carried out using 0.1 mol% of $RhI(PPh_3)_3$ at 60°C.
[b]The ratio was determined by ^1H NMR.
[c]An additional 0.6 mol of hydrosilane was added to the product mixture resulting from the experiment in entry 3.
[d]Ar = 4-Me-C_6H_4, $Y_3 = Me_2OSiMe_3$.

(*E*)-isomer **3a** resulted. The ratio did not change 1 h thereafter, while most of **1a** was confirmed (5).[5] Addition of **1a** (0.6 mol) to the reaction mixture reinitiated the isomerization to complete the transformation to (*E*)-isomer **3a** within 1 h. Use of a larger amount of **1a** accelerated the isomerization more (entries 4–6). Thus, the isomerization appears to be competitive with consumption of hydrosilane **1a**, a pathway independent of the isomerization, both presumably being catalyzed by the rhodium complex. (*Z*)-Isomer **2a′** with a *p*-tolyl group in place of the phenyl group isomerized faster than **2a** to give (*E*)-isomer **3a′** exclusively using 20 mol% of **1a** in 1 h at 60°C (entry 8). Isomerization of (*Z*)-isomer **2b** to (*E*)-isomer **3b** also occurred similarly in the presence of diethoxy(methyl) silane (**1b**) (6).[6]

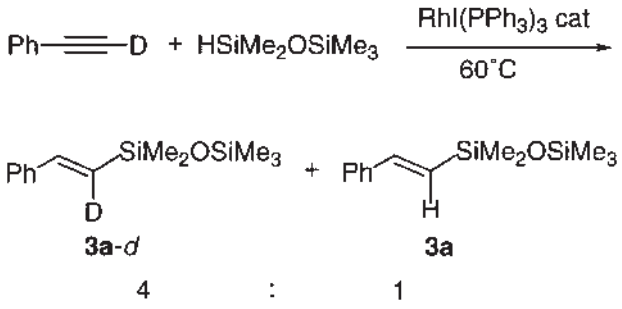
Table 2. Isomerization of *Z*-alkenylsilanes using hydrosilane with different substituents.



Entry	(*Z*)-Silane	1	Products[a] (%) –SiY3	Products[a] (%) –SiZ3
1	**2b**	**1a**	86	0
2	**2a**	**1b**	87	6
3	**2a**	**1c**	80	0

[a]Yields determined by ^1H NMR.

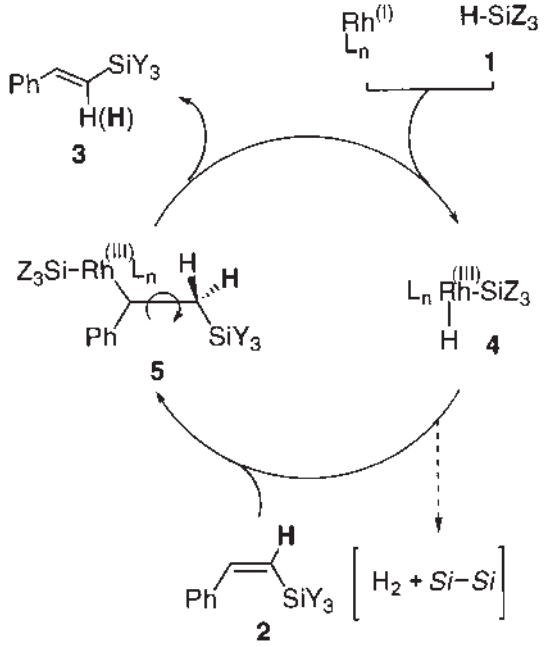
Table 2 shows scrambling experiments using an equimolar mixture of (*Z*)-2-phenylethenylsilane **2** and hydrosilane **1** with a different silyl group (SiY_3 or SiZ_3). Scrambling of a silyl group was at best 6% after isomerization at 60°C for 1 h. These results show that the silyl exchange does not occur extensively during the isomerization to the corresponding (*E*)-silane **3**.



On the other hand, the scrambling experiments using $DSiMe_2Ph$ (**1c**-*d*) revealed that a fair amount of deuterium was incorporated into the product. For example, as illustrated in Scheme 3, when the isomerization was carried out starting with an equimolar mixture of **1c**-*d* and (*Z*)-2-phenylethenylsilane **2a**, a 1.3:1 mixture of (*E*)-isomer **3a** and 1-deuterio-2-phenylethenylsilane **3a**-*d* resulted.[7,8]

Scheme 3.

[5]Reaction of **3a** in the presence of 0.1 mol% of $RhI(PPh_3)_3$ afforded the corresponding disilane as confirmed by ^1H NMR.
[6]We also observed the similar isomerization in the use of 0.1 mol% of $RhCl(PPh_3)_3$.
[7]Typical experimental procedure: To a screw-capped glass tube were added (*Z*)-2-phenylethenylsilane **2** (1.0 mmol), a hydrosilane (0.1–0.3 mmol), and $RhI(PPh_3)_3$ (0.1 mol%, 1 mg). The resulting mixture was heated at 60ºC for 1 h. The isomerization was monitored by taking an aliquot of the solution and measuring ^1H NMR spectra in a $CDCl_3$ solution. After the isomerization was completed, the corresponding (*E*)-silane **3** was isolated by bulb-to-bulb distillation.
[8]The major product of the following equation showed ^1H NMR spectrum identical to the deuterated product in Scheme 3. ^1H NMR ($CDCl_3$, 300 MHz) δ: 6.92 (t, *J* = 2.7 Hz, 1 H, Ph*CH*=CDSi) for **3a**-d; 6.95 (d, *J* = 19.2 Hz, 1 H, Ph*CH*=CHSi) for **3a**.



© 2001 NRC Canada

Above observations lead to a mechanism shown in Scheme 4: oxidative addition of $HSiZ_3$ to $Rh(I)L_n$ followed by insertion of (*Z*)-alkenylsilane **2** to the resulting of Rh(III) species **4** would furnish intermediate **5**. The scrambling experiments shown in Table 2 and Scheme 3 suggest that the insertion occurs at a Rh(III)—H bond in **4** rather than a Rh(III)—Si bond. The results contrast sharply to the fact that insertion of a carbon—carbon triple bond towards a H-Rh(III)-SiZ_3 species is considered to occur at a rhodium—silicon bond (3)[3]. Thus, the isomerization proceeds via an insertion–β-elimination mechanism, which is rarely considered for alkenylsilane isomerization though often discussed in olefin isomerization (7).[6] The regiochemistry is controlled to give **5** so that the rhodium atom is located at the β-position of SiY_3. Successive β-elimination leading to (*E*)-alkenylsilanes **3** would occur after C—C bond rotation to induce *syn*-periplanar conformation of a Rh-C-C-H moiety.

We have found that the rhodium-catalyzed isomerization of (*Z*)-2-phenylethenylsilane **2** to (*E*)-isomers **3** takes place in the presence of a catalytic amount of hydrosilane and a rhodium catalyst. Since hydrosilylation of 1-alkynes also proceeds in a similar stereochemical manner, it would be reasonable to assume that a similar isomerization pathway is involved in these cases also. In addition, the isomerization was demonstrated to proceed through insertion–β-elimination of a hydridorhodium (H-Rh(III)-Si) to alkenylsilane in contrast to the reaction of the species with a triple bond which has been considered for insertion at the rhodium—silicon bond.

Fourfold homologous anionic *ortho*-Fries rearrangement on a partially bridged resorc[4]arene

Oskar Middel, Willem Verboom, and David N. Reinhoudt

Abstract: Fourfold homologous anionic *ortho*-Fries rearrangement in the twofold bridged tetra-*O*-carbamate **3** gave the tetrakis(carboxamidomethyl)resorc[4]arene **4** in 68% yield. Compound **3** was prepared by selective carbamoylation of methylresorc[4]arene **1**, followed by the bridging of the remaining OH groups in tetra-*O*-carbamate **2**.

Key words: resorc[4]arenes, selective functionalizations, homologous anionic *ortho*-Fries rearrangement.

Résumé : Le réarrangement *ortho*-Fries anionique homologue quaternaire du tétra-*O*-carbamate **3** à pont binaire conduit à la formation du tétrakis(carboxamidométhyl)résorc[4]arène, **4**, avec un rendement de 68%. Le composé **3** a été préparé par carbamoylation sélective du méthylrésorc[4]arène, **1**, suivie de la formation d'un pont des groupes OH résiduels du tétra-*O*-carbamate **2**.

Mots clés : résorc[4]arènes, fonctionnalisation sélective, réarrangement *ortho*-Fries anionique homologue.

[Traduit par la Rédaction]

Over a time period of about 20 years the directed *ortho*-metalation strategy (D*o*M) (for recent examples see ref. 1*a*, 1*b*; for a review see ref. 1*c*) has developed as a common synthetic concept in aromatic chemistry. The Snieckus group is one of the leaders in this emerging field in synthetic organic chemistry and by their contemporary developments and collaborations, this synthetic concept has been applied in pharmaceutical chemistry, industrial processes, and the total syntheses of complex natural products. Recently, we (2) introduced the D*o*M concept in supramolecular chemistry as the first synthetic tool for the direct, selective introduction of functional groups at the lateral positions of the calix[4]arene skeleton.

Resorc[4]arenes (for a review see ref. 3) (octols), are the cyclic condensation products of aldehydes and resorcinol and the insertion of methylene bridges between adjacent phenolic moieties results in the formation of cavitands (3, 4). Only a few (selective) resorc[4]arene functionalizations, other than methylene bridge formation (4), are known, e.g., the Mannich reaction (5), radical aromatic bromination (6), and the alkylation (7) and (sulfonate) esterification (8, 9) of the phenolic groups. In this communication, we report our first results on the application of the D*o*M concept for the introduction of upper rim functional groups via a unique fourfold anionic *ortho*-Fries rearrangement (10) at the partially bridged resorc[4]arene **3**.

Results and Discussion

Synthesis[2]

Reaction of resorc[4]arene **1** (11) with diisopropylcarbamoyl chloride (20 equiv) in the presence of a large excess of NaH as a base in DMF at 65°C for 72 h afforded a mixture of tetra-*O*-carbamate regioisomers. Fractional crystallization of this mixture from MeOH–H_2O gave regioisomer **2**, having two diametrical pairs of substituted adjacent phenol groups, in 32% isolated yield.[3] The predominant formation of **2** is probably due to a stabilizing effect of the hydrogen bond between adjacent phenol groups. The selective formation of (tetrasulfonate) esters of resorc[4]arenes described by Shivanyuk and co-workers (8*a*), in which on two diametrical aryl rings two sulfonate esters were introduced, was explained by the formation of a strong hydrogen bond between a sulfonate ester and an adjacent phenol moiety.[4]

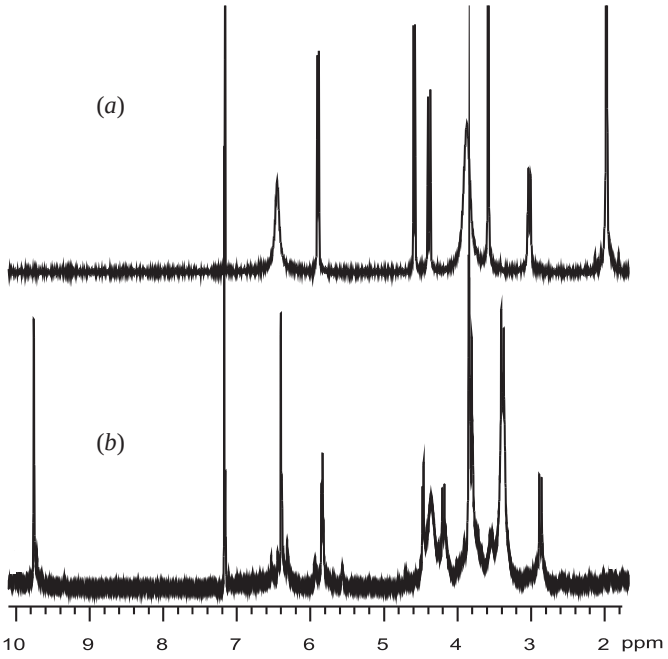
Scheme 1.

In our case, a corresponding hydrogen bond between an *O*-carbamate and a phenol moiety is probably disfavored by the steric hindrance caused by the diisopropylamine groups.



At temperatures between 297 and 333 K, compound **2** shows a broad ^{1}H NMR spectrum in $CDCl_3$, indicating the presence of rotational barriers in parts of the molecule caused by the *O*-carbamate moieties. The molecule equilibrates with rather high-energy barriers, via a *crown*[5] conformer (4), between all possible conformations almost equal in energy. Only the OH-, ArH-, and ArMe signals reside as slightly broadened singlets which suggests the presence of C_{2v}-planes of symmetry in the molecule. This symmetry element leaves two regioisomeric possibilities of which only one was isolated. Elemental analysis and FAB-MS prove that a tetra-*O*-carbamate regioisomer was obtained. However, in combination with ^{1}H NMR we have no conclusive evidence which of the two regioisomers was formed.

Definite proof for the formation of **2** was obtained by its reaction with CH_2Br_2 in the presence of K_2CO_3 as a base in DMF at 90°C for 60 h to give twofold-bridged resorc[4]arene **3** in 85% yield. The introduction of methylene bridges is only possible when adjacent phenol groups are present. The

[5] Two octol conformations are the most common: the *chair* and *crown* conformations which both can be bridged to a cavitand giving pairs of axial and equatorial lower rim substituents or exclusively axial substituents, respectively.

© 2001 NRC Canada

Fig. 1. ^{1}H NMR spectra of: (*a*) tetra-*O*-carbamate **3**; and (*b*) tetraamide **4**.

bridging reaction requires a higher reaction temperature and consequently, the use of CH_2Br_2 instead of CH_2BrCl[6], compared to the standard procedure for the fourfold bridging of both crown (3) and chair resorc[4]arenes (4). This is probably caused by the rather high rotational barriers in **2** (vide supra). Since there are no lateral substituents in **2**, the different conformers all give the same reaction product. The ^{1}H NMR spectrum of **3** (Fig. 1*a*) clearly proves the introduction of two bridges and shows a symmetry in which all ArH and $ArCH_3$ positions are equivalent in agreement with the proposed structure. This is an additional proof of the structure of the tetra-*O*-carbamate **2**.

Ortho-lithiation was accomplished by treating **3** with 10 equiv of *n*-BuLi in THF at –80°C. Upon warming, the reaction mixture slowly to room temperature and stirring at that temperature for 36 h, followed by quenching with aq NH_4Cl, the tetracarboxamide migrated compound **4** was obtained in 68%. The homologous anionic *ortho*-Fries rearrangement resulted in the migration of the carboxamide moieties to the methyl groups since they have the most acidic hydrogen atom upon *ortho*-lithiation in the presence of the *ortho*-directing diisopropyl-*O*-carbamates. The lateral bridge positions are less acidic and are sterically, as well as energetically disfavored for deprotonation since the formation of a five-membered intermediate structure (4) is not easily accomplished. Figure 1 shows the ^{1}H NMR spectra of the starting material (**3**) (*a*) and the rearranged product (**4**) (*b*), clearly visualizing the disappearance of the methyl groups upon migration. Furthermore, the signals for the phenolic groups and the resulting carboxamidomethyl moieties (Fig. 1*b*) reside as a singlet at δ 9.90 and as a double doublet at δ 3.52 and 3.93 (J_{AB} = 13.8 Hz), respectively. Consecutive functional group transformations using the phenol moieties, is demonstrated by the synthesis of tetra-γ-lactone **5,** which is obtained in 70% yield upon refluxing tetraamide **4** in AcOH for 24 h. The lack of isopropyl and ArOH signals in the ^{1}H NMR spectrum, the typical γ-lactone signal at 1812 cm^{-1} in the IR spectrum, and the molecular mass peak (EI–MS) prove the formation of tetra-γ-lactone **5**.

In conclusion, to the best of our knowledge, in this communication we have described the first example of a fourfold homologous anionic *ortho*-Fries rearrangement. By making use of the D*o*M concept, the twofold-bridged tetrakis-(carboxamidomethyl)resorc[4]arene **4** was obtained, which is, upon further transformations, of interest as a building block in supramolecular chemistry.

Asymmetric synthesis of 3-aryl-substituted 2,3-dihydro-1*H*-isoindol-1-ones

Dieter Enders, Volker Braig, and Gerhard Raabe

Abstract: The first asymmetric synthesis of 3-aryl substituted 2,3-dihydro-1*H*-isoindol-1-ones via a tandem nucleophilic 1,2-addition ring closure procedure from SAMP and (or) RAMP hydrazones and subsequent oxidative cleavage of the auxiliary is reported.

Key words: isoindolinones, asymmetric synthesis, hydrazones, 1,2-addition, N—N bond cleavage.

Résumé : On a réalisé la première synthèse asymétrique de 2,3-dihydro-1*H*-isoindol-1-ones substituées en position 3 par un groupe aryle; la synthèse est réalisée par le biais d'une réaction de fermeture de cycle par addition nucléophile 1,2 en tandem à partir des hydrazones SAMP et (ou) RAMP, suivie d'une fermeture oxydante de l'auxiliaire.

Mots clés : isoindolinones, synthèse asymétrique, hydrazones, addition-1,2, clivage de liaisons N—N.

[Traduit par la Rédaction]

Introduction

2,3-Dihydro-1*H*-isoindol-1-ones **1** are known under different names in the literature such as isoindolinones or phthalimidines and are found as a core unit in various natural products. Shamma and co-workers (1) isolated the compounds neuvamine **2**, chilenine **3**, lennoxamine **4**, magallanesine **5**, and pictonamine **6** (Fig. 1). Isoindolinone moieties can also be found in pharmacologically active synthetic substances. For example, compound **7** inhibits the activity of thromboxane A_2 analogue (U-46619)-induced vasoconstriction (2). 3-Substituted 2,3-dihydro-1*H*-isoindol-1-ones can also modulate the common allosteric binding site of the muscarine M_2 receptors, for example the dimer **8** (3). Finally, compounds such as **9** are inhibitors of the HIV-1 reverse transcriptase (4; for further examples see ref. 5).

There are many methods for the synthesis of 3-carbon-substituted isoindolinones described in the literature. The most common strategies are shown retrosynthetically in Fig. 2.

Method **I** may be achieved via substitution of a 3-chloroisoindolinone (6), a nucleophilic addition to either an *N*-acyliminium ion (7) or to a carbonyl group and subsequent reduction of the *N*,*O*-acetal (8, 6*b*). Another possibility for the cut **I** is the addition of an electrophile to a deprotonated isoindolinone (9, 10). Ring closure reactions are involved in methods **II**–**IV.** Method **II** is either possible via radical cyclisations (11) or as palladium-catalyzed ring closure reactions (12). 2-Vinyl-benzamides (13), 2-vinyl-benzonitriles (13*b*), or 2-acyl-benzamides (14) can be cyclised according to method **III**. The important reaction of method **IV** is the formation of the lactam ring (15). The common feature of methods **V**–**VII** is that the isoindolinone is built with two reactants, one is a substituted benzene and the other reactant contributes to the isoindolinone ring a one-atom unit. In method **V**, the 3-position carbon atom is brought into the ring (16). Method **VI** involves the reaction of an amine with either 2-acyl or 2-aroyl benzoic acids or esters (17), 2-(bromo-ethoxycarbonyl-methyl)-benzoic acid ethyl ester (18), or 2-(2-nitro-ethylen)-benzoic acid methyl ester (19). A newer version of method **VI** is based on *N*,*O*-acetals as intermediates, which can be opened, leading to enantiomerically enriched 3-subsituted isoindolinones (20). Method **VII** offers the possibility to obtain chiral 3-substituted isoindolinones, because the 3-position is not involved in the reaction (21). Method **VIII** is based on a nucleophilic addition to a C—N double bond to build the isoindolinone unit (22). It is also possible to synthesize isoindolinones via rearrangements (6*a*, 3*b*, 23) or the reduction of 3-alkylidene-isoindolinones to 3-alkyl-isoindilinones (24, 19).

In this paper, we report on the first asymmetric synthesis of 3-aryl-substituted isoindolinones via nucleophilic 1,2 addition to RAMP-hydrazones according to method **VIII**.

Results and Discussion

As shown in Scheme 1 the RAMP or SAMP hydrazones were prepared in good yields in a facile procedure. The freshly distilled aldehydes were condensed with neat RAMP or SAMP, to obtain the corresponding hydrazones **11a**–**c** in almost quantitative yields (Table 1).

The nucleophilic 1,2-addition to SAMP or RAMP hydrazones is a well-established method to obtain enantiopure

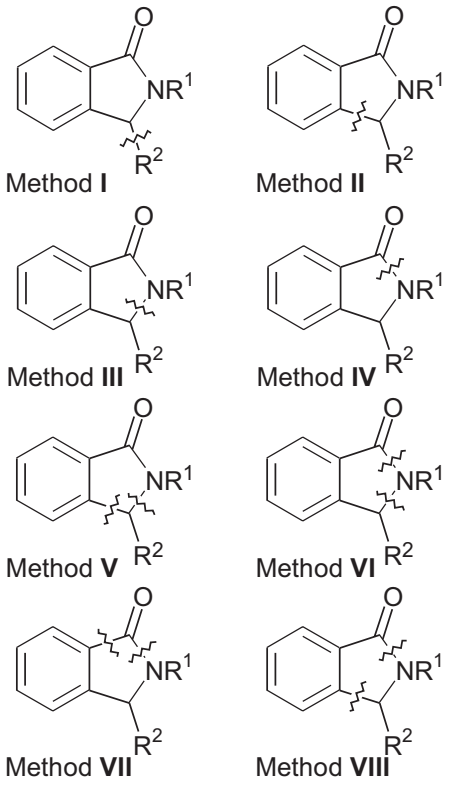
Fig. 1.

amines (25). For example, a recent application led to syntheses of the pheromone harmonine (26) and the defence alkaloid of the mexican bean beetle, *Epilachana varivestis* (Coccinellidae) (27). In our synthesis we applied lithiated diethylbenzamides as nucleophiles, generated by directed *ortho*-metalation (DoM) (28), which underwent smooth nucleophilic 1,2-addition to the C—N double bond of aldehydehydrazones **11a**–**c** followed by in situ ring closure to afford the corresponding isoindolinones **13a**–**e.** This tandem reaction was performed in satisfactory to good yields (Table 2) and high diastereomeric excesses.[2] To drive the reaction to completion, we had to use 11 equiv of diethylbenzamides **12a**–**b** and 10 equiv of *sec*-butyllithium. Reaction of only 4.5 equiv of both substrates gave a poor yield (17% of compound (*S*,*S*)-**13e**). We also investigated halogen metal exchange of 2-iodobenzoic acid esters and DoM of methylbenzamide instead of the diethylbenzamides **12a**–**b**, but no product was observed. Recrystallization of the SAMP-derivative (*S*,*S*)-**13e** allowed the assignment of the configuration of the new generated stereocenter by X-ray analysis (Fig. 3). It was found to be *S*-configured, as expected (29).



To obtain a good diastereomeric excess, careful control of the reaction temperature is important: if the warm-up of the reaction mixture was too fast the diastereomeric excesses were observed to decrease. To see if the reaction tolerated substitution at the aromatic ring, we used the benzamide **12b** with success. To further extend the scope of this reaction aliphatic hydrazones (R^1 = *tert*-butyl, isopropyl) were screened but no acceptable results could be obtained.

We next examined the N—N bond cleavage of the auxiliary to release the enantio-enriched amines (30). A variety of methods were applied to the hydrazines **13a**–**e**, but we obtained either a complex mixture (BH_3·THF, O_3, Raney Ni–H_2), no reaction at all ($Na_2S_2O_4$), or cleavage but racemisation (Li–NH_3(l), Ca–NH_3(l), Zn–AcOH). The only method we could apply with success was the oxidative cleavage with magnesium monoperoxyphthalate hexahydrate (MMPP) developed by Lassaletta and co-workers (31). They used MMPP to cleave N—N bonds of SAMP-derivatives. The *N*-unsubstituted isoindolinones **14a**–**e** were obtained in very good yields and high enantiopurity. Three compounds were purified via crystallization (**14a**, **14b**, **14e**) resulting an enantiomeric excess higher than 99%. Compounds **14c** and **14d** were purified via flash chromatography, leading to an enantiomeric excess of 97% and 99%. This indicates that we could remove the auxiliary without racemization. Enantiomeric excesses were determined by HPLC on a chiral stationary phase. The racemates were prepared by racemization

[2] Determination of the diastereomeric excess of the isoindolinones **13a**–**e** was achieved by ^{1}H NMR analysis of the crude products. The singlet due to the hydrogen at the 3-position of the isoindolinone ring was used (e.g., (*S*,*S*)-**13e** δ: 5.60 ppm; (*R*,*S*)-**13e** δ: 5.07 ppm).

of the enantiopure compounds with lithium diisopropylamide (LDA) in THF at 0°C.

In conclusion, we have developed the first asymmetric synthesis of 3-aryl-substituted 2,3-dihydro-1*H*-isoindol-1-ones via a tandem nucleophilic 1,2-addition ring closure procedure to SAMP- and (or) RAMP-hydrazones and subsequent oxidative removal of the auxiliary.

Experimental

All melting points (Büchi 510, system Dr. Tottoli) are uncorrected. Proton and carbon nuclear magnetic resonance (^{1}H NMR and ^{13}C NMR) were recorded on Varian Inova 400 (^{1}H NMR: 400 MHz; ^{13}C NMR: 100 MHz) or Varian Unity 500 (^{1}H NMR: 500 MHz; ^{13}C NMR: 125 MHz) spectrometers. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Coupling constants are given in Hertz (Hz). The following abbreviations report the multiplicity and shape of the signals: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and combinations e.g., dd (doublet of doublets). Mass spectra (MS) were obtained on Varian MAT 212 (EI: 70 eV; CI: 100 eV, Isobutan) or Finnigan MAT 95 (high resolution MS (HRMS): 70 eV). Intensities are given relative to the base peak. Infrared (IR) spectra were obtained on a PerkinElmer FT IR 1750. Elemental analyses were performed on a Heraeus CHN-O-Rapid. Optical rotations were measured with a PerkinElmer P 241 polarimeter. Reactions and the progress of chromatographic separations were monitored by TLC on silica gel (Merck Kieselgel 60 F_{254}). Flash chromatography was performed on silica gel (Merck Kieselgel 60). Reactions with moisture- or air-sensitive reagents were performed with Schlenk technique under an argon atmosphere. Tetrahydrofuran (THF) was freshly distilled from sodium lead alloy (5% Na) – benzophenone ketyl.

Synthesis of the RAMP or SAMP hydrazones 11a–c

After cooling of the aldehydes **10a–c** (1.2–2.4 equiv) to 0°C RAMP or SAMP (1 equiv) was added. This mixture was stirred for 30 min at 0°C. First, diethyl ether (4.2 mL per mmol SAMP and (or) RAMP) and then $MgSO_4$ were added. The reaction mixture was stirred overnight at room temperature. The removal of $MgSO_4$ and of the solvent afforded the oily crude hydrazones in virtually quantitative yield, which were purified by Kugelrohr distillation under reduced pressure. This reaction was typically run on a scale of 30 mmol.

Anal. calcd. for $C_{20}H_{22}N_2O_2$: C 74.51, N 8.69, H 6.88; found: C 74.63, N 8.66, H 6.96.

*Crystal data and refinement details for (S,S)-**13e**:* $C_{20}H_{22}N_2O_2$; fw = 322.41; orthorhombic; space group $P2_12_12_1$ (no. 19); *a* = 6.1386(8), *b* = 12.392(1), *c* = 22.328(6) Å; *V* = 1698.5(5) $Å^3$; *Z* = 4; ρ_c = 1.261 g cm^{-3}; μ = 6.51 cm^{-1}, no absorption correction; *T* = 150 K; CuKα (1.54179 Å). An irregularly shaped crystal (~0.3 × 0.3 × 0.3 mm^3) was mounted on top of a capillary in a stream of cooled nitrogen. 3472 unique reflections were collected in the range: *h*: ±7, *k*: ±15, and *l*: ±27 (r_{av} = 0.01(5)) on an Enraf–Nonius CAD4 diffractometer in the ω/2Θ mode. The structure has been solved by direct methods (GENSIN/GENTAN) as implemented in the Xtal3.4 suite of crystallographic routines (32). 3130 observed reflections ($I > 2\sigma(I)$) in the final full-matrix least-squares refinement of 217 variables terminating at *r* = 0.061 (r_w = 0.066, $w = \sigma^{-2}$), a residual electron density of –0.33/+0.40 e $Å^{-3}$, a max shift/error of 0.13 × 10^{-3}, and a goodness-of-fit of 1.744. The atomic scattering factors are those from ref. 33. No extinction correction. Hydrogen atoms were calculated in idealized positions and their *U*s were fixed at 1.5 times *U* of the relevant heavy atom prior to final refinement. No refinement of hydrogen positions. The chirality of the new generated stereocenter was fixed using the known configuration of the auxiliary (Fig. 3).

The refined non-hydrogen atomic coordinates for (*S*,*S*)-**13e** are listed in Table 4 while the hydrogen coordinates, temperature factors (anisotropic for carbon atoms), scale factor, and

N—N bond cleavage for the synthesis of title compounds 14a–e

MMPP·6 H_2O (2.0 to 2.5 equiv) was added to a solution of hydrazine **13a–e** (1.0 equiv) in methanol (13.0 mL per mmol hydrazine). Stirring at room temperature (24–96 h) was continued until no hydrazine remained (TLC monitoring). If the reaction stops before all hydrazine has reacted, it is possible to add a further amount of MMPP·6 H_2O (0.5 equiv). After dilution of the reaction mixture with ether (60.0 mL per mmol hydrazine), a sat. aq $NaHCO_3$ solution (43.0 mL per mmol hydrazine) was added. The aqueous layer was extracted with chloroform after phase separation. The combined organic extracts were dried ($MgSO_4$) and the solvent was removed in vacuo. The residue was either purified by flash chromatography or crystallization from ethyl acetate.

*(3*R*)-5-Methoxy-3-phenyl-2,3-dihydro-1*H*-isoindol-1-one ((*R*)-**14a**)*

Colorless solid, mp = 219°C. $[\alpha]_D^{26}$ = –52.2 (c = 0.81, $CHCl_3$). *m*/*z* (EI): 239 (100%)$(M)^+$, 208 (43)$(M\text{-}CH_3O)^+$, 162 (34)$(M\text{-}Ph)^+$. ν_{max} (KBr) (cm^{-1}): 1690, 1664, 1610. ^1H NMR (d_6-DMSO, 400 MHz) δ: 3.69 (s, 3H, OC*H*$_3$), 5.60 (s, 1H, NHC*H*), 6.73 (d, *J* = 1.5, 1H, O=CCCC*H*), 6.98 (dd, *J* = 8.5, 1.9, 1H, O=CCCH=C*H*), 7.21–7.35 (m, 5H, C*H*$_{Phenyl}$), 7.59 (d, *J* = 8.5, 1H, O=CCC*H*=CH), 8.81 (s, 1H, N*H*). ^{13}C NMR (d_6-DMSO, 100 MHz) δ: 56.4, 60.1, 108.7, 115.5, 124.4, 125.0, 127.2, 128.6, 129.4, 140.3, 151.1, 163.1, 170.3. Organometallic reactions in aqueous media — Antimony-mediated allylation of carbonyl compounds and the nature of allylstibine intermediates

Lian-Hai Li and Tak Hang Chan

Abstract: Commercial antimony metal, in aqueous 1 M H(D)Cl solution, reacts with allyl bromide and aldehydes to give the corresponding homoallylic alcohols in good yield. The reaction proceeds through the formation of allylstibine intermediates. The structures of the allylstibine intermediates are likely to be allylstibine dibromide and diallylstibine bromide.

Key words: allylation reaction, aqueous organometallic reactions, homoallylic alcohols, allylstibine dibromide, diallylstibine bromide.

Résumé : En solution aqueuse de H(D)Cl 1 M, l'antimoine métallique commercial réagit avec le bromure d'allyle et les aldéhydes pour donner lieu à la formation, avec de bons rendements, des alcools homoallyliques correspondants. La réaction se produit par le biais de la formation d'intermédiaires allylstibines. Les structures des allylstibines intermédiaires sont vraisemblablement celles du dibromure d'allylstibine et du bromure de diallylstibine.

Mots clés : réaction d'allylation, réactions d'organométalliques en milieu aqueux, alcools homoallyliques, dibromure d'allylstibine, bromure de diallylstibine.

[Traduit par la Rédaction]

Introduction

The allylation of carbonyl compounds has proved to be a very important reaction in organic synthesis. Numerous reagents and methods have been developed to accomplish this transformation (for general reviews, see ref. 1). The discovery (for reviews see ref. 2) in the past decade that this transformation could be achieved in aqueous media through a Barbier type reaction (for a recent monograph see ref. 3*b*), has drawn even more attention to this area of chemistry. Metals such as Zn (4), In (5), Bi (6), Sn (7), Pb (8), Mn (9), Mg (10), or Sb (11) have been reported to be effective in mediating the coupling between allyl halides and carbonyl compounds to give the corresponding homoallylic alcohols (Scheme 1). Among these reported metals, all of them except Sb were found to effect the transformation with commercially available metal powder, even though in cases such as Sn or Zn, activation was needed. In the case of antimony, however, commercial antimony metal was apparently not successful in mediating the allylation reaction in aqueous media (Barbier–Grignard type allylation of aldehydes with metallic antimony can be accomplished in nonaqueous media by refluxing in THF–HMPA (1:1) (see ref. 12*a*); recently, activation of antimony with fluoride salts in aqueous media has been reported (see ref. 12*b*)). Several publications have appeared in the literature to indicate that the antimony metal must be formed in situ through the reduction of antimony trichloride with a reducing reagent such as Al or Fe (11*a*) or $NaBH_4$ (11*b*). The "active" antimony, thus generated, could then mediate the allylation reaction in an aqueous and (or) organic solvent system. As part of our general program to study organometallic reactions in aqueous media, we are interested in finding conditions that can allow the use of commercial antimony directly without the need for the reductive generation step (12). Another objective is to have a better understanding of the mechanism of these reactions. Recently, we have investigated the nature of the organometallic intermediates that may be implicated in these reactions. We were able to conclude that in the indium mediated allylation reaction, an allylindium(I) intermediate rather than an allylindium(III) species was formed (13). In the tin-mediated allylation reaction, both diallyltin(IV) dibromide and allyltin(II) bromide were formed (14). On the other hand, in the zinc- or magnesium-mediated allylation reactions, there had been suggestion that the reaction may have occurred on the metal surface (10). We are interested therefore in the antimony-mediated reaction to see if any organostibine intermediate(s) were formed in the aqueous allylation reaction and to explore the nature of these intermediates.

Results and discussion

Investigations on the use of commercial antimony powder

Our investigation started with performing the reaction with commercial antimony powder in aqueous media. In agree-

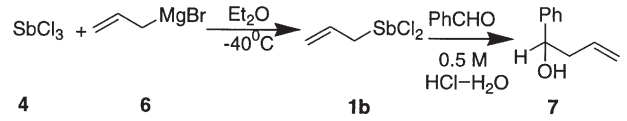
[a]The molar ratio of carbonyl compound:allyl bromide:Sb is shown as: A 1:2.5:5, B 1:2.5:1.2, C 1:2.5:2, D 1:2.5:3.
[b]While the yield was low, the starting carbonyl compound was recovered unchanged in good mass balance.
[c]Yield based on ^1H NMR spectrum analysis of the crude products mixture.

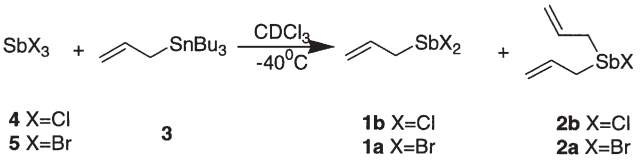
ment with previous reports, the reaction performed in distilled water with the molar ratio of Sb:benzaldehyde:allyl bromide at 5:1:2.5 gave no trace of the corresponding homoallylic alcohol even after a week of vigorous stirring of the reaction mixture (entry 1, Table 1). It was obvious that activation of the metal was needed for this reaction to proceed. Previous investigations of other metals showed that catalytic amount of acid such as hydrobromic acid (7), ammonium chloride (4), higher reaction temperature (7), or ultrasonic radiation (4) might be helpful in promoting such reactions. We tried, therefore, saturated ammonium chloride solution with the same ratio of the reactants and found the reaction did work but slowly (entry 2, Table 1). Increasing the concentration of the ammonium chloride helped improve the yield of the reaction but it was still too slow to be practical (entry 3, Table 1). The role of ammonium chloride might be due to increasing acidity or the effect of the chloride ion. When the ammonium chloride solution was substituted with a 0.1 M of hydrochloric acid solution, the reaction was found to proceed smoothly and be completed in 16 h (entry 5, Table 1). These results suggested that acidity played a role in promoting the reaction. Attempts to reduce the amount of the Sb used for the reaction caused the prolonging of the reaction time (entries 6–8, Table 1). The use of 2 equiv of Sb was found to be optimal. On the other hand, the use of 0.5 M instead of 0.1 M hydrochloric acid as solvent was found to accelerate the reaction (entry 9, Table 1). With these conditions, other aldehydes could be allylated to give excellent yields of the products (entries 10–18, Table 1). The results in Table 1 showed some interesting features of the antimony mediated allylation reaction. First, the reaction was not sensitive to the nature of the aldehydes used. The reaction proceeded well with either aromatic or aliphatic aldehydes. The allylation of α,β-unsaturated aldehyde as represented by *trans*-cinnamaldehyde (entry 18, Table 1) occurred in a regiospecific manner and gave solely the 1,2-addition product. Furthermore, electron donating or withdrawing groups on the aromatic ring did not seem to affect the reaction significantly either in the yield of the product or the rate of the reaction. Thirdly, the reaction conditions appeared not to be reductive in nature. Thus, we did not detect alcohols or pinacols as side products of the reactions as often found with Zn or Mg. In the same vein, nitro function was not reduced under the reaction conditions. Thus, *p*-nitrobenzaldehyde was successfully allylated. Usually, the nitro group was sensitive to reduction by metals and *p*-nitrobenzaldehyde could not be allylated under Barbier conditions by Zn, Sn, or In (15). Finally, the reaction was chemoselective. Efforts to allylate ketones failed (entries 19 to 20, Table 1) in agreement with previous literature reports using active antimony (11). In this respect, antimony seems to be different from indium, the commonly employed metal, in that indium mediates the allylation of both aldehydes and ketones effectively.

Table 2. The effect of acid sensors on antimony-mediated allylation of benzaldehyde.[a]



Entry	Solvents (in H_2O)	Time (h)	Isolated yields[b]
1	0.1 M HCl	4 days	93
2	0.5 M HCl	16	100
3	1 M HCl	8	89
4	0.5 M HBr	16	43
5	0.25 M H_2SO_4	16	81
6	0.5 M D-Tartaric acid	16	100[c]
7	0.5 M Oxalic acid	1	26
8	0.1 M Oxalic acid	1.5	70
9	0.025 M Oxalic acid	6	19

[a]The molar ratio of benzaldehyde:allyl bromide:Sb was 1:2.5:2 and the solvent used was 5 mL of benzaldehyde (1 mmol).
[b]While the yield was low benzaldehyde was recovered unchanged in good mass balance.
[c]No optical rotation could be observed.



We have also briefly examined other acids as promoters of the reaction. When hydrochloric acid was replaced by a 0.25 M aq H_2SO_4 solution, the reaction gave lower yield (Table 2, entry 5) in comparison with the same reaction in hydrochloric acid solution (Table 2, entry 2). These results showed that in addition to acidity, the counter anion might play a role in the reaction. In support of this observation, we found that the reaction can be promoted by oxalic acid or tartaric acid (entry 6, Table 2), even though the yield with oxalic acid (entries 7–9, Table 2) was lower. In the case of D-tartaric acid, it was a very effective promoter of the reaction; however, the product homoallylic alcohol derived from benzal-

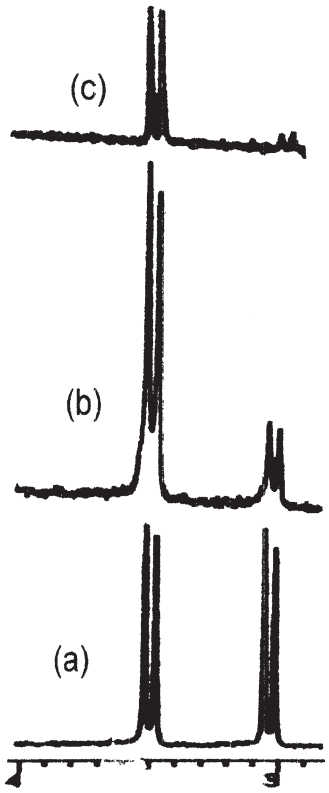
Scheme 3.

dehyde unfortunately did not show any optical activity. No asymmetric induction was observed (16).



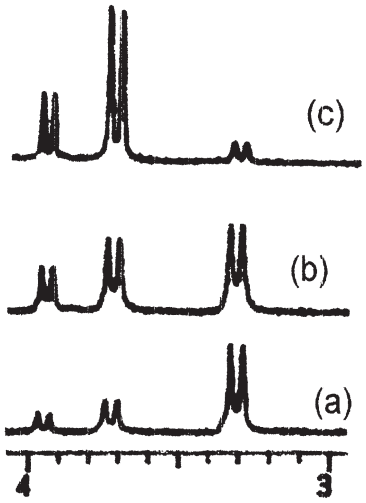
Investigations of the allylstibine intermediate

First, we tried to determine if an allylantimony intermediate can survive the aqueous conditions and allylate aldehydes. The reaction between a Grignard reagent and antimony(III) halide has been known to give the alkylantimony(III) dihalide (17). We therefore carried out the reaction of antimony trichloride with allylmagnesium bromide in ether (Scheme 2). When the supposed allylstibine dichloride (from 5 mmol of the Grignard reagent) prepared in this way was treated with benzaldehyde (1 mmol) in 0.5 M hydrochloric acid aqueous solution, the desired homoallylic alcohol was obtained in 81% yield. These results showed that the allylantimony species, whatever its structure, was able to exist in the aqueous media to some extent and perform the addition reaction to carbonyl compound in acidic conditions. We were, however, not able to isolate and characterize the presumed allylstibine intermediate by the usual method of isolation or purification.

Since in the indium and tin cases, we had some success in the direct observation of the reaction of metal with allyl bromide in aqueous media (as D_2O) using ^1H NMR analysis (13, 14), we followed the reaction of allyl bromide with antimony powder in 0.5 M DCl–D_2O (prepared by the hydrolysis of TMSCl in D_2O) by ^1H NMR but detected no new signals. However, when a 1 M DCl–D_2O solution was used as the solvent instead, two new doublets, one at about 3.8 ppm and the other at about 3.3 ppm were observed in about 12 min. These signals grew in intensity for about 45 min and then disappeared after 90 min. At the same time, the doublet at 3.7 ppm, due to the methylenic protons of allyl bromide, declined in intensity correspondingly. These results suggested that some allylstibine intermediates were formed in the reaction mixture.

What are the structures of these intermediates? The likely candidates are: allylstibine(III) dibromide (**1a**) and diallylstibine(III) bromide (**2a**) as well as their chloride counterparts **1b** and **2b** due to possible halide exchange in the presence of DCl. In the literature, allylstibine(III) dichloride (**1b**) had been prepared in situ by the reaction of antimony trichloride with allyltributyltin (**3**) in $CDCl_3$. Its NMR in $CDCl_3$ had been observed and the chemical shift of the allylic protons was reported to be at 3.51 ppm at –40°C (18). We, therefore, examined in some details the reaction between allyltributyltin

Fig. 1. Partial ^1H NMR spectra of the in situ-formed allylstibine intermediates by the reaction of antimony(III) chloride with allyltributyltin in $CDCl_3$ at –40°C. (*a*) Mol ratio $SbCl_3$:allyltributyltin = 1:1; (*b*) mol ratio $SbCl_3$:allyltributyltin = 1:0.66; (*c*) mol ratio $SbCl_3$:allyltributyltin = 1:0.33.



with antimony halides in $CDCl_3$ to generate the allylstibine halide intermediates (Scheme 3). When compound **3** and antimony trichloride (**4**) in equal molar amounts were mixed in $CDCl_3$ at –40°C, a doublet at 3.5 ppm, in agreement with literature report for **1b** (18), was observed in the ^1H NMR. However, another doublet at 3.0 ppm was observed as well. We attributed the presence of the second doublet at 3.0 ppm to diallylstibine chloride **2b.** In accordance with this explanation, it was found that when the amount of **3** added was reduced, the intensity of the doublet at 3.0 ppm declined relative to that of 3.5 ppm, as one would expect (Fig. 1*a*–*c*). Allylstibine chlorides **1b** and **2b,** thus prepared from a one-third molar amount of compound **3** to **4** in $CDCl_3$, were extracted into a solution of DCl–D_2O at 0°C and the ^1H NMR was observed. Signals at 3.6 and 3.0 ppm were observed, suggesting that the same allylstibine chlorides **1b** and **2b** existed in the aqueous media.[2]

Similar patterns were observed in the reaction of allyltributyltin (**3**) with antimony tribromide (**5**). When compounds **3** and **5** were mixed in equal molar amounts in $CDCl_3$ at –40°C, the ^1H NMR showed two doublets at 3.7 and 3.3 ppm. These two doublets are assigned to allylstibine dibromide **1a** and diallylstibine bromide **2a**, respectively. Again, as the amount of compound **3** was reduced successively from equal amount to one-half and then to one-third of **5**, the relative intensity of the 3.3 ppm doublet decreased

[2] Additional doublet at 2.3 ppm could be observed in DCl–D_2O which may be due to hydrolysis product under these conditions.

Fig. 2. Partial ^{1}H NMR spectra of the in situ-formed allylstibine intermediates by the reaction of antimony(III) bromide with allyltributyltin in $CDCl_3$ at –40°C. (*a*) Mol ratio $SbBr_3$:allyltributyltin = 1:1; (*b*) mol ratio $SbBr_3$:allyltributyltin = 1:0.66; (*c*) mol ratio $SbBr_3$:allyltributyltin = 1:0.33. The doublet at 3.95 ppm was due to the methylenic proton of allyl bromide which was found as a side product.

eventually to about one-tenth of the intensity of the 3.7 ppm doublet (Fig. 2*a*–*c*). Similar extraction of **1a** and **2a** from $CDCl_3$ solution into DBr–D_2O solution showed doublets at 3.8 and 3.4 ppm,[3] at nearly the same positions as those observed from the direct reaction between allyl bromide and antimony in DCl–D_2O.[4]

Experimental section

General procedure

All the reactions were carried out in distilled water. Purification of products with flash chromatography was performed over silica gel. The ^{1}H NMR spectra of the products were performed on a Gemini-200 spectrometer in chloroform-*d* with the solvent signal used as the internal standard. The DCl–D_2O solution was prepared by hydrolysis of trimethylchlorosilane (TMSCl) in D_2O. The antimony powder (325 mesh) was purchased from Alfa Aesar. The hydrochloric solution was prepared by dilution of reagent grade concentrated hydrochloric acid (36.5–38%) and was not titrated again. The aldehydes and ketones were used as purchased as long as their ^{1}H NMR spectra were satisfactory.

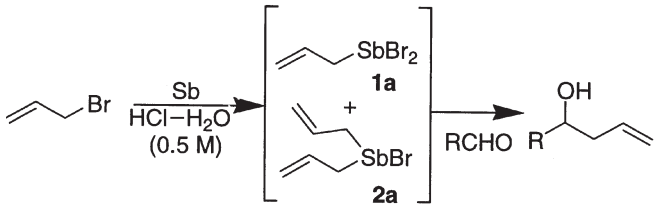
Standard procedures for the allylation of aldehydes

To a mixture of aldehyde (1 mmol) and allyl bromide (2.5 mmol) in 0.5 M hydrochloric acid solution (4 mL), antimony powder (2 mmol) was added in one portion and the mixture was vigorously stirred until the antimony powder was reacted (usually overnight). Ethyl ether was added to the reaction mixture and the organic layer was separated. The aqueous phase was extracted with ethyl ether. The organic extracts were combined and dried over Na_2SO_4, and were filtered and evaporated. The residue, for most of the aldehydes, afforded the corresponding homoallylic alcohols of sufficient purity according to ^{1}H NMR without the need for further purification. If necessary, purification was performed by flash chromatography over silica gel using hexane – ethyl acetate as eluent. All the homoallylic alcohols reported in Table 1 are known compounds: 1-phenylbut-3-en-1-ol (19), 1-decen–4-ol (20), 1-(4-chlorophenyl)but-3-en-1-ol (21), α-propenyl-cyclohexanemethanol (22), 1-phenyl-1,5-hexadien-3-ol (23), 1-(4-nitrophenyl)but-3-en-1-ol (24), 1-(4-methoxyphenyl)but-3-en-1-ol (25), 1-naphthylbut-3-en-1-ol (24), 1-(4-trifluoromethylphenyl)but-3-en-1-ol (26), 1-(4-methylphenyl)but-3-en-1-ol (26).

Procedures for the monitoring of the reaction intermediates by ^{1}H NMR in 1 M DCl–D_2O

To a stirring mixture of allyl bromide (2.5 mmol) in D_2O (5 mL) at room temperature, TMSCl (5 mmol) was added dropwise. The resulting mixture was stirred at room temperature for 10 min and then antimony powder (2 mmol) was added in one portion. The resulting reaction mixture was stirred vigorously. After the reaction mixture was stirred for 12 min, 30 min, 60 min, or 90 min, a sample was taken while stirring and the ^{1}H NMR spectrum was observed immediately (132 scans). The resulting spectrua showed that two new doublets at 3.8 and 3.3 ppm could be observed until the sample taken after 75 min.

Procedures for the allylation of benzaldehyde with allylstibine dichloride in water



At –78°C, under Ar atmosphere, allylmagnesium bromide (5 mL, 1 M in Et_2O) was added dropwise to a solution of antimony trichloride (5 mmol) in ether (40 mL). The resulting mixture was stirred at –40°C for 3 h. The solvent was then removed by high vacuum at –40°C and the solid residue was subjected to high vacuum at this temperature for 4 h. The solid residue was broken up with a spatula at –40°C under an Ar atmosphere in the flask. Then the cooling bath was removed and, at room temperature, a solution of 0.5 M aqueous hydrochloric acid solution (10 mL) or distilled water with benzaldehyde (106 mg, 1 mmol) was added to the flask containing the solid. The resulting mixture was stirred at room temperature for 2 h. Ethyl ether was used to extract the reaction mixture. The organic extracts were combined and dried over Na_2SO_4. The residue after evaporation was purified through flash chromatography (10% EtOAc–hexane) to afford the corresponding homoallylic alcohol as a colorless oil (120 mg, 81% yield).

[3] Additional doublets of weaker intensities at 3.6, 3.0, 2.7, and 2.5 ppm could be observed in DBr–D_2O which may be due to hydrolysis products under these conditions.

[4] The possibility of halide exchanges cannot be resolved completely. We were able to extract **1b** and **2b** from $CDCl_3$ into DBr–D_2O and found that the allylic signals were observed at 3.8 and 3.4 ppm. This observation suggested that **1b** and **2b** may have been converted to **1a** and **2a** through halide exchange. We were however not able to obtain good spectra by extracting **1a** and **2a** from $CDCl_3$ into DCl–D_2O to confirm that the reverse exchange did not take place.

Scheme 4.

Conclusions

The above studies demonstrate that antimony, in aq 1 M H(D)Cl solution, is able to react with allyl bromide and aldehydes to give the corresponding homoallylic alcohols in good yield. The reaction proceeds through the formation of allylstibine intermediates. The structures of the allylstibine intermediates are likely to be allylstibine dibromide **1a** and diallylstibine bromide **2a** (Scheme 4). Compounds **1a** and **2a** have been independently generated by transmetalation reaction between allyltributyltin and antimony tribromide. Together with the results in the cases of indium (13) and tin (14) where formation of allylindium and allyltin intermediates were observed, a general picture on the Barbier reaction in aqueous media begins to emerge. For these three metals (In, Sn, and Sb), discreet organometallic intermediates can be formed directly from allyl bromide and the metal in aqueous media. These allylic organometallic intermediates have finite stability in water, and sufficient reactivity with carbonyl compounds to make them useful synthetic reagents in aqueous media. It remains to be seen whether for other metals such as Bi, Pb, or Mn, discreet organometallic intermediates can equally exist in water with finite lifetimes.

A highly efficient strategy for the synthesis of 3-substituted salicylic acids by either directed *ortho*-lithiation or halogen–metal exchange of substituted MOM protected phenols followed by carboxylation.

Stephen Y.W. Lau and Brian A. Keay

Abstract: A highly efficient synthesis of various 3-substituted salicylic acids is described starting from inexpensive starting materials and requiring no special apparatus.

Key words: salicylic acids, *ortho*-metalation, halogen–metal exchange, methoxymethyl group.

Résumé : On décrit une synthèse très efficace d'acides salicyliques substitués en position 3, à partir de produits peu dispendieux et ne requérant pas d'appareils spéciaux.

Mots clés : acides salicyliques, *ortho*-métallation, échange halogène–métal, groupe méthoxyméthyle.

[Traduit par la Rédaction]

Introduction

During the course of our study on the effect of remote substituents on the enantioselectivity of a palladium-catalyzed polyene cyclization (**3** → **4**) (1), which has been used in the synthesis of (+)-xestoquinone (2), we required various 3-substituted salicylic acid derivatives **1** (Scheme 1). As only 3-chlorosalicylic acid was commercially available, other methods for the preparation of 3-substituted salicylic acids were found in the literature. Currently, there exist relatively few direct methods for the synthesis of 3-substituted salicylic acids (3, and for recent reports involving the use of 3-halogen substituted salicylic acids, see ref. 4). Some salicylic acid derivatives can be synthesized directly from their corresponding phenols via a Kolbe–Schmidt carboxylation (5), however, we did not possess the proper apparatus to work with carbon dioxide at high pressures and temperatures. Another common route is through Reimer–Tiemann (6) or Duff formylations (7) of the 2-substituted phenols to give the 3-substituted salicylaldehydes followed by oxidation to the acid (8). The main drawback of this reaction is that the formylation is rarely selective and the aldehyde can be introduced *ortho* and (or) *para* to the phenol (9). In our hands, formylation of 2-substituted phenols provided a mixture in which the *para* isomer was the major product. Other strategies, such as the direct bromination of salicylic acid, which is reported to give only the 3-brominated isomer (10), gave us mixtures of the 5-bromo- and 3,5-dibromo- products and never the desired isomer. An alternative synthesis of 3-bromosalicyclic acid was reported in 1923 (11) in which the 5-position of salicyclic acid could be blocked as a sulfonic acid, brominated in the 3-position, and then the sulfonic acid removed. However, bromination of 5-protected salicyclic acid gave only 2,4,6-tribromophenol. As we had no luck with existing procedures we designed a new synthetic strategy for preparing various 3-substituted salicyclic acids and report herein simple and inexpensive procedures for their preparation.

Our initial attempts at synthesizing 3-chlorosalicylic acid from 2-chlorophenol, using either 2 equiv. of *n*-BuLi or 1 equiv. of NaH and 1 equiv. of *n*-BuLi followed by treatment with CO_2 gas at ambient pressure, met with little success due to the weakness of the phenolic OLi group as an *ortho*-lithiation director (12). The methoxymethyl (MOM) ether of phenols is known to be a more efficient *ortho*-lithiation director than phenolic hydroxyl groups (13). Thus, treatment of either the *ortho*-fluoro- (**5**) or *ortho*-chlorophenol MOM ether (**6**) (14) with 1 equiv. of *n*-BuLi generated the *ortho*-anion, which was trapped with gaseous CO_2 at low temperature (15). An acidic workup with 6 M HCl protonated the carboxylic acid and cleaved the MOM ether in situ to afford the 3-fluoro- (**7**) or 3-chlorosalicylic acid (**8**) in 86 and 91% yields, respectively (Scheme 2). As expected, there was no evidence of halogen–lithium exchange with either sample. This method for the preparation of 3-fluorosalicyclic acid (**7**) is more efficient than a recently reported synthesis (3).

The 3-bromo derivative could not be synthesized in the same manner from *ortho*-bromophenol because, in this case,

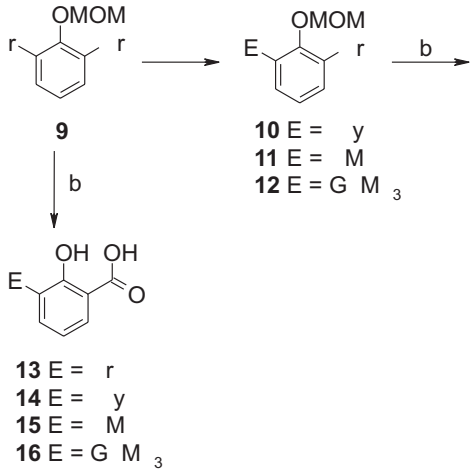
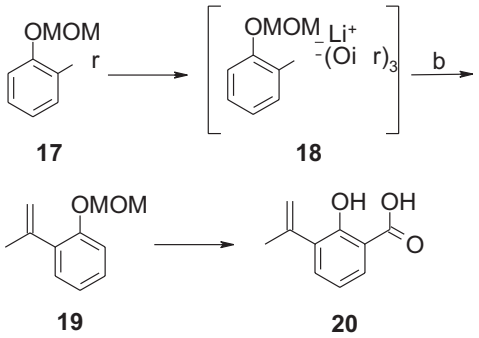
Scheme 1.

Scheme 2.



halogen–lithium exchange would occur more rapidly than deprotonation. We, thus, developed an alternative strategy starting from 2,6-dibromophenol that was easily prepared by treatment of a mixture of phenol and *tert*-butylamine with 2 equiv. of bromine at low temperature (16). The MOM protected 2,6-dibromophenol **9** (Scheme 3) was subjected to a monohalogen–lithium exchange with 2.1 equiv. of *t*-BuLi followed by quenching the anion with carbon dioxide. An acidic workup afforded the desired 3-bromosalicylic acid **13** in 97% yield.



We decided to extend the above strategy towards other 3-substituted salicylic acids by using **9** as the starting material. By trapping the initial anion formed by a monohalogen–metal exchange with suitable electrophiles, the remaining bromide could subsequently be exchanged and trapped with carbon dioxide to give 3-substituted salicylic acids. Allyl bromide, dimethyl disulfide, and trimethygermanium bromide were used as electrophiles to quench the initial anion to give the corresponding products (Scheme 3). 3-Substituted salicylic acids were prepared in high yield by subsequent treatment of **10**–**12** with *t*-BuLi followed by the addition of carbon dioxide and acidic workup. We realized that **14**–**16** could have been obtained from the MOM-ether of phenol via successive deprotonations *ortho* to the MOM group followed by quenching with suitable electrophiles; however, problems could arise in the second lithiation if the first electrophile introduced is itself an *ortho*-lithiation director. For example, it is well-documented that an SMe group will direct an *ortho*-lithiation (17). Thus, the second lithiation of 2-methylthio-*O*-methoxymethylphenol might have led to some lithiation *ortho* to the thiomethyl group. Having the bromide in compound **11** ensured that the subsequent anion would be formed *ortho* to the MOM group.

Finally, we decided to extend this strategy towards our in situ Suzuki coupling methodology (1*c*, 18) to synthesize various 3-substituted salicylic acids in which the substituent could

Scheme 3. Reagents: (*a*) 2.1 equiv. *t*-BuLi, Et_2O, then allyl bromide, MeSSMe or Me_3GeBr; (*b*) 2.1 equiv. *t*-BuLi, THF, then CO_2, then 6 M HCl.

Scheme 4. Reagents: (*a*) 2.1 equiv. *t*-BuLi, THF, $B(O\text{-}i\text{-}Pr)_3$; (*b*) 2 M Na_2CO_3, $Pd(PPh_3)_4$, 2-bromopropene; (*c*) 1.1 equiv. *n*-BuLi, THF, CO_2 then 6 M HCl.

not be obtained via conventional nucleophilic displacement of a halide. This method, however, precluded the use of **9** as a starting material to prevent homo-coupling of **9** and possible polymerization. Thus the MOM ether of *ortho*-bromophenol **17** underwent a halogen–lithium exchange with *t*-BuLi and the resulting anion was treated with triisopropylborate to form **18** in situ (Scheme 4). After stirring the mixture for 4 h, 2-bromopropene, $Pd(PPh_3)_4$, and Na_2CO_3 (2 M) were added and the mixture was heated at reflux to afford **19**. Subsequent *ortho*-lithiation of **19** followed by trapping the anion with carbon dioxide afforded 3-isopropenylsalicylic acid (**20**) in 87% yield after an acidic workup.

In conclusion, we have developed an efficient, high yielding strategy for the synthesis of 3-substituted salicylic acids beginning with inexpensive starting materials that requires no special equipment. Although salicylic acid derivatives were our target, this strategy certainly permits further elaboration, allowing one to synthesize various 2,6-disubstituted phenols with ease.

Experimental

General

Nuclear magnetic resonance (NMR) spectra were recorded on a Bruker ACE-200 (^{1}H 200 MHz, ^{13}C 50 MHz)

spectrometer. All spectra were obtained in $CDCl_3$ and the chemical shifts (ppm) are relative to the $CHCl_3$ peak as an internal reference (^{1}H 7.27 ppm, ^{13}C 77.00 ppm). Infrared (IR) spectra were recorded using a Mattson Galaxy Series 4030 FT-IR or a Nicolet Nexus 470 FT-IR ESP spectrophotometer. Mass spectra (MS) were run on either a Hewlett-Packard 5890 Series II gas chromatograph interfaced to a Hewlett-Packard 5971A mass selective detector or acquired by Mrs. Q. Wu, Department of Chemistry, University of Calgary, using a VG 7070 instrument. High resolution mass spectra (HRMS) were obtained by Mrs. D. Fox, Department of Chemistry, University of Calgary, on a Kratos MS-80 spectrometer. Elemental analyses were also performed by Mrs. D. Fox using a Control Equipment Corporation 440 Elemental Analyzer. All melting and boiling points are uncorrected. Anhydrous THF was distilled from sodium benzophenone ketyl. Anhydrous diethyl ether was distilled from CaH_2.

General procedure for the MOM protection of phenols (19)

Dry sodium hydride (432 mg, 18 mmol) was suspended in THF (10 mL) and was cooled to 0°C under N_2. A suitable phenol (12 mmol) was dissolved in THF (10 mL) and was added slowly dropwise to the NaH suspension over 10 min. The reaction mixture was allowed to stir at room temperature for 2 h. MOMCl (20) (6 mL, 6 M in methyl acetate, 36 mmol) was then added to the reaction mixture over 10 min and the reaction was stirred 2 h. The reaction mixture was concentrated in vacuo and the residue partitioned between diethyl ether and NaOH (0.1 M). The aqueous layer was extracted with diethyl ether and the organic layers were combined, washed once with NaOH (0.1 M), then with brine, dried over $MgSO_4$, and concentrated in vacuo. The resulting oil was purified via air bath distillation at reduced pressure to give a colorless oil.

*1-Fluoro-2-methoxymethoxybenzene (**5**)*

Yield 1.70 g (94%, 10.9 mmol); bp 90°C at 13 torr (lit. (21) 100°C at 20 torr) (1 torr = 133.322 Pa). ^{1}H NMR δ: 3.52 (s, 3H), 5.22 (s, 2H), 6.9–7.3 (m, 4H).

*1-Chloro-2-methoxymethoxybenzene (**6**)*

Yield 1.92 g (96%, 11.1 mmol); bp 100–110°C at 13 torr (lit. (21) 100–102°C at 11 torr). ^{1}H NMR δ: 3.53 (s, 3H), 5.27 (s, 2H), 6.9–7.01 (m, 1H), 7.18–7.23 (m, 2H), 7.34–7.41 (m, 1H).

*1-Bromo-2-methoxymethoxybenzene (**17**)*

Yield 2.18 g (91%, 10.1 mmol); bp 105–110°C at 13 torr (lit. (22) 98–99°C at 6 torr). ^{1}H NMR δ: 3.54 (s, 3H), 5.27 (s, 2H), 6.90 (ddd, J = 1.71, 7.13, 7.86 Hz, 1H), 7.16 (dd, J = 1.71, 8.29 Hz, 1H), 7.20–7.32 (m, 1H), 7.56 (dd, J = 1.54, 7.86 Hz, 1H).

*1,3-Dibromo-2-methoxymethoxybenzene (**9**)*

Yield 3.38 g (99%, 11.5 mmol); bp 60°C at 0.08 torr (lit. (23) 118–121°C at 5 torr). ^{1}H NMR δ: 3.73 (s, 3H), 5.20 (s, 2H), 6.90 (t, J = 8.0 Hz, 1H), 7.52 (d, J = 8.0 Hz, 2H).

*1-Isopropenyl-2-methoxymethoxybenzene (**19**)*

1-Bromo-2-methoxymethoxybenzene (11 mmol) was dissolved in THF (10 mL) and cooled to –78°C under N_2. *t*-BuLi (13.6 mL, 1.7 M in pentane, 23.1 mmol) was added dropwise over 10 min and then allowed to stir at –78°C for 1 h. Triisopropylborate (13.2 mmol) was added dropwise over 5 min and reaction mixture was stirred at room temperature for 4 h. Na_2CO_3 (6.6 mL, 2 M in H_2O, 13.2 mmol) was added and the mixture was allowed to stir for 10 min. $Pd(PPh_3)_4$ (0.55 mmol, 5 mol%) and 2-bromopropene (24.2 mmol) were added and the reaction mixture was heated to 50°C with vigorous stirring overnight. The reaction was diluted with diethyl ether and quenched with saturated sodium bicarbonate solution. The aqueous layer was extracted with diethyl ether and the organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated in vacuo. The resulting oil was purified via air bath distillation at reduced pressure to give a colourless oil. Yield 1.63 g (83%, 9.1 mmol); bp 100°C at 13 torr. General procedure for the formation of 2-bromo-6-substituted MOM protected phenols

1,3-Dibromo-2-methoxymethoxybenzene (12 mmol) was dissolved in diethyl ether (10 mL) and was cooled to –78°C under N_2. *t*-BuLi (15.5 mL, 1.7 M in pentane, 26.4 mmol) was added dropwise over 10 min and was allowed to stir at –78°C for 1 h. A suitable electrophile (14.4 mmol) was added dropwise over 5 min and the reaction mixture was stirred at room temperature for 1 h. The reaction mixture was diluted with diethyl ether and quenched with saturated sodium bicarbonate solution (10 mL). The aqueous layer was extracted with diethyl ether and the organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated in vacuo. The product was purified via air bath distillation at reduced pressure to give a colorless oil.

*1-Allyl-3-bromo-2-methoxymethoxybenzene (**10**)*

Yield 2.70 g (88%, 10.6 mmol); bp 70°C at 0.08 torr. MS *m*/*z* (%): 256 (3, M^+), 258 (3, $[M + 2]^+$). HRMS calcd. for $C_{11}H_{13}O_2{}^{79}Br$: 256.0099; found: 256.0092. Anal. calcd. for $C_{11}H_{17}BrO_2Ge$: C 39.58, H 5.19; found: C 39.40, H 5.13.

General procedure for (*i*) *ortho*-lithation; (*ii*) direct carboxylation; (*iii*) deprotection

The 1-substituted-2-methoxymethoxybenzene (11 mmol) was dissolved in THF (10 mL) and cooled to 0°C under N_2. *n*-BuLi (8.6 mL, 1.4 M in hexanes, 12.1 mmol) was added dropwise over 5 min and the reaction mixture was stirred at 0°C for 1.5 h. The mixture was then cooled to –78°C and CO_2(g) was passed through a column of Drierite and bubbled into the reaction for 1.5 h. The mixture was allowed to warm to room temperature, HCl (6 M, 10 mL) was added, and the reaction mixture was stirred vigorously overnight. The reaction mixture was extracted with diethyl ether and the combined organic layers was washed with brine, dried over $MgSO_4$, and concentrated in vacuo to give a solid, which was purified by flash chromatography.

*3-Fluorosalicylic acid (**7**)*

Yield 1.48 g (86%, 9.5 mmol); mp 144–147°C (lit. (3) 146–148°C). ^{1}H NMR δ: 6.84 (dt, *J* = 1.54, 8.04 Hz, 1H), 7.22–7.36 (m, 1H), 7.68 (dt, *J* = 4.62, 8.04 Hz, 1H).

*3-Chlorosalicylic acid (**8**)*

Yield 1.72 g (91%, 10.0 mmol); mp 183–185°C (lit. (24) 184–185°C). ^{1}H NMR δ: 6.90 (t, *J* = 8.0 Hz, 1H), 7.60 (dd, *J* = 1.7, 8.0 Hz, 1H), 7.87 (dd, *J* = 1.7, 8.0 Hz, 1H).

*3-Isopropenylsalicylic acid (**20**)*

Yield 1.71 g (87%, 9.6 mmol); mp 98–100°C (lit. (25) 110–110.5°C). MS *m*/*z* (%): 178 (1, M^+), 160 (54, $[M - 18]^+$). HRMS calcd. for $C_{10}H_{10}O_3$: 178.0630; found 178.0613. IR ($CHCl_3$) (cm^{-1}): 3063 (br, OH), 1655 (C=O). ^{1}H NMR δ: 6.90 (dd, *J* = 7.52, 8.04 Hz, 1H), 7.46 (dd, *J* = 1.71, 7.52 Hz, 1H), 7.88 (dd, *J* = 1.71, 8.04 Hz, 1H), 10.75 (br s, 1H). ^{13}C NMR δ: 22.8, 111.1, 116.1, 119.1, 129.9, 132.7, 136.4, 142.6, 159.6, 174.7. Anal. calcd. for $C_{11}H_{14}O_2$: C 67.41, H 5.66; found: C 67.51, H 5.80.

General procedure for (*i*) *ortho*-lithiation via lithium–bromide exchange; (*ii*) direct carboxylation; (*iii*) deprotection

The 1-bromo-3-substituted-2-methoxymethoxybenzene (11 mmol) was dissolved in THF (10 mL) and cooled to –78°C under N_2. *t*-BuLi (13.6 mL, 1.7 M in pentane, 23.1 mmol) was added dropwise over 10 min and the reaction mixture was stirred at –78°C for 1.5 h. CO_2(g) was passed through a column of Drierite and bubbled into the reaction for 1.5 h. The mixture was allowed to warm to room temperature, HCl (6 M, 10 mL) was added, and the reaction mixture was stirred vigorously overnight. The reaction mixture was extracted with diethyl ether and the organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated in vacuo to give a beige solid, which was purified by flash chromatography.

*3-Bromosalicylic acid (**13**)*

Yield 2.30 g (97%, 10.7 mmol); mp 177–180°C (lit. (10) 181–181.5°C). ^{1}H NMR δ: 6.84 (t, *J* = 7.95 Hz, 1H), 7.78 (dd, *J* = 1.71, 7.95 Hz, 1H), 7.90 (dd, *J* = 1.71, 7.95 Hz, 1H).

*3-Allylsalicylic acid (**14**)*

Yield 1.78 g (91%, 10.0 mmol); mp 90–92°C (lit. (26) 90–91°C). ^{1}H NMR δ: 6.88 (dd, *J* = 7.52, 7.86 Hz, 1H), 7.41 (dd, *J* = 1.71, 7.52 Hz, 1H), 7.82 (dd, *J* = 1.71, 7.86 Hz, 1H).

*3-Methylsulfanylsalicylic acid (**15**)*

Yield 1.36 g (67%, 7.4 mmol); mp 165–169°C (lit. (27) 168–170°C). ^{1}H NMR (lit. (27)) δ: 2.49 (s, 3H), 6.95 (t, *J* = 7.95 Hz, 1H), 7.44 (dd, *J* = 1.54, 7.95 Hz, 1H), 7.78 (dd, *J* = 1.54, 7.95 Hz, 1H).

*3-Trimethylgermanylsalicylic acid (**16**)*

Yield 2.51 g (89%, 9.8 mmol); mp 138–141°C. MS *m*/*z* (%): 256 (2, M^+), 241 (72, $[M - 15]^+$), 223 (100, $[(M - 15) - 18]^+$). HRMS calcd. for $C_{10}H_{14}O_3{}^{74}Ge$: 256.0155; found 256.0131. IR ($CHCl_3$) (cm^{-1}): 3073 (br, OH), 1660 (C=O). ^{1}H NMR δ: 0.46 (s, 9H), 6.93 (dd, *J* = 7.10, 7.95 Hz, 1H), 7.60 (dd, *J* = 1.71, 7.10 Hz, 1H), 7.91 (dd, *J* = 1.71, 7.95 Hz, 1H), 10.61 (s, 1H). ^{13}C NMR δ: –1.6, 110.0, 119.3, 131.3, 141.7, 163.2, 165.8, 174.6. Anal. calcd. for $C_{10}H_{14}O_3Ge$: C 47.14, H 5.54; found: C 47.99, H 5.70.

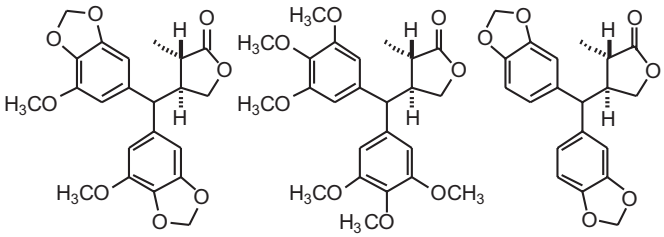
Enantioselective synthesis of peperomins A, C, D, and analogs — Examination of diastereoselective cuprate conjugate additions to *N*-enoyl-4-diphenylmethyl-2-oxazolidinones

Mukund P. Sibi, Michael D. Johnson, and T. Punniyamurthy

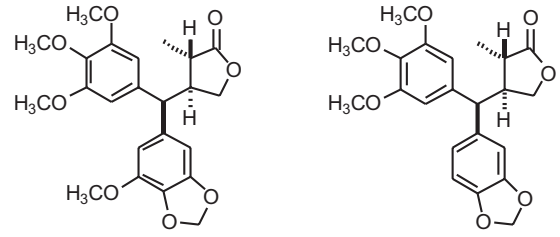
Abstract: A concise and general route to secolignans has been developed. The first total synthesis of secolignans peperomin A (**1a**), peperomin C (**1b**), and peperomin D (**1c**) was accomplished in ~28% overall yield over five synthetic steps. Peperomin analogs (**1d**) and (**1e**), possessing two differentially substituted aryl groups, were synthesized by a highly selective conjugate addition. The overall yield for the analogs **1d** and **1e** were 27 and 26%, respectively.

Key words: peperomins, secoliganans, conjugate additions, 4-diphenylmethyl-oxazolidin-2-one.



Résumé : On a mis au point une voie d'accès concise et générale conduisant aux sécolignanes. On a réalisé la première synthèse totale des sécolignanes pépéromine A (**1a**), pépéromine C (**1b**) et pépéromine D (**1c**), avec un rendement global d'environ 28% sur cinq étapes. Les analogues **1d** et **1e** de la pépéromine qui possèdent deux groupes aryles substitués de façon différente ont aussi été synthétisés par le biais d'une addition conjuguée hautement sélective. Les rendements globaux des synthèses des analogues **1d** et **1e** sont respectivement de 27 et 26%.

Mots clés : pépéromines, sécolignanes, additions conjuguées, 4-diphénylméthyloxazolidin-2-one.



[Traduit par la Rédaction]

Introduction

Recently, a novel and unusual class of lignans were isolated from *Peperomia japonica* Makino by Chen et al. (1). Three lignans, peperomins A, B, and C, with a novel seco structure, were isolated from this perennial herb. Peperomin D was also recently isolated from *Peperomia glabella* (2). The use of aqueous and alcoholic decoctions of the herb as folk medicine for the treatment of malignant tumors has been noted (1). Two other secolignans with insect antifeedant activity have also been isolated from *Peperomia dindigulensis* (3). These secolignans have structural features that are present in the combretastatins (4) and podophyllotoxin (5). In view of the high tubulin inhibitory activity of the combretastatins and podophyllotoxin, the evaluation of the biological activity of peperomins and their analogs could be important. The structure-activity relationship in this novel secolignan series could shed more light on the conformational requirements for tubulin binding at the colchicine–podophyllotoxin site. Towards this end we have started a program on the preparation and biological evaluation of peperomins and analogs. Only a single racemic synthesis of peperomin C has been reported in the literature so far (6). This paper describes the first total synthesis of peperomins A, C, D, and two analogs.

1a eperomin **1b** eperomin C **1c** eperomin D

1d eperomin analog **1e** eperomin analog

We have been investigating methodologies for the preparation of succinates with various substituents on the carbon backbone and their application to the synthesis of butyrolactone

natural products (Scheme 1) (for other selected approaches to substituted succinates see refs. 7*a–c*; for an example of enolate alkylation leading to similar structures see ref. 7*d*). Recently, we described a novel route to paraconic and lignan natural products by the conjugate addition of radical intermediates starting from fumarates (**3** → **2**) (8). We have also reported on alternate routes to paraconic acids using succinates as starting materials (**5** → **2**) (9). The chiral auxiliary appended β-aryl propionates have also served as starting materials in the synthesis of lignan natural products (**6** → **2**) (10). These three disconnections, however, were not suited for the preparation of the secolignans and an alternate approach (**4** → **2**) was required.

The synthetic strategy for the preparation of peperomins is shown in Scheme 2. The design is based on the conjugate addition of an aryl group to the enoyloxazolidinone **10** (X_c = chiral auxiliary). The conjugate addition is followed by electrophile incorporation in a step-wise manner to furnish **9**. The strategy provides the flexibility for the introduction of different aryl groups by either varying the nucleophile or the enoyloxazolidinone leading to a variety of β,β-diaryl propionic acids (for procedures describing methodologies for the synthesis of enantiomerically enriched 3,3-diaryl propanoic acids and derivatives see refs. 11*a–f*; for a recent effort see ref. 11*g*). The next step in the sequence involves chemoselective reduction of the carbonyl bearing the chiral auxiliary and cyclization to provide **8**. Enolate alkylation of **8** from the less-hindered face establishes the required *trans* stereochemistry in the natural products. The key bond construction in our synthesis is a conjugate addition of an aryl copper reagent to a chiral enoate. Of the variety of chiral auxiliaries examined for conjugate additions, the oxazolidinones have generally been inferior in terms of selectivity. Recently, several groups have undertaken a study of various auxiliaries in the addition of copper reagents to enoates (for a comparative study of chiral auxiliaries see ref. 12). Hruby and co-workers (13; for NMR studies see ref. 13*b*) have shown that the oxazolidinone derived from phenylglycinol provides high selectivity in the addition of aryl coppers to cinnamates. We describe the use of an oxazolidinone derived from diphenylalanine in conjugate additions to acyclic systems using copper nucleophiles and determine its effectiveness in controlling stereochemistry at the β-carbon with the traditional oxazolidinones.

Results and discussion

Initial targets for examining the feasibility of our methodology were the simpler peperomins A, C, and D, since these compounds do not possess a chiral center at the benzylic carbon. This would allow us to establish reaction conditions for the conjugate additions (protocols for conjugate additions to enoyloxazolidinones has been established, see ref. 14*a*; for other contributions from the Hruby group see ref. 14*b*; 14*c–h*; for work on superquat oxazolidinone auxiliaries see ref. 14*i*). The synthesis of peperomin A, C, and D started with the acylation of the 4-diphenylmethyl-2-oxazolidinone auxiliary developed in our laboratory (Scheme 3) (15).[3] Treatment of **11** with *n*-BuLi provided the anion which was acylated with 3-[3′,4′-methylenedioxy-5′-methoxy-phenyl]-2-propenoyl

[3] For the synthesis of chiral auxiliary **11** see ref. 15*a*. This chiral auxiliary is available commercially from Aldrich Chemical Company; see ref. 15*b*. For the application of this auxiliary in synthesis see ref. 15*c*.

chloride (16).[4] 3,4-(Methylenedioxy)-5-methoxybenzaldehyde was transformed into the corresponding acid chloride: (*a*) $Ph_3P{=}CHCO_2Et$ (1.1 equiv), 70°C, 16 h, C_6H_6, 92% (96% *E*-isomer); (*b*) (*i*) 2.2 equiv NaOH, reflux, 20 min, 99%; (*ii*) 3.2 equiv oxalyl chloride, 25°C, 3 h, 93%. to furnish **12** in high yield. The required cinnamic acid (17) was prepared by HWE reaction between 3,4-methylenedioxy-5-methoxybenzaldehyde (18) and phosphanoacetic acid. Cinnamates **13** and **14** were prepared in high yields using 3-[3′,4′,5′-trimethoxyphenyl]-2-propenoyl chloride and 3-[3′,4′-methylenedioxyphenyl]-2-propenoyl chloride and lithiated **11**, respectively. The two-step protocol for the introduction of the substituents was then undertaken (19).[5] Reaction of **12** with the copper reagent prepared from 3,4-methylenedioxy-5-methoxy bromobenzene (20) gave **15** in 84% yield. Similarly, treatment of **13** and **14** with the copper reagent derived from 3,4,5-trimethoxy bromobenzene and 3,4-methylenedioxy bromobenzene (21) gave **16** and **17**, respectively. The next step involved the introduction of the acetic acid chain. This was accomplished in respectable chemical yield and excellent diastereoselectivity (>98%) by treatment of **15** and **16** with sodium hexamethyldisilazide followed by quenching of the sodium enolate with *tert*-butylbromoacetate. The diastereoselectivity in the alkylation step was established by ^1H NMR analysis (400 MHz) of the crude product. The alkylation of **17** using bromo-*tert*-butylacetate gave moderate yields (60%). A change of the leaving group to an iodo group gave **20** in higher yields (74%). Similar small increments in chemical efficiency were also noted for simple substrates as well as the alkylation precursor for peperomin analogs (vide infra). Thus, the iodoacetates were used in all the alkylation reactions (for a recent example of variation in chemical efficiency and selectivity in enolate alkylations with haloacetates see ref. 22).

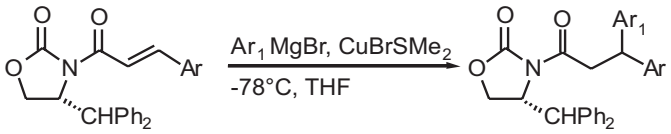
With the desired succinates at hand, chemoselective reduction of the carbonyl attached to the chiral auxiliary was achieved by using LAH at low temperatures (23). Work-up of the reduction product followed by silica gel column chromatography furnished the butyrolactones **21** and **22** directly in good yields over two steps.[6] Reduction of **20** using LAH was not clean, providing the desired alcohol as well as an over-reduced diol (reduction of imide as well as the ester). Thus, an alternate sequence was devised. The chiral auxiliary in **20** was selectively hydrolyzed using $LiOH–H_2O_2$ (24). The resulting acid ester was reduced chemoselectively using borane (25). Lactonization using catalytic amounts of *p*-toluenesulfonic acid gave **23**. The three-step sequence could be carried out with good efficiency without isolation of the intermediates.

Introduction of the 3-substituent in butyrolactones by enolate alkylation has been well established in the literature (for some examples of diastereoselective alkylation at the 3-position see ref. 26). Generation of the sodium enolate of **21** and quenching with methyl iodide gave a 10:1 to 12:1 mixture of the methylated product. The use of LDA as the base in the alkylation gave a 8:1 mixture of the alkylated products (stereoselectivity of alkylations in substituted butyrolactones has been examined, see ref. 27). Attempts to improve diastereoselectivity by variation of reaction conditions were unrewarding. The two diastereomers were inseparable by chromatographic methods. However, the major diastereomer (**1a**) could be separated and purified by careful recrystallization. The major diastereomer was established to posses the 3,4-*trans* stereochemistry by comparison of its spectral data with those reported for peperomin A (1). The synthesis of **1b** followed a similar reaction sequence but starting with **22** and spectral data of the major diastereomer (~10:1 ds) was consistent with those reported for peperomin C (1). The overall yields for peperomin A (**1a**) and peperomin C (**1b**) were 28% (five steps) and 28% (five steps), respectively. The alkylation of **23** using NaHMDS as the base gave peperomin D (**1c**) with moderate to good diastereoselectivity and chemical yield. The spectral characteristics of the synthetic material were consistent with those reported in the literature for the natural product (2). The overall yield for peperomin D (**1c**) is ~27% over seven steps.

The synthesis of peperomin analogs (**1d** and **1e**) required the development of a diastereoselective conjugate addition protocol using copper reagents. Several groups have recently compared the effectiveness of different auxiliaries in conjugate additions and noted that the camphor sultams are quite good (28).[7] Hruby and co-workers (see ref. 13. For selected examples from a large body of work see ref. 29)[8] have also demonstrated that an oxazolidinone derived from phenylglycinol is an excellent chiral auxiliary in conjugate addition to enoates using organocuprates as nucleophiles. We have recently shown that a chiral auxiliary derived from diphenylalanine is superior to Evans-type oxazolidinones in conjugate radical additions (30). Thus, we wished to briefly evaluate the utility of this auxiliary in conjugate addition using cuprates as nucleophiles. The protocol developed by Hruby and co-workers was adapted as the standard reaction conditions (the addition of Grignard reagent with the use of copper bromide – dimethyl sulfide complex as the copper source). Reactions with a variety of substrates with simple as well as more functionalized aromatic nucleophiles were investigated. Results from these experiments are shown in Table 1. The diastereoselectivity in the conjugate additions was determined by NMR and HPLC analyses. The data in the table indicates that the diastereoselectivity was very high. The addition of Grignard reagent derived from 3,4-methylenedioxy-5-methoxy-

[4] 3,4-(Methylenedioxy)-5-methoxybenzaldehyde was transformed into the corresponding acid chloride: (*a*) $Ph_3P{=}CHCO_2Et$ (1.1 equiv), 70°C, 16 h, C_6H_6, 92% (96% *E*-isomer); (*b*) (*i*) 2.2 equiv NaOH, reflux, 20 min, 99%; (*ii*) 3.2 equiv oxalyl chloride, 25°C, 3 h, 93%.

[5] For a review on enantioselective conjugate addition see ref. 19*b*. For other recent reviews see ref. 19*c*.



[6] The chiral auxiliary was recovered in >95% yield.

[7] (*S*)-4,4-Dimethylpyroglutamate as a chiral auxiliary, see ref. 28*a*. Addition of Yamamoto's reagent with high selectivity to *N*-enoyloxazolidinones; see ref. 28*b*. Comparison of auxiliaries see ref. 28*c*. Others: Oppolzer and Helmchen auxiliary; see ref. 28*d–f*. Addition of aryl Grignards and (or) coppers to oxazolidinone enoates see ref. 28*g*. Addition to 4-phenyl-oxazolidinone derived enoates see ref. 28*h*. For other efforts in the area see ref. 28*i*.

[8] Williams has recently shown that 4-benzyloxazolidinone is a useful chiral auxiliary in conjugate additions using Yamamoto's reagent. See ref. 12*b*.

[b]des were determined by NMR analysis.

bromobenzene (31) to **13** gave **26**, the intermediate in peperomin analog (**1d**) synthesis, in excellent yield and diastereoselectivity (entry 2). Similarly, intermediate for analog **1e**, was also obtained with high efficiency (entry 3). Conjugate additions to other substrates either varying the nucleophile or the acceptor did not diminish the selectivity (entries 1, 4, 5, and 6). Thus, the 4-diphenylmethyl substituted enoyl oxazolidinones undergo conjugate additions with high selectivity.

The efficient shielding of the β-carbon in conjugate additions by 4-phenyl- and 4-diphenylmethyl-oxazolidinones may suggest that these likely have similar structural organization in the transition states (structures **31** and **32**). In conjugate additions with 4-benzyloxazolidinones (13), the C-4-benzyl bond rotation (**33**) may play a role in the observed low selectivity. The high selectivity observed for organocuprate addition to 4-phenyl and 4-diphenylmethyl derived enoates is in stark contrast to conjugate radical additions where only auxiliary **11** showed high selectivity. Thus, the results depicted in the table and previous work from our laboratory (30) clearly show that the diphenylalanine-derived oxazolidinone can shield the β-carbon effectively in both organocuprate and radical conjugate additions.

33

The basic methodology used in the synthesis of peperomins A, C, and D was adapted for the synthesis of the more complex analogs **1d** and **1e** (Scheme 4). Installation of the two-carbon chain on the conjugate addition products **26** and **27** furnished **34** and **35**. The diastereoselectivity in these alkylations was high with the chiral auxiliary controlling the face selectivity. The succinates were converted to the lactones **36** and **37**, respectively by a hydrolysis–reduction–lactonization sequence. The overall yield for the three steps without purification of the intermediates was excellent. With the lactones at hand, the final installation of the C-3 methyl group was uneventful. As observed in the previous alkylations (vide supra), the diastereoselectivities in these reactions were only moderate (highest ds of 8:1). All attempts at purification of the diastereomeric mixture were not successful. The structural characteristics (^1H and ^{13}C NMR chemical shifts) of analog **1d** are similar to those reported for the natural product peperomin B (1). The structure for the major

diastereomer (*trans* stereochemistry) of **1d** and **1e** are consistent with the observed ^{1}H NMR coupling constants and spectral similarities to the natural peperomins. The overall yield for **1d** and **1e** were 27 and 26%, respectively.

In conclusion, we have developed a simple and efficient strategy for the synthesis of secolignans peperomin A, C, D, and two analogs. Additionally, we have also shown that 4-diphenylmethyl oxazolidin-2-one (**11**) is an excellent auxiliary in diastereoselective conjugate addition of organocuprates to enoates. The extension of the present methodology for the synthesis of analogs and biological evaluation of the secolignans is currently underway in our laboratory.

Experimental

General experimental details

Methylene chloride (CH_2Cl_2) was distilled from calcium hydride. Tetrahydrofuran (THF), diethyl ether (Et_2O), and benzene were distilled from benzophenone–ketyl prior to use. Methanol (MeOH) was distilled from magnesium turnings and I_2. Acetone was dried from $KMnO_4$ and K_2CO_3. Most of the organic compounds utilized in this study were purchased from Aldrich Chemical Company. All glassware were oven dried, assembled hot, and cooled under a stream of dry nitrogen before use. Reactions with air-sensitive materials were carried out by standard syringe techniques. All reactions were run under an atmosphere of nitrogen unless otherwise noted.

Chromatography and instrumentation

Thin layer chromatographic analyses (TLC) were performed on silica gel Whatmann-60F glass plates and components were visualized by illumination with UV light or by staining with phosphomolybdic acid. Flash column chromatography was performed using E. Merck silica gel 60 (230–400 mesh). ^{1}H NMR was recorded on a 500, 400, or 300 MHz spectrometer. ^{13}C NMR was recorded on 500 (125) MHz, 400 (100) MHz, and 300 (75) MHz spectrometers using broad band proton decoupling. Rotations were recorded on a JASCO-DIP-370 instrument. Elemental analyses were performed on a PerkinElmer Series II CHNS/O analyzer 2400. Melting points was determined using a Fisher–Johns melting point apparatus without correction.

Representative procedure for the acylation of (*R*)-4-diphenylmethyl-2-oxazolidinone (compound 13)

To an oven-dried 100 mL three- neck round- bottomed flask purged with N_2 was added 3.50 g (14.69 mmol) of 3,4,5-trimethoxycinnamic acid. To the solid was added 5 mL (57.23 mmol) of oxalyl chloride dropwise over 2 min and the mixture was allowed to stir at room temperature (rt) for 1 h. Removal of the excess oxalyl chloride under reduced vacuum gave 3.65 g of pure acid chloride (97% yield). To an oven-dried 250 mL three-neck round-bottomed flask purged with N_2 was added 3.0 g (11.86 mmol) of 4-diphenylmethyl-2-oxazolidinone **11** and 40 mL of dry THF. The reaction mixture was cooled to –78°C in an acetone – dry ice bath. To the mixture was added 5.19 mL (12.45 mmol) of *n*-BuLi dropwise over 10 min and the mixture was allowed to stir for 30 min. A solution of 3.35 g (13.05 mmol) of the 3,4,5-trimethoxy cinnamoyl chloride dissolved in 15 mL of dry THF was added dropwise to the solution over 8 min. The solution was stirred at –78°C for 3 h. The reaction was quenched with 10 mL NH_4Cl. The reaction mixture was extracted with ethyl acetate. The combined organics were washed with water followed by brine and dried over $MgSO_4$. Removal of solvent under reduced pressure followed by flash column purification of the crude mixture gave 5.0 g of the acylated product (89% yield).

*(4*R*)-4-(Diphenylmethyl)-3-[3-(3′,4′-methylenedioxy-5′-methoxyphenyl)-2(*E*)-propenoyl]-2-oxazolidinone (**12**)*

Yield: 86%; mp 88–90°C. $[\alpha]_D^{25}$ –192.8 (*c* 0.98, $CHCl_3$). *(4*R*)-4-(Diphenylmethyl)-3-[3-(3′,4′-methylenedioxyphenyl)-2(*E*)-propenoyl]-2-oxazolidinone (**14**)*

Yield: 91%; mp 188 to 189°C. $[\alpha]_D^{25}$ –163.3 (*c* 1.0, CH_2Cl_2). R_f 0.56 (50:50, EtOAc:hexanes). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.45 (m, 2H), 4.80 (d, *J* = 5.1 Hz, 1H), 5.42 (m, 1H), 6.01 (s, 2H), 6.81 (d, *J* = 8.1 Hz, 1H), 7.22 (m, 12H), 7.70 (s, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 50.7, 56.6, 64.9, 101.8, 107.1, 108.6, 114.8, 125.4, 127.1, 127.9, 128.5, 128.8, 128.9, 129.1, 129.5, 138.3, 139.8, 146.4, 148.4, 150.1, 153.6, 165.2. Anal. calcd. for $C_{26}H_{21}NO_5$: C 73.06, H 4.95, N 3.28; found: C 72.57, H 5.10, N 3.29.

Representative procedure for the conjugate addition — Preparation of 26

To an oven-dried 100 mL round-bottomed flask purged with N_2 was added 1.43 g (58.9 mmol) of magnesium turnings and 10 mL of dry THF. The flask was placed in a ultrasonic bath for 3 min before dropwise addition of 13.18 g (57 mmol) 5-bromo-3-methoxy-1,2-methylenedioxybenzene (dissolved in 24 mL of dry THF) over 20 min. To an oven-dried three-neck 500 mL round-bottomed flask purged with N_2 was added 5.86 g (28.5 mmol) of copper(I) bromide – dimethyl sulfide complex and 40 mL of dimethyl sulfide and 80 mL of dry THF. The reaction mixture was cooled to –48°C in an acetonitrile – dry ice bath. To the mixture was added the Grignard reagent dropwise over 30 min and the mixture was allowed to stir for 30 min. A solution of 9.0 g

© 2001 NRC Canada

(19.0 mmol) of the cinnamate **13** dissolved in 36 mL of dry THF was added dropwise to the solution over 30 min. The solution was stirred at −48°C for 4.5 h. The reaction was quenched with 30 mL NH_4Cl. Excess dimethyl sulfide was removed using a water aspirator. The residue was extracted with ethyl acetate. The combined organics was washed with 10% NH_4OH, water, followed by brine, and dried over $MgSO_4$. Removal of solvent under reduced pressure followed by flash column purification of the crude mixture gave 10.58 g of the addition product **26** (89% yield).

*(4*R*)-4-(Diphenylmethyl)-3-[3-(3,3-bis-3′,4′-methylenedioxy-5′-methoxyphenyl)-propanoyl]-2-oxazolidinone (**15**)*

Yield: 84%; mp 90 to 91°C. $[\alpha]_D^{25}$ –130.8 (*c* 1.0, $CHCl_3$). Representative procedure for alkylation (compound 34)

To an oven-dried 250 mL three- neck round-bottomed flask purged with N_2 was added 10.5 g (16.78 mmol) of **26** and 120 mL of dry THF. The reaction mixture was cooled to –78°C in an acetone –dry ice bath. To the mixture was added 18.46 mL (18.46 mmol) of a 1 M NaHMDS–THF solution dropwise over 20 min and the mixture was allowed to stir for 1 h. To the solution was added 2.92 mL (20.14 mmol) of *tert*-butyl iodoacetate dropwise over 6 min. The solution was stirred at –78°C for 6 h. The reaction was quenched with 20 mL NH_4Cl. The reaction mixture was extracted with ethyl acetate. The combined organics were washed with water, followed by brine, and dried over $MgSO_4$. Removal of solvent under reduced pressure followed by flash column purification of the crude mixture led to 9.3 g of the alkylated product **34** (75% yield).

*(3(2*S*),4*R*)-4-(Diphenylmethyl)-3-[bis-(3′,4′-methylenedioxy-5′-methoxyphenyl)-methyl]-(4-oxo-butyric acid* tert*-butyl ester)-2-oxazolidinone (**18**)*

Yield: 64%; mp 189 to 190°C. $[\alpha]_D^{25}$ –289.9 (*c* 1.09, $CHCl_3$). General procedure for the LAH reduction–cyclization (compounds 21 and 22)

To an oven-dried 25 mL two-neck round-bottomed flask purged with N_2 was added 1.00 g of **18** (1.38 mmol) of alkylated product and 2 mL of dry THF. The reaction mixture was cooled to –78°C in an acetone – dry ice bath. To the solution was added 265 mg (6.99 mmol) of LAH in 7 mL of dry THF dropwise over 15 min. The reaction was stirred at –78°C for 20 h before quenching with ethyl acetate. The mixture was filtered through Celite and dried over $MgSO_4$. Removal of solvent under reduced pressure led to the crude alcohol. The crude alcohol cyclized on standing and (or) during column chromatography over silica gel. Lactone (410 mg) was obtained after column chromatography (74% yield for **21**).

General procedure for hydrolysis–reduction–cyclization (for compounds 23, 36, 37)

To an oven-dried 250 mL three-neck round-bottomed flask purged with N_2 was added 3.00 g (4.05 mmol) of alkylated product **34**, 60 mL of THF, and 15 mL of H_2O. The reaction mixture was cooled to 0°C before the dropwise addition of 3.31 mL (32.4 mmol) of 30% H_2O_2 over 10 min. To the solution was added 747 mg (17.82 mmol) of LiOH–H_2O in 15 mL of H_2O dropwise over 20 min. The reaction was stirred at 0°C for 5 h before being allowed to warm to room temperature and stirred for 14 h. The reaction was cooled to 0°C before quenching with 4.20 g of Na_2SO_3 in 20 mL of H_2O. The mixture was washed with H_2O and extracted with CH_2Cl_2. The aqueous layer was acidified to pH = 2 with 5 M HCl before extraction with ethyl acetate. The organic extracts were not combined and both were dried over $MgSO_4$. Removal of solvent from the acid wash under reduced pressure led to 1.75 g of crude acid (86% yield). Evaporation of the neutral fraction provided crude chiral auxiliary.

General procedure for the borane reduction

To an oven-dried 100 mL three-neck round-bottomed flask purged with N_2 was added 1.90 g (3.77 mmol) of crude acid and 50 mL of dry THF. The reaction mixture was cooled to –10°C in an acetone – ice bath. To the solution was added 7.54 mL (7.54 mmol) of a 1 M BH_3–THF solution dropwise over 15 min. The reaction was stirred at –10°C for 6 h before warming to room temperature and stirred for 14 h. The reaction was quenched with 4 mL of a 1:1 solution of acetic acid and water. The aqueous layer was washed with a cold saturated solution of $NaHCO_3$ and extracted with ethyl acetate while being dried over $MgSO_4$. Removal of solvent under reduced pressure led to 1.43 g of crude alcohol (75% yield).

Lactonization

To an oven-dried 50 mL two-neck round- bottomed flask set up with a condenser purged with N_2 was added 1.60 g (3.26 mmol) of crude alcohol, 15 mg of PTSA, and 30 mL of benzene. The solution was heated to reflux for 2.0 h before being allowed to cool to room temperature. The mixture was washed with $NaHCO_3$ and water before extracting with ethyl acetate and drying over $MgSO_4$. Removal of solvent under reduced pressure followed by flash column purification of the crude mixture led to 1.2 g of the lactone **36** (89% yield).

*(4(1S),4S)-4-[1,1-(3′,4′,5′-Methoxyphenyl)-5-(3″,4″-methylenedioxyphenyl)methyl]-butyrolactone (**37**)*

Overall yield over three steps: 56% (average of three runs); mp 69 to 70°C. $[\alpha]_D^{25}$ –4.6 (*c* 1.0, CH_2Cl_2). R_f 0.26 (50:50, EtOAc:hexanes). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.25 (dd, *J* = 8.6, 17.7 Hz, 1H), 2.56 (dd, *J* = 9.1, 17.7 Hz, 1H), 3.30 (m, 1H), 3.64 (d, *J* = 11.6 Hz, 1H), 3.78 (s, 3H), 3.82 (s, 6H), 3.94 (dd, *J* = 7.0, 16.4 Hz, 1H), 4.25 (dd, *J* = 9.4, 19.1 Hz, 1H), 5.90 (m, 2H), 6.41 (s, 2H), 6.71 (m, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 34.1, 40.0, 55.3, 56.3, 60.9, 72.1, 101.3, 104.4, 107.7, 108.6, 120.5, 128.4, 135.6, 136.1, 137.0, 137.7, 138.1, 146.8, 148.2, 153.5, 176.6. Anal. calcd. for $C_{21}H_{22}O_7$: C 65.28, H 5.74; found: C 64.81, H 5.46.

Representative methylation procedure (compound 1d)

To an oven-dried 25 mL two-neck round-bottomed flask purged with N_2 was added 400 mg (0.961 mmol) of the lactone **36** and 7 mL of dry THF. The reaction mixture was cooled to –78°C in an acetone – dry ice bath. To the mixture was added 1.15 mL (1.15 mmol) of a 1 M NaHMDS–THF solution dropwise over 3 min and the mixture was allowed to stir for 50 min. To the solution was added 0.12 mL (1.92 mmol) of methyl iodide over 1 min. The solution was stirred at –78°C for 5 h. The reaction was quenched with 1 mL NH_4Cl. The reaction mixture was extracted with ethyl acetate. The combined organics were washed with water, followed by brine, and dried over $MgSO_4$. Removal of solvent under reduced pressure followed by flash column purification of the crude mixture led to 331 mg of the natural product peperomin B (**1d**) along with the diastereomer (80% yield).

*(3S,4S)-3-Methyl-4-[1-bis(3′,4′-methylenedioxy-5′-methoxyphenyl)methyl]-butyrolactone (peperomin A (**1a**))*

Yield: 98%; mp 143 to 144°C (abs. EtOH) (lit. (1) 143–145°C). $[\alpha]_D^{25}$ 22.7 (*c* 0.13, $CHCl_3$) (lit. (1) $[\alpha]_D^{27}$ 20.6 (*c* 0.14, $CHCl_3$)). Traceless solid-phase synthesis of 5-benzoylbenzimidazoles

Kyung Joo Lee and Kim D. Janda

Abstract: A traceless linker strategy for the solid-supported synthesis of 5-benzoylbenzimidazoles has been developed. A benzyl cyanide functional group was linked to 2% divinylbenzene cross-linked polystyrene through a dimethylsilyl linker. Coupling with 5-chloro-2-nitroaniline followed by oxidative decyanation gave benzophenone **11** as a key intermediate in an efficient one-pot reaction procedure. After reduction of the nitro group and oxidative cyclization with a variety of aldehydes in the presence of DDQ, a series of polymer-supported benzimidazoles was produced. Final traceless cleavage of the arylsilane linker with TBAF provided a small library of 5-benzoylbenzimidazoles.

Key words: solid-support, traceless linker, arylsilane, 5-benzoylbenzimidazole.

Résumé : On a développé une stratégie d'ancrage sans trace pour la synthèse sur support solide de 5-benzoylbenzimidazoles. Utilisant un diméthylsilyle comme ancre, on a relié un cyanure de benzyle fonctionnalisé à du polystyrène réticulé à 2% de divinylbenzène. Son couplage avec de la 5-chloro-2-nitroaniline, suivi d'une décyanation oxydante, conduit à la benzophénone **11**, un intermédiaire clé dans une réaction monotope efficace. Après réduction du groupe nitro et cyclisation oxydante avec une variété d'aldéhydes, en présence de DDQ, on obtient une série de benzimidazoles supportés par un polymère. Un clivage final sans laisser de trace de l'ancre arylsilane, par du TBAF, conduit à une série de 5-benzoylbenzimidazoles.

Mots clés : support solide, ancre sans trace, arylsilane, 5-benzoylbenzimidazole.

Introduction

Benzimidazoles and in particular 2-substituted benzimidazoles show a broad range of medicinal activity including fungicidal, antitumor, and antiviral, with the antiulcerative Omeprazole (1) and antihistamine Astemizole (2) being clinical examples. In addition, benzimidazole-based compounds have been found to be inhibitors of phosphodiesterase IV (3) and antagonists of angiotensin I (4). Because of their medicinal importance, the solid-phase synthesis of heterocycles such as benzimidazoles, diketopiperazines, diazines, and hydantoins that contain one or more nitrogen atoms has received considerable attention. Consequently, a general method for the rapid synthesis of a library of benzimidazoles might provide new lead compounds in drug discovery based efforts.

Our efforts in the library preparation of benzimidazoles were centered upon structures such as **1**, 2-substituted-5-benzoylbenzimidazole. We envisioned that this benzimidazole and the related supported intermediate **12** could be utilized as precursors to a range of medicinally important molecules such as Enviroxime, Enviradene, and Itemazole (5). In accessing such structures via a solid-supported methodology, linking group strategies must be considered a key element in the synthetic design. Indeed, major drawbacks inherent to solid-phase synthesis are related to the linking of the molecule to the support, the linker's chemical inertness, and ease of detachment of the final molecule. A further consideration is the potential remains of the linking functionality. Thus, carboxyl, carboxamide, amine, or hydroxyl functionalities are often left embedded within the target molecule as a result of the linking strategies engaged. Clearly, these moieties can affect the physico-chemical and biological properties of the target molecule. Therefore, the development of traceless linker strategies is an important challenge in solid-phase combinatorial synthesis.

Recently, several novel tactics that utilize a resin-bound arylsilane as a traceless linker have been successfully applied to the solid-phase synthesis of aromatic and heteroaromatic compounds including 1,4-benzodiazepines (6), benzofurans (7), tricyclics (8), and biaryl (9) structures. Furthermore, a number of papers describing the solid or soluble-polymer supported synthesis of benzimidazole derivatives (10, 11) have also appeared. However, in these reports of benzimidazoles, all the structures described show retained linker functionality within the final compound. Herein, we report the traceless solid-phase synthesis of 5-benzoylbenzimidazoles employing an arylsilane linkage.

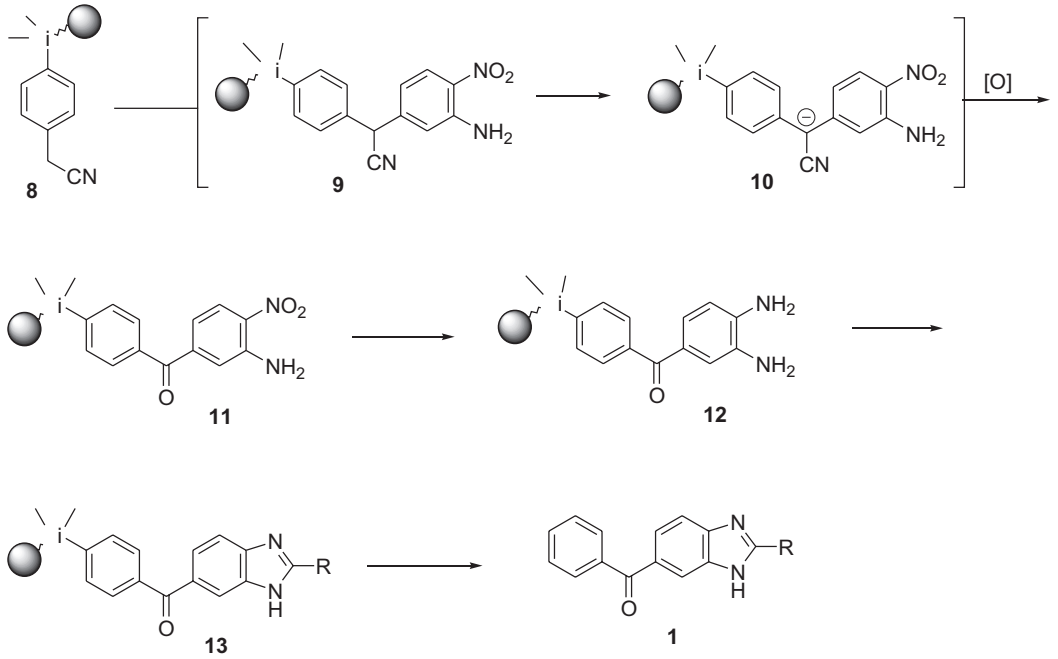
Results and discussion

We envisioned diamine **12** as the key intermediate in our approach to 5-benzoylbenzimidazoles (see below). In solution phase synthesis, this type of benzophenone can be prepared readily from a Friedel-Crafts acylation reaction; however, this strategy cannot be implemented in a polystyrene-based system due to the presence of the aromatic backbone on the resin. Alternatively, **12** could be prepared from an aldehyde and organolithium or organomagnesium reagent followed by oxidation of the resultant secondary alcohol; however, this reaction sequence requires rigorous anhydrous conditions not readily adaptable to a solid support and ultimately automation of the process.



We thus envisioned that **11** could be prepared by oxidative decyanation (12) of diaryl cyanide **9**. It was our contention that **9** could be obtained from the nucleophilic substitution reaction of 5-chloro-2-nitroaniline with the anion of solid-supported benzyl cyanide **8**. This kind of oxidative decyanation has been exemplified in the solution phase synthesis of various benzophenone derivatives (5*a*).

Our route to solid-supported benzyl cyanide **8** is illustrated in Scheme 1. Thus, **2** was lithiated and quenched with chlorodimethylallylsilane to give the arylsilane derivative **3** that was attached subsequently to the polymer in a two step procedure. Hydroboration of the allylsilane followed by in situ Suzuki coupling (13) with bromophenylsubstituted resin (1.97 mmol g^{-1}) provided the silyl-derivatized resin **4**. Deprotection of the TBS group with acid followed by bromination of the resultant alcohol gave the benzyl bromide derivative **5**. The key intermediate, polymer-supported benzyl cyanide **8** was then obtained from the reaction of **5** with sodium cyanide in a DMF–water solvent system. The loading level of **8** was determined to be 1.2 mmol g^{-1} by mass balance of 4-bromobenzyl cyanide, which was obtained from the electrophilic cleavage reaction of a small aliquot of the resin with Br_2. Alternatively, **8** could be accessed if the hydroboration–Suzuki coupling protocol was conducted at a later stage with preformed benzyl cyanide **7**. With intermediate **8** in hand, our 5-benzoylbenzimidazole library synthesis was accomplished as shown in Scheme 2.

Solid-supported benzyl cyanide **8** was treated with 5-chloro-2-nitroaniline in the presence of an excess of potassium *tert*-butoxide at room temperature. The requirement for excess base (>2 equiv.) is essential to drive the first step (nucleophilic aromatic substitution) of the reaction sequence to completion due to the increased acidity of the α-hydrogen found on the disubstituted nitrile product **9**. Oxidation of **9** was performed in situ with 30% aqueous hydrogen peroxide to afford the desired benzophenone derivative **11** after acidification, so that the overall reaction sequence to give ketone **11** can be accomplished conveniently in a one-pot procedure. To confirm the structure and to determine the loading value, an aliquot of **11** was subjected to cleavage. Usually, the aryl—silicon bond is cleaved by trifluoroacetic acid (i.e., protodesilylation). However, an aryl—silicon bond can be quite stable if the aromatic ring possesses a strong electron-withdrawing group within its nucleus. In this scenario the ipso-substituted intermediate, needed to generate a carbonium ion β to the silicon moiety is prevented. In such cases, fluoride ion has proven to be an effective alternative (9–11, 14). Thus, the benzophenone resin **11** was cleaved effectively with tetrabutylammonium fluoride (TBAF) to give 5-benzoyl-2-nitroaniline. This was confirmed by ^1H NMR as

Scheme 2. Reagents and conditions: (*a*) (*i*) 5-chloro-2-nitroaniline, *t*-BuOK, rt, 21 h, (*ii*) 30% H_2O_2, 0°C to rt, 22 h, (*iii*) 1 N HCl, rt, 15 min; (*b*) $SnCl_2 \cdot 2H_2O$, DMF, 65°C, 27 h; (*c*) RCHO (5 equiv.), DDQ (2 equiv.), DMF, rt, 7 h; (*d*) 1 M TBAF, THF, 60°C, 24 h.

well as high resolution mass spectrometry (HRMS) and a loading value between 0.34~0.5 mmol g^{-1} was calculated for **11**. Reduction of the polymer-supported nitroaniline **11** was achieved by treatment with $SnCl_2$ in DMF at 60°C (incomplete reduction was observed at room temperature even with a prolonged reaction time), and was confirmed by ^{1}H NMR after cleavage of a small amount of the resin with TBAF.

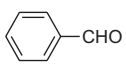
Among the many procedures for the preparation of benzimidazoles from diamines, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) mediated oxidative cyclocondensation with an aldehyde is attractive because of its mild reaction conditions (6*c*, 6*f*, 15). Thus, treatment of resin **12** with an aldehyde (5 equiv.) and DDQ (2 equiv.) in DMF at room temperature gave the resin bound benzimidazole **13**. Cleavage from the support was accomplished by treatment with TBAF in warm THF (60°C) to provide the desired 5-benzoylbenzimidazoles **1a**–**k** (Table 1).

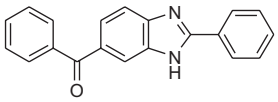
In general, the purities of the crude products as determined by ^{1}H NMR were greater than 85%. The isolated yields (following purification over silica gel), calculated based on the substitution level of the benzophenone resin **11**, were between 48 and 70%. The cyclocondensation–oxidation reaction was efficient with electron-rich aromatic (**1c**, **1g**), electron-deficient aromatic (**1b**, **1d**), heteroaromatic (**1e**, **1f**), and aliphatic (**1h**–**k**) aldehydes. All final compounds were characterized by ^{1}H NMR, ^{13}C NMR, and HRMS.

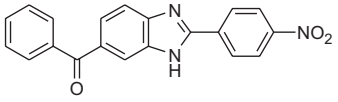
In summary, we have developed a traceless linker strategy for the solid-supported synthesis of 2-substituted-5-benzoylbenzimidazoles **1**. The key feature of our synthetic strategy was the oxidative decyanation of **9** to give ketone **11** in an efficient one-pot procedure. It is anticipated that resin-bound intermediates **12** and **13** could serve as scaffolds for more diversified compound libraries. For example, regiospecific acylation or sulfonylation of **12** and subsequent cyclization would give 1,2-disubstituted-5-benzoylbenzimidazoles. Furthermore, reduction of the carbonyl group found in **13** and subsequent derivatization of the resultant alcohol would give 2,5-disubstitutedbenzimidazoles. Efforts along these lines to construct more diversified libraries in the pursuit of interesting biological active compounds are currently in progress.

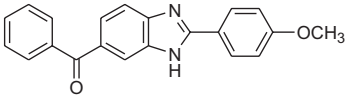
Experimental

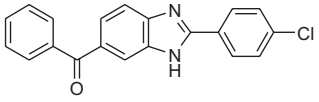
General

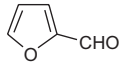


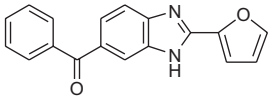


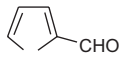


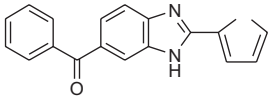


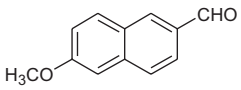


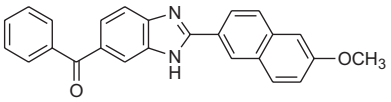


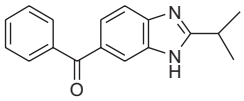


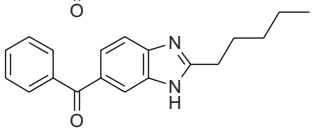


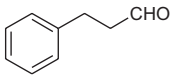


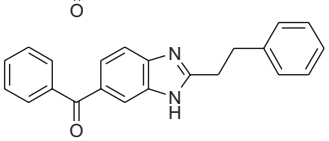


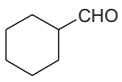


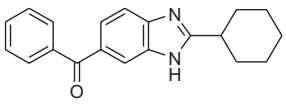












Unless otherwise noted, materials were obtained from commercial suppliers and used without further purification. Tetrahydrofuran (THF) was distilled immediately before use from sodium–benzophenone under N_2. Anhydrous dimethylformamide (DMF) was obtained from Aldrich in a SureSeal bottle. All reactions were run under an inert atmosphere with dry reagents and solvents and flame-dried glassware. Flash column chromatography was carried out using Merck 60 230–400 mesh silica gel. Thin layer chromatography was performed using 0.25 mm silica gel coated Kieselgel 60 F_{254} plates and visualized using aqueous cerium molybdate with heating. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AMX-400 spectrometer at 400 and 100 MHz, respectively, in $CDCl_3$ or CD_3OD at 25°C. Chemical shifts are reported in ppm on the δ scale from an internal TMS standard. 4-Bromopolystyrene resin was purchased from Novabiochem (San Diego, CA). Large scale solid-phase reactions were performed in peptide-flasks with glass tubes equipped for vacuum filtration (ChemGlass Inc., Vineland, NJ) and were agitated with a Ika-Vibrax-Vxr shaker (Germany).

O-tert-Butyldimethylsilyl-4-allyldimethylsilylbenzyl ether (3)

To a solution of *tert*-butyldimethylsilyl-4-bromobenzyl ether (**1**, 14.4 g, 47.8 mmol) in dry THF (150 mL) at –78°C was slowly added *n*-BuLi (29.9 mL, 1.6 M solution in hexane,

Preparation of 4

To a solution of **3** (3.0 g, 9.4 mmol) in dry THF (30 mL) was added 9-BBN (18.7 mL, 0.5 M solution in THF) at room temperature. After stirring for 3 h, $Pd(PPh_3)_4$ (324 mg, 3 mol%), a 2 M Na_2CO_3 solution (4.8 mL, 9.6 mmol), and 4-bromopolystyrene (3 g, 1.97 mmol g^{-1}, 5.9 mmol) were added and the reaction mixture was stirred gently at 65°C in the dark. After 48 h, additional $Pd(PPh_3)_4$ (160 mg) was added and the heating and stirring was continued for 24 h. After a total of 72 h of heating, the mixture was allowed to cool to room temperature. The resin was filtered and washed with THF, THF–H_2O (1:1), H_2O, MeOH, DMF, MeOH, and [CH_2Cl_2, MeOH]$_3$ and then dried under vacuum to give 3.6 g of polymer.

Preparation of 8

To a mixture of resin **4** (3.6 g) in THF–water (20:1 mL) was added a catalytic amount of *p*-TsOH·H_2O (50 mg). After shaking overnight at room temperature, the resin was washed with THF, THF–H_2O (1:1), H_2O, MeOH, and [CH_2Cl_2, MeOH]$_3$ and then dried under vacuum. To a mixture of this resin and Ph_3P (1.4 g) in CH_2Cl_2 (40 mL) was slowly added CBr_4 (1.7 g). After shaking overnight at room temperature, the resin was filtered and washed with THF, CH_2Cl_2, MeOH, and [CH_2Cl_2, MeOH]$_3$ and then dried under vacuum to give polymer **5**.

To the above resin **5** (3.5 g) swelled in DMF–H_2O (20:10 mL) was added an excess of sodium cyanide (2.0 g) and the suspension was stirred gently at 80°C for 3 h. The resin was filtered and washed with THF–H_2O (1:1), H_2O, MeOH, THF, and [MeOH, CH_2Cl_2]$_3$ and then dried under vacuum to give polymer **8**. To determine the loading level of resin **8**, 100 mg of the resin was swelled in 5 mL of CH_2Cl_2 and Br_2 (30 μL) was added. After stirring for 1 h at room temperature, the resin was filtered and washed with CH_2Cl_2. The combined filtrate was concentrated to give 4-bromobenzylcyanide (23.4 mg, 1.2 mmol g^{-1}), whose identity was confirmed by ^{1}H NMR and mass spectrometry.

Preparation of 11

To a mixture of resin **8** (3.0 g, 3.6 mmol) and 5-chloro-2-nitroaniline (2.4 g, 14.4 mmol) in anhydrous DMF (40 mL) was added potassium *tert*-butoxide (2.4 g, 21.6 mmol) in one portion at 0°C. The reaction mixture immediately turned to an intense dark red color. The mixture was stirred gently for 21 h at room temperature and then cooled to 0°C with an ice bath. Hydrogen peroxide (7.5 mL, 30% solution) was added and the mixture was stirred for 22 h at room temperature. At this time, the color changed to dark green. After the addition of 1 N HCl (45 mL) and stirring for 15 min, the color of the mixture turned bright yellow. The resin was washed thoroughly with THF, H_2O (5 times), DMF, H_2O, [THF, MeOH]$_3$, and [CH_2Cl_2, MeOH]$_3$ to give yellow beads (3.7 g). A portion of the above resin (100 mg) was treated with a 1 M solution of TBAF (50 μL) in THF at room temperature overnight. The resin was filtered, rinsed with THF and MeOH, and the combined filtrate was concentrated to afford a residue that was subjected to extractive work up with CH_2Cl_2–H_2O. The residue obtained from concentration of the CH_2Cl_2 layer was taken up in CH_2Cl_2 and further extracted with water to remove a small amount of residual TBAF. Removal of CH_2Cl_2 under reduced pressure provided 5-benzoyl-2-nitroaniline (10 mg, 0.41 mmol) as a bright yellow solid whose structure was confirmed by ^{1}H NMR and mass spectrometry.

Preparation 12

To resin **11** (3.0 g, 1.23 mmol) in DMF (30 mL) was added an excess of $SnCl_2 \cdot 2H_2O$ (4 g, 12.3 mmol) and the mixture was stirred gently at 65°C. After 10 h, additional $SnCl_2 \cdot 2H_2O$ (4 g) was added and the mixture was stirred for a further 10 h. The reaction mixture was cooled to room temperature and the resin was filtered, washed with DMF several times, and dried under vacuum to provide a dark red resin (2.9 g).

General procedure for the preparation of 5-benzoyl-benzimidazoles (1)

To resin **12** (0.2 g, 0.08 mmol) in DMF (5 mL) was added an aldehyde (5 equiv.) and DDQ (2 equiv.) and the mixture was stirred gently for 7 h at room temperature. The resulting resin was washed with CH_2Cl_2, DMF, and [CH_2Cl_2, MeOH]$_3$ and dried under vacuum to provide the resin bound benzimidazoles **13**. The resin was cleaved with 1 M solution of TBAF (2 mL) in THF at 65°C overnight and worked-up as in the cleavage of resin **11** vide supra. The crude residue was redissolved and purified by column chromatography ($CHCl_3$–MeOH, 20:1) to give **1a**–**k**.

Applications of crotyldiisopinocampheylboranes in synthesis: a formal total synthesis of (+)-calyculin A

Oren P. Anderson, Anthony G.M. Barrett, Jeremy J. Edmunds, Shun-Ichiro Hachiya, James A. Hendrix, Kiyoshi Horita, James W. Malecha, Christopher J. Parkinson, and Andrew VanSickle

Abstract: The formal total synthesis of the marine metabolite (+)-calyculin A is reported. The key steps involve (*i*) the use of Brown allylboration chemistry to control the relative and absolute stereochemistry of homoallylic alcohol arrays, thus setting eight of the desired stereocenters; (*ii*) Stille coupling methodology in the construction of the cyano tetraene unit of the natural product; and (*iii*) a modified Cornforth–Meyers approach to the synthesis of the oxazole fragment.

Key words: calyculin, marine natural product, phosphatase inhibitor, total synthesis, palladium catalyzed coupling reactions, allylboration reactions, aldol reactions, spiroketal, Cornforth–Meyers oxazole reaction.

Résumé : Une synthèse total d'un métabolite d'origine marine, la (+)-calyculine A, été descrite. Les étapes clés de la synthèse reposent sur l'utilisation: de la chimie d'allylboration de Brown afin de contrôler la stéréochemie relative et absolue d'une série d'alcools homoallyliques ayant ainsi permis la création de 8 centres asymétriques; de la réaction de couplage de Stille dans la construction du motif cyanotétraène du produit naturel; d'une approache modifiée de Cornforth–Meyers pour la préparation de la partie oxazole.

Mots clés : calyculine, produit naturel d'origine marine, inhibiteur de la phosphatase, synthèse totale, réactions de couplage catalysées par la palladium, réactions d'allylborations, réactions d'aldolisations, spirocétal, réaction d'oxazole selon Cornforth–Meyers.

[Traduit par la Rédaction]

Introduction

The calyculins represent a group of marine natural products isolated from the sponge *Discodermia calyx* (1). These structurally remarkable compounds have shown potent inhibitory activity toward phosphatase enzymes, notably the serine–threonine PP-1 and PP-2A protein phosphatases. For example, (–)-calyculin A, the antipode of **1**, is active against rabbit skeletal muscle type PP-2A phosphatases at 0.5–1.0 nmol dm^{-3} concentrations and is also 20–300 times more potent than okadaic acid against various PP-1 enzymes. (–)-Calyculin A is a representative member of a series of eight similar structures (calyculins B–H) (2), the other calyculins differing by the presence of an additional methyl unit at C-32 and (or) geometric differences at Δ^2 and (or) Δ^6. A further five related structures, calyculin J, the caliculinamides A, B, and F, and des-*N*-methylcalyculin A have recently been isolated (3). The dephosphono derivative of calyculin A has been obtained from the same marine organism (4). This compound also inhibits protein phosphatases, an unexpected phenomenon, as the presence of the phosphate group was believed to be key to the calyculins' biological activity (5). The relative stereochemistry of **1** was determined by X-ray analysis (1) and the absolute configuration later elucidated by Matsunaga and Fusetani (6), through analysis of the C(37)–C(33) and C(32)–C(29) degradation fragments and Shioiri and co-workers (7) through asymmetric synthesis of the C(37)–C(33) fragment. Total synthesis of (+)-calyculin **1**, the antipode of the natural product, by Evans et al. (8) later corroborated this absolute stereochemical assignment.

Due to the structural complexity of these marine metabolites and their associated biological profile, they have attracted a great deal of synthetic attention (for other synthetic efforts toward the synthesis of the calyculins, see ref. 9). This has culminated in several total syntheses of the calyculin family, the first reported by Evans et al. (8). Their approach centered on the union of a "southern" C(1)–C(25) spiroketal unit and "northern" C(26)–C(37) amide oxazole fragment through Wittig chemistry, the former subunit also

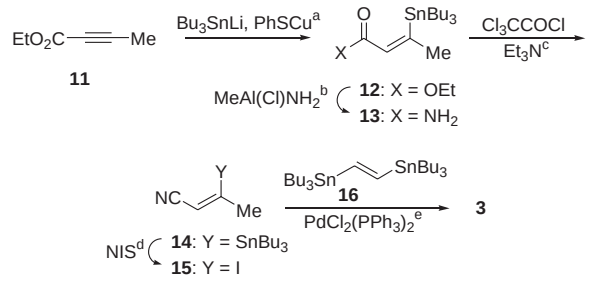
Scheme 1.

being constructed using this methodology at C(8)–C(9). Enantioselective synthesis of these fragments was achieved using auxiliary-based asymmetric aldol methodology, establishing ten of the fifteen stereocenters present in **1**. The approach to calyculin A **1** adopted by Masamune and co-workers (10) employed Wadsworth–Emmons type coupling to elaborate the C(8)–C(9) olefin with Stille coupling, was also used in the synthesis of the C(5)–C(6) bond, paralleling other synthetic endeavors in this area. Interestingly, they constructed the C(25)–C(26) alkene by utilizing a Julia-olefination approach to link up the "northern" and "southern" hemispheres. Smith et al. (11) have also recently published total syntheses of both ent-**1** and (–)-calyculin B utilizing an advanced intermediate to synthesize either compound through Peterson olefination at C(2). Their approach also elected to construct the C(25)–C(26) alkene through phosphonium ylide chemistry, as does the formal synthesis of calyculin A (**1**) by Shioiri and co-workers (12). Calyculin C has also succumbed to total synthesis through the efforts of Ogawa and Armstrong (13) using allylborane reagents in the elaboration of the spiroketal unit, notably the novel use of a tetrasubstituted allylborane in the synthesis of the *gem*-dimethyl moiety present in this subunit. Retrosynthetically, we considered that (+)-calyculin A **1** should be accessible from the oxazole amide **2**, the cyanostannane **3**, and the spiroketal fragment **4**, the later being constructed using aldol methodology between the methyl ketone **5** and aldehyde **6** to establish the C(14)–C(15) bond (Scheme 1). Key to our overall strategy, is the employment of the elegant masked aldol chemistry developed by Brown and co-workers (14*b*–*d*, *g*, *h*), employing the derivatives of diisopinocampheylborane **7**–**10** as versatile reagents for the construction of homoallylic alcohols. Our synthetic plan also parallels other endeavors (8, 11–13) in the synthesis of calyculin A **1**, whereby the coupling of oxazole **2** and spiroketal **4** fragments was based upon Wittig chemistry (for our previous publications towards the total synthesis of (+)-calyculin A, see ref. 15).

Results and discussion



Synthesis of the C(1)–C(5) cyanodiene fragment 3

Construction of the (*Z*,*E*)-cyano diene **3** was based upon the use of Stille chemistry for the elaboration of the C(3)–C(4) bond. This approach would also facilitate the elaboration of the (*E*,*E*)-isomer, an appropriate building block for the synthesis of other calyculins with this geometry at Δ^2. Therefore, conjugate addition of tributylstannyl cuprate (16) to ethyl but-2-ynoate **11** and quenching with methanol gave the (*Z*)-β-stannylcrotonate **12** (52%) and the corresponding (*E*)-isomer **17** (7%). The *trans*-geometry of the major product was established by measurement of the ^{117,119}Sn–H coupling constant (J = 97 Hz) in the ^{1}H NMR spectrum (17). Conversion of ester **12** to the corresponding amide **13** was achieved using the methodology of Weinreb and co-workers (18), and subsequent dehydration using trichloroacetyl chloride and triethylamine gave the nitrile **14**. Iododestannylation afforded solely the desired (*Z*)-iodide **15** and this was smoothly coupled with the distannane **16** (19) using Stille methodology to give the requisite C(1)–C(5) diene coupling fragment **3** with complete geometric retention (Scheme 2). For ease of synthesis upon scale up, in situ generation of the vinyl iodide **15**, using iodine in DMF and subsequent addition of bis(triphenylphosphino)palladium dichloride and distannane **16** gave the cyanodiene **3** in moderate yield (50%) in a one-pot procedure. This protocol also circumvented the need for the isolation of the volatile iodide intermediate **15**.

In parallel to the synthesis of stannane **3**, the minor *trans*-isomer **17** was converted by sequential reaction with trimethylaluminum and ammonium chloride (72%), trichloroacetyl chloride and triethylamine (95%), and iodine followed by stannane **16** and palladium(0) catalysis (39%) into the (*E*,*E*)-isomer **22**. Comparisons of spectral data for each in-

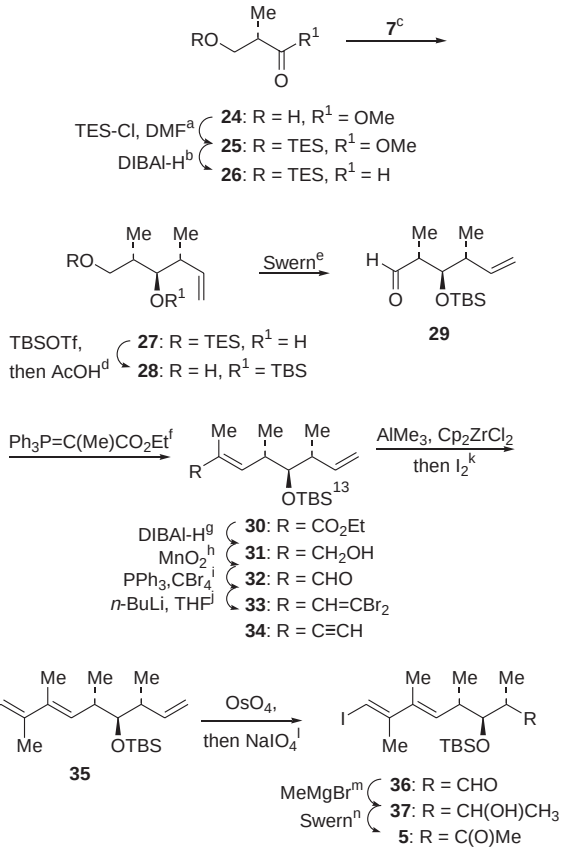
Reagents and Conditions: (a) $Bu_3SnSnBu_3$, *n*-BuLi, PhSCu, THF, -35°C then MeOH, Et_2O (52%); (b) $AlMe_3$, NH_4Cl, PhH, 50°C (76%); (c) Cl_3CCOCl, Et_3N, CH_2Cl_2, 0°C (95%); (d) NIS, THF, Et_2O (65%); (e) **16**, $PdCl_2(PPh_3)_2$ (cat) THF 60°C (55%)

termediate **12**, **13**, **14**, **15**, and **3** with the data for the corresponding (*E*)- and (*E*,*E*)-isomers **17**, **18**, **19**, **20**, and **22**, respectively, were fully consistent with assignment of stereochemistry in each case. Finally, separate iododestannylation of both **3** and **22** gave the corresponding (*Z*,*E*)- and (*E*,*E*)-dienyl iodides **21** and **23** with retention of geometry. These results unequivocally established the geometric integrity and purity of the key intermediate **3**.

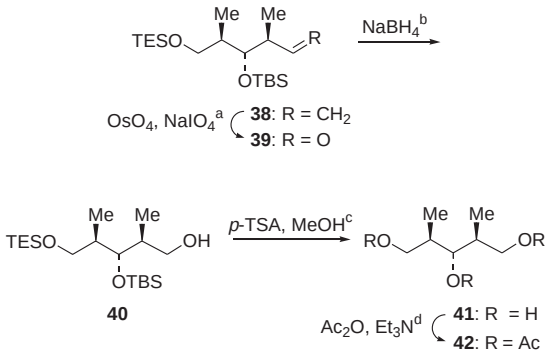


Synthesis of the C(6)–C(14) vinyl iodide subunit 5

We envisaged that construction of the vinyl iodide **5** would arise from the methylzirconation–iodinolysis of alkyne **34** according to the procedure of Negishi et al. (20). Alkyne **34** would in turn come from the suitably elaborated aldehyde **29**, the synthesis of which involves a key Brown homologation to unambiguously set the C(11) and C(12) stereochemistry (Scheme 3). Thus, synthesis of vinyl iodide **5** commenced from aldehyde **26**, prepared from commercially available methyl (*S*)-(+)-3-hydroxy-2-methylpropanoate **24** via triethylsilyl protection of the alcohol and DIBAl-H reduction. Brown homologation (14) of aldehyde **26** using the borane reagent **7** derived from (–)-pinene gave the homoallylic alcohol **27**, which was formed in excellent diastereomeric excess (>96%) as judged by ^1H NMR analysis.

In parallel to the conversion of ester **24** into ether **27** in Scheme 3, the early transformations were repeated in the antipode series starting from methyl (2*R*)-2-methyl-3-triethylsilyloxypropanoate. Whilst the intermediate **38** was not transformed further towards calyculin, it was used to confirm the stereochemistry of the key intermediate **28**. Conversion of the silyl ether **38** into the *meso*-triacetate **42** is outlined in Scheme 4. This was accomplished through catalytic osmium tetraoxide mediated dihydroxylation and periodate cleavage of the olefin giving aldehyde **39**. Subsequent re-

Scheme 3.



Reagents and Conditions: (a) TES-Cl, CH_2Cl_2, imidazole, DMAP (cat.) (90%); (b) DIBAl-H, hexanes, -70°C (89%); (c) **7**, THF, -78°C then $NaBO_3{\cdot}4H_2O$, H_2O (76%); (d) THF, TBSOTf, 2,6-lutidine, -78°C then AcOH, 25°C (84%); (e) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2 (78%); (f) $Ph_3P{=}C(Me)CO_2Et$, THF, reflux (96%); (g) DIBAl-H, THF, 25°C (86%); (h) MnO_2, CH_2Cl_2 (81%); (i) PPh_3, CBr_4, CH_2Cl_2 (89%); (j) *n*-BuLi, THF, -78°C (80%); (k) $AlMe_3$, Cp_2ZrCl_2, CH_2Cl_2 then I_2 (69-86%); (l) OsO_4 (cat.), NMO, acetone, H_2O (<61%) then $NaIO_4$, THF, MeOH, H_2O; (m) MeMgBr, THF, -78°C (80%, 2 steps); (n) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2 (79%).

duction with sodium borohydride gave alcohol **40** that was desilylated and per-acetylated to furnish the triacetate **42.** Both the lack of optical rotation and the ^1H and ^{13}C NMR spectra of **40** were fully consistent with the expected *meso*-stereochemistry. Since the synthesis of alcohol **27** started from methyl (2*S*)-2-methyl-3-triethylsilyloxypropanoate (**24**), this correlation established both the relative and absolute stereochemistry of the two CHMe stereocenters. The C(2)–C(3) *anti*-stereochemistry followed from the known stereochemical bias of the Brown crotylboration reaction (14) using reagent **7**. With the knowledge that the desired stereochemical configuration was in place, the synthesis of ketone **5** proceeded with the selective *tert*-butyldimethylsilylation and detriethylsilylation (21) of alcohol **27** to give ether **28**. Oxidation under Swern (22) conditions and homologation of the resulting aldehyde **29** gave the α,β-unsaturated ester **30** with excellent (*E*)-selectivity (>95%). Ester **30** was transformed via aldehyde **32** and homologated under the protocol of Corey and Fuchs (23) into the acetylene **34**. Elimination of

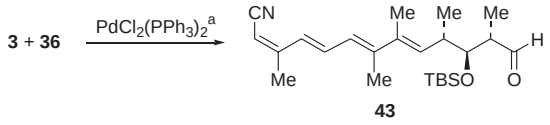
Scheme 4.

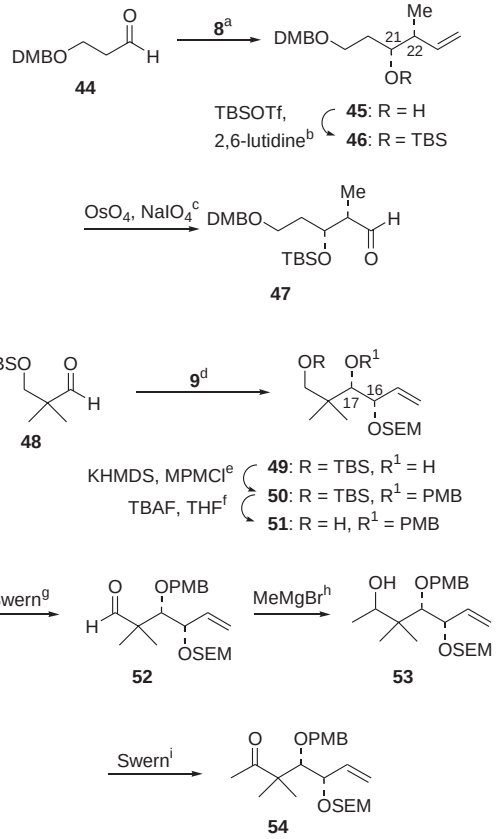
Reagents and Conditions: (a) OsO_4 , *N*-methylmorpholine -*N*-oxide, Me_2CO, H_2O; $NaIO_4$, THF, MeOH; (b) $NaBH_4$, MeOH, 0°C (93%); (c) *p*-$MeC_6H_4SO_3H$, MeOH (100%); (d) Ac_2O, Et_3N, DMAP, CH_2Cl_2 (97%).



the intermediate dibromide **33** was carried out using either lithium diisopropylamide (15) or *n*-butyllithium. However, in either case, rapid purification of **33** was required to obtain the acetylene **34** in acceptable yields. *Syn*-methylzirconation (20) of acetylene **34** followed by in-situ iodinolysis of the vinyl alane intermediate gave triene **35** exclusively as the (*E*)-isomer. This reaction, however, proved highly dependent upon the nature of the C(13) substituent. Attempted methylzirconation of protected derivatives of the analogous C(13) primary alcohol, C(13), C(14) diol, or the C(13) aldehyde gave intractable product mixtures. Quite remarkably, osmylation of triene **35** resulted in selective oxidation of the terminal olefin (Δ^{13}) thereby providing a route to the key ketone **5**. Subsequent periodate cleavage of the vicinal diol (24) gave aldehyde **36**, which was transformed through methylmagnesium bromide addition and subsequent Swern oxidation to the desired C(6)–C(14) calyculin A methyl ketone **5** (Scheme 3). Whilst this sequence of transformations from triene **35** into the C(13) ketone **5** did indeed work acceptably, it unfortunately proceeded in variable yields especially on scale up. However sufficient material was accumulated to further progress the synthesis.

Our projected route toward calyculin A **1** is flexible in the timing of the construction of the C(5)–C(6) bond. However, we wished at this stage to explore this chemistry and hence attempted the palladium(0) catalyzed reaction of the vinyl iodide **36** with the vinyl stannane **3** (Scheme 5). Much to our delight, this Stille coupling (25) afforded the tetraene nitrile **43** as a single geometric isomer in good yield (75%) and thus indicated the viability of our disconnection strategy.

Synthesis of the C(15)–C(25) spiroketal subunit

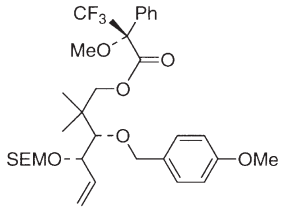


Our first synthetic approach toward the spiroketal core of the calyculins employed a convergent strategy, again using Brown allylborane chemistry to control the relative and absolute stereochemistry of the two fragments **47** and **54** prior to aldol reaction. Thus, reaction of aldehyde **44** with (–)-(*Z*)-crotonyldiisopinocampheylborane **8**, derived from (+)-pinene, furnished the corresponding homoallylic alcohol **45**. This established the desired *syn*-relative stereochemistry at C(21) and C(22) (>95% as determined by ^{1}H NMR analysis) with

Scheme 5.

Reagents and Conditions: (a) $PdCl_2(PPh_3)_2$ (cat.), THF, 60°C (75%).

Scheme 6.

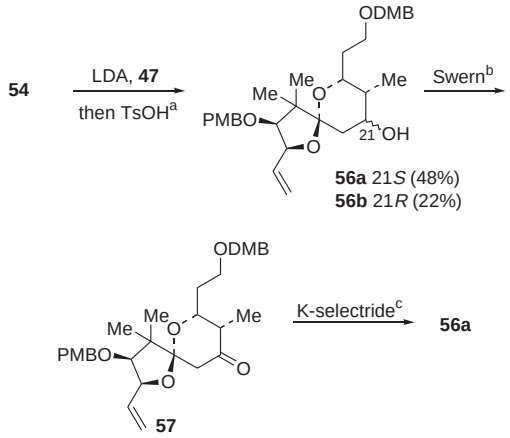


Reagents and Conditions: (a) **8**, THF, Et_2O, -78°C then $NaBO_3{\cdot}4H_2O$, H_2O (72%); (b) TBSOTf, 2,6-lutidine, CH_2Cl_2, (94%); (c) OsO_4 (cat.), NMO, acetone, H_2O then $NaIO_4$, THF, H_2O (88%); (d) **9**, THF, Et_2O, -78°C then $HOCH_2CH_2NH_2$, NaH (cat.) (60%); (e) KHMDS, THF, DMF, *p*-$MeOC_6H_4CH_2Cl$; (f) TBAF, THF (98% over both steps); (g) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, -78 to 20°C, (89%); (h) MeMgBr, THF (95%); (i) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, -78 to 20°C, (85%).

excellent enantiomeric excess, vide infra. Protection of the resultant alcohol as the *tert*-butyldimethylsilyl ether **46** and conversion of the terminal olefin into the corresponding aldehyde **47** was carried out via osmylation and periodate cleavage (Scheme 6). Addition of the (*Z*)-borane **9** to aldehyde **48** proceeded smoothly to yield the *syn*-diol derivative **49**, again with excellent control of relative (>95%) and absolute (>95%) stereochemistry, as estimated through ^{1}H NMR and Mosher ester **55** analysis (26). With the desired C(16) and C(17) stereochemistry established, transformation of alkene **49** into the methyl ketone **54** was accomplished using

© 2001 NRC Canada

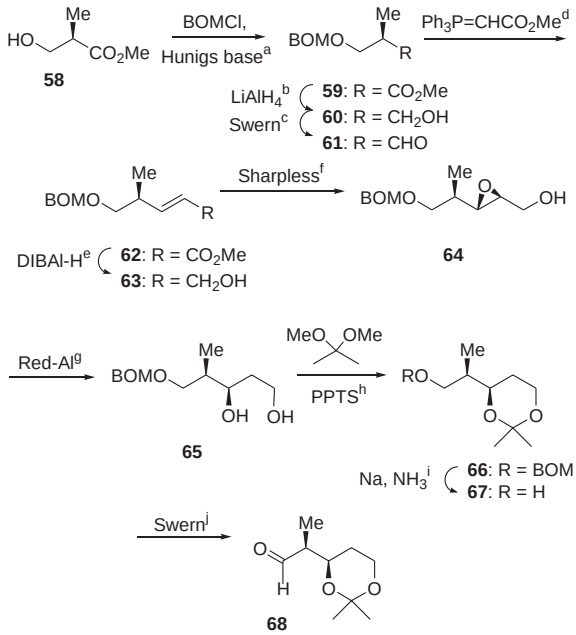
standard methodology. Thus, protection of the newly formed C(17) alcohol gave the *p*-methoxybenzyl ether **50**. Deprotection of the *tert*-butyldimethylsilyl ether using tetrabutylammonium fluoride, oxidation under Swern conditions, methyl Grignard addition, and reoxidation afforded the methyl ketone **54** in excellent overall yield (52% over 6 steps).



55

Lithium diisopropylamide mediated aldol coupling between ketone **54** and aldehyde **47** and subsequent acidification gave the spiroketal core as a mixture of C(21)-epimeric alcohols **56a** and **56b**. Much to our delight, the initial aldol adduct underwent clean cleavage of the robust SEM protecting group (21), removal of the *tert*-butyldimethylsilyl ether, and spiroketalization in a single operation under mild acidic conditions. The epimeric alcohols **56** could be easily separated and individually authenticated but on a larger scale the mixture was oxidized under Swern conditions to produce the ketone **57**, which was stereoselectively reduced using K-Selectride (27) yielding the desired axial diastereoisomer **56a** (Scheme 7). The final spiroketal **56a** was obtained free from other diastereoisomers (TLC, NMR; after the correction at C(21)). Since the high enantiomeric purity of alcohol **51** was established by ^{1}H NMR spectral analysis of ester **55**, the initial allylboration reaction and chromatographic purification must have given alcohol **45** with high absolute as well as relative stereocontrol.

A second approach towards the spiroketal unit was developed to provide additional material for the total synthesis. Thus, the commercial ester **58**, as employed in the construction of **38** (vide supra), was protected as the benzyloxymethyl ether **59** (21), reduced to the alcohol **60** using lithium aluminum hydride, and oxidized under Swern conditions to give aldehyde **61** (Scheme 8). Wittig homologation and reduction of the resultant α,β-unsaturated ester **62** with DIBAL-H furnished the allylic alcohol **63**. Sharpless asymmetric epoxidation (28) was used to elaborate the epoxy alcohol **64**, thereby controlling the absolute stereochemistry of C(23). Epoxide ring opening, through intramolecular hydride delivery upon treatment with Red-Al, gave diol **65**, which was smoothly converted to the corresponding acetonide **66** under standard conditions. Deprotection of the benzyloxymethyl ether using sodium in ammonia and Swern oxidation of the resultant primary alcohol gave the aldol partner **68** in excellent overall yield (77% over 10 steps, Scheme 8).



Aldol reaction of ketone **54** and aldehyde **68** gave, after acidification, the spiroketal system **69**, again as an epimeric mixture (Scheme 9). Oxidation gave the keto-aldehyde **70**, which upon reduction using K-Selectride gave diol **71** as a single diastereoisomer. The constitution and relative stereochemistry of spiroketal **71** was established by a single crystal X-ray structure determination (Fig. 1). The structure of

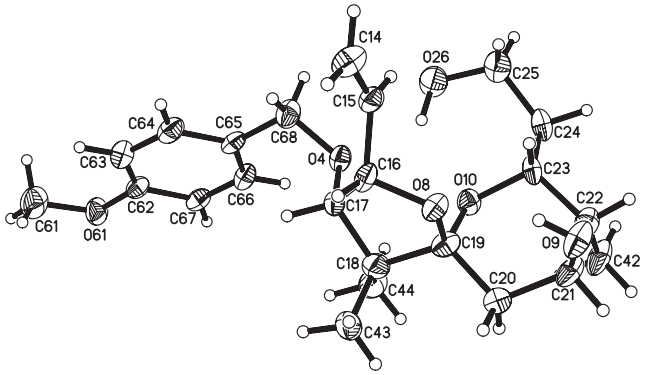
Scheme 9.



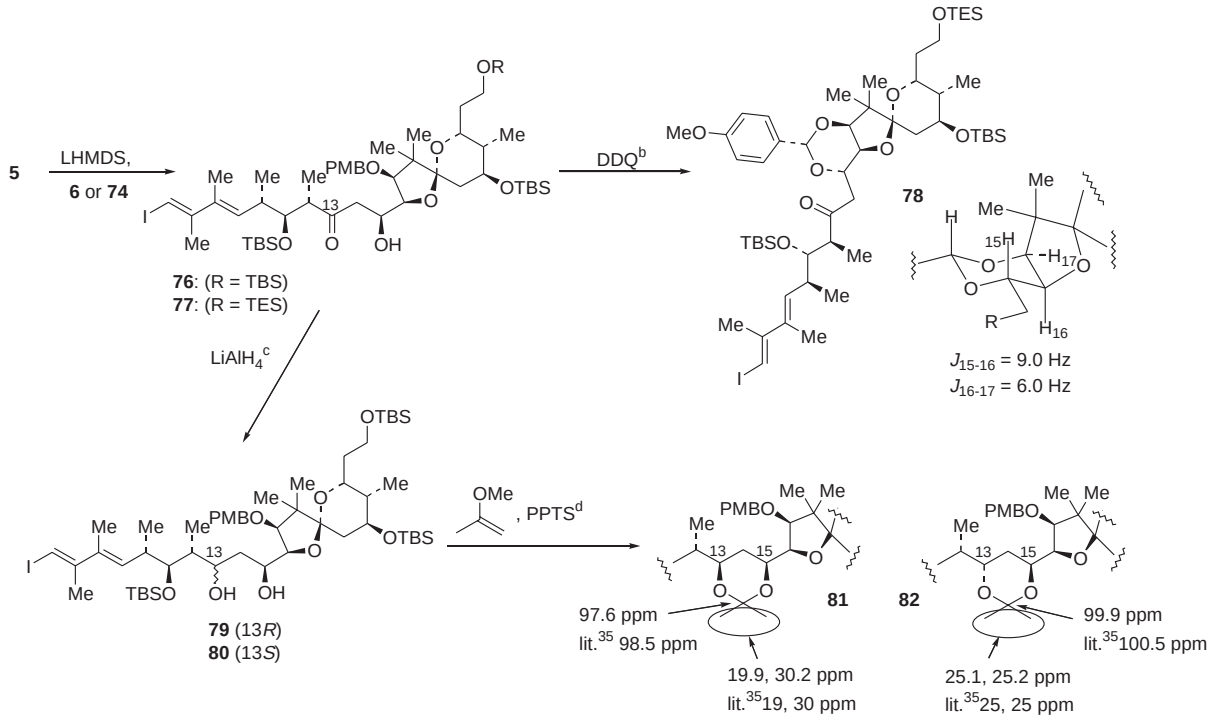
Reagents and Conditions: (a) LDA, THF, -78°C, **68** (96%) then TsOH, MeOH, 25°C (85%); (b) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, -78 to -20°C; (c) $KBH^{s}Bu_3$, THF, -78°C to -10°C then NaOH, H_2O_2 (76% over both steps); (d) TESCl, Et_3N, imidazole, CH_2Cl_2, -40°C (78%); (e) TBSOTf, $^{iso}Pr_2NEt$, CH_2Cl_2, -50 to -20 °C (100%); (f) TBSOTf, 2,6-lutidine, CH_2Cl_2, -5°C (90%); (g) O_3, CH_2Cl_2, -78 °C; Me_2S, -78°C to 25 °C (76%); (h) O_3, CH_2Cl_2, -78 °C; Me_2S, -78°C to 25 °C (89%).

C(19)-C(18) = 104.0(5)° (**71**), 108.2° (calyculin A); O(10)-C(19)-C(20) = 110.2(5)° (**71**), 105.6° (calyculin A). The inter-ring angles about C(19) differ less dramatically, if at all: O(8)-C(19)-O(10) = 110.8(5)° (**71**), 109.5° (calyculin A); C(18)-C(19)-C(20) = 116.6(5)° (**71**), 116.4° (calyculin A). Since one would expect that different crystal packing forces might exert maximum effect on the inter-ring angles, the observed differences in the intra-ring angles presumably result from the changes in the substituent pattern in the fused five- and six-membered rings in **71**. Since the spiroketal **71** was derived ultimately from methyl (*R*)-2-methyl-3-hydroxypropanoate, the ORTEP clearly identifies all the stereocenters are of correct absolute stereochemistry. The diol **71** was converted into the three silyl ethers **72**, **73**, and **75** by double triethylsilylation, selective C(25)-OH triethylsilylation followed by C(21)-OH *tert*-butyldimethylsilylation and double *tert*-butyldimethylsilylation respectively. Finally ozonolysis of alkenes **73** and **75** gave the corresponding aldehydes **74** and **6**, respectively, thereby completing the second calyculin building block, the C(15)–C(25) spiroketal unit.

Synthesis of the C(1)–C(25) spiroketal tetraene nitrile

We sought to construct the C(15)–C(25) tetraene nitrile entity of calyculin by aldol addition of the enolate derived from ketone **5** with the spiroketal **6** followed by alteration of

Fig. 1. Thermal ellipsoid plot for spiroketal **71**. Most hydrogen atoms have been omitted for clarify.



the C(13), C(15)-oxygen substituents and late palladium(0) catalyzed coupling with the dienylstannane **3**. Enolization of the ketone **5** using lithium hexamethyldisilazide and subsequent reaction with the C(1)–C(25) aldehydes **6** and **74** gave the β-hydroxy ketones **76** (76%) and **77** (43%), respectively. In the second unoptimized aldol reaction quantities of the starting ketone **5** (54%) and the aldehyde **74** (35%) were recovered unchanged. Both reactions proceeded with complete diastereoselectivity as judged by ^{1}H NMR spectroscopy of the crude reaction mixture. In the case of β-hydroxy ketone **77** the stereochemistry at C(15) was established by partial DDQ oxidation to produce the corresponding acetal **78** and analysis of the ^{1}H NMR spectrum. Thus, reaction of aldol **77** with DDQ in dichloromethane in the presence of molecular sieves (3 Å) gave the *p*-methoxybenzylidene acetal **78** (29). Analysis of its ^{1}H NMR spectrum (inter alia δ: 5.52 (s, 1H, ArC*H*), 4.04 (dd, 1H, *J* = 9.0, 6.0 Hz, 16-CH), 3.74 (d, 1H, *J* = 6.0 Hz, 17-CH), 2.83 (dd, 1H, *J* = 15.5, 3.0 Hz, 14-CH), 2.60 (dd, 1H, *J* = 15.5, 8.0 Hz, 14-CH)) was consistent with a *trans* disposition of H(15) and H(16) (*J* = 9 Hz) and a *cis* configuration of H(16) and H(17) (*J* = 6 Hz) corresponding to the (15*S*)-stereochemistry, the opposite to that found in (+)-calyculin A. It is not clear, without additional experimentation, as to the exact origin of this high stereochemical bias. Possibly it is the result of the aldol reaction proceeding by a chelation controlled addition pathway (tetrahydrofuran ether as the Lewis basic site) or via a Felkin-type addition pathway. Significant efforts to alter the stereochemical outcome of this key aldol reaction were unsuccessful.

Reduction of the β-hydroxy ketone **76** with lithium aluminum hydride, which presumably took place via ligand exchange at aluminum by the C(15) alcohol and intramolecular hydride delivery, gave a 5:1 mixture of the diols **79** and **80**. The stereochemistries of the two isomers **79** and **80** were determined by formation of the derived acetonides **81** and **82**, respectively, and Rychnovsky (30) analysis of the ^{13}C NMR spectra. The acetonide **81** derived from the major diol **79** showed inter alia ^{13}C NMR δ: 97.6, 30.2, and 19.9 (CMe_2), whereas the isomer **82** showed inter alia ^{13}C NMR δ: 99.9, 25.2, and 25.1 (CMe_2) consistent with the *syn*-acetonide and the *anti*-acetonide structures, respectively. Rychnovsky and co-workers have reported that *syn*-acetonides show the three isopropylidene resonances typically at δ 98.5, 30, and 19,

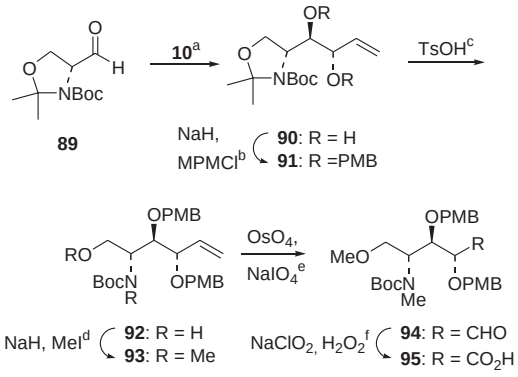
Scheme 10.

Reagents and Conditions: (a) LiHMDS, THF, -78°C then **6** (**76** 76%; **77** 34%); (b) (R = TES) DDQ, 3Å mol. sieves, CH_2Cl_2, -20°C to 0°C (49%); (c) $LiAlH_4$, THF, -78°C (**79** 73%; **80** 15%); (d) $CH_3C(OMe)=CH_2$, PPTS, CH_2Cl_2, 0°C to 25°C (**81** (13*R*) 65%; **82** (13*S*) 77%).

Scheme 11.



Reagents and Conditions: (a) TBSOTf, 2,6-lutidine, MeCN-CH_2Cl_2 (1:1), -78°C (74%); (b) Dess-Martin periodinane, CH_2Cl_2 (80%); (c) DIBAl-H, CH_2Cl_2, -78°C (97%); (d) *t*-BuOK, MeI, THF, -78°C (87%); (e) DDQ, CH_2Cl_2-pH 7 buffer-*i*-PrOH (5:2:2) (100%); (f) $PdCl_2(MeCN)_2$, NMP, **3**, -5°C to 5°C (91%).

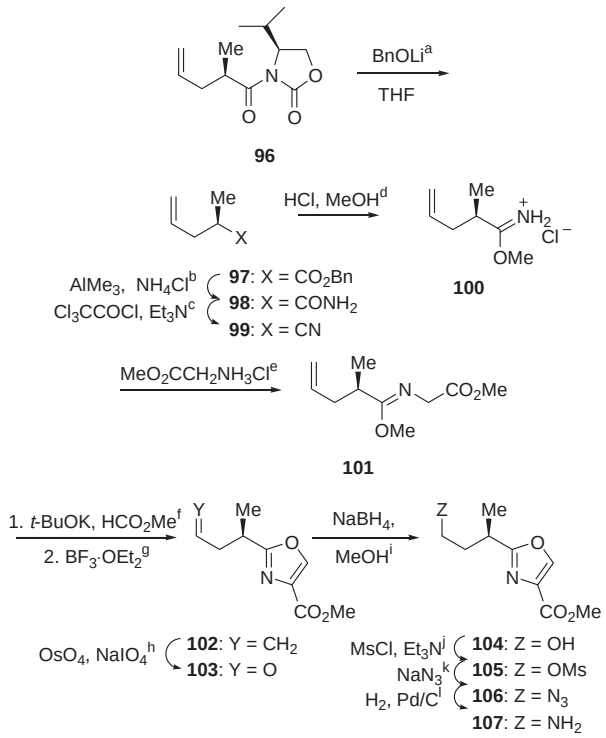
whereas the corresponding signals for *anti*-acetonides are at δ 100.5, 25, and 25 (Scheme 10).

Selective monosilylation of the C(13) alcohol in diol **79** was carried out using *tert*-butyldimethylsilyl triflate in acetonitrile and dichloromethane at –78°C to produce an alcohol most probably the C(15) alcohol **83** (Scheme 11). Subsequent oxidation using the Dess-Martin periodinane (31) gave a product that was assigned as the C(15) ketone

© 2001 NRC Canada

Scheme 12.

Reagents and Conditions: (a) **10**, THF, Et_2O, -78°C then H_2O_2, KF, $KHCO_3$ (reference 30); (b) NaH, DMF, *p*-$MeOC_6H_4CH_2Cl$, (65%); (c) TsOH, MeOH (90%); (d) NaH, MeI, DMF (72%); (e) OsO_4 (cat.), NMO, *t*-BuOH, Me_2CO then $NaIO_4$, MeOH, H_2O; (f) $NaClO_2$, H_2O_2, MeCN, NaH_2PO_4 (65% from **93**).



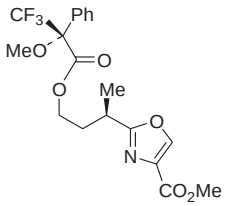
84. Since the NMR spectra of this compound and that of ketone **76** showed myriad resonance differences notwithstanding only the presence of an additional TBS group, the compound was most likely the C(15) ketone **84**. This assignment was consistent with changes in the positions of key peaks in the ^{1}H NMR spectra including the C(9) and (11) methyl peaks, the C(14) methylene and the C(16) and (17) methine peaks [(**76**: 3.64 (d, 1H, *J* = 5.7 Hz, 17-H), 3.20 (d, 1H, *J* = 18 Hz, 14-H), 2.45 (dd, 1H, *J* = 18, 10.3 Hz, 14-H), 1.00 and 0.81 (2d, each 3H, *J* = 7 Hz, 10-Me, 12-Me); **84**: 4.67 (d, 1H, *J* = 5.6 Hz, 16-H), 3.60 (d, 1H, *J* = 5.7 Hz, 17-H), 3.56 (dd, 1H, *J* = 18.5, 8.7 Hz, 14-H), 2.57 (dd, 1H, *J* = 18.5, 2.0 Hz, 14-H), 1.16 and 0.97 (2d, each 3H, *J* = 7 Hz, 10-Me, 12-Me)). As expected on the basis of the stereochemistry of the key aldol reaction to produce **76** and **77**, DIBAL-H reduction of ketone **84** proceeded to produce the (15*R*)-alcohol **85** (Scheme 11). The inversion of C(15) stereochemistry in the oxidation reduction sequence, which may have been the result of a chelation controlled addition pathway (tetrahydrofuran ether as the Lewis basic site) or via a Felkin-type addition pathway, was clearly apparent from comparisons of the ^{1}H NMR and ^{13}C NMR spectra.

Methylation of alcohol **85**, using excess potassium *tert*-butoxide and methyl iodide proceeded smoothly and gave methyl ether **86** in good yield (76%). Subsequent deprotection of the *p*-methoxybenzyl residue at C(17) using DDQ oxidation proceeded in quantitative yield to give the alcohol **87**. Finally, Stille coupling (25) of the dienyl stannane **3** with the dienyl iodide **87** using $PdCl_2(MeCN)_2$ as the catalyst at –5 to 5°C gave the (*Z*,*E*,*E*,*E*)-tetraene nitrile **88** (91%). Stille coupling at higher temperatures resulted in partial isomerization of the delicate tetraene entity. The product C(1)–C(25) (+)-calyculin A intermediate **88** showed data in agreement with that reported by the Evans group in their total synthesis of (+)-calyculin A (**1**) (8).

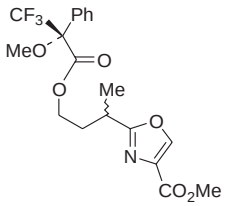
Synthesis of C(26)–C(37) amide-oxazole unit

We sought to prepare the amide oxazole entity **2** using a convergent strategy with late elaboration of the amide bond linking the C(37)–C(33) γ-amino acid with the C(32)–C(26) aminoalkyl oxazole. Again an allylboration strategy was used to elaborate the C(37)–C(33) γ-amino acid unit **95**. The diol **90** was prepared from the Garner aldehyde **89** (32) and the allylborane derivative **10** (33) with oxidative cleavage of the intermediate C–Si bond (for a review on the oxidation of the carbon–silicon bond, see ref. 34). Dialkylation with 4-methoxybenzyl bromide gave the diether **91** (Scheme 12). Selective hydrolysis of the isopropylidene ketal using 4-toluenesulfonic acid gave alcohol **92**, which was doubly methylated by reaction with methyl iodide and sodium hydride to produce the *O*,*N*-dimethylated ether **93**. Sequential catalytic osmium tetraoxide mediated dihydroxylation and periodate cleavage gave the corresponding aldehyde **94**, which was further oxidized using sodium chlorite and hydrogen peroxide (35) to produce the key carboxylic acid **95**.

Scheme 13.



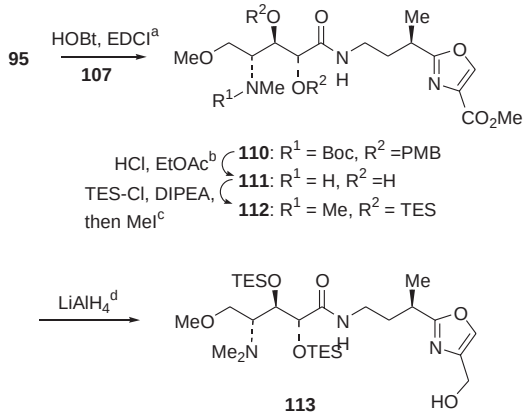
Reagents and Conditions: (a) n-BuLi, $PhCH_2OH$, THF, -20°C (97%); (b) NH_4Cl, $AlMe_3$, PhMe, 60°C (81%); (c) Cl_3CCOCl, Et_3N, CH_2Cl_2, 0°C (78%); (d) HCl, MeOH, -5°C (96%); (e) $MeO_2CCH_2NH_3Cl$, Et_3N, CH_2Cl_2, -10°C to 25°C (69%); (f) *t*-BuOK, HCO_2Me, THF, -10°C to 25°C; (g) $BF_3{\cdot}OEt_2$, THF, -78°C to 25°C (77% over both steps); (h) OsO_4, $NaIO_4$, H_2O, Me_2CO (79%); (i) $NaBH_4$, MeOH, -12°C (93%); (j) Et_3N, $MeSO_2Cl$, Et_2O, -10°C (84%); (k) Me_2SO, NaN_3, 70°C (87%); (l) H_2, Pd/C (cat.), MeOH (98%).



The synthesis of the oxazole unit was accomplished using a modified Cornforth–Meyers approach (Scheme 13) (36). Benzyl ester **97** was readily prepared using Evans alkylation (37) and cleavage of the resultant oxazolidinone **96** using lithium benzyloxide. Ester **97** was converted to the nitrile **99** via Weinreb amide (18) synthesis using trimethylaluminum and ammonium chloride and subsequent dehydration using

© 2001 NRC Canada

trichloroacetyl chloride and triethylamine (Scheme 13). The addition of methanol and hydrogen chloride (36) to nitrile **99** gave the imidate **100** that was allowed to react with glycine methyl ester to produce the *trans*-imidation product **101**. *C*-Formylation, using the Cornforth–Meyers protocol with methyl formate in the presence of potassium *tert*-butoxide, and boron trifluoride diethyl etherate mediated cyclization gave the oxazole **102**. Lewis acid catalysis in this step was found to be superior to the use of acetic acid (15). The alkene **102** was converted into the corresponding aldehyde **103** by osmium tetraoxide mediated dihydroxylation and periodate cleavage. Subsequent reduction with sodium borohydride in methanol proceeded smoothly to produce the alcohol **104**. Gratifyingly, this whole sequence of transformations from oxazolidinone **96** to alcohol **104** proceeded without any significant racemization. Thus, esterification of alcohol **104** with (*R*)-α-methoxy-α-(trifluoromethyl)phenylacetic acid, 4-(*N*,*N*-dimethylamino)pyridine, and 1,3-dicyclohexyl carbodiimide gave the Mosher ester **108**. In parallel, racemic benzyl 2-methyl-4-pentenoate was converted into the racemic modification of the alcohol **104** using exactly the same methods as in Scheme 13 and converted into the ester mixture **109**. Comparison of the ^{1}H NMR spectra for esters **108** and **109** were fully consistent with the diastereoisomic purity of **108** and the enantiomeric purity of alcohol **104**, respectively.



108

109

The alcohol **104** was converted into the corresponding amine **107** via methanesulfonylation, azide displacement, and hydrogenation over palladium on carbon. Initial attempts at coupling the C(26)–C(32)amine **107** with the C(33)–C(37) carboxylic acid **95** employed DCC and 1-hydroxybenzotriazole (HOBT) hydrate as coupling agents, but yields of amide **110** (Scheme 14) were disappointingly low and removal of the side product dicyclohexylurea proved troublesome. However, coupling of **95** with **107** using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDCI) and dehydrated HOBT in the presence of powdered molecular sieves (4 Å) in DMF proceeded in superior yields and gave the amide **110** (72%). Conversion of ester **110** to the Evans intermediate **112** (8) was achieved via cleavage of the Boc and 4-methoxybenzyl protecting groups upon treatment with a saturated solution of hydrogen chloride in ethyl acetate and direct triethylsilylation and *N*-methylation. These three transformations were most conveniently accomplished in a one-pot procedure. The product C(26)–C(37) amide-oxazole **112** showed data in agreement with that reported by the Evans group in their total synthesis of (+)-calyculin A (1) (8). Finally, lithium aluminum hydride reduction of the ester **112** gave the corresponding alcohol **113**. The product alcohol **113** also showed data in agreement with that reported by the Evans group in their total synthesis of (+)-calyculin A (**1**) (8).

Scheme 14.

Reagents and Conditions: (a)EDCI,1-HOBt, 4Å mol. sieves; **107**, DMF (72%); (b) HCl, EtOAc; (c) MeCN, ^{i}Pr$_2$NEt, TES-Cl; MeI (59% over both steps); (d) Et_2O, $LiAlH_4$, -78°C (62%).

Conclusions

We have demonstrated the synthetic utility of the powerful Brown allylboration methodology for the diastereoselective construction of heavily functionalized homoallylic alcohols and the use of this masked aldol methodology in the succinct preparation of complex natural product arrays. Utilizing this methodology, we have completed the synthesis of the C(1)–C(25) tetraene nitrile **88** and C(26)–C(37) oxazole amide **113** intermediates reported by Evans in his total synthesis of synthesis of (+)-calyculin (**1**). This work therefore constitutes a formal total synthesis of the (+)-antipode of this remarkable natural product.

Experimental

General procedures

All reactions were carried out under a dry argon or nitrogen atmosphere at ambient temperature unless otherwise stated. Low reaction temperatures were recorded as bath temperatures. Chromatography refers to column chromatography using E. Merck or BDH silica gel 60, 230–400 mesh (eluants are given in parenthesis). Analytical thin layer chromatography (TLC) was performed on E. Merck precoated silica gel 60 F_{254} plates. Solvents were purified by distillation. Anhydrous THF, Et_2O, PhH, and PhMe were distilled from sodium benzophenone ketyl. DMF was distilled at reduced pressure from BaO or Al_2O_3 and stored over molecular sieves (4 Å). CH_2Cl_2 was distilled from CaH_2. Et_3N and *i*-Pr_2EtN were distilled from CaH_2 and stored over KOH. All other chemicals were used without further purification unless otherwise stated. Optical rotations were measured in $CHCl_3$ solution.

Ethyl 3-(tributylstannyl)-(2*Z*)-propenoate (12)

$Bu_3SnSnBu_3$ (9.84 g, 17.0 mmol) was dissolved in THF (125 mL), cooled to 0°C and *n*-BuLi in hexanes (1.6 M, 10.6 mL, 0.017 mol) was added to generate a faint yellow solution. After stirring at 0°C for 5 min, the mixture was

© 2001 NRC Canada

cooled to –20°C and PhSCu (2.99 g, 17.3 mmol) added to generate a red-black mixture after stirring at –20°C for 15 min. The mixture was cooled to –78°C and treated with ester **11** (1.46 g, 13.0 mmol) in THF (25 mL). The mixture was stirred at –78°C for 10 min, then allowed to warm to –35°C and stirred between –35°C and –50°C for a further 3.5 h. MeOH (10 mL) and Et_2O (100 mL) were added sequentially and the mixture was allowed to warm to room temperature. The resulting solution was filtered through silica eluting with Et_2O. Chromatography (hexanes) afforded stannane **12** (2.72 g, 52%) and the corresponding *trans* stannyl ester **17** (0.409 g, 7%). The *cis*-isomer **12** was obtained as a colorless oil. TLC R_f = 0.2 (hexanes). EI-MS *m*/*z*: 401, 375, 347 ([M – Bu]$^+$), 319, 233, 205, 137, 57. EI-HRMS calcd. for $C_{14}H_{27}O_2Sn$: 347.1033 ([M – Bu]$^+$); found: 347.1042 ([M – Bu]$^+$). IR (film) (cm^{-1}): 1702, 1601, 1458, 1368, 1316, 1197, 1044, 863. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.41 (br s, 1H, $J_{Sn,H}$ = 106 Hz), 4.17 (q, 2H, J = 7.1 Hz), 2.13 (br d, 3H, J = 2 Hz, $J_{Sn,H}$ = 41 Hz), 1.47–0.88 (m, 30H). ^{13}C NMR (68 MHz, $CDCl_3$) δ: 171.4, 167.8, 129.3, 60.0, 29.2 (d, $J_{Sn,C}$ = 18.6 Hz), 27.4 (d, $J_{Sn,C}$ = 29 Hz), 27.3, 14.3, 13.7, 10.9. Anal. calcd. for $C_{18}H_{36}O_2Sn$: C 53.62, H 9.00; found: C 53.54, H 9.22. Stannyl ester **17** was obtained as a colorless oil. TLC R_f = 0.2 (hexanes). EI-MS *m*/*z*: 347 ([M – Bu]$^+$), 291, 235, 179, 113. IR (neat) (cm^{-1}): 1715, 1176. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.96 (m, 1H, $J_{Sn,H}$ = 64.4 Hz), 4.16 (q, 2H, J = 7.1 Hz), 2.40 (d, 3H, J = 1.5 Hz), 1.50, 1.30, 0.90 (3m, 30H). ^{13}C NMR (68 MHz, $CDCl_3$) δ: 168.8, 164.3, 128.2, 59.4, 28.9, 27.3, 22.3, 14.3, 13.5, 9.4. 3-(Tributylstannyl)-(2*Z*)-butenamide (13)

$AlMe_3$ in PhMe (2 M, 1.87 mL, 3.74 mmol) was added dropwise with stirring to a suspension of NH_4Cl (200 mg, 3.74 mmol) in PhH (20 mL) at 0°C. The colorless solution was stirred at 0°C for 30 min and at room temperature for 1 h. This mixture was transferred to ester **12** (500 mg, 1.24 mmol) in dry PhH (5 mL) and heated at 50°C for 24 h. The mixture was cooled, carefully quenched with H_2O, diluted with Et_2O, and stirred for 30 min. Buffer (pH 7) and saturated aqueous Na_2SO_4 were added and the mixture was filtered through Celite eluting with EtOAc (125 mL). The filtrate was washed with brine, dried ($MgSO_4$), and chromatographed (hexanes–Et_2O, 1 :1) to give stannane **13** (354 mg, 76%) as a crystalline solid: mp 35°C. TLC R_f = 0.25 (hexanes–Et_2O, 1:1). EI-MS *m*/*z*: 318 ([M – Bu]$^+$), 204, 184, 136, 57. EI-HRMS calcd. for $C_{12}H_{24}NOSn$: 318.0880 ([M – Bu]$^+$); found: 318.0848 ([M – Bu]$^+$). IR (CCl_4) (cm^{-1}): 3495, 3334, 1670, 1593, 1275, 788, 669. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.41 (m, 1H, $J_{Sn,H}$ = 107 Hz), 5.50, 5.30 (2 br s, 2H, NH_2), 2.14 (m, 3H, $J_{Sn,H}$ = 40 Hz), 1.45, 1.30, 0.90 (m, 27H). ^{13}C NMR (68 MHz, $CDCl_3$) δ: 169.4, 168.7, 129.3, 29.3 (d, $J_{Sn,C}$ = 10 Hz), 27.4, 26.7, 13.7, 11.5. Anal. calcd. for $C_{16}H_{33}NOSn$: C 51.36, H 8.89, N 3.74; found: C 51.42, H 9.07, N 3.77. A similar reaction of ester **17** with $AlMe_3$ and NH_4Cl gave amide **18** (72%) as low melting solid: mp 38–40°C. TLC R_f = 0.23 (hexanes–Et_2O, 1:1). EI-MS *m*/*z*: 318 ([M – Bu]$^+$), 298, 262, 242, 204, 179, 121. EI-HRMS calcd. for $C_{12}H_{24}NOSn$: 318.0880 ([M – Bu]$^+$); found: 318.0861 ([M – Bu]$^+$). Methyl (2*S*)-2-methyl-3-(triethylsilyl)oxypropanoate (25)

Et_3SiCl (40 mL, 0.238 mol) followed by **24** (24.0 g, 0.203 mol) and DMAP (10 mg) were added to ice cooled imidazole (33.3 g, 0.489 mol) in CH_2Cl_2 (100 mL). After 3 h at 0°C and 1 h at room temperature, the mixture was poured into pH 7 buffer and extracted with CH_2Cl_2, washed with pH 7 buffer, and the aqueous phase re-extracted with Et_2O. The combined organic phases were dried ($MgSO_4$) and filtered through alumina. The filtrate was rotary evaporated and the residue distilled (135°C) to afford ester **25** (49.5 g, 90%) as a colorless oil: bp 90°C (15–16 mm Hg). TLC R_f = 0.9 (hexanes–Et_2O, 9:1). $[\alpha]_D^{23}$ = +17.5° (*c* = 13.65). EI-MS *m/z*: 203 ([M – Et]$^+$), 119, 117. IR (film) (cm^{-1}): 1744, 1241, 1199, 1177, 1094. ^{1}H NMR (270 MHz, $CDCl_3$) δ: 3.77 (dd, 1H, *J* = 9.4, 6.9 Hz), 3.66 (s, 3H), 3.62 (dd, 1H, *J* = 9.9, 6.2 Hz), 2.63 (m, 1H), 1.12 (d, 3H, *J* = 7.0 Hz), 0.92 (m, 9H), 0.55 (m, 6H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 175.5, 64.9, 51.5, 42.5, 13.5, 6.6, 4.3. Anal. calcd. for $C_{11}H_{24}O_3Si$: C 56.85, H 10.41; found: C 56.97, H 10.57.

(2*S*)-2-Methyl-3-(triethylsilyl)oxypropanal (26)

DIBAl-H in hexanes (1.24 M, 50 mL, 0.062 mol) was added to ester **25** (14.4 g, 0.062 mol) in hexane (100 mL) at –70°C so as to maintain an internal temperature of –70°C. After 2 h at –70°C, MeOH (6 mL) was added and the cold mixture added to Na_2SO_4 (60 g) in H_2O (300 mL) and Et_2O (500 mL). After 1 h standing, the mixture was filtered through Celite and the organic phase was separated, washed with brine, dried ($MgSO_4$), and rotary evaporated. The resulting oil was dried under vacuum (65°C at 4 mm Hg) to afford aldehyde **26** (11.16 g, 89%) as a colorless oil: bp 145°C (20 mm Hg). TLC R_f = 0.43 (hexanes–Et_2O, 9:1). $[\alpha]_D^{23}$ = +31.4° (*c* = 9.65). IR (film) (cm^{-1}): 2726. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 9.74 (s, 1H), 3.83, (m, 2H), 2.55 (m, 1H), 1.09 (d, 3H, *J* = 7.0 Hz), 0.95 (m, 9H), 0.56 (m, 6H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 204.6, 63.2, 48.8, 10.2, 6.6, 4.2. This crude product was used directly without further purification.

(2*S*,3*R*,4*R*)-2,4-Dimethyl-1-(triethylsilyl)oxy-5-hexen-3-ol (27)

trans-2-Butene (5 mL) was added to *t*-BuOK in THF (1 M, 7.3 mL, 7.3 mmol) at –78°C. *n*-BuLi in hexanes (1.58 M, 4.62 mL, 7.3 mmol) was added dropwise at –78°C and the deep yellow solution stirred at –50°C for 10 min. The solution was recooled to –78°C and (+)-*B*-methoxydiisopinocampheylborane (2.77 g, 8.77 mmol) in Et_2O (8 mL) was added dropwise. After 30 min, $BF_3{\cdot}OEt_2$ (1.2 mL, 9.76 mmol) followed by aldehyde **26** (1.1 g, 5.44 mmol) in Et_2O (8 mL) were added dropwise. The mixture was stirred for 3 h at –78°C, then saturated aqueous sodium perborate (10 mL) was added and the mixture allowed to warm up to room temperature. Additional saturated aqueous sodium perborate (20 mL) was added, the mixture stirred for 12 h, and subsequently extracted with Et_2O (3 × 70 mL). The organic phase was washed with brine, dried (Na_2SO_4), and rotary evaporated to give alcohol **27** (1.064 g, 76%) as a colorless oil: bp 105°C (1 mm Hg). TLC R_f = 0.3 (hexanes–Et_2O, 9:1). $[\alpha]_D^{23}$ = +20.7° (*c* = 5.2). EI-MS *m/z*: 259 (M$^{\cdot+}$), 229 ([M – Et]$^+$), 203, 187, 173. (4*S*,5*R*,6*R*)-2,4,6-Trimethyl-5-(*tert*-butyldimethylsilyl)oxy-(2*E*,7)-octadien-1-ol (31)

DIBAl-H in hexanes (1 M, 13.0 mL, 0.013 mol) was added over 5 min to the ester **30** (2.0 g, 5.88 mmol) in CH_2Cl_2 (100 mL) at –78°C. After 1 h, the mixture was allowed to warm to –20°C over 1 h, recooled to –78°C and MeOH (1 mL) and saturated aqueous Na_2SO_4 (30 mL) were added sequentially. After allowing to warm to room temperature, the CH_2Cl_2 layer was removed by decantation. The remaining crystalline residue was washed with CH_2Cl_2 (100 mL) and the combined CH_2Cl_2 extracts washed with brine, dried ($MgSO_4$), and rotary evaporated. Chromatography (hexanes–Et_2O, 4:1 to 1:1) gave alcohol **31** (1.553 g, 86%) as a colorless oil. TLC R_f = 0.25 (hexanes–Et_2O, 4:1). $[\alpha]_D^{23}$ = –7.57° (*c* = 2.8). EI-MS *m*/*z*: 243 ($[M - C_4H_7]^+$), 225, 199, 159, 115. (5*S*,6*R*,7*R*)-1-Iodo-2,3,5,7-tetramethyl-6-(*tert*-butyldimethylsilyl)oxy-(1*E*,3*E*,8)-nonatriene (35)

$AlMe_3$ in PhMe (2 M, 1.92 mL, 3.84 mmol) was added dropwise to Cp_2ZrCl_2 (560 mg, 1.916 mmol) in CH_2Cl_2 (8 mL) and, after 10 min, alkyne **34** (510 mg, 1.75 mmol) in CH_2Cl_2 (6 mL) was added. After 16 h, I_2 (530 mg, 2.088 mmol) in THF (10 mL) was added and, after a further 30 min stirring, the solution was cooled to 0°C and carefully treated with H_2O (3 mL). The solution was filtered through Celite eluting with Et_2O and the organic phase was washed with pH 7 buffer and brine and dried ($MgSO_4$). Rotary evaporation and chromatography (hexanes) gave iodide **35** (520 mg, 69%) as an unstable oil that turned purple upon prolonged standing. TLC R_f = 0.9 (hexanes). EI-MS *m*/*z*: 379, 377 ($[M - Bu]^+$), 251, 199. EI-HRMS calcd. for $C_{15}H_{26}IOSi$: 377.0798 ($[M - Bu]^+$); found: 377.0795 ($[M - Bu]^+$). IR (film) (cm^{-1}): 1253, 1111, 1048, 1034, 836, 772. ^1H NMR (270 MHz, $CDCl_3$) δ: 6.26 (s, 1H), 5.80 (m, 2H), 5.00 (m, 2H), 3.49 (t, 1H, *J* = 4.4 Hz), 2.60 (m, 1H), 2.30 (m, 1H), 2.04 (d, 3H, *J* = 0.6 Hz), 1.77 (d, 3H, *J* = 1.0 Hz), 0.95 (d, 3H, *J* = 7.0 Hz), 0.91 (d, 3H, *J* = 7.0 Hz), 0.91 (s, 9H), 0.05 (s, 3H), 0.03 (s, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 148.5, 141.5, 132.8, 132.4, 114.1, 79.6, 78.1, 43.3, 36.6, 26.1, 22.6, 18.9, 18.3, 16.3, 14.5, –3.7, –4.0. Reaction on a smaller scale proceeded in superior yield to give iodide **35** (191 mg, 86%).

(5*S*,6*R*,7*S*)-6-(*tert*-Butyldimethylsilyl)oxy-1-iodo-8-oxo-2,3,5,7-tetramethylnonan-1*E*,3*E*-diene (5)

OsO_4 in THF (0.065 M, 3.5 mL, 0.244 mmol) and pyridine (77 μL) were added to diene **35** (88 mg, 0.203 mmol) in dry THF (4 mL) at room temperature. The mixture was stirred for 1.7 h when Celite (500 mg) and saturated aqueous sodium bisulfite (3 mL) were added. After further stirring for 2.5 h, the mixture was filtered and diluted with Et_2O (20 mL). The organic phase was washed with H_2O, 1 M HCl, aqueous $NaHCO_3$ (10%), and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 1:2.5) gave the crude diol (51 mg, 54%) as a colorless oil. TLC R_f = 0.5 (Et_2O). EI-HRMS calcd. for $C_{18}H_{34}IO_2Si$: 437.1373 ($[M - CH_2OH]^+$); found: 437.1388 ($[M - CH_2OH]^+$). IR (CCl_4) (cm^{-1}): 3399, 1253, 1075, 1032, 837, 773, 600. ^1H NMR (400 MHz, $CDCl_3$) major diastereoisomer δ: 6.28 (s, 1H), 5.69 (d, 1H, *J* = 9.9 Hz), 3.72–3.35 (m, 5H), 2.72 (m, 1H), 2.02 (s, 3H), 1.80 (s, 3H), 1.79 (m, 1H), 1.00 (d, 3H, *J* = 6.9 Hz), 0.92 (s, 9H), 0.79 (d, 3H, *J* = 7.1 Hz), 0.11 (s, 3H), 0.10 (s, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) major diastereoisomer δ: 148.2, 133.7, 131.3, 79.6, 78.6, 74.0, 64.7, 39.4, 37.4, 26.0, 22.6, 18.1, 17.9, 14.7, 14.3, –4.0, –4.4. *N*-Methylmorpholine-*N*-oxide (10 mg, 87 μmol) and OsO_4 in H_2O (0.3 M, ca 10 μL) were added to diene **35** (29 mg, 67 μmol) in Me_2CO and H_2O (1:1, 1 mL) at room temperature. The mixture was stirred for 7 h when sodium bisulfite was added and, after 20 min, the mixture was filtered through Celite. Rotary evaporation and chromatography (Et_2O) gave the crude diol (19 mg, 61%) and recovered triene **35** (6 mg, 21%). Both of these osmylation processes proved to be capricious and proceeded in variable yield on scale up. The crude diol from either preparation was used directly in the next step. The crude 1,2-diol (147 mg, 0.314 mmol) was allowed to react with $NaIO_4$ (174 mg, 0.91 mmol) in THF (5 mL), MeOH (0.8 mL), and H_2O (2 mL) for 30 min at room temperature. The resulting mixture was diluted with CH_2Cl_2 (50 mL) and washed with H_2O and brine. The organic layer was dried (Na_2SO_4) and rotary evaporated to leave the crude aldehyde **36** as a pale yellow oil. TLC R_f = 0.4 (hexanes–Et_2O, 9:1). $[\alpha]_D^{22}$ = +0.41° (*c* = 3.15). EI-MS *m*/*z*: 379 ($[M - Bu]^+$), 252, 201, 173, 145. IR (film) (cm^{-1}): 1723, 1463, 1378, 1254, 1075, 1034, 1006, 939, 838, 773, 673. ^1H NMR (400 MHz, $CDCl_3$) δ: 9.76 (d, 1H, *J* = 2.6 Hz), 6.31 (s, 1H), 5.68 (d, 1H, *J* = 9.5 Hz), 3.84 (t, 1H, *J* = 3.8 Hz), 2.65 (m, 1H), 2.48 (m, 1H), 2.03 (s, 3H), 1.79 (s, 3H), 1.06 (d, 3H, *J* = 7.0 Hz), 1.00 (d, 3H, *J* = 6.9 Hz), 0.90 (s, 9H), 0.08 (s, 3H), 0.06 (s, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 204.7, 148.1, 134.9, 130.2, 79.1, 77.7, 51.1, 37.9, 25.9, 22.6, 18.2, 17.8, 14.7, 11.8, –4.0, –4.1. The crude aldehyde **36** was used in the

© 2001 NRC Canada

next reaction without further purification. Aldehyde **36** (134 mg, crude) in dry THF (3.0 mL) was added dropwise to MeMgBr in PhMe and THF (3:1) (1.4 M, 722 μL, 1.0 mmol) in dry THF (4 mL) at –78°C. After 30 min, the mixture was poured into saturated aqueous NH_4Cl and ice and extracted with Et_2O. The extracts were combined, washed with brine, and dried ($MgSO_4$). Rotary evaporation and chromatography (Et_2O–hexanes, 1:3) gave alcohol **37** (114 mg, 80% from the diol). Since the alcohol **37** was unstable, it was used directly in the next reaction. DMSO (86 μL, 1.21 mmol) in dry CH_2Cl_2 (3 mL) was added dropwise to oxalyl chloride (88 μL, 1.01 mmol) in dry CH_2Cl_2 (4 mL) at –78°C. After 8 min, alcohol **37** (114 mg, 0.252 mmol) in dry CH_2Cl_2 (3 mL) was added and stirring was continued for 10 min at –78°C, when Et_3N (296 μL, 2.12 mmol) was added dropwise. The mixture was allowed to warm up to –30°C over 15 min and then diluted with Et_2O (50 mL). The organic phase was washed with H_2O, 0.5 M HCl, H_2O, saturated aqueous $NaHCO_3$, and brine and then dried ($MgSO_4$). Rotary evaporation and chromatography (hexanes–Et_2O, 6:1) gave ketone **5** (90 mg, 79%) as a colorless oil. TLC R_f = 0.43 (hexanes–Et_2O, 5:1). $[\alpha]_D^{20}$ = +23° (*c* = 0.70). EI-MS *m*/*z*: 435 ($[M - Me]^+$), 393, 301, 251, 215. EI-HRMS calcd. for $C_{18}H_{32}IO_2Si$: 435.1216 ($[M - Me]^+$); found: 435.1208 ($[M - Me]^+$). IR (film) (cm^{-1}): 1718, 1462, 1377, 1253. ^1H NMR (300 MHz, $CDCl_3$) δ: 6.28 (s, 1H), 5.80 (dq, 1H, *J* = 9.5, 1.0 Hz), 3.88 (dd, 1H, *J* = 7.5, 2.5 Hz), 2.64 (q, 1H, *J* = 7.5 Hz), 2.57 (ddt, 1H, *J* = 9.5, 7.5, 2.5 Hz), 2.14 (s, 3H), 2.03 (d, 3H, *J* = 1.0 Hz), 1.78 (d, 3H, *J* = 1.0 Hz), 0.97 (d, 3H, *J* = 7.5 Hz), 0.93 (d, 3H, *J* = 7.5 Hz), 0.87 (s, 9H), 0.06 (s, 3H), 0.02 (s, 3H). ^{13}C NMR (85 MHz, $CDCl_3$) δ: 211.9, 148.3, 134.3, 130.3, 78.8, 77.6, 52.0, 36.6, 31.1, 26.2, 22.7, 18.5, 18.3, 14.7, 13.4, –3.9, –4.3.

(2*R*,4*S*)-2,4-Dimethyl-1,3,5-pentanetriyl triacetate (42)

The silyl ether **38** was prepared from methyl (2*R*)-2-methyl-3-triethylsilyloxypropanoate (ent-**24**) (17.5 g) and (–)-*B*-methoxydiisopinocampheylborane following the methods as for the (*S*)-antipode **27**. Ether **38** was dissolved in Me_2CO (50 mL) and H_2O (5 mL), then OsO_4 in H_2O (5%, 1 mL) and *N*-methylmorpholine-*N*-oxide (9.5 g, 0.0698 mol) were added. After stirring for 6 h at room temperature, saturated aqueous sodium metabisulfite (20 mL) and Celite (20 g) were added and, after 3 h, the mixture was filtered. The filtrate was rotary evaporated, the resultant solid extracted with Et_2O (300 mL), and the filtrate washed with H_2O (2 × 50 mL), 1 M HCl (50 mL), H_2O (50 mL), 10% aqueous $NaHCO_3$ (50 mL), and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 8:1 to 3:2) gave the crude vicinal diol (14.2 g, 40% overall from ester ent-**24**). $NaIO_4$ (1.11 g, 6.21 mmol), MeOH (5 mL), and H_2O (2 mL) were added to an aliquot of the diol (2.1 g, 5.17 mmol) in THF (15 mL) and the mixture stirred for 20 min at room temperature. An insoluble solid was removed by filtration and the filtrate was extracted with CH_2Cl_2 (3 × 50 mL). The extracts were washed with H_2O and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 22:1) gave the crude aldehyde **39** (1.93 g, 100%). $NaBH_4$ (6.6 mg, 0.175 mmol) was added to an aliquot of the aldehyde **39** (80 mg, 0.175 mmol) in MeOH (1 mL) with ice cooling. After 20 min, rotary evaporation and chromatography (hexanes–EtOAc, 5:1) gave the crude alcohol **40** (75 mg, 93%). $TsOH \cdot H_2O$ (3 mg, 0.017 mmol) was added to alcohol **40** (75 mg, 0.163 mmol) in MeOH (1.6 mL) at room temperature. After 3 h, Et_3N (50 μL) was added and the mixture rotary evaporated and chromatographed (hexanes–EtOAc, 1:1 then MeOH:CH_2Cl_2, 1:9) to give the crude triol **41** (24 mg, 100%). Ac_2O (60 μL), Et_3N (80 μL), and DMAP (5 mg) were added to triol **41** (24 mg, 0.16 mmol) in CH_2Cl_2 (1 mL). After 30 min, excess Ac_2O was quenched with MeOH (0.1 mL). Rotary evaporation and chromatography (hexanes–EtOAc, 2:1) gave triester **42** (45 mg, 97%) as a colorless oil. $[\alpha]_D^{20}$ = 0° (*c* = 2.25). IR (film) (cm^{-1}): 2973, 1739, 1460, 1376, 1228, 1128. ^1H NMR (300 MHz, $CDCl_3$) δ: 4.90 (t, 1H, *J* = 6.5 Hz), 4.06 (dd, 2H, *J* = 4.5, 11.0 Hz), 3.92 (dd, 2H, *J* = 11.0, 6.5 Hz), 2.22–2.13 (m, 2H), 2.05 (s, 3H), 2.04 (s, 6H), 1.00 (d, 6H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 171.1, 170.6, 76.5, 65.5, 34.3, 21.0, 20.8, 14.9.

(10*S*,11*S*,12*S*)-3,7,8,10,12-Pentamethyl-13-oxo-11-(*tert*-butyldimethylsilyl)oxy-(2*Z*,4*E*,6*E*,8*E*)-tridecatetraenenitrile (43)

$PdCl_2(PPh_3)_2$ (3 mg) in THF (0.5 mL) was added to the aldehyde **36** (75 mg, 0.172 mmol) and stannyl nitrile **3** (80 mg, 0.21 mmol) in THF (0.5 mL) and the yellow mixture was heated with stirring at 60°C for 2 h. The resultant black mixture was cooled and directly chromatographed (hexanes–Et_2O, 4:1) to afford the tetra-ene nitrile **43** (52 mg, 75%) as a yellow oil. TLC R_f = 0.25 (hexanes–Et_2O, 9:1). $[\alpha]_D^{22}$ = +70.6° (*c* = 2.3). EI-MS *m*/*z*: 401 ($M^{\cdot+}$), 344, 315, 286, 252, 201, 173, 145, 115. EI-HRMS calcd. for $C_{24}H_{39}NO_2Si$: 401.2750 ($M^{\cdot+}$); found: 401.2751 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2208, 1723, 1592, 1583, 1462, 1379, 1254, 1040, 1034, 962, 838, 775. ^1H NMR (400 MHz, $CDCl_3$) δ: 9.76 (d, 1H, *J* = 2.7 Hz), 6.99 (dd, 1H, *J* = 14.2, 11.2 Hz), 6.85 (d, 1H, *J* = 14.8 Hz), 6.36 (d, 1H, *J* = 10.8 Hz), 5.82 (d, 1H, *J* = 9.5 Hz), 5.09 (br s, 1H), 3.86 (t, 1H, *J* = 4.7 Hz), 2.77 (m, 1H), 2.50 (m, 1H), 2.07 (d, 3H, *J* = 1.3 Hz), 2.00 (s, 3H), 1.86 (s, 3H), 1.07 (d, 3H, *J* = 7.0 Hz), 1.03 (d, 3H, *J* = 6.9 Hz), 0.90 (s, 9H), 0.09 (s, 3H), 0.06 (s, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 204.6, 156.5, 143.4, 136.1, 133.5, 131.7, 129.1, 125.0, 117.4, 95.1, 77.8, 51.2, 38.3, 34.1, 25.9, 22.3, 19.4, 18.2, 17.8, 14.6, 14.3, 14.1, 11.8, –4.0, –4.2.

3-(3,4-Dimethoxybenzyl)oxypropan-1-ol

Camphorsulfonic acid (50 mg) and 3,4-dimethoxybenzaldehyde (20 g, 0.120 mol) were added to 1,3-propanediol (22 g, 0.289 mol) in PhH (100 mL). The mixture was heated to reflux (Dean-Stark) for 12 h, cooled to room temperature, and treated with pH 7 buffer (50 mL). The organic phase was separated,washed with brine (2 × 100 mL), and dried ($MgSO_4$). The mixture was heated to reflux (Dean-Stark) for a further 2 h and cooled to 0°C. DIBAl-H in PhMe (1.46 M, 25 mL, 0.365 mmol) was added dropwise at 0°C, stirred for 5 min at 0°C and then 1 h at room temperature. A further aliquot of DIBAl-H in PhMe (1.46 M, 8 mL) was added and the mixture stirred at room temperature for 30 min. The solution was cooled to 0°C and quenched with EtOAc (10 mL) and aqueous NaOH (3 M, 7 mL). The resulting solution was filtered through Celite eluting with EtOAc and the organic fraction washed with

H_2O and brine and dried ($MgSO_4$). Rotary evaporation and chromatography (hexanes–EtOAc, 1:1, then EtOAc) gave 3-(3,4-dimethoxybenzyl)oxy-1-propanol (10 g, 37%) as a viscous oil: TLC R_f = 0.25 (Et_2O). EI-MS *m/z*: 226 ($M^{\cdot+}$), 211, 195, 167, 151. EI-HRMS calcd. for $C_{12}H_{18}O_4$: 226.1205 ($M^{\cdot+}$); found: 226.1197 ($M^{\cdot+}$). IR (film) (cm^{-1}): 3466, 1593, 1515, 1465, 1420, 1365, 1360, 1265, 1238, 1157, 1090, 1028, 820, 811, 765. ^1H NMR (400 MHz, $CDCl_3$) δ: 6.87–6.83 (m, 3H), 4.45 (s, 2H), 3.88 (s, 3H), 3.87 (s, 3H), 3.79–3.75 (m, 2H), 3.65–3.62 (m, 2H), 2.34 (m, 1H), 1.87–1.84 (m, 2H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 149.0, 148.6, 130.6, 120.2, 110.9, 110.9, 73.2, 69.1, 61.9, 55.91, 55.88, 55.84, 55.80, 32.1. Anal. calcd. for $C_{12}H_{18}O_4$: C 63.70, H 8.02; found: C 63.48, H 8.17.

3-(3,4-Dimethoxybenzyl)oxypropanal (44)

DMSO (3 mL, 0.042 mmol) in CH_2Cl_2 (4 mL) was added dropwise over 10 min to $(COCl)_2$ (3 mL, 0.034 mol) in CH_2Cl_2 (50 mL) at –78°C. After stirring at –78°C for 25 min, 3-(3,4-dimethoxybenzyl)oxypropan-1-ol (6.0 g, 0.0265 mol) in CH_2Cl_2 (4 mL) was added dropwise. After 45 min, Et_3N (20 mL, 0.143 mol) was added dropwise at –78°C and stirring was continued for a further 45 min; the solution was then allowed to warm to room temperature. Buffer (pH 7, 50 mL) and Et_2O (200 mL) were added and the ethereal layer was washed with brine and dried ($MgSO_4$). Chromatography (hexanes–EtOAc, 1:1) gave aldehyde **44** (4.59 g, 77%) as a colorless oil. TLC R_f = 0.4 (hexanes–Et_2O, 3:7). EI-MS *m/z*: 224 ($M^{\cdot+}$), 209, 193, 167, 151, 139. EI-HRMS calcd. for $C_{12}H_{16}O_4$: 224.1049 ($M^{\cdot+}$); found: 224.1046 ($M^{\cdot+}$). IR (film) (cm^{-1}): 1723, 1712, 1593, 1515, 1465, 1420, 1363, 1265, 1258, 1157, 1092, 1028, 856, 812, 766. ^1H NMR (300 MHz, $CDCl_3$) δ: 9.80, (t, 1H, *J* = 1.8 Hz), 7.2–6.8 (m, 3H), 4.45 (s, 2H), 3.89 (s, 3H), 3.88 (s, 3H), 3.82 (t, 2H, *J* = 6.1 Hz), 2.70 (dt, 2H, *J* = 6.1, 1.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 200.7, 149.1, 148.8, 130.4, 120.2, 111.2, 73.0, 63.5, 55.9, 43.8.

(3*R*,4*R*)-1-(3,4-Dimethoxybenzyl)oxy-4-methyl-5-hexen-3-ol (45)

Freshly condensed *cis*-2-butene (5 mL) was added to *t*-BuOK (2.675 g, 0.0238 mol) in THF (50 mL) at –78°C. *n*-BuLi in hexanes (1.6 M, 15 mL, 0.024 mol) was added dropwise resulting in the formation of a yellow precipitate, which was allowed to warm to –55°C and stirred for an additional 20 min. Upon recooling to –78°C, (–)-*B*-methoxydiisopinocampheylborane (8.27 g, 0.0262 mol) in Et_2O (30 mL) was added dropwise over 10 min. The colorless mixture was stirred at –78°C for 30 min, then $BF_3.OEt_2$ (4.19 mL, 0.034 mol) was added in one portion followed by aldehyde **44** (4.45 g, 0.020 mol) in Et_2O (25 mL) dropwise. The mixture was stirred at –78°C for 4 h and H_2O (20 mL) was added when the mixture was allowed to warm to room temperature. Sodium perborate (20 g) was added and the mixture was stirred vigorously overnight. The mixture was extracted with Et_2O (200 mL) and the extracts were washed with H_2O and brine, dried ($MgSO_4$), and rotary evaporated. Chromatography (hexanes–Et_2O, 1:1) gave alcohol **45** (4.00 g, 72%) as a colorless oil. TLC R_f = 0.4 (hexanes–Et_2O, 3:7). $[\alpha]_D^{23}$ = +9.5° (*c* = 9.95). EI-MS *m/z*: 280 ($M^{\cdot+}$), 224, 167, 151, 137, 107. EI-HRMS calcd. for $C_{16}H_{24}O_4$: 280.1675 ($M^{\cdot+}$); found: 280.1678 ($M^{\cdot+}$). IR (CCl_4) (cm^{-1}): 3469, 1612, 1593, 1465, 1420, 1364, 1265, 1239, 1168, 1139, 1088, 1030, 916, 767, 765. ^1H NMR (400 MHz, $CDCl_3$) δ: 6.87–6.82 (m, 3H), 5.78 (m, 1H), 5.05 (m, 2H), 4.46 (s, 2H), 3.89 (s, 3H), 3.88 (s, 3H), 3.65 (m, 3H), 2.85 (d, 1H, *J* = 3.4 Hz), 2.26 (m, 1H), 1.75 (m, 2H), 1.05 (d, 3H, *J* = 6.8 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 149.0, 148.5, 140.8, 130.5, 120.0, 114.4, 111.1, 73.8, 72.8, 68.6, 55.7, 55.6, 43.6, 33.4, 14.8. Anal. calcd. for $C_{16}H_{24}O_4$: C 68.54, H 8.63; found: C 68.45, H 8.84.

(3*R*,4*R*)-1-(3,4-Dimethoxybenzyl)oxy-4-methyl-3-(*tert*-butyldimethyl)oxy-5-hexene (46)

2,6-Lutidine (1 mL, 8.59 mmol) followed by *t*-$BuMe_2SiOTf$ (1.3 mL, 5.62 mmol) were added to alcohol **45** (1.43 g, 5.11 mmol) in CH_2Cl_2 (15 mL) at –78°C. The mixture was allowed to warm to room temperature over 90 min and quenched with pH 7 buffer (5 mL). The solution was diluted with Et_2O (100 mL), washed with brine, dried ($MgSO_4$), and evaporated to dryness. Chromatography (hexanes–Et_2O, 9:1) afforded the silyl alcohol **46** (1.89 g, 94%) as a colorless oil. TLC R_f = 0.5 (hexanes–Et_2O, 1:1). $[\alpha]_D^{22}$ = +28.1° (*c* = 7.2). EI-MS *m/z*: 394 ($M^{\cdot+}$), 339, 281, 251, 224, 199, 173, 167, 151. EI-HRMS calcd. for $C_{22}H_{38}O_4Si$: 394.2539 ($M^{\cdot+}$); found: 394.2524 ($M^{\cdot+}$). 2,2-Dimethyl-3-(*tert*-butyldimethylsilyl)oxypropanal (48)

Imidazole (15 g, 0.220 mol) followed by *t*-$BuMe_2SiCl$ (15 g, 0.1 mol) were added to 2,2-dimethyl-1,3-propanediol (20 g, 0.192 mol) in DMF (10 mL). The resulting viscous mixture was stirred at room temperature for 16 h, then Et_2O (200 mL) and H_2O (200 mL) were added. The ethereal layer was washed with pH 7 buffer (2 × 100 mL) and brine and dried ($MgSO_4$). After rotary evaporation, the residue was distilled to leave 2,2-dimethyl-3-(*tert*-butyldimethylsilyl)oxy-1-propanol (15.8 g, 63%) as a colorless oil. DMSO (1 mL, 0.014 mol) in CH_2Cl_2 (2 mL) was added to $(COCl)_2$ (1 mL, 0.011 mol) in CH_2Cl_2 (25 mL) at –78°C such that the internal reaction temperature did not increase by more than 5°C. This mixture was stirred at –78°C for 30 min and then the alcohol (2 g, 7.87 mmol) in CH_2Cl_2 (5 mL) was added dropwise. The mixture was stirred at –78°C for 35 min, then Et_3N (6 mL, 0.043 mmol) was added slowly and the mixture allowed to warm to –10°C. Buffer (pH 7, 20 mL) and Et_2O (100 mL) were added and the ethereal fraction washed with pH 7 buffer and brine and dried (Na_2SO_4). Chromatography (hexanes–Et_2O, 9:1) afforded aldehyde **48** (1.72 g, 86%) as a colorless oil. TLC R_f = 0.75 (hexanes–Et_2O, 9:1). IR (film) (cm^{-1}): 1730, 1472, 1362, 1401, 1256, 1103, 1006, 897, 864, 842, 775, 669. ^1H NMR (400 MHz, $CDCl_3$) δ: 9.57 (s, 1H), 3.59 (s, 2H), 1.04 (s, 6H), 0.86 (s, 9H), 0.03 (s, 6H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 206.2, 68.4, 48.1, 25.8, 18.6, 18.2, –5.6. The crude aldehyde **48** was used directly in the next step without any further purification.

(3*S*,4*S*)-2,2-Dimethyl-1-(*tert*-butyldimethylsilyl)oxy-4-(2-(trimethylsilyl)ethoxy)methoxy-5-hexen-3-ol (49)

sec-BuLi in hexanes (1.4 M, 20 mL, 0.028 mol) was added over 10 min to $Me_3SiCH_2CH_2OCHsOCH_2CH{=}CH_2$ (5.30 g, 0.028 mol) in THF (75 mL) at –78°C. The resulting yellow mixture was stirred at –78°C for a further 30 min, then (+)-*B*-methoxydiisopinocampheylborane (9.74 g, 0.031 mol) in Et_2O (30 mL) was added dropwise over 20 min to yield a colorless solution. After a further 20 min at –78°C, $BF_3{\cdot}OEt_2$ (4.9 mL, 0.0389 mol) was added immediately followed by the dropwise addition of aldehyde **48** (6.50 g, 0.026 mol) in Et_2O (30 mL). This viscous mixture was stirred for 4 h at –78°C and allowed to slowly warm to –40°C. Ethanolamine (10 mL, 0.166 mol) was added and the mixture allowed to warm up to room temperature and stirred for 1 h. Additional ethanolamine (10 mL) was added followed by NaH dispersion in oil (50%, 50 mg). After stirring for 12 h, the mixture was extracted with EtOAc–Et_2O (1:1, 500 mL), the extracts were washed with pH 7 buffer and brine, and dried ($MgSO_4$). Chromatography (hexanes–Et_2O, 9:1) afforded alcohol **49** (6.28 g, 60%) as a colorless oil. TLC R_f = 0.45 (hexanes–Et_2O, 9:1). $[\alpha]_D^{22}$ = +74.1° (*c* = 2.35). EI-MS *m*/*z*: 405 ($[M + H]^+$), 331, 289, 257, 217. EI-HRMS calcd. for $C_{17}H_{35}O_4Si$: 331.2305 ($[M - SiMe_3]^+$); found: 331.2148 ($[M - SiMe_3]^+$). IR (film) (cm^{-1}): 3500, 1473, 1389, 1251, 1099, 1025, 933, 837, 786. ^1H NMR (400 MHz, $CDCl_3$) δ: 5.94 (m, 1H), 5.25 (m, 2H), 4.73 (d, 1H, *J* = 7.0 Hz), 4.63 (d, 1H, *J* = 7.0 Hz), 4.22 (dd, 1H, *J* = 8.2, 2.4 Hz), 3.75 (m, 1H), 3.54 (d, 1H, *J* = 9.3 Hz), 3.52 (m, 1H), 3.48 (d, 1H, *J* = 2.7 Hz), 3.40 (d, 1H, *J* = 9.4 Hz), 1.02 (s, 3H), 0.93 (s, 3H), 0.89 (s, 9H), 0.88 (m, 2H), 0.05 (s, 6H), 0.01 (s, 9H). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 136.9, 118.2, 91.7, 79.1, 77.3, 72.5, 65.8, 39.0, 25.8, 21.9, 20.4, 18.2, 18.1, –1.5, –5.6. Anal. calcd. for $C_{20}H_{44}O_4Si_2$: C 59.35, H 10.96; found: C 59.15, H 11.11.

(3*S*,4*S*)-3-(4-Methoxybenzyl)oxy-2,2-dimethyl-4-(2-trimethylsilylethoxy)-methoxy-5-hexen-1-ol (51)

$KN(SiMe_3)_2$ (3.14 g, 0.0157 mol) in THF (20 mL) was added to alcohol **49** (5.60 g, 0.0138 mol) in THF (30 mL) at –78°C. After stirring for 10 min at –78°C, the mixture was stirred at 0°C for 10 min and treated with 4-$MeOC_6H_4CH_2Cl$ (2.2 mL, 0.0162 mol). After 1 h, the mixture was allowed to warm up to room temperature and DMF (10 mL) added. After 30 min, saturated aqueous NH_4Cl (10 mL) was added and the mixture was diluted with Et_2O (400 mL), washed with brine, and dried ($MgSO_4$). Rotary evaporation gave silyl ether **50** as a colorless oil. TLC R_f = 0.45 (hexanes–Et_2O, 1:1). EI-MS *m*/*z*: 524 ($M^{\cdot+}$), 409, 393, 289, 257. EI-HRMS calcd. for $C_{28}H_{52}O_5Si_2$: 524.3353 ($M^{\cdot+}$); found: 524.3357 ($M^{\cdot+}$). From **56a**: DMSO (243 μL, 3.42 mmol) in CH_2Cl_2 (5 mL) was added dropwise to $(COCl)_2$ (230 μL, 2.63 mmol) in CH_2Cl_2 (5 mL) at –78°C. After 5 min, spiroketal **56a** (1.05 g, 1.88 mmol) in CH_2Cl_2 (12 mL) and, after 10 min, Et_3N (767 μL, 5.5 mmol) were both slowly added. The mixture was allowed to warm up to 0°C over 15 min and diluted with Et_2O (80 mL). The ethereal layer was washed with H_2O (2 × 30 mL) and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 3:2) gave ketone **57** (992 mg, 95%) as a colorless oil. TLC R_f = 0.6 (Et_2O). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.27 (d, 2H, *J* = 9.5 Hz), 6.86 (d, 2H, *J* = 8.7 Hz), 6.79 (d, 2H, *J* = 8.0 Hz), 6.74 (m, 2H), 6.00 (m, 1H), 5.24 (dm, 1H, *J* = 16.2 Hz), 5.11 (dm, 1H, *J* = 10.0 Hz), 4.63 (dd, 1H, *J* = 8.6, 5.3 Hz), 4.44 (d, 1H, *J* = 10.9 Hz), 4.37 (d, 1H, *J* = 10.9 Hz), 4.32 (dm, 1H, *J* = 10.6 Hz), 4.15 (d, 1H, *J* = 11.6 Hz), 4.02 (d, 1H, *J* = 11.3 Hz), 3.87 (s, 3H), 3.86 (s, 3H), 3.74 (s, 3H), 3.58 (d, 1H, *J* = 5.4 Hz), 3.50 (m, 2H), 2.57 (d, 1H, *J* = 14.2 Hz), 2.30 (m, 1H), 2.21 (d, 1H, *J* = 15.0 Hz), 1.85 (m, 1H), 1.24 (s, 3H), 1.08 (m, 1H), 1.07 (d, 3H, *J* = 7.2 Hz), 0.96 (s, 3H). Alcohol **56b** (515 mg, 0.926 mmol) was converted into **57** (510 mg, 100%) under identical Swern oxidation conditions. The crude ketone from both experiments **57** was reduced directly without any further purification.

(2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-2-[2-(3,4-Dimethoxybenzyloxy)ethyl]-8-ethenyl-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]decan-4-ol (56a)

Ketone **57** (1.25 g, 2.17 mmol) in THF (20 mL) was added dropwise to K-Selectride in THF (0.5 M, 8.7 mL, 4.34 mmol) in THF (10 mL) at –78°C. After 2 h, the mixture was allowed to warm up to –20°C over 20 min. Excess K-Selectride was quenched with MeOH (2 mL), and then NaOH (3 M, 5 mL) and H_2O_2 (30%, 5 mL) were added. The resulting aqueous mixture was stirred for 1.5 h at 0°C and diluted with Et_2O (100 mL). The ethereal layer was washed with H_2O (2 × 30 mL) and brine (50 mL) and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 3:2) gave spiroketal **56a** (1.12 g, 93%).

(2*S*)-3-(Benzyloxy)methoxy-2-methyl-1-propanol (60) (38)

$PhCH_2OCH_2Cl$ (13.8 g, 0.088 mmol) was added to alcohol **58** (8.0 g, 0.067 mmol) and *i*-Pr_2NEt (18.5 mL, 0.106 mmol) in CH_2Cl_2 (30 mL) at 0°C. The mixture was subsequently stirred at room temperature for 12 h when MeOH (15 mL) was added. The solution was diluted with Et_2O (200 mL), washed sequentially with 1 M HCl, H_2O, 10% aqueous $NaHCO_3$, and brine. The organic layer was dried ($MgSO_4$) and rotary evaporated to leave a colorless oil, which was dissolved in Et_2O (100 mL) and added to $LiAlH_4$ (3.8 g, 1.0 mmol) in Et_2O (150 mL) at 0°C. After stirring for 15 min at 0°C and 1 h at room temperature, excess $LiAlH_4$ was quenched by the careful addition of MeOH. Following further stirring for 30 min, H_2O (15.2 mL) and aqueous NaOH (15%, 4 mL) were added and, after 1 h, the insoluble solid was removed by filtration. Rotary evaporation of the filtrate and chromatography (hexanes–Et_2O, 1:3) gave alcohol **60** (14.8 g, 100%).

Methyl (4*S*)-5-(benzyloxy)methoxy-4-methyl-2-pentenoate (62)

DMSO (9.5 g, 0.122 mol) in CH_2Cl_2 (80 mL) was added dropwise to $(COCl)_2$ (8.1 mL, 92.9 mmol) in CH_2Cl_2 (80 mL) at –78°C. After 10 min, alcohol **60** (14.0 g, 66.7 mmol) in CH_2Cl_2 (100 mL) was added, stirring was continued for 15 min at –78°C and Et_3N (33.7 mL, 0.241 mol) was slowly added. After stirring for 10 min, the resulting mixture was allowed to warm up to –10°C for 15 min, diluted with CH_2Cl_2 (100 mL), and washed with H_2O (3 × 15 mL) and brine. The organic layer was dried (Na_2SO_4) and rotary evaporated to leave the crude aldehyde **61**, which was used without further purification. $Ph_3P{=}CHCO_2Me$ (29.0 g, 0.867 mmol) was added to the aldehyde in $ClCH_2CH_2Cl$ (200 mL) and the mixture was heated at 70°C for 16 h. After rotary evaporation, the residue was diluted with Et_2O (200 mL). Filtration, rotary evaporation, and chromatography (hexanes–EtOAc, 7:1) gave ester **62** (for the (*R*)-antipode of **62**, see ref. 39) (16.7 g, 95%) as a colorless oil. $[\alpha]_D^{25}$ = –16° (*c* = 1.6). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.26–7.25 (m, 5H), 6.95 (dd, 1H, *J* = 16.0, 7.0 Hz), 5.87 (dd, 1H, *J* = 16.0, 1.5 Hz), 4.73 (s, 2H), 4.57 (s, 2H), 3.71 (s, 3H), 3.51 (d, 2H, *J* = 6.5 Hz), 2.66–2.57 (m, 1H), 1.08 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 167.0, 151.3, 137.9, 128.5, 127.9, 127.8, 120.8, 94.8, 71.7, 69.5, 51.5, 36.8, 16.1.

(4*S*)-5-(Benzyloxy)methoxy-4-methyl-2-penten-1-ol (63)

Ester **62** (16.2 g, 61.4 mmol) in CH_2Cl_2 (100 mL) was added dropwise to DIBAl-H in PhMe (1.5 M, 90 mL, 135 mmol) in CH_2Cl_2 (100 mL) at –78°C and, after 1 h, excess DIBAl-H was quenched with MeOH (30 mL). Stirring was continued until H_2 evolution ceased, then H_2O (40 mL) in THF (40 mL) was carefully added to the clear solution.

© 2001 NRC Canada

This was allowed to warm up to 0°C over 15 min and the resulting suspension stirred vigorously for 1.5 h. Filtration, rotary evaporation, and chromatography (hexanes–EtOAc, 1:1) gave alcohol **63** (for the (*R*)-antipode of **63**, see ref. 40) (14.3 g, 99%) as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.36–7.26 (m, 5H), 5.77–5.63 (m, 2H), 4.76 (s, 2H), 4.60 (s, 2H), 4.13–4.10 (m, 2H), 3.51 (dd, 1H, *J* = 9.5, 6.5 Hz), 3.46 (dd, 1H, *J* = 9.5, 6.5 Hz), 2.54–2.46 (m, 1H), 1.28 (t, 1H, *J* = 6.0 Hz), 1.06 (d, 3H, *J* = 7.0 Hz). The product was used directly without further purification.

(2*S*,3*S*)-2-[1-(Benzyloxy)methoxy-(2*R*)-propyl]-3-(hydroxymethyl)oxirane (64)

L-(+)-Diethyl tartrate (1.9 g, 9.21 mmol) and alkene **63** (14.3 g, 60.6 mmol) in CH_2Cl_2 (50 mL) were added sequentially to a suspension of powdered molecular sieves (3 Å, 8 g) in CH_2Cl_2 (50 mL). The mixture was cooled to –20°C and Ti(O-*i*-Pr)$_4$ (2.4 mL, 8.13 mmol) was added with stirring. After 20 min at –20°C, *t*-BuOOH in 2,2,4-trimethylpentane (3 M, 24 mL, 72.0 mmol) was added slowly and the mixture stirred for 1.5 h at room temperature. The solution was filtered through Celite, washing with CH_2Cl_2, and the combined washings dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 1:2) gave epoxide **64** (13.7 g, 90%) as a colorless oil. TLC R_f = 0.40 (hexanes–EtOAc, 1:1). $[\alpha]_D^{25}$ = –26° (*c* = 4.35). EI-MS *m*/*z*: 221 ([M – CH_2OH]$^+$), 191, 174, 91. EI-HRMS calcd. for $C_{13}H_{17}O_3$: 221.1178 ([M – CH_2OH]$^+$); found: 221.1182 ([M – CH_2OH]$^+$). IR (film) (cm^{-1}): 3448, 1497, 1455. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.37–7.29 (m, 5H), 4.75 (s, 2H), 4.60 (s, 2H), 3.89 (ddd, 1H, *J* = 12.5, 4.5, 2.5 Hz), 3.64 (ddd, 1H, *J* = 12.5, 4.5, 2.5 Hz), 3.55–3.53 (m, 2H), 3.05 (dt, 1H, *J* = 4.5, 2.5 Hz), 2.90 (dd, 1H, *J* = 7.0, 2.5 Hz), 1.77 (sept, 1H, *J* = 7.0 Hz), 1.67–1.64 (br m, 1H), 1.04 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 137.9, 128.6, 127.9, 127.8, 94.9, 70.4, 69.5, 62.0, 58.5, 58.0, 35.9, 13.6. Anal. calcd. for $C_{14}H_{20}O_4$: C 66.64, H 7.99; found: C 66.90, H 8.03.

(4*R*)-4-(1-(Benzyloxy)methoxy)-(2*R*)-propyl)-2,2-dimethyl-1,3-dioxane (66)

Epoxide **64** (13.7 g, 0.0544 mmol) in THF (80 mL) was added dropwise to Red-Al in PhMe (3.4 M, 22.6 mL, 76.8 mmol) in THF (80 mL) at –20°C. The solution was allowed to warm to room temperature over 15 min and left at this temperature for 3 h, after which excess Red-Al was quenched with MeOH at 0°C. H_2O (24 mL) and aqueous NaOH (15%, 24 mL) were added, the mixture was stirred for 1 h at room temperature, and the resulting insoluble solid removed by filtration. The filtrate was evaporated under reduced pressure and the residue chromatographed (hexanes–EtOAc, 1:5) to give the diol **65** (15.0 g) as a colorless oil. TLC R_f = 0.38 (hexanes–EtOAc, 1:2). $[\alpha]_D^{25}$ = +3.3° (*c* = 6.85). EI-MS *m*/*z*: 255 ([M + H]$^+$), 223 ([M – CH_2OH]$^+$), 205, 148. EI-HRMS calcd. for $C_{13}H_{19}O_3$: 223.1334 ([M – CH_2OH]$^+$); found: 223.1340 ([M – CH_2OH]$^+$). IR (film) (cm^{-1}): 3390, 1497, 1454. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.32–7.23 (m, 5H), 4.71 (s, 2H), 4.56 (s, 2H), 3.98–3.92 (m, 1H), 3.83–3.77 (m, 2H), 3.61–3.54 (m, 2H), 2.92 (d, 1H, *J* = 4.0 Hz), 2.58 (br t, 1H, *J* = 4.5 Hz), 1.87–1.70 (m, 2H), 1.58–1.48 (m, 1H), 0.90 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 138.5, 129.0, 128.4, 128.3, 95.4, 73.8, 72.2, 70.2, 62.2, 39.0, 36.0, 11.7. The diol **65** was used directly in the next step. Diol **65** (15 g) was allowed to react with $(MeO)_2CMe_2$ (20 mL) and pyridinium 4-toluenesulfonate (500 mg, 1.98 mmol) in PhH (100 mL) at room temperature for 3 h. Et_3N (ca. 1.0 mL) was added, and rotary evaporation and chromatography (hexanes–Et_2O, 1:1) gave ether **66** (15.9 g, 100% from epoxide **64**) as a colorless oil. $[\alpha]_D^{25}$ = –11.7° (*c* = 13.8). EI-MS *m*/*z*: 294 (M$^{\cdot+}$), 279, 115, 91. EI-HRMS calcd. for $C_{17}H_{26}O_4$: 294.1831 (M$^{\cdot+}$); found: 294.1817 (M$^{\cdot+}$). IR (film) (cm^{-1}): 3031, 1497, 1455. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.34–7.25 (m, 5H), 4.73 (s, 2H), 4.58 (s, 2H), 3.93 (dt, 1H, *J* = 11.5, 3.0 Hz), 3.89 (ddd, 1H, *J* = 8.5, 6.0, 2.5 Hz), 3.82 (ddd, 1H, *J* = 11.5, 5.5, 1.5 Hz), 3.58 (dd, 1H, *J* = 9.5, 6.0 Hz), 3.44 (dd, 1H, *J* = 9.5, 6.0 Hz), 1.79–1.63 (m, 2H), 1.41 (s, 3H), 1.34 (s, 3H), 1.37–1.30 (m, 1H), 0.96 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 138.0, 128.5, 127.9, 127.7, 98.2, 94.9, 69.9, 69.5, 69.3, 60.1, 38.6, 30.0, 28.5, 19.3, 12.2. Anal. calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.24, H 9.00.

(2*R*,3*R*)-3,5-Isopropylidenedioxy-2-methyl-propane-1-ol (67)

Ether **66** (3.4 g, 11.5 mmol) in THF (10 mL) was added dropwise to Na (630 mg, 27.3 mmol) in liquid NH_3 (10 mL) at –78°C. After 1 h, the mixture was allowed to warm to room temperature, for the NH_3 to vent, and then rotary evaporated. The residue was extracted with CH_2Cl_2, filtered, rotary evaporated, and chromatographed (hexanes–Et_2O, 1:1) to give alcohol **67** (2.09 g, 100%) as a colorless oil. $[\alpha]_D^{25}$ = –11° (*c* = 5.05). EI-MS *m*/*z*: 159 ([M – Me]$^+$), 115. EI-HRMS calcd. for $C_8H_{15}O_3$: 159.1021 ([M – Me]$^+$); found: 159.1025 ([M – Me]$^+$). IR (film) (cm^{-1}): 3425, 1461, 1382, 1271. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.05 (ddd, 1H, *J* = 12.0, 4.0, 2.5 Hz), 3.96 (dt, 1H, *J* = 11.5, 2.5 Hz), 3.86 (ddd, 1H, *J* = 11.5, 5.5, 2.5 Hz), 3.68 (ddd, 1H, *J* = 11.0, 7.5, 4.5 Hz), 3.55 (ddd, 1H, *J* = 11.0, 6.5, 4.0 Hz), 2.63 (dd, 1H, *J* = 6.5, 4.5 Hz), 1.90–1.77 (m, 2H), 1.43 (s, 3H), 1.36 (s, 3H), 1.34–1.27 (m, 1H), 0.88 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 98.4, 71.9, 65.2, 60.0, 39.3, 29.9, 26.9, 19.1, 11.6. Anal. calcd. for $C_9H_{18}O_3$: C 62.04, H 10.41; found: C 61.71, H 10.64.

(2*S*)-(2,2-Dimethyl-1,3-dioxolan-(4*R*)-yl)propanal (68)

DMSO (1.8 mL, 25.4 mmol) in CH_2Cl_2 (15 mL) was added to $(COCl)_2$ (1.8 mL, 20.9 mmol) in CH_2Cl_2 (20 mL) at –78°C. After 5 min, alcohol **67** (2.8 g, 16.1 mmol) in CH_2Cl_2 (15 mL) was added and stirring was continued for 10 min at –78°C, then Et_3N (7.0 mL, 50.0 mmol) was added slowly. The solution was allowed to warm to –20°C over 15 min and poured into H_2O. The aqueous mixture was extracted with CH_2Cl_2 (2 × 100 mL) and the extracts washed with H_2O and brine. The organic layer was dried (Na_2SO_4), rotary evaporated, and chromatographed (hexanes–Et_2O, 3:2) to give aldehyde **68** (2.65 g, 95%) as a colorless oil. IR (film) (cm^{-1}): 2993, 1725, 1458, 1382. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.74 (d, 1H, *J* = 1.0 Hz), 4.24 (ddd, 1H, *J* = 12.0, 5.0, 2.5 Hz), 3.97 (dt, 1H, *J* = 12.0, 3.0 Hz), 3.84 (ddd, 1H, *J* = 12.0, 5.0, 1.5 Hz), 2.48–2.39 (m, 1H), 1.76–1.58 (m, 2H), 1.09 (d, 3H, *J* = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 204.1, 98.5, 68.8, 59.6, 50.7, 29.7, 28.0,

© 2001 NRC Canada

19.0, 8.3. The unstable aldehyde **68** was used directly without further purification.

(2*R*,3*R*,4*RS*,6*R*,8*S*,9*S*)-8-Ethenyl-2-(2-hydroxyethyl)-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]-decan-4-ol (69)

n-BuLi in hexanes (1.6 M, 9.4 mL, 15.0 mmol) was added dropwise to *i*-Pr_2NH (2.1 mL, 15.0 mmol) in THF (15 mL) at 0°C. The clear solution was stirred for 10 min at 0°C and the cooled to –78°C, at which point ketone **54** (6.4 g, 15.2 mmol) in THF (30 mL) was slowly added over 10 min. The mixture was stirred at –60 to –45°C for 20 min and recooled to –78°C. Aldehyde **68** (2.6 g, 14.9 mmol) in THF (15 mL) was added dropwise and the mixture stirred for 30 min at –78°C and then allowed to warm to –20°C. The solution was poured into a mixture of saturated aqueous NH_4Cl and ice. The mixture was extracted with Et_2O (3 × 100 mL) and the organic phase washed with H_2O and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 3:2) gave recovered ketone **54** (2.4 g, 38%) and the aldol adduct (5.4 g, 61%; 96% allowing for recovered **54**). $TsOH·H_2O$ (100 mg, 0.526 mmol) was added to this adduct (4.9 g, 8.25 mmol) in MeOH (100 mL) and the mixture stirred for 3.5 h at room temperature. Et_3N (3 mL) was added, at which point rotary evaporation and chromatography (hexanes–EtOAc, 1:2) gave spiroketal **69** (2.86 g, 85%) as a mixture of diastereomeric alcohols, which were directly oxidized to produce the corresponding ketone **70**.

(2*R*,3*R*,4*S*,6*R*,8*S*,9S)-8-Ethenyl-2-(2-hydroxyethyl)-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]-decan-4-ol (71)

DMSO (716 μL, 10.1 mmol) in CH_2Cl_2 (7.5 mL) was added to $(COCl)_2$ (732 μL, 8.39 mmol) in CH_2Cl_2 (10 mL) at –78°C. After stirring for 5 min, the diastereomeric alcohols **69** (1.31 g, 3.23 mmol) in CH_2Cl_2 (10 mL) were added and stirring was continued for 10 min at –78°C. Et_3N (2.8 mL, 20.1 mmol) was added slowly, the solution was allowed to warm up to –20°C over 15 min and then poured into H_2O. The aqueous mixture was extracted with CH_2Cl_2 (2 × 100 mL) and the extracts washed with H_2O and brine. The organic layer was dried (Na_2SO_4) and rotary evaporated to give the crude keto-aldehyde **70** (1.25 g). This compound in THF (25 mL) was added dropwise to K-Selectride in THF (0.5 M, 17 mL, 8.5 mmol) in THF (10 mL) at –78°C. The mixture was stirred for 2 h at –78°C and excess K-Selectride quenched with MeOH (10 mL). The solution was allowed to warm up to –10°C and aqueous NaOH (15%, 8 mL) and aqueous H_2O_2 (30%, 10 mL) were added sequentially at –5°C. The resulting alkaline mixture was vigorously stirred for 2 h at 0°C when it was extracted with CH_2Cl_2 (10 mL) and the extract washed with H_2O and brine and dried (Na_2SO_4.). Rotary evaporation and chromatography (hexanes–EtOAc, 1:2) gave diol **71** (0.997 g, 76% from **69**) as colorless crystals: mp 96.5–98°C (from EtOAc–hexanes). TLC R_f = 0.41 (hexanes–EtOAc, 3:1). $[\alpha]_D^{20}$ = +10° (*c* = 1.1). EI-MS *m*/*z*: 406 ($M^{\cdot+}$), 388, 270, 234, 229, 211, 163. EI-HRMS calcd. for $C_{23}H_{34}O_6$: 406.2350 ($M^{\cdot+}$); found: 406.2346 ($M^{\cdot+}$). Anal. calcd. for $C_{23}H_{34}O_6$: C 67.95, H 8.43; found: C 67.60, H 8.03. Diffraction data from a single crystal of **71** was obtained on a Bruker P4 four-circle diffractometer operating in the θ–2θ scan mode at –100°C. The unit cell constants were obtained by refinement against the setting angles for 25 reflections widely distributed in reciprocal space. The diffraction pattern exhibited symmetry consistent with the space group $P2_12_12_1$ in the orthorhombic crystal system. The structure was solved by direct methods and refined by full-matrix least-squares.[2] All non-hydrogen atoms were refined with anisotropic thermal displacement parameters. Hydrogen atoms were placed in idealized positions, with the exception of H26 and H9, which were located in the difference Fourier map and were refined independently with isotropic thermal displacement parameters.

(2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-8-Ethenyl-9-(4-methoxybenzyl)oxy-2-(triethylsilyl)oxyethyl-3,10,10-trimethyl-1,7-dioxaspiro-[4.5]decan-4-ol (72)

Et_3SiCl (509 μL, 3.03 mmol) was slowly added over 1.5 h to diol **71** (1.1 g, 2.71 mmol), Et_3N (0.7 mL), and imidazole (454 mg, 6.67 mmol) in dry CH_2Cl_2 (30 mL) at –40°C (Ar). After the mixture was stirred for 2 h at –20°C, excess reagent was quenched with MeOH (1.0 mL) and the resultant mixture diluted with CH_2Cl_2 (50 mL). The solution was washed with H_2O and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 5:1) gave **72** (1.1 g, 78%) as a colorless oil. TLC R_f = 0.39 (hexanes–Et_2O, 1:1). $[\alpha]_D^{20}$ = +49.0° (*c* = 2.35). EI-MS *m*/*z*: 520 ($M^{\cdot+}$), 484, 429, 401, 317, 289, 241. (2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-4-(*tert*-Butyldimethylsilyl)oxy-2-(triethylsilyl)oxyethyl-((1*S*,4*S*,5*S*,6*S*)-5-(*tert*-butyldimethylsilyl)oxy-1-hydroxy-10-iodo-3-oxo-4,6,8,9-tetramethyldeca-7,9-dien-1-yl)-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]decane (77)

Ketone **5** (78 mg, 0.173 mmol) in dry THF (1 mL) was slowly added to $LiN(SiMe_3)_2$ in THF (0.26 M, 665 μL, 0.173 mmol), freshly prepared from $HN(SiMe_3)_2$ and *n*-BuLi at –78°C (Ar). After 7 min, aldehyde **74** (99 mg, 0.156 mmol) in dry THF (1 mL) was added at –78°C. After stirring for 30 min at –78°C, the mixture was allowed to warm to –50°C over 15 min, then solid NH_4Cl (100 mg) was added and the mixture was diluted with Et_2O (50 mL). The mixture was washed with H_2O and brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 9:1) gave **77** (73.5 mg, 43%) along with recovered starting ketone **5** (43 mg, 54%) and aldehyde **74** (35 mg, 35%). The aldol adduct **77** was obtained as a colorless oil. TLC R_f = 0.23 (hexanes–Et_2O, 6:1). $[\alpha]_D^{20}$ = +22° (*c* = 0.60). IR (film) (cm^{-1}): 3571, 1706, 1614, 1514, 1463, 1382, 1302. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.26 (d, 2H, *J* = 8.5 Hz), 6.84 (d, 2H, *J* = 8.5 Hz), 6.28 (s, 1H), 5.88 (d, 1H, *J* = 9.5 Hz), 4.57 (d, 1H, *J* = 11.5 Hz), 4.52 (d, 1H, *J* = 11.5 Hz), 4.31–4.25 (m, 1H), 4.01 (dd, 1H, *J* = 7.5, 2.0 Hz), 3.99 (dt, 1H, *J* = 9.0, 2.5 Hz), 3.88–3.73 (m, 3H), 3.77 (s, 3H), 3.60 (d, 1H, *J* = 5.5 Hz), 3.36 (dt, 1H, *J* = 10.0, 5.5 Hz), 3.15 (d, 1H, *J* = 2.5 Hz), 3.11 (dd, 1H, *J* = 18.5, 1.5 Hz), 2.64–2.54 (m, 2H), 2.41 (dd, 1H, *J* = 18.5, 10.5 Hz), 2.03 (s, 3H), 1.78 (s, 3H), 1.77–1.67 (m, 1H), 1.41–1.21 (m, 4H), 0.97 (d, 3H, *J* = 7.0 Hz), 0.97 (s, 3H), 0.91–0.77 (m, 18H), 0.88 (s, 9H), 0.84 (s, 9H), 0.50 (q, 6H, *J* = 8.0 Hz), 0.07 (s, 3H), 0.00 (s, 3H),–0.01 (s, 3H), –0.03 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 214.9, 159.1, 148.2, 133.7, 131.5, 130.5, 129.5, 113.8, 107.0, 86.8, 82.2, 78.8, 76.1, 74.8, 71.0, 67.0, 64.2, 61.7, 55.4, 52.7, 51.1, 47.7, 38.8, 36.6, 36.0, 30.4, 26.4, 26.0, 23.8, 22.8, 18.8, 18.6, 18.1, 17.5, 14.6, 13.0, 10.7, 7.0, 4.5, -3.6, –4.1, –4.5, –5.0. DDQ (3.4 mg, 16.6 μmol) was added to spiroketal **77** (15.0 mg, 13.8 μmol) and molecular sieves (3 Å, 10 mg) in CH_2Cl_2 (1 mL) at –20°C. The mixture was allowed to warm to 0°C and stirred for 10 min when it was diluted with Et_2O and quenched with saturated aqueous $NaHCO_3$. The organic phase was washed with H_2O (1 mL) and brine (1 mL) and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 6:1) gave acetal **78** (7.0 mg, 49%) as a colorless oil. TLC R_f = 0.44 (2 developments, hexanes–Et_2O, 7:1). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.40 (d, 2H, *J* = 8.5 Hz), 6.83 (d, 2H, *J* = 8.5 Hz), 6.23 (s, 1H), 5.77 (d, 1H, *J* = 9.0 Hz), 5.52 (s, 1H), 4.21–4.14 (m, 2H), 4.04 (dd, 1H, *J* = 9.0, 6.0 Hz) 3.93 (dd, 1H, *J* = 6.5, 2.5 Hz), 3.77 (s, 3H), 3.74 (d, 1H, *J* = 6.0 Hz), 3.77–3.73 (m, 1H), 3.60–3.52 (m, 1H), 3.49–3.41 (m, 1H), 2.83 (dd, 1H, *J* = 15.5, 3.0 Hz), 2.68 (dq, 1H, *J* = 7.0, 6.5 Hz), 2.60 (dd, 1H, *J* = 15.5, 8.0 Hz), 2.47 (dq, 1H, *J* = 7.0, 2.5 Hz), 2.00 (s, 3H), 1.70 (s, 3H), 1.66–1.37 (m, 5H), 1.09 (s, 3H), 0.90–0.79 (m, 39H), 0.49 (q, 6H, *J* = 8.0 Hz), 0.03 (s, 3H), 0.01 (s, 3H), –0.02 (s, 3H), –0.05 (s, 3H).

(2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-4-(*tert*-Butyldimethylsilyl)oxy-2-(*tert*-butyldimethylsilyl)oxyethyl-((1*S*,3*R*,4*S*,5*S*,6*S*)-5-(*tert*-butyldimethylsilyl)oxy-1,3-dihydroxy-10-iodo-4,6,8,9-tetramethyldeca-7,9-dien-1-yl)-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]decane (79) and (2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-4-(*tert*-butyldimethylsilyl)oxy-2-(*tert*-butyldimethylsilyl)oxyethyl-((1*S*,3*S*,4*S*,5*S*,6*S*)-5-(*tert*-butyldimethylsilyl)oxy-1,3-dihydroxy-10-iodo-4,6,8,9-tetramethyldeca-7,9-dien-1-yl)-9-(4-methoxybenzyl)oxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]decane (80)

$LiAlH_4$ in THF (1 M, 76 μL, 79 μmol) was added dropwise to ketone **76** (20.9 mg, 19.0 μmol) in THF (1 mL) at –78°C. After 1 h, the mixture was quenched with H_2O (100 μL) and allowed to warm to room temperature. The solution was diluted with CH_2Cl_2 and Celite and anhydrous Na_2SO_4 were added with vigorous stirring. After 30 min, the mixture was filtered through Celite with CH_2Cl_2. Rotary evaporation and chromatography (hexanes–Et_2O, 5:1) gave diol **80** (3.1 mg, 15%) and diol **79** (15.0 mg, 73%) both as pale yellow oils. Data for diol **80**: TLC R_f = 0.46 (hexanes–Et_2O, 5:1). $[\alpha]_D^{24}$ = +29.7° (*c* = 0.28). FAB-HRMS (NaI added) calcd. for $C_{53}H_{97}IO_9Si_3Na$: 1111.5383 ($[M + Na]^+$); found: 1111.5403 ($[M + Na]^+$). (10*S*,11*S*,12*R*,13*R*)-11,13-Di(*tert*-butyldimethylsilyl)oxy-((2*R*,3*R*,4*S*,6*R*,8*S*,9*S*)-4-(*tert*-butyldimethylsilyl)oxy-2-(*tert*-butyldimethylsilyl)oxyethyl-9-hydroxy-3,10,10-trimethyl-1,7-dioxaspiro[4.5]decane-8-yl)-15-methoxy-3,7,8,10,12-pentamethyl-pentadeca-2,4,6,8-tetraenenitrile (88) (8)

Stannyl diene **3** (41.2 mg, 107 μmol) in *N*-methylpyrrolidinone (2.0 mL) was added dropwise to iodide **87** (14.8 mg, 13.5 μmol) and $Pd(MeCN)_2Cl_2$ (2.0 mg, 7.71 μmol) in *N*-methylpyrrolidinone (2.0 mL) at –5°C. After 30 min, further $Pd(MeCN)_2Cl_2$ (2.0 mg, 7.71 μmol) was added and the solution was allowed to warm up to 5°C over 20 min. After 1 h, the mixture was poured into ice cooled saturated aqueous $NaHCO_3$, extracted with Et_2O (3 × 5 mL), and the combined extracts washed with H_2O (1 mL) and brine (1 mL) and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–Et_2O, 7:1) gave **88** (8) (13.0 mg, 91%) as a white foam. $[\alpha]_D^{22}$ = +73.9° (*c* = 0.18). FAB-HRMS (NaI added) calcd. for $C_{58}H_{111}NO_8Si_4Na$: 1084.7285 ([M + Na]$^+$); found: 1084.7249 ([M + Na]$^+$). IR (film) (cm^{-1}): 3492, 2210, 1592, 1471, 1380, 1361, 1254, 1102, 1073, 1031, 1006, 961, 877, 836, 775. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.01 (dd, 1H, *J* = 15.0, 11.1 Hz), 6.83 (d, 1H, *J* = 15.0 Hz), 6.35 (d, 1H, *J* = 11.1 Hz), 6.07 (d, 1H, *J* = 9.1 Hz), 5.06 (s, 1H), 4.58 (m, 1H), 4.24 (m, 1H), 3.96 (dd, 1H, *J* = 8.8, 4.0 Hz), 3.82 (m, 1H), 3.62 (s, 3H), 3.61 (m, 2H), 3.53–3.46 (m, 3H), 3.39 (d, 1H, *J* = 12.0 Hz), 2.75 (m, 1H), 2.07 (s, 3H), 2.00 (s, 3H), 1.87 (s, 3H), 1.83 (m, 1H), 1.75 (dd, 1H, *J* = 14.3, 3.9 Hz), 1.69–1.58 (m, 4H), 1.49 (m, 1H), 1.29 (m, 1H), 1.09 (s, 3H), 1.02 (d, 3H, *J* = 7.0 Hz), 0.94 (s, 9H), 0.88 (s, 18H), 0.87 (s, 12H), 0.83 (d, 3H, *J* = 7.1 Hz), 0.77 (d, 3H, *J* = 7.1 Hz), 0.17 (s, 3H), 0.09 (s, 3H), 0.08 (s, 3H), 0.05 (2s, 6H), 0.03 (s, 6H), 0.02 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 156.7, 144.3, 134.4, 133.9, 133.4, 128.5, 124.0, 117.5, 108.5, 94.6, 87.9, 80.2, 78.9, 77.6, 70.6, 68.4, 65.3, 60.1, 60.0, 49.3, 45.1, 37.3, 35.5, 34.1, 30.3, 26.4, 26.00, 25.96, 25.9, 22.1, 19.4, 18.6, 16.6, 14.5, 14.0, 10.3, 10.1, –3.5, –3.76, –3.83, –4.2, –4.7, –5.0, –5.4. The ^{1}H and ^{13}C NMR spectra of **88** were in agreement with spectra of authentic material kindly provided by Professor David A. Evans. The corresponding data reported by Evans et al. (8) were as follows: $[\alpha]_{577}^{25}$ = +76.6° (CH_2Cl_2, *c* = 0.59). FAB-HRMS (NaI added) calcd. for $C_{58}H_{111}NO_8Si_4Na$: 1084.7284 ([M + Na]$^+$); found: 1084.7275 ([M + Na]$^+$). Anal. calcd. for $C_{29}H_{41}NO_7$: C 67.55, H 8.01, N 2.72; found: C 67.77, H 8.32, N 2.71.

(3*R*,4*R*,5*R*)-4-(*N*-*tert*-Butyloxycarbonyl)-*N*-methylamino-5-methoxy-2,3-di(4-methoxybenzyl)oxyhexanoic acid (95)

OsO_4 (57 mg, 0.22 mmol) and *N*-methylmorpholine-*N*-oxide (1.72 g, 14.7 mmol) followed by H_2O (6 mL) were added to alkene **93** (6.31 g, 12.2 mmol) in *t*-BuOH (24 mL) and Me_2CO (12 mL). After stirring for 16 h, the solution was diluted with Et_2O (75 mL) and washed successively with 10% aqueous $Na_2S_2O_3$ (20 mL) and brine (20 mL). The organic phase was dried (Na_2SO_4) and rotary evaporated. The resulting oil was dissolved in MeOH (102 mL) and treated with $NaIO_4$ (3.12 g, 14.6 mmol) in H_2O (25 mL). After 20 min, solid material was removed via filtration through Celite and the filtrate rotary evaporated. The residue was partitioned between brine (20 mL) and Et_2O (60 mL) and the organic phase washed with 10% aqueous $Na_2S_2O_3$ (20 mL) and brine (20 mL) and then dried (Na_2SO_4). Rotary evaporation gave an oil, presumably containing the crude aldehyde **94**, which was dissolved in CH_3CN (25 mL) and mixed with $NaH_2PO_4 \cdot H_2O$ (0.69 g, 5.0 mmol) in 27% aqueous H_2O_2 (6.1 mL, 50 mmol). $NaClO_2$ (1.09 g, 12.0 mmol) was added in small portions over 1 h to this vigorously stirred mixture and stirring was maintained for 12 h. The mixture was diluted with PhMe (50 mL) and washed successively with brine (2 × 50 mL) and 20% aqueous $Na_2S_2O_3$ (50 mL). The product was extracted with aqueous KOH (0.21 M, 100 mL) and the aqueous layer back extracted with hexanes. The aqueous fraction was acidified with aqueous H_3PO_4 (0.49 M, 10 mL) and extracted with CH_2Cl_2 (2 × 50 mL). The extracts were dried (Na_2SO_4) and rotary evaporated to give acid **95** (4.26 g, 65%) as a foam. R_f = 0.40 (MeOH–$CHCl_3$, 1:9). $[\alpha]_D^{25}$ = +63.6° (*c* = 0.98). IR (film) (cm^{-1}): 3400, 1749, 1691, 1613, 1513, 1250, 1172. ^1H NMR (250 MHz, DMSO-d_6, 350 K) δ: 7.28 (m, 2H), 7.21 (m, 2H), 6.89 (m, 2H), 6.86 (m, 2H), 4.67 (d, 1H, *J* = 5.6 Hz), 4.62 (d, 1H, *J* = 5.0 Hz), 4.38 (d, 1H, *J* = 5.3 Hz), 4.34 (d, 1H, *J* = 5.8 Hz), 4.39 (br m, 1H), 4.06 (br m, 1H), 3.98 (m, 1H), 3.75 (s, 3H), 3.74 (s, 3H), 3.55 (m, 2H), 3.19 (s, 3H), 2.70 (s, 3H), 1.36 (s, 9H). ^{13}C NMR (62.5 MHz, DMSO-d_6, 350 K) δ: 171.1, 158.6, 154.6, 130.0, 129.8, 129.0, 128.7, 113.4, 79.6, 78.5, 78.2, 71.7, 71.0, 69.5, 57.5, 56.0, 54.8, 31.6, 27.7. (2*R*)-Benzyl-2-methyl-4-pentenoate (97)

n-BuLi in hexanes (1.6 M, 125 mL, 200 mmol) was added to $PhCH_2OH$ (27.6 mL, 266 mmol) in THF (150 mL) at –23°C. After 1 h, the 1,3-oxazolidinone **96** (37) (30.0 g, 133 mmol) in THF (125 mL) was added and the solution was kept at –20°C for 2.5 h. Half-saturated NH_4Cl (250 mL) was added, the mixture rotary evaporated and the aqueous residue extracted with CH_2Cl_2 (3 × 350 mL). The combined extracts were washed with pH 7 buffer (300 mL) and brine (200 mL), dried, rotary evaporated, and chromatographed (hexanes–EtOAc, 9:1) to give ester **96** (26.5 g, 97%) as a colorless oil. R_f = 0.52 (hexanes–EtOAc, 9:1).$[\alpha]_D^{25}$ = –2.7° (*c* = 2.5). EI-MS *m*/*z*: 204 ($M^{\cdot+}$), 130, 91, 69, 41. EI-HRMS calcd for $C_{13}H_{16}O_2$: 204.1150 ($M^{\cdot+}$); found: 204.1156 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2977, 1736, 1642, 1456, 1382, 1275, 1173, 917. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.34 (m, 5H), 5.72 (m, 1H), 5.11 (s, 2H), 5.06 (m, 2H), 2.58 (m, 1H), 2.43 (m, 1H), 2.19 (m, 1H), 1.17 (d, 3H, *J* = 6.8 Hz). ^{13}C NMR (101 MHz, $CDCl_3$) δ: 175.8, 136.1, 135.3, 128.5, 128.1, 116.9, 66.1, 39.2, 37.7, 16.5.

(2*R*)-2-Methyl-4-pentenamide (98)

$AlMe_3$ in PhMe (2 M, 55 mL, 110 mmol) was added slowly to a suspension of NH_4Cl (5.9 g, 110 mmol) in PhMe (200 mL) at 0°C. After 1 h at 0°C and 1.5 h at room temperature, gas evolution had ceased and the solution was transferred to ester **97** (7.5 g, 36.7 mmol) in PhMe (50 mL). The mixture was heated at 60°C for 36 h and allowed to cool to room temperature. HCl (5%) was added as a quench and the resulting precipitate removed by filtration, washing with EtOAc. The combined organic extracts were dried (Na_2SO_4), rotary evaporated, and chromatographed (hexanes–EtOAc, 1:1) to give amide **98** (3.40 g, 81%) as a colorless solid. R_f = 0.39 (EtOAc); mp 79 to 80°C. $[\alpha]_D^{25}$ = –22.9° (*c* = 1.3). EI-MS *m*/*z*: 113 ($M^{\cdot+}$). EI-HRMS calcd. for $C_6H_{11}NO$:

113.0840 ($M^{\cdot+}$); found: 113.0844 ($M^{\cdot+}$). IR ($CHCl_3$) 3354, 3186, 2974, 1659. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.44 (br s, 1H), 5.91 (br s, 1H), 5.87 (m, 1H), 5.77 (m, 2H), 2.38 (m, 2H), 2.16 (m, 1H), 1.16 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 178.9, 135.6, 116.8, 40.3, 38.1, 17.1. Anal. calcd. for $C_6H_{11}NO$: C 63.69, H 9.80; N. 12.37; found: C 63.49, H 9.73; N. 12.39.

(2*R*)-2-Methyl-4-pentenenitrile (99)

Et_3N (12.3 mL, 88.4 mmol) and Cl_3CCOCl (9.9 mL, 88.4 mmol) in CH_2Cl_2 (20 mL) were added to amide **98** (5.0 g, 44.2 mmol) in CH_2Cl_2 (140 mL) at 0°C. The mixture was stirred at 0°C for 3 h, diluted with pH 7 buffer (75 mL), and extracted with CH_2Cl_2 (3 × 100 mL). The combined extracts were dried ($MgSO_4$) and rotary evaporated. The residue was distilled under reduced pressure to give nitrile **99** (3.3 g, 78%) as a colorless oil; bp 68°C (151 mm Hg). $[\alpha]_D^{25}$ = –17.4° (c = 1.1). EI-MS m/z: 95 ($M^{\cdot+}$). EI-HRMS calcd. for C_6H_9N: 95.0891 ($M^{\cdot+}$); found: 95.0753 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2985, 2241, 1644. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.80 (m, 1H), 5.21 (m, 2H), 2.66 (m, 1H), 2.33 (m, 2H), 1.31 (d, 3H, J = 6.9 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 132.8, 122.2, 118.5, 37.6, 25.0, 17.1.

(2*R*)-Methyl 2-methyl-4-pentenimidate hydrochloride (100)

Anhydrous HCl was bubbled through nitrile **99** (2.64 g, 29.9 mmol) in MeOH (1.3 mL, 32.0 mmol) at –10°C until the solution was saturated. On standing at –5°C for 24 h, the mixture solidified and the solid was dried in vacuo, triturated with Et_2O, and the solid isolated by filtration to give hydrochloride **100** (4.66 g, 96%) as a colorless powder; mp 106 to 107°C. $[\alpha]_D^{25}$ = +35.8° (c = 1.0). EI-MS m/z: 126 ([M – H_2Cl]$^+$). EI-HRMS calcd. for $C_7H_{12}NO$: 126.0918 ([M – H_2Cl]$^+$); found: 126.0913 ([M – H_2Cl]$^+$). IR ($CHCl_3$) (cm^{-1}): 2886, 1654. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 5.76 (m, 1H), 5.12 (m, 2H), 4.29 (s, 3H), 3.27 (m, 1H), 2.48–2.32 (m, 2H), 1.30 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 182.5, 133.3, 118.5, 60.6, 38.2, 37.7, 16.7.

(5*R*)-Methyl 3-aza-4-methoxy-5-methyl-3,7-octadienoate (101)

Glycine methyl ester hydrochloride (3.86 g, 30.7 mmol) was added to hydrochloride **100** (4.79 g, 29.3 mmol) and glass chips in CH_2Cl_2 cooled to –10°C. This was followed by dropwise addition of Et_3N (4.16 mL, 29.9 mmol) over 2 h (syringe pump). After stirring for 1 h, the mixture was allowed to warm to room temperature and stirred for an additional 43 h. The solution was cooled to 0°C and quenched with cold pH 7 buffer (1.5 M, 100 mL), extracted with Et_2O (2 × 50 mL), and the combined ethereal extracts dried (Na_2SO_4). Rotary evaporation and distillation (Kugelrohr) gave imidate **101** (4.03 g, 69%) as a colorless liquid; bp 70°C (0.35 mm Hg). $[\alpha]_D^{25}$ = +22.6° (c = 1.7). EI-MS m/z: 199 ($M^{\cdot+}$). EI-HRMS calcd. for $C_{10}H_{17}NO_3$: 199.1208 ($M^{\cdot+}$); found: 199.1208 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2947, 1752, 1674. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.66 (m, 1H), 5.00 (m, 2H), 4.09 (s, 2H), 3.72 (s, 3H), 3.66 (s, 3H), 2.66 (m, 1H), 2.30 (m, 1H), 2.12 (m, 1H), 1.10 (d, 3H, J = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 171.1, 169.1, 135.7, 116.7, 52.6, 51.9, 49.9, 38.1, 33.2, 17.1. Anal. calcd. for $C_{10}H_{17}NO_3$: C 60.28, H 8.59, N 7.02; found: C 60.42, H 8.75, N 6.83.

Methyl 2-(4-penten-(2*R*)-yl)-4-oxazolecarboxylate (102)

Imidate **101** (1.64 g, 8.24 mmol) and HCO_2Me (0.6 mL, 9.9 mmol) in THF (12 mL) were added dropwise over 0.5 h to *t*-BuOK in THF (1 M, 8.2 mL, 8.2 mmol) at –10°C. The mixture was stirred for 3 h at –10°C and for 14 h at room temperature and then rotary evaporated. The residue was suspended in THF (40 mL), cooled to –78°C whereupon $BF_3{\cdot}OEt_2$ (2.2 mL, 18.0 mmol) was added over 5 min. The mixture was allowed to warm to room temperature over 1 h and stirred for a further 45 h. The resulting orange solution was poured into 10% aqueous $NaHCO_3$ (200 mL), extracted with Et_2O (2 × 100 mL), and the combined organic phases were washed with brine and dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 4:1) gave oxazole **102** (1.23 g, 77%) as a colorless oil. R_f = 0.63 (hexanes–EtOAc, 3:1). $[\alpha]_D^{25}$ = –4.5° (c = 1.0). EI-MS m/z: 195 ($M^{\cdot+}$). EI-HRMS calcd. for $C_{10}H_{13}NO$: 195.0895 ($M^{\cdot+}$); found: 195.0901 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2979, 1748, 1584. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.21 (s, 1H), 5.77 (m, 1H), 5.03 (m, 2H), 3.91 (s, 3H), 3.13 (m, 1H), 2.58 (m, 1H), 2.41 (m, 1H), 1.37 (d, 3H, J = 7.0 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 168.3, 161.3, 143.3, 134.5, 132.6, 116.9, 51.5, 38.6, 33.3, 17.2. Anal. calcd. for $C_{10}H_{13}NO$: C 61.52, H 6.71, N 7.17; found: C 61.15, H 6.69, N 7.08.

Methyl 2-(4-oxo-(2*R*)-butyl)-4-oxazolecarboxylate (103)

$NaIO_4$ (5.90 g, 27.6 mmol) in H_2O (50 mL) was added dropwise to oxazole **102** (2.57 g, 13.14 mmol) and OsO_4 in H_2O (2.5%, 16 drops) in Me_2CO (25 mL) and H_2O (25 mL). The mixture was stirred for 5 h, poured into H_2O (200 mL), and extracted with $CHCl_3$ (5 × 50 mL). After drying (Na_2SO_4) of the extracts, rotary evaporation, and chromatography (hexanes–EtOAc, 2:1 to 1:1) gave aldehyde **103** (2.05 g, 79%) as a colorless liquid. R_f = 0.34 (hexanes–EtOAc, 1:1). EI-MS m/z: 197 ($M^{\cdot+}$). EI-HRMS calcd. for $C_9H_{11}NO_4$: 197.0688 ($M^{\cdot+}$); found: 197.0681 ($M^{\cdot+}$). IR (film) (cm^{-1}): 3161, 2955, 1732, 1584. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.76 (s, 1H), 8.12 (s, 1H), 3.86 (s, 3H), 3.55 (m, 1H), 3.14 (dd, 1H, J = 18.2, 7.0 Hz), 2.76 (dd, 1H, J = 18.2, 6.7 Hz), 1.36 (d, 3H, J = 7.1 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 199.1, 167.5, 161.3, 143.6, 132.9, 51.7, 47.6, 27.7, 18.2.

Methyl 2-(4-hydroxy-(2*R*)-butyl)-4-oxazolecarboxylate (104)

$NaBH_4$ (0.39 g, 10.3 mmol) was added in small portions over 5 min to aldehyde **103** (2.03 g, 10.28 mmol) in MeOH (100 mL) at –12°C. After 1 h, chilled (5°C) aqueous $KHSO_4$ (1 M, 50 mL) was added, the mixture was extracted with $CHCl_3$ (5 × 50 mL), and the extracts dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 1:1, then EtOAc) gave alcohol **104** (1.90 g, 93%) as a colorless oil. R_f = 0.42 (EtOAc). $[\alpha]_D^{25}$ = –25.0° (c = 1.0). CI-MS m/z: 200 ([M + H]$^+$). CI-HRMS calcd. for $C_9H_{13}NO_4$: 199.0844 ($M^{\cdot+}$); found: 199.0829 ($M^{\cdot+}$). IR (film) (cm^{-1}): 3413, 2953, 1736, 1585. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.03 (s, 1H), 3.72 (s, 3H), 3.49 (m, 3H), 3.08 (m, 1H), 1.89 (m, 1H), 1.72 (m, 1H), 1.20 (d, 3H, J = 6.9 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 168.9, 161.4, 143.4, 132.3, 59.2, 51.6, 37.0, 30.1, 17.9. (*R*)-α-methoxy-α-(trifluoromethyl)phenylacetic acid

© 2001 NRC Canada

(26 mg, 0.11 mmol) in CH_2Cl_2 (0.25 mL), 1,3-dicyclohexyl carbodiimide (22 mg, 0.11 mmol), and DMAP (2 mg) were added sequentially with stirring to alcohol **104** (20 mg, 0.10 mmol). After 2 h, the mixture was diluted with Et_2O (10 mL) and filtered. The organic solution was evaporated and the residue chromatographed (hexanes–EtOAc, 1:1) to furnish ester **108** (38 mg, 91%) as a colorless oil. R_f = 0.50 (hexanes–EtOAc, 1:1). EI-MS *m*/*z*: 415 ($M^{\cdot+}$), 189, 150, 105. EI-HRMS calcd for $C_{19}H_{20}F_3NO_6$: 415.1217 ($M^{\cdot+}$); found: 415.1222 ($M^{\cdot+}$). IR (film) (cm^{-1}): 1756, 1274, 1166, 1114. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.09 (s, 1H), 7.46–7.34 (m, 5H), 4.35 (m, 2H), 3.90 (s, 3H), 3.52 (s, 3H), 3.08 (m, 1H), 2.26 (m, 1H), 2.02 (m, 1H), 1.33 (d, 3H, *J* = 7.0 Hz). The mixture of diastereoisomeric Mosher esters **109** prepared in the same way from the corresponding racemic alcohol (±)-**104** showed: ^1H NMR (400 MHz, $CDCl_3$) δ: 8.11 (s, 1H), 7.48–7.36 (m, 5H), 4.35 (m, 2H), 3.91 (s, 3H), 3.53 (s, 3H), 3.09 (m, 1H), 2.26 (m, 1H), 2.02 (m, 1H), 1.36 (d, 1.5H, *J* = 7.0 Hz), 1.35 (d, 1.5H, *J* = 7.0 Hz).

Methyl 2-(4-(methanesulfonyl)oxy-(2*R*)-butyl)-4-oxazolecarboxylate (105)

Et_3N (2.3 mL, 16.0 mmol) and $MeSO_2Cl$ (0.9 mL, 10 mmol) were added to alcohol **104** (1.61 g, 8.09 mmol) in Et_2O (40 mL) at –10°C. The mixture was stirred at –10°C for 45 min, diluted with H_2O (25 mL), and extracted with $CHCl_3$ (3 × 25 mL). The combined extracts were dried (Na_2SO_4), rotary evaporated, and chromatographed (EtOAc–CH_2Cl_2, 1:9) to give mesylate **105** (1.89 g, 84%) as a colorless solid; mp 61–63°C. R_f = 0.69 (EtOAc). $[\alpha]_D^{25}$ = –34.0° (*c* = 1.0). EI-MS *m*/*z*: 277 ($M^{\cdot+}$). EI-HRMS calcd. for $C_{10}H_{15}NO_4S$: 277.0620 ($M^{\cdot+}$); found: 277.0619 ($M^{\cdot+}$). Methyl 2-(4-amino-(2*R*)-butyl)-4-oxazolecarboxylate (107)

A suspension of 10% Pd(C) (8 mg) and azide **106** (96 mg, 0.43 mmol) in MeOH (1.5 mL) was purged with Ar and then maintained under a H_2 atmosphere for 2 h. The catalyst was removed by filtration and the filtrate rotary evaporated to leave amine **107** (83 mg, 98%) as a colorless oil. $[\alpha]_D^{25}$ = –29.6° (*c* = 1.1). EI-MS *m*/*z*: 198 ($M^{\cdot+}$). EI-HRMS calcd. for $C_9H_{14}N_2O_3$: 198.1004 ($M^{\cdot+}$); found: 198.0997 ($M^{\cdot+}$). IR (film) (cm^{-1}): 2927, 2877, 1742, 1671, 1622. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.06 (s, 1H), 3.78 (s, 3H), 3.05 (m, 1H), 2.57 (t, 2H, *J* = 7.1 Hz), 1.85 (m, 1H), 1.66 (m, 1H), 1.24 (d, 3H, *J* = 7.9 Hz), 1.19 (br s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 168.9, 161.2, 143.4, 132.7, 51.8, 39.5, 38.5, 31.2, 18.2.

(2*R*,3*R*,4*R*)-4-(*N*-(*tert*-Butyloxy)carbonyl-*N*-methyl)amino-2,3-di(4-methoxybenzyl)oxy-5-methoxy-*N*-(3*R*-((4-methoxycarbonyl)-2-oxazolyl)-1-butyl)pentamide (110)

1-Hydroxybenzotriazole (1.21 g, 8.96 mmol), powdered molecular sieves (4 Å, 3.0 g), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (0.855 g, 4.46 mmol) were added sequentially to acid **95** (2.49 g, 4.67 mmol) in DMF (10 mL) at 0°C. After 1 h, amine **107** (0.88 g, 4.5 mmol) in DMF (10 mL) was added and the mixture allowed to warm to room temperature and stirred for 10 h. The mixture was filtered and the filtrate rotary evaporated. The residue was partitioned between Et_2O (75 mL) and 10% aqueous $NaHCO_3$ (25 mL), the organic phase washed with aqueous citric acid (0.1 M, 25 mL) and brine (2 × 25 mL) and dried (Na_2SO_4). Chromatography (EtOAc–PhMe, 2:1) gave amide **110** (2.28 g, 72%) as a yellow oil. R_f = 0.55 (MeOH–$CHCl_3$, 1:9). $[\alpha]_D^{25}$ = +21.4° (*c* = 1.02). FAB-MS *m*/*z*: 714 ($M^{\cdot+}$). IR (neat) (cm^{-1}): 3420, 1745, 1688, 1612, 1584, 1513, 1455, 1246, 821, 775. ^1H NMR (250 MHz, DMSO-d_6, 350 K) δ: 8.61 (s, 1H), 7.60 (br s, 1H), 7.29 (m, 2H), 7.20 (m, 2H), 6.88 (m, 4H), 4.56 (m, 2H), 4.45 (d, 1H, *J* = 11.7 Hz), 4.36 (d, 1H, *J* = 10.9 Hz), 4.20 (br m, 1H), 3.96 (m, 2H), 3.80 (s, 3H), 3.75 (s, 3H), 3.74 (s, 3H), 3.61 (br m, 1H), 3.50 (m, 1H), 3.19 (s, 3H), 3.13 (m, 2H), 3.03 (m, 1H), 2.67 (s, 3H), 1.95 (m, 1H), 1.72 (m, 1H), 1.35 (s, 9H), 1.27 (d, 3H, *J* = 7.0 Hz). (2*R*,3*R*,4*R*)-4-Dimethylamino-5-methoxy-*N*-(3*R*-((4-methoxycarbonyl)-2-oxazolyl)-1-butyl)-2,3-di((triethylsilyl)oxy)pentamide (112)

Oxazole-amide **110** (586 mg, 0.821 mmol) was dissolved in EtOAc saturated with aqueous HCl (2.8M, 12 mL) and stirred at room temperature for 4 h. After rotary evaporation, the residue was washed with Et_2O and dissolved in CH_3CN (8.0 mL). Et_3SiCl (0.34 mL, 2.05 mmol) and *i*-Pr_2NEt (1.4 mL, 8.20 mmol) were added. After stirring for 2 h, MeI (0.26 mL, 4.10 mmol) was added. Following 10 h stirring at room temperature, the mixture was diluted with Et_2O and quenched with saturated aqueous $NaHCO_3$. The organic phase was washed with H_2O (1.0 mL) and brine (1.0 mL) and then dried (Na_2SO_4). Rotary evaporation and chromatography (hexanes–EtOAc, 1:2 to 1:4) gave oxazole **112** (8) (300 mg, 59%) as a yellow oil. $[\alpha]_D^{25}$ = +4.4° (*c* = 0.89). FAB-HRMS calcd. for $C_{29}H_{58}N_3O_7Si_2$: 616.3813 ($[M + H]^+$); found: 616.3734 ($[M + H]^+$). Chiral aluminum complexes as catalysts in asymmetric Baeyer-Villiger reactions of cyclobutanones

Carsten Bolm, Oliver Beckmann, and Chiara Palazzi

Abstract: BINOL-aluminum complexes were successfully employed as mediators and catalysts in asymmetric Baeyer-Villiger rearrangements of cyclobutanones. Good enantioselectivies were achieved with only 15 mol% of the chosen chiral Lewis acid. The enantiomeric excesses obtained have never been reached before in such metal-catalyzed Baeyer-Villiger reactions.

Key words: aluminum, asymmetric catalysis, lactones, oxidations, rearrangement.

Resumé : Des complexes d'aluminium-BINOL ont été employés avec succès en tant que médiateurs et catalyseurs dans des réactions de Baeyer-Villiger asymétriques de cyclobutanones. Avec des taux catalytiques pouvant aller jusqu'à seulement 15 mol% en acide de Lewis chiral, il a été possible d'obtenir des excès énantiomériques jamais atteints auparavant dans de tels oxydations de Baeyer-Villiger catalysées par des métaux.

Mots clés : aluminium, catalyse asymétrique, lactones, oxydation, réarrangement.

Introduction

More than 100 years after its discovery, the Baeyer-Villiger oxidation has become a valuable tool in organic synthesis, owing to its tolerance of functional groups, its regioselectivity, and retention of configuration during the migration step (1). However, the search for an asymmetric metal catalysis for this rearrangement is still a challenging task in modern chemistry. The metal systems that have been devised to render the reaction asymmetric either lack a broader scope of substrates and enantioselectivity or exhibit the drawback of relying on stoichiometric amounts of the metal (2).[3] Existing catalytic procedures employ platinum (3) or copper complexes (4), while (over)stoichiometric variants make use of titanium, tin, zinc, or zirconium (5). These approaches have in part provided appreciable results with respect to enantiomeric excesses, but none represent a practical, synthetically useful method. Thus, further development in this field of asymmetric oxygen insertion is still necessary.

In the present report we introduce a novel catalyst involving a BINOL-aluminum promoter, which has already been successfully applied to other reactions (6): the combination of Me_2AlCl with enantiopure BINOL under a dry, inert gas atmosphere furnishes a catalyst, which is able to oxidize cyclobutanones in an enantioselective manner upon addition of a hydroperoxide (Scheme 1).

To the best of our knowledge this is the first example of a main group metal complex that can mediate in substoichiometric amounts asymmetric Baeyer-Villiger oxidations.[4] The γ-butyrolactones formed are valuable intermediates in the synthesis of pharmaceuticals or natural products, particularly when they are obtained in an enantiomerically pure form, and hence there is a notable effort to gain synthetic access to these important building blocks (7).

Results and discussion

In principle, if a bicyclic cyclobutanone derivative such as **1** is oxidized, two regioisomeric lactones may be formed, since the insertion of oxygen can occur on either side of the carbonyl group. Thus, when the racemic bicyclooctanone **1** was used as the substrate, the novel Al-mediated oxidation afforded not only 7-oxabicyclo[4.3.0]nonan-8-one (**2a**), which is the normal predominately formed lactone in common Baeyer-Villiger reactions (1), but also its regioisomer, 8-oxabicyclo[4.3.0]nonan-7-one (**2b**), in fairly large quantity. With (*S*)-BINOL in combination with Me_2AlCl (metal-to-ligand ratio = 1:1, 50 mol%), the products were (+)-(1*R*,6*R*)-**2a** with 34% ee and (+)-(1*R*,6*S*)-**2b** with 96% ee, exhibiting a remarkably low ratio **2a**:**2b** of 2.7 (Table 1, entry 1). Apparently, this transformation represents an example of an enantiodivergent reaction. Hence, the regioisomeric, enantio-

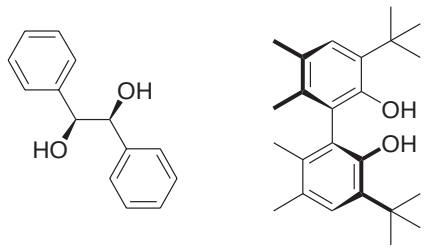
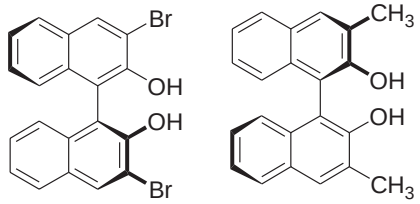
Scheme 1.

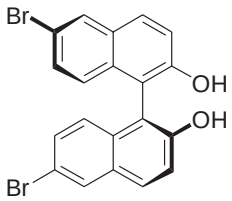
merically enriched lactone **2a** is produced chiefly from one enantiomer of the racemic starting material *rac*-**1**, while the substrate antipode gives rise to the other nonracemic regioisomeric product **2b**. Such a behavior has previously been found in biocatalytic Baeyer-Villiger reactions (8) and in the copper-catalyzed Baeyer-Villiger oxidation of the same substrate, *rac*-**1** (4b). Mathematically it was described by Kagan (9).



Furthermore, the bicyclic, commercially available ketone *rac*-**3** and the indene-derived cyclobutanone *rac*-**5** each led to two regioisomeric lactones (Table 1, entries 2 and 3). Here, the ratio **a**:**b** of regioisomers had shifted even more in favor of the unusual Baeyer-Villiger product (i.e., toward **4b** and **6b**, respectively). In parallel, the enantiomeric excesses of either lactone are leveling to nearly the same value. In addition, under the applied conditions, the olefinic ketone *rac*-**3** did not seem susceptible to epoxidation according to GC analysis.



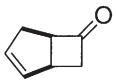
Besides the racemic disubstituted ketones **1**, **3**, and **5**, prochiral 3-monosubstituted cyclobutanones **7**, **9**, **11**, **13**, and **15** were also tested. These are accessible by means of [2+2]-cycloaddition of dichloroketene to an olefin with subsequent dehalogenation (11). The oxidation of 3-phenylcyclobutanone (**7**) yielded the corresponding lactone with 71% ee when 50 mol% of the Al-BINOL mixture was used (Table 1, entry 4). On reducing the catalyst loading to 15 mol%, the ee dropped only slightly to 68%,[5] which is the highest value reached to date in metal-catalyzed Baeyer-Villiger reactions of this substrate (2, 4*d*).

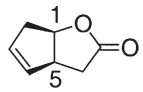


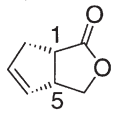
Neither the introduction of a chloro substituent on the arene nor the replacement of the aromatic substituent by an alkyl group at positon C3 had a detrimental effect with respect to the conversion and enantiomeric excess (Table 1, entries 5 and 6). In addition, 3-benzylcyclobutanones, whose lactones are intermediates in syntheses of pharmaceuticals and lignanes (7*e*, 12), proved to be suitable substrates for this (catalytic) asymmetric transformation. Albeit, piperonyl lactone **16** showed a modest ee of 58% in comparison to lactone **14** with 73% ee (Table 1, entries 7 and 8). All oxidations were complete within 12 h. No ketone could be detected by GC analysis and lactones **10** and **14** were isolated after column chromatography in 82 and 87% yield, respectively.

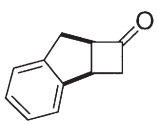
During the evaluation of the new Al-based Baeyer-Villiger system, different metal sources were employed. Aluminum reagents such as $EtAlCl_2$, $AlCl_3$, and $Al(O\text{-}t\text{-}Bu)_3$ in combination with BINOL did not lead to complete oxidation and afforded products with low ee's. Me_3Al with BINOL allowed full conversion but gave a racemate. Solely when dialkyl aluminum chlorides (R_2AlCl with R = Me, Et) were used was the reaction successful. Of the compounds tested, the dimethyl derivative gave somewhat higher enantiomeric excesses than the diethyl metalhalide (e.g., 71 vs. 63% ee for lactone **8** and 68 vs. 54% ee for lactone **10**). The different performances of dialkyl precursors with BINOL as ligand may be indicative of an intricate, oligomeric active species. Since Me_3Al is not an appropriate metal source, even though it readily reacts with diols, a simple mononuclear (BINOL)AlMe structure formed by reaction of BINOL with Me_2AlCl may be excluded as the catalyzing complex, since it should also be expected to be formed from Me_3Al. On the other hand a (BINOL)AlCl species cannot play a decisive role in the enantioselection because of the aforementioned influence of the alkyl rest, i.e., alkyl groups are likely to be still bound to an active aluminum complex. Thus, aluminum catalyst(s) incorporating two or more metal centers and bridging ligands are probable.[6]

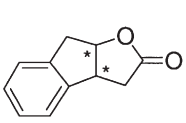
A survey of various chiral diols as ligands revealed the binaphthyl scaffold to be the most effective one for achieving

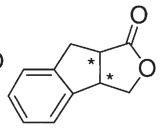


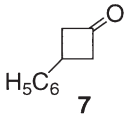


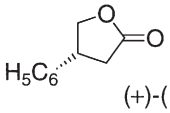


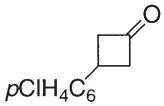


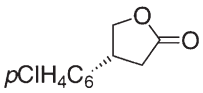


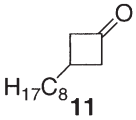


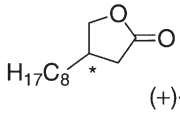


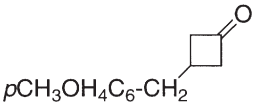


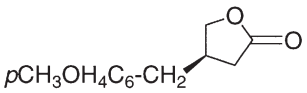


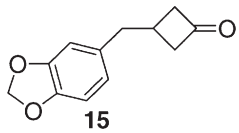


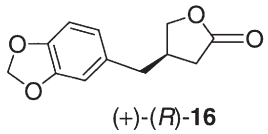












[5] A reduction of catalyst loading to 15 mol% was possible with 4-chlorophenyl cyclobutanone **9** as well (ee dropped from 68 to 57% at full conversion), but not with bicyclooctanone *rac*-**1**. In the latter case full conversion with 25 mol% of BINOL-Al (1:1) could no longer be achieved. However, when 25 mol% of BINOL and 50 mol% of Me_2AlCl were used, the oxidation of *rac*-**1** was still complete, albeit the enantioselectivity deteriorated (**2a**: 5% ee; **2b**: 80% ee).

[6] A similar interpretation was supported by ^{27}Al NMR studies and molecular weight determinations as described in ref. 13.

Entry	Ketone	Product(s)	ee (%) of product(s)	Ratio of lactones **a**:**b**[a]
1	*rac*-**1**	(+)-(1*R*,6*R*)-**2a** (+)-(1*R*,6*S*)-**2b**	34 (**2a**) 96 (**2b**)	2.7
2	 *rac*-**3**	 (+)-(1*R*,5*S*)-**4a**	 (+)-(1*S*,5*R*)-**4b**	79 (**4a**)[b] 74 (**4b**)	0.8
3	 *rac*-**5**	 **6a**	 **6b**	78 (**6a**) 68 (**6b**)	0.9
4	 **7**	 (+)-(*S*)-**8**	71	–
5	 **9**	 (+)-(*S*)-**10**	68	–
6	 **11**	 (+)-**12**	67	–
7	 **13**	 (+)-(*R*)-**14**	73	–
8	 **15**	 (+)-(*R*)-**16**	58	–

Note: For details see *Experimental*. (*R*)-BINOL as ligand gave the same results yet with inverted absolute configuration of the product.

[a]Calculated from area percentages in the GC.

[b]The ee analysis by chiral GC did not give baseline-separated signals.

enantioselectivity. Me_2AlCl in combination with L-diethyl tartrate, (*R*,*R*)-TADDOL, dianhydro D-mannitol, or D-erythrono lactone was not able to promote an asymmetric oxidation of ketone *rac*-**1** and **7**, and in some cases even failed to afford full conversion to the corresponding lactones. Furthermore, nitrogen-containing diols (salen-type ligands) prevented the ketones from being oxidized, which is consistent with the observed inhibitory effect of additives such as triethylamine, triphenylphosphine oxide, or tetrahydrofuran bearing coordinating sites. Eventually, it was (*S*,*S*)-hydrobenzoin **17**, (*S*)-$BIPHENH_2$ **18** (14*a*), and BINOL and derivatives thereof, in particular **21** (14b), that brought about noticeable enantiomeric excesses with a full conversion.

The test reaction involving 3-phenyl cyclobutanone (**7**) as the substrate and 3,3′-disubstituted BINOLs such as **19**, with two bromo substitutents, or BINOL with two biphenyl or naphthyl moieties, at C3 and C3′ (15), respectively, merely led to racemic lactones if they showed full conversion at all.[7] Only when 3,3′-dimethyl-BINOL ((*R*)-**20**) was used as the ligand, did the oxidation go to completion. Lactone **8** having

[7]We are grateful to Prof. K.A. Jørgensen (Aarhus University) for a kind donation of (*R*)-3,3′-bis(2,5-dimethoxyphenyl)-2,2′-dihydroxy-1,1′-dinaphthyl, which when employed as ligand unfortunately inhibited the Baeyer-Villiger oxidation.

© 2001 NRC Canada

an (*R*)-configuration was achieved with an enantiomeric excess of 40%.[8] However, 6,6′-disubstituted BINOL (*S*)-**21** proved to be the most effective ligand, leading to (*S*)-**8** with 77% ee, which is an even higher enantioselectivity than the one the unsubstituted BINOL ligand induced in the oxidation of **7**.[9] Hence, modifications at this end of the BINOL scaffold with different groups seem to be promising in regards to further improvement of the enantioselectivity. We are currently investigating these BINOL derivatives along with other oxidants and substrates in the aluminum-mediated Baeyer-Villiger oxidation.

Experimental

In a typical procedure, a solution of Me_2AlCl in hexanes (0.10 mL, 1.0 M, 0.10 mmol) was injected to enantiopure BINOL (29 mg, 0.10 mmol; obtained by resolution according to ref. 18) in absolute toluene under argon atmosphere. After stirring for 0.5–1 h at ambient temperature, the ketone (0.20 mmol) was added to the suspension, which within 15 min at room temperature became less turbid. The mixture was cooled down to –25°C before the addition of cumene hydroperoxide (technical grade 80%, 57 mg, 0.30 mmol) and then slowly let warm to room temperature again. After 12 h of stirring the mixture was treated with aq. HCl (0.5 M), then diluted with ether, washed with saturated. aq. $NaHCO_3$ and brine, and finally dried over $MgSO_4$. The obtained solution was directly subjected to GC analysis for the determination of the conversion (calculated from area percentages in the GC) and the ee (using chiral columns). The peak assignments were assured by comparison with chromatograms of ketones and racemic lactones.

For the correlations of optical rotations and absolute configurations, see ref. 10*a* for **2a**, ref. 10*b* for **2b**, ref. 10*c* for **8**, ref. 10*d* for **10**, ref. 7*e* for **14**, and ref. 10*e* for **16**. In ref. 7*a*, (*R*)-configurated 3-pentyl- and 3-hexyl-butyrolactones were shown to have a positive sign of optical rotation. Thus, the absolute configuration of octyl-bearing lactone (+)-**12** is supposed to be (*R*) too.

When isolated yields were to be determined, 1 to 2 mmol of ketone were employed and the product purified by column chromatography on silica gel.

Stereoelectronic and conformational effects on the stereochemical course of reduction of bicyclo[3.3.1]nonane 1,3-diketones

Eugenius Butkus, Arvydas Stončius, Julė Malinauskienė, Shuji Tomoda, and Daisuke Kaneno

Abstract: The stereoselectivity of the reduction of bicyclo[3.3.1]nonane 1,3-diketones was studied. The experimental data of π-facial stereoselection of the reduction of the carbonyl group were successfully rationalized by the application of the exterior frontier orbital extension (EFOE) model. The observed facial diastereoselectivity of the carbonyl reduction of bicyclo[3.3.1]nonane diketones could be reasonably explained by the ground-state facial anisotropy of the frontier orbital extension, steric effects, and the intrinsic reactivity of carbonyl groups. Although the EFOE density and PDAS values predicted the enhanced reactivity at the C-2 carbonyl compared to C-9 carbonyl, transition-state calculations at the B3LYP/6-31+G(d,p) level showed that the reactivity of C-9 and C-2 in a hydride addition to both carbonyl groups should be nearly the same. The EFOE analysis also strongly indicated that in the second hydride reduction step the corresponding oxobicyclononanolates are most likely to be involved in the reduction as the major species rather than the free hydroxyketones. The antiperiplanar effects in the transition states of the $LiAlH_4$ reduction as measured by both the elongation and the natural bond population of the antiperiplanar bonds clearly indicated they should not be an essential factor of the facial diastereoselection of studied diketones.

Key words: bicyclo[3.3.1]nonanedione, EFOE model, reduction, stereoselectivity, transition state.

Résumé : On a étudié la stéréosélectivité de la réduction de bicyclo[3.3.1]nonane-1,3-diones. On a pu rationaliser facilement les données expérimentales de la stéréosélectivité π-faciale de la réduction du groupe carbonyle par l'application du modèle de l'extension des orbitales frontières extérieures (« EFOE »). La diastéréosélectivité faciale observée de la réduction du carbonyle des bicyclo[3.3.1]nonanediones peut s'expliquer raisonnablement par l'anisotropie faciale de l'état fondamental de l'extension de l'orbitale frontière, par des effets stériques et par la réactivité intrinsèque des groupes carbonyles. Même si la densité EFOE et les valeurs de « PDAS » ont permis de prédire la plus grande réactivité du carbonyle en C-2 par rapport à celle du carbonyle en C-9, les calculs d'état de transition au niveau B3LYP/6-31+G(d,p) montrent que les réactivités des deux groupes carbonyles en C-2 et en C-9 vis-à-vis de l'hydrure devraient être assez semblables. L'analyse EFO" indique aussi fortement que, dans la deuxième étape de réduction par l'hydrure, il est probable que les oxobicyclononanolates correspondants sont impliqués dans la réduction sous la forme d'espèces majeures plutôt que sous la forme d'hydroxycétones libres. Les effets antipériplanaires dans les états de transition des réductions par $LiAlH_4$, tels que mesurés par l'élongation ainsi que la population naturelle de liaison des liaisons antipériplanaires, indiquent clairement qu'ils ne sont pas des facteurs essentiels de la diastéréosélectivité faciale des dicétones étudiées.

Mots clés: bicyclo[3.3.1]nonanedione, modèle EFOE, réduction, stéréosélectivité, état de transition.

[Traduit par la Rédaction]

Introduction

The most important aspect of the conversion of organic molecules containing one or more stereogenic centers is usually that of stereochemical control. The problem of π-facial stereoselection is one of the fundamental topics in theoretical and experimental organic chemistry. The state of art of this problem was recently reviewed in a special issue of *Chem. Rev.* (1). The origin of π-facial stereoselectivity is accounted for by two different transition-state (TS) models,

known as the Felkin–Ahn model (2) and Cieplak model (3). The former assumes that torsional and steric effects arise by interaction between the bonding orbital being formed and the antibonding orbitals of adjacent bonds can account for the experimental results (4). The Cieplak model places more importance in the interaction between the antibonding orbital of the incipient bond and the bonding orbitals of the adjacent bonds, and some interesting results in sterically unbiased systems were reviewed (5). An attempt to evaluate contributions of the above-mentioned approaches to explain the reaction selectivities by combining the stabilizing interactions was made by Li and le Noble (6) and Gung (7). Klein (8) introduced the frontier molecular orbital (FMO) distortion approach to π-facial selectivity. He pointed out that the anisotropic distribution of LUMO with respect to the carbonyl plane of the substrate in the ground state is governing the approach of nucleophile. The FMO approach was supported by ab initio calculations performed by Frenking et al. (9). The polarized π-frontier molecular orbital theory was shown to have some advantage over both the Anh and Cieplak models in the understanding of selectivity in some π-systems (10). However, these assumptions have been strongly criticized, and Felkin's torsional strain in the transition state maintained as the main factor governing the stereochemical outcome of π-facial additions (11). In spite of this, the electronic effects in terms of remote electrostatic effect or even the through-space orbital interaction in transition state were recognized as playing the significant role in nucleophile addition to carbonyl in sterically unhindered systems (12).

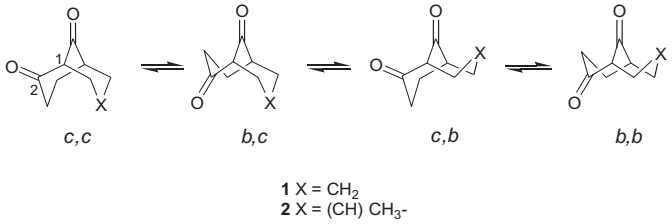
Recently the "exterior frontier orbital extension" (EFOE) model based on the Salem–Klopman kinetic equation has been suggested (13). The π-facial stereoselection in carbonyl group reduction and other nucleophilic addition reactions assumes the importance of the ground-state conformational and electronic properties of substrates generated over the exterior area of substrate ketones in the early stages of reaction, whereas the transition-state effects are most likely to have minor effects on facial selection (14). The calculation of the EFOE density and π-plane-divided accessible space (PDAS) provides a strong theoretical model for prediction of facial stereoselectivity of a hydride reduction and nucleophilic additions of a variety of ketones (15).

Further, an interesting study on diastereoselectivity observed in gas-phase reduction of a series of bicyclic ketones by silicon hydride has been published (16). The diastereoselectivity was remarkably consistent with results obtained in solution and in accord with the predictions by molecular orbital calculations. The results are rationalized in terms of competition among steric, torsional, and electrostatic effects, and also suggest that reduction stereoselectivity might be attributed to the intrinsic nature of the reactants.

However, it should be recognized that despite the power of prediction in many cases, the available models and procedures could not rationalize a number of stereochemical outcomes of π-facial additions. Consideration and comparison of the methods that are based entirely on second-order perturbation to predict diastereofacial selectivity led to a conclusion that there is no general explanation for the selectivities observed (17).

Earlier we studied the stereoselectivity of reduction of bicyclo[3.3.1]nonane ketones which seem to be suitable models to understand the stereochemical control of the reaction (18). However, an analysis of the TS structures at the 3-21G level and by the MNDO method did not give any definite explanation of stereoselectivites observed for bicyclo[3.3.1]nonane-2,9-dione. EFOE analysis is based upon a hybrid of ground-state (GS) and transition-state arguments. Therefore, a study of the applicability of the EFOE method to explain the stereoselectivity of the reduction of two diketones of this bicyclic structure was undertaken to interpret the stereoselectivity of the reaction.

Results and discussion



Reduction of bicyclo[3.3.1]nonanediones

The reduction of bicyclo[3.3.1]nonane-2,9-dione **1** and *exo*-7-methylbicyclo[3.3.1]nonane-2,9-dione **2** (Scheme 1) was performed using $NaBH_4$, $NaBH_3CN$, and $LiAlH_4$ in an appropriate solvent. The examination of a reaction course of bicyclo[3.3.1]nonane-2,9-dione **1** and $NaBH_4$ in methanol by GC and ^1H NMR showed that reduction of the first carbonyl group was not regioselective but was totally diastereoselective (18*a*). Though solvent effect on the reduction stereoselectivity could not be excluded in $NaBH_4$ reduction (19), there was no significant influence of it in this work. Only two of four possible hydroxyketones, i.e., the *anti*-9-hydroxybicyclo[3.3.1]nonan-2-one **1A** and the *endo*-2-hydroxybicyclo[3.3.1]nonan-9-one **1B** (Scheme 2) were formed in almost equal amounts. This ratio of hydroxyketones was found to be nearly constant during the reaction course. The stereochemical course of reduction of individual hydroxyketones was determined from the final ratio and configuration of diols, which in turn is dependent on the ratio of hydroxyketones formed in a reaction.

The examination of mixtures of diastereomeric diols obtained after a complete reduction of diketones by ^1H NMR, GC–MS, and circular dichroism spectroscopy of resolved enantiomeric derivatives provided us with the ratio of formed diols (Table 1). The reduction of bicyclo[3.3.1]nonane-2,9-dione **1** led to two main diols **1a** and **1b**, and an insignificant amount of the minor diol **1c** (4 ~ 8%). Essentially the same stereochemical course was observed in the reduction of *exo*-7-methylbicyclo[3.3.1]nonane-2,9-dione **2**. The distribution of the corresponding diastereomeric diols slightly varied in the reduction of **1** and **2** depending upon the hydride used and temperature of a reaction mixture. The most striking features of the investigated reduction of diones **1** and **2** was the low regioselectivity as contrasted with the high diastereoselectivity upon reduction of the first carbonyl group. At the first reduction step, hydride ion attacks the C-2 carbonyl group at the ring position from *exo*-face or the bridge C-9 carbonyl from *syn*-face, consequently *syn* attack with respect to both carbonyl groups occurs exclusively. Taking into account the fact that two hydroxyketones were forming in a substantial amount and the ratio of these hydroxyketones was found to be nearly constant during the reduction course, let us consider the reduction reaction as a two-step process. First, the reduction of one of the carbonyl groups of diketone leading to a formation of hydroxyketones, and second, a subsequent reduction of hydroxyketones. An attempt to interpret the product distribution was made by

Ground state conformational and EFOE analyses

An approach of the use of the EFOE model to account for the stereochemistry of the reduction of bicyclo[3.3.1]nonane-2,9-dione **1** and *exo*-7-methylbicyclo[3.3.1]nonane-2,9-dione **2** by complex metal hydrides is presented in this work. To explain the stereo- and regioselectivity of reduction, the theoretical calculation of properties of starting diketones and intermediate reduction products forming during the reaction was performed. The theoretical explanation of the stereochemical course of the reduction seems to be complicated due to the complexity of conformational and electronic properties of bicyclic diketones. A conformational mobility of investigated bicyclo[3.3.1]nonan-2,9-diones should be taken into account. Two six-membered rings of bicyclo[3.3.1]nonan-2,9-dione may adopt four possible conformations, namely *c*,*c*, *b*,*c*, *c*,*b*, and *b*,*b* (Scheme 1). Numerous calculations performed earlier (18*a*, 23*b*) and in this work (20) showed that only *c*,*c* and *b*,*c* conformations are significantly populated and the latter appeared to be more stable. In addition, a transannular interaction between the carbonyl groups should not be neglected in bicyclic diketones as demonstrated by ^{13}C NMR (21), photoelectron spectroscopy and calculations (22), or CD spectroscopy (23) experiments.

EFOE theory is based on a hypothesis that facial diastereoselection should not be dependent on thermodynamic stabilization effects towards the TS and one doesn't need to focus on the latter. Namely, the information on the facial diastereoselection is contained in the initial properties (interactions) of the reactants. Since the same reagent attacks two π-faces, one can predict diastereoselectivity by looking at the properties of the substrate (ketone). Thus the GS interactions might be decisive, and EFOE analysis, which implies evaluation of these interactions, provides a method for analyzing the polarization of π-wave functions. It is commonly accepted that properties of virtual orbitals are not as precise as the occupied orbitals. However, those of LUMO are pretty accurately predicted, because LUMO most significantly reflects the properties of occupied MOs through iterative variation procedure during MO calculation. Within the framework of the same method and basis sets (in this case, HF/6-31G(d)), one can reasonably compare the energies and spatial extension of LUMOs.

Two of the calculated MOs of the investigated bicyclic 1,3-diketones (**1**,**2**) could be recognized as π* MO, i.e., LUMO (lower energy) and LUMO + 1 (higher energy). These two MOs are located on both carbonyl groups and could be involved in π-facial stereoselection in investigated diketones. The difference in energy of LUMO and LUMO + 1, namely 0.42 ~ 1.2 eV at HF/6-31G(*d*) level (24), enabled us to consider that only the lower energy LUMO could be responsible for the new bond formation upon the hydride addition to the carbonyl group.

The EFOE analysis (13, 14) of a complete set of conformers of **1** showed that conformers should demonstrate significantly different reactivity in nucleophilic addition reactions. LUMO of **1***c*,*c* is the lowest one (3.56 eV) and gives significantly larger values of both EFOE density and PDAS over the *syn*-face of both carbonyls (Table 2). The LUMO of the main conformer **1***b*,*c* and of scantily populated conformers *c*,*b* and *b*,*b* showed much reduced values of both the EFOE density and PDAS. Therefore, the most reactive conformation that mainly contributes to the reaction should be **1***c*,*c* despite the slightly higher population of **1***b*,*c*. Similar values of the EFOE density and PDAS were obtained for LUMO of the most populated conformers of the diketone **2** (Table 2).

Overall, the EFOE model correctly predicted the preferred hydride approach from the *syn*-face to both carbonyls in agreement with experimental results, although the absence of regioselectivity at the first reduction step could not be understood by this approach. According to the EFOE analysis, the carbonyl group at C-2 is predicted to be more reactive compared to carbonyl at C-9 since both EFOE quantities of the LUMO for the *syn*-face are larger in the former group.

However, the thermodynamic stability of the products should affect the reaction rate according to the Marcus theory (25). The regioselectivity of some reactions of investigated diketones (26) and molecular mechanics, semiempirical or ab initio estimation of the relative stability of hydroxyketones **A** and **B** gave the following results: **1A***c*,*c* is more stable by 1.65 kcal mol^{-1} than **1B***c*,*c*, and **2A***c*,*c* is more stable by 2.90 kcal mol^{-1} than **2B***c*,*c*. It should be noted that exactly the same trend for the corresponding alkoxy anions (**1A**$^-$ < **1B**$^-$ (2.84 kcal mol^{-1}) and **2A**$^-$ < **2B**$^-$ (3.00 kcal mol^{-1})) was observed (Table 3).

Analysis of the transition states on addition of $LiAlH_4$

Transition states possibly forming in the reduction of the first carbonyl group were calculated. Lithium bicoordinate transition complexes of $LiAlH_4$ (Table 4) and substrate diketones were found to be uniformly more stable by about 1.5 kcal mol^{-1} over the Li-tricoordinate transition states. Ac-

cording to results at the HF/3-21* level, the first reduction step should proceed mainly via *c*,*c*-TS, which is lowest in energy (Table 4). Overwhelming *exo* preference was manifested by the large facial difference in the energy between the *exo*- and *endo*-*c*,*c*-C-2 TS (3.29 kcal mol^{-1}). The *c*,*c*-*syn*-C-9 transition state was found to be slightly more stable (0.46 kcal mol^{-1}) (Table 4). This is consistent with the prediction by the EFOE analysis. The energy of *b*,*c*-C-9 TS was found to be just slightly higher compared to that of the *c*,*c*-*exo*-C-2 or *c*,*c*-*syn*-C-9 TS. However, considering that the *b*,*c* conformation is more stable than *c*,*c*, the activation energy of the former is much higher compared to the latter.

Li-bicoordinate transition states of $LiAlH_4$ attack, calculated at the B3LYP/6-31+G(d,p) level taking into account the electron correlation effect, indicated that the energies of transition states of the C-2 and C-9 carbonyls are nearly the same and even more — *syn*-TS at C-9 is a bit more stable than the *exo*-TS at C-2 (Table 5 and Fig. 1).

Thus, in facial diastereoselection processes of hydride reductions, the kinetic activation energy (intrinsic barrier) has to prevail with a small effect of the thermodynamic activation energy. Consequently, in terms of the EFOE model, which reflects the kinetic part of the activation energy, it is predicted that C-2 may be kinetically more reactive compared to C-9. Owing to the strain relief at C-9 along the reaction pathway, thermodynamic activation energy at C-9 process lowers the TS more significantly than that at C-2, because the former is possibly much larger than the latter. As a result, the C-9 carbonyl may become slightly more reactive compared to C-2. This could be understood in terms of strain release and possible higher intrinsic reactivity of bridge carbonyl at C-9. However, this tendency was not observed at the MP2/6-311+G(2d,p) level. Finally, assuming that the initial complexes have nearly the same energy, the reactivity of the C-2 and C-9 carbonyls should be almost the same.

It is interesting to note that the antiperiplanar (AP) effect in transition states can not be used for the prediction of stereoselectivity in the studied molecules. We performed the natural bond population (NBO) analysis of all calculated transition states. The obtained values of population of antiperiplanar (AP) bonds along with the elongation of these bonds in comparison to the corresponding ground state values surprisingly predicted the opposite stereoselectivity to

that observed in the experiment. The greater loss of electrons and, respectively, the greater elongation of AP bonds was obtained for less energetically favored TSs in all cases (Table 6).

The EFOE analysis correctly predicted the observed stereoselectivity in the reduction of the first carbonyl group and the absence of regioselectivity at this reduction step could be understood in terms of combination of kinetic and thermodynamic components of the activation energy.

EFOE consideration of hydroxyketones

Hydroxyketones formed in the first reduction step undergo subsequent reduction. The reduction of *anti*-9-hydroxyketones **A** is stereoselective where *exo*-hydride approach prevails and the main *anti*-9-*endo*-2-diol **a** and only a small amount of *anti*-9-*exo*-2-diol **c** were formed (**1a**:**1c** = 93:7). The reduction of *endo*-2-hydroxyketones **1B** and **2B** yielded *syn*-9-*endo*-2-diols **1b**, **2b** and *anti*-9-*endo*-2-diols **1a**, **2a**, respectively. Approach of hydride from the *anti*-face of the bridge carbonyl group is prevailing and corresponding **b** was formed preferably over **a** (**1b**:**1a** = 80:20).

The EFOE analysis performed for hydroxyketones **A** and **B** in general correctly predicts the stereoselectivity observed experimentally (Table 3). The stereoselectivity is predicted to be large in reduction of hydroxyketone **A** by superiority of both the EFOE and PDAS values over the *exo*-face of the

Fig. 1. Geometries of Li-bicoordinate transition states at the B3LYP/6-31+G(d,p) level: (*a*) *endo*-C-2 TS; (*b*) *exo*-C-2 TS; (*c*) *anti*-C-9 TS; and (*d*) *syn*-C-9 TS. Distances are presented in Å, angles in degrees.

C-2-carbonyl leading to the *endo*-isomer **a**. However, the stereoselection in the hydroxyketone **B** should be weak due to almost equal EFOE values over two C-9-carbonyl faces (the *syn*-stereoselectivity is very slightly preferred) and a slightly different PDAS value (the opposite weak *anti*-stereoselectivity is predicted).

Both neutral hydroxyketone (**A** or **B**) and lithium or sodium oxobicyclononanolate ($\mathbf{A}^-$or $\mathbf{B}^-$) species could be formed in a reduction process. In particular, in the reduction of **B** the EFOE data strongly indicated that $\mathbf{B}^-$ should be the diastereoselectivity-determining species. The *anti*-face of $\mathbf{B}^-$ is far more reactive (EFOE density = 1.5489% and PDAS = 14.14 au^3) than any rotamer of **1B** *c,c* (rotation around the C—OH bond does not cause any significant changes in EFOE and PDAS data in all cases). Consequently, $\mathbf{B}^-$ should most significantly contribute to the production of the *syn*-isomer **b**.

The reason for the significant effects of the hydroxyanion group is that it is a strong electron-donating substituent. Substitution at C-3 of cyclohexanone by an electron-donating group causes a decrease in the PDAS value over the axial area owing to the ground-state Cieplak mode hyperconjugation between π^*(C=O) and C-2—C-3 (C-2—C-6) bonds (27) as it appears in $\mathbf{B}^-$. However, no significant

differences in both EFOE and PDAS values were found for **A** and $\mathbf{A}^-$ (Table 3).

The energies of LUMO for the hydroxyanions were uniformly significantly high (ca. 8 eV) compared to the neutral species (ca. 4 eV). This implies that the intermediate oxobicyclononanolate may be less reactive than any neutral ketones present in the reaction mixture. Namely, the second reduction may be slower than the first reduction step.

The EFOE data also strongly suggested that **A** should be more reactive than **B** due to the significantly larger EFOE densities and PDAS values in the *syn*-face of **A** and $\mathbf{A}^-$ than those in the *anti*-face of **B** and $\mathbf{B}^-$. However, the angle strain at C-9 should make hydroxyketones **B** more reactive. As a consequence of these competing factors their reactivities may become comparable.

Again, *b,c* conformers of hydroxyketones should make much less contribution to the diastereoselection compared to *c,c* conformers, which were found to be most stable and populated for all hydroxyketones (Table 3). The minor species $\mathbf{1A}^-$*b,c* are predicted to be very unreactive over both π-faces. The *anti*-face of the minor species $\mathbf{1A}^-$*b,c* is extremely sterically crowded, i.e., PDAS = 5.63 au^3 and the PDAS values for about 5 au^3 usually can be interpreted in this way. Thus, hydride approach from this face is essentially prohibited even though this face is electronically quite activated (EFOE density = 1.2172%). The *syn*-face of $\mathbf{1A}^-$*b,c* is sterically the most relaxed (PDAS = 37.72 au^3) but this face is electronically very unactivated (EFOE density = 0.2866%) and therefore these species may not contribute to the *syn*-stereochemical preference of this ketone. Consequently, the most reactive species should be **1A***c,c* and $\mathbf{1A}^-$*c,c*. Thus, taking into account the formation of oxobicyclo[3.3.1]nonanolates during the reaction course and conformational distribution along with the relative reactivity of conformers of hydroxyketones and corresponding oxobicyclononanolates, the EFOE model demonstrated the superior stereochemistry predicting abilities in the studied molecules.

Conclusions

The EFOE model correctly predicted the experimentally observed π-facial diastereoselectivity in the reduction of bicyclo[3.3.1]nonan-2,9-diones. The obtained results strongly indicate that among the four possible conformers of diketones, the double chair *c,c* conformer, which is slightly less stable than the most populated *b,c* conformer, might be the most reactive one. This is clearly demonstrated by the EFOE and PDAS values of the corresponding conformers. Although the EFOE density and PDAS values predicted enhanced reactivity at C-2 compared to C-9, transition-state calculations at the B3LYP/6-31+G(d,p) level showed that C-9 should be imperceptibly more reactive than C-2, which is in agreement with the experimental observations. EFOE analysis also strongly suggested that in the second hydride reduction step, the corresponding oxobicyclononanolates are most likely to be involved in the reduction as the major species rather than the free hydroxyketones. The antiperiplanar effects in the transition states of the $LiAlH_4$ reduction as measured by both the elongation and the bond population of the antiperiplanar bonds clearly indicated that they should not be an essential factor of the facial diastereoselection of studied diketones.

Studies on the reduction and hydrolysis of nitroso acetals

Scott E. Denmark, Vito Guagnano, and Jean Vaugeois

Abstract: Chemical transformation of nitroso acetals derived from tandem [4 + 2]/[3 + 2] cycloadditions of nitroalkenes have been investigated. New reduction methods were surveyed in an attempt to supplant the use of hydrogen and Raney nickel. Homogeneous catalytic hydrogenation was not successful, but samarium diiodide did effectively and selectively cleave one of the N—O bonds in a number of nitroso acetals. Acid-promoted hydrolysis of the nitroso acetals produced both α-alkoxy nitrones and hydroxamic acids selectively via expected pathways.

Key words: nitroso acetals, hydroxamic acids, α-alkoxy nitrones, reduction, hydrolysis.

Résumé : On a étudié les réactions de transformation chimique des acétals nitrosés obtenus par les cycloadditions en tandem [4 + 2]/[3 + 2] de nitroalcènes. On a évalué de nouvelles méthodes de réduction qui pourraient éventuellement supplanter l'utilisation de l'hydrogène et du nickel de Raney. L'hydrogénation catalytique homogène a été essayée sans succès; toutefois, le diiodure de samarium permet de cliver de façon efficace et sélective l'une des liaisons N—O dans un grand nombre d'acétals nitrosés. L'hydrolyse acidocatalysée des acétals nitrosés conduit à la formation sélective d'α-alkoxynitrones ainsi que d'acides hydroxamiques par le biais des voies prévues.

Mots clés : acétals nitrosés, acides hydroxamiques, α-alkoxynitrones, réduction, hydrolyse.

[Traduit par la Rédaction]

Introduction

The tandem [4 + 2]/[3 + 2] cycloadditions of nitroalkenes have evolved as a powerful strategy for the construction of highly functionalized polycyclic compounds adorned with multiple stereogenic centers (1). Over the past decade, we have extensively explored the development of this process in all of its manifold incarnations, i.e., with regard to the inter- or intramolecular nature of the two component cycloadditions. By far the most heavily investigated variant to date is the tandem intermolecular [4 + 2]/intramolecular [3 + 2] process. The unique feature of this mode that makes it attractive for synthesis is the diversity of product structures that are accessible by simply changing the point of attachment of the dipolarophilic tether as illustrated in Fig. 1. The critical transformation that makes all of these pathways useful is the hydrogenolysis of the nitroso acetals to reveal the final product. In general, the hydrogenolyses are mild, high yielding reactions that not only allow for the production of the target skeletons, but also provide for the release (and recovery) of the chiral auxiliary (G*OH) which controls the absolute stereochemical course of the cycloadditions.

The successful total syntheses of a variety of alkaloids disclosed from these laboratories (inter alia, rosmarinecine (1*a*), crotanecine (2*b*), detoxine (2*c*), castanospermine (2*d*), casuarine (2*e*), and mesembrine (2*f*)) made good use of the hydrogenolytic process to construct a pyrrolidine unit from the fused-mode cycloadduct. Similarly, spiro- (3) and bridge-mode (4) nitroso acetal cycloadducts have been cleanly transformed to cyclopentanes and cyclohexanes by this procedure.

To expand the scope of synthetic manipulations of the tandem cycloadducts, we have embarked on a broadly based examination of the chemistry of the nitroso acetals, a relatively unexplored class of compounds (for reviews see ref. 5). Our recognition that the tandem process represents a multicomponent reaction that may lend itself to solid-phase synthesis for combinatorial chemistry was another reason for finding new unmasking procedures. One such strategy for solid-phase applications would involve the attachment of the solid support linker at the vinyl ether moiety. Thus, unmasking would be coupled with cleavage from the resin. Clearly, catalytic heterogeneous hydrogenation is incompatible with the solid supported compounds, thus emphasizing the need for developing homogeneous methods for transforming these cycloadducts.

Background

Traditionally, Raney nickel has proven to be the promoter of choice in the hydrogenolysis of nitroso acetals. Other heterogeneous catalysts such as Pd/C, $Pd(OH)_2$, and PtO_2, have provided less satisfactory results (6). To our knowledge, no

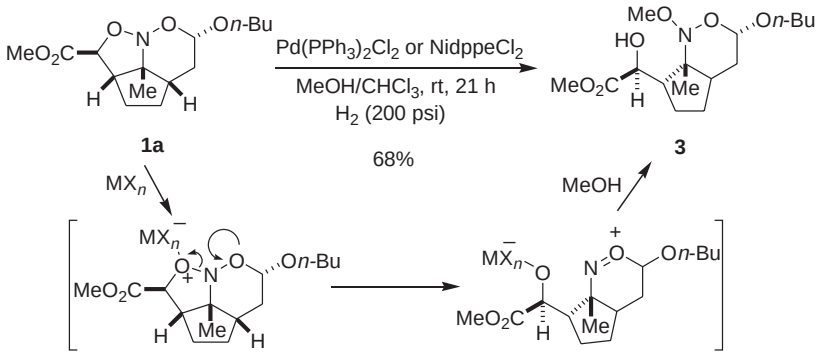
Scheme 2.

examples of homogeneous catalytic hydrogenation of nitroso acetals has been reported. Furthermore, the reductive cleavage of nitroso acetals by means of hydride sources has been attempted without much success. For example, Brook and Seebach (7) have shown that the reduction of nitroso acetal **i** with $LiAlH_4$ results in the selective reduction of the ester functionality, whereas the two N—O bonds remained untouched (Scheme 1). The resulting nitroso acetal **ii** underwent silica gel-catalyzed ring opening during column chromatography to afford isoxazoline **iii**. This interesting acid-catalyzed conversion of nitroso acetals to isoxazolines has been previously reported (8).

The paucity of attempts to explore the synthetic utility of nitroso acetals demonstrate that the chemistry of these compounds is still underinvestigated. Whereas there are no reported studies on the reductive cleavage of nitroso acetals, there are several methods for the homogenous reduction of other N—O containing compounds such as nitro groups, oximes, hydroxamic acids, and hydroxylamines (9). Among these the most appealing for our application are: (*i*) $TiCl_3$ in aqueous methanol (10); (*ii*) Zn in aq HCl or acetic acid (11); (*iii*) $Mo(CO)_6$ (12); (*iv*) $Fe_2(CO)_9$ (13); and (*v*) samarium diiodide (14). We report herein our efforts to develop mild, homogeneous methods for the reductive unmasking of nitroso acetals. In the course of these studies, we have discovered a series of novel acid-catalyzed transformations that would be suitable for application to solid-phase synthesis.

Results and discussion



Catalytic homogenous hydrogenation of nitroso acetals

The absence of literature reports documenting the homogenous catalytic reduction of nitroso acetals led us to investigate the use of homogenous catalysts that are commonly employed in the hydrogenation of related compounds. For example, ruthenium(II)-based catalysts have found application in the homogenous reduction of nitroalkanes to amines (15). These reactions are usually carried out at high temperatures and high hydrogen pressure and require the presence of a base. Furthermore, it is known that copper(I) salts are efficient homogenous catalysts for the hydrogenation of nitroalkanes to oximes in alkylpolyamines solvent (16).

Nitroso acetal **1a** (Scheme 2) was selected as the model substrate because of its thermal stability and its well-documented ability to undergo clean and high yielding hydrogenation in the presence of Raney nickel (82–85% yield) (17). In orienting experiments, the hydrogenation of **1a** was conducted in the presence of the Wilkinson's catalyst

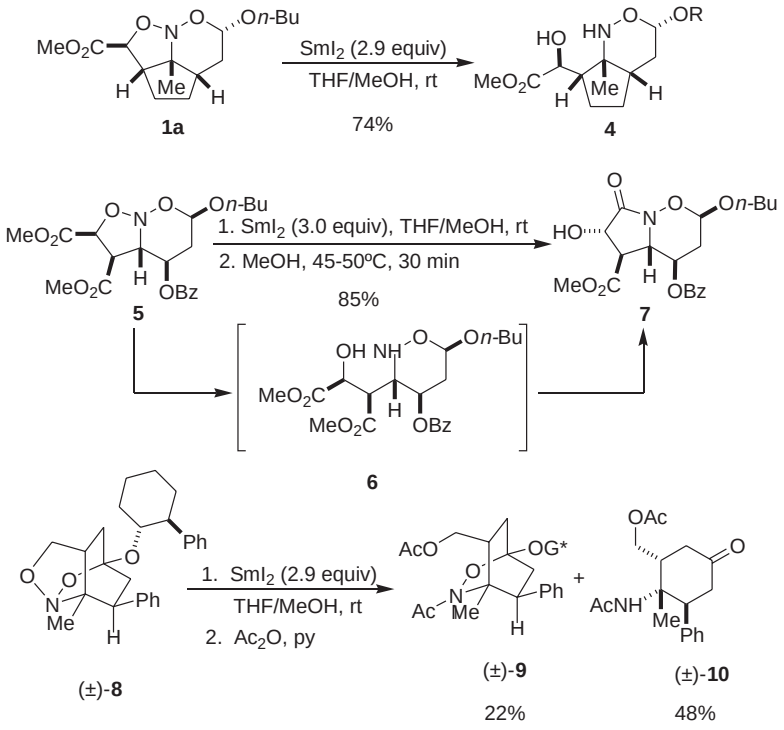
Scheme 3.

$(Rh(PPh_3)_3Cl)$ and of its congener $Ru(PPh_3)_3Cl_2$. No α-hydroxy lactam was ever detected and no other product could be isolated, while the starting material was recovered in good yield. An increase of the hydrogen pressure effected no improvement. Also, the ionic complex (1,5-cyclooctadiene)(pyridine)(tricyclohexylphosphine)iridium(I) hexafluorophosphate proved to be an unsuitable catalyst for the hydrogenation of nitroso acetal **1a**, since a low conversion of the starting material to a mixture of products was obtained.

The use of several palladium-based catalysts was also examined. Only three of the catalysts employed ($Pd(dba)_2$, $Pd_2(dba)_3$, $Pd(OAc)_2$) were able to partially convert **1a** into the lactam **2**, (17*e*) in methanol at 200 psi of H_2 pressure and at room temperature. In all the other instances, the reaction provided mixtures of products in which **2** could not be detected.[2] All the palladium catalysts were only sparingly soluble in methanol but quite soluble in the mixture MeOH–$CHCl_3$. Nonetheless, the hydrogenations carried out in this solvent mixture also provided unsatisfactory results. It is also noteworthy that, in all the cases examined, the reaction mixture after hydrogenation showed the presence of a black precipitate, which is presumed to be metallic Pd(0). Furthermore, whereas a 50% conversion of nitroso acetal **1a** into lactam **2** required 24 h, the formation of black Pd(0) was achieved in less than an hour. This observation leads to the conclusion that the formation of **2** was catalyzed by the metallic Pd(0) rather than by the starting complexes.

When the hydrogenation of nitroso acetal **1a** was carried out in the presence of either $Pd(PPh_3)_2Cl_2$ or $Ni(dppe)Cl_2$, a new compound was obtained as a mixture of stereoisomers (Scheme 3). On the basis of ^1H NMR and mass spectroscopic data, this compound is believed to be the bicyclic nitroso acetal **3** arising from methanolysis of the isoxazolidine ring of **1a**. The existence of two stereoisomers is explained by the presence of a noninverting nitrogen (18). The formation of **3** is proposed to involve initial coordination of the Lewis acidic metal to the oxygen in the five-membered ring, followed by assisted opening of the isoxazolidine and nucleophilic attack of MeOH to the nitrogen center. In support of this hypothesis, **3** was also obtained from **1a** in methanolic acetic acid (vide infra).

Samarium diiodide cleavage of N—O bonds in nitroso acetals



Our search for a general method for the cleavage of nitroso acetals under homogeneous conditions next turned to the use of $Mo(CO)_6$ and SmI_2 which have been shown to reduce N—O bonds in hydroxylamines, isoxazolidines, and oxazines (12, 14). Unfortunately, $Mo(CO)_6$ proved to be unsuitable for this purpose. Treatment of nitroso acetal **1a** with $Mo(CO)_6$ in aqueous acetonitrile at reflux for 1 h resulted in the complete conversion of the starting material into an intractable mixture of products. Much better results were obtained from the reaction of nitroso acetal **1a** with SmI_2. Although optimization was required to make the initially low yielding process synthetically attractive, we were eventually able to develop a protocol for the selective reduction of the N—O bond of the isoxazolidine ring in nitroso acetal **1a**. Thus, treatment of **1a** with 2.9 equiv of SmI_2 in THF–MeOH afforded the bicyclic oxazine **4** in 74% yield (Scheme 4). To assess the scope of this reaction, nitroso acetal **5** (derived from a tandem double intermolecular cycloaddition (19)) was subjected to the same reaction conditions. We were pleased to find that SmI_2 promoted the analogous reduction to afford the oxazine **6**. This compound underwent partial intramolecular cyclization at room temperature to afford the corresponding lactam **7**. The bicyclic product **7** could be obtained reproducibly and in high yield (85%) by heating a methanolic suspension of the crude oxazine **6** at 45–50°C for 30 min. Attempts to cleave the remaining N—O bond in lactam **7** were unsuccessful. Finally, the bridged nitroso acetal **8** underwent both single and double N—O bond cleavage under similar conditions to provide, after acetylation, a mixture of the bicyclic oxazine **9** and the aminocyclohexanone **10** in 22% and 48% yield, respectively, (Scheme 4).

The preferential cleavage of the isoxazolidine rings in **1a**, **5**, and **8** with SmI_2 implies that the LUMO has a large coefficient at that N—O bond and that there may be a significant strain release upon opening the five-membered ring. A similar observation was made in the partial hydrogenolysis of tricyclic nitroso acetals related to **1a** (six-membered carbocyclic ring) and **8**. Although this is fundamentally interesting, this cleavage mode does not lead to unraveling of the oxazine wherein the auxiliary or the linker to the solid phase would

[2] Although lactam **2** (when produced) was never isolated, its presence in the crude reaction mixture was confirmed by the appearance in the ^1H NMR spectrum of two diagnostic signals (a doublet at 4.70 ppm and a multiplet in the region 4.00–3.80 ppm).

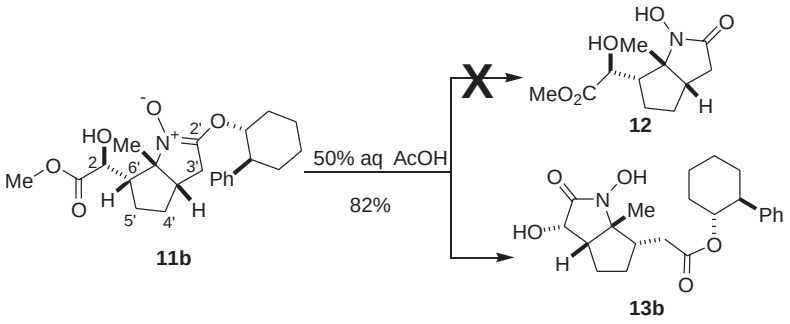
be attached. We thus began an investigation of dissolving metal type reductions in the hope that the acetal type function in the oxazine would exhibit enhanced reactivity.

Acetic acid cleavage of nitroso acetals



For this series of experiments we employed the same nitroso acetal subunit as in **1a** but this time derived from the 2-phenylcyclohexanol vinyl ether dienophile (**1b**) (17). Upon treating **1b** with Zn in acetic acid overnight, a new compound **11b** was obtained that differed from the Raney nickel reduction product **2**. That this new compound did not arise from a reductive process was revealed by a control experiment in acetic acid (without zinc) which afforded the same product. The diagnostic spectroscopic data for **11b** are collected in Table 1. Of primary importance was the mass spectral data which revealed that **11b** is an isomer of **1b**! ^{1}H NMR, ^{13}C NMR, and IR data supported the persistence of a methyl ester (δ 3.78 ppm, δ 173.3 ppm, and 1756 cm^{-1}) most likely flanked by a hydroxyl bearing methine group (δ 4.06 ppm, 3437 cm^{-1}). However, identifying a chemical function that fit the second combination of signals at δ 4.81 ppm, δ 153.5 ppm, and 1644 cm^{-1} proved more challenging. The signal at 153 ppm in the ^{13}C NMR is suggestive of carbonates or carbamates but their carbonyl stretching frequencies are usually 1800 and 1720 cm^{-1}. Unknown compound **11b** clearly does not contain any of these functions.

The structure of **11b** was ultimately secured by single crystal X-ray analysis.[3] Crystals suitable for X-ray crystallography were deposited from hexane – ethyl acetate in 73% yield. As we surmised, the α-hydroxy methyl ester moiety is indeed present (Scheme 5). The core of the structure is an azabicyclic[3.3.0] system containing two C—N bonds whose lengths are 1.293(2) and 1.501(2) Å, respectively. This indicates the presence of both C—N double and single bonds. The presence of one N—O bond of 1.3334(12) Å, typical

[3] Supplemenatry material has been deposited with the Depository of Unpublished Data, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada ((http://www.nrc.ca/cisti/irm/unpubl_e.shtml for information on ordering electronically). The crystallographic coordinates of **11b** and **13b** have been deposited with the Cambridge Crystallographic Data Centre (CCDC nos. 158 466 and 158 467). Copies of the data are available, free of charge, from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

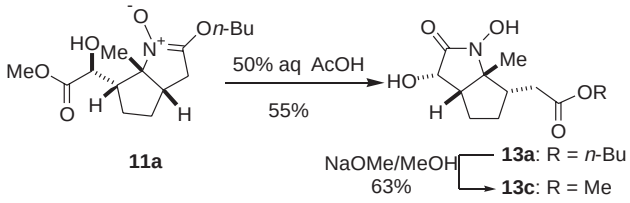
Scheme 6.

of *N*-oxides, is also noted. Hence the unexplained ^{13}C NMR (δ 153.5 ppm) and IR (1644 cm^{-1}) resonances arise from the rather uncommon α-alkoxy nitrone function (20).



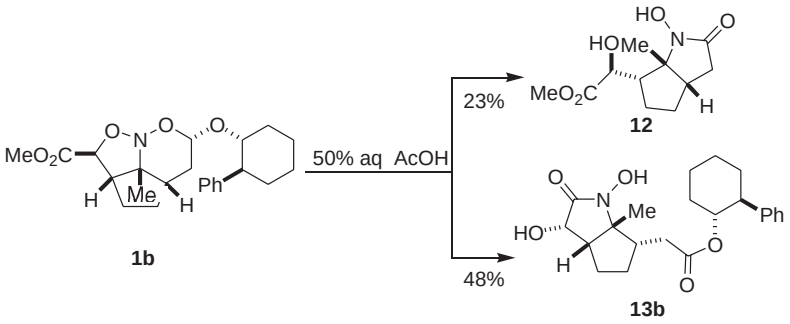
To establish the generality of this new transformation, compound **1a** was treated with glacial acetic acid for 2 h. After evaporation of the solvent, purification by column chromatography and recrystallization from dry dichloromethane–hexane under N_2, compound **11a** was obtained as a white crystalline solid in 56% yield. The identity of this structure was easily made by comparison of the spectroscopic data to those from **11b** (see Table 1). Although there are some differences in the ^{1}H NMR data primarily due to the anisotropic effect of the 2-phenylcyclohexyl moiety, one can confidently assign the structure by analogy on the basis of the ^{13}C NMR and IR spectra.

Although the transformation of **1** to **11** is interesting, it failed to accomplish our objective of separating the dienophile alkoxy group from the nitroso acetal. Therefore, we attempted to hydrolyze the α-alkoxy nitrone in hope of obtaining hydroxamic acid **12** (Scheme 6). Treatment of **11b** with 50% aqueous acetic acid at room temperature for 16 h afforded a new crystalline compound after recrystallization from acetonitrile–water. Much to our surprise, the ^{1}H NMR spectrum of the product indicated that the 2-phenylcyclohexyloxy group remained whereas the methyl ester did not. Moreover, the 2-phenylcyclohexyloxy carbinol proton was shifted downfield to δ 5.02 ppm and remained a doublet of triplets. The ^{13}C NMR spectrum of this compound displayed signals at δ 173.0 and 169.5 ppm and the IR spectrum showed strong absorbencies at 1740 and 1677 cm^{-1}. These data suggested that both ester and amide functionalities were present. The FAB mass spectrum shows an M + 1 signal at *m*/*z* 388.2 indicating loss of a methylene group from **11b**. Taken together, this information led to the formulation of hydroxamic acid **13b** as the structure of the new compound (Scheme 6). Our hypothesis was again validated by a single crystal X-ray analysis.[3]

The unexpected formation of **13b** could be attributed to the steric congestion in the vicinity of the hindered phenylcyclohexyl ester. Accordingly, compound **11a** was submitted to aqueous acetic acid with the expectation that an *n*-butyl group might allow formation of **12**. However, treatment of **11a** under similar conditions followed by purification by recrystallization from acetonitrile afforded a new material (**13a**) in 55% yield whose structure was easily assigned by analogy to compound **13b** (Scheme 7).

To streamline the hydrolytic transformation, we reasoned that compounds **13a** and **13b** should be accessible directly

Scheme 7.



from nitroso acetals **1a** and **1b** using a one-step treatment with aqueous acetic acid. Thus, compound **1b** was stirred with 50% aqueous acetic acid for 16 h at room temperature. The ^{1}H NMR spectrum of the white solid obtained clearly indicated the presence of **13b** along with 2-phenylcyclohexanol and another unknown compound. Because this new product retained the methyl ester signal we suspected that **12** had indeed been produced. The ratio of **13b** to **12** as determined by ^{1}H NMR integration was 2:1; however, isolation of **12** proved difficult. Purification of the mixture by column chromatography on silica gel with toluene – acetone – acetic acid (60:38:2), afforded a reddish solid! Elemental analysis of the reddish compound showed that it contained copper. We surmised that the powerful, metal-chelating hydroxamic acid moieties in both **13b** and **12** were leaching this trace metal from the adsorbent (21). Thus, the silica gel was extensively washed, dried, and then used for separation. In this fashion, we successfully obtained hydroxamic acids **13b** and **12** in 48 and 23% yield, respectively. The spectroscopic data from **12** (^{1}H NMR, ^{13}C NMR, IR, and MS) were fully consistent with the structure assigned (Scheme 8).

Although compound **12** is structurally distinct from the kinds of products usually produced from unmasking nitroso acetals, our goal for implementing tandem cycloadditions on the solid phase did not have a specific structural objective. Therefore, we were pleased to have identified a cleavage procedure that could function under mild, homogeneous conditions and next assayed the optimization of this hydrolytic process for the production of **12**. Unfortunately, all attempts to do so by varying acid concentration, temperature, or solvent proved fruitless. The only variable that influenced the ratio of **12**:**13b** was the reaction temperature. However lowering the temperature required that the reaction be left for much longer periods of time in order for **1b** to dissolve fully. Regrettably, the ratio of **12**:**13b** slightly decreased to 1:1 after 7 days at –10°C. As we could not favor the formation of only one compound in this fashion, the one-step avenue was abandoned.

Scheme 8.

Having failed to achieve a direct hydrolysis of **1b** to **12**, we next sought a procedure that might deliver **13b** directly from **1b** and thence to devise a protocol to cleave the pendant alkoxy moiety by ester saponification. Thus, compound **1b** was first treated with glacial acetic acid for 2 h and then an equal volume of distilled, deionized water was added and the solution was stirred for 16 h. By this protocol, **13b** was obtained in 87% yield after recrystallization. This represents a significant improvement compared to the two-pot procedure (59% yield). In a similar fashion, **1a** afforded **13a** in only a marginally higher yield (33% vs. 30% for the two-pot procedure).

With a high yielding procedure for the production of **13b** in hand, we turned our attention to the base promoted cleavage of the ester group. Remarkably, **13b** proved resistant to trans-esterification with sodium methoxide in methanol. Even attempts to engage the *N*-hydroxyl group of the hydroxamic acid with DMAP or K_2CO_3 in toluene at room temperature or at reflux resulted in recovery of the starting material. This surprising resistance to reaction at the ester carbonyl group in **13b** may be due to the shielding from the phenylcyclohexyl moiety. Support for this hypothesis was forthcoming in the successful trans-esterification of **13a** with sodium methoxide in methanol. After neutralization with acidic Dowex resin and recrystallization from acetonitrile, methyl ester acid **13c** was obtained in 63% yield (Scheme 7). We were thus, finally in possession of non-hydrogenolytic means to cleave the alkoxy moiety from a nitroso acetal created by a tandem [4 + 2]/[3 + 2] nitroalkene cycloaddition

Mechanistic analysis

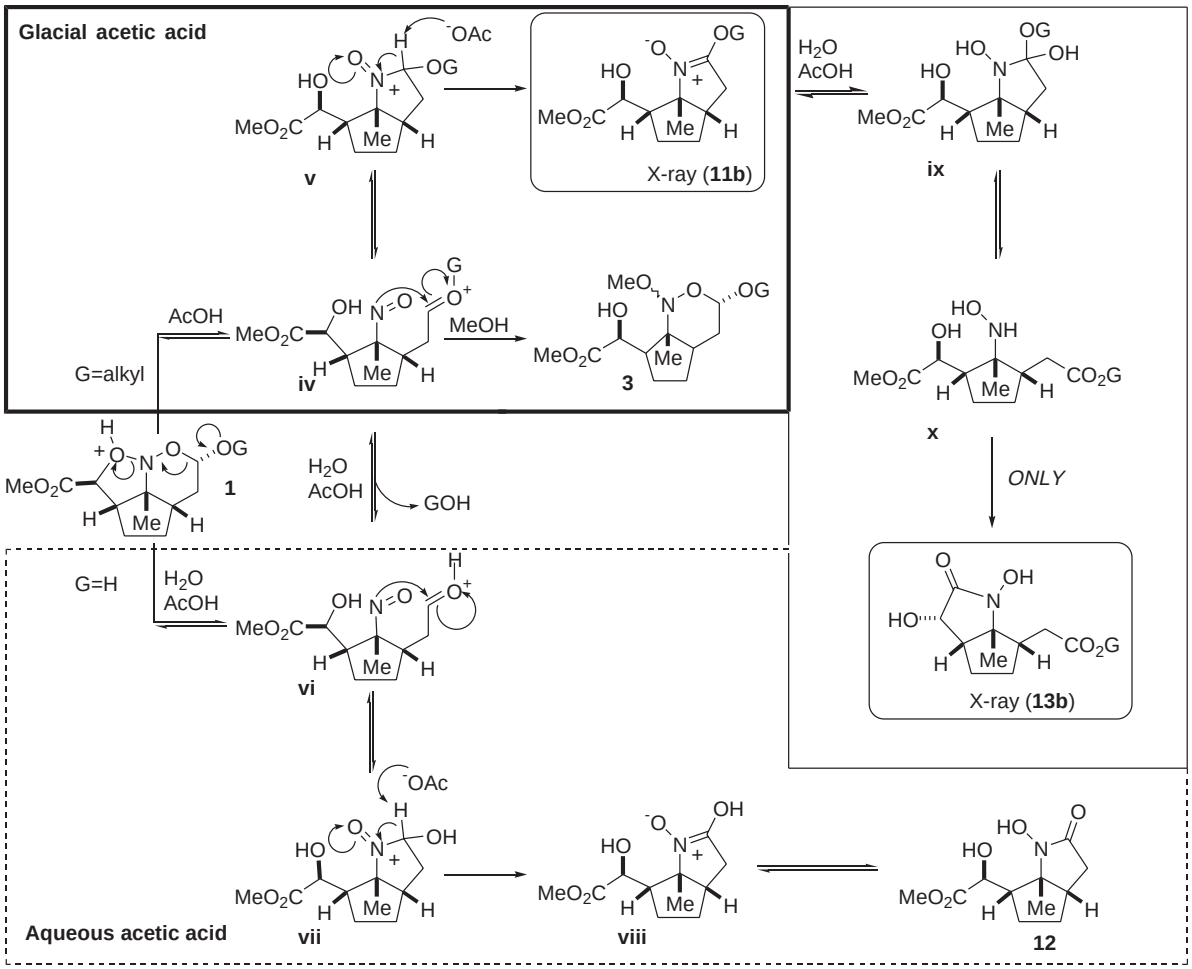
The divergent hydrolytic behavior of nitroso acetals **1a** and **1b** is intriguing. In glacial acetic acid, only alkoxy nitrones **11a**:**11b** are produced. Further, hydrolysis of **11a**:**11b** in 50% aqueous acetic acid leads exclusively to hydroxamic acid **13a**:**13b**. The alternate hydroxamic acid **12** is only formed by direct hydrolysis of **1b** with 50% aqueous acetic acid. A mechanistic scenario that can accommodate these unusual selectivities under various conditions is presented in Scheme 9.

The initial event in glacial acetic acid is proposed to be the fragmentation of the protonated nitroso acetal to produce the nitroso oxocarbenium ion **iv** (Glacial acetic acid pathway). In the absence of any nucleophile other than acetate, this species collapses by attack of the nitrogen atom on the oxocarbenium ion to produce a nitrosonium cation **v** which leads directly to the alkoxy nitrone **11** by simple deprotonation. Recall that if methanol is present, the cation **iv** can be intercepted to afford the opened nitroso acetal **3**.

One of the most unexpected results was the exclusive formation of **13b** from hydrolysis of **11b** in aqueous acetic acid and the observation of *both* **13b** and **12** from hydrolysis of **1b** under the same conditions. This clearly implies that the hydrolysis of **11b** and **1b** proceed through different intermediates. To accommodate these facts, two mechanistic scenarios are proposed in Scheme 9. Aqueous hydrolysis of **11b** is suggested to proceed by hydration the alkoxy nitrone to give **ix** which collapses to hydroxylamine ester **x**. For reasons that are not completely understood, the hydroxylamine moiety reacts exclusively with the α-hydroxy ester (most likely due to the activated nature of the carbonyl group) to afford **13b**.

To explain the formation of both **12** and **13b** from **1b** under these conditions requires that **12** arise from an independent pathway not involving hydroxylamine **x**. Accordingly, we propose that in aqueous acetic acid, two pathways are operative; the first is the Glacial acetic acid pathway and the second, Aqueous acetic acid pathway (Scheme 9). In this latter pathway, the alkoxy group OG in **1** is hydrolyzed to a hydroxyl group (by any of a number of mechanisms). As was proposed above, nitroso acetal fragmentation leads to nitroso oxocarbenium ion **vi** which again collapses to a nitronium ion **vii**. Now, however, the deprotonation of **vii** leads to a hydroxy nitrone which simply tautomerizes to the hydroxamic acid **12**. Most certainly, alternative mechanisms are conceivable, but all must provide a pathway for the formation of **12** which does not proceed via **x**.

Experimental



General experimental

All reactions were performed under an atmosphere of dry nitrogen in flame- or oven-dried (140°C) glassware. Solvents for chromatography and recrystallization were reagent grade or better. Reaction solvents were distilled from the indicated drying agents: dichloromethane (P_2O_5), methanol ($Mg(OMe)_2$). TLC was performed on Merck silica gel plates with QF-254 indicator. Plates were visualized using UV radiation (254 nm) in conjunction with the following reagents: $KMnO_4$ (alkenes, nitro compounds, alcohols), anisaldehyde (nitroso acetals), $FeCl_3$ (hydroxamic acids), or I_2 (alkenes, aromatics). Column (flash) chromatography was performed using 230–400 mesh silica gel purchased from EM Science or alumina purchased from Aldrich.

Melting points (mp) were determined on a Thomas–Hoover capillary melting point apparatus in vacuum sealed tubes and are uncorrected. ^1H and ^{13}C NMR spectra were recorded at

Scheme 9.

400 MHz, ^{1}H (100 MHz ^{13}C) or 500 MHz ^{1}H (125 MHz ^{13}C) in deuteriochloroform ($CDCl_3$) with chloroform (7.27 ppm ^{1}H, 77.0 ppm ^{13}C) as an internal reference. Chemical shifts are given in ppm (δ); multiplicities are indicated by s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), or b (broadened). Coupling constants (*J*) are reported in Hz. Infrared spectra (IR) were obtained on a Mattson Galaxy 5020 spectrophotometer. Peaks are reported in cm^{-1} with the following relative intensities: s (strong, 67–100%), m (medium, 34–66%), w (weak, 0–33%). Mass spectra were obtained through the Mass Spectrometry Laboratory, School of Chemical Sciences, University of Illinois. Low-resolution fast atom bombardment (FAB) spectra were obtained on a VG ZAB-SE spectrometer in magic bullet (3:1, dithiothreitol–dithioerythitol) or 3-nitrobenzyl alcohol. Data are reported in the form *m*/*z* (intensity relative to base = 100). Elemental analyses were performed by the University of Illinois Microanalytical Service Laboratory and are the average of two combustions.

2-Aza-4-butoxy-9-[(carbomethoxyhydroxy)methyl]-N-*methoxy-3-oxabicyclo[4.3.0]nonane (**3**)*

Acetic acid (0.057 mL, 1.0 mmol, 2 equiv) was added to a solution of nitroso acetal **1a** (150 mg, 0.5 mmol, 1 equiv) in MeOH (10 mL). The reaction mixture was stirred for 2 h and 30 min at room temperature (rt). After removal of MeOH and AcOH under vacuo, the resulting blue residue was dissolved in EtOAc (50 mL) and treated with SiO_2 (20 g). The suspension was stirred for 18 h at rt, then filtered and concentrated. The residue was dissolved in benzene and purified by silica gel column chromatography (hexane–EtOAc, 6:1) to afford 59.2 mg of a mixture of **3**:**3′** (1.44:1) and 53.3 mg of **3** for a combined yield of 112.5 mg (68%). Conclusion

A number of new transformations of nitroso acetals have been developed. For the reduction of nitroso acetals derived from tandem cycloadditions of nitroalkenes, catalytic hydrogenation over Raney nickel remains the method of choice. Hydrogenation under homogeneous conditions was shown to be unsuitable for this transformation. Samarium iodide was able to effect a selective cleavage of the N—O bond of the isoxazolidine ring in a number of structurally diverse cycloadducts.

The acid-promoted ring opening of nitroso acetal **1** has revealed new and interesting aspects of the chemistry of these compounds. α-Alkoxy nitrones and hydroxamic acids could be selectively produced under different reaction conditions. A two-step protocol was developed for the cleavage of the alkoxy group of which may find use in the application of tandem cycloaddition technology in combinatorial chemistry. Further studies on the chemistry of nitroso acetals and the implementation of tandem cycloadditions on the solid phase are planned.

Acknowledgment

We wish to thank the National Institutes of Health (R01 GM-30938) for financial support. We thank Dr. Scott R. Wilson for assistance with the X-ray crystallographic analyses.

The versatile reactivity of 2-aryl-4,6-dinitrobenzotriazole 1-oxides in Diels–Alder type condensations and in σ-complexation — A relationship between superelectrophilicity and pericyclic reactivity

Dominique Vichard, Taoufik Boubaker, François Terrier, Marie-José Pouet, Julian M. Dust, and Erwin Buncel

Abstract: A two-pronged study of a series of 2-aryl-4,6-dinitrobenzotriazole 1-oxide substrates (**2a**–**c**) is reported: Diels–Alder type pericyclic reactivity and covalent hydration to yield Meisenheimer type hydroxy anionic σ-adducts. The most activated benzotriazole 1-oxide **2a** is found to exhibit both dienophilic and heterodienic behaviour on treatment with cyclopentadiene, providing a highly functionalized stereoselective diadduct (**7**). This diadduct is shown to be the result of two consecutive inverse demand Diels–Alder condensations proceeding through the *endo* mode with a *trans* addition of two cyclopentadiene molecules. Kinetic and thermodynamic measurements of the ease of covalent hydration of **2a**–**c** to give σ-adducts **4a**–**c** in aqueous solution indicate that the electrophilic reactivity of the 4,6-dinitrobenzotriazole 1-oxide structure is much closer to that of the superelectrophilic 4,6-dinitrobenzofuroxan (DNBF, **1a**) than that of the standard Meisenheimer electrophile 1,3,5-trinitrobenzene (TNB). The pK_a values range from 6.70 for the 2-(2′,4′,6′-trinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (Pi-DNBT, **2a**) to 10.73 for the 2-phenyl-4,6-dinitrobenzotriazole 1-oxide (Ph-DNBT, **2c**). The observation that the most activated benzotriazole 1-oxide structure **2a** which resembles 4,6-dinitrobenzofuroxan (DNBF) in superelectrophilic behaviour, is the only one that undergoes Diels–Alder reactions, points to a direct relationship between superelectrophilic and pericyclic reactivity.

Key words: σ-complexes, arylnitrobenzotriazole 1-oxides, super-electrophiles, Diels–Alder condensations, pericyclic reactions.

Résumé : On a réalisé une étude d'une série de substrats 1-oxyde de 2-aryl-4,6-dinitrobenzotriazole (**2a**–**c**) et elle a été menée sur deux fronts: la réactivité péricyclique de type Diels–Alder et l'hydratation covalente conduisant à des adduits σ, des hydroxy anioniques de type Meisenheimer. On a observé que le traitement de l'oxyde de benzotriazole le plus activé (**2a**) avec du cyclopentadiène donne lieu à des comportements à la fois diénophile et hétérodiénique et qu'il permet d'obtenir un diadduit stéréosélectif hautement fonctionnalisé (**7**). On a démontré que ce diadduit résulte de deux condensations consécutives de Diels–Alder ayant des demandes inverses et qu'elles se produisent par le mode *endo* avec une addition *trans* de deux molécules de cyclopentadiène. Des mesures cinétiques et thermodynamiques de la facilité d'hydratation covalente des composés **2a**–**c** qui conduit à la formation des adduits σ correspondants (**4a**–**c**) indiquent que, en solution aqueuse, la réactivité électrophile de la structure 1-oxyde de 4,6-dinitrobenzotriazole est beaucoup plus proche de celle du 4,6-dinitrobenzofuroxane (DNBF, **1a**) superélectrophile que de celle du 1,3,5-trinitrobenzène (TNB), l'électrophile de Meisenheimer de référence. Les valeurs de pK_a vont de 6,70 pour le 1-oxyde de 2-(2′4′6′-trinitrophényl)-4,6-dinitribenzotriazole (Pi-DNBT, **2a**) à 10,73 pour le 1-oxyde de 2-phényl-4,6-dinitrobenzotriazole (P-DNBT, **2c**). On a observé que la seule structure à subir des réactions de Diels–Alder est la structure la structure la plus activée du 1-oxyde de benzotriazole (**2a**), qui ressemble au 4,6-dinitrobenzofuroxnae

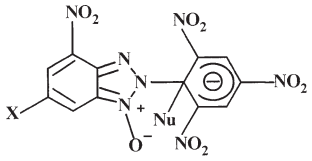
Introduction



Following the discovery of the extremely strong electrophilic character of the carbocyclic ring of 4,6-dinitrobenzofuroxan (DNBF, **1a**) (1–9), we have been engaged in an effort to design analogues of **1a** in which the oxygen atom in the furoxan ring is replaced by other electron-withdrawing moieties (10, 11). We thus found that 2-(2′,4′,6′-trinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (Pi-DNBT, **2a**) is also a powerful electrophilic heterocycle that undergoes facile σ-complexation at C-7 of the carbocyclic ring with a number of nucleophiles, including weak neutral nucleophiles like water, methanol, or ethanethiol (10*a*). A contrasting feature of **2a** is that the C-1′ carbon of the picryl ring is also susceptible to reaction with nucleophiles, giving rise to an S_NAr displacement reaction via the metastable σ-adduct **3a** (10, 11). The ambident (C-7 vs. C-1′) electrophilicity of **2a** (and other members of benzotriazole 1-oxides series, e.g., **2b**) has given new impetus to the study of reactivity–selectivity relationships in reactions of this and related ambident electrophiles with ambident nucleophiles (9*b*, 11).

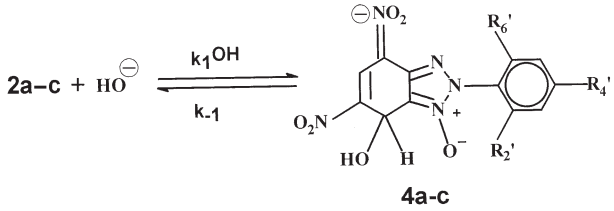
2c R_2' = R_4' = R_6' = H (Ph-DNBT)



3a

In probing the manifold reactivity of electron-deficient heteroaromatics like **1a**, we have discovered that nitrobenzofuroxans are also remarkably versatile reagents in pericyclic reactions such as the Diels–Alder, being capable of acting as dienophiles, carbodienes, or heterodienes depending upon the experimental conditions and reaction partners employed (12). To test whether this diverse pericyclic reactivity is a reflection of the low aromaticity of the carbocyclic ring of such compounds, studies have been undertaken of the 2-aryl-4,6-dinitrobenzotriazole 1-oxides (**2a**–**c**) in which the electron-withdrawing power of the 2-aryl moiety is systematically decreased through the sequential removal of nitro groups. In this paper, we report that **2a** exhibits ambident Diels–Alder reactivity towards cyclopentadiene (Cp). This discovery opens the way to the synthesis of highly functionalized benzotriazole derivatives with defined stereochemistry. Importantly, the results point to a direct relationship between superelectrophilic and pericyclic behaviour.

So far no firm assessment of the electrophilic reactivity of **2a** or related benziotriazole systems, in terms of meaningful thermodynamic and kinetic data, has been reported. Therefore, we have carried out a kinetic and thermodynamic study of the reactions of hydroxide ion in water with the various substrates **2a**–**c** yielding the hydroxide adducts **4a**–**c** according to eq. [1]. Our results reveal that the reactivity of compounds **2a**–**c** is greater than that of the conventional Meisenheimer electrophile 1,3,5-trinitrobenzene (TNB) (9), but only that of **2a** is found to approach that of **1a**, providing further evidence of the superelectrophilic behaviour of structure **2**.

Results

Reaction of Pi-DNBT (2a) with cyclopentadiene

Treatment of **2a** with excess cyclopentadiene in a CH_2Cl_2–THF mixture at room temperature results in nearly quantitative formation of a product (5 h), which was readily isolated as a pale yellow solid after addition of pentane. ^1H and ^{13}C NMR spectra of this solid (CD_3CN solvent) consisted of only one set of signals, indicating that the reaction has proceeded with a high stereoselectivity, affording only the diastereomer **7** (only one enantiomer is shown).

7

8

The proposed stereochemistry for **7** has been derived from a detailed NMR analysis which has included COSY, HETCOR, as well as *J*-modulation and NOE experiments. In particular, 2D-NOE experiments have revealed that the H-7, H-10, H-11, and

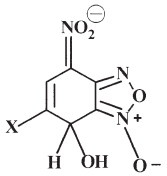
© 2001 NRC Canada

H-14 protons (but not the H-14′ proton) are located on the same side of the dihydrooxazine *N*-oxide and cyclopentene rings of **7**. The values of the related ^3J coupling constants ($^3J_{H7\text{-}H10}$ = 5.6, $^3J_{H10\text{-}H11}$ = 8.9 Hz) agree with the *cis* arrangement of the H-7, H-10, and H-11 protons (12*a*). On the other hand, the observation of a W-type ^4J coupling constant between the H-5 and H-7 protons ($^4J_{H5\text{-}H7}$ = 2.8 Hz) implies a *trans* addition of the two Cp molecules (13, 14). In accord with the strong electron-withdrawing effect of the O-N^+-O^- fragment of the dihydrooxazine ring, both the sp^3 carbon C-11 and the related H-11 proton of **7** are strongly deshielded (δC_{11} = 93.02, δH_{11} = 5.77 ppm in CD_3CN) with the C-11 resonance comparing well with that of the nitro-substituted quaternary carbon C-4 (δC_4 = 93.17 ppm) (15). The close analogy between the resonances of the protons and carbons of the three carbocyclic rings of **7** with those of the related DNBF adduct **8** further supports our stereochemical assignment (Tables 1 and 2) (12*c*). Note that the stereochemistry illustrated in structure **8** was determined independently by X-ray diffraction studies. That the benzotriazole **2a** undergoes addition of 2 mol of cyclopentadiene to give the diadduct **7** was also confirmed by mass spectrometry (HRMS). Attempts to get precise information on the reaction sequence leading to **7** by carrying out similar experiments at 0°C have been unsuccessful because of solubility problems.

Reactions of the 2-aryl-4,6-dinitrobenzotriazole 1-oxide series (2a–c) with OH^-

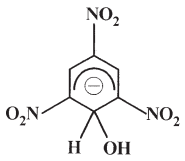
All rate and equilibrium measurements pertaining to eq. [1] were made at 25°C and constant ionic strength of 0.2 mol dm^{-3} maintained with KCl. Measurements of absorbance at λ max of the σ-adducts **4a–c** (λ max ca. 470 nm) were first made at equilibrium as a function of pH. These describe clear-cut acid–base behaviour, as evidenced by the observation of excellent straight lines with unit slopes fitting eq. [2]. Here, pK_a refers to the reaction of **2a–c** with water to produce **4a–c** and a proton.

$$[2] \qquad \log [\mathbf{4a\text{–}c}]/[\mathbf{2a\text{–}c}] = pH - pK_a$$



Plots are shown in Fig. 1 and yield the following pK_a values: **2a** 6.70 ± 0.05, **2b** 9.0 ± 0.05, **2c** 10.73 ± 0.05. The pH ranges required for these pK_a determinations were conveniently covered by using amine buffers made up from *N*-substituted aminoethane or propane sulfonic acids, namely TES, HEPES, TAPS, and CAPS which are known to be rather unreactive in nucleophilic processes (16).

Using a stopped-flow apparatus, the interconversions of **2a–c** and **4a–c** were then kinetically investigated under pseudo-first-order conditions. Solutions of the substrates (ca. 3×10^{-5} mol dm^{-3}) in water containing HCl (1×10^{-3} mol dm^{-3}) were mixed with the appropriate KOH solutions (2×10^{-3} – 6.1×10^{-2} mol dm^{-3}). In agreement with the direct equilibrium approach described by eq. [1], only one relaxation time corresponding to the complete formation of the adducts **4a–c** was observed in all cases. For each of the reactions studied, plots of k_{obsd} vs. the KOH concentration afforded excellent straight lines with zero intercepts. This shows that the k_{-1} pathway makes a negligible contribution so that the k_{obsd} values are given by the simple eq. [3] (Fig. 2). From the slopes of these lines, values of k_1^{OH} were readily determined. Then the k_{-1} values could be calculated by means of eq. [4].

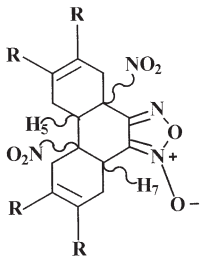


$$[3] \qquad k_{obsd} = k_1^{OH}[OH^-]$$

$$[4] \qquad k_{-1} = k_1^{OH} K_e [K_a]^{-1}$$

Values of the various rate and equilibrium parameters for the formation and decomposition of **4a–c** together with the related parameters for the DNBF adduct **5a**, the 4-nitrobenzofuroxan (NBF, **1b**) adduct **5b**, and the TNB adduct **6** are given in Table 3 for purposes of comparison.

5a X = NO_2
5b X = H



6

Discussion

The Diels–Alder reactivity of Pi-DNBT (2a)

Two main factors have long been suggested as contributing to the exceptional ease of formation and stability of adducts such as **5a** formed by reaction with the superelectrophile **1a**. The first is the combination of the strong electron-withdrawing effects of the nitro groups and the annelated furoxan ring (1–5). The result is not only a high electron deficiency at C-7 of the carbocyclic ring, and hence a high susceptibility of this ring position to nucleophilic attack, but also a high stability for the resultant σ-adducts, as a function of the high electron-delocalizing capability of the ring structure. The second factor is the relatively low aromaticity of the benzofuroxan system which is expected to favour covalent addition compared to most common aromatic and heteroaromatic systems, e.g., TNB or 3,5-dinitropyridine (9*a*, 17).

Evidence that the aromaticity factor is actually very important in determining the electrophilic reactivity of the nitrobenzofuroxan system has recently come from the discovery that DNBF is a remarkably versatile reagent in Diels–Alder reactions. We have shown that it may act as dienophile or heterodiene, depending upon the reaction partners employed and the experimental conditions (12, 18). In this regard, an early report by Kresze and Bathelt (19) that DNBF reacts to some extent with 2,3-dimethylbutadiene and 1,3-butadiene to afford the adducts **9** has remained essentially unnoticed in the literature.

Most importantly, strong pericyclic reactivity could be observed with other highly activated nitrobenzofuroxans, e.g., the 4-nitro-6-trifluoromethylsulfonyl and 4-aza-6-nitrobenzo-furoxans for which pK_a values of 2.95 and 3.8 have been measured, respectively, for water addition in aqueous solution, but not with less activated compounds such as 4-nitrobenzofuroxan itself (pK_a = 10.32) (18, 20, 21)[2]. It thus appears that there is a clear correlation between the superelectrophilic and pericyclic behaviours in this series of 10 π electron heteroaromatic substrates.

Since pericyclic reactions are governed by HOMO–LUMO interactions (22) and similarly electrophile–nucleophile reactions are governed by the LUMO energy of the electrophilic partner and the HOMO energy of the nucleophilic partner (23), this observed correspondence between pericyclic and superelectrophilic reactivity follows the parallelism in the fundamental nature of both types of processes. We emphasize the salient point that *it is only the most superelectrophilic member of the series of benzotriazole 1-oxides,* ***2a****, that also displays Diels–Alder reactivity.*

In this context, our finding that **2a** reacts with cyclopentadiene (Cp) at room temperature to afford the highly functionalized stereoselective diadduct **7** supports the idea that the 4,6-dinitro-substituted carbocyclic ring of the most activated benzotriazole has a relatively low aromaticity. Interestingly, neither the *N-para*-nitrophenyl nor the *N*-phenyl analogues **2b** and **2c** which have pK_a values comparable to that of NBF (**1b**) show similar pericyclic reactivity upon treatment with cyclopentadiene, thus adding to the evidence of a close relationship between the degree of electron deficiency of the carbocyclic ring and the Diels–Alder reactivity of this ring.

In the case of the reaction of **1a** with Cp, it has been clearly demonstrated that the formation of the diadduct **8** proceeds according to Scheme 1 (12*c*). Following a diastereoselective and regioselective normal electron-demand condensation leading to the formation of the monoadduct **10** under kinetic control (path A), the diadduct **8** is formed as the result of two consecutive inverse and normal electron demand processes which take place with a high stereoselectivity at the C-6—C-7 and C-4—C-5 double bonds of the carbocyclic ring. This reaction sequence is consistent with theoretical calculations which point to the activated 6,7-double bond of DNBF as being the preferred site for

Scheme 1.

normal as well as inverse Diels–Alder reactivity (24). Then, a second cycloaddition can take place at the remaining activated C-4—C-5 double bond of the resulting monoadduct **11**, akin to the reactivity of nitroolefins (25, 26). Although we were not able to carry out a similarly detailed study of the behaviour of **2a** at low temperatures (vide supra), it is reasonable to assume by analogy that the formation of the diadduct **7** is the result of the two-step sequence of path B in Scheme 1. That the two condensations leading to **12** and then to **7** proceed through *endo* processes with a *trans* addition of the two cyclopentadiene molecules is reminiscent of the situation which prevails in the formation of all DNBF diadducts (6*b*, 6*c*, 18, 20).

The electrophilic character of the 2a–c series

So far, the pK_a values of DNBF (3.73) (1*a*) and TNB (13.43) (26) represent the extremes in the scale of measuring

the electron deficiency of aromatic and heteroaromatic substrates as derived from the susceptibility of these compounds to undergo covalent hydration in aqueous solution (9). In this regard, Table 3 shows that the pK_a values for the three benzotriazole 1-oxides **2a–c** fall in the midrange between those of DNBF and TNB with the *N*-phenyl-substituted derivative **2c** being the weakest electrophile of the family, as expected, with a pK_a value (10.73) close to that of 4-nitrobenzofuroxan (10.32). Introduction of nitro groups in the phenyl ring of **2c** has a major effect on the ease of σ-complexation of the 4,6-dinitro-substituted carbocyclic ring, as evidenced by the measurement of pK_a values of 9.0 and 6.70 for formation of the hydroxy adducts **4b** and **4a** derived from the *N*-(4′-nitrophenyl) and *N*-(2′,4′,6′-trinitrophenyl) compounds **2b** and **2a**, respectively. This corresponds to a major shift in electrophilic character from that of the reference electrophile TNB, approaching in the case of **2a** the recognized superelectrophilic character of DNBF (1, 5–9). Interestingly, an X-ray analysis of **2a** has revealed that the picryl ring and the benzotriazole ring system are in an almost orthogonal orientation, due to a strong steric compression of the adjacent ortho–nitro and *N*-oxide functions (10*a*). This type of steric compression may be reasonably expected to also prevail in the corresponding adduct **4a**. Based on this, the strong activating effect exerted by the picryl ring on the susceptibility of the 4,6-dinitro-substituted carbocyclic ring of **2a** to covalent hydration must be the result of inductive and (or) field effects rather than conjugation effects.

Using again the data for the DNBF and TNB as the references, Table 3 also reveals that the k_1^{OH} rate constants for the hydroxide ion attack on our three benzotriazole 1-oxides (**2a–c**) to generate the adducts **4a–c** (eq. [1]), are intermediate between the two extremes, with relatively minor variations on going from **2c** to **2a**. In fact, a most noteworthy finding is that the k_{-1} values that measure the tendency of the three adducts **4a–c** to undergo spontaneous decomposition are all much lower than the value measured for the TNB adduct **6**. On the other hand, it is also of much interest that the changes in k_{-1} are essentially responsible for changes in the pK_a values for **2a–c**. This is clearly consistent with the idea that the Marcus intrinsic barrier for the σ-complexation process increases on going from **2c** to **2a**. This effect of nitro substitution on the intrinsic barrier may be understood as the result of charge delocalization being extensive in the resulting adducts **4a–c**, but only slightly developed at the transition state (27). In the case of **4c**, the k_{-1} value is about 30-fold greater than for the mononitrobenzofuroxan adduct **5b**, suggesting that some electron donation from the monosubstituted phenyl ring to the heterocyclic framework of the benzotriazole may occur in this instance.

Conclusions

The present work has shown definitively that the 4,6-dinitrobenzotriazole 1-oxide structure **2**, when appropriately substituted as in **2a**, can exhibit overall ambident pericyclic reactivity, i.e., normal and inverse electron demand cycloadditions take place with high stereoselectivity. This behaviour, which was found previously for **1a**, may extend to a wide range of low aromaticity heteroaromatics and investigation of the generality of such reaction is a thrust of inves-

tigations in our laboratories. It is also important to note that the relative ease of displacement of the picryl moiety from adducts such as **7** by nucleophiles would afford a facile route to the synthesis of functionalized triazole deriviatives of defined stereochemistry with potential pharmacological activity.

The kinetic and equilibrium data reported here show that the electrophilic character of the 4,6-dinitrobenzotriazole 1-oxide strudcture is closer to that of the nitrobenzofuroxans (i.e., **1a**, **1b**) than that of the standard aromatic electrophile TNB. This result is believed to be largely the reflection of a rleatively low aromaticity of the carbocyclic ring. Overall, the finding of a dual electrophilic and pericyclic behaviour for **2a** adds a new facet to the extremely rich chemistry of the benzotriazole 1-oxide structure (32, 33).

Experimental

Materials

The 4,6-dinitrobenzotriazole 1-oxides **2a** and **2b** were available from previous studies (11); the preparation of **2c** is described below. Reagent grade TES (2-*N*-[tris(hydromethyl) methyl]aminoethane sulfonic acid), HEPES (*N*-2-hydroxylethylpiperazine-*N*′-2-ethanesulfonic acid, (3-*N*-[tris(hydroxylmethyl)methyl]aminopropanesulfonic acid), and CAPS (3-[cyclohexylamino]propanesulfonic acid) were of the highest purity obtainable from commerical sources and used without further purification to prepare buffer solutions if the pH range required for the pK_a determinations of **2a**–**2c**. KOH solutions were prepared from Titrisol.

Synthesis of 2c

1-Chloro-2,4,6-trinitrobenzene (picryl chloride, 3.0 g, 0.012 mol) was dissolved in 95% ethanol (ca. 25 mL) in a 50 mL round-bottomed flask. Phenylhydrazine (2.8 g, 2.4 mL, 0.025 mol) was dripped into the stirring solution. The brick red picrylhydrazobenzene solidified in the flask, more ethanol was added (15 mL), and the suspension was stirred and warmed for 3 h. The final suspension was cooled to room temperature and the crude product collected by suction filtration, washed with dilute HCl (0.3 M), and then distilled water. The product was dried in a vacuum dry-box and recrystallized from 95% ethanol to give picrylhydrazobenzene (2.65 g, 69%), mp 179 to 180°C (lit. (29) 181°C). R_f (TLC, CH_2Cl_2) 0.26. Picrylhydrazobenzene (0.50 g, 1.6 mmol) was cyclized in glacial acetic acid to 2-phenyl-4,6-dinitrobenzotriazole 1-oxide (**2c**) according to the method of Joshi and Deorha (30). Yield (after recrystallization from CH_3CN): 0.25 g, 51% (metallic, golden plates), mp 248–254°C (lit. (31) 249 to 250°C). R_f (CH_2Cl_2) 0.36.

Synthesis of 7

2-(2′,4′,6′-Trinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (**2a**) (86 mg, 0.197 mmol) was dissolved in a CH_2Cl_2–THF mixture and an excess of freshly distilled cyclopentadiene (1 mL) was added. The solution was maintained under stirring at room temperature for 5 h, then concentrated under reduced pressure. After addition of an excess of pentane, a pale yellow solid was isolated and dried under pump vacuum. Compound **7** was obtained in 92% yield (103 mg) and gave satisfactory analytical data. ^{1}H NMR: 300 MHz, acetonitrile-d_3, see Table 2. ^{13}C NMR: (see Table 1). FAB$^+$-MS mass spectrum (obsd). *m*/*z*: 569.1017 (reference *m*-nitrobenzyl alcohol), $C_{22}H_{14}N_8O_{11}$ requires 569.0984.

Rate and pK_a measurements

Stopped-flow determinations were performed on an Applied Photophysics spectrophotometer, the cell compartment of which was maintained at 25° ± 0.2°C. Other kinetic and pK_a measurements were made using a Varian Cary 1E spectrophotometer. All kinetic runs were carried out in triplicate under pseudo-first-order conditions with a substrate concentration of 2 to 3 × 10^{-5} mol dm^{-3}. In the case of **2c**, the measurements have been made in 90% H_2O – 10% Me_2SO (v/v) to overcome solubility problems but this low Me_2SO content does not have any major influence on the discussion of the results (1*b*). All rate constants are accurate to ±3%.

Lewis acid-mediated intramolecular addition of silyl enol ethers to internal unactivated alkynes

Ken-ichiro Imamura, Eiji Yoshikawa, Vladimir Gevorgyan, Tomoko Sudo, Naoki Asao, and Yoshinori Yamamoto

Abstract: The $EtAlCl_2$-mediated intramolecular addition of silyl enol ethers to both terminal and internal unactivated alkynes, bearing alkyl and phenyl susbstituents at the alkyne moiety, gave mono- and bicyclic β,γ-unsaturated ketones in good to excellent yields. On the other hand, the silyloxy-substituted cyclic vinylsilanes were obtained in moderate to high yields when the reactions were catalyzed by $B(C_6F_5)_3$ in the presence of triethylsilane. All the reactions proceeded via *endo*-fashion exclusively. The mechanisms of these regiospecific Lewis acid-assisted carbocyclizations are proposed.

Key words: Lewis acid, silyl enol ethers, carbocyclization, alkynes.

Résumé : La réaction, catalysée par le $EtAlCl_2$, d'addition intramoléculaire d'éthers énoliques silylés sur des alcynes internes ou en position terminale portant des substituants alkyles et phényles au niveau de l'alcyne conduit à la formation de cétones β,γ-insaturées mono- et bicycliques, avec des rendements allant de bons à excellents. Par ailleurs, les réactions catalysées par du $B(C_6F_5)_3$ en présence de triéthylsilane conduisent à la formation de vinylsilanes cycliques, substitués par des groupes silyloxy, avec des rendements allant de modérés à élevés. Toutes les réactions se produisent exclusivement de façon *endo*. On propose des mécanismes pour ces carbocyclisations régiospécifiques assistées par des acides de Lewis.

Mots clés : acide de Lewis, éthers énoliques, carbocyclisation, alcynes.

[Traduit par la Rédaction]

Introduction

The development of new selective carbocyclization methodologies is an important task for synthetic organic chemists (for reviews see ref. 1). Carbocyclization of alkynes is of particular interest since it provides an access to unsaturated carbo- and heterocycles (for a review, see for example ref. 2). Among several known methods of carbocyclization of alkynes (1, 2), the intramolecular addition of silyl enol ethers to acetylenes has proven to become one of the effective complementary tools towards medium-sized carbocycles. Two approaches are known to date to encourage a weak nucleophile, such as a silyl enol ether, to add intramolecularly across a carbon—carbon triple bond (3).[2] First is a well explored $HgCl_2$-mediated *exo*-carbocyclization (eq. [1]) (4, 5),[3] in which mercury activates an enolate moiety of **1** by forming a transient α-keto mercurial species **2**. Either the product **4** or the isomeric *trans*-addition product **6** is obtained through *syn*-addition of enolate to the η^2 neutral **3** (pathway **A**) or *anti*-addition to the η^2 cationic **5** (pathway **B**) species, respectively.

The second is a very recent approach where a W complex catalytically activates an alkyne moiety (toward nucleophilic addition of enolate) via formation of the alkyne–vinilydene intermediate **7**, which, after concomitant *anti*-addition of silyl enol ether to its electrophilic central carbon, forms an *endo*-carbocyclization product **8** (eq. [2]) (6).[4]

Despite the obvious synthetic importance of the mentioned methodologies (7),[5] the scope of their application is limited to use of terminal (4–6)[3,4] and masked terminal (silyl-protected) (4*c*-4*d*, 7)[5] alkynes. Recently, we reported the first examples of the third alternative approach: Lewis acid-mediated intramolecular addition of silyl enol ethers to both terminal and internal unactivated alkynes (8). Now we report the $B(C_6F_5)_3$-catalyzed cyclization reactions of the carbon-tethered alkynyl silyl enol ether in the presence of

triethylsilane along with a detailed study on the $EtAlCl_2$-mediated reactions (Lewis acid-catalyzed intramolecular carbosilylation of alkynes are reported; see ref. 9).

Results and discussion

$EtAlCl_2$-mediated intramolecular addition of silyl enol ether to alkynes

As we have previously shown, the intramolecular addition of silyl enol ethers of **9** to internal alkynes is mediated by $EtAlCl_2$ to give cyclic products **10** in good to high yields (eq. [3], Table 1). The reaction of **9a** in the presence of stoichiometric amounts of $EtAlCl_2$[6] afforded the cyclization product **10a** in 70% isolated yield (entry 1). The reaction of **9b** bearing *t*-Bu-Me_2Si group instead of Me_3Si group also proceeded smoothly to give **10a** in 63% (entry 2). Optimization experiments revealed that the reaction under 0.1 mol L^{-1} concentration gave the best result (entries 1, 3–5). The carbocyclizations of methyl- (**9c**) and butyl-substituted (**9d**) alkynyl silyl enol ethers gave β,γ-unsaturated ketones **10b–c** in 57 and 80%, respectively. The reaction of the silyl enol ether containing trisubstituted alkene **9e** also proceeded smoothly to give **10d** in 76% yield. In all above cases, the β,γ-unsaturated ketones **10a–d** were accompanied with detectable amounts of isomeric α,β-unsaturated cyclohexenones **11a–d**, which are obviously the thermodynamic products.[7] It should be pointed out that in all cases the carbocyclizations proceeded in exclusive *endo*-fashion and no traces of *exo*-cyclization product **12** were detected by GC–MS and NMR analyses of the crude reaction mixtures.

9 **10** **11** **12**

not detected

[6] Other Lewis acids such as $HfCl_4$, $ZrCl_4$, and $InCl_3$ did not mediate this carbocyclization, whereas the use of $AlBr_3$, $MeAlCl_2$, Et_2AlCl, and $GaCl_3$ in some cases gave the carbocyclization products although the chemical yields with these Lewis acids were low (≤40%).

[7] The control experiments have confirmed that β,γ-enone **10** is the kinetic product, which isomerized into the thermodynamic product (α,β-enone **11**) under the reaction conditions. Thus, normally the carbocyclization of **9c** gives about a 95:5 ratio of **10c**:**11c** (eq. [3]); after being stirred for an additional 3 h at room temperature, the mentioned ratio changed to 44:56, whereas after 12 h, the isomeric **11c** became the major reaction product accompanied by traces of **10c**.

[a]Reactions were conducted in toluene at 0°C for 3 h.

$EtAlCl_2$-mediated carbocyclization of cyclic substrates **13**, as well as that of their acyclic analogues **9**, proceeded in exclusive *endo*-fashion to give bicylic β,γ-cyclohexenones **14** in good yields (eq. [4]). Substrates possessing both terminal (**13a**) and internal (**13b**) alkynyl moieties effectively cyclized to give the bicylic **14a** and **14c** in 78 and 84% isolated yields, respectively. Furthermore, quenching the reaction mixtures with electrophiles, such as D_2O and I_2, afforded the corresponding D- (**14b**) and I-containing (**14d**) products in good yields.

We propose the following plausible mechanism for the observed Lewis acid-mediated exclusive *endo*-carbocyclization of carbon-tethered alkynyl silyl enol ethers. As we previously proposed for the Lewis acid-catalyzed hydro- and allylmetalation of alkynes (9), the coordination of the triple bond of **15** to Lewis acid would form zwitterionic intermediate **16** (eq. [5]). The double bond of silyl enol ether moiety would attack the vinyl cation of **16** at the most nucleophilic terminal position in an *anti*-fashion affording the *endo*-mode cyclization intermediate **17**. The elimination of the TMSCl from **17** would form the vinyl metal **18**, which after trapping with an electrophile would produce **19**.

[5]

An application of the above methodology is shown in eq. [6]. Naphthol **21** could be synthesized from the unsaturated analogue **20**, although in modest unoptimized yield (40% by ^1H NMR, eq. [6]).

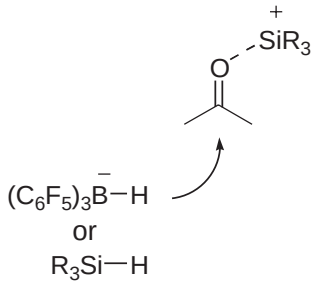
$B(C_6F_5)_3$-catalyzed intramolecular addition of silyl enol ether to alkynes

Although the above mentioned carbocyclization reaction demonstrated the first example of the Lewis acid-mediated addition of silyl enol ethers to internal unactivated alkynes, the synthetic utility of this methodology is limited by the fact that a stoichiometric amount of $EtAlCl_2$ is needed. This prompted us to search for a more synthetically useful catalyst for this reaction. Attempted reaction of **9b** in the presence of a catalytic amount of $B(C_6F_5)_3$ did not proceed at all. However, the $B(C_6F_5)_3$-catalyzed reaction proceeded dramatically by addition of triethylsilane and the silyloxy-substituted cyclic vinylsilane **22a** was obtained in 49% yield (eq. [7]) (10).[8] The compound **10a**, which was produced in the $EtAlCl_2$-mediated reaction, was not formed at all. The $B(C_6F_5)_3$-catalyzed cyclization reaction using other substituted substrates **9f** and **9g** also proceeded smoothly under the same conditions as those in the case of **9b** to afford **22b** and **22c** in 61 and 63% yield, respectively.

9b: R=Ph
9f : R=Me
9g: R=Bu

22a: R=Ph 49%
22b: R=Me 61%
22c: R=Bu 63%



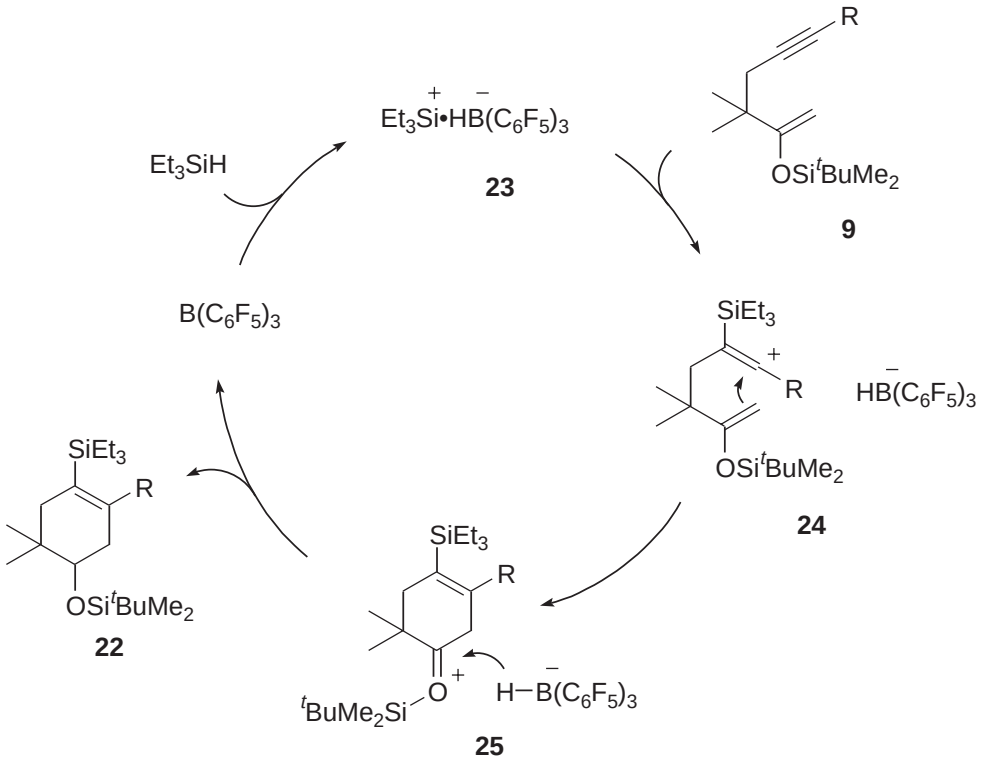
Piers and co-workers (10)[8] proposed the interesting silane activation mechanism in the $B(C_6F_5)_3$-catalyzed hydrosilylation of aldehydes and ketones; the ordinary mechanism, in which the carbonyl oxygen of the electrophiles coordinates to $B(C_6F_5)_3$ and thus carbonyl substrates are activated, is not operative in the $B(C_6F_5)_3$-catalyzed reduction. Their extensive mechanistic studies clarify that $B(C_6F_5)_3$ activates the silane via hydride abstraction to form the incipient silylium species which enhances the electrophilicity of carbonyl group, facilitating the reduction by $[HB(C_6F_5)_3]^-$ or R_3SiH (Fig. 1).

Most probably, silylium species **23** is generated here also and a plausible mechanism for the $B(C_6F_5)_3$-catalyzed cyclization reaction of **9** is shown in Scheme 1. The π-coordination of acetylenic bond of **9** to the silylium species would form the cationic intermediate **24**. The silyl enol ether moiety would attack the electron deficient triple bond from the side opposite to the silylium species to produce an oxonium cation **25**. The reduction of an intermediate **25** by $[HB(C_6F_5)_3]^-$ would form cyclization products **22** and regenerate $B(C_6F_5)_3$.

Experimental

^1H and ^{13}C NMR spectra were recorded on a JEOL LA-300 (300 MHz) and JEOL α–500 (500 MHz) spectrometers. IR spectra were recorded on a Shimadzu FT IR-8200A spectrometer. High-resolution mass spectra were recorded on a JEOL HX-110 spectrometer. Elemental analyses were carried out at the Analytical Center of Tohoku University. GC–MS analysis was performed on a Hewlett-Packard Model 6890 GC interfaced to a Hewlett-Packard Model 5973 mass selective detector (30 m × 0.25 mm capillary column). Column chromatography was carried out employing Merck silica gel (Kieselgel 230–400 mesh), and analytical thin layer chromatography (TLC) was performed on 0.2-mm precoated silica gel plates (Kieselgel 60 F_{254}). All manipulations were conducted under an argon atmosphere using standard Schlenk techniques. Anhydrous solvents were purchased from Kanto Chemicals. Alkyl-tethered alkynyl silyl enol ethers **9** were obtained by consecutive ester propargylation (for a review see ref. 13), conversion to ketone, and silyl enolization (for a review see ref. 14). All other compounds used were commercially available and purchased from Aldrich.

Fig. 1. Mechanism of the $B(C_6F_5)_3$-catalyzed hydrosilylation of the carbonyl group.



Preparation of alkynyl silyl enol ethers 9

The preparation of **9e** is representative. (*i*) To a solution of diisopropylamine (6.73 mL, 48 mmol) in THF (40 mL) was added *n*-BuLi (1.61 M in hexane, 28.6 mL) at 0°C. After being stirred for 30 min, the mixture was cooled to –78°C. To the solution was added methyl isobutyrate (4.58 mL, 40 mmol), and the reaction mixture was stirred for 1 h. To the resulting mixture, phenylpropargyl *p*-toluenesulfonate (11.4 g, 40 mmol) in THF (20 mL) – 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (5.0 mL) was added. The mixture was stirred for 15 min, and then allowed to warm to 0°C. After being stirred for additional 10 min at this temperature, the mixture was quenched with ice-cold saturated, aq NH_4Cl solution and three times extracted with ether. The combined organic phase was washed with H_2O, brine, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography (silica gel, eluent: hexane – ethyl acetate, 15:1) to give methyl 2,2-dimethyl-5-phenyl-4-pentylate (6.96 g, 80% yield). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.41–7.35 (m, 2H), 7.30–7.24 (m, 3H), 3.71 (s, 3H), 2.66 (s, 2H), 1.34 (s, 6H). (*ii*) To a solution of methyl 2,2-dimethyl-5-phenyl-4-pentylate (1.92 g, 8.9 mmol) in THF (18 mL) were added sequentially $TMSCH_2Li$ (1.0 M in pentane, 19.5 mL) and 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (2.15 mL, 18 mmol) at –78°C. After being stirred for 30 min, the mixture was quenched with ice-cold saturated, aq NH_4Cl solution and three times extracted with ether. The combined organic phase was washed with H_2O, brine, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography (silica gel, eluent: hexane – ethyl acetate, 30:1) to give 1-(trimethylsilyl)-3,3-dimethyl-6-phenyl-5-hexyn-2-one (1.85 g, 76% yield). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.40–7.34 (m, 2H), 7.30–7.24 (m, 3H), 2.59 (s,

[8] Piers and his co-workers found that $B(C_6F_5)_3$-catalyzed hydrosilylation of carbonyl functions, such as aldehydes, ketones, and esters, proceeded very smoothly to give the corresponding reduced compounds in high yields.

Scheme 1.

2H), 2.27 (s, 2H), 1.27 (s, 6H), 0.13 (s, 9H). (*iii*) To a mixture of 1-(trimethylsilyl)-3,3-dimethyl-6-phenyl-5-hexyn-2-one (1.85 g, 6.8 mmol) and NaI (1.22 g, 8.1 mmol) in CH_3CN (14 mL) were added sequentially Et_3N (4.54 mL, 33 mmol) and TMSCl (2.58 mL, 20 mmol) at room temperature. After being stirred for 30 min, the mixture was quenched with saturated, aq $NaHCO_3$ solution and three times extracted with pentane. The combined organic phase was washed with brine, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography (silica gel, eluent: hexane – ethyl acetate – pyridine, 20:1:0.1) to give **9a** (1.81 g, 98% yield). (*iv*) To a solution of **9a** (1.33 g, 4.9 mmol) in THF (9.8 mL) was added *n*-BuLi (1.54 M in hexane, 3.32 mL) at 0°C, and the mixture was stirred for 20 min. To the resulting mixture was added MeI (455 μL, 7.3 mmol), and the mixture was allowed to warm to room temperature. After being stirred for 25 min, the reaction mixture was quenched with ice-cold saturated, aq NH_4Cl solution and three times extracted with ether. The combined organic phase was washed with brine, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography (silica gel, eluent: hexane – ethyl acetate, 30:1) to give 4,4-dimethyl-7-phenyl-6-heptyn-3-one (327 mg, 31% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.40–7.33 (m, 2H), 7.30–7.24 (m, 3H), 2.61 (s, 2H), 2.59 (q, *J* = 7.2 Hz, 2H), 1.28 (s, 6H), 1.06 (t, *J* = 7.2 Hz, 3H). (*v*) To a solution of 4,4-dimethyl-7-phenyl-6-heptyn-3-one (281 mg, 1.3 mmol) in CH_2Cl_2 (2.8 mL) were added sequentially Et_3N (274 μL, 2.0 mmol) and TMSOTf (304 μL, 1.6 mmol) at 0°C. The mixture was stirred for 30 min, and then allowed to warm to room temperature. After being stirred for an additional 1 h at this temperature, the mixture was quenched with saturated, aq $NaHCO_3$ solution and three times extracted with pentane. The combined organic phase was washed with brine, dried over $MgSO_4$, filtered, and concentrated. The crude product was purified by column chromatography (silica gel, eluent: hexane – ethyl acetate – pyridine, 20:1:0.1) to give **9e** (302 mg, 81% yield).

*2-(Trimethylsilyloxy)-3,3-dimethyl-6-phenyl-1-hexen-5-yne (**9a**):* colorless oil. HRMS calcd. for $C_{17}H_{24}OSi$ 272.1597; found 272.1600. IR (neat) (cm^{-1}): 3125, 1654, 1624, 1599, 1254, 1021, 847, 755, 691. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.41–7.36 (m, 2H), 7.30–7.24 (m, 3H), 4.18 (d, *J* = 1.7 Hz, 1H), 4.04 (d, *J* = 1.7 Hz, 1H), 2.48 (s, 2H), 1.19 (s, 6H), 0.23 (s, 9H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 164.4, 131.5, 128.1, 127.4, 124.2, 88.4, 87.4, 82.2, 40.0, 30.8, 25.4, 0.2. Anal. calcd. for $C_{17}H_{24}OSi$: C 74.94, H 8.88; found: C 74.72, H 8.68.

*2-(*tert*-Butyldimethylsilyloxy)-3,3-dimethyl-6-phenyl-1-hexen-5-yne (**9b**):* colorless oil. HRMS calcd. for $C_{20}H_{30}OSi$: 314.2066; found: 314.2067. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.41–7.37 (m, 2H), 7.28–7.26 (m, 2H), 4.15 (d, *J* = 1.8 Hz, 1H), 4.03 (d, *J* = 1.8 Hz, 1H), 2.50 (s, 2H), 1.20 (s, 6H), 0.96 (s, 9H), 0.21 (s, 6H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 164.4, 134.5, 128.1, 127.4, 124.2, 88.4, 86.2, 82.2, 40.4, 30.9, 25.8, 25.5, 18.2, –4.8. Anal. calcd. for $C_{20}H_{30}OSi$: C 76.37, H 9.61; found: C 76.22, H 9.56.

*2-(Trimethylsilyloxy)-3,3-dimethyl-1-hepten-5-yne (**9c**):* colorless oil. HRMS calcd. for $C_{12}H_{22}OSi$: 210.1440; found: 210.1422. IR (neat) (cm^{-1}): 3125, 1655, 1622, 1254, 1021, 848. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 4.12 (d, *J* = 1.6 Hz, 1H), 3.99 (d, *J* = 1.6 Hz, 1H), 2.20 (q, *J* = 2.6 Hz, 2H), 1.78

$EtAlCl_2$-mediated carbocyclization of 9 (general procedure)

$EtAlCl_2$ (1.2 equiv) was added to a stirred solution of **9** (0.5 mmol) in toluene (5.0 mL) at 0°C. After being stirred for 3 h, the reaction mixture was quenched with Et_2NH, diluted with saturated, aq $NaHCO_3$ solution, and extracted with ether three times. The combined organic phase was washed with brine, dried over $MgSO_4$, filtered, and concentrated. The products (**10** and **11**) were purified by column chromatography (silica gel, eluent: hexane – ethyl acetate).

*6,6-Dimethyl-3-phenyl-3-cyclohexenone (**10a**):* colorless oil. HRMS calcd. for $C_{14}H_{16}O$: 200.1201; found: 200.1211. IR (neat) (cm^{-1}): 1714, 1672, 1599, 751, 694. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.41–7.25 (m, 5H), 6.22 (tt, J = 4.2, 1.8 Hz, 1H), 3.31 (dt, J = 1.8, 1.8 Hz, 2H), 2.46 (dt, J = 4.2, 1.8 Hz, 2H), 1.20 (s, 6H). ^{13}C NMR (75.5 MHz, CDCl3) δ: 213.4, 139.4, 134.2, 128.5, 127.5, 124.9, 122.1, 43.3, 40.8, 40.1, 24.3. *2,5-Dimethyl-9-oxobicyclo[3,3,1]non-2-ene (**14c**):* colorless oil. HRMS calcd. for $C_{11}H_{16}O$: 164.1200; found: 164.1205. IR (neat) (cm^{-1}): 2966, 2927, 1716, 1446, 1379. ^1H NMR (300 MHz, $CDCl_3$) δ: 5.54 (tq, *J* = 4.0, 1.5 Hz, 1H), 2.70 (t, *J* = 3.0 Hz, 1H), 2.43 (ddq, *J* = 18.0, 4.0, 2.0 Hz, 1H), 2.27 (d, *J* = 18.0 Hz, 1H), 2.00–1.87 (m, 2H), 1.84–1.75 (m, 2H), 1.66 (dt, *J* = 2.0, 1.5 Hz, 3H), 1.62–1.46 (m, 2H), 1.01 (s, 3H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 217.2, 133.8, 122.8, 52.8, 45.1, 44.7, 43.3, 31.5, 23.5, 21.3, 18.5. Anal. calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.42, H 9.93.

*2,5-Dimethyl-3-iodo-9-oxobicyclo[3,3,1]non-2-ene (**14d**):* colorless oil. HRMS calcd. for $C_{11}H_{15}IO$: 290.0167; found: 290.0177. IR (neat) (cm^{-1}): 2932, 2864, 1720, 1446. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.95 (t, *J* = 3.0 Hz, 1H), 2.95 (dd, *J* = 18.0, 2.0 Hz, 1H), 2.76 (d, *J* = 18.0 Hz, 1H), 2.05–1.70 (m, 7H), 1.63–1.53 (m, 2H), 1.00 (s, 3H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 213.5, 138.3, 95.3, 57.0, 54.8, 49.0, 44.4, 31.9, 27.5, 22.6, 18.8. Anal. calcd. for $C_{11}H_{15}IO$: C 45.54, H, 5.21, I 43.74; found: C 45.63, H 5.24, I 43.84.

*3-Propyl-1-naphthol (**21**):* colorless oil. HRMS calcd. for $C_{13}H_{14}O$: 186.1044; found: 186.1045. IR (neat) (cm^{-1}): 3393, 2958, 2929, 1638, 1599, 1578. ^1H NMR (300 MHz, $CDCl_3$) δ: 8.13–8.08 (m, 1H), 7.75–7.71 (m, 1H), 7.48–7.38 (m, 2H), 7.22 (s, 1H), 6.67 (s, 1H), 5.39 (s, 1H), 2.67 (t, *J* = 7.5 Hz, 2H), 1.70 (tq, *J* = 7.5, 7.5 Hz, 2H), 0.96 (t, *J* = 7.5 Hz, 3H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 151.2, 140.6, 134.8, 127.2, 126.4, 124.4, 122.8, 121.3, 119.2, 110.1, 38.2, 24.2, 13.8.

$B(C_6F_5)_3$-mediated carbocyclization of 9 (general procedure)

To a solution of $B(C_6F_5)_3$ (0.1 mmol, 20 mol%) in toluene (1.0 mL) were added triethylsilane (0.16 mL, 1.0 mmol) and substrate **9** (0.5 mmol) at 0°C, successively. After being stirred for 15 min, the reaction mixture was diluted with pentane, quenched with Et_2NH, filtered through Al_2O_3, and concentrated. The product was purified by column chromatography (silica gel, eluent: hexane).

*[5-(*tert*-Butyldimethylsilyloxy)-4,4-dimethyl-2-(triethylsilyl)-cyclohex-1-enyl]-benzene (**22a**):* colorless oil. *1-Butyl-5-(*tert*-butyldimethylsilyloxy)-4,4-dimethyl-2-(triethylsilyl)-cyclohexene (**22c**):* colorless oil. HRMS calcd. for $C_{24}H_{50}OSi_2$: 410.3401; found: 410.3400. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.46 (dd, *J* = 7.5 and 5.5 Hz, 1H), 2.12–1.73 (m, 6H), 1.39–1.26 (m, 4H), 0.91 (t, *J* = 8.0 Hz, 9H), 0.88 (s, 3H), 0.77 (s, 3H), 0.62 (q, *J* = 8.0 Hz, 6H), 0.03 (d, *J* = 3.7 Hz, 6H). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 145.9, 125.1, 74.4, 43.1, 37.7, 37.4, 34.1, 31.6, 31.3, 27.1, 25.9, 23.1, 22.7, 20.7, 18.0, 14.2, 7.6, 4.3, −4.0, − 4.9.

Conclusion

We demonstrated for the first time an intramolecular addition of silyl enol ethers to both terminal and internal unactivated alkynes by using Lewis acid. While the $EtAlCl_2$-mediated reaction gave cyclohexenone derivatives, the silyloxy-substituted cyclic vinylsilanes were produced in the $B(C_6F_5)_3$-catalyzed reaction in the presence of Et_3SiH. The presented *endo*-selective method could be used for the construction of mono- and bicyclic compounds possessing a cyclohexenone framework.

Synthetic studies of novel ninhydrin analogs

Richard R. Hark, Diane B. Hauze, Olga Petrovskaia, and Madeleine M. Joullié

Abstract: Ninhydrin is an essential tool in the analysis of amino acids, peptides, and proteins, and the preferred reagent for the detection of latent fingerprints on porous surfaces. The goal of this investigation was to prepare ninhydrin analogs with enhanced chromogenic and fluorogenic properties. Target compounds included structures with extended conjugation and (or) with the presence of sulfur-containing moieties. We have devised general convergent routes for novel heterocyclic and aryl-substituted ninhydrin analogs for use as reagents for amino acid detection.

Key words: ninhydrin analogs, synthesis, ketals, Suzuki cross-coupling reactions, Stille cross-coupling reactions.

Résumé : La ninhydrine est un outil essentiel pour l'analyse des acides aminés, des peptides et des protéines ainsi que le réactif privilégié pour la détection d'empreintes digitales latentes sur des surfaces poreuses. Le but de ce travail était de préparer des analogues de la ninhydrine ayant des propriétés chromogènes et fluorogènes accrues. Les composés cibles incluaient des structures avec conjugaison accrue et/ou comportant la présence de portions contenant du soufre. On a mis au point des voies générales convergentes permettant de préparer de nouveaux analogues hétérocycliques de la ninhydrine ainsi que d'autres portant des substituants aryles pour utiliser comme réactifs de détection des acides aminés.

Mots clés : analogues de la ninhydrine, synthèses, cétals, réaction de couplage croisé de Suzuki, réactions de couplage croisé de Stille.

[Traduit par la Rédaction]

Introduction

Ninhydrin or 2,2-dihydroxy-1,3-indanedione (**1**, Fig. 1) has earned a prominent place in chemistry, biochemistry, and forensic science due to its color-forming reaction with amino acids and amines found in fingerprint residues (1). The chemistry of this interesting compound has been the subject of several reviews (2–6).

Since its serendipitous discovery by Ruhemann (7), ninhydrin (**1**) has been a widely used reagent in several areas of chemistry. Although **1** reacts with a plethora of reagents to give a wide variety of structures (5), it is best known for its reactions with amines and amino acids to give the colored compound known as Ruhemann's purple (8, 9). These complex reactions have been a subject of prolonged investigations (5) and are still of current interest (10). Of particular relevance is the work of Grigg and co-workers (11–13), who established the intermediacy of 1,3-dipoles in the formation of Ruhemann's purple and the studies of the transition-metal complexes of Ruhemann's purple by Davies et al. (14, 15).

Our interest in the synthesis of novel ninhydrin analogs to be used in the detection of latent fingerprints has led us to investigate previously reported approaches to ninhydrin to prepare new reagents with enhanced optical properties. During the course of these investigations, we have examined several chemical and physical properties of substituted ninhydrin analogs and have devised new synthetic approaches to some of these compounds.

Ninhydrin (**1**) is the forensic specialist's top choice for latent print detection on porous surfaces (1). It is affordable and easy to apply. The developed dark purple fingerprints are easy to detect by the naked eye and do not require special viewing conditions. The ninhydrin reaction has the advantage of forming a product with a high molar extinction coefficient under very mild reaction conditions.

However, despite its obvious advantages for forensic applications, the fluorogenic and chromogenic properties of ninhydrin can be improved. For example, Herod and Menzel (16) reported that fingerprints which were developed with ninhydrin could be made to fluoresce after treatment with zinc chloride. Formation of fluorescent complexes resulted in enhanced sensitivity and improved contrast between the fingerprint and the background but at the expense of introducing an extra step in processing the prints. An ideal reagent should display high sensitivity as both a chromogen and a fluorogen without secondary treatment.

The high polarity of ninhydrin does not allow much versatility in choosing solvent formulations. The choice of sol-

1

vents presents a serious challenge (17) since the solvent has to be volatile, nontoxic, nonflammable, environmentally safe (ozone friendly), and affordable. Polar solvents, such as methanol, diffuse the ink frequently found in pieces of evidence and therefore are unsuitable for forensic applications. Previously used freon-based ninhydrin formulations that were once considered ideal are no longer acceptable because of the environmental impact of freons. The constraints imposed by solubility are a factor that must be considered in the design of new analogs.

Modifications in the structure of ninhydrin are an attractive approach for obtaining a highly effective amino acid reagent for forensic and analytical applications. Expansion of the conjugated system and introduction of appropriate substituents, such as amino, alkoxy, or thioalkoxy groups, can in principle, cause an increase in molar extinction coefficients, as well as blue or red shifts in absorption maxima of Ruhemann's purple analogs. An array of ninhydrin-type reagents with a wide range of absorption maxima allows for the optimal selection of visualizing reagents for specific backgrounds. Modifications of the chromophore can also induce fluorescence. Appended nonpolar moieties can improve the solubility of the reagent. The structural changes that affect the spectral properties of the products in the amino acid reactions should not, however, adversely affect the reactivity of the vicinal triketone fragment.

In view of these considerations, a large number of ninhydrin analogs has been synthesized and evaluated. By 1992, the data on approximately 30 ninhydrin analogs had been reported in the literature (18). At the present time, due to our efforts and those of other groups, this number has tripled. The term "ninhydrin analogs" is typically used to describe compounds with a vicinal cyclopentatrione moiety fused to an aromatic ring. They are usually represented in their most stable hydrate form (19).

Figure 2 gives an extensive overview of all known ninhydrin analogs, some of which will be subsequently described.

The first ninhydrin analog, **38**, was synthesized by Ruhemann in an attempt to prepare a compound with greater solubility in organic solvents (20, 21). Since that time numerous analogs (e.g., **5**, **7**, **13** (22), **8** (23), **40** (24), **73** (25), **80** (26, 27), **81**, **83** (28), **74**, **75** (29, 30), **73** (31), **34** (20), **44** (32), **72** (33), **76** (34), **78** (35), and **9**[5]) have been prepared for a variety of uses, including natural product synthesis and studies of reaction kinetics and charge transfer complexes. The majority of ninhydrin analogs have been prepared for forensic evaluation. Compounds **2**, **6**, **15**, **36**, **37**, **43**, **45**, **46**, and **69** were studied by Lennard et al. (36, 37). Joullié and co-workers have synthesized compounds **68** (38), **70**, **84** (38, 39), **23** (40), **10**, **47**–**49**, **52**–**62**, **67**, **86**, **87** (41, 18), **22**, and **85** (42). To identify potential fingerprint reagents, Almog et al. (43–47) have conducted extensive evaluations of ninhydrin analogs, many of which they have synthesized (**3**, **4**, **11**, **12**, **14**, **16**, **21**, **24**, **28**, **41**, **71**, and **77**). Recently, Della and co-workers (48–50) synthesized compounds **17**–**20**, **25**–**27**, **29**–**32**, **39**, **50**, **64**, and **79**.

At the time the present work was initiated, Cantu et al. (51) reported the forensic evaluation of eight ninhydrin analogs as well as **1**. Subsequently, other analogs were developed and evaluated by different groups (43, 52, 1, 53–55). Compounds **23** and **84** were considered to be the most promising reagents. These compounds displayed a combination of good chromogenic properties with good fluorogenic properties after zinc chloride treatment. These analogs were not commercially available, although **23** can now be obtained from BVDA International, Haarlem, Netherlands. It was therefore necessary to design a high-yielding and cost-effective synthesis that would allow a variety of fragments to be appended to the ninhydrin moiety for the purpose of generating an array of new reagents which could be screened for improved properties.

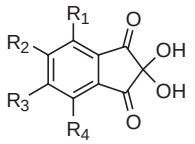
The syntheses of ninhydrin and its analogs usually involve oxidation of 1-indanones (**88**) or 1,3-indanediones (**89**). A retrosynthetic analysis of ninhydrins from these precursors is shown in Scheme 1.

1-Indanones are routinely obtained via Friedel–Crafts cyclization of the corresponding 3-phenylpropionic acids (**90**), which in turn can be obtained from aromatic aldehydes (**94**). An alternative approach to the synthesis of 1-indanones was devised by reacting substituted benzenes with 3-chloropropanoic acid chloride (56, 49). Sartori et al. (57) suggested a method of indanone ring closure that was somewhat similar to this approach. Attempts to reproduce this synthesis, as well as the 1,3-indanedione synthesis reported by the same group, were unsuccessful (58). A complex formed from dimethylacrylamide and triflic anhydride was found to react with some 1,2-dialkoxybenzenes and 1,2,3-trialkoxybenzenes to give the corresponding 1-indanones in good yields (59).

1,3-Indanediones (**89**) are usually obtained from the corresponding diesters (**91**) or phthalic anhydrides (**92**). 2-Indanone is a less suitable precursor for ninhydrin synthesis due to its low stability, and no syntheses of ninhydrin analogs from 2-indanones have been reported.

Since our review of synthetic methods, a few potential approaches to the carbon framework have appeared such as the ring contraction of pyranones (60, 61), the Pauson–Khand reaction (62), and other metal-catalyzed cyclizations. The disadvantage of such methods is the reaction complexity and the cost of the required starting materials. Our efforts were focused on the synthesis of a broad variety of ninhydrin analogs which could be assayed for utility as affordable, efficient reagents for the detection of amino acids.

Ninhydrin analogs



Our approach was to synthesize a broad variety of affordable, efficient analogs classified in three main categories.

Bisninhydrins in which a single molecule would contain two cyclopenta-1,2,3-trione moieties. The reaction of these compounds with amino acids in principle could afford polymeric Ruhemann's purple species.

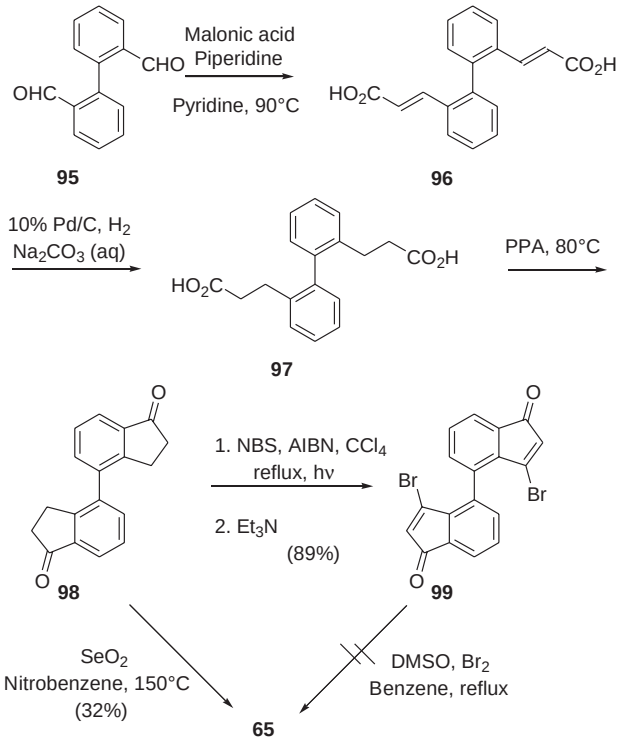
Scheme 1.

Sulfur-containing ninhydrin analogs based on the similarity of the physical properties of thiophene and benzene derivatives. The incorporation of sulfur into the aromatic ring fused to the tricarbonyl system was previously shown to produce analogs exhibiting superior color and fluorescence.

Aryl and heteroaryl analogs that extend the conjugation of the ninhydrin system. The parent compound of this series is 5-phenylninhydrin. Compounds with *para*-substituted phenyl groups were expected to produce interesting analogs, which are biphenyl derivatives.



Bisninhydrin analogs

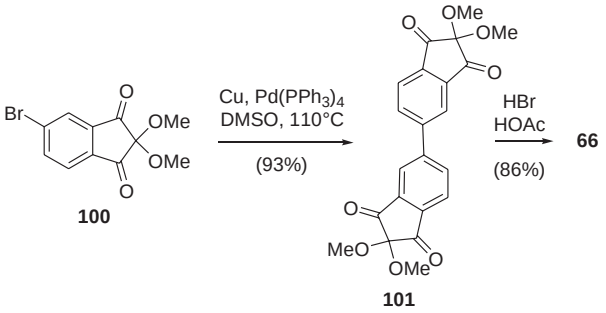
We first envisaged a 4,4′-bisninhydrin (**65**) which could be prepared by the same sequence of reactions used to prepare 5-methoxyninhydrin from anisaldehyde (39). Application of this protocol to synthesize 4,4′-bisninhydrin from 2,2′-biphenylcarboxaldehyde appeared to be a suitable route (Scheme 2).

The requisite 2,2′-biphenyldicarboxaldehyde (**95**) was prepared in good yield by ozonolysis of phenanthrene, followed by in situ reduction with sodium iodide in glacial acetic acid according to a known procedure (63). Knoevenagel condensation of dialdehyde **95** gave diacid **96** in only modest yield since the aldehyde groups are somewhat hindered due to the conformation of the biphenyl system. Catalytic hydrogenation of the unsaturated diacid **96** afforded diacid **97**, which was cyclized using polyphosphoric acid (PPA) to give bisindanone **98** (64).

The bisindanone **98** was oxidized with *N*-bromosuccinimide to form a tetrabromide, which subsequently eliminated hydrogen bromide and formed the bis-β-bromoindenone **99** in high yield. Attempts to transform this penultimate precursor into the desired bisninhydrin **65** using a modification of the Kornblum oxidation (40) led to a complex reaction mixture with substantial decomposition. Again, it is believed that steric congestion in the biphenyl system hindered the approach of the oxidizing agent. Originally, we had considered selenium dioxide to be an inferior choice for oxidizing indanones because of the relatively poor yields reported in the syntheses of other ninhydrin analogs. Selenium dioxide was also known to be toxic and had to be used in stoichiometric quantities while the two-step oxidation

Scheme 2.

method developed by Heffner and Joullié (39) was efficient and convenient. Selenium dioxide did have the advantage, however, of oxidizing indanones to ninhydrins in a single step.



Selenium dioxide oxidation of the bisindanone **98** gave a 15% yield of the desired bisninhydrin **65**, which was contaminated with a small amount of selenium by-products. Selenous acid and other selenium-containing compounds must be removed from the final product since these contaminants may act as a bleaching agent and would prevent the formation of the characteristic purple color (65). When the reaction was run in nitrobenzene at 150°C, selenium-containing by-products were easily removed from the reaction mixture and **65** was obtained in 32% yield (Scheme 2). Though ninhydrin itself is relatively easy to purify, substituted ninhydrins are generally more difficult to obtain in pure form, as methods which were successful in the case of ninhydrin were frequently not applicable.

Preliminary testing showed that the new bisninhydrin (**65**) reacted with amino acids to give the characteristic Ruhemann's purple color but no special optical properties were observed. This result suggested that the steric hindrance of the keto groups at the 3- and 3′-positions of the biphenyl ring prevented the two ninhydrin systems from being significantly conjugated. Each half of the compound behaved essentially as an isolated ninhydrin molecule.

The 5,5′-bisninhydrin (**66**, Fig. 2) was expected to show altered properties since no similar hindrance to conjugation existed other than that which is usual for an unsubstituted biphenyl system. However, this conjugative overlap made its preparation somewhat problematic. The synthesis of **66** following a route similar to that used to prepare **65** contained

© 2001 NRC Canada

Scheme 3.

several low yielding steps, therefore we opted for a different route.

The new approach is shown in Scheme 3.

Palladium chemistry provided an entry to not only aryl- and heteroaryl-substituted ninhydrins, whose syntheses will be described later, but also to this class of bisninhydrins (66). A key intermediate (2,2-dimethoxy-5-bromoindan-1,3-dione (**100**)), described later, was used in an Ullmann-type reaction to afford the desired bisninhydrin (**66**) in good yield after hydrolysis of the diketal precursor **101**. It is noteworthy that neither copper nor palladium(0) alone were sufficient to induce the coupling reaction. 5,5′-Bisninhydrin (**66**) exhibited low solubility in various solvents, and did not display any enhanced chromogenic or fluorogenic properties.

Sulfur-containing ninhydrin analogs

The sulfur-containing analogs are based on inclusion of a thiophene ring in the molecule. Thieno[*e*]ninhydrin (**85**), is an isomer of the superior reagent thieno[*f*]ninhydrin (51) (**84**) in which the five-membered tricarbonyl fragment is fused to a thiophene ring instead of a benzene ring (39). We were interested in examining the fluorescence of the Ruhemann's purple of **85**, and also in developing a reagent which would be easier to synthesize than the challenging thieno[*f*]ninhydrin (**84**).

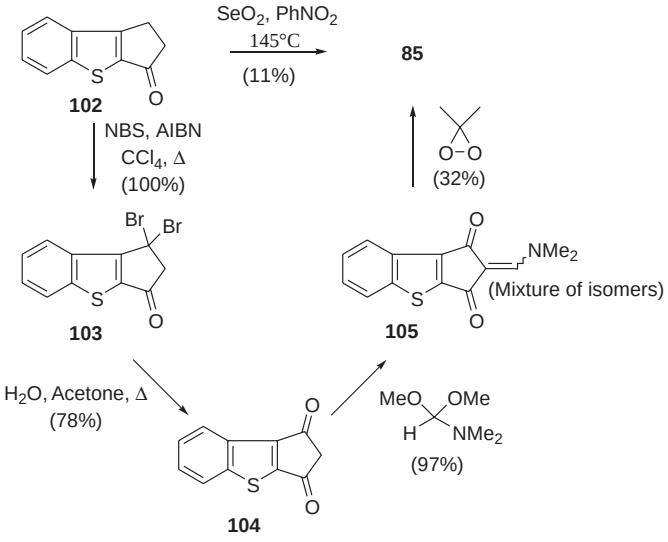
A Heck coupling reaction was chosen to attach the propenoic acid side chain to the aryl core. The tricyclic indanone **102** was obtained in three steps from benzo[*b*]thiophene using published procedures (42).

It was believed that indanone **102** (Scheme 4) would withstand the high temperature (145°C) used in selenium dioxide oxidations in nitrobenzene. However, the conversion proceeded in only 11% yield. The modification of the Kornblum reaction (39) also failed. As enamine formation and subsequent oxidation were successful in the synthesis of thianinhydrin (42); the same methodology was investigated in this case. We were interested in improving the synthesis of thieno[*e*]ninhydrin, and exploring the general applicability of this new approach.

Dibromination of indanone **102** proceeded in quantitative yield (Scheme 4).

The crude dibromide (**103**) was immediately hydrolyzed to avoid the problems experienced earlier in the bromination–elimination method. 1,3-Dione **104** was obtained in 78% yield after column chromatography. Reaction of the dione with DMF-dimethyl acetal proceeded in nearly quantitative

Scheme 4.



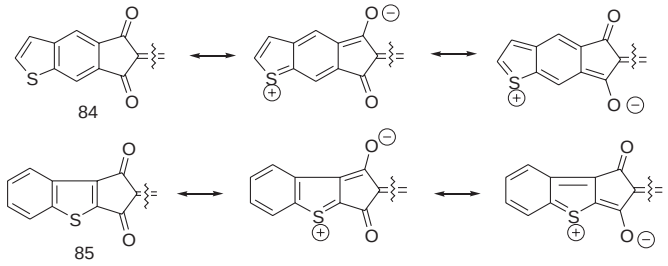


Fig. 3. Relationship between *p*-quinoid resonance structures and fluorescence for compounds **84** and **85.**

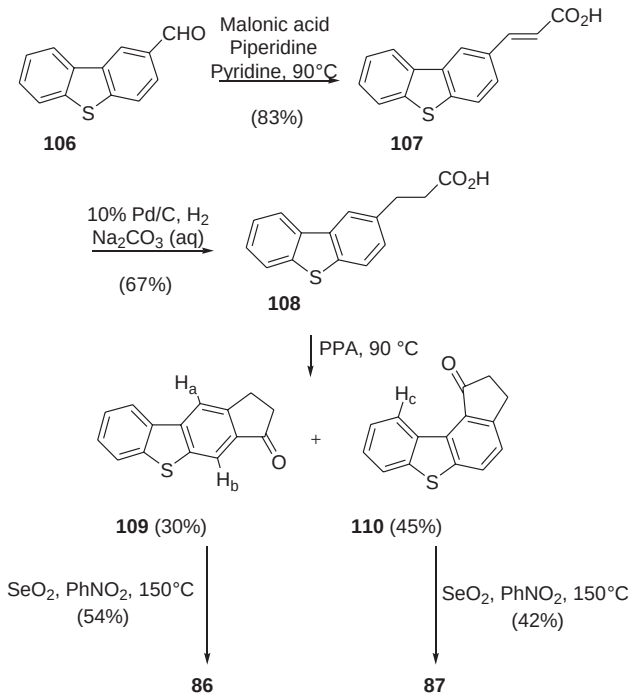
yield, and the enamine **105** was oxidized cleanly to thieno[*e*]ninhydrin (**85**) in 32% yield using dimethyl dioxirane.

Evaluation of thieno[*e*]ninhydrin (**85**) as a reagent for the development of latent fingerprints showed that the strong fluorescence of the Ruhemann's purple analog derived from **84** was not exhibited by **85**.



The disappointing results obtained for the sulfur analogs thianinhydrin (**80**) and for thieno[*e*]ninhydrin (**85**) might be rationalized as resulting from the lack of *p*-quinoid resonance structures of their Ruhemann's purple species. The Ruhemann's purple species of the superior reagents 5-(methylthio)ninhydrin (**23**) and thieno[*f*]ninhydrin (**84**) have resonance structures that exhibit an extended *p*-quinoid character from release of electron density of sulfur into the aromatic system. Analogs **80** and **85** cannot adopt such structures and, therefore, do not exhibit the strong fluorescence on reaction with amino acids.

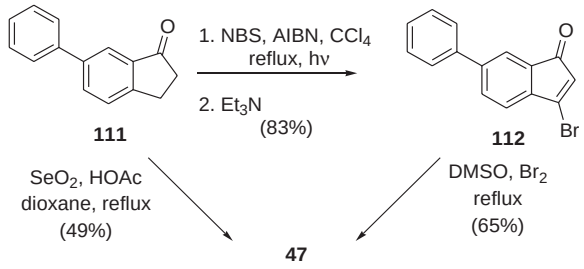
The relationship between the *p*-quinoid resonance structure and fluorescence may explain the differences in fluorescence intensity of the Ruhemann's purple analogs of thieno[*f*]ninhydrin and thieno[*e*]ninhydrin (Fig. 3). Benzo[*f*]ninhydrin (**68**), which reacts with amino acids to afford a highly fluorescent species, also has a Ruhemann's purple which can adopt a *p*-quinoid resonance structure. The weakly fluorescent Ruhemann's purple analog of benzo[*e*]ninhydrin adopts an *o*-quinoid structure.

What cannot be explained by this theory is the fluorescence of the Ruhemann's purple species derived from

© 2001 NRC Canada

Scheme 5.

dichlorothia[*c*]ninhydrin (**82**) (42) which cannot adopt the *p*-quinoid structure, yet is fluorescent without secondary treatment. However, the presence of the two chlorine substituents adds complexity to any interpretation of this result.



In an attempt to improve the properties of thieno[*f*]ninhydrin (**84**) (67), we initiated the synthesis of thianaphtheno[*f*]ninhydrin (**86**, Scheme 5) (18).

Knoevenagel condensation of aldehyde **106** (69) gave a 83% yield of the unsaturated acid (**107**). Catalytic hydrogenation afforded a 67% yield of **108** after recrystallization.

Cyclization of the saturated acid could lead to two potential regioisomers, with the linear isomer (**109**) predicted to predominate based on steric considerations. When the carboxylic acid was cyclized with PPA, two isomers were produced in an overall yield of 75%, with the nonlinear ketone (**110**) as the major product in a 3:2 ratio (Scheme 5) (18). These isomeric ketones could be readily distinguished by ^{1}H NMR. The proton in the 8-position of the nonlinear isomer (**110**) displayed a large down-field shift due to its proximity to the deshielding region of the neighboring carbonyl group. With sufficient quantities of **109** and **110** in hand, we elected to oxidize both ketones. The ninhydrin analog (**87**) derived from **110**, although not one of our original target molecules, was also prepared.

Purification problems associated with selenium dioxide oxidations were avoided by carrying out the reaction in nitrobenzene. The elevated reaction temperature caused the red allotropic form of selenium to undergo a phase transition (which occurs at 140°C) so that nearly all of the selenium metal by-product could easily be removed by filtration in its black form. The solvent can then be removed by steam distillation of the crude mixture. The selenium dioxide oxidation of the isomeric ketones afforded a 54% and 42% yield of **86** and **87**, respectively, (Scheme 5). These analogs did not display superior fluorogenic properties.

Scheme 6.

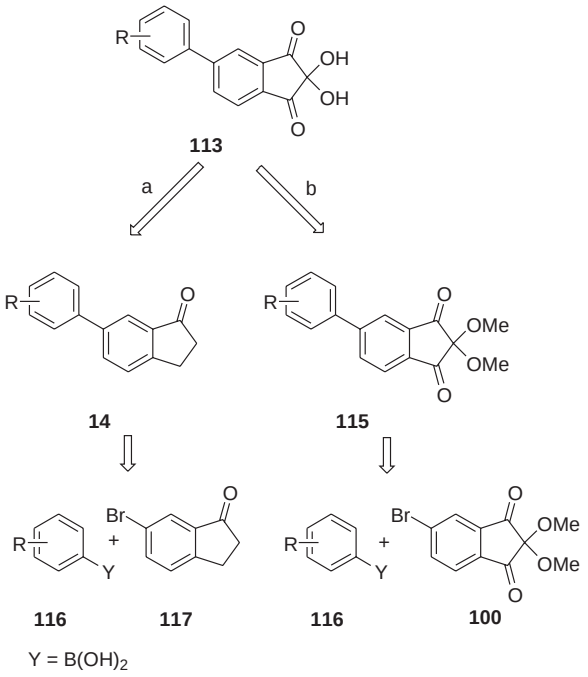
Aryl and heteroaryl ninhydrin analogs

We expected that extending the conjugation of the substituents on a ninhydrin ring would increase the fluorescence of the corresponding Ruhemann's purple species. Addition of an aryl substituent at the 5-position of ninhydrin should accomplish this goal. Substituents at the 4-position were not considered because some reported 4-substituted analogs did not show the desired properties (46).

We first synthesized phenylninhydrin (**47**) starting from biphenyl carboxaldehyde using the protocol previously described for the preparation of **109** and **110** (Scheme 5). Radical bromination of ketone **111** with NBS provided **112** in 83% yield (Scheme 6) (39).

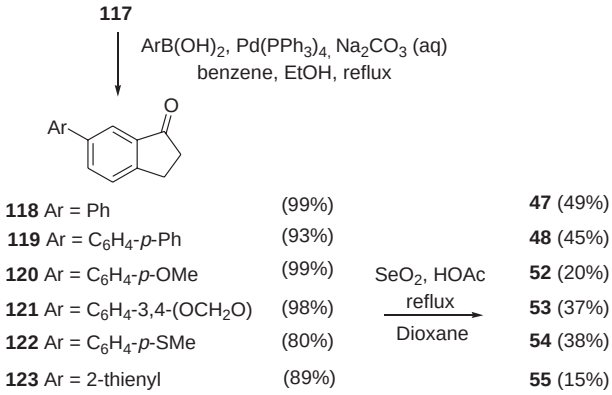
The bromide was oxidized to phenylninhydrin with DMSO and heat in 65% yield. One-step oxidation with selenium dioxide gave a 49% yield of **47**. Although analog **47** was similar to ninhydrin in most of its properties, on reaction with amino acids, a short-lived phosphorescence was observed. A similar method was also used to prepare 5-fluoroninhydrin (**22**) from commercially available 6-fluoro-1-indanone (Aldrich). The chromogenic and fluorogenic properties of analog **22** were also similar to those of **1**.

The synthetic protocol illustrated in Scheme 6 was a good method for the preparation of an aryl ninhydrin analog. However, a more convergent route was needed to synthesize a large number of analogs. Scheme 7 shows the retrosynthetic analysis of our approach.



We envisioned employing metal-catalyzed coupling reactions to append a large number of aryl substituents to the ninhydrin nucleus. Our initial efforts utilized the Suzuki cross-coupling (69–71) reaction in which a suitably substituted boronic acid (**116**, Scheme 7) would be coupled to a bromo-substituted ninhydrin precursor (**100** or **117**). The introduction of a dimethyl ketal in the 2-position is necessary since ninhydrin is unstable under the basic conditions (72) required for Suzuki couplings. Of the two routes pictured in Scheme 7, route b was considered to be more attractive since it required only deprotection of a ketal as the final step.

The choice of the protecting groups for the overall synthetic sequence is somewhat limited by the logic of the synthesis and the nature of the substrates. Protecting groups that are highly base-sensitive cannot be employed, since the tricarbonyl will undergo ring opening upon generation under basic conditions (73).

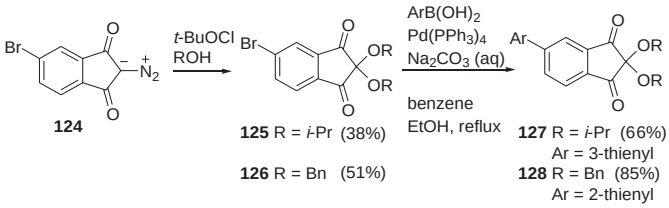


Since 5-bromo-2,2-dibromo-1,3-indanedione was available (18), we decided to use this compound directly in a Suzuki coupling (69, 70). The reaction of this compound with a boronic acid gave none of the desired product but led

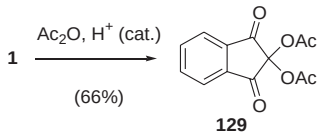
© 2001 NRC Canada

Scheme 7.

Scheme 8.



only to decomposition of the starting material. A possible explanation for this behavior was that the aqueous base had hydrolyzed the geminal dibromide to give 5-bromoninhydrin (**33**), which was not stable in basic solution. This result ruled out the possibility that the dibromo derivative could be used in a Suzuki coupling reaction.



5-Bromo-1,3-indanedione was likewise unsuitable for the Suzuki conditions presumably due to enolization of the 1,3-dione and subsequent reactions of the resulting enol with palladium species. Therefore, a 2,2-dimethyl ketal seemed to be the most practical intermediate for any coupling procedure involving basic conditions.

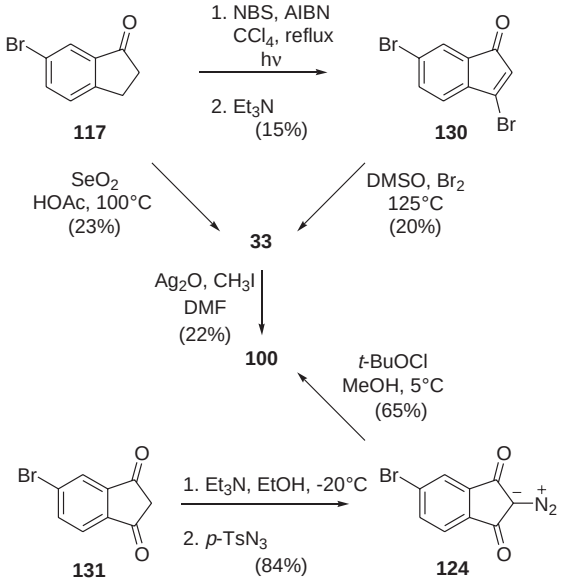
The stability of 2,2-dimethoxy-1,3-indandione in the presence of acids resembles that of an ether. The conditions for its deprotection are quite harsh (HBr – acetic acid – water, 80°C). Since some of the heterocycles that could be appended to the ninhydrin moiety decompose under these conditions, it was necessary to investigate alternative protocols. A number of protic acids (chloroacetic acid, formic acid, trifluoroacetic acid, hydrochloric acid, toluenesulfonic acid) in solvents ranging from benzene to water failed to achieve the deprotection. Trimethylsilyl iodide also failed to yield a product. Hydroiodic acid, and addition of potassium iodide, a logical choice as a source of a nucleophile in ketal deprotection, did not offer any significant improvement.

Scheme 9.

Scheme 10.

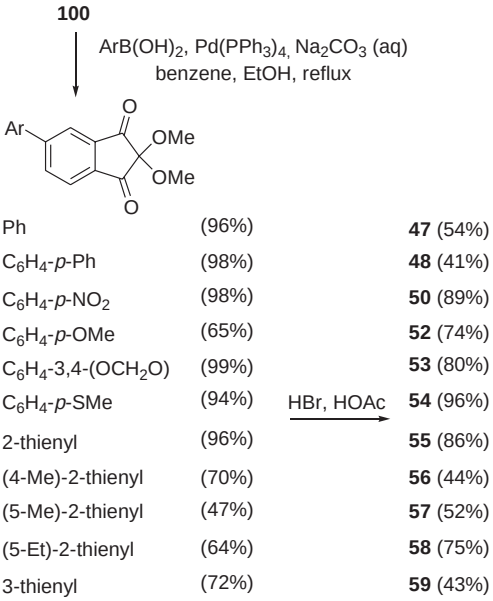
To test the viability of route a in Scheme 7, we used the Suzuki coupling to prepare a series of 6-aryl-1-indanones. The boronic acids used in this project were prepared from commercially available aryl halides according to published procedures (18, 66). All of the boronic acids used were known compounds. The reactions of **117** with several boronic acids proceeded in high yield to give the corresponding 1-indanones (**118**–**123**). Conversion of these ketones to the corresponding ninhydrins (**47**, **48**, **52**–**55**) using the one-step selenium dioxide oxidation was accomplished in poor to moderate yields (Scheme 8).

Other alternatives to the dimethoxy ketal were explored (Scheme 9).



The diisopropyl (**125**) and dibenzyl ketals (**126**) were synthesized from diazodione **124**. Suzuki cross-coupling of these compounds with thienylboronic acids gave compounds **127** and **128** in good yields. Deprotection of the diisopropyl ketal **127** in trifluoroacetic acid at room temperature caused decomposition of the product due to the presence of the thiophene ring. Ketal **125** could be deprotected with trifluoroacetic acid to give 5-bromoninhydrin (**33**). The benzyl group in **128** could not be removed using mild acidic conditions, hydrogenolysis, DDQ, or dimethyldioxirane oxidation (74). An alternative approach, which merits further investigation, is the use of a 2,2-diacetoxy-protecting group. 2,2-Diacetoxy-1,3-indandione was synthesized from **1** (**129**, Scheme 10) and was stable under mildly basic conditions.

Use of the diacetoxy-protecting group may be more compatible with acid-sensitive heteroaromatic moieties, since acidic hydrolysis of the ester group in the presence of water could be carried out under conditions that are milder than the ones required for hydrolysis of dimethyl ketals.



The most straightforward approach to 2,2-dimethoxy-5-bromoindan-1,3-dione (**100**) was the direct bromination of ninhydrin using dibromoisocyanuric acid (DBI) (75), followed by formation of its ketal using methyl iodide and silver oxide. The reaction of DBI with ninhydrin in concentrated

sulfuric acid gave an intractable mixture of polyhalogenated products. 5-Bromoninhydrin (**33**) was prepared in modest yield by selenium dioxide oxidation of 6-bromo-1-indanone (**117**) or using the two-step oxidation (Scheme 11).

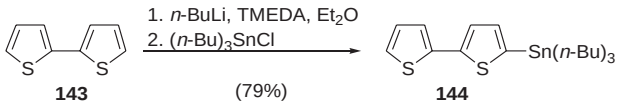
Conversion of **33** to ketal **100** could only be accomplished in low yield. To obtain sufficient amounts of **100**, a new synthesis was devised starting from 5-bromo-1,3-indanedione (**131**) (76, 77). The investigations of Regitz and co-workers (78–81) with diazo group transfer reactions afforded a reliable method for the preparation of **100** (Scheme 11). Deprotonation of dione **131** with triethylamine at –20°C, followed by addition of *p*-toluenesulfonyl azide gave an 84% yield of **124**. The diazodione is unstable when heated and decomposed explosively at its melting point. *p*-Toluenesulfonyl azide is toxic, shock sensitive, and potentially explosive at elevated temperatures so due care should be exercised in its use. The diazo transfer reagent 4-dodecylbenzenesulfonyl azide or *p*-acetamidobenzenesulfonyl azide are safer alternatives (82, 83). Slow addition of *tert*-butylhypochlorite to a cooled slurry of **124** in methanol gave ketal **100** in 65% yield. The temperature of this reaction must be carefully monitored since *tert*-butylhypochlorite has been known to explode as a result of improper temperature control (84).

With multi-gram quantities of common intermediate **100** and suitable boronic acid partners in hand, we turned our attention to the coupling and (or) deprotection reactions. In moderate scale reactions, the Suzuki coupling typically gave high yields of ketals **132**–**142** (Scheme 12).

Deprotection using a 1:1:1 mixture of 48% hydrogen bromide, glacial acetic acid, and water was found effective for most ketals. This protocol was used to prepare the compounds shown in Scheme 12.

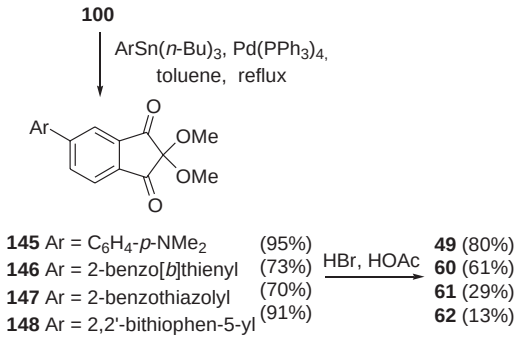
Deprotection of ketal **135** presented an interesting question since it was known that 48% hydrobromic acid could convert aryl methyl ethers into phenols (85). After refluxing **135** using a less concentrated HBr solution, a 74% yield of product (**52**) was obtained with no evidence of ether cleavage. Boron tribromide was used to simultaneously cleave the ether and deprotect the ketal to give 65% yield of **51** as a dark green solid (Scheme 13) (86).

^{1}H and ^{13}C NMR indicated that the compound existed as a mixture of tautomeric forms. The presence of a small amount of the quinoid tautomer could be responsible for the green coloration of the solid as evidenced by weak electronic transitions in the visible region at 594 and 492 nm. Another possibility would be the presence of a small amount of trione.



The Suzuki cross-coupling protocol served very well to synthesize a number of ninhydrin analogs. However, there were still several compounds which could not be made by this method due to the difficulty of preparing the required boronic acids. The Stille reaction provided an alternative coupling technique that could be used to make additional novel ninhydrin analogs (88, 89). The synthesis of many other stannanes have been reported in the literature and could potentially be used to produce new ninhydrin analogs (89–94). In another report, Lee and Dai (95) described the synthesis of a variety of arylstannanes in high yield via a sonochemical Barbier reaction.

The synthesis of 5-(tributylstannyl)-2,2′-bithiophene (**144**) began with treatment of **143** with *n*-butyllithium and TMEDA at –78°C to generate a 5-lithio species in situ. This species was quenched with tributyltin chloride (Scheme 14). The product was purified by distillation under reduced pressure to afford a 79% yield of **144**.



The other stannanes were prepared directly from *p*-dimethylaminobenzene, benzo[*b*]thiophene, and benzothiazole in good yields by a similar method. The common intermediate

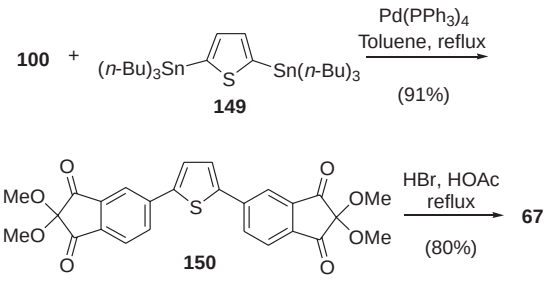
Scheme 14.

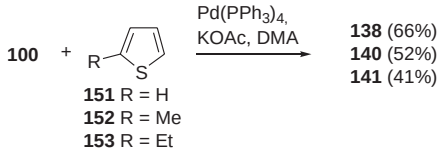
Scheme 15.

100 was heated with an equimolar amount of arylstannane in toluene with a catalytic amount of $Pd(PPh_3)_4$ to give good yields of coupled products (**145**–**148**, Scheme 15).



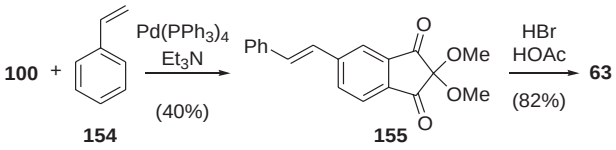
Deprotection under acidic conditions gave poor to good yields of the corresponding ninhydrin analogs (**49**, **60**–**62**) possibly due to decomposition of the heterocyclic rings of **147** and **148**. As compound **49** was not accessible using the Suzuki procedure, its synthesis demonstrates the complementary nature of the Stille methodology.

We next turned our attention to the synthesis of a bisninhydrin analog using the Stille methodology. A previous attempt to accomplish a double coupling of a diboronic acid using Suzuki conditions had been unsuccessful. Literature precedent showed that such a tandem coupling was possible using the Stille reaction (96). Based on the apparent utility of 5-(2-thienyl)ninhydrin (**55**) (41, 67), we were particularly interested in preparing the analog which consisted of two ninhydrin molecules tethered together by a thiophene moiety (**67**). This type of compound incorporates all the ideas for improving the properties of ninhydrin analogs.



Synthesis of 2,5-bis(tributylstannyl)thiophene (**149**, Scheme 16) proceeded smoothly in good yield (97). The direct syntheses of several dilithio heteroarene species, such as **149**, have been reported (97, 98). Stille coupling of **100** and **149** afforded a high yield of ketal **150**, which was deprotected in acid to give **67**.

Compound **55** (Fig. 2) showed good initial development and good fluorescent properties (51, 18). This finding led us to the investigation of other thienyl-substituted analogs. Thienyl ninhydrins with alkyl chains on the thiophene ring were of interest since these side chains could potentially improve the solubility of target analogs in solvents of lower polarity. Initially, Suzuki coupling of **100** with substituted thienyl boronic acids was chosen as the method to append heterocyclic moieties to the ninhydrin framework. Unfortunately, these boronic acids (99, 100) could only be obtained in low yields due to side-chain deprotonation in the lithiation step. Alkyl-substituted thienyl boronic acids were difficult to purify and as a consequence were used crude and in excess



Scheme 16.

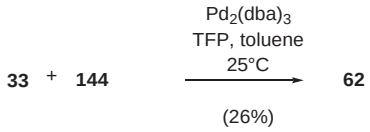
Scheme 17.

Scheme 18.

in Suzuki couplings to give modest yields of coupled products (**138**–**142**, Scheme 12).

An alternative procedure was tested to circumvent the difficulties encountered in the synthesis of several boronic acids. Electron-rich heterocycles such as furans, benzofurans, thiophenes, and benzothiophenes are known to undergo palladium-catalyzed cross-coupling reactions with electron-poor aryl halides (101, 102). Although the mechanistic details of this uncommon cross-coupling reaction were not discussed by the authors, it is reasonable to assume that the mechanism is similar to the Heck coupling. Thiophene (**151**), 2-methyl thiophene (**152**), and 2-ethyl thiophene (**153**) were reacted with compound **100** to yield coupled products (**138**, **140**, **141**, Scheme 17) in moderate yields.

The low yields encountered in deprotection of thienyl-substituted analogs (**139**, **140**, **142**, Scheme 12) are due to the formation of high molecular weight side products as observed in the thiophene–isatin condensation (known also as the indophenine reaction) in the presence of sulfuric acid. The term refers to formation of a colored product obtained by condensation of thiophene compounds that have no substitution in 2,5- or 2,3-positions with vicinal polycarbonyls, such as benzil or ninhydrin (103).



The Heck coupling reaction conditions were used to obtain yet another compound in the series of substituted ninhydrins, a styryl ninhydrin (**63**, Scheme 18), which is an ethylenic homolog of 5-phenylninhydrin (**47**).

Ketal **100** was coupled with styrene (**154**) to afford **155**, which was deprotected in excellent yield. Other interesting compounds could be made using this methodology.

An effective palladium catalyst, using tri-2-furylphosphine (TFP) as a ligand, had been reported (104). The dramatic increase in reactivity of this catalyst provided a solution for

© 2001 NRC Canada

Scheme 19.

Stille reactions that required excessive temperatures (105). This catalyst was easily prepared in situ by ligand exchange with tris-(dibenzylideneacetone)dipalladium(0) (106). Both compounds are commercially available (107). To test the efficacy of this milder coupling procedure, we chose the analog (**62**) that had given us the poorest yield in the deprotection step. The reaction is shown in Scheme 19.

After formation of the catalyst, 5-bromoninhydrin (**33**) and stannane **144** were added to the solution at room temperature. The product was obtained in 26% yield. This yield represents an overall yield of 20% for three steps from 5-bromo-1,3-indanedione (**131**) as compared to 6.4% for the corresponding coupling and (or) deprotection route. This attractive approach deserves to be explored and optimized.

The goal of the described structural modifications was the optimization of the chromophoric and luminescent properties of the Ruhemann's purple product arising from the reaction of ninhydrin analogs with amino acids. It is difficult to predict a priori which modifications will result in enhanced optical properties. Therefore, in spite of the large number of analogs synthesized, only a few were found to afford significant improvement over ninhydrin.

In conclusion, new chromogenic and fluorogenic reagents for amino acid detection were synthesized and evaluated. Evaluation of the analogs showed that thienyl-substituted compounds, especially **55** and **59**, were promising reagents, exhibiting fluorogenic properties without secondary treatment. Some correlations between the structure of ninhydrin analogs and the spectral properties of the resulting Ruhemann's purple analog have been demonstrated but no general method of predicting the spectral properties has evolved, thereby making evaluation of modified structures the only available route to better reagents.

Although a wide variety of reagents is currently known and employed for the detection of amines and amino acids in analytical chemistry, only a few of these reagents have found their way into forensic practice because of the different requirements of reactions occurring in solution and on porous surfaces.

Experimental section

General procedures

All solvents were reagent grade and were distilled from appropriate drying agents. *N*-Bromosuccinimide (NBS) was recrystallized from water. Tri-*n*-butylstannyl chloride was distilled under reduced pressure. Organic acids were reagent grade. *n*-Butyllithium was purchased as a solution in hexanes (1.6 M). Tetrakis(triphenylphosphine)palladium(0) ($Pd(PPh_3)_4$) was purchased commercially and stored in a refrigerator (5°C) under a N_2 atmosphere. Tosyl azide (81, 80) and dimethyl dioxirane (108, 109) were prepared as described in the literature. Melting points (mp) were determined with a Thomas–Hoover capillary melting point apparatus and are uncorrected. Analytical thin layer chromatography (TLC) was performed on Merck silica gel (60F-254) plates (0.25 mm), precoated with a fluorescent indicator. Visualization was effected with ultraviolet light or a suitable chemical reagent. Flash column chromatography was carried out on E. Merck silica gel 60 (240–400 mesh) using the solvent systems listed under the individual experiments. Proton magnetic resonance spectra (^{1}H NMR) and carbon magnetic resonance spectra (^{13}C NMR) were recorded on a Bruker/IBM AC-250 (250 MHz) (or a Bruker AMX-500 (500 MHz) where noted) Fourier transform (FT) spectrometer using $CDCl_3$, DMSO-d_6, D_2O, or acetone-d_6, as solvents. Chemical shifts are measured in parts per million (δ) relative to tetramethylsilane (TMS) or chloroform as the internal standard. Coupling constants (*J* values) are in Hertz (Hz). Infrared spectra (IR) were obtained on a PerkinElmer Model 281-B or a PerkinElmer Model 781 spectrometer. Solid samples were analyzed as potassium bromide (KBr) disks. Liquids or oils were analyzed as neat films between sodium chloride plates. Absorptions are reported in wave numbers (cm^{-1}), and intensities are designated as broad (br), strong (s), medium (m), or weak (w). The spectra taken were referenced to the 1601 cm^{-1} band of polystyrene, and only the most prominent or characteristic absorptions are noted. High resolution mass spectra (HRMS) were obtained on VG 7070H or VG ZAB-E high resolution, double focusing, mass spectrometers, employing either chemical ionization (CI) or fast atom bombardment (FAB) using a Cesium (Cs) ion gun. The mass spectrometers were interfaced with a VG/DEC 11–73 data system. Ultraviolet spectra (UV) were recorded on an IBM 9420 UV–vis spectrophotometer. Elemental analyses were performed by National Chemical Consulting, Inc., Tenafly, New Jersey or at the elemental analysis facility of the University of Pennsylvania.

*3,3′-Dibromo[4,4′]biindenyl-1,1′-dione (**99**)*

To a solution of dione **98** (620 mg, 2.37 mmol) in CCl_4 (115 mL) at 25°C was added NBS (1.77 g, 9.94 mmol) and a catalytic amount of AIBN. The mixture was heated at reflux, while being irradiated with a 150 W light. After 3.5 h, the reaction was cooled to 5°C in an ice bath, triethylamine (2.40 mL, 16.5 mmol) was added, and the reaction was then allowed to stir for 1 h at 25°C. A precipitate was removed by filtration and the solid was washed with CCl_4 (25 mL). The filtrate was evaporated in vacuo to give a dark residue which was dissolved in Et_2O (100 mL), washed first with 0.1 M HCl (100 mL), and then water (1 × 50 mL). The solution was dried over Na_2SO_4 and filtered. The solvent was evaporated in vacuo to afford 970 mg of an orange-red solid. The crude product was purified by column chromatography (EtOAc – petroleum ether, 1:9 and 1:4) to provide 876 mg (89% yield) of **99** as an orange solid; mp 183–186°C dec. R_f 0.30 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{18}H_8Br_2O_2$ $(M)^+$: 413.8891; found: 413.8938. IR (KBr) (cm^{-1}): 1700 (s). ^{1}H NMR ($CDCl_3$) δ: 7.46 (dd, J = 7.1 Hz, J = 1.1 Hz, 2H), 7.34 (dd, J = 9.0 Hz, J = 7.1 Hz, 2H), 7.23 (dd, J = 9.0 Hz, J = 1.1 Hz, 2H), 6.24 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 193.4, 147.8, 136.4, 132.1, 130.1, 130.6, 129.7, 129.4, 127.5, 122.0.

*2,2,2′,2′-Tetrahydroxy[4,4′]biindenyl-1,3,1′,3′-tetrone (**65**)*

Method A: A mixture of dione **98** (510 mg, 1.94 mmol) and SeO_2 (1.08 g, 9.72 mmol) in glacial acetic acid (25 mL) was heated at 100°C for 2 h. The reaction mixture was filtered through Celite while still hot to remove a red precipitate. The precipitate was washed with water (25 mL) and the filtrates were combined. Upon cooling in an ice bath, a precipitate formed which was collected and dried to give a yellow-orange solid (120 mg). The volume of the solution was reduced several times by heating to obtain additional crops of material (198 mg) for a total yield of 15%.

Method B: A mixture of dione **98** (0.87 g, 3.3 mmol) and selenium dioxide (1.49 g, 13.4 mmol) in nitrobenzene (5 mL) was heated at 145–150°C. After 50 min, the reaction was filtered through Celite while still hot to remove a dark precipitate. The precipitate was washed with EtOAc (15 mL) and the filtrates were combined. Water (300 mL) was added and the organic solvents were removed by steam distillation. The solution was filtered again while still hot to remove a dark, sticky precipitate. Additional precipitate, which formed after standing at room temperature overnight, was also removed by filtration. The filtrate was extracted with EtOAc (3 × 50 mL) and the combined extracts were dried over Na_2SO_4, filtered, and the solvent evaporated under reduced pressure. The residue was dried in vacuo to provide 390 mg (32% yield) of **65** as a pink solid, mp 200–202°C dec. R_f 0.40 (CH_2Cl_2 – MeOH – acetic acid, 90:10:1). UV (CH_3CN) (nm): 242 (ε 33 000). IR (KBr) (cm^{-1}): 3650–2100 (br, s), 1705 (s), 1180 (s), 1160 (s). ^1H NMR (DMSO-d_6) δ: 8.06–8.13 (m, 4H), 7.90 (m, 2H), 7.49 (br s, 4H, exchangeable with D_2O). ^{13}C NMR (DMSO-d_6) δ: 196.7, 196.1, 138.7, 138.4, 136.5, 135.9, 135.6, 123.9, 87.3. Anal. calcd. for $C_{18}H_{10}O_8$: C 61.02, H 2.85; found: C 60.83, H 3.17.

*2,2,2′,2′-Tetramethoxy[5,5′]biindenyl-1,3,1′,3′-tetrone (**101**)*

Powdered Cu (495 mg, 7.80 mmol) was added to a solution of **100** (556 mg, 1.95 mmol) in DMSO (3 mL). The reaction mixture was flushed with N_2 and then stirred in a N_2 atmosphere for 2 h. $Pd(PPh_3)_4$ (115 mg, 5% mol) was added, and the reaction mixture was allowed to stir at 110–120°C under N_2 for 17 h in a dark hood. At that time, the reaction mixture was diluted with EtOAc, and inorganic solids were removed by filtration. The solvents were evaporated under reduced pressure to yield an oil that was purified by column chromatography (acetone – petroleum ether (1:4), and CH_2Cl_2) to afford 90 mg (16% recovery) of **100** and 310 mg (78% yield, 93% yield based on recovered starting material) of **101** as a yellow solid, mp 210°C. R_f 0.46 (EtOAc – petroleum ether, 2:3). HRMS–CI(NH_3) calcd. for $C_{22}H_{22}NO_8$ $(M+NH_4)^+$: 428.1346; found: 428.1340. IR (KBr) (cm^{-1}): 1747 (s), 1718 (s), 1179 (s), 1037 (s). ^1H NMR ($CDCl_3$) δ: 8.07 (d, J = 8.4 Hz, 2H), 7.58 (dd, J = 8.4 Hz, J = 2.2 Hz, 2H), 7.47 (d, J = 2.3 Hz, 2H), 3.65 (s, 12 H). ^{13}C NMR ($CDCl_3$) δ: 193.0, 192.7, 146.9, 140.2, 39.2, 135.7, 125.3, 122.9, 91.2, 51.8. Anal. calcd. for $C_{22}H_{18}O_8$: C 64.39, H 4.42; found: C 64.03, H 4.61.

*2,2,2′,2′-Tetrahydroxy[5,5′]biindenyl-1,3,1′,3′-tetrone (**66**)*

Tetrone **101** (140 mg, 0.341 mmol) was dissolved in glacial acetic acid (2 mL) and an equal amount of water and concd aq HBr (48%) were added to form a fine suspension. The reaction mixture was heated at reflux for 2 h and filtered while hot. The filtrate was diluted with water and the precipitate which formed after cooling in an ice bath was collected by filtration, washed with water, and air dried to give 103 mg (86% yield) of **66** as a beige solid. IR (KBr) (cm^{-1}): 3270 (s), 1754 (s), 1719 (s), 1182 (s). ^1H NMR (DMSO-d_6) δ: 8.53 (dd, J = 8.1 Hz, J = 1.4 Hz, 2H), 8.46 (s, 2H), 8.15 (d, J = 8.0 Hz, 2H), 7.61 (br s, 1.2 H). ^{13}C NMR (DMSO-d_6) δ: 196.6, 196.5, 146.2, 139.2, 138.2, 136.5, 124.6, 122.9, 87.9. Anal. calcd. for $C_{18}H_{10}O_8 \cdot H_2O$: C 58.07, H 3.25; found: C 58.08, H 2.99.

*1,1-Dibromo-1,2-dihydrobenzo[*b*]cyclopenta[*d*]thiophen-3-one (**103**)*

To a solution of **102** (0.203 g, 1.08 mmol) in CCl_4 (12 mL) was added NBS (0.422 g, 2.37 mmol) and a catalytic amount of AIBN. The mixture was heated at reflux for 5 h while following the reaction by TLC. The mixture was cooled and filtered. The collected solid was washed with additional CCl_4 (8 mL) and the filtrate was concentrated under reduced pressure to afford **103** (0.372 g) in quantitative yield. The crude solid was used in the next step without further purification. R_f 0.71 (CH_2Cl_2 – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{11}H_{10}NOSBr_2$ $(M+NH_4)^+$: 361.8850; found: 361.8857. ^1H NMR (500 MHz, $CDCl_3$) δ: 8.35 (m, 1H), 7.90 (m, 1H), 7.59 (m, 2H), 4.24 (s, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 188.5, 162.8, 148.4, 139.3, 131.3, 129.1, 125.7, 125.1, 124.4, 66.7, 42.1.

*Benzo[*b*]cyclopenta[*d*]thiophene-1,3-dione (**104**)*

To a solution of **103** (0.372 g, 1.08 mmol) in acetone (15 mL) was added H_2O (25 mL) and the mixture was heated at reflux for 3 h. The mixture was cooled and the acetone was removed under reduced pressure. The aqueous layer was extracted with $CHCl_3$ (3 × 15 mL). The combined organic layers were dried (Na_2SO_4), filtered, and concentrated under reduced pressure. The orange solid was purified using column chromatography (CH_2Cl_2 and 2% MeOH–CH_2Cl_2) to afford 0.169 g (78% yield) of **104** as a bright yellow solid, mp > 280°C. R_f 0.57 (2% MeOH–CH_2Cl_2). HRMS–CI (NH_3) calcd. for $C_{11}H_{10}NO_2S$ $(M+NH_4)^+$: 220.0166; found: 220.0166. IR (KBr) (cm^{-1}): 3500–2500 (br, w), 1735 (m), 1701 (s), 1671 (s). ^1H NMR (500 MHz, $CDCl_3$) δ: 8.37 (m, 1H) 7.95 (m, 1H), 7.58 (m, 2H), 3.51 (s, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 190.2, 189.9, 157.9, 152.7, 148.1, 130.4, 129.2, 127.1, 126.0, 124.0, 49.1.

*2-Dimethylaminomethylenebenzo[*b*]cyclopenta[*d*]thiophene-1,3-dione (**105**)*

To a solution of **104** (0.169 g, 0.837 mmol) in CH_2Cl_2 (4 mL) was added dimethylformamide dimethyl acetal (0.22 mL, 1.67 mmol) and the solution was stirred at ambient temperature for 24 h. The crude material was purified directly using column chromatography (1% MeOH–CH_2Cl_2 and 2% MeOH–CH_2Cl_2) to afford 0.211 g (97% yield) of **105** (mixture of isomers) as an orange solid, mp 182–184°C. R_f 0.48 (2% MeOH–CH_2Cl_2). HRMS–CI(NH_3) calcd. for $C_{14}H_{12}NO_2S$ $(M+H)^+$: 258.0589; found: 258.0594. IR (neat) (cm^{-1}): 1698 (m), 1652 (s), 1610 (s). ^1H NMR (500 MHz, $CDCl_3$) δ: 8.29 (d, J = 7.9 Hz, 1H), 7.88 (m, 1H), 7.45 (m,

© 2001 NRC Canada

2H), 7.25 (m, 1H), 3.67 (s, 3H), 3.29 (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 187.5, 184.2, 154.6, 151.1, 149.5, 146.7, 131.8, 126.9, 126.1, 124.8, 123.8, 104.2, 47.5, 43.2.

*2,2-Dihydroxybenzo[*b*]cyclopenta[*d*]thiophene-1,3-dione (**85**)*

Method A: Ketone **102** (0.373 g, 1.98 mmol) was oxidized with SeO_2 (0.839 g, 4.46 mmol) in nitrobenzene using a procedure similar to that described for the preparation of compound **65** to give an orange oil. The oil was purified by recrystallization from H_2O and decolorizing carbon to give 50 mg (11% yield) of **85** as a yellow solid.

Method B: To a solution of enamine **105** (0.211 g, 0.823 mmol) in acetone (10 mL) was added dimethyldioxirane in acetone (excess, 5 mL) and the golden solution turned pale yellow within 2 min. After stirring for 15 min, the solution was concentrated under reduced pressure. The crude solid was dissolved in hot H_2O (50 mL), Norit was added, and the suspension was filtered hot. The filtrate was concentrated to 10 mL and refrigerated overnight to give 62 mg (32% yield) of **85** as peach colored needles. HRMS–CI calcd. for $C_{11}H_5O_3S$ $(M)^+$: 216.9959; found: 216.9963. IR (KBr) (cm^{-1}): 3400 (s, br), 1740 (s), 1705 (s, br), 1070 (s). ^{1}H NMR (500 MHz, acetone-d_6) δ: 8.85 (m, 1H), 8.76 (m, 1H), 8.27–8.28 and 8.34 (m, 2H, exchangeable with D_2O), 8.21 (m, 2H). ^{13}C NMR (125 MHz, acetone-d_6) δ: 200.8, 200.5, 165.2, 158.5, 158.0, 141.2, 140.5, 138.0, 136.2, 135.2.

*3-Dibenzothiophen-2-yl-acrylic acid (**107**)*

A solution of aldehyde **106** (3.41 g, 16.0 mmol), malonic acid (2.50 g, 24.0 mmol), pyridine (16 mL), and piperidine (10 drops) was heated to 95°C for 2 h and then at reflux for 15 min. After brief cooling, the mixture solidified. The solid was mixed with 2 M HCl (250 mL) and the precipitate was collected. The solid was washed with 2 M HCl (250 mL) and water (50 mL) and then dried overnight in an oven (70°C) to afford 3.03 g (83% yield) of 107 as small off-white crystals after recrystallization from 2-propanol–water, mp 275–277°C dec. R_f 0.41 (Et_2O). HRMS–CI (NH_3) calcd. for $C_{15}H_{14}NO_2S$ $(M+NH_4)^+$: 272.0745; found: 272.0740. IR (KBr) (cm^{-1}): 3300–2200 (br, s), 1690 (s), 1630 (s), 1350 (s). ^{1}H NMR (DMSO-d_6) δ: 12.45 (br s, 1H, exchangeable with D_2O), 8.74 (d, J = 1.3 Hz, 1H), 8.45 (m, 1H), 8.04 (d, J = 8.4 Hz, 1H), 8.02 (m, 1H), 7.82 (dd, J = 8.4 Hz, J = 1.3 Hz, 1H), 7.77 (d, J = 16.0 Hz, 1H), 7.49–7.56 (m, 2H), 6.74 (d, J = 16.0 Hz, 1H). ^{13}C NMR (DMSO-d_6) δ: 167.8, 144.0, 140.5, 139.0, 135.7, 134.8, 131.2, 127.5, 126.8, 125.0, 123.4, 123.2, 122.4, 122.0, 119.1.

*3-Dibenzothiophen-2-yl-propionic acid (**108**)*

Unsaturated acid **107** (5.67 g, 22.3 mmol) was hydrogenated in 0.5 M Na_2CO_3 (90 mL) with 10% Pd on activated carbon (402 mg) in a Parr apparatus. When TLC indicated that the reaction was complete, the mixture was filtered through Celite and the solids were washed with water (50 mL). The filtrate was then acidified with 1 M HCl and the precipitate was collected and recrystallized from 2-propanol–water to afford 3.82 g (67% yield) of **108** as white crystals, mp 123–125°C dec. R_f 0.48 (Et_2O). HRMS–CI (NH_3) calcd. for $C_{15}H_{16}NO_2S$ $(M+NH_4)^+$: 274.0901; found: 274.0913. IR (KBr) (cm^{-1}): 3400–2350 (br, s), 1690 (s). ^{1}H NMR (DMSO-d_6) δ: 12.24 (br s, 1H, exchangeable with D_2O), 8.29 (m, 1H), 8.21 (s, 1H), 7.97 (m, 1H), 7.87 (d, J = 8.1 Hz, 1H), 7.47 (m, 2H), 7.38 (d, J = 8.1 Hz, 1H), 3.01 (m, 2H), 2.67 (m, 2H). ^{13}C NMR (DMSO-d_6) δ: 173.9, 139.0, 137.8, 136.3, 135.3, 135.0, 127.8, 127.0, 124.7, 123.1, 122.8, 122.0, 121.5, 35.6, 30.5.

*2,3-Dihydro-9-thiacyclopenta[*b*]fluoren-1-one (**109**) and 2,3-dihydro-6-thiacyclopenta[*c*]fluoren-1-one (**110**)*

To a mechanically stirred solution of polyphosphoric acid (165 g) in a 400 mL beaker heated at 80°C in an oil bath, was carefully added a solution of acid **108** (4.43 g, 17.3 mmol) in CH_2Cl_2 (20 mL). The color of the mixture changed from light yellow to deep red. After 30 min, the reaction was poured over ice (500 g) and water (250 mL) was used to wash the residue from the beaker. The resulting mixture was extracted with CH_2Cl_2 (3 × 150 mL). The organic extracts were combined, washed first with saturated $NaHCO_3$ (2 × 100 mL) and then water (2 × 100 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated under reduced pressure to give 4.03 g of a yellow solid which contained two products as indicated by TLC. The crude product was purified by column chromatography (Et_2O – petroleum ether, 3:7) to afford 919 mg (22% yield) of pure ketone **110** as a white solid and 654 mg (16% yield) of pure ketone **109** as a yellow solid. Analytical samples of each compound were obtained by collecting the crystals that formed in several chromatography fractions. The mixed fractions were combined and evaporated under reduced pressure to give a light yellow solid (1.50 g). ^{1}H NMR analysis indicated this solid contained a mixture of only the two isomeric ketones in the ratio of 62:38 (**110**:**109**). Therefore, the total yield of ketone **109** was 30% and the total yield of ketone **110** was 45%. The physical and spectroscopic data for each compound are given below.

*2,3-Dihydro-9-thiacyclopenta[*b*]fluoren-1-one (**109**):* Yellow crystals, mp 217 to 218°C. R_f 0.48 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{15}H_{10}OS$ $(M)^+$: 238.0453; found: 238.0438. IR (KBr) (cm^{-1}): 1690 (s). ^{1}H NMR ($CDCl_3$) δ: 8.13 (m, 1H), 7.41–7.53 (m, 2H), 7.81 (m, 1H), 8.15 (m, 1H), 8.11 (m, 1H), 3.23 (m, 2H), 2.76 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.0, 150.4, 141.6, 138.8, 135.7, 134.1, 133.0, 128.2, 124.6, 123.0, 122.5, 118.8, 118.2, 37.0, 25.5. Anal. calcd. for $C_{15}H_{10}OS$: C 75.60, H 4.23; found: C 75.46, H 4.00.

*2,3-Dihydro-6-thiacyclopenta[*c*]fluoren-1-one (**110**):* White needles, mp 167 to 168°C. R_f 0.60 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{15}H_{10}OS$ $(M)^+$: 238.0453; found: 238.0434. UV (CH_3CN) (nm): 356 (ε 5 700), 345 (ε 4300), 314 (ε 10 600), 276 (ε 5200). IR (KBr) (cm^{-1}): 1700 (s). ^{1}H NMR (DMSO-d_6) δ: 9.77 (m, 1H), 7.87 (d, J = 8.1 Hz, 1H), 7.82 (m, 1H), 7.46–7.50 (m, 2H), 7.31 (d, J = 8.1 Hz, 1H), 3.12 (m, 2H), 2.73 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.5, 155.0, 140.0, 139.0, 135.3, 133.2, 133.1, 128.7, 128.5, 127.3, 124.4, 124.0, 121.9, 36.8, 26.3. Anal. calcd. for $C_{15}H_{10}OS$: C 75.60, H 4.23; found: C 75.26, H 4.08.

*2,2-Dihydroxy-9-thiacyclopenta[*b*]fluoren-1,3-dione (**86**)*

Ketone **109** (740 mg, 3.10 mmol) was oxidized with SeO_2 (689 mg, 6.20 mmol) in nitrobenzene using a procedure sim-

© 2001 NRC Canada

ilar to that described for the preparation of compound **65** to give 480 mg (54% yield) of **86** as an off-white solid after recrystallization from water, mp 296–298°C dec. R_f 0.18 (benzene – EtOAc – formic acid, 85:15:5). HRMS–CI (NH_3) calcd. for $C_{15}H_8O_4S$ $(M)^+$: 284.0143; found: 284.0159. UV (CH_3CN) (nm): 295 (ε 43 300), 267 (ε 13 800). IR (KBr) (cm^{-1}): 3650–2600 (br, s), 1755 (s), 1715 (s), 1175 (s), 1075 (s). ^1H NMR (DMSO-d_6) δ: 9.02 (s, 1H), 8.75 (s, 1H), 8.70 (d, J = 7.7 Hz, 1H), 8.13 (d, J = 7.7 Hz, 1H), 7.56–7.69 (m, 2H), 7.59 (s, 2H, exchangeable with D_2O). ^{13}C NMR (DMSO-d_6) δ: 196.7, 196.6, 147.5, 142.0, 140.8, 135.7, 134.9, 133.7, 129.6, 125.7, 124.2, 123.5, 119.3, 117.4, 88.6.

*2,2-Dihydroxy-6-thiacyclopenta[c]fluoren-1,3-dione (**87**)*

Ketone **110** (920 mg, 3.80 mmol) was oxidized with SeO_2 (860 mg, 7.70 mmol) in nitrobenzene using a procedure similar to that described for the preparation of compound **65** to give 234 mg (21% yield) of **87** as a light orange solid after column chromatography (Et_2O and EtOAc), mp 286–288°C dec. R_f 0.29 (benzene – EtOAc – formic acid, 85:15:5). HRMS–CI (NH_3) calcd. for $C_{15}H_8O_4S$ $(M)^+$: 284.0143; found: 284.0154. UV (CH_3CN) (nm): 304 (ε 22 900), 268 (ε 15 700). IR (KBr) (cm^{-1}): 3600–2900 (br, s), 1740 (s), 1710 (s). ^1H NMR (DMSO-d_6) δ: 9.66 (m, 1H), 8.70 (d, J = 8.2 Hz, 1H), 8.15 (m, 1H), 8.06 (d, J = 8.2 Hz, 1H), 7.67 (s, 2H, exchangeable with D_2O) 7.59–7.71 (m, 2H). ^{13}C NMR (DMSO-d_6) δ: 197.5, 196.4, 148.3, 140.1, 137.7, 134.1, 133.5, 132.0, 132.0, 128.9, 127.1, 125.4, 123.2, 120.5, 87.7. Anal. calcd. for $C_{15}H_8O_4S$: C 63.37, H 2.84; found: C 63.15, H 2.76.

*3-Bromo-6-phenylinden-1-one (**112**)*

To a solution of ketone **111** (1.50 g, 7.17 mmol) in CCl_4 (60 mL) at 25°C was added NBS (4.20 g, 23.6 mmol) and a catalytic amount of AIBN. The mixture was heated at reflux, while being irradiated with a 150 W light. After 4 h, the reaction was cooled to 5°C in an ice bath, triethylamine (4.00 mL, 28.7 mmol) was added, and the reaction was then allowed to stir for 90 min at 25°C. A precipitate was removed by filtration and the solid was washed with CCl_4 (25 mL). The filtrate was washed first with 2 M HCl (2 × 100 mL) and then water (3 × 75 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated in vacuo and the residue was purified by column chromatography (petroleum ether and EtOAc – petroleum ether, 1:9) to provide 1.70 g (83% yield) of **112** as an orange solid, mp 213–215°C. R_f 0.55 (Et_2O – petroleum ether, 1:1). HRMS–CI (CH_4) calcd. for $C_{15}H_9BrO$ $(M)^+$: 283.9837; found: 283.9810. IR (KBr) (cm^{-1}): 1705 (s), 1595 (m). ^1H NMR ($CDCl_3$) δ: 7.57–7.69 (m, 3H), 7.24–7.56 (m, 5H), 6.24 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 148.7, 139.5, 131.7, 129.0, 128.2, 127.5, 126.9, 121.6, 120.9 (note: only 9 out of a potential 13 signals were observed.). Anal. calcd. for $C_{15}H_{12}O$: C 86.51. H 5.81; found: C 86.14, H 5.92.

*2,2-Dihydroxy-5-phenylindan-1,3-dione (**47**)*

Method A: To a solution of **112** (960 mg, 3.30 mmol) in DMSO (50 mL) was added Br_2 (1 drop). The solution was heated at reflux for 8 h, cooled to 25°C, and then poured into water (200 mL) to form a viscous orange mixture. The mixture was extracted with EtOAc (4 × 100 mL). The combined organic extracts were washed with brine (3 × 25 mL), dried over Na_2SO_4, and filtered. The solvent was removed under reduced pressure to give a red oil which was dried in vacuo to afford 550 mg (65% yield, mp 64 to 65°C dec) of **47** as an orange-red foam.

Method B: A mixture of **111** (1.04 g, 5.00 mmol) and SeO_2 (1.22 g, 11.0 mmol) in dioxane (12 mL) and glacial acetic acid (2 mL) was heated at reflux for 2 h. The reaction mixture was filtered through Celite while still hot and the solids were washed with EtOAc. The filtrate was poured into water and the mixture was extracted with EtOAc. The organic extracts were combined, washed with brine, dried over Na_2SO_4, and filtered. The solvent was evaporated under reduced pressure and the residue heated at reflux with water and a small amount of decolorizing carbon. The mixture was filtered while hot and allowed to cool. No solid formed even after reducing the volume of the mixture so the solution was extracted with EtOAc (2 × 100 mL) and the combined organic extracts were washed with brine (1 × 50 mL), dried over $MgSO_4$, and filtered. The solvent was removed under reduced pressure and the residue dried in vacuo to afford 0.59 g of **47** as a yellow solid (49% yield), mp 86–88°C dec. R_f 0.51 (CH_2Cl_2 – MeOH – acetic acid, 90:10:1). HRMS–CI (NH_3) calcd. for $C_{15}H_{10}O_4$ $(M)^+$: 254.0579; found: 254.0539. UV (CH_3CN) (nm): 294 (ε 17 400). IR (KBr) (cm^{-1}): 3700–2600 (br, s), 1755 (s), 1730 (s), 1715 (s), 1600 (s). ^1H NMR (DMSO-d_6) δ: 8.31 (d, J = 8.0 Hz, 1H), 8.19 (s, 1H), 8.07 (d, J = 8.0 Hz, 1H), 7.82 (m, 2H), 7.62 (s, 2H, exchangeable with D_2O), 7.43–7.54 (m, 3H). ^{13}C NMR (DMSO-d_6) δ: 197.2, 196.7, 148.7, 139.4, 137.9, 137.3, 135.8, 129.4, 127.6, 124.8, 121.4, 88.1. Anal. calcd. for $C_{15}H_{10}O_4$: C 70.86, H 3.96; found: C 71.13, H 4.01.

Suzuki coupling reactions of 117

To a solution of **117** (1.0 equiv) in benzene (0.20–0.50 M) was added aq 2 M Na_2CO_3 (2.0 equiv) and a solution of a boronic acid (1.1–1.3 equiv) dissolved in ethanol (1.0–1.5 M). Dissolved oxygen was removed by placing the reaction flask in a dry ice – acetone bath followed by evacuation under reduced pressure. The evacuated flask was then filled with N_2 and allowed to warm to room temperature. When the contents of the flask were completely fluid, the freeze–pump–thaw process was repeated two more times. A catalytic amount of $Pd(PPh_3)_4$ (1–3 mol%) was added and the mixture was heated at reflux under a N_2 atmosphere and protected from light. When the reaction was completed (1–6 h as determined by TLC), 30% hydrogen peroxide (0.5 mL) was added and the reaction mixture was stirred. After 45 min, the contents of the flask were poured into water and the mixture was extracted with Et_2O or CH_2Cl_2. The organic extract was washed with brine, dried over Na_2SO_4, filtered, and the solvent was evaporated under reduced pressure. The crude product was purified by column chromatography.

*6-Phenylindan-1-one (**118**)*

Compound **117** (528 mg, 2.50 mmol) was coupled with phenylboronic acid (335 mg, 2.75 mmol) to afford 546 mg of a yellow solid after purification by column chromatography (Et_2O – petroleum ether, 1:1). The solid was dissolved in CH_2Cl_2 (50 mL) and the solution was stirred with decolorizing carbon for several hours at 25°C. The mixture

© 2001 NRC Canada

was filtered through a pad of Celite and the solvent evaporated in vacuo to provide 515 mg (99% yield) of **118** as an off-white solid, mp 108–110°C (18). R_f 0.33 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{15}H_{12}O$ $(M)^+$: 208.0888; found: 208.0885. UV (CH_3CN) (nm): 306 (ε 2100), 239 (ε 32 300). IR (KBr) (cm^{-1}): 1710 (s). ^1H NMR ($CDCl_3$) δ: 7.94 (s, 1H), 7.78 (d, J = 8.0 Hz, 1H), 7.57 (d, J = 8.0 Hz, 1H), 7.30–7.55 (m, 5H), 3.11 (m, 2H), 2.69 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.8, 153.9, 140.4, 139.7, 137.5, 133.5, 128.8, 127.5, 126.9, 126.8, 121.5, 35.4, 25.4.

*6-Biphenyl-4-yl-indan-1-one (**119**)*

Compound **117** (2.12 g, 10.0 mmol) was coupled with 4-biphenylboronic acid (2.98 g, 15.0 mmol) to afford 2.66 g (93% yield) of **119** as a yellow solid after purification by column chromatography (Et_2O – petroleum ether, 1:4, 1:1; and CH_2Cl_2–Et_2O, 1:1). An analytical sample was prepared by recrystallization from $CHCl_3$–MeOH (1:1) using decolorizing carbon to give small, white crystals which were dried in vacuo for 48 h, mp 213.5 to 215°C. R_f 0.36 (Et_2O – petroleum ether, 1:1). UV (CH_3CN) (nm): 280 (ε 29 000), 250 (ε 16 900). IR (KBr) (cm^{-1}): 1700 (s). HRMS–CI (NH_3) calcd. for $C_{21}H_{17}O$ $(M+H)^+$: 285.1279; found: 285.1271. ^1H NMR ($CDCl_3$) δ: 8.02 (d, J = 1.6 Hz, 1H); 7.87 (dd, J = 8.0 Hz, J = 1.6 Hz, 1H), 7.67 (m, 4H), 7.63 (d, J = 8.0 Hz, 3H), 7.32–7.56 (m, 5H), 3.18 (m, 2H), 2.75 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 207.1, 154.2, 140.6, 140.4, 140.1, 138.8, 137.7, 133.6, 128.8, 127.6, 127.5, 127.1, 127.0, 121.7, 36.6, 25.6 (note: only 16 of a possible 17 signals were observed).

*6-(4-Methoxyphenyl)indan-1-one (**120**)*

Compound **117** (2.12 g, 10.0 mmol) was coupled with 4-methoxyphenylboronic acid (2.28 g, 15.0 mmol) to afford 1.63 g (68% yield, mp 145–147°C) of **120** as orange crystals after recrystallization (THF–hexane, 1:4). A small analytical sample was purified by column chromatography (Et_2O – petroleum ether, 1:4) to give 153 mg (6% yield) of light yellow crystals (74% overall yield), mp 149 to 150°C (lit. (110) mp 148 to 149°C), purified by column chromatography eluting with EtOAc–cyclohexane, 1:1). R_f 0.31 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{16}H_{14}O_2$ $(M+H)^+$: 239.1072; found: 239.1059. UV (CH_3CN) (nm): 312 (ε 1300), 263 (ε 18 600). IR (KBr) (cm^{-1}): 1690 (s), 1245 (s), 1175 (s). ^1H NMR ($CDCl_3$) δ: 7.87 (s, 1H), 7.74 (d, J = 8.0 Hz, 1H), 7.44–7.51 (m, 3H), 6.94 (m, 2H), 3.80 (s, 3H), 3.09 (m, 2H), 2.68 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 207.0, 159.3, 153.4, 140.0, 137.5, 133.1, 132.2, 128.0, 126.8, 121.0, 114.2, 55.2, 36.5, 25.4. Anal. calcd. for $C_{16}H_{14}O_2$: C 80.65, H 5.92; found: C 80.49, H 5.93.

*6-Benzo[1,3]dioxo-5-yl-indan-1-one (**121**)*

Compound **117** (730 mg, 3.45 mmol) was coupled with benzo[1,3]dioxole-5-boronic acid (630 mg, 3.80 mmol) to afford 820 mg (94% yield) of **121** after purification by column chromatography (Et_2O – petroleum ether, 1:4 and 1:1). It was necessary to use CH_2Cl_2 to extract the product from the crude reaction mixture. An analytical sample was prepared by recrystallization from Et_2O–CH_2Cl_2 to give light yellow crystals, mp 160–162°C. R_f 0.33 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{16}H_{12}O_3$ $(M)^+$: 252.0786; found: 252.0786. UV (CH_3CN) (nm): 298 (ε 7900), 268 (ε 8900). IR (KBr) (cm^{-1}): 1700 (s), 1480 (s), 1220 (s), 1035 (s). ^1H NMR ($CDCl_3$) δ: 7.82 (d, J = 2.0 Hz, 1H), 7.69 (dd, J = 8.0 Hz, J = 2.0 Hz, 1H), 7.44 (d, J = 8.0 Hz, 1H), 7.00–7.03 (m, 2H), 6.82 (m, 1H), 5.95 (s, 2H), 3.08 (m, 2H), 2.67 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.8, 153.6, 148.2, 147.3, 140.2, 137.5, 134.1, 133.3, 126.8, 121.3, 120.6, 108.6, 107.4, 101.2, 36.5, 25.4. Anal. calcd. for $C_{16}H_{12}O_3$: C 76.18, H 4.80; found: C 76.03, H 4.70.

*6-(4-Methysulfanylphenyl)indan-1-one (**122**)*

Compound **117** (211 mg, 1.00 mmol) was coupled with 4-methylsulfanylphenylboronic acid (252 mg, 1.50 mmol) to afford 202 mg (80% yield, mp 120–124°C) of **122** after purification by column chromatography (Et_2O – petroleum ether, 1:4 and 1:1). An analytical sample was prepared by recrystallization from MeOH to afford yellow crystals, mp 126 to 127°C. R_f 0.35 (Et_2O – petroleum ether, 1:1). HRMS-CI (NH_3) calcd. for $C_{16}H_{18}NOS$ $(M+NH_4)^+$: 272.1108; found: 272.1120.UV (CH_3CN) (nm): 284 (ε 24 400). IR (KBr) (cm^{-1}): 1700 (s). ^1H NMR ($CDCl_3$) δ: 7.91 (s, 1H), 7.77 (d, J = 8.0 Hz, 1H), 7.48–7.51 (m, 3H), 7.29 (d, J = 8.1 Hz, 2H), 2.50 (s, 3H), 3.13 (m, 2H), 2.70 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.9, 153.9, 139.7, 138.2, 137.5, 136.4, 133.2, 127.2, 126.9, 126.7, 121.2, 36.5, 25.4, 15.5. Anal. calcd. for $C_{16}H_{14}OS$: C 75.17, H 5.71; found: C 75.57, H 5.55.

*6-Thiophen-2-yl-indan-1-one (**123**)*

Compound **117** (1.10 g, 5.21 mmol) was coupled with thiophen-2-ylboronic acid (1.00 g, 7.82 mmol) to afford 993 mg (89% yield) of **123** as a white solid after purification by column chromatography (Et_2O – petroleum ether, 1:1), mp 115 to 116°C. R_f 0.40 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{13}H_{10}OS$ $(M)^+$: 214.0452; found: 214.0445. UV (CH_3CN) (nm): 285 (ε 15 300). IR (KBr) (cm^{-1}): 1705 (s). ^1H NMR ($CDCl_3$) δ: 7.94 (dd, J = 1.8 Hz, J = 0.6 Hz, 1H), 7.80 (dd, J = 8.0 Hz, J = 1.8 Hz, 1H), 7.45 (dd, J = 8.0 Hz, J = 0.6 Hz, 1H), 7.33 (dd, J = 3.6 Hz, J = 1.1 Hz, 1H), 7.27 (dd, J = 5.1 Hz, J = 1.1 Hz, 1H), 7.06 (dd, J = 5.1 Hz, J = 3.6 Hz, 1H), 3.11 (m, 2H), 2.70 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 206.2, 160.6, 153.4, 137.1, 133.2, 131.7, 127.6, 126.6, 126.5, 124.7, 123.1, 119.7, 35.9, 25.0. Anal. calcd. for $C_{13}H_{10}OS$: C 72.86, H 4.70; found: C 73.02, H 4.55.

Selenium dioxide oxidation of 6-aryl-substituted indanones

These compounds were prepared according to the general procedure described for **47**. The solid which formed after recrystallization from water and decolorizing carbon was collected, washed with water, and dried in vacuo. The yields were not optimized.

*5-Biphenyl-4-yl-2,2-dihydroxyindan-1,3-dione (**48**)*

Dark yellow solid (45% yield), mp 270–272°C dec. R_f 0.56 (MeOH – CH_2Cl_2 – acetic acid, 90:10:1). HRMS–CI (NH_3) calcd. for $C_{21}H_{14}O_4$ $(M)^+$: 330.0892; found: 330.0878. UV (CH_3CN) (nm): 312 (ε 25 400), 254 (ε 21 100). IR (KBr) (cm^{-1}): 3600–2600 (br, s), 1720 (s), 1175 (s). ^1H NMR (DMSO-d_6) δ: 8.38 (dd, J = 8.1 Hz, J = 1.6 Hz, 1H), 8.28 (d, J = 1.6 Hz, 1H), 8.08 (d, J = 8.1 Hz, 1H), 7.95 (d, J = 8.4 Hz, 2H), 7.81 (d, J = 8.4 Hz, 2H), 7.73 (m, 2H), 7.61 (s,

*5-Benzo[1,3]dioxo-5-yl-2,2-dihydroxyindan-1,3-dione (**53**)*

Yellow solid (37% yield), mp 231–233°C dec. R_f 0.22 (benzene – EtOAc – formic acid, 85:10:5). HRMS–CI (NH_3) calcd. for $C_{16}H_{11}O_6$ $(M+H)^+$: 299.0555; found: 299.0561. UV (CH_3CN) (nm): 332 (ε 8300). IR (KBr) (cm^{-1}): 3650–2500 (br, s), 1755 (s), 1720 (s), 1705 (s). ^1H NMR (DMSO-d_6) δ: 8.26 (d, J = 8.1 Hz, 1H), 8.14 (s, 1H), 8.01 (d, J = 8.1 Hz, 1H), 7.56 (s, 2H, exchangeable with D_2O), 7.47 (d, J = 1.6 Hz, 1H), 7.36 (dd, J = 8.2 Hz, J = 1.6 Hz, 1H), 7.04 (d, J = 8.2 Hz, 1H), 6.09 (s, 2H). ^{13}C NMR (DMSO-d_6) δ: 197.1, 196.5, 148.5, 148.4, 148.3, 139.4, 136.8, 135.3, 132.0, 124.6, 122.0, 120.8, 109.0, 107.8, 101.7, 88.1. Anal. calcd. for $C_{16}H_{10}O_6$: C 64.43, H 3.38; found: C 64.74, H 3.65.

*2,2-Dihydroxy-5-(4-methylsulfanylphenyl)indan-1,3-dione (**54**)*

Orange crystals (37% yield), mp 228–230°C dec, which were dried in vacuo for 24 h to provide an analytical sample. R_f 0.25 (benzene – EtOAc –mformic acid, 85:10:5). HRMS–CI (NH_3) calcd. for $C_{16}H_{12}O_4S$ $(M)^+$: 300.0456; found: 300.0450. UV (CH_3CN) (nm): 331 (ε 14 500). IR (KBr) (cm^{-1}): 3600–2400 (br, s), 1750 (s), 1725 (s), 1715 (s), 1160 (s). ^1H NMR (DMSO-d_6) δ: 8.33 (d, J = 8.1 Hz, 1H), 8.20 (s, 1H), 8.05 (d, J = 8.1 Hz, 1H), 7.83 (d, J = 8.4 Hz, 2H), 7.55 (s, 2H, exchangeable with D_2O), 7.39 (d, J = 8.4 Hz, 2H), 2.53 (m, 1H). ^{13}C NMR (DMSO-d_6) δ: 197.1, 196.5, 148.0, 140.4, 139.4, 137.0, 135.2, 133.9, 127.9, 126.2, 124.6, 120.7, 88.0, 14.3. Anal. calcd. for $C_{16}H_{12}O_4S$: C 63.98, H 4.03; found: C 63.50, H 3.94.

*2,2-Dihydroxy-5-thiophen-2-yl-indan-1,3-dione (**55**)*

Yellow solid (25% yield), mp 90–92°C dec. R_f 0.23 (benzene – EtOAc – formic acid, 85:10:5). HRMS–CI (NH_3) calcd. for $C_{13}H_8O_4S$ $(M)^+$: 260.0143; found: 260.0130. UV (CH_3CN) (nm): 331 (ε 17 900). IR (KBr) (cm^{-1}): 3600–2300 (br, s), 1740 (m), 1705 (s), 1145 (s), 1105 (s). ^1H NMR (DMSO-d_6) δ: 8.30 (dd, J = 8.1 Hz, J = 1.6 Hz, 1H), 8.18 (d, J = 1.6 Hz, 1H), 8.02 (d, J = 8.1 Hz, 1H), 7.79 (d, J = 5.0 Hz, 1H), 7.56 (s, 2H, exchangeable with D_2O), 7.24 (dd, J = 5.0 Hz, J = 3.8 Hz, 1H), 7.11 (d, J = 3.8 Hz, 1H). ^{13}C NMR (DMSO-d_6) δ: 197.0, 196.1, 141.9, 139.5, 136.8, 133.7, 131.4, 129.3, 128.7, 127.6, 125.0, 119.0, 87.9. Anal. calcd. for $C_{13}H_8O_4S \cdot H_2O$: C 56.11, H 3.62; found: C 55.78, H 3.30.

Suzuki coupling reactions of ketal intermediates

Compounds **100**, **125**, or **126** were coupled to a variety of boronic acids using the procedure described for the coupling reactions of **117**.

*2,2-Dimethoxy-5-phenyl-indan-1,3-dione (**132**)*

Compound **100** (1.43 g, 5.00 mmol) was coupled with phenylboronic acid (920 mg, 7.50 mmol) to afford 1.36 g (96% yield) of **132** after purification by column chromatography (Et_2O – petroleum ether, 1:1). A yellow, crystalline precipitate, which formed in several of the chromatography fractions, was collected and dried in vacuo to afford an analytical sample, mp 145 to 146°C. R_f 0.31 (Et_2O – petroleum ether, 1:4). HRMS–CI (CH_4) calcd. for $C_{17}H_{14}O_4$ $(M)^+$: 282.0892; found: 282.0880.UV (CH_3CN) (nm): 297 (ε 13 700), 249 (ε 16 800). IR (KBr) (cm^{-1}): 1750 (s), 1720 (s), 1160 (s), 1050 (s). ^1H NMR ($CDCl_3$) δ: 8.13 (dd, J = 1.7 Hz, J = 0.6 Hz, 1H), 8.08 (dd, J = 8.0 Hz, J = 1.7 Hz, 1H), 8.01 (dd, J = 8.0 Hz, J = 0.6 Hz, 1H), 7.62 (s, 2H), 7.42–7.51 (m, 3H), 3.65 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.6, 193.0, 149.8, 140.0, 138.4, 137.9, 135.5, 129.3, 129.22, 127.4, 124.7, 122.0, 91.1, 51.7. Anal. calcd. for $C_{17}H_{14}O_4$: C 72.34, H 5.00; found: C 72.25, H 4.96.

*5-Biphenyl-4-yl-2,2-dimethoxyindan-1,3-dione (**133**)*

Compound **100** (1.43 g, 5.00 mmol) was coupled with 4-biphenylboronic acid (1.49 g, 7.50 mmol) to afford 1.75 g (98% yield) of **133** after purification by column chromatography (Et_2O – petroleum ether, 1:1). A white-yellow, crystalline precipitate, which formed in several of the chromatography fractions, was collected and dried in vacuo to afford an analytical sample, mp 156 to 157°C. R_f 0.30 (Et_2O – petroleum ether, 1:4). HRMS–CI (NH_3) calcd. for $C_{23}H_{22}NO_4$ $(M+NH_4)^+$: 376.1548; found: 376.1553. UV (CH_3CN) (nm): 320 (ε 23 400), 254 (ε 17 900). IR (KBr) (cm^{-1}): 1750 (s), 1720 (s), 1190 (s), 1165 (s), 1035 (s). ^1H NMR ($CDCl_3$) δ: 8.20 (d, J = 1.6 Hz, 1H), 8.13 (dd, J = 8.0 Hz, J = 1.6 Hz, 1H), 8.04 (d, J = 8.0 Hz, 1H), 7.72 (s, 4H), 7.63 (m, 2H), 7.33–7.49 (m, 3H), 3.68 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.6, 149.3, 142.2, 140.1, 139.9, 138.0, 137.1, 135.3, 128.9, 127.9, 127.9, 127.8, 127.0, 124.8, 121.8, 91.2, 51.7 (note: only 22 of a potential 23 signals were observed observed). Anal. calcd. for $C_{23}H_{18}O_4$: C 77.08, H 5.06; found: C 77.19, H 4.89.

*2,2-Dimethoxy-5-(4-nitrophenyl)indan-1,3-dione (**134**)*

Compound **100** (428 mg, 1.5 mmol) was coupled with 4-nitrophenylboronic acid (250 mg, 1.5 mmol) to afford 321 mg (66% yield) of **134** as a yellow solid after purification by column chromatography (EtOAc – petroleum ether, 1:3), mp 155 to 156.5°C. R_f 0.50 (EtOAc – petroleum ether, 1:3). HRMS calcd. for $C_{17}H_{14}NO_6$ $(M+H)^+$: for 328.0821; found: 328.0813. IR (KBr) (cm^{-1}): 1751 (s), 1719 (s), 1163 (s), 1038 (s), 973 (m), 883 (m). ^1H NMR (500 MHz, $CDCl_3$) δ: 8.36–8.38 (m, 2H), 8.20 (d, J = 1.3 Hz, 1H), 8.11 (d, J = 1.0 Hz, 2H), 7.81 (dd, ^1J = 6.9 Hz, ^2J = 2.0 Hz, 2H), 3.67 (s, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 193.2, 192.8, 148.3, 147.2, 144.7, 140.1, 139.0, 135.6, 128.5, 125.1, 124.5, 122.7, 91.2, 51.8. Anal. calcd. for $C_{17}H_{13}NO_6$: C 62.39, H 4.00, N 4.28; found: C 62.65, H 3.80, N 4.68.

*2,2-Dimethoxy-5-(4-methoxyphenyl)indan-1,3-dione (**135**)*

Compound **100** (1.26 g, 4.42 mmol) was coupled with 4-methoxyphenylboronic acid (1.01 g, 6.63 mmol) to afford 1.37 g (99% yield), mp 105–108°C of **135** after purification by column chromatography (Et_2O – petroleum ether, 1:1). Slow evaporation of a CH_2Cl_2 solution of the product gave yellow crystals which were washed with cold Et_2O (1.0 mL) and dried in vacuo to afford an analytical sample, mp 112–114°C. R_f 0.28 (Et_2O – petroleum ether, 1:4). HRMS–CI (NH_3) calcd. for $C_{18}H_{20}NO_5$ $(M+NH_4)^+$: 330.1341; found: 330.1334. UV (CH_3CN) (nm): 326 (ε 19 700). IR (KBr) (cm^{-1}): 1710 (s), 1590 (s), 1245 (s), 1170 (s), 1160 (s), 1030 (s). ^1H NMR ($CDCl_3$) δ: 8.01 (d, *J* = 1.5 Hz, 1H), 7.98 (dd, *J* = 8.1 Hz, *J* = 1.5 Hz, 1H), 7.91 (d, *J* = 8.1 Hz, 1H), 7.52 (d, *J* = 8.8 Hz, 2H), 6.93 (d, *J* = 8.8 Hz, 2H), 3.79 (s, 3H), 3.62 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.6, 192.8, 160.6, 149.2, 139.9, 137.2, 134.7, 130.4, 128.5, 124.5, 120.9, 114.6, 91.1, 55.2, 51.5.

*5-Benzo[1,3]dioxo-5-yl-2,2-dimethoxyindan-1,3-dione (**136**)*

Compound **100** (1.43 g, 5.00 mmol) was coupled with benzo[1,3]dioxole-5-boronic acid (1.24 g, 7.50 mmol) to afford 1.62 g (99% yield) of **136** after purification by column chromatography (Et_2O – petroleum ether, 1:1). A yellow, crystalline precipitate, which formed in one of the chromatography fractions, was collected and dried in vacuo to afford an analytical sample, mp 158–160°C. R_f 0.24 (Et_2O – petroleum ether, 1:4). HRMS–CI (CH_4) calcd. for $C_{18}H_{14}O_6$ $(M)^+$: 326.0790; found: 326.0796. UV (CH_3CN) (nm): 341 (ε 12 600). IR (KBr) (cm^{-1}): 1740 (m), 1710 (s), 1235 (s), 1030 (s). ^1H NMR ($CDCl_3$) δ: 7.97–8.02 (m, 3H), 7.06 (s, 1H), 7.10 (d, *J* = 8.1 Hz, 1H), 6.87 (d, *J* = 8.1 Hz, 1H), 6.01 (s, 2H), 3.64 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.6, 192.9, 149.4, 148.8, 148.6, 140.0, 137.5, 135.0, 132.4, 124.6, 121.6, 121.4, 108.9, 107.5, 101.6, 91.1, 51.7. Anal. calcd. for $C_{18}H_{14}O_6$: C 66.25, H 4.32; found: C 66.14, H 4.36.

*2,2-Dimethoxy-5-(4-methylsulfanylphenyl)indan-1,3-dione (**137**)*

Compound **100** (2.85 g, 10.0 mmol) was coupled with 4-methylsulfanylphenylboronic acid (2.52 g, 15.0 mmol) to afford 3.08 g (95% yield) of **137** after purification by column chromatography (Et_2O – petroleum ether, 1:1). A yellow, crystalline precipitate, which formed in the chromatography fractions, was collected and dried in vacuo to give an analytical sample, mp 112 to 113°C. R_f 0.25 (Et_2O – petroleum ether, 1:4). HRMS–CI(CH_4) calcd. for $C_{18}H_{16}O_4S$ $(M)^+$: 328.0769; found: 328.0765. UV (CH_3CN) (nm): 339 (ε 19 900). IR (KBr) (cm^{-1}): 1715 (s), 1585 (s), 1190 (s), 1160 (s), 1030 (s). ^1H NMR ($CDCl_3$) δ: 8.02 (dd, *J* = 1.6 Hz, *J* = 0.5 Hz, 1H), 7.99 (dd, *J* = 8.1 Hz, *J* = 1.6 Hz, 1H), 7.93 (dd, *J* = 8.1 Hz, *J* = 0.5 Hz, 1H), 7.49 (d, *J* = 8.5 Hz, 2H), 7.24 (d, *J* = 8.5 Hz, 2H), 2.45 (s, 3H), 3.61 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.4, 192.7, 148.8, 140.9, 139.8, 137.5, 134.8, 134.3, 127.4, 126.2, 124.6, 121.1, 91.0, 51.5, 15.0. Anal. calcd. for $C_{18}H_{16}O_4S$: C 65.83, H 4.91; found: C 65.69, H 4.86.

*2,2-Dimethoxy-5-thiophen-2-yl-indan-1,3-dione (**138**)*

Compound **100** (4.28 g, 15.0 mmol) was coupled with 2-thienylboronic acid (2.88 g, 22.5 mmol) to afford 4.18 g (96% yield) of **138** after purification by column chromatography (Et_2O – petroleum ether, 1:1 and CH_2Cl_2). A yellow, crystalline precipitate, which formed in the chromatography fractions, was collected and dried in vacuo to afford an analytical sample, mp 133 to 134°C. R_f 0.28 (Et_2O – petroleum ether, 1:4). HRMS–CI (CH_4) calcd. for $C_{15}H_{12}O_4S$ $(M)^+$: 288.0456; found: 288.0475. UV (CH_3CN) (nm): 335 (ε 16 600), 250 (ε 12 000), 224 (ε 18 500). IR (KBr) (cm^{-1}): 1740 (s), 1710 (s), 1585 (s), 1185 (s), 1155 (s), 1040 (s), 1020 (s), 720 (s). ^1H NMR ($CDCl_3$) δ: 8.05 (dd, *J* = 1.7 Hz, *J* = 0.6 Hz, 1H), 8.30 (dd, *J* = 8.1 Hz, *J* = 1.7 Hz, 1H), 8.02 (dd, *J* = 8.1 Hz, *J* = 0.6 Hz, 1H), 7.47 (dd, *J* = 5.1 Hz, *J* = 1.1 Hz, 1H), 7.41 (dd, *J* = 3.8 Hz, *J* = 1.1 Hz, 1H), 7.09 (dd, *J* = 5.1 Hz, *J* = 3.8 Hz, 1H), 3.66 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.4, 192.4, 142.5, 141.2, 140.1, 137.4, 133.4, 128.7, 128.3, 126.3, 124.8, 119.7, 91.0, 51.6. Anal. calcd. for $C_{15}H_{12}O_4S$: C 62.15, H 4.20; found: C 62.48, H 4.06.

*2,2-Dimethoxy-5-(4-methylthiophen-2-yl)indan-1,3-dione (**139**)*

Compound **100** (4.28 g, 15 mmol) was coupled with 2-(4-methylthienyl)boronic acid (3.42 g, 22.5 mmol) to afford 3.18 g (70% yield) of **139** as a yellow solid after purification by column chromatography (Et_2O – petroleum ether, 1:4), mp 108 to 109°C. R_f 0.27 (Et_2O – petroleum ether, 1:4). HRMS–CI calcd. for $C_{16}H_{18}O_4S$ $(M+NH_4)^+$: 320.0957; found: 320.0963. IR ($CHCl_3$) (cm^{-1}): 1750 (s), 1725 (s), 1165 (s), 1065 (s). ^1H NMR (500 MHz, $CDCl_3$) δ: 8.08 (d, *J* = 1.2 Hz, 1H), 8.02 (dd, *J* = 8.1 Hz, *J* = 1.7 Hz, 1H), 7.93 (dd, *J*= 8.4 Hz, *J* = 0.6 Hz, 1H), 7.34 (d, *J* = 1.2 Hz, 1H), 7.02 (d, *J* = 1.1 Hz, 1H), 3.64 (s, 6H), 2.28 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 193.3, 192.3, 141.0, 133.4, 128.6, 125.1, 124.9, 124.0, 119.6, 91.2, 51.8, 15.8. Anal. calcd. for $C_{16}H_{14}O_4S$: C 63.56, H 4.67; found: C 63.86, H 4.70.

*2,2-Dimethoxy-5-(5-methylthiophen-2-yl)indan-1,3-dione (**140**)*

Compound **100** (3.5 g, 12.3 mmol) was coupled with 2-(5-methylthienyl)boronic acid (2.6 g, 18.4 mmol) to afford 1.75 g (47% yield) of **140** as a yellow solid after purification by column chromatography (Et_2O – petroleum ether, 1:4), mp 113 to 114°C. R_f 0.27 (Et_2O – petroleum ether, 1:4). HRMS–CI calcd. for $C_{16}H_{14}O_4S$ $(M+NH_4)^+$: 320.0957; found: 320.0950. IR ($CDCl_3$) (cm^{-1}): 1750 (s), 1720 (s), 1155 (s), 1055 (s). ^1H NMR (500 MHz, $CDCl_3$) δ: 8.02 (d, *J* = 1.9 Hz, 1H), 7.97 (dd, *J*= 8.1 Hz, *J*= 1.6 Hz, 1H), 7.90 (dd, *J* = 7.4, *J* = 3.5 Hz, 1H), 7.32 (d, *J* = 3.6 Hz, 1H), 6.77 (d, *J* = 3.7 Hz, 1H), 3.67 (s, 6H), 2.51 (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 193.6, 192.5, 143.0, 140.2, 138.9, 137.2, 133.0, 127.2, 126.5, 124.8, 119.1, 91.2, 51.7, 15.6. *3,6-Dibromoinden-1-one (**130**)*

Ketone **117** (2.11 g, 10.0 mmol) was reacted with NBS (5.78 g, 32.5 mmol) and a catalytic amount of AIBN in CCl_4 (50 mL) according to the procedure previously described for the preparation of **99** to provide 420 mg (15% yield) of **130** as an orange solid after column chromatography (petroleum ether and Et_2O – petroleum ether, 15:85), mp 266–268°C. R_f 0.46 (Et_2O – petroleum ether, 1:4). HRMS–CI (NH_3) calcd. for $C_9H_4Br_2O$ $(M)^+$: 285.8629; found: 285.8596. IR (KBr) (cm^{-1}): 1715 (s). ^{1}H NMR ($CDCl_3$) δ: 7.58 (dd, *J* = 7.8 Hz, *J* = 1.8 Hz, 1H), 7.49 (d, *J* = 1.8 Hz, 1H), 7.05 (d, *J* = 7.8 Hz, 1H), 6.20 (s, 1H). ^{13}C NMR ($CDCl_3$) δ: 192.2, 148.2, 141.3, 135.8, 131.6, 127.3, 125.1, 124.6, 122.5.

*5-Bromo-2,2-dihydroxyindan-1,3-dione (**33**)*

Method A: Enone **130** (200 mg, 0.69 mmol) was heated with Br_2 (1 drop) in DMSO (10 mL) for 3.5 h according to the procedure previously described for the preparation of **112** to provide 35 mg (20% yield) of **33** as a light green solid after column chromatography (petroleum ether and Et_2O – petroleum ether, 1:1 and CH_2Cl_2).

Method B: Ketone **117** (500 mg, 2.37 mmol) was heated with SeO_2 (1.30 g, 11.8 mmol) in dioxane (50 mL) for 2 h according to the procedure previously described for the preparation of **65** to afford 140 mg (23% yield) of **33** as a yellow-green foam, mp 68–72°C. R_f 0.24 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_9H_5BrO_4$ $(M)^+$: 255.9371; found: 255.9358. UV (CH_3CN) (nm): 338 (ε 890), 265 (ε 13 200). IR (KBr) (cm^{-1}): 3700–2200 (br, s), 1720 (s), 1175 (s). ^{1}H NMR (D_2O) δ: 7.89–7.93 (m, 2H), 7.68 (d, *J* = 8.1, 1H) (note: the hydroxyl protons do not appear in the spectrum due to exchange with D_2O). ^{13}C NMR (D_2O) δ: 195.7, 195.3, 139.2, 136.6, 132.5, 131.6, 129.6, 124.1, 86.6.

*5-Bromo-2-diazoindan-1,3-dione (**124**)*

A suspension of finely divided **131** (48.0 g, 213 mmol, passed through a 40 mesh screen) in absolute EtOH (100 mL) was cooled to –30°C in a dry ice – acetone bath. Triethylamine (38.6 mL, 278 mmol) was added all at once to the slurry. The mixture immediately turned dark red, the solid dissolved, and the temperature rose to approximately –10°C. After stirring for 10 min, tosyl azide (53.4 g, 271 mmol) (CAUTION: toxic, potentially explosive at elevated temperatures) was slowly added over 10 min and the flask was transferred to an ice bath. The mixture gradually turned purple and a precipitate formed. After stirring for 1 h, the precipitate was collected, dried in air (1 h), and then in vacuo (2 h) to afford 45.0 g (84% yield) of **120** as a purple solid, mp 131 to 132°C dec. R_f 0.37 (Et_2O – petroleum ether, 1:4). HRMS–CI (CH_4) calcd. for $C_9H_3BrN_2O_2$ $(M)^+$: 249.9378; found: 249.9365. IR (KBr) (cm^{-1}): 2320 (w), 2125 (s), 1680 (s). ^{1}H NMR ($CDCl_3$) δ: 7.91 (d, *J* = 1.7 Hz, 1H), 7.83 (dd, *J* = 8.0 Hz, *J* = 1.7 Hz, 1H), 7.65 (d, *J* = 8.0 Hz, 1H). ^{13}C NMR ($CDCl_3$) δ: 180.8, 180.4, 138.3, 137.5, 135.3, 130.0, 125.8, 123.9 (note: a signal for C-2 was not observed).

*5-Bromo-2,2-dimethoxyindan-1,3-dione (**100**)*

Method A: Compound **33** (200 mg, 0.78 mmol) was dissolved in DMF (10 mL). Methyl iodide (870 mg, 14.0 mmol), silver(I) oxide (415 mg, 1.79 mmol), and water (5 drops) were added and the mixture was stirred at 25°C overnight. $CHCl_3$ (50 mL) was added and a precipitate was collected. The

© 2001 NRC Canada

solid was washed with $CHCl_3$ (25 mL) and the filtrates were combined. The $CHCl_3$ solution was treated with 5% aq KCN (50 mL), washed with water (2 × 50 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated under reduced pressure and the residue was purified by column chromatography (petroleum ether and Et_2O – petroleum ether, 1:1) to give 48 mg (22% yield, mp 103–105°C) of **100** as a yellow solid.

Method B: A mixture of diazodione **124** (45.0 g, 179 mmol) and MeOH (100 mL) was cooled to 5°C in an ice bath. To the purple slurry was added *tert*-butyl hypochlorite (23.4 mL, 195 mmol) over 10 min. Gentle bubbling (loss of N_2) was observed and a yellow precipitate formed. The solid was collected after 1 h, washed with ice cold MeOH (20 mL), dried in air and then in vacuo to give 33.0 g (65% yield, mp 103.5 to 104.5°C) of **100** as a yellow solid. An analytical sample of the product was obtained by recrystallization from MeOH to afford yellow crystals, mp 106 to 107°C. R_f 0.38 (Et_2O – petroleum ether, 1:4). ^{1}H NMR ($CDCl_3$) δ: 8.05 (d, J = 1.1 Hz, 1H), 7.94 (dd, J = 8.1 Hz, J = 1.1 Hz, 1H), 7.79 (d, J = 8.1 Hz, 1H), 3.58 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 192.3, 192.1, 140.4, 139.8, 137.8, 132.4, 127.3, 125.6, 90.8, 51.7. IR (KBr) (cm^{-1}): 1720 (s). HRMS–CI (NH_3) calcd. for $C_{11}H_{13}BrNO_4$ $(M+NH_4)^+$: 302.0027; found: 302.0049. Anal. calcd. for $C_{11}H_9BrO_4$: C 46.34, H 3.18; found: C 46.35, H 3.05.

*5-Bromo-2,2-diisopropoxyindan-1,3-dione (**125**)*

A mixture of diazodione **124** (2.27 g, 9.00 mmol) and 2-propanol (10 mL) was treated with *tert*-butyl hypochlorite (1.11 g, 10 mmol) according to the procedure described for compound **100** to give 1.15 g (38% yield) of **125**, mp 97 to 97.5°C. R_f 0.52 (Et_2O – petroleum ether, 1:9). HRMS calcd. for $C_{15}H_{18}BrO_4$ $(M+H)^+$: 341.0389; found: 341.0392. IR (KBr) (cm^{-1}): 1755 (s), 1728 (s), 1171 (s), 1042 (s). ^{1}H NMR ($CDCl_3$) δ: 8.11 (d, J = 1.3 Hz, 1H), 7.98 (dd, J = 8.2 Hz, J = 1.7 Hz, 1H), 7.85 (d, J = 8.0 Hz, 1H), 4.55–4.70 (m, 2H), 1.14 (d, J = 6.2 Hz, 12 H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 193.9, 193.6, 140.2, 139.7, 137.5, 132.2, 127.2, 125.5, 91.4, 67.3, 23.7. Anal. calcd. for $C_{15}H_{17}BrO_4$: C 52.80, H 5.02; found: C 52.25, H 5.12.

*5-Bromo-2,2-dibenzyloxyindan-1,3-dione (**126**)*

A mixture of diazodione **124** (2.0 g, 8.0 mmol) and benzyl alcohol (4 mL) was treated with *tert*-butyl hypochlorite (2.6 g, 24 mmol) according to the procedure described for compound **100** to give 1.77 g (51% yield) of **126**. R_f 0.63 (EtOAc – petroleum ether, 1:3). HRMS–CI calcd. for $C_{23}H_{18}BrO_4$ $(M+H)^+$: 437.0389; found: 437.0386. IR (KBr) (cm^{-1}): 1754 (m), 1717 (s), 1174 (s), 1055 (s). ^{1}H NMR ($CDCl_3$) δ: 8.13 (d, J = 1.2 Hz, 1H), 7.99 (dd, J = 8.1 Hz, J = 1.6 Hz, 1H), 7.85 (d, J = 8.1 Hz, 1H), 7.27–7.29 (m, 10 H), 5.05 (s, 4H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 192.2, 191.9, 140.5, 139.9, 137.8, 136.9, 132.5, 128.4, 127.9, 127.8, 127.4, 125.7, 91.3, 66.2. Anal. calcd. for $C_{23}H_{17}BrO_4$: C 63.17, H 3.92; found: C 63.09, H 4.03.

*2,2-Diacetoxy-1,3-indandione (**129**)*

Ninhydrin (**1**) (2.0 g, 11.2 mmol) was added to 5 mL (53 mmol) of acetic anhydride. One drop of concentrated (98%) sulfuric acid was added, and the temperature of the reaction mixture increased to ~40°C. The reaction mixture was stirred for 15 min at room temperature and then heated in an oil bath at 100°C for 48 h. Upon cooling the reaction mixture solidified. The solid was washed with Et_2O and recrystallized from EtOAc to yield 1.94 g (66% yield) of **129** as transparent crystals, mp 174.5 to 175.5°C. R_f 0.63 (EtOAc – petroleum ether, 2:3). HRMS calcd. for $C_{13}H_{11}O_6$ $(M+H)^+$: 263.0556; found: 263.0556. IR (KBr) (cm^{-1}): 1749 (s), 1728 (s), 1222 (s), 1066 (s). ^{1}H NMR ($CDCl_3$) δ: 7.93–7.98 (m, 2H), 7.85–7.90 (m, 2H), 2.11 (s, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 190.5, 168.0, 139.1, 136.2, 123.4, 19.9 (note: one quaternary carbon signal was not observed). Anal. calcd. for $C_{13}H_{10}O_6$: C 59.55, H 3.84; found: C 59.20, H 3.81.

Deprotection of ketals

The ketal was dissolved in glacial acetic acid (0.2 M) and an equal amount of water and concentrated aqueous hydrobromic acid (48%) were added to form a fine suspension. The reaction mixture was heated at reflux for 2 h and filtered while hot. The filtrate was diluted with water and the precipitate which formed after cooling in an ice bath was collected by filtration, washed with water, and air-dried to give the ninhydrin analog without further purification, in most cases.

*2,2-Dihydroxy-5-phenylindan-1,3-dione (**47**)*

Ketal **132** (930 mg, 3.29 mmol) was deprotected to give 450 mg (54% yield) of **47** as an orange-brown solid, mp 70–73°C dec.

*5-Biphenyl-4-yl-2,2-dihydroxyindan-1,3-dione (**48**)*

Ketal **133** (870 mg, 2.42 mmol) was deprotected to give 330 mg (41% yield) of **48** as an orange-brown solid, mp 228–231°C dec.

*2,2-Dihydroxy-5-(4-nitrophenyl)indan-1,3-dione (**50**)*

Ketal **134** (90 mg, 0.275 mmol) was deprotected to give 65 mg (89% yield) of **50** as a beige solid, mp 229–230°C dec. R_f 0.35 (EtOAc – petroleum ether, 2:3). IR (KBr) (cm^{-1}): 3412 (br), 1757 (s), 1715 (s), 1706 (s). ^{1}H NMR (DMSO-d_6) δ: 8.44 (dd, J = 8 Hz, J = 1.5 Hz, 1H), 8.35–8.38 (m, 3H), 8.13–8.19 (m, 3H), 7.62 (s, 2H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 196.2, 196.1, 147.8, 146.1, 144.2, 139.2, 138.1, 136.1, 129.1, 124.7, 124.2, 122.4, 106.1, 87.9. Anal. calcd. for $C_{15}H_9NO_6$: C 60.21, H 3.03; found: C 60.07, H 2.99.

*2,2-Dihydroxy-5-(4-methoxyphenyl)indan-1,3-dione (**52**)*

Ketal **135** (312 mg, 1.00 mmol) was deprotected to give 211 mg (74% yield) of **52** as an orange foam after column chromatography (Et_2O – petroleum ether, 1:4, and Et_2O), mp 62–65°C dec.

*5-Benzo[1,3]dioxo-5-yl-2,2-dihydroxyindan-1,3-dione (**53**)*

Ketal **136** (1.21 g, 3.71 mmol) was deprotected to give 890 mg (80% yield) of **53** as a dark yellow solid, mp 112–115°C dec (hydrated form); an orange-red foam was obtained after drying an analytical sample sample in vacuo for 48 h, mp 236–239°C dec.

© 2001 NRC Canada

*2,2-Dihydroxy-5-(4-methylsulfanylphenyl)indan-1,3-dione (**54**)*

Ketal **137** (750 mg, 2.28 mmol) was deprotected to give 660 mg (96% yield) of **54** as a yellow solid, mp 77 to 78°C dec.

*2,2-Dihydroxy-5-thiophen-2-yl-indan-1,3-dione (**55**)*

Ketal **138** (1.00 g, 3.47 mmol) was deprotected to give 770 mg (86% yield) of **55** as a yellow-tan solid, mp 260–262°C dec.

*2,2-Dihydroxy-5-(4-methylthiophen-2-yl)indan-1,3-dione (**56**)*

Ketal **139** (2.65 g, 8.75 mmol) was deprotected to give 1.05 g (44% yield) of **56** as cream-colored flakes. HRMS–CI calcd. for $C_{14}H_8O_3S$ $(M\text{-}H_2O)^+$: 256.0194; found: 256.0199. IR (KBr) (cm^{-1}): 3280 (m), 1750 (s), 1715 (s), 1165 (s). ^1H NMR (DMSO-d_6) δ: 8.14 (dd, J = 8.2 Hz, J = 1.6 Hz, 1H), 8.12 (s, 1H), 7.99 (d, J = 8.1 Hz, 1H), 7.78 (s, 1H), 7.50 (s, 2H, exchangeable with D_2O), 7.37 (s, 1H), 2.26 (s, 3H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 196.9, 196.0, 142.0, 140.2, 139.5, 139.3, 136.7, 133.4, 129.7, 124.9, 124.5, 118.6, 87.9, 15.4. Anal. calcd. for $C_{14}H_{10}O_4S$: C 61.31, H 3.67; found: C 60.94, H 3.55.

*2,2-Dihydroxy-5-(5-methylthiophen-2-yl)indan-1,3-dione (**57**)*

Ketal **140** (410 mg, 1.36 mmol) was deprotected to give 195 mg (52% yield) of **57** as cream-colored flakes. HRMS calcd. for $C_{14}H_{10}O_4S$ $(M)^+$: 274.0300; found: 274.0306. IR (KBr) (cm^{-1}): 3250 (s), 1745 (s), 1710 (s), 1160 (s). ^1H NMR (500 MHz, acetone-d_6) δ: 8.40 (dd, J = 8.1 Hz, J = 1.7 Hz, 1H), 8.26 (d, J = 1.3 Hz, 1H), 8.17 (d, J = 8.2 Hz, 1H), 7.83 (d, J = 3.6 Hz, 1H), 7.09 (d, J = 3.6 Hz, 1H), 6.65 (s, 2H, exchangeable with D_2O), 3.01 (s, 3H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 197.0, 195.9, 143.2, 142.0, 139.5, 138.3, 136.4, 133.1, 127.8, 127.7, 124.9, 118.2, 87.9, 15.2. Anal. calcd. for $C_{14}H_{10}O_4S$: C 61.31, H 3.67; found: C 61.20, H 3.47.

*2,2-Dihydroxy-5-(5-ethylthiophen-2-yl)indan-1,3-dione (**58**)*

Ketal **141** (3.27 g, 10.35 mmol) was deprotected to give 2.23 g (75% yield) of **58** as cream-colored flakes, mp 108 to 109.5°C dec. R_f 0.40 (benzene – EtOAc – formic acid, 85:10:5). IR (KBr) (cm^{-1}): 3285 (m), 1745 (s), 1710 (s), 1160 (s). HRMS calcd. for $C_{15}H_{12}O_4S$ $(M)^+$: 288.0456; found: 288.0449. ^1H NMR (500 MHz, acetone-d_6) δ: 8.38 (dd, J = 8.1 Hz, J = 1.8 Hz, 1H), 8.25 (dd, J = 1.5 Hz, J = 0.5 Hz, 1H), 8.15 (dd, J = 8.2 Hz, J = 0.7 Hz, 1H), 7.81 (d, J = 3.7 Hz, 1H), 7.10 (d, J = 3.8 Hz, 1H), 3.07 (q, J = 7.5 Hz, 2H), 1.48 (t, J = 7.5 Hz, 3H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 197.0, 195.9, 150.6, 142.1, 139.5, 137.9, 136.4, 133.1, 127.6, 126.1, 124.9, 118.2, 87.9, 23.0, 15.6. Anal. calcd. for $C_{15}H_{12}O_4S$: C 62.49, H 4.20; found: C 62.25, H 4.19.

*2,2-Dihydroxy-5-(thiophen-3-yl)indan-1,3-dione (**59**)*

Ketal **142** (2.01 g, 7.0 mmol) was deprotected to give 0.78 g (43% yield) of **59** as cream-colored flakes, mp 124–126°C dec. IR (KBr) (cm^{-1}): 3370 (m), 1745 (s), 1710 (s). HRMS–CI calcd. for $C_{13}H_8O_4S$ $(M)^+$: 260.0143; found: 260.0150. ^1H NMR (500 MHz, acetone-d_6) δ: 8.57 (dd, J = 8.6 Hz, J = 1.8 Hz, 1H), 8.44 (d, J = 1.2 Hz, 1H), 8.36 (dd, J = 2.9 Hz, J = 1.4 Hz, 1H), 8.22 (dd, J = 7.9 Hz, J = 0.5 Hz, 1H), 7.94 (dd, J = 5.1 Hz, J = 1.4 Hz, 1H), 7.85 (dd, J = 4.0 Hz, J = 2.0 Hz, 1H), 6.66 (s, 2H, exchangeable with D_2O). ^{13}C NMR (125 MHz, acetone-d_6) δ: 210.6, 210.4, 149.0, 145.2, 144.9, 142.6, 139.8, 132.8, 131.4, 129.8, 129.7, 125.6, 93.0. Anal. calcd. for $C_{13}H_8O_4S\cdot H_2O$: C 56.11, H 3.62; found: C 55.93, H 3.43.

*5-(4-Dimethylaminophenyl)-2,2-dihydroxyindan-1,3-dione (**49**)*

Ketal **145** (1.00 g, 3.07 mmol) was deprotected to give 730 mg (80% yield) of **49** as a brown solid. An analytical sample was purified by column chromatography (EtOAc – petroleum ether, 1:4 and 1:1) to give a khaki-colored solid, mp 90–94°C. R_f 0.33 (MeOH–CH_2Cl_2, 4:96). HRMS–CI (NH_3) calcd. for $C_{17}H_{14}NO_3$ $(M\text{-}OH)^+$: 280.0974; found: 280.0963. UV (CH_3CN) (nm): 625 (ε 300), 396 (ε 13 900), 258 (ε 14 400). IR (KBr) (cm^{-1}): 3600–2800 (br, m), 1740(m), 1720(s). ^1H NMR (DMSO-d_6) δ: 8.28 (m, 1H), 8.10 (m, 1H), 7.96 (m, 1H), 7.79 (m, 2H), 7.62 (br s, 2H, exchangeable with D_2O), 6.82 (m, 2H), 3.33 (s, 6H). ^{13}C NMR (DMSO-d_6) δ: 197.7, 196.5, 151.4, 149.1, 139.8, 135.9, 134.1, 128.5, 125.1, 124.4, 119.2, 112.8, 88.3 (note: the absorption for the dimethylamino-group carbons occurs in a region where it is obscured by the multiplet associated with DMSO-d_6).

*5-(2-Benzo[*b*]thienyl)-2,2-dihydroxy-1*H*-indene-1,3(2*H*)-dione (**60**)*

Ketal **146** (2.17 g, 6.41 mmol) was deprotected to give 1.22 g (61% yield) of **60** as a yellow-tan solid, mp 309–311°C dec. R_f 0.25 (benzene – EtOAc – formic acid, 85:10:5). HRMS–CI (NH_3) calcd. for $C_{17}H_{10}O_4S$ $(M)^+$: 310.0300; found: 310.0316. UV (CH_3CN) (nm): 340 (ε 17 700), 258 (ε 13 000). IR (KBr) (cm^{-1}): 3600–2300 (br, s), 1740 (s), 1730 (s), 1710 (s), 1250 (s), 1180 (s), 1145 (s), 1080 (s). ^1H NMR (DMSO-d_6) δ: 8.35 (d, J = 8.1 Hz, 1H), 8.26 (s, 2H), 8.04 (d, J = 8.1 Hz, 1H), 7.87–8.03 (m, 2H), 7.62 (br s, 2H, exchangeable with D_2O), 7.41 (m, 2H). ^{13}C NMR (DMSO-d_6) δ: 196.9, 196.2, 141.6, 140.4, 140.1, 139.5, 139.4, 137.4, 134.3, 126.0, 125.3, 125.0, 124.7, 124.3, 122.7, 120.0, 88.0. Anal. calcd. for $C_{17}H_{10}O_4S$: C 65.79, H 3.25; found: C 65.65, H 3.02.

*5-Benzothiazol-2-yl-2,2-dihydroxyindan-1,3-dione (**61**)*

Ketal **147** (890 mg, 2.62 mmol) was deprotected to give 238 mg (29% yield) of **61** as a light tan solid, mp 272–274°C dec. R_f 0.21 (benzene – EtOAc – formic acid, 85:10:5). HRMS–CI (NH_3) calcd. for $C_{16}H_8NO_4S$ $(M\text{-}OH)^+$: 294.0225; found: 294.0211. UV (CH_3CN) (nm): 334 (ε 12 200). IR (KBr) (cm^{-1}): 3600–2300 (br,s), 1760 (s), 1720 (s), 1140 (s), 1110 (s). ^1H NMR (DMSO-d_6) δ: 8.63 (d, J = 8.0 Hz, 1H), 8.48 (s, 1H), 8.09–8.19 (m, 3H), 7.68 (s, 2H, exchangeable with D_2O), 7.48–7.60 (m, 2H). ^{13}C NMR (DMSO-d_6) δ: 196.5, 196.4, 164.8, 153.4, 140.1, 139.5, 139.2, 135.3, 135.1, 127.2, 126.6, 125.2, 123.6, 122.7, 121.6, 88.0. Anal. calcd. for $C_{16}H_9NO_4S\cdot(H_2O)_{0.5}$: C 59.99, H 3.15; found: C 60.14, H 2.77.

*5-[2,2′-Bithiophen-5-yl]-2,2-dihydroxyindan-1,3-dione (**62**)*

Ketal **148** (2.15 g, 5.81 mmol) was deprotected to give 267 mg (13% yield) of **62** as an orange brown solid, mp 90–93°C dec. The solid was dried in vacuo for 48 h to provide a dark green-brown solid which was used as an analytical

*5-[5′-(2,2-Dihydroxy-1,3-dioxoindan-5-yl)-thiophen-2-yl]-2,2-dihydroxyindan-1,3-dione (**67**)*

Ketal **150** (1.23 g, 2.50 mmol) was deprotected to give 880 mg (80% yield) of **67** as a bright yellow solid, mp 298–300°C dec. R_f 0.27 (MeOH–CH_2Cl_2, 4:96). UV (CH_3CN) (nm): 380 (ε 30 900). IR (KBr) (cm^{-1}): 3600–2500 (br, s), 1700 (s), 1150 (s). ^1H NMR (DMSO-d_6) δ: 8.38 (d, J = 8.2 Hz, 2H), 8.30 (s, 2H), 8.09 (s, 2H), 8.07 (d, J = 8.2 Hz, 2H), 7.58 (s, 4H, exchangeable with D_2O). ^{13}C NMR (DMSO-d_6) δ: 196.9, 196.1, 143.0, 141.0, 139.5, 137.3, 133.8, 129.4, 125.1, 119.4, 87.9. Anal. calcd. for $C_{22}H_{12}O_8S\cdot(H_2O)_{1.5}$: C 57.02, H 3.26; found: C 57.22, H 3.60.

*2,2-Dihydroxy-5-styrylindan-1,3-dione (**63**)*

Ketal **155** (154 mg, 0.5 mmol) was deprotected to give 120 mg (82% yield) of **63** as a beige solid. IR (KBr) (cm^{-1}): 1747 (s), 1711 (s). ^1H NMR (DMSO-d_6) δ: 8.26 (d, J = 8.1 Hz, 1H), 8.20 (s, 1H), 8.00 (d, J = 8.0 Hz, 1H), 7.67–7.37 (m, 3H), 7.53 (d, J = 13.3 Hz, 1H), 7.50 (s, 2H), 7.35–7.49 (m, 3H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 197.2, 196.2, 146.0, 139.3, 137.0, 136.2, 134.9, 134.0, 128.8, 127.2, 126.5, 124.4, 120.7, 87.9 (note: the signal for one aromatic carbon was not detected). Anal. calcd. for $C_{17}H_{12}O_4$: C 72.85, H 4.32; found: C 72.99, H 4.26.

*2,2-Dihydroxy-5-(4-hydroxyphenyl)indan-1,3-dione (**51**)*

A solution of ketal **135** (376 mg, 1.20 mmol) in CH_2Cl_2 (50 mL) was placed under an N_2 atmosphere and cooled to 5°C in an ice bath. Boron tribromide in CH_2Cl_2 (6.00 mL, 6.00 mmol) was added via a syringe over 10 min and the color of the solution changed from yellow to red. The reaction mixture was stirred for 3 h at 25°C and then poured into 1 M HCl (50 mL). Water (50 mL) was added and the mixture was extracted with EtOAc (2 × 150 mL), washed with brine (50 mL), dried over Na_2SO_4, and filtered. The solvent was evaporated under reduced pressure and the residue heated at reflux with water and a small amount of decolorizing carbon. The mixture was filtered while hot and allowed to cool. No solid formed even after reducing the volume of the mixture so the solution was extracted with EtOAc (6 × 100 mL) and the combined organic extracts were washed with brine (50 mL), dried over $MgSO_4$, and filtered. The solvent was removed under reduced pressure and the residue dried in vacuo to afford 211 mg (65% yield) of **51** as a dark green solid, mp 112–114°C dec. R_f 0.27 (benzene – EtOAc – formic acid, 85:10:5). FAB–HRMS (NBA) calcd. for $C_{15}H_{10}O_5$ $(M)^+$: 270.0528; found: 270.0533. UV (CH_3CN) (nm): 594 (ε 280), 492 (ε 740), 323 (ε 12 200). IR (KBr) (cm^{-1}): 3700–2200 (br, s), 1710 (s), 1260 (s), 1170 (s). ^1H NMR (DMSO-d_6) δ: 9.96 (s, 1H, exchangeable with D_2O), 8.27 (d, J = 8.2 Hz, 1H), 8.12 (s, 1H), 8.01 (d, J = 8.2 Hz, 1H), 7.73 (d, J = 8.3 Hz, 2H), 7.70 (s, 2H, exchangeable with D_2O), 6.90 (d, J = 8.3 Hz, 2H). ^{13}C NMR (DMSO-d_6) δ: 197.2, 196.4, 159.0, 148.7, 139.4, 136.3, 134.7, 129.0, 128.3, 124.5, 119.9, 116.2, 88.0 (note: only the signals associated with the major tautomer are given for ^1H and ^{13}C NMR).

*5-Tributylstannyl[2,2′]bithiophene (**144**)*

A flame-dried 500 mL two-necked, round-bottomed flask under a dry N_2 atmosphere, was charged with anhyd Et_2O (100 mL) and *n*-BuLi in hexanes (12.0 mL, 30.0 mmol). TMEDA (4.50 mL, 30.0 mmol) was added via a syringe. The solution was stirred for 10 min, cooled to 5°C in an ice bath and 2,2′-bithienyl (**143**, 5.00 g, 30.0 mmol) was added. After 30 min, tributyltin chloride (8.10 mL, 30.0 mmol) was added via a syringe. The mixture was warmed to 25°C and stirred overnight. To remove unreacted tributyltin chloride in the form of polymeric tributyltin fluoride, potassium fluoride (1.4 g, 28 mmol) was then added and the mixture was stirred for 1 h. Solids were collected by filtration and rinsed with CH_2Cl_2 (50 mL). The filtrate was evaporated under reduced pressure and the residue was dried in vacuo to give a yellow-orange oil (14.3 g). The oil was purified by distillation under reduced pressure to afford 10.8 g (79% yield, bp 190–205°C at 1 torr (1 torr = 133.322 Pa)) of **144** as a yellow oil. R_f 0.51, (petroleum ether). HRMS–CI (NH_3) calcd. for $C_{20}H_{32}S_2Sn$ $(M)^+$: 456.0967; found: 456.0988. IR (neat) (cm^{-1}): 2970 (s), 2940 (s), 2880 (s), 2860 (s). ^1H NMR ($CDCl_3$) δ: 7.96 (d, J = 4.8 Hz, 1H), 7.33 (d, J = 3.3 Hz, 1H), 7.21 (d, J = 3.3 Hz, 1H), 7.11 (d, J = 3.3 Hz, 1H), 7.02 (dd, J = 4.8 Hz, J = 3.3 Hz, 1H), 0.96–1.64 (m, 27H). ^{13}C NMR ($CDCl_3$) δ: 142.7, 137.6, 136.5, 136.0, 127.6, 124.9, 123.9, 123.4, 28.9, 27.2, 13.6, 10.8.

Stille coupling reactions

To a solution of compound **100** (1.0 equiv) in toluene (0.10 M) was added a stannane (1.0 to 1.1 equiv). A catalytic amount of $Pd(PPh_3)_4$ (2 mol%) was added and the mixture was heated at reflux under an N_2 atmosphere and protected from light. After 6 h, the reaction mixture was evaporated under reduced pressure and the residue was purified by column chromatography using petroleum ether and Et_2O – petroleum ether (1:1) and (or) recrystallization. In some instances, the crude residue was washed with hexanes and (or) taken up in Et_2O and stirred with an excess of potassium fluoride for 36 h to remove tributylstannyl chloride as polymeric tributyltin fluoride before further purification.

*5-(4-Dimethylaminophenyl)-2,2-dimethoxyindan-1,3-dione (**145**)*

Compound **100** (2.85 g, 10.0 mmol) was coupled with 4-tributylstannyldimethylaniline (4.11 g, 10.0 mmol) to afford 3.08 g (95% yield) of **145** as a yellow solid, mp 101–103°C. R_f 0.15 (Et_2O – petroleum ether, 1:4). HRMS–CI (NH_3) calcd. for $C_{19}H_{20}NO_4$ $(M+H)^+$: 326.1392; found: 326.1394. UV (CH_3CN) (nm): 626 (ε 100), 396 (ε 28 100), 258 (ε 26 100). *5-Benzo[*b*]thiophen-2-yl-2,2-dimethoxyindan-1,3-dione (**146**)*

Compound **100** (4.30 g, 15.0 mmol) was coupled with 2-tributylstannylbenzo[*b*]thiophene (6.35 g, 15.0 mmol) to afford 3.73 g (73% yield) of **146** as light yellow crystals, mp 182 to 183°C (MeOH). R_f 0.35 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{19}H_{14}O_4S$ $(M)^+$: 338.0613; found: 338.0625. UV (CH_3CN) (nm): 344 (ε 25 800), 258 (ε 17 900). IR (KBr) (cm^{-1}): 1735 (s), 1710 (s), 1180 (s), 1145 (s), 1030 (s). ^{1}H NMR ($CDCl_3$) δ: 8.80 (dd, *J* = 8.1 Hz, *J* = 1.6 Hz, 1H), 8.16 (d, *J* = 1.6 Hz, 1H), 7.92 (d, *J* = 8.1 Hz, 1H), 7.73–7.80 (m, 2H), 7.69 (s, 1H), 7.32–7.36 (m, 2H), 3.66 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.3, 192.5, 142.5, 140.8, 140.2, 140.0, 140.0, 138.0, 134.0, 125.8, 125.1, 124.8, 124.4, 123.1, 122.4, 120.6, 91.1, 51.7. Anal. calcd. for $C_{19}H_{14}O_4S$: C 67.44,H 4.17; found: C 67.81, H 4.18.

*5-Benzothiazol-2-yl-2,2-dimethoxyindan-1,3-dione (**147**)*

Compound **100** (4.30 g, 15.0 mmol) was coupled with 2-tributylstannylbenzothiazole (7.00 g, 16.5 mmol) to afford 3.50 g (70%) of **147** as yellow crystals, mp 176 to 177°C (MeOH). R_f 0.42 (Et_2O – petroleum ether, 1:1). HRMS–CI (NH_3) calcd. for $C_{18}H_{13}NO_4S$ $(M)^+$: 339.0565; found: 339.0553. UV (CH_3CN) (nm): 334 (ε 25 500). IR (KBr) (cm^{-1}): 1750 (m), 1720 (s), 1185 (s), 1150 (s), 1055 (s). ^{1}H NMR ($CDCl_3$) δ: 8.59 (dd, *J* = 8.1 Hz, *J* = 1.5 Hz, 1H), 8.52 (dd, *J* = 1.5 Hz, *J* = 0.6 Hz, 1H), 8.06 (m, 1H), 8.02 (dd, *J* = 8.0 Hz, *J* = 0.5 Hz, 1H), 7.89 (dd, *J* = 8.0 Hz, *J* = 0.8 Hz, 1H), 7.38–7.54 (m, 2H), 3.66 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 192.8, 192.6, 164.4, 153.8, 141.1, 140.0, 139.9, 135.4, 135.0, 126.9, 126.4, 124.8, 124.0, 122.6, 121.8, 91.0, 51.7.

*5-[2,2′-Bithiophen-5-yl]-2,2-dimethoxyindan-1,3-dione (**148**)*

Compound **100** (4.30 g, 15.0 mmol) was coupled with 5-tributylstannyl-[2,2′]bithiophene (6.82 g, 15.0 mmol) to afford 5.07 g (91% yield) of **148** as bright yellow crystals, mp 126–128°C (Et_2O – petroleum ether). R_f 0.17 (Et_2O – petroleum ether, 1:4). HRMS–CI (NH_3) calcd. for $C_{19}H_{14}O_4S_2$ $(M)^+$: 370.0334; found: 370.0330. UV (CH_3CN) (nm): 387 (ε 23 500). IR (KBr) (cm^{-1}): 1745 (s), 1715 (s), 1155 (s), 1030 (s). ^{1}H NMR ($CDCl_3$) δ: 8.09 (d, *J* = 1.5 Hz, 1H), 8.04 (dd, *J* = 8.1 Hz, *J* = 1.5 Hz, 1H), 7.96 (d, *J* = 8.1 Hz, 1H), 7.46 (d, *J* = 3.9 Hz, 1H), 7.30 (dd, *J* = 4.8 Hz, *J* = 0.7 Hz, 1H), 7.24 (dd, *J* = 3.6 Hz, *J* = 0.7 Hz, 1H), 7.19 (d, *J* = 3.9 Hz, 1H), 7.06 (dd, ^1J = 4.8 Hz, ^2J = 3.6 Hz, 1H), 3.70 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 193.5, 192.4, 142.2, 140.5, 140.1, 139.4, 137.3, 136.3, 133.0, 128.1, 127.1, 125.6, 125.0, 124.9, 124.6, 119.2, 91.1, 51.7.

*5-[5′-(2,2-Dimethoxy-1,3-dioxoindan-5-yl)thiophen-2-yl]-2,2-dimethoxyindan-1,3-dione (**150**)*

Compound **100** (5.70 g, 20.0 mmol) was coupled with 2,5-bis(tributylstannyl)thiophene (6.60 g, 10.0 mmol) and toluene (100 mL) was added $Pd(PPh_3)_4$ (347 mg, 1.5 mol%). The mixture was heated at reflux under a nitrogen atmosphere for 6 h. The mixture was concentrated and the residue purified by chromatography (petroleum ether, Et_2O – petroleum ether) to afford a solid (5.10 g) contaminated with organotin products. The crude solid was recrystallized from CH_2Cl_2–hexanes to afford 4.45 g (91% yield) of **150** as an orange powder, mp 232–235°C (CH_2Cl_2–hexanes). R_f 0.26 (Et_2O – petroleum ether, 1:1). FAB–HRMS (NBA) calcd. for $C_{26}H_{20}O_8S$ $(M)^+$: 492.0879; found: 492.0883. UV (CH_3CN) (nm): 383 (ε 46 700). IR (KBr) (cm^{-1}): 1750 (s), 1720 (s), 1155 (s), 1030 (s). ^{1}H NMR ($CDCl_3$) δ: 8.13 (s, 2H), 8.08 (d, *J* = 8.1 Hz, 2H), 7.98 (d, *J* = 8.1 Hz, 2H), 7.57 (s, 2H), 3.64 (s, 12H). ^{13}C NMR ($CDCl_3$) δ: 193.2, 192.3, 143.6, 141.5, 140.2, 138.1, 133.4, 127.7, 125.1, 119.9, 91.0, 51.7. Anal. calcd. for $C_{26}H_{20}O_8S$: C 63.41, H 4.09; found: C 63.46, H 3.94.

*5-[2,2′-Bithiophen-5-yl]-2,2-dihydroxyindan-1,3-dione (**62**)*

A solution of 174 mg of tris(dibenzylideneacetone)dipalladium ($Pd_2(dba)_3$) and 90 mg of tri-2-furylphosphine (TFP) and toluene under an N_2 atmosphere was stirred at 25°C for 10 min. The initial purple color of the solution slowly turned to yellow. After in situ preparation of the catalyst, **33** (975 mg, 3.08 mmol) and **144** (1.72 g, 3.77 mmol) were added and the solution was stirred at 25°C. A precipitate began to form after 30 min. After 21 h, the precipitate was collected, washed with hot hexanes (bp 68 to 69°C), and dried in vacuo to give 274 mg (26% yield) of **62** as a yellow-orange solid.

*2,2-Dimethoxy-5-styrylindan-1,3-dione (**155**)*

Ketal **100** (1.43 g, 5 mmol), styrene (1 mL, 8.74 mmol), and freshly distilled triethylamine (2 mL) were placed in a sealed tube. The reaction mixture was flushed with N_2 and then stirred in an atmosphere of N_2 for 2 h. $Pd(PPh_3)_4$ (58 mg, 1 mol%) was added, and the reaction mixture was stirred at 100°C under N_2 for 8 h in a dark hood. Triethylamine and unreacted styrene were removed under reduced pressure. The resulting solid was dissolved in CH_2Cl_2 and washed with water. The CH_2Cl_2 solution was dried over anhyd Na_2SO_4, and filtered. The solvent was then removed under reduced pressure. Upon purification of the residue by column chromatography (Et_2O – petroleum ether, 1:4) 0.61 g (40% yield) of **155** was obtained as a yellow solid, mp 134°. R_f 0.23 (Et_2O – petroleum ether, 1:4). HRMS calcd. for $C_{19}H_{16}O_4$ $(M)^+$: 308.1049; found: 308.1043. IR (KBr) (cm^{-1}): 1744 (s), 1713 (s), 1203 (s), 1191 (s), 1152 (s), 1033 (s). ^{1}H NMR (DMSO-d_6) δ: 8.28 (d, *J* = 8.1 Hz, 1H), 8.22 (s, 1H), 7.98 (d, *J* = 8.1 Hz, 1H), 7.68–7.76 (m, 3H), 7.52 (d, *J* = 16.5 Hz, 1H), 7.32–7.46 (m, 3H), 3.51 (s, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 193.7, 192.7, 146.2, 140.1, 138.0, 135.9, 134.7, 134.5, 129.2, 128.9, 127.2, 126.1, 124.6, 120.8, 91.2, 51.7. Anal. calcd. for $C_{19}H_{16}O_4$: C 74.07, H 5.23; found: C 74.42, H 5.12.

Coupling procedure

Ketal **100** (1 equiv), an electron-rich heterocycle (**151**–**153**, 3 to 4 equiv) and potassium acetate (1.5 equiv) were stirred in DMA under N_2 for 2 h. $Pd(PPh_3)_4$ (1–3 mol%) was added, and the reaction mixture was stirred at 90°C in a

© 2001 NRC Canada

sealed tube under N_2 for 24 h. The solvent was removed under reduced pressure and the residue was dissolved in CH_2Cl_2 and washed with water. The organic phase was separated, dried over Na_2SO_4, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography.

*2,2-Dimethoxy-5-(thiophen-2-yl)indan-1,3-dione (**138**)*

Ketal **100** (1.95 g, 6.84 mmol) was reacted with an excess of thiophene (**151**) to give 1.3 g (66% yield) of **138** as a yellow solid.

*2,2-Dimethoxy-5-(5-methylthiophen-2-yl)indan-1,3-dione (**140**)*

Ketal **100** (2.85 g, 10.0 mmol) was reacted with an excess of 2-methylthiophene (**152**) to give 1.57 g (52% yield) of **140** as a yellow solid.

*2,2-Dimethoxy-5-(5-ethylthiophen-2-yl)indan-1,3-dione (**141**)*

Ketal **100** (1.43 g, 5.00 mmol) was reacted with an excess of 2-ethylthiophene (**153**) to give 0.65 g (41% yield) of **141** as a yellow solid.

Acknowledgments

We are grateful for the financial support provided by the National Institutes of Justice (92-IJ-CX-K015), Unites States Secret Service, National Institutes of Health (CA-40081), and National Science Foundation (CHE-01449). We thank Dr. Antonio Cantu and Mr. Robert Ramotowski of the United States Secret Service, Dr. Josef Almog of the Israel National Police and Professor Chris Lennard of the Canberra Forensic Science Division for testing of compounds and for helpful discussions.

An ^{1}H and ^{13}C NMR conformational study of 2-(benzotriazol-1-yl)-substituted tetrahydropyrans

Alan R. Katritzky, Novruz G. Akhmedov, Sergey N. Denisenko, and Subbu Perumal

Abstract: Proton and carbon NMR signals for 2-(benzotriazol-1-yl)tetrahydropyrans are assigned on the basis of spin decoupling, *H*,*H*-COSY, HETCOR, and nuclear Overhauser enhancement experiments. Conformational preferences are deduced. It was found that 2-(benzotriazol-1-yl) substituents: (*i*) prefer the equatorial orientation; and (*ii*) display a rotameric preference to minimize the electronic repulsion and (or) steric interaction.

Key words: anomeric, NMR, tetrahydropyrans.

Résumé : On a attribué les signaux RMN du proton et du carbone de 2-(benzotriazol-1-yl)tétrahydropyranes grâce à des expériences de: découplage de spin, « *H*,*H*-COSY », « HETCOR » ainsi que de rehaussement Overhauser nucléaire. On en a déduit les préférences conformationnelles. On a trouvé que les substituants 2-(benzotriazol-1-yles) : (*i*) préfèrent occuper une orientation équatoriale et (*ii*) montrent une préférence rotamérique pour minimiser la répulsion électronique et/ou l'interaction stérique.

Mots clés : anomère, RMN, tétrahydropyranes.

[Traduit par la Rédaction]

Introduction

The normal (or *endo*-) anomeric effect in tetrahydropyrans causes a significant preference for the conformer with the anomeric substituent in the axial orientation (α-anomer) compared to that with the anomeric substituent equatorial (β-anomer). This effect is believed to originate from an overlap between the unshared electrons of the ring oxygen atom and the antibonding σ* orbital of the anticoplanar anomeric carbon—heteroatom bond (1–3) (Scheme 1). Nitrogen-containing substituents in an anomeric position behave differently from their oxygen and halogen analogs. Neutral 2-aminotetrahydropyrans and their heterocyclic derivatives exist with the *N*-linked substituent equatorial (3, 4) due to the *exo*-anomeric effect. This conformational preference is rationalized (3, 5) by delocalization of electron density from the *exo*-cyclic substituent X to the antibonding orbital of the carbon—oxygen bond. Thus, the overall anomeric effect is a balance between the sum of the *endo*- and *exo*-anomeric effects (3) in both the equatorial and axial conformers (Scheme 1). However, this "double bond – no-bond resonance" model fails to explain the so-called reverse anomeric effect postulated for the glycosyl imidazolinium ions and glycosyl pyridinium ions (6).

In the present study, the NMR spectra of 2-(benzotriazol-1-yl)-substituted tetrahydropyrans **1**–**3** (Scheme 2) have been recorded and their chemical shifts and coupling constants used to investigate the conformational preferences of these molecules.

Investigation of the stereochemical preference of a benzotriazol-1-yl group attached to an anomeric carbon in the tetrahydropyran system is relevant particularly in view of the: (*i*) known dual nature of the benzotriazolyl group which can act either as an electron-withdrawing (nucleofuge) or as an-electron donating (nucleophile) moiety in many important synthetic transformations (7*a*); and (*ii*) evidence for the vinylogues anomeric effect in 4-(benzotriazol-1-yl)pyrans (7*b*).

Recent photoelectron spectra and electronic structure studies of 1-fluoromethyl- and 1-chloromethyl-1*H*-benzotriazoles (8) shown significant interactions of the benzotriazole HOMO orbital with an α-C—heteroatom bond. By contrast, the ionization potential for the unshared oxygen electron pair was higher in 1-methoxymethyl-1*H*-benzotriazole as compared to dimethyl ether. This was ascribed to the electron acceptor character of the benzotriazole system. Thus, both *exo*- and *endo*-anomeric effect could be important factors for the stereochemical behavior of 2-(benzotriazol-1-yl)-substituted tetrahydropyrans **1**–**3**.

Results and discussion

Studies on 2-(benzotriazol-1-yl)tetrahydropyrans 1–3

The proton chemical shifts for unsubstituted 2-(benzotriazol-1-yl)tetrahydropyran (1) were assigned as follows: (*i*) the protons of the benzotriazolyl ring in **1** gave four signals in the far down-field region (see Table 1). These signals are

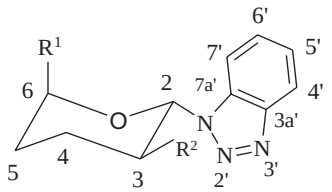

Scheme 1.

readily assignable to the aromatic protons of the benzotriazol-1-yl ring as shown in Table 1 on the basis of the *H*,*H*-COSY and HETCOR spectra; (*ii*) the doublet of doublets of **1** appearing far down-field at 6.02 ppm, with $^3J_{H-2,H-3}$ values of 8.3 and 3.0 Hz, is assigned to H-2 of the tetrahydropyran ring on the basis that only H-2 has just two vicinal protons. The other tetrahydropyran ring protons have either a geminal or more than two vicinal protons and furnish more complex multiplets. That the chemical shift of H-2 appears far downfield is probably due to the interplay of several factors including the ring current effect of the aromatic benzotriazole system and the rotamer preference; (*iii*) the unresolved multiplets centered at ~2.18 and ~1.80 ppm are assigned to the overlapping resonances of (H-3*ax* + H-4*eq*) and (H-4*ax* + H-5*ax* + H-5 *eq*), on the basis of COSY and spin-decoupling experiments, respectively. Individual coupling constants were not resolved. Cross-peaks were observed in the COSY spectrum between the doublet of doublets at 6.02 ppm for H-2*ax* and each of the resonance signals at 2.18 and 2.60 ppm; these latter are therefore assigned to H-3*ax* and H-3*eq*, respectively. Irradiation of the overlapping signals centered at 1.80 ppm (H-4*ax* + H-5*ax* + H-5 *eq*) simplifies the multiplets centered at 3.78 ppm (H-6*ax*) and 3.94 ppm (H-6 *eq*), which appeared in the selectively decoupled ^{1}H NMR spectrum as doublets of doublets with $^2J_{AB}$ of 12.6 Hz; (*iv*) the chemical shifts of the remaining protons of **1** were assigned in a similar manner as listed in Table 1. The H-3*ax* and H-5*ax* gave signals, which are shifted slightly downfield compared to those of the corresponding equatorial protons; this is ascribable to the van der Waals interactions between each of the axial protons and the axial unshared pair of electrons of oxygen.

Compound **1** could adopt several rotameric forms depending on the H-C(2)-N(1′)-C(7a′) dihedral angle (Φ) (Scheme 3). In

Scheme 2.

1: $R^1 = R^2 = H$; **2**: $R^1 = OCH_3$; $R^2 = H$; **3**: $R^1 = H$; $R^2 = CH_2N(Me)Ph$

the two rotamers **1a** (Φ = 20°) and **1b** (Φ = 160°) shown in Scheme 3, *exo*-anomeric interaction between the N-1′ π electron orbital and the σ^*_{C-O} orbital should be developed most strongly. Rotamer **1b** should have strong van der Waals interaction between H-3*ax* and H-7′. Rotamer **1a** is likely to suffer from repulsion between anomeric H-2*ax* and H-7′. Indeed, we observed a NOE effect of 5% for H-7′ while irradiating H-2*ax*, however no NOE effect was found between H-7′ and H-3*ax*. Two other possible rotamers with the N-1′ π orbital orthogonal to the C—O bond are less likely to be preferred due to dipole–dipole repulsions between lone pairs of the O and N-2′ atoms and (or) repulsion between the lone pairs of the O and H-7′. Nevertheless, a small NOE effect was observed for H-3*eq* while irradiating H-7′, suggesting at least partial population of the rotamer **1c** (Scheme 3).

Detailed ^{1}H, ^{13}C, and two-dimensional NMR spectroscopic measurements have been made for two bis-substituted tetrahydropyrans **2** and **3** (Scheme 4). In **2** and **3,** the presence of an additional substituent could bias the conformational equilibrium in favor of a single conformer. We expected that the OCH_3 group in position 6[2] of **2** should favor the axial orientation as a result of classical anomeric effect, while the large *N*-methyl-*N*-phenylaminomethyl group of **3** would be in the equatorial orientation (9). Indeed, only the *trans* diastereomer of 2-methoxy-6-(benzotriazol-1-yl)tetrahydropyran **2** was obtained from the reaction of benzotriazole and 2-methoxy-3,4-dihydropyran (10), in consonance with the known axial preference of the anomeric methoxy group.

The chemical shifts of **2** are listed in Table 1. The H-2 signal at 6.41 ppm is shifted downfield 0.39 ppm compared to that of H-2 in **1**, which is ascribable to the van der Waals interaction with the axial methoxy group. The H-2 appears as a doublet of doublet with $^3J_{H-2,H-3}$ couplings of 10.7 and 2.7 Hz. The broadened triplet (overlapping doublet of doublets) at 4.92 ppm was assigned to the H-6*eq* proton. The axial orientation of the OCH_3 group, and the corresponding equatorial orientation of H-6, is supported by the $^3J_{H-6,H-5}$ value of 2.3 Hz, as well as by the NOE effect between OCH_3 and both H-2*ax* and H-6*eq*.

The chemical shifts and coupling constants for *trans*-2-(benzotriazol-1-yl)-3-(*N*-methyl-*N*-phenylaminomethyl)tetrahydropyran **3** are listed in Table 1. The doublet for the H-2 of **3** at 5.87 ppm (with $^3J_{H-2,H-3}$ = 7.5 Hz) is in accord with the diequatorial arrangement of the two substituents. Interestingly, strong steric repulsion between these groups could be detected by a 4.5% Overhauser effect for the H-7′ proton while irradiating C-3-CH_2-N protons. Similarly to the com-

[2] Here, we use an unconventional numbering of the carbon atoms of the tetrahydropyran ring, assigning the number 2 for the carbon atom connected to the benzotriazole substituent (Scheme 4).

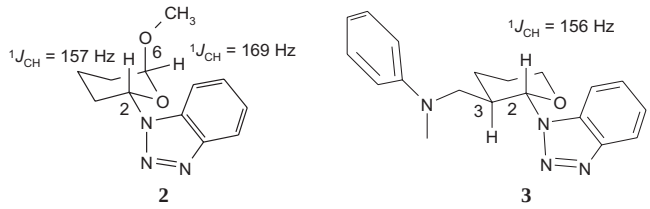
Scheme 3.



1 **1a** **1b** **1c**

pound **1**, a rotamer with strong interaction of the H-2 and H-7′ was indicated by NOE between these protons. The 0.15 ppm upfield shift of H-2 in **3** as compared to **1** may be due to shielding H-2 in **3** by the aniline ring in some of the populated conformations.

The $^3J_{H\text{-}2,H\text{-}3}$ values of the coupling constants for H-2 in compounds **1**–**3** each indicate the predominance of the equatorial orientation for the benzotriazol-1-yl group. However, the $^3J_{H\text{-}2,H\text{-}3ax}$ values in **1** and **3** (8.3 and 7.5 Hz, respectively) are significantly less than that in **2** (10.7 Hz). This could suggest significant contributions to the conformational equilibrium of **1** and **3** from conformers with the axial benzotriazolyl group. However, a low-temperature ^{1}H NMR study of **1** in CD_2Cl_2 at about –92°C did not reveal the existence of any other conformer. Thus, the ^{1}H NMR spectrum of **1** shows at –92°C neither new signals nor any significant change in the chemical shifts. The only variation found is the lack of fine splitting for the aliphatic protons of the tetrahydropyran ring, probably ascribable to the rapid spin-lattice relaxation or increasing viscosity at a low temperature. We believe that variations in the rotameric conformational populations of the benzotriazolyl ring system in these molecules are probably responsible for the variation in the $^3J_{H\text{-}2,H\text{-}3}$ values in **1**–**3**, with the equatorial conformer uniformly preferred throughout.

Scheme 4.

2 **3**

The equatorial orientation of the benzotriazole group in **1**–**3** is also supported by the values of the direct CH coupling constant $^1J_{CH}$, which are different for protons in the α- or β-anomeric position (11). Whereas the equatorial proton at C-6 in **2** causes splitting of carbon signal with a constant of 169 Hz, the axial proton at C-2 couples with its carbon with $^1J_{CH}$ = 156 to 157 Hz in **1**–**3** (Schemes 3 and 4). The ^{13}C NMR chemical shifts of mono- and di-substituted tetrahydropyrans **1**–**3** are shown in Table 2.

Consequently, the preference of the equatorial orientation by the benzotriazolyl group in these compounds appears to be due to the influence of both steric and electronic factors. The preference of the benzotriazolyl group equatorially orientated conformers for **1**–**3** may be ascribed to: (*i*) hyperconjugative interaction of the π orbital on the N-1′ with the C-O antibonding orbital in the so-called *exo*-anomeric effect; and (*ii*) steric interactions that may be encountered when the

[b]Phenyl group: 2/C_{ortho} = 112.3; 2/C_{meta} = 129.1; C_{para} = 116.9; δ (NCH_2) = 53.9 ppm; δ (NCH_3) = 39.5 ppm.

benzotriazole ring takes up an axial orientation with the 1,3-*syn*-axial hydrogen atoms. Similar behavior was reported (12) for 2-methylaminotetrahydropyran, where the basic nitrogen (good donor, poor acceptor) gives rise to a strong *exo*-anomeric effect.

Experimental

The ^1H, ^{13}C, and two-dimensional NMR spectra (*H*,*H*-COSY, *C*,*H*-COSY) and difference NOE experiments were recorded using Varian instruments (VXR-S-300 MHz and Mercury-300 MHz) in 5 mm NMR tubes in $CDCl_3$ solution (Cambridge Isotope Laboratories) at 25°C. Chemical shifts are expressed in parts per million (ppm) from tetramethylsilane as an internal standard.

The two-dimensional homonuclear correlation (*H*,*H*-COSY) spectra were recorded with a 1024 × 1024 data matrix and 256 time increments each of 16 scans, in magnitude mode, and processed with zero-filling in F1 and unshifted sine-bell apodization function. For the proton composite pulse decoupled (WALTZ-16) ^{13}C NMR experiments, the conditions were as follows: spectral width 14 000 Hz (220 ppm), number of data points 65 K, acquisition time 0.8 s, recycle delay 2 s, flip angle 30°. The FIDs in ^1H and ^{13}C NMR experiments were apodized by an exponential windowing prior to Fourier transformation (WFT) to improve the signal-to-noise ratio in the NMR spectra.

2-(Benzotriazol-1-yl)tetrahydropyrans **1**–**3** were prepared according to literature procedures (10, 13).

Conclusions

The conformational behavior of the 2-(benzotriazol-1-yl)-substituted tetrahydropyrans **1**–**3** is determined by a balance of electronic and steric effects. The *exo*-anomeric effect is pronounced, resulting in equatorial orientations for the benzotriazolyl moieties. This study further reveals that, with respect to the conformational preferences of tetrahydropyrans, the 2-(benzotriazol-1-yl) group stands closer to the other nitrogen heterocyclic groups than to a halogen or an alkoxy group.

Structure assignment of aminoconduritols by ^{15}N NMR correlation spectroscopy; synthesis of a positional isomer of 7-deoxypancratistatin

Stefan Schilling, Uwe Rinner, Collin Chan, Ion Ghiviriga, and Tomas Hudlicky

Abstract: A positional isomer of 7-deoxypancratistatin was synthesized in 12 steps from epoxyaziridines **4** and **5**. An intermolecular opening of the aziridine rather than the epoxide in the early stages of the synthesis led to **13**, which did not match the properties of tetraacetate **10** derived from 7-deoxypancratistatin. At no stage of the synthesis did standard NMR techniques, involving ^{1}H–^{1}H or ^{1}H–^{13}C coupling, prove adequate for the structure assignment. Unambiguous structure was assigned by ^{1}H–^{15}N correlation NMR spectroscopy as well as by the conversion of epoxide **11** to diol **29** synthesized independently by another route. Experimental and spectral details are reported for all new compounds.

Key words: ^{15}N NMR spectroscopy, iso-7-deoxypancratistatin, Lewis acid catalyzed intramolecuar opening of epoxides, aminoconduritols.

Résumé : On a synthétisé un isomère de position de la 7-désoxypancrastistatine en douze étapes à partir des époxyaziridines **4** et **5**. Au cours des premières étapes de la synthèse, une ouverture intermoléculaire de l'aziridine à la place d'une ouverture de l'époxyde a conduit au produit **13** dont les propriétés ne correspondent pas à celles du tétraacétate **10** qui dérive de la 7-désoxypancratistatine. Les techniques normales de RMN impliquant les couplages ^{1}H–^{1}H ou ^{1}H–^{13}C ne se sont avérés adéquates pour faire des attributions de structures. La structure a été attribuée sans ambiguïté par spectroscopie RMN de corrélation ^{1}H–^{15}N ainsi que par conversion de l'époxyde **11** en diol **29** qui a été synthétisé de façon indépendante par une autre voie. On rapporte les détails expérimentaux et les spectres de tous les nouveaux composés.

Mots clés : spectroscopie ^{15}N RMN, iso-7-désoxypancratistatine, ouverture intramoléculaire d'époxydes catalysée par un acide de Lewis, aminoconduritols.

Introduction

Several total syntheses of the Amaryllidaceae alkaloids have been recently completed by our research group and by others (1–4). We have reported the first asymmetric synthesis of pancratistatin (1*b*, *c*), as well as brief routes to lycoricidine (4*j*), 7-deoxypancratistatin (2*c*), *ent*-7-deoxypancratistatin (5), and narciclasine (3*b*). Attempting to improve on the 14-step preparation of pancratistatin, which featured an intermolecular aziridine opening by an aryl cuprate (2*c*), we chose to pursue what appeared to be a more efficient strategy based on a novel intramolecular opening of the aziridine in **3**, Fig. 1.

Our strategy, shown in Fig. 1, relies on the availability of epoxyaziridines **4** and **5**, which can be rapidly synthesized from the commercially available diene **8** by established methods (6). Stereoelectronic considerations indicate that the nucleophilic opening of either isomer of epoxide with piperonol **6** followed by alkylation of the resulting alcohol with piperonyl bromide **7** will provide an intermediate in which both oxygens bear identical functionality. Such redundant operations (7) greatly improve the practicality of a synthesis because no attention need be paid either to the control of stereochemistry at the intermediate stage or to the separation of the isomers of epoxides **4** and **5**. Lewis acid catalyzed aziridine opening, oxidation, and recyclization would lead to the phenanthridine core of the alkaloid. We are aware of only three previous examples of intramolecular opening of aziridines (8) before we applied the technique to our synthesis, which is conceptually similar to the opening of the epoxide derived from *myo*-inositol as reported by Bender (9).

In this paper we report the synthesis of tetracetate **13,** a positional isomer of **10**, shown in Fig. 2. The latent func-

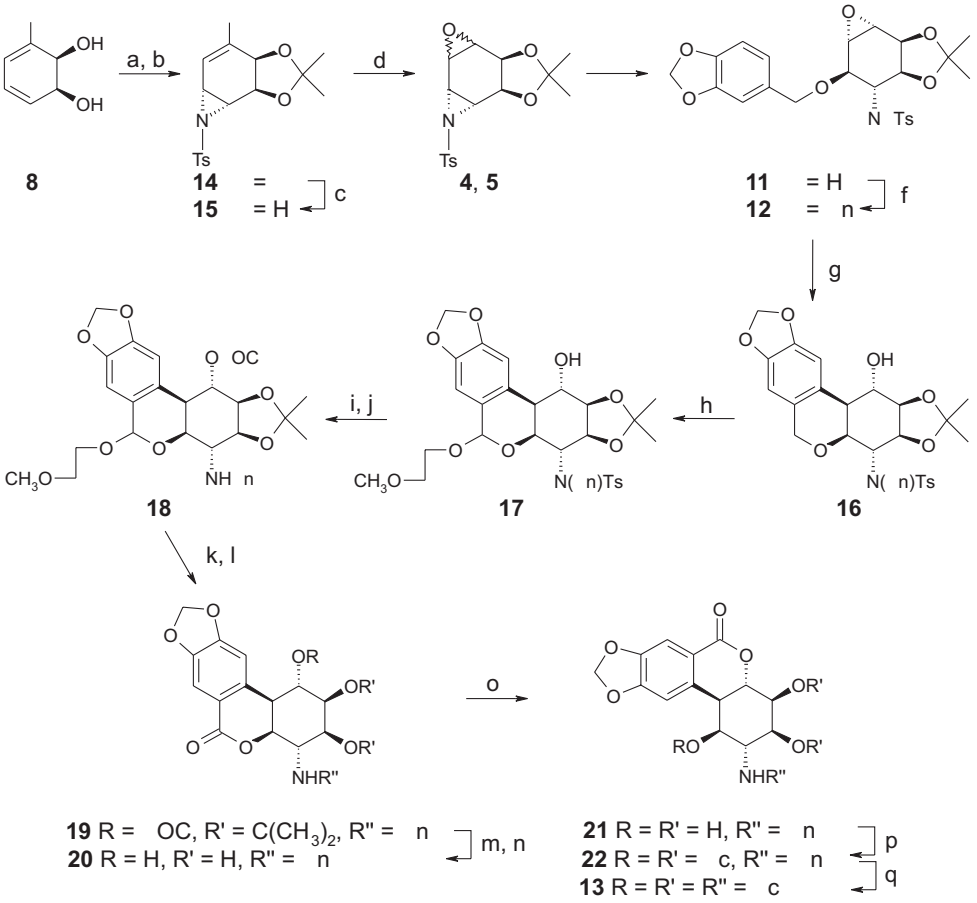
tional symmetry of epoxyaziridines **4** and **5** and their tendency to react with nucleophiles made structural assignment difficult throughout the synthesis. The inherent difficulties in precise stereochemical and regiochemical assignments in all intermediates propagated the errors resulting from the initial incorrect assignment of regiochemistry in the opening of aziridines **4** and **5** under basic conditions. A full structural correlation is reported along with experimental details for the preparation of tetraacetyl aminolactone **13**.



Results and discussion

Enantiomerically pure diol **8** was obtained by whole-cell biooxidation with recombinant *E. coli* JM109 (pDTG601) according to the established procedure (10). Diol **8** was protected as its acetonide and then reacted with (*N*-tosylimino)phenyliodinane according to the protocol established by Evans et al. (11*a*) and Jacobsen and co-workers (11*b*) to produce aziridine **14** in 45% overall yield (1*c*), as shown in Scheme 1. Dehalogenation of **14** with *n*-Bu_3SnH–THF generated vinylaziridine **15** (1*c*), which was subsequently oxidized (*m*CPBA, 1,2-dichloroethane, 85°C) to furnish an inseparable mixture (2.6:1) of α- and β-epoxyaziridines **4** and **5**, respectively. In our group, earlier work on nucleophilic opening of this material indicated that carboxylate salts (12) opened the epoxide under slightly basic conditions and that alcohols (13) under $BF_3 \cdot Et_2O$ catalysis also opened the epoxide with the aziridine ring intact. Following this precedent, the potassium salt of piperonol was reacted with the epoxyaziridines **4** and **5** and the product subjected to benzylation. Spectroscopic evidence, as presented below, suggested that compound **9** had been obtained, and therefore the rest of the synthesis was carried out. However, the compound, isolated in 71% yield as a single isomer, turned out to be epoxide **12**, ascertained only at the end of the synthesis when tetracetate **13** was identified.

The analysis of ^1H NMR spectra of conduramine and conduritol derivatives is not trivial, viz. the patterns of epoxy vs. aziridinyl methines and the chemical shift differences between *O*-benzyl vs. *N*-benzyl groups in structures where various shielding parameters could lead to pronounced shifts of the benzylic protons. This error in structure assignment was propagated through 12 steps without detection or ambiguity. The functional symmetry of epoxy aziridines **4** and **5** and the difficulty in deciphering the outcome of the first step contributed to the error.

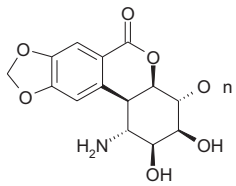
Scheme 1. Reagents and conditions: (*a*) DMP, *p*-TSA (cat.), acetone, rt; (*b*) PhI=NTs, $Cu(acac)_2$, CH_3CN, rt, 63% (over 2 steps); (*c*) Bu_3SnH, AIBN, THF, reflux, 78%; (*d*) *m*CPBA, $C_2H_4Cl_2$, reflux, 80%; (*e*) potassium piperonoxide, 18-C-6, DME, rt; (*f*) (*i*) NaH, THF, (*ii*) BnBr, Bu_4NI, rt, 71% (over 2 steps); (*g*) Me_2AlCl, CH_2Cl_2, –25°C, 77%; (*h*) DDQ, 2-methoxyethanol, CH_2Cl_2, rt, 78%; (*i*) NaH, $(BOC)_2O$, THF, reflux; (*j*) Na–naphthalene, DME, –50°C, 85% (over 2 steps); (*k*) CSA, THF, H_2O, rt; (*l*) PCC, CH_2Cl_2, rt, 72% (over 2 steps); (*m*) $C_6H_5CO_2Na$, MeOH–H_2O, reflux; (*n*) *p*-TsOH, MeOH, 84% (over 2 steps); (*o*) K_2CO_3, MeOH, 44%; (*p*) Ac_2O, DMAP, pyridine, 61%; (*q*) (*i*) H_2, $Pd(OH)_2$, MeOH, (*ii*) Ac_2O, DMAP, pyridine, 55% (over 2 steps).

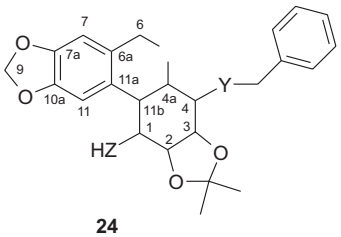


The actual sequence of steps was as follows: treatment of piperonyl ether **12** with Me_2AlCl resulted in cyclization to pentacycle **16** in 77% yield. Benzylic oxidation of ether **16** by means of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in the presence of 2-methoxyethanol gave acetal **17** in 78% yield. Acylation of acetal **17** followed by reductive detosylation (sodium–naphthalene–DME) generated acetal **18** in 85% overall yield. Deprotection of the acetal followed by oxidation of the resulting lactol provided lactone **19** in 72% yield. Removal of the carbamate by thermolysis followed by deketalization gave amino diol **20**, which upon hydrolysis (K_2CO_3–methanol) furnished lactone **21** in 44% yield.

The last stages of the synthesis were reached with what we thought to be lactone **23**, to which the conditions of Paulsen (2*b*) were applied for the final lactone–lactam interconversion, a sequence driven by the greater stability of the *trans*-fused lactam. Following this rearrangement, a protocol for debenzylation was carried out, ultimately leading to the isolation of a compound whose tetraacetate provided ^1H NMR remarkably similar to the ^1H NMR of the known tetraacetate of 7-deoxypancratistatin (2*c*), but whose R_f value in thin layer chromatography was lower by 0.6. The interesting point here is that lactone **20** did isomerize to the more stable lactone **21**, with distinctly different chromatographic and spectral properties; at the time we assumed that we were observing the expected equilibrium-driven transformation to the lactam.

20 actual

23 p oj ct d



^1H NMR, ^{13}C NMR, and other analytical methods failed to confirm the structure of this material, which had evidently undergone a lactone rearrangement of some kind. An unambiguous assignment was finally made by means of ^{15}N HMQC spectroscopy, described in the next section.

Assignment of regio- and stereochemistry of tosylamide 16

Throughout the synthesis, 2D NMR was employed to confirm the structural integrity of key compounds, namely **16**,

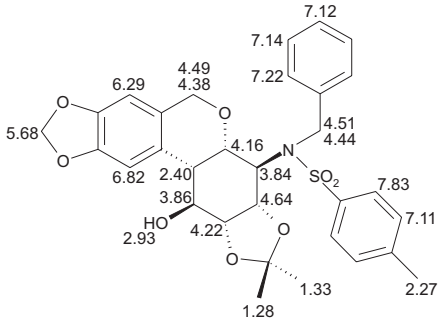
19, and **21**. However, the $^1H–^1H$ couplings and NOE's, and the one-bond and long-range $^1H–^{13}C$ couplings fail to discriminate between compounds from the projected and actual series. In the case of compound **16** for instance, the $^1H–^1H$ and $^1H–^{13}C$ correlations indicate functionalized benzophyranyl system **24**, where X, Y, and Z are two O atoms and one NTs group. Uncertainty arises because there can be no $^1H–^{13}C$ long range coupling between atoms in the tosyl group and atoms at its point of attachment.

24



Formula **24** describes a compound in the projected series for X, Y = O and Z = NTs, as well as the actual **16**, for X, Z = O and Y = NTs. The same ambiguity is seen in compound **17**; however, compounds produced after the reductive detosylation step possess a proton attached to nitrogen, which in theory can be used to reveal the location of the trivalent nitrogen. In reality though, fast exchange with residual water in the sample precluded the observation of any coupling of this proton and even of its chemical shift for both **18** and **19**. The peracetylated derivative of **20** (R = R′ = R″ = Ac) displayed coupling of the NH proton with the proton in position 4 and not with the proton in position 1 as expected, thus revealing that the compounds synthesized were different from the projected ones.

Direct evidence for the structure of compound **16** came from the long-range $^1H–^{15}N$ couplings, revealed by the gHMBC spectrum at natural abundance (Fig. 3). Enough sample for the experiment was obtained by repeating the synthesis to provide 100 mg of tosylamide **16**. The nitrogen signal at 277.9 ppm on the nitromethane scale displayed cross-peaks with the benzylic protons (4.44 and 4.51 ppm) and the proton at 4.16 ppm of the cyclohexyl unit.

Chemical proof via structure correlation

In addition to the evidence for the structure of tosylamide **16** based on spectroscopy, including $^1H–^{13}C$ as well as $^1H–^{15}N$ correlation experiments, its structural integrity was confirmed through an independent synthesis. As illustrated in Scheme 2, opening of vinylaziridine **15** with the potassium salt of piperonol generated tosylamide **25**, which was converted to olefin **26** following benzylation. Stereoselective dihydroxylation of the olefin furnished *cis*-diol **27**; moreover, opening of epoxide **12**, derived from opening of the mixture of epoxyaziridines **4** and **5**, with hydroxide provided the *trans*–diol **28**. Cleavage of the diol functionalities in both tosylamides **27** and **28** gave rise to the corresponding dialdehydes, which upon reduction afforded *N*-benzyl tosylamide **29**, whose spectral and physical properties (^1H NMR, R_f, mass spectrum fragmentation pattern) were identical for the materials obtained by two independent synthetic routes.

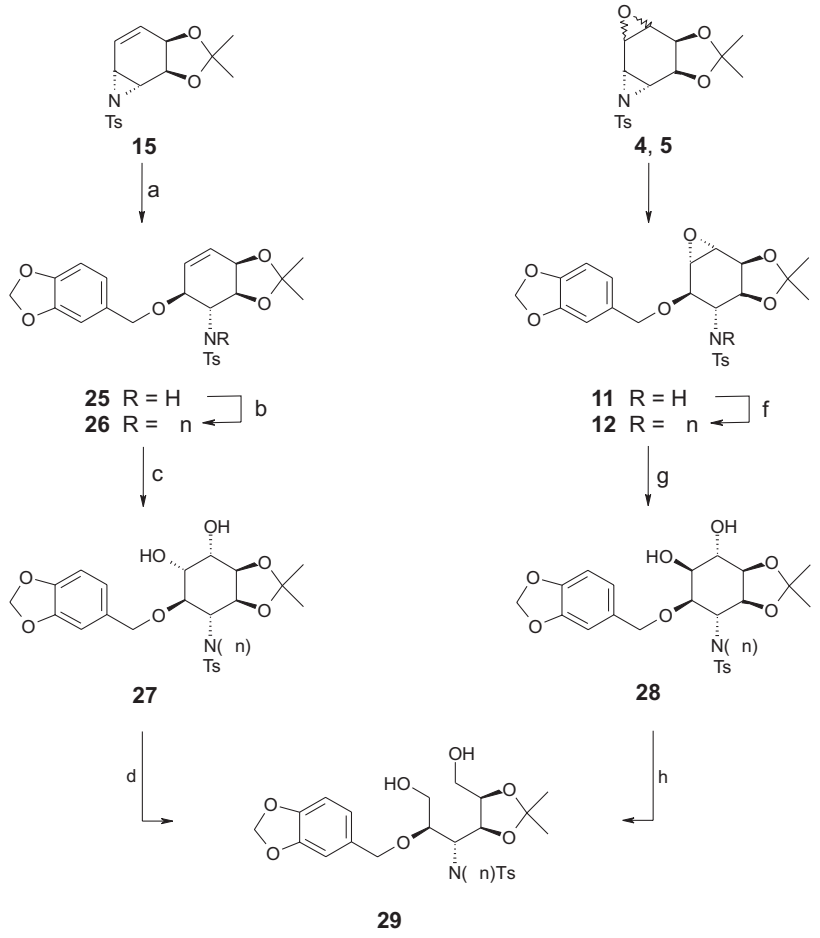
Fig. 3. Proton assignment of tosylamide **16**.

16

Conclusion

The latent functional symmetry of epoxyaziridines **4** and **5** made it difficult to differentiate clearly the outcome of the initial nucleophilic opening of either of the three-membered rings. Standard structural assignment could not distinguish between the two regioisomers during a 12 step synthesis until a physical match was made. Philosophically, this case should raise interesting questions about the global probability of similar errors, undetected because of limited or nonexisting comparisons of physical properties, in today's literature.

Experimental



All reactions were carried out in an argon atmosphere with standard techniques for the exclusion of air and moisture. Glassware used for moisture-sensitive reactions was flame-dried under vacuum. Tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) were distilled from sodium benzophenone ketyl. Dichloromethane and 1,2-dichloroethane were distilled from calcium hydride. Reactions were monitored by thin layer chromatography on K6F silica gel (Whatman) plates. Flash column chromatography was performed on Merck silica gel (grade 60, 230–400 mesh). Melting points were determined on a Thomas-Hoover Unimelt apparatus and are uncorrected. Infrared spectra were obtained on a PerkinElmer 1600 Series FT-IR spectrometer. High resolution mass spectra (HRMS) were measured on a Finnigan Mat 95Q mass spectrometer. Nuclear magnetic resonance spectra were recorded on either a Varian VXR-300, Gemini 300, or Inova 500 FT NMR spectrometer in $CDCl_3$ unless otherwise noted. Coupling constants are measured in Hertz and chemical shifts are reported in ppm downfield from tetramethylsilane. Optical rotations were measured on a PerkinElmer model 341 polarimeter.

(1*S*,2*S*,4*R*,5*S*,6*S*,7*S*)-5,6-(Isopropylidenedioxy)-3-(4′-methylphenylsulfonyl)-8-oxa-3-aza-tricyclo[5.1.0.0]octane (4) and (1*R*,2*S*,4*R*,5*S*,6*S*,7*R*)-5,6-(isopropylidenedioxy)-3-(4′-methylphenylsulfonyl)-8-oxa-3-aza-tricyclo[5.1.0.0]-octane (5)

To a degassed solution of aziridine **15** (2.18 g, 6.79 mmol) in 1,2-dichloroethane (70 mL) was added *m*CPBA (8.37 g, 70%, 34.0 mmol) along with 3-*tert*-butyl-4-hydroxy-5-

To a suspension of NaH (12 mg, 0.50 mmol) in THF (5 mL) was added a solution of acetal **17** (208 mg, 0.319 mmol) in THF (8 mL). The resulting solution was stirred at room temperature for 20 min after which a solution of di-*tert*-butyl dicarbonate (105 mg, 0.481 mmol) in THF (2 mL) was added dropwise. The solution was heated at reflux for 5 h. After the solution cooled to room temperature, the reaction was quenched with water, and the mixture extracted with ethyl acetate (3 × 30 mL). The combined organic extracts were dried over $MgSO_4$ and concentrated in vacuo. A solution of the remaining residue in DME (5 mL) cooled to –50°C was treated with a 0.6 M solution of Na–naphthalene in DME until a dark color persisted. The resulting solution was stirred at –50°C for 30 min, and then the reaction was quenched with water. After it had warmed to room temperature, the reaction mixture was extracted with ethyl acetate (3 × 25 mL), and the combined organic extracts were dried over $MgSO_4$. Removal of the solvent under reduced pressure and purification of the residue by chromatography (hexanes – ethyl acetate – triethylamine, 3:1:1) gave carbonate **18** (163 mg, 85%) as a white foam; $[\alpha]_D^{25}$ +21.5 (*c* 1.0, $CHCl_3$). R_f = 0.24 (hexanes – ethyl acetate, 1:1). FAB-HRMS calcd. for $C_{32}H_{42}NO_{10}$: 600.2809; found: 600.2813. IR (KBr) (cm^{-1}): 3448, 1751, 1508, 1490, 1243, 1039. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.34–7.32 (m, 5H), 6.74 (s, 1H), 6.63 (s, 1H), 5.86 (d, *J* = 18.0 Hz, 2H), 5.64 (s, 1H), 5.09 (dd, *J* = 11.7, 7.8 Hz, 1H), 4.43–4.38 (m, 2H), 4.20 (t, *J* = 5.9 Hz, 1H), 4.01–3.82 (m, 4H), 3.58 (m, 2H), 3.34 (s, 3H), 3.23 (dd, *J* = 6.7, 3.3 Hz, 1H), 2.64 (dd, *J* = 11.6, 2.9 Hz, 1H), 1.69 (br s, 1H), 1.45 (s, 3H), 1.35 (s, 3H), 1.32 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 152.8, 147.7, 147.3, 140.3, 128.9, 128.7, 127.6, 126.6, 112.6, 110.2, 109.9, 108.1, 101.3, 98.0, 82.6, 78.0, 77.9, 76.4, 72.4, 69.9, 68.0, 59.4, 59.2, 52.7, 38.8, 28.3, 27.9, 26.4.

(1*S*,2*R*,3*S*,4*R*,5*S*,6*R*)-4-Benzylamino-1-(*tert*-butoxycarbonyloxy)-2,3-(isopropylidenedioxy)-2,3,4,4a,6,11b-hexahydro-1*H*-5,8,10-trioxa-cyclopenta[*b*]phenanthrene-6-one (19)

A solution of acetal **18** (204 mg, 0.340 mmol) in 30% aqeous THF (13 mL) was treated with CSA (395 mg, 1.70 mmol) and stirred at room temperature for 21 h. The solution was then diluted with ethyl acetate and washed successively with saturated $NaHCO_3$ solution, water, and brine. The organic layer was dried over Na_2SO_4 and then concentrated in vacuo. To a solution of the remaining residue in CH_2Cl_2 (9 mL) and molecular sieves (3 Å) was added PCC (112 mg, 0.520 mmol). The resulting solution was stirred at room temperature for 3 h. The reaction mixture was then filtered over silica and was subsequently washed with several portions of CH_3OH. Removal of the solvent under reduced pressure and purification of the residue by chromatography (silica gel, hexanes – ethyl acetate, 1:1) provided lactone **19** (131 mg, 72%) as a white solid; mp 201–203°C. $[\alpha]_D^{27}$ –28.1 (*c* 1.0, $CHCl_3$). R_f = 0.23 (hexanes – ethyl acetate, 1:1) FAB-HRMS calcd. for $C_{29}H_{34}NO_9$: 540.2234; found: 540.2238. A solution of diol **27** (21.1 mg, 0.0353 mmol) in a 40% aqueous acetone solution (2 mL) was treated with a solution of $NaIO_4$ (10.2 mg, 0.0477 mmol) in water (0.2 mL) and stirred at room temperature for 3 h. The reaction mixture was concentrated in vacuo and the resulting solution was extracted with ethyl acetate (4 × 25 mL). The combined organic extracts were dried over Na_2SO_4 and the solvent removed under reduced pressure. The remaining residue was dissolved in MeOH (1 mL), cooled to 0°C, and treated with neat $NaBH_4$. The solution was slowly warmed to room temperature and stirred for 18 h. The reaction mixture was treated with water and then concentrated in vacuo. The remaining solution was extracted with ethyl acetate (4 × 20 mL) and the combined organic extracts dried over Na_2SO_4. Removal of the solvent under reduced pressure gave a residue, which was purified by chromatography (silica gel, hexanes – ethyl acetate, 1:2) furnishing diol **29** (11.1 mg, 52%) as a film; $[\alpha]_D^{25}$ +66.8 (*c* 1.0, $CHCl_3$). R_f = 0.30 (hexanes – ethyl acetate, 1:2). FAB-HRMS calcd. for $C_{31}H_{38}NO_9S$: 600.2267; found: 600.2264. The total synthesis of (+)-aspicilin using 2,3-butane diacetal protected butane tetrols via a chiral memory protocol

Darren J. Dixon, Alison C. Foster, and Steven V. Ley

Abstract: The total syntheses of the polyhydroxylated macrolactone (+)-aspicilin and a diastereoisomer have been achieved via a concise route, starting from the spatially desymmetrized (*R′*,*R′*,*R*,*S*)-2,3-butanediacetal-protected butane tetrol **13**. The key steps include a regioselective silyl protection of **13** and a stereoselective Lewis acid mediated addition of allyltributylstannane to the equatorially disposed aldehyde of **4**. Macrocyclization is achieved using ring closing metathesis, after which selective hydrogenation and protecting group removal yields the natural product.

Key words: aspicilin, butanediacetal, desymmetrization, macrolactone, metathesis.

Résumé : Les synthèses totales de la macrolactone polyhydroxylée (+)-aspiciline et d'une de ses diastéréoisomères ont été effectvé par le biais d'une route concise partant d'un butanetétrol désymétrisé d'un point de vue spacial sous la forme de (*R′*,*R′*,*R*,*S*)-butanediacétal protégé, **13**. Les étapes clés impliquent une protection régiosélective du composé **13** par un silyle et une addition stéréosélective, catalysée par un acide de Lewis, de l'allyltributylstannane sur un aldéhyde en position équatoriale du composé **4**. On réalise la macrocyclisation en exploitant à une réaction de fermeture de cycle par métathèse, suivie d'une hydrogénation sélective et d'une élimination du groupe protecteur pour conduire au produit naturel.

Mots clés : aspiciline, butanediacétal, désymétrisation, macrolactone, métathèse.

Introduction

The desymmetrization of *meso* compounds as a method for obtaining enantiomerically enriched products has become a powerful tool for synthetic organic chemists. Enzymes are frequently used to effect this kind of transformation (1); however, considerable work has also been carried out using chiral reagents or catalysts (2).

Tartaric acid is a readily available four-carbon building block in either the (+)-, (–)-, or *meso* forms. Terminal group manipulation of the two homochiral tartrates affords the *syn*-1,2-diol motif, whereas elaboration of the *meso* form provides *anti*-1,2-diols but as a racemate. Polyhydroxylated natural products are important synthetic targets, consequently several methods have been devised for the introduction of a 1,2-diol. However, the number of ways to prepare *anti*-1,2-diols is much less than for the corresponding *syn*-1,2 unit. Even the powerful Sharpless asymmetric dihydroxylation procedure favors *syn*-1,2-diol formation from *trans* alkenes in a higher enantiomeric excess (ee) than when *cis* alkenes are used as precursors for the *anti*-1,2-diol motif (3). Alternative methods for the introduction of enantiomerically pure *anti*-1,2-diols are therefore crucial to expand the repertoire of the synthetic organic chemist.

Previous work developed in our group using the homochiral C_2 symmetric bis(dihydropyran) (BDP) unit to protect 1,2-diols was one solution to the problem, allowing for the desymmetrization of *meso* compounds such as glycerol and *myo*-inositol (4–7). This protecting group makes use of the anomeric stabilization effect and the preference for all other substituents to be placed in equatorial environments. Here we report in full a cheaper alternative process that relies on the use of 1,2-butane diacetals operating through a chiral memory protocol to obtain the desired desymmetrized *meso* tartaric acid derivatives and then use of this in the synthesis of the *anti*-1,2-diol containing macrolactone natural product (+)-aspicilin **1**.

This 18-membered macrolactone metabolite, was first isolated from *Lecanoraceae* lichen in 1900 by Hesse (9, 10), but despite the elucidation of the connective structure in 1973 (8), the relative and absolute stereochemistry remained unknown until 1985 (11). Although no biological function for **1** has been reported, its structure, which contains four stereogenic centres, three of which occur as an *anti*, *syn*-triol unit, consequently makes it an ideal target to explore the use of our new chiral building blocks in a stereoselective synthesis of **1** (12). Other syntheses of (+)-aspicilin have also been reported (13–27).

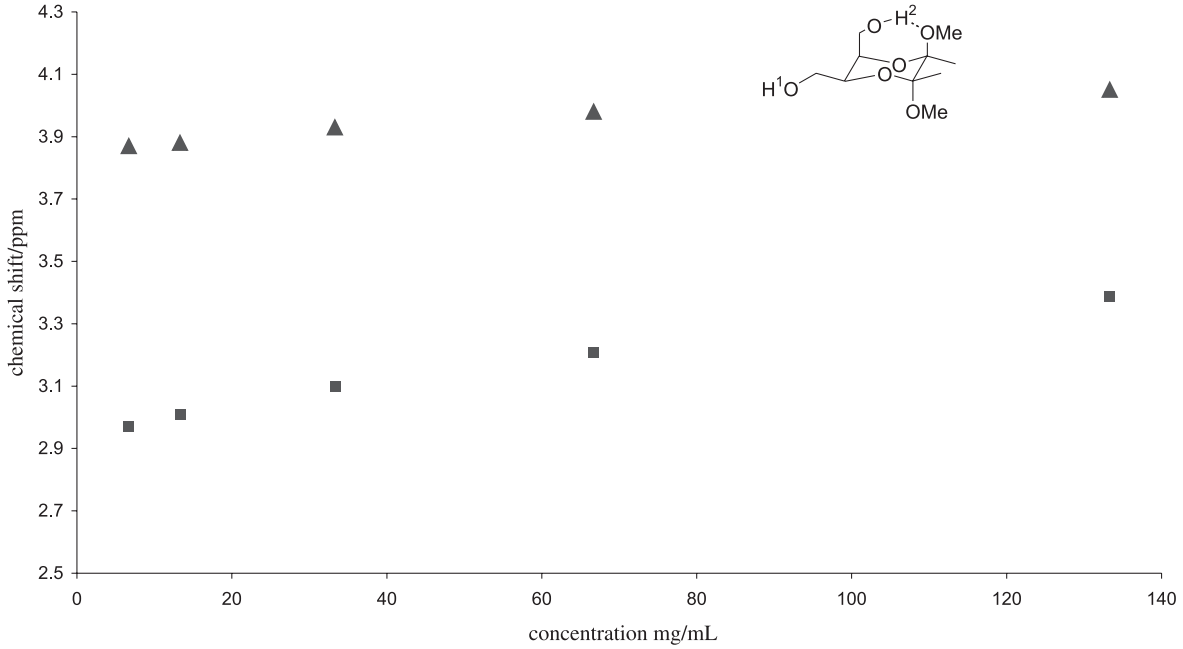
Scheme 1.

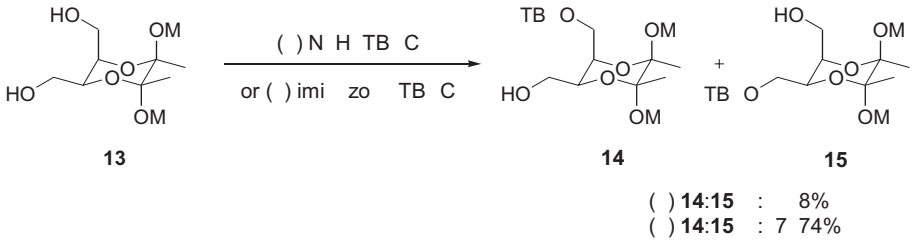
Scheme 2.

Our general route to aspicilin is shown in Scheme 1. Ring closing metathesis of **3** to give the large ring olefin **2** suggests that **3** could be constructed by a stereoselective Masamune–Roush coupling of the phosphonoacetate **5** and aldehyde **6**. In turn compound **5** should be available from ring opening of propylene oxide **8** with the Grignard derived from **9**, and finally esterification with **7** (28). The preparation of **6** follows from an anticipated stereoselective addition of an allyl side chain to the *R,R,R′,R′*-butane diacetal protected aldehyde derivative **4**. Compound **4** would be obtained by chemistry already established in our group.



The synthesis begins from commercially available dimethyl L-tartrate, which was transformed to the desymmetrized diol **13** using our recently developed chiral memory protocol (29, 30). Firstly, the enantiopure diester was protected as the butane diacetal **10** using butane-2,3-dione and catalytic acid. The resulting diacetal was then oxidized, via double deprotonation and treatment with iodine, to give the unsaturated diester **11**. Upon hydrogenation using rhodium on alumina as the catalyst, the spatially desymmetrized diester **12** was produced. All the compounds in Scheme 2 are highly crystalline therefore avoiding the need for tedious chromatographic purification. Diester **12** was then reduced to give the diol **13** where the two hydroxyl groups are in spatially differentiated environments, one being axially and the other equatorially disposed. This efficient four-step protocol was carried out in multigram quantities.

The two hydroxyl protons of the diol **13** were clearly identified in the ^{1}H NMR spectrum. The relative chemical shifts indicate the axial hydroxyl proton to be in a more electronegative environment and this together with ^{1}H NMR studies at varying concentrations revealed the axial hydroxyl group to be involved in an intramolecular hydrogen bond to the backbone methoxy group (Fig. 1).



Either hydroxyl group of **13** could be selectively protected as a *tert*-butyl dimethyl silyl ether. The two diastereomeric

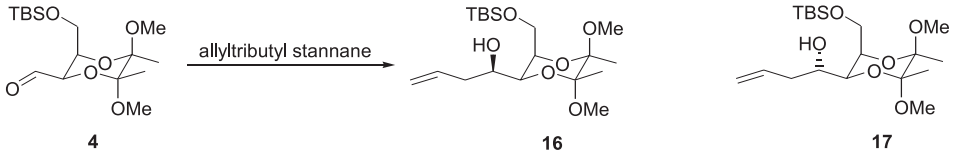

Fig. 1. Effect of concentration on hydroxyl proton chemical shift (■ H^1, ▲ H^2).

Scheme 3.

Scheme 4.

ethers **14** and **15** are readily separable by column chromatography to afford pure materials. Upon treatment of the diol with one equivalent of sodium hydride a mono-alkoxide precipitates, which then reacts with the silylating reagent to give predominantly the axial ether **14** (7:1), whereas treatment of the diol **13** with imidazole and the silyl chloride gave the equatorial ether **15** as the major product (17:1) (Scheme 3).

Thus we can infer that the alkoxide that precipitates upon treatment with sodium hydride is consistent with deprotonation of the hydroxyl group on the axial ring substituent, with this being thermodynamically more stable due to the interactions with the lone pair electrons on the oxygen atom as shown in Fig. 1. The equatorial alcohol is preferentially silylated in the presence of imidazole due to the less sterically hindered nature of this hydroxyl group.

Once the two alcohols had been differentiated, oxidation of the free hydroxyl occurred smoothly using the method of Swern to give the aldehyde **4** (31). The key stereoselective addition of an allyl group to this aldehyde using allyltributylstannane as the nucleophile was then investigated. Following similar conditions for the analogous addition to aldehydes derived from (*R*′,*R*′,*S*,*S*)- and (*S*′,*S*′,*R*,*R*)-2,3-butanediacetal protected butane tetrols (32), aldehyde **4** was dissolved in diethyl ether and lithium perchlorate was added until the solution was saturated (~5 M). Allyltributyl stannane (3 equiv.) was added and the reaction left to stir overnight at room temperature. On work up, two diastereomeric products **16** and **17** were detected in the ratio of 9:1, respectively. Chromatographic purification afforded the diastereomerically pure homoallylic alcohol **16** in 70% yield. However, even after extended reaction times a small amount of aldehyde starting material could still be detected in this reaction.

During the course of investigations to increase the yield as well as the observed selectivity of this addition reaction we observed an interesting result. When zinc chloride was used

$Yb(OTf)_3$	1.4:1	87
$MgBr_2$	13:5	92

[a]Isolated yield of **16** only.

as the Lewis acid, the reaction proceeded to completion in a shorter time and in improved yield. However, the opposite sense of stereochemical induction was observed giving products **17** and **16** in a ratio of 9:1 (Scheme 4). In an attempt to explain this result the reaction was repeated using other Lewis acids. The use of ytterbium(III) triflate gave essentially a 1:1 ratio of alcohols, whilst magnesium bromide gave a lower ratio than (but with the same major product) the reaction with lithium perchlorate. A straightforward addition of allylmagnesium bromide gave a ratio of 2:1 in favor of the alcohol **16** (Table 1).

Attempts to determine the stereochemistry of the newly formed secondary alcohols by formation of the Mosher esters were not successful due to the hindered nature of these alcohols. However, a single crystal X-ray structure of the diol derived from the major product **16** confirmed that the sense of the asymmetric induction in the lithium perchlorate mediated reaction was consistent with addition occurring through chelation control.[2]

With these compounds available the synthesis of both natural and 6-*epi* aspicilin was investigated (Scheme 5). The preparation of both these diastereoisomers began with protection of the corresponding homoallylic alcohol as the methoxymethyl (MOM) ether. This was possible but required forcing conditions analogous to those used for the protection of tertiary alcohols (33). Thus alcohol **16** was treated with in situ generated methoxymethyliodide and Hünig's base in DME at reflux for 13 h affording the desired MOM protected compound **18** in 72% yield after chromatographic purification. Standard TBS removal and Swern oxidation gave the axially disposed aldehyde **19** in quantitative yield over 2 steps.

The phosphonate **5** required for the olefination reaction was obtained in a two step process (Scheme 6). Firstly, the Grignard reagent was generated in situ from the commercially available 8-bromooct-1-ene (**9**) and reacted with (*S*)-propylene oxide (**8**) in the presence of $CuLi_2Cl_4$ to give the long chain alcohol **20** in good yield. A transesterification of the thioester **7** with long chain alcohol **20** was mediated by silver trifluoroacetate and gave the required phosphonate **5** in 84% yield. To minimize the possibility of epimerization of the axially disposed aldehyde, the Masamune–Roush conditions were chosen for the subsequent olefination reaction (34). Accordingly, aldehyde **19** was treated with phosphonate ester **5**, lithium chloride, and Hünig's base at room temperature for 14 h to give the corresponding olefin as a 10:1 mixture of *E*:*Z* isomers. Chromatographic purification afforded the isomerically pure *E*-isomer **21** in 58% yield as well as the *Z*-isomer in 8% yield (Scheme 5). The axial nature of the side chain could clearly be seen from the size of the coupling constant between H-2 and H-3 (J = 4 Hz).

Macrocyclization of triene **21** was possible using standard ring-closing metathesis (RCM) conditions (35). Thus, a dilute solution of **21** in dichloromethane at room temperature was treated with a catalytic quantity of Grubb's catalyst (10%) for 14 h and afforded the desired material **22** in 73% yield and as a 1.5:1 mixture of *Z*:*E* isomers. The product of RCM across the double bond of the α,β-unsaturated ester, cyclohexene **23**, was also detected in 26% yield (Scheme 5).

Co-elution of the starting material and product meant that early attempts to reduce only the isolated double bond resulted in formation of the fully saturated system due to over-reduction. Partial hydrogenation of the isomeric mixture of alkenes **22**, however, occurred smoothly using palladium on barium sulfate in ethyl acetate under an atmosphere of hydrogen, when the reaction time was limited to 40 min, to give fully protected aspicilin in 100% yield.

The synthesis of protected 6-*epi*-aspicilin was carried out in an analogous manner, the yields at all stages up to this point being comparable to those of the natural system. Global deprotection using the standard conditions for BDA removal, namely treatment with a 90% aqueous solution of trifluoroacetic acid followed by removal of volatiles in vacuo was first attempted on the unnatural diastereoisomer. The reaction proceeded smoothly in this case to give the triol product **24** in 44% yield (Scheme 7).

When these deprotection conditions were applied to the natural diastereoisomer the reaction gave no desired product. However, treatment with ethanedithiol and boron trifluoride etherate afforded (+)-aspicilin **1** in 73% yield. The ^1H and ^{13}C NMR, IR, melting point, MS, and specific rotation ($[\alpha]_D^{26}$ +35.0 (*c* 0.20, $CHCl_3$) (lit. $[\alpha]_D^{26}$ +37.5 (*c* 0.55, $CHCl_3$)) of the synthesized material were in excellent agreement with the reported data and that of an authentic sample.[3]

In summary, a short and efficient stereoselective synthesis of the polyhydroxylated natural product (+)-aspicilin **1** and that of its C-6 epimer **24**, has been achieved using (*R*′,*R*′,*R*,*S*)-2,3-butanediacetal protected butane tetrol **13** as the starting material. The key step relied on the stereoselective allylation of the equatorially disposed aldehyde in **4**. Terminal group manipulation and olefination using phosphonate ester **5** followed by macrocyclization via ring closing metathesis afforded, after partial hydrogenation and global deprotection, the target compounds. Both diastereoisomers of aspicilin have been submitted for full biological evaluation.

tion of dimethyl L-tartrate (100 g, 561 mmol) in MeOH (246 mL) and the reaction was heated to reflux for 7 h. After cooling to room temperature for 1.5 h, $NaHCO_3$ (100 g) was added and the reaction stirred for 2.5 h. The solid was removed by filtration and the filtrate concentrated in vacuo. The residue was taken up in ether (1.6 L) and washed with water (2 × 1.6 L). Each 1.6 L of water was reextracted with ether (0.8 L). The combined organic layers were washed with brine (1.6 L), dried ($MgSO_4$), and concentrated in vacuo. Recrystallization from ether–petrol (650:750 mL) gave white crystals of diester **10** (100.46 g, 61%); mp 109 to 110°C. $[\alpha]_D^{29}$ –148° (*c* 1.00, CH_2Cl_2). R_f = 0.28 (petrol–ether, 1:1). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.54 (2H, C*H*CO_2CH_3), 3.77 (s, 6H, CO_2CH_3), 3.33 (s, 6H, OCH_3), 1.36 (s, 6H, CH_3). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 168.4 (*C*O_2CH_3), 99.2 (C-5, C-6), 68.7 (C-2, C-3), 52.5 (CO_2CH_3), 48.4 (OCH_3), 17.3 (CH_3). Anal. calcd. for $C_{12}H_{20}O_8$: C 49.3, H 6.90; found: C 49.3, H 6.87.

(–)-(5*R*,6*R*)-5,6-Dimethoxy-5,6-dimethyl-5,6-dihydro-1,4-dioxin-2,3-dimethyl dicarboxylate (11)

LDA (9.3 mL, 1.0 M in THF) was added via cannula to a stirred solution of diester **10** (1.29 g, 4.43 mmol) in THF

© 2001 NRC Canada

(10 mL) at –78°C. The solution was then stirred at –78°C for 1 h before iodine (1.12 g, 4.43 mmol), as a solution in THF (10 mL), was added via cannula. Saturated aqueous ammonium chloride solution (5 mL) was added to the resultant precipitate and the reaction was warmed to room temperature before being diluted with ether (50 mL) and water (50 mL). The organic layer was separated and the aqueous layer reextracted with ether (10 mL). The combined organic layers were dried ($MgSO_4$) and concentrated in vacuo. The resulting solid was recrystallized from EtOAc–petrol (1:20) to give the diester **11** (732 mg, 57%) as white prisms; mp 83–85°C. $[\alpha]_D^{30}$ –304° (*c* 1.00, $CHCl_3$). R_f = 0.41 (petrol–ether, 1:1). FAB-MS *m*/*z* (%): 291 ($[M + H]^+$, 68), 116 (100) (anal. calcd. (+FAB) for $C_{12}H_{19}O_8$: 291.1080 (MH); found: 291.1081 $[M + H]^+$). ν_{max} (thin film) (cm^{-1}): 1739 (s), 1652 (s). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.79 (s, 6H, CO_2CH_3), 3.35 (s, 6H, OCH_3), 1.53 (s, 6H, CH_3). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 167.9 (CO_2CH_3), 130.9 (C-2, C-3), 98.8 (C-5, C-6), 52.5 (CO_2CH_3), 49.4 (OCH_3), 16.7 (CH_3). Anal. calcd. for $C_{12}H_{18}O_8$: C 49.65, H 6.25 found: C 49.67, H 6.28.

(–)-(2*R*,3*S*,5*R*,6*R*)-5,6-Dimethoxy-5,6-dimethyl-1,4-dioxane-2,3-dimethyl dicarboxylate (12)

Rhodium on alumina catalyst (1.00 g, 20 mol%) was added to a solution of unsaturated diester **11** (5.00 g, 17.0 mmol) in MeOH (25 mL). The reaction tube was inserted into a pressure bomb and pressurized with hydrogen to 80 bar (1 bar = 1×10^5 Pa). The reaction was then stirred vigorously for 6 days. After this time the pressure was released and the reaction filtered through celite and washed through with copious MeOH. The solvent was removed in vacuo and the residue was chromatographed (petrol–ether, 1:1) to give diester **12** (4.83 g, 97%) as white prisms; mp 100–102°C. $[\alpha]_D^{30}$ –138° (*c* 1.03, CH_2Cl_2). R_f = 0.26 (petrol–ether, 1:1). FAB-MS *m*/*z* (%): 315 ($[M + Na]^+$, 100), 261 (45), 101 (28) (anal. calcd. (–)-(2*S*,3*R*,5*R*,6*R*)-2,3-Dimethanol-5,6-dimethoxy-5,6-dimethyl-1,4-dioxane (13)

$LiAlH_4$ (2.05 mL, 1.0 M solution in THF, 2.05 mmol) was added dropwise to a solution of diester **12** (545 mg, 1.86 mmol) in ether (15 mL) at 0°C. Upon completion of the addition the ice bath was removed and the reaction left to warm to room temperature, ca. 30 min. The reaction was then cooled back to 0°C before quenching with EtOAc (1 mL). Sodium sulfate decahydrate (2.0 g) was then added and the reaction stirred at room temperature for 2 h. The solid was filtered off under reduced pressure through a pad of $MgSO_4$ and washed with EtOAc (100 mL). Solvent removal in vacuo left a colorless oil which was chromatographed (ether) to give diol **13** (361 mg, 82%) as a colorless oil which crystallized on standing; mp 69°C. $[\alpha]_D^{29}$ –132° (*c* 1.0, CH_2Cl_2). R_f = 0.17 (ether). FAB-MS *m*/*z* (%): 259 ($[M + Na]^+$, 75), 173 (100) (anal. calcd. (–)-(2*R*,1′*R*,3*R*,5*R*,6*R*)-3-*tert*-Butyldimethylsilyloxymethanol-2-(1′-hydroxy-but-3′-ene-1′-yl)-5,6-dimethoxy-5,6-dimethyl-1,4-dioxane (16) and (–)-(2*R*,1′*S*,3*R*,5*R*,6*R*)-3-*tert*-butyldimethylsilyloxymethanol-2-(1′-hydroxy-but-3′-ene-1′-yl)-5,6-dimethoxy-5,6-dimethyl-1,4-dioxane (17)

Method 1: zinc(II) chloride mediated allyl addition

$ZnCl_2$ solution (15.5 mL, 0.5 M in THF, 7.75 mmol) was added to a solution of aldehyde **4** (900 mg, 2.58 mmol) in ether (8 mL) at 0°C. The reaction was stirred at 0°C for 20 min before allyltributylstannane (2.4 mL, 7.75 mmol) was added neat. The resulting solution was warmed to room temperature and left stirring overnight. The reaction was diluted with ether (50 mL) and washed with water (2 × 50 mL). The aqueous layer was reextracted with ether (40 mL) and the combined organic layers were washed with brine (40 mL), dried ($MgSO_4$), and concentrated in vacuo. Crude ^{1}H NMR indicated a 9:1 ratio of homoallylic alcohols, which were separated by flash column chromatography (petrol–ether (5:1) + 1% Et_3N) to give **17** (802 mg, 80%) and **16** (96 mg, 9%).

Method 2: ytterbium(III) triflate mediated allyl addition

Ytterbium(III) triflate (534 mg, 0.86 mmol) was added to a solution of aldehyde **4** (100 mg, 0.29 mmol) in ether (2 mL) at 0°C and the reaction stirred for 15 min. Neat allyltributylstannane (267 μL, 0.86 mmol) was then added, the cooling bath removed, and the reaction stirred at room temperature for 14 h. Ether (50 mL) and water (50 mL) were added, the layers separated, and the organic layer dried. After concentration in vacuo the residue (crude ratio of products by ^{1}H NMR 1.4:1) was chromatographed (petrol–ether (4:1) + 1% Et_3N) to give homoallylic alcohols **16** (57 mg, 50%) and **17** (42 mg, 37%).

Method 3: lithium perchlorate mediated allyl addition

Aldehyde **4** (2.0 g, 5.74 mmol) was added to a solution of lithium perchlorate in ether (30 mL, 5 M) and the reaction stirred at 0°C for 15 min. The allyltributylstannane was then added and the reaction warmed to room temperature and stirred for 14 h. Ether (250 mL) and water (250 mL) were added, the layers separated, and the organic layer dried ($MgSO_4$) and concentrated in vacuo. The residue (crude ratio of products by ^{1}H NMR 1:9) was chromatographed (petrol:ether (4:1) + 1% Et_3N) to give the major homoallylic alcohol **16** as a colorless oil (1.56 g, 70%). The minor product co-eluted with some unreacted starting aldehyde.

Method 4: magnesium(II) bromide mediated allyl addition

Magnesium(II) bromide (225 mg, 0.86 mmol) was added to a solution of aldehyde **4** (100 mg, 0.29 mmol) in ether

© 2001 NRC Canada

(2 mL) at 0°C and the reaction stirred for 15 min. The allyltributylstannane (267 μL, 0.86 mmol) was then added, the cooling bath removed, and the reaction stirred at room temperature for 14 h. Ether (50 mL) and water (50 mL) were added, the layers separated, and the organic layer dried ($MgSO_4$). After concentration in vacuo the residue (crude ratio of products by ^1H NMR, 5:13) was chromatographed (petrol–ether (4:1) + 1% Et_3N) to give homoallylic alcohols **17** (23 mg, 20%) and **16** (81 mg, 72%).

Method 5: allyl MgBr addition

Allyl MgBr solution (1.0 M THF, 0.72 mmol, 720 μL) was added to a solution of aldehyde **4** (50 mg, 0.14 mmol) in THF (1 mL) at –78°C and the reaction stirred at –78°C for 6 h. The reaction was then quenched with water and warmed to room temperature. The reaction was diluted with ether and washed with water before the organic layer was dried ($MgSO_4$) and concentrated in vacuo. The crude ^1H NMR showed a 1:2 ratio of **17** to **16**. Purification of the residue by flash column chromatogaphy gave pure homoallylic alcohols (100%).

MOMCl (0.74 mL, 9.79 mmol) was added to a solution of sodium iodide (1.15 g, 7.68 mmol) in DME (15 mL). The reaction was left to stir at room temperature for 1 h before alcohol **17** (750 mg, 1.92 mmol) and DIPEA (1.84 mL, 10.56 mmol) were added as a solution in DME (15 mL). The reaction was then stirred for 1 h at room temperature, warmed to 65°C for 1 h, and then heated to reflux for a further 17 h before finally cooling to room temperature. Saturated sodium carbonate solution (10 mL) was added followed by CH_2Cl_2 (100 mL) then water (50 mL). After separation of the layers, the organic layer was washed again with water (50 mL). The aqueous layer was reextracted with CH_2Cl_2 (50 mL), then the combined organic layers washed with brine (50 mL), dried ($MgSO_4$), and concentrated in vacuo. Purification by flash column chromatography (petrol–ether (5:1) + 1% Et_3N) gave MOM ether as a colorless oil (714.6 mg, 86%). $[\alpha]_D^{28}$ –100° (*c* 0.72, $CHCl_3$). (2*R*,1′*S*,3*R*,5*R*,6*R*)-5,6-Dimethoxy-2-(1′-methoxymethylhydroxy-but-3′-ene-1′-yl)-5,6-dimethyl-1,4-dioxane-3-carbaldehyde

DMSO (30 μL, 0.42 mmol) as a solution in CH_2Cl_2 (1 mL) was added to a solution of oxalyl chloride (18 μL, 0.20 mmol) in CH_2Cl_2 (1 mL) at –78°C. The reaction was stirred at –78°C for 30 min before alcohol (50 mg, 0.16 mmol) was added dropwise as a solution in CH_2Cl_2 (1 + 0.5 mL washout) over 30 min. The reaction was then left stirring at –78°C for 1.5 h before Et_3N (78 μL, 0.56 mmol) was added over 15 min. The reaction was then removed from the cooling bath and allowed to warm to room temperature over 1 h. The reaction was diluted with CH_2Cl_2 (10 mL) and washed with water (2 × 8 mL). The organic layer was dried ($MgSO_4$) and concentrated in vacuo. R_f = 0.42 (petrol–ether, 1:1). Used crude.

(+)-(*S*)-10-Hydroxy-undec-1-ene (20)

Three drops of 1,2-dibromoethane were added to a stirred suspension of magnesium turnings (837 mg, 34.4 mmol) in THF (10 mL) at room temperature. A solution of 8-bromo-oct-1-ene (**9**) (4.13 mL, 24.6 mmol) in THF (16 mL) was then added as the solution was warmed to 30°C. The reaction was heated to reflux for 6 h, cooled to room temperature, and THF (20 mL) was added. $CuLi_2Cl_4$ (17.2 mL, 0.1 M in THF, 1.72 mmol) was added to (*S*)-propylene oxide **8** (1.0 g, 17.2 mmol) in THF (20 mL) at –78°C. The Grignard solution was further cooled to –78°C, added to the cooled propylene oxide solution, and the reaction stirred for 1 h at –78°C before warming to 0°C over 1 h. The reaction was quenched by addition of saturated aqueous ammonium chloride solution (200 mL) and then EtOAc (200 mL) was added. The layers were separated and the aqueous phase reextracted with EtOAc (150 mL). The combined organic layers were dried ($MgSO_4$) and concentrated in vacuo. The crude product was chromatographed (petrol–EtOAc, 5:1) to give alcohol **20** as a pale yellow liquid (2.53 g, 86%). $[\alpha]_D^{28}$ +6.9° (*c* 1.14, $CHCl_3$). R_f = 0.3 (petrol–EtOAc, 5:1). Grubb's catalyst (18.4 mg, 0.02 mmol) was added to a stirred solution of triene (107 mg, 0.21 mmol) in CH_2Cl_2 (140 mL). The reaction was stirred at room temperature overnight and concentrated in vacuo. Purification by flash column chromatography (petrol–ether, 4:1) afforded cyclic lactone, a 6:4 inseparable mixture of double bond isomers, as a colorless oil (48 mg, 45%). R_f = 0.66 (petrol–ether, 1:1). ν_{max} (CH_2Cl_2 solution) (cm^{-1}): 2931 (s), 2864 (s), 1712 (s), 1655 (w), 1602 (w), 1377 (m), 1254 (s), 1215 (m), 1183 (m), 1142 (s), 1107 (s), 1038 (s). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.48–7.58 (m, $1H_A$ + $1H_B$, 17-H), 6.02 (d, J = 16, $1H_A$, 16-H), 5.97 (d, J = 16, $1H_B$, 16-H), 5.41–5.56 (m, $1H_A$ + $1H_B$, 4-H or 5-H), 5.33–5.40 (m, $1H_A$ + $1H_B$, 4-H or 5-H), 5.14–5.22 (m, $1H_A$ + $1H_B$, 2-H), 4.52–4.65 (m, $2H_A$ + $2H_B$, C*H*$_2$OCH$_3$), 4.32 (dd, $1H_A$, J = 4, 11, 1-H or 18-H), 4.26 (dd, J = 4, 11, $1H_B$, 1-H or 18-H), 4.03–4.08 (m, $1H_A$ + $1H_B$, 1-H or 18-H), 3.37 (s, $3H_A$, CH$_2$OC*H*$_3$), 3.36 (s, $3H_B$, CH$_2$OC*H*$_3$), 3.28 (s, $3H_B$, OCH_3), 3.26 (s, $3H_A$, OCH_3), 3.20 (s, $3H_A$, OCH_3), 3.17 (s, $3H_B$, OCH_3), 2.39–2.53 (m, $1H_A$ + $1H_B$, 3-H), 2.04–2.27 (m, $2H_A$ + $2H_B$, 3-H), 1.85–1.94 (m, $1H_A$ + $1H_B$), 1.39–1.54 (m, $2H_A$ + $2H_B$), 1.15–1.33 (m, $21H_A$ + $21H_B$, 3 × CH_3 and 6 × CH_2).

(16*E*)-(1*S*,2*S*,13*S*,18*R*,19a*R*,19b*R*)-19a,19b-Dimethoxy-2-methoxymethylhydroxy-13,19a,19b-trimethyl-14,19,20-trioxa-bicyclo[16.4.0]doicosa-16-ene-15-one

Pd-$BaSO_4$ (0.5 mg) was added to a solution of diene (5 mg, mmol) in EtOAc (0.5 mL). The reaction was stirred under an atmosphere of hydrogen for 40 min, the catalyst was removed by filtration and the solvent removed in vacuo to leave crude product (5 mg, 100%). $[\alpha]_D^{29}$ –85.6° (*c* 0.45, $CHCl_3$). R_f = 0.66 (petrol–ether, 1:1). EI-MS *m*/*z* (%): 455 ($[M - OMe]^+$, 5), 419 (5), 379 (20), 338 (30), 276 (30), 247 (40), 116 (100). (anal. calcd. (2*R*,1′*R*,3*R*,5*R*,6*R*)-3-*tert*-Butyldimethylsilyloxymethanol-5,6-dimethoxy-2-(1′-methoxymethylhydroxy-but-3′-ene-1′-yl)-5,6-dimethyl-1,4-dioxane (18)

MOMCl (1.55 mL, 20.4 mmol) was added to a solution of sodium iodide (2.39 g, 16.0 mmol) in DME (30 mL) at room temperature and the reaction stirred for 1 h. A solution of alcohol **16** (1.56 g, 4.0 mmol) and DIPEA (3.83 mL, 22.0 mmol) in DME (30 mL) was then added and the reaction stirred for a further hour at room temperature. The reaction was heated to 65°C for 1 h and then to reflux for 13 h. After cooling to room temperature, saturated sodium carbonate solution (20 mL) was added followed by CH_2Cl_2 (200 mL) and water (100 mL). The layers were separated and the organic layer washed again with water (100 mL). The combined aqueous layers were reextracted with CH_2Cl_2 (100 mL), the organic layers washed with brine, dried ($MgSO_4$), and concentrated in vacuo. Purification by flash column chromatography (petrol–ether (4:1) + 1% Et_3N) gave homoallylic ether **18** (1.25 g, 72% (85% brsm)) as a colorless oil. $[\alpha]_D^{30}$ –74.1° (*c* 1.09, $CHCl_3$). R_f = 0.51 (petrol–ether, 3:1). ES-MS *m*/*z* (%): 457 ($[M + Na]^+$, 100) (anal. calcd.
